P

PODODERMATITIS

BASICS

DEFINITION
An inflammatory, multifaceted complex of diseases that involves the feet of dogs and cats.

PATHOPHYSIOLOGY
- Depends on the underlying cause.
- Psychogenic dermatosis (rare cause).

SYSTEMS AFFECTED
Skin/exocrine.

INCIDENCE/PREVALENCE
- Dogs—common. • Cats—uncommon.

SIGNALMENT

Breed Predilections
- Dogs, short-coated breeds—most commonly affected; English bulldog, Great Dane, basset hound, mastiff, bull terrier, boxer, dachshund, Dalmatian, German shorthaired pointer, and Weimaraner. • Dogs, long-coated breeds—German shepherd dog, Labrador retriever, golden retriever, Irish setter, and Pekingese. • Cats—none.

Mean Age and Range
- Any age. • Young dogs—hypersensitivity, demodicosis, infection, follicular cysts, autoimmune dermatoses. • Old dogs—also neoplasia or systemic diseases.

Predominant Sex
- Dogs—male. • Cats—none.

SIGNS

General Comments
History and physical findings vary considerably depending on the underlying cause.

Historical Findings
- Environment and general husbandry—indoor vs. outdoor, working dog, unsanitary conditions, contact irritants, hookworms. • Age of onset.
- Seasonality—atopic dermatitis, allergic contact dermatitis, or irritant contact dermatitis.
- Lesions elsewhere on the body or confined to just the feet; note which feet are affected and what parts of the feet are affected (entire foot, one area, or one digit). • Response to previous therapy—antibiotics, antifungals, and corticosteroids. • Diet, travel history, and other medical problems.

Physical Examination Findings
Infectious (Dogs)
- Erythema and edema, nodules, inflammatory plaques (fungal "kerions"), ulcers, fistulae, hemorrhagic bullae, or serosanguineous or seropurulent discharge.
- Feet—may be grossly swollen; often interdigital swellings that have a history of opening and draining, may have pitting edema of the metacarpal and metatarsal areas.
- Skin—may be alopecic and moist from constant licking; patient may have some degree of pain, pruritus, and paronychia.
- Regional lymph nodes may be enlarged.

Infectious (Cats)
- Painful paronychia, involving one or more claws. • Higher incidence of nodular, often ulcerated lesions, compared to dog.
- Footpads and periungual areas—commonly involved. • Interdigital spaces—seldom affected. • Scaly and crusted lesions—occasionally seen.

Allergic (Dogs)
- Salivary staining, erythema and alopecia (dorsal or ventral or both) secondary to pruritus; dorsal surfaces may be more severely affected than ventral surfaces. Hypersensitivities typically do not produce draining tracts. • Interdigital erythema. • Allergic contact dermatitis—uncommon; ventral interdigital surfaces most affected.

Allergic (Cats)
- Single or multiple, exudative or ulcerated, pruritic plaques of the digits, periungual, and interdigital spaces. • Eosinophilic granuloma complex lesions.

Immune-Mediated (Dogs)
- Crusts and ulcerations—most common lesions; occasional vesicles or bullae. • All feet affected, especially the ungual folds and footpads. • Hyperkeratotic and erosive dermatitis of the footpad margins—common finding in pemphigus foliaceus.

Immune-Mediated (Cats)
- Lesions—generally involve the footpad, including hyperkeratosis and ulceration.
- Lameness and paronychia with ungual fold exudate.

Endocrine/Metabolic (Dogs)
- Lesions—usually consistent with secondary infection. • Hepatocutaneous syndrome (superficial necrolytic dermatitis)—rare condition; skin disease precedes the onset of signs of internal disease; hyperkeratosis (with adherent crusts), fissures, and ulceration of the footpads. • Metastatic calcinosis cutis—seen with chronic renal disease; painful swollen footpads that ulcerate/discharge chalk-like material.

Endocrine/Metabolic (Cats)
- Cutaneous xanthomatosis—seen with diabetes mellitus; whitish nodules resembling candle wax. • Metastatic calcinosis cutis—seen with chronic renal disease; painful swollen footpads that ulcerate/discharge chalk-like material.

Neoplastic
- Dogs—nodules, variably ulcerated, scale, erythema, depigmentation of the footpads; may have only one digit involved (clawbed carcinoma, ungual keratoacanthoma); multiple feet involvement with clawbed squamous cell carcinoma, epitheliotropic lymphoma; pruritus variable. • Cats—nodules; variably ulcerated and painful; localized destruction variable, depends on tumor type foot pad tumors may develop *de novo* or be metastatic carcinoma.

Environmental (Dogs and Cats)
- Involve one digit or foot (foreign body, trauma) or multiple digits (irritant contact dermatitis, thallium toxicity, housing on rough surface or in moist environment).
- Chronic interdigital inflammation, ulceration, pyogranulomatous abscesses, draining tracts, or swelling, with or without pruritus.

Miscellaneous
- Hyperkeratosis of the footpads (dogs)—associated with several diseases (e.g., zinc-responsive dermatosis), and idiopathic digital hyperkeratosis. • Interdigital follicular cysts—interdigital nodules, fistulae and draining tracts dorsally; most often affects the lateral interdigital space of the front feet; history of recurrence and poor to no response to antibiotics, with an area of alopecic, thickened skin with comedones ventrally. • Nodules without draining tracts (dogs)—associated with sterile pyogranuloma in several breeds and nodular dermatofibrosis of German shepherd dogs and golden retrievers.
- Hypomelanosis of the footpads (cats)—associated with vitiligo. • Hypermelanosis of the footpads (cats)—associated with lentigo simplex. • Acral mutilation and analgesia—seen in pointers (English and German shorthaired) and spaniels (English springer and French)—cause unknown; often runts of the litter; no known treatment; dogs are usually euthanized within days to months of diagnosis.

CAUSES

Infectious (Dogs)
- Bacterial—*Staphylococcus pseudintermedius*, *Pseudomonas* spp., *Proteus* spp., *Mycobacterium* spp., *Nocardia* spp., *Actinomyces* spp.
- Fungal—dermatophytes, intermediate mycoses (sporotrichosis, mycetoma), deep mycoses (blastomycosis, cryptococcosis).
- Parasitic—*Demodex canis*, *Pelodera strongyloides*, hookworms.
- Protozoal—leishmaniasis.

Infectious (Cats)
- Bacterial—same as dog; *Pasteurella* spp.
- Fungal—same as dog, excluding blastomycosis. • Parasitic—*Neotrombicula autumnalis*, *Notoedres cati*, *Demodex* spp.
- Protozoal—*Anatrichosoma cutaneum*.

Allergic
- Dogs—atopy; food hypersensitivity; allergic contact dermatitis. • Cats—atopy; rare for flea allergic dermatitis, food hypersensitivity, or contact dermatitis to involve paws (except lesions of eosinophilic granuloma complex).

(CONTINUED) PODODERMATITIS

Immune-Mediated
• Dogs—pemphigus foliaceus; systemic lupus erythematosus; erythema multiforme; cold agglutinin disease; pemphigus vulgaris; bullous pemphigoid; epidermolysis bullosa acquisita, symmetrical lupoid onychodystrophy.
• Cats—pemphigus foliaceus; systemic lupus erythematosus; erythema multiforme; vasculitis; cold agglutinin disease; plasma cell pododermatitis.

Endocrine/Metabolic
• Dogs—hypothyroidism; hyperadrenocorticism; hepatocutaneous syndrome; chronic renal failure. • Cats—hyperthyroidism; hyperadrenocorticism; cutaneous xanthomatosis (secondary to diabetes mellitus); chronic renal failure; endocrine pododermatitis rare.

Neoplastic
• Higher incidence in cats than in dogs.
• Dogs—squamous cell carcinoma; epitheliotropic lymphoma, melanoma; mast cell tumor; keratoacanthoma; inverted papilloma; eccrine adenocarcinoma.
• Cats—papilloma; squamous cell carcinoma; trichoepithelioma; fibrosarcoma; malignant fibrous histiocytoma; metastatic primary adenocarcinoma or squamous cell carcinoma of the lung (feline lung-digit syndrome).

Environmental
• Dogs—irritant contact dermatitis; trauma; concrete and gravel dog runs; excessive exercise; clipper burn; foreign bodies; thallium toxicity. • Cats—irritant contact dermatitis; foreign bodies; thallium toxicity.

Miscellaneous
• Dogs—sterile interdigital granuloma; interdigital follicular cyst (see Physical Examination Findings). • Cats—see Physical Examination Findings.

RISK FACTORS
• Lifestyle and general husbandry conditions—influence development. • Excess exercise, abrasive or moist housing, poor grooming, and/or lack of preventive medical care may predispose an animal or exacerbate condition.
• Body size, foot conformation, and breed influence the development of interdigital follicular cysts.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
See Signs and Causes.

CBC/BIOCHEMISTRY/URINALYSIS
Depends on the underlying cause.

IMAGING
Depends on the underlying cause.

DIAGNOSTIC PROCEDURES
• Skin scrapings or hair plucks—demodicosis.
• Fungal culture—dermatophytosis.
• Exudate or pustule smear—bacterial or yeast infection. • Culture and sensitivity from exudates and/or biopsy tissues. • Dogs—biopsies indicated if skin scrapings are negative and lesions (nodules, draining tracts) are seen; samples from the ventral surface with draining tracts may reveal follicular cysts and pyogranulomatous inflammation leading to the dorsal surface. • Cats—biopsies may be indicated in all cases; pedal dermatosis is relatively rare. • Restricted-ingredient food trial—food hypersensitivity. • Intradermal testing—atopy. • Endocrine assays—hypothyroidism, hyperadrenocorticism, diabetes mellitus.

PATHOLOGIC FINDINGS
Depends on the underlying cause.

TREATMENT

APPROPRIATE HEALTH CARE
Outpatient, unless surgery is indicated.

NURSING CARE
Foot soaking and/or bandaging may be necessary, depending on cause.

CLIENT EDUCATION
• Depends on underlying cause and severity of condition. • Discuss husbandry and preventive medical practices. • Many etiologies can be managed but not cured.

SURGICAL CONSIDERATIONS
• Melanoma and squamous cell carcinoma—very poor prognosis; early diagnosis necessitates amputation of the digit(s) or paw.
• Infectious—may benefit from surgical debridement of devitalized tissue before medical therapy. • Recurrent draining tracts caused by interdigital follicular cysts may be cleared with laser ablation.

MEDICATIONS

DRUG(S) OF CHOICE
• Depend on the underlying cause and secondary infections; see related chapters for dosages of appropriate medications.
• Antibiotics based on culture and sensitivity; 4–6 weeks minimum.

PRECAUTIONS
Depend on the treatment protocol selected for the underlying cause; see specific drugs and their precautions.

POSSIBLE INTERACTIONS
Depends on the underlying cause and treatment protocol selected.

FOLLOW-UP

PATIENT MONITORING
Depends on the underlying cause and treatment protocol selected.

PREVENTION/AVOIDANCE
Environmental cause—good husbandry and preventive medical care.

POSSIBLE COMPLICATIONS
Depends on the underlying cause and treatment protocol selected.

EXPECTED COURSE AND PROGNOSIS
• Success of therapy depends on finding the underlying cause; often the cause is unknown; even when the cause is known, management can be frustrating owing to relapses or lack of affordable therapeutics. • Often the disease can only be managed and not cured.
• Referral to dermatologist often appropriate.
• Surgical intervention is sometimes necessary.

MISCELLANEOUS

ZOONOTIC POTENTIAL
Depends on the underlying cause; uncommon.

PREGNANCY/FERTILITY/BREEDING
Depends on treatment protocol selected.

P

POISONING (INTOXICATION) THERAPY

BASICS

DEFINITION

- Acutely ill patients are often diagnosed as poisoned when no other diagnosis is obvious.
- Direct initial efforts toward stabilizing the patient.
- Proper patient and toxicant assessment are critical in determining the appropriate decontamination and therapy needs for patient.
- Goals of treatment—provide emergency intervention; prevent further exposure; prevent additional absorption; apply specific antidotes; hasten elimination; provide supportive measures.
- Valuable time can be saved by applying the appropriate treatment for a suspected or known intoxicant.
- Suspected intentional intoxication—suspected toxic materials and specimens may be valuable from a medical–legal aspect; maintain a proper chain of physical evidence and keep excellent medical records if malicious intent is suspected.
- Initial patient evaluation includes the following:
  - Assess patient status and review signalment.
  - Determine any current or past medical conditions and current medications.
  - Determine the toxicant patient was exposed to as well as the route, dose, and time since exposure.
  - Determining location of exposure may be helpful at ruling in or out additional potential concerns.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Definitive diagnosis is often difficult; animals may come in contact with varying substances that pet owners are unaware of.
- Pet Poison Helpline, ASPCA Animal Poison Control Center, local poison control centers, and state diagnostic laboratories all offer support in determining toxicity risk and potential therapy needs for animal.
- When suspected exposure and clinical signs do not correlate—offer symptomatic and supportive care to treat current signs.
- Confirmation of diagnosis—most commonly achieved by finding remnants of exposed substance and animal's clinical status; chemical analysis (rarely done and is often after the fact).

TREATMENT

APPROPRIATE HEALTH CARE

Supportive Care

- Control body temperature.
- Maintain respiratory and cardiovascular function.
- Control acid–base balance.
- Control CNS disorders—see specific chapters.
- Alleviate pain.

Emergency

- Establish a patent airway.
- Assisted ventilation, as needed.
- Cardiopulmonary resuscitation methods, as needed.
- After stabilization—proceed with more specific therapeutic measures.

Prevent Absorption

- Remove patient from the affected environment, especially with inhaled toxins.
- Protect caregivers as well from inhaled toxins.
- Decontamination methods include dermal, ocular, respiratory, and gastrointestinal.

Dermal Decontamination: Bathing Skin/Haircoat

- Indicated for external toxicants.
- Bathe to remove the noxious agent using liquid dishwashing detergent.
- *Caution*: Use protective measures to avoid contamination of those handling the patient.

Ocular Decontamination

- Irritants—rinse eye(s) with eye wash or tap water for 10–15 minutes. Monitor for signs of irritation.
- Corrosives—rinse eye(s) with eye wash or tap water for 15–20 minutes and perform fluorescein stain; treat as needed.

Respiratory Decontamination

- Removal from source is often sufficient.
- Oxygen and humidified oxygen therapy may be necessary in more affected patients.

Gastrointestinal Decontamination

- Emetics:
  - Of little value beyond 1–2 hours after ingestion of many toxicants. Exceptions include large ingestions, grapes/raisins, gum, chocolate, and plant material.
  - Do not induce in patients who have neurologic abnormalities including severe agitation or severe depression/sedation. Avoid emesis after ingestion of strong acids, alkalis, petroleum distillates or substances that may result in a rapid onset of neurologic abnormalities.
  - Apomorphine—most effective and reliable for use in dogs; dopaminergic agonist; 0.03–0.04 mg/kg IV or IM, crushed tablet for conjunctival administration; emesis occurs within 10 minutes.
  - 3% Hydrogen peroxide—emetic of choice for home use; 1–2 mL/kg PO, do not exceed 45 mL in most dogs, 60 mL in large dogs; ineffective and contraindicated in cats, not always effective in dogs.
  - Dexmedetomidine—most effective and reliable for use in cats; α_2 agonist; 5–10 µg/kg IM; emesis expected within 10–20 minutes; reverse with atipamezole (equal volume in mL).
  - Xylazine—α_2 agonist for use in cats 0.44–1 mg/kg IM or SQ. Can be reversed with an α_2-adrenergic antagonist such as atipamezole or yohimbine.
  - Hydromorphone- mu opioid agonist for use in cats; 0.1 mg/kg SQ; emesis expected within 5–15 minutes; reverse with naloxone (0.01–0.04 mg/kg Im or SQ).
  - Ipecac—not recommended.
  - Salt or salt solution—not recommended; may result in salt toxicity.
- Activated charcoal:
  - Adsorbant—prevents absorption of toxic substance for certain toxicants.
  - Highly adsorptive of many toxicants including rodenticides, insecticides, and most over-the-counter and prescription medications.
  - Ineffective against xylitol, alcohols, chlorate, cyanide, heavy metals, corrosive and caustic chemicals, and petroleum distillates.
  - Administered after emetic—increases efficacy of toxicant elimination.
  - Dosage 1–5 g/kg body weight; generally a single dose administration; multidose administration if substance undergoes enterohepatic circulation (1–2 g/kg PO q6-8h for 24 hours).
  - Generally administered with a cathartic such as sorbitol; only the first dose should contain a cathartic. Magnesium-containing cathartics should be avoided or used with caution.
  - Hypernatremia has been reported after administration of activated charcoal, especially when a cathartic (sorbitol) is used in a dehydrated patient. Sub q or IV fluids can help to minimize risk.
- Gastric lavage:
  - Indicated in patients who are not acceptable candidates for emesis, have ingested a potentially life-threatening toxin or if emesis was unsuccessful. Most effective if performed in the first 1–2 hours.
  - An appropriately sized cuffed endotracheal tube must be in place prior to starting the lavage procedure.
  - Orogastric (stomach) tube size—use the largest possible; a good rule: use the same size as the cuffed endotracheal tube (1 mm = 3 Fr), measured to the last rib.

(CONTINUED) POISONING (INTOXICATION) THERAPY

- Volume of warm water or lavage solution for each washing—5–10 mL/kg body weight; avoid forceful administration.
- Agitate stomach and either aspirate or allow gravity drainage of stomach contents. Activated charcoal with a cathartic can be infused, if indicated, before removing orogastric tube; however, caution should be used to ensure patient maintains a protected airway in the event of regurgitation.
- Procedure should only be used in appropriate exposures and proper patient status.

• Surgery or endoscopic removal:
- May be indicated for coins, metals, batteries, and drug-infused patches.

• Enemas:
- May hasten the elimination of toxicants from the lower gastrointestinal tract.
- Warm water ± lubricant.
- Take care to avoid the induction of dehydration and electrolyte imbalances with overzealous treatment.

Enhance Elimination

• Absorbed toxicants—often excreted by the kidneys; may be excreted by other routes (e.g., bile, feces, lungs, and other body secretions).
• Renal excretion—may be manipulated in many animals.
• Urinary excretion—may be enhanced using diuretics or by altering the pH of the urine; not frequently performed.

Diuretics

• Enhance urinary excretion of some toxicants—requires maintenance of adequate renal function.
• If minimum urine flow cannot be established—must use peritoneal dialysis (normal urine output is 1–2 mL/kg/h).
• Agents of choice—furosemide 2 mg/kg IV q6–8h, if no response increase dose to 4–6 mg/kg IV q6–8h, or mannitol 1–2 g/kg IV slowly over 20–30 minutes q6h.
• Caution should be used as electrolyte abnormalities may occur.

Manipulating Urine pH

• Not routinely performed; elimination may not be enhanced to a level that improves clinical outcome and may cause or worsen metabolic acidosis.
• Acidic compounds remain ionized in alkaline urine; alkaline compounds remain ionized in acidic urine.
• IV 0.9% sodium chloride—rapid, urinary acidifying agent.
• IV sodium bicarbonate may be used as an alkalinizing agent.

Fluid Therapy

• Consider volume replacement with crystalloids and colloids if necessary.
• May enhance elimination of toxicants that undergo renal excretion.

Peritoneal Dialysis

• Potentially indicated for water-soluble, low-molecular-weight, poorly protein-bound compounds with a small volume of distribution such as alcohols, lithium, and salicylates.
• Indicated for simple removal of absorbed toxicants in patient with normal renal function.
• pH of the solution—may be altered to maintain the ionized state of the offending compound.

Lipid Emulsion Therapy

• Promising use as antidote for toxicosis from many fat-soluble drugs.
• Has been used successfully in veterinary medicine to treat toxicity from highly lipophilic drugs such as baclofen, beta antagonists, calcium channel antagonists, ivermectin, moxidectin, and other fat-soluble medications.
• Exact mechanism of action remains unknown, but may act as a lipid sink.
• Potential adverse effects, although rare, include hyperlipidemia, hepatosplenomegaly, jaundice, seizures, hemolytic anemia, prolonged clotting time, thrombocytopenia, and fat embolism.
• Dosage extrapolated from humans using the 20% commercially available fat emulsion product. Standard protocol: 1.5–4 mL/kg IV over 5–10 minutes followed by 0.25 mL/kg/min CRI over 30–60 minutes. Repeat approximately every 6 hours, as needed, for up to 3–5 doses. If serum lipemia is present, wait 1–2 hours before readministration. See Appendix V on Antidotes and Useful Drugs.

MEDICATIONS

Specific antidotes or procedures are available for the more common toxicants; see specific chapters and Appendix V.

FOLLOW-UP

Specific monitoring depends on the toxicant and the patient's signs and laboratory abnormalities.

P

POLIOENCEPHALOMYELITIS—CATS

BASICS

OVERVIEW
• Subacute to chronic nonsuppurative encephalomyelitis with a predominance of pathologic changes in the gray matter, mainly affecting the medulla oblongata and the spinal cord.
• This disease is considered rare, with a prevalence of less than 1% in cats presented with spinal cord diseases.

SIGNALMENT
• There is no breed or sex predilection.
• Cats of any age can be affected.
• The disease is sporadic but has been observed worldwide, especially in northern Europe.

SIGNS
• Ataxia, paresis, and decreased postural reactions of pelvic or all four limbs.
• Lower motor neuron signs may be also possible (muscle atrophy and decreased to absent segmental spinal reflexes).
• Intracranial signs (seizures, cerebellar signs, and cranial nerve deficits) are uncommon.
• The progression is subacute to chronic (over weeks to months) but may also stabilize.

CAUSES & RISK FACTORS
The underlying cause remains still unknown but pathologic findings are highly suggestive of a viral agent.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Feline infectious peritonitis.
• Toxoplasmosis.
• Fungal infection.
• Bacterial infection.

CBC/BIOCHEMISTRY/URINALYSIS
• Laboratory changes not well characterized.
• Nonspecific changes (e.g., leukopenia and non-regenerative anemia) rare.

OTHER LABORATORY TESTS
N/A

DIAGNOSTIC PROCEDURES
• The presumptive diagnosis is based on history, clinical signs, and possibly CSF changes (mononuclear pleocytosis with or without moderate increased total protein levels).
• The final diagnosis is based on histopathology (disseminated inflammatory lesions in the brain and spinal cord and, as the disease progresses, there is extensive neuronal loss and astrogliosis with little inflammation).

TREATMENT
No curative treatment has been found.

MEDICATIONS

DRUG(S) OF CHOICE
• No drug therapy used in reported cases.
• Because lesions are nonsuppurative, steroid therapy may palliate clinical signs, at least temporarily.
• Supportive treatment with antiepileptic medication to control seizures if indicated.

FOLLOW-UP
Prognosis can be good if the neurologic signs are mild and nonprogressive.

Author Elsa Beltran

POLYARTHRITIS, EROSIVE, IMMUNE-MEDIATED

BASICS

DEFINITION
• An autoimmune disease of the joint that results in destruction of articular cartilage, subchondral bone and surrounding ligaments. This damage can result in joint instability, laxity and deformation with chronicity. • Canine syndromes: ○ Rheumatoid arthritis—antibody response against rheumatoid factors or autoantibodies that results in severe damage to the articular cartilage, periarticular bone and ligaments. ○ Felty's syndrome—constellation of arthritis, neutropenia, and splenomegaly. ○ Erosive polyarthritis of greyhounds—minimal subchondral changes despite necrosis of the articular cartilage and proliferative synovitis; peripheral lymphadenopathy. • Feline erosive polyarthritis: ○ Periosteal proliferative polyarthritis—acute onset of pain and systemic manifestations (fever, lymphadenopathy) related to arthropathy with prolific periarticular periosteal bone formation. ○ Feline rheumatoid arthritis—insidious development of joint deformity accompanied by less systemic illness and periosteal bone formation.

PATHOPHYSIOLOGY
• Immune-complex deposition within the synovial membrane results in an inflammatory response (involving complement and cytokines) leading to cartilage erosion. Release of matrix-degrading enzymes (metalloproteases) responsible for cartilage destruction. • Chronic synovitis results in a pannus, or granulation tissue, across the articular cartilage that extends into subchondral bone, replacing areas of destruction. • Destruction of joint ligaments leads to joint instability and luxation.

SYSTEMS AFFECTED
Musculoskeletal

GENETICS
No genetic predisposition known.

INCIDENCE/PREVALENCE
• Uncommon to rare. • Nonerosive disease more common.

SIGNALMENT

Species
Dog and cat.

Breed Predilections
• More common in small-breed dogs; Shetland sheepdogs, cocker spaniels, collies appear more affected. • Siamese cats.

Mean Age and Range
• Canine—middle age (3–9.5 years). • Feline—bimodal distribution of young adults and middle-aged to older cats.

Predominant Sex
• Feline—predominantly male. • Dogs—none.

SIGNS

General Comments
• Typically affects more distal joints (carpus, elbow, stifle and tarsal joints more frequently, digital joints and vertebral column may be affected). • Clinically, it can appear as though only one joint is affected. • Evaluate cats for causes of reactive polyarthritis (septic arthritis, systemic infection and neoplasia).

Historical Findings
• Progressive, intermittent, or shifting-leg lameness. • Reluctance to walk or stand, inappetence and weight loss.

Physical Examination Findings
• Pain and/or effusion detected on palpation of one or more joints. • Deformation, instability, and luxation of the joint is unique to erosive (as compared to nonerosive) arthritis; occurs with chronicity. May be associated with cranial cruciate ligament rupture (CCLR). • Stiffness on gait evaluation, decreased range of motion and muscle atrophy. • Pyrexia and/or peripheral lymphadenopathy. • Cats may resent handling. May present with acute signs or may be more insidious over weeks to months.

CAUSES
• Underlying etiology has yet to be identified. • Canine distemper virus within synovial fluid can result in sustained inflammation within the joint possibly predisposing a dog to erosive arthritis. • Feline leukemia virus (FeLV) and feline syncytium-forming virus are associated with feline periosteal proliferative polyarthritis (FPPP), but causation has not been shown.

RISK FACTORS
None currently known.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Other causes of arthropathy—infectious arthritis, degenerative joint disease, neoplasia (e.g., synovial cell sarcoma), hemarthrosis, congenital arthropathies (elbow dysplasia, osteochondrosis dissecans), tick-borne disease. • Hypertrophic osteodystrophy. • Panosteitis. • Polymyositis. • Steroid-responsive meningitis–arteritis. • Systemic lupus erythematosus (SLE). • Reactive polyarthritis due to antigenic stimulation from systemic disease. • Drug-induced polyarthritis (sulfa drugs, phenobarbital, erythropoietin, penicillins, cephalosporins, vaccines). • Trauma.

CBC/BIOCHEMISTRY/URINALYSIS
• Hemogram—a mild, non-regenerative anemia and mild leukocytosis may be present although hemogram can be unremarkable. • Chemistry—hyperglobulinemia may be present. • Urinalysis and urine culture—generally unremarkable. Proteinuria should be quantified with a UPC.

OTHER LABORATORY TESTS
• Synovial fluid analysis—aseptic, neutrophilic, or mixed inflammation with greater than 10% non-degenerate neutrophils: ○ Protein concentration often >3.0 g/dL and total nucleated cell count (TNCC) usually >3,000 cells/μL (not associated with severity). ○ Make a direct smear prior to lab submission. • Synovial fluid culture (bacteria and mycoplasma)—negative results do not entirely rule out septic arthritis. • Antinuclear antibody titers—usually negative, unlikely to be clinically useful unless SLE suspected. • Rheumatoid factor testing—positive test is supportive only when erosive disease is present; other causes of joint disease can elevate rheumatoid factor levels: ○ Positive results seen in cats with rheumatoid arthritis, not in FPPP. • Testing for infectious diseases (tick-borne disease (*Borrelia*, *Ehrlichia*, *Rickettsia*), FeLV/feline immunodeficiency virus (FIV) testing, systemic mycoses, *Leishmania* if endemic, blood and urine culture, ± echocardiogram for bacterial endocarditis). • CSF collection, serum creatine kinase, and direct Coombs' testing can be considered on an individual basis to evaluate for systemic diseases.

IMAGING
• Joints: ○ Imaging of multiple joints is recommended; initial radiographs may be unremarkable without obvious change for 6 or more months. ○ Progressive disease results in subchondral bone lysis, irregular joint surface, and narrowing or widening of the joint space, calcification of soft tissues around the joint, and extensive bone destruction. ○ Cats can have periosteal new bone formation and enthesophytes. • Thoracic and vertebral radiographs with abdominal ultrasound can help rule out reactive polyarthritis.

DIAGNOSTIC PROCEDURES
Arthrocentesis (joint tap): four joints should be sampled.

PATHOLOGIC FINDINGS
• Grossly, the synovium can be discolored, thickened, and ulcerated with extension of granulation tissue into the subchondral bone. • Histopathology of synovial membrane is rarely necessary, but may reveal synovial hypertrophy and hyperplasia, necrosis, and mononuclear inflammation (often lymphoplasmacytic).

POLYARTHRITIS, EROSIVE, IMMUNE-MEDIATED (CONTINUED)

TREATMENT

APPROPRIATE HEALTH CARE
Outpatient

NURSING CARE
Larger dogs may require more assistance and support during treatment.

ACTIVITY
Strict rest is recommended while symptomatic and painful.

DIET
No dietary restrictions.

CLIENT EDUCATION
• Management is lifelong. • Erosive disease is often progressive and less responsive to treatment. • Importance of weight management.

SURGICAL CONSIDERATIONS
• Arthrodesis (primarily carpal) has been used for joint luxation to improve quality of life.
• Surgical repair of CCLR if necessary.
• Synovectomy, arthroplasty, or joint replacement can be considered.
• Splenectomy as last resort in Felty's syndrome.

MEDICATIONS

DRUG(S) OF CHOICE

Antibiotics
• Doxycycline or minocycline recommended in cats and dogs while infectious disease testing is pending. • Tylosin trial in greyhounds for mycoplasma.

Dogs

Initial Therapy
• Prednisone or prednisolone 1–2 mg/kg/day or 50 mg/m^2, until remission encountered (often 4 weeks), then taper. • Cyclosporine 5 mg/kg PO q12—suitable alternative to corticosteroids.

Combination Therapy
Can be helpful to achieve remission, allow for tapering of corticosteroids and aid in refractory cases; each can be combined with corticosteroids:
• Mycophenolate mofetil 10 mg/kg PO q12h; taper by 50% after 2–3 weeks or if hemorrhagic gastrointestinal signs noted.
• Leflunomide 3–4 mg/kg PO q24h; allow 4–6 weeks before decreasing dose to every 48 hours then every 72 hours. • Azathioprine 1.6–2 mg/kg PO q24h for 2 weeks or until remission, then taper to every 48 hours.
• Other immunosuppressives to consider include chlorambucil, cyclophosphamide, levamisole, methotrexate.

Cats
• Prednisolone 2 mg/kg PO q12h followed by a taper; ~50% of cats with FPPP show improvement in signs and slowing of progression when used with analgesia. • 58% of cats improved using a protocol of methotrexate + leflunomide: methotrexate 2.5 mg/cat PO q12h for 3 consecutive doses (7.5 mg/24 hours) repeated weekly until improvement then 2.5 mg/cat PO weekly; leflunomide 10 mg/cat PO q24h until improvement then 10 mg/cat PO twice weekly. • Other immunosuppressive agents that can be considered include cyclosporine or chlorambucil.

Other
Omega-3 fatty acid supplementation.

Analgesia
Gabapentin 5–15 mg/kg PO q8–12h; amantadine 3–5 mg/kg PO q24h; nonsteroidal anti-inflammatory drug (NSAIDs) as appropriate if not using corticosteroids.

CONTRAINDICATIONS
Glucocorticoids should not be given with NSAIDs.

PRECAUTIONS
• Tapering immunosuppressive therapy too soon can lead to relapses. • Confirm aseptic inflammation prior to initiating immunosuppressive therapy. • Consider secondary immunosuppressive agent if unable to attain remission or if symptoms relapse while still on glucocorticoids. • Monitor for infectious diseases and opportunistic infections.

POSSIBLE INTERACTIONS
Concurrent use of multiple immunosuppressives with the same mechanism of action.

FOLLOW-UP

PATIENT MONITORING
• Monitor for potential side effects of treatments (liver enzymes, hyperglycemia, etc.) and concurrent disorders (e.g., hematologic abnormalities, proteinuria, etc.) as necessary, • Tapering of medications often possible after 4 weeks of therapy. A 50% taper every month or dose reduction of 25–30% every 2–3 weeks with a minimum of 4 months of therapy can be considered. • If relapse occurs during taper, increase corticosteroid to the most recent effective dose and/or consider a second agent, if not already utilized. • If relapse occurs after the taper, a short course of corticosteroid and the dose of the second agent that maintained clinical control can be utilized long term.
• Serial or repeated arthrocentesis can be performed to rule out poor control of immune-mediated disease in cases of ongoing or recurrent lameness. In some dogs, this may identify degenerative joint disease as the cause of lameness rather than relapse of polyarthritis.

EXPECTED COURSE AND PROGNOSIS
• Erosive disease is typically progressive; ~50% of cats will improve with good quality of life. • Monitoring recommended if initially nonerosive. • Tick-borne disease usually responds to appropriate antibiotic therapy within 7 days.

MISCELLANEOUS

ABBREVIATIONS
• CCLR = cranial cruciate ligament rupture.
• FeLV = feline leukemia virus.
• FIV = feline immunodeficiency virus.
• FPPP = feline periosteal proliferative polyarthritis.
• SLE = systemic lupus erythematosus.
• TNCC = total nucleated cell count.

POLYARTHRITIS, NONEROSIVE, IMMUNE-MEDIATED, DOGS

BASICS

DEFINITION
• Nonerosive polyarthritis—a non-infectious inflammatory disease of multiple (>2) joints without radiographic evidence of bone or cartilage involvement. • Most common polyarthropathy in dogs, idiopathic or type I immune-mediated polyarthritis (IMPA). • Reactive polyarthropathy, where inflammation in the joints is secondary to distant disease, includes types II, III, and IV—disease is secondary to chronic inflammatory or infectious disease, chronic gastrointestinal disease, and neoplasia, respectively. • Systemic lupus erythematosus (SLE), familial shar-pei fever (FSF), and familial juvenile-onset polyarthritis of Akitas are less common nonerosive polyarthritides.

PATHOPHYSIOLOGY
• All causes of nonerosive polyarthritis are immune-mediated. • Immune complex deposition is the underlying mechanism in idiopathic IMPA (type I) and reactive polyarthropathy (types II, III, and IV). • Reactive polyarthropathy involves immune stimulus distant to the joints due to underlying infectious, inflammatory, or neoplastic disease, as well as adverse drug reactions, with subsequent immune complex deposition in the synovium. • SLE is the result of immune complex deposition secondary to autoantibodies (antinuclear antibodies [ANA]) formed against tissue proteins and DNA. • FSF is the result of amyloid deposition in the synovium.

SYSTEMS AFFECTED
• Musculoskeletal: ○ Appendicular joints are more commonly affected than axial joints. Intervertebral joints are not usually affected. ○ Distal joints (carpus, tarsus) are more commonly affected than proximal joints (stifle, shoulder, coxofemoral) in IMPA. ○ The hock joints are typically affected in FSF. • Hemic/lymphatic/immune: ○ Immune stimulus may result in fever, lethargy, and poor appetite. ○ Hemolytic anemia and thrombocytopenia may be present in SLE. • Skin/exocrine: ○ Immune-mediated skin disease targeting the mucocutaneous junctions is common in SLE. • Renal/urologic: ○ Immune-complex deposition in the kidneys and protein-losing nephropathy may be present in SLE. ○ Glomerulonephropathy and proteinuria secondary to amyloidosis may occur in FSF.

GENETICS
MTBP gene missense mutation is believed to be responsible for FSF.

INCIDENCE/PREVALENCE
• Idiopathic IMPA is common in dogs. • Reactive polyarthritis accounts for only 25% of nonerosive polyarthritis cases in dogs. • IMPA is rare in cats.

SIGNALMENT
Species
Dog and cat.

Breed Predilections
• Large-breed dogs, such as Labrador retrievers, golden retrievers, Rottweilers, Irish setters, Shetland sheepdogs, cocker spaniels, and American Eskimo dogs are overrepresented for idiopathic IMPA. • Doberman pinschers are overreported in cases of polyarthropathy secondary to sulfonamide administration.

Mean Age and Range
Mean age 4–6 years old, range 6 months to 12 years.

Predominant Sex
None reported.

SIGNS
Historical Findings
• Shifting limb lameness. • Stiff gait. • Fever. • Reluctance to walk. • Lethargy. • Inappetence. • Exercise intolerance. • Lymphadenopathy.

Physical Examination Findings
• Joint pain. • Joint effusion. • Fever. • Lameness.

CAUSES
• Type I IMPA—idiopathic. • Immune-mediated dermatopathy and hepatopathy are among the most common noninfectious causes of type II IMPA. Infectious sources to consider include endocarditis, discospondylitis, prostatitis, deep pyoderma, and systemic infections (fungal, protozoal). • Type III IMPA occurs secondary to chronic gastrointestinal disease such as inflammatory bowel disease, but is rare. • Type IV IMPA has been reported secondary to renal carcinoma, mammary carcinoma, leiomyoma, Sertoli cell tumor, and seminoma. • Drugs implicated in adverse drug reaction-related polyarthropathy (type II) include human albumin, erythropoeitin, phenobarbital, and antibiotics such as sulfonamides, cephalosporins, penicillins, lincosamides, and macrolides. This should be considered a potential cause when administered 5–20 days prior to the onset of signs. • Reports of postvaccinal polyarthropathy have included canine distemper and Lyme vaccines, typically within 30 days of vaccine administration.

RISK FACTORS
N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Infectious polyarthritis, including rickettsial disease, *Mycoplasma*, bacterial, and fungal etiologies: ○ *Borrelia burgdorferi*, *Anaplasma phagocytophilum*, *Rickettsia rickettsii*, *Ehrlichia canis*, *E. ewingii*, and *E. chaffeensis* are among the rickettsial diseases that should be considered for polyarthropathy. • Leishmaniasis should be considered, particularly in instances of significant systemic involvement, presence of skin lesions, and/or history of travel to the Mediterranean/southern Europe, Africa, India, or South America within the past 7 years. • Panosteitis and hypertrophic osteodystrophy should be considered, particularly in young dogs with lameness and fever. • Degenerative joint disease (DJD) should be considered in middle-age to older animals. • Viral etiologies have been implicated as a cause of polyarthritis in cats, including feline calicivirus and feline coronavirus associated with feline infectious peritonitis.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC—mild non-regenerative anemia and mild leukocytosis; leukopenia is also possible. Presence of thrombocytopenia may be suggestive of tick-borne disease or when severe, SLE. • Chemistry—often normal, except when distant (reactive polyarthropathy) or polysystemic disease (SLE) is present. • Urinalysis—proteinuria may be present and should prompt obtaining a UPC.

OTHER LABORATORY TESTS
• Definitive diagnosis can be obtained by arthrocentesis and cytology of multiple joints. • Aerobic and anerobic joint culture to definitively exclude septic arthritis in all cases; sensitivity is ~50% and can be improved with broth-enrichment media and incubation prior to culture. • Fungal cultures of joint fluid may be considered, though direct joint involvement is rare. • Mycoplasmal PCR or culture of synovial fluid may be considered, with PCR being more sensitive. • Tick PCR panels to exclude rickettsial disease should be performed in all cases. Quantitative serology may be considered but positive results may lag behind onset of clinical signs, and false-negative results are common. Qualitative tests for antibody production, including SNAP ELISA tests, may be indicated in cases with high index of clinical suspicion for rickettsial diseases such as Lyme disease. • Serologic fungal titers may be considered where fungal disease is endemic or there has been travel history to rule it out as a cause of reactive polyarthropathy. • Blood and urine cultures should be considered to exclude bacterial causes of reactive polyarthropathy in cases where no obvious infectious or inflammatory focus is identified. Positive blood cultures may be indicative of primary septic polyarthritis of hematogenous origin given relatively low sensitivity of bacterial culture of synovial fluid. • C-reactive protein (CRP) can be measured as a nonspecific indicator of inflammation and reassessed for response to therapy. • ANA titer may be submitted in cases where there is multisystemic immune-mediated involvement.

POLYARTHRITIS, NONEROSIVE, IMMUNE-MEDIATED, DOGS (CONTINUED)

IMAGING
• Appendicular radiographs including affected joints are necessary to exclude erosive causes of polyarthropathy, though these diseases are uncommon in dogs and may not be radiographically visible initially. Absence of palpable joint effusion should not preclude recommendation to obtain radiographs in cases where clinical suspicion is otherwise suggestive of polyarthritis and screening radiographs of multiple joints should be obtained. • Joint effusion is the main radiographic finding. Radiographic signs of osteoarthritis may be concurrently present and do not exclude nonerosive polyarthritis as a diagnosis. • Thoracic radiography, abdominal ultrasonography, and echocardiography should ideally be performed to assess for causes of reactive polyarthropathy.

DIAGNOSTIC PROCEDURES
• Arthrocentesis should be performed aseptically on 3–5 joints for synovial fluid collection, under sedation or general anesthesia. • Synovial biopsy can be used for confirmation in challenging cases.

PATHOLOGIC FINDINGS
• Turbid ± reduced viscosity of synovial fluid, ± voluminous fluid. • Synovial fluid cytology characterized by predominantly neutrophilic (>10%) inflammation without evidence of infectious agents in the synovial fluid.

TREATMENT

APPROPRIATE HEALTH CARE
• Typically outpatient therapy.
• Systemic signs (i.e., fever, inappetence) may necessitate hospitalized supportive care.

ACTIVITY
Activity restriction to avoid exacerbation of pain and lameness.

DIET
Weight reduction as applicable to avoid undue stress on joints.

CLIENT EDUCATION
Discuss failure to control clinical signs, particularly in cases where underlying disease cannot be eliminated, and possibility or recurrence and/or need for lifelong medication and monitoring.

MEDICATIONS

DRUG(S) OF CHOICE
• Immunosuppressive dose of steroids, i.e., prednisone (dog) or prednisolone (cat): 2 mg/kg/day PO for 4 weeks, then gradually tapered over at least 4 months unless combination immunosuppressive protocols are used. • Nonsteroidal anti-inflammatory drugs (NSAIDs) for FSF, i.e., carprofen 2.2 mg/kg PO twice daily.

PRECAUTIONS
Consider risks and complications of prolonged steroid courses, including immunosuppression, diabetes mellitus, risk for congestive heart failure, and muscle-wasting.

POSSIBLE INTERACTIONS
NSAIDs and steroids should be not be given together due to increased risk of gastrointestinal ulceration; a 7-day washout period is indicated between medications.

ALTERNATIVE DRUG(S)
• Cyclosporine—dog: 5 mg/kg PO twice daily; cat: 4 mg/kg PO twice daily. • Mycophenolate mofetil—dog: 10 mg/kg PO or IV twice daily. • Leflunomide—dog: 2–4 mg/kg PO once daily; cat: 10 mg/cat PO once daily. • Azathioprine—dog: 2 mg/kg PO once daily, tapered to 0.5–2 mg/kg PO every other day. • Chlorambucil—dog: 1–2 mg/m^2 PO once daily; cat: 15 mg/m^2 PO once daily for 4 days once every 3 weeks or 2 mg/cat every other day. • Cyclophosphamide—dog: 1.5 mg/kg PO when patient >25 kg, 2 mg/kg PO when patient 5–25 kg, 2.5 mg/kg PO when patient <5 kg every other day or 4 consecutive days of the week; cat: 2.5 mg/kg once daily. • Analgesics may be considered for additional pain control (e.g., gabapentin (dog), 5–10 mg/kg PO twice daily). • Given the disease is rare in cats, consider doxycycline 5 mg/kg PO twice daily for 14 days to treat infectious etiologies prior to initiating immunosuppression.

FOLLOW-UP

PATIENT MONITORING
• Repeat arthrocentesis may be considered for evaluation of response to treatment, especially prior to medication changes (i.e., at 4 weeks, prior to beginning steroid taper). • CRP has a modest correlation to synovial fluid cytology and may be performed as a noninvasive means of patient monitoring. • CRP and IL-6 may be used to distinguish recurrence of IMPA from osteoarthritis.

PREVENTION/AVOIDANCE
Avoid nonessential vaccination for prevention of recurrence. Canine distemper vaccine should not be given if seroprotective antibody titer levels are present.

POSSIBLE COMPLICATIONS
• Immunosuppression and risk of secondary infection, particularly when multiple immunosuppressive drugs are used.
• Subsequent DJD may occur following IMPA. Patients may show lameness when steroid therapy is tapered, however most are afebrile.

EXPECTED COURSE AND PROGNOSIS
• Good prognosis for idiopathic IMPA with expected improvement in clinical signs within 7 days. • Recurrence is possible and reported in almost 30% of cases. • 10% of cases fail to respond to immunosuppressive therapy.
• Variable prognosis for reactive polyarthropathy, depending on the ability to eliminate or control the underlying disease process.
• Guarded prognosis for SLE.

MISCELLANEOUS

ABBREVIATIONS
• ANA = antinuclear antibody. • CRP = C-reactive protein. • DJD = degenerative joint disease. • FSF = familial shar-pei fever. • IL-6 = interleukin-6. • IMPA = immune-mediated polyarthritis. • NSAID = nonsteroidal anti-inflammatory drug. • SLE = systemic lupus erythematosus.

POLYCYSTIC KIDNEY DISEASE

BASICS

OVERVIEW
Disorder in which large portions of normal renal parenchyma are displaced by multiple cysts; renal cysts develop in nephrons and collecting ducts; both kidneys are invariably affected. In most cases the disease is inherited, irreversible, and progressive.

SIGNALMENT
- Persian and related breeds (e.g., exotic shorthair, Himalayan, British shorthair) more commonly affected.
- Dog breeds affected include Cairn terriers and beagles.

SIGNS
- Cysts are clinically silent until their increasing size and number contribute to azotemia or abdominal enlargement.
- May detect bosselated (lumpy) kidneys by abdominal palpation.
- Most renal cysts are not painful when palpated, but acute secondary infection may cause rapid distension of the renal capsule and pain.

CAUSES & RISK FACTORS
- Autosomal-dominant inheritance in Persian cats.
- Cause of renal cyst formation remains obscure; genetic, endogenous, and environmental factors appear to influence the process.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other multicystic diseases of the kidneys.
- Glomerulocystic disease of collies.
- Renal cystadenocarcinoma associated with nodular fibrosis in German shepherd dogs.
- Renal cysts associated with chronic kidney disease (CKD) or renal dysplasia.
- Renal neoplasia.
- Hydronephrosis.
- Perirenal pseudocysts.
- Mycotic or bacterial nephritis.

CBC/BIOCHEMISTRY/URINALYSIS
- Results unremarkable unless patient has CKD.
- Hematuria is rare.

OTHER LABORATORY TESTS
- Genetic tests are available to identify the autosomal dominant polycystic kidney disease (AD-PKD) type 1 mutation in cats. This test is useful to screen kittens less than 3–4 months old when ultrasonography may be less sensitive, as well as in breeding cats. Other mutations may also cause inherited kidney cysts.
- Cyst fluid can be clear, cloudy, or hemorrhagic, and the fluid from two cysts in the same kidney can differ.
- Bacterial culture of cyst fluid aids in diagnosing infection.

IMAGING

Radiography
Survey radiography and IV contrast urography are insensitive methods of confirming cystic disease.

Ultrasonography
- Reveals anechoic cavitating lesions characterized by sharply marginated smooth walls and distal enhancement.
- Can usually detect cysts >2 mm in diameter.
- Cysts have been detected in cats as young as 7 weeks; screening cats younger than 6 months is associated with higher false-negative results.
- Hypoechoic cystic cavities may be seen in some cysts infected with bacteria.
- Detection of cysts in other organs which helps to differentiate AD-PKD from other inherited or acquired multicystic disorders of the kidneys.

DIAGNOSTIC PROCEDURES
Evaluation of fine-needle aspirates of the kidney may allow differentiation of cystic disease from other diseases that cause renomegaly.

TREATMENT
- Usually not life-threatening, but pyelonephritis and cyst involvement warrant immediate measures to prevent sepsis and mortality.
- Most cysts increase in size and number, often impairing adjacent renal parenchyma.
- Elimination of renal cysts is not yet feasible; treatment is limited to minimizing the consequences of renal cyst formation (i.e., CKD, infection, hematuria, and pain).
- Removing fluid from large cysts may minimize pain and compression of adjacent renal parenchyma. This procedure is impractical in kidneys with multiple large cysts.
- A vasopressin antagonist (tolvaptan), has been shown to slow kidney enlargement and slow decline in kidney function in people with AD-PKD.
- Some patients require treatment for concomitant CKD.
- Consider nephrectomy only if infected cysts are associated with uncontrollable sepsis.
- Disease eradication by selective breeding of unaffected cats may be impossible because ~40% of Persians are affected.

MEDICATIONS

DRUG(S) OF CHOICE
- Bacterial infection of cysts is rare. Unless infection is accompanied by pyelonephritis, bacteria may not be observed in urine. Consider parenchymal infection when cysts are associated with renal pain and fever, even in absence of bacteriuria.
- The acidic cyst fluid and its epithelial barrier may reduce concentrations of acidic antibiotics (e.g., cephalosporins and penicillins) within cystic lumens. Alkaline, lipid-soluble antibiotics (e.g., trimethoprim–sulfonamide, fluoroquinolones, chloramphenicol, tetracycline, and clindamycin), which penetrate epithelial barriers and become ionized and trapped in cyst lumens, are recommended.

FOLLOW-UP
- Monitor every 2–6 months for progressive disease (e.g., CKD, renal infection, and pain).
- In the absence of sepsis, the short-term prognosis is favorable.

MISCELLANEOUS

ABBREVIATIONS
- AD-PKD = autosomal dominant-polycystic kidney disease.
- CKD = chronic kidney disease.

POLYCYTHEMIA VERA

BASICS

OVERVIEW
Myeloproliferative disorder of the chronic myelogenous leukemia (CML) spectrum, resulting in high blood viscosity secondary to an increased red blood cell (RBC) mass.

SIGNALMENT
- Dog and cat.
- Primarily old animals.

SIGNS
- Gradual in onset; may be incidental diagnosis.
- Depression.
- Anorexia.
- Weakness.
- Polydipsia and polyuria.
- Erythema of skin and mucous membranes.
- Dilated and tortuous retinal blood vessels.
- Uveitis.
- Acute blindness.
- Splenomegaly and hepatomegaly uncommon.

CAUSES & RISK FACTORS
A *JAK2* mutation has been implicated in the disease pathogenesis.

DIAGNOSIS
Diagnostic tests should exclude all other conditions that may lead to increased packed cell volume (PCV) and RBC mass.

DIFFERENTIAL DIAGNOSIS
- Severe dehydration.
- Renal neoplasia.
- Chronic pyelonephritis.
- Hyperadrenocorticism.
- Androgen stimulation.
- Chronic pulmonary disease.
- Cardiac disease with right-to-left shunts.

CBC/BIOCHEMISTRY/URINALYSIS
- High PCV.
- Absolute increase in RBC mass.
- Prerenal azotemia possible.
- Leukocytosis in 50% of dogs.

OTHER LABORATORY TESTS
- Pao_2—normal.
- Serum erythropoietin concentrations are usually low to zero and often overlap with those reported for other causes of polycythemia.
- Cytologic examination of bone marrow and core biopsy, in parallel with peripheral blood count analysis.

IMAGING
- Radiography—assess kidneys and cardiopulmonary system.
- Abdominal ultrasonography—assess kidneys and adrenal glands.
- Echocardiography—evaluate for right-to-left cardiac shunts.

DIAGNOSTIC PROCEDURES
- Bone marrow biopsy.
- Electrocardiography—assess heart disease.
- Retinal examination/ophthalmologic consult.
- Blood pressure measurement.

TREATMENT
- Phlebotomy and concurrent replacement with intravenous isotonic fluids—to provide relief of signs during clinical crisis.
- Hydroxyurea—may temporarily decrease the RBCs and provide disease control.
- Consult a veterinary medical oncologist for most current recommendations and disease management.

MEDICATIONS

DRUG(S) OF CHOICE
Hydroxyurea 40–50 mg/kg PO divided twice daily; titrate to response and toxicity (dog and cat).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A

FOLLOW-UP
Periodic reexaminations with serial CBCs, retinal examinations, and serum biochemical profiles to monitor disease control and hydroxyurea side effects on bone marrow and other organs.

MISCELLANEOUS

ABBREVIATIONS
- CML = chronic myelogenous leukemia.
- PCV = packed cell volume.
- RBC = red blood cell.

POLYNEUROPATHIES (PERIPHERAL NEUROPATHIES)

BASICS

DEFINITION
Diseases affecting peripheral motor, sensory, autonomic, and/or cranial nerves, in any combination.

PATHOPHYSIOLOGY
• Inherited or acquired (degenerative, idiopathic, metabolic/endocrine, neoplastic/paraneoplastic, immune-mediated inflammatory, infectious, drugs/toxic). • Primary pathologic process—(1) *axonal neuropathies*, caused by either destruction or degeneration of neuronal cell bodies in dorsal root ganglia, ventral horn cells, or autonomic ganglia (neuronopathies) or axonal degeneration with secondary demyelination (axonopathies), or (2) *demyelinating neuropathies* with primary demyelination due to disease of the Schwann cells or myelin sheath.

SYSTEMS AFFECTED
• Nervous—peripheral nervous system (occasionally also affecting CNS); possible involvement of the cranial nerves. • Other organ systems may be involved in the primary disease process.

GENETICS
• Most inherited—autosomal recessive disorders. • Spinal muscular atrophy in Brittany spaniels, laryngeal paralysis in bouvier des Flandres—autosomal dominant.

INCIDENCE/PREVALENCE
• Inherited—rare. • Peripheral nerve involvement in metabolic and neoplastic diseases—incidence unknown.
• Inflammatory—uncommon; coonhound paralysis (CHP) most frequent.

GEOGRAPHIC DISTRIBUTION
• CHP—North and Central America, parts of South America. • Distal denervating disease—dogs in UK; not reported elsewhere.
• Dysautonomia—mostly dogs (occasionally cats) in Missouri, Oklahoma, and Kansas; cats in Scandinavia and UK.

SIGNALMENT

Species
Dog and cat.

Breed Predilections—Inherited
Spinal Muscular Atrophy
• Brittany spaniel, Swedish Lapland dog, English pointer, German shepherd dog, Doberman pinscher, Rottweiler, griffon Briquet, Saluki, Maine Coon cats. • Progressive neuronopathy—Cairn terrier.

Axonopathies
• Giant axonal neuropathy—German shepherd dog. • Progressive axonopathy—boxer. • Laryngeal paralysis—bouvier des Flandres. • Laryngeal paralysis/polyneuropathy complex—Dalmatian, Rottweiler, Pyrenean mountain dog. • Distal sensorimotor polyneuropathy—Rottweiler, Alaskan Malamute, Great Dane, Leonberger dog, bouvier des Flandres. • Progressive central and peripheral sensorimotor axonopathy—golden retriever. • Central-peripheral distal axonopathy—Birman cat. • Axonal neuropathy—Snowshoe cat. • Primary hyperoxaluria—domestic shorthair cats.

Demyelination
• Hypertrophic neuropathy—Tibetan mastiff. • Congenital hypomyelination neuropathy—golden retriever.
• Demyelinating polyneuropathy–miniature schnauzers. • Recurrent demyelinating-remyelinating polyneuropathy—Bengal cat.

Lysosomal Storage Diseases
• Globoid cell leukodystrophy—West Highland white terrier, Cairn terrier, domestic shorthair cats • Alpha-L-fucosidosis—English Springer spaniel. • Mannosidosis—Persian and domestic shorthair cats. • G_{M1} gangliosidosis type II—Siamese and Korat cats. • Sphingomyelinosis (Niemann–Pick disease type A)—Siamese and Balinese cats. • Glycogenosis type IV—Norwegian forest cat.

Sensory Neuropathy
• Longhaired dachshund, English pointer, German shorthaired pointer, English springer spaniels, French spaniels, Jack Russell terrier, border collies. • Ganglioradiculitis—Siberian husky.

Breed Predilections—Acquired
• CHP—higher incidence in coonhounds.
• Clinical diabetic polyneuropathy—more common in cat than dog. • Insulinomas—German shepherd dog, boxer, Irish setter, standard poodle, collie.

Mean Age and Range
Inherited
• Often begin at <6 months of age. • Feline hyperchylomicronemia—1–8 months.
• Feline hyperoxaluria—5–9 months.
• Rottweiler, bouvier, Leonberger distal polyneuropathies—>1 year. • Giant axonal neuropathy in German shepherd dog—14–16 months. • Intermediate and chronic forms of spinal muscular atrophy in heterozygote Brittany spaniel—6–12 months.

Acquired
• Secondary to neoplasia and insulinoma-associated hypoglycemia—middle-aged to older animals. • *Neospora caninum* polyradiculoneuritis—usually dogs <6 months of age. • Ganglioradiculitis—>1 year.

SIGNS

Historical Findings
Inherited
• Most—progressive lower motor neuron (LMN) tetraparesis; generalized weakness, muscle tremors and atrophy, plantigrade/palmigrade stance; stridor/voice change if laryngeal paralysis. • Sensory neuropathies—self-mutilation (nociceptive deficits), mild to severe ataxia. • Lysosomal storage diseases—slowly progressive CNS involvement (head tremors, ataxia, dysmetria, seizures, blindness, dementia) occur in conjunction with the LMN signs. • Sphingomyelinosis in cats—often present only with progressive motor and sensory neuropathy. • Giant axonal neuropathy of German shepherd dogs—rapidly progressive generalized weakness (<3 weeks).

Acquired
• Rapid or slow progression. • Rapidly progressive course—initial stiff, stilted gait, leading to generalized LMN paresis or paralysis (CHP, distal denervating disease).
• Slowly progressive course—generalized weakness and muscle atrophy; in distal polyneuropathies (diabetic neuropathy especially in cats), plantigrade/palmigrade stance. • Dysautonomia—primarily acute onset (<48 hours) of depression, anorexia, regurgitation, vomiting, paralytic ileus, xerostomia, keratoconjunctivitis sicca (KCS), third eyelid protrusion, urinary incontinence.
• Metabolic—owner reports non-neurologic clinical signs associated with weakness.
• Paraneoplastic—primary tumor may be clinically silent at time of presentation or revealed on thoracic radiographs or abdominal ultrasound.

Physical Examination Findings
• Motor and sensorimotor—tetraparesis to tetraplegia, hyporeflexia to areflexia, hypotonia to atonia, and muscle atrophy classic; muscle tremors common. • Sensory—proprioceptive deficits, hypoesthesia to anesthesia, without muscle atrophy or hyporeflexia (except in boxers); sensory ataxia.
• Paraesthesia—feline diabetic neuropathy, sensory neuropathies. • Hypothyroidism—may be associated with generalized polyneuropathy, laryngeal and/or facial nerve paralysis, megaesophagus, and vestibular signs.
• Lysosomal storage diseases—hepatosplenomegaly common. • Paraneoplastic—may find evidence of neoplasia. • Dysautonomia—dry nose, KCS, bradycardia, anal areflexia.
• Primary hyperchylomicronemia (cats)—lipid granulomata, which can be palpated under the skin and abdomen. • Primary hyperoxaluria (cats)—enlarged, painful kidneys on palpation. • Cranial nerve abnormalities (including dysphonia/aphonia)—variable.

CAUSES

Acquired
• Immune-mediated—primary or secondary; may be seen with systemic lupus erythematosus (SLE), glomerulonephritis, polyarthritis.
• Metabolic/endocrine—diabetes mellitus (cats), hypothyroidism, hyperadrenocorticism.
• Neoplastic/paraneoplastic—insulinoma, carcinomas, malignant melanoma, mast cell tumor, osteosarcoma, multiple myeloma,

POLYNEUROPATHIES (PERIPHERAL NEUROPATHIES) (CONTINUED)

lymphosarcoma. • Infectious—*N. caninum,* feline leukemia virus (FeLV), feline immunodeficiency virus (FIV). • Chemotherapy drugs—vincristine, vinblastine, cisplatin. • Toxic—thallium, organophosphates, salinomycin (cats), lasalocid (dogs). • Idiopathic.

RISK FACTORS
Development of specific diseases (metabolic, immune, neoplastic) or exposure to specific drugs/toxins or causal factors (raccoon saliva).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Acute—botulism; tick paralysis; fulminant myasthenia gravis; acute multifocal myelopathies. • Chronic—polymyopathy; chronic multifocal myelopathies.

CBC/BIOCHEMISTRY/URINALYSIS
• Standard laboratory tests—often normal; may indicate underlying metabolic or neoplastic disease. • High serum creatine kinase—indicates an accompanying myopathy or diagnosis of polymyopathy.

OTHER LABORATORY TESTS
• Antinuclear antibody, Coombs' test—if immune disease suspected. • Low total thyroxine (T_4), low free T_4, and high endogenous thyroid-stimulating hormone (TSH)—hypothyroidism. • Amended insulin: glucose ratio >30—supports the diagnosis of insulinoma. • Serology—assists in the diagnosis of *N. caninum,* FIV, FeLV infection. • Diminished lysosomal enzyme activity in leukocytes, cultured fibroblasts—lysosomal storage diseases. • Pharmacologic testing (pilocarpine ophthalmic drops, bethanechol challenge)—dysautonomia. • High serum cholesterol and triglycerides, low lipoprotein lipase—hyperchylomicronemia. • Oxalate and/or L-glyceric acid in urine—primary hyperoxaluria. • Monoclonal gammopathy—multiple myeloma.

IMAGING
Thoracic and abdominal radiographs—search for a neoplastic cause; megaesophagus, ileus, bladder atony, constipation, and delayed gastric emptying in dysautonomia.

DIAGNOSTIC PROCEDURES
• Electrophysiology (EMG, motor and sensory nerve conduction studies ventral and dorsal nerve root studies)—cornerstone for diagnosis. • Lumbar CSF analysis—valuable in diagnosing nerve root involvement. • Muscle biopsy—confirms denervation. • Peripheral nerve biopsy (distal)—further characterizes disease process.

PATHOLOGIC FINDINGS
Lesion distribution along peripheral nerves (proximal, distal, widespread) and degree of axonal degeneration, demyelination, and/or neuronal cell body degeneration depends on the specific condition present.

TREATMENT

APPROPRIATE HEALTH CARE
• Usually outpatient. • Inpatient—observe dogs with CHP closely for respiratory failure in early progressive phase of disease.

NURSING CARE
• Dysautonomia—may require IV fluid therapy and/or parenteral feeding. • Physical therapy.

DIET
• Generally no special management, unless megaesophagus or dysphagia occurs. • Hyperchylomicronemia—low-fat diet alone can resolve the polyneuropathy in 2–3 months. • Paralysis—ensure patient can reach food and water. • Regurgitation and/or vomiting—temporarily halt oral intake; consider gastrostomy tube. • Diabetes mellitus—monitor food intake; in cats, feed a low-carbohydrate, high-protein diet; diabetic neuropathy often reversible with treatment.

CLIENT EDUCATION
• Treatment of primary cause may not lead to reversal of signs; in some cases, deterioration will continue. • Canine axonal degeneration—progressive deterioration.

MEDICATIONS

DRUG(S) OF CHOICE
• Inherited—most untreatable. • Acquired—treat primary cause with the hope that the secondary polyneuropathy improves or resolves; not always successful. • Chronic relapsing demyelinating neuropathy—most likely of immune origin; may improve with long-term immunosuppressive therapy (prednisone, azathioprine, cyclophosphamide); response of individual patient variable. • SLE-related—treat as for chronic relapsing polyneuropathy. • Neoplasia—treat primary neoplasia. • *Neospora*-associated polyradiculoneuritis—clindamycin combined with pyrimethamine. • Dysautonomia—treat symptomatically with IV fluids, artificial tears, metoclopramide, bethanechol (cats, 0.5–2.5 mg SC q12h or 2.5–10 mg PO q6–8h; dogs, 0.5–15 mg SC q12h or 2.5–30 mg PO q6–8h), and pilocarpine eye drops.

CONTRAINDICATIONS
Corticosteroids—contraindicated in *Neospora*-associated polyradiculoneuritis, hyperadrenocorticism, and CHP.

FOLLOW-UP

PATIENT MONITORING
Repeat neurologic examinations.

PREVENTION/AVOIDANCE
• Avoid breeding patients with *Neospora* (placental transfer of the organism from the bitch). • Avoid contact with raccoons. • Avoid future vaccinations if suspected associated with vaccines.

POSSIBLE COMPLICATIONS
Continued neurologic deterioration leading to inability to ambulate, severe muscle atrophy, pressure sores, urinary tract infection, muscle fibrosis, aspiration pneumonia.

EXPECTED COURSE AND PROGNOSIS
• Demyelinating conditions—more rapid improvement than axonal neuropathies (majority), which can take months for partial or complete recovery, if at all. • Inherited—most have a poor prognosis (except hyperchylomicronemia in cats). • Acute polyradiculoneuritis (CHP)—good long-term prognosis; may take weeks to months to recover. • Metabolic—fair-to-good prognosis with successful treatment of primary metabolic abnormality; insulinomas have high recurrence rate. • Other acquired—most show continued deterioration despite treatment.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING
Immunosuppressive agents—contraindicated.

ABBREVIATIONS
• CHP = coonhound paralysis. • EMG = electromyography. • FeLV = feline leukemia virus. • FIV = feline immunodeficiency virus. • LMN = lower motor neuron. • KCS = keratoconjunctivitis sicca. • SLE = systemic lupus erythematosus. • T_4 = thyroxine. • TSH = thyroid-stimulating hormone.

POLYPHAGIA

BASICS

DEFINITION
Increased food intake.

PATHOPHYSIOLOGY
- Failure to assimilate or loss of nutrients (e.g., maldigestion/malabsorption syndromes such as exocrine pancreatic insufficiency).
- Inability to use nutrients (e.g., diabetes mellitus, poor-quality diets, gastrointestinal parasites).
- Hypoglycemia (e.g., insulinoma, insulin overdose).
- Increased metabolic rate or demand (e.g., hyperthyroidism, cold environments, pregnancy, lactation).
- Psychologic or learned behaviors (e.g., palatable diets, competition with other household pets).
- Iatrogenic (e.g., drugs such as anticonvulsants or glucocorticoids).
- Genetic (e.g., Labrador and flat-coated retrievers).

SYSTEMS AFFECTED
- Cardiovascular—obesity can worsen clinical cardiac disease.
- CNS—tumors of the brain, especially of the hypothalamus, can cause polyphagia.
- Integument—obese animals, especially cats, are susceptible to dermatitis.
- Musculoskeletal—overweight patients are susceptible to arthritis and other orthopedic problems.
- Respiratory—obesity exacerbates dyspnea in patients with respiratory disease.

SIGNALMENT
- Dogs and cats.
- Some dog breeds are prone to obesity: beagle, Rottweiler, cocker spaniel, dachshund, Shetland sheepdog, dalmation, and the retrievers.

SIGNS

Historical Findings
- Eating more frequently and/or a greater quantity than normal.
- Excessive food-seeking and food-stealing behaviors.
- Weight loss may occur with certain disease states (e.g., exocrine pancreatic insufficiency, diabetes mellitus, hyperthyroidism).
- Polyuria/polydipsia (PU/PD) occurs in some patients (diabetes mellitus, hyperthyroidism, hyperadrenocorticism).

Physical Examination Findings
Patients may have excessive body fat, but those with an underlying medical problem (e.g., exocrine pancreatic insufficiency, diabetes mellitus, hyperthyroidism) may be thin.

CAUSES

Physiologic
- Pregnancy.
- Lactation.
- Growth.
- Response to a cold environment.
- Increased exercise.
- Genetic predispositions:
  - 14-bp deletion in the pro-opiomelanocortin (*POMC*) gene of Labrador and flat-coated retrievers leading to increases in obesity, adiposity, and food motivation.
  - Polymorphism in the melanocortin 4 receptor gene (*MC4R*: c.92C>T) predisposing obese cats to development of diabetes mellitus.

Pathologic
- Diabetes mellitus.
- Hyperthyroidism—cats.
- Hyperadrenocorticism—dogs.
- Exocrine pancreatic insufficiency.
- Gastrointestinal parasites.
- Insulinoma.
- Insulin overdose.
- Lymphangiectasia.
- Growth hormone-secreting pituitary tumor.
- Megaesophagus.
- Lymphocytic plasmacytic enteritis in cats—uncommon.
- Neoplasms of the brain—rare.
- Gastrointestinal neoplasms—rare.
- Compulsive polyphagia—rare.

Iatrogenic
- Corticosteroids.
- Progestins.
- Benzodiazepines.
- Anticonvulsants.
- Palatable food.
- Free feeding/overfeeding.
- Poor diet.
- Competition for food.

RISK FACTORS

Environmental
- Lower income owners.
- Older age of the patient.
- Older age of the owner.
- Female spayed > male neutered > intact both sexes.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
PU/PD (excessive trips to food/water area)—differentiate by observation.

CBC/BIOCHEMISTRY/URINALYSIS
- Neutrophilia, monocytosis, lymphopenia, and eosinopenia with hyperadrenocorticism, and in patients receiving corticosteroids.
- Hyperglycemia with diabetes mellitus, growth hormone-secreting pituitary tumors (cats, insulin-resistant diabetes mellitus), and hyperadrenocorticism (mild).
- Hypercholesterolemia with recent food intake, hyperadrenocorticism, and diabetes mellitus, and in patients receiving corticosteroids.
- High alkaline phosphatase and alanine aminotransferase activity with hyperadrenocorticism (dogs), hyperthyroidism (cats), and diabetes mellitus, and in patients receiving corticosteroids.
- Hypoproteinemia with protein-losing enteropathies (e.g., lymphangiectasia, inflammatory bowel disease).
- Hypoglycemia in patients with insulinoma or insulin overdose.
- Low urine specific gravity with diabetes mellitus, diabetes insipidus, hyperthyroidism, and hyperadrenocorticism, and in patients receiving corticosteroids.
- Glucosuria, possibly ketonuria, with diabetes mellitus.

OTHER LABORATORY TESTS
- Fecal examination to rule out gastrointestinal parasites.
- Serum trypsin-like immunoreactivity to diagnose exocrine pancreatic insufficiency.
- Total serum T_4 to rule out hyperthyroidism (cats); T_3 suppression testing if hyperthyroidism is suspected but serum total T_4 is normal.
- Low-dose dexamethasone suppression or adrenocorticotropic hormone (ACTH) stimulation test to diagnose hyperadrenocorticism; plasma ACTH level or high-dose dexamethasone suppression testing to differentiate pituitary-dependent hyperadrenocorticism from adrenal tumor if hyperadrenocorticism is confirmed with the low-dose dexamethasone suppression test or ACTH stimulation test.
- Serum insulin levels in hypoglycemic patients to rule out insulinoma.

IMAGING
- Abdominal radiology may demonstrate hepatomegaly associated with hyperadrenocorticism, diabetes mellitus, and corticosteroid administration.
- Abdominal ultrasonography may demonstrate an adrenal mass or bilateral adrenomegaly (hyperadrenocorticism), hepatomegaly (hyperadrenocorticism, diabetes mellitus, and corticosteroid administration), bowel wall thickening or bowel wall layering disruption (inflammatory bowel disease, lymphoma, lymphangiectasia), and pancreatic masses (insulinoma).
- MRI could be used to visualize a neoplasm of the hypothalamus.

DIAGNOSTIC PROCEDURES
Endoscopy with biopsy of the upper gastrointestinal tract to rule out gastrointestinal diseases.

POLYPHAGIA (CONTINUED)

TREATMENT

- Usually outpatient medical management.
- Polyphagia without weight gain or with weight loss is more likely due to a medical problem; evaluate the animal prior to food restriction or manipulation.
- Once pathologic causes of polyphagia have been excluded, limit the amount of food available, feed a reduced-calorie diet, and/or increase exercise if obesity or weight gain is present:
  - Owners must measure food to accurately assess intake.
  - Gram scale measuring provides best accuracy.
  - Some dogs may benefit by the addition of low-calorie bulky foods such as canned or frozen green beans.
  - Feeding smaller meals 2–3 times daily may be beneficial for some patients, provided the total food provided remains the same as required by life stage and activity to promote weight loss or prevent weight gain.
  - Removing the pet during human meal preparation and consumption to reduce begging behavior and the pet obtaining additional food.
- Slowing down the rate of eating may be beneficial in some dogs, using food-dispensing toys that require manipulation to obtain daily ration.
- If social issues within the home influence intake these must be addressed:
  - Feed all dogs in separate locations, preferably without visual contact.
  - Have multiple feeding stations available in a multiple-cat home.
- The average animal's daily caloric need can be estimated by the formula 30 × weight (kg) + 70:
  - Alternatively, using the website https://petnutritionalliance.org/ can provide clinicians with the ability to quickly calculate necessary weight loss and feeding amounts based on specific diet being fed.
- Chew toys can be used as a substitute for food and desires for mastication.
- Dietary options:
  - High fiber, high protein diets provide greater satiety and reduce begging behavior (e.g., Royal Canin Veterinary Diet® Canine and Feline Satiety® Support).
  - Metabolism-increasing diets naturally increase metabolic rate (e.g., Hill's® Prescription Diet® Metabolic Canine and Feline).

MEDICATIONS

DRUG(S) OF CHOICE

- See specific diseases for detailed therapy.
- Drug-induced—attempt to taper or discontinue drug.
- If a compulsive eating disorder is suspected in dogs, clomipramine 1–3 mg/kg PO q12h or fluoxetine 1–2 mg/kg q24h may be used or in cats clomipramine 0.25–1.0 mg/kg q24h or fluoxetine 0.5–1.0 mg/kg q24h.

FOLLOW-UP

PATIENT MONITORING

- Monitor body weight in patients with nonpathologic causes of polyphagia.
- Assess compliance with feeding regime and food measurement to decrease intake and promote weight loss.

POSSIBLE COMPLICATIONS

- Obesity in nonpathologic polyphagia.
- Owner compliance:
  - Owner responds to begging behavior and caloric intake is not decreased.
  - Owner does not factor treats or additives into daily caloric count.
- Weight loss/emaciation in pathologic causes of polyphagia.
- Worsening of respiratory or cardiovascular disease processes in obese patient.
- Difficulty achieving level of appropriate exercise due to respiratory, cardiovascular, or musculoskeletal diseases.
- Decreased metabolic rate after spaying/neutering.
- Increased resource guarding behaviors.
- Increased irritability and aggression.
- Anesthetic complications associated with obesity and adiposity.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Obesity

PREGNANCY/FERTILITY/BREEDING

A normal physiologic response to pregnancy.

POLYPOID CYSTITIS

BASICS

OVERVIEW

A chronic inflammatory condition of the urinary bladder characterized by villous or polypoid protrusions from the mucosa and associated with chronic infectious or noninfectious causes. Also called proliferative cystitis. Polypoid projections are diffusely located over the luminal surface of the bladder. It is unclear if proliferative urethritis is a separate disease with different causes. If polyps erode and ulcerate, varying degrees of hematuria and dysuria occur. The gross appearance of polyps cannot be distinguished from that of bladder neoplasms, such as transitional cell carcinomas (TCCs), without histological evaluation.

SIGNALMENT

- Dogs with chronic urinary tract infection (UTI)s or urolithiasis.
- No cases reported in cats.

SIGNS

- Initially, may be asymptomatic.
- Hematuria is the most common sign.
- Gross hematuria often occurs at the end of the micturition stream during maximal bladder contraction.
- Pollakiuria and dysuria may also be present and are associated with irritation of the polyps.
- Urethral obstruction could occur if a sufficient number of bladder polyps are located in the trigone of the bladder. Polyps originating or in the urethra may also cause partial or total obstruction.
- Ureteral obstruction may occur if polyps surround the ureteral orifice.
- UTI may be present concurrently, which can predispose to upper UTI.

CAUSES & RISK FACTORS

- Causes of polypoid cystitis in dogs have not been well documented, but this disorder is commonly associated with UTI, urolithiasis, and other types of chronic irritation.
- Chronic infection and inflammation secondary to long-term indwelling transurethral urinary catheters and urinary stents have been associated with polypoid cystitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Polypoid cystitis should be ruled out in cases of hematuria, pollakiuria, dysuria, and recurrent UTI.
- Bladder neoplasms (such as TCC), UTI, and urolithiasis are the most common rule-outs.

CBC/BIOCHEMISTRY/URINALYSIS

- Serum biochemistry profiles should be normal in most cases of polypoid cystitis unless azotemia occurs as a result of obstruction to urine outflow and/or concurrent pyelonephritis.
- Urinalysis may reveal hematuria, pyuria, and transitional epithelial cells.

OTHER LABORATORY TESTS

- Urine should be cultured by clean midstream collection, clean catheterization or at the time of cystoscopy. Culture by cystocentesis is also appropriate once TCC has been ruled out. This will prevent potential spread of TCC along the needle track.
- Representative polyps removed via cystoscopy or cystotomy should be preserved in formalin for light microscopic examination.
- An adequate sample of bladder tissue should be placed in culture media suitable for growth of microbes, preferably prior to antibiotic administration.
- Survey radiographs may reveal a normal bladder, an irregular thickening of the surface contour of the bladder, and/or concurrent urolithiasis.
- Double-contrast cystography or positive-contrast cystography may reveal irregular polypoid fronds projecting in the bladder lumen and/or a thickened bladder wall. The most common location of involvement is the cranioventral bladder wall. Single large polyps with a narrow or broad base may be observed scattered throughout the contrast puddle. Uroliths will migrate to the most dependent portion of the contrast puddle.
- Ultrasonography may show polyps scattered along the mucosal surface of the bladder, especially in the cranioventral aspect.

DIAGNOSTIC PROCEDURES

- Cystoscopic or ultrasound-guided biopsy may be used to obtain representative portions of the polyps for light microscopic examination of stained sections of the lesions.
- More invasive, full-thickness biopsy of the wall of the bladder via cystotomy may be required to include the base of the polyps with an adequate margin of healthy tissue.

PATHOLOGIC FINDINGS

- Gross changes involving the mucosal surface of the urinary bladder include single or multiple small masses ranging from 1 to 10 mm in size. The masses may be nodular with a broad base or attached to the bladder wall by a thin stalk.
- Light microscopic changes include polypoid projections of hyperplastic epithelium that surround a core of proliferative connective tissue mixed with acute and chronic inflammation (congestion, edema, and acute and chronic inflammatory cells). Findings characteristic of malignancy (e.g., disproportionate enlargement of nuclei in relation to the cytoplasm; increase in chromatin content causing hyperchromasia; structural changes such as aberrant chromatin patterns, lack of distinct cell boundaries, irregularity in cell outlines; enlargement and/or increase in number of nuclei; multinucleated cells with atypical nuclei; abnormal number of mitotic figures; cytoplasmic inclusions and vacuolization; invasion of basement membranes) are conspicuously absent. Eosinophils have been present; their significance is unknown. In some patients, changes typical of granulomatous inflammation predominate.
- Fluorescence in situ hybridization identifies bacteria when urine and tissue culture was negative.

TREATMENT

- Elimination of bacteria that are a source of chronic irritation is a rational therapeutic goal.
- Nonsurgical removal of urocystoliths (voiding urohydropropulsion, lithotripsy, dietary management) that are causing chronic irritation may result in elimination of inflammatory polyps.
- The polyps can be removed nonsurgically (stone basket extraction, laser ablation, electrocautery via cystoscopy or surgically via cystotomy).
- Partial cystectomy may be required to remove polyps affecting large portions of the bladder. The remaining portion of the urinary bladder may return to normal size in 3–6 months.

MEDICATIONS

DRUG(S) OF CHOICE

- Select an antimicrobic based on culture of urine and polyp tissue. Optimal duration of antibiotic therapy is unknown. Post-therapy urine cultures can be used to determine if longer courses of antimicrobs are needed.
- Use of piroxicam and immunosuppressive drugs are suggested, but efficacy is variable.

FOLLOW-UP

PATIENT MONITORING

- A urine culture should be performed 7–10 days after antimicrobial therapy is initiated, to confirm urine sterility. Follow-up urinalysis and urine cultures should also be performed by cystocentesis 7 days after antimicrobial therapy has ceased and 1 month post therapy.
- Ultrasonographic reevaluation of the urinary tract is recommended at 1, 3, and 6 months.
- Persistent asymptomatic polyps are not treated.

PREVENTION/AVOIDANCE

Control of predisposing factors such as UTI, urolithiasis, urinary stenting.

POLYPOID CYSTITIS (CONTINUED)

POSSIBLE COMPLICATIONS
- Chronic UTIs.
- Upper UTI.
- Complete obstruction of ureters or urethra.

EXPECTED COURSE AND PROGNOSIS
- The expected course is favorable and the prognosis good if the underlying cause is treated and eradicated.
- Rarely patients with polypoid cystitis develop TCC several years after initial diagnosis. It is unknown if some of these cases represent early carcinoma *in situ*.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- Urinary tract infection.
- Urolithiasis.

AGE-RELATED FACTORS
No age-related factors have been reported, but usually not found in immature dogs.

SEE ALSO
- Hematuria.
- Transitional Cell Carcinoma.
- Urinary Tract Obstruction.
- Urolithiasis.

ABBREVIATIONS
- TCC = transitional cell carcinoma.
- UTI = urinary tract infection.

POLYURIA AND POLYDIPSIA

BASICS

DEFINITION
- Polyuria (PU)—increased urine production (dogs, >45 mL/kg/day; cats, >40 mL/kg/day).
- Polydipsia (PD)—increased water consumption (dogs, >90 mL/kg/day; cats, >45 mL/kg/day).

PATHOPHYSIOLOGY
- The volumes of urine produced and water consumed are controlled by interactions between the kidneys, pituitary gland, and hypothalamus through monitoring of plasma osmolality. Volume receptors within the atria and aortic arch also influence thirst and urine production. PU may occur when the quantity of functional antidiuretic hormone (ADH) synthesized in the hypothalamus or released from the posterior pituitary is limited, or when the kidneys fail to respond normally to ADH. PD occurs when the thirst center in the anterior hypothalamus is stimulated.
- In most PU patients, plasma becomes relatively hypertonic and activates thirst mechanisms; the PD maintains hydration as a compensatory response. Occasionally PD is the primary process and PU is compensatory. In this case, the patient's plasma becomes relatively hypotonic because of excessive water intake, ADH secretion is reduced, resulting in PU.

SYSTEMS AFFECTED
- Urologic—full bladder.
- Cardiovascular—circulating volume.
- Endocrine/metabolic—pituitary gland, hypothalamus play a role in compensation to PU or PD.

SIGNALMENT
- Dog and cat.
- Congenital diseases in many breeds (e.g., central diabetes insipidus [CDI], nephrogenic diabetes insipidus [NDI], portovascular anomaly, kidney disease).
- Kidney disease, hyperadrenocorticism (HAC), hyperthyroidism, neoplasia affecting the pituitary or hypothalamus predominantly affect middle-aged and older animals.

CAUSES
- Primary PU due to impaired kidney response to ADH—kidney disease, HAC, hyperthyroidism, pyelonephritis, leptospirosis, pyometra, hepatic failure, hypercalcemia, hypokalemia, kidney medullary solute washout, dietary protein restriction, drugs, congenital NDI.
- Primary PU caused by osmotic diuresis—diabetes mellitus (DM), primary kidney glucosuria, postobstructive diuresis, some diuretics (e.g., mannitol and furosemide), ingestion or administration of large quantities of solute (e.g., sodium chloride or glucose), and hypersomatotropism.
- Primary PU due to ADH deficiency—idiopathic, traumatic, neoplastic, or congenital CDI; some drugs (e.g., alcohol and phenytoin).
- Primary PD—behavioral, pyrexia, pain, organic disease of the anterior hypothalamic thirst center of neoplastic, traumatic, or inflammatory origin.

RISK FACTORS
- Kidney, liver and/or endocrine disease.
- Administration of diuretics, corticosteroids, anticonvulsants.
- Low-protein diets.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Differentiating Similar Signs
- Differentiate PU from pollakiuria. Pollakiuria: often associated with dysuria, stranguria, hematuria. Patients with PU void large quantities of urine; patients with pollakiuria frequently void small quantities of urine. Confirm PU/PD by measuring 24-hour water intake and urine output (3- to 5-day collection period preferred).
- Urine specific gravity (USG) measurement may provide evidence of hypersthenuria (dogs, >1.030; cats, >1.035), ruling out persistent PU/PD.

Differentiating Causes
- Kidney disease, HAC, DM, hyperthyroidism.
- Progressive weight loss—consider chronic kidney disease, DM, hyperthyroidism, hepatic failure, pyometra, pyelonephritis, hypoadrenocorticism, malignancy-induced hypercalcemia.
- Decreased appetite—consider kidney disease, pyelonephritis, malignancy-induced hypercalcemia, hepatic disease, hypoadrenocorticism.
- Polyphagia—consider DM, hyperthyroidism, HAC, acromegaly.
- Bilateral alopecia or other cutaneous problems—consider HAC, endocrinologic disorders
- Uremic breath and stomatitis—consider advanced kidney disease.
- Vomiting—consider kidney disease, hypoadrenocorticism, pyelonephritis, hepatic failure, hypercalcemia, hypokalemia, hyperthyroidism, DM.
- Malaise and/or weakness—kidney disease, hypoadrenocorticism, pyometra, hypercalcemia, DM, hepatic disease, hypokalemia, HAC.
- Palpable thyroid nodule—consider hyperthyroidism.
- Hypertensive retinopathy—consider chronic kidney disease (CKD), hyperthyroidism, DM, HAC.
- Recent estrus (previous 2 months) in a middle-aged intact female—consider pyometra.
- Abdominal distention—consider hepatic failure, HAC, pyometra, nephrotic syndrome.
- Lymphadenopathy, anal sac mass or other neoplastic process—consider hypercalcemia of malignancy.
- Behavioral or neurologic disorder—consider hepatic failure, primary PD, CDI.
- Marked PD (patients almost continuously seek and consume water)—consider primary PD, CDI, NDI.
- Consider drug-induced (steroids, diuretics, anticonvulsants) PU/PD.
- Consequence of urolith prevention/dissolution or high salt diet.

Key point: PU/PD may be the first symptom of many diseases.

CBC/BIOCHEMISTRY/URINALYSIS
- Urinalysis is useful to confirm PU, discriminate water diuresis from solute diuresis, and identify urinary tract infection (UTI).
- Serum sodium concentration or osmolality may help differentiate primary PU from PD. Measuring serum osmolality is preferred; calculated serum osmolality is not an acceptable alternative.
- Relative hypernatremia or high serum osmolarity suggests primary PU.
- Hyponatremia or low serum osmolarity suggests primary PD, except in animals with hypoadrenocorticism, which have hyponatremia and primary PU.
- Azotemia is typical of kidney causes for PU/PD, but may also indicate dehydration resulting from inadequate compensatory PD.
- Unexpectedly low BUN concentrations suggest hepatic failure.
- With high hepatic enzymes, consider HAC, hyperthyroidism, hepatic failure, pyometra, DM, or administration of drugs (e.g., anticonvulsants and corticosteroids).
- Persistent hyperglycemia suggests DM.
- Hyperkalemia, particularly if associated with hyponatremia, suggests hypoadrenocorticism or therapy with potassium-sparing diuretics.
- Hypercalcemia induces PU only when it results from increased ionized calcium (not protein-bound calcium) concentration.
- Hypoalbuminemia supports kidney or hepatic causes of PU/PD.
- Neutrophilia is consistent with pyelonephritis, pyometra, HAC, corticosteroid administration.
- USG values 1.001–1.003 suggest primary PD, CDI, and congenital NDI.
- Glucosuria supports a diagnosis of DM or kidney glucosuria.
- Pyuria, white blood cell casts, and/or bacteriuria should prompt consideration of pyelonephritis.

POLYURIA AND POLYDIPSIA (CONTINUED)

OTHER LABORATORY TESTS
- ACTH stimulation or dexamethasone suppression tests rule out HAC.
- Thyroxine concentration to rule out hyperthyroidism.
- Bile acids (fasting and postprandial) to rule out portosystemic shunt or hepatic failure.
- Urine culture—chronic pyelonephritis cannot be conclusively excluded by absence of pyuria or bacteriuria.
- Cytology from lymph node aspirate may diagnose lymphoma, which induces PU by hypercalcemic nephrotoxicity or direct infiltration of kidney tissues.
- Paired *Leptospira* titer to rule out leptospirosis.
- ADH response test to rule out CDI.
- Water deprivation testing (see Diagnostic Procedures) is controversial due to dehydration risk; use selectively.

IMAGING
Abdominal survey radiography, ultrasonography: may provide evidence of kidney, hepatic, adrenal, or uterine disorders that can cause PU/PD.

P

DIAGNOSTIC PROCEDURES
Modified Water Deprivation with ADH Response Test
- Differentiates CDI from primary PD and NDI. Rule out other causes for PU/PD before performing this test. Controversial, some suggest omitting water deprivation and proceeding directly to ADH administration to rule in CDI, however administration of ADH to patients with primary PD may be dangerous.
- Contraindicated in dehydrated and azotemic patients; ADH response testing may be performed safely in these patients.
- Patients that concentrate urine adequately in response to water deprivation have adequate ADH production and kidney response to ADH. If other causes have been ruled out, primary PD is presumed to be present.
- Failure to concentrate urine adequately in response to properly designed water deprivation tests, but forming concentrated urine in response to administration of exogenous ADH = CDI.
- Failure to concentrate urine adequately in response to water deprivation and also failure to further concentrate urine in response to administration of exogenous ADH = NDI.

TREATMENT
- Serious medical consequences are rare if patient has free access to water and is able to drink. Until the mechanism of PU is understood, discourage owners from limiting access to water. Direct treatment at the underlying cause.
- Provide PU patients with free access to water unless they are vomiting. If vomiting, give replacement maintenance fluids parenterally after appropriate samples have been collected for initial diagnostics. Provide fluids parenterally when other conditions limit oral intake or dehydration persists despite PD.
- Base fluid selection on the underlying cause for fluid loss; lactated Ringer's solution is acceptable for most patients.
- When dehydration has resulted from withholding water, or when urine is hyposthenuric, providing oral water or parenteral administration of dextrose 5% in water may be preferred to lactated Ringer's solution.
- Primary PD—treat by gradually limiting water intake to a normal daily volume. May be necessary to reduce water intake over days–weeks to avoid undesirable behavior such as barking, urine consumption, or other bizarre behavior. Monitor patient closely to avoid iatrogenic dehydration. Salt (1 g/30 kg q12h) or sodium bicarbonate (0.6 g/30 kg q12h) may be given orally to help reestablish kidney medullary solute gradient. Consider behavior modification if water restriction alone is unsuccessful.

CLIENT EDUCATION
Do not withhold water from patients with PU because potentially dangerous dehydration may result.

MEDICATIONS
DRUG(S) OF CHOICE
Varies with underlying cause.

CONTRAINDICATIONS
Do not administer ADH to patients with primary PD due to risk of inducing water intoxication (hyponatremia, hypoosmolality, and neurologic complications).

PRECAUTIONS
Until kidney disease and hepatic failure have been excluded as potential causes for PU/PD, use caution in administering any drug eliminated via these pathways.

FOLLOW-UP
PATIENT MONITORING
- Hydration status—assessment of hydration, serial evaluation of body weight.
- Fluid intake and urine output provide a useful baseline for assessing response to therapy.

POSSIBLE COMPLICATIONS
Dehydration, hypovolemic shock, hypernatremia.

MISCELLANEOUS
ASSOCIATED CONDITIONS
- Bacterial UTI.
- Urinary incontinence may develop in dogs with concurrent urethral sphincter dysfunction, presumably because of increased bladder filling associated with PD.

SEE ALSO
- Acute Kidney Injury.
- Chronic Kidney Disease.
- Congenital and Developmental Renal Diseases.
- Diabetes Insipidus.

PORTOSYSTEMIC SHUNTING, ACQUIRED

BASICS

OVERVIEW

• Acquired portosystemic shunts (APSS)—develop subsequent to portal hypertension (PH) and involve complex physiology aberrations and adaptations; experimentally form 5–14 weeks after onset of PH.
• Prehepatic PH—compromised perfusion through abdominal portion of the portal vein.
• Intrahepatic PH—classified as presinusoidal, sinusoidal, postsinusoidal causes.
• Posthepatic PH—rostral to hepatic vein; cardiac, pericardial, or major vein causes.
• APSS evolve from preexisting remnant vessels and the process of angiogenesis.
• APSS common in dogs and cats but differ in location from the clinically symptomatic esophageal APSS common in humans; common APSS in dogs and cats involve communications between left gonadal remnants vessels, the left renal vein, and splenic veins with the caudal vena cava.

SIGNALMENT

• Most common—in dogs with chronic necroinflammatory liver disease.
• Less common—in dogs with ductal plate malformations (DPM, congenital hepatic fibrosis [CHF] phenotype), rare noncirrhotic portal hypertension (NCPH), recovery from severe panlobular necrosis, dogs with portosystemic vascular anomaly (PSVA) intolerant to surgical shunt attenuation, or dogs simply with severe portal vein hypoplasia/atresia.
• APSS in cats—DPM with CHF phenotype, severe CCHS (rare), or PSVA intolerant to surgical shunt attenuation (severe portal hypoplasia) or rarely just severe portal vein atresia.
• Extrahepatic bile duct obstruction (EHBDO) >6 weeks.
• Certain disorders—have age or breed incidence (see Ductal Plate Malformation (Congenital Hepatic Fibrosis); Cirrhosis and Fibrosis of the Liver; Hepatitis, Chronic).
• Breeds—DPM more common in domestic longhair, Persian and Himalayan cats, boxer dogs but may affect any pure- or mixed-breed dog.

SIGNS

• Clinical signs—sequelae of PH, impaired hepatic perfusion, and hepatofugal circulation (hepatofugal = splanchnic portal circulation away from the liver) with or without or reduced hepatic function depending on cause.
• Ascites—common but variable; often fluctuates in severity.
• APSS may associate with episodic hepatic encephalopathy (HE)— may manifest as neurobehavioral or neurocognitive abnormalities, amaurotic blindness, polyuria/polydipsia (PU/PD), anorexia, lethargy, vomiting; neurologic signs may localize to cerebrum, brainstem, or suggest transverse myelopathy.
• PH leads to hypertensive splanchnic vasculopathy—may provoke gastroduodenal bleeding/ulceration because of thin-walled dilated arterials; may progress to perforation and septic peritonitis, life-endangering blood loss if coexistent coagulopathy; can provoke severe HE; causes anorexia, vomiting, diarrhea, abdominal pain, anemia, and sometimes iron deficiency (if chronic blood loss).
• Urogenital—obstructive uropathy due to ammonium biurate urolithiasis, gross or microscopic hematuria, pollakiuria, dysuria, rare severe hematuria (ureteral APSS varices).

CAUSES & RISK FACTORS

• Multiple tortuous vessels—represent acquired vasculature interconnecting portal and systemic venous circulations.
• Lack of valves in main portal vein structure allows blood to follow "a path of least resistance" through APSS to vena cava (systemic circulation). Valves in portal tributaries influence hepatofugal circulatory routes.
• PH—results from many disease processes.
• Common causes of PH—diffuse hepatic fibrosis with or without cirrhosis; chronic unresolved EHBDO (>6 weeks); portal venous thromboembolism (TE), hepatic sinusoidal occlusion syndrome (zone 3, injury causing regional parenchymal collapse or vascular damage to hepatic venules, veins).
• Less common causes of PH involve idiopathic PH or NCPH (obliteration of tertiary portal venules), blockade of large hepatic veins or prehepatic vena cava (Budd–Chiari syndrome) by thrombi, neoplasia or vascular "kinking"; disorders constraining splanchnic portal circulation: vascular stricture or strangulation, severe portal vein atresia rare congenital or acquired hepatic AV malformation(s) causing arterialization of the portal circulation, or severe intrahepatic portal vein atresia.
• Episodic HE.
• Ammonium urate urolithiasis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• CNS signs—infectious disorders (e.g., FIP, FeLV- or FIV-related infections or conditions, canine distemper, toxoplasmosis, other); toxicities (e.g., lead, mushrooms, drugs, acute hepatic failure); hydrocephalus; idiopathic epilepsy; metabolic disorders (e.g., severe hypoglycemia, hypo- or hyperkalemia, hypocalcemia, severe hypophosphatemia).
• Gastrointestinal signs—bowel obstruction; dietary indiscretion; foreign body ingestion; inflammatory bowel disease.
• Urinary tract signs—bacterial urinary tract infection; urolithiasis; obstructive uropathy.
• PU/PD—disorders of urine concentration (diabetes insipidus, diabetes mellitus, adrenal hyperplasia, hypercalcemia), primary PD, congenital or acquired renal disease.
• Causes of abdominal effusion—cardiopulmonary disorders causing right-sided heart failure; pericardial disease; primary inflammatory hepatopathies; infiltrative hepatic disease (e.g., neoplasia, amyloid); liver lobe torsion; nonhepatic abdominal disorders associated with effusions (e.g., splenic torsion, visceral neoplasia, carcinomatosis, pancreatitis); or peritonitis: chemical (e.g., bile, urine, chyle) or septic.

CBC/BIOCHEMISTRY/URINALYSIS

• CBC—microcytosis (reflects portosystemic shunting or iron deficiency); mild non-regenerative anemia common; poikilocytes (cats) and target cells (dogs).
• Biochemistry—low BUN, low to low-normal creatinine, glucose, albumin, and cholesterol are common; variable liver enzyme activity (ALP usually high in young animals), ALP induction by inflammatory cytokines or cholestasis, ALT normal or elevated; bilirubin variable; features depend on underlying cause and chronicity.
• Urinalysis—variable urine concentration; ammonium biurate crystalluria, hematuria, pyuria, and proteinuria reflect urolithiasis or infection.

OTHER LABORATORY TESTS

• Total serum bile acids (TSBA)—sensitive indicator of PSS; variable pre- with markedly increased post-meal values (>100 µmol/L); "shunting pattern" implicated by relatively low pre- and markedly increased post-meal values; *however*, 10–20% dogs and cats have higher pre- than post-meal TSBA reflecting slow gastric or enteric transit or delayed gallbladder contraction.
• Blood ammonia—fasting, sensitive but inconsistent indicator of HE and shunting; ammonium biurate crystalluria infers high blood ammonia (evaluate 3 urine specimens, 4–8 hours after eating); ammonia tolerance testing—(oral or rectal $NHCl_4$) best test for ammonia intolerance; *caution*: may induce HE.
• Coagulation tests—prolonged PT, aPTT, reflect severity of liver dysfunction, synthetic failure, DIC, or vitamin K_1 adequacy; low protein C activity reflects PSVA or APSS, enteric or renal losses or consumption.
• Abdominal effusion—usually pure or modified transudate.

IMAGING

Abdominal Radiography

• Liver size depends on underlying cause; microhepatia common in dogs with chronic liver disease with APSS, PSVA, or severe portal vein atresia. Some disorders associate with large liver size or large liver lobes: AV malformations, some DPM (cystic lesions).

PORTOSYSTEMIC SHUNTING, ACQUIRED (CONTINUED)

• Abdominal effusion—impairs visualization of visceral margins; ascites associated with severe portal atresia, some PSVA after surgical attenuation, some animals with DPM (CHF phenotype) with APSS, chronic liver disease with APSS, and other causes of PH.
• Ammonium biurate calculi—radiolucent unless radiodense mineral shell (infection).
• Size of post-hepatic vena cava may reflect pericardial or cardiac causes (distended vein).

Radiographic Portovenography

Demonstrates multiple APSS; not recommended due to complicating risks, see alternatives.

Abdominal Ultrasonography

• Liver size depends on underlying cause. May disclose change in size or absence of specific liver lobes or gallbladder in DPM or AV malformations.
• May disclose disease-related hepatic parenchymal or biliary changes.
• APSS—characterized by hepatofugal portal flow (unreliable US detection) and APSS using color-flow Doppler; tortuous APSS varices have turbulent blood flow; APSS often situated adjacent to left kidney or associated with splenic vasculature.
• Intrahepatic AV communication/fistula—pulsating arterialized vascular within enlarged liver lobe, abdominal effusion and APSS.
• Other causes of PH and APSS are detected using US color-flow Doppler: portal venous thrombi or stricture, hypoplastic portal vein at porta hepatis, diminished hepatic venule/vein filling (venoocclusive syndrome), or Budd–Chiari hepatic vein outflow obstruction.
• Abdominal effusion—common.
• Uroliths—renal pelvis, urinary bladder; rare ureteral.

Colorectal (CRS) or Splenoportal (SPS) Scintigraphy

• Sensitive noninvasive test that confirms PSS.
• Cannot definitively differentiate PSVA from APSS.
• CRS—administer Tc^{99m} pertechnetate into colon.
• SPS—isotope splenic injection via US guidance under heavy sedation or anesthesia; advantage in using less isotope, may miss caudal rectal PSVA.

Multisector CT

Noninvasive imaging of choice; details vascular anatomy, visceral abnormalities.

DIAGNOSTIC PROCEDURES

Fine-Needle Aspiration Cytology

• Hepatic aspiration—usually cannot differentiate disorders causing APSS.
• Liver biopsy—open surgical wedge biopsy or laparoscopic sampling best approach; obtain tissue from several (n = 3) liver lobes; Tru-Cut samples may not provide adequate tissue for definitive diagnosis.

PATHOLOGIC FINDINGS

• Gross—small, irregularly contoured liver with chronic liver disease (cirrhosis, fibrosis).
• Normal to large liver in early venous outflow obstruction: Budd–Chiari, sinusoidal occlusion syndrome.
• Isolated large liver lobe—intrahepatic AV malformation.
• Normal to small liver—DPM (CHF phenotype), NCPH, portal TE, portal atresia, PSVA.
• Normal to large liver in some cats with DPM.

TREATMENT

Appropriate Health Care

Inpatient—severe signs of HE or tense abdominal effusion requiring therapeutic abdominocentesis and critical care.

Diet

• Nutritional support—essential to maintain body condition to optimize control of hyperammonemia-associated HE; species-specific balanced, restricted-protein diet (avoid red meat, organ meat, fish in dogs); protein allowance optimized to tolerance (see Hepatic Encephalopathy). Cats have different protein requirements compared to dogs.
• Protein allowance titrated to response with adjunctive treatment modulating production and absorption of enteric toxins contributing to HE (colonic products mainly); use commercial diets formulated for liver disease or moderate renal insufficiency as a baseline diet.
• Dogs—commercial liver diets provide 2.2–2.5 g protein/kg body weight when fed to meet energy requirements; titrate protein using 0.25 g/kg additional allocations q5–7 days until optimized tolerance determined: dairy and soy protein are best sources for dogs; if necessary white meat chicken can be introduced in small amounts to stimulate appetite.
• Cats—pure carnivores require meat-derived protein; use diets for renal insufficiency.
• Parenteral nutrition rarely used—see Hepatic Encephalopathy.
• Sodium restriction important in dogs with ascites; 50–100 mg sodium/100 kcal or <0.2% dry matter basis formula of sodium; initiate before or with start of diuretic therapy.

Client Education

• Depends on underlying cause.
• Educate client of HE and potential for ammonium biurate obstructive uropathy (males); permanent pre-scrotal urethrostomy may be needed (persistent ammonium biurate uroliths).
• Educate client how to adjust diuretics (as-needed basis) to mobilize abdominal effusion.
• Educate client how to adjust oral medications and use enemas (as-needed basis) to ameliorate HE.
• Emphasize importance of sodium restriction if ascites.

MEDICATIONS

DRUG(S) OF CHOICE

• Enteric hemorrhage—associated with hypertensive splanchnic vasculopathy and coagulopathy; some clinicians use *prophylactic* acid blockers or gastroprotectants to reduce risk, however, ulceration is not linked with hypergastrinemia; symptomatic animals treated with proton pump inhibitor (omeprazole; pantoprazole) and sucralfate; may require blood component therapy or DDAVP (see Coagulopathy of Liver Disease) if critical hemorrhage.
• Abdominal effusion—sequentially measure weight, girth (standardize measurements: location and operator) to monitor ascites; advise dietary sodium restriction combined with titrated dosing of furosemide with spironolactone.
• Conventional diuretics—combined use of furosemide and spironolactone is superior to single drugs alone; furosemide 0.5–2 mg/kg PO q12–24h and spironolactone 0.5–2 mg/kg PO q12h, single loading dose of spironolactone (doubled dose) followed by dose titrations based on response q4–5 days with close monitoring of serum electrolytes and renal function. Adjustments: incremental 25–50% dose increase. Spironolactone is potassium sparing and a less potent diuretic than furosemide. Furosemide is potassium wasting and typically initiates a brisk diuresis that can provoke RAAS response with effect attenuated by spironolactone.
• Vasopressin V_2 antagonists (aquaretics) *may* be superior for ascites control compared to conventional diuretics (proven in humans, e.g., tolvaptan); this class of drugs is not routinely available or affordable for veterinary patients; no relevant clinical experience.
• Diuretic-resistant ascites—may require therapeutic abdominocentesis (see Hypertension, Portal). May reflect insidious increased sodium intake or RAAS response to diuresis.
• Avoid dehydration or hypokalemia by frequent monitoring initially: these can provoke HE.

Precautions

• Remain aware of altered drug metabolism due to reduced first-pass extraction (PSS),

altered hepatic metabolism/biotransformation, and reduced protein binding.
• Remain vigilant for diuretic-induced dehydration and electrolyte dysregulation that may provoke HE and/or hepatorenal syndrome (acute renal failure due to severe vasoconstriction).
• Beware that aggressive therapeutic abdominocentesis may provoke hypotensive post-centesis syndrome (see Ascites).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Avoid metoclopramide if using spironolactone (blocks effect); avoid NSAIDs as these may inhibit furosemide-induced diuresis, potentiate renal injury, or provoke sodium accumulation.

FOLLOW-UP

PATIENT MONITORING

• Reevaluate patient's at-home demeanor and appetite as a reflection of HE.
• Monitor clinical signs, appetite, body condition, muscle mass, weight, abdominal girth, CBC, serum biochemistry, and urine (concentration, ammonium biurate crystalluria); TSBA not useful for sequential evaluation as these are predictably increased with APSS and ursodeoxycholic acid (drug measured in assay) administration.
• Adjust medical management to alleviate episodic HE, ammonium biurate crystalluria, and abdominal effusion.
• Inspect patient carefully for evidence of clinical bleeding; determine need for intermittent chronic vitamin K_1 administration (parenteral route).

PREVENTION/AVOIDANCE

• Early treatment of acquired liver disease and EHBDO minimizes fibrosis/remodeling.
• Cautious PSVA attenuation.

POSSIBLE COMPLICATIONS

• Treat underlying disorder(s).
• Enteric hemorrhage associated with hypertensive vasculopathy; may require acute intensive care: manage hypovolemia, coagulopathy, and ensuing HE; may require surgical resection of involved gut (rare).
• Dehydration, contraction alkalosis, azotemia, acute renal failure—complications of diuretics.
• Death risk—from liver failure, HE complications, lethal enteric hemorrhage, or sepsis.

EXPECTED COURSE AND PROGNOSIS

• Varies with underlying cause.
• Management of chronic liver disease or hepatic fibrosis seemingly extends life.
• Animals with NCPH and DPM (CHF phenotype) may live >5 years if managed successfully during symptomatic illnesses.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Ammonium urate urolithiasis.
• Ascites.
• Coagulopathy.
• Hepatic encephalopathy.
• Enteric bleeding/ulceration.
• Obstructive uropathy.

SEE ALSO

• Ascites.
• Cirrhosis and Fibrosis of the Liver.
• Coagulopathy of Liver Disease.
• Ductal Plate Malformation (Congenital Hepatic Fibrosis).
• Hepatic Encephalopathy.
• Hepatitis, Chronic.
• Portal Hypertension.
• Portosystemic Vascular Anomaly, Congenital.

ABBREVIATIONS

• APSS = acquired portosystemic shunt.
• AV = arteriovenous.
• CCHS = cholangitis/cholangiohepatitis syndrome.
• CHF = congenital hepatic fibrosis.
• CRS = colorectal scintigraphy.
• DPM = ductal plate malformation.
• EHBDO = extrahepatic bile duct obstruction.
• HE = hepatic encephalopathy.
• NCPH = noncirrhotic portal hypertension.
• NSAID = nonsteroidal anti-inflammatory drug.
• PH = portal hypertension.
• PSVA = portosystemic vascular anomaly.
• PU/PD = polyuria/polydipsia.
• SPS = splenoportal scintigraphy.
• TE = thromboembolism.
• TSBA = total serum bile acids.

PORTOSYSTEMIC VASCULAR ANOMALY, CONGENITAL

BASICS

DEFINITION
• Aberrant venous connections between the portal and systemic circulations; macroscopic shunts permit portal hepatofugal circulation (flow away from or around the liver).
• May be extrahepatic portosystemic vascular anomaly (E-PSVA) or intrahepatic (I-PSVA).
• Most are single vessels; occasionally two shunts may be identified.
• Most small-breed dogs with PSVA also have microscopic vascular abnormalities (see Hepatoportal Microvascular Dysplasia).

PATHOPHYSIOLOGY
• Clinical signs—reflect hepatofugal circulation that prohibits hepatic cleansing of enteric toxins, food-derived nitrogenous toxins, and other noxious colonic substances from portal blood.
• Microhepatia—deprivation of splanchnic hepatotrophic factors (e.g., insulin) causes hepatic atrophy.
• Episodic hepatic encephalopathy (HE)—associated with consumption of high-protein foods, gastrointestinal bleeding, other causes of increased heme turnover (blood transfusions, hemolysis), dehydration, azotemia, alkalosis, hypokalemia, infections, constipation, catabolism, and certain drugs.
• Ammonium biurate crystalluria/urolithiasis—reflect hyperammonemia and impaired conversion of uric acid to water-soluble allantoin; may be a presenting problem.
• Severity of clinical signs reflect the magnitude of macroscopic shunting.

SYSTEMS AFFECTED
• Nervous—episodic HE in most but not all.
• Gastrointestinal—intermittent inappetence; vomiting; diarrhea; pica; ptyalism (cats).
• Urogenital— "plump" kidneys; ammonium urate urolithiasis; 50% male dogs cryptorchid in one retrospective report.
• Asymptomatic—up to 20% of dogs with PSVA.

GENETICS
• E-PSVA—most common in small-breed dogs (e.g., Yorkshire terrier, Cairn terrier, Maltese, Tibetan spaniel, miniature schnauzer, Norfolk terrier, pug, shih tzu, Havanese, papillon.
• I-PSVA—most common in large-breed dogs (e.g., Irish wolfhound, Labrador retriever, Old English sheepdog, golden retrievers).
• Autosomal dominant complex polygenic inheritance suspected to cause PSVA/microvascular dysplasia (MVD) trait in small-breed dogs; MVD most common phenotype.
• I-PSVA—appears heritable in Irish wolfhounds patent ductus venosus type I-PSVA and kindred of Labrador retrievers, Old English sheepdogs, golden retrievers.

INCIDENCE/PREVALENCE
0.2–0.6% of large referral clinic.

GEOGRAPHIC DISTRIBUTION
Reported worldwide.

SIGNALMENT
Species
Dog and cat; most common in small-breed dogs.

Breed Predilections
Higher risk—purebred and mixed small "terrier" type dogs; cats—domestic shorthair, fewer pure breeds.

Mean Age and Range
• Usually identified in juveniles; some asymptomatic dogs as old as 13 years at initial diagnosis.
• Asymptomatic animals present older; miniature schnauzers and dogs with porto-azygous shunts.

Predominant Sex
N/A

SIGNS
Historical Findings
• Stunted growth—common.
• Signs often initiate with weaning of puppy or kitten to commercial growth foods.
• Gastrointestinal signs—inappetence, vomiting, diarrhea, pica.
• Cats—ptyalism.
• Episodic HE—most dramatic and predominating sign in many dogs, improves with fluids, broad-spectrum antibiotics, and lactulose.
• CNS signs—weakness, propulsive circling or pacing, vocalization, apparent hallucinations, ataxia, disorientation, head pressing, signs consistent with transverse myelopathy, vague hyperpathia, amaurotic blindness, behavioral changes (aggression in cats), twitching or trembling, focal or generalized seizures, or progressive obtundation to coma.
• Urinary signs—polyuria/polydipsia (PU/PD); ammonium biurate crystalluria: pollakiuria, dysuria; hematuria; urethral/ureteral ammonium biurate urolith obstruction.
• Asymptomatic—up to 20% of dogs.
• Affected bitches may produce viable litters.

Physical Examination Findings
• Normal appearance, but most have stunted stature; microhepatia; HE; copper-colored irises in non-blue-eyed cats (note: Persian, Russian blue, some others normally have copper-colored iris; iris color does not change with PSVA ligation).
• Neurologic signs.

CAUSES
Congenital developmental vascular malformations.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• CNS signs—infectious disorders (FIP-, FeLV- or FIV-related infections in cats, canine distemper, toxoplasmosis); toxicities (lead, mushrooms, recreational drugs); congenital CNS malformations (hydrocephalus); congenital storage disorders; idiopathic epilepsy; metabolic disorders (severe hypoglycemia, hypokalemia, hyperkalemia, hypocalcemia); necrotizing meningoencephalitis or granulomatous meningoencephalitis—idiopathic inflammatory CNS syndromes in small-breed dogs (e.g., pug, Maltese, Yorkshire terriers).
• Gastrointestinal signs—bowel obstruction; dietary indiscretion; foreign body ingestion; inflammatory bowel disease.
• Urinary tract signs—bacterial urinary tract infection or other forms of urolithiasis.
• PU/PD—disorders of urine concentration (diabetes insipidus, diabetes mellitus, abnormal adrenal function, hypercalcemia), primary polydipsia.
• Primary liver disease.
• MVD—in asymptomatic PSVA animals.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC—microcytosis; mild non-regenerative anemia; poikilocytosis (cats); target cells (dogs).
• Biochemistry—inconsistent low BUN, creatinine, cholesterol; hypoglycemia—in young tiny toy breeds, variable liver enzyme activity (ALP high in young patients), ALT normal or elevated; bilirubin normal; hypoalbuminemia inconsistent and mild.
• Urinalysis—normally concentrated or dilute urine; ammonium biurate crystalluria; hematuria, pyuria, and proteinuria: with urolithiasis or infection.

OTHER LABORATORY TESTS
• Total serum bile acid (TSBA)—sensitive indicator of portosystemic shunting (PSS); random fasting values may be within reference intervals; 2 hours post-meal values usually markedly high (>100 μmol/L); always use paired samples around confirmed meal ingestion; no need to fast before testing. TSBA often remain abnormal in small-breed dogs after PSVA attenuation due to concurrent MVD. Important TSBA testing strategy—food-initiated enterohepatic bile acid challenge essential; verify meal consumption; feed typical size meal; feed dog's regular diet for testing.
• Blood ammonia—fasting, sensitive but inconsistent indicator of HE and shunting; ammonia tolerance testing—oral or rectal $NHCl_4$ administration; may cause transient HE.
• Coagulation tests—prolonged clotting times compared to healthy dogs but not clinically significant; are not associated with increased risk for bleeding.

(CONTINUED) PORTOSYSTEMIC VASCULAR ANOMALY, CONGENITAL

• Protein C—low values help differentiate PSVA from MVD; usually <70% in symptomatic PSVA, usually >70% in MVD, may be ≥70% in asymptomatic PSVA. Test reflects magnitude of macroscopic shunting. Protein C especially useful for postoperative assessment after PSVA ligation if initial activity subnormal; normalization coordinates with good surgical outcome despite sustained high TSBA values. Protein C is *not* similarly applicable in cats.

IMAGING

Abdominal Radiography

• Microhepatia—dogs > cats.
• Renomegaly—some dogs.
• Ammonium urate urolithiasis—radiolucent unless combined with radiodense mineral shell.

Radiographic Portovenography

• Mesenteric portography—old gold standard for PSVA diagnosis.
• Currently used as intraoperative assessment of hepatic portal perfusion via fluoroscopy, accurate PSVA localization and assesses postligation liver perfusion.

Abdominal Ultrasonography

• Subjective assessment of microhepatia and vascular profiles; difficult to identify some PSVA (portoazygos, splenophrenic, gastrophrenic); US identification of PSVA is highly operator dependent.
• Color-flow Doppler—assists in US PSVA verification.
• I-PSVA—usually more easily imaged with US than E-PSVA.
• Other US features—renomegaly, uroliths: bladder, renal pelvis, rare ureteral.
• US microbubble study—can confirm PSS; splenic injection of agitated heparinized blood (microbubbles).

Colorectal (CRS) or Splenoportal (SPS) Scintigraphy

• Tc^{99m} pertechnetate CRS or SPS measures shunt fraction; normal dog shunt fraction ≤15%; PSVA shunt fraction usually >60% but depends on severity of macroscopic shunting; shunt fraction in MVD is usually mildly increased above normal.
• CRS—sensitive noninvasive test confirming macroscopic shunting; cannot differentiate PSVA from acquired PSS (APSS) or E-PSVA from I-PSVA.
• SPS—may miss caudal PSVA; details insufficient to differentiate type of shunt (APSS vs. PSVA or I-PSVA, E-PSVA).

Multisector CT

Gold standard imaging modality defining arterial and venous circulations; definitively demonstrates PSVA and APSS.

DIAGNOSTIC PROCEDURES

• Vascular imaging provides definitive diagnosis of PSVA.
• Fine-needle aspiration cytology—cannot diagnose PSVA or MVD.
• Liver biopsy—required for definitive diagnosis of portal venous hypoperfusion; rules out most acquired hepatobiliary disorders causing increased TSBA except splanchnic portal thromboembolism (TE), noncirrhotic portal hypertension (NCPH) and cannot usually differentiate MVD from PSVA.
• Open surgical wedge or laparoscopic liver biopsies preferred with samples collected from several (n = 3) liver lobes; avoid sampling caudate lobe.
• Needle core samples may be inadequate for definitive diagnosis of portal venous hypoperfusion.

PATHOLOGIC FINDINGS

• Gross—small, smooth-surfaced liver; PSVA may be difficult to verify at autopsy due to collapse of portal vasculature.
• Histologic features—cannot discriminate MVD, PSVA, NCPH, or extrahepatic portal venous TE/occlusion without history, clinical findings, and imaging details. Note: dogs with MVD lacking PSVA have histologic features identical to PSVA but lack macroscopic shunting.
• Portal venous hypoplasia—invalid histologic diagnosis as failure to identify perfused portal veins can reflect any cause of portal venous hypoperfusion.
• Note: dogs ≤4 months of age demonstrate increased juvenile or small portal triads.

TREATMENT

APPROPRIATE HEALTH CARE

Inpatient—severe signs of HE; medical intervention prior to liver biopsy and PSVA ligation.

NURSING CARE

See Hepatic Encephalopathy.

DIET

• Nutritional support—essential to maintain body condition and muscle mass.
• Species-specific balanced protein-restricted diet—use commercial canine liver diet for dogs and feline renal diet for cats as a baseline diet. To these diets, additional protein allocations are titrated based on patient response, in combination with treatments ameliorating HE.
• Dogs—as tolerated, add an additional 0.25 g up to 1.0 g protein/kg body weight using dairy quality protein (e.g., cottage cheese, cheddar cheese, yogurt, scrambled eggs); incrementally adjust observing over 5–7 day intervals (see Hepatic Encephalopathy).
• Cats—as tolerated, additional white meat chicken may be used.
• Avoid organ meats, fish, and red meat as protein sources.
• Asymptomatic or minimally symptomatic animals can survive well with dietary and medical interventions.

CLIENT EDUCATION

• Explain therapeutic options: medical vs. surgical and risks of each managerial strategy.
• Surgical ligation—has potential to cure; expect improvement in all symptomatic dogs that tolerate some degree of shunt attenuation.
• Postoperative clinical signs—may persist despite PSVA attenuation requiring chronic nutritional and medical management; some dogs can have medical and dietary interventions withdrawn.
• Clinical improvement may occur after surgical ligation despite persistent high TSBA values.
• Surgical/anesthetic risks—influenced by surgeon skill and experience, hospital, supportive critical care, type of PSVA, and histologic liver features.
• Monitoring protein C—can document improved portal perfusion in dogs with sustained high TSBA values; protein C activity will increase and may normalize with successful surgery (if low preoperatively); retest 2–6 months after surgery. This test is useful in cats for this purpose.
• If surgery not pursued or ligation not tolerated: remain vigilant for ammonium biurate obstructive uropathy; urethral obstruction (males) may require permanent urethrostomy.

SURGICAL CONSIDERATIONS

• HE—should be mitigated with medical management before anesthesia and surgery.
• ICU monitoring—recommended postoperatively for 72–96 hours.
• Surgical PSVA ligation—optimal goal of complete ligation; may not be tolerated leading to APSS. APSS may develop with any method of shunt attenuation: direct silk ligation, ameroid device, cellophane banding, or IV coiling (I-PSVA).
• Partial PSVA ligation—improves patient health in most cases.
• Degree of tolerated PSVA closure judged at surgery—physiologic responses to temporary shunt occlusion but intraoperative assessments can still be inaccurate or misleading.
• Intraoperative portography advised—verifies correct PSVA identification and evaluates immediate change in hepatic portal perfusion as a real-time assessment.
• Ameroid constrictor, cellophane banding, IV coiling—gradual PSVA attenuation, reduce immediate postoperative surgical risk; *caution*: may later result in APSS in some patients, degree of PSVA attenuation is unknown with these methods without follow-up vascular imaging.
• Intrahepatic PSVA—more difficult to ligate than E-PSVA; right-sided I-PSVA most difficult, left-sided I-PSVA consistent with

PORTOSYSTEMIC VASCULAR ANOMALY, CONGENITAL (CONTINUED)

patent DV easiest; IV coiling an alternative method but may require multiple procedures for optimal response, is expensive, requires interventional training.
• Ammonium biurate urolith removal—bladder stones most common, ensure urethra is free of uroliths by retrograde catheterization/flushing.
• Occasional male dog may require permanent urethrostomy.

Postoperative Complications

• Prolonged postoperative recovery—small patients developing intraoperative hypothermia.
• Acute severe PH—may reflect intolerance to PSVA ligation, flipping of ameroid constrictor, portal vein thrombi; mesenteric ischemia characterized by acute enteric hemorrhage, abdominal pain, tachycardia, hyper- or hypothermia, pancreatitis, endotoxemia, sepsis, acute renal failure and hypovolemic shock.
• Seizures—usually develop within 96 hours of PSVA ligation; risk factors remain unclarified with no demonstrated association with presence or absence of preoperative seizures, type of PSVA, method or degree of shunt attenuation, or patient age. Postoperative seizure prevalence—recent large multihospital study of dogs with seizures within 7 days of surgery: 6.7% of 524 dogs without preoperative levetiracetam treatment and 8.3–11.2% of 416 dogs receiving different pre- and postoperative levetiracetam protocols. One study implicates greater risk for pugs. Postoperative seizures reported in ~22% of cats undergoing PSVA ligation.
• Management of postligation seizures—often unsuccessful with persistent neurologic deficits in survivors, especially cats. Treatment remains anecdotal and requires consideration of cerebral edema if protracted seizure activity and intensive supportive care; successful management protocols (dogs and cats) include: IM phenobarbital (4–6 mg/kg IM q12h) combined with propofol CRI (0.3–0.6 mg/kg/minute titrated to achieve heavy sedation to drug-induced coma), and in one dog additional medetomidine (CRI (0.016 µg/kg/min). Initial treatment with IV levetiracetam has variable short-term response; flumazenil has no effect. Follow-up at-home treatments with phenobarbital, KBr, and/or levetiracetam have been successfully used.
• Abdominal effusion—typically transient after shunt ligation resolving within 7 days; alone, does not indicate intolerable PSVA attenuation; serious PH indicated by signs of mesenteric ischemia; monitor girth and body weight postoperatively to evaluate effusion.
• Administration of hetastarch can increase perioperative bleeding.
• Blood component therapy containing acid citrate dextrose may provoke hypocalcemia and coagulopathy (hypercitratemia) in patients <5 kg.
• Emergency surgery—rarely required for ligature removal after PSVA attenuation; ameroid constrictors difficult to impossible to remove; IV coils nonretrievable.

MEDICATIONS

DRUG(S) OF CHOICE

See Hepatic Encephalopathy and previous description of postoperative seizure management.

PRECAUTIONS

Remain aware of altered drug metabolism related to reduced first-pass extraction, altered hepatic metabolism/biotransformation.

FOLLOW-UP

PATIENT MONITORING

• Reevaluate—at-home behavior, cognitive function, water consumption, body condition, weight, girth circumference; CBC for resolution of microcytosis, biochemistry for normalization of cholesterol, BUN, creatinine, urinalysis for resolution of ammonium biurate crystalluria.
• TSBA (small-breed dogs)—persistent high values do not substantiate surgical failure because of common coexistent MVD.
• If low preoperative protein C (<70%), reevaluate 2–4 months after surgery as evidence of improved liver perfusion—values will improve or normalize.

POSSIBLE COMPLICATIONS

See Surgical Considerations.

PREVENTION/AVOIDANCE

Multiple APSS—should be detected preoperatively by US imaging; if identified these indicate need for liver biopsy, contraindicate shunt ligation, and implicate severe portal atresia or another underlying disorder causing PH; PSVA is not associated with PH and APSS.

EXPECTED COURSE AND PROGNOSIS

• Cannot predict individual response to surgery but asymptomatic dogs with preoperative normal protein C activity have the best prognosis for curative ligation.
• Dogs—ligation improves signs in ~80% symptomatic patients.
• Cats—increased risk for development of APSS with full ligation.
• Post-surgery—continue HE management (especially diet) until reevaluation and observations confirm improvements.
• Some patients—require indefinite nutritional and medical support after surgical ligation.
• Partial ligation—may result achieve full shunt attenuation by granulation response to ligature.
• Ameroid constrictor—may result in full ligation within hours or a few days, may cause APSS; rare erosion of portal vein causes catastrophic hemorrhage.
• Cellophane banding—some procedures fail because wrong type of cellophane used.
• Increased risk for poor surgical outcome—small dogs with zone 3 lipogranulomas shrouding hepatic venules; cats generally have less predictable surgical outcome compared to dogs.
• Despite initial good response, recrudescent shunting may develop 3 years post ligation.
• Asymptomatic nonligated PSVA dogs can have normal life expectancy with optimized medical management.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Ammonium urate urolithiasis.
• Copper-colored iris (cats).
• Cryptorchidism (dogs).
• Hepatic encephalopathy.

AGE-RELATED FACTORS

• Surgical outcome may be good in young and old patients, especially those with minimal signs of HE (asymptomatic).
• Dogs with PSVA identified at older ages are usually asymptomatic for HE and may have easily attenuated shunts (portoazygous, splenophrenic, or gastrophrenic).

PREGNANCY/FERTILITY/BREEDING

• Asymptomatic bitches can carry viable litters to term.
• Asymptomatic dogs have been naively used for stud.
• Breeding PSVA dogs not advised (genetic disorder, especially small-breed dogs).

SYNONYMS

Portacaval shunt.

SEE ALSO

• Ductal Plate Malformation (Congenital Hepatic Fibrosis).
• Hepatic Encephalopathy.
• Hepatoportal Microvascular Dysplasia.
• Hypertension, Portal.
• Portosystemic Shunting, Acquired.

ABBREVIATIONS

• APSS = acquired portosystemic shunt.
• CRS = colorectal scintigraphy.
• DV = ductus venosus.
• E-PSVA = extrahepatic PSVA.
• HE = hepatic encephalopathy.
• I-PSVA = intrahepatic PSVA.
• MVD = microvascular dysplasia.
• NCPH= noncirrhotic portal hypertension.

P

(CONTINUED) **PORTOSYSTEMIC VASCULAR ANOMALY, CONGENITAL**

- PH = portal hypertension.
- PSS = portosystemic shunting.
- PSVA = portosystemic vascular anomaly.
- PU/PD = polyuria/polydipsia.
- SPS = splenoportal scintigraphy.
- TSBA = total serum bile acids.

Client Education Handout available online

POXVIRUS INFECTION—CATS

BASICS

OVERVIEW
- Member of the genus *Orthopoxvirus*, family Poxviridae.
- Enveloped, double-stranded DNA virus, resistant to drying (viable for years) but readily inactivated by most disinfectants.
- Geographically limited to Eurasia.
- Relatively common.
- Serologic evidence of infection may approach 10% in cats in western Europe.

SIGNALMENT
- Cats—domestic and exotic.
- No age, sex, or breed predisposition.

SIGNS
- Skin lesions—multiple, circular; dominant feature; usually develop on head, neck, or forelimbs.
- Primary lesions—crusted papules, plaques, nodules, crateriform ulcers, or areas of cellulitis or abscesses.
- Secondary lesions—erythematous nodules that ulcerate and crust; often widespread; develop after 1–3 weeks.
- Oral lesions—erosions, ulcers either concurrently or alone (20% of cases).
- Pruritus variable.
- Systemic—20% of cases; anorexia, lethargy, pyrexia, vomiting, diarrhea, oculonasal discharge, conjunctivitis, pneumonia.

CAUSES & RISK FACTORS
- Reservoir host—wild rodents (voles, mice, gerbils, ground squirrels).
- Infection in cat thought to be acquired during hunting and being wounded by infected rodents; most common in young adults and active hunters, often from rural environment.
- Lesions—often develop at the site of a bite wound (presumably inflicted by the prey animal carrying the virus).
- Most cases occur between August and October, when small wild mammals are at maximum population and most active.
- Severe cutaneous and systemic signs with poor prognosis are frequently associated with immunosuppression (iatrogenic or coinfection with feline leukemia virus or feline immunodeficiency virus).
- Cat-to-cat transmission—rare; causes only subclinical infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Bacterial and fungal infections.
- Eosinophilic granuloma complex.
- Neoplasia—particularly mast cell tumor; lymphoma.
- Miliary dermatitis.

CBC/BIOCHEMISTRY/URINALYSIS
Noncontributory.

OTHER LABORATORY TESTS
Serologic testing—demonstrate rising titers; hemagglutination inhibition, virus neutralizing, complement fixation, or ELISA; titers may remain high for months or years.

DIAGNOSTIC PROCEDURES
- Virus isolation from scab material—definitive diagnosis; 90% positive.
- Electron microscopy of extracts of scab, biopsy, or exudate—rapid presumptive diagnosis; 70% positive.
- Skin biopsy—characteristic histologic changes of epidermal hyperplasia and hypertrophy, multilocular vesicle and ulceration, large eosinophilic intracytoplasmic inclusion bodies, immunofluorescence tests.
- PCR.
- Serologic assays: immunofluorescent antibody, ELISA, and virus neutralization assays.

TREATMENT
- No specific treatment.
- Clean and treat ulcerated areas to prevent secondary infection.
- Supportive (antibiotics, fluids) when necessary.
- Elizabethan collar—to prevent self-induced damage.

MEDICATIONS

DRUG(S) OF CHOICE
Antibiotics—prevent secondary infections.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Immunosuppressive agents (e.g., glucocorticoids, megestrol acetate)—absolutely contraindicated because they can induce fatal systemic disease.

FOLLOW-UP

PREVENTION/AVOIDANCE
- Natural reservoir hosts are probably small rodents, with cats infected incidentally; therefore, housing cats indoors should help prevent infection in cats.
- Vaccines—none available; vaccinia virus may be considered for valuable zoo collections, but its effects in nondomestic cats have not been investigated.

EXPECTED COURSE AND PROGNOSIS
- Most cats recover spontaneously in 1–2 months.
- Healing may be delayed by secondary bacterial skin infection.
- Prognosis is poor with severe respiratory or pulmonary involvement.

MISCELLANEOUS

ZOONOTIC POTENTIAL
- Rare human poxvirus infections have been linked to contact with infected cats with skin lesions; use basic hygiene precautions (disposable gloves) when handling infected cats.
- Infection is usually mild and transient in healthy humans, but severe and even lethal infections can occur in immunocompromised individuals.
- May cause painful skin lesions and severe systemic illness, particularly in the very young or elderly, people with a preexisting skin condition, and the immunodeficient.
- With discontinuation of vaccination against smallpox (with its cross-reactive immune effect) may expect increase in human poxvirus infections.
- Virus is hardy, can survive in scabs for weeks to months in environment where it can be source for human infection.

P

PREGNANCY EDEMA IN THE BITCH

BASICS

DEFINITION
• Edema associated with pregnancy varies from mild to severe pitting edema of the distal pelvic limbs, the ventral abdomen, mammary glands, and perineal subcutaneous tissues; sometimes accompanied with an increase in intrauterine amniotic/allantoic fluid accumulation.
• Abnormal fluid accumulation in the fetus/neonate, hydrops fetalis, is a separate disorder, and not a comorbidity.
• Edema in canine pregnancy has been referred to as "hydrops" by breeders; there is no evidence that the condition is comparable to hydrops in humans. The pathophysiology of the pregnancy edema syndrome in the dog has not yet been established. Hydrops allantois and hydrops amnii have been reported in mares and cows.

PATHOPHYSIOLOGY
• Edema can occur secondary to venous/lymphatic compression from an enlarged, gravid uterus.
• In humans, pregnancy edema can be normal (80%), or can be associated with preeclampsia, pregnancy toxemia, and eclampsia (proteinuric hypertension); a placental trigger is suspected (immunologic).
• During normal pregnancy total body water increases both extracellularly and interstitially. There is also cumulative retention of sodium distributed between the maternal extracellular compartments and the fetus. Changes in factors governing renal sodium and water handling accompany alterations in local Starling forces whereby there is a moderate fall in interstitial fluid colloid osmotic pressure and a rise in capillary hydrostatic pressure, as well as changes in hydration of connective tissue.

SYSTEMS AFFECTED
• Cardiovascular.
• Endocrine/metabolic.
• Hemic/lymphatic/immune.
• Hepatobiliary.
• Musculoskeletal.
• Renal/urologic.
• Reproductive.

GENETICS
Heritability unknown, breed tendencies (see Signalment) support DNA sampling in confirmed cases for future genetic evaluation.

INCIDENCE/PREVALENCE
Uncommon

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
Pregnancy edema occurs most commonly in bitches with very large litters in mid to late gestation. Many breeds have been affected, most commonly reported are golden retrievers, Labrador retrievers, pugs, Doberman pinschers, English bulldogs and French bulldogs, and bullmastiffs.

SIGNS
• Swelling/pitting edema of pelvic limbs, paws, mammary glands, perineum, ventrum, vulva.
• Marked abdominomegaly.
• Marked and sudden weight gain.
• Variable anorexia, nausea and lethargy; sometimes hemorrhagic gastroenterocolitis.
• Possible systemic hypertension.
• Possible increased allantoic/amniotic fluid volume.
• Possible ascites.

CAUSES
N/A

RISK FACTORS
• Large litter (10–12+).
• Occurs variably with previous/subsequent pregnancies.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Uteromegaly—closed pyometra, pregnancy.
• Edema—cardiogenic, secondary to electrolyte abnormalities, hypoalbuminemia, vasculitis, protein losing nephropathy or enteropathy, thrombosis, or hepatopathy.
• Abdominomegaly—ascites, hepato/splenomegaly, ruptured uterus, uterine torsion.
• Hypertension—primary, secondary to renal disease, endocrine disease.

CBC/BIOCHEMISTRY/URINALYSIS
• May be normal; anticipated anemia of pregnancy, stress leukogram, possible electrolyte abnormalities (e.g., hyponatremia, hyperkalemia, hypomagnesemia). Proteinuria possible.
• Hypomagnesemia is associated with preeclampsia in women.

OTHER LABORATORY TESTS
• Consider urine electrolyte evaluation if electrolyte abnormalities exist.
• Urine protein creatinine ratio if proteinuric.
• Adrenocorticotropic hormone stimulation test can identify hypo- or hyperadrenocorticism.

IMAGING
• Abdominal ultrasound with attention to fetal viability, and intra-abdominal, intrauterine, placental, allantoic and amniotic fluid volumes.
• Echocardiography for evaluation of dam for cardiac disorders.

DIAGNOSTIC PROCEDURES
• Blood pressure measurement, serial if hypertensive.
• Tocodynamometry to assess myometrial activity/irritability.
• Fetal heart rate determinations with Doppler or ultrasound to determine fetal wellbeing.

PATHOLOGIC FINDINGS
• Poorly characterized; collection of deceased fetuses, placentae encouraged for histopathologic evaluation.
• Consider uterine/placental biopsy during cesarean section.
• Complete necropsy with histopathology desirable in the event of maternal death to elucidate the cause.

TREATMENT

APPROPRIATE HEALTH CARE
• Address life-threatening conditions (malignant hypertension, hypomagnesemia) first, then secondary conditions (edema, nausea).
• Medical pregnancy termination not advised due to the fragile condition of the bitch and likely myometrial hypocontractility.

NURSING CARE
Mild distal limb edema can benefit from mild walking, hydrotherapy, or massage. Elevating the limbs and avoiding further compression of the caudal abdominal veins/lymphatics can help disseminate edema.

ACTIVITY
Appropriate but not excessive restriction.

DIET
• Mild sodium restriction if advanced heart disease is present.
• Appropriate-for-pregnancy dietary protein, especially if hypoalbuminemia or significant proteinuria present.

CLIENT EDUCATION
Anticipate the likely need for cesarean section due to litter size, uterine wall distension, and vulvar edema contributing to an obstructive dystocia.

SURGICAL CONSIDERATIONS
Elective cesarean section at term, or pregnancy termination via ovariohysterectomy should be considered in cases of severe edema.

MEDICATIONS

DRUG(S) OF CHOICE
• Hypertension—hydralazine 0.5–2 mg/kg PO q12h, titrate up to effect; or 0.2 mg/kg IM; repeat q2h as needed; monitor for hypotension, hospitalize until normotensive. Continue blood pressure monitoring until normotension is maintained.
• Hypomagnesemia and related signs—magnesium sulfate 0.7–1 mEq/kg/ day IV CRI; 0.25 mEq/kg slow IV bolus (loading dose); reduce 50% if patient is azotemic.

PREGNANCY EDEMA IN THE BITCH (CONTINUED)

• Edema—medical treatment of edematous conditions in pregnancy in the bitch is controversial and without evidence-based data. In human medicine, diuretics are *not* advised to treat physiologic edema of pregnancy and do not prevent preeclampsia.
• Nausea/anorexia—metoclopramide (0.1–0.2 mg/kg SC or PO q12h, ondansetron [FDA pregnancy category B; 0.5–1 mg/kg PO q8–12h], maropitant [1 mg/kg SC or 2 mg/kg PO q 24h × 5d.] Note: safe use of maropitant in pregnant dogs has not been evaluated.)

CONTRAINDICATIONS
Furosemide can cause a significant decrease in placental intervillous blood flow. Diuretics are contraindicated with contracted IV volume. Caution must be exercised if diuretic therapy is implemented.

PRECAUTIONS
• Any drug used is likely to cross the placenta; fetal effects should be considered and informed consent acquired.
• The use of diuretics can exacerbate hypertension by promoting dehydration, and at this time, use of diuretics cannot be routinely recommended unless studies demonstrate benefit to the dam/fetuses (beyond anecdotal reports).
• In humans, the role of diuretics in obstetric practice is restricted to the management of pulmonary edema in preeclampsia.

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUGS
Anecdotal use of the aldosterone antagonist spironolactone (1–2 mg/kg PO q12h) or furosemide (1–2 mg/kg PO q12h) has occurred in veterinary practice. The effects of these drugs on the fetuses are unknown (spironolactone is an antiandrogen and can feminize male rats) and their use is not recommended.

FOLLOW-UP

POSSIBLE COMPLICATIONS
• Dystocia secondary to uterine inertia related to stretching of the uterine wall.
• Fetal and maternal mortality.

EXPECTED COURSE AND PROGNOSIS
Fair to guarded prognosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
N/A

PREGNANCY/FERTILITY/BREEDING
• Consider pedigree evaluation. If an increased incidence occurs in related bitches, removal from the breeding program should be strongly considered.
• Research litter size associated with various stud dogs/brood bitches; select away from large litter size (>8).

SYNONYMS
None, as they syndrome is not well defined; hydrops (allantois, amnion) has been suggested but not documented to be the equivalent disease in humans and dogs.

SEE ALSO
• Dystocia.
• Hypertension, Portal.
• Hypertension, Pulmonary.
• Hypertension, Systemic Arterial.

PREGNANCY TOXEMIA

BASICS

OVERVIEW
Pregnancy toxemia is a rare condition in the bitch associated with an insufficient supply of carbohydrates to meet the increased energy demands of the late-gestational fetus. Sustained anorexia or carbohydrate-deficient diets result in a relative hypoglycemia and a negative energy balance. Prolonged negative energy balance causes hepatic lipolysis and the production of ketone bodies. Hypoglycemia and ketonemia are seen in bitches with pregnancy toxemia.

SYSTEMS AFFECTED
- Endocrine/metabolic.
- Gastrointestinal.
- Hepatobiliary.
- Nervous.
- Neuromuscular.
- Renal/urologic.
- Reproductive.

SIGNALMENT
Pregnant bitches, of any breed, typically late in gestation.

SIGNS
- Anorexia.
- Lethargy/malaise.
- Ataxia.
- Weakness.
- Collapse.
- Seizure.
- Coma.

CAUSES & RISK FACTORS
- Pregnancy.
- Large litters.
- Any event inciting sustained anorexia.
- Carbohydrate-deficient diets.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Puerperal tetany (hypocalcemia).
- Gestational diabetes.
- Sepsis/septic shock.

CBC/CHEMISTRY/URINALYSIS
- Ketonuria (no glucosuria) or ketonemia.
- Hypoglycemia.
- Elevations in hepatocellular enzyme activities.

OTHER LABORATORY TESTS
Venous blood gas analysis: metabolic acidosis.

IMAGING
Abdominal ultrasonography of the bitch to assess fetal viability and fetal stability. Fetal stress is associated with fetal heart rate <160.

DIAGNOSTIC PROCEDURES
N/A

TREATMENT
- Mildly affected (alert and appetent)—may resolve with appropriate carbohydrate intake; feed an energy-dense diet ad libitum.
- Moderately affected (clinically ill)—dextrose IV (0.5 g/kg IV bolus, may also be added to isotonic crystalloid fluids to a total concentration of 2.5% or 5% dextrose, and administer as constant IV infusion); tailor therapy to maintain euglycemia and prevent swings in blood glucose; taper treatment slowly as patient oral intake increases.
- Severely affected (nonresponsive to above therapy)—termination of pregnancy or cesarean section.

MEDICATIONS
Supportive care.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Concurrent hepatic lipidosis may decrease hepatic metabolism of certain drugs. Choose analgesics and anesthetics with caution.

FOLLOW-UP

PATIENT MONITORING
- Serial blood glucose concentration monitoring (q2–4h); adjust therapy as necessary.
- Serial urine or serum ketone measurements.
- Response to treatment (increased carbohydrate intake, euglycemia, and resolving ketonuria).

PREVENTION/AVOIDANCE
Feeding an energy-dense diet during pregnancy.

POSSIBLE COMPLICATIONS
Fetal mortality.

EXPECTED COURSE AND PROGNOSIS
Prognostic outcome depends on severity and response to treatment. If clinical signs are mild, the prognosis is good for dam and pups. Increased carbohydrate intake, alert mentation, and resolving ketonuria are good prognostic indicators in the dam. However, prolonged negative energy balance and ketonuria increase chances of fetal mortality. In severe cases pregnancy toxemia can be life-threatening for the dam and pups.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Hypocalcemia

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
N/A

PREGNANCY/FERTILITY/BREEDING
- Incidence of recurrence, effects on fertility, and heritability not investigated.
- If underlying cause of pregnancy toxemia is identified and correctable (i.e., poor nutrition), bitch could theoretically be used for breeding in the future.

SEE ALSO
Hypocalcemia

Consulting Editor Erin E. Runcan

PREMATURE LABOR

BASICS

OVERVIEW
Inappropriate myometrial activity preterm, which can lead to loss of pregnancy.

SIGNALMENT
Gravid female dog or cat; no age or breed predilection.

SIGNS
- Early—often no signs, fetal resorption evident ultrasonographically.
- Late—vulvar discharge: hemorrhagic or lochia, abortion.
- History of unexplained loss of pregnancy.

CAUSES & RISK FACTORS
- Often idiopathic; genetics can play a role. Secondary luteolysis results without intervention.
- Myometrial activity inappropriate for stage of pregnancy precedes luteolysis.
- Primary luteal insufficiency has not been documented.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Term gestation, onset of normal labor.
- Pathologic loss of pregnancy (see Miscellaneous).

CBC/BIOCHEMISTRY/URINALYSIS
- Usually normal.
- Anemia of pregnancy can be present, and rarely signs of hemorrhage.
- Inflammatory leukogram possible.

OTHER LABORATORY TESTS
Serum progesterone: will be <2 ng/mL when resorption/abortion occurs.

IMAGING
- Ultrasonographic evaluation of fetal heart rate (stress evidenced by heart rates consistently <170 bpm).
- Abnormal morphologic appearance of fetuses in uterus following death (see Web Figures 1 and 2).

DIAGNOSTIC PROCEDURES
- Tocodynamometry is diagnostic—finding >0–2 contractions/hour is not normal for preterm (earlier than 8th week) gestation.
- Progesterone measurement with a quantitative (chemiluminescence, fluorescence enzyme immunoassay) progesterone assay or accurate in house equipment should be performed to detect levels <2.0 ng/mL.

TREATMENT
- In humans, bed and pelvic rest and antibiotics do not contribute to a positive outcome, although frequently prescribed.
- Tocolytic agents are advised in veterinary cases (beta-agonists, calcium channel blockers, magnesium sulfate, prostaglandin synthetase inhibitors).

MEDICATIONS

DRUG(S) OF CHOICE
- Tocolytics (terbutaline 0.03 mg/kg PO q6–12h PRN); the dose is titrated based on uterine monitoring.
- Progestogens compounds—progesterone in oil (2 mg/kg IM q72h); altrenogest (Regu-Mate), a synthetic progestogen (0.088 mg/kg PO q24h); oral progesterone (Prometrium®; 10 mg/kg PO q24h) with monitoring of serum progesterone q24–48h for dosage adjustments. Clients should be informed of probable side effects with exogenous progesterone; it should only be used if the serum progesterone is <2 ng/mL and tocolytics have failed.
- Systemic antibiotics are rarely indicated.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
- Prolonged gestation if terbutaline or progestogen compounds are not withdrawn 24–48 hours before due date calculated from first progesterone rise, luteinizing hormone peak, or day 1 cytologic diestrus (see Breeding, Timing) if natural whelping is planned. Many successfully managed cases have ineffective labor despite drug discontinuation. If elective cesarean section is planned, medications can be continued until day of surgery.
- Poor lactation if progestogen compounds are used (inhibits normal prolactin elevation resulting from declining progesterone level).
- Masculinization of female fetuses if progestogen compounds are used, resulting in infertility and genitourinary abnormalities.
- Forced retention of a pathologic pregnancy if idiopathic premature labor is misdiagnosed.

FOLLOW-UP
- Serial abdominal ultrasound and/or fetal heart rate monitoring with Doppler to evaluate fetal viability.
- Serial tocodynamometry evaluating effective tocolysis.

MISCELLANEOUS
Usually a retrospective diagnosis by exclusion of all other causes of late-term abortion (see Abortion, Spontaneous) prompting midterm proactive tocodynamometry at the next pregnancy.

PROLAPSED GLAND OF THE THIRD EYELID (CHERRY EYE)

BASICS

OVERVIEW
• Definition—prolapsed gland of the third eyelid.
• Pathophysiology—the gland is normally anchored by a fibrous attachment to the periorbita beneath the third eyelid. In cases of prolapse these attachments are weak, resulting in dorsal movement of the gland. Commonly occurs in dogs and rarely in cats; animals may have unilateral or bilateral prolapse.

SIGNALMENT
• Dog and cat.
• Dog—usually in young dogs (6 months to 2 years of age); common breeds: American cocker spaniel, English bulldog, beagle, bloodhound, Lhasa apso, mastiff, shih tzu, other brachycephalic breeds.
• Cat—rare; occurs in Burmese, Persians, and has been reported in domestic shorthair cats.

SIGNS
• Oval, hyperemic mass protruding from behind the leading edge of the third eyelid in the medial canthus.
• May be unilateral or bilateral.
• May see signs of epiphora, hyperemic conjunctiva, keratitis, or blepharospasm.
• Additional swelling and hyperemia of the exposed gland can result from environmental exposure leading to irritation and desiccation.

CAUSES & RISK FACTORS
• Congenital weakness of the attachment of the gland of the third eyelid.
• Inheritance unknown but considered complex and multigenic.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Scrolled or everted cartilage of the third eyelid—seen in Weimaraner, Great Dane, German shorthaired pointer, and other breeds in which the T-shaped cartilage of the third eyelid is rolled away from the surface of the cornea instead of conforming to the surface of the cornea.
• Neoplasia of the third eyelid—usually seen in older animals. Most common third eyelid neoplasms in the dog are adenocarcinoma, adenoma, and squamous cell carcinoma. May also see lymphoma or fibrosarcoma. Most common third eyelid neoplasms in the cat are adenocarcinoma followed by squamous cell carcinoma. A small incisional biopsy is indicated to differentiate.
• Orbital fat prolapse—may dissect anteriorly between the conjunctiva and globe; occasionally occurs in the medial canthus.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

DIAGNOSTIC PROCEDURES
N/A

TREATMENT
• Surgical replacement of the gland (various techniques can be performed)—see Suggested Reading.
• Gland excision contraindicated; gland can produce up to 50% (or more) of the aqueous tear film; puts patient at substantial risk for developing keratoconjunctivitis sicca as the dog ages. Excision may be considered if neoplasia is confirmed, although potential complications and risks should be discussed.
• Elizabethan collar—to prevent self-trauma.

MEDICATIONS

DRUG(S) OF CHOICE
• Topical anti-inflammatory medications, such as corticosteroids (if no corneal ulceration) or nonsteroidal anti-inflammatory medications—may be used before and after surgery.
• Topical lubricating medications (ointments or gels)—may be used to reduce environmental exposure causing irritation and/or desiccation.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A

FOLLOW-UP
• Recurrence—5–20%, depending on the breed, with large-breed dogs (e.g., mastiff) having the highest recurrence rates; re-replacement of the gland is encouraged.
• If unilateral, warn client that the other gland may also prolapse and that no preventive procedure or medication exists.

MISCELLANEOUS

SYNONYMS
Cherry eye.

Acknowledgment The author and editors acknowledge the prior contribution of Brian C. Gilger.

PROPTOSIS

BASICS

OVERVIEW
- Forward displacement of globe, with eyelids trapped behind globe's equator (see Web Figures 1 and 2).
- Frequently acute and due to bite wounds, head trauma.
- Vision threatening.
- Immediate repositioning of globe critical.

SIGNALMENT
- More common in brachycephalic breeds (shallow orbit, large palpebral fissure).
- May occur in any species or breed with severe enough traumatic force.

SIGNS

Possible Accompanying Signs
- Subconjunctival or intraocular hemorrhage.
- Pupil dilated or constricted.
- Intraocular inflammation (uveitis).
- Globe deviation/strabismus/rupture.
- Corneal ulceration/desiccation.
- Periocular bite wounds.
- Fractures of bony orbit or skull.
- Systemic injuries.

CAUSES & RISK FACTORS
Trauma—primary cause; may be relatively minor force (e.g., restraint) in brachycephalic breeds; usually severe impact or trauma in other breeds.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Buphthalmia—globe enlargement; rarely acute.
- Exophthalmia—forward displacement of globe due to retrobulbar space-occupying lesion; may be acute, rarely peracute.

CBC/BIOCHEMISTRY/URINALYSIS
Normal, unless trauma-related abnormalities present.

IMAGING
Skull CT or radiographs—may show trauma-related fractures. Further diagnostic workup indicated if other systemic injuries.

TREATMENT
- Prevent further trauma—lubricate cornea, Elizabethan collar.
- Stabilize patient and perform thorough systemic physical examination before surgery.

Repositioning the Globe
- As soon as safely possible.
- Performed under sedation and local anesthesia or general anesthesia.
- Fluorescein—stain cornea prior to replacing globe.
- Lateral canthotomy—may ease tension on eyelids and allow easier globe repositioning; not always necessary.
- Engage eyelid margins with eyelid forceps (e.g., Von Graefe or Allis forceps) or strabismus/muscle hooks, pull eyelids forward and away from globe while protecting and gently pushing globe back into orbit (e.g., with lubricated scalpel blade handle), preventing forward traction on globe and optic nerve.
- Place 2–3 temporary tarsorrhaphy mattress sutures (sutures emerge from eyelid margin in line with meibomian gland openings) with stents; suture lateral canthotomy wound.

Eye Removal
With extensive globe or periocular tissue damage (loss of shape and turgor of ruptured globe, most conjunctival and muscle attachments severed), enucleation may be best option.

MEDICATIONS

DRUG(S) OF CHOICE
- Systemic and topical broad-spectrum antibiotics—until suture removal.
- Systemic corticosteroids—use initially; may be continued if marked periorbital/retrobulbar swelling.
- Topical corticosteroids—treat uveitis or hyphema, if no corneal ulceration.
- Topical atropine—for intraocular inflammation or hemorrhage; relieve ciliary spasm and lower risk of synechiae.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
- Topical corticosteroids—do not use with corneal ulcerations.
- Systemic corticosteroids—do not use with peri- or retrobulbar infection.

FOLLOW-UP

PATIENT MONITORING
Suture removal—usually sequential, starting 10–14 days after surgery. Reassess integrity of globe and vision.

PREVENTION/AVOIDANCE
Bilateral medial and/or lateral canthoplasty to shorten palpebral fissure and prevent future proptosis in brachycephalic breeds.

POSSIBLE COMPLICATIONS
- Blindness.
- Most patients retain dorsolateral strabismus and slight forward displacement of medial side of globe due to rupture of inferior oblique and medial rectus muscles. May improve with time.
- Decreased tear production—perform Schirmer tear tests after suture removal.
- Corneal denervation causing neurotrophic keratitis with chronic ulceration, decreased corneal sensitivity.
- Exposure keratitis from forward displacement of globe, decreased tear production, facial nerve palsy and/or corneal denervation (decreased blink reflex).
- Phthisis bulbi.

EXPECTED COURSE AND PROGNOSIS
- Most affected eyes can be salvaged; if in doubt, reposition and try to salvage the globe; majority will be blind.
- Extensive tissue damage, avulsion of three or more extraocular muscles, facial and/or orbital fractures, and corneal or scleral rupture—grave prognosis for vision and globe salvage for cosmesis.
- Normal retinal vessels and optic nerve, normal intraocular pressure, and short time from occurrence to repair—relatively favorable prognosis for maintaining vision.
- Positive menace response, dazzle and/or pupillary light reflexes—good prognosis for maintaining vision (always observe indirect pupillary light reflex in healthy eye originating from injured eye!).
- Pupil size at time of injury—not an accurate prognostic indicator.

PROSTATE DISEASE IN THE BREEDING MALE DOG

BASICS

OVERVIEW

• The prostate is the only accessory sex gland in the dog and is palpable per rectum as a bilobed oval gland with a median septum. • Dihydrotestosterone (DHT) stimulates growth of prostate gland; 5-α reductase in prostatic epithelial cells metabolizes serum testosterone to DHT.

Benign Prostatic Hyperplasia

• Commonly diagnosed in intact dogs—a result of diffuse, hormone-dependent, glandular, stromal hyperplasia and hypertrophy of prostate. • Cystic hyperplasia may occur later in disease process. • Contributing factors include age-associated changes in intraprostatic estrogen:androgen ratio, which potentiates hyperplastic response, and DHT-permissive growth of prostate. • Clinical effects minimal or absent in most dogs. • Renders prostate more susceptible to ascending infection and development of bacterial prostatitis.

Prostatitis/Prostatic Abscess

• Inflammation/infection of prostate. • Acute or chronic bacterial infection, abscess usually secondary to chronic bacterial prostatitis. • Also associated with benign prostatic hyperplasia (BPH) or retention cysts. • Bacterial colonization is typically via ascending urinary tract pathogens; hematogenous spread possible. • Common isolates include *Escherichia coli*, *Klebsiella*, *Pseudomonas*, *Pasteurella*, streptococci, and staphylococci species. • Concurrent bacterial urinary tract infection is not always noted with chronic bacterial prostatitis. • *Brucella canis* may be associated with acute or chronic prostatitis and has zoonotic potential. • Fungal prostatitis has been reported (*Blastomyces* and *Cryptococcus*).

Prostatic Cysts

• Within prostatic parenchyma, coalescing glandular/cystic hyperplasia and ductular occlusion (retention cysts) caused by estrogen effects (e.g., from Sertoli cell tumor) on prostatic epithelium. • Paraprostatic cysts are attached to prostate, lined by secretory epithelium, and variable in size; larger cysts may be transabdominally palpable; almost always sterile.

Prostatic Neoplasia

• Prostatic adenocarcinoma (ACA) is most common; other tumor types include fibrosarcoma, leiomyosarcoma, and squamous cell carcinoma (SCC). • Prostatic transitional cell carcinoma (TCC) arise from the prostatic urethra and invade the prostate gland. • BPH is not a risk factor for prostatic neoplasia. • Tumor development is androgen independent; castration is not protective. • Tumors typically detected after metastatic spread as clinical signs occur late and early screening is unavailable. • ACA bone metastasis is common, typically to spine or pelvis; intraprostatic fibrosis with some areas of ossification and hyperplasia is seen.

SIGNALMENT

• BPH—50% of intact dogs exhibit histologic evidence by 5 years of age, >95% by 9 years of age. • Prostatitis/prostatic abscess: common. • Prostatic cysts—prevalence around 14%; 42% of these had evidence of bacterial infection. • Neoplasia—prevalence 0.2–0.6% in general population, 5–7% of dogs with prostatic disease.

Mean Age and Range

• BPH—microscopic onset by 5 years of age. • Prostatitis/prostatic abscess—any age; more common in adults. • Prostatic cysts—more common after 8 years of age. • Neoplasia—mean age 10 years.

SIGNS

General Comments

• Dogs with prostatic disease display overlapping clinical signs. • Many dogs are asymptomatic. • Dyschezia, tenesmus, constipation, ribbon-like stool with advanced disease. • Sanguinous urethral/preputial discharge. • Dysuria, hematuria, stranguria. • Hemospermia.

Benign Prostatic Hyperplasia

• If mild, generally asymptomatic. • Hematuria and hemospermia are most common signs.

Prostatitis—Acute

• Systemic illness (vomiting, fever, inappetence). • Pyuria. • Stiff-legged gait.

Prostatitis—Chronic

• Recurrent/chronic urinary tract infection. • Stiff gait. • Infertility.

Prostatic Cyst

• If mild, generally asymptomatic. • If infected see signs associated with prostatitis.

Prostatic Neoplasia

• Emaciation. • Dyschezia. • Rear limb locomotory disturbance. • Lumbosacral pain.

Physical Examination Findings

Benign Prostatic Hyperplasia

Large, symmetrically enlarged, nonpainful prostate.

Prostatitis—Acute

• Fever. • Dehydration. • Sepsis/shock. • Caudal abdominal pain. • Normal to enlarged, asymmetric, painful prostate.

Prostatitis—Chronic

• Symmetric, nonpainful, firm, normal size prostate. • May have fluctuant areas (focal cysts) on palpation.

Prostatic Cyst

• Symmetric, enlarged prostate with fluctuant areas; large cysts may preclude rectal palpation, enlarged prostate may be transabdominally palpable. • External signs of feminization if cyst formation is due to estrogen exposure.

Prostatic Neoplasia

• Large, asymmetric, irregular painful prostate. • Rectal, abdominal, lumbosacral pain. • Palpable abdominal mass. • Lymphadenopathy (sublumbar).

CAUSES & RISK FACTORS

Benign Prostatic Hyperplasia

Older, intact males.

PROSTATITIS

• BPH and/or prostatic cysts. • Breeding dogs may have higher risk for *Brucella canis*.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Hematuria

• Urinary tract infection. • Thrombocytopenia. • Trauma. • Neoplasia.

TENESMUS

Colonic or rectal disease.

Hind Limb Gait/Locomotory Disturbance

• Arthritis. • Degenerative disc disease. • Neuromuscular disease.

CBC/BIOCHEMISTRY/URINALYSIS

Benign Prostatic Hyperplasia

Typically normal, except hematuria.

Prostatitis—Acute

• Leukocytosis and neutrophilia (± immaturity and signs of toxicity). • Pyuria. • Bacteriuria. • Hematuria.

Prostatitis—Chronic

• Occasionally leukocytosis. • Pyuria. • Bacteriuria. • Hematuria.

Prostatic Cyst

• Anemia (if hyperestrogenism present). • Biochemistry and urinalysis typically normal.

Prostatic Neoplasia

• Leukocytosis and neutrophilia. • Elevated alkaline phosphatase. • Pyuria. • Hematuria. • Atypical cells may be noted in urine sediment.

OTHER LABORATORY TESTS

• Prostatic fluid culture—culture third ejaculate fraction or fine-needle aspirate of prostate; positive growth supports bacterial prostatitis. • Paired seminal fluid and urethral culture—prostatitis is confirmed when seminal fluid bacterial growth (in colony-forming units) is ≥100 times corresponding urethral/urine growth. • Semen evaluation—may be normal or hemospermic with BPH; neutrophils, phagocytized bacteria, variable degree of

PROSTATE DISEASE IN THE BREEDING MALE DOG (CONTINUED)

reduced sperm motility and teratospermia with bacterial prostatitis. • Prostate-specific antigen/canine prostatic-specific esterase are not of clinical use in dogs. • Positive urine screening for cells with *BRAF* gene mutations (CADET™ *BRAF*) is highly sensitive and specific for the presence of prostatic urethral TCC.

IMAGING

• Abdominal ultrasound—detects size, homogeneity of prostate. Identifies focal parenchymal abnormalities (cysts or abscesses); loss of tissue homogeneity (prostatitis or neoplasia); regional lymph nodes and paraprostatic structures (paraprostatic cysts). • Abdominal radiography—bony metastases; degree of prostatomegaly. • Lack of prostatic mineralization in intact dogs with prostatomegaly has a negative predictive value of 96% for neoplasia. • Retrograde cystourethrogram—evaluates urethral compression, identifies contrast leakage.

DIAGNOSTIC PROCEDURES

• Prostatic wash to obtain culture and cytologic evaluation of prostatic fluid. • Ultrasound-guided fine-needle aspirate—cytologic evaluation may distinguish between BPH, prostatitis, and neoplasia; aspiration of active infections may seed periprostatic and subcutaneous tissues; aspiration of cysts rarely provides clinical resolution • Ultrasound-guided transabdominal biopsy—provides definitive diagnosis for BPH, prostatitis, prostatic neoplasia.

TREATMENT

• Temporary indwelling urethral catheter placement in animals with severe pain or urethral obstruction. • Analgesia. • Stool softeners and low-residue diets to ease defecation.

Benign Prostatic Hyperplasia

• Treat symptomatic dogs. • Castration is curative. • Finasteride is medical treatment of choice in breeding animals; decreases prostatic weight and diameter; prostate returns to pretreatment size 8 weeks after stopping therapy; typically used to reduce clinical signs permitting frozen semen stores to be generated; castrate when desired doses of semen are stored.

Prostatitis—Acute and Chronic

• Antimicrobials (based on culture and sensitivity) and that penetrate blood–prostate barrier (e.g., veterinary fluoroquinolone for Gram-negative organisms and clindamycin or a macrolide for Gram-positive organisms). Chloramphenicol and trimethoprim–sulfonamide are additional options. • Antimicrobials with poor penetration through an intact blood–prostate barrier should not be used. • Antimicrobials should be administered for a minimum of 4 weeks in acute cases, and up to 6 weeks for chronic cases. • Response to therapy should be monitored based on clinical signs, prostatic size and architecture, return of semen quality. Repeat cultures are not recommended unless poor initial response. • Finasteride may be considered to treat underlying prostatic pathology in dogs with future breeding intent. Castration is advised for nonbreeding animals and those that respond poorly to appropriate therapy.

Prostatic Abscess

Prostatic abscesses should be percutaneously drained with ultrasound guidance after administration of perioperative antimicrobials.

Prostatic Cyst

• Castration—treatment of choice. • Finasteride may be useful if associated with BPH. • Remove source of estrogen if squamous metaplasia. • Large solitary cysts—surgical marsupalization and castration. • Paraprostatic cysts—may be surgically excised. • Aspiration and drainage of cysts—not associated with resolution; fluid should be cultured.

Prostatic Neoplasia

• Differentiation between ACA and TCC will determine appropriate treatment (see specific chapters). • Urine culture. • A piroxicam trial should always be offered with or without chemotherapy.

Client Education

• Regular *B. canis* testing for breeding animals (minimum every 6 months). • Proactive semen freezing at young age prior to onset of prostatic disease/BPH.

MEDICATIONS

DRUG(S) OF CHOICE

• Finasteride 0.1 mg/kg PO q24h to a maximum of 5 mg PO q24h. • Antimicrobials—drug used and duration will vary with culture results and disease process; chronic prostatitis requires lipid-soluble antibiotics to reach parenchyma (e.g., enrofloxacin 10–20 mg/kg PO q24h) for 4–6 weeks.

Precautions

• Estrogens and progestogens—decrease prostatic mass via negative feedback on serum testosterone concentrations; however, toxic side effects are common and their use is not recommended. • Nonsteroidal anti-inflammatory drugs—may be associated with hepatic and/or renal dysfunction, gastrointestinal ulceration. • Trimethoprim–sulfamethoxazole—may be associated with keratoconjunctivitis sicca, thrombocytopenia, and hepatic necrosis.

Alternative Drug(s)

Deslorelin (Suprelorin)—not approved for this use in United States; not recommended for dogs intended for breeding; dramatically suppresses hypothalamic–pituitary–gonadal axis and testosterone production.

FOLLOW-UP

PATIENT MONITORING

• Serial prostatic fluid cultures to document antimicrobial efficacy. • Semen evaluation should be performed 70 days after resolution of illness in any breeding dog. • Serial abdominal ultrasound to evaluate response to treatment. • Dogs testing positive for brucellosis should not be used for breeding.

EXPECTED COURSE AND PROGNOSIS

• BPH generally responsive to finasteride. • Chronic prostatitis more refractory to medical management; castration may be indicated. • Poor prognosis for prostatic neoplasia.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Sertoli cell tumor. • Infertility. • Recurrent urinary tract infection.

ABBREVIATIONS

• ACA = adenocarcinoma.
• BPH = benign prostatic hyperplasia.
• DHT = dihydrotestosterone.
• SCC = squamous cell carcinoma.
• TCC = transitional cell carcinoma.

Suggested Reading

Author Sophie A. Grundy
Consulting Editor Erin E. Runcan

PROSTATIC CYSTS

BASICS

OVERVIEW

• Prostatic cysts in dogs include those associated with diffuse epithelial cystic change from androgen-dependent benign prostatic hyperplasia (BPH), cavitating retention cysts within the prostatic parenchyma, fluid-filled lesions with a distinct capsule, and paraprostatic cysts that are cavitating, fluid-filled lesions with a distinct capsule located outside of the prostatic parenchyma. Prostatic cysts may range in diameter from a few millimeters to more than 20 cm.
• Paraprostatic cysts usually arise craniolateral to the prostate, displacing the bladder cranially and ventrally, or caudal to the prostate in the pelvis. Prostatic cysts may represent dilated embryonal remnants of the wolffian ducts.
• Pathogenesis is unknown, but the occurrence of retention cysts in dogs with estrogen-secreting Sertoli cell tumors causes speculation that these cysts are dilations of prostatic acini secondary to estrogen-induced squamous metaplasia.

SIGNALMENT

• Male intact dogs; rare occurrence in castrated dogs.
• Age range 2–12 years, mean age 8 years.
• Large dogs more commonly affected than small dogs.

SIGNS

• Asymptomatic.
• Lethargy and anorexia.
• Abdominal distention.
• Tenesmus if the cyst compresses the rectum.
• Dysuria if the cyst compresses the urethra.
• Sanguinous urethral discharge in the presence of BPH.

CAUSES & RISK FACTORS

• BPH.
• Androgenic hormones.
• Estrogenic hormones.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• BPH—distinguished by ultrasound.
• Prostatic abscess—distinguished by ultrasound and semen culture.
• Distended urinary bladder—distinguished by cystocentesis, imaging.
• Caudal abdominal mass of undetermined origin—distinguished by imaging.

CBC/BIOCHEMISTRY/URINALYSIS

No abnormalities.

OTHER LABORATORY TESTS

• Examination of prostatic fluid collected by ejaculation or prostatic massage confirms absence of infection.
• Culture and cytology of cyst fluid collected by ultrasound-guided fine-needle aspiration or by aspiration at surgical exploration reveals sterile clear or sanguineous fluid consistent with prostatic fluid.

IMAGING

Retrograde contrast urethrocystography followed by prostatic ultrasonography confirms presence, location, echo-texture, and size of prostatic cysts, and differentiates retention cysts from paraprostatic cysts.

DIAGNOSTIC PROCEDURES

Collection of prostatic fluid by ejaculation followed by prostatic imaging is recommended prior to fine-needle aspiration of cystic fluid to rule out bacterial infection.

PATHOLOGIC FINDINGS

Epithelial cysts within the prostatic parenchyma occur with parenchymal hypertrophy and hyperplasia; squamous metaplasia of the ducts and alveoli may be present. Retention cysts and paraprostatic cysts are lined by a single layer of prostatic epithelium or fibrous connective tissue and contain clear to sanguineous fluid with fibrin.

TREATMENT

• Intraprostatic cysts (epithelial, retention) respond to prostatic involution via castration or the 5α-reductase inhibitor finasteride. Large cysts may be drained percutaneously with ultrasound guidance prior to initiation of finasteride therapy.
• Large retention cysts and paraprostatic cysts should be partially or completely surgically resected, depending on adherence to surrounding structures, or marsupialized and drained for 1–2 months.
• Simple drainage of the cyst is not recommended as persistence of the capsule may result in recurrence.

MEDICATIONS

DRUG(S) OF CHOICE

Prostatic parenchyma and diffuse epithelial cysts involute following treatment with finasteride 0.1–1 mg/kg PO q 24 h, not to exceed 5 mg/dog, for 2–4 months or as long as the dog remains intact to treat BPH. Finasteride prevents conversion of testosterone to dihydrotestosterone, causing prostatic involution without adversely affecting libido or spermatogenesis. BPH recurs following cessation of finasteride therapy. Paraprostatic cysts do not respond to finasteride treatment.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

• Imaging assessment of cyst size at 4-week intervals following treatment.
• Standard postoperative monitoring of marsupialized stoma.

MISCELLANEOUS

ABBREVIATIONS

• BPH = benign prostatic hyperplasia.

PROSTATITIS AND PROSTATIC ABSCESS

BASICS

DEFINITION

Acute Prostatitis
Infection of the canine prostate with bacteria, mycoplasmas, or fungi with systemic signs of fever, anorexia, lethargy, pain, and inflammatory exudate in prostatic fluid. Abscessation is variable, but occasionally rupture into the peritoneal cavity, causing sepsis, shock, and death.

Chronic Prostatitis
Subclinical infection of the canine prostate in absence of prostatic abscessation and polysystemic signs. Affected animals are asymptomatic except for inflammatory exudate in the prostatic fluid, which causes infertility. Chronic prostatitis may occur after or independently of acute prostatitis.

PATHOPHYSIOLOGY
- Predisposing pathology is benign prostatic hyperplasia (BPH), which occurs under the influence of dihydrotestosterone (DHT) in more than 80% of intact male dogs >5 years of age (see Benign Prostatic Hyperplasia).
- Infection of the hypertrophied canine prostate develops most commonly from ascending flora—rarely from blood-borne bacteria or from penetrating wounds. The prostate of intact dogs constantly secretes prostatic fluid, which is deposited into the prostatic urethra and then flows into the urinary bladder and out of the penile urethra. With prostatitis, prostatic fluid containing blood, inflammatory exudate, and microorganisms is deposited into the urinary bladder and discharged intermittently from the tip of the penis.

SYSTEMS AFFECTED
- Hemic/lymphatic/immune—mature or immature neutrophilia in acute prostatitis.
- Polysystemic—septic shock if prostatic abscesses rupture, fever, and focal or generalized peritonitis.
- Urinary—dysuria if the enlarged prostate compresses the urethra; deposition of prostatic fluid with inflammatory exudate into the urinary bladder.
- Reproductive—pain at copulation and reduction in libido; infertility from infected prostatic fluid in the ejaculate.

INCIDENCE/PREVALENCE
Intact male dogs >5 years of age are at highest risk, though overall incidence is low. Infection is reported in 40% of dogs with prostatic disease. Prostatitis in castrated males is exceedingly rare.

SIGNALMENT

Species
Dog

Breed Predilections
All breeds.

Mean Age and Range
Mean age range 7–11 years.

Predominant Sex
Intact male dogs; may occur secondary to prostatic neoplasia in castrated dogs.

SIGNS

Acute Prostatitis
- Lethargy/depression.
- Anorexia.
- Pyrexia.
- Pain at prostatic or caudal abdominal palpation.
- Sanguineous or purulent urethral discharge.
- Stiff hind limb gait.
- Septic shock.
- Tenesmus.
- Dysuria.

Chronic Prostatitis
- Asymptomatic.
- Sanguinous or purulent urethral discharge.
- Tenesmus.
- Dysuria.

CAUSES
- Infection of the hypertrophied prostate with ascending urethral flora (most commonly *E. coli*), anaerobic bacteria, or *Mycoplasma*.
- Infection of the hypertrophied prostate with systemic bacterial infection, including *Brucella canis.*
- Systemic or local puncture wound infection with *Blastomyces dermatitidis*.

RISK FACTORS
- Increasing age.
- Intact male.
- BPH and, less commonly, prostatic neoplasia.
- Historical androgen or estrogen administration.
- Impaired host defense mechanisms.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- BPH distinguished by prostatic cytology or semen culture.
- Prostatic cysts distinguished by ultrasound and semen culture.
- Prostatic neoplasia distinguished by ultrasound, tissue biopsy, and castrated state.
- Abdominal mass or abscess distinguished by abdominal imaging.

CBC/BIOCHEMISTRY/URINALYSIS
- CBC—include immature neutrophilia and toxic neutrophils; immature neutropenia may occur with sepsis. Most dogs with chronic prostatitis have a normal CBC.
- Serum chemistry—abnormalities are variable with acute prostatitis, normal in most chronic cases.
- Urinalysis—hematuria, pyuria, and causative microbes arise from deposition of infected prostatic fluid into the urinary bladder.

OTHER LABORATORY TESTS
- Cytology, and culture of whole semen or the prostatic fluid fraction of semen or fluid collected at prostatic massage yields inflammatory exudate with microorganisms. Normal prostatic fluid should contain <100,000 cfu/mL, and <5 leukocytes per hpf following fluid centrifugation.
- Although infection with *B. canis* is uncommon, because of the zoonotic potential of this infection, serology is recommended.

IMAGING
Survey radiography of the caudal abdomen, retrograde urethrocystography, and prostatic ultrasonography can evaluate prostatic size, echotexture, and detection of cavitating prostatic lesions.

DIAGNOSTIC PROCEDURES
- Collection and evaluation of prostatic fluid in seminal plasma or by prostatic massage.
- Ultrasound-guided percutaneous fine-needle aspirate of the prostate.

PATHOLOGIC FINDINGS
- Gross pathology of the infected prostate includes focal, multifocal, or diffuse enlargement, variable loss of symmetry of the dorsal median raphe, and variable presence of fluid-filled abscesses within or on the surface of the gland.
- Infection causes suppurative (bacterial) or granulomatous (fungal) inflammation, which may be focal, multifocal, or diffuse. Abscesses contain purulent fluid exudate.
- Biopsy of the infected prostate is not recommended because biopsy may result in the spread of infection to adjacent tissues.

TREATMENT

APPROPRIATE HEALTH CARE
- Acute prostatitis, prostatic abscess, and rupture of prostatic abscesses into the peritoneal cavity are potentially life-threatening emergencies that can lead to septic shock and death. Hospitalize affected patients and collect diagnostic samples immediately.
- Chronic prostatitis patients may be seen as outpatients for diagnostic procedures and started on therapy when laboratory results are available.

NURSING CARE
- Dogs with acute prostatitis or prostatic abscess should receive IV antimicrobial drugs.
- If abscess rupture and peritonitis is suspected, administer therapy for septic shock.

(CONTINUED) PROSTATITIS AND PROSTATIC ABSCESS

ACTIVITY
Breeding should be avoided until bacteria have been cleared from the prostatic fluid.

CLIENT EDUCATION
- Castration is recommended for nonbreeding dogs with prostatitis and/or prostatic abscess, as castration induces permanent prostatic involution.
- If maintenance of breeding potential is desired, long-term treatment with finasteride (see Benign Prostatic Hyperplasia) is recommended to induce prostatic involution. BPH recurs over time in intact male dogs after treatment with finasteride is discontinued, and BPH increases risk of recurrence of prostatitis.

SURGICAL CONSIDERATIONS
- Surgical management of prostatic abscesses should be deferred until after initiation of antimicrobial therapy and prostatic involution; involution is associated with resolution of smaller abscesses, often making surgery unnecessary.
- Castration is recommended for induction of prostatic involution in nonbreeding dogs with prostatitis; castration should be deferred until after identification and treatment (for at least 1 week) of the causative bacterial/fungal agent.
- Surgical drainage with subsequent packing of the cavity with omentum has been associated with the fewest adverse sequelae among surgical treatments. Referral to a surgical specialist is recommended.

MEDICATIONS

DRUG(S) OF CHOICE

Eradicating Infection
- Choice of antimicrobial agent is based on culture of the prostatic fluid and the ability of the antibiotic to cross the blood–prostate barrier. Antibiotics should be lipophilic, not highly protein-bound, and be a weak base.
- Antibiotics of choice—fluoroquinolones, trimethoprim, chloramphenicol, and macrolides. In acute prostatitis, the blood–prostate barrier is disrupted and almost any antibiotic will penetrate the prostatic parenchyma initially, but once healing has begun one of the preferred antibiotics discussed should be used.
- Antibiotic therapy should be administered for 4 weeks with repeat culture of prostatic fluid performed 1–2 weeks after the end of antibiotic treatment.

Inducing Prostatic Involution
- Treatment of choice in nonbreeding dogs for inducing permanent prostatic involution is castration.
- Alternatively, the 5α-reductase inhibitor finasteride (0.1–1 mg/kg PO q 24 h; not to exceed 5 mg/dog) for 2–4 months induces involution of the prostatic parenchyma and diffuse epithelial cysts and abscesses.
- Finasteride prevents conversion of testosterone to DHT, thereby causing prostatic involution without adversely affecting libido or spermatogenesis.
- BPH recurs following cessation of finasteride therapy; intact males should be maintained on finasteride.

CONTRAINDICATIONS
Estrogens and androgens cause squamous metaplasia of the prostate and BPH, respectively.

PRECAUTIONS
Long-term therapy with trimethoprim may lead to keratoconjunctivitis sicca or hypothyroidism.

FOLLOW-UP

PATIENT MONITORING
- Serial evaluation of semen culture, cytology, and prostatic imaging.
- Intervals between reevaluations vary with severity of signs, presence of an abscess, selection of castration or finasteride therapy for prostatic involution, and use of the dog in a breeding program. Intervals between evaluations range from 1 to 8 weeks, with recheck recommended prior to breeding.
- Continue patient monitoring until the dog has been castrated.

PREVENTION/AVOIDANCE
Castration is recommended in nonbreeding, affected dogs to induce prostatic involution, resolution of BPH, and prevention of recurrent infection. Breeding males should be maintained on finasteride.

POSSIBLE COMPLICATIONS
- Recurrence of infection if prostatic involution is not induced or antibiotic therapy is discontinued prematurely.
- Surgical drainage of abscesses is associated with many complications, including urinary incontinence, recurrent abscessation, hypoproteinemia, scrotal edema, anemia, sepsis, and shock.

EXPECTED COURSE AND PROGNOSIS
- Prognosis is good to excellent except in the case of rupture of prostatic abscesses into the peritoneal cavity.
- Castration prevents recurrence and improves prognosis.
- Surgical management of prostatic abscesses is associated with complications and a poorer prognosis than medical/surgical induction of prostatic involution.

MISCELLANEOUS

ASSOCIATED CONDITIONS
When prostatic fluid is infected, blood, inflammatory exudate, and microbial organisms may reflux into the urinary bladder, which, if detected in a urine sample collected by cystocentesis, may be misinterpreted as primary urinary tract infection.

ZOONOTIC POTENTIAL
Rare; *B. canis* and *Blastomyces dermatitidis* have been isolated from the urine of dogs with prostatic infection, but human infection from these sources has not been reported.

PROSTATOMEGALY

BASICS

DEFINITION
Abnormally large prostate gland determined by rectal or abdominal palpation, abdominal radiography, or prostatic ultrasonography. The enlargement can be symmetrical or asymmetrical, painful or nonpainful. Normal prostate size varies with age, body size, castration status, and breed so assessment of enlargement is subjective.

PATHOPHYSIOLOGY
Enlargement can result from epithelial cell hyperplasia or hypertrophy (e.g., benign prostatic hyperplasia [BPH]), neoplasia of prostatic epithelium or stroma, cystic change within the prostatic parenchyma, or inflammatory cell infiltration (e.g., acute and chronic bacterial prostatitis and prostatic abscess).

SYSTEMS AFFECTED
- Urinary.
- Reproductive.

SIGNALMENT
- Dog.
- Typically occurs in middle-aged to older males.

SIGNS
- May be none.
- Straining to defecate.
- Ribbon-like stools.
- Dysuria.
- Urethral outflow obstruction.

CAUSES
- BPH.
- Squamous metaplasia.
- Adenocarcinoma.
- Transitional cell carcinoma.
- Sarcoma.
- Metastatic neoplasia.
- Acute or chronic bacterial prostatitis.
- Prostatic abscess.
- Prostatic cyst.

RISK FACTORS
- Castration lowers the risk of BPH and bacterial prostatitis.
- Risk of adenocarcinoma may be increased threefold in castrated dogs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- BPH—typically causes nonpainful symmetrical enlargement of the prostate gland; not found in neutered dogs.
- Primary or metastatic neoplasia—typically causes painful, nonsymmetric enlargement of the prostate gland; weight loss, impaired appetite, rear limb weakness observed in some patients; suspect neoplasia in castrated dogs.
- Acute bacterial prostatitis—typically results in slight-to-moderate symmetric or nonsymmetric enlargement of the prostate gland with prostatic pain. Fever, impaired appetite, rear limb weakness, and painful abdomen observed in some patients.
- Chronic bacterial prostatitis—signs similar to those seen in dogs with acute prostatitis or those related to recurrent lower urinary tract infection (e.g., dysuria and hematuria). Systemic signs less common than in acute bacterial prostatitis; bacterial prostatitis uncommon in castrated dogs.
- Prostatic abscess—may result in signs similar to those in patients with acute or chronic prostatitis; abscess rupture causes fever and caudal abdominal pain.
- Prostatic cysts—may be associated with palpable caudal abdominal mass, straining to urinate, or straining to defecate; patient may also be asymptomatic.

CBC/BIOCHEMISTRY/URINALYSIS
- CBC normal in patients with BPH.
- Leukocytosis in patients with prostatic abscess and bacterial prostatitis, occasionally with chronic bacterial prostatitis and prostatic neoplasia.
- High bilirubin and alkaline phosphatase in some patients with prostatic abscess.
- Urinalysis—usually normal.
- Hematuria in patients with BPH.
- Pyuria, hematuria, proteinuria, and bacteriuria in patients with bacterial prostatitis
- Pyuria, hematuria, proteinuria, and, occasionally, neoplastic cells in dogs with prostatic neoplasia.

OTHER LABORATORY TESTS
Serum canine prostate-specific arginine esterase concentration may be high in dogs with BPH.

IMAGING

Radiographic Findings
Prostatomegaly

Ultrasonographic Findings
- Abscess or cyst—hypoechoic or anechoic lesions with distal enhancement.
- Acute bacterial prostatitis—uniform prostatic echogenicity.
- BPH—uniform prostatic echogenicity; small fluid-filled cysts in some patients.
- Chronic bacterial prostatitis—focal or diffuse hyperechogenicity.
- Prostatic neoplasia—focal to multifocal areas of coalescing echogenicity and acoustic shadowing (if dystrophic mineralization occurs).

DIAGNOSTIC PROCEDURES
- Examination of prostatic fluid obtained by ejaculation or prostatic massage may reveal red blood cells with BPH, neutrophils with prostate infection, or neoplastic cells with carcinoma
- Bacterial culture of prostatic fluid typically reveals >100,000 cfu/mL in dogs with bacterial prostatitis.
- Needle biopsy of the prostate with ultrasound guidance provides visualization of the area to be sampled and increases the likelihood of obtaining a diagnostic sample; take care to avoid iatrogenic rupture of a prostatic abscess.

TREATMENT
- Varies with the cause of prostatomegaly.
- Surgical castration—indicated in symptomatic nonbreeding dogs with BPH and after acute infection resolves in dogs with bacterial prostatitis.
- Surgical drainage—indicated in dogs with prostatic abscess or large prostatic cysts.

MEDICATIONS

DRUG(S) OF CHOICE

BPH
If castration is not desired, the following drugs may produce a temporary response:
- Finasteride 0.1–0.5 mg/kg/day PO; not to exceed 5 mg/dog, for as long as the dog remains intact.
- Medroxyprogesterone 3 mg/kg SC once.
- Osaterone acetate 0.25 mg/kg PO once daily for 7 days.
- Delmadinone acetate 3 mg/kg SC once.
- Deslorelin acetate (SC implant administered every 6–12 months).

Bacterial Prostatitis
Choose antibiotics on the basis of antibacterial susceptibility testing of the isolated pathogen and ability of the antibiotic to diffuse into prostatic fluid in therapeutic concentrations. Good choices for the latter include fluoroquinolones, trimethoprim–sulfamethoxazole, chloramphenicol, and macrolides. Treatment should be for a minimum of 4 weeks.

Prostatic Carcinoma
Cox-2 inhibitors such as piroxicam and carprofen have been shown to prolong acceptable quality of life an average of 6 months compared to 3 weeks in nontreated dogs. These are used sometimes in combination with chemotherapeutic agents such as mitoxantrone, vinblastine, or metronomic chlorambucil. Referral to an oncologist is recommended.

PRECAUTIONS
Long-term administration of medroxyprogesterone and trimethoprim–sulfamethoxazole can cause diabetes mellitus and keratoconjuctivitis sicca, respectively.

FOLLOW-UP

PATIENT MONITORING

- Abdominal radiographs or prostatic ultrasonography to assess efficacy of treatment in BPH, prostatic carcinoma, or bacterial prostatitis.
- Urine and prostatic fluid culture to access efficacy of treatment in patients with bacterial prostatitis.

POSSIBLE COMPLICATIONS

- Metastatic disease.
- Subfertility.
- Dysuria.

MISCELLANEOUS

SEE ALSO

- Adenocarcinoma, Prostate.
- Benign Prostatic Hyperplasia.
- Prostatic Cysts.
- Prostatitis and Prostatic Abscess.

ABBREVIATIONS

- BPH = benign prostatic hyperplasia.

PROTEIN-LOSING ENTEROPATHY

BASICS

DEFINITION
• A disease process characterized by excessive loss of protein into the gastrointestinal (GI) lumen. • Protein-losing enteropathy (PLE) may be associated with primary GI diseases (e.g., inflammatory bowel disease, intestinal lymphoma, or intestinal lymphangiectasia) and systemic disorders (e.g., fungal disease or congestive heart failure [CHF]).

PATHOPHYSIOLOGY
• Under physiologic conditions, two-thirds of normal protein loss in dogs occurs through the small intestine. • Plasma proteins that leak into the GI lumen are rapidly digested into constituent amino acids that can be reabsorbed and used for the synthesis of new proteins. • This normal loss of plasma proteins can be accelerated by GI mucosal disease or by increased leakage of lymph into the GI lumen. • GI protein loss is associated with loss of both albumin and globulin, often resulting in panhypoproteinemia. • In response to increased GI protein loss, the liver increases albumin synthesis. However, the liver cannot increase albumin synthesis to more than twice the normal output. • When protein loss exceeds protein synthesis, hypoproteinemia results. • Hypoproteinemia causes decreased plasma oncotic pressure, which may lead to hemodynamic changes, effusion into body cavities or peripheral edema.

SYSTEMS AFFECTED
• Coagulation—patients with PLE lose antithrombin and other anticoagulants, resulting in a hypercoagulable state which may lead to thromboembolic events such as pulmonary thromboembolism (PTE). • GI—primary GI disease may be associated with diarrhea, vomiting, or weight loss. • Hemodynamic—decreased oncotic pressure leading to cavitary effusion. • Lymphatic—lymphangiectasia. • Respiratory—dyspnea due to pleural effusion or PTE. • Skin—subcutaneous edema.

GENETICS
PLE due to specific underlying causes is suspected to be hereditary based on an increased prevalence in specific dog breeds.

INCIDENCE/PREVALENCE
• Unknown. • Many dogs with subacute or acute gastroenteritis have transient PLE.

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
Species
Dog and cat.

Breed Predilections
Soft-coated wheaten terrier, Basenji, Yorkshire terrier, and Norwegian lundehund.

Mean Age and Range
Any age.

Predominant Sex
No predilection.

SIGNS
General Comments
Clinical signs are variable.

Historical Findings
• Chronic diarrhea, weight loss, sarcopenia, and lethargy are most frequently reported. However, many dogs with PLE have normal stools. • Vomiting is uncommon. • Dogs can be presented for apparent weight gain or abdominal distension.

Physical Examination Findings
• Ascites, dependent edema, and dyspnea from pleural effusion may be detected in patients with marked hypoproteinemia. • Abdominal palpation may reveal thickened bowel loops, though this is uncommon.

CAUSES
Disorders of Lymphatics
• Intestinal lymphangiectasia. • GI lymphoma. • Granulomatous infiltration of the small bowel. • CHF leading to lymphatic hypertension.

Diseases Associated with Increased Mucosal Permeability or Mucosal Ulceration
• Viral gastroenteritis—parvovirus and others. • Bacterial gastroenteritis—salmonellosis and others. • Fungal gastroenteritis—histoplasmosis and others (note: serum globulin concentrations can be within the reference interval due to increased production secondary to massive antigenic stimulation). • Parasitic enteritis—hookworms, whipworms, and others. • Inflammatory bowel disease—lymphocytic-plasmacytic, eosinophilic, or granulomatous gastroenteritis. • Adverse food reactions. • Mechanical enteropathies—chronic intussusception, chronic foreign body, and others. • Intestinal neoplasia—lymphoma, adenocarcinoma, and others. • Gastric or intestinal ulcers.

RISK FACTORS
• GI disease. • Lymphatic disease. • Heart disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Hypoalbuminemia due to hepatic failure—often associated with normal or increased serum globulin concentration. Hepatic enzyme activity may be increased, serum BUN, cholesterol, and glucose may be decreased, and serum pre- and postprandial bile acids concentrations may be increased. • Hypoalbuminemia due to protein-losing nephropathy (PLN)—mild in patients with fever or hyperadrenocorticism, moderate to severe in patients with glomerulonephritis or amyloidosis; commonly associated with a normal or increased serum globulin concentration; ruled out by a normal urine protein:creatinine ratio. • Hypoalbuminemia due to severe blood loss: excluded by assessment of the CBC and a thorough physical examination; in some cases a test for fecal occult blood may be necessary. • Starvation is a rare cause of hypoalbuminemia.

CBC/BIOCHEMISTRY/URINALYSIS
• Hypoalbuminemia and frequently hypoglobulinemia (panhypoproteinemia). • Normal or increased serum globulin concentration in some cases, if the underlying disease is associated with chronic antigenic stimulation (e.g., immunoproliferative enteropathy of the basenji). • Hypocalcemia. • Hypocholesterolemia. • Lymphopenia may be seen with lymphangiectasia.

OTHER LABORATORY TESTS
• Increased fecal α_1-protease inhibitor concentration (must be assessed in naturally passed and freshly frozen fecal samples from 3 consecutive days). • Once PLE has been identified as the cause of the hypoalbuminemia, specific tests may be useful to determine the cause of PLE: multiple fecal examinations to rule-out intestinal parasitism as a cause of PLE; serum cobalamin and folate concentrations to diagnose small intestinal dysbiosis or cobalamin deficiency.

IMAGING
• Thoracic radiographs may show evidence for cardiac, mediastinal, or fungal disease. • Abdominal radiographs may show evidence for a mechanical enteropathy (i.e., foreign body, intussusception, or other). • Abdominal ultrasound may show evidence for a mechanical enteropathy or other causes of PLE. • Abdominal ultrasound is helpful for evaluating the pattern of intestinal wall layering that can be associated with a variety of enteropathies. Hyperechoic mucosal striations ("tiger stripe" effect), mucosal speckles, and a hyperechoic line within the mucosa that runs parallel to the submucosa are common findings in dogs with intestinal lymphangiectasia. • Echocardiogram may show evidence for cardiac disease.

DIAGNOSTIC PROCEDURES
• Broad-spectrum anthelminthic agent to treat for potential parasitism. • Elimination diet trial using a novel or hydrolyzed protein source to rule out food sensitivity. One study in a group of soft-coated wheaten terriers suggests a hydrolyzed protein diet may be the best choice in dogs with PLE. • Histoplasma antigen test (serum or urine) and rectal mucosal scraping in geographic regions where histoplasmosis is endemic. • Gastroduodenoscopy and colonoscopy—to visualize the GI mucosa and to collect endoscopic biopsies for histopathologic evaluation. Visualization of white "plaques" (e.g., chylomicron distended lacteals) along the mucosa suggests lymphangiectasia. • Abdominal exploratory laparotomy may show dilated intestinal lymphatics and allows for full-thickness biopsies of intestines and lymph

(CONTINUED) PROTEIN-LOSING ENTEROPATHY

nodes. • Fecal α_1-protease inhibitor concentration to document excessive GI protein loss. Assays are species-specific and currently only an assay for measurement of α_1-protease inhibitor in dogs is available through the GI Laboratory at Texas A&M University. Samples from 3 consecutive defecations need to be collected in special preweighed fecal tubes that can be sourced from the GI Lab.

PATHOLOGIC FINDINGS

• In dogs with PLE due to lymphangiectasia, gross findings may include dilated lymphatics that are visible as a web-like network throughout the mesentery and serosal surface. • May see small yellow-white nodules and foamy granular deposits adjacent to lymphatics (lipogranulomas). • Lacteal dilatation, villous blunting, and crypt lesions (e.g., dilatation, cysts, abscesses) are the most consistent findings on histopathology in dogs with lymphangiectasia and PLE. • PLE due to other causes may show lesions specific for the disease.

TREATMENT

APPROPRIATE HEALTH CARE

Inpatient or outpatient medical management depending on the severity of clinical signs at the time of diagnosis.

NURSING CARE

• With clinical signs due to edema or effusion from severe hypoalbuminemia, albumin transfusion, or colloids (such as hetastarch) may be considered to increase plasma oncotic pressure. Both human and canine albumin can provide a temporary increase in serum albumin, but human albumin transfusion may be associated with adverse reactions in dogs. • Abdominocentesis to remove ascites or pleurocentesis to remove pleural effusion is indicated in cases where effusion has led to respiratory compromise. • Consider placement of an esophageal feeding tube in hyporexic patients to meet increased caloric demands.

ACTIVITY

Normal

DIET

• May need to be modified depending on the underlying cause of PLE. • If lymphangiectasia is diagnosed or highly suspected, an ultra-low-fat diet, containing 20 g fat/1,000 kcal or less, is indicated. It should be noted that there are currently no commercial diets lower than 20 g fat/1,000 kcal and one study has suggested that an even lower fat content is beneficial.

CLIENT EDUCATION

Prepare clients for long-term therapy; spontaneous cures are rare.

SURGICAL CONSIDERATIONS

• Hypoalbuminemia increases postoperative morbidity because of slow wound healing. • Some causes of PLE (e.g., intussusception, chronic foreign body, and some intestinal neoplasms), however, require surgical intervention.

MEDICATIONS

DRUG(S) OF CHOICE

• There is no pharmacologic therapy for PLE itself. Instead, the underlying cause of PLE must be addressed.
• However, patients with PLE also lose antithrombin and other anticoagulants and can be hypercoagulable. Thus, patients should be treated with a platelet aggregation inhibitor: ○ In dogs or cats—clopidogrel bisulfate (1–4 mg/kg PO q24h in dogs; 18.75 mg/cat PO q24h, which equals one-fourth of a 75 mg tablet). ○ In dogs—low-dose aspirin (0.5 mg/kg PO q12h; use an 81 mg tablet of aspirin and put into the barrel of a 10 mL syringe, add 8.1 mL of water and shake until completely dissolved to make a 10 mg/mL solution; discard unused portion immediately).

CONTRAINDICATIONS

• Aspirin and clopidogrel should not be used concurrently.
• Clopidogrel should not be used with NSAIDs, phenytoin, torsemide, or warfarin.

PRECAUTIONS

Bleeding may be enhanced in patients treated with platelet aggregation inhibitors that have to undergo surgery.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

• Diuretics such as furosemide (1 mg/kg PO q12h) in combination with spironolactone (1 mg/kg PO q12h) have been used by some clinicians to control edema, pleural effusion, and ascites. However, they do not work consistently in patients with PLE because of decreased plasma oncotic pressure and may be associated with side effects. • There are anecdotal reports about the use of the long-acting somatostatin analogue octreotide in dogs with PLE, but no clinical trials have been completed to date and no specific dosing regimen has been suggested.

FOLLOW-UP

PATIENT MONITORING

Check body weight, serum albumin concentration, and evidence of recurrent clinical signs (i.e., pleural effusion, ascites, and/or edema). Frequency depends on the severity of the condition. Monitor serum cobalamin concentration if patient was hypocobalaminemic and supplemented with cobalamin.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

• Thromboembolic events, especially PTE.
• Respiratory difficulty from pleural effusion or PTE. • Severe protein-calorie malnutrition.
• Intractable diarrhea.

EXPECTED COURSE AND PROGNOSIS

• Prognosis is guarded and depends on the underlying cause. Smaller breed dogs carry a more favorable prognosis because nutritional support is easier to perform. • The primary disease cannot be treated in many cases.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Soft-coated wheaten terriers may have PLN in conjunction with PLE and should be evaluated accordingly.

AGE-RELATED FACTORS

P

PROTEINURIA

BASICS

DEFINITION
• Urinary protein detected by dipstick analysis, urinary protein:creatinine ratio (UP:C ≥0.4 in cats or ≥0.5 in dogs), urinary albumin:creatinine ratio (UA:C >30 mg/g), or 24-hour urine protein content (> 20 mg/kg). UP:C of 0.2–0.4 in cats and 0.2–0.5 in dogs is borderline.
• Microalbuminuria (MA) is the abnormal presence of low concentrations of albumin in the urine (1–30 mg/dL), below the limit of detection of standard urine dipsticks.

PATHOPHYSIOLOGY
• Prerenal—greater than normal delivery of low-molecular-weight plasma proteins to glomeruli.
• Renal, glomerular—excessive loss of larger molecular weight proteins (e.g., albumin) across the glomerular basement membrane (GBM) secondary to altered permselectivity of glomeruli.
• Renal, tubular—reduced tubular reabsorption of proteins.
• Postrenal—exudation of blood or plasma into lower urinary tract.

SYSTEMS AFFECTED
• Renal/urologic—chronic glomerular proteinuria causes progressive tubular damage resulting in chronic kidney disease (CKD).
• Cardiovascular—systemic hypertension.
• Hemic/lymphatic/immune—severe glomerular proteinuria can lead to edema and/or hypercoagulability. Hypercoagulability is brought about by vascular stasis, hyperfibrinogenemia, platelet abnormalities, loss of antithrombic substances, and an increase in procoagulant factors. The pathogenesis of edema involves both inappropriate renal sodium retention and decreased plasma oncotic pressure.

GENETICS
Familial nephropathies associated with glomerular proteinuria have been described in several breeds of dogs; in only a few has the mode of inheritance been established: Samoyed (X-linked), English cocker spaniel (autosomal recessive), bull terrier (autosomal dominant), Dalmatian (autosomal dominant), Bernese mountain dog (autosomal recessive), Brittany spaniel (autosomal recessive), bullmastiff (autosomal recessive), Newfoundland (autosomal recessive), soft-coated wheaten terrier (complex), Chinese shar-pei (suspect autosomal recessive). Doberman pinscher, Rottweiler, Pembroke Welsh corgi, beagle, English foxhound, and others.

INCIDENCE/PREVALENCE
• In a study of urinalysis data from 500 dogs, the prevalence of proteinuria was approximately 19%.
• The prevalence of MA was 25% in dogs and 25% in cats. Prevalence increased with advancing age.

GEOGRAPHIC DISTRIBUTION
None, however an association may be observed with some infectious diseases that are regional.

SIGNALMENT
Species
Dog and cat.

Breed Predilections
Glomerular proteinuria may be the initial manifestation of several familial renal diseases (see Genetics).

Mean Age and Range
Proteinuria can occur at any age. Familial renal diseases tend to occur in younger animals; acquired glomerular proteinuria more likely in middle-aged or older animals

Predominant Sex
Varies with different diseases

SIGNS
• Vary with underlying cause and severity of proteinuria.
• Patients with glomerular proteinuria are frequently asymptomatic or have signs attributable to underlying diseases.

Historical Findings
• Weight loss and lethargy; animals with pulmonary thromboembolism may have acute dyspnea.
• Patients with lower urinary tract (LUT) disorders may have dysuria, pollakiuria, inappropriate urination, and/or hematuria.

Physical Examination Findings
• May have edema or abdominal distention.
• May have oral ulceration (if uremic), edema or cavitary effusion, or changes in pulse quality (if thromboembolic).

CAUSES
Prerenal Proteinuria
Overload proteinuria—tubular resorptive capacity exceeded by large amounts of low-molecular-weight plasma proteins in glomerular filtrate (e.g., excessive hemolysis or rhabdomyolysis, neoplastic production of paraproteins or Bence Jones proteins).

Renal Proteinuria
• Functional proteinuria—strenuous exercise, fever, hypothermia, seizures, or venous congestion.
• Glomerulonephritis (e.g., immune complex-mediated, membranous, membranoproliferative, proliferative), minimal change disease, hereditary nephritis, amyloidosis, podocyopathy, focal segmental glomerulosclerosis, glomerulosclerosis.
• All glomerular diseases can be associated with severe proteinuria, subsets of immune complex-mediated (particularly membranoproliferative and membranous) may be associated with higher magnitude proteinuria than others.
• Tubular dysfunction resulting in failure of tubular protein reabsorption is associated with mild-to-moderate proteinuria.

Postrenal Proteinuria
Hemorrhage or inflammation of the urogenital tract.

RISK FACTORS
• Chronic inflammatory (e.g., infectious and immune-mediated) and neoplastic diseases can lead to development of glomerulonephritis or amyloidosis. Examples include dirofilariasis, ehrlichiosis, borreliosis, babesiosis, chronic bacterial infections (e.g., endocarditis, pyoderma), pyometra, bartonellosis, feline immunodeficiency virus, mast cell tumor, lymphosarcoma, hyperadrenocorticism, and systemic lupus erythematosus.
• Systemic hypertension.
• Chronic hyperlipidemia.
• Multiple myeloma can produce Bence Jones proteinuria.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Differentiate prerenal, postrenal, and renal-tubular from glomerular causes.

CBC/BIOCHEMISTRY/URINALYSIS
• Urine dipstick and sulfosalicylic acid (SSA) tests allow qualitative and semiquantitative assessment of urine protein content. Results are affected by urine concentration and must be interpreted in context of urine specific gravity. Low urine protein (trace or 1+) may be normal in a concentrated urine sample.
• The dipstick lacks specificity (dog, 69%; cat, 31%) and sensitivity (dog, 54%; cat, 60%).
• False-positive test results occur when urine is highly alkaline (pH >8–9) or when the dipstick is immersed in the urine for a prolonged time.
• Low concentrations of Bence Jones proteins or gamma globulins may not be detected by urine dipstick.
• SSA turbidometric test results are falsely increased by radiographic contrast media, penicillins, sulfisoxazole, or the urine preservative thymol.
• SSA test results are falsely decreased by very alkaline urine and increased by uncentrifuged urine.
• If proteinuria is detected by these methods, the urine sediment should be evaluated for hematuria, pyuria, and/or bacteriuria. Hematuria alone typically does not increase urine albumin content above the negligible range (i.e., >1 mg/dL) or the UP:C above 0.4

until there is a color change in the urine. 81% of dogs with pyuria had normal UP:C.
• To determine persistence, repeat the urine protein screening test in proteinuric patients that initially have a normal urine sediment or have been treated for urinary tract inflammation or hemorrhage. If proteinuria is transient and the urine sediment is normal, consider functional proteinuria or false-positive test results.
• Although not all animals with glomerular disease are hypoalbuminemic, glomerular proteinuria should be suspected when proteinuria and hypoalbuminemia are concurrent. As disease progresses, clinicopathologic changes consistent with glomerular disease may develop.

OTHER LABORATORY TESTS
• Urine protein should be quantified in dogs and cats that have hypoalbuminemia and/or repeatedly positive urine dipstick or SSA tests in absence of LUT hemorrhage or inflammation. The UP:C is the preferred because more is known about use of this test and it is technically easier to perform than 24-hour urine collections.
• MA is detected in dogs using a point-of-care immunoassay or quantitation using an immunoassay. MA is an early predictor of proteinuria. If repeatedly positive, and if the concentration is increasing, the patient may be at risk for glomerular disease.
• Thoroughly evaluate an animal for an underlying disease when persistent proteinuria is believed to be of glomerular origin.
• Urine and serum protein electrophoresis may identify pre-glomerular proteinuria in patients with monoclonal gammopathies or urinary immunoglobulin light chains (Bence Jones proteins).

IMAGING
Ultrasound and radiographs may reveal an underlying infectious, inflammatory, or neoplastic disease process or evidence of LUT disease. Ultrasound may show structural changes suggesting primary renal disease (e.g., loss of corticomedullary distinction, hyperechogenicity, and irregular surface margin) or evidence in support of LUT disease.

DIAGNOSTIC PROCEDURES
• Blood pressure should be monitored in patients with persistent renal proteinuria.
• Renal biopsy is needed to specifically diagnose the glomerular disease when an underlying disease cannot be identified or proteinuria has persisted following treatment of an underlying disease.

PATHOLOGIC FINDINGS
• Vary with cause of proteinuria.
• Biopsy from an animal with glomerular proteinuria may reveal any of the following: glomerulonephritis (e.g., immune complex-mediated, membranous, membranoproliferative, proliferative), minimal change disease, hereditary nephritis, amyloidosis, podocyopathy, focal segmental glomerulosclerosis, glomerulosclerosis.
• Animals with tubular proteinuria most often have a degree of tubulointerstitial nephritis.
• Postrenal proteinuria would be expected to have inflammatory, neoplastic, or polypoid lesions.

TREATMENT

APPROPRIATE HEALTH CARE
Most can be managed as outpatients. Inpatient care may be required during select diagnostic evaluation (renal biopsy) or when there are complications associated with uremia, thromboembolism or edema in patients with glomerular proteinuria.

NURSING CARE
Physical therapy and exercise may limit formation of edema in patients with glomerular proteinuria and hypoalbuminemia.

ACTIVITY
Activity should not be restricted in animals with proteinuria.

DIET
If glomerular disease is suspected, feed a diet formulated for kidney disease.

CLIENT EDUCATION
It is important to determine the cause of persistent proteinuria, which may indicate the presence of kidney disease. Renal proteinuria is a risk factor for progressive kidney disease, thromboembolism, and edema.

SURGICAL CONSIDERATIONS
Animals with severe hypoalbuminemia (i.e., <2 g/dL) present unique challenges to anesthesia. Consideration should be given to referral of these patients to a secondary or tertiary care facility if anesthesia and/or surgery are indicated.

MEDICATIONS

DRUG(S) OF CHOICE
An angiotensin receptor blocker (ARB) or angiotensin-converting enzyme (ACE) inhibitor should be administered. Preliminary evidence suggests telmisartan (ARB) may be more efficacious in reducing proteinuria than ACE inhibitors. Combined use of an ARB and an ACE inhibitor should be done with caution as this is associated with a greater risk of death in people. Use of aldosterone antagonists in management of proteinuria needs further investigation but may be indicated for patients that have increased aldosterone concentrations following treatment with an ACE inhibitor or ARB. Animals with hypertension may be controlled with telmisartan alone, however some may require addition of a calcium channel blocker (e.g., amlodipine) to control both hypertension and proteinuria. Supplementation with *n*-3 polyunsaturated fatty acid (PUFA) should be considered in dogs, and possibly cats, with glomerular proteinuria when the diet being fed does not have a reduced *n*-6/*n*-3 PUFA ratio that approximates 5:1. Dogs with glomerular disease should also be given low-dose aspirin or clopidogrel as thromboprophylaxis.

CONTRAINDICATIONS
There are no known contraindications in animals with proteinuria.

PRECAUTIONS
Drugs highly bound to albumin may have an altered effect if hypoalbuminemia is present. The use of warfarin as an anticoagulant should be avoided. With hypoalbuminemia or azotemia, higher doses of furosemide may be required to mobilize edema effectively; however, it should be used with extreme caution.

POSSIBLE INTERACTIONS
There are no known important drug interactions in dogs with proteinuria other than the previously mentioned concern with highly protein-bound drugs.

ALTERNATIVE DRUG(S)
ARB and ACE inhibitor are alternatives to each other.

FOLLOW-UP

PATIENT MONITORING
• UP:C, urinalysis, systemic arterial blood pressure and serum albumin, creatinine and potassium concentrations should be monitored at least quarterly.
• Use the UP:C to assess progression of disease. Response to treatment should be evaluated for several months after resolution of any underlying disease. Reduction of UP:C to <0.5 (dog) or <0.2 (cat) without inappropriate worsening of renal function is considered a therapeutic success. However, this target is often not achieved and a reduction in UP:C of >50% is the recommended alternate target.
• Monitor serum creatinine—reduced proteinuria or reduced albuminuria that is concurrent to a rising serum creatinine may reflect deteriorating renal function.
• Because UP:Cs may vary, 2–5 serial assessments may be needed to evaluate response to treatment or progression in patients with glomerular proteinuria. Alternatively, the UP:C can be measured in a

PROTEINURIA (CONTINUED)

sample that has been pooled by adding equal aliquots of 2–3 samples that have been collected and refrigerated over a 48-hour time period.
• When given an ACE inhibitor or an ARB, dogs with stage 1 or 2 CKD can have an increase in serum creatinine of up to 30% without warranting a change in treatment. Worsening of renal function in dogs with stage 3 or 4 CKD should be avoided. During therapy the serum potassium concentration should not be >6 mmol/L and the systolic blood pressure should not be <120 mmHg.

PREVENTION/AVOIDANCE

Annual urinalyses and UP:C are recommended. Repeat in 2–4 weeks if proteinuria is detected. Patients with persistent proteinuria or MA of glomerular origin should be evaluated more thoroughly for underlying causes of glomerular injury. Potential underlying causes should be eliminated or managed. If proteinuria persists, potential underlying causes have been managed appropriately or underlying causes were not identified, consider renal biopsy.

POSSIBLE COMPLICATIONS

- Edema.
- Thromboembolism.
- Systemic hypertension.
- Progressive kidney disease.
- Poor wound healing.

EXPECTED COURSE AND PROGNOSIS

- Vary with the cause of proteinuria.
- Postrenal and prerenal proteinuria should resolve following resolution of inciting causes.
- Most diseases associated with renal tubular proteinuria are progressive.
- The rate of progression varies and spontaneous remissions have been reported. Animals with persistent glomerular proteinuria may develop renal tubular damage resulting in advanced CKD and eventual uremia and death. Some dogs die shortly after the initial detection of proteinuria, while others remain alive for years. Dogs with nephrotic syndrome and/or azotemia may have a shorter survival.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Hypoalbuminemia, hypoglobulinemia (rare), hypercholesterolemia, low antithrombin III, thrombocytosis, hyperfibrinogenemia, edema, thromboembolism, and systemic hypertension.

AGE-RELATED FACTORS

Familial glomerular diseases should be considered in young animals with glomerular range proteinuria.

ZOONOTIC POTENTIAL

Proteinuria does not have a zoonotic potential. However, glomerular proteinuria can occur with a variety of infectious diseases, some of which could have a zoonotic potential.

PREGNANCY/FERTILITY/BREEDING

Some drugs used in the treatment of diseases associated with proteinuria may be contra-indicated in pregnancy.

SYNONYMS

None

SEE ALSO

- Amyloidosis.
- Azotemia and Uremia.
- Glomerulonephritis.
- Hematuria.
- Hypoalbuminemia.
- Nephrotic Syndrome.
- Pyuria.

ABBREVIATIONS

- ACE = angiotensin-converting enzyme.
- ARB = angiotensin receptor blocker.
- CKD = chronic kidney disease.
- GBM = glomerular basement membrane.
- LUT = lower urinary tract.
- MA = microalbuminuria.
- PUFA = polyunsaturated fatty acid.
- SSA = sulfosalicylic acid.
- UA:C = urinary albumin:creatinine ratio.
- UP:C = urine protein:creatinine ratio.

PROTOTHECOSIS

BASICS

OVERVIEW
Algal infection in warm-blooded animals.

SYSTEMS AFFECTED
• Skin/exocrine. • Gastrointestinal. • Nervous. • Ophthalmic.

SIGNALMENT
• Dogs—young female adult, medium- to large-breed dogs, boxer and collie are overrepresented. • Cats—uncommon, usually cutaneous form.

SIGNS

Historical Findings

Dogs

• Intermittent and chronic large bowel diarrhea with fresh blood. • Chronic weight loss. • Acute onset blindness. • Neurologic disease; deafness, seizures, ataxia. • Cutaneous lesions.

Cats

• Chronic cutaneous or mucous membrane ulceration with few systemic signs.

Physical Examination Findings

Dogs

• Gastrointestinal, ocular, or neurologic disease most common. • Severe weight loss and debilitation. • Hemorrhagic colitis, vomiting, anorexia. • Blindness due to chorioretinitis and/or detached retinas. • CNS—depression, ataxia, vestibular signs, seizures and/or paresis. • Cutaneous—ulcers and crusts on the extremities and mucosal surfaces.

Cats

• Large cutaneous nodules on the face or limbs.

CAUSES & RISK FACTORS
• *Prototheca wickerhamii* and *P. zopfii* (genotype 1 and 2)—single-celled achlorophyllous blue-green algae (Chlorophyta). • Dogs—usually *P. zopfii* (75-90%); *P. wickerhamii* infection may also occur. • Cats—usually *P. wickerhamii*. • Basis for the pathogenicity of *Prototheca* spp. unknown; likely traumatic inoculation. • Organism—ecological niche is sewage; contaminants of water, soil, and food; occasionally isolated from fecal samples. • Dogs and humans—depressed cell-mediated immunity may predispose to infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Systemic or subcutaneous mycoses. • Mycobacterioses. • Neoplasia. • Pythiosis. • Actinomycosis. • Nocardiosis.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

OTHER LABORATORY TESTS
CSF tap—pleocytosis with mononuclear cells; increased protein; organisms.

DIAGNOSTIC PROCEDURES

Cytology

• Rectal or colonic mucosa, vitreous humor, CSF, cutaneous aspirations. • Organisms—unicellular, nonpigmented, oval or round cell walls often appear folded; diagnostic characteristic is endospore formation with internal septation in two planes.

Histopathology

• Biopsy specimens—identification of organisms is diagnostic. • Organisms—3–30 µm in diameter. *P. wickerhamii* round with sporangia (7–13 µm) with up to 50 spherical sporangiospores. *P. zopfii* are usually oval or cylindrical and produce sporangia (14–25 µm) with up to 20 sporangiospores.

Culture

• Blood agar or Sabouraud's dextrose agar. • Specific identification by selective agars or biochemical tests in culture (susceptibility to clotrimazole, sugar, and alcohol assimilation tests) or immunohistochemistry.

PCR Assays

PCR and DNA to determine species. Specimens can be taken from biopsies, CSF, or urine.

PATHOLOGIC FINDINGS

Dogs

• Small granulomatous foci or hemorrhagic ulcers—found in many organs, especially kidneys. • Nodular thickening of the gastrointestinal mucosa with ulceration. • Nonspecific inflammatory foci surrounding organisms or pyogranulomas—poorly organized; mixed with other inflammatory cells.

Cats

• Cutaneous masses—localized; extend deep into subcutaneous tissues; consist of granulomatous inflammation and mixed-cell inflammation; with numerous fungal organisms.

TREATMENT
• Dogs—surgical excision and combination drug therapy. • Cats—excision of localized cutaneous masses is primary therapeutic modality.

MEDICATIONS

DRUG(S) OF CHOICE
• Amphotericin B—use for localized disease after surgical excision; 0.25–0.5 mg/kg IV three times weekly until 8 mg/kg cumulative dose; lipid formulation 1 mg/kg every other day until 12 mg/kg cumulative dose.
• Concurrent administration of tetracycline or amikacin may provide synergistic effect.
• Itraconazole 5–10 mg/kg PO twice daily—used with amphotericin B, or as sole agents for less life-threatening disease.
• Clotrimazole. • Potassium iodide.
• Amphotericin B cream or clotrimazole enemas for colitis. • Nystatin 100,000–150,000 IU PO q8h for at least 90 days.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Difficult to eradicate with drug therapy.
• No definitive therapeutic protocol.
• Dogs—prognosis guarded to grave (median survival 4 months). • Cats—prognosis fair to good for cutaneous disease if lesions completely excised.

MISCELLANEOUS

ZOONOTIC POTENTIAL
None

PRURITUS

BASICS

DEFINITION
Pruritus (itch) is an unpleasant sensation that causes the clinical symptom of scratching, rubbing, hair pulling, and/or licking.

PATHOPHYSIOLOGY
Keratinocytes, mast cells, eosinophils and lymphocytes interact with neuronal cells via the release of cytokines, neurotrophins, and neuropeptides. The sensation of itch is conducted via the peripheral nervous system to the sensory cortex. Other factors can modify the perception of pruritus at this level. Pruritus is an adaptive protective mechanism, however excessive itch can lead to cutaneous damage. Identification and treatment or removal of the causative agent(s) is the most important aspect of long-term control. Avoidance or reduction of long-term medical therapy should be pursued when possible. Chronic cases may be best handled by a dermatologist.

SYSTEMS AFFECTED
- Skin/exocrine/neuronal.
- Behavioral.

SIGNS
- Scratching, licking, biting, rubbing, hair pull, or chewing.
- Variable evidence of self-trauma and cutaneous inflammation.
- Non-well-demarcated alopecia with or without excoriations, and without obvious gross inflammation may be the only sign.

CAUSES
- Parasitic—fleas, *Sarcoptes* spp., *Demodex* spp., *Otodectes* spp., *Notoedres* spp., *Cheyletiella* spp., *Trombicula* spp., lice, *Pelodera* spp., endoparasite migration.
- Allergic—flea allergy, atopic dermatitis, food allergy, contact allergy, drug allergy, bacterial hypersensitivity, malassezia hypersensitivity.
- Bacterial/fungal—*Staphylococcus* spp. and *Malassezia pachydermatis*; rarely dermatophyte (*Trichophyton* is more pruritic than other dermatophytes).
- Miscellaneous—primary and secondary seborrhea, calcinosis cutis, cutaneous neoplasia, immune-mediated dermatoses, and endocrinopathies are variably pruritic; psychogenic diseases may also be associated with pruritus (especially in cats).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Pruritus often causes alopecia.
- Alopecia without pruritus may accompany endocrine diseases. Some animals excessively lick themselves without the owner's knowledge.
- Demodicosis, dermatophytosis, superficial pyoderma (bacteria), *Malassezia* dermatitis, immune-mediated dermatoses, seborrhea, some cutaneous neoplasms, and unusual diseases such as leishmaniasis may cause alopecia with varying degrees of inflammation and pruritus.
- History is paramount for determining the diagnostic workup.
- Severe pruritus that keeps the patient and owner awake may suggest scabies, allergies (flea allergy/infestation, food allergy, atopic diseases) or *Malassezia* dermatitis. All but the latter typically have an acute onset.
- Uncomplicated atopic diseases (dermatitis, rhinitis, conjunctivitis, asthma) are steroid-responsive and may manifest seasonally, but may progress to nonseasonal pruritus of the face, feet, ears, forelimbs, axillae, and caudal body.
- Flea-allergic and food-allergic animals may be predisposed to atopic diseases and may show similar signs. Food allergy is the least common of these three differentials.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

DIAGNOSTIC PROCEDURES

Miscellaneous Procedures
- Identification and treatment of the underlying cause of pruritus is of paramount importance. It is common for multiple causes to be present concurrently and this can significantly complicate the workup and management of pruritus.
- Skin scrapes, epidermal cytology, and dermatophyte cultures
- A skin biopsy is useful when the lesions associated with pruritus are unusual, an immune-mediated dermatosis is suspected, or the history and physical findings do not correlate.

Allergy Testing
- Allergy testing does not diagnose atopic disease: The presence of positive test results does not diagnose that allergy is the cause or even a contributory cause of pruritus. Results must be carefully correlated with the patient's history and physical examination.
- Two methods for allergy testing—intradermal and serum:
  - Intradermal testing remains the gold standard and the preferred method for allergy testing.
  - Serum tests for allergy measure serum IgE and do not measure localized IgE found in the skin. Patients with symptoms of atopic disease but negative on testing are diagnosed as having "atopic-like disease."
- Positive reactions identified on testing are correlated with the history, in order to formulate allergen-specific immunotherapy solution (ASIT). The choice of allergens is based on the patient's history, test results, local allergen exposure, and the veterinarian's experience in treating allergies; not just the highest reactive allergens in the testing panel should be selected. Administration of immunotherapy may be via either subcutaneous or sublingual routes.

Trial Courses of Treatment as a Diagnostic Tool
- A trial course of therapy for scabies may be appropriate in some animals; canine scabies can be difficult to diagnose and skin scrapes are often negative.
- Laboratory tests (serum, hair, saliva) cannot be used for the diagnosis of food allergy; a properly performed strict dietary trial must be conducted. Novel protein diets based on the patient's history or hydrolysate diets should be fed during the testing period. Careful client counseling to avoid all treats, supplements, chews, and flavored medications is necessary for a diet trial to succeed. Diet trials should be continued until the patient improves or for a duration of 8–10 weeks. Challenge with the original diet is a critical part of the test, and demonstrates that improvement was not due to concurrent therapy (e.g., relief of parasites, resolution of infection).

TREATMENT
- More than one disease can contribute to itching.
- Secondary infections are common and may result in self-perpetuation of pruritus.

MEDICATIONS

DRUG(S) OF CHOICE

Topical Therapy
- Topical therapy is helpful for pruritic patients.
- Colloidal oatmeal—duration of effect is usually less than 2 days.
- Topical antihistamines have not demonstrated efficacy.
- Topical anesthetics may offer only a very short duration of effect.
- Topical corticosteroids—can be effective. But if used excessively, can cause localized and systemic side effects.
- Antimicrobial shampoos help control bacterial and/or yeast infections that cause itching; they can be excessively drying, necessitating use of moisturizers.
- Lime sulfur is mildly antipruritic as well as being antiparasitic, antibacterial, and antifungal.

Systemic Therapy
- Therapy is complex and depends on the etiology.

• Parasite prevention/treatment—fleas, scabies, demodicosis.
• ASIT—atopic disease.
• Chronic medical therapy with corticosteroids, cyclosporine, lokivetmab, or oclacitinib without evaluation by a dermatologist should be avoided.
• Corticosteroids affect many biological responses associated with pruritus. For acute relief, oral prednisone/prednisolone results in significant benefit for 2–5 days but rarely causes significant side effects.
• Cyclosporine 5 mg/kg/day initially; every other day maintenance—very useful in the treatment of atopic dermatitis. Adverse effects include gastrointestinal upset, oral papilloma, gingival hyperplasia, and hirsuitism. Not useful for quick relief due to its long lag phase (4–6 weeks).
• Oclacitinib 0.4–0.6 mg/kg twice daily for 14 days, then 0.4–0.6 mg/kg q24h—fast acting without the common side effects of prednisone. Useful for temporary control of pruritus. Not for use in dogs less than 12 months of age; may cause a mild, dose-dependent reduction in hemoglobin, hematocrit, and reticulocyte counts as well as decreases in leukocytes. Potential for immune suppression, demodicosis, recurrent pyoderma, exacerbation of neoplastic conditions and pneumonia. Agitation with use reported. Avoid use at higher than recommended dosage.
• Lokivetmab 2 mg/kg—caninized monoclonal antibody against interleukin 31; for dogs only. Rapid onset (within 3 days from administration) and duration of effect between 2 and 8 weeks; effective in 60–70% of dogs with pruritus. Few side effects reported, including anaphylaxis, transient lethargy, and behavioral changes. Efficacy may be diminished by development of an immune response to this biologic medication and/or secondary infection.
• Fatty acids—block formation of inflammatory mediators; require 6–8 weeks of administration for maximum effect.

CONTRAINDICATIONS

• Some topicals will exacerbate pruritus: monitor treatment response.
• Corticosteroids should be avoided in cases of pruritus caused by an infectious etiology.

PRECAUTIONS

• Client frustration is common.
• Scabies is curable.
• Food allergy is manageable without medications if a proper food trial is conducted.
• Atopic dermatitis disease is a progressive common cause of pruritus and ASIT is the only therapy that can safely manage the disease alone or in combination with other medications.
• Corticosteroids—potentially significant long-term side effects.
• Cyclosporine—serum drug levels should be measured at least once initially in cats and in dogs if the maintenance dosage required to control symptoms is above the standard recommendation.
• Oclacitinib—long-term use associated with potential immunosuppression.

FOLLOW-UP

PATIENT MONITORING

• Patient monitoring as well as client communication are imperative.
• Many different unrelated diseases may contribute to pruritus and the control of one disease does not mean that other causes cannot remain.
• Multiple etiologies such as *Malassezia* dermatitis, flea bite allergy, atopic dermatitis, and pyoderma are commonly present in a single patient. Elimination of these may not be enough to significantly reduce the pruritus. Animals with both food allergy and atopic disease may do well during the winter season with a hypoallergenic diet only to become pruritic during the warmer months in association with atopic dermatitis.
• Patients receiving chronic medication should be evaluated every 3–12 months for potential side effects as well as the occurrence of new contributing factors.

POSSIBLE COMPLICATIONS

• Skin scrapes and other tests that may have been negative or normal during the original workup should be repeated if symptoms return.
• Complications and/or gradual loss of efficacy are not uncommon with chronic medical therapy.

MISCELLANEOUS

ABBREVIATIONS

• ASIT = allergen-specific immunotherapy solution.

PSEUDOEPHEDRINE/PHENYLEPHRINE TOXICOSIS

BASICS

OVERVIEW

- Syndrome resulting from exposure to excessive levels of pseudoephedrine or phenylephrine.
- Present in various concentrations in a variety of over-the-counter (OTC) cold and allergy products.

SIGNALMENT

Any species may be affected, but dogs are most commonly involved in accidental overdoses.

SIGNS

- Mydriasis, panting, hyperthermia, agitation/hyperactivity, tachycardia, hypertension are common. Other signs include vomiting, vocalization, tremors, disorientation, or lethargy.
- Head-bobbing, sinus arrhythmias, scleral hemorrhage, or seizure-like activity are possible. Acute collapse may follow.
- Signs of acute intoxication may persist 1–3 days, depending on dose ingested.
- Severe cases may progress to disseminated intravascular coagulation (DIC), myoglobinuremia/uria with secondary renal injury, or permanent CNS dysfunction.

CAUSES & RISK FACTORS

- Pseudoephedrine is a synthetic salt of ephedrine and is an indirect sympathomimetic amine.
- Phenylephrine is a synthetic sympathomimetic amine chemically related to ephedrine and pseudoephedrine. Phenylephrine has poor oral bioavailability and generally will have less severe cardiovascular effects than pseudoephedrine.
- Pseudoephedrine indirectly stimulates alpha- and, to a lesser degree, beta-adrenergic receptors.
- Pseudoephedrine dosages >1 mg/kg can result in agitation, hyperactivity, and panting.
- Phenylephrine dosages >3–4 mg/kg may cause vomiting, lethargy or hyperactivity, hypertension, and tachycardia.
- Head-bobbing, DIC, or myoglobinuria indicate serious intoxication and a more guarded prognosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other CNS stimulants and sympathomimetics—amphetamines, cocaine, serotonergic antidepressants, phenylpropanolamine, methylxanthines, ephedra.

CBC/BIOCHEMISTRY/URINALYSIS

- No specific clinical pathology alterations are expected in most cases.
- In severe cases DIC, myoglobinemia, myoglobinuria, or azotemia may occur.

OTHER LABORATORY TESTS

Urine or serum from patients with pseudoephedrine toxicosis may give a positive test for amphetamine in OTC drug test kits or human hospital drug screens.

TREATMENT

- Manage severe or life-threatening signs first.
- Control CNS stimulation, then manage cardiovascular (CV) stimulation, as blood pressure and heart rate may decrease significantly once CNS signs are managed.
- For seizures, use propofol, pentobarbital, or phenobarbital; consider gas anesthetic for refractory cases.
- For agitation, hyperactivity, or other CNS stimulation, use acepromazine or chlorpromazine.
- Cyproheptadine has been used with some success to manage dysphoria, vocalization, and hyperthermia.
- Propranolol (or other beta-blocker) may be considered in patients with sustained tachycardia.
- External cooling measures may be required for hyperthermic patients.
- IV fluid administration assists in stabilization of CV effects, support of kidney function, and excretion of pseudoephedrine and its metabolites.
- Monitor heart rate/rhythm, body temperature, and blood pressure. In severely affected patients, monitor renal function, coagulation parameters, hydration, and electrolytes.
- Gastrointestinal decontamination (induction of emesis, administration of activated charcoal) may be considered in patients that have ingested >1 mg/kg of pseudoephedrine and are not displaying significant clinical signs.

MEDICATIONS

DRUG(S) OF CHOICE

- Propofol 0.1–0.6 mg/kg/min IV.
- Pentobarbital 30 mg/kg IV to effect.
- Phenobarbital 3–4 mg/kg IV.
- Acepromazine 0.05–1.0 mg/kg IM or IV; start low and titrate up as needed.
- Chlorpromazine 0.5–1.0 mg/kg IV or IM; start low and titrate up as needed.
- Cyproheptadine 1.1 mg/kg PO or per rectum q6h (dogs); 2–4 mg PO or per rectum (cats).
- Propranolol 0.02–0.06 mg/kg IV q6–8h PRN.
- Emetics—Dogs: 3% hydrogen peroxide 2.2 mL/kg PO, maximum 45 mL, may repeat once if first dose unsuccessful; apomorphine crushed and diluted with sterile saline and instilled in conjunctival sac, rinse eye after emesis, or 0.03 mg/kg IV; ropinirole hydrochloride 3.75 mg/m^2 as directed by product label. Cats: dexmedetomidine 6–18 µg/kg IM; xylazine 0.44 mg/kg IM; hydromorphone 0.1 mg/kg SC.
- Activated charcoal 1–3 g/kg suspended in 50–200 mL of water.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

The use of diazepam to control CNS stimulation should be avoided, as diazepam may induce a dysphoric effect in these patients and worsen the CNS excitation.

FOLLOW-UP

Renal insufficiency resulting from myoglobinuria may require long-term follow-up and care.

MISCELLANEOUS

ABBREVIATIONS

- CV = cardiovascular.
- DIC = disseminated intravascular coagulation.
- OTC = over-the-counter.

PSEUDOMACROTHROMBOCYTOPENIA (INHERITED MACROTHROMBOCYTOPENIA)

BASICS

OVERVIEW
- A common cause of thrombocytopenia and increased mean platelet volume (MPV) in cavalier King Charles spaniels (CKCS), and infrequently in other breeds.
- Caused by an inherited mutation that impairs platelet maturation, resulting in the early release of platelets from the bone marrow. The released platelets are significantly larger than normal.
- Overall platelet mass (product of platelet number and average size) is unaffected, therefore clinical signs of hypocoagulability are not seen.

SIGNALMENT
- Dogs—primarily CKCS with infrequent reports in Norfolk terriers, Cairn terriers, English toy spaniels, and Jack Russell terriers; other breeds also sporadically affected.
- A similar condition is also reported in Akitas, although a specific mutation has not yet been identified in this breed.
- The condition is present from birth, but is often not detected until a CBC is performed. The mutation is autosomal, therefore there is no sex predilection.

SIGNS
Not associated with clinical signs; often incidentally noted on a CBC performed for other reasons.

CAUSES & RISK FACTORS
- Caused by point mutations in the gene encoding β1-tubulin, which is involved in platelet formation. The mutations impair the formation of microtubules in the megakaryocyte (platelet precursor) and result in the release of lower numbers of platelets that are larger than normal.
- The condition is inherited in an autosomal fashion, with homozygotes exhibiting moderate to marked thrombocytopenia and moderate to marked increases in MPV. Heterozygotes are less severely affected and may have a mild thrombocytopenia and/or mild increase in MPV.
- In the United States, it has been estimated that approximately 47% of CKCS are homozygous for the mutation and 45% are heterozygous.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Must be differentiated from causes of pathologic thrombocytopenia such as immune-mediated thrombocytopenia, disseminated intravascular coagulation, infectious diseases (especially tick-borne diseases), and causes of decreased platelet production (i.e., bone marrow disease).
- Breed (especially CKCS), absence of clinical signs, and a normal plateletcrit (PCT) (see CBC/Biochemistry/Urinalysis) are strongly suggestive of inherited macrothrombocytopenia.
- Blood smear evaluation is also recommended to rule out *in vitro* platelet clumping, which artifactually induces a decreased platelet count and increased MPV.

CBC/BIOCHEMISTRY/URINALYSIS
- CBC—moderate to marked thrombocytopenia (40,000–200,000/μL) with significantly increased MPV; PCT expected to be within reference interval (RI = 0.129–0.403%).
- PCT—a numeric representation of overall platelet mass (product of platelet number and average size). Some automated analyzers calculate the value automatically. If not provided, PCT can be calculated using the following formula:

$$PCT = (PLT \times MPV)/10{,}000$$

where PLT is platelet count and MPV is mean platelet volume.

OTHER LABORATORY TESTS
If definitive diagnosis is desired, genetic testing to confirm the presence of the mutation can be performed; currently, this is available through the Auburn University Hemostasis Laboratory.

TREATMENT
None required—nonpathogenic condition without clinical signs.

MEDICATIONS
N/A

FOLLOW-UP
Once affected individuals are identified, platelet mass in these patients should be evaluated via PCT; if this value falls below the reference interval, a concurrent pathologic thrombocytopenia may be present.

MISCELLANEOUS

ABBREVIATIONS
- CKCS = cavalier King Charles spaniel.
- MPV = mean platelet volume.
- PCT = plateletcrit.
- PLT = platelet count.

Author Megan N. Caudill
Consulting Editor Melinda S. Camus

P

PTYALISM

BASICS

DEFINITION
• Excessive production and secretion of saliva (see Web Figure 1). • Pseudoptyalism is the excessive release of saliva that has accumulated in the oral cavity due to inability to swallow.

PATHOPHYSIOLOGY
• Saliva is constantly produced and secreted into the oral cavity from the salivary glands. • Saliva production increases when salivary nuclei in the brainstem are stimulated. • Higher centers in the CNS can excite or inhibit salivary nuclei. • Taste and tactile stimuli in the oral cavity increase saliva production. • Physiologic hypersalivation may occur with: anticipation of eating, hyperthermia and purring (cats). • Saliva production may be increased with gastrointestinal (GI) or CNS disorders.

SYSTEMS AFFECTED
Skin—may cause salivary staining.

GENETICS
N/A

INCIDENCE/PREVALENCE
Variable

GEOGRAPHIC DISTRIBUTION
Worldwide

SIGNALMENT

Species
Dog and cat.

Breed Predilections
• Congenital portosystemic shunts—Yorkshire terrier, Maltese, Australian cattle dog, miniature schnauzer, and Irish wolfhound. • Congenital megaesophagus—wirehaired fox terrier and miniature schnauzer; familial predispositions have been reported in German shepherd dog, Newfoundland, Great Dane, Irish setter, Chinese Shar-Pei, greyhound, retriever breeds, and Siamese cats. • Congenital hiatal hernia—Chinese Shar-Pei. • Lip conformation—giant breeds, such as Saint Bernard, Great Dane, and mastiff. • Brachycephalic airway syndrome—pug, English and French bulldog.

Mean Age and Range
Young animals are more likely to have congenital abnormalities and to ingest foreign materials.

SIGNS

Historical Findings
• Anorexia—with oral lesions, GI disease, and systemic disease. • Eating behavior changes—with oral disease or cranial nerve (CN) dysfunction: may refuse hard food, chew only on the unaffected side (if unilateral lesion), maintain an unusual head/neck position, or drop food. • Other behavioral changes—irritability, aggressiveness, and reclusiveness, especially if painful. • Dysphagia. • Nausea. • Regurgitation—with esophageal disease. • Vomiting—with GI or systemic disease. • Weight loss. • Pawing at the face or muzzle—with oral discomfort. • Neurologic signs—with exposure to caustic drugs or toxins, hepatic encephalopathy, seizure disorders or other intracranial disease.

Physical Examination Findings
• Periodontal disease. • Gingivitis/stomatitis—with toxins, infection, immune-mediated disease or nutritional deficiency. • Oral mass • Glossitis—with ulceration, mass or foreign body. • Oropharyngeal inflammation, ulceration, mass, or foreign body. • Blood in the saliva—with bleeding from the oral cavity, pharynx, or esophagus. • Halitosis—with oral disease (most common), or esophageal and gastric disease. • Facial pain. • Dysphagia. • CN deficits—trigeminal nerve (CN V) lesions can cause drooling due to inability to close the mouth; facial nerve palsy (CN VII) can cause drooling from the affected side; glossopharyngeal (CN IX), vagus (CN X), and hypoglossal (CN XII) nerve lesions can cause a loss of the gag reflex or inability to swallow. • Cheilitis or acne—persistent drooling can lead to dermatologic lesions.

CAUSES

Conformational Disorder of the Lips
Most common in giant-breed dogs.

Oral and Pharyngeal
• Oral trauma. • Foreign body (e.g., stick, foxtail, or sewing needle). • Neoplasm. • Abscess. • Gingivitis or stomatitis—secondary to periodontal disease, bacterial, viral (e.g., feline leukemia virus [FeLV] or feline immunodeficiency virus [FIV]) or fungal infection, immune-mediated disease (e.g., lymphoplasmacytic stomatitis, pemphigus vulgaris), uremia, ingestion of a caustic agent, poisonous plants, effects of radiation therapy to the oral cavity or burns (e.g., biting on an electrical cord). • Swallowing disorders.

Salivary Gland
• Sialoadenitis. • Sialolithiasis. • Sialadenosis (idiopathic enlargement). • Mucocele. • Fistula. • Foreign body. • Neoplasm. • Infarct. • Immune-mediated disease (rare).

Esophageal or GI
• Esophageal foreign body. • Esophageal neoplasm. • Esophageal stricture. • Esophagitis. • Gastroesophageal reflux disease (GERD). • Infection (e.g., spirocercosis, pythosis). • Hiatal hernia. • Megaesophagus. • Esophageal dysmotility. • Gastric distension/volvulus. • Gastric ulcer. • Gastroenteritis.

Metabolic
• Hepatic encephalopathy (especially in cats). • Hyperthermia. • Uremia.

Neurologic
• Rabies—decreased swallowing causes increased drooling. • Pseudorabies in dogs. • Botulism. • Tetanus. • Dysautonomia. • Disorders causing dysphagia. • Disorders causing facial nerve palsy or a dropped jaw. • Seizures—during a seizure, ptyalism may occur because of autonomic discharge or reduced swallowing of saliva, and may be exacerbated by chomping of the jaws. • Nausea associated with vestibular disease. • Anxiety.

Drugs and Toxins
• Caustic substances (e.g., household cleaning products). • Anesthesia may induce reflux esophagitis. Drugs used for premedication may induce nausea, vomiting or ptyalism. • Oral, otic or ophthalmic medications that are poorly palatable (especially in cats). • Those that induce hypersalivation, including organophosphate compounds, cholinergic drugs, insecticides containing boric acid, pyrethrin and pyrethroid insecticides, ivermectin (dogs), fluids containing benzoic acid derivatives (cats), clozapine (a tricyclic dibenzodiazepine), caffeine, and illicit drugs such as amphetamines, cocaine, and opiates. Has also been reported with capromorelin administration in dogs and cats. • Animal venom (e.g., black widow spider, Gila monster, and North American scorpion). • Toad and newt secretions. • Plant consumption or prehension (e.g., poinsettia, Christmas trees, *Amanita* mushrooms) may cause increased salivation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Differentiating causes of ptyalism and pseudoptyalism requires a thorough history, including vaccination status, current medications, possible toxin exposure, and duration of ptyalism. • May be able to distinguish salivation associated with nausea (signs of depression, lip smacking, and retching) from dysphagia by observing the patient. • Complete physical examination (with special attention to the oral cavity and neck) and neurologic examination are critical; wear examination gloves when rabies exposure is possible.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC—often unremarkable; leukocytosis in patients with immune-mediated, inflammatory or infectious disease. • Stress leukogram—common in animals that have ingested a caustic agent or organophosphate. • FeLV-infected cats may have leukopenia and nonregenerative anemia. • Serum creatine kinase activity should be evaluated in all dysphagic patients. • Possible microcytosis with portosystemic shunts. • Biochemical analysis—usually unremarkable except in patients with renal disease (azotemia, hyperphosphatemia), and hepatic encephalopathy (possibly elevated hepatic enzyme activities, decreased BUN, hypoalbuminemia,

hypocholesterolemia, hyperbilirubinemia, and hypoglycemia). • Marked ptyalism can result in hypokalemia and acidosis from the loss of potassium and bicarbonate-rich saliva. • Urinalysis—often normal; decreased urine specific gravity with renal or hepatic disease. • Urate urolithiasis may be noted in patients with portosystemic shunts.

OTHER LABORATORY TESTS

• Fasting and postprandial bile acids and/or fasting ammonia when hepatic encephalopathy is suspected. • Serologic FeLV and FIV testing in cats with oral lesions. • Acetylcholine receptor antibody titer if focal myasthenia gravis is suspected. • Serum cholinesterase level if organophosphate toxicosis is suspected. • Post-mortem fluorescent antibody testing of brain tissue if rabies is suspected.

IMAGING

• Survey radiography of the oral cavity, neck, and thorax when foreign body, structural abnormality, or neoplasm is suspected. • Abdominal radiographs ± abdominal ultrasound may help diagnose cause of vomiting; may also help diagnose hepatic or renal disease. • Ultrasonographic evaluation, CT angiography, portal venography, or portal scintigraphy may help diagnose a portosystemic shunt. • Fluoroscopic evaluation of swallowing may be useful in dysphagic patients to evaluate esophageal function and motility; use caution during barium administration in animals that are dysphagic. • MRI or CT for suspected intracranial lesions. • CT of head is more sensitive than radiographs, especially when foreign body or neoplasia is suspected.

DIAGNOSTIC PROCEDURES

• Biopsy and histopathology of mucocutaneous lesions—possibly including immunofluorescence testing when immune-mediated disease (e.g., pemphigus vulgaris) is suspected. • Fine-needle aspiration of oral lesions and regional lymph nodes. • Biopsy and histopathology of oral lesion, salivary gland, or mass. • Consider esophagoscopy or gastroscopy if lesions distal to the oral cavity are suspected; endoscopic removal of foreign bodies may be possible.

PATHOLOGIC FINDINGS

Varies as to the underlying condition.

TREATMENT

APPROPRIATE HEALTH CARE

• Treat the underlying cause (refer to sections pertaining to specific conditions). • Symptomatic treatment to reduce the flow of saliva—generally unnecessary, may be of little value to the patient, and may mask other signs of the underlying cause and thus delay diagnosis; only recommended when hypersalivation is prolonged and severe and, if possible, after the underlying condition has been diagnosed.

NURSING CARE

• Petroleum jelly can be applied to areas of the face constantly wet from saliva to help prevent moist dermatitis. • Astringent solutions applied for 10 minutes q8–12h can be used to treat areas of moist dermatitis.

ACTIVITY

N/A

DIET

• Enteral nutritional support (esophagostomy, gastrostomy tubes, etc.) may be needed in patients with ptyalism and anorexia secondary to severe oral, GI, or metabolic causes. • Reduced protein diets may be recommended for patients with hepatic encephalopathy, but are not necessarily warranted in animals with portosystemic shunts that are not encephalopathic.

CLIENT EDUCATION

Client education will depend on the underlying disease process.

SURGICAL CONSIDERATIONS

• Surgical procedures will vary depending on underlying cause; ligation of parotid salivary duct has been described. • Corrective surgery for brachycephalic airway surgery may result in improved GI signs.

MEDICATIONS

DRUG(S) OF CHOICE

• Anticholinergic medications may be given symptomatically to reduce the flow of saliva; atropine 0.05 mg/kg SC PRN or glycopyrrolate 0.01 mg/kg SC PRN. However, this is typically unnecessary as treatment should focus on underlying disease. • Antiemetics for nausea (see Acute Vomiting, for list of antiemetics and dosages). • Crystalloid fluids may be given IV or SC to treat dehydration caused by prolonged or severe ptyalism. • Antacid therapy may be useful for treatment of GERD (e.g., proton pump inhibitors—omeprazole 1 mg/kg PO q12h). • Phenobarbital 2 mg/kg PO q12h has been effective in treating idiopathic hypersialosis. • Anticonvulsant therapy is indicated for seizure activity.

CONTRAINDICATIONS

N/A

PRECAUTIONS

Depends on underlying cause.

ALTERNATIVE DRUG(S)

• Some clinicians have anecdotally used levetiracetam for idiopathic hypersialosis. • Other acid-reducing agents may be used.

FOLLOW-UP

PATIENT MONITORING

• Depends on the underlying cause. • Continually monitor hydration, body weight, serum electrolytes, and nutritional status, especially in dysphagic or anorexic animals.

PREVENTION/AVOIDANCE

Depends on underlying cause.

POSSIBLE COMPLICATIONS

• Metabolic acidosis. • Dehydration. • Hypokalemia. • Moist dermatitis. • Aspiration pneumonia.

EXPECTED COURSE AND PROGNOSIS

Depends on underlying cause. If underlying cause is correctable, prognosis for resolution may be more favorable.

PULMONARY CONTUSIONS

BASICS

OVERVIEW
• Hemorrhage in the lung parenchyma caused by tearing and crushing from direct thoracic trauma. • Relatively small volumes of blood in the parenchyma markedly compromise lung function. • Fluid resuscitation for treatment of shock can exacerbate lung dysfunction from secondary edema.

SIGNALMENT
Dog and cat.

SIGNS
• History of trauma. • Tachypnea. • Abnormal respiratory effort. • Postural adaptations to respiratory distress. • Cyanotic or pale mucous membranes. • Auscultation of harsh bronchovesicular sounds or crackles. • Expectoration of blood or blood-tinged fluid. • Additional injuries secondary to trauma and shock can also be noted.

CAUSES & RISK FACTORS
• Blunt trauma. • Motor vehicle accidents. • Falls from a height. • Abuse.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Hemothorax—auscult dull lung sounds ventrally. • Pneumothorax—auscult dull lung sounds dorsally. • Diaphragmatic hernia—distinguished radiographically. • Coagulopathy can result in pulmonary hemorrhage; identified by abnormal coagulation tests or platelet count. • Acute onset of pulmonary hemorrhage—can be seen with neoplasia or pulmonary infarction from bacterial endocarditis or heartworm disease. • Expectoration of bloody fluid (not frank hemorrhage) can occur in animals with acute respiratory distress syndrome (ARDS) or congestive heart failure. • If no known history of trauma, pneumonia or edema (cardiogenic and noncardiogenic) are possible differentials.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC—can reveal anemia or mature neutrophilia. • Biochemistry profile—can demonstrate hypoproteinemia (blood loss); can reveal damage to other organ systems.

IMAGING
Thoracic Radiography
• Usually a patchy alveolar pattern—focal or asymmetrical, but can be generalized. • Contusions generally worse in the area of rib fractures if present. • Always perform thoracic radiographs in trauma patients after stabilization to rule out hemothorax, pneumothorax, and diaphragmatic hernia.

Thoracic Focused Assessment with Sonography for Trauma (TFAST®) and Focused Lung Ultrasound
• Point-of-care emergency ultrasound helps identify intrathoracic trauma during initial triage. • Increased lung rockets (B-lines) indicative of contusions or edema. • Absence of a glide sign dorsally indicative of pneumothorax. • Pleural effusion noted indicative of hemothorax.

DIAGNOSTIC PROCEDURES
• Coagulation tests for coagulopathy or disseminated intravascular coagulation. • Pulse oximetry or arterial blood gas analysis—can confirm hypoxemia. • Examination of tracheal wash cytology—can show excessive numbers of erythrocytes and macrophages.

TREATMENT
• Usually inpatient for stabilization. • Support respiratory function, stabilize cardiovascular function. • If pneumothorax suspected, thoracocentesis should be performed. • Assess and treat injuries to other organ systems. • Restrict activity, minimize stress, and monitor carefully for deterioration. • Respiratory support—oxygen supplementation for hypoxemia; intubation and positive-pressure ventilation if severe. • Shock—fluids generally required; judicious fluid therapy to avoid exacerbation of pulmonary edema. • Blood or plasma transfusion—consider if anemia or coagulopathy. • Nutritional support—as needed to maintain body condition and immune status.

MEDICATIONS

DRUG(S) OF CHOICE
• Oxygen supplementation if dyspnea or hypoxemia. • Analgesics administered as warranted. • Low-dose diuretics—contraindicated unless suspected volume overload and respiratory distress is severe.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Diuretics—no value in the early stages of pulmonary contusions and potentially harmful; decrease intravascular volume, which is contraindicated for shock.

FOLLOW-UP

PATIENT MONITORING
• Monitor respiratory rate and effort, mucous membrane color, heart rate, pulse quality, and lung sounds. • Measure serial packed cell volume (PCV) and total solids and perform pulse oximetry and/or arterial blood gas analysis as needed for the first 24 hours. • Monitor ECG frequently to detect ventricular arrhythmias associated with hypoxemia or traumatic myocarditis. • Radiographs—repeated if clinically indicated.

PREVENTION/AVOIDANCE
Appropriate restriction of the animal to prevent trauma.

POSSIBLE COMPLICATIONS
• Bacterial pneumonia (uncommon)—owing to systemic immunosuppression from trauma, shock, and reduced pulmonary defenses. • Development of a moist productive cough and failure to improve within 48 hours—suspect pneumonia. • Patients with severe shock can develop ARDS (less common).

EXPECTED COURSE AND PROGNOSIS
• Respiratory function can deteriorate during the initial 12–24 hours and then should gradually improve. • Clinical improvement within 48 hours with radiographic resolution likely in 7–10 days. • If patient fails to improve clinically after 48 hours, evaluate for complications or concurrent disease.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Pneumothorax. • Fractured ribs. • Flail chest. • Ruptured trachea, bronchi, or esophagus. • Cardiac arrhythmias—ventricular. • Other possible complications of trauma.

SEE ALSO
Pneumothorax

ABBREVIATIONS
• ARDS = acute respiratory distress syndrome. • PCV = packed cell volume. • TFAST® = Thoracic Focused Assessment with Sonography for Trauma.

PULMONARY EDEMA, NONCARDIOGENIC

BASICS

DEFINITION
Accumulation of edema fluid in the pulmonary interstitium and alveoli, in the absence of heart disease.

PATHOPHYSIOLOGY
• Associated with increased pulmonary vascular permeability and leakage of fluid into the interstitium and alveoli; if severe, can be accompanied by an inflammatory response and accumulation of neutrophils and macrophages. • Several mechanisms contribute to changes in pulmonary vascular permeability. • Stimulation of brainstem (medulla) vasomotor centers can lead to a reflex systemic release of catecholamines resulting in systemic vasoconstriction and temporary shunting of blood into the pulmonary circulation resulting in transient pulmonary circulatory overload and endothelial damage—likely pathogenesis in patients with neurogenic edema, electrocution, and upper airway obstruction. • In patients with upper airway obstruction, negative intrathoracic pressure from inspiratory attempts against an airway obstruction also contributes to edema formation. • Increased vascular permeability can be part of a generalized inflammatory response that develops in patients with systemic inflammatory response syndrome (SIRS), sepsis, or pancreatitis. • The inciting insult can trigger a cascade inflammatory response that often worsens over 24 hours following the initial episode. • Severity of clinical manifestation varies, ranging from mild to severe; the most seriously affected patients can progress from normal to death rapidly after the incident.

SYSTEMS AFFECTED
• Respiratory. • Cardiovascular—hypotension, tachycardia, and shock. • Hemic/lymphatic/immune—if severe and causing respiratory failure, can be associated with disseminated intravascular coagulation (DIC). • Renal/urologic—acute renal failure.

GENETICS
Unknown

INCIDENCE/PREVALENCE
Uncommon

SIGNALMENT

Species
Dog and cat.

Breed Predilections
None specific; brachycephalic dogs are more prone to airway obstruction, older large-breed dogs—laryngeal paralysis, small-breed dogs—tracheal collapse.

Mean Age and Range
• Higher incidence in pediatrics—associated with strangulation, head trauma, and electric cord bites. • Older—associated with laryngeal obstruction and neoplasia.

SIGNS

General Comments
Vary, depending on underlying cause and severity.

Historical Findings
• Predisposing causes—airway obstruction; electric cord bite; seizures; head trauma; near drowning; smoke exposure; adverse drug effects. • Acute onset of dyspnea.

Physical Examination Findings
• Mild to severe dyspnea. • Increased respiratory rate and effort; open-mouthed breathing. • Postural adaptations to respiratory distress (if severe)- orthopnea, unwillingness to lie down. • Pale or cyanotic mucous membranes (severe). • Harsh lung sounds (early, mild) or generalized crackles (late, severe) on auscultation. • Expectoration of pink froth or bubbles; can have large volumes of bloody fluid flowing out of endotracheal tube in severely affected intubated animals. • Normal cardiac auscultation; can detect arrhythmias; tachycardia common. • Oral ulceration or burns if electrocution. • Cranial nervous system abnormalities or other indications of neurologic disease. • Stridor over the upper airway in cases of brachycephalic syndrome, airway masses/abscesses, or foreign bodies. • Smokey odor or burns indicative of smoke exposure.

CAUSES
• Upper airway obstruction—laryngeal paralysis; choke-chain injury; mass; abscess. • Electrocution. • Acute neurologic disease—head trauma; intra-cranial hypertension, prolonged seizures. • Smoke inhalation. • Aspiration pneumonia. • Systemic inflammatory response syndrome—sepsis; endotoxemia; pancreatitis. • Anaphylaxis (cats). • Near drowning. • Adverse drug reactions including certain anesthetic drugs (ketamine), thiazides, or certain antineoplastics (vincristine, cisplatin in cats). • Transfusion-related acute lung injury—limited evidence in veterinary medicine. • Vasculitis.

RISK FACTORS
• Hypoproteinemia. • Crystalloid fluid resuscitation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Cardiogenic pulmonary edema. • Pulmonary infection—bacterial, viral, or fungal pneumonia. • Pulmonary neoplasia. • Pulmonary hemorrhage (e.g., anticoagulant rodenticide exposure). • Pulmonary thromboembolism.

CBC/BIOCHEMISTRY/URINALYSIS
• Leukocytosis common, leukopenia and thrombocytopenia possible due to neutrophil sequestration in the lung and platelet consumption. • Biochemistries—usually normal; may note hypoalbuminemia owing to pulmonary protein loss; mild stress-related hyperglycemia. • Urinalysis—usually normal.

OTHER LABORATORY TESTS
Coagulation testing—mild to moderate prolongation of prothrombin time/partial thromboplastin time (PT/PTT) in animals with consumption and DIC. Severe coagulopathy may indicate hemorrhage as true cause for respiratory signs.

IMAGING
• Thoracic radiographs—vital; can reveal prominent interstitial pattern with mild or early disease; alveolar infiltrates with moderate or severe disease; infiltrates commonly but not always in dorsocaudal lung, sometimes asymmetrical and predominantly right-sided. Cardiac silhouette generally normal. • Echocardiography—rule out cardiogenic pulmonary edema. • Point-of-care thoracic ultrasound—increased lung rockets (B-lines) may indicate pulmonary edema, increased left atrial:aortic ratio more indicative of cardiogenic edema and underlying heart disease.

DIAGNOSTIC PROCEDURES
• Cytology of airway fluid—inflammatory: neutrophils and some alveolar macrophages. Fluid tends to have high protein values >3 g/dL. Culture negative unless concurrent bacterial pneumonia. • Edema fluid to plasma ratio (EF:PL) compares protein in the edema fluid to plasma protein. An increased ratio (>0.65) is indicative of noncardiogenic pulmonary edema. • Pulse oximetry—noninvasive, continuous monitoring of arterial hemoglobin saturation with oxygen and arterial blood gas analysis. Demonstrates mild to severe hypoxemia and hypocapnia; not specific but indicates the severity of pulmonary dysfunction. • B-type natriuretic peptide (NT-proBNP) testing in cats and dogs can suggest underlying heart disease and supports a diagnosis of cardiogenic edema.

PATHOLOGIC FINDINGS
• Gross—lungs usually heavy, red, or congested; fail to collapse; often exhibit a wet cut surface; can ooze foam from major airways. • Histopathology—depends on severity of the insult; early, mild: may note eosinophilic amorphous material filling the alveoli or can be near normal because fluid removed in processing; severe: alveolar hyaline membranes, alveolitis, and interstitial inflammatory infiltrates with neutrophils and macrophages evident and

PULMONARY EDEMA, NONCARDIOGENIC (CONTINUED)

accompanied by atelectasis, vascular congestion, and hemorrhage; lesions can be found within hours of a severe insult.

TREATMENT

APPROPRIATE HEALTH CARE

• Inpatient vs. outpatient—depends on the severity of respiratory dysfunction and the underlying cause (e.g., airway obstruction or seizures generally require hospitalization). • Make every effort to resolve and treat the underlying cause. • Mild to moderate—patients generally improve within 24–48 hours; cardiovascular and respiratory support while the lung repairs. • Severe—difficult to treat; usually requires positive-pressure ventilation (PPV) due to respiratory failure; many patients die despite treatment.

NURSING CARE

• Oxygen therapy—vital in moderate to severe disease; administer via mask or hood, nasal catheter, or oxygen cage; inspired oxygen concentration depends on the severity of disease; most patients do well on 40–50% oxygen, but severe disease can require 80–100% to maintain stability. • Severe—can require PPV and positive end-expiratory pressure (PEEP). • Judicious fluid therapy with a balanced electrolyte solution as replacement solution for dehydration or shock; use cautious fluid administration and avoid fluid overload. • Plasma, albumin, or synthetic colloids—consider with severe hypoproteinemia or low colloid osmotic pressure; improved oncotic pressure may minimize movement of fluid into lungs.

ACTIVITY

Exercise restriction and minimal stress to decrease oxygen requirements.

CLIENT EDUCATION

• Warn client that the condition can worsen before improving. • Inform client that severe disease progressing rapidly to fulminant pulmonary edema and respiratory failure is associated with a very poor prognosis.

SURGICAL CONSIDERATIONS

Relevant only for treating the underlying cause.

MEDICATIONS

DRUG(S) OF CHOICE

• Damaged endothelium in the pulmonary vasculature—no specific treatment available. • Inflammatory response—generated by a variety of mediators and cascades; cannot effectively be blocked by anti-inflammatory drugs. • Furosemide—diuresis not indicated as edema due to permeability changes, not high hydrostatic pressure. May act as bronchodilator and decrease pulmonary shunting, though evidence is limited. Can consider cautious boluses (0.5–2 mg/kg IV, IM) or nebulization, particularly early in course of disease. • Corticosteroids—for reduction of airway swelling in patients with upper airway obstruction; generally ineffective for pulmonary inflammatory response; if used, recommend anti-inflammatory dosage (e.g., dexamethasone SP at 0.05–0.1 mg/kg IV). • The use of beta-adrenergic agonists such as terbutaline may increase clearance of alveolar fluid. • Sedatives—use cautiously if anxiety is contributing to respiratory distress or airway obstruction. Sedation can decrease central respiratory drive, contributing to progression of respiratory failure. • Additional therapy as indicated by underlying cause—anticonvulsants, analgesia for oral ulcerations.

PRECAUTIONS

• Diuretics (e.g., furosemide)—can cause dehydration and decrease in intravascular volume, exacerbating cardiovascular collapse or shock with minimal effect on edema. • Corticosteroids—can predispose patients to infectious complications (e.g., pneumonia).

FOLLOW-UP

PATIENT MONITORING

• Monitor respiratory rate, pattern and auscultation (every 2–4 hours) for the first 24–48 hours, depending on severity of disease. • Assess pulmonary function by pulse oximetry or arterial blood gas analysis (initially every 2–4 hours), depending on severity of disease. • Assess packed call volume (PCV) and total solids. Evaluate mucous membranes, pulse quality, heart rate, blood pressure, and urine output every 2–4 hours to assess cardiovascular status and possible progression to shock.

PREVENTION/AVOIDANCE

• Avoid contact with electric wire. • Correct and avoid airway obstruction. • Manage seizures and neurologic disease.

POSSIBLE COMPLICATIONS

Usually none if patient recovers from the acute crisis.

EXPECTED COURSE AND PROGNOSIS

• Mild to moderate—resolution of signs in 24–72 hours with supportive care. • Severe—difficult to treat; can require PPV if respiratory failure. • Overall survival rates—80–90%. • Long-term prognosis—excellent if responsive to therapy.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Acute respiratory distress syndrome.

SYNONYMS

• Acute alveolar failure. • Acute lung injury. • Capillary leak syndrome. • Congestive atelectasis. • Hemorrhagic lung syndrome. • Progressive respiratory distress. • Shock lung. • Traumatic wet lung.

SEE ALSO

Acute Respiratory Distress Syndrome.

ABBREVIATIONS

• DIC = disseminated intravascular coagulation.
• NT-ProBNP = B-type natriuretic peptide.
• PCV = packed cell volume.
• PEEP = positive end-expiratory pressure.
• PPV = positive-pressure ventilation.
• PT = prothrombin time.
• PTT = partial thromboplastin time.
• SIRS = systemic inflammatory response syndrome.

PULMONARY THROMBOEMBOLISM

BASICS

DEFINITION
Develops when a thrombus lodges in the pulmonary arterial (PA) tree, occluding blood flow to the portion of lung supplied by that artery.

PATHOPHYSIOLOGY
• Pulmonary thromboembolism (PTE) associated with heartworm disease (HWD) occurs *in situ* in the pulmonary vessels; in most other instances, thrombus origin is unclear. • Potential sites of origin include right atrium, venae cavae, and jugular, femoral or mesenteric veins; thrombi are carried in the venous circulation to the lungs, and lodge in the pulmonary arteries. • Abnormal blood flow (stasis), vascular endothelial damage, and hypercoagulability are believed to predispose to thrombus formation. • Often a complication of another primary disease process.

SYSTEMS AFFECTED
• Cardiovascular—pulmonary hypertension (PH) may result, leading to right ventricular enlargement, right ventricular failure (cor pulmonale), and reduced cardiac output. • Respiratory—diminished pulmonary blood flow leads to arterial hypoxemia and dyspnea.

GENETICS
N/A

INCIDENCE/PREVALENCE
• Unknown—likelihood of PTE increases with abnormal coagulation or severe systemic disease. • Uncommon in the dog and cat; likely underdiagnosed due to nonspecific clinical signs, lack of clinical suspicion, and paucity of noninvasive, definitive diagnostic tests.

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
Species
Dog and cat.

Breed Predilections
N/A

Mean Age and Range
• More frequently seen in middle-aged to older dogs. • Bimodal age distribution reported in cats; peak occurrence <4 years and >10 years of age.

Predominant Sex
N/A

SIGNS
Historical Findings
• Often reflect the primary disease process. • May include peracute dyspnea, anorexia, syncope, collapse, cough, hemoptysis, weakness, exercise intolerance, and inability to sleep or get comfortable.

Physical Examination Findings
• Tachypnea and dyspnea in most animals; • Tachycardia, weak pulses, jugular vein distension, pale or cyanotic mucous membranes, delayed capillary refill time, right-sided heart murmur, and split or loud S2 in severe cases.

CAUSES
• HWD. • Neoplasia. • Hyperadrenocorticism (Cushing's disease) or corticosteroid administration. • Protein-losing nephropathy or enteropathy. • Immune-mediated hemolytic anemia (IMHA). • Pancreatitis. • Pulmonary hypertension (PH). • Orthopedic trauma or surgery. • Sepsis. • Disseminated intravascular coagulation. • Liver disease.

RISK FACTORS
• Coagulopathy, especially any hypercoagulable state. • Diseases listed under Causes are associated. • Estrogen administration, immobility, and air travel may be causative in humans.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Other diseases that cause clinically important dyspnea and hypoxemia without profound radiographic findings include upper airway obstruction, laryngeal paralysis, and diffuse airway disease processes (e.g., toxin inhalation and interstitial lung disease). • Upper airway obstruction often manifests as inspiratory dyspnea; breath sounds often loudest over trachea or larynx. • PTE should be a leading diagnostic consideration in a patient with acute onset of dyspnea or collapse and a known associated disease.

CBC/BIOCHEMISTRY/URINALYSIS
CBC—may be normal; thrombocytopenia may be seen in up to 50% of dogs with PTE; leukocytosis may develop. Biochemistry—results often reflect underlying disease. Urinalysis—results often reflect underlying disease; evaluate for proteinuria.

OTHER LABORATORY TESTS
• Arterial blood gases often show arterial hypoxemia (Pa_{O_2} often <65 mmHg) and low Pa_{CO_2} with respiratory alkalosis. • Metabolic and respiratory acidosis may develop in severely affected patients. • D-dimers result from the breakdown of crosslinked fibrin, indicate physiologic or pathologic thrombosis and testing plays a pivotal role in diagnostic algorithms for PTE in humans; however, utility for PTE diagnosis in veterinary patients is uncertain. • Thromboelastography provides a global assessment of coagulation and thrombolysis; may be useful in diagnosing systemic hypercoagulability but not widely available. • Coagulation profile may show high fibrin degradation products, abnormal fibrinogen, or alterations in one-stage prothrombin time (PT) and activated partial thromboplastin time (PTT).
• Heartworm serology (antigen testing in dogs; antigen and antibody testing in cats) should be performed in any animal with suspected PTE. • Cardiac biomarkers—cardiac troponin I and B-type natriuretic peptide (NT-proBNP) levels may be elevated.

IMAGING
Thoracic Radiography
• May be normal. • PA enlargement or pruning. • Cardiomegaly. • Interstitial and alveolar lung patterns. • Small-volume pleural effusion. • Areas of regional hyperlucency (Westermark sign).

Echocardiography
• Right ventricular enlargement. • Enlarged PA segment. • Flattening of the interventricular septum. • Reduced left ventricular cavity size. • High-velocity tricuspid or pulmonic regurgitation jets provide evidence of PH in some patients. • Infrequently a thrombus is imaged in the right heart or the main PA segments.

CT, Angiography, and Radionuclide Studies
• One or more of these tests usually required for definitive diagnosis. • CT angiography is gold standard for the diagnosis of PTE. • Spiral CT nonselective angiography may show intraluminal filling defects created by emboli, peripheral wedge-shaped pulmonary infiltrates, or pleural effusion. • Right-sided cardiac catheterization with pulmonary angiography may permit identification of intraluminal filling defects or regions of reduced pulmonary blood flow. • Nonselective angiography using conventional radiographic techniques has a low level of diagnostic success. • Combined ventilation and perfusion scans with radioisotopes permit identification of well-ventilated lung regions that are not receiving normal blood flow.

DIAGNOSTIC PROCEDURES
ECG
• Acute cor pulmonale—right axis deviation, P pulmonale, ST segment deviation, large T waves. • Arrhythmias.

PATHOLOGIC FINDINGS
• Thrombi in major PA branches. • Some patients exhibit multiple smaller thrombi in small PA vessels, eventually leading to marked respiratory dysfunction and death. • Concurrent lung pathology (e.g., pneumonia, pulmonary edema, neoplasia, interstitial fibrosis) is common.

TREATMENT

APPROPRIATE HEALTH CARE
Hospitalize patients documented with PTE until hypoxemia is resolved.

P

PULMONARY THROMBOEMBOLISM (CONTINUED)

NURSING CARE
• Administer IV fluids cautiously unless preexisting volume depletion; they may precipitate right-sided congestive heart failure. • Administer oxygen if dyspneic and/or PaO_2 <65 mmHg; response to oxygen therapy is variable.

ACTIVITY
N/A

DIET
N/A

CLIENT EDUCATION
• Alert that condition is often fatal; further episodes likely unless an underlying cause is identified and corrected; sudden death is not unusual. • Traditional anticoagulants can lead to bleeding complications requiring frequent clotting time reevaluation (e.g., PT and PTT) for successful management; low-molecular-weight heparins (LMWHs) are safer and require less monitoring but are more expensive; anticoagulants may be required for several months, even after resolution of the causative disease.

P

SURGICAL CONSIDERATIONS
N/A

MEDICATIONS

DRUG(S) OF CHOICE
• Always identify and treat underlying disease; if this is unlikely to be successful, aggressive efforts to treat PTE will probably be in vain.
• Unfractionated heparin may help to prevent further thrombi from developing; low dosages are probably inadequate for initial management; a dosage of 200–300 units/kg SC q8h or alternatively a bolus of 200 units/kg IV followed by a CRI at 15–30 units/kg/h adjusted to maintain the PTT at 1.5–2 times the baseline value. • Thrombolytics (e.g., urokinase, streptokinase, or tissue plasminogen activator) may also be useful in hemodynamically unstable cases; these are expensive and carry a higher risk of bleeding complications. • Warfarin—may occasionally be considered for long-term treatment (0.1 mg/kg q24h), with dosage adjustments to maintain a PT 1.5–2 times the baseline value; animals must be heparinized prior to warfarin therapy to avoid initial hypercoagulable phase. • LMWHs are likely associated with fewer bleeding complications than unfractionated heparin or warfarin, require less intensive monitoring, and are more suitable for long-term management; however, their cost may be a limiting factor. • Thromboprophylactic effects have been demonstrated for dalteparin 150 units/kg SC q12h in the absence of prolonged bleeding times or adverse effects; enoxaparin has been used at 1 mg/kg SC q12h.
• Sildenafil 1–2 mg/kg PO q8h may help in some animals with PTE and concomitant PH.

CONTRAINDICATIONS

PRECAUTIONS
Warfarin—interacts with many other drugs; degree of anticoagulation may change after giving these drugs, or with diet alterations. Dose titration may be difficult in patients with diseases that result in coagulopathy. Review mechanism of action and pharmacology of antithrombotic drugs before use.

POSSIBLE INTERACTIONS
See Precautions for warfarin.

ALTERNATIVE DRUGS
N/A

FOLLOW-UP

PATIENT MONITORING
Serial arterial blood gases and/or pulse oximetry—may help determine improvement in respiratory function.

PREVENTION/AVOIDANCE
• Activity or physical therapy may improve venous blood flow and prevent development of venous thrombi in immobile patients with severe systemic disease. • Aspirin (0.5–5 mg/kg PO q12–24h) may have some preventive role but is inadequate as treatment.
• Clopidogrel (1–2 mg/kg PO q24h) is an alternative antiplatelet drug that may have some role in prevention. A single loading dose, up to 10 mg/kg, can be administered for rapid platelet inactivation in cases with active thrombosis. • Heparin may be administered to hospitalized animals predisposed to the development of PTE (200 units/kg IV initially and 75–200 units/kg SC q8h). • Alternatively, dalteparin (150 units/kg SC q12h) or enoxaparin (1 mg/kg SC q12h) may be used for thromboprophylaxis. • Rivaroxaban, an oral factor Xa inhibitor, has been used in small animals (1 mg/kg PO q24h). Rivaroxaban and other newer oral antithrombotics, such as fondaparinux, apixaban, or dabigatran may be as effective as warfarin for prevention of recurrent thrombosis in people and require less monitoring; these drugs may play a future role in longer term anticoagulation of veterinary patients but further study on dosing and safety in animals is needed.

POSSIBLE COMPLICATIONS
Bleeding complications may arise with anticoagulants. Bleeding may occur from any organ system. Anticipate active bleeding or anemia necessitating blood or plasma transfusion and have blood products readily available.

EXPECTED COURSE AND PROGNOSIS
Generally guarded to poor; depends on resolution of the precipitating cause. For irreversible diseases (e.g., some neoplasias and advanced protein-losing nephropathy), prognosis is poor; it is somewhat better for

PULMONIC STENOSIS

BASICS

DEFINITION
Congenital narrowing of the right ventricular outflow tract, obstructing the passage of flow from the right ventricle (RV) to the pulmonary artery (PA); usually valvular, but may be subvalvular or supravalvular. Double-chambered RV is a variant of subvalvular pulmonic stenosis (PS) characterized by a focal muscular or fibromuscular stenosis in the mid RV.

PATHOPHYSIOLOGY
The stenosis causes a pressure overload of the RV, resulting in concentric hypertrophy. The RV develops high systolic pressures to overcome the stenosis, whose magnitude correlates with the severity of the stenosis. The difference between the high right ventricular pressure and the normal PA pressure (i.e., the pressure gradient) is often used to describe the severity of the stenosis. Hypertrophy of the RV increases the risk of myocardial ischemia and arrhythmias. The geometric changes in the RV can result in secondary tricuspid insufficiency, although tricuspid insufficiency can also be associated with concurrent tricuspid dysplasia. Syncope can occur with exercise, as the RV may be unable to increase stroke volume adequately. Tricuspid insufficiency with or without myocardial failure of the RV can lead to high right atrial pressures and right-sided congestive heart failure (R-CHF). A concurrent atrial septal defect or patent foramen ovale can cause right-to-left shunting, especially with exercise, resulting in cyanosis on exertion. Mild PS usually produces no significant hemodynamic effects apart from an ejection murmur.

SYSTEMS AFFECTED
- Cardiovascular—R-CHF, arrhythmias.
- Hepatobiliary—hepatomegaly with R-CHF.
- Respiratory—pleural effusion.
- Nervous—cerebral hypoperfusion during exercise.

GENETICS
Inherited defect in beagles; polygenic mode of transmission suggested.

INCIDENCE/PREVALENCE
- Most surveys show PS to be among the three most common congenital cardiac defects in dogs; comprising 21–32% of congenital heart defects.
- Uncommon in cats, especially as an isolated defect; comprised 3% of congenital heart defects in one study.

SIGNALMENT
Species
Dog and cat.

Breed Predilections
English bulldog, Chihuahua, French bulldog, miniature schnauzer, West Highland white terrier, Samoyed, cocker spaniel, beagle, boxer, Pomeranian, German shepherd dog, whippet. Bulldog breeds are particularly predisposed to PS caused by anomalous coronary artery anatomy, where the left coronary artery originates from the same vessel as the right coronary, and causes stenosis as it wraps around the main PA.

Mean Age and Range
Present from birth and may be detected as a murmur in puppies; if murmur is not detected, affected animals may not be identified until clinical signs develop later in life.

Predominant Sex
A predilection for males in English bulldogs and possibly other breeds.

SIGNS
General Comments
- Mild stenosis—usually no clinical signs.
- Severely affected patients—may develop CHF, exertional syncope, or sudden death.

Historical Findings
- Abdominal distension.
- Dyspnea.
- Exertional syncope, exercise intolerance, or sudden death.
- Asymptomatic.

Physical Examination Findings
- Systolic murmur loudest over the left heart base; may radiate widely but particularly dorsally on left.
- Murmur—midsystolic or holosystolic, and crescendo–decrescendo.
- Louder murmurs with a precordial thrill—generally associated with more severe stenosis.
- Arrhythmias may occur; the heart rate may be high in CHF.
- Other signs of CHF include ascites, jugular venous distension, and tachypnea.

CAUSES
Congenital

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Similar murmurs may be found with: ○ Aortic stenosis. ○ Ventricular or atrial septal defects with marked left-to-right shunting. ○ Tetralogy of Fallot.
- R-CHF associated with a left-sided murmur may be seen with: ○ Acquired valvular disease. ○ Dilated cardiomyopathy.

CBC/BIOCHEMISTRY/URINALYSIS
- Generally unremarkable.
- Polycythemia may be present with right-to-left shunting.
- NT-proBNP is increased, particularly with severe stenosis or if clinical signs present.

IMAGING
Radiography
- Thoracic radiographs usually show right-sided cardiac enlargement, with a post-stenotic PA bulge visible on the dorsoventral view at 1–2 o'clock.
- The caudal vena cava may be wide, and ascites may be present with or without pleural effusion in congestive failure.

Echocardiography
- Right ventricular hypertrophy, with flattening of the interventricular septum and a "figure-eight" appearance on short axis views in severe cases.
- Can usually image the site of the stenosis, but may be more difficult when the valve is hypoplastic; dysplastic pulmonic valves appear as thickened echodense leaflets; fused leaflets have abnormal motion with systolic doming; discrete subvalvular or supravalvular stenoses may appear as a localized hyperechoic narrowing.
- Post-stenotic dilation of the PA often present.
- Double-chambered RV can be difficult to image in conventional views.
- Localized hypertrophy may be seen in the right ventricular infundibular region.
- Anomalous coronary anatomy can be difficult to image.

Doppler Echocardiography
- Can use spectral Doppler to measure the elevated PA flow velocity to calculate the pressure gradient across the stenosis. Pressure gradients under 50 mmHg generally represent mild stenosis; those over 80 mmHg indicate severe stenosis.
- Color-flow Doppler may reveal tricuspid regurgitation.

Angiography
- Selective cardiac angiography can help identify the precise morphologic abnormalities prior to surgery; may image dysplastic valves and hypertrophy of the infundibulum more clearly.
- Useful in identifying PS caused by an anomalous coronary artery encircling the right ventricular outflow tract, which may affect the choice of therapy; recommended for bulldogs and brachycephalic breeds.

CT Angiography
Best technique to delineate coronary artery anomalies if resolution adequate and images are ECG-gated.

DIAGNOSTIC PROCEDURES
Electrocardiography
- QRS complex waveform changes include deep S waves in leads I, II, III, and aVF and right axis deviation.

P

PULMONIC STENOSIS (CONTINUED)

• Atrial fibrillation may occur with severe right atrial enlargement.

PATHOLOGIC FINDINGS

• Various forms exist; most result in right ventricular hypertrophy and post-stenotic dilation of the PA; infundibular hypertrophy may occur proximal to the obstruction.
• Hypoplastic pulmonic valve, with thickened leaflets ("dysplastic pulmonic valve").
• Normal pulmonic valve annulus with fused commissures, often attached to vessel at supravalvular level.
• Anomalous coronary arteries.
• Discrete supravalvular or subvalvular stenosis, with possible concurrent tricuspid dysplasia.
• Fibromuscular bands dividing the right ventricular inflow and outflow tracts in double-chambered RV.

TREATMENT

APPROPRIATE HEALTH CARE

Most managed as outpatients.

NURSING CARE

Rarely, pleural effusions may need draining; ascites is usually treated medically.

ACTIVITY

Exercise should be restricted in cases with syncope or CHF, and severe exertion should be avoided in asymptomatic cases with severe stenosis.

DIET

Low-salt diets may benefit those with refractory ascites.

CLIENT EDUCATION

• Mildly affected animals may lead normal lives.
• Moderately and severely affected patients may benefit from interventions such as balloon catheter dilation or surgery; improved clinical signs and survival has been associated with successful balloon procedures.
• Prognosis is guarded once congestive signs develop.
• Do not breed affected animals.

SURGICAL CONSIDERATIONS

• Balloon catheter dilation—relatively safe procedure that involves passing a catheter across the stenosis and inflating a balloon to dilate the obstruction; in many cases, the pressure gradient is significantly reduced, especially when the lesion is caused by fused commissures; less successful with dysplastic or hypoplastic valves and should be used with caution with anomalous coronary arteries.
• Generally unsuccessful in double-chambered RV.
• Stenting of the stenotic pulmonic valve has been described in cases where balloon valvuloplasty has been unsuccessful.
• Alternative surgical techniques include valvulotomy or patch-ventriculectomy procedures; mortality rates tend to be higher than with balloon valvuloplasty.

MEDICATIONS

DRUG(S) OF CHOICE

If signs of CHF, treat ascites with furosemide 1–4 mg/kg PO q8–12h; in refractory failure, it is worth adding spironolactone 1–2 mg/kg PO q12h; aim should be to control CHF signs prior to catheter intervention.

CONTRAINDICATIONS

Vasodilators (e.g., hydralazine) may cause hypotension without relieving the stenosis, positive inotropes may further increase myocardial oxygen consumption.

PRECAUTIONS

Avoid overuse of diuretics. angiotensin-converting enzyme inhibitors may be helpful with congestive signs, but may cause hypotension. Start with low doses and monitor blood pressure.

FOLLOW-UP

PATIENT MONITORING

Use serial echocardiograms to follow the pressure gradient and cardiac chamber size.

PREVENTION/AVOIDANCE

Do not breed affected animals.

POSSIBLE COMPLICATIONS

• R-CHF.
• Chylothorax.
• Arrhythmias.
• Exercise intolerance.
• Exertional syncope.
• Sudden death.

EXPECTED COURSE AND PROGNOSIS

• Mildly affected animals may remain asymptomatic with a normal lifespan.
• Severely affected animals have a guarded prognosis because they may develop CHF or sudden death; clinical signs are generally more common in animals >1 year of age.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Ventricular septal defects, atrial septal defects, and patent foramen ovale.
• English bulldogs described with a single right coronary artery from which an anomalous left main coronary artery arises and then encircles and constricts the base of the pulmonic valve; other coronary variations have also been described.

AGE-RELATED FACTORS

Defect and murmur are present from birth.

PREGNANCY/FERTILITY/BREEDING

Do not breed affected animals.

SYNONYMS

Pulmonary stenosis.

SEE ALSO

• Congestive Heart Failure, Right-Sided.
• Murmurs, Heart.

ABBREVIATIONS

• ECG = electrocardiography.
• PA = pulmonary artery.
• PS = pulmonic stenosis.
• R-CHF = right-sided congestive heart failure.
• RV = right ventricle.

PUPPY BEHAVIOR PROBLEMS

BASICS

DEFINITION
These problems include behaviors that are normal and common to most puppies but not acceptable to the family. They require some degree of modification by training and shaping to become acceptable. Training and behavior issues include confinement training, housetraining, destructive chewing, play-biting, jumping on people, and getting on counters or furniture.

SYSTEMS AFFECTED
Behavioral

GENETICS
- Activity levels and behaviors of young pups may be similar to those of their parents.
- Some problems may be more prevalent in breeds or lines with a high need for exercise and mental stimulation.

INCIDENCE/PREVALENCE
Common to almost all puppies.

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
Species
Dog.

Breed Predilections
Breeds selected for high-energy, stamina, and working functions.

Mean Age and Range
3–6 months of age but some dogs mature later and problems can persist into adulthood.

Predominant Sex
May be higher frequency in males.

SIGNS
Confinement Training
N/A

Housetraining
N/A

Playbiting
- The pet bites hands, legs, and/or clothing. Bites are usually inhibited but can cause injuries due to sharp teeth or insufficient bite inhibition.
- Growling and barking may be present but usually a higher pitch, with lower tones associated with social aggression.
- Attacks are usually triggered by movement or play with a family member but can be spontaneous.

Getting on Counters/Furniture
The pet gets on furniture and counters .

CAUSES
General
- Normal play and exploration.
- Inadequate supervision, training, socialization, or providing for mental stimulation or environmental enrichment.
- Owner responses may reinforce or exacerbate the behaviors.

Playbiting
A normal behavior, but rough play, teasing, and encouraging the pet to bite hands and feet may contribute to problems

Getting on Counters/Furniture
- Insufficient outlets for normal play and exploration.
- Tempting objects or food left on counters/furniture.
- Desire for social interaction.
- No acceptable alternative resting/bedding area.

RISK FACTORS
See Causes.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Confinement Training
N/A (if distress or soiling during confinement rule out separation anxiety and barrier frustration).

Housetraining
N/A (rule out medical).

Playbiting
- Fear-related and defensive aggression—aggression accompanied by signs of fear and/or submission (lowered body, ears and tail down/tucked, horizontal retraction of oral commissures):
  - Occurs when the pet is in a situation perceived as threatening.
  - May be due to confrontation or punishment. Vocalization might include growling or yelping.
- Possessive aggression—occurs in situations in which there is competition for a resource:
  - Pet stiffens and hovers over the guarded object.
  - Increase in the speed of eating or quickly grasping an object tightly in the mouth may also be observed.
  - Growling has a deep tone.
  - Piloerection may occur, as might lunging, snapping, and biting.
- Reinforced aggression—the pet learns that aggressive behavior is effective at achieving goals (avoid being picked up, pushed off couch, restrained by collar, nails trimmed).
- Conflict-related aggression—the pet bites in situations where it is frustrated or uncertain how to behave due to inconsistent responses by the family, including punishment.
- Medical, e.g., viral encephalitis, toxins, congenital disorders, usually accompanied by other signs of illness.

Getting on Counters/Furniture
N/A

CBC/BIOCHEMISTRY/URINALYSIS
Housesoiling might require a urinalysis, fecal exam, or other tests as suggested by physical exam and history.

DIAGNOSTIC PROCEDURES
N/A except to rule out concurrent illness, e.g., hepatic shunt, CNS anomalies that affect learning.

TREATMENT

APPROPRIATE HEALTH CARE
Outpatient

NURSING CARE
N/A

ACTIVITY
Provide a regular daily routine of exercise, play, social interaction and mental stimulation.

DIET
Provide sufficient food to reduce the motivation to guard food.

CLIENT EDUCATION
General
- Constantly look for and reward acceptable behaviors.
- Avoid punishment, confrontation and corrections (e.g., striking, shaking the scruff, rolling on the back, or squeezing lips). These can worsen problems, negatively impact the bond with the pet, and lead to more serious problems, such as social fear and aggression).
- Teach the pet to sit or down using reward training. Direct him into the behavior prior to getting anything he wants or needs.

Confinement Training
- Choose an appropriate confinement area. A crate is good for intermittent confinement but no longer than the pet can control urination and defecation (gradually increasing from 1 to 5 hours). If the pet must be confined for longer a larger housing area should be provided with an elimination area within.
- Place treats, toys, or food in the area so that he is motivated to enter. For rest and sleep, place him in his confinement area. The pup should never be roughly forced in. A confinement area is for safety and comfort not punishment.
- Some degree of distress vocalization may occur the first few times the pup is confined. Music or talk radio may help to calm and mask environmental noises that trigger barking. A calming pheromone (Adaptil™) may help the puppy adapt. Avoid releasing the pup when he cries. Wait until he is quiet or squeak a toy from out of sight to get the pup to quiet before he is released.

PUPPY BEHAVIOR PROBLEMS (CONTINUED)

Housetraining

- The puppy should be taken out to eliminate each hour when awake during the daytime when possible. If he does not eliminate within 10 minutes, return indoors, supervise closely for 15–30 minutes and try again. Take the pet out after play, exercise, naps, eating, drinking, or confinement, as well as prior to confinement, and whenever he exhibits preelimination circling and sniffing. Offer food 2–3 times daily at the same time to help establish an elimination routine.
- Until the puppy has completed 4 weeks without soiling, he should either be within eyesight or in his confinement area. A leash will help keep the pet close for supervision. Most pups can control elimination through the night by 3–4 months of age. By 4 months, most puppies will have more of control during the daytime. Soiling can be prevented by closing doors or using barriers to limit access to areas.
- Do not punish. If caught in the act of soiling, calmly redirect the pup, and take outdoors. Elimination odors should be removed.
- If the pup eliminates in his crate—he may have been left there longer than he can control eliminating; the crate may be so large that he sleeps in one end and eliminates in the other; the puppy did not eliminate prior to confining; the meals were not matched to the elimination schedule; there is anxiety about confinement or being left alone (see Separation Anxiety Syndrome); there is an underlying medical cause.
- If it is not practical to take the pup outside frequently enough, he should be confined to a larger confinement area (e.g., pen) with an elimination pad within.
- Medical issues that may contribute to housetraining problems include problems that cause increased volume or frequency of elimination, and CNS problems that interfere with learning (hepatic encaphalopathy, hydrocephalus).

Playbiting

- Provide abundant opportunities for play/exercise.
- Have toys available at all times to toss and distract the pet.
- Use treat- and kibble-filled toys to keep the pet occupied and to provide outlets for exploration and scavenging.
- Use a leash attached to the supervised pup for more control.
- Confine the pup to his rest area when the family cannot effectively engage him in acceptable activities.
- Avoid games that encourage biting hands or feet.
- Make all interactions structured and predictable by training the pet to sit before giving toys, food, play, and attention.
- Do not reinforce attention-seeking behavior such as whining, barking, or pawing for attention.
- Say "Ouch" and immediately redirect or walk away to interrupt hard bites during play.
- Avoid physical corrections that can cause fear, anxiety, and aggression or stimulate the pup.
- Consider a head halter for head control of difficult pups.
- Enroll in puppy classes early (8–10 weeks of age).

Getting on Counters/Furniture

- Keep appealing objects off counters and furniture.
- Constantly supervise and monitor.
- Block access to problem areas.
- Confine the pup to his bed/rest area when he cannot be supervised.
- Provide interesting toys on the floor.
- Meet the pet's needs for food, chewing, mental stimulation, and exploration.

MEDICATIONS

DRUG(S) OF CHOICE

Drugs are not indicated except for problems associated with anxiety.

ALTERNATIVE DRUG(S)

Dog-appeasing pheromones, nutraceuticals such as alpha-casozepine or L-theanine, or a calming probiotic may aid in stressful situations.

FOLLOW-UP

PATIENT MONITORING

- Phone follow-ups at approximately 10 days, 20 days, and 6 weeks following the initial visit are helpful.
- This can be done by a trained support staff member.

PREVENTION/AVOIDANCE

- Provide preventive counseling for all first puppy visits about normal behavior and behavioral needs (e.g., mental stimulation, socialization, exercise, object play).
- Discuss timing and use of rewards to teach what is desirable while behaviors that are undesirable should be prevented (supervision and confinement strategies) and not punished.
- Begin food-lure reward training at 7–8 weeks of age.
- Make interactions predictable by teaching the pet to sit before giving anything of value.
- Enroll in a puppy class at 8–10 weeks of age.
- Provide regular sessions of physical exercise, mental stimulation including reward training, food puzzle toys, and safe items to explore and chew.

POSSIBLE COMPLICATIONS

- Damage to household objects and clothing.
- Food stealing.
- Intestinal foreign bodies/obstructions.
- Injuries from playbites and jumping up.
- Owner frustration, weakened bond, and possible relinquishment.

EXPECTED COURSE AND PROGNOSIS

- Prognosis is generally good.
- The frequency and intensity should decrease with age.
- Playbiting can usually be quickly managed if the family is consistent with training.
- Confinement training should take a few days to several weeks.
- Housetraining can be accomplished in a few weeks, but may take longer if the family is not consistent in supervision and training or the family schedule does not address the dog's needs.

PUPPY SOCIALIZATION AND PUPPY CLASSES

BASICS

OVERVIEW

• Early experiences set the foundation for future behavior, having lasting effects on social behavior, temperament, and the ability to learn and relate to various stimuli and to cope in various environmental contexts.
• To grow up into a well-adjusted adult dog, adequate socialization and environmental exposure is needed during the socialization period and beyond into the first year of life.

Definitions

• Socialization—a process of learning normal behavior, communication, and social skills for appropriate interactions with other individuals in various contexts.
• Socialization period—a sensitive window of development whereby a dog learns to communicate and relate to other dogs, humans, and the environment.
• Puppy classes—called socialization, preschool, or kindergarten classes. Allow dogs to socialize with other dogs, breeds, a variety of people and to be exposed to multiple and varied environmental stimuli in a positive and nonthreatening manner.

Pathophysiology

Potential effects on behavioral and neurological development.

SIGNALMENT

Species

Dogs

Breed Predilections

• Smaller breeds may mature faster and progress more quickly through windows of behavioral development.
• Amount of handling and exposure toward humans needed to reduce people-shyness may be genetically variable.
• The timing of first fear response is genetically variable, 39–55 days.

Mean Age and Range

• The primary socialization period is between 3 and 5 weeks. Puppies recognize kin and learn to relate and interact with other members of their species. The secondary socialization period occurs from 6 to 12 weeks, during this time most puppies are removed from its mother and littermates and raised with human caregivers. The ideal time for placement in a new home is probably after 7 or 8 weeks of age.
• For puppy classes—healthy dewormed puppies should begin attending group socialization classes 10 days after receiving their first vaccine of their immunization series. Typical age at time of the first classes is between 8 and 12 weeks.

Predominant Sex

Male puppies play more than females.

SIGNS

• Lack of adequate socialization experiences during sensitive periods of development.
• Dog-directed fear and/or aggression—lack of early familiarity and positive exposure results in fear and aggression or reactivity to unfamiliar dogs.
• Human-directed fear and/or aggression—exposure with humans prior to 14 weeks is necessary, otherwise fear, avoidance, aggression, and behaving as if "feral."
• Predatory aggression—social exposure, even to prey species, can reduce predatory behavior later in life.
• Reduced ability to copulate—in male dogs, lack of socialization toward conspecifics from 3 weeks on results in the display of normal sexual behavior toward estrus females, but poor performance. In female dogs, timidity toward other dogs may preclude breeding.
• Fear and anxiety in unfamiliar environments with various sights, sounds, and smells.
• Attendance at group puppy classes during sensitive periods of development can prevent future behavior problems and/or allow for the early identification of abnormal and problematic behavior.
• Puppy socialization classes—age specific (to begin at 8–12 weeks) for group-controlled interactions. Focus is education on normal behavior, prevention of behavior problems, and addressing problem behaviors through management, supervision, and positive reinforcement training.
• Group classes of older puppies in their juvenile (3–6 months) and adolescent (6–18 months) stages. Focus primarily on training manners, positive reinforcement training and teaching dogs to focus on their owners/handlers.

CAUSES & RISK FACTORS

• Avoiding environmental and social experiences prior to the completion of puppy vaccination series increases the risk of future behavior problems.
• Risk of contracting parvovirus was not increased when puppies attended well-run group socialization classes prior to completion of their vaccination series.
• Risks of exposure to infectious disease with socialization needs to be considered along with the risk of being undersocialized and not suitable as a pet because of fear, anxiety, and/or aggression.
• Along with a clean bill of health, initial vaccinations must have been administered at least 1 week and preferably 10 days before puppy socialization classes start.
• Puppies should be dewormed according to the Companion Animal Parasite Council guidelines: https://capcvet.org/guidelines/general-guidelines/
• Puppies should be free of clinical disease such as respiratory and gastrointestinal prior to each class.
• Puppy socialization with people and dogs is only beneficial to behavioral development if the puppy finds human and/or dog contact enjoyable. Forced exposure, when it induces fear, is likely to exacerbate fear and/or aggression.
• Experiences at the veterinary clinic should employ Fear Free® and Low Stress techniques to prevent fear, anxiety, stress, and aggression during future veterinary visits.
• Overly shy, fearful, reactive or hyperactive puppies during routine veterinary health checks are likely to display the same behavior at 1 year of age.
• Puppies displaying fear and avoidance of being handled are likely to display fear and/or aggression with handling later in life.
• Excessive mouthing/biting or aggression over food resources at 8 weeks may indicate increased risk of aggression toward family members.
• Pet store puppies and those with early illness are more likely to develop behavior problems.
• Traumatic fear-inducing experiences, particularly during sensitive fear periods, between 8 and 10 weeks and between 6 and 12 months (lasting up to 3 weeks), should be avoided.
• Removal from the mother and littermates prior to 6 weeks may increase the risk of separation anxiety and interdog aggression with poor interdog social skills.
• Avoiding exposure to other species during socialization can lead to fear or aggression towards the species.
• At the juvenile period, beginning at 3–4 months of age, puppies may become less social and more fearful with increased independence seen in adolescence.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Identify abnormal and/or problematic behavior and make a behavioral diagnosis or schedule/refer for a behavior consultation.
• Behavioral manifestations of a lack of socialization may include: ◦ Global fears, encompassing fears of people, dogs, objects, sounds, and environments. ◦ Generalized anxiety and situational anxiety in unfamiliar environments. ◦ Specific fears, neophobia, and failure to habituate to novelty or stimuli. ◦ Noise sensitivity, aversions, and phobias. ◦ Hyperexcitability and hypervigilance with an inability to settle due to lack of early environmental enrichment. ◦ Aggression toward people and dogs in various contexts with various motivations (e.g., fear, predatory).

CBC/BIOCHEMISTRY/URINALYSIS

Indicated when considering behavioral medications.

PUPPY SOCIALIZATION AND PUPPY CLASSES (CONTINUED)

TREATMENT

Recommendations for Socialization

- Attendance at group puppy socialization classes and social exposure is recommended for all healthy puppies prior to 16 weeks of age and prior to being fully vaccinated.
- Socialization "vaccinates" against the development of future behavioral problems and it should begin concurrently with the puppy immunization series.
- Food treats should be used liberally with new and repeated socialization experiences.
- Social play and exploration should be encouraged using toys.
- Healthy puppies usually have voracious appetites. If the puppy is not consuming food treats, it suggests the puppy is fearful and the experience is not beneficial for socialization.
- Healthy and well-adjusted puppies play. If the puppy will not engage in play it suggests the puppy is fearful and the experience is not beneficial for socialization.
- Socialization by the breeder—gentle handling should occur daily, shortly after birth, and include exposure to various smells and different surfaces with mild fluctuations in temperature.
- Socialization at the owner's home—allow the puppy to choose to interact and make exposure positive with the liberal use of food treats: ○ Meet people of different ages, stature, gait, and complexion. ○ Meet friendly dogs of different breeds. ○ Meet other pets in the home (such as cats).

Recommendations for Puppy Socialization Classes

- All healthy puppies, between 8 and 12 weeks of age should be enrolled into group puppy socialization classes.
- Puppies attending are deemed healthy by a veterinary examination, free from clinical signs (e.g., coughing, diarrhea), have been dewormed, and have started their vaccination series.
- Classes are attended by puppies and their owners at least weekly and are typically about an hour in length.
- Rotating classes should cover the following topics: ○ Play sessions—controlled and monitored off-leash play (5–10 minutes) with other puppies in a secure environment, typically at the start and end of class. ○ Health and handling—instruction and positive handling for routine health and grooming procedures in the veterinary clinic, at the grooming facility, and at home. ○ Sights and sounds—exposure to novel environments, objects, surfaces, and sounds. Attending people have opportunities for interacting with puppies in a positive manner. ○ Rearing advice—education on normal dog body language, learning, behavior problem-solving/prevention, and puppy raising. ○ Basic manners—positive reinforcement training to address mouthing/biting, jumping, chewing, stealing objects, food bowl safety, confinement training, leash manners, and house training. ○ Puppy classes offered at the veterinary hospital can also help to insure a focus on positive exposures to the veterinary facility, equipment, and procedures.

MEDICATIONS

DRUG(S) OF CHOICE

- Selective serotonin reuptake inhibitors and tricyclic antidepressants may be indicated for the treatment of fear, anxiety, and aggression-related problems when combined with behavior and environmental modification.
- May "in effect" chemically place the puppy back into a socialization state and aid socialization experiences.
- Consider daily or situational behavior medications based on the underlying condition; for dogs, 12 weeks or greater, who demonstrate abnormal fear, anxiety, aggression or reactivity.

Nutraceuticals/Supplements

- Alpha-casozepine, a bovine-sourced hydrolyzed milk protein may have calming properties.
- L-Theanine, an extract found in green tea, may reduce fear, anxiety, and stress.
- Calming Care (Purina®) probiotic may help to maintain calm behavior.

Pheromones

Adaptil (CEVA), a synthetic dog-appeasing pheromone, may improve socialization experiences and facilitate adaptation to new environments.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Avoid selective serotonin reuptake inhibitors and tricyclic antidepressants in combination and use with caution with other serotonin-influencing drugs.

FOLLOW-UP

PATIENT MONITORING

Question owners about behavior problems routinely and encourage concerns regarding problematic behavior to be brought to their veterinarian's attention as soon as possible.

PREVENTION/AVOIDANCE

- Preventive counseling at the first puppy visit reduces risk of housesoiling, mounting, excess play, mouthing of people, demanding food, and fear of unfamiliar people.
- Prevention of problems is preferable and easier than treatment.
- Socialization experiences must be positive for the puppy to benefit from the experiences.

POSSIBLE COMPLICATIONS

- Negative social and environmental experiences can sensitize the puppy as it is difficult to habituate to stimuli that induce fear, anxiety, and stress.
- Puppies raised in suboptimal environments may be resistant to socialization.
- Unwillingness to consume treats, explore, and/or play in socialization contexts suggest that the exposure is not positive for the puppy.

EXPECTED COURSE AND PROGNOSIS

Early identification and intervention gives the best prognostic outcome and chance for cure.

PUPPY STRANGLES (JUVENILE CELLULITIS)

BASICS

OVERVIEW
- Uncommon granulomatous and pustular disorder of puppies.
- Rarely seen in adult dogs.
- Affects primarily the face, pinnae, and submandibular lymph nodes.
- Immunopathogenesis unknown.

SIGNALMENT
- Dogs.
- Age range—usually between 3 weeks and 4 months.
- Predisposed breeds—golden retriever, Labrador retriever, dachshund, and Gordon setter.

SIGNS
- Acutely swollen face (eyelids, lips, and muzzle).
- Submandibular lymphadenopathy.
- Marked pustular and exudative dermatitis; frequently fistulates; develops within 24–48 hours.
- Purulent otitis externa.
- Lesions often become crusted.
- Affected skin is usually painful.
- Lethargy—50% of cases.
- Anorexia, pyrexia, and sterile suppurative arthritis—25% of cases.
- Sterile pyogranulomatous panniculitis (rare) over the trunk, preputial, or perianal area; lesions may appear as fluctuant subcutaneous nodules that fistulate.

CAUSES & RISK FACTORS
Unknown—an immune dysfunction with a heritable cause is suspected.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Bacterial folliculitis/furunculosis.
- Demodicosis.
- Drug reaction/eruption.
- Deep fungal infection.
- Cutaneous hypersensitivity.
- Vaccination reaction.
- Hymenoptera or insect envenomation.
- Acute lymphoma.

OTHER LABORATORY TESTS
- Cytology—pyogranulomatous inflammation with no microorganisms; nondegenerate neutrophils.
- Culture—often sterile in early cases; secondary infection with chronicity.

DIAGNOSTIC PROCEDURES
Skin biopsy.

PATHOLOGIC FINDINGS
- Multiple discrete or confluent granulomas and pyogranulomas—clusters of large epithelioid macrophages and neutrophils.
- Sebaceous glands and apocrine glands may be obliterated.
- Suppurative changes in the dermis—predominate in later stages.
- Panniculitis.
- Exudate culture—important for selection of antibiotics if secondary infection suspected.

TREATMENT
- Early and aggressive therapy necessary because scarring may be severe.
- Topical therapy—may be soothing and palliative; adjunct to corticosteroids.

MEDICATIONS

DRUG(S) OF CHOICE
- Corticosteroids—high doses required; prednisolone 2.2 mg/kg divided q12h for at least 2 weeks then decreased over 2–4 weeks or dexamethasone 0.2 mg/kg q24h.
- Do not taper too rapidly.
- Corticosteroid—resistant cases: cyclosporine 5 mg/kg q24h.
- Adult dogs with panniculitis may require longer therapy.
- Antibiotics—only if there is evidence of secondary bacterial infection or as an adjunct therapy with immunosuppressive doses of corticosteroids.

FOLLOW-UP
- Most cases do not recur.
- Scarring may persist, especially around the eyes.

MISCELLANEOUS

SYNONYMS
- Juvenile pyoderma.
- Juvenile sterile granulomatous dermatitis and lymphadenitis.

PYELONEPHRITIS

BASICS

DEFINITION
Microbial colonization of the upper urinary tract, including the renal pelvis, collecting diverticula, renal parenchyma, and ureters; because it is not usually limited to the renal pelvis and parenchyma, a more descriptive term is upper urinary tract infection (UTI); this chapter is limited to bacterial pyelonephritis.

PATHOPHYSIOLOGY
- Infection of any portion of the urinary tract usually requires impairment of normal host defenses against UTI (see Lower Urinary Tract Infection chapters); normal defenses against ascending UTI include mucosal defense barriers, ureteral peristalsis, ureterovesical flap valves, unidirectional flow of urine, and an extensive renal blood supply. Pyelonephritis usually occurs by ascension of microbes causing lower UTI. Hematogenous seeding of the kidneys is an uncommon cause of pyelonephritis. Regardless of the route of infection, an upper UTI is frequently accompanied by lower UTI.
- Pyelonephritis can develop secondarily to infected nephroliths. Upper UTI with urease-producing bacteria can predispose to struvite nephroliths (see Urolithiasis, Struvite—Dogs).
- Obstruction of an infected kidney or ureter can rapidly cause septicemia (urosepsis).

SYSTEMS AFFECTED
- Renal/urologic.
- Can cause urosepsis, thus affecting any body system.

INCIDENCE/PREVALENCE
- Unknown.
- Probably occurs more commonly than is recognized clinically, because many animals with pyelonephritis are asymptomatic or have signs limited to lower UTI.

SIGNALMENT
Species
Detected more frequently in dog than cat.

Mean Age and Range
- Dogs of any age can be affected.
- Cats—UTI is uncommon in young to middle-age cats. UTI is more common in cats >10 years of age.

Predominant Sex
UTI affects females more commonly than males.

SIGNS
General Comments
Differentiation between pyelonephritis, subclinical bacteriuria, and lower UTI may be difficult in some patients.

Historical Findings
- Polyuria/polydipsia.
- Abdominal or lumbar pain (uncommon).
- Signs associated with lower UTI may predominate—e.g., dysuria, pollakiuria, periuria, stranguria, hematuria, and malodorous or discolored urine.
- Signs attributable to chronic kidney disease (CKD)—e.g., polyuria/polydipsia, anorexia, vomiting, diarrhea, lethargy.

Physical Examination Findings
- May lack specific signs related to upper UTI.
- Fever.
- Pain upon palpation of kidneys.
- One or both kidneys may be reduced in size with chronic pyelonephritis, or kidneys may be increased in size with acute pyelonephritis.

CAUSES
Usually, ascending UTI caused by aerobic bacteria; most common isolates are *Escherichia coli* and *Staphylococcus* spp.; other bacteria, including *Proteus*, *Streptococcus*, *Klebsiella*, *Enterobacter*, and *Pseudomonas* spp., which frequently infect the lower urinary tract, may ascend into the upper urinary tract. Anaerobic bacteria, ureaplasma, and fungi uncommonly infect the upper urinary tract.

RISK FACTORS
- Ectopic ureters, vesicoureteral reflux, congenital renal dysplasia, and lower UTI.
- Conditions that predispose to bacteriuria—e.g., diabetes mellitus, hyperadrenocorticism, exogenous steroid administration, CKD, indwelling urinary catheters, urine retention, uroliths, urinary tract neoplasia, perineal urethrostomy.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Clinical diagnosis of pyelonephritis is usually presumptive, based on results from CBC, biochemical analysis, urinalysis, urine culture, and diagnostic imaging; definitive diagnosis is not usually required for planning treatment.
- Since many lack specific symptoms attributable to pyelonephritis, any patient with UTI could potentially have pyelonephritis; the best methods for differentiating between upper and lower UTI are ultrasonography or excretory urography.
- Consider pyelonephritis as a rule-out for fever of unknown origin, polyuria/polydipsia, acute decline in renal function, and/or lumbar/abdominal pain.

CBC/BIOCHEMISTRY/URINALYSIS
- CBC—results often normal with chronic pyelonephritis; leukocytosis and immature neutrophilia may be detected in some patients.
- Biochemistry—values usually normal unless chronic pyelonephritis leads to CKD (azotemia with inappropriate urine specific gravity).
- Urinalysis may reveal hematuria, pyuria, proteinuria, bacteriuria, and leukocyte casts. Leukocyte casts are diagnostic for renal inflammation, but unfortunately are very uncommon. Observe dilute urine specific gravity in patients with nephrogenic diabetes insipidus, which may occur secondary to pyelonephritis from Gram-negative bacteria. Absence of these abnormalities does not rule out pyelonephritis.

OTHER LABORATORY TESTS
- Quantitative urine culture to confirm UTI; see Lower Urinary Tract Infection chapters for interpretation.
- Dogs with chronic pyelonephritis may have a negative urine culture and may require multiple urine cultures to confirm UTI.

IMAGING
- Ultrasonography and excretory urography are the best methods for presumptively differentiating between upper and lower UTI. Ultrasonography is more sensitive than excretory urography for identification of mild-to-moderate acute pyelonephritis.
- Ultrasonographic findings supporting pyelonephritis include dilation of the renal pelvis and proximal ureter and a hyperechoic mucosal margin line within the renal pelvis and/or proximal ureter.
- IV urography may reveal decreased opacity of the nephrogram phase, dilation and blunting of the renal pelvis with lack of filling of the collecting diverticula, decreased opacity of contrast media in the collecting system, and dilation of the proximal ureter.
- In patients with acute pyelonephritis, the kidneys may be large; in patients with chronic pyelonephritis, the kidneys may be small, with an irregular surface contour.
- Concomitant nephroliths detected in some patients by survey radiography or ultrasonography.

DIAGNOSTIC PROCEDURES
Definitive diagnosis requires urine cultures obtained from the renal pelvis. Pyelocentesis can be performed percutaneously using ultrasound guidance or during exploratory surgery. Urine cultures from the renal pelvis usually are similar to cultures from the bladder unless obstruction is present.

PATHOLOGIC FINDINGS
- Kidneys affected by chronic pyelonephritis may have areas of infarction and scarring on the capsular surface. The renal pelvis and collecting diverticula may be dilated and distorted from chronic infection and inflammation. Purulent exudate is occasionally observed in the renal pelvis.

• Light microscopic findings include papillitis, pyelitis, interstitial nephritis, and leukocyte casts in tubular lumens.

TREATMENT

APPROPRIATE HEALTH CARE
Outpatient treatment with oral antibiotics if the animal is clinically well. Hospitalized care if patient is dehydrated, has decreased renal function or if sepsis is suspected.

ACTIVITY
Unlimited

DIET
Renal therapeutic diets are recommended for concomitant CKD.

CLIENT EDUCATION
• Recurrent pyelonephritis may be asymptomatic. Unresolved chronic pyelonephritis may lead to progression of CKD; diagnostic follow-up is important to document resolution or progression of pyelonephritis.
• In patients with infected nephroliths, resolution of pyelonephritis is unlikely unless the nephroliths are removed.

SURGICAL CONSIDERATIONS
• Complete obstruction of the upper urinary tract of a patient with pyelonephritis may rapidly progress to septicemia and therefore should be regarded as a medical emergency. The cause of the obstruction should be corrected by endoscopic or surgical ureteral stent placement.
• Infected nephroliths—remove surgically, medically dissolve (struvite), or fragment by extracorporeal shock wave lithotripsy; use periprocedural antibiotics to reduce the risk of urosepsis when manipulating infected nephroliths.
• Unilateral nephrectomy is usually not effective for elimination of suspected unilateral pyelonephritis.

MEDICATIONS

DRUG(S) OF CHOICE
• Base antibiotic selection on urine culture and susceptibility testing. Initiate antibiotics pending culture results.
• Antibiotics should be bactericidal, achieve good serum and urine concentrations, and not be nephrotoxic.
• High serum and urinary antibiotic concentrations do not necessarily ensure high tissue concentrations in the renal medulla; thus, chronic pyelonephritis may be difficult to eradicate.
• If systemically ill or azotemic, administer IV antibiotics for initial 48 hours.
• Give orally administered antibiotics at full therapeutic dosages for 2–6 weeks. Duration of antibiotics required for resolution of pyelonephritis is not definitively known.
• Do not use drugs that achieve good concentrations in urine but poor concentrations in serum (e.g., nitrofurantoin).

CONTRAINDICATIONS
Do not use aminoglycosides unless no other alternatives exist on the basis of urine culture and susceptibility testing.

PRECAUTIONS
Trimethoprim-sulfa combinations can cause side effects (keratoconjunctivitis sicca, blood dyscrasias, and polyarthritis) when administered for more than 4 weeks.

FOLLOW-UP

PATIENT MONITORING
Perform urine cultures and urinalysis during antibiotic administration (~5–7 days into treatment) and 1 and 4 weeks after antibiotics are finished.

PREVENTION/AVOIDANCE
Eliminate factors predisposing to UTI; correct ectopic ureters.

POSSIBLE COMPLICATIONS
Progressive CKD, recurrent pyelonephritis, struvite nephroliths, septicemia, septic shock, metastatic infection (e.g., endocarditis, polyarthritis).

EXPECTED COURSE AND PROGNOSIS
• Patients with acute or subacute pyelonephritis—fair to good, with a return to normal health unless the patient also has nephroliths, CKD, or some other underlying cause for UTI (e.g., obstruction or neoplasia).
• Established chronic infection of the renal medulla may be difficult to resolve because of poor tissue penetration of antibiotics.
• Patients with CKD caused by pyelonephritis—prognosis determined by the severity and rate of progression of the CKD.
• Recurrent pyelonephritis is likely if infected nephroliths are not removed.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Hyperadrenocorticism, exogenous glucocorticoid administration, CKD, hyperthyroidism (cats), and diabetes mellitus are associated with lower UTI, which can ascend into the ureters and kidneys.

PREGNANCY/FERTILITY/BREEDING
Use antibiotics that are safe for the pregnant bitch or queen.

SYNONYMS
Upper UTI, pyelitis.

SEE ALSO
• Chronic Kidney Disease.
• Lower Urinary Tract Infection, Bacterial.
• Lower Urinary Tract Infection, Fungal.
• Nephrolithiasis.
• Urinary Tract Obstruction.
• Urolithiasis, Struvite—Dogs.

ABBREVIATIONS
• CKD = chronic kidney disease.
• UTI = urinary tract infection.

P

PYODERMA

BASICS

DEFINITION
- Bacterial infection of the skin.
- Surface bacterial infections—often referred to as a "hot spot;" represents an acute moist dermatitis involving the surface of the skin.
- Superficial pyoderma—involves the epidermis and the intact hair follicle; includes mucocutaneous pyoderma.
- Deep pyoderma—involves the dermis and possibly subcutis; furunculosis is often present; patients can be systemically ill.

PATHOPHYSIOLOGY
- Skin infections occur when the surface barrier of the skin has been broken, the skin has become macerated by chronic exposure to moisture, the population of resident bacterial flora has been altered, circulation has been impaired, and/or immunocompetency of the patient has been negatively impacted by systemic illness or immunosuppressive therapy.
- Pyoderma is usually secondary to an underlying cause; the primary, underlying cause should be identified and managed to reduce the frequency and recurrence of skin infections.

SYSTEMS AFFECTED
Skin/exocrine.

GENETICS
N/A

INCIDENCE/PREVALENCE
- Dogs—very common.
- Cats—uncommon.

SIGNALMENT

Species
Dog and cat.

Breed Predilections
- Dog—short-coated breeds, especially those with excessive skin folds.
- German shepherd dog—severe, inflammatory and deep pyoderma that responds to antibiotics; frequently relapses.

Mean Age and Range
Age of onset is usually directly related to the underlying cause.

Predominant Sex
None

SIGNS

General Comments
- Superficial—usually involves the trunk; extent of lesions may be obscured by hair coat.
- Deep—often affects the chin, dorsal muzzle, pressure points, and feet; may be generalized and associated with symptoms of systemic illness, such as pyrexia and/or pain.

Historical Findings
- Acute or gradual onset.
- Variable pruritus—typically pruritic; the underlying cause may be pruritic or the staphylococcal infection itself may be pruritic; may not be pruritic if associated with hypercortisolemia.

Physical Examination Findings
- Papules.
- Pustules.
- Crusted papules.
- Crusts.
- Epidermal collarettes.
- Circular erythematous or hyperpigmented patches (macules).
- Alopecia; moth-eaten hair coat.
- Hemorrhagic bullae.
- Scaling.
- Lichenification.
- Erosions.
- Ulcerations.
- Target lesions.
- Abscess.
- Furunculosis, cellulitis.

CAUSES
- *Staphylococcus pseudintermedius*—most frequent dogs and cats.
- *Pasteurella multocida*—cats.
- Deep bacterial skin infections may be complicated by Gram-negative organisms (e.g., *Escherichia coli*, *Proteus* spp., *Pseudomonas* spp.).
- Rarely caused by higher bacteria (e.g., *Actinomyces*, *Nocardia*, *Mycobacteria*, *Actinobacillus*).

RISK FACTORS
- Hypersensitivity—flea allergic dermatitis; atopic dermatitis; cutaneous adverse reaction to food; contact allergic dermatitis.
- Parasites—especially *Demodex* spp.
- Fungal infection—dermatophytosis (*Microsporum canis*, *Microsporum gypseum*, or *Trichophyton mentagrophytes*) most common.
- Endocrine diseases—hypothyroidism; hyperadrenocorticism; sex hormone imbalance.
- Immunosuppression—excessive corticosteroid administration; young animals.
- Seborrhea—chin acne; schnauzer comedo syndrome.
- Conformation—short coat; skin folds; redundant interdigital skin.
- Trauma—pressure points; grooming; scratching; rooting behavior; irritants.
- Foreign body—foxtail; grass awn.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Hypersensitivity—pruritus precedes lesions; persists with resolution of pyoderma.
- Flea allergic dermatitis or atopic dermatitis—may be seasonal.
- Endocrinopathy—relapsing pyoderma; consider if not associated with pruritus or pruritus resolves with resolution of the pyoderma; may be associated with systemic symptoms.
- Pustular diseases—dermatophytosis; demodicosis; pemphigus foliaceus; and subcorneal pustular dermatosis.
- Deep furunculosis—higher bacterial infection; demodicosis; dermatophytosis; opportunistic fungal infections; deep fungal infections; panniculitis; and zinc-responsive dermatosis.
- Superficial pyoderma in short-coated breeds often misdiagnosed as urticaria due to acute onset of pruritic papules and follicular tufting.

CBC/BIOCHEMISTRY/URINALYSIS
- Superficial pyoderma—normal or may reflect underlying cause (e.g., anemia due to hypothyroidism; stress leukogram and high serum alkaline phosphatase due to hyperadrenocorticism; eosinophilia due to parasitism).
- Generalized, deep pyoderma—may demonstrate leukocytosis with a regenerative left shift and hyperglobulinemia; abnormalities related to an underlying cause may be present.

OTHER LABORATORY TESTS
N/A

DIAGNOSTIC PROCEDURES
- Multiple skin scrapings—demodicosis.
- Direct smear from intact pustule—neutrophils with intracellular bacteria, typically cocci.
- Cytology from underneath a crust or edge of an epidermal collarette; help differentiate pemphigus foliaceus (acantholytic keratinocytes) and deep fungal infections (blastomycosis, cryptococcosis) from pyoderma; tissue grains may identify filamentous organisms characteristic of higher bacteria.
- Trichograms—dermatophytosis, follicular abnormalities.
- Dermatophyte culture—dermatophytosis.
- Surface or papule/pustule cytology—pemphigus foliaceus.
- Intradermal allergy testing—atopy.
- Elimination diet trial—food hypersensitivity.
- Endocrine tests—hypothyroidism, hyperadrenocorticism.
- Skin biopsy is rarely useful unless the infection is deep in nature; utilized to obtain tissue sample for macerated tissue culture.

Culture and Susceptibility Testing
- Recommended in recurrent cases and/or failure to respond to empiric antibiotics.
- Often positive for *S. pseudintermedius*.
- Other organisms besides staphylococci and higher bacteria may be cultured from lesions of deep pyoderma.
- Contents of an intact pustule—most reliable results for superficial infections.
- Punch biopsy obtained utilizing sterile technique for macerated tissue culture; especially and removal of the epidermis for

deep pyoderma; more likely false-negative results with superficial pyoderma.
• Freshly expressed exudate from a draining tract or from beneath a crust—may yield the pathogen or a contaminant if the lesion is not intact.

PATHOLOGIC FINDINGS
• Subcorneal pustules.
• Intraepidermal neutrophilic microabscesses.
• Perifolliculitis.
• Folliculitis.
• Furunculosis.
• Nodular to diffuse dermatitis.
• Panniculitis.
• Inflammatory reaction—suppurative or pyogranulomatous.
• Tissue grains within pyogranulomas—observed most often with *Actinomyces*, *Actinobacillus*, and *Nocardia*.
• Special stains—used to identify Gram-negative bacteria or acid-fast organisms.

TREATMENT

APPROPRIATE HEALTH CARE
Usually outpatient, except for severe, generalized deep pyoderma.

NURSING CARE
• Severe, generalized, deep pyoderma—may require IV fluids, parenteral antibiotics, and/or daily whirlpool baths.
• Benzoyl peroxide or chlorhexidine shampoos—remove surface debris.
• Frequent topical therapy can help reduce the severity and frequency of recurrence.
• Whirlpool baths—deep pyoderma; remove crusted exudate; encourage drainage; decrease inflammation and improve tissue oxygenation.

DIET
Novel protein or hydrolysate diet if secondary to cutaneous adverse reaction to food.

SURGICAL CONSIDERATIONS
Fold pyoderma may require surgical correction to prevent recurrence.

MEDICATIONS

DRUG(S) OF CHOICE
• *S. pseudintermedius* isolates—usually susceptible to cephalosporins, amoxicillin–clavulanate, erythromycin, clindamycin, and trimethoprim–sulfamethoxazole; somewhat less responsive to lincomycin; frequently resistant to amoxicillin, ampicillin, penicillin.
• Amoxicillin–clavulanate—most isolates of *Staphylococcus* and *P. multocida* susceptible; generally effective for skin infections in cats.
• Superficial pyoderma—initially treated empirically with one of the antibiotics listed above.
• Recurrent, resistant, or deep infections—choose antibiotic therapy based upon culture and susceptibility testing (e.g., chloramphenicol).
• Multiple organisms with different antibiotic susceptibilities—select antibiotic on basis of the staphylococcal susceptibility.

CONTRAINDICATIONS
Corticosteroids—mask inflammation causing therapy to be discontinued prematurely and resulting in selection for resistant organisms; if used concurrently, therapy should be extended and the patient should be reevaluated before discontinuing antibiotic therapy.

PRECAUTIONS
• Cephalosporins, erythromycin, lincomycin, and clindamycin—vomiting; administer with food.
• Aminoglycosides—renal toxicity usually precludes prolonged systemic use.
• Trimethoprim–sulfamethoxazole—kerato-conjunctivitis sicca, fever, hepatotoxicity, polyarthritis, and hematologic abnormalities, especially neutropenia; not recommended for use in Doberman pinschers.
• Chloramphenicol—use with caution in cats; mild, reversible anemia in dogs (uncommon); associated with aplastic anemia in humans; rear temporary limb muscle weakness is a possible side effect.

POSSIBLE INTERACTIONS
Trimethoprim-sulfamethoxazole—falsely decreased thyroid hormone test results.

ALTERNATIVE DRUG(S)
Bacterin (Staphage Lysate, Delmont Laboratories), staphoid AB, or autogenous injections—may improve antibiotic efficacy and decrease infection recurrence.

FOLLOW-UP

PATIENT MONITORING
Administer oral antibiotics for a minimum of 7–10 days beyond clinical cure; approximately 3–4 weeks for superficial pyoderma; 6–10 weeks for deep pyoderma.

PREVENTION/AVOIDANCE
• Routine bathing with benzoyl peroxide or chlorhexidine shampoos—may help prevent recurrences.
• Padded bedding—may ease pressure point pyoderma; also consider causes for poor wound healing including hypothyroidism.
• Topical benzoyl peroxide gel or mupirocin 2% ointment may be helpful adjunct therapies—chin acne, fold pyoderma, respectively.
• Identification and management of the underlying cause is crucial to prevent recurrence.

POSSIBLE COMPLICATIONS
Bacteremia and septicemia.

EXPECTED COURSE AND PROGNOSIS
Likely to be recurrent or nonresponsive if underlying cause is not identified and effectively managed.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
• Impetigo—affects young dogs before puberty; can be associated with poor husbandry; often requires only topical therapy.
• Superficial pustular dermatitis—occurs in kittens; associated with overzealous "mouthing" by the queen.
• Pyoderma secondary to atopic dermatitis—usually begins between 1 and 3 years of age.
• Pyoderma secondary to endocrine disorders—usually begins in middle adulthood.

ZOONOTIC POTENTIAL
• Cutaneous tuberculosis—rare.
• Feline leprosy—unknown.

PREGNANCY/FERTILITY/BREEDING
N/A

SEE ALSO
• Acne—Cats.
• Acne—Dogs.
• Perianal Fistula.
• Pododermatitis.

P

PYODERMA—METHICILLIN-RESISTANT

BASICS

OVERVIEW

• Staphylococcal bacterial skin infection resistant to *all* β-lactam antibiotics.
• Most often caused by *Staphylococcus pseudintermedius*; rarely *Staphylococcus aureus*.

SIGNALMENT

Dogs and Cats

• More common with chronic, primary skin conditions; associated with exposure to one or more courses of antibiotic therapy.
• Pyoderma less common in cats.

SIGNS

Dogs and Cats

• Papules. • Pustules. • Crusts. • Crusted papules. • Epidermal collarettes.
• Furunculosis, cellulitis if deep. • Circular erythematous or hyperpigmented spots (macules). • Alopecia, moth-eaten hair coat, especially in short-coated breeds.
• Hemorrhagic bullae. • Scale.
• Lichenification. • Abscess. • Pyoderma that persists despite appropriate empiric therapy.

CAUSES & RISK FACTORS

• Hypersensitivity—flea allergic dermatitis; atopic dermatitis; cutaneous adverse reaction to food; contact allergic dermatitis.
• Parasites—especially *Demodex* spp.
• Endocrine—hypothyroidism; hyperadrenocorticism (especially if nonpruritic).
• Immunosuppression—iatrogenic due to chronic glucocorticoid therapy; young animals. • Seborrhea—chin acne; schnauzer comedo syndrome. • Additional—short coat; skin folds; redundant interdigital skin; trauma of pressure points, especially in hypothyroid dogs; excessive grooming; scratching; rooting behavior; irritants; foreign bodies (foxtail; grass awn).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Dogs

• Demodicosis. • Dermatophytosis.
• Methicillin-sensitive pyoderma.
• Pemphigus foliaceus. • Systemic lupus erythematosus. • Other primary causes for pyoderma. • Epitheliotropic lymphoma (older animals).

Cats

• Dermatophytosis. • Flea-allergic dermatitis.
• Demodicosis. • Pemphigus foliaceus.
• Methicillin-sensitive pyoderma.
• Epitheliotropic lymphoma in older animals.

CBC/BIOCHEMISTRY/URINALYSIS

Generalized, deep pyoderma—may demonstrate leukocytosis with regenerative left shift and hyperglobulinemia; in addition, may reflect underlying cause; sepsis is a concern, especially if patient is immunosuppressed.

DIAGNOSTIC PROCEDURES

• Culture and susceptibility testing—*essential* when methicillin-resistant infection is suspected; should be performed when there is inadequate response to empiric treatment with antibiotics or in cases with a history of methicillin-resistant *S. pseudintermedius* (MRSP). • Multiple skin scrapings—demodicosis. • Direct smear from intact pustule—neutrophils with intracellular bacteria. • Cytology—from underneath crust or edge of epidermal.collarette. • Skin biopsy—rarely useful unless infection deep; used to obtain tissue sample for macerated tissue culture. • Dermatophyte culture—fungal infection. • Intradermal allergy testing—atopic dermatitis. • Elimination diet trial—cutaneous adverse reaction to food.
• Endocrine tests—hypothyroidism, hyperadrenocorticism.

PATHOLOGIC FINDINGS

• Subcorneal pustules. • Intraepidermal neutrophilic microabscesses. • Perifolliculitis.
• Folliculitis. • Furunculosis—deep infection. • Nodular to diffuse dermatitis.
• Panniculitis—deep infection.
• Inflammatory reaction—suppurative; pyogranulomatous with deep infections.

TREATMENT

• Topical therapy essential—chlorhexidine shampoo or spray, dilute bleach bathing, mupirocin ointment, for localized disease.
• Some cases resolve with topical therapy only—must be consistent/frequent.
• Generalized, deep pyoderma—hospitalization, IV fluids, IV antibiotics, whirlpool baths, depending on severity and risk for sepsis.

MEDICATIONS

DRUG(S) OF CHOICE

• Antibiotic therapy must be based on culture and susceptibility data. • Appropriate antibiotics must be administered long enough to resolve infection.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Corticosteroid steroids—masks inflammation and suppresses immune system function; therapy should be discontinued. Oclacitinib—may suppress immune system function and delay resolution.

FOLLOW-UP

PATIENT MONITORING

Regular reevaluation of patient while still receiving treatment aids in decision regarding continuation of therapy or need for additional diagnostic tests.

PREVENTION/AVOIDANCE

• Choose antibiotic therapy from culture and susceptibility data—treatment failure occurs when antibiotic changes made without evidence. • Successful management of underlying disease. • Handwashing before and after handling patient.

EXPECTED COURSE AND PROGNOSIS

• Good if antibiotic choice is based on culture and susceptibility data and underlying cause is managed. • Methicillin-resistant infections not more virulent, but fewer antibiotic choices available for treatment.

MISCELLANEOUS

ZOONOTIC POTENTIAL

• Exposure of humans and animals to methicillin-resistant *S. aureus* (MRSA) and MRSP is common. • MRSP infections in humans are rare. • MRSP is not MRSA—MRSA infections in animals are rare and most associated with exposure to humans with MRSA infection.

SEE ALSO

• Pododermatitis.
• Pyoderma.

ABBREVIATIONS

• MRSA = methicillin-resistant *S. aureus*.
• MRSP = methicillin-resistant *S. pseudintermedius*.

P

PYOMETRA

BASICS

DEFINITION
Pyometra is a bacterial suppurative inflammation of the endometrium leading to intraluminal accumulation of purulent exudate within the uterus.

PATHOPHYSIOLOGY
- Incompletely understood and multifactorial.
- Classic theory—repeated exposure of endometrium to high concentrations of estrogen during proestrus and estrus followed by high concentrations of progesterone during diestrus without pregnancy leads to development of cystic endometrial hyperplasia (CEH), which predisposes uterus to ascending bacterial infections.
- Strains of *Escherichia coli* with uropathogenic virulence factors that allow adhesion to the endometrium and establishment of an infection without CEH enter uterus during proestrus and estrus and act as a mucosal irritant stimulating development of CEH under the influence of progesterone. Uterine secretions may act as a growth medium for ascending bacteria.
- Regardless of underlying cause, pyometra does not occur in absence of progesterone (endogeneous or exogeneous).

SYSTEMS AFFECTED
- Reproductive.
- Hemic/lymphatic/immune.

GENETICS
- Genetic predisposition suspected in some related bitches.
- Suggested breed predisposition in Bernese mountain dog, Rottweiler, rough-coated collie, oriental cat breeds.

INCIDENCE/PREVALENCE
Accurate assessment difficult because most dogs and cats in the United States undergo elective ovariohysterectomy (OHE). A recent Swedish study reported overall incidence of pyometra in bitches as 199 per 10,000 dogs at risk and in queens as 17 per 10,000 cats at risk. Lower incidence in queens because they are induced ovulators.

SIGNALMENT
Species
Dog and cat.

Mean Age and Range
Usually >6 years old; range 4 months to 16 years; mean 7.25 years.

Predominant Sex
- Female—ovary intact.
- Spayed bitches and queens with ovarian remnant syndrome may develop a stump pyometra.

SIGNS
Historical Findings
- Dogs—usually within 12 weeks of last estrus.
- Cats—usually within 4 weeks of last estrus.
- History of treatment with estrogens and/or progestogens.

Physical Examination Findings
- Uterus—may be enlarged on abdominal palpation.
- Systemic illness—depends on duration and severity.
- Open cervix—bloody, purulent vaginal discharge, may not be noticed in queens.
- Closed cervix—systemically ill from endotoxemia and bacteremia: polyuria, polydipsia, lethargy, inappetence/anorexia, vomiting, abdominal distension, dehydration, shock.
- Pyrexia.

CAUSES
- Dogs—repeated exposure of endometrium to estrogen followed by prolonged exposure to progesterone without pregnancy.
- Cats—may be the result of estrogen at estrus followed by a progestational (pseudopregnancy) phase caused by spontaneous ovulation or ovulation induction.

RISK FACTORS
- Middle-aged to older, nulliparous ovary-intact females may be predisposed.
- Pharmacologic use of estrogen (mismate shot) during midestrus to early diestrus.
- No correlation with pseudopregnancy in dogs.
- Long-term and high-dose use of progestagens (for estrus prevention) in both queens and bitches.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Pregnancy.
- Vaginitis.
- Metritis and retained fetal membranes (associated within first days post partum).
- Hydrometra (serous intrauterine discharge); mucometra (mucoid intrauterine discharge); hematometra (hemorrhagic intrauterine discharge).
- Other causes of polyuria/polydipsia—diabetes mellitus, hyperadrenocorticism, renal disease.

CBC/BIOCHEMISTRY/URINALYSIS
- Neutrophilia or neutropenia with left shift ± toxic change; more severe with closed cervix.
- Normocytic, normochromic anemia.
- Hyperglobulinemia, hyperproteinemia, hypoalbuminemia, hypercholesterolemia, elevated C-reactive protein concentration.
- Azotemia.
- Elevated alanine aminotransferase and alkaline phosphatase enzyme activities.
- Electrolyte disturbances.
- Urinalysis—isosthenuria, bacteriuria, glucosuria, and proteinuria possible. Collect sample by catheterization of urinary bladder to avoid risk of uterine puncture with cystocentesis. Midstream urine sample may be contaminated by vaginal discharge.

OTHER LABORATORY TESTS
- Cytologic examination of vulvar discharge—degenerate neutrophils, phagocytized bacteria; may be indistinguishable from purulent discharge associated with vaginal disease (e.g., vaginitis, vaginal mass, foreign object). Vaginoscopy can confirm origin and rule out other causes of discharge.
- Bacterial culture and sensitivity—vulvar discharge sample to be taken directly from the uterus transcervically or cranial vagina with the aid of a vaginal speculum and guarded swab. A free-catch urine sample can also be useful as the causative agent in the pyometra is often located in the bladder.
- Serologic testing for *Brucella canis*—rapid slide agglutination test as a screen; sensitive but not specific. If positive, recheck by an agar gel immunodiffusion test or bacterial culture of whole blood, lymph node aspirate, or vulvar discharge.
- Hormone assay—in most cases, progesterone concentration will be >2 ng/mL; important to measure in animals that present in anestrus, as treatment with a progesterone receptor antagonist will be ineffective.

IMAGING
Radiography
- Enlarged, distended uterus (see Web Figure 1).
- Rule out pregnancy— fetal skeletal ossification occurs 45 days after ovulation.

Ultrasonography
- Uterine horns distended with intraluminal fluid, with or without flocculation. Uterine wall thickened with irregular edges and small hypoechoic areas consistent with cystic change (CEH) (see Web Figure 2), uterine wall can appear thin if severely distended; monitoring of the volume of uterine fluid is necessary during medical therapy; presence of severe CEH and/or ovarian cysts associated with poorer prognosis for medical management and fertility.
- Rule out pregnancy—20–24 days after ovulation.
- Pyometra may rarely occur with pregnancy in dogs.

DIAGNOSTIC PROCEDURES
Vaginoscopy—indicated in dogs with purulent vulvar discharge and no apparent uterine enlargement; allows determination of site of origin of the discharge; not possible in cats.

PYOMETRA (CONTINUED)

PATHOLOGIC FINDINGS

• Endometrium (dogs and cats)—cobblestone appearance (see Web Figure 3).
• Cystic endometrial surface—covered by malodorous, mucopurulent exudate; thickened by increased endometrial gland size and cystic gland distension.

TREATMENT

APPROPRIATE HEALTH CARE

• Inpatient; life-threatening condition if the cervix is closed, resulting in endotoxemia, bacteremia, and sepsis. Resuscitation requires immediate IV fluid administration and broad-spectrum antibiotics to stabilize for anesthesia and surgery.
• Open-cervix pyometra may be a candidate for medical therapy.

NURSING CARE

Supportive care.

CLIENT EDUCATION

• Medical treatment only recommended for valuable, young (<4 years) breeding animals that are not azotemic and systemically well. For all other animals, OHE is the treatment of choice. The prognosis for successful medical treatment and future fertility in older animals and animals with evidence of uterine and ovarian pathology is poor.
• Historically, medical treatment of closed-cervix pyometra was associated with uterine rupture and peritonitis, but new pharmacologic agents and treatment protocols now make this a rare event.
• Bitches that are refractory or chronic cases that do not respond to medical treatment are candidates for OHE.
• Warn of possible recurrence of pyometra after medical therapy—important to breed at the next heat and spay when desired number of litters is achieved.

SURGICAL CONSIDERATIONS

• Complete OHE is the preferred treatment in all animals not intended for breeding, older bitches (>4 years), bitches with evidence of chronic CEH changes and/or ovarian follicular cysts, bitches that present systemically unwell and require immediate emergency care and stabilization.
• Patients should be systemically stabilized prior to anesthesia for surgery (correction of any acid–base derangements, dehydration, hypotension, shock, electrolyte abnormalities, arrythmias) and administered IV fluids and IV broad-spectrum antibiotics.
• Closed-cervix pyometra—exercise great care in handling the enlarged and friable uterus (see Web Figure 4).
• Place saline-soaked laparotomy sponges in abdomen to prevent leakage of purulent material into peritoneal cavity.

MEDICATIONS

DRUG(S) OF CHOICE

Antibiotics

• Empirical, pending results of bacterial culture and sensitivity:
  ◦ Broad-spectrum—ampicillin 22 mg/kg PO, IV q8h; amoxicillin and clavulonic acid 22 mg/kg, PO, q12h; ampicillin and sulbactam 22–30 mg/kg IV q8–12h or cefazolin 22 mg/kg IV, IM q8h combined with enrofloxacin 5–10 mg/kg PO q24h.
  ◦ Continue for at least 14 days after resolution of vulvar discharge and fluid in uterine lumen.
• Rationale of medical therapy—remove progesterone and its effects on uterus, eliminate bacteria from uterus, promote cervical dilation and drainage of pus from the uterus.

Aglepristone

• Progesterone receptor antagonist; competitively binds to progesterone receptor with greater affinity than natural progesterone, preventing biological effect of progesterone. Will not lower progesterone levels.
• Dose—10 mg/kg SC, days 1, 2, 8, and if not cured day 14 and 28 in bitches. An additional injection at day 5 has been associated with an improved treatment success rate. In queens, 15 mg/kg SC is recommended. Minimal side effects. Excellent choice for closed pyometras as it dilates the cervix with minimal uterine contractions. Evacuation of uterus may be improved by adding prostaglandin. Aglepristone is not registered or approved by FDA in United States and not suitable for use in bitches with poor liver or kidney function.

Prostaglandins (PGF2α)

• Doses listed here for native compound only (dinoprost tromethamine; Lutalyse®); has both luteolytic and ecobolic actions.
• Lower doses minimize side effects and ecobolic effect, especially in closed pyometras. Once the cervix is fully dilated the dose can be gradually increased if tolerated.
• Animals should be monitored in hospital for at least 1 hour after each treatment. If animal is systemically well, may be managed as outpatient.
• Side effects (dose-dependent)—tachypnea, vomiting, diarrhea, urination, anxiety; seen 20 minutes after administration and last for 15–30 minutes. Use of PGF2α in brachycephalic breeds is contraindicated due to their predisposition to bronchospasm.
• Dogs and cats—10 µg/kg SC q5-6h day 1, then increase to 20–25 µg/kg q5–6h if tolerated for 1–2 days; then increase to 50 µg/kg q5–6h for 3–4 days. Queens are more resistant to PGF2α than bitches; often higher doses for longer periods are required.

Cloprostenol

• Synthetic PGF2α analogue; longer action (>30 hours) than natural form of PGF2α.
• Dogs—1 µg/kg SC q24h for 7–14 days; convenience of once a day or every 2–3 days treatment but greater side effects, stimulates less uterine contractions and prolonged time to resolution compared to natural form of PGF2α.

Dopamine Agonists

Cabergoline (5 µg/kg PO q24h for 7–14 days) or bromocriptine (10–20 µg/kg PO q8h); both given with food to reduce risk of vomiting; cabergoline has fewer side effects. Prolactin antagonists (e.g., have luteolytic action); best used in combination with PGF2α—should see cervical opening within 24–48 hours. Only effective after 25 days post ovulation.

CONTRAINDICATIONS

High-dose PGF2α and cloprostenol cause strong uterine contractions that may cause uterine rupture or force purulent exudate through the oviducts if used with closed-cervix pyometra.

ALTERNATIVE DRUG(S)

Misoprostol—synthetic PGE1 analogue (10 µg/kg PO or 200 µg tablet in <20 kg and 400 µg in >20 kg bitch intravaginally). Side effects minimal, facilitates cervical relaxation. Best used in combination with aglepristone and PGF2α (PGE1 does not induce luteolysis).

FOLLOW-UP

PATIENT MONITORING

• OHE—For patients not responding to medical treatment within 5 days or those refractory to medical treatment.
• Clinical improvement should be seen within 48 hours after initiation of treatment:
  ◦ Vaginal discharge—should reduce in volume and character over 5 days.
  ◦ Ultrasonography—to assess response to treatment; reduction in uterine wall thickness and intraluminal fluid should be seen within 3 days after start of treatment; fluid in lumen should be absent within 5–7 days.
• Serum progesterone concentrations decline within 48 hours of treatment with PGF2α and should be <2 ng/mL at 5–7 days; recurrence of pyometra can occur if complete luteolysis not achieved.
• CBC should return to normal within 2 weeks.
• Continue treatment until no vulvar discharge is present and no fluid is seen within uterus on ultrasound. Prolonged treatment correlated with poor fertility.

PREVENTION/AVOIDANCE

• Animals not intended for breeding should be spayed.

• Exogenous progestagens for estrus suppression should be used with caution.
• Breeding females should be bred while they are young (<4 years) and spayed as soon as the desired number of litters has been obtained; a pregnant uterus reduces the risk of developing pyometra and maximizes uterine health.
• Animals that have been medically treated for pyometra should be bred on the very next estrus; gravid uterus is less susceptible to reinfection.
• Antimicrobial therapy at subsequent heat may or may not be helpful (controversial). Antibiotic selection based on culture and sensitivity of uterine fluid until 21 days of gestation.
• Mibolerone (androgen-receptor agonist) may be helpful following medical treatment of pyometra to postpone subsequent heat and allow endometrium to repair.

POSSIBLE COMPLICATIONS

• Recurrence of pyometra at subsequent heats.
• Uterine rupture leading to sepsis.
• Bacteremia-associated infection affecting various organs (i.e., uveitis, septic arthritis, osteomyelitis, etc.).

EXPECTED COURSE AND PROGNOSIS

• Prognosis for survival is good if uterine rupture does not occur; 4% mortality rate in bitches and 8% in queens.
• Prognosis for response to medical therapy is good, especially if young, healthy animals (average 86% in bitches; 95% in queens).
• Recurrence rate of pyometra is dependent on age, parity, and preexisting uterine pathology (reported range 20–65%).
• Variable pregnancy rates reported after treatment for pyometra (50–90%).

MISCELLANEOUS

ASSOCIATED CONDITIONS

Pyometra of the uterine stump in spayed animals—may develop any time after ovariohysterectomy; associated with ovarian remnant.

PREGNANCY/FERTILITY/BREEDING

Drugs used for treatment of pyometra are abortificants—always rule out pregnancy before administration, caution while handling.

SEE ALSO

• Breeding, Timing.
• Infertility, Female—Dogs.
• Ovarian Remnant Syndrome.

ABBREVIATIONS

• CEH = cystic endometrial hyperplasia.
• OHE = elective ovariohysterectomy.
• PGF2α = prostaglandin F2α

PYOTHORAX

BASICS

DEFINITION
Accumulation of septic suppurative inflammation in the pleural cavity.

PATHOPHYSIOLOGY
• Infectious—from transpulmonary, transesophageal, or transthoracic inoculation of bacteria into the pleural space, with subsequent suppurative pleuritis. • Dogs—often associated with an inhaled grass awn or other foreign object or a penetrating wound to the thorax. • Other causes include extension of discospondylitis, esophageal perforation, parasitic migration, hematogenous spread, previous thoracic surgery, and neoplasia with abscess formation. • Cats—most commonly associated with penetrating bite wounds, foreign bodies, or aspiration of oropharyngeal flora and extension of subsequent pneumonia into the pleural space.

SYSTEMS AFFECTED
• Respiratory. • Cardiovascular. • Renal—protein-losing nephropathy.

GEOGRAPHIC DISTRIBUTION
Etiology is regionally dependent. For example, inhaled grass awn or foxtails are common in the western United States. *Spirocerca lupi* should be considered as a predisposing cause in endemic areas (Africa, Asia, southeastern United States).

SIGNALMENT

Species
Dog and cat.

Breed Predilections
Dogs—hunting and sporting breeds; for example, Labrador retrievers, German shorthaired pointers, springer spaniels, and border collies.

Mean Age and Range
Median ~4 years, although there is wide variation.

Predominant Sex
Male animals overrepresented.

SIGNS

General Comments
• Often insidious in onset, with few clinical signs until late in the course of disease. • Respiratory compromise—often not severe unless disease is advanced. • Vomiting/diarrhea may be initial presenting complaint in 25% of canine cases.

Historical Findings
• Diminished activity. • Collapse after exercising and slow recovery. • Weight loss and partial anorexia can be the only clinical signs.

Physical Examination Findings
• Tachypnea. • Cachexia. • Cough. • Pyrexia. • Thoracic auscultation—muffled heart and lung sounds. • Cats—may show few clinical signs before onset of apparently acute respiratory distress, collapse, and septic shock; bradycardia and hypersalivation associated with poor outcome. • Injury to the thoracic wall—may not be apparent or may be healed at the time of examination.

CAUSES
• Infectious—Dogs: *Actinomyces* spp., *Nocardia* spp., anaerobes (*Bacteroides*, *Peptostreptococcus*, *Fusobacterium*), *Corynebacterium*, *Escherichia coli*, *Pasteurella*, and *Streptococcus* spp.; fungal agents. Cats: oral commensals (e.g., *Pasteurella multocida* and *Bacteroides* spp.) most common; obligate anaerobes (*Peptostreptococcus*, *Fusobacterium*) common. • Parasitic—Dogs: esophageal rupture of *S. lupi* granuloma. • Neoplastic—rarely with intrathoracic tumors secondary to tumor necrosis.

RISK FACTORS
• Dogs—hunting, field trials, and other strenuous outdoor sporting activities; *S. lupi* endemic areas. • Cats—multiple cat households, outdoor cats, pneumonia, upper respiratory infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Other pleural effusions—chylothorax and hemothorax; nonseptic exudates (feline infectious peritonitis or neoplasia); transudative effusions; differentiated via cytologic examination. • Diseases associated with fever of unknown origin should be considered for animals with nonlocalizing signs.

CBC/BIOCHEMISTRY/URINALYSIS
• Marked neutrophilic leukocytosis with left shift, monocytosis, and anemia of chronic disease. • Regenerative anemia—can be seen with substantial hemorrhage into the pleural cavity. • Hyperglobulinemia—possible due to chronic inflammation. • Hypoalbuminemia as a negative acute-phase reactant or due to renal loss, if glomerulonephritis results from chronic antigenic stimulation. • Azotemia—prerenal and/or renal.

IMAGING
• Radiography—unilateral or bilateral pleural effusion with pleural fissure lines; pulmonary parenchymal lesions (consolidation, atelectasis, masses) common; mediastinal lesions possible. • Ultrasonography—pleural effusion; may show marked amount of fibrinous deposition in the pleural space; may identify consolidated lung masses, mediastinal masses, and abscessed or neoplastic lung nodules. • CT—focal interstitial to alveolar pulmonary opacities; pleural thickening; enlarged intrathoracic lymph nodes; pleural effusion; pneumothorax; and foreign body identification.

DIAGNOSTIC PROCEDURES

Thoracocentesis
• Cytologic evaluation—necessary to confirm the diagnosis; many effusions appear grossly hemorrhagic. • Gram stains—can facilitate early identification of pathogenic organisms. • Sulfa granules (small accumulations of purulent debris) in the exudate—characteristic of infection by filamentous organisms (e.g., *Actinomyces* and *Nocardia*). • Organisms are often seen on cytologic examination, often within degenerative neutrophils.

Microbiology
• Culture fluid samples aerobically and anaerobically. Consider *Mycoplasma* culture if standard cultures are negative. • Filamentous, anaerobic organisms are slow-growing or difficult to grow; cultures should be maintained longer than standard samples. • Sulfa granules—maceration may enhance culturing; contain higher concentrations of bacteria. • Fungal organisms—culture depends on history and geographic location. • Urine samples—culture with suspected pyelonephritis.

Esophagoscopy
If *S. lupi* is suspected.

PATHOLOGIC FINDINGS
• Fibrinous and suppurative pleuritis, with or without pulmonary abscessation. • Organisms may be identified on histopathology. • Glomerulonephritis.

TREATMENT

APPROPRIATE HEALTH CARE
• Inpatient—often for several days to weeks. • Treat like any abscess; drainage is critical—without it resolution is highly unlikely. • Surgical exploration, debridement, and potential lobectomy required in some cases.

NURSING CARE
• Continuous evacuation via tube thoracostomy with low-pressure suction through a perforated tube; use a large-bore tube to minimize occlusion; continue until net drainage is <2–3 mL/kg/day and intracellular bacteria are no longer visible on Gram stain; drainage may be slightly higher with red rubber tubes because they are more irritating. • Cats—usually require general anesthesia for tube placement. • Dogs with severe respiratory compromise—may

substitute local anesthesia and regional analgesia for general anesthesia. • Periodic thoracic radiography—to ensure proper tube placement, and lack of pocketing or loculation of exudate, determine whether bilateral tube placement is necessary; document primary pulmonary pathology that may not have been apparent on initial examination. • Thoracic lavage—every 6–8 hours with warm, sterile saline; may help break down consolidated debris. Consider addition of heparin (1,500 units/L) to lavage fluid. • Coupage (rapid thoracic percussion)—may help remove consolidated debris. • Repeat bacterial culture if the patient fails to improve.

ACTIVITY

• Inpatient—encourage light exercise (10 minutes every 6–8 hours); promotes ventilatory efforts and helps break down pleural adhesions. • After discharge, gradually increase exercise over 2–4 months.

DIET

• High-calorie food. • Consider feeding tube placement if prolonged anorexia.

CLIENT EDUCATION

Warn client that the duration of treatment (inpatient and outpatient) is long and expensive; recurrence is possible with either medical or surgical management.

SURGICAL CONSIDERATIONS

• Surgery—higher cure rate expected with surgery if pulmonary abscessation, pleural fibrosis, lung lobe torsion, extensive loculation of pus is present, or if mediastinum is involved. • Thoracoscopy can be utilized as an intermediate step to assess degree of severity and need for more aggressive intervention. • Identified foreign body via thoracic imaging (radiography, ultrasound, or CT)—thoracotomy and retrieval indicated; grass awns are uncommonly found, even during surgery.

MEDICATIONS

DRUG(S) OF CHOICE

Antimicrobials

• Ultimately, choice determined by results of *in vitro* sensitivity testing. • Suspected specific pathogen—initiate treatment before culture results are available; choose on the basis of common antibiotic sensitivities of particular organisms; *Actinomyces* spp. and *Bacteroides* (non-*fragilis*) spp. often susceptible to beta-lactams or lincosamides; *Nocardia* spp. often susceptible to potentiated sulfonamides; obligate anaerobic bacteria (including *B. fragilis*) susceptible to amoxicillin–clavulanic acid, chloramphenicol, and usually metronidazole; *Pasteurella* spp. often susceptible to potentiated penicillins. • Ampicillin or amoxicillin with a β-lactamase inhibitor—ampicillin and sulbactam 20–30 mg/kg IV q8h followed by amoxicillin–clavulanic acid 12–25 mg/kg PO q8h when medications can be given orally. • Clindamycin 5.5–11.0 mg/kg IV or PO q12h. • Multiple antibiotics occasionally necessary.

Analgesics

• Required following thoracotomy or during thoracocentesis. • Consider multimodal analgesia—systemic opioids, nonsteroidal anti-inflammatory drugs; intrapleural analgesia.

CONTRAINDICATIONS

Glucocorticoids and immunosuppressive agents—avoid with infectious pyothorax.

PRECAUTIONS

Potentiated sulfas—can be associated with keratoconjunctivitis sicca, polyarthropathy, hypothyroidism, thrombocytopenia, and anemia, especially with prolonged use.

FOLLOW-UP

PATIENT MONITORING

• Decreasing thoracic fluid production, decrease in cell count in pleural fluid, and absence of bacteria usually noted within 4–7 days indicate that drains can be removed. Fluid should be submitted for aerobic and anaerobic culture at the time of drain removal. • Evaluate thoracic radiographs—ensure adequate evacuation of fluid. • Antibiotics—continue for 1 month after the patient is clinically normal, the hemogram is normal, and there is no radiographic evidence of fluid reaccumulation; average duration of therapy is 3–4 months but may continue for 6–12 months or longer. • Assess CBC and radiographs monthly—residual radiographic changes may be permanent, but fluid should be absent.

POSSIBLE COMPLICATIONS

• Incorrect insertion of the thoracostomy tube—may prevent adequate drainage or produce pneumothorax; placement too far cranially may put pressure on brachial arteries and veins, resulting in unilateral limb edema or lameness; lung laceration during placement. • Persistent, recurrent pyothorax—compartmentalization of exudate; premature discontinuation of treatment; pulmonary lesions. • Chronic fibrosing pleuritis and poor performance after apparent recovery—may occasionally respond to further surgery. • Persistent granulomatous mediastinitis.

EXPECTED COURSE AND PROGNOSIS

• With aggressive management—prognosis fair to excellent (60–90% survival). • Dependent on severity of clinical signs. • Overall better prognosis in dogs (83%) than in cats (62%). • Return to performance—dependent on chronicity of disease and level of management.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Retroperitoneal abscessation and discospondylitis caused by migration of a foreign body through the diaphragm into the retroperitoneal space—occasionally seen. • Glomerulonephropathy—can be reversible with successful resolution of pyothorax.

SYNONYMS

• Empyema. • Pleurisy. • Suppurative pleuritis.

SEE ALSO

• Chylothorax.
• Dyspnea and Respiratory Distress.
• Panting and Tachypnea.
• Pleural Effusion.

PYRETHRIN AND PYRETHROID TOXICOSIS

BASICS

OVERVIEW

• Insecticides. • Pyrethrins—natural. • Pyrethroids—synthetic. • Based on cases managed by the ASPCA Animal Poison Control Center exposures reported by generic from most to least are permethrin, deltamethrin, flumethrin, etofenprox, pyrethrins, cyfluthrin, cyphenothrin, imiprothrin and lambda cyhalothrin. • Affect the nervous system—reversibly prolong sodium conductance in nerve axons, resulting in repetitive nerve discharges. • With the advent of oral insecticides, safer topicals, and improved client education pyrethrin/pyrethroid adverse event reports continue to decrease. In 2017, 15.1% of all insecticide-related calls to the ASPCA Animal Poison Control Center were attributed to pyrethrin/pyrethroid-containing products.

SIGNALMENT

More frequently in cats; small dogs; and young, old, sick, anemic, or debilitated animals.

SIGNS

• Result from immune-mediated allergic hypersensitivity and anaphylactic reactions, genetic-based idiosyncratic reactions, and neurotoxic reactions. • Mild—hypersalivation; paw flicking; ear twitching; mild depression; vomiting; diarrhea. • Moderate—protracted vomiting and diarrhea; marked depression; ataxia; muscle tremors. • Extreme dermal or oral overdose—may produce seizures or death. • Cats—sensitive to pyrethroids. Cats inappropriately treated with permethrin-containing products for use on dogs, often develop muscle tremors, ataxia, seizures, hyperthermia, and death within hours if not treated. • Dogs may develop tremors following exposure to liquid or granular lawn products containing bifenthrin. • Allergic reactions—urticaria; hyperemia; pruritus; anaphylaxis; shock; respiratory distress; (rarely) death.

CAUSES & RISK FACTORS

• Cats—more sensitive; less-efficient metabolic pathways, combined with grooming habits. Direct contact with permethrin spot-on treated dogs. • Patients with subnormal body temperatures after bathing, anesthesia, or sedation—predisposed to clinical signs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Exposure history (amount and frequency of product usage), type and severity of clinical signs, and onset and duration of clinical signs—must be consistent before a tentative diagnosis can be made. • Misapplication of permethrin-containing dog-only flea product on cats. • Organophosphorous compounds, carbamate, or d-limonene toxicosis. • Strychnine, metaldehyde, tremorgenic mycotoxins, methylxanthines, amphetamines, serotonergic drug overdose, alcohol intoxication from isopropyl alcohol-based sprays.

OTHER LABORATORY TESTS

• Pyrethrins—analytical tests not generally available. • Pyrethroids—some compounds can be detected in tissues, especially on hair, to confirm exposure. Hair analysis for permethrin can be valuable when severity of the adverse event in cats is much greater than anticipated based on the reported product application. Cats with generalized full-body tremors or seizures after reported application of a cat-approved flea product are suspect for exposure to a permethrin-containing product.

TREATMENT

• Mild adverse reactions (salivation, paw flicking, and ear twitching)—often self-limiting and resolve with no care. • Continued mild signs—bathe at home with a mild hand dish-washing detergent (strictly avoid hypothermia). • Patient saturated with spray products—dry with a warmed towel; brush. • Progression to tremors and ataxia—hospitalize. • Bathing upon stabilization (tremors controlled) with liquid hand dish-washing detergent and warm water is critical. • Seriously affected patient—IV fluid support recommended. • Maintenance of a normal body temperature—critical.

MEDICATIONS

DRUG(S) OF CHOICE

• Tremors or seizures—especially for cats exposed to permethrin; methocarbamol injectable at 55–220 mg/kg IV not to exceed 330 mg/kg/day; administer one-half dose slowly IV, wait until the patient begins to relax, continue administration to effect; do not exceed 2 mL/min injection rate, and start with lower dose initially. • Diazepam at low dosages has been used to control minor hyperesthesia. Seizure control has been achieved with pentobarbital, propofol (3–6 mg/kg IV or 0.1 mg/kg/min CRI) and inhalant anesthetics. Methocarbamol remains the agent of choice and can also be used orally for treating mild tremors (50–100 mg/kg q8h; 30 minutes onset time). • Activated charcoal (2 g/kg PO) is rarely beneficial or recommended. • Emetics—rarely warranted.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Atropine sulfate—not antidotal; avoid; may cause tachycardia, CNS stimulation, disorientation, drowsiness, respiratory depression, and even seizures.

FOLLOW-UP

PREVENTION/AVOIDANCE

• Proper application of flea-control products—greatly reduces reactions. • Reduction of salivation—spray onto a grooming brush; evenly brush through hair coat. • Liquids—term "dip" common; never submerge animal; pour on body; sponge to cover dry areas. • Premise products—do not apply topically unless labeled for such use; after treating house or yard, do not allow animal in the area until product has dried, and environment has been ventilated. • Do not apply dog-only products on cats. • Do not use permethrin spot-on products on dogs in households where cats groom or sleep in physical contact with dogs.

EXPECTED COURSE AND PROGNOSIS

• Hypersalivation—may recur for several days after use of flea-control product when patient (especially cat) grooms itself. • Most clinical signs (mild to severe) resolve within 24–72 hours.

PYRUVATE KINASE DEFICIENCY

BASICS

OVERVIEW

• Red blood cells (RBCs) require energy in the form of ATP for maintenance of shape, deformability, active membrane transport, and limited synthetic activities; mature RBCs lack mitochondria and depend on anaerobic glycolysis for ATP generation.
• Pyruvate kinase (PK) catalyzes an important rate-controlling ATP-generating step in glycolysis; consequently, energy metabolism is markedly impaired in PK-deficient RBCs, resulting in shortened RBC lifespan and anemia; bone marrow compensation is reflected by erythroid hyperplasia and marked reticulocytosis.
• Hepatic failure may result from chronic iron overload.

SIGNALMENT

• Autosomal recessive trait recognized in basenji, beagle, West Highland white terrier, Cairn terrier, miniature poodle, dachshund, Chihuahua, pug, American Eskimo, and Labrador retriever dogs, and in Abyssinian, Somali, and domestic shorthair cats.
• Heterozygous-deficient Bengal, Egyptian Mau, La Perm, Maine coon, Norwegian Forest, Savannah, Siberian, and Singapura cats.
• Affected homozygous animals are generally not recognized as abnormal until several months of age or adulthood.

SIGNS

• Affected cats are often asymptomatic.
• Signs of anemia and shock (lethargy, tachycardia, exercise intolerance, pale mucous membranes).
• Splenomegaly may be present.
• Systolic heart murmur due to anemia.
• Icterus is occasionally seen in cats but rarely in dogs, unless hepatic failure present.
• Affected dogs may be slightly smaller than normal for their breed and age and may exhibit weakness and muscle wasting.
• Affected cats may exhibit diarrhea, inappetence, poor coat quality, and weight loss.

CAUSES & RISK FACTORS

• RBCs from normal adult dogs exhibit only one PK isozyme (the R-type).
• Breed-specific defects in the *PKLR* gene result in erythrocyte PK deficiency in dogs.
• A common molecular defect in the *PKLR* gene has been described in cats.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Other causes of hemolytic anemia—immune-mediated hemolytic anemia, hemotropic mycoplasmosis, babesiosis, Heinz body hemolytic anemia, microangiopathic hemolytic anemia, and phosphofructokinase deficiency (dogs).
• Affected animals—negative Coombs' test, no parasites or Heinz bodies in stained blood films, seronegative for *Babesia* spp., and no evidence of disseminated intravascular coagulation or heartworm disease.

CBC/BIOCHEMISTRY/URINALYSIS

• Dogs—persistent macrocytic hypochromic anemia, with hematocrit (HCT) of 16–28% and reticulocyte counts of 15–50%.
• Cats—anemia is intermittent (HCT 13–40%), with slightly to markedly increased aggregate reticulocyte counts.
• Normal or slightly high total leukocyte counts.
• Normal to slightly high platelet counts.
• Moderate to marked polychromasia, anisocytosis, and increased nucleated RBCs on stained blood films.
• Poikilocytosis in splenectomized dogs.
• Possible abnormal clinical chemistry findings, such as hyperferremia, hyperbilirubinemia, and slightly high serum alanine aminotransferase and alkaline phosphatase activities. Hyperglobulinemia common in cats.
• Normal urinalysis, except for bilirubinuria in dogs.

OTHER LABORATORY TESTS

• Total RBC PK activity—low value diagnostic in cats and some dogs; many affected dogs have normal or high activities because of the expression of an M2 isozyme that does not normally occur in mature RBCs; approximately 50% of normal activity in heterozygous animals.
• Additional assays (e.g., enzyme heat stability test, measurement of RBC glycolytic intermediates, electrophoresis of isozymes, and enzyme immunoprecipitation)—to reach a diagnosis in dogs whose total enzyme activity is not low.
• DNA diagnostic tests—screening for cats and several dog breeds (available at http://research.vet.upenn.edu/penngen).

TREATMENT

• Affected animals can be cured by bone marrow transplantation or gene therapy.
• Splenectomy may reduce the severity of the anemia in cats.

MEDICATIONS

DRUG(S) OF CHOICE

Long-term treatment with iron-chelating drugs might prolong the life expectancy of affected dogs.

FOLLOW-UP

• Hepatic iron overload—develops in affected dogs; can result in cirrhosis and liver failure.
• Myelofibrosis and osteosclerosis—develop in affected dogs with age; most die by 5 years old as a result of bone marrow or liver failure.
• Severe anemia with minimal reticulocytosis or abnormal liver function tests and ascites secondary to hypoalbuminemia indicate the terminal stage of the disease in dogs.

MISCELLANEOUS

ABBREVIATIONS

• HCT = hematocrit.
• PK = pyruvate kinase.
• RBC = red blood cell.

PYTHIOSIS

BASICS

DEFINITION
Infectious disease primarily affecting skin or gastrointestinal (GI) tract of dogs and cats; caused by the aquatic pathogen *Pythium insidiosum*, an organism in the class Oomycetes.

PATHOPHYSIOLOGY
- Infective form of *P. insidiosum* is thought to be a motile biflagellate zoospore, which is released into warm water environments and is chemotactically attracted to damaged tissue and animal hair; animals likely infected when they enter or ingest water containing infective zoospores.
- *P. insidiosum* considered pathogenic rather than opportunistic because immune suppression is not prerequisite for infection.
- In GI tract, *P. insidiosum* causes chronic pyogranulomatous disease with severe segmental transmural thickening of one or more areas of stomach or intestine.
- In skin, pythiosis typically causes non-healing wounds and invasive masses that contain ulcerated nodules and draining tracts.

SYSTEMS AFFECTED
- GI and cutaneous forms of disease encountered with equal frequency in dogs; cats are infrequently infected, cutaneous form more common.
- With exception of occasional dissemination to regional lymph nodes, pythiosis usually affects only one body system in each patient; multisystemic involvement rare.
- GI pythiosis most often affects gastric outflow tract, proximal small intestine, ileocolic junction, colon, and mesentery; esophagus rarely affected.
- In dogs, GI disease, local thromboembolic events, or vascular invasion may lead to bowel wall ischemia, GI perforation, or hemoabdomen.
- Dogs with cutaneous pythiosis are often presented for solitary or multiple cutaneous or subcutaneous lesions involving extremities, tailhead, ventral neck, perineum.
- In cats, cutaneous lesions or subcutaneous masses involving retrobulbar, periorbital, or nasopharyngeal regions, tailhead, or footpads have been observed.

GENETICS
Large-breed dogs most often affected; no genetic predisposition documented.

INCIDENCE/PREVALENCE
- Dependent on geographic distribution.
- Affected animals more often presented in fall or early winter.

GEOGRAPHIC DISTRIBUTION
- Primarily in tropical and subtropical areas of the world.
- In United States, occurs most often in states bordering Gulf of Mexico, but documented in many other states.
- Outside the United States, reported in Australia, Brazil, Burma, Colombia, Costa Rica, Indonesia, Japan, New Guinea, and Thailand.

SIGNALMENT

Species
Dog, less commonly cat.

Breed Predilections
- Large-breed dogs, especially those in hunting or field trial work near water.
- Labrador retrievers overrepresented.
- German shepherd dogs may be predisposed to cutaneous pythiosis.

Mean Age and Range
Animals <6 years old are most common.

Predominant Sex
Males affected more often than females, possibly due to increased exposure.

SIGNS

General Comments
Dogs not usually severely ill until late in course of disease.

Historical Findings
- Chronic weight loss, intermittent vomiting.
- Diarrhea if colon or large segment of small intestine affected.
- Regurgitation with esophageal disease.
- Cutaneous disease characterized by nonhealing wounds with nodules that drain and ulcerate.

Physical Examination Findings
GI Pythiosis
- Emaciation.
- Palpable abdominal mass.
- Despite severe weight loss, affected dogs usually bright and alert.
- Systemic signs and abdominal pain may occur with intestinal obstruction, infarction, or perforation.

Cutaneous Pythiosis
- Cutaneous or subcutaneous lesions appear as nonhealing wounds, edematous regions, or poorly defined nodules that ulcerate.
- Multiple tracts draining serosanguineous or purulent exudate.

CAUSES
P. insidiosum.

RISK FACTORS
- Environmental exposure to swampy areas, bayous, ponds, or lakes containing infective zoospores.
- Outdoor activities such as hunting.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

GI Pythiosis
- Intestinal obstruction (foreign body, intussusception).
- Histoplasmosis.
- Gastric or intestinal neoplasia (lymphosarcoma, carcinoma, etc.).
- Inflammatory bowel disease.
- Basidiobolomycosis, protothecosis.
- Histiocytic or idiopathic colitis.

Cutaneous Pythiosis
- Lagenidiosis, paralagenidiosis (caused by oomycotic pathogens in genera *Lagenidium* and *Paralagenidium*, respectively).
- Zygomycosis (infections caused by *Basidiobolus* or *Conidiobolus* spp.).
- Other mycotic skin diseases, such as cryptococcosis, coccidioidomycosis, sporotrichosis, eumycotic mycetoma, and phaeohyphomycosis.
- Nodular bacterial skin diseases, such as actinomycosis, mycobacteriosis, botryomycosis, and brucellosis.
- Protothecosis or nodular leishmaniosis.
- Noninfectious pyogranulomatous diseases, such as foreign body reaction, idiopathic nodular panniculitis, sebaceous nodular adenitis, canine cutaneous sterile pyogranuloma/granuloma syndrome.
- Cutaneous neoplasia.
- Systemic vasculitis and cutaneous embolic disease.

CBC/BIOCHEMISTRY/URINALYSIS
- Laboratory findings nonspecific.
- Eosinophilia, leukocytosis, anemia of chronic inflammatory disease possible.
- Hyperglobulinemia and/or hypoalbuminemia in chronically affected dogs.
- Hypokalemia, hyponatremia, hypochloridemia, metabolic alkalosis, in dogs with gastric outflow obstruction.
- Hypercalcemia—reported in a single dog.

OTHER LABORATORY TESTS
Serology—ELISA available at Auburn University College of Veterinary Medicine.

IMAGING
- Abdominal radiography may reveal obstructive pattern, bowel wall thickening, or abdominal mass.
- Abdominal ultrasonography may reveal segmental transmural thickening and loss of normal wall layering of the stomach, proximal small intestine, or ileocolic junction. Granulomas or enlarged lymph nodes may be evident in the mesentery.

(CONTINUED) PYTHIOSIS

DIAGNOSTIC PROCEDURES
• Biopsy of GI or skin lesions demonstrates histologic changes suggestive of, but not definitive for, pythiosis.
• Definitive diagnosis is based on specific PCR amplification or sequencing of DNA extracted from infected tissue or cultured isolates; submit samples to experienced laboratory via overnight shipping at room temperature.

PATHOLOGIC FINDINGS
• GI and skin lesions characterized by pyogranulomatous and eosinophilic inflammation associated with broad (4–6 µm), irregularly branching, infrequently septate hyphae with thick, nonparallel walls.
• Predominance of eosinophils within inflammatory reaction differentiates pythiosis, lagenidiosis, zygomycosis from other mycotic infections.
• Hyphal organisms usually not visible on hematoxylin and eosin-stained sections; readily visualized with silver stain.
• GI lesions—severe segmental thickening of portions of stomach and/or bowel, often with obstruction of intestinal lumen.
• Mesenteric lymphadenopathy is common, but presence of *P. insidiosum* hyphae within lymph nodes is uncommon.
• GI pythiosis characterized by eosinophilic and pyogranulomatous inflammation with necrotic foci and discrete granulomas that contain hyphae.

TREATMENT

APPROPRIATE HEALTH CARE
Treatment of choice is aggressive surgical excision of all infected tissue with 3–5 cm margins. Unfortunately, many animals are not presented until late in disease when complete resection is not possible. Addition of prednisone at anti-inflammatory dosages to antifungal therapy has improved efficacy of medical treatment for nonresectable GI pythiosis.

NURSING CARE
Supportive care should include IV fluids with potassium supplementation and nutritional support. Antibiotics may be indicated to treat secondary pyoderma in dogs with cutaneous lesions.

ACTIVITY
Limit activity.

DIET
Feed a highly digestible, calorie-dense diet.

CLIENT EDUCATION
• Treatment is expensive.
• Prognosis for cutaneous pythiosis is guarded to poor unless complete resection with wide margins is feasible. For dogs with GI pythiosis, complete resolution of disease may occur when medical therapy includes prednisone.

SURGICAL CONSIDERATIONS
• Attempt wide surgical excision to obtain 5 cm margins (and two fascial planes deep if cutaneous).
• Amputation recommended for treatment of extremity lesions.
• Enlarged mesenteric lymph nodes should be biopsied but often do not contain infective hyphae, thus do not have to be removed.
• Dogs often improve after obstructive lesions are resected, even if significant gross disease is still present.
• Reevaluation of ELISA serology 2–3 months after surgery may provide prognostic information.

MEDICATIONS

DRUG(S) OF CHOICE
• Itraconazole 10 mg/kg PO q24h combined with terbinafine 10 mg/kg PO q24h and prednisone appears to be most effective combination:
  ◦ Prednisone is given at 1 mg/kg PO q12h for 5–7 days, then q24h for 1 month, then slowly tapered if there is clinical improvement.
  ◦ Antifungal therapy should be continued for minimum of 6 months.
  ◦ Compounded bulk itraconazole should not be used; give with food.

PRECAUTIONS
• Azole drugs should not be used in animals with severe liver disease.
• Anorexia, high liver enzymes, and cutaneous vasculitis are most common adverse effects of itraconazole.

POSSIBLE INTERACTIONS
Antacids and anticonvulsants may decrease blood levels of itraconazole.

ALTERNATIVE DRUG(S)
Prednisone used alone improves clinical signs in short term. In addition, the author has observed complete long-term resolution of clinical signs in a small number of dogs with GI pythiosis treated with prednisone alone. This is not recommended as a primary treatment for dogs with resectable lesions, but should be considered as palliative therapy in dogs with nonresectable disease when client finances preclude use of antifungals.

FOLLOW-UP

PATIENT MONITORING
• ELISA serology can be used to monitor response to therapy; serology should be checked 2–3 months after surgery or every 3 months during medical therapy.
• Abdominal ultrasonography is useful for reevaluating intestinal lesions.
• Liver enzyme activities should be evaluated monthly while patient is on itraconazole.

PREVENTION/AVOIDANCE
Monitor for signs of recurrence.

POSSIBLE COMPLICATIONS
Acute abdomen and death from GI thrombosis or perforation.

EXPECTED COURSE AND PROGNOSIS
Prognosis is guarded unless a complete resection is possible.

MISCELLANEOUS

AGE-RELATED FACTORS
Young animals are predisposed.

ZOONOTIC POTENTIAL
There is no evidence of direct transmission from animals to humans; infections in humans are very rare and are from a common environmental source.

PREGNANCY/FERTILITY/BREEDING
Azole antifungals are teratogenic and should not be used in pregnant animals.

SYNONYMS
• Phycomycosis.
• Swamp cancer.

ABBREVIATIONS
• GI = gastrointestinal.

P

PYURIA

BASICS

DEFINITION
• White blood cells (WBCs) (i.e., neutrophils, eosinophils, monocytes, lymphocytes, or plasma cells) in urine.
• More than 5 WBCs per high-power field is generally considered abnormal, but the number of WBCs found in urinary sediment varies with method of collection, sample volume and concentration, degree of cellular destruction after collection, and laboratory technique.

PATHOPHYSIOLOGY
• Large numbers of WBCs in voided urine indicate active inflammation along the urogenital tract.
• Can be associated with any pathologic process (infectious or noninfectious) that causes cellular injury or death; tissue damage evokes exudative inflammation characterized by leukocytic extravasation (pyuria) and increased vascular permeability (hematuria and proteinuria).

SYSTEMS AFFECTED
• Renal/urologic—urethra, urinary bladder, ureters, and kidneys.
• Genital—prepuce, prostate, vagina, and uterus.

SIGNALMENT
Dog and cat.

SIGNS
General Comments
• Historical and physical examination findings depend on the underlying cause, organ(s) affected, degree of organ dysfunction, and magnitude of systemic inflammatory responses.
• Nonobstructive lesions confined to the urinary bladder, urethra, vagina, or prepuce rarely cause systemic signs of inflammation. Systemic signs may accompany disease of the kidneys, prostate, or uterus.

Physical Examination Findings
Local Effects of Inflammation
• Erythema of mucosal surfaces.
• Tissue swelling.
• Exudation of leukocytes and protein-rich fluid.
• Pain.
• Loss of function.

Systemic Effects of Inflammation
• Fever.
• Depression.
• Anorexia.
• Dehydration.

CAUSES
Kidney
• Pyelonephritis.
• Nephrolith.
• Neoplasia.
• Trauma.
• Immune-mediated.

Ureter
• Ureteritis.
• Ureterolith.
• Ureteral stent.
• Neoplasia.

Urinary Bladder
• Cystitis.
• Urocystolith.
• Neoplasia.
• Trauma.
• Overdistension—urethral obstruction.
• Pharmacologic—cyclophosphamide.

Urethra
• Urethritis.
• Urethrolith.
• Neoplasia.
• Trauma.
• Foreign body.

Prostate
• Prostatitis/abscess.
• Neoplasia.

Penis/Prepuce
• Balanoposthitis.
• Neoplasia.
• Foreign body.

Uterus
• Pyometra/metritis.

Vagina
• Vaginitis.
• Neoplasia.
• Foreign body.
• Trauma.

RISK FACTORS
• Any disease process, diagnostic procedure, or therapy that alters normal urinary tract defenses and predisposes to infection.
• Any disease process, dietary factor, or therapy that predisposes to formation of metabolic uroliths.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Voided Specimens
• Rule out vaginitis—vaginal discharge, erythema of vaginal mucosa, licking of vulva, and attracting male dogs.
• Rule out pyometra, metritis—vaginal discharge, large uterus, pyrexia, depression, anorexia, polyuria, polydipsia, and a recent history of estrus, parturition, or progestin administration.
• Rule out balanoposthitis—preputial discharge, erythema of preputial or penile mucosa, and licking of prepuce.
• Rule out prostatitis, prostatic abscess, or prostatic neoplasia—urethral discharge, prostatomegaly, pyrexia, depression, dysuria, tenesmus, caudal abdominal pain, and stiff gait.
• Rule out urethritis, urethroliths, urethral neoplasms—dysuria, pollakiuria, stranguria, or palpable uroliths or mass lesions in the urethra.
• Rule out inflammatory disorders of urinary bladder and kidneys.

Specimens Collected by Cystocentesis
• Rule out urethral obstruction—stranguria, anuria, and a large overdistended urinary bladder.
• Rule out prostatic and urethral disorders (see above); purulent prostatic or urethral exudates can reflux into the urinary bladder.
• Rule out cystitis, urocystoliths, and urinary bladder neoplasia—dysuria, pollakiuria, stranguria, and/or palpable uroliths or mass lesions in the urinary bladder.
• Rule out pyelonephritis—pyrexia, depression, anorexia, polyuria, polydipsia, renal pain, and renomegaly.
• Rule out post-traumatic pyuria—history of trauma, including iatrogenic causes.

LABORATORY FINDINGS
Drugs That May Alter Laboratory Results
• WBCs lyse rapidly in hypotonic or alkaline urine. Administration of alkalinizing agents or agents that produce hypotonic urine may falsely decrease urine WBC numbers.
• Leukocyte esterase reagent strip (dipstick) is not recommended for evaluating canine and feline urine. Nitrofurantoin, cephalosporins, and gentamicin can cause false-positive leukocyte esterase reactions.
• Urinary WBC concentrations can be low in patients with inflammatory disorders who have been given steroidal or nonsteroidal anti-inflammatory drugs.

Disorders That May Alter Laboratory Results
• Disorders with diminished WBC function or absolute neutropenia can artificially lower WBC values.
• Disorders with production of hypotonic urine or alkaline urine artificially lower WBC values.

Miscellaneous Factors That May Alter Laboratory Results
Dipstick (leukocyte esterase reaction) testing may result in false-negative results in dogs and both false-positive and false-negative results in cats.

Valid if Run in Human Laboratory?
Valid if urinary sediment is examined microscopically; invalid if only leukocyte esterase reagent strip (dipstick) method is used.

CBC/BIOCHEMISTRY/URINALYSIS
• Pyuria in specimens collected by voiding, manual compression, or transurethral catheterization indicates an inflammatory lesion involving at least the urinary or genital tracts.
• Pyuria in specimens collected by cystocentesis localizes the site of inflammation to at least the

(CONTINUED) PYURIA

urinary tract, but does not exclude the urethra and genital tract. Reflux of prostatic exudates into the urinary bladder may result in pyuria in patients with prostatic disease.
• Pyuria with WBC casts is evidence of renal parenchymal inflammation.
• Generalized renal injury may be associated with concomitant leukocytosis, isosthenuria, and azotemia.
• Pyuria associated with bacteria, fungi, or parasite ova in sufficient numbers indicates that the inflammatory lesion was caused or complicated by urinary tract infection (UTI).
• Pyuria associated with neoplastic cells indicates neoplasia. Diagnosis of urinary tract neoplasia by cytologic examination of urine may be complicated by epithelial cell hyperplasia and atypia caused by urinary tract inflammation or the physiochemical properties of urine.

OTHER LABORATORY TESTS
• Perform quantitative urine culture on all patients with pyuria; it provides the most definitive means of identifying and characterizing UTI. The absence of pyuria does not rule out bacteriuria as patients with bacteriuria frequently do not have pyuria.
• Negative urine culture results suggest a noninfectious cause of inflammation (e.g., uroliths, neoplasia) or inflammation associated with UTI caused by fastidious organisms (e.g., mycoplasmas and viruses) or by organisms capable of forming intracellular bacterial colonies or biofilms. False-negative culture results may also be due to recent antimicrobic therapy, sample mishandling, or delays between specimen collection and culture.
• Cytologic evaluation of urinary sediment, prostatic fluid, urethral or vaginal discharges, or biopsy specimens obtained by catheter or needle biopsy may help evaluate patients with localized urinary or genital tract disease. Cytologic examination may establish a definitive diagnosis of urinary tract neoplasia, but negative cytologic findings do not rule out neoplasia.

IMAGING
Abdominal radiography, contrast urethrocystography, urinary tract ultrasonography, and excretory urography are important means of identifying and localizing underlying causes.

DIAGNOSTIC PROCEDURES
• Urethrocystoscopy—indicated in patients with persistent lesions of the lower urinary tract for which a definitive diagnosis has not been established by other, less invasive, means.
• Microscopic evaluation of tissue specimens—indicated in patients with lesions of the urinary or genital tracts for which a definitive diagnosis has not been established by other, less invasive, means; tissue specimens may be obtained by traumatic catheterization biopsy, cystoscopy and forceps biopsy, or exploratory laparotomy; aspiration and punch biopsy techniques may be used to evaluate the prostate gland.

TREATMENT
• Treatment varies, depending on the underlying cause and specific organs involved.
• Pyuria associated with systemic signs of illness (i.e., pyrexia, depression, anorexia, vomiting, dehydration, leukocytosis, polyuria, and polydipsia) or urinary obstruction warrants aggressive diagnostic evaluation and initiation of specific, supportive, and/or symptomatic treatment.

MEDICATIONS
DRUG(S) OF CHOICE
Depend on underlying cause.

CONTRAINDICATIONS
• Avoid glucocorticoids or other immunosuppressive agents in patients suspected of having urinary or genital tract infection.
• Avoid potentially nephrotoxic drugs in febrile, dehydrated, or azotemic patients and those suspected of having pyelonephritis, septicemia, or preexisting renal disease.

FOLLOW-UP
PATIENT MONITORING
Response to treatment by serial urinalyses, including examination of urine sediment; collect specimens from most patients by cystocentesis to avoid contamination by preputial or vaginal exudates; perform transurethral catheterization if the expected benefits outweigh the risk of iatrogenic bacterial UTI.

POSSIBLE COMPLICATIONS
• Infectious and noninfectious inflammatory disorders of the urinary tract can cause renal failure, urinary obstruction, uremia, septicemia, and death.
• Pyuria is a potential risk factor for formation of matrix or matrix-crystalline urethral plugs and subsequent urethral obstruction in male cats.

MISCELLANEOUS
ASSOCIATED CONDITIONS
• Hematuria.
• Proteinuria.
• Bacteriuria.

SYNONYMS
Leukocyturia.

SEE ALSO
• Dysuria, Pollakiuria, and Stranguria.
• Hematuria.
• Lower Urinary Tract Infection, Bacterial.
• Lower Urinary Tract Infection, Fungal.
• Proteinuria.
• Pyelonephritis.

Q FEVER

BASICS

OVERVIEW

- Caused by the zoonotic rickettsia *Coxiella burnetii*.
- Infection—most commonly by inhalation or ingestion of organism via infected body fluids (parturient discharges, urine, milk, or feces), tissues (especially placenta), or carcasses of infected animal reservoir hosts (cattle, sheep, goats); can occur after tick exposure (many species of ticks implicated).
- Lungs—thought to be main portal of entry to systemic circulation.
- Organism replicates in vascular endothelium; causes widespread vasculitis; vasculitis results in necrosis and hemorrhage in lungs, liver, and CNS; severity depends on the pathogenicity of the strain of organism and host immune response.
- An extended latent period exists after recovery until chronic immune-complex phenomena develop; organism reactivated out of the latent state during parturition, resulting in large pathogen load in placenta, parturient fluids, urine, feces, and milk.
- Endemic in mammals worldwide; most cases in the United States in western states.

SIGNALMENT

Cats and dogs of any age, sex, or breed.

SIGNS

Historical Findings

- History of contact with farm animals or ticks.
- Fever.
- Lethargy.
- Depression.
- Anorexia.
- Abortion—especially cats.
- Ataxia and seizures—especially dogs.

Physical Examination Findings

- Usually unremarkable.
- Splenomegaly often only clinical finding.
- Multifocal neurologic abnormalities—dogs.

CAUSES & RISK FACTORS

- *Coxiella burnetii*.
- Exposure to infected animals (especially following parturition) and ticks.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cats—other causes of abortion: infections (viral rhinotracheitis, panleukopenia, feline leukemia virus, toxoplasmosis; bacteria including coliforms, streptococci, staphylococci, salmonellae); fetal defects; maternal problems (nutrition, genital tract abnormalities); environmental stress; endocrine disorders.
- Dogs—canine parvovirus, canine distemper, other causes of encephalitis.

CBC/BIOCHEMISTRY/URINALYSIS

Nonspecific

OTHER LABORATORY TESTS

Serology and PCR

- Serology (immunofluorescence or ELISA)—a four-fold increase in IgG titer over a 4-week period is diagnostic; utility of increased IgM titer in a single sample is not well documented in small animals; crossreactivity with *Bartonella* species is possible.
- PCR—used to detect organisms in tissue culture or tissue specimens (e.g., placenta); whole blood can also be tested during 1st week of acute infection but negative blood PCR does not rule out infection.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Organism not detected on routine blood cultures; organism isolation may be performed by qualified laboratories.

TREATMENT

- Alert client of possible zoonotic risk.
- Inpatient—avoids zoonotic risk to client
- Wear personal protective equipment (gloves, gown, mask, eye shield) when treating an infected animal or when attending an aborting cat.
- Isolate aborting and postpartum animals.
- Survives long periods in environment; inactivated by 5% hydrogen peroxide.

MEDICATIONS

DRUG(S) OF CHOICE

- Tetracycline 22 mg/kg PO q8h for 2 weeks.
- Doxycycline 10 mg/kg PO q12h for 1 week.
- Enrofloxacin 10–20 mg/kg PO q24h (dogs only) for 1 week; should be effective but no clinical reports; effective *in vitro*.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Tetracycline drugs are associated with yellowing of teeth in young animals; do not use in animals with renal failure.
- Doxycycline may cause esophagitis and stricture.
- Enrofloxacin may cause cartilage defects in young animals at high doses.
- Enrofloxacin may cause retinal degeneration in cats.

FOLLOW-UP

- Difficult to determine success of therapy because many animals spontaneously improve.
- Even asymptomatic cases should be aggressively treated because of the zoonotic potential.
- Utility of predicting success of therapy based on serologic improvement unknown.

MISCELLANEOUS

ZOONOTIC POTENTIAL

- Major zoonotic potential.
- Humans contract the disease by inhaling infected aerosols (e.g., after parturition); children commonly infected from ingesting raw milk but are usually asymptomatic.
- By the time a diagnosis is made in a pet, human exposure and infection have usually occurred.
- Instruct owners and people in contact with the pet to seek medical advice immediately.
- Previous urban outbreaks have been related to exposure to infected cats.
- Incubation period from time of contact until the first signs of illness is 5–32 days.
- Person-to-person transmission possible.

QUADRIGEMINAL CYST

BASICS

OVERVIEW

• CSF-filled diverticula within the subarachnoid space at the quadrigeminal cisterna (dorsal to the midbrain and adjacent to the third ventricle). More recently the term supracollicular fluid accumulation (SFA) has been used to described the anatomical location of the condition. CSF may be secreted by the arachnoid cells lining the cyst cavity. It is suspected that an anomaly of CSF flow from the choroid plexus during the stage of development forces a separation within the arachnoid layer. • Clinical signs may develop as a result of gradual expansion of the subarachnoid space by a valve mechanism associated with pulsating CSF flow. • May be an incidental finding.

SIGNALMENT

Dog and cat.

Breed Predilections

Mainly in small breeds and brachycephalic patients—shih tzu, Maltese, pug, cavalier King Charles, Yorkshire terrier, Lhasa apso, Chihuahua, Pekingese, Pomeranian and bulldog.

Mean Age and Range

Mean—5 years; range—2 months–10 years.

SIGNS

• Seizures. • Abnormal behavior. • If associated with hydrocephalus, could manifest with disorientation, behavioral changes, cortical blindness, compulsive circling, head pressing.

CAUSES & RISK FACTORS

• Disturbance of embryogenesis where splitting of the primitive arachnoid membrane leads to fluid accumulation. • Inflammatory conditions affecting the meninges. • Postsurgical trauma (intervertebral disc disease, spinal tumor). • Neoplasia and hemorrhage. • Intracystic hemorrhage secondary to trauma may result in expansion of the cyst and subsequent compression of the adjacent brain parenchyma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Primary intracranial cyst-like lesions include intra-arachnoid, epidermoid, dermoid and choroid plexus cysts. • Congenital brain anomalies (anencephaly, hydrocephalus, other). • Storage disease. • Infectious inflammatory diseases—viral (distemper virus, other viruses); fungal (*Blastomyces dermatitidis*, *Coccidioides* spp., *Cryptococcus neoformans*); ricketssial (*Rickettsia rickettsii*); bacterial (*Ehrlichia* spp., *Escherichia coli*, *Streptococcus*); protozoal (*Neospora caninum*, *Toxoplasma gondii*). • Other inflammatory disease—breed-related encephalitis (necrotizing encephalitis of the Yorkshire terrier, Maltese, and pug). • Brain tumor—meningioma, glioma, choroid plexus papilloma, lymphoma.

IMAGING

• The prevalence of SFAs was 2.19% among CT studies (n = 4,427) and 2.2% among MRI studies (n = 626). • MRI—extra-axial CSF-filled cyst at the quadrigeminal cisterna. On T1-weighted images, the lesion is hypointense to brain tissue and isointense to CSF. On T2-weighted images, the lesion is hyperintense to brain tissue and isointense to CSF. On fluid attenuated inversion recovery (FLAIR) sequences, the cyst is hypointense, confirming the presence of CSF. Dilation of the ventricular system may be present if the cyst is obstructing CSF flow.

DIAGNOSTIC PROCEDURES

CSF—rule out concomitant inflammation. If CSF inflammatory, the cyst may be an incidental finding.

TREATMENT

• Medical therapy to control seizures and reduce CSF production. • If signs are progressive, surgical cyst fenestration through craniotomy or craniectomy can result in clinical improvement. When hydrocephalus is present, surgical shunting can be considered. Other disease process must be ruled out before considering surgery. The cystic structure may be an incidental finding. • Stable patients can be discharged with recommended medical therapy. • Sequential assessment of pupillary size and reaction to light, and mentation are helpful to determine risk of brain herniation.

MEDICATIONS

DRUG(S) OF CHOICE

• Glucocorticosteroids—dexamethasone 0.1 mg/kg IV or PO q24h for 3 days followed by prednisone 0.25–0.5 mg/kg PO q24h for 10 days, then reassess response and adjust dose. To prevent gastrointestinal ulceration, add omeprazole 0.5 mg/kg PO q24h or famotidine 0.5–1 mg/kg IV or PO q12h to steroid therapy. • Antiepileptic drugs—phenobarbital 2 mg/kg IV or PO q12h, levetiracetam 20 mg/kg PO q8–12h, or zonisamide 5–10 mg/kg PO q12h. • Diuretic—acetazolamide 10 mg/kg q6–8h as a carbonic anhydrase inhibitor that may help reduce CSF production and intracranial pressure. Omeprazole may act as an agent to reduce CSF production and provide gastric protection during steroid therapy.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

The combination of glucocorticosteroid and diuretic may cause marked dehydration and increased blood viscosity that can result in poor cerebral perfusion and neurologic deterioration.

FOLLOW-UP

PATIENT MONITORING

• Repeat neurologic examination periodically (every 2–4 weeks). • Corticosteroid may be necessary for a long period or for life. The goal is to find the dose that keeps the clinical signs controlled with minimal side effects. • Evaluate phenobarbital levels after 4–5 weeks of starting therapy. • If phenobarbital is continued, recheck biochemical profile and bile acids to assess hepatic function every 6 months.

POSSIBLE COMPLICATIONS

• Deterioration of clinical signs despite aggressive treatment. • Status epilepticus, dementia, brain herniation, and death.

EXPECTED COURSE AND PROGNOSIS

• Prognosis is variable depending on severity of clinical signs and response to therapy. • Quadrigeminal cyst may be incidental or may result in progressive neurologic deterioration.

RABIES

BASICS

DEFINITION
A severe, fatal, viral polioencephalitis of warm-blooded animals, including humans.

PATHOPHYSIOLOGY
Virus—enters body through a wound (usually from a bite of rabid animal) or via mucous membranes, replicates in myocytes, spreads to the neuromuscular junction and neurotendinal spindles, travels to the central nervous system (CNS) via intra-axonal fluid within peripheral nerves, spreads throughout the CNS; finally spreads centrifugally within peripheral, sensory, and motor neurons.

SYSTEMS AFFECTED
- Nervous—brain, spinal cord, ± peripheral nervous system (PNS).
- Salivary glands—contain large quantities of infectious virus particles that are shed in saliva.

GENETICS
None

INCIDENCE/PREVALENCE
- Incidence of disease within infected animals—high (approaches 100%).
- Prevalence—overall low; can be significant in enzootic areas; especially high in countries where vaccination of dogs and cats is not routine.

GEOGRAPHIC DISTRIBUTION
- Worldwide.
- Exceptions—New Zealand, Hawaii, Japan, Iceland, and parts of Scandinavia.
- Species-adapted strains—specific geographic distributions within endemic countries.

SIGNALMENT

Species
- All warm-blooded mammals, including dogs, cats, and humans.
- United States—five strains endemic within fox, raccoon, skunk, coyote, and insectivorous bat populations; all five strains can be transmitted to dogs and cats.

Breed Predilections
None

Mean Age and Range
All ages, but animals that come in contact with wildlife at highest risk.

Predominant Sex
None

SIGNS

General Comments
- Variable; atypical presentation is the rule rather than the exception.
- Can present with focal or multifocal signs affecting either brain, spinal cord, PNS, or any combination.
- Three classical progressive stages of disease described:
  - Prodromal—mentation change (more docile or more agitated) ± fever.
  - Furious—prosencephalon signs including hyperactivity, aggression, seizures ± ataxia; 90% of rabid cats have furious form.
  - Paralytic—lower motor neuron (LMN) paresis or paralysis starting near site of inoculation then spreading through nervous system; paralytic form can follow furious form, especially in cats.

Historical Findings
- Mentation/behavior change—variable; can include unusual shyness, excitability, aggression.
- Seizures.
- Gait change—lameness, ataxia, paralysis.
- Licking or chewing at site of inoculation, although wound not always identified.
- Change in tone of bark.
- Excess salivation or frothing at the mouth.

Physical Examination Findings
- All or some of the historical findings
- Fever.
- Cranial nerve deficits—myosis, anisocoria, absent pupillary light reflex (PLR); dropped jaw; absent gag reflex (assess by compressing larynx and avoid hand in mouth if rabies suspected).
- Hypersalivation.
- Laryngeal paralysis.

CAUSES
Rabies virus—a single-stranded, enveloped, bullet-shaped RNA virus; genus *Lyssavirus*; family *Rhabdoviridae*.

RISK FACTORS
- Exposure to wildlife, especially skunks, raccoons, bats, and foxes.
- Inadequate vaccination against rabies.
- Bite or scratch wounds from unvaccinated dogs, cats, or wildlife.
- Exposure to aerosols in bat caves.
- Immunocompromised animal—use of modified live virus rabies vaccine.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Must seriously consider rabies for any dog or cat showing acute behavior change or unaccountable neurological signs, especially those not previously vaccinated for rabies. Caution: handle with considerable care to prevent possible transmission of the virus to individuals caring for or treating the animal.
- Acute, progressive CNS and/or PNS disease—infectious (e.g., viral encephalitis or myelitis), immune-mediated (e.g., granulomatous or necrotizing meningoencephalitis, necrotizing leukoencephalitis, polymyositis), metabolic (e.g., hepatic encephalopathy, hypoadrenocorticism), neoplastic, degenerative.

CBC/BIOCHEMISTRY/URINALYSIS
No characteristic hematologic or biochemical changes.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

DIAGNOSTIC PROCEDURES
- There are no definitive premortem diagnostics. Diagnostics performed on rabies suspects should be done with extreme caution to prevent exposure to infective tissues. Consider consultation with a neurologist.
- Direct immunofluorescent antibody (DFA) test of nervous tissue—rapid and sensitive; collect head or entire body following death or euthanasia, chill sample immediately. Submit to a state-approved laboratory for rabies diagnosis. Caution: use extreme care when collecting, handling, and shipping these specimens to prevent exposure of veterinarians, staff or handlers.
- DFA test of dermal tissue—skin biopsy of the sensory vibrissae of the maxillary area, including deeper subcutaneous hair follicles; approved for human diagnostics, but not for animal diagnostics; accurate if positive, but negative test does not rule out rabies.
- Rabies antibody titer—a serologic antibody titer of 0.5 IU/mL is considered adequate for protection in vaccinated people and animals. In most states in the United States, titers are not considered a legal replacement for vaccination.

PATHOLOGIC FINDINGS
- Gross changes—generally absent.
- Histopathologic changes—acute to chronic polioencephalitis; gradual increase in the severity of the nonsuppurative inflammatory process in the CNS as disease progresses; large neurons within the brain may contain classic intracytoplasmic inclusions (Negri bodies).

TREATMENT

APPROPRIATE HEALTH CARE
Strictly inpatient.

NURSING CARE
Administer with extreme caution.

ACTIVITY
- Confine to secured quarantine area with clearly posted signs indicating suspected rabies.
- Runs or cages should be locked; only designated people should have access.
- Feed and water without opening the cage or run door.

(CONTINUED) RABIES

DIET
Soft, moist food; most patients will not eat.

CLIENT EDUCATION
- Thoroughly inform client of the seriousness of rabies to the animal and the zoonotic potential.
- Ask client about any human exposure (e.g., contact, bite) and strongly urge client to see a physician immediately.
- Local public health official must be notified.

SURGICAL CONSIDERATIONS
- Generally none.
- Skin biopsy—may help establish antemortem diagnosis; must be confirmed by identification from CNS tissue.

MEDICATIONS

DRUG(S) OF CHOICE
- No treatment.
- Once the diagnosis is likely, euthanasia is indicated.

CONTRAINDICATIONS
None

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
- All suspected rabies patients should be securely isolated and monitored for any development of mood change, attitude change, or clinical signs that might suggest the diagnosis.
- An apparently healthy dog or cat that bites or scratches a person should be monitored for a period of 10 days; if no signs of illness occur in the animal within 10 days, the person has had no exposure to the virus; dogs and cats do not shed virus for more than 3 days before development of clinical disease.
- An unvaccinated dog or cat that is bitten or exposed to a known rabid animal must be quarantined according to local or state regulations, often for up to 6 months.

PREVENTION/AVOIDANCE
- Vaccines (dogs and cats)—vaccinate according to standard recommendations and state and local requirements; all dogs and cats with any potential exposure to wildlife or other dogs; vaccinate after 12 weeks of age, then 12 months later, then every 3 years using a vaccine approved for 3 years; use only inactivated or recombinant vector vaccines for cats.
- Vaccinated animals exposed to possible or confirmed rabies suspect should receive booster vaccine, according to applicable local laws.
- Rabies-free countries—entering dogs and cats are quarantined for long periods, usually 6 months.
- Disinfection—any contaminated area, cage, food dish, or instrument must be thoroughly disinfected; use a 1:32 dilution (4 ounces/gallon) of household bleach to quickly inactivate the virus.

POSSIBLE COMPLICATIONS
- Development of acute neurological signs, death.
- Difficulty of antemortem diagnosis my lead to humans and other animals being exposed to virus.

EXPECTED COURSE AND PROGNOSIS
- Prognosis—grave; almost invariably fatal.
- Dogs and cats with clinical infection usually succumb within 1–10 days of onset of clinical signs; often within 3–4 days.

MISCELLANEOUS

ASSOCIATED CONDITIONS
None

AGE-RELATED FACTORS
None

ZOONOTIC POTENTIAL
- Extreme.
- Humans must avoid bites and contact with saliva or CNS tissue from a rabid animal or an asymptomatic animal that is incubating the disease.
- Suspected rabies cases must be strictly quarantined and confined to prevent exposure to humans and other animals. Full personal protective equipment should be worn if interaction is necessary.
- Local and state regulations must be adhered to carefully and completely.

PREGNANCY/FERTILITY/BREEDING
Infection during pregnancy is fatal to dam.

SYNONYMS
N/A

ABBREVIATIONS
- CNS = central nervous system
- DFA = direct immunofluorescent antibody.
- LMN = lower motor neuron.
- PLR = pupillary light reflex.
- PNS = peripheral nervous system.

RECTAL AND ANAL PROLAPSE

BASICS

OVERVIEW
- Eversion of one or more layers of the rectum through the anus.
- An anal prolapse (incomplete prolapse) is a protrusion of anorectal mucosa through the external anal orifice.
- A rectal prolapse (complete prolapse) is a double-layer invagination of the full thickness of the rectal tube through the anal orifice.

SIGNALMENT
- Dog and cat (especially Manx).
- Any age, sex, or breed.
- High prevalence for young, parasitized dogs or cats with diarrhea.

SIGNS
- Persistent tenesmus.
- Incomplete prolapse—protrusion of a portion of the circumference of the rectal mucosa that typically appears worse immediately after defecation and then subsides.
- Complete prolapse appears as a tubular hyperemic mass protruding from the anus.
- Chronic prolapses may be dark blue or black in color or the mucosa may be ulcerated.

CAUSES & RISK FACTORS
- Gastrointestinal disorders that cause diarrhea and tenesmus, such as parasitism, colitis/enteritis, constipation/obstipation, rectal foreign body, rectal deviation and diverticulum, proctitis, and rectal or anal tumors.
- Urogenital disorders, such as cystitis, urolithiasis, prostatitis, prostatic hypertrophy, and dystocia.
- Tenesmus following perineal, rectal, or urogenital surgery (e.g., perineal herniorrhaphy).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Prolapsed intussusception—rule out by passing a finger or blunt probe between the mass and the anus (the probe should not penetrate more than 1–2 cm before contacting the fornix; if the probe easily passes 5–6 cm, then suspect prolapsed intussusception) or by abdominal ultrasonography (look for increased intestinal layering).
- Neoplasia—rule out by palpation, fine-needle aspiration and cytology, and/or biopsy and histopathology.

CBC/BIOCHEMISTRY/URINALYSIS
- Usually unremarkable.
- Inflammatory or stress leukogram may be present.

OTHER LABORATORY TESTS
Fecal examination may confirm parasitism.

IMAGING
- Abdominal radiography and ultrasonography—usually unremarkable.
- Abdominal radiography—may demonstrate foreign body, prostatomegaly, cystic calculi, or colonic fecal distention.
- Abdominal ultrasonography—may demonstrate prostatomegaly, cystic calculi, bladder wall thickening, or intussusception.

DIAGNOSTIC PROCEDURES
- Rectal examination to palpate for perineal hernia.
- Colonoscopy may help evaluate recurrent prolapse for an underlying cause.

PATHOLOGIC FINDINGS
Assess viability of the prolapsed tissue by surface appearance and tissue temperature—vital tissue appears swollen and hyperemic, and red blood exudes from the cut surface; devitalized tissue appears dark purple or black, and dark cyanotic blood exudes from the cut surface; ulcerations may be present.

TREATMENT
- Must identify and treat underlying cause.
- Conservative medical management—gently replace prolapsed tissue through the anus with the use of lubricants (e.g., KY Jelly and gentle massage); osmotic agents (e.g., 50% dextrose solution) may help if severe swelling exists.
- Use of an epidural may facilitate treatment and relieve discomfort.
- Place a purse-string suture to aid retention and prevent acute recurrence; place the suture loose enough to allow room for defecation.
- Decrease straining with stool softeners.
- Colopexy recommended for recurrent viable prolapses or if straining persists after rectal resection and anastomosis.
- When prolapse is nonreducible and/or devitalized, rectal resection and anastomosis are necessary.

MEDICATIONS

DRUG(S) OF CHOICE
- Appropriate anesthetic/analgesics as needed.
- Appropriate perioperative antibiotics are recommended (e.g., cefoxitin sodium 30 mg/kg IV) for resection and anastomosis.
- Stool softeners—docusate sodium (dogs, 50–200 mg PO q8–12h; cats, 50 mg PO q12–24h) or lactulose (10 g/15 mL solution or syrup, 1 mL/4.5 kg q8–12h to effect); continue for 2–3 weeks after removal of the purse-string suture.
- Anthelmintic based on fecal examination.
- Feed a low-residue diet until purse-string suture is removed.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

PATIENT MONITORING
- Purse-string suture removal in 3–7 days.
- Examine for rectal stricture if straining persists following anastomosis.

POSSIBLE COMPLICATIONS
- Recurrence—especially if underlying cause is not eliminated.
- Postoperative—may include infection, anastomosis dehiscence within 5–7 days postoperatively, or rectal stricture.
- Fecal incontinence after resection (sensory incontinence resulting from removal of receptors in rectal wall).

MISCELLANEOUS

ASSOCIATED CONDITIONS
Intestinal parasitism.

SEE ALSO
- Colitis and Proctitis.
- Dyschezia and Hematochezia.
- Intussusception.

Consulting Editor Mark P. Rondeau

R

RECTAL STRICTURE

BASICS

OVERVIEW
- Diminution in the size of the rectal or anal lumen either from cicatricial contracture or scarring as a result of wound healing or chronic inflammation or from proliferative neoplastic disease.
- Gastrointestinal function is compromised because of outflow obstruction.

SIGNALMENT
- Dog and cat.
- Any age, breed, or gender.

SIGNS
- Vary with severity.
- Tenesmus.
- Dyschezia.
- Constipation.
- Hematochezia.
- Mucoid feces.
- Large bowel diarrhea.
- Secondary megacolon can develop.

CAUSES & RISK FACTORS
- Inflammatory—rectoanal abscess, anal sacculitis, perianal fistulae, proctitis, histoplasmosis, pythiosis.
- Traumatic— foreign body, laceration.
- Neoplastic—rectal adenocarcinoma, leiomyoma, or polyps.
- Iatrogenic—rectal anastomosis, mass excision, or biopsy.
- Congenital—atresia ani.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Space-occupying processes that lead to diminished rectal capacity (extraluminal compression [e.g., prostatic disease, pelvic fractures], intraluminal obstruction [e.g., pseudocoprostasis, foreign body]) and functional constriction (muscle spasms).
- Differentiate by rectal palpation and imaging.

CBC/BIOCHEMISTRY/URINALYSIS
- Usually unremarkable.
- May have an inflammatory leukogram.

OTHER LABORATORY TESTS
N/A

IMAGING
- Survey abdominal radiography and contrast studies (e.g., barium, air, or double-contrast enema and barium gastrointestinal series) may reveal consistent narrowing of the rectal lumen.
- Abdominal ultrasonography may reveal thickening and altered architecture if infiltrative rectocolonic disease is present (e.g., pythiosis, neoplasia).

DIAGNOSTIC PROCEDURES
- Digital rectal palpation.
- Proctoscopy/colonoscopy to visualize stricture, determine extent, and procure biopsy specimens.
- Colonic scrapings may aid in cytologic diagnosis of fungal (histoplasmosis) and neoplastic diseases.
- Biopsy to classify the disease process and establish a prognosis.

TREATMENT
- Treat the underlying cause when possible.
- Medical treatment for palliation (stool softeners/enemas) or the elimination of infective agents or inflammatory conditions.
- Fluid therapy to optimize hydration prior to administering an enema to constipated or obstipated patients.
- Anesthesia may be necessary for enema administration.
- Balloon dilation of non-neoplastic and postoperative strictures—multiple procedures may be needed.
- Surgical reconstruction of focal strictures (plasty procedures).
- Resection and anastomosis may be necessary for extensive lesions and recurrent strictures.
- Colorectal stent placement may relieve obstruction due to nonresectable neoplasms and non-neoplastic lesions.
- Radiotherapy and/or chemotherapy for some neoplasms.

MEDICATIONS

DRUG(S) OF CHOICE
- Stool softeners—docusate sodium; lactulose.
- Corticosteroids—prednisone to treat inflammatory conditions (0.5–1 mg/kg PO q24h or divided q12h) and after balloon dilation to prevent stricture recurrence. Intralesional injection of triamcinolone prior to dilatation may prevent recurrence.
- Chemotherapy or antifungal therapy if indicated.
- Broad-spectrum perioperative antimicrobial therapy (e.g., cefoxitin sodium 30 mg/kg IV) with balloon dilation or surgical therapy.
- Antibiotics continued after dilation if mucosal tearing occurs.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
- Corticosteroids when infection is possible.
- Corticosteroids may slow healing after surgical correction.

FOLLOW-UP

PATIENT MONITORING
- Clinical signs.
- Recurrence or metastasis of neoplastic lesions.
- Following balloon dilation patients should be reevaluated for stricture reformation 7–14 days after the procedure to determine the need for additional dilation procedures.

POSSIBLE COMPLICATIONS
- Medical treatment—can include inefficacy, diarrhea, and adverse effects of medications.
- Balloon dilation can result in deep rectal tears, hemorrhage, or possibly full-thickness perforation. Stricture recurrence is common following balloon dilation. Multiple dilations may be needed.
- Surgical treatment—fecal incontinence, secondary stricture formation, and wound dehiscence.

EXPECTED COURSE AND PROGNOSIS
- Varies with the severity of the stricture.
- Patients with benign strictures that are readily managed medically or with balloon dilation or bougienage may have a good long-term outcome.
- Surgical resection has more guarded prognosis because of the frequency of complications.
- Most patients with recognizable clinical signs due to neoplasia have a guarded-to-poor prognosis for complete resolution.

MISCELLANEOUS

AGE-RELATED FACTORS
Atresia ani is seen within weeks of birth.

SEE ALSO
- Colitis and Proctitis.
- Constipation and Obstipation.
- Dyschezia and Hematochezia.
- Histoplasmosis.
- Perianal Fistula.
- Pythiosis.

Suggested Reading

Aronson LR. Rectum, anus, perineum. In: Tobias KM, Johnston SA, eds., Veterinary Small Animal Surgery. St. Louis, MO: Elsevier Saunders, 2012, pp. 1564–1600.

Author Eric R. Pope
Consulting Editor Mark P. Rondeau

RECTOANAL POLYPS

BASICS

OVERVIEW
Most rectoanal polyps are benign growths located in the distal rectum. Histopathologic evaluation typically reveals adenomas, but lesions may undergo malignant transformation.

SIGNALMENT
• Dog and rarely cat. • Middle-aged to older. • No breed or sex predilection established but German shepherd dogs, collies, and West Highland white terriers overrepresented in some studies.

SIGNS
• May be none (incidental finding on wellness exam). • Hematochezia with relatively well-formed feces. • Mucus-covered feces. • Pencil-thin or ribbon-like feces. • Tenesmus. • Dyschezia. • Soft, well-vascularized, friable, and often ulcerated mass(es) may be seen or palpated rectally. • Usually single but multiple polyps can occur. • May be pedunculated or broad-based sessile masses.

R

CAUSES & RISK FACTORS
Unknown

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Carcinoma *in situ* and adenocarcinoma. • Other neoplasms—leiomyoma, lymphoma, papilloma. • Inflammatory polyps—primarily reported in miniature dachshunds in Japan; lesions appear as diffuse small white polyps that are responsive to immunosuppressive therapy. • Proctitis. • Pythiosis. • Colitis (clinical signs are characterized by diarrhea with a marked increase in frequency, scant volume of feces, increased fecal mucus, and tenesmus. These clinical signs are vastly different to those of dogs with rectoanal polyps which do not cause diarrhea). • Incomplete rectal prolapse.

CBC/BIOCHEMISTRY/URINALYSIS
Usually unremarkable.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

DIAGNOSTIC PROCEDURES
• Rectal palpation. • Direct visualization through anus. • Proctoscopy—viable low-cost procedure that allows one to visualize the descending colon after cleansing the animal's colon. This method is suitable in most dogs and cats because the polyps are usually localized to the rectoanal or colorectal region and tend not to metastasize. • Colonoscopy—may be recommended to evaluate the entire rectum and colon for additional polyps but in a review of 82 cases, no lesions were found orad to the colorectal junction. • Cytologic examination of polyp aspirate or scraping may help the initial diagnosis, although cytology should be interpreted with caution given the inherent challenges of differentiating benign adenomas from adenocarcinomas cytologically. • Histopathologic examination of excised tissue is required for definitive diagnosis and to assess completeness of the excision.

PATHOLOGIC FINDINGS
• Adenomatous polyp. • Adenomatous hyperplasia. • Carcinoma *in situ*.

TREATMENT
• Surgical excision is the treatment of choice. • Most polyps can be exteriorized directly through the anus and removed with submucosal resection. • Close the mucosal defect with absorbable sutures, avoiding compromise of the lumen diameter. • Lesions that cannot be exteriorized may be removable transanally by electrosurgery with endoscopic guidance or can be directly exposed through a dorsal rectal approach. • One study in dogs showed significant improvement in clinical signs following administration of piroxicam, but long-term follow-up is not available. Numerous nonsteroidal anti-inflammatory drugs (NSAIDs) have been evaluated in humans with mixed results (see Internet Resources).

MEDICATIONS

DRUG(S) OF CHOICE
• Appropriate perioperative antibiotics are recommended (e.g., cefoxitin sodium 30 mg/kg IV). • Stool softeners may help decrease tenesmus—docusate sodium (dogs, 50–200 mg PO q8–12h; cats, 50 mg PO q12–24h) or docusate calcium (dogs, 50–100 mg PO q12–24h; cats, 50 mg PO q12–24h). • Alternative stool softener—lactulose (1 mL/4.5 kg PO q8h to effect).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

PATIENT MONITORING
• Examine the excision site 14 days after surgery and again at 3 and 6 months to ensure absence of recurrence or stricture. • Twice yearly examination thereafter to assess for recurrence.

POSSIBLE COMPLICATIONS
• Recurrence. • Rectal stricture (rare).

EXPECTED COURSE AND PROGNOSIS
• Dogs with focal single adenomas have a good prognosis with a low rate of recurrence. • Dogs with multiple and/or diffuse lesions (involvement of >50% of circumference of rectal wall) have much higher rates of recurrence. • Malignant transformation of benign lesions can occur in up to 50% of dogs. • Excised tissues should be submitted for histopathology even when preoperative biopsies have been performed. The diagnosis may change in up to one-third of the cases in which preoperative endoscopic biopsies are performed.

MISCELLANEOUS

SEE ALSO
• Adenocarcinoma, Anal Sac.

RED EYE

BASICS

DEFINITION
Erythema of the eyelids, increased or hyperemic ocular surface vasculature, or hemorrhage within the eye.

PATHOPHYSIOLOGY
- Active dilation of ocular vessels—in response to extraocular or intraocular inflammation or passive congestion.
- Hemorrhage from existing or newly formed blood vessels.

SYSTEMS AFFECTED
Ophthalmic—eye and/or ocular adnexa.

SIGNALMENT
Dog and cat.

SIGNS

Historical Findings
Depends on cause.

Physical Examination Findings
- Depends on cause.
- May affect one or both eyes.
- Result of systemic disease—abnormalities in other organ systems common.

CAUSES
- Blepharitis.
- Conjunctivitis.
- Keratitis.
- Episcleritis or scleritis.
- Anterior uveitis.
- Glaucoma.
- Hyphema.
- Orbital disease—usually the orbital abnormality is more prominent.

RISK FACTORS
- Systemic infectious or inflammatory diseases.
- Immunocompromise.
- Coagulopathy.
- Systemic hypertension.
- Irritation by potentially any topical ophthalmic medication.
- Neoplasia.
- Trauma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
More than one cause may occur simultaneously.

Similar Signs
- Rule out normal variations.
- Palpebral conjunctiva—normally redder than bulbar conjunctiva.
- One or two large episcleral vessels—may be normal if the eye is otherwise quiet.
- Transient mild hyperemia—with excitement, exercise, and straining.
- Horner's syndrome—may cause mild conjunctival vascular dilation; differentiated by other signs and pharmacologic testing.

Causes
- Superficial (conjunctival) vessels—originate near the fornix, move with the conjunctiva, branch repeatedly, and blanch quickly with topical 2.5% phenylephrine or 1:100,000 epinephrine. Suggests ocular surface disorders (e.g., conjunctivitis, superficial keratitis, blepharitis).
- Deep (episcleral) vessels—originate near the limbus, branch infrequently, do not move with the conjunctiva, and blanch slowly or incompletely with topical sympathomimetics. Suggests episcleritis or intraocular disease (e.g., anterior uveitis or glaucoma).
- Discharge—mucopurulent to purulent: typical of ocular surface disorders and blepharitis; serous or none: typical of intraocular disorders.
- Swollen or inflamed eyelids—suggest blepharitis.
- Corneal opacification, neovascularization, or fluorescein stain retention—suggest keratitis.
- Aqueous flare or cell (increased protein or cells in the anterior chamber)—confirms diagnosis of anterior uveitis.
- Pupil—miotic: common with anterior uveitis; dilated: common with glaucoma; normal: with blepharitis and conjunctivitis.
- Abnormally shaped or colored irides—suggest anterior uveitis.
- Luxated or cataractous lenses—suggest glaucoma or anterior uveitis.
- Intraocular pressure (IOP)—high: diagnostic for glaucoma; low: suggests anterior uveitis.
- Loss of vision—suggests glaucoma, anterior uveitis, or severe keratitis.
- Glaucoma and anterior uveitis—may complicate hyphema.

CBC/BIOCHEMISTRY/URINALYSIS
Typically normal, except with anterior uveitis, glaucoma, or hyphema secondary to systemic disease.

OTHER LABORATORY TESTS
Depends on cause—see specific types of red eye (conjunctivitis, uveitis, etc.).

IMAGING
- Chest radiographs—consider with anterior uveitis or if intraocular neoplasia is a possibility.
- Abdominal radiography or ultrasonography—may rule out infectious or neoplastic causes.
- Ocular ultrasonography—if the ocular media are opaque; may define the extent and nature of intraocular disease or identify intraocular tumor.

DIAGNOSTIC PROCEDURES
Tonometry—must perform in every patient with an unexplained red eye.

Ocular Surface Disorders
- Aerobic bacterial culture and sensitivity—with a purulent discharge, chronic disease, or poor response to treatment.
- Schirmer tear test.
- Cytologic examination of affected tissue.
- Cats—consider PCR or immunofluorescent antibody (IFA) test on corneal or conjunctival scrapings for feline herpesvirus and *Chlamydia*; collect sample before fluorescein staining to avoid false-positive results on IFA.
- Fluorescein stain.
- Conjunctival biopsies—with chronic conjunctivitis or with a mass lesion.
- See specific disease—Conjunctivitis—Cats, Conjunctivitis—Dogs; Blepharitis; Keratitis chapters.

Intraocular Disorders
- Fluorescein stain.
- See specific disease: Anterior Uveitis—Cats; Anterior Uveitis—Dogs; Hyphema; Glaucoma.

TREATMENT
- Usually outpatient.
- Elizabethan collar—to prevent self-trauma
- Avoid dirty environments or those that may lead to ocular trauma, especially if topical corticosteroids are used.
- Because there is a narrow margin for error, consider referral if the diagnosis is uncertain and/or glaucoma cannot be ruled out.
- Few causes are fatal; however, a workup may be indicated (especially with anterior uveitis and hyphema) to rule out potentially fatal systemic diseases.
- Deep corneal ulcers and glaucoma—may be best treated surgically.

MEDICATIONS

DRUG(S) OF CHOICE
- Depends on specific cause.
- Generally, control ocular pain, inflammation, infection, and IOP.
- Carprofen 2.2 mg/kg PO q12h or 4.4 mg/kg PO q24h to control mild inflammation and reduce pain

CONTRAINDICATIONS
- Topical corticosteroids—contraindicated if the cornea retains fluorescein stain.
- Systemic corticosteroids—avoid until infectious systemic causes have been ruled out.

RED EYE (CONTINUED)

PRECAUTIONS
- Topical aminoglycosides—may be irritating; may impede reepithelization if used frequently or at high concentrations.
- Topical solutions—may be preferable to ointments if corneal perforation is possible.
- Atropine—may exacerbate keratoconjunctivitis sicca (KCS) and glaucoma.
- Nonsteroidal anti-inflammatory drugs (NSAIDs)—use with caution in hyphema.

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
- Depends on cause.
- Repeat ophthalmic examinations—as required to ensure that IOP, ocular pain, and inflammation are well controlled.
- The greater the risk of loss of vision, the more closely the patient needs to be followed; may require daily or more frequent examination.

POSSIBLE COMPLICATIONS
- Loss of the eye or permanent vision loss.
- Chronic ocular inflammation and pain.
- Death.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Numerous systemic diseases.

AGE-RELATED FACTORS
N/A

PREGNANCY/FERTILITY/BREEDING
Systemic corticosteroids may complicate pregnancy.

SEE ALSO
- Anterior Uveitis—Dogs.
- Anterior Uveitis—Cats.
- Conjunctivitis—Dogs.
- Conjunctivitis—Cats.
- Episcleritis.
- Glaucoma.
- Keratitis, Ulcerative.

ABBREVIATIONS
- IFA = immunofluorescent antibody.
- IOP = intraocular pressure.
- KCS = keratoconjunctivitis sicca.
- NSAID = nonsteroidal anti-inflammatory drug.

R

REGURGITATION

BASICS

DEFINITION
Passive, retrograde movement of undigested gastric or esophageal contents into the oral cavity. Reflux refers to the retrograde movement of gastric juice across the gastroesophageal sphincter into the esophagus.

PATHOPHYSIOLOGY
Regurgitation results from a loss of normal esophageal motility. In the normal esophagus, the presence of a food bolus in the proximal esophagus stimulates afferent sensory neurons. Signals are transferred centrally, via the vagus and glossopharyngeal nerves, to the tractus solitarius and nucleus ambiguus. Motor impulses travel back via the vagus nerve to stimulate striated muscle (canine) and striated and smooth muscle (feline) to cause esophageal peristalsis. Lesions anywhere along this pathway may lead to regurgitation. Esophagitis secondary to reflux can cause esophageal dysmotility and subsequent regurgitation. Delayed gastric emptying is a common and underappreciated cause of reflux and possible regurgitation.

SYSTEMS AFFECTED
- Gastrointestinal—dysphagia, weight loss.
- Musculoskeletal—weakness, weight loss.
- Nervous—polyneuropathies, CNS disease.
- Respiratory—aspiration pneumonia.

GENETICS
- Regurgitation due to megaesophagus can be inherited in smooth fox terriers (autosomal recessive) and miniature schnauzers (autosomal dominant or 60% penetrance autosomal recessive). In addition, Jack Russell terriers, springer spaniels, long-haired miniature dachshunds, golden retrievers, Labrador retrievers, and Samoyeds are predisposed to the congenital form of myasthenia gravis. A breed predisposition for acquired megaesophagus also exists for the German shepherd dog, Great Dane, Irish setter, Labrador retriever, pug, and Chinese Shar-Pei. The site and pathogenesis of the lesion in idiopathic megaesophagus is unknown. Suggested hypotheses include abnormalities of the afferent limb of the reflex arc (receptors, neurons) or of the swallowing center in the CNS. • Boxers and Newfoundlands have a genetic predisposition for inflammatory myopathy that is associated with esophageal dysmotility. • Brachycephalic breeds are predisposed to sliding hiatal hernias (type I) that is typically associated with gastroesophageal reflux and regurgitation.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
Species
Dog (more commonly) and cat.

Breed Predilections
- Smooth fox terriers, miniature schnauzers. Other predisposed breeds include Great Dane, German shepherd dog, Irish setter, Labrador retriever, Newfoundland, and boxer, brachycephalic breeds (shar-pei, pug, Boston terrier, English bulldog, French bulldog).
- Siamese and Siamese-related cats.

Mean Age and Range
- Congenital cases present soon after birth (congenital megaesophagus) or at weaning (vascular ring anomalies) during the transition from liquid diet to solid foods.
- Acquired cases may be seen at any age, depending on the etiology.

Predominant Sex
No gender predilection has been identified.

SIGNS
General Comments
- Clients often report vomiting; the veterinarian must differentiate vomiting from regurgitation using a comprehensive history. Having owner videotape events may be helpful. • Regurgitation—passive process; little to no abdominal effort; no prodromal phase; regurgitated material has increased amounts of thick mucus. • Vomiting—active process; prodromal phase is identified; vomited material may have increased amounts of bile staining. • The shape of the expelled material (i.e., tube-like), presence of undigested food, and length of time from ingestion to regurgitation or vomiting are less helpful to differentiate.

Historical Findings
- Vomiting (as perceived by owner).
- Dysphagia. • Coughing. • Ravenous appetite. • Weight loss. • Ptyalism. • Other signs, depending upon underlying etiology.

Physical Examination Findings
- Cervical swelling may be noted. • Ptyalism.
- Halitosis. • Increased respiratory noises.
- Nasal discharge and fever (if concurrent pneumonia). • Cachexia. • Weakness.

CAUSES
Congenital Pharyngeal or Pharyngoesophageal
- Cleft or short palate (typically associated with nasal reflux). • Cricopharyngeal muscle achalasia (typically associated with nasal reflux and dysphagia). • Myasthenia gravis.

Congenital Esophageal
- Vascular ring anomaly (e.g., persistent right aortic arch). • Megaesophagus. • Glycogen storage disease. • Esophageal diverticulum.
- Bronchoesophageal fistula.

Acquired Pharyngeal or Pharyngoesophageal
- Cricopharyngeal dysphagia. • Foreign (botulism). • Myopathy/neuropathy/junctionopathy.

Acquired Esophageal
- Megaesophagus. • Myasthenia gravis. • Stricture. • Neoplasia.
- Hypoadrenocorticism. • Hypothyroidism.
- Hiatal hernia. • Dysmotility.
- Gastroesophageal intussusception.
- Gastroesophageal reflux. • Periesophageal masses. • Dysautonomia. • Myopathy/neuropathy. • Foreign bodies. • Granulomatous disease. • Toxicity (lead). • Idiopathic.
- Gastric dilatation/volvulus. • Parasitic infection (*Spirocerca lupi*). • Bronchoesophageal fistula.

Congenital or Acquired Gastric (Increase Gastroesophageal Reflux)
- Pyloric outflow obstruction. • Gastric foreign body. • Gastric hypomotility.

RISK FACTORS
- Increased risk of gastroesophageal reflux with general anesthesia; the resultant esophagitis may lead to stricture formation and regurgitation. • Administration of doxycycline or clindamycin have been associated with esophagitis and stricture formation. • Esophageal foreign body.
- Swallowing caustic agents causing esophagitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Regurgitation is a clinical sign, not a diagnosis, and is the hallmark of esophageal disease. • It is important to differentiate vomiting from regurgitation.

CBC/BIOCHEMISTRY/URINALYSIS
- There are no pathognomonic changes for regurgitation. • Inflammatory leukogram may be seen if aspiration pneumonia is present. • Most helpful for evaluation of possible underlying etiologies: e.g., erythrocyte changes with lead toxicosis, elevated creatine kinase (CK) with myopathy, hyperkalemia and hyponatremia with hypoadrenocorticism, hypercholesterolemia with hypothyroidism.

OTHER LABORATORY TESTS
These elucidate etiologies of acquired conditions causing regurgitation and include adrenocorticotropic hormone (ACTH) stimulation test or baseline cortisol level (hypoadrenocorticism); thyroid serology (hypothyroidism); acetylcholine receptor antibody level (myasthenia gravis); blood lead levels (toxicosis).

IMAGING
- Thoracic and cervical radiography—evidence of a gas-, fluid-, or ingesta-filled esophagus with megaesophagus; may also show aspiration

REGURGITATION (CONTINUED)

hernia, etc. • Contrast studies—both liquid barium and barium-coated food for radiolucent foreign bodies or esophageal strictures. Iohexol may also be used. Esophagram does not allow one to evaluate functional disorders such as intestinal dysmotility or cricopharyngeal muscle achalasia. Caution: contrast studies may increase the risk for aspiration pneumonia with regurgitation. • Videofluoroscopy—for pharyngeal weakness, cricopharyngeal muscle dysfunction, esophageal motility disorders, hiatal hernia, or gastroesophageal reflux. • Other imaging studies include scintigraphy and high-resolution manometry for motility evaluation and ultrasound for pharyngeal or cervical masses. • Cervical and thoracic CT scans may also be utilized.

DIAGNOSTIC PROCEDURES

• Esophagoscopy can be useful for esophagitis, strictures, vascular ring anomalies, neoplasia, and foreign bodies. • Electromyography and nerve/muscle biopsies may be used for neuropathic or myopathic conditions. • Transtracheal wash or bronchoalveolar lavage if aspiration pneumonia is present or suspected.

PATHOLOGIC FINDINGS

Gross and histologic findings depend upon the underlying etiology and the presence of complicating factors.

R

TREATMENT

APPROPRIATE HEALTH CARE

• Therapy for underlying etiology should be instituted. • Important to meet nutritional requirements and treat or prevent aspiration pneumonia.

NURSING CARE

• Aspiration pneumonia may require supplemental oxygen therapy, nebulization/coupage, and fluid therapy with balanced electrolyte solution. • These animals may be recumbent and require soft bedding. They should be maintained in sternal recumbency or turned to alternate down sides every 4 hours.

ACTIVITY

Depending on etiology, restricted activity is not necessary.

DIET

• Experimentation with different food consistencies is essential. Liquid gruel, small meatballs, or blenderized slurries may be used. • Some cases benefit from gastrostomy feedings, though regurgitation may still occur. • Both food and water should be elevated, and animal should be maintained in an upright position for 10–15 minutes after eating or drinking. Use of a Bailey chair facilitates keeping the dog upright for 10–15 minutes after a meal. • The recommend caloric requirement amount should be calculated and the diet should be monitored so that

CLIENT EDUCATION

• If regurgitation is due to megaesophagus, most cases require lifelong therapy, even if an underlying etiology is found. Client dedication is important for long-term management. • Most animals succumb to aspiration pneumonia or intractable regurgitation. • Placement of a percutaneous gastrostomy tube (PEG) tube in dogs with megaesophagus can reduce the frequency of aspiration pneumonia, leading to prolonged survival.

SURGICAL CONSIDERATIONS

• Surgical intervention is indicated for vascular ring anomalies, cricopharyngeal muscle achalasia, bronchoesophageal fistula, and others. • Esophageal dysfunction is permanent in most cases. • Balloon dilation is indicated for cases of esophageal stricture.

MEDICATIONS

DRUG(S) OF CHOICE

• Antibiotics for aspiration pneumonia (broad-spectrum or based on culture and sensitivity from transtracheal wash or bronchoalveolar lavage). • Specific therapy for underlying etiology if indicated. • Prokinetics—metoclopramide 0.2–0.4 mg/kg SC or PO q6–12h, or 1–2 mg/kg q24h as a CRI increases lower esophageal sphincter (LES) tone and increases gastric motility. Cisapride 0.5 mg/kg PO q8–12h is more effective for esophageal reflux than metoclopramide and has been documented to enhance gastric emptying and increase LES tone in dogs. • Other motility agents (e.g., erythromycin) can enhance gastric emptying and possibly increase LES tone. • H_2 receptor antagonists can be used for the short term to manage mild to moderate esophagitis—ranitidine 1–2 mg/kg PO, IV q12h, famotidine 0.5–1 mg/kg PO, SC, IM, IV q12h; however, are subject to tachyphylaxis (tolerance) when used for >4–5 days and are less potent compared to proton-pump inhibitors. Proton-pump inhibitors may be used in moderate to severe cases, and are also effective when administered for prolonged periods of time—omeprazole 0.7–1.5 mg/kg PO q12h. • Sucralfate caplets or suspension can be administered to help reduce esophageal pain and promote healing of esophagitis and esophageal erosions or ulcerations.

CONTRAINDICATIONS

N/A

PRECAUTIONS

• Absorption of orally administered drugs may be compromised when coadministered with sucralfate. • Injectable forms of acid suppressants should be used when applicable to avoid concerns with regurgitation of the drug before absorption.

POSSIBLE INTERACTIONS

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

• Animals with aspiration pneumonia should have thoracic radiographs and complete blood counts checked until resolution, or if recurrence is suspected. • Animals should be monitored, weighed, and body condition scores applied to ensure adequate caloric intake.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

• Aspiration pneumonia. • Others depending on presence of underlying diseases (e.g., hypothyroidism).

EXPECTED COURSE AND PROGNOSIS

• Older animals with idiopathic megaesophagus have a poor prognosis. • Aspiration pneumonia is the typical cause of death or euthanasia.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Aspiration pneumonia. • Megaesophagus.

AGE-RELATED FACTORS

Young animals may regain some esophageal function with appropriate therapy, depending on etiology.

ZOONOTIC POTENTIAL

None

PREGNANCY/FERTILITY/BREEDING

N/A

SEE ALSO

• Dysautonomia (Key-Gaskell Syndrome).

RENAL TUBULAR ACIDOSIS

BASICS

OVERVIEW

• Hyperchloremic metabolic acidosis due to decreased bicarbonate reabsorption in the proximal renal tubule (proximal or type 2 renal tubular acidosis [RTA]) or decreased hydrogen ion secretion in the distal tubule (distal or type 1 RTA) in patients with normal or near normal glomerular filtration rate and absence of diarrhea.
• Aldosterone deficiency or resistance can cause type 4 distal RTA and hyperkalemia.
• Proximal RTA has not been documented as an isolated entity in dogs but has been observed as part of Fanconi syndrome.
• In distal RTA urine cannot be maximally acidified despite moderately to markedly decreased plasma bicarbonate concentration as a consequence of impaired hydrogen secretion in the collecting ducts. Urine pH typically is >6.0 (urine pH should be 4.5–5.0 in the presence of systemic acidosis).

SIGNALMENT

• Uncommon in both dogs and cats.
• No breed or sex predilection.
• Age range at time of diagnosis, 1–13 years.

SIGNS

• Acidemia may cause lethargy, muscle weakness (may be due to hypokalemia), inappetence, nausea, weight loss, stunted growth, and neurologic signs.
• Other signs depend on the associated diseases (e.g., pyelonephritis).
• Panting.
• Polyuria and polydipsia usually associated with hypokalemia or calciuresis.
• Vomiting.
• Hematuria and dysuria secondary to urolithiasis.
• Osteomalacia associated with chronic metabolic acidosis.

CAUSES & RISK FACTORS

• May be primary (i.e., inherited), or secondary to hypercalciuria, toxins, drugs (e.g., amphotericin B), altered calcium metabolism causing nephrocalcinosis (e.g., hypervitaminosis D, primary hyperparathyroidism), autoimmune (e.g., immune-mediated hemolytic anemia, systemic lupus erythematosus [SLE], renal transplant rejection), hypergammaglobulinemic disorders (e.g., multiple myeloma, SLE), and tubulointerstitial nephropathies.
• In cats, distal RTA has been associated with pyelonephritis, hepatic lipidosis, idiopathic with secondary hyperaldosteronism, and topical ophthalmic carbonic anhydrase inhibitor.
• In dogs, clinical cases were idiopathic or associated with immune-mediated hemolytic anemia, leptospirosis, gastric-dilation-volvulus, zonisamide therapy, or experimentally induced renal ischemia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Consider other causes of hyperchloremic normal anion gap metabolic acidosis (e.g., diarrhea, carbonic anhydrase inhibitors, ammonium chloride, cationic amino acids, post-hypocapnic metabolic acidosis, dilutional acidosis, hypoadrenocorticism). Small bowel diarrhea is the most important differential.

CBC/BIOCHEMISTRY/URINALYSIS

• Results vary depending on associated diseases.
• Hypokalemia due to increased renal excretion.
• Alkaluria (pH >6.0); rule out urease-positive urinary tract infection.

OTHER LABORATORY TESTS

Venous blood gas and serum electrolyte analysis indicates hyperchloremic normal anion gap metabolic acidosis. Urine pH is >6.0 in distal RTA vs. <5.5 in proximal RTA.

IMAGING

Radiography—may detect uroliths or osteomalacia.

DIAGNOSTIC PROCEDURES

• The key diagnostic feature is normal anion gap metabolic acidosis accompanied by an inappropriately alkaline urine pH (>6.0).
• Ammonium chloride tolerance test—administer 200 mg/kg PO; measure urine pH before and hourly for 5 hours; empty the bladder hourly. Urine pH in normal dogs decreases to <5.5 within 4 hours. Avoid this test in severe acidemia.
• Type 1 and 2 RTA can be differentiated based on response to sodium bicarbonate infusion (0.5–1.0 mEq/kg/h). Fractional excretion of bicarbonate will increase markedly in type 2 RTA.

TREATMENT

• Individualize depending on the nature and severity of associated conditions.
• Less bicarbonate is needed to resolve metabolic acidosis caused by distal RTA than is needed with proximal RTA.
• Hypokalemia may resolve with bicarbonate or citrate administration, but additional potassium supplementation may be required.

MEDICATIONS

DRUG(S) OF CHOICE

• Acidosis—depending on the serum potassium concentration give potassium citrate alone ± sodium citrate; or sodium bicarbonate.
• Potassium supplementation—potassium gluconate if hypokalemia does not resolve with potassium citrate therapy alone.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Citrate should be avoided in patients receiving aluminum hydroxide; citrate can lead to excessive aluminum absorption.

FOLLOW-UP

• Serial blood gas with electrolyte analyses (e.g., every 3–5 days) until acid–base status has normalized.
• Long-term prognosis depends on the nature and severity of associated conditions; may be reasonably good in patients without other diseases, little information exists on the long-term course of this disease.

MISCELLANEOUS

SEE ALSO

• Acidosis, Metabolic.
• Fanconi Syndrome.
• Hypokalemia.

ABBREVIATIONS

• RTA = renal tubular acidosis.
• SLE = systemic lupus erythematosus.

Suggested Reading

Authors Joao Felipe de Brito Galvao and Stephen P. DiBartola
Consulting Editor J.D. Foster

RENOMEGALY

BASICS

OVERVIEW

One or both kidneys are abnormally large as detected by abdominal palpation or diagnostic imaging.

Pathophysiology

The kidneys may enlarge due to abnormal cellular infiltration (e.g., inflammation, infection, and neoplasia), urinary tract obstruction, acute tubular necrosis, or development of renal cysts or pseudocysts.

Systems Affected

- Endocrine/metabolic—metabolic acidosis with decreased kidney function.
- Gastrointestinal—inappetence, vomiting, diarrhea, or melena due to gastrointestinal ulceration in uremia.
- Hemic/lymphatic/immune—anemia from uremic blood loss or decreased red blood cell survival; impaired production of erythropoietin.
- Hepatobiliary—may occur with portosystemic shunts.
- Nervous—depression and lethargy associated with uremia.
- Renal/urologic.
- Respiratory—tachypnea or respiratory distress due to uremic pneumonitis or metabolic acidosis compensation.

SIGNALMENT

- Cat and dog.
- Polycystic kidney disease (PKD) occurs in several breeds of dogs and cats. Autosomal dominant inheritance in bull terriers and Persian cats; autosomal recessive in Cairn and West Highland white terriers.

SIGNS

Historical Findings

- May be asymptomatic, especially if only one kidney is affected.
- Lethargy.
- Loss of appetite.
- Weight loss.
- Vomiting.
- Diarrhea.
- Polyuria and polydipsia.
- Discolored urine.
- Abdominal enlargement.
- Rarely lameness because of hypertrophic osteopathy associated with renal neoplasia.

Physical Examination Findings

- Abdominal mass or pain.
- One or both kidneys palpably large.
- Abdominal enlargement.
- Asymmetric kidneys.
- Dehydration.
- Pallor.
- Oral ulcers.
- Uremic halitosis.

CAUSES & RISK FACTORS

Developmental/Acquired Disorders

- Hydronephrosis—unilateral or bilateral renomegaly secondary to ureteral obstruction or ectopic ureters.
- PKD—bilateral renomegaly in cats leading to chronic kidney disease (CKD).
- Hematoma—secondary to trauma.
- Compensatory hypertrophy—unilateral renomegaly secondary to disease of the other kidney.
- Perinephric pseudocyst—unilateral or bilateral enlargement. Kidney size may be normal, but subcapsular fluid accumulation enlarges capsule margins.

Metabolic

- Portosystemic shunt, acromegaly.
- Males have larger kidneys than females.

Neoplastic

- Lymphoma—most often occurs in cats and causes bilateral renomegaly; rarely unilateral.
- Renal carcinoma—most common renal tumor of dogs; often causes unilateral renomegaly.
- Nephroblastoma—congenital renal tumor, may not be diagnosed until the patient is older; usually unilateral.
- Sarcoma—usually cause unilateral renomegaly.
- Cystadenocarcinoma—bilateral renal tumor in German shepherd dogs; often associated with skin lesions.

Infectious/Inflammatory

- Amyloidosis.
- Leptospirosis.
- Feline infectious peritonitis (FIP).
- Feline leukemia virus (FeLV) infection predisposes cats to renal lymphoma.
- Acute kidney injury.
- Renal abscess.

Toxic

- Ethylene glycol—bilateral renomegaly secondary to renal tubular swelling and infiltration by calcium oxalate crystals.
- See Acute Kidney Injury.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Distinguish from other abdominal masses.
- Confirmation may require diagnostic imaging or exploratory celiotomy.

CBC/BIOCHEMISTRY/URINALYSIS

- Azotemia, hyperphosphatemia, and inadequate urine concentration.
- Leukocytosis—infectious, inflammatory, and neoplastic causes.
- Nonregenerative anemia—CKD or inflammatory disorder.
- Hyperglobulinemia—infectious or inflammatory disorder.
- Hematuria and proteinuria—renal neoplasia.
- Polycythemia and leukocytosis rarely accompany some renal neoplasms.
- Neoplastic cells rarely observed in urine with renal neoplasia.

OTHER LABORATORY TESTS

- Test for FeLV infection if renal lymphoma is suspected.
- Serum protein electrophoresis distinguishes polyclonal from monoclonal hyperglobulinemia.
- Test for leptospirosis if indicated.

IMAGING

Radiographic Findings

- Abdominal radiographs to confirm renomegaly and identify causes of ureteral obstruction.
- Renomegaly on the ventrodorsal view: >3 or 3.5 times the length of the L2 vertebra in cats or dogs, respectively.
- Excretory urography or CT to confirm renomegaly, hydronephrosis, and space-occupying masses.
- Antegrade pyelography may exclude ureteral obstruction.
- Thoracic radiography indicated to detect metastases.

Ultrasonographic Findings

- Distinguish between PKD, perinephric pseudocysts, hydronephrosis, neoplasia, abscess, and subcapsular hematoma.
- Acute inflammation may be associated with increased cortical echogenicity, perinephric effusion, or a medullary band of increased echogenicity.

DIAGNOSTIC PROCEDURES

- Cytologic examination of fine-needle aspirate can confirm renal cyst, abscess, or neoplasia. Due to potential for seeding of neoplastic cells in the abdominal wall, fine-needle aspiration should be avoided if some renal tumors (e.g., renal carcinoma) are suspected.
- If renal aspirate is nondiagnostic, biopsy may be indicated.

TREATMENT

- Diagnose and treat underlying cause of renomegaly.
- Outpatient unless dehydration or decompensated renal failure exist.
- Therapeutic renal diet is indicated to prolong survival time for CKD when serum creatinine exceeds 2 mg/dL.
- Administer balanced electrolyte solution intravenously or subcutaneously to maintain hydration as needed.

• If the patient has dehydration or continuing fluid losses such as vomiting or diarrhea, administer fluids intravenously to correct hydration deficits, maintain daily fluid need, and replace ongoing losses.

MEDICATIONS

DRUG(S) OF CHOICE
Vary with the cause.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Avoid nephrotoxic drugs.

FOLLOW-UP

PATIENT MONITORING
• Perform physical examination and weigh patient to assess hydration.
• CBC, serum chemistries, urinalysis, blood pressure measurements are indicated depending on the underlying cause.

POSSIBLE COMPLICATIONS
CKD, depending on underlying cause of renomegaly.

MISCELLANEOUS

ZOONOTIC POTENTIAL
Leptospirosis can be spread by contact with infected urine.

SEE ALSO

RESPIRATORY PARASITES

BASICS

DEFINITION
Helminths, arthropods, and protozoa that reside in the respiratory tract or pulmonary vessels of dogs and cats.

PATHOPHYSIOLOGY
Infestation with parasites causes rhinitis, bronchitis, pneumonitis, or arteritis, depending on the location of the organism within the respiratory system. Eosinophilic inflammation usually results from invasion of the parasite.

SYSTEMS AFFECTED
• Respiratory. • Cardiovascular. • Hepatic—with hepatopulmonary migration of some parasites (*Toxocara* spp.). • Neurologic—with migration of parasites to the brain (*Cuterebra*) or cerebral hemorrhage (*Angiostrongylus*).

GENETICS
There is no genetic basis.

INCIDENCE/PREVALENCE
Depends on parasite.

GEOGRAPHIC DISTRIBUTION
• *Pneumonyssoides caninum*, *Aelurostrongylus abstrusus*, *Linguatula serrata*, *Oslerus (Filaroides) osleri*, *Crenosoma vulpis*, *Eucoleus (Capillaria) aerophilus*, *Toxoplasma gondii*, *Toxocara* spp.—worldwide. • *Eucoleus boehmi*, *Cuterebra* spp., *Filaroides hirthi*, *Paragonimus kellicotti*—primarily North America. • *Andersonstrongylus (Filaroides) milksi*—North America, Europe. • *Angiostrongylus vasorum*—various countries of Europe, Africa, South America, North America.

SIGNALMENT
Species
Dog and cat.

SIGNS
General Comments
• Four basic categories—upper airway (nasal cavity and sinuses), lower respiratory (trachea and bronchi), pulmonary parenchyma, and vascular; based on location and lifestyle of parasite. • Often insidious and chronic, with few clinical signs. • Respiratory compromise often not severe.

Historical Findings
• Upper respiratory—sneezing; nasal discharge (serous, sanguinous); reverse sneezing; nasal irritation or rubbing; neurologic signs with *Cuterebra* spp. • Lower respiratory and parenchyma—may have no clinical signs, variable coughing, tachypnea, or altered respiratory pattern. • Vascular—can have weight loss, lethargy, coughing, exercise intolerance. Acute onset of respiratory distress if embolization or hemorrhage occurs.

Physical Examination Findings
• Upper respiratory—similar to historical findings; variable. • Lower respiratory and parenchyma—cough elicited on tracheal palpation; occasionally harsh lung sounds. • Vascular—may present with signs of pulmonary disease, right-sided heart failure, anemia, coagulopathy, neurologic signs.

CAUSES
• Upper respiratory (nasal cavity and sinuses)—*Pneumonyssoides caninum*, *Eucoleus boehmi*, *Linguatula serrata*, *Cuterebra* spp. • Lower airway (trachea and bronchi)—dogs and cats: *Eucoleus (Capillaria) aerophilus* (rare in cats); dogs: *Oslerus osleri*, *Filaroides hirthi*, *Andersonstrongylus milksi*, *Crenosoma vulpis*. *Cuterebra* spp. in the trachea. • Pulmonary parenchyma—dogs and cats: *Paragonimus kellicotti*, *Toxoplasma gondii*; dogs: *Filaroides hirthi*, *Andersonstrongylus milksi*; cats: *Aelurostrongylus abstrusus*, *Troglostrongylus brevior*, *Troglostrongylus subcrenatus*. • Vascular—dogs and cats: *Dirofilaria immitis*, larval migration of *Toxocara canis* and *T. cati*; dogs: *Angiostrongylus vasorum*.

RISK FACTORS
• Depends on the specific parasite—some have intermediate or paratenic hosts that must be ingested by the definitive host, putting hunting or scavenging animals at higher risk. • *Crenosoma vulpis*—snails. • *Paragonimus kellicotti*—snails, crabs, shellfish. • *Aelurostrongylus abstrusus*—snails and slugs; transport hosts: rodents, frogs, lizards, birds. • *Linguatula serrata*—ingestion of sheep offal. • *Toxoplasma gondii*—ingestion of infected small mammals and birds or less commonly by ingesting sporulated oocysts in soil or water. • Multi-animal households with unhygienic living conditions—allows fecal–oral or direct-contact transmission. • *Angiostrongylus vasorum*—gastropods (slugs/snails) or frogs are the intermediate host. Frogs can also serve as paratenic hosts.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Upper respiratory—other causes of epistaxis, rhinitis, or sinusitis (see specific chapters). • Lower respiratory—acute bronchitis (nonparasitic); chronic bronchitis; infectious tracheobronchitis. • Pulmonary parenchyma—eosinophilic lung disease; bronchopneumonia; granulomatous pneumonia; pulmonary granulomatosis. • Vascular—other causes of coagulopathy, right-sided heart failure, or pulmonary artery disease.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC—variable; may note eosinophilia, basophilia, neutrophilia, and monocytosis; can see anemia with *Angiostrongylus vasorum*. • Biochemistry—often normal; high liver enzyme activity with some parasites during early stages as a result of hepatic migration if burden is substantial. • Urinalysis—normal.

OTHER LABORATORY TESTS
Coagulopathy with *Angiostrongylus vasorum* or severe cases of heartworm disease (disseminated intravascular coagulation).

IMAGING
Thoracic Radiography
• Often nonspecific findings—generalized interstitial pattern; peribronchiolar infiltrates, nodular to alveolar pattern. • *Oslerus*—soft tissue nodular densities within the trachea at the level of the carina. • *Paragonimus*—can see bullae, cystic lesions or pneumothorax due to bulla or cyst rupture. • *Dirofilaria*—right-sided heart enlargement, tortuous and truncated pulmonary arteries, pulmonary infiltrates (dogs). Few cardiac changes in cats, large pulmonary arteries possible.

DIAGNOSTIC PROCEDURES
Sputum Examination
May reveal eggs or larvae (L-1).

Fecal Examination
• Multiple examinations often necessary; negative results do not rule out infection. • Direct fecal smear: *Angiostrongylus* (larvae). • Standard fecal flotation: *Eucoleus aerophilus* (eggs), *Eucoleus boehmi* (eggs). • Zinc sulfate centrifugation: *Aelurostrongylus* (larvae), *Oslerus osleri*, *Andersonstrongylus milksi*, *Filaroides hirthi* (larvae, larvated eggs), *Angiostrongylus vasorum* (larvae). • Baermann: *Aelurostrongylus* (larvae), *Oslerus osleri*, *Andersonstrongylus milksi*, *Filaroides hirthi* (larvae, eggs), *Crenosoma* (larvae, larvated eggs), *Angiostrongylus* (larvae). • Sedimentation: *Paragonimus* (eggs).

Rhinoscopy
• Upper respiratory—examination via retrograde pharyngoscopy or rhinoscopy with antegrade flushing of anesthetic gas can allow visualization of nasal mites; retrograde nasal lavage and cytologic examination of fluid can be helpful. • *Eucoleus boehmi*—histopathology can reveal eggs deep within the epithelium. • *Linguatula serrata*—diagnosis made by observation of eggs in nasal secretions or around the nares.

Bronchoscopy
• Lower respiratory and parenchyma—rarely can see tracheal and bronchial parasites and parasitic nodules; occasionally can be removed for definitive identification. • Tracheal wash or bronchoalveolar lavage can allow identification of larvae (*Oslerus osleri*, *Aelurostrongylus*, *Crenosoma*, *Filaroides hirthi*, *Andersonstrongylus milksi*, *Angiostrongylus*); eggs (*Eucoleus aerophilus, Paragonimus*); organisms (*Toxoplasma*). • *Oslerus osleri*—can also be diagnosed by brushings or histopathology of nodules at the carina.

(CONTINUED) # RESPIRATORY PARASITES

PATHOLOGIC FINDINGS
• Upper respiratory—may find nasal mites or worms in epithelium of sinuses and nasal cavity. • Lower respiratory and parenchyma—can see pulmonary nodules containing parasites throughout the parenchyma or within bronchi. • Vascular—changes include thrombi and intimal proliferation of the vascular walls. • *Cuterebra* spp. can be found in brain sections when associated with neurologic signs.

TREATMENT

APPROPRIATE HEALTH CARE
Most commonly outpatient—upper and lower respiratory parasites; may need repeated examinations to monitor response.

NURSING CARE
Supportive care and oxygen therapy can be needed depending on the severity of disease.

ACTIVITY
Strict cage rest if severe pulmonary dysfunction occurs with upper or lower respiratory parasites; also with vascular parasite infection or bullous lung disease associated with *Paragonimus*.

DIET
No special restrictions.

CLIENT EDUCATION
• Explain that treatment duration and response depend on the type of parasite. • Warn client of the risk of recurrence in animals that maintain lifestyles conducive to transmission of the parasites (e.g., hunting, sporting dogs, multidog households, outdoor cats).

SURGICAL CONSIDERATIONS
Ruptured *Paragonimus* cysts generally require surgical excision.

MEDICATIONS

DRUG(S) OF CHOICE
• Anthelmintics—few studies confirm efficacy; most data anecdotal. For treatment of *Dirofilaria*, see chapters on Heartworm Disease. • *Pneumonyssoides caninum*—selamectin 6–24 mg/kg applied every 2 weeks for three treatments. milbemycin oxime 0.5–1 mg/kg PO weekly for 3 weeks, ivermectin 200 µg/kg SC or PO for two treatments 3 weeks apart; *note:* not labeled for use in dogs at this dosage. • *Cuterebra*—ivermectin 300 µg/kg SC or PO every other day for three doses combined with a tapering dose of corticosteroids. • *Linguatula serrata*—physical removal of organisms from the sinuses. • *Eucoleus aerophilus, E, boehmi*—ivermectin 200 µg/kg PO once; fenbendazole 25–50 mg/kg q12h for 10–14 days; very difficult to clear. • *Oslerus osleri*—efficacious therapy not fully determined. Consider ivermectin 400 µg/kg SC or PO q3 weeks for four doses. • *Crenosoma vulpis*—levamisole 7.5 mg/kg SC q48h (two doses); fenbendazole 50 mg/kg PO q24h for 7 days; milbemycin oxime 0.5 mg/kg PO once. • *Aelurostrongylus abstrusus*—fenbendazole 25–50 mg/kg PO q24h for 10 days; ivermectin 400 µg/kg SC, selamectin spot-on formula 45 mg/cat, two doses, 23 days apart. • *Filaroides hirthi*, *Andersonstrongylus milksi*—fenbendazole 50 mg/kg PO q24h for 14 days; albendazole 50 mg/kg PO q12h for 5 days, repeat in 3 weeks. • *Paragonimus kellicotti*—praziquantel 25 mg/kg PO, SC q8h for 3 days; fenbendazole 25–50 mg/kg PO q12h for 14 days. • *Toxoplasma*—clindamycin 12.5 mg/kg PO q12h for 28 days. • *Angiostrongylus vasorum*—fenbendazole 20–50 mg/kg PO q24h for 5–21 days; milbemycin oxime 0.5 mg/kg PO weekly for 4 weeks; single topical application of moxidectin 2.5 mL/kg. • *Toxocara* spp. larval migration—fenbendazole 50 mg/kg PO q24h for 10 days. • Anti-inflammatory agents—recommendations for concurrent use of steroids vary.

CONTRAINDICATIONS
Ivermectin—not labeled for use in dogs or cats other than for heartworm prophylaxis; contraindicated at dosages >100 µg/kg in breeds with known sensitivity (collies, collie breeds, and Australian shepherd dogs).

PRECAUTIONS
None

ALTERNATIVE DRUG(S)
None

FOLLOW-UP

PATIENT MONITORING
• Serial fecal Baermann larval extractions or examination for eggs—some anthelmintics can suppress egg or larval production in some species and intermittent shedding reduces value of repeated fecal exams. • Resolution of clinical signs—suggests response to treatment; does not indicate complete clearance of parasites. • Peripheral eosinophilia, if noted initially, may subside with treatment. • Repeat bronchoscopic examination—can help assess efficacy of treatment for *Oslerus osleri*.

PREVENTION/AVOIDANCE
• Avoid activity that predisposes to infestations (often not practical). • Avoid contact with wildlife reservoirs (especially wild canids and felids). • Consider prophylactic treatment for heartworm.

POSSIBLE COMPLICATIONS
• Chronic pulmonary damage—possible with persistent and heavy lower respiratory parasite burdens. • Infestations generally not fatal; however, severe pulmonary damage can result with some species; *Cuterebra* spp. and *Angiostrongylus* can cause fatal neurologic complications. • *Pneumonyssoides caninum* has been associated with gastric dilation and volvulus.

EXPECTED COURSE AND PROGNOSIS
• With aggressive management—prognosis usually fair to excellent; variable. • Return to performance—depends on chronicity of disease and level of chronic pulmonary damage by lower respiratory parasites. • Recurrence possible.

MISCELLANEOUS

ZONOTIC POTENTIAL
None

SYNONYMS
• Lungworm infestation—*Aelurostrongylus*, *Eucoleus (Capillaria) aerophilus*, *Crenosoma*, *Oslerus osleri*, *Filaroides hirthi*, *Andersonstrongylus milksi*. • Nasal mite infestation—*Pneumonyssoides caninum*, *Pneumonyssus caninum*. • French heartworm—*Angiostrongylus vasorum*.

SEE ALSO
• Heartworm Disease—Cats.

R

RETAINED PLACENTA

BASICS

OVERVIEW
• Dogs—placenta retained beyond the immediate postpartum period; placentas usually passed within 15 minutes of birth of a puppy; may develop acute metritis secondary to retained placenta.
• Cats—may retain placentas for days without signs of illness.
• Extremely uncommon.

SIGNALMENT
• Dog—rare, most common in toy dog breeds.
• Cat—rare.

SIGNS

Historical Findings
• Recent parturition.
• Continued vulvar discharge of lochia.
• Owner may note number of placentas passed, although this information is frequently unreliable.

Physical Examination Findings
• Green lochia vulvar discharge.
• Palpation of firm mass in uterus—not always possible.
• Concurrent clinical signs of postpartum metritis.

CAUSES & RISK FACTORS
• Toy breed.
• Large litter size.
• Dystocia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Postpartum metritis—physical examination and vaginal cytologic examination show no signs of infection with uncomplicated retained placenta; metritis may develop concurrently.
• Retained fetus—differentiated by radiography or ultrasonography.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal when uncomplicated.

OTHER LABORATORY TESTS
Vaginal cytologic examination—parabasal epithelial cells; may note erythrocytes; biliverdin clumps.

IMAGING
Ultrasonography—echogenic but nonfetal mass within the uterus.

DIAGNOSTIC PROCEDURES
Celiotomy or hysterotomy—may be required for diagnosis.

TREATMENT

• Outpatient for healthy bitch or queen.
• Instruct owner to monitor rectal temperature and observe for signs of systemic illness.
• Ovariohysterectomy—curative; recommended if future breeding is not a consideration.
• Surgical removal—indicated if medical treatment is unsuccessful and the bitch develops metritis.

MEDICATIONS

DRUG(S) OF CHOICE
• Oxytocin—known or suspected condition in otherwise healthy cats and dogs; dogs: 0.5 IU/kg IM, up to 5 IU total dose; cats: 0.5–1 IU IM. Oxytocin may be ineffective after 48 hours postpartum.
• Can precede oxytocin treatment with calcium gluconate (10%); dogs and cats, 0.5–1.5 mL/kg IV slowly over 15 minutes; monitor for bradycardia during injection.
• Metritis—treat accordingly (see Metritis).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Do not give progestational drugs.

FOLLOW-UP

• Monitor temperature and physical condition.
• Acute metritis (dogs)—may develop if the placenta is not passed; fair to good prognosis for recovery with treatment.
• Prognosis for future reproduction—good without metritis; fair to poor with metritis.

RETINAL DEGENERATION

BASICS

DEFINITION
• Degeneration of the retina from inherited or acquired causes. • Inherited—generalized progressive retinal atrophy (PRA); a group of progressive retinal diseases; may be subdivided into photoreceptor dysplasias (begin before retina fully develops <8 weeks) and photoreceptor degenerations (begin after retina matures).

PATHOPHYSIOLOGY
• A number of genetic defects in photoreceptor metabolism have been identified. • May be secondary to retinal pigment epithelial or choroidal disease; amino acid metabolic disorders, and storage diseases. • Central PRA: genetic defect in vitamin E metabolism, or acquired with vitamin E deficiency. • May be idiopathic, secondary to diffuse or focal inflammation and scarring (e.g., chorioretinitis), toxin exposure, nutritional deficiency, or previous retinal detachment. • Sudden acquired retinal degeneration syndrome (SARDS): idiopathic, may be immune-mediated retinitis.

SYSTEMS AFFECTED
• Nervous. • Ophthalmic.

GENETICS
Dogs
• PRA—generally autosomal recessive, dominant in mastiffs. • Neuronal ceroid lipofuscinosis—generally autosomal recessive. • Hemeralopia—cone degeneration, autosomal recessive. • Inheritance in many breeds not determined.

Cats
• Early onset—mixed breed and Abyssinian retinal dysplasia (rod-cone dysplasia), autosomal dominant. Persians, autosomal recessive. • Late onset—Abyssinian rod-cone degeneration, autosomal recessive. • Late onset—PRA in many breeds, including Siamese.

INCIDENCE/PREVALENCE
• Hereditary—prevalence greater in dogs than cats. • Taurine deficiency—uncommon with nutritionally complete cat foods.

GEOGRAPHIC DISTRIBUTION
Central PRA—more common in dogs from Europe than United States.

SIGNALMENT
Species
Dog and cat.

Breed Predilections
Hereditary—Dogs • Retinal dysplasia—Bedlington terrier, Sealyham terrier, English springer spaniel, cocker spaniel, others. • Early-onset PRA—Irish setter, collie, Norwegian elkhound, miniature schnauzer, Belgian shepherd dog, mastiff, Cardigan Welsh corgi, American Staffordshire terrier, pit bull terrier, briard (congenital stationary night blindness). • Late-onset PRA—miniature and toy poodle, American and English cocker spaniel, basenji, Labrador retriever, Tibetan terrier, dachshund, Akita, Samoyed, Siberian husky. • Central PRA—Labrador, golden retriever, border collie, collie, Shetland sheepdog, briard, others. • Cone degeneration disease—German shorthaired pointer, Alaskan Malamute, and Australian shepherd dog. • Neuronal ceroid lipofuscinosis—English setter, border collie, American bulldog, Dalmatian, Tibetan terrier, collie. • SARDS—Brittany spaniel, miniature schnauzer, dachshund, others.

Hereditary—Cats
• Abyssinian, Somali, Persian. • Siamese breed group—autosomal recessive (CEP290).

Mean Age and Range
• Early PRA and dystrophies—3 months–2 years. • Late PRA—clinical signs >4–6 years. • Cone degeneration disease—3–4 months. • SARDS—middle-aged to old.

Predominant Sex
• PRA—X-linked recessive condition in Siberian husky and Samoyed, therefore primarily males. • SARDS—70% female.

SIGNS
Historical Findings
• PRA (dog)— gradually progressing nyctalopia that ultimately affects vision in bright light; may note dilated pupils or brighttapetal reflex; may appear acutely blind. Dysplasias have early onset and blindness by 2 years. Degenerations are later onset and blind in later life. • Hemeralopia or cone degeneration disease—rare. Between 8 and 12 weeks of age puppies show photophobia and trouble navigating in bright light. Progresses to total day blindness. Night vision remains normal. • Central PRA (dogs)—rare in United States; central vision lost; may never become completely blind. • SARDS—vision lost in 1–4 weeks; polyuria, polydipsia, and polyphagia common.

Physical Examination Findings
• If severe—direct and consensual pupillary light reflexes impaired or nearly abolished. • Tapetal hyperreflectivity and nontapetal depigmentation or mottled hyperpigmentation; retinal blood vessel attenuation and optic nerve atrophy. • PRA (dogs)—cataracts and vitreous degeneration can occur. • SARDS (dogs)—obesity; may note slow or absent pupillary light reflexes (PLR). Chromatic PLR testing (melan 100), reduced or no red PLR, normal blue PLR. • Borzoi chorioretinopathy—multifocal chorioretinal lesions (hyperpigmented and hyperreflective). • Taurine-deficient retinopathy (cats)—begins as a spot in area centralis; then horizontal band forms superior to optic nerve; finally, diffuse degeneration and hyperreflectivity. • Storage diseases—may have cloudy corneas and possibly neurologic signs. • Neuronal ceroid lipofuscinosis—mental deterioration, paralysis, and death.

CAUSES
Degenerative
• PRA—affects both eyes symmetrically. • Chronic or uncontrolled glaucoma—retinal and optic nerve atrophy. • Secondary to scarring from previous multifocal or diffuse retinal detachment or inflammation.

Anomalous
• Rod-cone dysplasias—affect both eyes. • Other dysplasias—may be multifocal and nonblinding (e.g., English springer spaniel, Labrador retriever). • Oculoskeletal dysplasia in Labrador and Samoyed.

Metabolic
• Storage disease—mucopolysaccharidosis, gangliosidosis, mannosidosis, fucosidisis (English springer spaniel). • Ornithine aminotransferase deficiency—progressive and total atrophy of choroid and retina; older cats.

Neoplastic
Neoplastic infiltrate may lead to scars from previous retinal detachment if treated.

Nutritional
• Severe deficiency of vitamin E or A (dogs and cats)—may cause partial or complete degeneration. • Taurine deficiency (cats)—retinal degeneration, dilated cardiomyopathy.

Infectious/Immune
• Retina will degenerate from inflammation; may be focal, multifocal, or generalized. SARDS—some cases are immune-mediated retinitis.

Idiopathic
SARDS—dogs; post-inflammatory—dogs and cats.

Toxic
• Idiosyncratic reaction to griseofulvin or enrofloxacin (cats). • Radiation—dogs or cats treated for nasal or CNS neoplasia. • Phototoxicity—operating microscopes, welding light exposure.

RISK FACTORS
• Ocular disease—cataracts, panuveitis, chorioretinitis, retinal detachment, glaucoma. • Cats—enrofloxacin dose should not exceed 5 mg/kg/day. Toxicity noted at lower doses in compromised animals (i.e., renal disease).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Acute vision loss, PLR slow or absent—SARDS, optic neuritis, retinal detachment, unrecognized PRA, or glaucoma; PLR normal—rapidly developing diabetic cataracts

RETINAL DEGENERATION (CONTINUED)

or visual cortex disease. • Slowly progressive visual loss—PRA, cataracts, severe corneal disease (e.g., pigmentation, scarring, or edema), chronic retinitis, chorioretinitis, vitreal inflammation.

CBC/BIOCHEMISTRY/URINALYSIS
• Usually normal, unless systemic disease. • SARDS (dogs)—may suggest hyperadrenocorticism.

OTHER LABORATORY TESTS
• Test for hyperadreoncorticism, evaluate sex hormone levels, check blood pressure, evaluate for proteinuria with SARDS. • Taurine concentration (cats)—especially with dilated cardiomyopathy. • Serum and urine ornithine concentrations (cats)—elevated with ornithine aminotransferase deficiency. • Genetic testing - many tests are available from many different companies; VetGen, Animal Genetics, Animal Labs, Embark Vet are examples. May identify affected, non-affected and carriers.

IMAGING
• Thoracic radiographs and cardiac ultrasound—in cats with suspected taurine deficiency. • CT or MRI—investigate causes of central blindness.

R

DIAGNOSTIC PROCEDURES
• Ophthalmic examination. • Electroretinography—localizes cause of blindness when retina not visible or appears normal. • Chromatic PLR (Melan 100)—differentiates outer retinal layer problems (red reduced) vs. inner retina layers (absent blue). Definitive diagnosis requires electroretinogram as interpretation can be confounded by iris atrophy and stress-induced mydriasis. • Cerebrospinal fluid tap—for cases of suspected optic neuritis.

PATHOLOGIC FINDINGS
• Thin retina. • Edges of focal retinal scars—sharply delineated. • Hyperpigmented areas—associated with postinflammatory scars or central PRA. • End-stage degenerations—marked photoreceptor atrophy and reduction in retinal cell density. • Lipopigment accumulated in neuroepithelium—central PRA, ceroid lipofuscinosis, congenital stationary night blindness. • Lysosome storage diseases—accumulation in neuronal/retinal layers/cornea.

TREATMENT

DIET
• Cats—food should contain 500–750 ppm taurine. • Dogs—balanced diet, avoid those high in polyunsaturated fats.

CLIENT EDUCATION
• Most blind animals function well in stable environment. • Blind dogs should be supervised if outside, in unfenced yards or in an area with a pool. • Suggest playing with toys that make sounds. • Older blind animals with hearing loss or senility may not adapt well. • Some blind animals experience behavioral changes such as aggression or reduced activity. • Animals with only one blind eye can function normally. • Blind cats should be kept indoors.

SURGICAL CONSIDERATIONS
Not indicated unless painful.

MEDICATIONS

DRUG(S) OF CHOICE
• None currently effective. • Pyridoxine—for ornithine aminotransferase deficiency (cats). • Adequate dietary taurine—halt progression of taurine-deficient retinopathy. • SARDS—if autoimmune retinitis, immune suppressive treatment may preserve/restore some vision.

GENE THERAPY
Experimental—retinal pigment epithelium dystrophy in briard.

CONTRAINDICATIONS
N/A

PRECAUTIONS
Cataract surgery—not recommended if retinal degeneration is severe; perform preoperative electroretinogram.

FOLLOW-UP

PATIENT MONITORING
• Serial fundic examinations—signs of degeneration over weeks with SARDS; months with PRA. • Cataract formation—with PRA or SARDS.

PREVENTION/AVOIDANCE
• Do not breed known or suspected carriers of PRA or other heritable diseases. • Genetic testing on breeding animals.

POSSIBLE COMPLICATIONS
• Cataracts. • Glaucoma. • Uveitis. • Ocular trauma (result of visual impairment). • Obesity (reduced activity).

EXPECTED COURSE AND PROGNOSIS
• Inherited PRA—progresses to blindness; slow progression allows patient to adapt to visual loss. • Degeneration from inflammation—usually does not progress unless persistent or recurrent inflammation. • SARDS—irreversible blindness. • Taurine deficiency (cats)—degeneration may halt at any stage.

MISCELLANEOUS

ASSOCIATED CONDITIONS
SARDS—hyperadrenocorticism, proteinuria, hypertension, elevated sex hormones.

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL

RETINAL DETACHMENT

BASICS

DEFINITION
Separation of the neural retina from the retinal pigment epithelium (RPE).

PATHOPHYSIOLOGY
• Subretinal space—a potential space between RPE and neural retina in which fluid or exudates accumulate. • Etiopathogenesis is one or a combination of rhegmatogenous (retinal tear), subretinal exudation, or traction.

Rhegmatogenous Retinal Detachment (RRD)
A tear or hole in retina related to age, cataracts, traction from inflammatory debris or vitreal degeneration, trauma, or retinal degeneration. Vitreous fluid moves into the subretinal space, resulting in detachment. Probably the predominant type occurring in association with cataracts and after cataract or lens surgery.

Exudative
• Fluid accumulates in the subretinal space because of breakdown of blood–retinal barrier. • Subretinal fluid—serous, hemorrhagic, or exudative. • Hematogenous/systemic pathogenetic factors—common. • Vasculitis, hypertension, and hyperviscosity—may cause serous detachment with or without hemorrhage.

Traction
• Fibrous or fibrovascular tissue; detaches retina and/or may cause retinal tear. • Associated with trauma, intraocular foreign bodies, or any cause of severe vitreal inflammation.

SYSTEMS AFFECTED
• Nervous. • Ophthalmic. • May be manifestation of systemic disease or neoplasia.

GENETICS
Depends on cause—dogs with hereditary cataracts or lens luxation may develop RRD. Some breeds may develop RRD from primary vitreous abnormalities (shih tzu), colobomas of optic nerve (collie), or severe retinal dysplasia inducing retinal tears or traction.

INCIDENCE/PREVALENCE
• Exudative—most common in dogs and cats. • RRD—uncommon. More common in dogs because of the greater prevalence of severe vitreal degeneration, cataracts, and cataract surgery.

GEOGRAPHIC DISTRIBUTION
Varies with the distribution of infectious etiologies.

SIGNALMENT

Species
Dog and cat.

Breed Predilections
• Depends on cause. • Terrier breeds—predisposed to primary lens luxation, may contribute to RRD. • Breeds that develop cataracts. • Shih-tzu, Boston terrier, Italian greyhound, Chihuahua, corgi—predisposed to spontaneous RRD owing to abnormal liquefied vitreous. • Dogs with merle coat color (Australian shepherd dog, Shetland sheepdog, Great Dane, collie) may have severe retinal dysplasia and optic nerve or scleral colobomas, leading to RRD. • Breeds with severe retinal dysplasia: English springer spaniel, Labrador retriever, Bedlington terrier. • Breeds with serous retinopathy (also known as RPE dysplasia, canine multifocal retinopathy): Great Pyrenees, mastiff, coton de Tulear.

Mean Age and Range
• Depends on cause. • Older patients—cataracts and systemic diseases (e.g., hypertension, neoplasia, immune-mediated disease). • Young dogs—retinal dysplasia, canine multifocal retinopathy, uveodermatologic syndrome.

SIGNS
• Blindness or reduced vision in affected eye. • Dilated pupil with slow or no pupillary light response (PLR). PLR may be near normal if detachment is acute. • Blood vessels or a "membrane" may be observed easily through the pupil just behind the lens. • Vitreous abnormalities—floaters, hemorrhage, or syneresis (liquefaction); common. • Interruption or alteration of course of blood vessels due to retinal elevation. • With clear subretinal fluid—vessels may cast shadows. • With exudative fluid or blood, tapetum/RPE may not be visible. • Other signs related to underlying systemic disease or inflammation (see Chorioretinitis). • Canine multifocal retinopathy—multifocal gray to tan elevated lesions (focal detachments) of various size. Starts around 11 weeks, progresses with time.

CAUSES
Bilateral—suggests a systemic problem, except in breeds with a predisposition to severe vitreal degeneration (e.g., shih tzu).

Degenerative
End-stage progressive retinal degeneration—may lead to RRD if retina tears.

Anomalous
• Colobomas—collie eye anomaly; abnormal retina around colobomatous optic nerve or large choroidal staphylomas may lead to RRD (merle ocular dysgenesis). • Severe retinal dysplasia, or oculoskeletal dysplasia (Labrador retrievers, Samoyeds). • Canine multifocal retinopathy. • Multiple ocular anomalies.

Metabolic
• Hyperviscosity (e.g., due to hyperproteinemia from multiple myeloma or other causes). • Polycythemia. • Shock. • Dogs—systemic hypertension, hypothyroidism, hypercholesterolemia . • Cats—systemic hypertension (usually related to hyperthyroidism, chronic renal disease).

Neoplastic
• Primary or metastatic. • Multiple myeloma, lymphoma, and intraocular masses (e.g., ciliary body adenocarcinoma or melanoma). • Pheochromocytoma may cause hypertension.

Infectious
• Infectious retinitis or chorioretinitis may cause focal or diffuse detachment. • Infection may extend from or to the CNS.

Immune-Mediated/Inflammatory
• Immune complex disease—vasculitis or inflammation can result in exudative detachment: ○ Dogs—systemic lupus erythematosus (SLE); uveodermatologic syndrome, meningoencephalitis of unknown etiology. ○ Cats—periarteritis nodosa; SLE.

Idiopathic
• If all other causes are ruled out, including retinal tears. • Idiopathic steroid-responsive detachment—reported in giant-breed dogs; may occur in any breed.

Trauma and Toxic
• Penetrating injury or foreign body. • Severe blunt trauma with inflammation or hemorrhage, usually unilateral. • Surgical trauma—if lens or vitreous disturbed (e.g., cataract surgery), can lead to RRD. • Toxic—drug reactions (e.g., trimethoprim-sulfa, ethyelene glycol, griseofulvin [cats]).

RISK FACTORS
• Systemic hypertension. • Old age—retinal thinning, severe vitreal degeneration. • Hypermature, intumescent cataracts that may rupture (e.g., diabetic cataracts). • Luxated lenses. • Lens extraction. • Hereditary—young dogs that have more severe retinal dysplasia and/or multiple ocular anomalies.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Blindness or impaired vision—optic neuritis, glaucoma, cataracts, progressive retinal atrophy, sudden acquired retinal degeneration syndrome (SARDS; see Retinal Degeneration), CNS disease. • Dilated pupil with slow or absent pupillary light reflexes—glaucoma, oculomotor nerve lesion, optic neuritis, progressive retinal atrophy, SARDS. • Membrane or vessels associated with or behind lens—persistent tunica vasculosa lentis, persistent pupillary membranes, fibrovascular membrane due to intraocular neoplasia or inflammation.

RETINAL DETACHMENT (CONTINUED)

CBC/BIOCHEMISTRY/URINALYSIS
Typically normal, unless systemic disease present.

OTHER LABORATORY TESTS
• Depends on suspected systemic problem. • Protein electrophoresis or documentation of Bence Jones proteinuria. • Coagulation profile. • Bacterial culture of ocular or body fluids. • Thyroid hormone measurement. • Serologic or PCR testing for infectious diseases.

IMAGING
• Thoracic and abdominal radiographs, ultrasound, and/or CT. • Spinal radiographs may reveal bony changes consistent with multiple myeloma. • Ocular ultrasound—if ocular media is opaque, can identify retinal detachments or intraocular masses.

DIAGNOSTIC PROCEDURES
• Ophthalmic examination. • Serial blood pressure measurement—normal systolic arterial pressure <160 mmHg. • Cerebral spinal fluid tap—indicated if CNS disease or optic neuritis. • Vitreocentesis or subretinal fluid aspirate—if other testing fails to determine cause and infection or neoplasia is suspected; may aggravate inflammation or induce hemorrhage.

R

PATHOLOGIC FINDINGS
• Retina separated from the RPE and choroid. • May note masses, subretinal exudate, or etiologic infectious organism. • Chronic—retinal atrophy and tombstone appearance to RPE.

TREATMENT

APPROPRIATE HEALTH CARE
• Usually outpatient; depends on condition of patient. • Vision may be restored if underlying cause is rapidly identified and treated, but degeneration occurs quickly.

CLIENT EDUCATION
• May be a sign of systemic disease. • If associated with vitreal degeneration, lens luxation, or cataract surgery, fellow eye at risk for same condition. • Blind pets can adapt remarkably well and live a good-quality life.

SURGICAL CONSIDERATIONS
• RRD—may be surgically repaired by an ophthalmologist. • Laser retinopexy—may reverse detachments associated with optic disc colobomas; may stabilize partial/small detachments. May prevent detachment in predisposed fellow eye.

MEDICATIONS

DRUG(S) OF CHOICE
• Depends on underlying systemic cause. • Prednisone for immunosuppression (for immune-mediated causes) 2–4 mg/kg PO, divided q12 for 3–10 days (dog, cat), then taper slowly over months (do not exceed 80 mg per day). Rule out systemic mycosis prior to use; may facilitate retinal reattachment. • Corticosteroids at anti-inflammatory doses—prednisone 0.5–1 mg/kg PO q24h (dog), prednisolone 1–2 mg/kg PO q24h (cat), then taper; may be useful for exudative detachments of an infectious nature as long as the underlying disease is being definitively treated. • Antihypertensive agents—amlodipine 0.1–0.5 mg/kg PO q12–24h (dog); 0.625–1.25 mg/cat PO q12–24h (cat). Consult with internist or cardiologist if persistent hypertension.

CONTRAINDICATIONS
Systemic corticosteroids—do not use unless systemic mycosis is ruled out or is being definitively treated.

ALTERNATIVE DRUG(S)
Adjunctive immunosuppressive therapy (azathioprine, cyclosporine, mycophenolate, leflunomide) may be needed in some immune-mediated retinal detachment if prednisone is not effective or tolerated long term.

FOLLOW-UP

PATIENT MONITORING
• Some immunosuppressive therapy (e.g., azathioprine) requires regular CBC and serum biochemistry analysis to monitor for bone marrow suppression or hepatotoxicity.
• Serial blood pressure monitoring in hypertensive patients.

POSSIBLE COMPLICATIONS
• Permanent blindness. • Cataracts. • Glaucoma—if eye becomes blind and painful enucleation may be necessary. • Chronic ocular pain. • Death secondary to systemic disease/neoplastic process.

EXPECTED COURSE AND PROGNOSIS
• Prognosis for vision with complete detachment—guarded. Exception is hypertensive retinopathy that is diagnosed and treated promptly. • Surgical reattachment of retina is about 72% successful at restoring vision for up to 1.5 years. • Vision may return if underlying cause is removed and reattachment occurs. • Blindness—may develop in days to weeks even with reattachment (more likely and rapid with exudative than serous detachments). • Focal or multifocal chorioretinitis—does not markedly impair vision; will leave scars.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Cataracts. • Trauma. • Vitreous abnormalities. • Primary neurologic disease or systemic disease affecting CNS.

ABBREVIATIONS
• PLR = pupillary light reflex. • RPE = retinal pigment epithelium. • RRD = rhegmatogenous retinal detachment. • SARDS = sudden acquired retinal degeneration syndrome. • SLE = systemic lupus erythematosus.

RETINAL HEMORRHAGE

BASICS

DEFINITION
- Focal or generalized areas of bleeding into part or all layers of the retina.
- May be acute or chronic.

PATHOPHYSIOLOGY
- Trauma-induced retinal detachments may tear retinal blood vessels.
- Intoxications, vasculitis, coagulopathy (including thrombocytopenia or thrombocytopathia), neoplasia, and systemic infectious disease may cause focal or widespread hemorrhage.
- Systemic hypertension may cause local hemorrhage with vascular abnormalities and/or complete or partial retinal detachments.
- Congenital malformations, concurrent vascular abnormalities, and neovascularization syndromes.
- Diabetes mellitus may be associated with retinopathy that includes vascular microaneurysms with accompanying hemorrhage.

SYSTEMS AFFECTED
Ophthalmic

GENETICS
- Collie eye anomaly—autosomal recessive trait.
- Retinal dysplasia—suspected to be autosomal recessive inheritance.
- Retinal detachment—depends on causative factor, hereditary when observed in conjunction with above conditions.

INCIDENCE/PREVALENCE
- Common in hypertensive retinopathy of elderly cats.
- Common nonspecific finding with many systemic diseases.

SIGNALMENT

Species
Dog and cat—any breed, age, or sex.

Breed Predilections
- May have genetic basis (e.g., collies with collie eye anomaly, Labrador retrievers with congenital vitreoretinal dysplasia).
- Hereditary breed-specific congenital defects that might cause detachment or severe retinal dysplasia—collies and Shetland sheepdogs with collie eye anomaly, Australian shepherd dogs with merle ocular dysgenesis, Labrador retrievers, Sealyham terriers, Bedlington terriers, and English springer spaniels with retinal dysplasia, and miniature schnauzers with retinal dysplasia and persistent hyperplastic primary vitreous.

Mean Age and Range
- Old cats are often affected by systemic hypertension.
- Congenital defects can be observed in puppies at 5–7 weeks.

Predominant Sex
No sex predilection.

SIGNS

General Comments
Depend on underlying causes such as inflammatory disease in the posterior segment, systemic disease, or ocular malformations.

Historical Findings
- Often none.
- Vision loss, bumping into objects.

Physical Examination Findings
- Light or dark red appearance of the posterior segment.
- Blood-filled anterior chamber (hyphema).
- Evidence of bleeding elsewhere—petechia, ecchymoses, melena, hematuria.
- Leukocoria (whitish-appearing pupil) with or without reddish coloration behind the lens.
- Absence of menace response.
- Abnormal pupillary responses.

CAUSES

Congenital
- Retinal detachment secondary to severe congenital malformations in the eye.
- Vitreoretinal defects (e.g., persistent hyperplastic primary vitreous [PHPV] or persistent hyperplastic tunica vasculosa lentis [PHTVL]).
- Retinal defects in geographic or complete retinal dysplasia or in partial or complete retinal detachment.

Acquired
- Trauma.
- Systemic hypertension—renal disease, cardiac disease, hyperthyroidism, hyperadrenocorticism, idiopathic.
- Intoxication—anticoagulant rodenticides; sulfonamide or estrogen-related compound toxicity causing thrombocytopenia.
- Infectious—*Rickettsia rickettsia*, *Ehrlichia* spp., systemic mycoses (cryptococcosis).
- Neoplasia—lymphosarcoma, multiple myeloma (hyperviscosity).
- Hematologic disorders—coagulopathy (hemophilia, hepatic failure), thrombocytopenia, thrombocytopathia (von Willebrand disease), polycythemia.
- Diabetic retinopathy.
- Retinal detachment.
- Vasculitis.

RISK FACTORS
- Systemic hypertension or renal disease.
- Hematologic disease, coagulopathy.
- Vascular membranes.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Normal choroidal vessel pattern in a subalbinotic fundus—seen in lightly pigmented eyes. Blood is contained in vascular channels and not outside of the vessels.
- Vitreal opacities:
  - Vitreal hemorrhage (reddish coloration of the pupil, impossible to rule out concurrent retinal hemorrhage).
  - Vitreal inflammation (generalized or local blurring or lack of fundus detail, usually no reddish coloration).
  - Persistent hyaloid arteries.
  - Neoplasia—especially lymphoma or ciliary body tumors.
  - Also caused by uveitis, glaucoma, lens luxation, trauma, foreign bodies, and spread from local or systemic infectious diseases.
- Pigment spots in retina that look like microhemorrhage. Will not change over time.

CBC/BIOCHEMISTRY/URINALYSIS
- Usually normal unless indicative of systemic disease.
- Hyperglycemia and/or glucosuria—indicative of diabetes mellitus.
- Azotemia and/or proteinuria—renal disease (may cause systemic hypertension).
- Thrombocytopenia, anemia/polycythemia, hyperglobulinemia, or other changes consistent with hematologic disorders.

OTHER LABORATORY TESTS
- Endocrine—thyroid and adrenal function testing.
- Infectious agents—serologic or urine antigen testing for infectious agents.
- Coagulation, von Willebrand factor antigen testing.

IMAGING
- Ocular ultrasound—evaluate position of lens and retina in cases with blood-filled posterior segment.
- Thoracic radiographs—to identify metastatic neoplasia or fungal disease.
- Abdominal ultrasound—if systemic disease or neoplasia suspected.

DIAGNOSTIC PROCEDURES
- Ophthalmic examination with a penlight—usually permits diagnosis of complete retinal detachment with partial retinal hemorrhage; detached neuroretina may often be visualized through the pupil as a whitish veil of tissue.
- Indirect ophthalmoscopy—diagnosis of funduscopic and vitreal changes.
- Vitreous paracentesis and cytologic examination—aid in the diagnosis for suspected neoplasia or mycotic disease.

RETINAL HEMORRHAGE (CONTINUED)

• Blood pressure measurement—indicated in all patients with severe retinal and vitreal hemorrhage.

PATHOLOGIC FINDINGS

• Findings include preretinal, intraretinal, or subretinal hemorrhage that may be focal or extensive.
• Secondary morphologic changes include fibrotic areas with proliferation of cellular extensions into the subretinal space, intraretinal, and thickening of the external limiting membrane.

TREATMENT

APPROPRIATE HEALTH CARE

• Infections and intoxications—require specific treatment. Systemic hypertension should be treated in a timely fashion to improve chances of retinal reattachment.

• NURSING CARE

Supportive care often needed.

ACTIVITY

Retinal detachment due to trauma—cage rest until the retina is reattached.

DIET

Possible dietary recommendations if the primary disorder is due to hepatic or renal disease.

CLIENT EDUCATION

• Discuss living with a blind dog or euthanasia of young puppies with severe bilateral hemorrhage due to congenital abnormalities.
• Advise client that unilaterally affected dogs can function as pets but should not be used for breeding.

SURGICAL CONSIDERATIONS

Surgery—referral to an ophthalmologist for vitrectomy and/or reattachment surgery.

MEDICATIONS

DRUG(S) OF CHOICE

• Corticosteroids—if workup is declined and infectious disease is unlikely: prednis(ol)one 1–2 mg/kg/day PO for 7–14 days, then taper; long-term treatment of 4–6 weeks; especially for traumatic retinal detachment.
• Doxycycline 4 mg/kg PO q12h for 14–21 days, or other appropriate systemic antibiotic based on infectious disease testing.
• Primary systemic hypertension—amlodipine 0.1–0.25 mg/kg PO q24h (dog); 0.625–1.25 mg/cat PO q24 (cat); also consider angiotensin-converting enzyme inhibitor (see Hypertension, Systemic Arterial).
• Itraconazole, fluconazole—for cryptococcosis or other systemic mycosis (see Cryptococcosis or other specific mycoses).
• Besides corticosteroids, other immunosuppressive medications to treat immune-mediated disease include mycophenolate, azathioprine, or leflunomide.

CONTRAINDICATIONS

Systemic corticosteroids and other immunosuppressive drugs—use with caution in patients with systemic infection, do not coadminister with nonsteroidal anti-inflammatory drugs.

PRECAUTIONS

Azathioprine may result in myelosuppression, hepatotoxicity, and gastrointestinal upset.

FOLLOW-UP

PATIENT MONITORING

• Repeated monitoring—required to ensure that condition subsides and retinal morphology normalizes.
• Preretinal hemorrhages—usually absorbed within a few weeks to several months if localized.
• Larger or repeated hemorrhages—may be followed by fibroplastic processes; may lead to the formation of fibrous preretinal membranes and vitreoretinal adhesions, which may cause vitreoretinal traction and retinal detachment.
• Intraretinal hemorrhage—reabsorbed within several weeks to months; may produce retinal scarring.

POSSIBLE COMPLICATIONS

• Retinal detachment.
• Blindness.
• Impaired vision.
• Chronic uveitis.
• Glaucoma.

EXPECTED COURSE AND PROGNOSIS

• Most retinal hemorrhagic lesions are small, observed during routine ophthalmoscopic examination, usually heal rapidly, and cause no visual problems.
• Retinal hemorrhage due to systemic diseases or retinal malformations is more serious; most have an uncertain prognosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Trauma—may have other injuries; traumatic brain injury.
• Hypertension—cardiac, renal disease, hyperthyroidism, or hyperadrenocorticism.
• Coagulopathy—hypovolemic shock, internal bleeding.
• Cryptococcus infection—concurrent leptomeningitis and pneumonitis.
• Neoplasia—various other organ system involvement.
• Hematologic disorders—hemorrhage and anemia.
• Secondary cataracts—may develop within weeks after the onset of diabetes mellitus in dogs.

AGE-RELATED FACTORS

• May occur at any age.
• Congenital or developmental diseases usually recognized in younger animals.

PREGNANCY/FERTILITY/BREEDING

• Dogs with hereditary retinal disease should not be bred.
• Corticosteroids and immunosuppressive drugs may cause complications with pregnancy.

SEE ALSO

• Chorioretinitis.
• Hypertension, Systemic Arterial.
• Hyphema.
• Retinal Detachment.

ABBREVIATIONS

• PHPV = persistent hyperplastic primary vitreous.
• PHTVL = persistent hyperplastic tunica vasculosa lentis.

Client Education Handout available online

RHINITIS AND SINUSITIS

BASICS

DEFINITION
• Rhinitis—inflammation of nasal epithelium. • Sinusitis—inflammation of paranasal sinuses; includes frontal sinus and maxillary recess in dogs; frontal and sphenopalatine sinuses in cats. • The nasal cavity communicates directly with the sinuses; thus rhinitis and sinusitis often occur together.

PATHOPHYSIOLOGY
Inflammation and irritation stimulate serous glandular secretion in the nasal mucosa. Opportunistic bacterial infections develop in compromised nasal mucosa causing discharge to become mucoid or mucopurulent. The inflammatory process can lead to turbinate destruction and erosion of the vasculature that results in epistaxis.

SYSTEMS AFFECTED
• Respiratory—sneezing and nasal discharge usually indicate upper respiratory tract disease. • Nervous—fungal and neoplastic disease can destroy the cribriform plate and invade the brain. • Ocular—epiphora with inflammation or obstruction of the nasolacrimal ducts. Conjunctivitis, keratitis, and/or corneal ulcerations with feline herpesvirus type 1 (FHV-1)-related disease. Chorioretinitis with canine distemper or *Cryptococcus*. • Oral cavity—calicivirus, feline leukemia virus (FeLV), and feline immunodeficiency virus (FIV) are associated with stomatitis, glossitis, faucitis. Tooth root abscess, oronasal fistula or cleft palate possible. • Lymphatics—medial retropharyngeal lymphadenopathy possible with infectious and neoplastic sinonasal disease.

INCIDENCE/PREVALENCE
• Primary bacterial rhinosinusitis is rare; secondary infection from dental disease common or in association with chronic rhinitis. • Cats—chronic rhinosinusitis common. • Dogs—neoplasia, inflammatory rhinitis (lymphoplasmacytic rhinitis), fungal disease common. Nasal foreign body may cause acute sneezing.

GEOGRAPHICAL DISTRIBUTION
Chronic Fungal Rhinitis
• *Aspergillus* and *Penicillium* spp.—worldwide. • *Rhinosporidium seeberi*—mostly India, Africa, and South America. • *Blastomycoses dermatitidis*—endemic to North America: Pacific Northwest, Great Lakes region, Mississippi, Ohio, Missouri, Tennessee, and St. Lawrence river valleys. • *Cryptococcus neoformans*—worldwide.

SIGNALMENT
Species
Dog and cat.

Breed Predilections
• Brachycephalic cats more prone to chronic rhinitis and *Aspergillus* infection. • Dolichocephalic dogs more prone to *Aspergillus* infection and nasal tumors.

Mean Age and Range
• Cats—acute viral rhinosinusitis and nasopharyngeal polyps more common in young kittens (6–12 weeks). • Congenital diseases (cleft palate, ciliary dyskinesia) more common in young animals. • Neoplasia and dental disease—older animals. • Foreign bodies more common in young dogs.

Predominant Sex
No sex predilection.

SIGNS
Historical Findings
• Sneezing, nasal discharge, epistaxis. • Discharge usually is serous initially and becomes mucoid, mucopurulent, serosanguinous, or hemorrhagic. • Unilateral discharge suggests foreign body, tooth root abscess, early neoplasia, or early fungal infection. Idiopathic inflammatory rhinitis can also present with unilateral signs. • Bilateral discharge more common with viral or bacterial rhinosinusitis, inflammatory rhinitis, pharyngeal disease, or congenital abnormalities. Chronic presentation of neoplasia or fungal rhinitis is often bilateral. • Facial deformity or facial pain—usually with fungal or neoplastic disease. • Reverse sneezing more common in dogs, inappetence more common in cats.

Physical Examination Findings
• Check for decreased nasal air flow, bilateral or unilateral. • Evaluate oral cavity for tooth root abscess, oronasal fistula, cleft palate or ulcers. • Look for epiphora, conjunctivitis. Horner's syndrome can be seen with middle ear disease. • Fundic examination—chorioretinitis possible with infectious diseases; hypertension can result in tortuous retinal vessels or hemorrhage, platelet abnormalities can be associated with retinal hemorrhage or petechiation.

CAUSES
Dogs
Primary Inciting Causes
• Intranasal neoplasia—adenocarcinoma most common (31.5%); others include lymphoma, chondrosarcomas, or osteosarcomas. • Fungal disease—*Aspergillus fumigatus* most common. *Penicillium* spp., *Rhinosporidium seeberi*, *Blastomycoses dermatitidis*, *Cryptococcus neoformans* are rare causes. • Tooth root abscess. • Foreign body. • Congenital abnormalities such as cleft palate or primary ciliary dyskinesia. • Parasitic causes—nasal mites (*Pneumonyssoides caninum*), *Capillaria aerophila, Eucoleus boehmii*. • Immune-mediated rhinitis—allergic rhinitis rare, idiopathic lymphoplasmacytic rhinitis more common. • Other infectious diseases include canine distemper or *Bordetella bronchiseptica*. • Local trauma can cause bone or turbinate deformity and predispose to chronic rhinitis or *Aspergillus* infection. • Nasopharyngeal stenosis can be congenital or acquired.

Secondary Causes
• Lower airway disease or vomiting can result in nasal signs through nasopharyngeal regurgitation. • Nasal discharge can occur with eosinophilic bronchopneumopathy. • Epistaxis can be related to hypertension, thrombocytopenia, thrombocytopathia, or rarely other coagulopathies; trauma or foreign body also possible.

Cats
Primary Inciting Causes
• Viral infections—FHV-1 and calicivirus account for 90% of acute infections in kittens. • Bacteria—*Bordetella bronchiseptica* is uncommonly a primary pathogen. • Neoplasia—adenocarcinoma and lymphoma most common. • Fungal disease—*Cryptococcus neoformans* most common, *Aspergillus felis*, *Penicillium*, *Microsporum canis* (rare). • Nasopharyngeal polyps in young cats. • Nasopharyngeal stenosis—congenital or secondary to chronic infection or inflammation. • Tooth root abscess or oronasal fistula. • Foreign bodies. • Congenital abnormalities include cleft palate.

Secondary Causes
• Opportunistic infection with bacteria can complicate viral rhinosinusitis. • Epistaxis due to coagulopathy or hypertension. • Aspiration of vomitus into the nasopharynx.

RISK FACTORS
• Dolichocephalic breeds—fungal disease. • Brachycephalic cats—rhinosinusitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Rule out secondary causes of rhinitis including coagulopathy and hypertension for epistaxis, lower airway disease, chronic vomition.

CBC/BIOCHEMISTRY/URINALYSIS
• Hemogram is nonspecific—may show leukocytosis (neutrophilia or eosinophilia) with infectious agents. Regenerative anemia with severe blood loss from coagulopathy. Nonregenerative anemia with chronic disease or neoplasia. Thrombocytopenia seen with coagulopathies or severe blood loss. • Serum biochemistry and urinalysis typically normal.

OTHER LABORATORY TESTS
• PCR testing for viral etiologies. • FeLV and FIV serologic tests. • Oropharyngeal, conjunctival, and nasal swabbing in cats for

RHINITIS AND SINUSITIS (CONTINUED)

virus isolation and bacterial culture. • Latex agglutination test for cryptococcal capsular antigen. • *Aspergillus* titers—agar gel immunodiffusion (AGID) in dogs: false negatives possible, false positives uncommon; ideally combine AGID with nasal tissue culture/biopsy or direct visualization. ELISA in cats—high sensitivity and specificity for disease.
• Coagulation profile if epistaxis present.

IMAGING
• Radiography—chest radiographs if lower airway disease or neoplasia suspected.
• Dental radiographs highly sensitive for detecting periodontal disease. • Skull radiographs—loss of turbinate structures can be seen with all causes of rhinosinusitis. Open-mouth or intraoral ventrodorsal views avoid superimposition of the mandible.
• Nasopharyngeal polyps occasionally seen within the nasopharynx. • CT/MRI—superior to plain radiography in evaluating the extent of disease and assessing the integrity of the cribriform plate. Also useful in evaluating disease of the palate, nasopharyngeal meatus, maxillary sinus, periorbital tissues, middle ear canal, and for presence of medial retropharyngeal lymphadenopathy.

R

DIAGNOSTIC PROCEDURES

Arterial Blood Pressure
Evaluate for hypertension if epistaxis.

Lymph Node Aspirate
Can be diagnostic for neoplasia or *Cryptococcus*.

Cytology
Nasal swab may reveal *Cryptococcus*.

Culture
• Usefulness of bacterial culture is controversial since most animals have secondary bacterial infection. Potential bacterial pathogens are more commonly isolated in cats. • Fungal culture of a plaque lesion visualized on endoscopy aids in diagnosis of aspergillosis. • Asymptomatic intranasal carriage of *Cryptococcus* possible.

Endoscopy
• An otoscope evaluates only the rostral nasal cavity. A rigid endoscope can be guided to the ethmoid turbinates, flexible endoscope provides good visualization rostrally, and can be retroflexed in the nasopharynx to visualize the caudal choanae. • Guided biopsy is possible with rigid and flexible endoscopy. Other techniques include core or blind pinch biopsies.

Surgery
Exploratory rhinotomy most invasive diagnostic tool, can be required for difficult foreign body or mass removal, if endoscopy is unsuccessful. Rarely required to obtain a definitive biopsy sample.

PATHOLOGIC FINDINGS
Chronic inflammation causes turbinate resorption, mucosal ulceration and necrosis. Lymphoplasmacytic infiltrate indicates chronicity, neutrophilic usually signifies acute component. Neoplasia and fungus also cause bony lysis or destruction.

TREATMENT

APPROPRIATE HEALTH CARE
Overcrowded shelters and hoarding conditions increase stress and exposure to infectious pathogens.

NURSING CARE
Humidification can aid in moistening and mobilizing nasal secretions. Saline intranasal drops helpful if tolerated. Keep nares clean of obstructive mucus.

DIET
Malnutrition is common in young kittens with infectious causes of rhinitis. Appetite stimulants may be helpful.

CLIENT EDUCATION
Signs of chronic rhinitis can be variably controlled but are rarely eliminated.

SURGICAL CONSIDERATIONS
• Rhinotomy is reserved for obtaining a biopsy or foreign body/mass removal when endoscopic intervention is unsuccessful. Rarely provides an advantage over endoscopy.
• Surgery useful for polyp removal, dental-related nasal disease (tooth root abscess, oronasal fistula, cleft palate).

MEDICATIONS

DRUG(S) OF CHOICE

Antibiotics
Antibiotics help control secondary bacterial rhinitis. Selection of antibiotic is mainly empirical. Long-term use often needed.

Antifungals
See Cryptococcosis and Aspergillosis chapters for detailed treatment discussion.

L-Lysine
Inhibits FHV-1 replication; may be useful—250 (kitten)–500 (cat) mg PO q12h.

Anti-inflammatory Agents
Piroxicam (NSAID) or more commonly meloxicam used for palliation of nasal tumors (via COX-2 inhibition), either as sole agent or in conjunction with chemotherapy.

Steroids
Consider use with chronic rhinosinusitis in cats or lymphoplasmacytic rhinitis in dogs at anti-inflammatory doses when mucus obstruction limits appetite.

Antihistamines
Efficacy is debated; unlikely helpful.

Antiparasitics
Ivermectin 300 µg/kg PO or SC once weekly for 3–4 treatments or milbemycin oxime 1 mg/kg PO once weekly for 3 weeks for treatment of nasal mites.

CONTRAINDICATIONS
Avoid chronic steroid use.

PRECAUTIONS
• NSAIDs can cause gastrointestinal ulceration. • Tetracycline may stain teeth of young animals.

POSSIBLE INTERACTIONS
Use of NSAIDs and corticosteroids together is contraindicated.

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
Patients taking oral azole antifungal medication typically require monthly biochemistry monitoring of hepatic values.

PREVENTION/AVOIDANCE
Vaccinations in kittens can lessen severity and duration of viral infection.

POSSIBLE COMPLICATIONS
• Extension of fungal or neoplastic invasion into brain. • Seizures and other neurologic signs are possible if topical antifungal therapy is used when the cribriform plate is not intact.

EXPECTED COURSE AND PROGNOSIS
• Dependent on etiology and extent of disease. • Acute viral/bacterial rhinitis—good prognosis; chronic rhinitis—guarded for control of signs. • Fungal—fair to guarded prognosis depending on invasiveness and response to therapy.
• Neoplastic—3–5 months prognosis with no treatment; 9–23 months with radiation therapy.

MISCELLANEOUS

AGE-RELATED FACTORS
Infectious upper respiratory tract disease is a common cause of morbidity and mortality in stray and shelter kittens.

(CONTINUED) RHINITIS AND SINUSITIS

ZOONOTIC POTENTIAL

Cryptococcus, *Aspergillus*, *Penicillium* are transmissible to humans via shared environment. No direct transmission.

SYNONYMS

Nasosinusitis, rhinosinusitis, sinonasal.

SEE ALSO

- Aspergillosis, Disseminated Invasive
- Aspergillosis, Nasal.
- Cryptococcosis.
- Epistaxis.
- Nasal and Nasopharyngeal Polyps.
- Nasal Discharge.
- Respiratory Parasites.
- Stertor and Stridor.

ABBREVIATIONS

- AGID = agar gel immunodiffusion.
- FeLV = feline leukemia virus.
- FHV = feline herpesvirus. • FIV = feline immunodeficiency virus.

RIGHT BUNDLE BRANCH BLOCK

BASICS

DEFINITION
Conduction delay or block in the right bundle branch resulting in late activation of the right ventricle; the block can be complete or incomplete.

ECG Features
- A right axis deviation and wide QRS (≥0.08 seconds in dogs; ≥0.06 seconds in cats) in most patients.
- Large, wide S waves in leads I, II, III, and aVF.
- Incomplete right bundle branch block has right axis deviation with normal width QRS complexes.

PATHOPHYSIOLOGY
- The right bundle branch is anatomically vulnerable to injury because it is a thin strand of tissue and has a long undivided course.
- No hemodynamic compromise.

SYSTEMS AFFECTED
Cardiovascular

GENETICS
N/A

INCIDENCE/PREVALENCE
- Dog—most frequent form of intraventricular conduction defect.
- Cat—not as frequent as left anterior fascicular block.

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT

Species
Dog and cat.

Breed Predilections
In beagles, incomplete right bundle branch block can result from a genetically determined localized variation in right ventricular wall thickness.

Predominant Sex
N/A

SIGNS

Historical Findings
- Usually an incidental ECG finding—does not cause hemodynamic abnormalities.
- Observed signs, if any, are usually associated with the underlying condition.

Physical Examination Findings
- Splitting of heart sounds because of asynchronous activation of ventricles in some patients.
- Does not cause signs of hemodynamic compromise.

CAUSES
- Occasionally seen in normal and healthy dogs and cats.
- Congenital heart disease.
- Chronic valvular fibrosis.
- After surgical correction of a cardiac defect.
- Trauma.
- Chronic infection with *Trypanosoma cruzi* (Chagas' disease).
- Neoplasia.
- Heartworm disease.
- Acute thromboembolism.
- Cardiomyopathy.
- Hyperkalemia (most commonly in cats with urethral obstruction).

RISK FACTORS
N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Right ventricular enlargement—absence of right ventricular enlargement on thoracic radiographs or echocardiogram supports a diagnosis of right bundle branch block.
- Can also be confused with ventricular ectopic beats (especially if the block is intermittent), but consistent PR intervals and no pulse deficits with right bundle branch block.

CBC/BIOCHEMISTRY/URINALYSIS
- No specific changes.
- Serum potassium may be extremely high in cats with urethral obstruction.

OTHER LABORATORY TESTS
- Occult heartworm test may be positive in dogs or cats.
- Chagas' indirect fluorescent antibody test, direct hemagglutination, and complement fixation test may be positive in dogs.

IMAGING
- Echocardiogram may show structural heart disease; absence of right heart enlargement supports diagnosis of right bundle branch block.
- Thoracic and abdominal radiographs may show masses or pulmonary metastatic lesions; traumatic injuries could cause localized or diffuse pulmonary densities.

DIAGNOSTIC PROCEDURES
- Electrocardiography (ECG).
- Echocardiography.

PATHOLOGIC FINDINGS
Possible lesions or scarring on endocardial surface in the path of the right bundle branch; applying Lugol's iodine to the endocardial surface within 2 hours post-mortem gives clear visualization of the conduction system.

TREATMENT

APPROPRIATE HEALTH CARE
Direct treatment toward the underlying cause.

NURSING CARE
N/A

ACTIVITY
Unrestricted

DIET
No modifications unless required to manage underlying condition.

CLIENT EDUCATION
- Does not cause hemodynamic abnormalities itself.
- The lesion causing the block could progress, leading to more serious arrhythmias or complete heart block.

SURGICAL CONSIDERATIONS
N/A

MEDICATIONS

DRUG(S) OF CHOICE
None required unless needed to manage underlying condition.

CONTRAINDICATIONS
N/A

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
Serial ECG may show resolution of the lesion or progression to complete heart block.

PREVENTION/AVOIDANCE
N/A

POSSIBLE COMPLICATIONS
- The causative lesion could progress, leading to a more serious arrhythmia or complete heart block.
- First- or second-degree AV block may indicate involvement of the left bundle branch.

EXPECTED COURSE AND PROGNOSIS
No hemodynamic compromise.

(CONTINUED) RIGHT BUNDLE BRANCH BLOCK

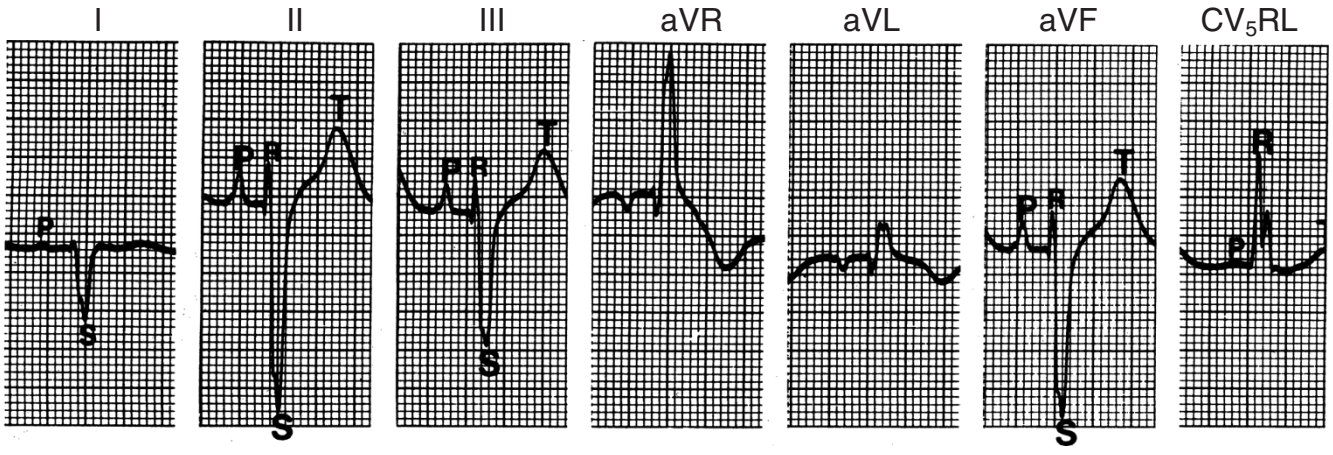

Figure 1.

Right bundle branch block in a dog. The electrocardiographic features include QRS duration of 0.08 seconds; positive QRS complex in aVR, aVL, and CV_5RL (M-shaped); and large wide S waves in leads I, II, III, and aVF. There is a right axis deviation (approximately –110°) (50 mm/s, 1 cm = 1 mV). (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

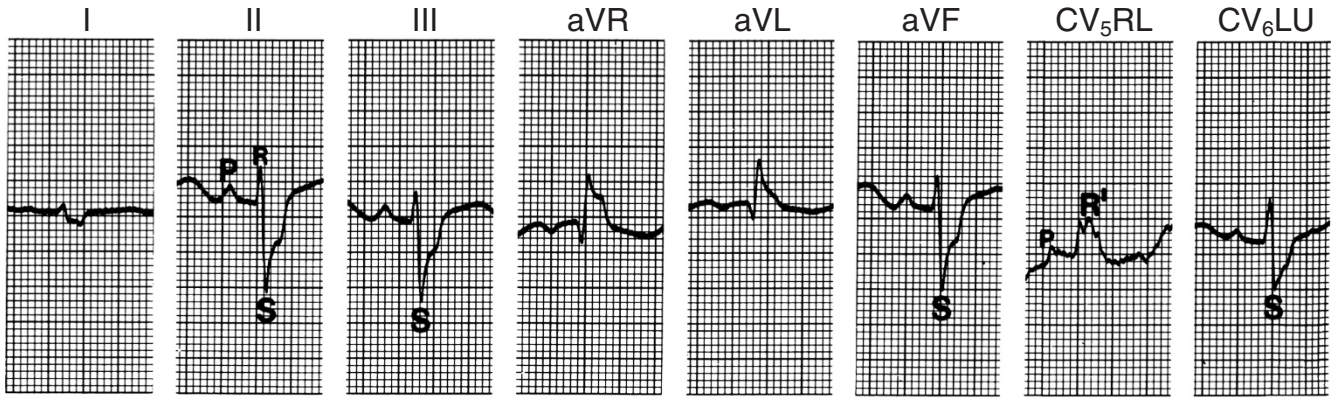

Figure 2.

Right bundle branch block in a cat with the dilated form of cardiomyopathy. The QRS duration is 0.08 seconds (4 boxes). Large and wide S waves are present in leads I, II, III, aVF, and CV_6 LU. The QRS in CV_5RL has a wide R wave (M-shaped). There is a marked axis deviation (approximately –90°). Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.

ROCKY MOUNTAIN SPOTTED FEVER

BASICS

DEFINITION
A tick-borne disease, caused by *Rickettsia rickettsii*, that affects dogs and is considered the most important rickettsial disease in humans.

PATHOPHYSIOLOGY
• Pathogen—*Rickettsia rickettsia*, a Gram-negative, intracellular bacteria. • Vector—various species of ticks including *Dermacentor variabilis* (United States, east of Great Plains region), *D. andersoni* (western United States and Canada), *Rhipicephalus sanguineus* (throughout North and South America), *Amblyomma cajennense* (Latin America).
• Transmission—via saliva of the vector or by blood transfusion; tick must be attached for 5–20 hours to infect host (humans, dogs, cats) or reservoir host (rodents and dogs).
• Incubation period—2 days–2 weeks.
• Infection—organism invades and multiplies in vascular endothelium; causes microvascular hemorrhage; platelet aggregation and antiplatelet antibodies cause thrombocytopenia, widespread vasculitis results in increased vascular permeability, plasma loss into interstitial space, hypotension, and eventually shock and disseminated intravascular coagulation (DIC).

SYSTEMS AFFECTED
• Cardiovascular—vasculitis, hypotension, shock. • Hemic/lymphatic/immune—hemorrhage due to thrombocytopenia and vasculitis; lymphadenopathy, splenomegaly.
• Ophthalmic—conjunctivitis, scleral injection, retinal hemorrhage, anterior uveitis.
• Skin/exocrine—multifocal edema, petechiae and ecchymoses, dermal necrosis.
• Musculoskeletal—joint and muscle pain.
• Nervous—meningoencephalitis: seizures, vestibular deficits, stupor, coma, cervical pain.
• Respiratory—dyspnea, cough. • Renal/urologic— vasculitis and prerenal azotemia from dehydration and shock.

GENETICS
N/A

INCIDENCE/PREVALENCE
• Tick season—late March through October.
• Prevalence—overall infections in ticks <2%; varies by geographic location.

GEOGRAPHIC DISTRIBUTION
• United States— RMSF has been diagnosed in most states; highest infection rates in southeastern states. • North and South America.

SIGNALMENT

Species
Dog

Breed Predilections
• Purebred dogs seem more prone to developing clinical illness than mixed-breed dogs. • German shepherd dogs—more common.

Mean Age and Range
Any age

Predominant Sex
None

SIGNS

Historical Findings
• Fever—within 2–3 days of tick attachment.
• Lethargy, depression, anorexia. • Swelling (edema)—lips, scrotum, prepuce, ears, extremities. • Stiff gait—especially with scrotal or preputial edema. • Spontaneous bleeding—sneezing, epistaxis. • Respiratory distress, cough. • Neurologic—ataxia, head tilt, seizures. • Ocular pain.

Physical Examination Findings
• Clinical—variable in severity; lasts 2–4 weeks untreated. • Ticks may still be present in acute cases. • Pyrexia. • Cutaneous lesions—edema of face, limbs, prepuce, scrotum. • Extremities—necrosis.
• Conjunctivitis. • Scleral injection.
• Respiratory—dyspnea, exercise intolerance resulting from pneumonitis, increased bronchovesicular sounds. • Generalized lymphadenopathy. • Neurologic—vestibular dysfunction, altered mental status, seizures.
• Myalgia/arthralgia. • Petechia, ecchymoses—ocular, oral, genital mucous membranes.
• Hemorrhagic diathesis—epistaxis, melena, hematuria; in severe cases. • Cardiac arrhythmias. • DIC and death from shock—in severe acute cases.

CAUSES
R. rickettsii infection.

RISK FACTORS
• Exposure to ticks. • Coinfection with other pathogens (tick-borne). • English springer spaniels with phosphofructokinase deficiency are prone to a more severe form of RMSF.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Canine ehrlichiosis—*Ehrlichia canis*; not seasonal; can be clinically indistinguishable from RMSF (especially acute cases); differentiate with serologic testing; both respond to same treatment. • Primary immune-mediated thrombocytopenia—not usually associated with fever or lymphadenopathy; differentiate by ruling out infectious causes; may treat for both until results are known. • Systemic lupus erythematosus—antinuclear antibody titer usually negative with RMSF; serologic testing diagnostic.
• Brucellosis—scrotal edema; serologic testing diagnostic.

CBC/BIOCHEMISTRY/URINALYSIS

CBC
• Thrombocytopenia (~ 40% of cases)—due to antiplatelet antibody and consumption; platelet counts frequently 25,000–250,000/µL.
• Mild anemia (normochromic, normocytic).
• Mild leukopenia (early in infection), leukocytosis and monocytosis develop later.

Biochemistry
• Usually nonspecific. • Hypoalbuminemia—increased vascular permeability
• Hypercholesterolemia—consistently found; cause unknown • Mild increases in alanine aminotransferase, alkaline phosphatase, BUN, creatinine, and total bilirubin (rare). • Hyponatremia, hypochloremia, and metabolic acidosis have also been reported.

Urinalysis
• Proteinuria—with or without azotemia; from glomerular/tubular damage.
• Hematuria—coagulation defects.

OTHER LABORATORY TESTS
• Several tests are available to measure serum antibodies including the micro-immunofluorescence (micro-IF), ELISA, and latex agglutination tests. • Diagnosis by antibody measurement requires an increased (single) IgM titer, or a four-fold increase in IgG between acute and convalescent measurements. Paired IgG titers should be drawn 3 weeks apart and submitted for analysis at the same time. High antibody titers can be detected for up to 1 year after treatment. • Latex agglutination test—higher specificity, lower sensitivity than the micro-IF test. • PCR on whole blood and tissue specimens—detects DNA before seroconversion in some dogs.

IMAGING
Thoracic radiographs—diffuse interstitial pattern in patients with respiratory signs.

DIAGNOSTIC PROCEDURES
• Direct immunofluorescence—punch biopsies from affected lesions; allows early detection of rickettsial antigens. • CSF analysis—often normal; may show increased protein and polymorphonuclear and mononuclear cells.

PATHOLOGIC FINDINGS
• Widespread petechia, splenomegaly, and generalized hemorrhagic lymphadenopathy.
• Necrotizing vasculitis with perivascular cell infiltration (mononuclear and neutrophilic).
• Vascular lesions—most prominent in skin, kidneys, myocardium, meninges, retina, pancreas, gastrointestinal tract, and urinary bladder. • Hepatic and focal myocardial necrosis, nodular gliosis in brain, and

(CONTINUED) ROCKY MOUNTAIN SPOTTED FEVER

interstitial pneumonia. • Special stains—to identify organisms.

TREATMENT

APPROPRIATE HEALTH CARE
Inpatient management recommended until stable and showing response to treatment.

NURSING CARE
• IV fluid therapy—correct dehydration; use caution; excessive fluid therapy can worsen edema. • Blood transfusion—for patients with clinical signs of anemia. • Fresh whole blood or platelet transfusion—severe hemorrhage due to thrombocytopenia. • Provide analgesia for patients with muscle, joint, and severe skin involvement.

ACTIVITY
Restricted during acute illness.

DIET
N/A

CLIENT EDUCATION
• Prognosis—good in acute cases with appropriate and prompt therapy. • Response occurs within hours of treatment. • If treatment is not instituted until CNS signs occur or later in disease process, mortality is high; a patient with CNS signs may die within hours.

SURGICAL CONSIDERATIONS
If surgery is required for other reasons, blood transfusion may be needed to correct anemia and/or marked thrombocytopenia.

MEDICATIONS

DRUG(S) OF CHOICE
• Doxycycline 10 mg/kg PO, IV q24h (or 5 mg/kg PO, IV q12h) for 10 days; given IV if patient is vomiting. Extended doxycycline therapy was required to clear infection in one experimentally infected dog. • Enrofloxacin and chloramphenicol may also be used. • Prednisone—concurrent use; anti-inflammatory or immunosuppressive dose; given early in course of disease does not seem to be detrimental to recovery. May alleviate immune-mediated thrombocytopenia and cerebral edema.

CONTRAINDICATIONS
Renal insufficiency—do not use tetracycline due to renal excretion; doxycycline may be given (excreted via gastrointestinal tract).

PRECAUTIONS
• Tetracycline (or derivatives)—discoloration of teeth in patients <6 months old. • Enrofloxacin—articular cartilage damage can occur in young dogs. • Chloramphenicol— reduces titers to a greater extent than tetracyclines; warn client of human health risks; avoid use in dogs with thrombocytopenia, pancytopenia, or anemia.

POSSIBLE INTERACTIONS
None

ALTERNATIVE DRUG(S)
• Chloramphenicol—puppies <6 months of age; 20 mg/kg PO q8h for 14 days; recommended to avoid discoloration of erupting teeth or in pregnant patients. • Enrofloxacin 10 mg/kg PO, IM, IV q24h for 7 days. • Oxytetracycline and tetracycline 22 mg/kg PO q8h for 14 days.

FOLLOW-UP

PATIENT MONITORING
Monitor platelet count every 2–3 days until normal.

PREVENTION/AVOIDANCE
• Avoid tick-infested areas and control tick infestation on dogs. • Flea and tick collars, topical or enteral tick preventives—may reduce reinfestation. • Environment—tick eradication impossible; organism maintained in rodents and other reservoir hosts. • Manually remove ticks—use gloves (see Zoonotic Potential); ensure mouth parts are removed.

POSSIBLE COMPLICATIONS
N/A

EXPECTED COURSE AND PROGNOSIS
• Early antibiotic treatment—reduces fever and albumin extravasation; improvement within 24–48 hours. • Platelet counts—should return to normal within 2–4 days after initiating treatment. • Serologic titers remain positive during convalescence. • Naturally infected dogs do not seem to become reinfected. • Acute cases—excellent prognosis with appropriate and early treatment. • With CNS disease—poor prognosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS
None

AGE-RELATED FACTORS
None

ZOONOTIC POTENTIAL
• Source of infection (humans)—ticks from wooded areas or carried into environment by dogs (RMSF not directly transmitted to humans by dogs), exposure to infectious material when removing infected ticks from dogs. • Clinical signs in humans are similar to those seen in dogs. • Treatment with tetracycline results in a rapid recovery, overall mortality rate is 2–10%.

PREGNANCY/FERTILITY/BREEDING
N/A

ABBREVIATIONS
• DIC = disseminated intravascular coagulation.
• Micro-IF = microscopic immunofluorescence.
• RMSF = Rocky Mountain spotted fever.

R

RODENTICIDE TOXICOSIS—ANTICOAGULANTS

BASICS

DEFINITION
• Anticoagulant rodenticide intoxication results in a delayed-onset (3–5 days) coagulopathy caused by the reduction of vitamin K1-dependent clotting factors (II, VII, IX, X).
• There are two primary types of anticoagulant rodenticides: first- and second-generation. First-generation anticoagulants, such as warfarin, are generally less toxic and shorter acting than second-generation which tend to persist longer in the liver and require 3–4 weeks of antidote therapy.

PATHOPHYSIOLOGY
• Anticoagulant rodenticides inhibit vitamin K1 epoxide reductase, DT-diaphorase, and possibly other enzymes involved in the reduction of vitamin K1 epoxide to vitamin K1.
• Vitamin K1 is required for carboxylation of clotting factors II, VI, IX, and X; uncarboxylated clotting factors do not bind calcium sufficiently to participate in clot formation.

R

SYSTEMS AFFECTED
• Hemic/lymphatic/immune.
• Respiratory.

INCIDENCE/PREVALENCE
• Still common but fewer exposures.
• In 2011, the US Environmental Protection Agency (EPA) banned the use of second-generation anticoagulants (i.e., brodifacoum, bromadiolone, difenacoum, and difethialone) for residential use unless placed by a pest control operator.
• In 2013, the EPA gave notice of cancelling registration and denial of future applications for certain rodenticide products including warfarin, brodifacoum, and difethialone. In response, manufacturers have begun the process of transition to non-anticoagulant baits such as bromethalin and cholecalciferol.

SIGNALMENT
No breed or gender predilections; younger animals may ingest bait more readily.

SIGNS
General Comments
• May be slightly more prevalent in the spring and fall when rodenticide products are used.
• Clinical signs typically begin 3–5 days after ingestion. Early signs maybe noted at 48 hours.

Historical Findings
• Use of anticoagulant rodenticides.
• Evidence of rodenticide dye in vomitus or feces.
• Coughing, dyspnea, tachypnea, or exercise intolerance are often the first clinical signs.
• Bleeding from body orifices; subcutaneous or joint swelling, petechiation of the skin and gums may also be observed.

Physical Examination Findings
• Evidence of hemorrhagic shock (i.e., tachycardia, hypovolemia, hypotension, poor pulse quality, pallor).
• Coughing, dyspnea, tachypnea, pale mucous membranes.
• Hematomas—often ventral and at venipuncture sites; subcutaneous hematomas.
• Bleeding from body orifices, periorbital bleeding, scleral hemorrhage.
• Hemarthrosis, lameness.
• Exercise intolerance, lethargy, depression.
• Muffled heart or lung sounds.
• Distended abdomen (hemoabdomen).

CAUSES
Ingestion of anticoagulant rodenticides or, rarely, ingestion of prey that have been exposed to anticoagulant rodenticides (see Risk Factors).

RISK FACTORS
• Dogs are much more sensitive to anticoagulant rodenticides than cats.
• Small doses over several days may add up to a toxic dose.
• Secondary or relay toxicosis by consumption of poisoned rodents is possible but unlikely.
• There is a wide range of toxicity between anticoagulant rodenticides. In general, if the ingestion exceeds 1/5–1/10 the LD_{50}, decontamination and monitoring for coagulopathy are indicated.
• Dogs:
  - Brodifacoum, LD_{50} 0.25–2.5 mg/kg.
  - Bromadiolone, LD_{50} 11–20 mg/kg.
  - Chlorophacinone, LD_{50} 50–100 mg/kg.
  - Difethialone, LD_{50} 4 mg/kg.
  - Diphacinone, LD_{50} 3–7.5 mg/kg.
  - Warfarin, LD_{50} 20–50 mg/kg.
• Cats:
  - Brodifacoum, LD_{50} 25 mg/kg.
  - Bromadiolone, LD_{50} >25 mg/kg.
  - Difethiolone, LD_{50} >16 mg/kg.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Congenital clotting factor deficiencies.
• Immune-mediated thrombocytopenia—platelet count will reveal severe thrombocytopenia.
• Coagulation factor deficiency secondary to hepatic disease—assay for factor deficiencies (e.g., factor VII), liver function, bile acids.
• Disseminated intravascular coagulopathy which is typically associated with neoplasia, sepsis, pancreatitis, or concurrent disease. Lab evidence includes prolonged prothrombin time (PT), partial thromboplastin time (PTT), elevated fibrin degradation products, D-dimer with thrombocytopenia.
• Fat malabsorption.
• Hemorrhagic shock from trauma, neoplasia, bone marrow suppression, immune-mediated hemolytic anemia.

CBC/BIOCHEMISTRY/URINALYSIS
• Anemia with marked hemorrhage, often acute and nonregenerative.
• Thrombocytopenia, mild. Typically 50,000–150,000 × 10^3/μL.

OTHER LABORATORY TESTS
• Activated clotting time >150 seconds supports coagulopathy but is not specific for anticoagulant rodenticide poisoning.
• Prolonged PT and PTT support exposure to anticoagulant rodenticide; PT will be prolonged 6–18 hours earlier than PTT. These values will normalize with vitamin K1 therapy.
• Protein-induced vitamin K absence or antagonist (PIVKA) assay, rarely used.
• Anticoagulant rodenticide detection in the blood or liver will confirm exposure to a specific product.
• Anticoagulant rodenticide detection in the stomach or intestinal contents is not reliable due to the delay between consumption of bait and appearance of clinical signs.

IMAGING
• Thoracic radiography may reveal pleural effusion (i.e., hemothorax); multilobular, alveolar infiltration (i.e., pulmonary hemorrhage) or an enlarged cardiac silhouette (i.e., hemopericardium).
• Ultrasound of both the pleural and peritoneal cavities may reveal effusion consistent with hemorrhage.

DIAGNOSTIC PROCEDURES
Thoracentesis may confirm hemothorax.

PATHOLOGIC FINDINGS
• Free blood in the thoracic cavity, lungs, and abdominal cavity is a common post-mortem finding.
• Hemorrhage into the cranial vault, gastrointestinal tract, subcutaneous space, intramuscular space, and urinary tract is less common.

TREATMENT

APPROPRIATE HEALTH CARE
• Patients in acute crisis should be hospitalized.
• Patients without active hemorrhaging or a stabilized coagulopathy may be treated on an outpatient basis.
• Vitamin K1 is antidotal at 2.5–5 mg/kg q24h or divided q12h. The preferred route of administration is oral; however, in case of a coagulopathic patient, the subcutaneous route

(CONTINUED) # RODENTICIDE TOXICOSIS—ANTICOAGULANTS

is preferred due to the potential for limited gastrointestinal absorption. Use a small needle in multiple locations, if needed, and monitor for anaphylactoid reaction.
• Treat acute hemorrhagic shock with IV crystalloids, colloids, or blood products as needed. Initial crystalloid boluses of 10–20 mL/kg can be given over 15–20 minutes during stabilization. Repeat 2–3 times as needed to increase blood pressure.
• Packed RBCs, whole blood, fresh frozen plasma, or frozen plasma may be necessary to replace coagulation factors.
• Treat life-threatening cardiac tamponade or hemothorax with pericardiocentesis or thoracocentesis as indicated. If the patient is stable and responding to treatment, these procedures should be avoided. With time, the blood will reabsorb.

NURSING CARE
Provide supportive care as needed.

ACTIVITY
Confine the patient until the coagulopathy is stabilized as activity enhances blood loss.

DIET
Feed a nutritious, high-quality protein diet to support coagulation factor synthesis.

CLIENT EDUCATION
• Warn client that reexposure, even months to years later, could be a serious problem due to persistence of second-generation anticoagulants in the liver.
• Encourage the owner to pick up all loose/unprotected bait on the property.
• Do not discontinue vitamin K1 therapy early, even if the patient is asymptomatic.

SURGICAL CONSIDERATIONS
• Thoracentesis may be important for removing free thoracic blood, which causes dyspnea and respiratory failure (see Appropriate Health Care).
• The coagulopathy must be corrected before surgery.

MEDICATIONS

DRUG(S) OF CHOICE
Vitamin K1, 2.5–5.0 mg/kg PO q12h for 5–7 days for most first-generation anticoagulants and PO q24h for 4–6 weeks for most second-generation anticoagulants; bioavailability may be enhanced by the concurrent feeding of a small amount of fat, such as canned dog food.

CONTRAINDICATIONS
• Vitamin K3 is not efficacious in the treatment of anticoagulant rodenticide toxicosis and should not be used.
• IV vitamin K1 has been reported to cause anaphylactoid reactions. Avoid this route of administration.
• Minimize stress, trauma, jugular venipuncture, and cystocentesis due to the risk of acute and catastrophic hemorrhage.

PRECAUTIONS
• Avoid large-bore hypodermic needles, unnecessary surgical procedures, and parenteral injections.
• Use the smallest possible needle when giving an injection or collecting samples.

POSSIBLE INTERACTIONS
Sulfonamides and phenylbutazone may displace anticoagulant rodenticides from plasma binding sites, leading to freer toxicant and increased risk of toxicosis.

FOLLOW-UP

PATIENT MONITORING
PT (preferred) test 2–3 days after the last dose of vitamin K1 to assess duration of therapy. If the PT is prolonged, administer another 1–3 weeks of vitamin K1 and retest.

PREVENTION/AVOIDANCE
Prevent pet's access to anticoagulant rodenticides by using bait stations and keeping stored bait in a secure location.

POSSIBLE COMPLICATIONS
• Secondary bacterial pneumonia may occur following intrapulmonary hemorrhage.
• Intracranial and intra-articular hemorrhage may occur.
• Pregnant animals can abort due to placental hemorrhage and detachment.

EXPECTED COURSE AND PROGNOSIS
If the patient survives the first 48–72 hours of acute coagulopathy, the prognosis improves.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING
• Warfarin, diphacinone, and perhaps other anticoagulant rodenticides may pass into amniotic fluid and to the fetuses of an exposed pregnant animal. These toxicants may also pass via the milk and present concerns for nursing offspring. In general, antidotal treatment of the pregnant or nursing patient is recommended. Alternatively, nursing young may be weaned.
• Pregnant animals can abort due to placental hemorrhage and detachment.

ABBREVIATIONS
• EPA = US Environmental Protection Agency.
• PIVKA = protein-induced vitamin K absence or antagonist.
• PT = prothrombin time.
• PTT = partial thromboplastin time.

R

RODENTICIDE TOXICOSIS—BROMETHALIN

BASICS

OVERVIEW
• Bromethalin is a neurotoxic rodenticide that produces cerebral edema and elevated CSF pressure, resulting in progressive CNS depression, coma, paresis, and paralysis.
• Clinical signs and death have been reported in dogs and cats exposed to bromethalin at doses as low as 0.36 and 0.24 mg/kg, respectively.
• Trade names include Tomcat, Fastrac, Top Gun, Gladiator, and others. Bromethalin concentrations in products can vary from 0.01 to 0.025%.

SIGNALMENT
• Dogs and cats. Other species including humans may be affected.
• Any breed or age may be affected.

SIGNS
• Ingestion most often results in a delayed neurotoxic syndrome that develops within 2–7 days of ingestion; however, delays of up to 2 weeks may occur.
• Common clinical signs include anorexia, progressive ataxia, paresis, and hind limb paralysis, moderate to severe central nervous system depression, fine muscle tremors, and focal motor or generalized seizures.
• Forelimb extensor rigidity and decerebrate postures are often seen.
• Ingestion of high doses of bromethalin less commonly results in an acute onset (within 1–2 hours) of CNS excitation, muscle tremors, and seizures.

CAUSES & RISK FACTORS
Bromethalin ingestion most often occurs in animals <1 year of age.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Neurologic syndromes produced by trauma, neoplasia, cerebral vascular disorders, as well as infectious and other toxic agents.

CBC/BIOCHEMISTRY/URINALYSIS
Alterations in routine serum electrolytes and chemistries are not anticipated.

OTHER LABORATORY TESTS
Analytical chemical confirmation of bromethalin residues in fresh frozen fat, liver, kidney, and brain tissue.

IMAGING
Neuroimaging (MRI) may reveal generalized brain edema.

DIAGNOSTIC PROCEDURES
• CSF generally reveals normal cytology, protein concentration, specific gravity, and cell count.
• EEG findings can change during the course of the toxic syndrome and may include spike and spike-and-wave activity, marked voltage depression, and abnormal high-voltage slow-wave activities.

PATHOLOGIC FINDINGS
• Histologic lesions are generally confined to the CNS and include spongy degeneration in the cerebrum, cerebellum, brainstem, spinal cord, and optic nerve white matter due to myelin edema.
• Gross evidence of cerebral edema is generally mild.

TREATMENT
• Aggressive early treatment with oral activated charcoal and a cathartic to reduce gastrointestinal absorption is warranted.
• Prolonged anorexia and may require supplemental feeding to maintain caloric intake.
• Use cage padding to reduce the risk of decubitus ulcer formation in recumbent animals.

MEDICATIONS

DRUG(S) OF CHOICE
• Gastrointestinal tract decontamination including early induction of emesis followed by administration of activated charcoal (1–2 g/kg PO) with an osmotic cathartic (sorbitol) × 1 dose) followed by activated charcoal alone q6–8h × 24 hours. Pay attention to sodium concentration. The efficacy of these treatments remains unknown.
• Control of cerebral edema with mannitol 500 mg/kg q6h slow IV bolus, dexamethasone 1–2 mg/kg q6h IV, and furosemide 1–2 mg/kg q6h IV may have limited efficacy.
• Diazepam 0.5–1 mg/kg, IV as needed, or other anticonvulsants may be given to abolish severe muscle tremors and seizures.
• 20% IV lipid emulsions (ILE)—bolus dose 1.5 mL/kg over 2–3 minutes; CRI of 0.25 mL/kg/min for 30–60 minutes. Check serum q2h until it becomes clear; repeat as needed; if no clinical improvement after 3 doses, discontinue. Other ILE dosing regimens can be used.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
• Contraindications for the use of mannitol include renal disease, pulmonary edema, dehydration, and intracranial hemorrhage.
• Animals receiving mannitol therapy may become dehydrated.
• Rehydration may be associated with a worsening of clinical signs, possibly due to rebound cerebral and pulmonary edema. Maintenance of hydration is important and can be more safely accomplished through the administration of oral fluids.
• Adverse effects of ILE may relate to contamination of the lipid product or direct reaction to the emulsion.

FOLLOW-UP
• May require several weeks to recover from mild poisoning.
• Prognosis is poor for the severely affected animals.
• Prevent ongoing rodenticide ingestion.

MISCELLANEOUS
Relay toxicity arising from the consumption of animals poisoned with bromethalin may occur.

ABBREVIATIONS
• EEG = electroencephalogram.
• ILE = IV lipid emulsion.

RODENTICIDE TOXICOSIS—CHOLECALCIFEROL

BASICS

DEFINITION
Hypercalcemic disorder resulting from ingestion of vitamin D rodenticide preparations.

PATHOPHYSIOLOGY
- Cholecalciferol is metabolized to 25-hydroxycholecalciferol in the liver. 25-hydroxycholecalciferol is metabolized to several metabolites in the kidney, including calcitriol, the most potent metabolite in terms of enhancing calcium absorption from the gut and calcium resorption from bones under physiologic conditions.
- 1,25-dihydroxycholecalciferol is the active metabolite of cholecalciferol under physiologic conditions.
- Under toxic conditions, 25-hydroxycholecalciferol is the predominant circulating and active metabolite.
- 25-hydroxycholecalciferol increases absorption of calcium from the gut, stimulates bone resorption, and enhances calcium absorption in renal distal tubules, resulting in hypercalcemia (serum calcium >12.5 mg/dL).
- Serum phosphorus is also increased.
- The outcome is metastatic and dystrophic mineralization of soft tissues, resulting in pathophysiology of the affected organs.

SYSTEMS AFFECTED
- Cardiovascular—mineralization, arrhythmias.
- Gastrointestinal—anorexia; mineralization; emesis; hematemesis; constipation; increased gastric acid secretion.
- Musculoskeletal—bone demineralization; muscle tremors.
- Nervous—seizures or depression.
- Renal/urologic—calcification, proximal tubular necrosis, dilute urine, and renal failure.
- Respiratory—lung mineralization; dyspnea.

INCIDENCE/PREVALENCE
- Cholecalciferol rodenticide toxicosis—most common cause of vitamin D poisoning in dogs and cats.
- Incidence of poisoning unknown but growing in popularity as rodenticide as the use of anticoagulant rodenticides declines.
- Suckling pups and kittens can be poisoned through milk.

SIGNALMENT
Species
- Dogs and cats.
- Other species, particularly exotics.

Mean Age and Range
All ages affected; younger dogs (<6 months) and cats are the most sensitive.

SIGNS
General Comments
Cholecalciferol rodenticides—signs develop within 12–36 hours post ingestion.

Historical Findings
- Inactivity.
- Vomiting.
- CNS depression.
- Weakness.
- Anorexia.
- Polydipsia.
- Polyuria.
- Diarrhea.
- Melena.
- Hematemesis.
- Loss in body weight.
- Constipation.
- Seizures.
- Muscle tremors.

Physical Examination Findings
- Depression.
- Vomiting.
- Diarrhea.
- Hematemesis.
- Hematochezia.
- Polyuria.
- Polydipsia.
- Dehydration.
- Renal pain on palpation.
- Gastrointestinal hemorrhage.
- Abdominal pain.
- Hypersalivation.
- Oropharyngeal erosive lesions.
- Bradycardia; ventricular premature contractions.
- Dyspnea.

CAUSES
Cholecalciferol rodenticides (0.075%)—Quintox, Rampage, Ortho Rat-B-Gone, Ortho Mouse-B-Gone, others; clinically normal dogs and cats have developed hypercalcemia at 0.5 mg/kg body weight; signs have occurred in dogs and cats at 0.1 mg/kg body weight.

RISK FACTORS
- Preexisting renal, gastrointestinal, cardiac, lung, or CNS diseases.
- Dehydration.
- Neoplasia.
- Primary hyperparathyroidism.
- Hypoadrenocorticism.
- Granulomatous diseases (e.g., blastomycosis).
- Juvenile hypercalcemia.
- Age—young animals are most susceptible.
- Feline idiopathic hypercalcemia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other hypercalcemic disorders, including lymphosarcoma and other malignancies, hypoadrenocorticism, chronic renal failure, primary hyperparathyroidism, and granulomatous lesions in soft tissues.
- Juvenile hypercalcemia.
- Anticoagulant rodenticide and nonsteroidal anti-inflammatory drug (NSAID) toxicity—due to hematemesis and melena.

CBC/BIOCHEMISTRY/URINALYSIS
- Calcium—hypercalcemia (total serum calcium >12.5 mg/dL, ionized calcium >6.0 mg/dL). Hypercalcemia is immediate (2–3 hours) and transient (will decline to normal within 24 hours post ingestion) with calcipotriol ingestion. In cholecalciferol rodenticide toxicity, hypercalcemia is evident 12 hours post ingestion and persists for weeks if not treated.
- Hyperphosphatemia (>8 mg/dL) may precede hypercalcemia.
- Hypokalemia.
- Azotemia.
- Hyposthenuria, proteinuria, and glucosuria.
- Metabolic acidosis.

OTHER LABORATORY TESTS
- In acute, one-time ingestions, serum 25-hydroxy vitamin D concentration is increased at least 10 times normal (normal ranges: dogs, 60–215 nmol/L; cats, 65–170 nmol/L) in cholecalciferol toxicosis.
- In chronic intoxications, serum 25-hydroxy vitamin D concentrations can increase from 1.5 to 5 times above normal values.
- Serum 1,25-dihydroxy vitamin D is only transiently increased and is of limited diagnostic value.
- The total calcium-to-total phosphorus ratio in renal cortex of deceased dogs is in the range of 0.4–0.9 (normal <0.3) for all vitamin D-related intoxications.
- Renal cortical 25-hydroxy vitamin D concentration >80 nmol/L supports a diagnosis of cholecalciferol toxicosis.
- Biliary 25-hydroxy vitamin D concentration >100 nmol/L supports a diagnosis of cholecalciferol toxicosis.
- Decreased intact parathyroid hormone (iPTH) (normal in dogs is 3–17 pmol/L and for cats is 0–4 pmol/L).
- Normal Na/K ratio.

IMAGING
Ultrasonography—renal, gastric wall, lung hyperechogenicity.

DIAGNOSTIC PROCEDURES
- Electrocardiogram—may show bradycardia, sinus tachycardia, ventricular premature complexes.
- Endoscopy—may reveal erosive/hemorrhagic gastric mucosa.

PATHOLOGIC FINDINGS
- Diffuse mineralization of gastric wall and intestines; hemorrhage in gastric mucosa; mineralization of the soft palate, salivary glands, other soft tissues.

RODENTICIDE TOXICOSIS—CHOLECALCIFEROL (CONTINUED)

• Necrosis and mineralization of myocardium (especially the atria) and large blood vessels; myocardial degeneration.
• Mineralization of glomerular mesangium and capsule, and renal tubular basement membranes.
• Tubular necrosis.
• Mineralization of lungs.

TREATMENT

APPROPRIATE HEALTH CARE

• Cholecalciferol—once clinical signs show (usually 24–36 hours post ingestion), gastric decontamination is not worth while.
• Hospitalization with close observation in all cases for at least 48 hours post ingestion.

NURSING CARE

• Correct dehydration and electrolyte imbalances (hypokalemia).
• Enhance calciuresis with fluid therapy—strongly recommended for all patients.
• Peritoneal dialysis with a calcium-free dialysate—for severe azotemia and hypercalcemia.
• Blood transfusion—if anemia is severe or in case of hypovolemia.
• Antibiotic therapy—as needed.
• Parenteral alimentation—recommended to rest the gut and to overcome anorexia.

DIET

Offer low-calcium, low-phosphorus diets.

CLIENT EDUCATION

• Caution client to keep all rodenticide products in places that are inaccessible to pets.
• Warn client that vitamin D toxicity is a severe and costly disease to treat with prolonged therapy and hospitalization.

MEDICATIONS

DRUG(S) OF CHOICE

• Pamidronate disodium—to treat hypercalcemia.
• Salmon calcitonin—to treat hypercalcemia.

Decontamination of Gastrointestinal Tract

• Within 2 hours of vitamin D ingestion.
• Emetic and activated charcoal followed by osmotic cathartics.
• Dogs—apomorphine 0.02–0.04 mg/kg IV, IM, SC, or subconjunctivally.
• Cats—xylazine 0.4–0.5 mg/kg IV.
• Activated charcoal powder (1–4 g/kg) combined with a saline cathartic (magnesium or sodium sulfate, 250 mg/kg)—PO or by gastric tube.

Hypercalcemia Reduction

• Pamidronate disodium 1.3–2.0 mg/kg in 0.9% sodium chloride slow IV over 2–4 hours; repeat once in 3–4 days for large ingestions; do not combine with salmon calcitonin.
• Salmon calcitonin 4–6 IU IM or SC every 6 hours till calcium concentration stabilizes; rarely used as limited efficacy and patients may become refractory.
• IV fluids: 0.9% sodium chloride or 5% dextrose with 0.45% sodium chloride fluids to begin; change as needed.
• Prednisolone—dogs and cats: 2–6 mg/kg IM or PO q12h.
• Furosemide—dogs, 2–6 mg/kg; cats, 1–4 mg/kg SC, IV, or IM q8–12h.

Seizure Control

• Diazepam 0.5–1 mg/kg IV, repeat as necessary.

Control of Clinically Significant Ventricular Arrhythmias

• Lidocaine—dogs, 2–4 mg/kg IV over 1 minute, repeat up to 8 mg/kg; cats, use cautiously at 0.25–0.5 mg/kg IV slowly.

Gastrointestinal Protection

• Sucralfate 0.25–1 g PO q6–8h.
• Famotidine 0.5–1 mg/kg IV, IM, PO q12h.

Antiemetics

• Maropitant 1 mg/kg SQ, IV or PO q24h.

PRECAUTIONS

• Supratherapeutic doses of pamidronate disodium may worsen renal failure.
• Salmon calcitonin—associated with side effects: anorexia, anaphylaxis, and emesis. Rarely used.
• Xylazine—may aggravate respiratory depression and result in vagal-mediated slowing of the heart rate.
• Prolonged prednisolone therapy may result in adrenocortical suppression; taper doses gradually over a 2- to 4-week treatment period.

FOLLOW-UP

PATIENT MONITORING

• Following pamidronate therapy—serum calcium and BUN at 24, 48, and 72 hours following exposure; if hypercalcemia still present, repeat pamidronate infusion 72 or 96 hours after the first infusion and monitor serum calcium and BUN q48h.
• Following calcitonin therapy—serum calcium and BUN; monitor q24h and continue adjusting dose until calcium returns to normal (24–48 hours for calcipotriol, or 2–4 weeks for cholecalciferol).
• Cholecalciferol-induced hypercalcemia is persistent, requiring long-term management and supportive care (2–4 weeks).

PREVENTION/AVOIDANCE

Keep rodenticides out of reach of pets.

POSSIBLE COMPLICATIONS

• Chronic renal failure—inability to concentrate urine.
• Subclinical renal, cardiovascular, and gastrointestinal sequelae—due to mineralization.

EXPECTED COURSE AND PROGNOSIS

Cholecalciferol—depends on severity and duration of hypercalcemia; if hypercalcemia is unresponsive or severe mineralization occurs before therapy is initiated, prognosis is poor.

MISCELLANEOUS

AGE-RELATED FACTORS

Distinguish from normal juvenile hypercalcemia.

PREGNANCY/FERTILITY/BREEDING

Vitamin D has antiproliferative effects and the potential for teratogenesis.

SYNONYMS

N/A

ABBREVIATIONS

• iPTH = intact parathyroid hormone.
• NSAID = nonsteroidal anti-inflammatory drug.

RODENTICIDE TOXICOSIS—PHOSPHIDES

BASICS

OVERVIEW
• Used as a rodenticide since the early 1930s at various concentrations (2–10%) in a powder, pellet, or paste formulation. Available as zinc, aluminum, and magnesium salts. • Distinctive odor, often described as acetylene, rotten fish, or garlic. • Most common route of exposure is ingestion; however, toxicosis can occur via inhalation and absorption through broken skin. • Hydrolysis leads to phosphine gas production. Phosphine gas has corrosive and irritant effects on the gastrointestinal (GI) mucosa, which leads to vomiting, hematemesis, or melena. The gas is rapidly absorbed and systemically distributed leading to effects on other organ systems. • Phosphine leads to the production of free radicals and oxidative stress, causing direct cellular damage and may inhibit cellular respiration. • Toxic exposure is reported to be 20–40 mg/kg; however, the gastric pH is reported to affect toxicity.

SIGNALMENT
No known age, breed, or sex predilection.

SIGNS
• Within 15 minutes to 4 hours but can be delayed up to 18 hours. • GI—anorexia, vomiting, and melena. • Cardiovascular—direct myocardial damage, arrhythmias, decreased inotropy, hypotension. • Respiratory—pulmonary edema, pleural effusion. • Hemic/lymphatic/immune—methemoglobinemia, Heinz body production. • Nervous—ataxia, weakness, tremors, hyperesthesia, and seizures. • Renal/urologic—azotemia, acute renal failure. • Hepatobiliary—increased alanine transaminase (ALT), aspartate transferase (AST), and total bilirubin. • Endocrine/metabolic—metabolic acidosis, electrolyte imbalance. • Musculoskeletal—weakness, ataxia.

CAUSES & RISK FACTORS
• Increased hydrolysis in a moist, acidic environment; thus, recent food ingestion lowers gastric pH and increases hydrolysis. Owner should be instructed not to feed their pet. • Owners and veterinary staff are at risk for inhalation exposure if the animal vomits in a poorly ventilated area. Owners should be told to lower their windows on the way to the clinic.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Organophosphate. • Metaldehyde. • Serotonin syndrome. • Nonsteroidal anti-inflammatory drug (NSAID) toxicosis. • Tremorgenic mycotoxins. • Acute GI disease (hemorrhagic gastroenteritis [HGE], gastroenteritis, parvovirus). • Congestive heart failure. • Respiratory disease (noncardiogenic pulmonary edema—secondary to electrocution, near drowning, seizures, or acute respiratory distress syndrome [ARDS]). • Metabolic disease (renal, hepatic, pancreatitis).

CBC/BIOCHEMISTRY/URINALYSIS
• May see increased liver enzymes (ALT, AST, and total bilirubin); can be delayed 3–5 days. • Electrolyte alterations (decreased potassium or magnesium). • Methemoglobinemia, Heinz body formation, and subsequent hemolysis.

OTHER LABORATORY TESTS
• Confirmation through gas chromatography or a Dräger detection tube (referral laboratory testing). • Post-mortem samples from the liver, kidney.

IMAGING
If respiratory signs, thoracic radiographs to assess for pulmonary edema.

PATHOLOGIC FINDINGS
Are nonspecific.

TREATMENT
• No antidote. • The goal of treatment with recent, asymptomatic patients is to safely decontaminate. • Administration of a liquid antacid such as magnesium hydroxide, aluminum hydroxide, calcium carbonate, or even a 5% sodium bicarbonate solution may help to increase the gastric pH and thus decrease phosphine gas production. • Emesis induction with apomorphine, hydrogen peroxide, or gastric lavage for gastric emptying. • Activated charcoal may help decrease toxicity but should be given only if the patient's clinical status allows. • IV fluid therapy with monitoring for any clinical signs or progression of signs for at least 18 hours. • Supplemental oxygen for hypoxemia.

MEDICATIONS
• GI protectants—famotidine 0.5–1 mg/kg IV/PO q12–24h, omeprazole 0.5–1 mg/kg PO q12–24h, sucralfate 0.25–1 g PO q8–12h, or possibly misoprostol 2–5 µg/kg PO q8h. • Tremors—methocarbamol 44–220 mg/kg IV or to effect; do not exceed 330 mg/kg/day. • Seizures—diazepam 0.5–1 mg/kg IV, phenobarbital 4–16 mg/kg IV to effect, levetiracetam 30–60 mg/kg IV, or propofol 1–8 mg/kg or to effect, followed by a CRI at 0.1–0.6 mg/kg/h. • Liver effects—hepatoprotectants (*S*-adenosylmethionine 18 mg/kg PO q24h, silymarin/milk thistle 50–250 mg/day PO q24h. If associated coagulopathy—vitamin K_1 2–3 mg/kg PO q12–24h. • Oxidative damage or for methemoglobinemia—*N*-acetylcysteine. • Painful—opioids (hydromorphone 0.05–0.1 mg/kg IV) or tramadol 2–4 mg/kg PO q8–12h. Avoid NSAIDs.

FOLLOW-UP
Varies on a case basis.

PATIENT MONITORING
Several organ systems may be affected; vitals, heart rhythm, blood pressure, and CNS should be monitored for 18 hours.

PREVENTION/AVOIDANCE
Have owners remove all baits from environment.

POSSIBLE COMPLICATIONS
Liver or renal failure.

EXPECTED COURSE AND PROGNOSIS
• Asymptomatic patients should be monitored for up to 12–18 hours. • Symptomatic patients should be monitored for at least 48 hours or until life-threatening signs have resolved.

MISCELLANEOUS

ABBREVIATIONS
• ALT = alanine transaminase. • ARDS = acute respiratory distress syndrome. • AST = aspartate transferase. • GI = gastrointestinal. • HGE = hemorrhagic gastroenteritis. • NSAID = nonsteroidal anti-inflammatory drug.

ROUNDWORMS (ASCARIASIS)

BASICS

OVERVIEW

• Ascariasis caused by *Toxocara canis* (dogs), *T. cati* (cats), and *Toxascaris leonina* (dogs, cats); *Baylisascaris* (raccoons) can infect dogs and causes neural larval migrans in people. • Transplacental transmission of *T. canis* larvae from bitch to pups causes prenatal infection; transmammary transmission of larvae occurs with both *Toxocara* spp.; no transplacental or transmammary transmission with *Toxascaris*. • In first month of life, infected neonatal pups may develop abdominal pain and rapidly deteriorate before *Toxocara* eggs appear in feces. • Older pups and kittens can acquire by ingesting eggs spread by dams with postgestational infection; dams can be infected by ingesting immature worm stages in pups' feces or vomitus or by predation on vertebrate transport hosts. • Adult ascarids occur in lumen of small intestine; larval stages of *Toxocara* spp. may migrate in liver and lungs. • If numerous, ascarids (up to 10–12 cm long) can distend intestine and cause colic, interference with gut motility, inability to utilize food, intestinal rupture.

SIGNALMENT

• Dog and cat. • Important in puppies/kittens due to *in utero*/transmammary transmission.

SIGNS

• Abdominal distension; often with palpable intestinal distension. • Colic. • Weakness, loss of condition, cachexia; poor nursing or appetite; scant feces. • Coughing due to larval lung migration. • Entire litter may be affected.

CAUSES & RISK FACTORS

• Dormant *Toxocara* larvae in dam's tissues is infection reservoir for puppies during gestation; queen becomes infected during late pregnancy or lactation and transfers to kittens via transmammary route. • Access to infected transport hosts. • Concurrent enteric infections. • *Toxocara* larvae undergo extensive migration and can cause granulomatous inflammation (visceral larva migrans). Visceral larva migrans caused by ascarids is cause of human morbidity. • Somatically arrested larvae in small vertebrates are source of infection for dogs/cats that hunt.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Transmammary perinatal infection of neonates with hookworms (anemia, melena, weakness, lethargy, pallor, enteritis) or *Strongyloides* (diarrhea); coccidiosis, giardiasis; examine feces for eggs or larvae. • *Physaloptera*.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal.

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

• Fecal flotation to detect eggs: ◦ *Toxocara* eggs spherical pitted outer shell membrane, single dark cell filling interior, 80–85 µm (*T. canis*), ~75 µm (*T. cati*). ◦ *Baylisascaris* eggs similar to *T. canis* eggs but smaller (~76 × 60 µm), more finely pitted shell. ◦ *Toxascaris* eggs ovoid, smooth exterior shell membrane, 1–2 cells with light-colored cytoplasm; cells do not fill interior of egg; 80 × 70 µm in diameter. • Necropsy of siblings—identify ascarids by size, appearance. • Fecal ELISA—commercial test detects antigen produced by adult and immature roundworms of both sexes; can detect prepatent infection.

TREATMENT

• Generally outpatient. • Acute severe cases treated as inpatients; provide parenteral fluids. • Alert client to possibility of sudden death or chronic debilitation. • Treat dam with adulticide/larvicide anthelmintic to remove intestinal stages and limit transmission to subsequent litters.

MEDICATIONS

DRUG(S) OF CHOICE

Adulticide/Larvicide Anthelmintics

• Fenbendazole 50 mg/kg PO q24h for 3 days. • Milbemycin oxime 0.5 mg/kg (dogs) or 2 mg/kg (cats) PO q30 days. • Moxidectin (dogs) 2.5 mg/kg, topically, q30 days. • Moxidectin (in combination with imidacloprid) 10 mg/kg, topically, q30 days. • Emodepside 3 mg/kg, or praziquantel 12 mg/kg, topically once for cats ≥8 weeks old; repeat in 30 days if cat is reinfected.

Adulticide Anthelmintics

• Pyrantel pamoate 5 mg/kg PO (dogs) or 10–20 mg/kg PO (cats, extra-label). • Pyrantel/praziquantel, label dose for cats. • Febantel/praziquantel/pyrantel, label dose for dogs. • Ivermectin/pyrantel, label dose for dogs. • Selamectin 6 mg/kg, topically, once (*T. cati,* cats): dogs, extra-label.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING

Repeat post-treatment fecal exams on puppies/kittens and/or repeat anthelmintic treatment every 2–3 weeks until old enough for monthly anthelmintic product.

PREVENTION/AVOIDANCE

• Minimize environmental contamination, treat infected dogs/cats with anthelmintic, dispose of feces promptly. • Prevent dogs/cats from hunting or ingesting transport hosts. • Extra-label treatment of dam with adulticide/larvicide anthelmintic to remove intestinal stages and decrease vertical transmission.

POSSIBLE COMPLICATIONS

Transplacental transmission of large numbers of larvae can result in fetal death or birth of weak, nonviable offspring.

EXPECTED COURSE AND PROGNOSIS

Prognosis good after anthelmintic treatment; guarded with severe prenatal *T. canis* infection.

MISCELLANEOUS

AGE-RELATED FACTORS

Greater concern in neonates.

ZOONOTIC POTENTIAL

• Visceral larva migrans, ocular larva migrans, neural larva migrans, chronic abdominal or cutaneous problems may follow ingestion of infective *Toxocara* spp. or *Baylisascaris* eggs by humans; advise clients to practice good hygiene after handling feces. • Most likely cause of neural larva migrans is *Baylisascaris*; virtually all raccoons become infected with *Baylisascaris* and therefore extreme caution should be exercised with clients having raccoons as "pets."

SAGO PALM TOXICOSIS

BASICS

OVERVIEW
• Cycad palms, also called sago palms, belong in the family Cycadaceae. • Native to tropical and subtropical regions but have become popular ornamental plants in the United States. • *Cycas revoluta*, *Cycas circinalis,* and *Zamia floridana* are the most common species. • Contain the toxins cycasin, betamethylamino-L-alanine, and an unidentified high-molecular-weight compound. • Toxins present in all parts of the plant; highest concentrations in seeds. • Cycasin is metabolized by the intestinal flora to the active hepatotoxic, carcinogenic, mutagenic, teratogenic, and neurotoxic compound methylazoxymethanol (MAM). • Cycad toxicosis has been documented in several animal species (dogs and ruminants) and humans. • In dogs, gastrointestinal (GI) disturbances and hepatic damage predominate; nervous system involvement is less common.

SIGNALMENT
• Dogs—no breed, sex, or age predilection. • Cats—no cases reported.

SIGNS
• GI disturbances such as vomiting, diarrhea, and abdominal pain. • Signs associated with hepatic damage (ecchymoses, petechiae, hemorrhage, edema, etc.). • Gait abnormalities; paresis/paralysis; tremors. • Depression, coma, and death.

CAUSES & RISK FACTORS
Access to and ingestion of cycad palm.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other Causes of Acute GI Upset
• Infectious. • Metabolic. • Toxic. • Dietary.

Other Causes of Acute Liver Failure
• Microcystins (hepatotoxic blue-green algal toxins)—access to water with algal bloom, algal material on legs or in stomach contents, detection of microcystins in stomach contents. • Amanitin—access to mushrooms (*Amanita*, *Galerina*, and *Lepiota* spp.), GI signs between 6 and 24 hours after ingestion. • Cocklebur (*Xanthium* spp.)—access to cocklebur (only seeds and two-leaf cotyledon stage are toxic). • Aflatoxins—access to moldy food. • Acetaminophen overdose. • Xylitol—access to xylitol-containing products (sugar-free gum, chewable vitamins, baked goods); initial hypoglycemia. • Severe acute pancreatitis.

CBC/BIOCHEMISTRY/URINALYSIS
• Anemia. • Elevated serum liver enzymes (alanine transaminase, aspartate transaminase, alkaline phosphatase, bilirubin). • Hypoalbuminemia. • Hypoglycemia. • Glucosuria, hemoglobinuria, myoglobinuria, bilirubinuria, proteinuria, and increased urine specific gravity.

OTHER LABORATORY TESTS
• Ammonia tolerance test—hyperammonemia. • Prolonged prothrombin time/partial thromboplastin time.

IMAGING
N/A

DIAGNOSTIC PROCEDURES
• History of cycad palm ingestion and presence of appropriate clinical signs. • Identification of plant in ingesta or feces. • Biopsy and histopathology of liver—hepatic necrosis. • Necropsy—hepatic centrilobular necrosis.

PATHOLOGIC FINDINGS
• Detection of cycad palm material in GI tract and/or in feces. • Gross detection of liver enlargement. • Histologic detection of centrilobular and midzonal coagulative hepatocellular necrosis.

TREATMENT
• No antidote available. • GI decontamination with activated charcoal can be attempted but efficacy is unknown. • Supportive care including close monitoring and, depending on the severity of clinical signs, IV fluids, correction of electrolyte imbalances and hypoglycemia, vitamin K1, and plasma transfusions.

MEDICATIONS

DRUG(S) OF CHOICE
• Activated charcoal—multi-dose activated charcoal at 1–4 g/kg PO q4–6h for 2–3 days post ingestion. Mix activated charcoal in water at 1 g/5–10 mL of water. • IV fluids—maintain hydration, induce diuresis, correct hypoglycemia. • Dextrose—50% dextrose 1 mL/kg IV slow bolus (1–3 minutes). • Vitamin K1—0.5–1.5 mg/kg SC or IM q12h; 1 mg/kg PO q24h. • Blood products—dependent on hemostatic test results.

ALTERNATIVE DRUG(S)
• *S*-Adenosylmethionine—antioxidant and hepatoprotectant; no data on efficacy in sago palm toxicosis available. Dose 20 mg/kg PO q24h. • Ascorbic acid and cimetidine—hepatocyte protectors; no data on efficacy in sago palm toxicosis available. Can be given for supportive therapy. • *N*-Acetylcysteine—antioxidant; no data on efficacy in sago palm toxicosis available. A glutathione precursor that can be included in the treatment regimen for acute fulminant hepatic failure at 140 mg/kg IV load, followed by 70 mg/kg IV q6h for 7 treatments.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

PATIENT MONITORING
• Liver enzymes/function. • Coagulation status.

PREVENTION/AVOIDANCE
Deny access to sago palms.

POSSIBLE COMPLICATIONS
• Hepatic encephalopathy. • Disseminated intravascular coagulation. • Renal failure.

EXPECTED COURSE AND PROGNOSIS
• Dogs develop vomiting within minutes, followed by further GI upset. • Changes in clinical laboratory values occur after 24–48 hours. • Nadir serum albumin levels and nadir platelet counts are important prognostic indicators. • Liver failure within a few days. • Prognosis is poor to guarded.

MISCELLANEOUS

ABBREVIATIONS
• GI = gastrointestinal. • MAM = methylazoxymethanol.

SALIVARY MUCOCELE

BASICS

OVERVIEW

• Salivary mucoceles (sialoceles) are nonepithelial-lined cavities filled with saliva that has leaked from a damaged salivary gland or duct; they are surrounded by granulation tissue that forms secondary to inflammation caused by the free saliva.
• There are four major pairs of salivary glands: parotid, mandibular, sublingual, and zygomatic. Smaller salivary glands are located in the soft palate, lips, cheeks, and tongue.
• Types of mucoceles are listed in Table 1. The most common type occurs with injury to the sublingual gland or its duct.

SYSTEMS AFFECTED

Gastrointestinal

SIGNALMENT

• Three times more frequent in dogs than in cats.
• Commonly affected breeds include miniature poodle, German shepherd dog, dachshund, and Australian silky terrier.
• Slight predisposition of males compared to females.
• No age predisposition.

SIGNS

Cervical Sialocele

• Soft, fluctuant, minimally painful or nonpainful, gradually developing cervical mass.
• Pain is usually manifested only during the acute-manifestation phase of the sialocele.

Sublingual Sialocele

• Soft, sublingual swelling (also called ranula; from Latin: *rana*, frog).
• Often blood-tinged saliva secondary to self-trauma while eating.
• Abnormal tongue movement, tongue displaced, dysphagia.

Pharyngeal Sialocele

• Swelling in pharyngeal wall.
• Dysphagia and respiratory distress when very large.

Zygomatic Sialocele

• Periorbital swelling.
• Exophthalmos and protrusion of third eyelid.
• Divergent strabismus.
• Periocular pain.
• Pressure-related neuropathy of the optic nerve.

CAUSES & RISK FACTORS

The cause is rarely identified. Suspected causes:
• Blunt trauma to the head and neck (choke chains).
• Bite wound.
• Penetrating foreign body.
• Ear canal surgery, parotid duct transposition, maxillectomy.
• Sialoliths.
• Dirofilariasis.

DIAGNOSIS

• Diagnosis is based on history, visual examination, and paracentesis of the fluid-filled swelling.
• Determine the site of origin with help of oral examination, palpation, sialography, or exploration of the sialocele.

DIFFERENTIAL DIAGNOSIS

• Sialoadenitis (second most common salivary gland disease; usually involving the zygomatic gland; often concurrent with sialoliths and other ductal foreign bodies).
• Sialadenosis (nonpainful, noninflammatory salivary gland swelling; usually mandibular gland).
• Necrotizing sialometaplasia (painful salivary gland swelling; squamous metaplasia with ischemic necrosis; usually mandibular gland).
• Salivary neoplasia (rare; mandibular and parotid glands most commonly involved; usually adenocarcinomas).
• Sialoliths (calcium phosphate or carbonate).
• Cervical abscess.
• Foreign body.
• Hematoma.
• Abscessed or neoplastic lymph nodes.

CBC/BIOCHEMISTRY/URINALYSIS

Laboratory abnormalities are rarely seen.

OTHER LABORATORY TESTS

N/A

IMAGING

• Ideally CT or MRI with contrast.
• Skull and upper neck radiography only helpful to identify sialoliths, foreign bodies, or neoplasia.
• Sialography (injection of iodinated, water-soluble contrast agent into the salivary duct) reserved for patients with trauma, previous surgeries, or fistulous draining tracts and can be helpful to determine the size and source of sialoceles.
• Retrobulbar ultrasound.

DIAGNOSTIC PROCEDURES

Aseptic Paracentesis

• Differentiates sialoceles from neoplasia and abscess.
• Aspirated fluid is viscous, clear, or pink, yellow, brown or black (blood-tinged) with a low cell count; surrounding soft tissue may show low-grade chronic plasmacytic-lymphocytic inflammation.
• Cytologic evaluation (Wright's stain) reveals diffuse or irregular clumps of pink to violet-staining mucin, large phagocytic cells with small, round nuclei and foamy cytoplasm, intermixed salivary gland epithelial cells, and nondegenerate neutrophils in small numbers.
• Stain with a mucus-specific stain (e.g., periodic acid–Schiff) for definitive diagnosis.

TREATMENT

• Patients with acute respiratory distress (pharyngeal sialoceles) might need to be intubated or have a temporary tracheostomy performed. Transoral drainage via stab incision may be required prior to intubation.
• Complete surgical excision of the involved gland–duct complex and drainage of the sialocele is the treatment of choice. Permanent drainage may be achieved with marsupialization of sublingual and pharyngeal sialoceles.

MEDICATIONS

DRUG(S) OF CHOICE

Antibiotics based on bacteriologic evaluation, if concurrent abscessation or sialadenitis.

CONTRAINDICATIONS

Nonsurgical treatment with repeated drainage or injection of cauterizing or anti-inflammatory agents is not curative and will complicate subsequent surgery by causing abscessation or fibrosis.

FOLLOW-UP

PATIENT MONITORING

Penrose drains placed after sialadenectomy are usually removed 24–72 hours following surgery.

POSSIBLE COMPLICATIONS

• Seroma formation (after excessive tissue dissection, insufficient dead space management, and when Penrose drains are not used following sialadenectomy).
• Infection.
• Sialocele recurrence (<5% with complete resection).

EXPECTED COURSE AND PROGNOSIS

• Excellent prognosis with complete surgical excision.
• Seroma formation and infection complicate successful surgical excision.

Table 1

Types of sialoceles.

Type	*Location*	*Gland/duct involved*
Cervical	Intermandibular space, jaw angle, upper cervical region	Sublingual or mandibular
Sublingual	Sublingual tissue	Sublingual or mandibular
Pharyngeal	Pharyngeal wall	Sublingual
Zygomatic	Ventrolateral to the globe	Zygomatic
Parotid mucocele	Side of the face, jaw angle, ventral to ear	Parotid

MISCELLANEOUS

ASSOCIATED CONDITIONS

Sialoadenitis (resected salivary glands often show various degrees of inflammation histologically).

SYNONYMS

- Salivary mucocele.
- Sialocele.

SALMON POISONING DISEASE

BASICS

OVERVIEW
• Infection with rickettsial organism *Neorickettsia helminthoeca*, an obligate intracellular pathogen that resides within trematode (fluke) vector *Nanophyetus salmincola*.
• Organism invades small intestinal epithelium and associated lymphoid tissue after ingestion of uncooked or undercooked fluke-infected salmonid fish; animal develops acute systemic illness with high fever, gastrointestinal signs.
• Geographically restricted to coastal regions of northern California, Oregon, Washington, southern British Columbia due to the geographic distribution of the *Oxytrema silicula*, intermediate host for trematode.

SIGNALMENT
• All ages; median 3 years old.
• Dogs of all breeds and sexes; intact male dogs and Labrador retrievers may be overrepresented.

SIGNS
• Inappetence.
• Lethargy.
• Fever (up to 107.6°F/42°C); terminal hypothermia may develop.
• Lymphadenopathy.
• Splenomegaly.
• Vomiting.
• Diarrhea, may contain melena or frank blood.
• Weight loss.
• Uncommonly, mental obtundation, cervical pain, twitching, seizures.

CAUSES & RISK FACTORS
• Residence in endemic area.
• Ingestion of uncooked or undercooked fish containing fluke metacercariae that harbor *N. helminthoeca*; salmonid fish (salmon and trout) most common; other freshwater fish can be infected.
• Any part of fish can be infected.
• Supermarket-bought fish have been implicated in some cases.
• Dogs from non-endemic areas can develop disease after ingesting transported fish.
• Infection also reported after swimming, without apparent fish ingestion.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Lymphoma.
• Toxicosis.
• Canine parvovirus type 2 infection.
• *Ehrlichia canis* infection.
• *Anaplasma phagocytophilum* infection.
• Canine distemper virus infection.
• Rocky Mountain spotted fever.
• Salmonellosis.
• Whipworm infestation.
• Pancreatitis.
• Hypoadrenocorticism.
• Disseminated cryptococcosis.

CBC/BIOCHEMISTRY/URINALYSIS
• Thrombocytopenia (90% of dogs), neutrophilia with a left shift, lymphopenia.
• Serum chemistry nonspecific—electrolyte abnormalities, hypoproteinemia, increased activity of alkaline phosphatase, hypocholesterolemia.
• Urinalysis—proteinuria, bilirubinuria.

OTHER LABORATORY TESTS
Some dogs have laboratory findings suggestive of disseminated intravascular coagulation.

IMAGING
Abdominal ultrasound—splenomegaly with mottled echotexture, abdominal lymphadenomegaly; fluid-distended intestinal loops with wall thickening, corrugation, hypermotility or hypomotility.

DIAGNOSTIC PROCEDURES
• Lymph node aspirates—increased numbers of histiocytes containing basophilic granular material in cytoplasm (rickettsial inclusions).
• Fecal examination—operculated eggs of trematode *N. salmincola*; using combination of centrifugal fecal flotation and fecal sedimentation maximizes sensitivity of test (sensitivity 93%).
• Where available, PCR assays for *N. helminthoeca* can be performed on lymph node aspirates or feces.

PATHOLOGIC FINDINGS
• Lymphoid tissue enlargement—tissues yellowish with prominent white foci.
• Petechial hemorrhages.
• Gastrointestinal tract thickening with white nodules.
• Intestinal contents—frequently contain free blood; flukes may not be grossly visible.
• Histopathology—depletion of lymph node follicles; infiltration of lymphoid tissues and intestinal submucosa by histiocytes; cytoplasm contains numerous lymphoid follicles; flukes may be found embedded in gastrointestinal mucosa.

TREATMENT
• Inpatient—acutely ill patients.
• Supportive therapy—IV fluids with electrolytes; colloids or packed red blood cell transfusions may be needed; consider antiemetics and parenteral nutrition.

MEDICATIONS

DRUG(S) OF CHOICE
• Oxytetracycline 7.5–10 mg/kg IV q12h for 7–14 days.
• Doxycycline 5 mg/kg PO, IV q12h for 7–14 days.
• Praziquantel 10–30 mg/kg PO q24h for 1–2 days to kill flukes.

FOLLOW-UP

PATIENT MONITORING
Monitor hydration, electrolytes, acid–base balance, body temperature.

PREVENTION/AVOIDANCE
• Avoid feeding/eating improperly cooked fish.
• Inform client of necessity to act quickly; consider other dogs that may have eaten same raw fish.

EXPECTED COURSE AND PROGNOSIS
• Animals succumb within 5–10 days of infection unless treated.
• With early diagnosis and treatment—prognosis excellent. Animals without severe gastrointestinal signs show rapid clinical response to oral doxycycline (within 24–48 hours); dogs with severe gastrointestinal signs may require hospitalization and aggressive treatment for >1 week.
• Untreated—often fatal.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Infection with *N. salmincola* does not itself cause severe clinical disease.

ZOONOTIC POTENTIAL
N. salmincola can cause gastrointestinal disturbances and eosinophilia in humans; *N. helminthoeca* does not cause human disease.

SALMONELLOSIS

BASICS

DEFINITION
Infection caused by many different serotypes of *Salmonella*, causing enteritis, septicemia, and abortions.

PATHOPHYSIOLOGY
- *Salmonella*—Gram-negative bacterium; colonizes small intestine (ileum); adheres to and invades enterocytes; enters and multiplies in lamina propria and local mesenteric lymph nodes; cytotoxin and enterotoxin are produced; inflammation and prostaglandin synthesis ensue; results in secretory diarrhea, mucosal sloughing.
- Uncomplicated gastroenteritis—organisms are stopped at the mesenteric lymph node stage; patient has only diarrhea, vomiting, dehydration.
- Bacteremia and septicemia following gastroenteritis—more serious; focal extra-intestinal infections (abortion, joint disease) or endotoxemia may result; may cause thrombosis, disseminated intravascular coagulation (DIC), death.
- Some patients recover from septicemia but have prolonged recovery.

SYSTEMS AFFECTED
- Gastrointestinal—enterocolitis; inflammation, mucosal sloughing, secretory diarrhea.
- Systemic disease (e.g., bacteremia, focal infections, septicemia)—multiorgan infarction, thrombosis, abscesses, meningitis, osteomyelitis, abortion.

GENETICS
N/A

INCIDENCE/PREVALENCE
- True incidence unknown; prevalence in healthy dogs/cats similar to diarrheic animals.
- Most infections subclinical.
- Dogs—clinical disease most often seen in the young and pregnant bitches. Common in racing greyhounds and sled dogs due to raw meat diets; presence of *Salmonella* in feces does not necessarily imply infection.
- Cats—natural resistance; stressed, hospitalized, and shelter cats at risk. Pandemics of salmonellosis in migrating songbirds (usually *Salmonella* Typhimurium) in spring lead to epidemics in bird-hunting cats.
- Raw meat diet (especially chicken) risks—*Campylobacter* spp. in addition to *Salmonella* spp. and *Listeria spp*. Outbreaks linked to pet foods/treats common.

GEOGRAPHIC DISTRIBUTION
Worldwide

SIGNALMENT
Species
Dog and cat.

Mean Age and Range
- Dogs—neonatal/immature puppies, pregnant bitches. Most adult carrier dogs clinically normal.
- Cats—adults highly resistant unless treated with an antimicrobial prior to exposure.

SIGNS
General Comments
Disease severity—subclinical (carrier state, more common) to severe clinical cases in neonatal and stressed adult animals.

Historical Findings
- Diarrhea, can be hemorrhagic.
- Vomiting.
- Fever.
- Malaise.
- Anorexia.
- Vaginal discharge/abortion—dogs.
- Chronic febrile illness—persistent fever, anorexia, malaise without diarrhea.

Physical Examination Findings
- Asymptomatic carrier states—no clinical signs.
- Gastroenteritis—fever (102–104°F/39–40°C), diarrhea with mucus and/or blood, dehydration, abdominal pain, tenesmus, pale mucous membranes, weight loss.
- Gastroenteritis with bacteremia, septic shock, or endotoxemia—brick-red mucous membranes, tachycardia, bounding pulses, rapid capillary refill time (unless decompensatory shock), tachypnea, abdominal pain, weakness.
- Focal extraintestinal infections—conjunctivitis, cellulitis, pyothorax, diskospondylitis.
- Cats—chronic febrile illness, vague, nonspecific clinical signs.
- Recovering patients—chronic intermittent diarrhea for 3–4 weeks (may shed *Salmonella* in stool ≥6 weeks).

CAUSES
- Any one of more than 2,000 serotypes of salmonellae.
- Two or more simultaneous serotypes in host animal can occur:
  - Most common serotypes—Newport, Typhimurium, Albany, 4,5,12:i:, Dublin, Heidelberg.

RISK FACTORS
Disease Agent
- *Salmonella* serotype determines virulence, infectious dose, and route of exposure.
- Host factors that increase susceptibility:
  - Age—neonatal/young dogs and cats; immature immune system.
  - Health—debilitated young animals (immature gastrointestinal tract, poorly developed normal microbial flora) or adults with concurrent disease.
  - Disrupted gastrointestinal flora (adult cats)—antimicrobial treatment; exposure to salmonellae during hospitalization.

Environmental Factors
- Diet:
  - Raw food diet is major risk factor.
  - Contaminated dog treats (e.g., pig ears).
  - Dehydrated (dry) pet food; semi-moist foods usually not as risky.
- Coprophagia.
- Grooming habits—can contaminate environment, feed and water dishes.
- Dense population—colonies, boarding facilities, shelters:
  - Build up of *Salmonella* in environment, more efficient fecal–oral cycling.
  - Stress.
  - Exposure to infected (or carrier) animals.
- Unsanitary environment.

Hospitalized Animals
Nosocomial exposure (plus stress) or activation (by stress) of preexisting asymptomatic (carrier) *Salmonella* infection, especially in animals treated with antimicrobial drugs.

Vaccinated Cats
Death reported in kittens (likely to be subclinically infected by *Salmonella*) post vaccination, with high titers of modified live panleukopenia vaccine.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Acute gastroenteritis—infectious, foreign body, neoplasia:
  - Viral gastroenteritis—canine enteric coronavirus, canine parvovirus, rotavirus, canine distemper.
  - Bacterial gastroenteritis—*Escherichia coli*, *Campylobacter jejuni*, *Yersinia enterocolitica*.
- Bacterial overgrowth syndrome—Clostridium difficile, C. perfringens.
- Parasites—helminths, protozoa (Giardia, Coccidia, Cryptosporidia), salmon poisoning.
- Acute gastritis—erosions or ulcers.
- Diet-related—allergy or food intolerance.
- Drug- or toxin-induced distress.
- Extraintestinal disorders (metabolic disease).

CBC/BIOCHEMISTRY/URINALYSIS
- CBC—variable; depends on stage of illness: initially neutropenia, left-shifted neutrophils, lymphopenia, thrombocytopenia, non-regenerative anemia.
- Hypoalbuminemia, electrolyte abnormalities related to gastrointestinal losses.

DIAGNOSTIC PROCEDURES
- Fecal/rectal bacterial culture—special media needed:
  - Subclinical carriers may have intermittent positive fecal culture (≥6 weeks).
  - Use of antimicrobials before sampling may yield false-negative culture.
  - Serotyping of cultured organisms—helpful to define outbreak.

SALMONELLOSIS (CONTINUED)

• Cultures of blood and joint fluid, ileum, mesenteric lymph node, liver/spleen, bone marrow.
• Fecal cytology—leukocytes present.
• Fecal *Salmonella* PCR.
• Abdominal ultrasound (clinical gastroenteritis)—lymphadenomegaly, enterocolitis, typhlitis, peritonitis.

PATHOLOGIC FINDINGS
Lymphoplasmacytic, neutrophilic typhlitis/enteritis with ulceration, crypt abscessation, lymphoid hyperplasia, pyogranulomas; lymphadenitis.

TREATMENT

APPROPRIATE HEALTH CARE
• Outpatient—uncomplicated gastroenteritis.
• Inpatient—with bacteremia/septicemia, gastroenteritis in neonatal/immature animals (rapidly debilitated).

NURSING CARE
• Varies according to severity of illness—assess dehydration, body weight, ongoing fluid loss, shock, hematocrit, albumin, electrolytes, acid–base status.
• Supportive care—fluid and electrolyte replacement:
  ◦ Parenteral, balanced, polyionic isotonic replacement solution (lactated Ringer's).
  ◦ Oral fluids—hypertonic glucose solutions; for secretory diarrhea.
• Plasma transfusions—if serum albumin <2 g/dL.

ACTIVITY
• Isolate patients.
• Cage rest, provide warmth during illness.

DIET
Restrict food 24 hours in adults; gradually introduce highly digestible, low-fat diet.

CLIENT EDUCATION
Instruct client to wash hands frequently and to restrict access to patient in acute stages of disease; large numbers of salmonellae may be shed in stool.

MEDICATIONS

DRUG(S) OF CHOICE

Asymptomatic Carrier State
• Antimicrobials—contraindicated:
  ◦ Quinolones—clear carrier states in humans; controlled trials in animals needed before this can be recommended.

Uncomplicated Gastroenteritis
• Antimicrobials not indicated.
• Locally acting intestinal adsorbents and supportive therapy.

Neonates, Aged, and Debilitated Animals
• Antimicrobial therapy—indicated; culture and susceptibility testing with minimal inhibitory concentration recommended:
  ◦ Trimethoprim-sulfa: 15 mg/kg PO, SC q12h.
  ◦ Enrofloxacin: 5 mg/kg q24h (cat); 10 mg/kg PO, IM, q24h (dog).
  ◦ Chloramphenicol: dogs, 50 mg/kg PO, IV, IM, SC q8h; cats, 50 mg/kg total PO, IV, IM, SC q12h.
• Recent strains of *Salmonella* are multidrug-resistant; adjust empirical therapy based on antimicrobial susceptibility testing.

PRECAUTIONS
• Chloramphenicol, trimethoprim-sulfa—use cautiously in neonatal and pregnant patients.
• Fluoroquinolones—avoid use in pregnant, neonatal, or growing animals because of concern for adverse effects on cartilage; do not administer to cats at dosages higher than 5 mg/kg q24h.

FOLLOW-UP

PATIENT MONITORING
• Fecal culture—repeat monthly for few months to assess development of carrier state.
• Other animals—monitor for secondary spread of infection.
• Advise client to contact veterinarian if patient shows signs of recurring disease.

PREVENTION/AVOIDANCE
• Keep animals healthy—proper nutrition; avoid raw meat diets; vaccinate for other infectious diseases; clean, disinfect cages, runs, and food/water dishes frequently; store food, feeding utensils properly.
• Reduce overcrowding.
• New arrivals—isolate and screen; monitor for sickness before mixing with other animals.
• Protect animals being treated with antimicrobial drugs from exposure to *Salmonella*-contaminated environment (e.g., animal hospital).
• Experimental live attenuated vaccine shows promise, especially for racing dogs.

POSSIBLE COMPLICATIONS
• Spread of infection to other animals or humans within household.
• Development of chronic infection with diarrhea.
• Recurrence of disease with stress.

EXPECTED COURSE AND PROGNOSIS
• Uncomplicated gastroenteritis—prognosis excellent; frequently self-limited; patients recover with good nursing care.
• Recovered animals may shed *Salmonella* intermittently for months or longer.
• Neonatal, aged, pregnant, stressed animals—can develop sepsis or abortion; can be severe, debilitating; may lead to death if untreated.

MISCELLANEOUS

AGE-RELATED FACTORS
Clinical disease is frequently seen in neonatal, or aged animals.

ZOONOTIC POTENTIAL
• High potential, especially in children, elderly, immunosuppressed, and antimicrobial drug users.
• Multidrug-resistant salmonellae have been reported.

PREGNANCY/FERTILITY/BREEDING
• May complicate disease.
• Abortion—may be a sequela to infection.
• Antimicrobial therapy—consider the effect on the fetus.

ABBREVIATIONS
• DIC = disseminated intravascular coagulation.

INTERNET RESOURCES
• http://www.cfsph.iastate.edu/DiseaseInfo/disease.php?name=salmonella-nontyphoidal&lang=en

S

SALT TOXICOSIS

BASICS

DEFINITION
• Salt ingestion results in direct irritation to the gastrointestinal mucosa, causing vomiting, diarrhea, and anorexia. Polydipsia is a common early sign that hypernatremia is developing.
• Hypernatremia (typically Na^+ >170 mEq/L, dogs; >175 mEq/L, cats) may cause neurologic signs including lethargy, behavioral changes, ataxia, muscle tremors, and seizures. Coma and death may occur.
• LD_{50} (dogs) = 4 g NaCl/kg, <1 teaspoonful of table salt/kg body weight.

PATHOPHYSIOLOGY
• Hypernatremia causes water movement from intracellular space to extracellular space (interstitium and blood vessel), resulting in cellular shrinkage/dehydration.
• In the brain, this may cause the parenchyma to pull away from the skull, causing intracerebral and subarachnoid hemorrhage.
• In the lungs, fluid movement into the interstitial tissue may cause pulmonary edema.
• Idiogenic osmoles begin to develop intracellularly within hours to prevent cellular dehydration but take 1–7 days for full compensation.

SYSTEMS AFFECTED
• Gastrointestinal—vomiting, diarrhea, anorexia, polydipsia.
• Neuromuscular—twitching, muscle tremors, ataxia, seizures, coma.
• Pulmonary—edema, respiratory distress.
• Cardiovascular—hypervolemia, tachycardia.

INCIDENCE/PREVALENCE
With ingestion, gastrointestinal signs and mild hypernatremia are common but neurologic signs occur in severe cases.

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
Species
Dogs and cats equally affected. There are no breed, age or sex predilections.

Mean Age and Range
N/A

Predominant Sex
N/A

SIGNS
• Severity of signs is dependent on sodium level.
• Mild—lethargy, vomiting, diarrhea, polydipsia ± polyuria.
• Severe—behavioral changes, twitching, muscle tremors, ataxia, seizures, coma, death.

Historical Findings
• Ingestion of homemade playdough or clay.
• Administration of salt as an emetic.
• Exposure to other forms of salt (i.e., rock salt, baking soda).
• Swimming in the ocean/ingestion of saltwater.

Physical Examination Findings
• Abnormal hydration:
  ◦ Dehydration with vomiting and diarrhea.
  ◦ Overhydration and hypervolemia with saltwater ingestion or secondary to treatment.
• Tachycardia.
• Ataxia, muscle weakness, muscle tremors.
• Hyperreflexia.

CAUSES
• Salt intake:
  ◦ Salt ingestion—table salt, baking soda, salt for water softeners, deicing salt, ocean/saltwater.
  ◦ Other products made with table salt—homemade or commercial playdough, ornament dough.
  ◦ Iatrogenic with IV hypertonic saline or IV sodium bicarbonate; sodium phosphate enemas.
• Decreased water intake (typically chronic).
  ◦ Adipsia.
  ◦ No access to water.
• Free water loss:
  ◦ Mannitol bolus or CRI causes free water loss via kidneys.
  ◦ Activated charcoal with sorbitol (more common with multidose activated charcoal or high doses) causes free water loss via gastrointestinal tract.

RISK FACTORS
• Swimming in oceans and intake of saltwater.
• Outdoor pets with frozen or spilled water.
• Patients predisposed to dehydration—kidney disease, unregulated diabetes mellitus, central diabetes insipidus, chronic vomiting and diarrhea, hyperthermia/fever.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Hypernatremic hyperosmolar nonketotic diabetes, chronic kidney disease, diabetes mellitus.
• Primary neurologic disease.
• Toxins that cause neurologic signs: (ethylene glycol, bromethalin, metaldehyde, baclofen, pyrethrins/pyrethroids, organophosphates/carbamates).
• Paintball ingestion

CBC/BIOCHEMISTRY/URINALYSIS
Biochemistry—hypernatremia, hyperchloremia, azotemia with dehydration, possible elevation of liver enzymes.

OTHER LABORATORY TESTS
CSF sodium concentration can be measured. Normal is 135–150 mEq/L; >180 mEq/L is consistent with salt toxicosis.

IMAGING
• Thoracic radiography if respiratory signs to evaluate for hypervolemia and signs of fluid overload and pulmonary edema.
• MRI or CT—evaluate for subarachnoid or cerebral hemorrhage.

DIAGNOSTIC PROCEDURES
CSF tap for sodium concentration (rarely performed) and rule out other causes for neurologic signs.

PATHOLOGIC FINDINGS
• Hemorrhage of stomach, small intestine, and colon.
• Cerebral edema, perivascular hemorrhage and fibrinous exudate.
• Pulmonary edema.
• Acute renal and hepatic necrosis.

TREATMENT

APPROPRIATE HEALTH CARE
Hospitalization recommended for electrolyte monitoring.

NURSING CARE
Asymptomatic
• Decontamination with emesis if appropriate time frame.
• Monitor Na level in the hospital for 6 hours post exposure.
• If asymptomatic and Na remains normal, discharge patient to be monitored at home.

Symptomatic
• Stabilize neurologic signs as needed.
• Decontamination with emesis if indicated.
• IV fluids for rehydration. May need to match fluid Na content to patient serum Na depending on chronicity and degree of hypernatremia.
• Calculate free water replacement for hypernatremia:
  ◦ IV use D_5W or 0.45% NaCl + 2.5% dextrose; use with caution in patients with hyperglycemia.
  ◦ Water oral or via nasoesophageal tube—use for stable patients that are not vomiting or those with underlying cardiac disease/failure or evidence of fluid overload. Can be used with IV therapy.
  ◦ Acute toxicity (<24 hours)—lower Na acutely (over 1–2 hours) until neurologic signs resolve, then replace remaining free water over 6–24 hours.
  ◦ Chronic toxicity (>24 hours) or unknown time frame—lower Na slowly, not to exceed 12 mEq/day (0.5 mEq/h).

SALT TOXICOSIS (CONTINUED)

• Free water deficit calculation:
[(patient Na ÷ normal Na) − 1] × (0.6 × body weight$_{kg}$) × 1000 = Free water deficit in milliliters

DIET
Oral water can be offered to lower Na. Water intake should be regulated so that Na level does not drop too rapidly.

CLIENT EDUCATION
Outdoor pets may be susceptible to decreased intake with frozen or empty water containers or if they become trapped in a garage or shed. Heated water bowls and multiple water sources should be available.

SURGICAL CONSIDERATIONS
Gastrotomy may be needed to remove homemade playdough or ornament dough if unable to remove with emesis or gastric lavage.

MEDICATIONS

DRUG(S) OF CHOICE
• Antiemetic for vomiting—maropitant 1 mg/kg SC or IV q24h.
• Proton pump inhibitor if signs of stomach mucosal irritation:
  ◦ Pantoprazole 1 mg/kg IV slowly q24h.
  ◦ Omeprazole 1 mg/kg PO q24h.
• Methocarbamol 55–220 mg/kg IV slowly, to effect for muscle tremors; do not exceed 330 mg/kg/day.
• Anticonvulsant such as diazepam 0.5–2 mg/kg IV for seizures.
• Furosemide 1–4 mg/kg IV q2–8h or a CRI 0.1–0.5 mg/kg/h IV titrated to effect for hypervolemia or pulmonary edema until signs resolve.

CONTRAINDICATIONS
Activated charcoal—will worsen hypernatremia.

PRECAUTIONS
• Mannitol, hypertonic saline, and sodium bicarbonate should be used with caution as they may worsen hypernatremia.
• Diuretics such as furosemide may be helpful for Na excretion via the kidney but hydration status needs to be monitored carefully.
• Hyponatremia or rapid correction of chronic hypernatremia (due to idiogenic osmole formation) during treatment can cause cerebral edema formation and worsening or reoccurrence of neurologic signs.

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
• Sodium level should be monitored during treatment; frequency depends on severity of signs and chronicity of hypernatremia but generally every 2–4 hours.
• Hydration status monitored every 4–6 hours.

PREVENTION/AVOIDANCE
Salt should not be recommended or given as an emetic.

POSSIBLE COMPLICATIONS
Persistent neurologic impairment with severe toxicity.

EXPECTED COURSE AND PROGNOSIS
• Neurologic signs should improve with improvement of Na level.
• Prognosis is generally good. Guarded to poor prognosis with severe neurologic signs and poor response to treatment.

SARCOPTIC MANGE

BASICS

OVERVIEW
A nonseasonal, intensely pruritic, highly contagious parasitic skin disease of dogs and other mammalian species caused by *Sarcoptes scabiei* var. *canis* mites.

PATHOPHYSIOLOGY
Burrowing mites induce hypersensitivity, causing intense pruritus.

SYSTEMS AFFECTED
Skin/exocrine

SIGNALMENT
- All in-contact dogs usually affected.
- Transient pruritus of in-contact other species: cats, humans.

SIGNS
- Nonseasonal, progressively worsening intense pruritus.
- Pruritus develops within 4–6 weeks of exposure.
- Seroconversion 3 weeks after clinical signs develop.
- Rare individuals do not seroconvert and therefore may not develop severe pruritus.
- Elbows, pinnal margins, ventrum, and hocks affected first.
- Crusted papules leading to generalized alopecia, crusting, and excoriations; lichenification and thickening with chronicity.
- Poor response to antihistamines and anti-inflammatory doses of steroids.
- Mite numbers often low.
- Immunocompromised individuals may harbor larger numbers of mites.

CAUSES & RISK FACTORS
- Close contact with other dogs in animal shelters, boarding kennels, groomers, dog parks, and veterinary offices.
- Exposure to fox or coyote.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Hypersensitivity dermatitis.
- Bacterial folliculitis.
- Parasitic dermatitis (demodicosis, *Pelodera*, *Otodectes*, *Cheyletiella*, *Trombicula*, *Dirofilaria*).
- Dermatophytosis.
- *Malassezia* dermatitis.
- Zinc-responsive dermatosis.
- Ear margin seborrhea.
- Pemphigus foliaceus.

OTHER LABORATORY TESTS
ELISA—available in some countries to identify *Sarcoptes*-infested dogs: False positives due to crossreactivity with other mites.

DIAGNOSTIC PROCEDURES
- Pinnal–pedal reflex—rubbing the ear margin between the thumb and forefinger induces the dog to scratch with its hind leg.
- Superficial skin scrapings—positive in 20–50% of scabies cases; false-negative results are common.
- Fecal flotation—may reveal mites or ova.
- Response to scabicidal treatment—most common method for diagnosing scabies.

TREATMENT
- All in-contact dogs must be treated.
- Resolution of pruritis may take several weeks due to hypersensitivity reaction to the mite.
- *Sarcoptes* mites usually die quickly in the environment; however, mites have been reported to survive for up to 3 weeks. Thorough cleaning of the dog's environment is recommended in crowded conditions.

MEDICATIONS

DRUG(S) OF CHOICE
- Selamectin—labeled application every 30 days, or application every 2 weeks for at least three treatments.
- Isoxazoline parasiticides (afoxalaner, lotilaner, fluralaner or sarolaner)-at labeled dosage/frequency.
- Ivermectin 0.2–0.4 mg/kg SC or PO every 1–2 weeks.
- Milbemycin 2 mg/kg PO every 1–2 weeks.
- Doramectin 0.2–0.6 mg/kg SC or PO weekly.
- Moxidectin 0.2–0.3 mg/kg SC or PO weekly; with imidacloprid topical at labeled frequency.
- Lime sulfur 2–4% applied weekly for 4–6 weeks.
- Fipronil spray applied to entire skin surface every 2 weeks for three treatments.
- Topical antiseborrheic therapy in conjunction with scabicidal therapy.
- Systemic antibiotics—may be needed to resolve secondary pyoderma.
- Prednisolone 1 mg/kg for 5–7 days or longer if necessary to relieve pruritus and self-mutilation.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
- Ivermectin—do not use/use with caution in *ABCB1* mutant dogs; increased risk of avermectin toxicity in herding breeds: Shetland sheepdogs, Old English sheepdogs, Australian shepherd dogs, and their crosses.
- Potential increased risk of neurotoxicosis with concurrent use of spinosad, macrocyclic lactone, or systemic azole medications.
- Isoxazoline parasiticides—potential for neurologic adverse events in dogs and cats reported.

FOLLOW-UP
- Response to therapy may require 4–6 weeks.
- Topical scabicidal treatments are more prone to failure because of incomplete application of the treatment solution.
- Immunity or tolerance does not develop: reinfection may occur with subsequent contact with infected animals.
- Approximately 30% of dogs with *Sarcoptes* infections will also react to house dust mite antigens on intradermal tests. House dust mite allergy may be a sequela to scabies infection.

MISCELLANEOUS

ZOONOTIC POTENTIAL
- Sarcoptic mange is zoonotic. People in close contact with an affected dog may develop a pruritic, papular rash on body areas in frequent contact with dogs.
- Lesions resolve spontaneously when the affected animals are treated.

ABBREVIATIONS
- ELISA = enzyme-linked immunosorbent assay.

SCHIFF–SHERRINGTON PHENOMENON

BASICS

OVERVIEW

• Thoracic limb extension associated with pelvic limb paralysis or paresis after acute and usually severe spinal cord lesion caudal to the cervical intumescence, best observed when the patient is in lateral recumbency.
• Posture—caused by damage to the border cells or their ascending processes, which are interneurons located in the lumbar spinal cord (mainly L2–4) and normally inhibit the extensor motor neurons of the cervical intumescence.

SIGNALMENT

Any dog suffering from thoracolumbar spinal cord injury.

SIGNS

• Thoracic limbs—rigidly extended; normal gait and postural reactions (because the lesion is caudal to the cervical intumescence).
• Pelvic limbs—depends on the severity and location of the lesion; usually upper motor neuron in type, but may be lower motor neuron.
• In severe, acute thoracolumbar myelopathies, spinal shock may be present in addition to the Schiff–Sherrington phenomenon: there is an initial flaccid paralysis caudal to the level of the lesion, with loss of myotatic and flexor reflexes. In dogs and cats, spinal shock is uncommon and usually resolves within an hour, with more typical signs of upper motor neuron disease subsequently developing caudal to the spinal cord lesion.

CAUSES & RISK FACTORS

• Trauma secondary to vehicular accident and intervertebral disc disease—most common.
• Vascular myelopathies (e.g., fibrocartilaginous embolism, coagulopathies, etc.).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Decerebrate rigidity—observed with brainstem disease in which all four limbs are rigid and have upper motor neuron dysfunction; opisthotonus present; patient is unconscious.
• Decerebellate rigidity—observed with cerebellar disease in which the forelimbs are rigid but the hind limbs are flexed; consciousness is usually altered.
• Cervical spinal cord injury—may have extensor hypertonia in the thoracic limbs; upper motor neuron and proprioceptive deficits of all four limbs are also seen.
• The key feature in differential diagnosis is that in the Schiff–Sherrington phenomenon, function and postural reactions in the forelimbs are normal despite their extensor rigidity, while they are abnormal in the pelvic limbs.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

IMAGING

Radiology (radiography, myelography, CT, MRI)—demonstrate the thoracolumbar spinal lesion.

TREATMENT

• Directed toward the underlying thoracolumbar spinal cord lesion.
• No specific treatment available.
• Condition resolves if adequate spinal cord function is restored.
• Schiff–Sherrington phenomenon is not a prognostic indicator; prognosis is determined by the severity of signs caudal to the spinal cord lesion.

MEDICATIONS

DRUG(S) OF CHOICE

As indicated for underlying spinal cord disease.

FOLLOW-UP

• Posture may persist for days to weeks; not an indication of a hopeless prognosis.
• With rapid and aggressive treatment, the patient may recover, especially if there is pain perception caudal to the lesion.

S

SCHWANNOMA

BASICS

OVERVIEW
Schwannomas are tumors of nerve sheath origin, arising from Schwann cells. The term peripheral nerve sheath tumor encompasses schwannomas, neurofibromas, and neurofibrosarcomas, as these tumors arise from the same cell. Importantly, schwannomas are grouped with several other soft tissue sarcomas (e.g., hemangiopericytoma and fibrosarcoma) for therapeutic and prognostic purposes, as the biologic behaviors of this group of tumors are similar.

SIGNALMENT
- Dogs—median of 10 years, no sex predisposition, no known breed predilection.
- Cats rarely affected.

SIGNS
Vary depending on tumor location, which can be peripheral (e.g., skin or tongue) or more central (e.g., axillary region).

CAUSES & RISK FACTORS
None identified.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other neoplasia that can involve the connective tissues.
- Orthopedic disease.
- Other neurologic disease (e.g., intervertebral disc disease).

CBC/BIOCHEMISTRY/URINALYSIS
Results usually normal.

OTHER LABORATORY TESTS
None

IMAGING
- Myelography may be helpful in cases with dorsal or ventral nerve root involvement.
- Contrast CT or, ideally, MRI provides the most information regarding extent and location of disease.

DIAGNOSTIC PROCEDURES
Electromyography consistently reveals abnormal, spontaneous electrical activity in muscles of the affected limb.

TREATMENT

- Surgical excision is the treatment of choice.
- Radiotherapy following incomplete surgical resection is likely to result in excellent long-term outcome.
- Excision of a distal mass may still result in a functional limb; amputation is required in most cases.
- Radiotherapy as a single treatment modality shows promise for small lesions.
- Laminectomy is necessary in cases of nerve root involvement; local recurrence is common if the primary extends into the spinal canal.

MEDICATIONS

DRUG(S) OF CHOICE
- Chemotherapy—no successful chemotherapeutic management has been described.
- Corticosteroid therapy—may help to reduce peritumoral edema and temporarily relieve clinical signs.
- Gabapentin for neuropathic pain alleviation.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- Recurrence common following incomplete surgical excision (up to 72% of cases).
- The more distal the tumor, the better the possibility of a surgical cure.
- For tumors involving the brachial or lumbosacral plexus, median disease-free interval is 7.5 months.
- For tumors involving dorsal or ventral nerve roots, median disease-free interval is 1 month.
- High-histologic-grade tumors (e.g., grade 3) may metastasize to regional lymph nodes or lung.

Consulting Editor Timothy M. Fan

SEBACEOUS ADENITIS, GRANULOMATOUS

BASICS

OVERVIEW
- A destructive inflammatory disease process directed against cutaneous adnexal structures (sebaceous glands).
- May be genetically inherited, immune-mediated, or metabolic.
- Initial defect—a keratinization disorder or an abnormality in lipid metabolism (accumulation of toxic intermediate metabolites).

SYSTEMS AFFECTED
Skin/exocrine

SIGNALMENT
- Young adult to middle-aged dogs; very rare in cats.
- Two forms—long- and short-coated breeds (short-coated form now called "idiopathic pyogranulomatous periadnexal dermatitis").
- Predisposed—standard poodle, Akita, Samoyed, German shepherd dog, Havanese, Bernese Mountain dog and vizsla.

SIGNS

Long-Coated Breeds
- Symmetrical, partial alopecia.
- Dull, brittle hair.
- Tightly adherent silver-white scale.
- Follicular casts around hair shaft ("keratin-collaring").
- Small tufts of matted hair.
- Lesions—often first observed along dorsal midline and dorsum of the head.
- Severe—secondary bacterial folliculitis, pruritus, and malodor.
- Akitas—often relatively severely affected; morbidity associated with deep secondary bacterial infections.
- Standard poodles—affected dogs frequently described as having excellent hair coats prior to developing lesions; secondary bacterial folliculitis rare; most patients do not exhibit systemic illness.

Short-Coated Breeds
- Alopecia—moth-eaten, circular, or diffuse.
- Mild scaling.
- Lesions often plaque-like.
- Affects the trunk, head, and pinnae.
- Secondary bacterial folliculitis rare.
- Lesions can produce significant scarring.

CAUSES & RISK FACTORS
- Mode of inheritance is being studied; an autosomal recessive mode of inheritance is documented in the standard poodle and suspected in the Akita.
- Multiple pathophysiologic causes theorized including autoimmunity against sebaceous glands and/or leakage of sebaceous gland contents into surrounding dermis causing an inflammatory reaction and eventual destruction of glands.
- Destruction of sebaceous glands may be secondary—"innocent bystander" from other inflammatory conditions.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Primary seborrhea—keratinization disorder.
- Bacterial folliculitis.
- Demodicosis.
- Dermatophytosis.
- Pemphigus foliaceus.
- Endocrine skin disease.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

DIAGNOSTIC PROCEDURES
- Skin scrapings—normal.
- Dermatophyte culture—negative.
- Endocrine function tests—normal.
- Skin biopsy.

PATHOLOGIC FINDINGS
- Nodular granulomatous to pyogranulomatous inflammatory reaction at the level of the sebaceous glands.
- Orthokeratotic hyperkeratosis and follicular cast formation; more prominent in long-coated breeds.
- Advanced—complete loss of sebaceous glands; periadnexal fibrosis.
- Destruction of entire hair follicle and adnexal unit rare.

TREATMENT
- Clinical signs may wax and wane irrespective of treatment.
- Controlled studies have not been done to document efficacy of any therapy.
- Results extremely variable; response may depend on severity of disease at the time of diagnosis.
- Akita—breed most refractory to treatment.

MEDICATIONS

DRUG(S) OF CHOICE
- Propylene glycol and water—50–75% mixture; spray every 24 hours to affected areas.
- Baby oil—soak affected areas for 1 hour; follow with multiple shampoos to remove oil and scales; used monthly or as needed to reduce severe accumulations of crusts.
- Frequent bathing with keratolytic shampoos (twice weekly).
- EFA supplementation and evening primrose oil (500 mg PO q12h); possible side effects include vomiting, diarrhea, and flatulence.
- Cyclosporine 5 mg/kg PO q12–24h; side effects include vomiting, diarrhea, gingival hyperplasia, hirsutism, papillomatous skin lesions, increased incidence of infections, nephrotoxicity, and hepatotoxicity.
- Doxycycline 5 mg/kg PO q12h and niacinamide 250 mg PO q8h, <10 kg; 500 mg PO q8h >10 kg with vitamin E.
- Isotretinoin (Accutane) 1 mg/kg PO q12h; reduce to 1 mg/kg q24h after 1 month and to 1 mg/kg q48h after 2 months; continue as needed for maintenance; rarely used.
- Bactericidal antibiotics for secondary bacterial folliculitis.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Isotretinoin (Accutane)—known teratogen; do not use in pregnant dogs; advise owners of risk.

FOLLOW-UP
Affected dogs should be registered so that mode of inheritance can be determined.

SEIZURES (CONVULSIONS, STATUS EPILEPTICUS)—CATS

BASICS

DEFINITION

• Epilepsy—recurrence of seizures from primary brain origin. • Genetic epilepsy—syndrome that is only epilepsy, with no demonstrable underlying brain lesion or other neurologic signs; the genetic origin must be proven through family studies, gene isolation, or other specific forms of evidence (International League Against Epilepsy); rare in cats. • Structural epilepsy—syndrome in which the epileptic seizures are the result of identifiable structural brain lesions; frequent in cats. • Epilepsy of unknown cause—structural epilepsy suspected but a lesion cannot be demonstrated; frequent in cats. • Cluster seizures—>1 seizure/24 hours. • Status epilepticus (SE)—continuous seizure activity, or seizures repeated at brief intervals without complete recovery between seizures. Can be nonconvulsive. • Convulsive SE—life-threatening medical emergency.

PATHOPHYSIOLOGY

• Paroxysmal disorganization of one or several brain functions originating from the thalamocortex. Any thalamocortical disturbance or disease process may lead to seizure activity. • Not all cortical regions have the same propensity to seize; from the most to the least likely to cause seizures—temporal, frontal, parietal, and occipital lobes. • As more seizures occur, the tendency for neuronal damage and propensity for more seizures or SE increases; this kindling effect does not occur in all cortical regions. • The clinical appearance of the seizure is directly related to the location of the neuronal hyperactivity. If the electrical abnormality remains regional, the seizure is focal. If there is recruitment of both hemispheres, the seizure is generalized. • Great majority of seizures and SE in cats are secondary to structural brain lesions.

SYSTEMS AFFECTED

Nervous

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Cats of any breed, age, or sex.

SIGNS

General Comments

• Nonconvulsive generalized seizures—frequent in cats; movements of facial musculature predominate, such as bilateral twitches of eyelids, whiskers and ears, salivation, lip smacking; may be associated with whole body trembling/shaking, piloerection, dilated pupils. Nonconvulsive SE frequent in cats. • Focal seizure—when limited to one hemisphere; frantic running and colliding with objects (aura), unilateral facial twitches or eyelid blinks, unilateral limb motions or head/neck turning to one side. Focal seizures often generalize. • Generalized convulsive seizures—bilateral symmetrical tonic–clonic contractions of limb muscles and dorsiflexion of the head, often associated with autonomic signs such as salivation, urination, defecation. At time of admission, the gross motor activity may have stopped, but there may still be twitching of the lids and body/limb jerks. • Mutilation frequent—biting of tongue, nail avulsion.

Historical Findings

• Confirm that seizure activity has indeed occurred. • Pattern of seizures (age at seizure onset, type and frequency of seizures)—most important factor in listing the possible causes. • Metabolic diseases may cause generalized seizures (GS). • With most seizurogenic toxins, there is a crescendo of hyperexcitability, shaking, trembling, with ultimately GS and death. • Asymmetry in the signs (eyelid twitches, limb movements primarily on one side, circling) before, during, or after the seizure suggests focal cortical lesion. • Overdose of insulin, postrenal transplant, or bilateral thyroidectomy lead to GS shortly after the fact. • Presence of abnormal behavior in the days/weeks preceding the seizure activity indicates structural brain disease. • Presence of concomitant gastrointestinal (GI), respiratory, or other systemic signs indicates multisystem disease.

Physical Examination Findings

• If chorioretinitis present, look for infectious diseases. • Dark red mucous membranes suggest polycythemia vera.

Neurologic Examination Findings

• Mental status, menace responses, responses to nasal septum stimulation, and proprioceptive positioning are neurologic tests that evaluate the cerebral cortex. Asymmetry indicates structural brain lesion on the contralateral side of the deficits. • In most cases of structural epilepsy, neurologic deficits are present at presentation.

CAUSES

Extracranial

Metabolic—hypoglycemia from insulin overdose, hypocalcemia from bilateral thyroidectomy, severe hyperthyroidism, hypertension secondary to renal transplant, hepatic encephalopathy, uremia, polycythemia vera, severe hypertriglyceridemia.

Toxins; Intracranial

• Anatomic—congenital malformation. • Metabolic—cell storage disease (e.g., neuronal ceroid–lipofuscinosis reported in one cat with myoclonus and seizure activity). • Neoplastic—meningioma, astrocytoma, lymphoma. • Inflammatory infectious—viral non-feline infectious peritonitis (FIP), FIP, toxoplasmosis, cryptococcosis. • Toxicity—organochlorines, pyrethrins, and pyrethroids; seizures usually observed at end stage; chlorambucil in lymphoma treatment. • Vascular—polycythemia vera secondary to hyperviscosity, feline ischemic encephalopathy secondary to *Cuterebra* larva. • Trauma has not been linked to seizures in cats.

RISK FACTORS

• Any forebrain lesion. • Diabetes mellitus. • Treatment with chlorambucil. • Renal failure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Sleep disorders—the cat does not wake up, or has a normal waking behavior following the episode. • Syncope—the body is limp with a rapid recovery phase, with no abnormal behavior. • When seizures are preceded by 2–3 weeks of vague transient systemic illness (decreased appetite, GI signs) in an otherwise healthy cat—viral non-FIP encephalitis or epilepsy of unknown cause. • When seizures are preceded by systemic signs that persist (>3 weeks)—FIP, cryptococcosis. • Insidious abnormal behavior with/without circling in a cat >10 years old presented for seizure activity suggests meningioma. • Cats with hepatic encephalopathy drool excessively. • Cats with polycythemia vera have GI signs and dark mucous membranes.

CBC/BIOCHEMISTRY/URINALYSIS

• Extracranial metabolic causes are diagnosed on history, physical examination, and blood test results. • High packed cell volume (>60%) in polycythemia vera. • Low blood glucose in insulin overdose. • Low calcium in bilateral post thyroidectomy. • High BUN and creatinine with low specific gravity in acute renal failure. • Creatine kinase—mild to markedly elevated in cats with SE, even nonconvulsive; with or without myoglobulinuria; indicates muscle necrosis.

OTHER LABORATORY TESTS

• Serologic testing—feline immunodeficiency virus, feline leukemia virus titers often noncontributory to diagnosis; FIP and *Toxoplasma gondii* titers nonreliable by themselves. • Bile acid testing—in cats with suspected hepatic encephalopathy.

IMAGING

• Thoracic radiographs and abdominal ultrasound—if infectious disease suspected; to evaluate lung pathology if SE; to look for neoplasia if tumor suspected. • MRI—best to define location, extent, and nature of lesion.

SEIZURES (CONVULSIONS, STATUS EPILEPTICUS)—CATS (CONTINUED)

DIAGNOSTIC PROCEDURES
CSF—sensitive to detect structural disease; unspecific in itself to reach diagnosis except when organism is seen (e.g., cryptococcosis).

PATHOLOGIC FINDINGS
• Findings reflect etiology. • It is unknown if hippocampal necrosis is a cause or the consequence of seizures. • Small lesions may be easily missed in cats diagnosed with epilepsy of unknown cause.

TREATMENT

APPROPRIATE HEALTH CARE
• Outpatient—isolated recurrent seizures in an otherwise healthy cat. • Inpatient—cluster seizures and SE. Isolated recurrent seizures in an ill cat.

NURSING CARE
• Constant supervision. • Install IV line for drug and fluid administration. • Draw blood for rapid measurement of blood gases, glucose, calcium, and antiepileptic drug levels if pertinent. • Cool if hyperthermia.

CLIENT EDUCATION
Antiepileptic treatment in structural epilepsy may not help until the primary cause is addressed. Seizures can be difficult to stop in cases of SE, especially with nonconvulsive status.

SURGICAL CONSIDERATIONS
Craniotomy—tumor excision with meningioma or other accessible mass.

MEDICATIONS

DRUG(S) OF CHOICE
Seizure type and frequency determine therapeutic approach.

Isolated Recurrent Generalized Seizures
• First line—phenobarbital 7.5–15 mg/cat q12h; optimal therapeutic serum levels 100–130 µmol/L (23–30 µg/L). • Second line—gabapentin 3–8 mg/cat q8–12h. • Levetiracetam—20 mg/kg q8h (serum levels humans 10–40 µg/mL). • Initiate gradually to avoid overt sedation.

Convulsive Cluster and Status Epilepticus
• Treat cluster and generalized SE early—the more seizures in a given time, and the more drugs for seizure control, time for recovery, and cost for treatment. • No ongoing seizure activity at presentation and patient naïve to the drug—phenobarbital IV bolus 10 mg/kg to a maximum of 60 mg/cat over 15 minutes, continued with phenobarbital maintenance dosage PO 12 hours later. • Ongoing seizure activity at presentation—diazepam IV bolus 0.5–1 mg/kg, continuing with CRI at 0.25–0.5 mg/cat/h in an inline burette using a fluid pump; IV bolus of diazepam can be repeated 5 minutes after the first bolus if gross seizure activity persists; in this case, add phenobarbital to CRI at 4 mg/cat/h. • Start oral phenobarbital at maintenance dose as soon as patient can swallow. • After 6 hours seizures-free, wean CRI gradually over 4–6 hours.

Persistent Seizures
Subanesthetic doses of IV propofol 1–3.5 mg/kg bolus and 0.01–0.25 mg/kg/minute CRI titrated to effect.

Non-Antiepileptic Drug Treatment
• Dexamethasone 0.25 mg/kg IV q24h for 1–3 days, to improve edema secondary to SE and treat the primary cause if systemic infectious disease is not suspected; dexamethasone alters CSF results. • Thiamine—5–50 mg/cat in any cat presented with acute neurologic signs, including seizures.

CONTRAINDICATIONS
• Do not use KBr in cats; side effects include life-threatening respiratory disease. • Avoid giving aminophylline, theophylline, ketamine, and fentanyl to epileptic cats.

PRECAUTIONS
• Prolonged use of propofol (>24 hours) may cause Heinz body anemia in cats. • Cats on CRI of antiepileptic drug(s) are often overtly sedated; cardiovascular and respiratory depression may occur; close monitoring necessary; lubricate eyes, express bladder manually, correct hypothermia. • Close monitoring necessary to observe if mild ongoing seizure activity persists.

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUG(S)
• Zonisamide—5–10 mg/kg PO q24h (serum levels humans 15–45 µg/mL). • Diazepam—0.5–2.0 mg/kg/day PO divided q12h.

FOLLOW-UP

PATIENT MONITORING
• CBC, biochemistry, urinalysis prior to initiating antiepileptic drug. • Phenobarbital-induced hepatotoxicity is not a problem in the cat. • Creatine kinase to evaluate muscular necrosis and indirectly subtle ongoing seizure activity in cats presented in SE. • Measure phenobarbital serum level 2 weeks after initiation; correct dosage accordingly; it is difficult to titrate phenobarbital in cats, i.e., a mild increase in dosage often leads to a major increment of the serum levels. • CBC and biochemistry—repeat every 6–12 months. • If structural epileptic patient has recovered from primary disease and remains seizure-free for 6 months—seizures may recur when drug is weaned off.

POSSIBLE COMPLICATIONS
• SE—seizure control may not be reached despite polypharmacy. • Rare hypersensitivity to phenobarbital—thrombocytopenia, neutropenia, pruritus, swollen feet; do CBC 4–6 weeks after onset of phenobarbital. • Diazepam rarely may cause acute hepatic necrosis and death. • Cardiovascular and respiratory collapse from overdose during SE treatment.

EXPECTED COURSE AND PROGNOSIS
• Depends on the underlying cause and response to treatment. • Cats with epilepsy of unknown cause have good long-term prognosis. • Cats can recover despite episode of severe cluster-seizures and generalized SE.

MISCELLANEOUS

AGE-RELATED FACTORS
Cats with seizure onset prior to 1 year of age and diagnosed with epilepsy of unknown cause have guarded prognosis for seizure control.

SEE ALSO
• Feline Ischemic Encephalopathy.
• Meningioma—Cats and Dogs.

ABBREVIATIONS
• FIP = feline infectious peritonitis.
• GI = gastrointestinal.
• GS = generalized seizures.
• SE = status epilepticus.

SEIZURES (CONVULSIONS, STATUS EPILEPTICUS)—DOGS

BASICS

DEFINITION

- Epilepsy—recurrence of seizures from primary brain origin.
- Genetic epilepsy—epilepsy with no observable underlying brain lesion or other neurologic signs or symptoms.
- Structural epilepsy—seizures are the result of identifiable structural brain lesions.
- Epilepsy of unknown cause—structural epilepsy is suspected but a lesion cannot be demonstrated.
- Cluster seizures—>1 seizure/24 hours.
- Status epilepticus (SE)—continuous seizure activity or seizures repeated at brief intervals without complete recovery between seizures.
- SE can be convulsive or nonconvulsive.
- Seizures are classified as focal (limited to one hemisphere), generalized (involve both hemispheres), and focal with secondary generalization.

PATHOPHYSIOLOGY

- Any thalamocortical disturbance may lead to seizure activity.
- Not all cortical regions have equal propensity to seize; from the most to the least likely to cause seizures—temporal, frontal, parietal, and occipital lobes.
- As more seizures occur, the tendency for neuronal damage and propensity for more seizures or SE increases; this kindling effect does not occur in all cortical regions.
- The clinical appearance of a seizure is related to the location of the neuronal hyperactivity.

SIGNALMENT

- Dogs of any breed, age, or sex.
- SE—overrepresentation of German shepherd dog, English foxhound, pug, teacup poodle, Boston terrier, Lakeland terrier.

Mean Age and Range

SE—4.2–5 years (0.15–15 years).

SIGNS

General Comments

- Prodrome—hours to days prior to the seizure; no electroencephalogram (EEG) changes.
- Aura—short period (seconds) prior to generalization of a seizure where the dog seeks help, looks lost, frightened or has a glazed look. Focal seizure. If it precedes the tonic–clonic generalized seizure, the seizure has a focal onset.
- Ictus—may start with an aura and progress to generalized seizure (GS); lateral recumbency with bilateral symmetrical tonic–clonic contractions of limb muscles; often with autonomic signs, e.g., salivation, urination, defecation.
- GS—may be mild, the animal remaining sternal or even standing during the event; may be long-lasting, 20 minutes or more. Convulsive or nonconvulsive.
- Post-ictal phase—disorientation, confusion, aimless pacing, blindness, polydipsia, polyphagia.
- A seizure lasts <2 minutes.
- Most seizures occur when dog is resting or sleeping.

Historical Findings

- Confirm that seizure has occurred.
- Seizure pattern (age at onset of seizure, seizure type and frequency)—most important factor in establishing list of possible causes.
- Metabolic diseases usually cause generalized seizures.
- Asymmetric neurologic signs before, during, or after the seizure suggest structural brain lesion.
- Presence of behavioral changes in the days/weeks preceding seizure onset indicates structural brain disease.

Neurologic Examination Findings

- Mental status, menace responses, responses to nasal septum stimulation, and proprioceptive positioning—neurologic tests that evaluate the cerebral cortex. Asymmetry indicates structural brain lesion contralateral to deficits.
- Compensated SE, first 30 minutes—salivation, hyperthermia, tachycardia, arrhythmia, increased blood pressure.
- Decompensated SE—difficulty breathing, weak pulse, low blood pressure, poor capillary refill.

CAUSES

Extracranial

- Metabolic—electrolyte disturbances, hypoglycemia (insulinoma); hypocalcemia; acute renal failure; hepatic encephalopathy.
- Toxicities—metaldehyde, pyrethrins/pyrethroids, lead, hexachlorophene, chlorinated hydrocarbons, organophosphates, bromethalin, mycotoxins, macademia nut, theobromine (chocolate), 5-fluorouracil.

Intracranial

- Degenerative—encephalopathy.
- Malformations—cortical dysplasia.
- Genetic epilepsy.
- Metabolic—cell storage diseases.
- Neoplasia—primary (meningioma, gliomas); secondary (metastatic).
- Inflammatory infectious—viral (e.g., canine distemper); fungal; protozoal (*Neospora*, *Toxoplasma*); rickettsial (ehrlichiosis, Rocky Mountain spotted fever).
- Inflammatory noninfectious—meningoencephalomyelitis of unknown origin, eosinophilic meningoencephalomyelitis; breed-related encephalitis (pug, Maltese, Yorkshire terriers, etc.).
- Trauma.
- Vascular—cerebrovascular accident.
- Epilepsy of unknown cause—post-encephalitic glial scar.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Syncope—body is limp, rapid recovery with no abnormal behavior; occurs at exercise, cough, excitement.
- Insulinoma—seizures occur at exercise, excitement.
- Obsessive compulsive behaviors or stereotypes—complex and goal-directed behaviors; behavior can be stopped.
- Seizurogenic toxins—progression from whole body tremor to SE and death if left untreated.
- Metabolic encephalopathy—seizures unusual and accompanied with obtunded mental state and abnormal behavior; no lateralizing signs.
- Structural brain disease likely—if acute onset of >2 GS within first week of onset, acute onset of focal seizures with gradual progression to GS, or presence of interictal neurologic deficits including behavioral changes.
- Genetic epilepsy—differentiated on age, breed, and seizure pattern; progressive onset of GS with/without aura.
- Cervical pain/spasms—may be mistaken for focal seizures.
- Head bobbing or idiopathic head tremor—dog remains active; can eat, drink, walk.

CBC/BIOCHEMISTRY/URINALYSIS

- Infectious CNS diseases—may reflect multisystem involvement.
- Hypoglycemia—small/toy breeds during SE; insulinoma.
- Hepatic and renal dysfunction—advanced SE.
- Urinalysis—rule out myoglobinuria.

OTHER LABORATORY TESTS

- Blood gases—metabolic acidosis frequent with SE. Respiratory acidosis needs immediate treatment.
- Coagulation profile—disseminated intravascular coagulation (DIC) in advanced SE.
- Bile acids—suspected hepatic encephalopathy.
- Fasting blood glucose and amended insulin: glucose ratio—dogs >5 years with occasional seizures during exercise.
- Serology (infectious diseases)—as suggested by systemic signs and laboratory abnormalities.
- Toxicity screen—cholinesterase levels.

IMAGING

- Thoracic radiographs and abdominal ultrasound—to identify metastatic or systemic illness, or lung pathology from SE.
- MRI—best to define location, extent, and nature of lesion.

SEIZURES (CONVULSIONS, STATUS EPILEPTICUS)—DOGS (CONTINUED)

DIAGNOSTIC PROCEDURES

Electrocardiogram (ECG)—arrhythmias can occur in SE due to myocardial damage. CSF—if intracranial structural cause is suspected; CSF and serum titers and PCR for diagnosing infectious diseases. EEG—to document ongoing seizure activity once physical manifestations have ceased.

TREATMENT

APPROPRIATE HEALTH CARE

- Outpatient—isolated seizures in an otherwise healthy dog.
- Inpatient—cluster seizures and SE.

NURSING CARE

- SE and cluster-seizures—constant supervision.
- Ensure airway patency. May need to be suctioned due to excessive salivation.
- Administer 100% oxygen via non-rebreathing mask.
- Cool down if hyperthermia.
- Install IV line for drug and fluid administration.
- Draw blood for rapid measurement of blood gases, glucose, calcium, renal and hepatic function, and antiepileptic drug (AED) levels if pertinent.
- Monitor urine output with indwelling urinary catheter.

CLIENT EDUCATION

- Treat cluster of GS and generalized status epilepticus (GSE) early—the more seizures in a given time, and the more drugs for seizure control, time for recovery, and cost for treatment.
- Antiepileptic treatment in structural epilepsy may not help until the primary cause is addressed.
- Client to keep a seizure calendar noting date, time, severity, and length of seizures to objectively evaluate response to treatment.
- Outline an in-home treatment emergency plan for cluster-seizures.

MEDICATIONS

- Electrolytes imbalance—treat immediately with fluid therapy.
- Low glucose—50% dextrose diluted to 25% (500 mg/kg IV) over 15 minutes or treat with oral glucose syrup.

DRUG(S) OF CHOICE

Seizure type and frequency determine the therapeutic approach. Important to seek and treat primary cause.

Convulsive Cluster Seizures or Status Epilepticus

Diazepam

- Administer 0.5–1 mg/kg IV bolus; repeat 5 minutes later if gross motor activity has not subsided; follow with CRI of 0.5–1 mg/kg/h added to hourly maintenance fluids in an inline burette or through syringe pump.
- Rectal—only where IV access cannot be obtained; may diminish or stop gross motor seizure activity to allow IV catheter placement.
- Refractoriness may rapidly develop, necessitating the addition of phenobarbital CRI.

Phenobarbital

- Add if seizures persist after second diazepam bolus or during diazepam CRI; administer CRI phenobarbital (2–6 mg/dog/h added to diazepam infusion) if patient already treated with phenobarbital, or loading dose if patient naïve to phenobarbital.
- Loading dose—12–24 mg/kg given as boluses of 4 mg/kg IV, 20 minutes apart until desired effect is reached, to a maximum of 24 mg/kg. Optimal therapeutic range—100–120 µmol/L (23–28 mg/L).
- If patient already on phenobarbital, obtain serum level prior to initiating phenobarbital CRI. IV bolus 2–6 mg/kg can be administered once while awaiting results if serum levels believed inadequate.
- Once seizures have been controlled for 4–6 hours, gradually wean the patient off CRI over as many hours.
- Start/resume oral maintenance AED using phenobarbital and/or other GS AED as soon as patient can swallow.

Other

- If seizures continue, propofol at 1–2 mg/kg IV slowly over 60 seconds, followed by CRI at 0.1–0.6 mg/kg/min to effect; monitor anesthetized patient with EEG to evaluate treatment response.
- Ketamine is also used occasionally at 5 mg/kg IV bolus followed by CRI at 5 mg/kg/h.
- Dexamethasone—0.2 mg/kg q24h for 1–3 days; reduce cerebral edema.
- Dexamethasone—for acute treatment of cerebral edema secondary to severe inflammatory CNS disease, even if infectious.

Acute Focal Status Epilepticus

- Often harbors brain lesion.
- Diazepam and phenobarbital CRI—effective for focal and GS.
- Frequently difficult to reach seizure control.
- Instances of chronic nonconvulsive generalized or focal SE—owner unaware it is occurring (e.g., senile encephalopathy); if seizures remain focal and patient's quality of life not significantly altered, no treatment necessary. Long-term antiepileptic treatment if necessary—phenobarbital 3–5 mg/kg q12h PO, levetiracetam 20 mg/kg q8h PO, or zonisamide 5 mg/kg q12h PO.

CONTRAINDICATIONS

- Potassium bromide—do not use to treat SE; too long half-life; loading dose not recommended.
- Aminophylline, theophylline—CNS excitement; may cause seizure.
- Steroids—alter CSF parameters; avoid if considering CSF analysis.

PRECAUTIONS

- Phenobarbital—liver disease, lower dose; monitor levels closely; for SE, add cautiously to diazepam because the drugs potentiate each other, cardiac/respiratory depression may ensue.
- Steroids—contraindicated in infectious diseases, but one dose of dexamethasone 0.2 mg/kg IV may decrease brain edema when impending brain herniation or life-threatening edema is suspected.

POSSIBLE INTERACTIONS

- Cimetidine, ranitidine, and chloramphenicol—interfere with phenobarbital metabolism; may lead to phenobarbital toxic level.
- Phenobarbital decreases zonisamide serum levels. Dosage recommended when drugs are used simultaneously—10 mg/kg q12h.
- If levetiracetam used concomitantly with phenobarbital—measure serum levels (humans 10–40 µg/mL).

ALTERNATIVE DRUG(S)

Levetiracetam—20–60 mg/kg IV; use upper end dosage if patient already on oral phenobarbital. Good alternative in liver disease or portosystemic shunts, as the drug is not metabolized in the liver. Use with caution in patients with renal disease.

FOLLOW-UP

PATIENT MONITORING

- Inpatients—constant supervision for seizure monitoring.
- Eyelid or lip twitching in a heavily sedated patient is sign of ongoing seizure activity.
- Monitor heart rate, respiratory rate, oxygenation/ventilation, body temperature, blood pressure, urine production, neurologic examination.
- EEG monitoring for ongoing seizure activity.
- Patient may need 7–10 days before returning to normal after SE.

POSSIBLE COMPLICATIONS

- Phenobarbital—hepatotoxicity after long-term treatment with serum levels >140 µmol/L (>33 µg/L); acute neutropenia (rare) in the first few weeks of use requires permanent withdrawal.
- Paradoxical hyperexcitability.
- Permanent neurologic deficits (e.g., blindness, abnormal behavior, cerebellar signs) may follow severe SE.

(CONTINUED) SEIZURES (CONVULSIONS, STATUS EPILEPTICUS)—DOGS

• GSE may lead to hyperthermia, acid–base and electrolyte imbalances, pulmonary edema, cardiovascular collapse, and death.

EXPECTED COURSE AND PROGNOSIS

• Genetic epilepsy or epilepsy of unknown cause represents a large proportion of dogs with GSE or cluster-seizures. In-home emergency measure using diazepam rectal/nasal should be provided.
• Dogs with encephalitis and GSE—poor outcome.
• Structural epileptic dogs recovered from primary disease (e.g., *Ehrlichia canis*)—slowly (over months) wean patient off AEDs after 6 months seizure-free; if seizures recur, reinstate AED.

MISCELLANEOUS

AGE-RELATED FACTORS

• The immature brain has a higher propensity to seize.
• Genetic epilepsy—6 months–5 years; often epilepsy refractory when onset at <2 years.
• Phenobarbital—higher dose needed in puppies (<5 months) to reach therapeutic range.

ABBREVIATIONS

• AED = antiepileptic drug.
• DIC = disseminated intravascular coagulation.
• ECG = electrocardiogram.
• EEG = electroencephalogram.
• GS = generalized seizure.
• GSE = generalized status epilepticus.
• SE = status epilepticus.

Author Joane M. Parent

Client Education Handout available online

SEMINOMA

BASICS

OVERVIEW
Sex cord stromal tumor of the testicle arising from the spermatic germinal epithelium.

SIGNALMENT
- Median age, 10 years.
- Boxer, German shepherd dog, Afghan hound, Weimaraner, Shetland sheepdog, collie, and Maltese may be at increased risk.
- 33–52% of all testicular tumors in dogs; extremely rare in cats.

SIGNS
- Usually none.
- Fertility issues in breeding dogs.
- 4–20% of dogs will have more than one type of testicular tumor.
- Up to 50% of dogs will have bilateral tumors, only 12% of contralateral tumors will be palpable.

CAUSES & RISK FACTORS
Cryptorchidism

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Sertoli cell tumor.
- Interstitial (Leydig cell) cell tumor.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal unless hormone productive and consequent male feminization syndrome.

IMAGING
- Testicular sonography may aid in differential diagnosis.
- Abdominal sonography for retained testicles and to evaluate for concurrent malignancies.

DIAGNOSTIC PROCEDURES
N/A

TREATMENT
- Bilateral orchiectomy and scrotal ablation is the treatment of choice.
- Exploratory laparotomy for retained testicles.
- Histopathologic examination of appropriate tissue.
- Immunohistochemistry may be necessary to identify cell of origin in some cases.
- Radiotherapy—reported effective in patients with regional metastasis.

MEDICATIONS

DRUG(S) OF CHOICE
None reported in dogs.

FOLLOW-UP

PREVENTION/AVOIDANCE
Castration at a young age.

POSSIBLE COMPLICATIONS
None likely.

EXPECTED COURSE AND PROGNOSIS
Bilateral orchiectomy and scrotal ablation are often curative. Reported rate of region or distant metastasis <15%.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- Prostate disease.
- Perianal adenoma.
- Perineal hernia.

SEE ALSO
- Interstitial Cell Tumor, Testicle.
- Sertoli Cell Tumor.

SEPARATION ANXIETY SYNDROME

BASICS

DEFINITION
A distress response of dogs (occasionally cats) separated from the person or persons to whom they are most attached, usually their owner(s). The separation may be real (the owner is gone) or perceived (pet is separated from the owner). In other cases the pet may be distressed because a fear-inducing event has occurred while home alone (e.g., thunderstorms, loud noises or home invasions), resulting in distress responses during subsequent departures. Distress may be exhibited as destruction, vocalization, and elimination in the owner's absence. Separation anxiety is a subset of separation-related problems that may have different underlying motivations, including fear, anxiety, overattachment to owner(s), and lack of appropriate stimulation or interactions.

PATHOPHYSIOLOGY
Unknown but suspected changes in brain pathology due to aging, anxious temperament, noise or location phobias, insecure attachment to humans in family.

SYSTEMS AFFECTED
- Behavioral—escape attempts, howling, whining, depression, hyperactivity.
- Cardiovascular—tachycardia.
- Endocrine/metabolic—increased cortisol, stress-induced hyperglycemia.
- Gastrointestinal—inappetence, diarrhea, vomiting
- Musculoskeletal—self-induced trauma from escape attempts.
- Nervous—adrenergic/noradrenergic overstimulation.
- Respiratory—tachypnea.
- Skin/exocrine—acral lick dermatitis.
- Oral—dental damage during escape attempts.

GENETICS
None known.

INCIDENCE/PREVALENCE
It is speculated that 13–28% of companion dogs experience some degree of separation anxiety. May be different underlying pathology with young dogs and senior dogs.

SIGNALMENT

Species
Primarily dogs; possible in cats.

Mean Age and Range
Any age, most commonly in dogs >6 months; may be another increase in prevalence in dogs >8 years.

Predominant Sex
Male and neutered male dogs overrepresented in recent studies.

SIGNS

General Comments
Destruction, vocalization, and elimination in the absence of the owner alone are not diagnostic for separation distress.

Historical Findings
- Destruction, vocalization (whining, howling, barking), and indoor elimination. Destruction targets windows and doors and/or owner possessions.
- Other signs include behavioral depression, anorexia, drooling, hiding, shaking, panting, pacing, attempts to prevent owner departure, and self-trauma from lick lesions. Diarrhea and vomiting are occasionally seen.
- Signs of strong pet–owner attachment may be present: excessive attention-seeking behaviors and following behaviors are not necessary for diagnosis and do not occur in all patients.
- Frequently owners report excessive, excited, and prolonged greeting behavior upon return.
- Separation anxiety behavior(s) usually occurs regardless of the length of owner absence, often within 15–30 minutes of owner departure.
- Specific triggers that are predictive of possible departure may initiate the anxiety response: getting keys, putting on outer garments, or packing the car but are not seen in all patients.
- May occur on every departure and absence or only with atypical departures, e.g., after-work, evening, or weekend departures; the reverse pattern may also be seen.
- Some animals may initially show signs in the presence of acute fear- or anxiety-inducing events such as thunderstorms or fireworks when home alone but may recur with future departures even in the absence of stimuli.
- In cats, elimination problems in the owner's absence may be linked to separation-related anxiety.
- May be excessive water consumption upon owner return.
- Distress may also be initiated by a change in daily routine or in the household (e.g., moving house).
- What appears as distress may also be frustration at being alone, being confined, inability to pursue other activities, living in an impoverished environment or lack of enrichment.

Physical Examination Findings
- Usually normal.
- Injuries may be incurred in escape attempts or destructive activities.
- Skin lesions from excessive licking.
- Rare cases of dehydration from drooling or diarrhea due to stress.

CAUSES
Specific causes unknown. Causal factors may include:
- Insecurity or anxiety about owner departure and absence.
- Frustration due to lack of the ability to engage in normal behaviors (lack of enrichment, exercise or social contact).
- Lack of appropriate pet–owner interactions.
- Prolonged contact with humans without learning how to be alone.
- Improper or incomplete early separation from the bitch (French behavior school).
- Traumatic episodes during owner absence.
- Concurrent anxiety disorders, e.g., noise and storm fears and phobias.
- Change in household routine/schedule.
- Medical issues contributing to anxiety, including endocrine dysfunction, pain, sensory decline, or cognitive decline.

RISK FACTORS
- Suspected risk factors—adoption from humane shelters, extended time with preferred person such as during vacation or illness, boarding, lack of detachment when young.
- Geriatric animals seem to be overrepresented.
- Possible correlation between separation anxiety and other anxiety disorders including noise phobias.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Vocalization—response to outdoor stimuli, territorial displays, play with other pets in the home, fears.
- Destructive behaviors—occur both when the owner is present and absent (e.g., territorial destructive displays at windows and doors; destruction due to fear-producing stimuli such as noises and thunderstorms). Lack of appropriate outlets for normal chewing and play.
- Housesoiling—inadequate housetraining, illness, endocrine dysfunction, cognitive decline.
- Fear-based conditions.
- Barrier frustration—dogs unable to be confined in crates or behind barriers but are fine if not confined.
- Underlying medical conditions including endocrinopathies, sensory decline, pain, cognitive dysfunction syndrome, and dermatologic conditions leading to self-trauma.

CBC/BIOCHEMISTRY/URINALYSIS
Indicated to rule out concurrent medical conditions and as baseline prior to medication.

SEPARATION ANXIETY SYNDROME (CONTINUED)

OTHER LABORATORY TESTS
Endocrine testing if indicated by history, examination and/or CBC/biochemistry results.

IMAGING
MRI or CT if neurologic disorders are suspected.

DIAGNOSTIC PROCEDURES
- Behavioral history using standard questionnaires.
- Video recordings of the pet when home alone to verify diagnosis.
- Questionnaires targeting cognitive decline are advisable for geriatric dogs.
- Endoscopy with biopsy if gastrointestinal signs.

TREATMENT

ACTIVITY
- Regular, scheduled daily exercise and playtime.
- Enriching the environment with toys that are interactive and/or dispense food.

DIET
None unless gastrointestinal signs.

S

CLIENT EDUCATION

General Comments
Once other causes of destruction and elimination have been ruled out or addressed, it is important to help the owner understand that the destruction or elimination is due to anxiety and not spite. Set a realistic expectation of the time course of treatment and the need for behavior modification to have successful resolution of the problem. Problem behavior may take weeks or months to resolve, depending on severity and duration of the problem. Treatment may include some or all of the following.

Independence Training
- Teach the dog to remain calm when not in close proximity to the owners to encourage the dog to be more independent of the owner(s).
- Teach the dog to calmly stay in a location away from the owner and create a safe haven for the dog to settle and relax on command. Initially this can be a dog bed on the floor 1–2 feet from the owner. The dog must be calm and relaxed when the owner is home for gradually longer times and gradually increasing separation to be calm and relaxed when they are gone.
- When possible, and without creating more anxiety, cue a behavior such as "sit" prior to attention or affection. Longer and more relaxed responses can be very gradually shaped.
- When possible, decrease following behavior while the owner is home, perhaps by sending the dog to the safe bed or mat to wait and reinforcing with attention and treats.
- Owners should strive to give attention in a predictable and calm manner—requesting a sit or other calm behavior such as down before petting, giving treats or chews, throwing a ball, going out for a walk, etc.

Changing the Predictive Value of Pre-Departure Cues
- Some dogs begin to get anxious when they see cues that indicate owner departure.
- For those dogs, presentation of pre-departure cues (picking up keys, walking to the door) without leaving may be helpful; but not if it causes increased anxiety.
- Repeat 2–4 times daily until the dog does not respond to cues with anxious behaviors (panting, pacing, following, or increased vigilance).
- Goal is to disassociate the cues with departures and diminish the anxious response. If the dog becomes more anxious, this step is discontinued.

Counter-Conditioning
- Teach the dog to sit/stay near the typical exit door.
- Owner gradually increases the distance between the dog and the exit door.
- Owner slowly progresses toward the door, increasing the time away on each trial.
- Eventually elements of departure, such as opening and closing the door, are added.
- Finally, the owner steps outside the door and returns.

Classical Counter-Conditioning
- Pairing favored treats with departure cues. Leaving the dog a delectable food treat or food-stuffed toy on departure.
- Associating departure with something pleasant.

Changing Departure and Return Routine
- Passively ignore the pet for 15–30 minutes prior to departure and upon return.
- On return, attend to the dog only when it is calm and quiet.
- Allow the dog outside to eliminate.

Graduated Planned Departures and Absences
- Begun after dog is not responding anxiously to pre-departure cues.
- Use short absences to teach the dog how to be home alone.
- Departures must be short enough not to elicit a separation anxiety response; the pet must be calm when owners depart and calm when they return.
- Goal—animal learns consistency of owner return and to experience departure and absence without anxiety.
- Departures must be just like real departures (owner must do all components of departure, including leaving in the car if that is how he or she usually departs).
- Owner can leave a safety cue (radio or television on, ring a bell) on planned departures only (must not be used on departures where length of absence is not controlled, such as work departures).
- Initial departures must be very short, 1–5 minutes.
- Length of absence is slowly increased at 3–5 minute intervals if no signs of distress at the shorter interval (excited greetings, barking etc.).
- Increase in interval must be variable; intersperse short (1–3 minute) with longer (5–20 minute) departures.
- If destruction, elimination, or vocalization occurs, the absence was too long. Use video recordings, remote monitoring or audio recordings of vocalization to assess pet anxiety and monitor progress.
- Once the pet can be left for 2–3 hours on a planned departure, it often can be left all day.
- Cue can be slowly phased out over time or can be used indefinitely.

Arrangements for the Pet During Retraining and Owner Absence
- If possible, prevent further departures that lead to anxiety.
- If departures and absences are continued while distress behaviors are present, the problem will get worse.
- Mixing up or eliminating triggering departure cues may help diminish the anxious responses.
- Doggie daycare arrangements or pet sitters.
- Gradual positive conditioning to a crate as a safe haven if the dog is not distressed and will settle.
- Crates must be used cautiously if at all and only in dogs that are calm when left in a crate as they may increase anxiety, resulting in pet injury.

SURGICAL CONSIDERATIONS
If animal is on medication, use caution prior to administering anesthesia.

MEDICATIONS

DRUG(S) OF CHOICE

Drugs for Chronic (Ongoing) Therapy
Clomipramine (Branded product "Clomicalm™")
- Tricyclic antidepressant (TCA)—approved for use in the treatment of separation anxiety in dogs.

• Dosage—dogs: 2–4 mg/kg daily; dogs may do better with dividing the dose and administering twice daily. Must be given daily, not on an "as needed" basis, and in conjunction with a behavior modification plan.
• May take 2–4 weeks before behavioral effect is evident.
• Side effects—vomiting, diarrhea, and lethargy.

Fluoxetine (Branded product Reconcile™)
• Selective serotonin reuptake inhibitor (SSRI)—approved for use in the treatment of separation anxiety in dogs.
• Dosage—1–2 mg/kg PO q24h.
• Administer in conjunction with a behavior modification plan.
• Side effects—lethargy, decreased appetite, weight loss, and vomiting.

Drugs for Acute Anxiety at Departure
• While waiting for SSRI or TCA effect, concurrent use of short-term anxiolytics and pheromones is advisable in most cases.
• Benzodiazepines—alprazolam for panic at owner departure (dog, 0.01–0.1 mg/kg) 30 minutes prior to departure. Some dogs experience paradoxical excitement with benzodiazepines, which may resolve with altered dosage or change to another benzodiazepine. Polyphagia is also common with benzodiazepine administration.
• Trazodone—a serotonin receptor antagonist and reuptake inhibitor and can be used in conjunction with a TCA or SSRI to augment calming effects. Dosage recommendation (dog) is to begin with 2–3 mg/kg PO prior to departure and titrate up gradually to effect (up to 8–10 mg/kg). Dose should be increased cautiously, especially if using with an SSRI or TCA due to potential for serotonin syndrome. Side effects include vomiting, diarrhea, sedation, ataxia, hypotension, excitement or agitation and panting and rare reports of polyphagia.
• Dog-appeasing pheromone (Adaptil)—synthetic analogue of the maternal appeasing pheromone; may calm dogs in fearful, stressful, and anxiety situations such as separation anxiety and noise phobias; available as a plug-in diffuser for dog's housing area, a spray for the cage or mat, and collar.

CONTRAINDICATIONS
• Clomipramine and fluoxetine should not be used in combination or combined with monoamine oxidase inhibitors (MAOIs) such as amitraz and selegiline or within 14 days after an MAOI.
• Use clomipramine with caution in patients showing cardiac conduction disturbances.
• Caution advised using in conjunction with CNS-active drugs, including general anesthesia, neuroleptic, anticholinergic, and sympathomimetic drugs for dogs on either clomipramine or fluoxetine.
• A 6-week washout interval should be observed following discontinuation of fluoxetine prior to administration of any drug that may interact with fluoxetine.
• Fluoxetine should be used cautiously in dogs with epilepsy or with drugs that lower the seizure threshold (phenothiazines).

PRECAUTIONS
• Studies to determine effects of medication in patients less than 6 months of age have not been conducted.
• Studies to assess the interaction of fluoxetine with TCAs have not been conducted.
• Improperly applied behavioral modification may increase anxiety.
• Crating can result in serious physical damage to the pet if it attempts to escape; should only be recommended cautiously for animals that are already crate-trained.

POSSIBLE INTERACTIONS
Serotonin syndrome with combinations of MAOI and SSRI or SSRI and TCA.

ALTERNATIVE DRUG(S)
• TCA such as amitriptyline (dog, 1–2 mg/kg q12h) might be considered in place of clomipramine or fluoxetine.
• Clonidine—an alpha-2 agonist which might be used prior to departures in combination with a TCA or SSRI at a dose of 0.01–0.05 mg/kg. Begin at the lowest end of the dose range and increase cautiously.
• Natural products that might be used adjunctively—alpha-casozepine alone or in a diet with L-tryptophan; L-theanine alone or in combination products containing whey protein, *Phellodendron amurense*, and *Magnolia officinalis*; melatonin; S-adenosyl methionine; *Souroubea* and *Plantanus* products; probiotic calming supplement; lavender aromatherapy; classical musical.

FOLLOW-UP

PATIENT MONITORING
Good client follow-up is necessary to monitor both the behavioral treatment plan and medication if prescribed. Weekly follow-up is best in the early stages to assess efficacy of the treatment plan and owner compliance. Once the dog has become more independent, habituated to pre-departure cues, and calmer on departures and returns, graduated planned departures may be implemented.

PREVENTION/AVOIDANCE
Habituating to spending time alone, safe haven training, training independence.

POSSIBLE COMPLICATIONS
• Injuries during escape attempts.
• Ongoing destruction and elimination disrupt the human–animal bond and result in pet relinquishment.
• Other anxieties causing signs that mimic separation distress; if not identified and treated, the problem may worsen.

EXPECTED COURSE AND PROGNOSIS
Separation anxiety often responds well to behavioral modification with or without medication. Some cases can be very resistant to treatment. Other concurrent behavioral disorders may make resolution more difficult. Drug therapy alone is rarely curative for most behavioral disorders. Realistically, drug therapy can be expected to decrease the anxiety associated with owner departure, but the dog still must be taught how to accept and be comfortable left alone during owner absences.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Other anxiety conditions, including noise phobias, generalized anxiety, fears, and compulsive disorders.

AGE-RELATED FACTORS
May be increased prevalence in senior dogs.

SYNONYMS
Hyperattachment–separation distress.

SEE ALSO
• Cognitive Dysfunction Syndrome.
• Excessive Vocalization and Waking at Night—Dogs and Cats.
• Fears, Phobias, and Anxiety—Dogs.
• Thunderstorm and Noise Phobias.

ABBREVIATIONS
• MAOI = monoamine oxidase inhibitor.
• SSRI = selective serotonin reuptake inhibitor.
• TCA = tricyclic antidepressant.

SEPSIS AND BACTEREMIA

BASICS

DEFINITION

• Sepsis—life-threatening organ dysfunction caused by dysregulated host response to severe infection. • Bacteremia—presence of viable bacterial organisms in the bloodstream.
• Terms are not synonymous, although often used interchangeably.

PATHOPHYSIOLOGY

• With severe infection, immune system is stimulated by pathogen-associated products such as lipopolysaccharide (LPS) (Gram-negative bacteria); lipoteichoic acid, peptidoglycan, bacterial DNA, exotoxins (Gram-positive bacteria); fungal cell walls; flagellin (protozoans). • Macrophage-derived cytokines activate and recruit neutrophils and other inflammatory cells, activate coagulation cascade, increase capillary permeability.
• Activation of inducible nitric oxide synthase (iNOS) produces large quantities of nitric oxide, causing diffuse, profound vasodilation; refractory hypotension or vasodilatory shock may result. • White blood cells (WBCs) and platelets at sites of inflammation activate coagulation, produce thrombin, and activate platelets; anticoagulant and fibrinolytic pathways inhibited. Procoagulant state favors microthrombi that can lead to decreased tissue oxygen delivery, multiple organ dysfunction, and organ failure. Progression to a hypocoagulable state can occur. • Cryptic shock—decreased microcirculatory perfusion despite normal global hemodynamic parameters; results from decreased functional capillary density. • Endothelial cell dysfunction—disruption of endothelial glycocalyx, changes in deformability of red blood cells (RBCs), WBC activation, microthrombosis, loss of vascular smooth muscle autoregulation, changes in capillary permeability. • Cytopathic hypoxia—sepsis-induced mitochondrial dysfunction renders cells unable to use oxygen to make ATP. • Bacteremia—may be transient and subclinical or escalate to overt sepsis when immune system overwhelmed; generally of more pathologic significance when source is venous or lymphatic drainage sites.

SYSTEMS AFFECTED

• Cardiovascular—increased or decreased cardiac output, decreased systemic vascular resistance, and increased vascular permeability.
• Hemic/lymphatic/immune—procoagulant state favors formation of microthrombi, may progress to hypocoagulable state (consumption).
• Endocrine—relative adrenal insufficiency (critical illness-related corticosteroid insufficiency [CIRCI]). • Respiratory. • Gastrointestinal.
• Hepatobiliary. • Renal. • All systems can be affected by sepsis via systemic inflammatory response syndrome and multiple organ dysfunction syndrome.

SIGNALMENT

Species

• Dog and cat. • No age, sex, or breed predispositions. • Large-breed male dogs—predisposed to bacterial endocarditis, discospondylitis.

SIGNS

General Comments

• May be acute or occur in vague or episodic fashion. • May involve single or multiple organ systems.

Historical Findings

Historical findings variable depend on underlying cause.

Physical Examination Findings

• Signs of sepsis vary with stage. • Dog:
○ Early sepsis—hyperdynamic state: tachycardia, bounding pulses, rapid capillary refill time, red mucous membranes, fever.
○ Late sepsis—thready pulses, prolonged capillary refill time, pale mucous membranes, cool extremities, stupor, hypothermia. • Cat:
○ Lethargy, pale mucous membranes, tachypnea, weak pulses, hypotension, hypothermia, icterus, diffuse abdominal pain (even in absence of primary abdominal problem).
○ May present with tachycardia or a relative bradycardia (heart rate inappropriately low given illness, e.g., 120–150 bpm). • Specific clinical signs relate to site of infection or secondary organ dysfunction: ○ Lameness.
○ Heart murmur—diastolic murmur may indicate aortic valve endocarditis.
○ Abdominal pain, peritoneal effusion.
○ Dyspnea. ○ Dysuria, prostatomegaly.
○ Neurologic deficits—primary deficit or secondary to hypoglycemia, hypotension.

CAUSES

• Infection from bacterial (most common), viral, protozoal, fungal, or parasitic organisms. • Specific causes include:
○ Cardiovascular—endocarditis.
○ Cutaneous—bite wounds, deep pyoderma, infected burns, surgical site infection, abscess.
○ Gastrointestinal—septic peritonitis, gastrointestinal perforation, translocation, gastroenteritis, colitis. ○ Genitourinary—pyelonephritis, pyometra, prostatitis/prostatic abscess. ○ Hemic/immune—blood-borne parasites, vector-borne infections.
○ Hepatobiliary—hepatitis, hepatic abscess, cholangitis, cholangiohepatitis.
○ Musculoskeletal—necrotizing fasciitis, osteomyelitis, septic arthritis. ○ Neurologic—discospondylitis. ○ Respiratory—pneumonia, pyothorax. • Dogs: Gram-negative organisms (especially *E. coli*) most common; polymicrobial infection reported in ~20% of dogs with positive blood cultures. • Cats—bloodstream pathogens usually Gram-negative bacteria from *Enterobacteriaceae* family or obligate anaerobes; *E. coli* and *Salmonella* most common Gram-negative organisms cultured.

RISK FACTORS

• Predisposing factors—hyperadrenocorticism, diabetes mellitus, liver or renal failure, splenectomy, malignancy, burns. • Immunodeficient state—chemotherapy, feline leukemia virus or feline immunodeficiency virus infection, splenectomy, endogenous or exogenous corticosteroids. • IV catheters. • Indwelling urinary catheters or other drainage devices.
• Surgical implants.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Other causes of fever, heart murmur, joint or back pain, or hypotension. • Clinical signs of chronic bacteremia may be similar to immune-mediated disease. • Other causes of distributive/vasodilatory shock—hypoadrenocorticism, anaphylaxis or mast cell tumor degranulation, antihypertensive drug overdose.

CBC/BIOCHEMISTRY/URINALYSIS

• Neutrophilic leukocytosis with a left shift and monocytosis. • Neutropenia may develop. • Hypoalbuminemia and a high alkaline phosphatase activity (2 times upper limit of normal)—~50% of affected dogs.
• Hypoglycemia—~25% of affected dogs; hyperglycemia or hypoglycemia in cats.
• Blood lactate concentration—persistent lactate elevation despite therapy portends poor prognosis.

OTHER LABORATORY TESTS

• Aerobic and anaerobic cultures of site of infection—recommended but *should not delay timely antibiotic therapy*. • Suspected catheter-induced sepsis—culture catheter tip. • Urine culture—urinary tract may be primary or secondary source of infection.
• Endocarditis—consider *Bartonella* testing (see Bartonellosis). • PCR, serology for tick-borne disease, as indicated. • PCR, serology or for organisms of interest, as indicated (e.g., *Leptospira*, influenza, *Babesia*).
• Fungal antigen testing. • Coagulation parameters should be monitored in most cases.

IMAGING

• Radiographs and ultrasound—may identify source of sepsis (e.g., pyometra, pneumonia) or secondarily infected organs (e.g., discospondylitis). • Ultrasound may help guide fine-needle aspiration for cytology/culture. • Echocardiography—for suspected endocarditis. • CT, MRI—may identify some sources of sepsis or for surgical planning.

SEPSIS AND BACTEREMIA (CONTINUED)

DIAGNOSTIC PROCEDURES

• Abdominocentesis, thoracocentesis, fine-needle aspirate—for cytology, culture/sensitivity of effusion, masses: ◦ Neutrophilic or pyogranulomatous inflammation, eosinophilic. ◦ Diagnostic peritoneal lavage if strong suspicion for abdominal sepsis without effusion. • Endo- or transtracheal wash, broncho-alveolar lavage—samples for cytology, culture/sensitivity, PCR. • Fecal cytology, fecal PCR. • Blood cultures—in any patient that develops fever (or hypothermia), leukocytosis (especially with a left shift), neutropenia, shifting leg lameness, recent onset or changing heart murmur, or any sign of sepsis for which the source cannot be identified.

PATHOLOGIC FINDINGS

Varies with underlying cause.

TREATMENT

APPROPRIATE HEALTH CARE

• Success requires early identification of the problem and aggressive intervention; careful monitoring is essential, patient status may change rapidly. • *Start IV antibiotics within 1 hour of identifying sepsis or septic shock*. • Fluid therapy—IV bolus isotonic replacement crystalloids (cat, 10–15 mL/kg; dog, 20–30 mL/kg), repeat as necessary; then administer crystalloids to provide maintenance needs, replace dehydration deficits and meet ongoing losses; provide albumin and plasma for hypoalbuminemia and coagulation abnormalities, respectively; consider synthetic colloids if clinical hypoproteinemia and hypotension are ongoing and biologic colloid sources unavailable. • Add dextrose to IV fluids if hypoglycemic. • Electrolytes and acid–base balance—correct abnormalities. • Pressor, inotrope therapy for persistent hypotension; refer early. • Source control—should be completed after patient is normotensive and stable; provide appropriate wound care, bandage changes, or surgical intervention, as indicated.

NURSING CARE

• Goals—systolic blood pressure >90 mmHg, heart rate 80–140 bpm (dogs) and 160–225 bpm (cats), capillary refill time 1.5 seconds, urine output >1–2 mL/kg/h, blood lactate <2.5 mmol/L in dogs. • Inadequate response to therapy prompts vasopressor administration (norepinephrine, dopamine, vasopressin). Most commonly recommended vasopressor is norepinephrine. Dopamine may be a good choice for cats with relative bradycardia. • As appropriate for each patient's situation.

DIET

Nutritional support—provide by assisted feeding or feeding tube.

CLIENT EDUCATION

Prognosis should be discussed with client.

SURGICAL CONSIDERATIONS

Any identifiable focus of infection such as an abscess should be located and removed where possible.

MEDICATIONS

DRUG(S) OF CHOICE

Antibiotics

• IV antibiotics should be *started within 1 hour* of recognizing sepsis, septic shock. • Pending culture and sensitivity results, treat for organisms commonly isolated from presumed source of infection, or empirically cover Gram-positive, Gram-negative, aerobic, anaerobic organisms: ◦ Initial therapy—Gram-negative (enrofloxacin, cefotaxime, amikacin); Gram-positive (ampicillin, clindamycin); anaerobes (metronidazole). ◦ Ampicillin 22 mg/kg IV q6–8h. ◦ Ampicillin/sulbactam 25–30 mg/kg IV q6–8h. ◦ Clindamycin 12 mg/kg IV q12h. ◦ Cefotaxime 20–80 mg/kg IV q8h. ◦ Enrofloxacin 10–15 mg/kg IV q24h (dogs); 5 mg/kg/day IV (cats). ◦ Amikacin 10–15 mg/kg IV q24h. ◦ Metronidazole 10 mg/kg IV q8–12h. • De-escalate (reduce unnecessary antibiotics) once sensitivity results are available. • For many *bacterial* infections, total duration of therapy can be limited to 7–10 days; longer if source cannot be eliminated/drained or immune deficiencies are present.

Corticosteroids

Physiologic doses (e.g., 0.25 mg/kg prednisone or 0.05 mg/kg of dexamethasone) may be indicated if patient has persistent hypotension unresponsive to fluid therapy and catecholamines.

CONTRAINDICATIONS

NSAIDs—high risk of renal failure (acute kidney injury) or gastrointestinal ulceration in patient with sepsis/septic shock.

PRECAUTIONS

Aminoglycosides—use with caution in patient with renal impairment.

FOLLOW-UP

PATIENT MONITORING

• Aminoglycoside therapy—monitor renal function. • Blood pressure, ECG, electrolytes, blood lactate.

POSSIBLE COMPLICATIONS

Multiple organ failure.

EXPECTED COURSE AND PROGNOSIS

Sepsis has a mortality rate of ~50%, with higher mortality for animals with multiorgan failure.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Discospondylitis (dogs)— screen for *Brucella* spp. • See Risk Factors.

SYNONYMS

• Septic shock. • Septicemia.

SEE ALSO

• Abscessation.
• Anaerobic Infections.
• Endocarditis, Infective.
• Shock, Septic.

ABBREVIATIONS

• CIRCI = critical illness-related corticosteroid insufficiency.
• iNOS = inducible nitric oxide synthase.
• LPS = lipopolysaccharide.
• NSAID = nonsteroidal anti-inflammatory drug.
• RBCs = red blood cells.
• WBCs = white blood cells.

SERTOLI CELL TUMOR

BASICS

OVERVIEW
Sex cord stromal tumor of the testicle arising from the sustenacular cells of Sertoli.

SIGNALMENT
- Median age, 10 years.
- Boxer, German shepherd dog, Afghan hound, Weimaraner, Shetland sheepdog, collie, and Maltese may be at increased risk.
- 8–33% of all testicular tumors in dogs, extremely rare in cats.

SIGNS
- Usually none. Fertility issues in breeding dogs.
- 4–20% of dogs will have more than one type of testicular tumor.
- Up to 50% of dogs will have bilateral tumors, only 12% of contralateral tumors will be palpable.
- >50% of dogs will have hyperestrogenism. Most common clinical signs include: bilateral symmetric alopecia and hyperpigmentation, pendulous prepuce, gynecomastia, galactorrhea, atrophy of the penis, squamous metaplasia of the prostate.
- Clinical signs associated with severe pancytopenia include weakness, hemorrhage, and febrile episodes.
- Abdominal mass—if patient is cryptorchid.

CAUSES & RISK FACTORS
- Cryptorchid testicles 12.7 per 1000 dog-years (vs. 0 for scrotally located testicles).
- Cryptorchid and ≥6 years of age, 68.1 per 1000 dog-years.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Interstitial cell tumor.
- Seminoma.
- Hyperadrenocorticism.
- Hypothyroidism.
- More likely to have an abdominal location than other testicular tumors; high testicular temperature in the abdominal location may destroy spermatogenic cells and leave Sertoli cells unregulated.

CBC/BIOCHEMISTRY/URINALYSIS
Transient neutrophilia followed by progressive neutropenia, thrombocytopenia, and non-regenerative anemia.

OTHER LABORATORY TESTS
Low testosterone-to-estradiol ratio.

IMAGING
Testicular and abdominal sonography to aid in differential diagnosis and identify retained testicles and comorbidities.

DIAGNOSTIC PROCEDURES
- Histopathologic examination of testicular mass.
- Immunohistochemistry may be necessary to identify cell of origin.
- Serum anti-müllerian hormone may differentiate testicular tumors.

TREATMENT
- Bilateral orchiectomy is the treatment of choice.
- Exploratory laparotomy for retained testicles.
- Supportive care for dogs with bone marrow hypoplasia.

MEDICATIONS

DRUG(S) OF CHOICE
N/A

FOLLOW-UP

PATIENT MONITORING
- Recurrence of feminization may be associated with metastasis.
- Serum hormone levels may be correlated with resolution of clinical signs.

POSSIBLE COMPLICATIONS
Irreversible bone marrow ablation resulting in life-threatening hemorrhage and recurrent infection.

EXPECTED COURSE AND PROGNOSIS
- Good in most patients.
- Guarded if cytopenias exist at diagnosis.
- Poor prognosis if aplastic anemia present.
- Clinical signs of hyperestrogenism expected to resolve within 1–3 months following castration; however, bone marrow hypoplasia might be irreversible.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- 50% of dogs with Sertoli cell tumor associated with hyperestrogenism and feminization.
- Hyperestrogenism can cause hematopoietic failure.

SEE ALSO
Hyperestrogenism (Estrogen Toxicity).

SEXUAL DEVELOPMENT DISORDERS

BASICS

DEFINITION

• Errors in the establishment of chromosomal, gonadal, or phenotypic sex causing abnormal sexual differentiation. • Varies from ambiguous genitalia to apparently normal genitalia with sterility.

PATHOPHYSIOLOGY

• Sexual differentiation is a sequential process—chromosomal sex established at fertilization (dog: 78,XX or 78,XY; cat: 38,XX or 38,XY), development of gonadal sex, and finally development of phenotypic sex. • Testis differentiation normally determined by sex chromosome constitution; *SRY* (on the Y chromosome) and *SOX9* (autosomal gene), expressed by Sertoli cells, are critical for testis differentiation. • Ovarian differentiation—an active process involving *WNT4/RSPO1* and β-catenin. • Phenotypic sex differentiation (tubular reproductive tract and external genitalia) depends on gonadal sex—basic embryonic plan is female; male phenotype results if testes are capable of secreting anti-Müllerian hormone and testosterone at the correct time during embryogenesis, and functional androgen receptors (X-linked gene) are present on genital tissues. • Consensus terminology for categorizing disorders of sexual development (DSD) recently revised. Previous nomenclature also noted.

Sex Chromosome DSD

• Defects in number or structure of sex chromosomes—chromosomal non-disjunction during meiosis causes trisomy, monosomy; mitotic non-disjunction of a single zygote causes mosaicism; fusion of zygotes leads to chimerism. • XXY (Klinefelter) syndrome—79,XXY (dog); 39,XXY (cat): hypoplastic testes; phenotypic male (normal to hypoplastic genitalia); sterile; some tortoiseshell male cats. • XO (Turner) syndrome—77,XO (dog); 37,XO (cat): dysgenetic ovaries; phenotypic female; infantile genitalia; sterile. • XXX syndrome—79,XXX (dog): hypoplastic ovaries; anestrus to irregular estrous cycles; female phenotype. • True hermaphrodite chimera—XX/XY or XX/XXY (dogs and cats): ovarian and testicular tissue; phenotypic sex depends on amount of testicular tissue. • XX/XY chimera with testes and XY/XY chimera with testes (dogs and cats)—vary from phenotypic female with abnormal genitalia to male with possible fertility; some tortoiseshell males.

XY DSD

Disorders of Testicular Development

• Complete or partial testicular dysgenesis—*SRY*-positive 78,XY dog: genitalia incompletely masculinized (enlarged clitoris); testes undescended or perivulvar; Müllerian and Wolffian duct derivatives variably present. • Ovotesticular DSD—XY sex reversal, true hermaphrodite.

Disorders in Androgen Synthesis or Action

• Complete androgen insensitivity syndrome—38,XY cat: testes at caudal pole of kidneys; no Wolffian or Müllerian duct derivatives; blind-ended vagina; vulva. • Partial androgen insensitivity syndrome—78,XY dog: vulva; perivulvar scrotal-like swellings at 6 months of age; blind vaginal pouch; hypoplastic testes; epididymides, partially developed vasa deferentia; vulvar fibroblasts unable to bind dihydrotestosterone. • Persistent Müllerian duct syndrome (male pseudohermaphrodite)—XY (dogs and cats): testes (50% are unilateral or bilateral cryptorchid); epididymides, vasa deferentia, prostate, oviducts, uterus, cervix, cranial vagina; penis, prepuce, and scrotum usually normal. • Isolated hypospadias—incomplete masculinization of urogenital sinus during urethral development causing abnormal location of urinary orifice from glans penis (mild) to perineum (severe); external genitalia unambiguous; testes (cryptorchid or scrotal) or bifid scrotum (cats) with spermatogenesis.

XX DSD

Ovoteseticular DSD and Testicular DSD

• Canine XX DSD (sex reversal)—*SRY*-negative 78,XX reported in 28 dog breeds, not in cats: autosomal gene causing testis induction presently unknown; two phenotypes: ○ Ovotesticular DSD, XX true hermaphrodite (90% of cases)—ovotestis (at least one); masculinized female phenotype; varies from normal to abnormal vulva, normal or enlarged clitoris (os clitoris possible), uterus, oviducts, epididymides, and vasa deferentia; rarely fertile. ○ Testicular DSD, XX males (10% of cases)—testes (usually cryptorchid); epididymides, vasa deferentia, prostate; bicornuate uterus, no oviducts; hypoplastic penis and prepuce; hypospadias common.

Androgen Excess

• Fetal origin—single report of congenital adrenal hyperplasia in a phenotypic male cat (38,XX, ovaries, oviducts, epididymides, vasa deferentia, bicornuate uterus) due to 11 β-hydroxylase deficiency. • Maternal origin (female pseudohermaphrodite)—XX; ovaries; masculinized genitalia (mild clitoral enlargement to nearly normal male genitalia); oviducts, uterus, cranial vagina; prostate variable; caused by exogenous sex steroid administration (progestegen oversupplementation) during pregnancy.

SYSTEMS AFFECTED

• Reproductive—anomalies of the gonads, tubular tract, and external genitalia. • Renal/urologic—occasionally affected (e.g., agenesis, incontinence, hematuria, cystitis). • Skin/exocrine—perivulvar dermatitis (hypoplastic vulva); perineal or peri-preputial dermatitis (hypospadias); hyperpigmentation (Sertoli cell tumor).

GENETICS

• Chromosomal sex abnormalities—usually caused by random events during gamete formation or early embryonic development. • XX DSD—autosomal recessive trait in American cocker spaniels and likely in beagles, German shorthaired pointers; familial in English cocker spaniels, pugs, Kerry blue terriers, Norwegian elkhounds, Weimaraners; other reported breeds include soft-coated wheaten terriers, vizslas, Walker hounds, Doberman pinschers, basset hounds, American pit bull terriers, border collies, Afghan hounds. • Persistent Müllerian duct syndrome (PMDS)—autosomal recessive trait in miniature schnauzers in the United States, bassett hounds in the Netherlands, and possibly Persian cats; expression limited to XY individuals. • Hypospadias familial in Boston terriers. • Failure of androgen-dependent masculinization (predominantly cats) probably X-linked.

INCIDENCE/PREVALENCE

• Generally rare. • In affected breeds—may be common within families or within the breed as a whole.

SIGNALMENT

Species

Dog and cat.

Breed Predilections

See Genetics.

Mean Age and Range

All are congenital disorders, but individuals with normal external genitalia may not be identified until breeding age or at routine gonadectomy.

Predominant Sex

Phenotypic females and males.

SIGNS

General Comments

• Depends on type of disorder. • Listed are possible findings for any of the conditions; not all occur with each specific disorder.

Historical Findings

• Failure to cycle. • Infertility and sterility. • Vulva, clitoris, prepuce, or penis—abnormal size, shape, or location. • Urine stream—abnormal location. • Affected phenotypic males attractive to other males. • Urinary incontinence. • Vulvar discharge. • Polyuria/polydipsia.

(CONTINUED) # SEXUAL DEVELOPMENT DISORDERS

Physical Examination Findings

• Vulva normal or hypoplastic. • Clitoris normal or enlarged; os clitoris. • Perivulvar dermatitis and vulvar discharge. • Testes scrotal, unilateral or bilateral cryptorchid; bifid scrotum. • Penis and prepuce normal or hypoplastic. • Urethral meatus normal or abnormal location. • Dermatologic signs of hyperestrogenism in males. • Abdominal mass.

CAUSES

• Congenital—heritable or nonheritable.
• Exogenous steroid hormone administration during gestation.

RISK FACTORS

Androgen or progestagen administration during pregnancy (female pseudohermaphrodite).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Individuals with Unambiguous Genitalia

• Female infertility—male infertility, mistimed breeding, subclinical cystic endometrial hyperplasia/endometritis, hypothyroidism. • Failure to cycle (female)—silent heat, hypothyroidism, hypercorticism, previous gonadectomy. • Male infertility—female infertility, mistimed breeding, exogenous drug use affecting fertility, orchitis or epididymitis, testicular degeneration or hypoplasia, prostatitis.

CBC/BIOCHEMISTRY/URINALYSIS

• Usually normal. • Neutrophilia, normochromic, normocytic anemia; hyperglobulinemia, hyperproteinemia, azotemia are possible. • Urinalysis—may reveal cystitis with anatomic abnormalities that affect the location of the urethral meatus.

OTHER LABORATORY TESTS

• Serum concentrations of sex steroid hormones (progesterone, testosterone, and estradiol)—generally below the normal range; may be normal if disorder mild and patient not sterile. • Detect testicular tissue—gonadotropin-releasing hormone (GnRH) or human chorionic gonadotropin (hCG) simulation test; resting serum anti-Müllerian hormone (AMH; see Cryptorchidism).
• Karyotyping—to define chromosomal sex (Molecular Cytogenetics Laboratory, Texas A&M University).

IMAGING

• Routine radiography and ultrasonography—may be of diagnostic value for suspected abdominal mass (e.g., testicular neoplasia with PMDS, testicular feminization, or XX DSD); males with signs referable to pyometra (female pseudohermaphrodite or PMDS). • Contrast studies (lower urogenital tract)—may be useful in diagnosing female pseudohermaphrodites.

PATHOLOGIC FINDINGS

Gross

Precisely describe the genitalia—size and location of the vulva or prepuce; presence and appearance of the clitoris, penis, scrotum, prostate, caudal vagina, or os clitoris; position of the urinary orifice (identifies the phallic structure as penis or clitoris).

Histopathologic

• Examination of all tissues removed—to define the type of disorder. • Gonads—vary from nearly normal architecture to dysgenic or a combination of ovary and testis (ovotestis). • Essential to describe the components of the Müllerian and/or Wolffian duct system, if found.

TREATMENT

APPROPRIATE HEALTH CARE

• Usually outpatient. • Inpatient—if exploratory laparotomy.

NURSING CARE

Phenotypic females with a hypoplastic vulva and perivulvar dermatitis and males with hypospadias—local therapy to improve dermatologic sequelae (see Dermatoses, Erosive or Ulcerative).

SURGICAL CONSIDERATIONS

• Most patients with no identified chromosomal abnormalities—exploratory laparotomy to determine the location and morphology of the gonads and internal genitalia. • Gonadectomy and hysterectomy (if a uterus is found)—recommended. • Amputation of an enlarged clitoris—recommended if the mucosal surface is repeatedly traumatized.
• Reconstructive surgery of the prepuce and malformed penis—dogs; may be necessary with testicular DSD, XX males, or hypospadias.

MEDICATIONS

CONTRAINDICATIONS

Avoid androgen or progestagen use during pregnancy.

FOLLOW-UP

PREVENTION/AVOIDANCE

Sterilize individuals with heritable disorders.

POSSIBLE COMPLICATIONS

• Infertility. • Sterility. • Urinary tract problems—incontinence; cystitis. • Testicular neoplasia.• Pyometra.

MISCELLANEOUS

AGE-RELATED FACTORS

Patients not diagnosed at an early age—pyometra (e.g., PMDS; female pseudohermaphrodite); testicular neoplasia (e.g., PMDS; any DSD with cryptorchidism).

SYNONYMS

• Hermaphrodites. • Intersexes. • Klinefelter syndrome. • Pseudohermaphrodites. • Sex reversal. • Turner syndrome.

SEE ALSO

• Breeding, Timing.
• Cryptorchidism.
• Infertility, Female—Dogs.
• Infertility, Male—Dogs.

ABBREVIATIONS

• AMH = anti-Müllerian hormone.
• DSD = disorders of sexual development.
• GnRH = gonadotropin-releasing hormone.
• hCG = human chorionic gonadotropin.
• PMDS = persistent Müllerian duct syndrome.

SHAKER/TREMOR SYNDROME, CORTICOSTEROID RESPONSIVE

BASICS

OVERVIEW
Fine, rapid, whole-body tremor.

SYSTEMS AFFECTED
Nervous

SIGNALMENT
- Primarily dogs, but similar syndrome recently reported in 2 cats.
- Small to medium-size breed (<15 kg), young adult dogs (<5 years), regardless of coat color.
- Dogs with white-hair coats (e.g., Maltese and West Highland white terriers) historically have been overrepresented.
- Both sexes affected.

SIGNS
- Acute-onset, fine, rapid whole-body tremors.
- Clinical signs initially can be confused with signs of apprehension or hypothermia.
- Less commonly, signs can include abnormal nystagmus, hypermetria, head tilt, menace response deficits, and opsoclonus.

CAUSES & RISK FACTORS
Most often associated with mild inflammatory CNS disease.

S

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Toxin ingestion—mycotoxins (penitrem A, roquefortine); metaldehyde (snail bait); pyrethrins/pyrethroids; organophosphates, many others.
- Seizures.
- Hypomyelination—seen in puppies; chow chow, springer spaniel, Samoyed, Weimaraner, and Dalmatian.
- Metabolic disorder—hypoglycemia, hypoadrenocorticism, hypocalcemia, magnesium imbalance.
- Behavioral—fear.
- Hypothermia.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Cerebellomedullary cistern CSF analysis—mild mononuclear pleocytosis; CSF can be normal.

TREATMENT
Inpatient or outpatient, depending on severity of clinical signs.

MEDICATIONS

DRUG(S) OF CHOICE
- Prednisolone or prednisone (1–2 mg/kg PO q12h) for the first 1–2 weeks.
- Depending on clinical response, taper dosage slowly (usually over 4–6 months); assess periodically for clinical deterioration; if dosage reduced too rapidly, clinical signs may recur, necessitating reintroduction of initial dosage.
- Many patients do not require further treatment.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Corticosteroids—may be contraindicated with infectious encephalitis.

FOLLOW-UP

PATIENT MONITORING
Weekly evaluations for approximately 1 month; then monthly until corticosteroids are discontinued.

EXPECTED COURSE AND PROGNOSIS
- Clinical signs usually subside in 3–7 days from onset of steroid treatment.
- In some patients, recurrence necessitates reinstitution of corticosteroids.
- A small percentage of patients require every-other-day, low-dose corticosteroids, indefinitely, to maintain remission.

MISCELLANEOUS

SYNONYMS
- Idiopathic cerebellitis.
- White shaker syndrome.
- Idiopathic generalized tremor syndrome.

SEE ALSO
- Movement Disorders.
- Tremors.

Author Philip Schissler

SHOCK, CARDIOGENIC

BASICS

DEFINITION
• Severe manifestation of forward heart failure in which patients have both clinical and biochemical evidence of inadequate tissue perfusion. • Profound impairment of cardiac function resulting in poor cardiac output and life-threatening end-organ hypoperfusion and hypoxia in the presence of adequate intravascular volume and systemic vascular resistance. • Cardiac impairment may result from systolic dysfunction (dilated cardiomyopathy, sepsis, myocarditis, ischemia), diastolic dysfunction (hypertrophic cardiomyopathy, restrictive cardiomyopathy, tension pneumothorax/mediastinum, restrictive pericarditis, pericardial tamponade), conduction defects and arrhythmias, valvular diseases, obstructive diseases, pulmonary thromboembolism, and structural defects. Understanding the underlying defect and its hemodynamic consequences is imperative to institute appropriate therapy. • In congestive heart failure (CHF), sometimes referred to as backward heart failure, the ventricle cannot adequately pump out the returning blood, resulting in systemic and/or pulmonary edema. This is in contrast to forward heart failure, when the heart is not pumping enough blood out to meet the needs of the body. Most, but not all, veterinary patients that present in cardiogenic shock will have concurrent CHF.

PATHOPHYSIOLOGY
• Decreased cardiac output leads to hypotension and systemic hypoperfusion. • Hypotension decreases coronary perfusion, resulting in ischemia that provokes further myocardial dysfunction. • Peripheral vasoconstriction increases myocardial work and exacerbates tissue ischemia and energy depletion, resulting in organ dysfunction.

SYSTEMS AFFECTED
• Cardiovascular—cardiac dysfunction is causative, myocardial ischemia exacerbates cardiac dysfunction. • Musculoskeletal—weakness. • Nervous—altered mental status. • Respiratory—as cardiac dysfunction progresses and atrial pressure increases, pulmonary edema and/or pleural effusion develop and hypoxemia ensues. • Endocrine—hyperglycemia and insulin resistance. • Gastrointestinal—mucosal necrosis and sloughing, hemorrhage, bacterial translocation. • Hepatobiliary—hepatocellular enzyme leakage, cholestasis, reduced clearance of bacteria and bacterial by-products, and abnormal synthetic function; hepatic congestion may result from right-sided CHF. • Renal—ischemic tubular damage, oliguria, development of acute kidney injury. • Hemic—homeostatic imbalances lead to microvascular thrombosis.

GENETICS
Many breeds are predisposed to specific cardiac diseases.

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
Unknown

SIGNALMENT
• Dog and cat. • Any breed, age, or sex.

SIGNS

Historical Findings
• Cardiac decompensation may be associated with a history of previously compensated heart disease and cardiac drug administration. • A suspicion of previously undiagnosed cardiac disease may result from a history of coughing, exercise intolerance, weakness, or syncope.

Physical Examination Findings
• Markers of poor perfusion: ○ Weakness. ○ Altered mental status. ○ Cool extremities and hypothermia. ○ Pale mucous membranes. ○ Prolonged capillary refill time. ○ Weak femoral pulse quality. ○ Oliguria. • Muffled heart sounds if pericardial or pleural effusion is present. • Variable heart rate with possible cardiac arrhythmia, murmur or gallop sound. • Variable respiratory rate with possible increased bronchovesicular sounds, crackles, or moist cough.

CAUSES

Primary Cardiac Disease
• All cardiomyopathies (e.g., dilated, hypertrophic, unclassified, restrictive). • Severe mitral insufficiency or other end-stage valvular disease. • Chordae tendineae rupture. • Tachy- or brady-arrhythmias. • Myocarditis. • Endomyocarditis (cats). • Structural defects (e.g. congenital heart disease).

Secondary Cardiac Dysfunction
• Cardiac tamponade. • Sepsis. • Severe electrolyte derangement. • Pulmonary thromboembolism. • Tension pneumothorax/mediastinum. • Caval syndrome.

RISK FACTORS
• Underlying cardiac disease. • Concurrent illness causing hypoxemia, acidosis, electrolyte imbalances, or as in sepsis, release of myocardial depressant factors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Cardiogenic shock is differentiated from other causes of circulatory shock when there is evidence of decreased cardiac output and tissue hypoxia in the face of adequate intravascular volume and systemic vascular resistance.

CBC/BIOCHEMISTRY/URINALYSIS

CBC
Mature neutrophilia and lymphopenia secondary to stress.

Biochemistry Panel
• Hyperglycemia—stress. • Elevated anion gap—accumulation of lactic and renal acids. • Elevated hepatocellular enzyme activity—hepatic hypoxia. • Elevated phosphorus—decreased glomerular filtration rate (GFR). • Azotemia—decreased GFR or hypoxia induced renal injury. • Hyponatremia and mild hypoalbuminemia—suggestive of chronic CHF.

Urinalysis
Isosthenuria—concomitant diuretic therapy or acute kidney injury.

OTHER LABORATORY TESTS
• Blood gas analysis—metabolic acidosis, respiratory alkalosis or acidosis, hypoxemia, and evidence of increased tissue oxygen extraction (widened arteriovenous oxygen difference and/or decreased venous oxygen concentration in the absence of hypoxemia or anemia). • Hyperlactatemia—tissue hypoperfusion. • Increased cardiac troponin I levels—sensitive and specific marker of myocardial injury. • B-type natriuretic peptide (NT-proBNP)—useful in ruling out intrinsic cardiac dysfunction.

IMAGING

Radiographs
Thoracic radiography may reveal cardiomegaly and evidence of CHF (pulmonary edema, pleural effusion).

Cageside Focused Pulmonary and Cardiac Ultrasound
• Lung ultrasound may reveal pleural effusion and/or B-lines (CHF). • Cardiac ultrasound to detect pericardial tamponade; patients with cardiogenic shock secondary to primary cardiac disease and some with secondary causes will have an increased left atrial size.

Echocardiography
To characterize cardiomyopathy, valvular disease, myocardial contractility, structural disease, pericardial disease, and heartworm infection.

DIAGNOSTIC PROCEDURES
Thoraco-, abdomino-, and pericardiocentesis when indicated may elucidate underlying etiology.

PATHOLOGIC FINDINGS
Cardiac abnormalities consistent with various underlying etiologies; abnormalities consistent with tissue hypoxia and CHF.

TREATMENT

APPROPRIATE HEALTH CARE
Emergency inpatient intensive care management.

SHOCK, CARDIOGENIC (CONTINUED)

NURSING CARE
• Minimize stress—patients are extremely fragile and at risk of cardiac arrest. • Oxygen supplementation. • Pleural effusion—relieve with thoracocentesis. • Respiratory failure—may require mechanical ventilation. • Patients should *not* receive *any* fluid therapy until the etiology of the underlying cardiac dysfunction is understood and cardiac function improved; exceptions include cardiogenic shock secondary to pericardial tamponade, tension pneumothorax and mediastinum, and pulmonary thromboembolism. • Pericardial tamponade—relieve with pericardiocentesis.

ACTIVITY
Minimize patient exertion.

DIET
Free choice access to water; withhold food until shock is resolved.

CLIENT EDUCATION
Discuss risk of imminent cardiac arrest and confirm "code status" in advance if possible.

SURGICAL CONSIDERATIONS
• Bradyarrhythmia may require pacemaker implantation. • Tension pneumothorax may require thoracostomy tube placement or exploratory thoracotomy. • Caval syndrome secondary to *Dirofilaria immitis* infection requires worm extraction.

S

MEDICATIONS

DRUG(S) OF CHOICE
• Fast-acting positive inotropes to improve cardiac function and preserve end-organ perfusion in patients with reduced myocardial contractility (pimobendan 0.25–0.3 mg/kg PO q12h in dogs and cats [IV formulation available in some countries]; dobutamine 5–20 µg/kg/min CRI in dogs; 2.5–15 µg/kg/min CRI in cats). While dobutamine can be used safely in many feline patients, seizures have been observed in some cats at doses exceeding 5 µg/kg/min. • Arrhythmias and conduction abnormalities should be corrected promptly with antiarrhythmic therapy, cardioversion, or pacemaker implantation. • Ventricular tachycardia: ○ Dogs—lidocaine (2–4 mg/kg slow IV loading dose then 25–100 µg/kg/min CRI) or procainamide (5–15 mg/kg slow IV loading dose then 25–50 µg/kg/min CRI). Due to many common adverse effects, amiodarone (2–5 mg/kg IV, infused over 30–60 minutes) should only be used short term and the formulation should not contain polysorbate-80. • Sotalol (1–2.5 mg/kg PO, bid). Use with caution and at the lower end of the dosage range in dogs with concurrent CHF or DCM. ○ Cat procainamide (1–2 mg/kg IV slowly over 20 minutes) or lidocaine (0.25–0.5 mg/kg slow IV bolus then if needed 10–20 µg/kg/min). Caution when using lidocaine in cats as they may be at higher risk of toxicosis. • Supraventricular tachyarrhythmia: ○ Treatments to slow the heart rate include vagal maneuvers, calcium channel blockers (diltiazem 0.125–0.35 mg/kg IV over 2–3 minutes or 0.125–0.35 mg/kg/h CRI), beta-blockers (esmolol 0.5 mg/kg IV over 1 minute), and procainamide (6–8 mg/kg IV over 5–10 minutes then 20–40 µg/kg/min CRI). ○ Patients unresponsive to vagal maneuvers or emergency drug therapy may require DC cardioversion or overdrive pacing. • Bradyarrhythmia: ○ Cardiac pacing. ○ Some patients may benefit from atropine (0.02–0.04 mg/kg IV) or isoproterenol (0.4 mg in 250 mL D_5W slowly to effect). • Concurrent CHF: ○ Furosemide to treat pulmonary edema in dogs and cats (2–8 mg/kg IV or IM; or 0.5–1.0 mg/kg/h CRI); IV route is preferable, but IM is appropriate when manual restraint to obtain IV access puts the patient at risk. ○ Relief of pain or anxiety with morphine sulfate (0.1–0.5 mg/kg/h IV CRI, or 0.2–2 mg/kg IM) can reduce excessive sympathetic activity and decrease oxygen demand, preload, and afterload.

CONTRAINDICATIONS
• Avoid diuretic therapy in patients with pericardial tamponade, tension pneumothorax/mediastinum, and pulmonary thromboembolism. • Avoid beta-blockers and calcium channel blockers in patients with reduced myocardial contractility.

PRECAUTIONS
• Catecholamine infusions must be carefully titrated to maximize coronary perfusion with the least possible increase in myocardial oxygen demand. • Afterload reducers and vasodilators (angiotensin-converting enzyme inhibitors, nitroglycerin, and nitroprusside) should be used with caution because of the risk for worsening hypotension and decreasing coronary blood flow.

ALTERNATIVE DRUG(S)
Dopamine may be used to improve systolic function as an alternative to dobutamine at a dose of 5–10 µg/kg/min (dogs and cats).

FOLLOW-UP

PATIENT MONITORING
• Serial assessment of perfusion (mentation, mucous membrane color, capillary refill time, pulse quality, muscle strength, temperature, serum lactate, urine output, heart rate, BP, and oxygenation indices), respiratory rate and effort, and pulmonary auscultation is required to optimize therapy. • Blood gas analysis and pulse oximetry to assess tissue oxygenation, ventilation, and acid–base balance. • Packed cell volume, serum total protein, serum electrolytes, hepatocellular enzymes, BUN, and serum creatinine to monitor effects of systemic tissue hypoxia. • Daily cardiac troponin I levels to assess degree of myocardial injury in some cases. • BP measurement may document hypotension. • Electrocardiography may aid detection and characterization of arrhythmias. • Pulse oximetry may document low oxygen saturation. • Central venous pressure monitoring may aid in assessment of cardiac preload and central venous oxygen saturation. • Hemodynamic monitoring to assess mixed venous oxygen saturation, cardiac output and systemic vascular resistance.

PREVENTION/AVOIDANCE
Prevention strategies aimed at the various underlying etiologies.

POSSIBLE COMPLICATIONS
• CHF. • Cardiac arrhythmias. • Syncope. • Acid–base and electrolyte disturbances. • Renal dysfunction. • Cardiac arrest.

EXPECTED COURSE AND PROGNOSIS
Dependent on underlying etiology. Patients with primary cardiac disease have generally worse prognosis (poor to grave) as compared to those with secondary cardiac dysfunction.

MISCELLANEOUS

ASSOCIATED CONDITIONS
CHF

AGE-RELATED FACTORS
Variable, depending on underlying etiology.

ZOONOTIC POTENTIAL
None

PREGNANCY/FERTILITY/BREEDING
Variable, depending on underling etiology.

SHOCK, HYPOVOLEMIC

BASICS

DEFINITION
Inadequate circulating volume and perfusion due to fluid loss.

PATHOPHYSIOLOGY
- Hemorrhage or other fluid loss results in a critical decrease in intravascular volume, diminished venous return, and decreased cardiac output.
- Compensatory neuroendocrine responses lead to peripheral vasoconstriction thus exacerbating tissue ischemia and energy depletion, resulting in organ dysfunction.

SYSTEMS AFFECTED
- Cardiovascular—increased heart rate, increased cardiac contractility, and peripheral vasoconstriction; increased cardiac oxygen demand in the face of reduced oxygen delivery may cause arrhythmias.
- Respiratory—hyperventilation to compensate for metabolic acidosis.
- Musculoskeletal—weakness.
- Nervous—altered mental status.
- Endocrine—hyperglycemia and insulin resistance.
- Gastrointestinal (GI)—mucosal necrosis and sloughing, hemorrhage, bacterial translocation.
- Hepatobiliary—hepatocellular enzyme leakage, cholestasis, reduced clearance of bacteria and their by-products, abnormal synthetic function.
- Renal—ischemic tubular damage, oliguria, acute kidney injury.
- Hemic—homeostatic imbalances lead to microvascular thrombosis as well as hyper- and hypocoagulability.

GENETICS
N/A

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
- Dog and cat.
- Any breed, age, or sex.

SIGNS

Historical Findings
May have history of trauma, weakness, collapse, surgery, vomiting, diarrhea, decreased water intake, and polyuria.

Physical Examination Findings
- Compensated shock/warm shock/preshock:
  - Compensatory mechanisms may allow an otherwise healthy pet to be relatively asymptomatic despite a 10% reduction in total effective blood volume. When homeostatic mechanisms fail, decompensated shock ensues.
- Decompensated shock:
  - Poor perfusion (pale mucous membranes [may be compounded by anemia], prolonged capillary refill time, weak peripheral pulses, weakness, altered mental status, hypothermia/cool extremities, oliguria).
  - Absent/minimal jugular vein distension.
  - Tachycardia ± arrhythmia.
  - Tachypnea.
  - Clinical dehydration (decreased skin turgor, tacky mucous membranes, and sunken eyes) more common in patients with fluid loss than hemorrhage.

CAUSES

Hemorrhage
- Trauma.
- Ruptured neoplasm.
- GI bleeding (e.g., ulcerative disease, neoplasia, severe thrombocytopenia).
- Coagulopathy (e.g., severe thrombocytopenia/thrombocytopathy, von Willebrand factor deficiency, anticoagulant rodenticide intoxication, synthetic liver failure, disseminated intravascular coagulation, hemophilia, other bleeding disorders).

Fluid Loss
- GI (vomiting and diarrhea).
- Urinary (renal failure, diabetes mellitus, diabetes insipidus, hypercalcemia, Addison's, and Cushing's diseases).
- Burns.
- Third spacing (any disease resulting in significant effusion).

RISK FACTORS
No specific risk factors; caused by another condition.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Hypovolemic shock differentiated from other causes of circulatory shock when inadequate circulating volume results in decreased cardiac output in the face of normal or increased cardiac function and normal or increased systemic vascular resistance.

CBC/BIOCHEMISTRY/URINALYSIS

CBC
- Stress leukogram.
- Hematocrit and platelet count are variable (may be decreased with hemorrhage).

Biochemistry Panel
- Hyperglycemia.
- Variable total protein (TP) and albumin (decreased with hemorrhage; increased in fluid loss).
- Elevated hepatocellular enzyme activity (alanine aminotransferase, aspartate aminotransferase).
- Variable electrolyte derangements (more likely in fluid loss).
- Variable anion gap.
- Azotemia due to decreased glomerular filtration rate.

Urinalysis
- Urine specific gravity may be increased; however, acute tubular injury due to renal hypoxia may cause isosthenuria.

OTHER LABORATORY TESTS
- Blood gas analysis may reveal metabolic acidosis and evidence of increased tissue oxygen extraction (widened arteriovenous oxygen difference and/or decreased venous oxygen concentration in a patient without hypoxemia or anemia).
- Hyperlactatemia reflects decreased clearance and increased production of lactate.
- Coagulation testing if critically ill or if evidence of significant hemorrhage.

IMAGING
- Thoracic radiography may reveal microcardia and pulmonary vascular underperfusion.
- May have radiographic or ultrasonographic findings of pleural or abdominal effusion.

DIAGNOSTIC PROCEDURES
Thoracocentesis, abdominocentesis, or pericardiocentesis, if indicated, may provide insight into underlying etiology.

PATHOLOGIC FINDINGS
Consistent with tissue hypoxia and underlying etiology.

TREATMENT

APPROPRIATE HEALTH CARE
Emergency inpatient intensive care management.

NURSING CARE
- Maximize blood oxygen content:
  - Assess and stabilize airway and breathing as necessary.
  - Supplemental oxygen and ventilatory support as needed.
  - Significant anemia (packed cell volume [PCV] <25–30%) in a hypovolemic patient is concerning and should be corrected.
- Control further fluid loss:
  - External bleeding controlled with direct pressure; internal bleeding may require surgical intervention.
- Control of fluid loss, other than hemorrhage, aimed at control of signs (e.g., antiemetics) and correcting underlying disorder.
- Fluid resuscitation:
  - Once IV or IO access obtained, initial fluid resuscitation performed with isotonic crystalloid such as lactated Ringer's solution, normal saline, Plasmalyte-A, and

SHOCK, HYPOVOLEMIC (CONTINUED)

Normosol-R (20–30 mL/kg, dog; 15–20 mL/kg, cat; over 15 minutes). If no significant dehydration and no other contraindications, addition of 7.5% hypertonic saline (4 mL/kg over 15 minutes) may expedite resuscitation.
  - Assess response to initial bolus. If vital signs and other resuscitation parameters return to normal, monitoring must be continued to ensure stability. If vital signs and other resuscitation parameters transiently improve or if little or no improvement seen, another crystalloid bolus should be infused and colloids such as hydroxyethylstarch (dose variable, dependent on type) or appropriate blood products (10–20 mL/kg) considered.
  - Process is repeated until resuscitation parameters normalize. When bolusing fluids to correct perfusion deficits, monitor not only for response to therapy, but also for potential complications.
  - While fluid boluses are used to correct perfusion deficits, hydration deficits must be corrected more slowly. After perfusion has normalized, patient is reassessed and fluid therapy targeted to correct hydration deficits over 12–24 hours.
- Traditional endpoints of resuscitation (restoration of normal vital signs, blood pressure, and urine output) remain the standard of care; however, it has been documented that critically ill patients have evidence of ongoing tissue hypoxia despite normalization of these parameters, suggesting occult oxygen debt and the presence of compensated shock. There is evidence that normalization of vital signs, blood lactate, base deficit, and oxygen transport indices such as cardiac index, oxygen delivery, oxygen consumption, and mixed venous oxygen and central venous oxygen saturation in concert are more sensitive markers for adequacy of tissue perfusion than any of these variables alone. Until stronger support exists for preferential selection of one endpoint over others, utilization of as many of these markers as are available seems advisable.

ACTIVITY
Minimize patient exertion.

DIET
Withhold oral intake until shock is resolved.

CLIENT EDUCATION
Discuss risk of cardiac arrest and confirm "code status" in advance if possible.

SURGICAL CONSIDERATIONS
Identify and repair source of fluid loss (most common in hemorrhage-induced).

MEDICATIONS

DRUG(S) OF CHOICE
- For patients with refractory hypovolemic shock, rule out ongoing losses (especially if hemorrhage-induced); administer blood products as needed.
- If adequate circulating volume is assured and patient is still demonstrating clinical signs of shock (not very common with hypovolemic shock), consider:
  - Pressors such as dopamine (5–20 µg/kg/min), norepinephrine (0.05–2 µg/kg/min), or vasopressin (0.5–2 mU/kg/min). These can be used for vasopressor support in dogs and cats. Monitor for tachyarrhythmia and excessive peripheral vasoconstriction.
  - Positive inotropes such as dobutamine (2–20 µg/kg/min) may be beneficial in patients with decreased contractility or myocardial depression. Monitor for tachyarrhythmia. While dobutamine can generally be used safely in dogs, seizures have been observed in some cats at doses exceeding 5 µg/kg/min.
- For bleeding dogs, antifibrinolytic medications such as ε-aminocaproic acid (50–100 mg/kg IV or PO q6h) or tranexamic acid (10 mg/kg IV bolus over 20 minutes, followed by 10 mg/kg/h IV CRI for 3 hours, then 10 mg/kg over 20 minutes q6h) may be considered.

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
- Serial assessment of perfusion:
  - Physical exam including mentation, mucous membrane color, capillary refill time, pulse quality, muscle strength, temperature, and heart rate.
  - Hemodynamic monitoring to include arterial blood pressure (frequently reveals disproportionately low diastolic pressure), and in a subset of patients central venous pressure, cardiac output and tissue oxygenation.
  - Laboratory data including serum lactate and base deficit; patients with hemorrhage-induced hypovolemic shock should have minimum of daily PCV, and TP assessed more frequently.
- Serial assessment of respiratory rate and effort, and pulmonary auscultation is required to optimize therapy.
- Urine output as indicator of glomerular filtration rate and renal blood flow.
- ECG may aid in characterization of arrhythmias.
- Minimum of daily PCV, serum TP, blood glucose, blood gas, serum electrolytes, hepatocellular enzymes, BUN, and serum creatinine to monitor effects of systemic tissue hypoxia and to guide clinical management.

PREVENTION/AVOIDANCE
Prevention strategies aimed at the various underlying etiologies.

POSSIBLE COMPLICATIONS
- Acid–base disturbances.
- Anemia and thrombocytopenia.
- Multiple organ dysfunction.
- Low colloid oncotic pressure.
- Volume overload with clinical signs of pulmonary and/or peripheral edema.
- Dilutional coagulopathy can occur in patients receiving very large resuscitation volumes (more than 1–2 blood volumes), due to dilution of clotting factors and proteins respectively, but is rare within the first hour of resuscitation. Coagulation times should be used to guide the administration of fresh frozen plasma.
- Cardiac arrest.

EXPECTED COURSE AND PROGNOSIS
Depends on underlying etiology and ability to institute appropriate therapy.

SHOCK, SEPTIC

BASICS

DEFINITION
Sepsis-induced hypotension, attributable to low systemic vascular resistance that persists despite adequate intravascular volume and cardiac output.

PATHOPHYSIOLOGY
• In sepsis, an elaborate interaction of inflammatory cells and mediators decreases systemic vascular resistance and provokes maldistribution of blood flow (distributive effect). Vasodilation is primarily mediated by increased nitric oxide and prostacyclin synthesis induced by endotoxin and inflammatory cytokine interaction with vascular endothelial cells. In the face of severe arterial vasodilation, cardiac output is insufficient to maintain tissue oxygen delivery. • Infectious agents trigger large-scale activation of monocytes, macrophages, and neutrophils that interact with endothelial cells, inducing a generalized inflammatory response. Endothelial injury is a universal feature, mediated by cellular and humoral factors that increase capillary permeability, and fluid shifts out of the intravascular space. Presence of interstitial edema and microvascular sludging further compound oxygen delivery, and tissue hypoxia leads to organ failure and death.

SYSTEMS AFFECTED
• Cardiovascular—arterial vasodilation and maldistribution of blood flow with hypotension predominates; cardiac output frequently normal or high; however, myocardial dysfunction due to circulating factors can be important. • Nervous—altered mental status. • Endocrine—may have hyperglycemia and insulin resistance, or insufficient production of either corticosteroids or vasopressin. • Gastrointestinal—mucosal necrosis, hemorrhage, bacterial translocation. • Respiratory—interstitial and alveolar edema due to enhanced microvascular permeability; hypercoagulopathy may result in pulmonary thromboembolism. • Hepatobiliary—hepatocellular enzyme leakage, cholestasis, reduced bacterial clearance, hypoglycemia and abnormal synthesis. • Hemic—microvascular thrombosis, hyper- and hypocoagulopathy. • Renal—ischemic tubular damage, oliguria, acute kidney injury.

GENETICS
N/A

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
• Dog and cat. • Any breed, age, or sex.

SIGNS
Historical Findings
Recent infection, injury, serious illness, surgery, or immunosuppression.

Physical Examination Findings
• Dogs may have a hyperdynamic form, typified by altered mental status, weakness, hypotension, tachycardia, tachypnea, hyperemia, fast capillary refill time (CRT), bounding pulses, and fever. Cats rarely have hyperdynamic signs. • Patients with the hypodynamic form are more likely to exhibit altered mental status, weakness, hypotension, bradycardia, tachypnea, pale mucous membranes, prolonged CRT, weak pulses, and hypothermia.

CAUSES
• Septic peritonitis—ruptured viscus; penetrating wound. • Respiratory and pleural space—pneumonia, pyothorax. • Skin or soft tissue—wounds, burns, cellulitis, abscess. • Urinary tract—pyelonephritis. • Reproductive—prostatitis, metritis, pyometra. • Cardiovascular—endocarditis, bacteremia. • Musculoskeletal—septic arthritis, osteomyelitis. • Iatrogenic—catheters, implants, surgical sites. • CNS—meningitis, encephalitis.

RISK FACTORS
• Extremes of age. • Concurrent disease (e.g., diabetes mellitus, Cushing's disease, malignancy). • Immunosuppression. • Surgery, trauma, burns. • Prior antibiotics.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Other causes of distributive shock (e.g., drug/toxin reaction, anaphylaxis, adrenal insufficiency). • Hypovolemic shock. • Cardiogenic shock. • Heatstroke.

CBC/BIOCHEMISTRY/URINALYSIS
• Neutrophilia or neutropenia, left shift, and toxic change. • Lymphopenia. • Thrombocytopenia. • Variable hematocrit and blood glucose. • Hypoalbuminemia. • Elevated bilirubin and liver enzyme activity. • Electrolyte derangements. • Azotemia. • Isosthenuria and variably active urine sediment.

OTHER LABORATORY TESTS
• Prolonged activated partial thromboplastin and prothrombin times, increased D-dimers and fibrin degradation products, and decreased levels of antithrombin and protein C. • Blood gases may reveal hypoxemia and acid–base disturbances. • Hyperlactatemia. • Cytology, Gram stain, and culture and sensitivity on samples obtained from potential sites of infection may reveal etiologic organisms. • Culture and sensitivity of urine and blood may be useful when the source of sepsis is unknown. • Adrenocorticotropic hormone (ACTH) stimulation test in patients unresponsive to standard therapy.

IMAGING
• Thoracic radiographs and CT may reveal septic focus or cause for respiratory dysfunction; may also provide insights into volume status. • Echocardiography may document a vegetative valvular lesion and/or characterize cardiac function and volume status. • Abdominal ultrasonography and CT may detect source of infection.

DIAGNOSTIC PROCEDURES
When indicated, tissue aspirates, thoraco-, abdomino-, and arthrocentesis may provide insight into underlying etiology.

PATHOLOGIC FINDINGS
Consistent with inflammation, tissue hypoxia, and underlying etiology.

TREATMENT

APPROPRIATE HEALTH CARE
Emergency inpatient intensive care management. Early surgical intervention when possible to control source of infection.

NURSING CARE
Maximize Blood Oxygen Content
• Assess and stabilize the airway and breathing as necessary. • Administer supplemental oxygen and provide ventilatory support as needed. • Significant anemia (packed cell volume [PCV] <25%) should be corrected.

Resuscitation
Most septic patients are hypovolemic and require initial fluid resuscitation with isotonic crystalloids such as lactated Ringer's solution, normal saline, Plasmalyte-A, and Normosol-R (20–30 mL/kg, dog; 15–20 mL/kg, cat, over 15 minutes). If no significant dehydration, addition of 7.5% hypertonic saline (4 mL/kg over 15 minutes) may expedite resuscitation: • After the initial bolus, patient is reassessed. If vital signs and other resuscitation parameters normalize, continue monitoring to ensure stability. If vital signs and other resuscitation parameters transiently improve or if little or no improvement is seen and patient is still deemed hypovolemic, sequential crystalloid boluses should be infused and colloids (dose variable, dependent on type) may be considered. • Septic patients receiving large fluid volumes may achieve adequate circulating volume without normalization of BP and other perfusion parameters. Continued aggressive fluid therapy in these patients will result in volume overload and vasopressors and/or positive inotropes are indicated. Monitor closely since infusion of large volumes may precipitate pulmonary

SHOCK, SEPTIC (CONTINUED)

edema in patients with capillary leak. • IV fluids, vasopressors, and positive inotropes are titrated until resuscitation endpoints have been achieved. Traditional endpoints of resuscitation (restoration of normal vital signs, BP, and urine output) remain the standard of care; however, it has been documented that critically ill patients have evidence of ongoing tissue hypoxia despite normalization of these parameters, suggesting occult oxygen debt and presence of compensated shock. There is evidence that normalization of vital signs, blood lactate, base deficit, and oxygen transport indices are more sensitive markers for adequacy of tissue perfusion than any of these variables alone. Until stronger support exists for preferential selection of one endpoint over others, utilization of as many of these markers as are available seems advisable. • Blood products should be administered based on patient need. Packed red blood cells are administered to anemic patients to improve oxygen-carrying capacity and plasma products are used to correct coagulation deficits.

ACTIVITY
Minimize patient exertion.

DIET
Withhold oral intake until shock is resolved.

S

CLIENT EDUCATION
Discuss risk of cardiac arrest and confirm "code status" in advance if possible.

SURGICAL CONSIDERATIONS
Identify and eliminate infection source when, and as early as, possible.

MEDICATIONS

DRUG(S) OF CHOICE
• Once adequate circulating volume is achieved, improvement in systemic BP and other clinical resuscitation parameters may require one or more vasopressors and/or positive inotropes: ○ Norepinephrine (0.05–2 µg/kg/min), vasopressin (0.5–2 mU/kg/min), or dopamine (5–20 µg/kg/min) can be used for vasopressor support (dogs and cats). Monitor for tachyarrhythmia and excessive peripheral vasoconstriction. ○ Dobutamine (2–20 µg/kg/min) is primarily used as a positive inotrope in canine septic shock patients with decreased contractility or myocardial depression. Monitor for tachy-arrhythmia. While dobutamine can be used safely in many feline patients, seizures have been observed in some cats at doses exceeding 5 µg/kg/min. • It is essential that IV, empiric, broad-spectrum antibiotic therapy be instituted early in septic patients; the spectrum should be narrowed when culture results become available. Empiric selection based on patient's underlying immune status, suspected source and organism(s) responsible, specific antibiotic properties (tissue penetration, cidal versus static activity), and considerations for resistance (previous antibiotic use, hospital- or community-acquired infection). • It is not unreasonable to empirically treat patients not responding adequately to standard therapy with 0.75–1.0 mg/kg q6h IV hydrocortisone after undergoing a standard ACTH stimulation test. Therapy should be continued in patients in whom relative adrenal insufficiency is documented.

CONTRAINDICATIONS

FOLLOW-UP

PATIENT MONITORING
• Serial assessment of perfusion to optimize titration of fluids and vasoactive drugs: ○ Physical exam including mentation, mucous membrane color, CRT, pulse quality, muscle strength, temperature, and heart rate. ○ Hemodynamic monitoring to include arterial BP (frequently reveals disproportionately low diastolic pressure), and in some patients central venous pressure, cardiac output, and tissue oxygenation. ○ Thoracic ultrasound to monitor for pulmonary changes and to aid in assessing patient volume status and cardiac systolic function. ○ Laboratory data including serum lactate and base deficit. • Blood gas analysis and pulse oximetry to follow tissue oxygenation, ventilation, and acid–base status. • Serial assessment of respiratory rate and effort, and pulmonary auscultation. • Continuous ECG to detect arrhythmia. • Urine output as an indicator of glomerular filtration rate and renal blood flow. • Minimum of twice daily PCV, serum total protein, blood glucose, and serum electrolytes; once daily hepatocellular enzymes, blood urea nitrogen, and serum creatinine to monitor effects of systemic tissue hypoxia. Patients with coagulopathy should have coagulation indices, PCV and total protein assessed as needed.

PREVENTION/AVOIDANCE
• Timely and effective wound treatment.
• Appropriate antimicrobial therapy.

POSSIBLE COMPLICATIONS
• Volume overload. • Pulmonary edema. • Vasculitis and peripheral edema. • Acid–base disturbances. • Anemia. • Thrombocytopenia and other coagulopathy. • Multiple organ dysfunction. • Cardiac arrest.

EXPECTED COURSE AND PROGNOSIS
Dependent on underlying etiology and ability to institute appropriate therapy.

SHOULDER JOINT, LIGAMENT, AND TENDON CONDITIONS

BASICS

DEFINITION
These make up the majority of causes for lameness in the canine shoulder joint, excluding osteochondritis dissecans lesions.

PATHOPHYSIOLOGY

Bicipital Tenosynovitis
- Strain injury to the tendon of the biceps brachii.
- Mechanism of injury—direct trauma; indirect trauma (more common).
- Pathologic changes—from partial disruption of the tendon to chronic inflammatory changes, including dystrophic calcification.
- Proliferation of the fibrous connective tissue and adhesions between the tendon and the sheath—limit motion; cause pain.

Fibrotic Contracture of the Infraspinatus Muscle
- Primary muscle–tendon disorder—not a neuropathy.
- Fibrous tissue replaces normal muscle.
- Loss of elasticity and function.
- Degeneration and atrophy of affected muscle.
- Partial muscle disruption—likely caused by repetitive strain injuries.

Medial Shoulder Instability
- Structural damage (stretch and rupture) of the capsulotendinous structures of the medial joint—the medial glenohumeral ligament, subscapularis tendon, and medial joint capsule.
- Likely secondary to repetitive strain injury—overuse injury vs. altered shoulder mechanics due to concurrent ipsilateral elbow disease.

Other
- Rupture of the biceps brachii tendon of origin—strain injury or disruption of the tendinous fibers at or near the junction with the supraglenoid tubercle of the scapula.
- Mineralization of the supraspinatus tendon; granular deposits between the fibers of the tendon; unknown cause; probably repetitive strain injury.
- Avulsion or fracture of the insertion of the supraspinatus tendon—bone is avulsed from the greater tubercle of the proximal humerus.
- Strain injury to other muscles/tendons in the region.

SYSTEMS AFFECTED
Musculoskeletal

INCIDENCE/PREVALENCE
Common cause of forelimb lameness.

SIGNALMENT

Species
Dog

Breed Predilections
Medium- to large-breed dogs.

Mean Age and Range
- Skeletally mature dogs ≥1 year of age.
- Usually 3–7 years of age.

SIGNS

Historical Findings
- Bicipital tenosynovitis—onset usually insidious; often of several months duration; may be a traumatic incident as the inciting cause; subtle, intermittent lameness that worsens with exercise.
- Rupture of the biceps brachii tendon of origin—similar to bicipital tenosynovitis; may have acute onset due to a known traumatic event; usually subtle, chronic lameness that worsens with exercise.
- Medial shoulder instability— onset usually insidious; often of several months duration; may be a traumatic incident as the inciting cause; subtle, intermittent lameness that worsens with exercise.
- Mineralization of the supraspinatus tendon—onset usually insidious; chronic lameness that worsens with activity.
- Avulsion/fracture of the supraspinatus tendon—similar to mineralization of supraspinatus tendon.
- Fibrotic contracture of the infraspinatus muscle—usually sudden onset of lameness during a period of outdoor exercise (e.g., hunting); shoulder lameness and tenderness gradually disappears within 2 weeks; condition results in chronic, persistent lameness 3–4 weeks later, which is not particularly painful but has characteristic gait and limb carriage.

Physical Examination Findings
- Bicipital tenosynovitis—short and limited swing phase of gait owing to pain on extension and flexion of the shoulder; pain inconsistently demonstrated on manipulation of shoulder; pain most evident by applying deep digital pressure over the tendon in the intertubercular groove region while simultaneously flexing the shoulder and extending the elbow.
- Rupture of the biceps brachii tendon—similar to above, however full rupture will result in exaggerated extension of the elbow with simultaneous flexion of the shoulder (when compared to the contralateral side).
- Medial shoulder instability—pain on abduction of the thoracic limb with excessive abduction when compared to the contralateral side. Under sedation, abnormal abduction angles have been measured to be approximately 50 degrees, while normal abduction angles are approximately 30 degrees.
- Mineralization of the supraspinatus tendon—similar; manipulations often do not produce pain; may palpate firm swelling over the greater tubercle.
- Avulsion or fracture of the supraspinatus tendon—similar to mineralization of the supraspinatus tendon.
- Fibrotic contracture of the infraspinatus muscle—usually not painful on manipulation; not possible to internally rotate (pronate) the shoulder joint; when forced, the caudal aspect of the scapula elevates off the trunk, when standing—elbow adducted; paw abducted and outwardly rotated; when patient is walking—lower limb swings in a lateral arc (circumduction) as the paw is advanced; marked atrophy of the infraspinatus muscle on palpation.

CAUSES
- Indirect or direct trauma—likely.
- Repetitive strain injury (indirect trauma)—most common.

RISK FACTORS
- Overexertion and/or fatigue.
- Poor conditioning before performing athletic activities.
- Obesity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Examination, palpation, and radiography that localizes disease to the shoulder will only be accurate 80% of the time—20% of the time, disease localized to the shoulder will actually be the result of elbow pathology/dysplasia.
- Luxation or subluxation of the shoulder joint—history of trauma with an acute onset of lameness; often severe lameness with marked pain on manipulation of the shoulder joint.
- Osteosarcoma of the proximal humerus—progressive lameness with varying degrees of pain on manipulation of the shoulder; may note swelling and tenderness of the proximal humerus.
- Brachial plexus nerve sheath tumor—slow, insidious, progressive lameness over a period of months; marked atrophy of the muscles with chronic disease; may feel a firm mass deep in the axillary region that is painful to digital pressure.

IMAGING

Radiology
- Required for differentiation.
- Craniocaudal and mediolateral views necessary for all patients.
- Skyline projections are helpful for highlighting the biceps groove.

Bicipital Tenosynovitis
- Radiographs generally normal with recent injuries.
- Mediolateral view (chronic disease)—may see bony reaction on the supraglenoid tubercle,

SHOULDER JOINT, LIGAMENT, AND TENDON CONDITIONS (CONTINUED)

dystrophic calcification of the bicipital tendon, sclerosis of the floor of the intertubercular groove, and osteophytes in the intertubercular groove (also in the skyline view).

Ruptured Origin of the Biceps Brachii Tendon

Chronic disease—may see bony, irregular reaction on the supraglenoid tubercle.

Mineralization of the Supraspinatus Tendon

- Mediolateral view—calcified foci in tendon cranial and immediately medial to the greater tubercle of the proximal humerus.
- Tangential or skyline view of the intertubercular region of the proximal humerus—eliminates superimposition; allows distinction from calcification of the biceps brachii tendon.
- Often bilateral radiographically but rarely produces bilateral lameness.

Avulsion/Fracture of the Supraspinatus Tendon

- Similar to mineralization of the supraspinatus tendon.
- Avulsion fragment—may be seen as a defect in the greater tubercle of the humerus; generally not as radiographically dense as that identified with mineralization of the supraspinatus tendon.

Fibrotic Contracture of the Infraspinatus Muscle

Radiographically normal.

CT, Ultrasonography, and MRI

- May help identify muscle injuries, bicipital tenosynovitis, and rupture of the biceps brachii tendon of origin.
- Useful for determining the location of calcific densities near the intertubercular groove.
- MRI may be useful in evaluating medial shoulder disease, however extensive peer-reviewed publications are lacking.

DIAGNOSTIC PROCEDURES

- Joint tap and analysis of synovial fluid—identify intra-articular disease; fluid should be straw-colored with normal to decreased viscosity; cytologic evaluation: <10,000 nucleated cells/μL (>90% are mononuclear cells).
- Arthroscopic exploration of the shoulder joint—diagnose bicipital tenosynovitis and rupture of the biceps brachii tendon of origin; evaluate support structures of the medial shoulder, confirm lack of other intra-articular disease (osteochondrosis or traumatic injury).

PATHOLOGIC FINDINGS

- Bicipital tenosynovitis—mineralization of the biceps tendon; osteophytosis of the intertubercular groove; proliferative synovitis; impingement of the supraspinatus tendon of insertion on the biceps tendon, and fibrous adhesions between the biceps tendon and its synovial sheath; histologically, synovial proliferation, edema, fibrosis, dystrophic mineralization, and lymphocytic–plasmacytic infiltration of the tendon and synovium.
- Ruptured origin of the biceps brachii tendon—partial to complete rupture of the biceps tendon at its insertion on the supraglenoid tubercle, proliferative synovitis, and fibrous adhesions between the biceps tendon and its synovial sheath; histologically, synovial proliferation, edema, fibrosis, and occasional dystrophic mineralization.
- Medial shoulder instability—identify fraying, stretching or complete disruption of the medial glenohumeral ligament or the subscapularis tendon.
- Mineralization of the supraspinatus tendon—tendon often looks normal, but longitudinal incision reveals numerous pockets of mineralized debris within the fibers; histologically, chondromucinous stromal degeneration of the tendon with multiple foci of dystrophic mineralization.
- Avulsion of the supraspinatus tendon insertion—often looks normal, but longitudinal incision reveals bone fragment(s) surrounded by a fibrous tissue capsule; usually see a corresponding bony defect in the greater tubercle.

TREATMENT

APPROPRIATE HEALTH CARE

- Overall, identification and appropriate treatment of ligamentous shoulder pathology is considered one the more controversial areas in canine orthopedics.
- Outpatient—early diagnosis.
- Inpatient—chronic, severe disease requires surgical intervention.
- Bicipital tenosynovitis—50–75% success with medical treatment; requires surgery with evidence of chronic changes and failure of medical management.
- Medial shoulder instability treatment depends on the severity of the disease with mild to moderate instability typically being amenable to conservative therapy, while severe ligamentous disruption and instability requiring medial shoulder stabilization.
- Subtotal rupture of the origin of the biceps brachii tendon generally requires surgery.
- Mineralization of the supraspinatus tendon—may be an incidental finding; requires surgery after excluding other causes of lameness and medical treatment.
- Avulsion or fracture of the supraspinatus tendon—often requires surgery because of persistent bone fragment irritation of the tendon.
- Fibrotic contracture of the infraspinatus muscle—requires surgery.

NURSING CARE

- Cryotherapy (ice packing)—immediately post surgery; helps reduce inflammation and swelling at the surgery site; performed 5–10 minutes every 8 hours for 3–5 days.
- Regional massage and range-of-motion exercises—improve flexibility; decrease muscle atrophy.
- Rehabilitation therapy by a licensed veterinary rehabilitation professional is considered crucial to improve the speed of, and likelihood of recovery from shoulder pathology with or without surgical intervention.

ACTIVITY

- Medical treatment—requires strict confinement for 4–6 weeks; activity; premature return to normal activity likely exacerbates signs and induces a chronic pathological state.
- Post surgery—depends on procedure performed.

DIET

Weight control—decrease the load applied to the painful joint.

SURGICAL CONSIDERATIONS

- Bicipital tenosynovitis—recommended with poor response to medical treatment and chronic disease; goal: eliminate movement of the biceps tendon within the inflamed synovial sheath by performing a tenodesis or, more commonly, release of the bicipital tendon; either arthroscopic, or open, or percutaneous (± ultrasound guidance) tendon release.
- Rupture of the biceps brachii tendon of origin—reattach tendon to the proximal lateral aspect of the humerus with a screw and spiked washer or pass the tendon through a bone tunnel and suture it to the supraspinatus tendon. Alternatively arthroscopy to confirm complete release of the tendon, followed by rehabilitation therapy can be considered.
- Medial shoulder instability—sporadic and conflicting reports of the efficacy of radiofrequency capsulorrhaphy for moderate pathology. Prosthetic ligament reconstruction for the treatment of severe instability is recommended.
- Mineralization of the supraspinatus tendon—longitudinally incise the tendon; remove the calcium deposits.
- Avulsion or fracture of the supraspinatus tendon—remove the bone fragment(s).
- Fibrotic contracture of the infraspinatus muscle—tenotomy and excision of part of the tendon of insertion; often feel a distinct pop after excision of the last adhesion, which allows complete range of motion of the shoulder joint.

(CONTINUED) SHOULDER JOINT, LIGAMENT, AND TENDON CONDITIONS

MEDICATIONS

DRUG(S) OF CHOICE

Bicipital Tenosynovitis

- Local therapy—intra-articular injection (corticosteroid or platelet rich plasma)—initial treatment of choice.
- Do not inject into a septic joint; perform complete synovial fluid analysis if any doubt.
- Prednisolone acetate 20–40 mg, depending on size.
- Lameness markedly improved but not eliminated—give a second injection in 3–6 weeks.
- Systemic treatment (nonsteroidal anti-inflammatory drugs [NSAIDs] or steroids)—not as effective.
- Incomplete resolution—recommend surgery.

NSAIDs and Analgesics

- May be used for symptomatic treatment; minimize pain, decrease inflammation.
- Carprofen 2.2 mg/kg PO q12h or 4.4 mg/kg PO q24h.
- Deracoxib 1–2 mg/kg PO q24h, chewable.
- Etodolac 10–15 mg/kg PO q24h.
- Firocoxib 5 mg/kg PO q24h.
- Grapiprant 2 mg/kg PO q24h, to animals >3.6 kg.
- Meloxicam—load 0.2 mg/kg PO, then 0.1 mg/kg PO q24h—liquid.
- Tepoxalin—load 20 mg/kg, then 10 mg/kg PO q24h.

CONTRAINDICATIONS

- Avoid prolonged use of corticosteroids because of the potential side effects and articular cartilage damage associated with long-term intra-articular use.
- Direct injection of a corticosteroid into the biceps tendon—may promote further tendon disruption and eventual rupture.

PRECAUTIONS

NSAIDs—gastrointestinal irritation or renal/hepatic toxicity may preclude use in some patients.

ALTERNATIVE DRUG(S)

- Chondroprotective drugs, e.g., polysulfated glycosaminoglycans, green-lipped mussel extract, and glucosamine/chondroitin sulfate (limited supportive data)—may help limit associated cartilage damage and degeneration.
- Nonspecific anti-inflammatory supplements, e.g., green-lipped mussel extract and omega 3 fatty-acid supplementation.

FOLLOW-UP

PATIENT MONITORING

Most patients require a minimum of 1–2 months of rehabilitation after treatment.

EXPECTED COURSE AND PROGNOSIS

- Medically managed bicipital tenosynovitis—often successful after one or two treatments (50–75% of cases) with no chronic changes.
- Surgically treated bicipital tenosynovitis—good to excellent results (90% of cases); recovery to full function may take 2–8 months.
- Surgically treated release or tenodesis of the bicipital brachii tendon—good to excellent prognosis; >85% of patients show improved return to function.
- Surgically treated medial shoulder instability—variable results and highly dependent on concurrent pathology and adherence to postoperative restriction and rehabilitation therapy.
- Surgically treated mineralization of the supraspinatus tendon—good to excellent prognosis; recurrence possible but uncommon.
- Surgically treated avulsion or fracture of the supraspinatus tendon—good to excellent prognosis; recurrence possible but uncommon.
- Surgically treated fibrotic contracture of the infraspinatus muscle—good to excellent prognosis; patients uniformly return to normal limb function.

MISCELLANEOUS

ABBREVIATIONS

- NSAID = nonsteroidal anti-inflammatory drug.

SICK SINUS SYNDROME

BASICS

DEFINITION
A disorder of impulse formation within, and conduction out of, the sinus node; dysfunction of subsidiary pacemakers and other segments of the cardiac conduction system frequently coexist with the sinus node dysfunction.

ECG Features
• Arrhythmias noted with sick sinus syndrome (SSS) include any or all of the following: inappropriate sinus bradycardia, sinus pauses (representing sinus arrest or sinoatrial exit block), slow ectopic atrial rhythm, or alternating periods of sinus bradyarrhythmias and supraventricular tachycardia (SVT) (Figure 1). • Paroxysms of SVT may alternate with prolonged periods of sinus node inertia and often atrioventricular (AV) nodal inertia as well, producing tachycardia–bradycardia syndrome, a variant of SSS. • P waves and QRS complexes are usually normal. • P waves may be abnormal or absent with slow atrial ectopic rhythm or junctional escape rhythm.

PATHOPHYSIOLOGY
• ECG manifestations may precede development of clinical signs. • Clinical signs usually result from the failure of subsidiary pacemakers to generate escape rhythms when sinus node dysfunction occurs. • The common clinical manifestations reflect transient decreases in organ perfusion, particularly reduced cerebral and skeletal muscle perfusion. • Rarely, congestive heart failure develops.

SYSTEMS AFFECTED
• Cardiovascular. • Nervous, musculoskeletal, and renal systems may be secondarily affected because of hypoperfusion.

GENETICS
• May be heritable in miniature schnauzers and West Highland white terriers.
• Doberman pinschers and boxers can have syncope associated with long sinus pauses, suggestive of SSS.

SIGNALMENT

Species
Dog

Breed Predilections
• Miniature schnauzer (may be heritable).
• Noted commonly in cocker spaniel, dachshund, and West Highland white terrier.

Mean Age and Range
Most dogs >6 years old.

Predominant Sex
Female

SIGNS

Historical Findings
• Clinical signs vary from asymptomatic to weakness, syncope, collapse, and/or seizures.
• Sudden death is infrequent.

Physical Examination Findings
• Heart rate may be abnormally rapid or abnormally slow. • Pauses may be noted.
• Some patients appear normal.

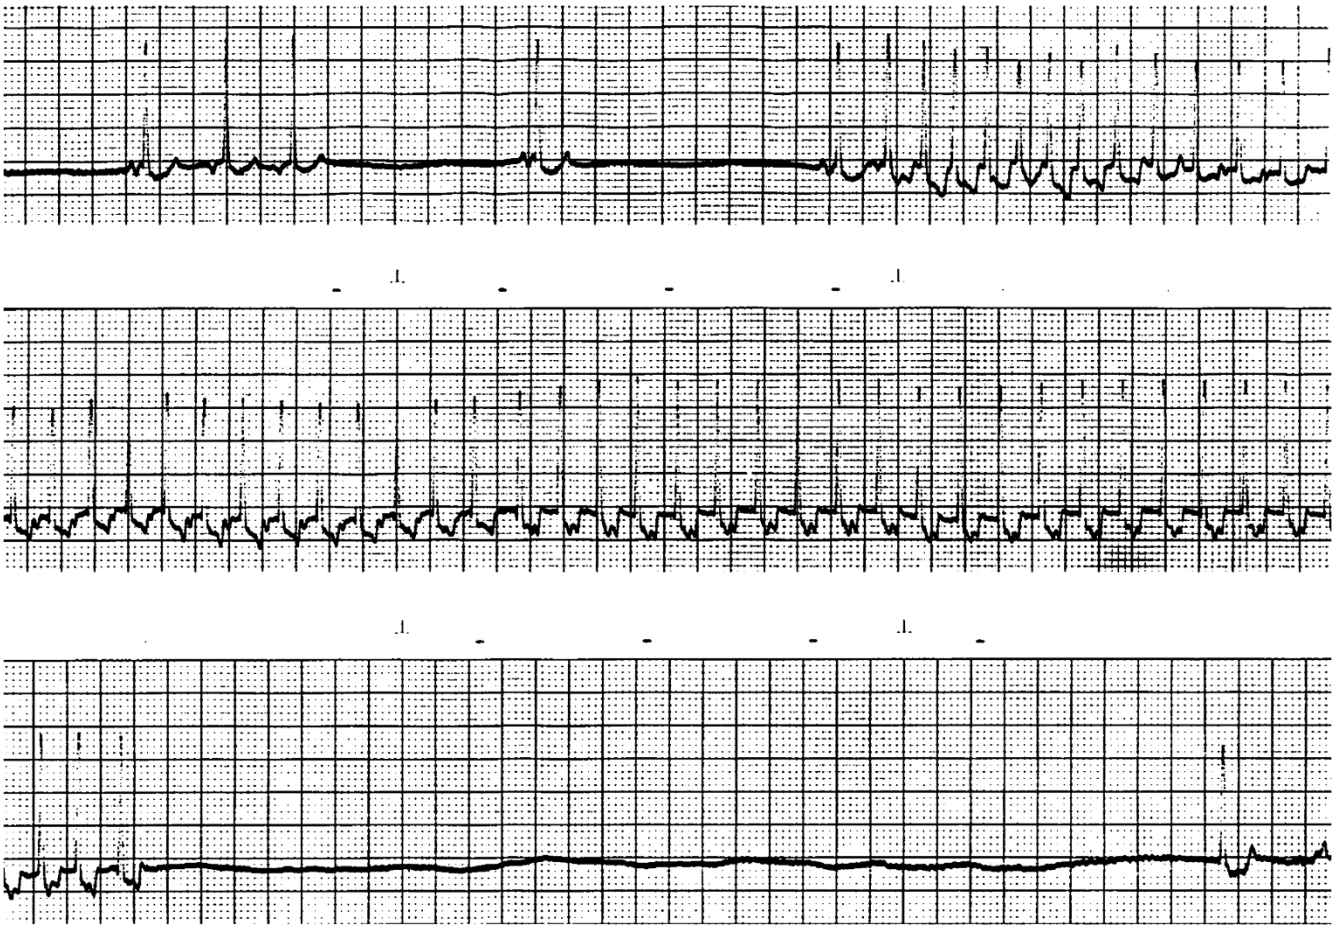

Figure 1.

A continuous lead II rhythm strip (25 mm/s) recorded from a dog with sick sinus syndrome showing an ectopic atrial rhythm interrupted by several short pauses. The third pause initiates a paroxysm of supraventricular tachycardia (250 bpm) followed by asystole (6.6 seconds) terminated by a junctional escape complex.

(CONTINUED) # SICK SINUS SYNDROME

CAUSES
• Idiopathic. • Familial in miniature schnauzers. • Metastatic disease. • Ischemic disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Healthy dogs may exhibit sinus bradycardia (rate as low as 30 beats/min) and sinus pauses (as long as 3.5 seconds) normally during sleep. • Bradycardia and sinus arrest due to normal or enhanced vagal tone. • Drug-induced (digitalis, α-adrenergic antagonists, α_2-adrenergic agonists, calcium channel antagonists, cimetidine, opioids). • Seizures or syncope due to noncardiac disease. • Atrial standstill secondary to hyperkalemia or atrial disease. • Weakness due to neurologic, musculoskeletal, or metabolic diseases.

CBC/BIOCHEMISTRY/URINALYSIS
Normal

IMAGING
Breeds predisposed to SSS are also predisposed to degenerative valvular disease; echocardiography may be used to confirm presence of significant valvular disease when heart murmur is present.

DIAGNOSTIC PROCEDURES
• Atropine response testing—indicated in dogs with sinus bradycardia, sinus arrest, and sinoatrial exit block. Administer atropine 0.04 mg/kg IM and evaluate the ECG 20–30 minutes later. A normal (positive) response is >50% increase in heart rate with abolishment of pauses; dogs with SSS generally have no response or an incomplete response to atropine. • Electrophysiologic testing of sinus node recovery time and sinoatrial conduction time. • 24-hour ambulatory ECG (Holter) or event recording to correlate clinical signs with arrhythmia.

PATHOLOGIC FINDINGS
Vary with cause.

TREATMENT

APPROPRIATE HEALTH CARE
• Hospitalization rarely necessary except for electrophysiologic testing or pacemaker implantation. • Do not treat asymptomatic animals.

ACTIVITY
Avoid vigorous exercise and stressful situations.

DIET
Modifications unnecessary.

CLIENT EDUCATION
Owner should be aware that medical management is often ineffective.

SURGICAL CONSIDERATIONS
• Permanent artificial pacemaker necessary for dogs failing to respond to medical treatment and those exhibiting unacceptable medication side effects. • Permanent artificial pacemaker usually required for dogs with bradycardia–tachycardia syndrome. • Transvenous placement of a pacing lead in the right atrium or auricle may successfully abolish the sinus pauses.

MEDICATIONS

DRUG(S) OF CHOICE
• Do not treat asymptomatic animals. • Symptomatic dogs are grouped into those showing primarily bradycardia, sinus arrest, and/or sinoatrial exit block and those with supraventricular tachycardia followed by sinus arrest. • Atropine-responsive symptomatic dogs with bradycardia or sinus arrest—anticholinergic agents (propantheline: small dogs, 3.75–7.5 mg PO q8–12h; medium dogs, 15 mg PO q8h; large dogs, 30 mg PO q8h; hyoscyamine: 3–6 µg/kg q8h). • Dogs with bradycardia and sinus arrest—may try theophylline (Theo-Dur) 20 mg/kg PO q12h, terbutaline 0.2 mg/kg PO q8–12h, or hydralazine 1–2 mg/kg PO q8–12h if anticholinergic drugs are ineffective (avoid hydralazine if patient is hypotensive). • Dogs with bradycardia–tachycardia whose clinical signs are due to tachycardia or tachycardia-induced sinus arrest—can give digoxin 5 µg/kg PO q12h or atenolol 0.5–1 mg/kg PO q12–24h in attempt to suppress the SVT (monitor closely for exacerbation of bradycardia). • Therapy for tachycardias should only be considered, once pacing is established to avoid worsening of bradyarrhythmias.

CONTRAINDICATIONS
Avoid drugs that may worsen sinus node dysfunction (e.g., β-adrenergic antagonists, calcium channel blocking agents, phenothiazines, class I and III antiarrhythmic agents, opioids, cimetidine, α_2-adrenergic agonists).

PRECAUTIONS
• Attempts to manage bradycardia–tachycardia syndrome medically without prior pacemaker implantation carry significant risk because drugs used to control SVT may worsen the bradyarrhythmias, and vice versa. • Adverse effects of anticholinergic medication (constipation, difficulty voiding, keratoconjunctivitis sicca, emesis, anxiety) occur commonly.

FOLLOW-UP

PATIENT MONITORING
• ECG in asymptomatic patients—to detect progression of disease. • ECG in patients treated medically or with pacemaker implantation.

POSSIBLE COMPLICATIONS
• Rarely, reduced cerebral or renal perfusion results in chronic renal dysfunction or CNS damage. • Presence of significant valvular disease has implications for type of permanent pacing mode selected.

EXPECTED COURSE AND PROGNOSIS
• Good, following pacemaker implantation in animals without congestive heart failure. • Medical management—often ineffective; initial beneficial effects often not sustained.

MISCELLANEOUS

SYNONYMS
• Bradycardia–tachycardia syndrome. • Sinus node dysfunction. • Tachycardia–bradycardia syndrome.

SEE ALSO
• Sinus Arrest and Sinoatrial Block.
• Sinus Bradycardia.
• Supraventricular Tachycardia.

ABBREVIATIONS
• AV = atrioventricular.
• ECG = electrocardiogram.
• SSS = sick sinus syndrome.
• SVT = supraventricular tachycardia.

S

SINUS ARREST AND SINOATRIAL BLOCK

BASICS

DEFINITION

• Sinus arrest—a disorder of impulse formation caused by slowing or cessation of spontaneous sinus nodal automaticity; failure of the sinoatrial (SA) node to initiate an impulse at the expected time. P-P interval does not equal a multiple of basic P-P interval. • Sinoatrial block—a disorder of impulse conduction; an impulse formed within the sinus node fails to depolarize the atria or does so with delay; most commonly the basic rhythmicity of the sinus node is not disturbed and the duration of the pause is a multiple of the basic P-P interval. Classified into first-, second-, and third-degree SA block (similar to degrees of atrioventricular [AV] block). Difficult to diagnose first- and third-degree SA block from electrocardiogram (ECG). Second-degree SA block most common: Mobitz type I (Wenckebach) SA block—P-P interval progressively shortens prior to a pause; duration of pause is less than two P-P cycles; Mobitz type II SA block—duration of pause occurring after a sinus beat is exact multiple (two, three, or four times normal) of basic P-P interval.

S

ECG Features

• A normal P wave exists for each QRS complex with a pause equal to or greater than twice the normal P-P interval; rhythm is regularly irregular or irregular with pauses (Figure 1). • Junctional or ventricular escape beats—occur if pauses significantly prolonged. Subsidiary pacemaker takes over rhythm with escape beats normally from AV junctional tissue or Purkinje fibers; intermittent absence of P waves noted or P waves may be negative and precede, be superimposed on or follow the QRS complexes. • Surface ECG cannot differentiate sinus arrest from block in the dog because of normal R-R interval variation (sinus arrhythmia).

PATHOPHYSIOLOGY

• Sympathetic and parasympathetic influences can alter spontaneous sinus node depolarization; vagal stimulation of acetylcholine, which binds to SA nodal receptor sites, can slow automaticity of the sinus node by reducing the slope of phase 4 depolarization; sympathetic stimulation releases norepinephrine that binds to β1 receptors on the SA node, enhancing spontaneous SA nodal discharge rate. • An overdrive inhibition phenomenon occurs when sinus arrest follows a run of ectopic beats. The sinus node requires a warming-up period until the usual rate of automaticity is reestablished. • Intrinsic disease of the sinus node may affect the balance between the parasympathetic and sympathetic efferent traffic to the SA node and its spontaneous discharge rate. • Duration of sinus arrest may be long and possibly irreversible when the sinus node is suppressed by an ectopic tachycardia, particularly with severe underlying heart disease. Persistent sinus arrest that is not drug induced often indicates sick sinus syndrome (SSS).

SYSTEMS AFFECTED

Cardiovascular—clinical signs of weakness or syncope may appear if sinus arrest or block causes sufficiently long periods (generally 5 seconds or longer) of ventricular asystole with no escape beats initiated by latent pacemakers.

GENETICS

• Seen in purebred pugs with hereditary stenosis of the bundle of His. • Seen in female miniature schnauzers predisposed to SSS. Is the most common arrhythmia in miniature schnauzers with SSS.
• Congenitally deaf Dalmatian coach hounds often have abnormal SA node and multiple atrial arteries. May be a genetic component to the cause of SSS in those breeds predisposed (see Breed Predilections).

INCIDENCE/PREVALENCE

• Normal incidental finding in brachycephalic breeds of dogs in which inspiration causes a reflex increase in vagal tone. • Common in dog breeds predisposed to SSS. • Uncommon in cats.

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dog and cat.

Breed Predilections

• Brachycephalic breeds. • Breeds predisposed to SSS (e.g., miniature schnauzers, dachshunds, cocker spaniels, pugs, boxers and West Highland white terriers).

Mean Age and Range

If associated with SSS, generally middle-aged to older animals.

Predominant Sex

If associated with SSS, older females.

SIGNS

General Comments

Generally no clinical significance by itself if terminated by sinus node depolarization, or latent pacemakers promptly escape to prevent ventricular asystole.

Historical Findings

• Usually none. • Signs of low cardiac output (e.g., weakness and syncope) may occur with failure of the SA node to fire on time if no lower pacemaker focus takes over the rhythm. • Sudden death is possible should prolonged periods of ventricular asystole occur.

Physical Examination Findings

• May be normal. • Heart sounds following a pause may be louder because the ventricles have longer filling time and therefore eject a larger amount of blood. • Extremely slow heart rate if arrest or block is prolonged or frequent. • With significant pathologic cardiac disease—may be findings consistent with poor cardiac output (e.g., prolonged perfusion time, pale mucous membranes, weak femoral pulses).

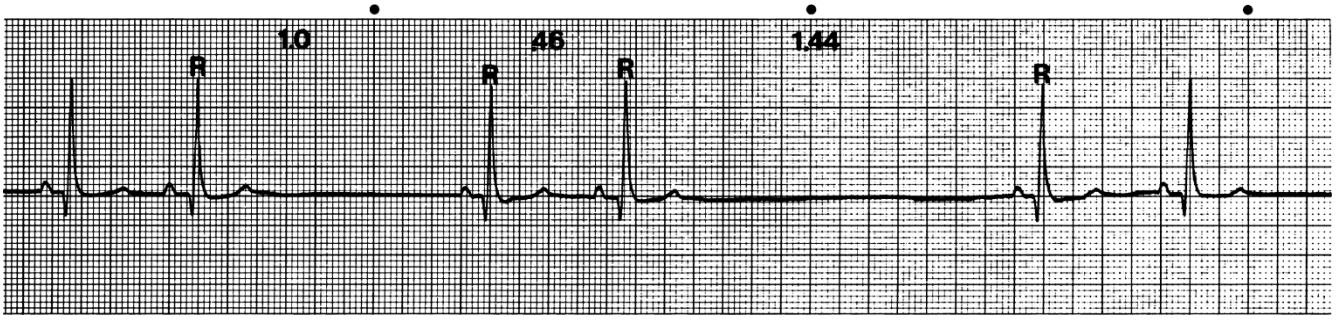

Figure 1.

Intermittent sinus arrest in a brachycephalic breed with an upper respiratory disorder. The pauses (1 and 1.44 seconds) are greater than twice the normal P-P interval (0.46). (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, Interpretation and Treatment, 3rd ed. Baltimore, MD: Williams and Wilkins, 1992, Reprinted with permission of Wolters Kluwer.)

(CONTINUED)

SINUS ARREST AND SINOATRIAL BLOCK

CAUSES

Physiologic

• Vagal stimulation secondary to coughing, pharyngeal irritation. • Ocular or carotid sinus pressure. • Surgical manipulation.

Pathologic

• Degenerative heart disease (fibrosis). • Dilatory heart disease. • Acute myocarditis. • Neoplastic heart disease. • SSS. • Irritation of vagus nerve secondary to thoracic or cervical neoplasia. • Electrolyte imbalance. • Drug toxicity (e.g., digoxin).

RISK FACTORS

• Certain drugs, including digitalis, quinidine, propranolol, xylazine, acepromazine, hydromorphone. • Respiratory tract disease. • Vagal maneuvers.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Marked sinus arrhythmia and sinus bradycardia. • Not always possible to differentiate sinus arrest from SA block without direct recordings of sinus node discharge; pauses that are precise multiples of the dominant beat interval suggest sinus block.

CBC/BIOCHEMISTRY/URINALYSIS

Serum electrolyte abnormalities, especially hyperkalemia (serum K^+ >5.7 mEq/L).

OTHER LABORATORY TESTS

N/A

IMAGING

• Thoracic radiographs if neoplastic or cardiac disease suspected. • Cardiac ultrasound if structural or neoplastic heart disease suspected.

DIAGNOSTIC PROCEDURES

• Provocative atropine response test to assess sinus node function. Administer 0.04 mg/kg atropine IM; evaluate ECG lead II rhythm strip 30 minutes later for response or administer 0.04 mg/kg atropine IV followed by ECG in 10 minutes. Resolution of the arrhythmia suggests high vagal tone as the underlying cause. • Ambulatory monitoring may reveal prolonged periods of failure of impulses from the SA node if signs of weakness or syncope. • In humans, a period of sinus arrest following right carotid massage that lasts longer than 3 seconds suggests inappropriate sinus responsiveness. • Electrophysiologic studies of sinus node. • Serum digoxin concentration, if applicable; trough level recommended (just before next dose or at least 8 hours post pill); therapeutic serum concentrations are typically 0.5–1.5 ng/mL.

PATHOLOGIC FINDINGS

Histologic study of the SA node may reveal necrosis, fibrosis, and/or degenerative changes.

TREATMENT

APPROPRIATE HEALTH CARE

Asymptomatic sinus arrest or block does not require therapy. If clinical signs, therapeutic approach depends on cause, underlying cardiac status, and severity of symptoms. Any indicated treatment may be outpatient unless pacemaker implantation is necessary, which necessitates hospital management.

NURSING CARE

Correct any electrolyte abnormalities.

ACTIVITY

Unrestricted unless signs of weakness, syncope, or congestive heart failure (CHF) develop.

CLIENT EDUCATION

An artificial pacemaker may be necessary when patient is symptomatic and nonresponsive to medical management.

SURGICAL CONSIDERATIONS

Implantation of an artificial demand pacemaker in animals with clinical signs nonresponsive to therapy.

MEDICATIONS

DRUG(S) OF CHOICE

• Only if patient is symptomatic, consider atropine 0.04 mg/kg IV, IM, glycopyrrolate 5–10 µg/kg IV, IM, or isoproterenol 10 µg/kg IM, SC q6h or dilute 1 mg in 500 mL of 5% dextrose or Ringer's solution, and infuse IV at 0.04–0.08 µg/kg/min. • If responsive to injectable anticholinergic drugs (e.g., atropine)—can prescribe parasympatholytic drug such as oral propantheline bromide 0.25–0.5 mg/kg q8–12h or hyoscyamine 3–6 µg/kg q8h for at-home management. Sympathomimetic agents including methylxanthine theophylline 10 mg/kg extended release formulation q12h or terbutaline 0.2 mg/kg q8–12h PO (dogs) and 0.1–0.2 mg/kg q12h (cats) could be considered for oral therapy.

CONTRAINDICATIONS

If patient is symptomatic secondary to prolonged pauses, discontinue any drugs that may be causative (e.g., digitalis, beta-blockers, calcium channel blockers).

PRECAUTIONS

Avoid drugs that depress SA node function.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUG(S)

If medical therapy does not resolve signs, consider pacemaker implantation.

FOLLOW-UP

PATIENT MONITORING

When indicated, periodic serial ECG evaluation to assess therapeutic efficacy and possible progression to a more serious dysrhythmia.

POSSIBLE COMPLICATIONS

If associated with primary cardiac disease, CHF may develop and necessitate appropriate therapies.

EXPECTED COURSE AND PROGNOSIS

If cause is SSS, symptomatic patient may respond well to medical intervention; if poorly responsive, permanent pacemaker implantation would improve prognosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

SINUS ARRHYTHMIA

BASICS

DEFINITION

• Normal sinus impulse formation characterized by a phasic variation in sinus cycle length. An irregular R-R interval is present that has more than 10% variation in sinus cycle length (or variability of 0.12 seconds [dog], 0.10 seconds [cat], or more exists between successive P waves) (Figure 1).
• Two basic forms exist—respiratory sinus arrhythmia (RSA): P-P interval cyclically shortens during inspiration due primarily to reflex inhibition of vagal tone and lengthens during expiration; nonrespiratory sinus arrhythmia: phasic variation in P-P interval unrelated to the respiratory cycle.

ECG Features

• Other than the irregular rhythm, all other criteria for sinus rhythm are present.
• Normal heart rate.
• Positive P wave in leads, I, II, III, and aVF, unless a wandering pacemaker is present, where the P waves may be positive, diphasic, or negative temporarily.
• A P wave is present for every QRS complex.
• A QRS complex is present for every P wave.
• PR interval is relatively constant.

PATHOPHYSIOLOGY

• Sinus node discharge rate depends on the two opposing influences of the autonomic nervous system. Vagal stimulation decreases spontaneous sinus nodal discharge rate and predominates over sympathetic stimulation. Negative intrathoracic pressure occurring with inspiration causes decreased pressure on the vagus nerves. Feedback from the cardioregulatory and vasomotor centers in the medulla produces cardiac acceleration by decreasing vagal restraint on the sinus node; the opposite occurs during exhalation. The genesis of sinus arrhythmia also depends on reflexes involving pulmonary stretch receptors (Hering–Breuer reflex), pressure–volume sensory receptors in the heart (Bainbridge reflex whereby atrial stretch stimulates receptors in the atrial wall, causing vagal inhibition and increase in heart rate; baroreceptors in the carotid sinus and aortic arch elicit inverse changes in heart rate with acute changes in arterial blood pressure), blood vessels, and chemical factors of the blood.
• RSA is measured as a high-frequency component of heart rate variability (HRV) and is used as an index of cardiac vagal control. HRV measures beat to beat changes in heart rate and R-R variability from the ECG. HRV is a widely accepted clinical and research tool for evaluation of cardiac autonomic changes.

SYSTEMS AFFECTED

Cardiovascular—generally no hemodynamic consequence, but marked sinus arrhythmia may produce a long enough sinus pause to produce syncope if not accompanied by an escape rhythm.

GENETICS

N/A

INCIDENCE/PREVALENCE

Most frequent form of arrhythmia in dogs.

SIGNALMENT

Species

• RSA frequent normal finding in dogs.
• While common in cats asleep and in home environment, in a clinical setting sympathetic dominance occurs and RSA is rare without underlying pathology.

Breed Predilections

• Brachycephalic breeds predisposed.
• Dogs—bulldog, Lhasa apso, Pekingese, pug, shar-pei, shih tzu, boxer.
• Cats—Persian, Himalayan.

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

General Comments

• Uncommon, but weakness may develop if pauses between beats are excessively long; syncope can occur when a marked sinus arrhythmia and sinus bradycardia develop.
• In general, symptoms more common in nonrespiratory than in respiratory form.

Historical Findings

• RSA—none.
• Nonrespiratory sinus arrhythmia—may be findings related to underlying disease.

Physical Examination Findings

• May be normal.
• Irregular rhythm on auscultation.
• May be findings related to specific disease accentuating vagal tone (e.g., stertor and stridor in a patient with brachycephalic airway syndrome).

CAUSES

• Normal cyclic change in vagal tone associated with respiration in the dog; heart rate increases with inspiration and decreases with expiration.
• Underlying conditions that increase vagal tone—high intracranial pressure, gastrointestinal disease, respiratory disease, cerebral disorders, digitalis toxicity, organophosphates.
• Carotid sinus massage or ocular pressure (vagal maneuver) may accentuate.

RISK FACTORS

• Brachycephalic conformation.
• Digoxin therapy.
• Any disease that increases vagal tone.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Auscultation of sinus arrhythmia is often confusing; ECG helps differentiate normal

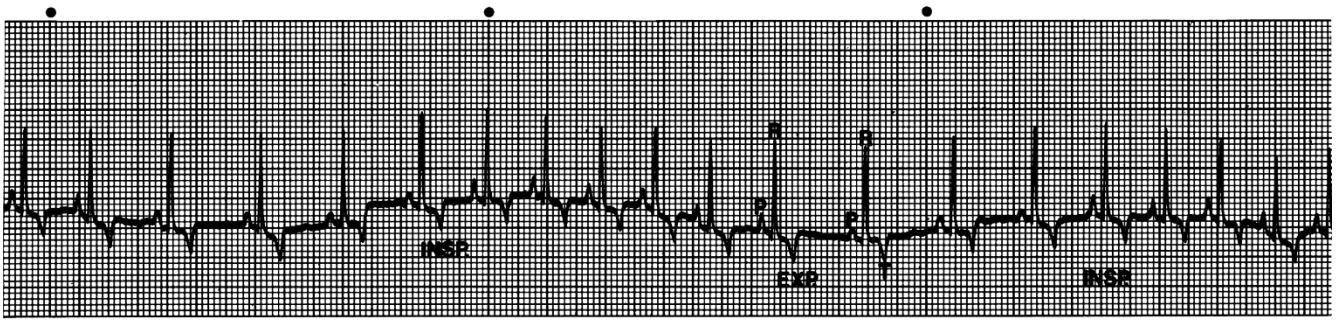

Figure 1.

Respiratory sinus arrhythmia with an average rate of 120 bpm (6 complexes between 1 set of time lines or 3 seconds × 20) (paper speed, 25 mm/s; 10 mm/mV). The rate increases during inspiration (INSP) and decreases during expiration (EXP). The fluctuation of the baseline correlates with the movement of the electrodes by the thoracic cavity. (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

(CONTINUED) SINUS ARRHYTHMIA

sinus arrhythmia from true pathologic arrhythmia.
• Wandering sinus pacemaker frequently associated and a variant of sinus arrhythmia. Site of impulse formation shifts within the sinoatrial node or to an atrial focus or atrioventricular (AV) node, changing the configuration of the P wave.
• Important to differentiate normal sinus arrhythmia from pathologic arrhythmias including atrial premature complexes, sick sinus syndrome, slow atrial fibrillation, and AV dissociation.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Cats with chronic respiratory disease may be positive for feline leukemia virus or feline immunodeficiency virus.

IMAGING
Radiographs, CT, or MRI of head and neck to assess for abnormal anatomic conformation that might predispose to airway problems.

DIAGNOSTIC PROCEDURES
• Pharyngoscopy/laryngoscopy if upper airway disease suspected.
• Atropine challenge test (administer atropine 0.04 mg/kg IM followed by ECG in 30 minutes or 0.04 mg/kg atropine IV followed by ECG in 10 minutes) if associated with sinus bradycardia and primary dysfunction of sinus node is suspected. Subsequent heart rate should be greater than 150 bpm.

PATHOLOGIC FINDINGS
See specific disease.

TREATMENT

APPROPRIATE HEALTH CARE
Generally, specific treatment required only when associated with symptomatic sinus bradycardia; if not related to respiration, underlying cause is treated. If patient is suffering respiratory distress, appropriate inpatient management indicated until patient is stable.

NURSING CARE
None unless associated with underlying disease.

ACTIVITY
Not restricted unless associated with specific disease (e.g., brachycephalic animals may need to limit exercise, especially in high ambient temperatures).

DIET
Caloric restriction for obese animals with airway compromise.

CLIENT EDUCATION
None unless associated with specific disease.

SURGICAL CONSIDERATIONS
None unless associated with specific disease.

MEDICATIONS

DRUG(S) OF CHOICE
• Generally no therapy indicated; this is a normal rhythm.
• Infectious respiratory diseases require appropriate antibiotic therapy.
• If associated with symptomatic sinus bradycardia or sinus arrest or block, anticholinergics may be indicated—atropine 0.02–0.04 mg/kg IV, IM, SC or glycopyrrolate 5–10 µg/kg IV, IM, SC.

CONTRAINDICATIONS
Discontinue digoxin if toxicity is a problem.

PRECAUTIONS
Avoid atropine in patients with respiratory disease; an adverse effect is drying of secretions.

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
Only if associated with specific disease.

PREVENTION/AVOIDANCE
N/A

POSSIBLE COMPLICATIONS
N/A

EXPECTED COURSE AND PROGNOSIS
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Sick sinus syndrome.
• Brachycephalic airway syndrome.
• Asthma.
• Chronic obstructive pulmonary disease.

AGE-RELATED FACTORS
Generally more pronounced in young adult.

ZOONOTIC POTENTIAL
N/A

PREGNANCY/FERTILITY/BREEDING
Increased incidence of arrhythmias.

SYNONYMS
• Nonrespiratory sinus arrhythmia = nonphasic sinus arrhythmia; sinus irregularity.
• Respiratory sinus arrhythmia = phasic sinus arrhythmia.
• Ventriculophasic sinus arrhythmia—form of nonphasic sinus arrhythmia in which atrial cycles containing ventricular complexes are shorter than those in which they are absent. That is, the P-P interval that includes the QRS complex is shorter than the P-P interval without a QRS complex. This can be seen with second-degree AV block, complete AV block or in the presence of ventricular premature complexes with a full compensatory pause.

SEE ALSO
• Brachycephalic Airway Syndrome.
• Sick Sinus Syndrome.
• Sinus Arrest and Sinoatrial Block.

ABBREVIATIONS
• AV = atrioventricular.
• HRV = heart rate variability.
• RSA = respiratory sinus arrhythmia.

SINUS BRADYCARDIA

BASICS

DEFINITION
Sinus rhythm in which impulses arise from the sinoatrial (SA) node at slower than normal rate for an animal's signalment and activity (Figure 1).

ECG Features
• Dogs—sinus rate <60 bpm). • Cats—sinus rate <110 bpm at home or <130 bpm at the clinic. • Rhythm regular, often with a slight variation in R-R interval; may be irregular; often coexists with sinus arrhythmia.
• Normal P wave for each QRS complex.
• P-R interval constant.

PATHOPHYSIOLOGY
• Can be an incidental finding in healthy animals or during sleep. • May represent normal physiologic response to athletic training; may result from enhanced cardiac parasympathetic tone or decreased sympathetic tone as well as from intrinsic changes in the sinus node. • Automaticity of the heterogeneous sinus node is a very complex phenomenon invoking the calcium and voltage clock mechanisms. More than 16 autonomically influenced currents with the I_f (funny) channel predominating and Ca^{2+} release from the sarcoplasmic reticulum critical to maintain autonomic balance and changes in heart rate. • May represent pathophysiologic response due to high vagal tone, change in blood pH, Pco_2, Po_2, or serum electrolyte disorders, hypothyroidism, increased intracranial pressure, toxins and certain drugs. • May be a result of sick sinus syndrome (SSS).

SYSTEMS AFFECTED
Cardiovascular—most instances benign arrhythmia; may be beneficial by producing a longer period of diastole and increased ventricular filling time; can be associated with syncope if due to abnormal reflex (neurocardiogenic) or intrinsic disease of sinus node.

GENETICS
Female miniature schnauzer, West Highland white terrier, boxer, cocker spaniel, dachshund, and pug predisposed to SSS—may cause bradycardia.

INCIDENCE/PREVALENCE
• Common in the dog; less common in cat.
• Clinical interpretation of sinus node rate also depends on environment and type of patient. For example, a sinus rate can be as low as 20 bpm in a normal dog that is sleeping.

SIGNALMENT
Species
Dog and cat.

Breed Predilections
Bradycardia associated with SSS—miniature schnauzer, cocker spaniel, dachshund, pug, and West Highland white terrier.

Mean Age and Range
• Decreased prevalence with advancing age unless associated with intrinsic disease of SA node. • SSS typically seen in middle-aged to geriatric patients.

Predominant Sex
With SSS, older female miniature schnauzers.

SIGNS
Historical Findings
• Often asymptomatic. • Lethargy.
• Weakness. • Exercise intolerance.
• Syncope. • Episodic ataxia.

Physical Examination Findings
• Pulse rate slow. • Hypothermia may be present. • Poor perfusion. • Syncope.
• Decreased level of consciousness.

CAUSES
Physiologic
• Athletic conditioning. • Hypothermia.
• Intubation with pharyngeal or soft palate tension. • Sleep. • Cushing's reflex with increased intracranial pressure. • Gastrointestinal distension. • Activation of baroreceptor reflex with increase in systemic blood pressure (BP).

Pathophysiologic
• High vagal tone associated with gastrointestinal, respiratory, neurologic, and pharyngeal diseases. • Reflex-mediated/neurocardiogenic/vasovagal—e.g., carotid sinus hyperactivity; situational (micturition, defecation, cough, swallowing).

Pathologic
• High intracranial pressure. • Hyperkalemia.
• Hyper- or hypocalcemia. • Hypermagnesemia. • Hypoxemia. • Hypothyroidism.
• Hypoglycemia. • May precede cardiac arrest. • SSS (rare in the cat). • Feline dilated cardiomyopathy. • Viral myocarditis. • SA block. • In humans, mutations in the I_f channel and drugs which block I_f (such as ivabradine) have been associated with bradycardia.

Pharmacologic
• General anesthesia. • Any negative chronotrope including: ○ Phenothiazines. ○ Beta-adrenergic blockers. ○ Digitalis glycosides. ○ Calcium channel blockers. ○ α_2-Adrenergic agonists. ○ Sotolol. ○ Amiodarone. ○ Centrally acting opioids: morphine, hydromorphone, butorphanol, fentanyl.

RISK FACTORS
• Any situation or disease that may increase parasympathetic tone. • Oversedation.
• Hypoventilation under anesthesia. • Breeds predisposed to SSS.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Persistent and marked sinus bradycardia (SB) should raise possibility of SSS.
• Clinical signs may mimic cerebral dysfunction.

CBC/BIOCHEMISTRY/URINALYSIS
• Hyperkalemia, hypercalcemia, hypocalcemia, or hypermagnesemia possible. • CBC and serum chemistry profile may reveal changes associated with metabolic disease such as renal failure.

OTHER LABORATORY TESTS
• Serum thyroxine (T_4), free T_4, and thyroid-stimulating hormone assays if hypothyroidism suspected. • Measure trough serum digoxin concentration, if applicable, 8 hours after last dose or close to next dosing; normal therapeutic serum concentration should be 0.5–1.5 ng/mL. • Toxicologic screen.

DIAGNOSTIC PROCEDURES
• Provocative atropine response test to assess sinus node function—administer atropine 0.04 mg/kg IV, wait 10–15 minutes, then record ECG or administer same dose IM, wait 30 minutes, then record ECG; persistent sinus tachycardia at >140 bpm is expected response. Lower doses of atropine have increased tendency to cause initial accentuation of SB and first- or second-degree atrioventricular block because of centrally mediated increase in vagal tone. • 24-hour Holter monitoring or ECG event recorder, an owner-triggered device, useful if transient bradyarrhythmia is suspected cause for clinical signs.

TREATMENT

APPROPRIATE HEALTH CARE
• Many animals exhibit no clinical signs and require no treatment. In dogs without structural heart disease, heart rates as low as 40–50 bpm generally provide normal cardiac output at rest. • Therapeutic approaches—vary markedly; depend on the mechanism for SB, the ventricular rate, and severity of clinical signs. • Inpatient or outpatient management—depends on underlying cause and clinical status of patient.

NURSING CARE
• Provide general supportive therapy including IV fluid therapy for hypothermic and hypovolemic patients. • Discontinue any causative drug. • Correct any serious electrolyte imbalance with appropriate fluid therapy.

(CONTINUED) SINUS BRADYCARDIA

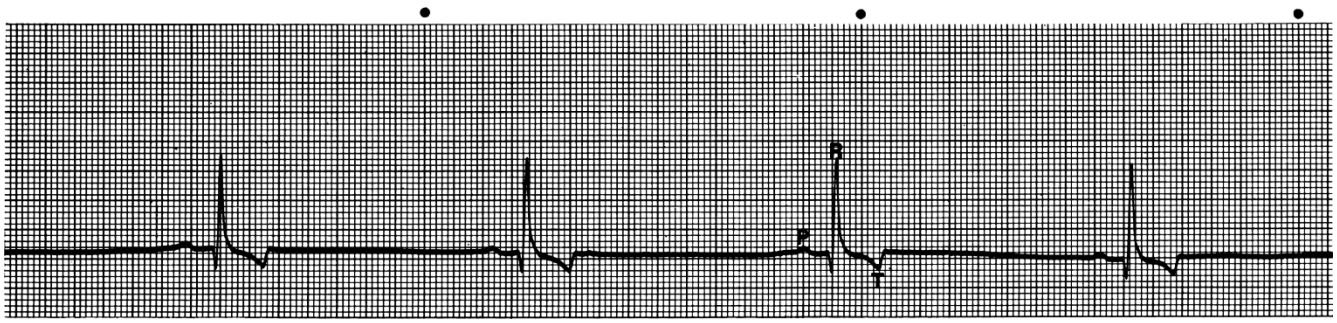

Figure 1.

Sinus bradycardia at a rate of 75 bpm in a cat from anesthetic complications during surgery. Note the tall R waves. (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

CLIENT EDUCATION

• Discuss importance of complying with daily medical management when treating. • Advise that persistent symptomatic bradycardia may necessitate permanent pacemaker implantation for reliable long-term management.

SURGICAL CONSIDERATIONS

• If progressive bradycardia occurs during anesthesia and is attributed to hypoventilation, immediately discontinue inhalation anesthetics and provide adequate ventilation; atropine is generally ineffective in this situation. • If surgical manipulation triggering vagal reflexes (eye, vagus nerve, larynx) is anticipated, pretreatment with atropine 0.02 mg/kg IM, SC or glycopyrrolate 5–10 µg/kg IM, SC may prevent bradycardia. • Severe bradycardia may precipitate cardiopulmonary arrest; identify the causative agent or condition for effective management.

MEDICATIONS

DRUG(S) OF CHOICE

• If patient is hypothyroid, supplement with L-thyroxine. • For severe hypocalcemia (<6 mg/dL) administer 10% calcium gluconate 0.5–1.5 mL/kg IV slowly over 15–30 minutes; monitor with ECG. • For symptomatic drug-induced bradycardias, disorders causing excessive vagal tone, and initial management of bradycardia associated with SSS, administer atropine 0.04 mg/kg IV or glycopyrrolate 5–10 µg/kg IV; anticholinergic therapy may be continued short term using atropine 0.02–0.04 mg/kg IM, SC q6–8h or glycopyrrolate 0.01 mg/kg IM, SC q6–8h. Consider propantheline bromide 0.25–0.5 mg/kg PO q8–12h, hyoscyamine 3–6 µg/kg PO q8h, methylxanthine theophylline, an adenosine receptor antagonist (extended release formulation 10 mg/kg PO q12h, dogs; 12.5 mg PO q24h in the evening, cats), and/or terbutaline (0.2 mg/kg q8–12h PO, dogs; 0.625–1.25 mg/cat PO, cats) to manage symptomatic bradycardia associated with SA node disease.

• For temporary management of symptomatic persistent bradycardia until pacing can be accomplished, consider continuous IV infusion of isoproterenol 0.04–0.08 µg/kg/min IV. Temporary pacing, if available, would be the initial procedure of choice.

CONTRAINDICATIONS

• For hypothermia-induced bradycardia with a pulse, rewarming and supportive measures should be mainstay of treatment. Parasympatholytics generally not recommended. • Parasympatholytic agents contraindicated for acidotic, hypercarbic patients under anesthesia (hypoventilation); bradycardia in this setting may protect the myocardium by decreasing oxygen consumption.

PRECAUTIONS

• Close ECG monitoring recommended when administering calcium solutions for treatment of hypocalcemia; if QT interval shortening or bradycardia, stop administration temporarily. • In patients with heart disease, a lower initial dose of L-thyroxine is advised to allow adaptation to higher metabolic rate. • Administer atropine selectively; rapid IV administration may predispose to ventricular arrhythmias by altering autonomic balance. • Caution when administering parasympatholytic agent to dogs with suspect SSS—could result in tachycardias that overdrive suppress escape rhythms and thus have a potential risk of asystole after termination of the tachycardia.

ALTERNATIVE DRUG(S)

• Bradycardia associated with structural heart disease is most reliably treated by permanent pacemaker implantation. • Glycopyrrolate may have longer vagal blocking effect and cause less frequent ventricular ectopic beats than atropine.

FOLLOW-UP

PATIENT MONITORING

• Assess total T_4 6 hours post pill. • Addison's disease—assess electrolytes every 3–4 months after patient is stable. • ECG check of pacemaker function and pacing rate is recommended during each follow-up examination.

PREVENTION/AVOIDANCE

• Maintain normal PaO_2 under anesthesia with proper ventilation; monitor with pulse oximetry or blood gases. • Avoid hypothermia intraoperatively.

EXPECTED COURSE AND PROGNOSIS

• Signs, if present, should resolve with correction of causative metabolic or endocrine problem. • Treatment of symptomatic SB with a permanent pacemaker generally offers a good prognosis for rhythm control.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Sick sinus syndrome. • Heart block. • Sinus arrhythmia.

PREGNANCY/FERTILITY/BREEDING

Postparturient hypocalcemia usually develops 1–4 weeks postpartum, but can occur at term, prepartum, or late lactation.

SEE ALSO

• Digoxin Toxicity. • Eclampsia. • Hypercalcemia. • Hyperkalemia. • Hypermagnesemia. • Hypocalcemia. • Hypothermia. • Hypothyroidism. • Organophosphate and Carbamate Toxicosis. • Sick Sinus Syndrome.

ABBREVIATIONS

• ECG = electrocardiogram. • SA = sinoatrial. • SB = sinus bradycardia. • SSS = sick sinus syndrome. • T_4 = thyroxine.

Author Deborah J. Hadlock
Consulting Editor Michael Aherne

SINUS TACHYCARDIA

BASICS

DEFINITION
Disturbance of sinus impulse formation; acceleration of the sinoatrial node beyond its normal discharge rate (Figure 1).

ECG Features
• Dogs—heart rate (HR) >160 bpm (puppies HR >220 bpm). • Cats—HR >180 bpm; (kittens HR >240 bpm). • ECG shows a rapid regular rhythm with possible slight variation in R-R interval. • P wave of sinus origin for each QRS complex with constant P-R interval. • P waves may be partially or completely fused with preceding T waves. • Generally has a gradual onset and termination.

PATHOPHYSIOLOGY
• Accelerated phase 4 diastolic depolarization of sinus nodal cells (as a result of voltage- and calcium-dependent mechanisms) generally responsible for sinus tachycardia (ST). • Enhanced adrenergic effect or cholinergic inhibition results in high rate of sinus impulse formation; changes in heart rate usually involve a reciprocal action of the parasympathetic and sympathetic divisions of the autonomic nervous system.

SYSTEMS AFFECTED
Cardiovascular—cardiac output = heart rate × stroke volume. Changes in heart rate affect preload, afterload, and contractility, which determine stroke volume; severe tachycardia can compromise cardiac output. Rapid rates shorten diastolic filling time, and particularly in diseased hearts, the increased heart rate can fail to compensate for decreased stroke volume, resulting in decreased cardiac output and coronary blood flow. Chronic tachycardias can cause cardiac dilation (tachycardiomyopathy) which often resolves with control of the tachycardia. However, ST is most often present due to elevated sympathetic tone and is physiologic (because of hypovolemia, fear, pain, etc.).

GENETICS
N/A

INCIDENCE/PREVALENCE
• Most common benign arrhythmia in the dog and cat. • Most common rhythm disturbance in the postoperative patient.

GEOGRAPHIC DISTRIBUTION
None

SIGNALMENT

Species
Dog and cat.

Breed Predilections
None

SIGNS

General Comments
Often no clinical signs because ST is almost always a consequence of a variety of physiologic or pathophysiologic stresses.

Historical Findings
• In general, ST itself does not produce any symptoms. • If associated with primary cardiac disease, weakness, exercise intolerance, or syncope may be reported. • If associated with other medical conditions, signs may be seen specific to the disease present.

Physical Examination Findings
• High HR. • May otherwise be normal if not associated with a pathologic condition. • Pale mucous membranes if associated with anemia or congestive heart failure (CHF). • Fever may be present. • Signs of CHF (e.g., dyspnea, cough, cyanosis, ascites) if associated with primary cardiac disease.

CAUSES

Physiologic
• Exercise. • Pain. • Restraint. • Excitement. • Any hyperadrenergic state.

Pathologic
• Fever. • CHF. • Chronic lung disease. • Shock. • Pericardial effusion. • Anemia. • Pain. • Infection. • Hypoxia. • Pulmonary thromboembolism. • Hypotension. • Hypovolemia. • Functional pheochromocytoma. • Hyperthyroidism. • Pericarditis. • Pneumothorax. • Hypoglycemia. • Vestibulosympathetic hypovolemia.

Pharmacologic
• Atropine. • Epinephrine. • Ketamine. • Tiletamine (Telazol®). • Quinidine. • Xanthine bronchodilators. • β-Adrenergic agonists.

RISK FACTORS
• Thyroid medications. • Primary cardiac diseases. • Inflammation. • Pregnancy. • Anesthesia. • Certain toxins (*Amanita muscaria*, scorpion venom, black widow spider venom), plants (Jimson weed, mandrake), and drugs (antihistamines, tricyclic antidepressants).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Must differentiate from supraventricular tachycardia (SVT), including atrial tachycardia, atrial flutter with 2:1 AV block, and AV junctional tachycardia; as sinus rate increases, the P wave appears closer to the T wave of the previous beat. At very rapid rates, it becomes difficult to distinguish this condition from other pathologic SVT. Gradual slowing of the rate is suggestive of ST.

CBC/BIOCHEMISTRY/URINALYSIS
• Low packed cell volume if patient is anemic. • Leukocytosis with left shift if inflammation or infection is causative.

OTHER LABORATORY TESTS
• High serum thyroxine (T_4) or free T_4 concentration (cats) if secondary to hyperthyroidism. • Triiodothyronine (T_3) suppression test and thyrotropin-releasing hormone (TRH) response test if T_4 values are normal and hyperthyroidism is suspected. • Functional testing for pheochromocytoma: ○ Metanephrines (breakdown metabolites of epinephrine and norepinephrine); measured in plasma or urine. ○ Serum inhibin, a hormone involved in reproductive physiology; undetectable levels supportive of pheochromocytoma. • 24-hour Holter monitoring. • Cardiac

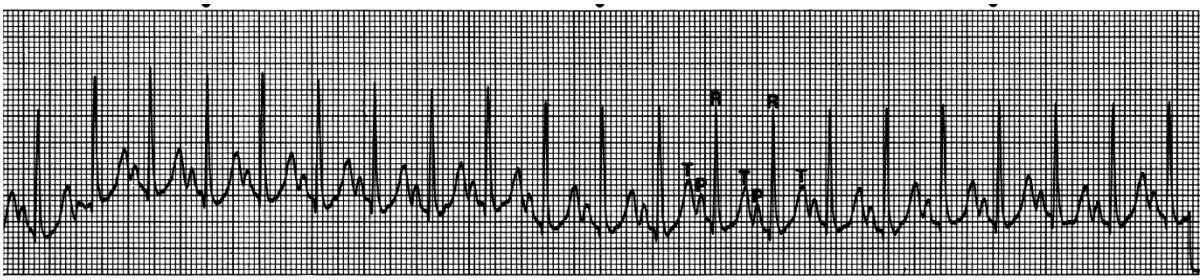

Figure 1.

Sinus tachycardia at a rate of 272 bpm in a dog in shock. The rhythm is sinus because the P waves are normal, the P-R relationship is normal, and the rhythm is regular. (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

electrophysiologic studies. • Plasma N-terminal pro-brain natriuretic peptide (NT-proBNP) assay may be helpful if evaluating for cardiac disease.

IMAGING

• Thoracic radiographs and echocardiography to evaluate for evidence of primary cardiac disease. • Thyroid scintigraphy to evaluate for hyperthyroidism. • Abdominal ultrasound and angiography to evaluate for adrenal mass. • CT and MRI as well as functional imaging modalities very sensitive for detecting adrenal masses.

DIAGNOSTIC PROCEDURES

• A nonpharmacologic vagal maneuver can differentiate ST from other SVTs; carotid sinus or ocular pressure may terminate ectopic SVT. With effective vagal maneuvers, the HR in ST gradually slows. Less commonly, varying degrees of AV block (usually first-degree or Wenckebach) may occur transiently. ECG monitoring is recommended during these vagal maneuvers. • Pharmacologic agents can be used if no response to the vagal maneuver. Similarly, an abrupt reduction in HR suggests SVT whereas gradual slowing suggests ST: ○ IV diltiazem 0.25 mg/kg administered over 2 minutes. If no response, can be repeated in 15 minutes. ○ IV esmolol 50–100 µg/kg bolus q5min up to 500 µg/kg; 25–200 µg/kg/min CRI. • A precordial thump may be used to differentiate ST from other SVT. ST usually not affected, whereas the SVT may stop for at least 1 or 2 beats. • Serial arterial BP measurement may document hypertension in patients with hyperthyroidism, pheochromocytoma, or renal disease.

PATHOLOGIC FINDINGS

• None if associated with physiologic or pharmacologic cause. • Pathologic findings depend on the primary disease process.

TREATMENT

APPROPRIATE HEALTH CARE

• Identify and correct underlying disorders whenever possible. • Whether inpatient or outpatient depends on clinical status of patient and primary disease, if any (e.g., if CHF, treat as outpatient unless animal is dyspneic or severely hypotensive). • If associated with pericardial effusion, avoid drug therapy and perform pericardiocentesis. • If associated with a certain drug (e.g., hydralazine, bronchodilators), discontinue the medication or adjust the dose. • If associated with hypovolemia, replace fluid volume.

NURSING CARE

Depends on whether associated with a specific disease.

ACTIVITY

Exercise restriction recommended if symptomatic cardiac disease.

DIET

Sodium restriction generally advised with hypertension and CHF.

CLIENT EDUCATION

Discuss importance of managing any primary disease appropriately, with medical or surgical intervention.

SURGICAL CONSIDERATIONS

• Thyroidectomy—treatment option for hyperthyroidism (cats). • Tumor removal is the definitive treatment for patients with pheochromocytoma.

MEDICATIONS

DRUG(S) OF CHOICE

• Establish underlying cause and treat appropriately; specific antiarrhythmic therapy is generally limited to patients in CHF or those with secondary cardiac disease due to hyperthyroidism or hypertension. • Dogs—if CHF is the cause, administer pimobendan along with appropriate diuretic therapy and angiotensin-converting enzyme inhibitor. Digoxin may be indicated in some cases such as CHF with atrial fibrillation. If ST persists despite above management, consider adding a calcium channel blocker (e.g., diltiazem 0.5–2.5 mg/kg PO q8h) or a beta-blocker (e.g., atenolol 0.25–1 mg/kg q12h, sotalol 1–2 mg/kg q12h PO) *only* after congestion is controlled. • Cats—if ST is associated with hyperthyroidism without CHF, a beta-blocker (e.g., atenolol 0.25–1 mg/kg PO q12–24h) may lower the HR. Consider digoxin (0.01875–0.03125 mg per average-size cat, equal to 1/8–1/4 of a 0.125 mg tablet—tablet preferred) if CHF present with atrial fibrillation and rapid ventricular response rate. Although still controversial, pimobendan (0.1–0.3 mg/kg PO q12h) has become more commonly accepted as treatment for CHF. If ST associated with hypertrophic cardiomyopathy, administer atenolol 6.25–12.5 mg/cat PO q12h or diltiazem 1.75–2.4 mg/kg PO q8h.

CONTRAINDICATIONS

Avoid drugs such as atropine or catecholamines (epinephrine) that may further increase the HR.

PRECAUTIONS

• Beta-blockers can potentially worsen signs of congestion and lower cardiac output in patients with systolic dysfunction. • Suppression of ST may be catastrophic if occurring as natural compensatory response to maintain cardiac output in a systemically ill patient.

POSSIBLE INTERACTIONS

See manufacturer's insert for specific drugs.

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

Depends on specific disease—for CHF, serial ECG, thoracic radiographs, BUN, creatinine, and serum electrolytes; for hyperthyroidism, serial serum T_4, complete blood count, and biochemistry.

PREVENTION/AVOIDANCE

Minimize stress, exercise, and dietary sodium, if heart disease.

POSSIBLE COMPLICATIONS

• Weakness or syncope if associated with low cardiac output. • Development of CHF if persistent ST associated with heart disease.

EXPECTED COURSE AND PROGNOSIS

• ST usually resolves with correction of the underlying cause. • Poor despite treatment if ST is associated with CHF. • Favorable for remission of ST when hyperthyroidism is controlled medically, surgically, or by radioactive iodine.

MISCELLANEOUS

ASSOCIATED CONDITIONS

See list of pathologic and physiologic causes.

PREGNANCY/FERTILITY/BREEDING

Increase in cardiac output in late pregnancy (third trimester) largely due to an accelerated HR.

SYNONYMS

• Inappropriate sinus tachycardia. • Postural tachycardia syndrome.

SEE ALSO

• Atrial Fibrillation and Atrial Flutter.
• Congestive Heart Failure—Left-Sided.
• Congestive Heart Failure—Right-Sided.
• Hyperthyroidism. • Pheochromocytoma.
• Supraventricular Tachycardia.

ABBREVIATIONS

• AV = atrioventricular. • CHF = congestive heart failure. • ECG = electrocardiogram. • HR = heart rate. • NT-proBNP = N-terminal pro-brain natriuretic peptide. • ST = sinus tachycardia. • SVT = supraventricular tachycardia. • T_3 = triiodothyronine. • T_4 = thyroxine. • TRH = thyrotropin-releasing hormone.

S

SJÖGREN-LIKE SYNDROME

BASICS

OVERVIEW
• A systemic autoimmune disease characterized by keratoconjunctivitis sicca, xerostomia, and lymphoplasmacytic adenitis.
• Underlying mechanism unknown; however, autoantibodies directed against glandular tissues have been identified.
• Associated with other autoimmune or immune-mediated diseases, such as rheumatoid arthritis and pemphigus.

SIGNALMENT
• Higher incidence in several canine breeds—English bulldogs, West Highland white terriers, and miniature schnauzers.
• Chronic disease of adult dogs.
• Cats unaffected.

SIGNS
Historical Findings
• Adult onset.
• Conjunctivitis and keratitis.
• Keratitis sicca most prominent clinical feature.

Physical Examination Findings
• Blepharospasm.
• Conjunctival hyperemia.
• Corneal lesions (opacity to ulceration).
• Gingivitis.
• Stomatitis.

CAUSES & RISK FACTORS
• Possible genetic predisposition in breeds with high incidence.
• Develops concurrently with other immune-mediated and autoimmune diseases.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Other causes of keratoconjunctivitis sicca—canine distemper, trauma, and drug toxicities.
• Keratoconjunctivitis sicca associated with other immune-mediated diseases—atopy, lymphocytic thyroiditis, polymyositis, systemic lupus erythematosus, rheumatoid arthritis, and pemphigoid diseases.

CBC/BIOCHEMISTRY/URINALYSIS
Normal

OTHER LABORATORY TESTS
• Hypergammaglobulinemia revealed by serum protein electrophoresis.
• Positive antinuclear antibody test.
• Positive lupus erythematosus cell test.
• Positive rheumatoid factor test.
• Positive indirect fluorescent antibody test for autoantibodies.

IMAGING
N/A

DIAGNOSTIC PROCEDURES
Schirmer tear test (0–5 mm/min; reference interval is 15–20 mm/min).

PATHOLOGIC FINDINGS
• Histologic changes in salivary glands—lymphoplasmacytic adenitis.
• Conjunctival biopsy—conjunctivitis.

TREATMENT

• Directed at controlling keratoconjunctivitis sicca.
• Any concurrent disease must be medically managed.
• May include administration of anti-inflammatory or immunosuppressive drugs.
• Surgical management of keratoconjunctivitis sicca indicated in animals that fail to respond to medical treatment.

MEDICATIONS

DRUG(S) OF CHOICE
• Topical tear preparations.
• Appropriate topical antibiotics for secondary bacterial infection, if present.
• Immunosuppressive or anti-inflammatory drugs.
• For more aggressive medical treatment and surgical intervention, see Keratoconjunctivitis Sicca.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Use of topical steroids in patients with acute keratoconjunctivitis sicca may cause corneal ulceration and is not recommended.

FOLLOW-UP

• Reexamine patients weekly until keratoconjunctivitis sicca controlled.
• Additional monitoring may be indicated to manage underlying or concurrent disease.
• Immunosuppressive drugs—monitor patients every other week for possible side effects.
• Prognosis variable and depends on existence of concurrent disease.

MISCELLANEOUS

SKIN FRAGILITY SYNDROME, FELINE

BASICS

OVERVIEW
- A disorder of multifactorial causes characterized by extremely fragile skin.
- Tends to occur in old cats that may have concurrent hyperadrenocorticism, diabetes mellitus, excessive use of megestrol acetate or other progesterone compounds, or as a paraneoplastic syndrome.
- A small number of cats have no biochemical alterations.

SYSTEMS AFFECTED
- Skin/exocrine.
- Endocrine/metabolic.

SIGNALMENT
- Naturally occurring disease tends to be recognized in old cats.
- Iatrogenic cases have no age predilection.
- No breed or sex predilection.

SIGNS

Historical Findings
- Gradual onset of clinical signs.
- Progressive alopecia (not always present).
- Often associated with weight loss, lusterless coat, poor appetite, and lack of energy.

Physical Examination Findings
- Skin becomes markedly thin and tears with normal handling.
- Skin rarely bleeds upon tearing.
- Multiple lacerations (both old and new) may be noted on close examination.
- Partial to complete alopecia of the truncal region may be noted.
- Sometimes associated with "rat tail," pinnal folding, pot-belly appearance.
- Differentiated from cutaneous asthenia by lack of hyperextensibility.

CAUSES & RISK FACTORS
- Hyperadrenocorticism—pituitary- or adrenal-dependent.
- Iatrogenic—secondary to excessive corticosteroid or progesterone drug administration.
- Diabetes mellitus—rare, unless associated with hyperadrenocorticism.
- Possibly idiopathic or paraneoplastic syndrome.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Cutaneous asthenia.
- Feline paraneoplastic syndrome—pancreatic neoplasia, hepatic lipidosis, cholangiocarcinoma.

CBC/BIOCHEMISTRY/URINALYSIS
- Little diagnostic significance in most cases.
- Approximately 80% of cats with hyperadrenocorticism have concurrent diabetes mellitus (hyperglycemia, glucosuria).

OTHER LABORATORY TESTS
- Adrenocorticotropic hormone (ACTH)-stimulation test—70% of cats with hyperadrenocorticism have an exaggerated response.
- Low-dose dexamethasone-suppression test—15–20% of normal cats may fail to decrease cortisol levels; typically unsuppressed with hyperadrenocorticism and nonadrenal illness.
- High-dose dexamethasone-suppression test—normal cats show decreases in cortisol concentrations; typically decreased with nonadrenal illnesses; considered by many clinicians to be the best screening test for hyperadrenocorticism; unreliable for discriminating between adrenal tumors and pituitary-dependent causes of hyperadrenocorticism, because both conditions fail to show suppression.
- Endogenous ACTH levels—normal range for most labs is 20–100 pg/mL.

IMAGING
- Abdominal ultrasonography—adrenal masses are often small until end-stage disease; cholangiocarcinoma and hepatic lipidosis have been reported.
- CT and MRI—small pituitary tumors may be difficult to visualize; MRI may be more successful.

PATHOLOGIC FINDINGS
Histopathology—suggestive, not diagnostic; epidermis and dermis are thin; attenuated collagen fibers are evident.

TREATMENT
- Underlying metabolic disease should be ruled out.
- Many patients are debilitated and require supportive care.
- Surgical correction of the lacerations—difficult because the tissue cannot withstand pressure from sutures.
- Protect skin—clothing; reduce activities that can traumatize the skin; remove sharp edges from the environment; prevent damage from interaction with other animals.
- Discontinue exogenous corticosteroids if administered.
- Hyperadrenocorticism—adrenalectomy is the preferred treatment.
- Cobalt-60 radiation therapy—variable success in the treatment of pituitary tumors.

MEDICATIONS

DRUG(S) OF CHOICE
- Medical management—may be useful for preparing patient for surgery and for minimizing postoperative complications (e.g., infections and poor wound healing).
- No known effective medical therapy for feline hyperadrenocorticism.
- Mitotane (1,1-(*o*,*p*′-dichlorodiphenyl)-2,2-dichloroethane [*o*,*p*′-DDD]) 12.5–50 mg/kg PO q12h; response has been equivocal; side effects include anorexia, vomiting, and diarrhea.
- Metyrapone 65 mg/kg PO q12h; clinical improvement noted more often with this drug than the others.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Hyperadrenocorticism—closely monitor diabetic cats; adjust insulin to prevent hypoglycemia when the cortisol levels fall.

FOLLOW-UP
Patients are often quite debilitated, making any form of treatment risky; close monitoring is required in all cases.

MISCELLANEOUS

ABBREVIATIONS
- ACTH = adrenocorticotropic hormone.

SMALL INTESTINAL DYSBIOSIS

BASICS

DEFINITION
• Small intestinal dysbiosis (SID) is a clinical syndrome caused by an alteration of the small intestinal microbiota. • Previously, a variety of different terms have been used to describe SID: ○ Small intestinal bacterial overgrowth (SIBO)—defined as $>10^4$ anaerobic and/or $>10^5$ total bacterial cfu/mL in duodenal juice from dogs. However, these criteria are now controversial. ○ Antibiotic-responsive diarrhea (ARD)—used by several authors to describe patients that have diarrhea that responds to antibiotic therapy. Neither the type of bacteria nor the type of antibiotic that is effective has been defined for ARD. ○ Tylosin-responsive diarrhea (TRD)—used by a group of clinicians in Finland to describe several dogs with chronic diarrhea that failed to respond to a variety of antibiotics or corticosteroids, but did respond to treatment with tylosin. • Currently, there is no consensus on the quantitative makeup of the gastrointestinal microbiota in healthy dogs or cats. • Note that SID differs from colonization of the alimentary tract by known pathogenic bacteria (e.g., *Salmonella* spp., *Campylobacter jejuni*, enterotoxigenic *Clostridium perfringens*, enterotoxic *Escherichia coli*, or others).

PATHOPHYSIOLOGY
• Bacteria are constantly ingested with food and/or saliva. • Host-protective mechanisms prevent overgrowth of pathogenic or potentially pathogenic bacteria through gastric acid secretion, intestinal motility (peristalsis), secretion of antimicrobial substances in bile and pancreatic juice, and local enteric IgA production. • The ileocolic valve is a physiologic barrier between the large bowel, which is populated by large numbers of bacteria, and the less populated small bowel. • When these natural defense mechanisms fail and excessive numbers of certain bacterial species persist in the upper small intestine, they may cause pathology, even though they are not considered obligate pathogens. • Anaerobic bacteria (e.g., *Bacteroides* spp. and *Clostridium* spp.) have been considered more likely to cause pathology than many aerobic bacteria.

SYSTEMS AFFECTED
• Gastrointestinal—normal absorptive function is disrupted, resulting in loose stool and weight loss. • Hepatobiliary—portal vein carries bacterial toxins and other substances to the liver, which may lead to hepatic changes.

GENETICS
• No genetic basis for SID has been identified. However, recent studies would suggest that histiocytic ulcerative colitis should be considered a type of dysbiosis of the large intestine. Since the majority of cases have been described in the boxer, genetic factors that predispose dogs of this breed to this type of dysbiosis are likely. • Certain canine breeds (e.g., German shepherd dog, Chinese Shar-Pei, and beagle) appear to be at an increased risk for SID.

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
Species
Dog and cat.

Breed Predilections
Subjectively, German shepherd dog, Chinese Shar-Pei, and beagle appear to have an increased incidence.

Mean Age and Range
• Unknown. • Can be diagnosed in dogs and cats of any age (age range: <1 year to >8 years).

Predominant Sex
No predilection.

SIGNS
General Comments
Alterations in the gut microbiota can cause clinical signs of small intestinal disease, such as loose stool or diarrhea, weight loss, and/or others.

Historical Findings
• Chronic loose stools or diarrhea (small bowel or large bowel type diarrhea)—common. • Weight loss, despite a reasonable appetite—common. • Borborygmus and flatulence—common. • Vomiting—occasional/variable. • Clinical signs of the underlying disease process may be seen in cases of secondary SID. • Clinical signs may wax and wane or be continuous.

Physical Examination Findings
Unremarkable or evidence of weight loss and decreased body condition.

CAUSES
• Primary SID is probably uncommon, but a definitive cause of SID often remains undiagnosed and thus many dogs are diagnosed with idiopathic SID. • Secondary SID (more common): ○ Altered small intestinal anatomy—inherited or acquired (e.g., congenital blind loop, partial obstructions, neoplasia, foreign body, intussusception, stricture, adhesion, or diverticulum). ○ Altered intestinal motility—hypothyroidism, autonomic neuropathies. ○ Exocrine pancreatic insufficiency (EPI)—approximately 70% of dogs with EPI have concurrent SID. ○ Hypochlorhydria or achlorhydria—spontaneous or iatrogenic (e.g., proton pump inhibitor treatment). ○ Altered immune system—immunodeficiency, decreased mucosal defense, and preexisting intestinal disease.

RISK FACTORS
Intestinal diseases that affect local defense mechanisms (e.g., inflammatory bowel disease [IBD], adverse food reactions, parasite infestation, others).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Secondary gastrointestinal disease (e.g., hepatic failure, renal failure, EPI, chronic pancreatitis, hypothyroidism, hypoadrenocorticism). • Primary gastrointestinal disease (i.e., infectious, inflammatory, neoplastic, mechanical, toxic, or other).

CBC/BIOCHEMISTRY/URINALYSIS
• Usually unremarkable. • Hypoalbuminemia—uncommon finding; when present, it suggests particularly severe intestinal disease and warrants an aggressive diagnostic and therapeutic approach.

OTHER LABORATORY TESTS
Serum Cobalamin and Folate Concentrations
• Serum folate concentration may be increased, as many bacterial species synthesize folate and an increased abundance of folate-producing bacterial species will lead to an overabundance of folic acid in the small intestine. • Serum cobalamin concentration may be decreased, as many bacterial species compete with the host for dietary cobalamin. • The finding of an increased serum folate concentration and a decreased serum cobalamin concentration is suggestive, but not specific for SID in dogs. In addition, not all patients with SID show this pattern.

Qualitative and Quantitative Bacterial Culture of Small Intestinal Juice
• Aerobic and anaerobic quantitative culture of duodenal fluid has long been considered the "gold standard" for the diagnosis of SIBO in human patients. • Invasive—requires endoscopy or laparoscopy. Not practical and not routinely available. • Recent work would suggest the species of bacteria that comprise the small intestinal microbiota may be more important than bacterial numbers. • No standardized protocols have been established for sampling, handling, and culturing of duodenal juice, leading to high variability in bacterial counts.

Dysbiosis index (DI)
• The fecal DI is a PCR-based assay that quantifies the abundances of eight bacterial groups in fecal samples of dogs and summarizes them in one single number. • A DI below 0 indicates a normal fecal microbiota; a DI above 0 indicates dysbiosis. Approximately 15% of clinically healthy dogs have an increased DI, with most of them falling into the equivocal range between 0 and 2. • Many dogs with chronic enteropathy or EPI have an abnormal

(CONTINUED) # SMALL INTESTINAL DYSBIOSIS

fecal DI. • Due to anatomical and physiological differences along the intestine, evaluation of the fecal DI may not accurately reflect microbiota changes in the small intestine. • Concurrent evaluation of serum concentration of cobalamin/folate with assessment of the fecal DI may help in the diagnosis of SID.

IMAGING
Not useful for the diagnosis of primary SID. However, may reveal findings indicative of an underlying cause.

DIAGNOSTIC PROCEDURES
Therapeutic Trial
• Treatment of patients with suspected SID with an antibiotic, a prebiotic, or a probiotic. • Interpreting the results of a therapeutic trial may be difficult as more than one disease (e.g., IBD plus SID, dietary intolerance plus SID) may be present, and lack of a clinical response might lead to the incorrect conclusion that SID is absent; incorrect selection of the treatment that is trialed might also cause failure of a clinical response.

PATHOLOGIC FINDINGS
• No macroscopic findings upon exploratory laparotomy or endoscopy. • Histopathology of small intestinal mucosal biopsies is typically unremarkable unless SID is caused by underlying intestinal disease.

TREATMENT
APPROPRIATE HEALTH CARE
• Outpatient medical management. • SID can be managed with antibiotics, prebiotics, probiotics, or a combination thereof:
○ Antibiotics—see Medications.
○ Prebiotics—see Diet. ○ Probiotics—there has been a lot of interest in probiotic use for dogs and cats with chronic diarrhea, although little is known about the efficacy. Currently, because of quality issues with many products, only probiotics from major manufacturers can be recommended. • Improvement may take a few days to several weeks.

NURSING CARE
• Usually none. • Supportive care for emaciated or hypoalbuminemic patients.

ACTIVITY
Unrestricted

DIET
• Highly digestible diet. • A diet containing fructooligosaccharides has been shown to be beneficial in dogs with SID.

CLIENT EDUCATION
• Some patients show clinical improvement within days. • Some patients require weeks of therapy before demonstrating improvement—treat for 2–3 weeks before concluding that therapy is ineffective. • Any concurrent or predisposing diseases (e.g., IBD, EPI, dietary intolerance/allergy, alimentary tract neoplasia, partial obstruction) must also be treated. • Continuous or repeated treatment is often required.

SURGICAL CONSIDERATIONS
Only indicated for some underlying causes of SID (i.e., partial obstruction, diverticulum, or intestinal mass).

MEDICATIONS
DRUG(S) OF CHOICE
• Broad-spectrum, orally administered antibiotics effective against both aerobic and anaerobic bacteria are preferred. • Tylosin (10–20 mg/kg PO q12h for 6 weeks) is the primary choice. Tylosin is usually used in a powder formulation that is marketed for use in poultry and pigs. It is administered in the food because of its bitter taste. It can be used long-term and is very safe and inexpensive. For small dogs and cats the drug should be reformulated into capsules. For larger dogs the dose can be approximated by using a teaspoon and administering the drug in food. • Metronidazole (10–15 mg/kg PO q12h for 6 weeks) is used commonly in routine practice because of its activity against anaerobic bacteria. Metronidazole may also have immunomodulatory effects. However, metronidazole can have significant side effects. • Dogs with SID may be cobalamin deficient, and parenteral or oral supplementation of vitamin B12 is indicated. See Cobalamin Deficiency for dosing information.

CONTRAINDICATIONS
None

PRECAUTIONS
Metronidazole can be associated with gastrointestinal side effects and in rare cases with neurologic side effects.

POSSIBLE INTERACTIONS
None

ALTERNATIVE DRUG(S)
In dogs with EPI and SID, concurrent therapy for SID is only indicated if enzyme replacement alone does not resolve the diarrhea and/or lead to weight gain.

FOLLOW-UP
PATIENT MONITORING
• Body weight and, in hypoproteinemic patients, serum albumin concentrations are the most important parameters; improvement suggests effective therapy. • Diarrhea should resolve. • If diarrhea persists despite improved body weight and/or increased serum albumin concentration, investigation for concurrent intestinal disease is indicated.

PREVENTION/AVOIDANCE
N/A

POSSIBLE COMPLICATIONS
N/A

EXPECTED COURSE AND PROGNOSIS
Primary SID without complicating factors (e.g., IBD, lymphoma) usually has a good prognosis, although relapses can be seen following cessation of antibiotic therapy.

MISCELLANEOUS
ASSOCIATED CONDITIONS
• SID has been suspected as a cause of IBD in some patients. • EPI.

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
None

PREGNANCY/FERTILITY/BREEDING
Avoid oxytetracycline or metronidazole, especially during early pregnancy.

SYNONYMS
SIBO, ARD, or TRD may be used synonymously by some authors.

SEE ALSO
• Cobalamin Deficiency. • Diarrhea, Chronic—Cats. • Diarrhea, Chronic—Dogs.
• Exocrine Pancreatic Insufficiency.
• Inflammatory Bowel Disease.
• Lymphoma—Cats. • Lymphoma—Dogs.

ABBREVIATIONS
• ARD = antibiotic responsive diarrhea. • DI = dysbiosis index. • EPI = exocrine pancreatic insufficiency. • IBD = inflammatory bowel disease. • SIBO = small intestinal bacterial overgrowth. • SID = small intestinal dysbiosis. • TRD = tylosin-responsive diarrhea.

SMOKE INHALATION

BASICS

OVERVIEW

• Injury secondary to direct heat damage to upper airway and nasal mucosa. Inhalation of toxins directly irritates the airway, and particulate matter adheres to the airways and alveoli. • Carbon monoxide decreases tissue oxygen delivery by preferentially binding to hemoglobin. • Cyanide interferes with oxygen usage in oxidative phosphorylation. • Extent of damage depends on the degree and duration of exposure and the material that was burning. • Serious lung injury possible with little external evidence of burning. • Lung reaction—initially bronchoconstriction, airway edema, mucus production and airway occlusion; then an inflammatory response, necrotizing tracheobronchitis, and pulmonary fluid accumulation due to increased capillary permeability. • Lung dysfunction typically progresses during initial 2–3 days. • Secondary bacterial infections—common cause of morbidity late in the disease.

SIGNALMENT

Dog and cat.

SIGNS

• Historical findings consistent with exposure. • Smoky odor. • Tachypnea and increased respiratory effort. • Inspiratory effort suggests upper airway obstruction by edema. • Postural adaptations to hypoxemia. • Mucous membranes can be cherry red (from carboxyhemoglobin), pale, or cyanotic. • Auscultation of wheezes, harsh broncho-vesicular sounds, or crackles. • Cough. • Burns, shriveled whiskers, conjunctival edema, corneal ulcers. • Neurologic signs indicate carbon monoxide or cyanide toxicity. • Cardiac arrhythmias and hypotension can be seen secondary to hypoxemia, smoke and carbon monoxide inhalation, and burn injuries.

CAUSES & RISK FACTORS

Exposure to smoke, usually from being trapped in a burning building.

DIAGNOSIS

CBC/BIOCHEMISTRY/URINALYSIS

• Neutropenia—poor prognostic sign; suggests neutrophil sequestration in the lungs. • Thrombocytopenia—suggests platelet sequestration or consumption. • Biochemistry profile—evidence of hypoxic damage to other organ systems can be present.

IMAGING

Thoracic radiographs—establish a baseline; findings vary from normal to a broncho-interstitial or alveolar pattern.

DIAGNOSTIC PROCEDURES

• Bronchoalveolar lavage/endotracheal wash if suspected secondary bacterial infection: culture; cytology—acute suppurative reaction with excessive mucus, neutrophils, and alveolar macrophages; intracellular bacteria indicate concurrent infection. • Arterial blood gas to confirm hypoxemia. Pulse oximetry difficult to interpret as carboxy-hemoglobin falsely increases values. Co-oximetry showing carboxyhemoglobin levels >15% indicates toxicity. • Bronchoscopy demonstrates severity of airway damage, and is used to remove foreign particles and accumulated secretions.

TREATMENT

• Initial management—stabilize respiratory function; establish patent airway; severe upper airway edema or obstruction can require intubation or temporary tracheostomy. • Oxygen—administer immediately to displace carbon monoxide from hemoglobin; use the highest available concentration for 2–4 hours (or longer); after elimination of carboxyhemoglobin, supplement as needed. • Fluid therapy—crystalloid fluid resuscitation as needed to maintain perfusion with care to avoid fluid overload and progressive pulmonary edema. Associated burns can result in significant fluid and protein losses which may also require concurrent colloidal support (synthetic, albumin, plasma). • Nebulization of saline—moistens airway secretions to facilitate clearance. • Mechanical ventilation needed in severe cases. • Nutritional support—maintain body condition and immune status.

MEDICATIONS

DRUG(S) OF CHOICE

• Suspected bacterial infection—broad-spectrum antibiotics, ideally after bacterial culture has been obtained. • Bronchodilators—improve respiratory function if severe bronchoconstriction, especially cats (e.g., terbutaline 0.01 mg/kg IV, IM, SC). Inhaled beta-agonists can also be beneficial. • Corticosteroids—controversial, single early, anti-inflammatory dose or aerosolized corticosteroids may decrease airway edema. • Analgesia—as required for associated discomfort. Avoid oversedation due to decreased respiratory drive.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

• Diuretics—decrease IV volume without a major beneficial effect. • Corticosteroids—use only once and if absolutely necessary; can predispose the patient to bacterial infection.

FOLLOW-UP

PATIENT MONITORING

• Respiratory rate and effort, mucous membrane color, heart rate, pulse quality, lung auscultations, and packed cell volume/total solids for 24–72 hours. • Repeat radiographs in 72 hours—ensure condition is resolving; monitor for bacterial pneumonia. • Pulse oximetry and arterial blood gas analysis—to monitor hypoxemia and response to therapy.

POSSIBLE COMPLICATIONS

• Bacterial tracheobronchitis or pneumonia. • Profound pulmonary inflammatory response or severe systemic inflammatory response syndrome may result in acute respiratory response syndrome. Bronchiectasis can develop secondary to airway injury and impaired mucociliary clearance. • Carbon monoxide toxicity may lead to acute and delayed neurologic signs including seizures, cerebral edema, ataxia, paresis, and changes in mental status.

EXPECTED COURSE AND PROGNOSIS

• Good if responding to treatment—likely to worsen prior to improving. Prognosis declines if complications occur. • Severe burns or organ injury—poor prognosis.

SNAKE VENOM TOXICOSIS—CORAL SNAKES

BASICS

OVERVIEW

- Two clinically important species in North America—*Micrurus fulvius*, eastern coral snake (North Carolina to the north; southern Florida to the south; west of the Mississippi River) and *Micrurus tenere*, Texas coral snake (west of Mississippi; in Arkansas, Louisiana, and Texas).
- Family Elapidae—fixed front fangs.
- Color pattern—bands fully encircling the body; red, yellow, and black; distinguished from the harmless tricolored king snake (*Lampropeltis elapsoides*) by the arrangement of the bands: if yellow (caution) and red (danger) color bands touch, then stay clear; relatively small head; black snout; round pupils.

Bites

- Relatively uncommon due to snake's reclusive behavior and nocturnal habits.
- Often occur on the lip. Snakes remain attached due to chewing action.
- Distinct fang marks may not be obvious.
- Primary cause of death—respiratory collapse.

SIGNALMENT

Dogs and cats.

SIGNS

- Onset of clinical signs may be delayed several hours (up to 18 hours).
- Localized signs generally absent.
- Generalized weakness and ataxia.
- Bulbar paralysis—affecting cranial motor nerves, respiratory tract, and skeletal muscles; acute flaccid quadriplegia.
- Salivation—caused by dysphagia.
- Dyspnea.
- Dysphonia.
- Hyporeflexive spinal reflexes.
- Seizures.
- Urinary incontinence.

CAUSES & RISK FACTORS

- Size of the snake.
- Size and duration of bite.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Myasthenia gravis.
- Botulism.
- Polyradiculoneuritis.
- Tick bite paralysis.
- Black widow spider bite (*Latrodectus* spp.).

CBC/BIOCHEMISTRY/URINALYSIS

- Hemolysis—dogs only.
- Red blood cell burring.
- May note high creatine kinase.
- Hemoglobinuria—dogs only.

OTHER LABORATORY TESTS

N/A

DIAGNOSTIC PROCEDURES

N/A

TREATMENT

- First aid—generally avoid; most effective measure is rapid transport to a veterinary facility for antivenom administration; Australian technique for elapid bites is a pressure wrap of the bitten limb with ace-type bandage to decrease blood flow and venom uptake.
- *Caution*: do not wait for onset of clinical signs to initiate treatment.
- Inpatient—hospitalize for a minimum of 48 hours.
- Monitor CNS and respiratory function closely for 24 hours.
- Specific antivenin is extremely limited for *M. fulvius* envenomations in the United States and typically not accessible for veterinary use. However, protective crossreactivity occurs with the following antivenins: Coralmyn (Fab2 equine origin) (Instituto Bioclon, Mexico), Costa Rican coral snake antivenin (Instituto Clodomiro Picado, Costa Rica), and Australian tiger snake *Notechis scutatus* (CSL Limited, Parkville, Victoria, Australia). Expense may be a consideration. Local zoos may have antivenom available. Application for an INR permit from the US Department of Agriculture may allow a veterinary hospital to acquire these antivenoms.
- If antivenin unavailable—provide ventilatory support for several days in a critical care facility.

MEDICATIONS

DRUG(S) OF CHOICE

- *M. fulvius* reactive antivenin (see Treatment)—indicated if the history includes recent coral snake interaction; evidence of puncture wounds; clinical signs consistent with coral snake envenomation; administer 1–2 vials; additional vials may be necessary (technique same as for pit viper antivenin).
- Broad-spectrum antibiotics are not routinely recommended and should only be used if there is indication of infection.
- Neostigmine – may be useful to reverse neuromuscular blockade if antivenin not available. Has been used successfully to treat *M. frontalis* envenomation in Brazil.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Corticosteroids—not indicated.
- Observe precautions outlined for pit viper antivenin administration (see Snake Venom Toxicosis—Pit Vipers).

FOLLOW-UP

- Marked clinical signs may last 1–1.5 weeks.
- Full recovery may take months as receptors regenerate.

MISCELLANEOUS

SEE ALSO

Snake Venom Toxicosis—Pit Vipers.

SNAKE VENOM TOXICOSIS—PIT VIPERS

BASICS

OVERVIEW

• Pit vipers—*Crotalus* spp. (rattlesnakes), *Sistrurus* spp. (pigmy rattlesnakes and massasauga), and *Agkistrodon* spp. (copperheads and cottonmouth water moccasins); retractable fangs; heat-sensing pit between the nostril and eye; triangle-shaped head.
• Range—throughout the United States (not found in Alaska, Hawaii, Maine).
• Toxicity—considered hemotoxic; several species have subpopulations with lethal neurotoxic components (e.g., Mohave rattlesnake); general ranking of severity: (1) rattlesnakes, (2) moccasins, (3) copperheads.

Pathophysiology

• Venom—enzymes: hyaluronidase and phospholipase A (cause local tissue injury) and others that interfere with the coagulation cascade (cause major coagulation defects); non-enzymatic polypeptides: affect the cardiovascular and respiratory systems.
• Bite—80% of victims have altered laboratory values and clinically important swelling; severe hypotension from pooling of blood within the splanchnic (dogs) or pulmonary (cats) vessels; fluid loss from the vascular compartment secondary to severe peripheral edema.
• Approximately 20% crotalid bites considered "dry bites" with little if any venom deposited and no associated toxicity.

Systems Affected

• Behavioral—usually related to pain.
• Cardiovascular—lower blood pressure, direct cardiotoxins (Eastern and Western Diamondback rattlesnake venom).
• Gastrointestinal—nausea, diarrhea.
• Hematologic—coagulopathies (hypercoagulation or consumptive), thrombocytopenia.
• Musculoskeletal—rhabdomyolysis.
• Nervous—multiple crotalid species have individuals with venom containing Mojave toxin, a potent neurotoxin.
• Skin—puncture wounds possible local tissue necrosis.

SIGNALMENT

Dogs and cats.

SIGNS

General Comments

May be delayed for 8 hours after envenomation.

Historical Findings

• Outdoors, rural setting, indigenous snake.
• Owner saw bite or heard snake.

Physical Examination Findings

• Puncture wounds on head and forelimbs in most animals.
• Local tissue swelling and pain surrounding bite site.
• Bruising, with possible necrosis and sloughing of bite site tissue.
• Ecchymosis and petechiation of tissues and mucous membranes.
• Hypotension and shock.
• Tachycardia.
• Shallow respiration.
• Depression, lethargy, and muscle weakness.
• Nausea and excessive salivation.

CAUSES & RISK FACTORS

Outdoor activity.

Snake-Associated

• Toxic peptide fraction: enzyme fraction ratio—higher in spring and lower in fall (not well documented); high in very young snakes.
• Amount of venom production since last bite.
• Size, fang length, aggressiveness, and motivation of snake.

Victim-Associated

• Bite site—bites to tongue and torso are of major concern.
• Size of victim.
• Elapsed time between bite and initiation of treatment.
• Activity level of victim after the bite—activity increases absorption of venom.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Angioedema secondary to insect envenomation (spider, scorpion, large centipede).
• Blunt trauma.
• Penetrating wound.
• Animal bite.
• Penetration of foreign body.
• Draining abscess.

CBC/BIOCHEMISTRY/URINALYSIS

• Hemoconcentration.
• Frequent burring of red blood cells within first 24 hours (echinocytes).
• Thrombocytopenia.
• Hypokalemia.
• Elevated creatine kinase.
• Hematuria or myoglobinuria.

OTHER LABORATORY TESTS

Clotting tests—reduced platelets and fibrinogen, monitor for prolonged activated clotting time, prothrombin time, and partial thromboplastin time; may note elevated fibrin degradation products.

DIAGNOSTIC PROCEDURES

• Clinical evaluation of bite for edema, ecchymosis, fang punctures, pain.
• Electrocardiogram—may detect ventricular arrhythmia, especially in severely depressed patients.

PATHOLOGIC FINDINGS

• Puncture wounds.
• Tissue necrosis.
• Hemorrhage, petechiation, ecchymosis.
• Pulmonary hemorrhage, edema.

TREATMENT

• Tissue reaction around the bite site—not a reliable indicator of systemic toxicity.
• Bite location—may affect uptake of venom; bites to tongue and torso are of major concern. Distal limb bites may result in significant tissue damage and compromise limb function.
• First aid measures—minimize activity, calm patient, provide analgesia if indicated; transport quickly to a veterinary facility.
• Swelling can be objectively monitored with circumferential measurements using a cloth or flexible tape measure.
• Antivenom is only proven specific treatment (see Medications). Expense may be an important factor.
• IV fluids—correct hypotension.
• Analgesics to reduce pain and stress.
• Antibiotics—infection is rare and antibiotics are not recommended unless there is evidence of infection.
• Repeat coagulation profile after administration of antivenom for comparison to earlier labs (typically the author performs on entry, 6 hours and 12 hours unless patient is obviously worsening). Recurrence of clinical signs or coagulation abnormalities can occur with any antivenin. This usually happens when initial coagulopathy is more severe. If initial coagulopathy resolved with antivenin administration, recurrence can occur within the next few days, although rarely as severe as initial. There are no documented cases of clinical bleeding with subsequent coagulopathy; however, the clinician should be aware of the possibility.

Activity

Initially restrict exercise as this can increase uptake of venom, once envenomation syndrome under control—activity as the patient will tolerate.

Client Education

• Monitor patient for ecchymosis or petechiation.
• Monitor for evidence of serum sickness.

MEDICATIONS

DRUG(S) OF CHOICE

Antivenom

• Always flush antivenom vial after initial removal of antivenom, second flush can increase antibody collection by 30%.

(CONTINUED) SNAKE VENOM TOXICOSIS—PIT VIPERS

• Allergic reaction—stop antivenom; give diphenhydramine; after 5 minutes, restart antivenom infusion at a slower rate.
• Mix each vial of antivenom with 100–150 mL of a crystalloid fluid and administer IV slowly while taking into consideration the patient's weight and overall fluid load. Infuse over 30 minutes–1 hour.
• Carefully monitor the inner pinna for onset of hyperemia (indicator of possible allergic reaction).
• With the exception of Crofab™ all antivenoms have approximately 20% of their protein content as actual antibodies against snake venom.
• Frequent administration of antivenom controls the animal's pain.
• Other analgesics as needed to control pain.

Veterinary Licensed

• VenomVet™ (Crotalidae polyvalent, equine origin, Fab2). Injectable solution, no need to reconstitute. Two South American immunizing snake species.
• Antivenin™ (Crotalidae polyvalent, equine origin, whole IgG—Boehringer-Ingelheim), reactions more common due to extraneous proteins. Lyophilized. Two North American snake species and two South American species immunizing snake species.
• Rattler Antivenin™ (polyvalent, equine origin, whole IgG—Mg Biologics) equine plasma product, frozen. Four North American immunizing snakes.

FDA Licensed but Published Studies in Dogs

• Crofab® (polyvalent, ovine Fab1—BTG International) first prospective clinical trial of antivenom in dogs. Purified antibody fragments provide much less possibility for reactions. 99% protein is Fab1 antibodies against snake venom.
• Antivipmyn® (polyvalent, equine Fab2—Rare Disease Therapeutics) has completed safety and clinical trials in dogs. Purified antibody particles much less possibility for reactions.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

• *Caution*: in animals receiving beta-blockers, the onset of anaphylaxis may be masked; therefore, the condition may be more advanced once recognized and more difficult to treat effectively.
• Corticosteroids—of no value.
• Dimethyl sulfoxide (DMSO)—enhances uptake and spread of venom.
• Heparin—do not use; not effective against thrombin-like enzymes and worsens coagulopathies.

Alternative Drug(s)

Rattlesnake vaccine for dogs is currently marketed. Its efficacy is unknown, but several published papers have shown mixed results; only anecdotal evidence at this time. Not recommended until peer-reviewed efficacy data available.

FOLLOW-UP

• Repeated laboratory analysis—6 hours after admission to hospital.
• Clinical signs—may last 1–1.5 weeks.
• Once released, owner should monitor for recurrence of coagulopathies or delayed serum sickness.

MISCELLANEOUS

AGE-RELATED FACTORS

• None unless underlying pathology (e.g. renal disease).
• Patients receiving other medications (e.g. nonsteroidal anti-inflammatory drugs).

PREGNANCY/FERTILITY/BREEDING

• Antivenom has been given to pregnant animals and humans with no adverse events.
• Pregnancy is at risk from venom effects upon placenta and fetal tissue.

S

SNEEZING, REVERSE SNEEZING, GAGGING

BASICS

DEFINITION
• Sneezing—a normal, protective, expiratory reflex that serves to expel air and material from the lungs through the nasal cavity and mouth.
• Reverse sneezing—a normal protective, repetitive inspiratory reflex that serves to remove irritants from the nasopharynx (also termed the aspiration reflex).
• Gagging—a normal protective reflex to clear secretions from the larynx, trachea, pharynx, or esophagus. Prevents irritating/toxic material from entering these structures; often misinterpreted as vomiting by owners.

PATHOPHYSIOLOGY
• Irritation of submucosal irritant receptors; various stimuli (infectious, parasitic, irritant, mechanical—especially accumulated secretions) will elicit these reflexes depending on where the irritation is applied.
• Sneezing—nasal mucosal irritation; improves with chronicity.
• Reverse sneezing—caudodorsal nasopharyngeal mucosal irritation triggers pharyngeal muscle spasms, subsequent laryngeal obstruction and movement of material into the oropharynx.
• Gagging—intraoral stimulation (tracheal, laryngeal, oropharyngeal, potentially esophageal mucosal irritation) detected by afferent limb of gag reflex. Efferent limb gives rise to uncoordinated muscle movement characteristic of gagging.

SYSTEMS AFFECTED
• Respiratory—frequently associated with infectious or inflammatory conditions involving the upper respiratory tract.
• Gastrointestinal—gagging may also be caused by swallowing, esophageal, or gastric disorders.

GENETICS
N/A

INCIDENCE/PREVALENCE
These are common, normal reflexes in both dogs and cats in response to mucosal irritation.

GEOGRAPHIC DISTRIBUTION
Worldwide

SIGNALMENT
• Any dog or cat may be affected.
• These reflexes associated with the conditions that cause them; examples include:
  ○ Young animals—infection, congenital defects (cleft palate0, primary ciliary dyskinesia.
  ○ Older animals—nasal tumors, dental disease.
• Acute sneezing in dogs is most often caused by a nasal foreign body, while in cats it is most often associated with acute viral rhinitis.

SIGNS
• Head and mouth position may help owners determine which of these reflexes are present.
• Sneezing typically results in sudden, explosive expiratory effort(s) with the mouth closed and head thrown downward; may result in the animal's nose hitting the ground.
• Reverse sneezing is a sudden, often paroxysmal, noisy, inspiratory effort with the head pulled back, mouth closed, and lips sucked in.
• Gagging is an expiratory effort; typically, with the head and neck extended and mouth held open; usually ends with the animal swallowing (with little to nothing expelled).
• Nasal discharge commonly seen with sneezing and reverse sneezing. Retching, coughing and vomiting may accompany gagging.

CAUSES
• Any mucosal irritation or inflammation can elicit these airway reflexes. The reflex localizes the site of irritation for further evaluation.
• Nasal causes of sneezing and reverse sneezing include excess nasal secretions, rhinitis (idiopathic, secondary bacterial, viral or mycotic infections), foreign body, non-neoplastic masses (nasopharyngeal polyps, inflammatory polyps of the nasal turbinates), neoplasia, and parasites; dogs—*Pneumonyssoides*; dogs and cats—*Cuterebra*, *Eucoleus* (*Capillaria*), *Linguatula*.
• Extranasal diseases resulting in reverse sneezing, sneezing and gagging—pneumonia, esophageal strictures, megaesophagus, chronic vomiting, cricopharyngeal disorders, dental disease (oronasal fistulas, tooth root abscess).
• Reverse sneezing may be idiopathic, especially in small-breed dogs with no other associated clinical signs.
• Causes of gagging include:
  ○ Secretions being coughed up from the lower airways and into the larynx or cervical trachea.
  ○ Pharyngeal/laryngeal dysfunction resulting in airway aspiration due to loss of motor and/or sensory function that normally protects the airway.
  ○ Vomiting from esophageal and gastrointestinal disease.

RISK FACTORS
• Brachycephalic and dolichocephalic breeds may be overrepresented.
• Incompletely or unvaccinated animals are at a higher risk of developing infection.
• Outdoor animals, especially hunting dogs, perhaps more at risk for nasal foreign bodies and nasal infections.
• Chronic dental disease can cause rhinitis and either sneezing or reverse sneezing.
• Environmental factors like dusty areas, smoke inhalation, perfumes, cold air.
• Productive coughing may produce excess secretions that can be propelled into the nasopharynx and lead to reverse sneezing.
• Nasal mites may cause both reverse sneezing and sneezing in dogs (but not cats); in the United States, incidence is inversely proportional to heartworm preventive usage.
• Reverse sneezing is often associated with excitement.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Similar Signs
• Differentiate regular sneezing (occurs on expiration) from reverse sneezing (occurs on inspiration and localizes the site of irritation to the nasopharynx).
• Gagging is often misinterpreted as vomiting.

CBC/BIOCHEMISTRY/URINALYSIS
Nonspecific for any cause of sneezing, reverse sneezing, or gagging. Identifies comorbidities.

OTHER LABORATORY TESTS
Virus isolation, culture or PCR for upper respiratory tract infections (FCV, FHV-1, feline and canine influenza); retroviral testing (FeLV, FIV); cryptococcal antigen testing; *Aspergillosis* testing; bacterial cultures (*Mycoplasma* spp., *Bordetella bronchiseptica*); cytology, histopathology and coagulation studies if indicated.

IMAGING
• Sneezing and reverse sneezing—skull radiographs, CT/MRI.
• Gagging—thoracic radiographs, fluoroscopy (dynamic swallow study), CT/ MRI.

DIAGNOSTIC PROCEDURES
• Sneezing and reverse sneezing—antegrade and retrograde rhinoscopy, nasal biopsy (histopathology), nasal culture (deep nasal flush sample), periodontal probing.
• Gagging—neurologic examination (CN V, IX, X, XII), sedated oropharyngeal exam, transtracheal wash, or bronchoalveolar lavage.

PATHOLOGIC FINDINGS
Nonspecific inflammation can be found in the nasal cavity or nasopharynx.

TREATMENT

APPROPRIATE HEALTH CARE
Removal of the inciting mucosal irritation, where/when possible, will result in relief from these reflexes.

NURSING CARE
Outpatient therapy generally indicated, except perhaps following rhinoscopic biopsy.

ACTIVITY
Exercise and activity should be restricted after rhinoscopic biopsies to prevent excessive bleeding.

DIET
N/A

CLIENT EDUCATION
- Educate clients so they understand these are normal reflexes. Diagnostic testing is required to determine the underlying cause and to allow appropriate treatment.
- Close contact with other animals should be limited until treatment for the underlying cause (if infectious) is completed.
- Episodes of paroxysmal reverse sneezing may be lessened by inducing swallowing (rubbing the throat, giving water) or breath holding (cover nose and mouth).

SURGICAL CONSIDERATIONS
- Anesthesia for surgery or endoscopy—abscessed tooth, foreign body, masses or anatomical airway abnormality, treatment of fungal infections.
- Use surgery for laryngeal disease with caution when gagging is prominent due to an increased risk of aspiration pneumonia when concurrent esophageal dysfunction is present.

MEDICATIONS

DRUG(S) OF CHOICE
- There is no drug that specifically suppresses these reflexes; treatment is directed at the underlying irritant.
- Nasal bacterial infections best treated with antibiotics directed against Gram-positive bacteria (most common). Fungal disease treated with systemic and local infusion of antifungals.
- Nasal mites are treated with ivermectin 200–300 µg/kg PO or SC weekly for 3 weeks, selamectin 6–24 mg/kg applied topically every 2 weeks for 3 doses, or milbemycin (in collies and similar breeds) 0.5–1 mg/kg PO weekly for 3 weeks. All dogs in the household should be treated to prevent reinfection.
- When no underlying nasal condition is found to explain sneezing, nasal mite treatment is recommended. Immunomodulatory antibiotics such as doxycycline 5–10 mg/kg PO q12–24h and azathioprine 1–2 mg/kg/day PO in combination with piroxicam 0.3 mg/kg PO daily may be considered.
- Lower airway diseases with excess secretions are treated with antibiotics if bacterial infection is confirmed; Gram-negative bacteria are most common.
- Anti-inflammatory—prednisolone 1–2 mg/kg q12–24h or piroxicam 0.3 mg/kg PO q24–48h if no infection, for nonspecific airway inflammation.
- No treatment for gagging secondary to sensory loss in the larynx with recurring aspiration; elevation of food and water bowls is recommended. Altering the consistency of food offered may also be helpful.

CONTRAINDICATIONS
- Ivermectin in collies and similar breeds (*MDR1* gene mutation).
- Use of piroxicam concurrently with other nonsteroidal anti-inflammatory drugs or corticosteroids, as well as in patients with renal insufficiency.

PRECAUTIONS
The safety of most recommended drugs has not been established in pregnant animals.

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUG(S)
- Topical decongestants— 0.125% phenylephrine or 0.025% oxymetazoline.
- Antihistamines (diphenhydramine, Zyrtec, Claritin) may reduce secretions and sneezing in some cases with underlying allergic component.

FOLLOW-UP

PATIENT MONITORING
Expect reduction in sneezing/reverse sneezing with appropriate therapy.

PREVENTION/AVOIDANCE
Limit access to foreign bodies, provide adequate dental care and appropriate vaccination.

POSSIBLE COMPLICATIONS
If gagging is secondary to laryngeal sensory loss, serious aspiration pneumonia may develop.

EXPECTED COURSE AND PROGNOSIS
- Nasal mites should respond to treatment within 3 weeks.
- Sneezing and reverse sneezing secondary to foreign material resolve quickly after removal of the foreign body.
- Neoplasia may carry a poorer prognosis (chemotherapy or radiation therapy may be indicated).

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
Rare; immunocompromised individuals at greater risk with infectious causes.

PREGNANCY/FERTILITY/BREEDING
N/A

SEE ALSO

SOFT TISSUE SARCOMA

BASICS

DEFINITION
• A mesenchymal neoplasm arising within or from connective tissues. • Tumors in this heterogeneous group have different histologic origins yet demonstrate similar pathologic features and clinical behavior, and include fibrosarcoma, leiomyosarcoma, peripheral nerve sheath tumor, and myxosarcoma. Histology reports may commit only to soft tissue arcoma (STS) or spindle cell sarcoma, and may not distinguish among cell of origin without immunohistochemistry. • Because of divergent pathogenesis and biologic behavior, this group of tumors does not include hemangiosarcoma and other tumors that sometimes share the suffix (for example melanosarcoma, osteosarcoma, or lymphosarcoma). Histiocytic sarcoma is also considered separately.

PATHOPHYSIOLOGY
• Tumors can arise in connective tissues in any anatomic location. • Locally invasive behavior is typical with tumor extension beyond gross visible margins. • Tumors often have low (<20%, low grade/grades 1–2) to moderate (40–50%, high grade/grade 3) metastatic potential. • Tumors can develop at sites of chronic inflammation such as following ocular trauma or injection sites (cats). Also in vaccine-induced sarcomas in cats, the aluminum adjuvant may have inflammation-independent carcinogenic effects.

SYSTEMS AFFECTED
• Skin—most commonly arise from skin or subcutis. • Musculoskeletal—from muscle, fascial and fibrous tissues. • Nervous—originate from neurovascular structures. • Respiratory—STS metastasize hematogenously, with predilection for pulmonary metastases development in advance disease stages. • Lymphatic—regional lymph nodes are rare sites of metastasis.

GENETICS
There are no specific breed predilections that would suggest genetic predisposition.

INCIDENCE/PREVALENCE
• STS constitute 7% and 15% of skin and subcutaneous tumors in the cat and dog, respectively. • Incidence annually around 17 per 100,000 cats at risk; 35 per 100,000 dogs at risk.

SIGNALMENT
Species
All including the dog and cat.

Breed Predilections
None identified but large-breed dogs are often overrepresented.

Mean Age and Range
• Dogs—middle-aged, range 2–15 years. An exception is rhabdomyosarcoma of the bladder that often arises in younger dogs. • Cats—middle-aged, range 1.4–18.8 years.

Predominant Sex
No predilection.

SIGNS
Historical Findings
• Rate of growth often reflects grade (low grade = slow-growing; high grade = rapid). • Typically nonpainful, fluctuant to firm mass. • Signs depend on location and local structures affected by tumor presence or invasion. • Tumors arising in the abdomen may elicit signs due to compression of the gastrointestinal tract and could include vomiting and/or diarrhea, anorexia, and weight loss. Additionally signs of intestinal obstruction and occasionally perforation can occur with gastrointestinal leiomyosarcoma. • Urinary signs of hematuria and dysuria may be seen in young dogs with bladder rhabdomyosarcoma. • Peripheral nerve sheath tumors affecting the brachial or lumbosacral plexus can cause signs of lameness and pain, muscle atrophy, limb weakness progressing to paralysis. • Signs of hypoglycemia (paraneoplastic) such as weakness, collapse, and seizures can occur with leiomyoma or leiomyosarcoma.

Physical Examination Findings
• Soft tissue mass that is soft, fluctuant, or firm on palpation. • Often adhered to underlying tissue. • Nonpainful unless ulcerated or invading into muscles or nerves.

CAUSES
• Dogs—STS have been documented following radiation therapy, trauma, orthopedic implants, foreign bodies, and the parasite *Spirocerca lupi* (esophageal sarcoma). • Cats—See Pathophysiology.

RISK FACTORS
See Causes.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Abscess. • Other cutaneous tumors, both benign and malignant (lipoma, basal cell tumors, mast cell tumors). • Fungal granuloma.

CBC/BIOCHEMISTRY/URINALYSIS
• Usually normal. • Hypoglycemia in dogs with leiomyoma or leiomyosarcoma (paraneoplastic syndrome mediated primarily by insulin-like growth factors produced by tumor).

OTHER LABORATORY TESTS
N/A

IMAGING
• Three-view thoracic radiographs are recommended before treatment as the lungs are the most likely site of metastasis for STS when it occurs. • Contrast CT or MRI can be used to determine extent of disease and to optimize treatment planning (surgery or radiation). • Abdominal ultrasound may be indicated for diagnosis of intra-abdominal STS and to allow assessment of liver, spleen, and abdominal lymph nodes.

DIAGNOSTIC PROCEDURES
• Fine-needle aspiration and cytology can rule out other differential diagnoses and may suggest a diagnosis but a nondiagnostic sample is possible as cells do not always exfoliate well. • Incisional biopsy and histopathology is essential to confirm diagnosis, determine grade of the tumor, and plan surgical approach. • Regional lymph node evaluation (cytology or histopathology) is indicated for assessment of enlarged regional lymph nodes and for high-grade tumors to evaluate for regional metastasis.

PATHOLOGIC FINDINGS
Dogs
• Over 20 different histopathologic subtypes of STS exist; biologic behavior is similar regardless of subtype. • Histologic grading based on differentiation, number of mitotic figures per 10 high power fields and percentage necrosis: ◦ Grade I (low grade). ◦ Grade II (intermediate grade). ◦ Grade III (high grade) is the most biologically aggressive.

Cats
• Some similarities between histopathologic subtypes compared to dogs. Peripheral nerve sheath tumors are rare in cats. • Vaccine or injection site sarcomas have a more aggressive histologic appearance compared to other naturally occurring sarcomas.

TREATMENT

CLIENT EDUCATION
A mass lesion with nondiagnostic and low cellularity cytology should be suspicious for a sarcoma. Postvaccination lumps in cats should be biopsied if they are growing larger within 1 month, are greater than 2 cm, or persist beyond 3 months after first appearing.

SURGICAL CONSIDERATIONS
• Early, aggressive, *en bloc* surgical excision is the treatment of choice. Conventional recommendations are 3 cm margins and 1 fascial plane deep (2 fascial planes deep for feline injection site sarcoma [FISS]). Even with complete excision, FISS can recur (30% or greater). • Do not place a drain through normal adjacent tissue during surgery if margins are uncertain. • Microscopically,

(CONTINUED) SOFT TISSUE SARCOMA

cancer cells extend far beyond palpable tumor borders and recurrence is common if only macroscopic tumor is removed or peeled away from pseudocapsule. • Pseudocapsule composed of compressed cancer cells is common. • A second surgery (scar resection) can be performed prior to recurrence after incomplete excision to achieve more complete margins and decreased risk of recurrence. • After excision, tack mobile fascial layers in place and apply ink to surgical borders to thoroughly evaluate margins; submit the entire sample to a pathologist for surgical margin evaluation. Mark margins of greatest interest with suture or different color ink. • Toe or limb amputation may be necessary with large tumors that may be otherwise unresectable. • Rib resection or abdominal wall resection may be required for tumors of the trunk. • The first surgery usually provides the best opportunity for local tumor control. • Recurrent tumors will require different therapy rather than just repeating the same surgery (typically radiation therapy or a much larger surgery).

RADIATION THERAPY

Dogs

Radiation therapy can be used to treat microscopic disease (postoperatively with incomplete histologic margins, finely fractionated) or for measurable/unresectable disease (often hypofractionated).

Cats

Given the high rate of recurrence with feline injection site sarcoma, fractionated radiation therapy should be considered regardless of quality of margins, though outcomes after complete excision followed by radiation therapy are superior to those following incomplete excision and radiation therapy.

MEDICATIONS

DRUG(S) OF CHOICE

Dogs

• Doxorubicin-based chemotherapy can be used after excision of a high-grade (grade III) tumor, though a significant benefit has not been reported (1 mg/kg for small dogs or 30 mg/m^2 for medium and large dogs, IV, 5 doses q14–21 days). • Low-dosage (metronomic) cyclophosphamide chemotherapy 10–15 mg/m^2 PO q48h in combination with piroxicam 0.3 mg/kg PO q24–48h may help delay local recurrence when the tumor is incompletely resected.

Cats

• Role of postoperative chemotherapy in cats with STS is unclear. Chemotherapy treatment may improve local disease control but has minimal effect on survival in cats following wide surgical excision or radiation therapy (doxorubicin 1 mg/kg IV q3 weeks for 5 doses). • Toceranib has not been effective in treating FISS.

CONTRAINDICATIONS AND PRECAUTIONS

• Doxorubicin—cardiotoxic in dogs, avoid if underlying myocardial disease; nephrotoxic in cats, avoid if underlying renal disease; myelosuppressive in both species; severe vesicant, causes severe local tissue necrosis with extravasation (treat with dexrazoxane immediately). • Cyclophosphamide—can cause sterile hemorrhagic cystitis. Monitor for signs of hematuria and pollakuria; discontinue medication if this occurs. • Both drugs require adequate hepatobiliary function.

ALTERNATIVE DRUG(S)

Analgesia if needed.

FOLLOW-UP

PATIENT MONITORING

Every 3 months for 1 year, then every 4–6 months thereafter: • Physical examination—local regrowth. • Thoracic radiographs—pulmonary metastasis.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

• Surgical complications including infection or incisional dehiscence. • Chemotherapy toxicity (see Contraindications and Precautions).

EXPECTED COURSE AND PROGNOSIS

• Strong prognostic factors—grade, especially mitotic index (recurrence, metastasis, survival time), size at surgery (>5 cm more likely to recur) and incomplete surgical margins (recurrence). • Low-grade STS of the distal extremities in dogs might have a low recurrence rate following surgical excision (<20%). • In dogs, cure is possible with low- and intermediate-grade STS with wide surgical resection, or surgery and adjuvant radiation therapy with median survival times of over 3 years. • The prognosis is more guarded and variable with high-grade tumors (7–24 months). • Cats with FISS treated with surgery and radiation therapy have median survival times of 2–3 years.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING

While receiving chemotherapy, dogs should not be bred.

SYNONYMS

Spindle cell tumor/sarcoma.

ABBREVIATIONS

• STS = soft tissue sarcoma.
• FISS = feline injection site sarcoma.

SPERMATOCELE/SPERM GRANULOMA

BASICS

OVERVIEW
• Spermatocele—a local, cystic distension of the efferent ductules or epididymis.
• Sperm granuloma—a chronic inflammatory reaction resulting from the immune response following sperm leakage from the efferent ductules or epididymal duct.

SIGNALMENT
Intact male dogs and cats.

SIGNS
• Sperm granuloma—oligozoospermia or azoospermia if obstruction exists.
• Spermatocele—cystic mass adjacent to the testicle, with or without discomfort.

CAUSES & RISK FACTORS
• Trauma to epididymal duct causing release of sperm antigens into the surrounding tissue.
• Epithelial hyperplasia of the epididymis as documented in dogs of increasing age.
• Congenital occlusion of epididymal duct.
• Complication of surgical vasectomy.

S

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Azoospermia—testicular degeneration, hypoplasia, retrograde ejaculation, incomplete ejaculation.
• Scrotal discomfort—epididymitis; orchitis; scrotal dermatitis.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC and biochemistry profile—usually normal.
• Urinalysis (cystocentesis) after ejaculation—rule out retrograde ejaculation.

OTHER LABORATORY TESTS
• Assay for serum canine follicle-stimulating hormone (FSH) concentration—elevated with degeneration and hypoplasia; normal in azoospermic dogs experiencing retrograde ejaculation or bilateral epididymal blockage. Currently commercially unavailable.
• Alkaline phosphatase concentration of seminal plasma—concentration <5,000 U/L consistent with bilateral epididymal blockage or incomplete ejaculation (see Infertility, Male—Dogs).

IMAGING
Ultrasonography—useful to differentiate from other testicular or scrotal conditions.

DIAGNOSTIC PROCEDURES
Surgical testicular biopsy and excisional biopsy of affected epididymal tissue—allows visualization of epididymis, assess spermatogenesis (diagnostic for testicular degeneration); spermatoceles appear as yellow cysts within the epididymis.

PATHOLOGIC FINDINGS
Histologic examination of testicular biopsy—complete spermatogenesis in an azoospermic dog indicates blockage.

TREATMENT
Azoospermia rarely resolves if due to bilateral epididymal blockage; microsurgical anastomosis of the ductus deferens to the dilated epididymal tubule has been attempted.

MEDICATIONS

DRUG(S) OF CHOICE
None described in the literature to unblock the duct system.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Unilateral sperm granuloma resulting in oligozoospermia—case-dependent; could be good to guarded for fertility depending on total sperm number and accuracy of breeding management (see Breeding, Timing).
• Bilateral sperm granuloma resulting in azoospermia—poor prognosis for fertility.

MISCELLANEOUS

SEE ALSO
• Breeding, Timing.
• Infertility, Male—Dogs.

ABBREVIATIONS
• FSH = follicle-stimulating hormone.

SPERMATOZOAL ABNORMALITIES

BASICS

OVERVIEW

- Teratozoospermia—sperm abnormalities of ≥40% in the ejaculate (i.e., low percentage of morphologically normal sperm).
- High percentage of sperm abnormalities may affect fertility.
- Some fertile cats inherently have ≥40% abnormalities.
- Sperm abnormalities may also be classified as primary (those occurring during spermatogenesis) or secondary (those occurring during epididymal storage and transport or from inappropriate semen handling).

SIGNALMENT

- Dogs and cats of any age; older dogs and cats more likely to have age-related conditions.
- No breed predilection.

SIGNS

- Persistent infertility after appropriately timed mating to several reproductively proven bitches.
- Abnormalities identified during semen evaluation.

CAUSES & RISK FACTORS

Congenital

- Canine fucosidosis—rare lysosomal storage disorder (α-l-fucosidase deficiency); acrosomal defects, proximal droplets, bent tails; autosomal recessive inheritance in English springer spaniels.
- Primary ciliary dyskinesia—ultrastructural abnormality of cilia causing absent or abnormal motility of ciliated cells; affected animals are infertile; probably autosomal recessive inheritance.
- Idiopathic.
- Testicular hypoplasia.
- Inbreeding.

Acquired

- Conditions disrupting normal testicular thermoregulation—trauma, hematocele, hydrocele, orchitis, epididymitis, fever, obesity (increased scrotal fat), high environmental temperatures, exercise-induced heat exhaustion.
- Infections of the reproductive tract.
- Overuse.
- Testicular neoplasia.
- Testicular degeneration.
- Prolonged sexual abstinence.
- Drugs—anabolic steroids, androgens, estrogen, progestogens, corticosteroids, ketoconazole, amphotericin B, cimetidine, phytoestrogen, gonadotropin-releasing hormone antagonists, intratesticular injections of zinc arginine.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Excessive kinked or coiled tails may be iatrogenic, caused by morphology stain; reexamine the sample under phase contrast microscopy after dilution with formalin phosphate-buffered saline solution.

OTHER LABORATORY TESTS

- Hormonal profile—concentrations of gonadotropin and steroid hormones should be determined to rule out endocrinopathies.
- Azoospermic ejaculates—alkaline phosphatase concentration should be >5,000 U/L in complete ejaculates.
- Rapid slide agglutination test (brucellosis)—used as a screening test, recommend recheck of dogs with positive slide test with agar gel immunodiffusion test or other listed methods (see Brucellosis).

IMAGING

Ultrasonography—to visualize abnormalities in testes or scrotum that may promote abnormal spermatogenesis.

DIAGNOSTIC PROCEDURES

- Semen morphology (bright-field microscopy)—eosin–nigrosin stain or modified Giemsa stain; a minimum of 100 (preferably 200) sperm cells are counted under oil immersion (100× objective).
- Acrosome staining—acrosomal damage can be evaluated by Coomassie Brilliant blue staining or Spermac stain.
- Wet-mount semen morphology (phase contrast or differential interference contrast light microscopy)—samples diluted with formalin phosphate-buffered saline solution; verifies if presence of kinked or coiled tails on a stained slide is due to staining artifact.

PATHOLOGIC FINDINGS

- Biopsy—reveals spermatogenic capability of testicle; absence of spermatids or spermatocytes confirms impaired spermatogenesis.
- Inflammation—peritubular lymphocytic accumulation.
- Degenerative changes.
- Hypoplasia.
- Neoplasia.

TREATMENT

- Unilateral orchiectomy for unilateral testicular tumors or severe orchitis.
- Sexual rest for edema or hematocele associated with trauma.
- If inciting cause was transient and has resolved, semen collection may "improve" individual ejaculate quality by depleting affected sperm cells.
- Adjust environment and avoid exercise/competitive events that may induce heat stress in the 2 months leading up to when optimal semen quality is needed for breeding or processing.

MEDICATIONS

CONTRAINDICATIONS

- Exogenous hormones—anabolic steroids, estrogens, testosterone, progestagens.
- Ketoconazole, amphotericin B.
- Chemotherapeutic agents.
- Glucocorticoids.
- Cimetidine.

FOLLOW-UP

PATIENT MONITORING

- In cases from reversible causes, a complete improvement in sperm morphology will not occur before 70 days (approximate length of a complete spermatogenic cycle).
- After an underlying cause is identified and treated, a semen evaluation performed at 70 days will provide an indication as to long-term expectations for semen quality.

PREVENTION/AVOIDANCE

- Climate-controlled environment for animals not adapted to high environmental temperatures.
- Avoid heat exhaustion during exercise or grooming.

SPIDER VENOM TOXICOSIS—BLACK WIDOW

BASICS

OVERVIEW

• Black widow spider (*Latrodectus* spp.)—four species indigenous to the United States (*L. mactans*, *L. geometricus*, *L. hesperus*, *L. variolus*); females toxic; 2–2.5 cm in length; shiny black; red or orange hourglass mark on the ventral abdomen; immature female brown with red to orange stripes that change into the hourglass shape as she darkens to black and ages.
• Bites—15% may be dry (no venom injected).
• Range—genus found in every state except Alaska; often found around buildings and human habitation.
• Venom—contains α-latrotoxin, a potent presynaptic neurotoxin; opens cation-selective channels at the nerve terminal; causes massive release of acetylcholine and norepinephrine, which causes sustained muscular spasms. Two classes of receptors for α-latrotoxin: the neurexins, which are brain-specific cell adhesion molecules binding in a Ca^{2+}-dependent manner, and latrophilins (and CIRLs), which are not brain specific, expressed in many tissues, and bind α-latrotoxin independent of Ca^{2+}.

SIGNALMENT

Dogs and cats.

SIGNS

Historical Findings

• Usually sudden onset.
• May be delayed several days with mild envenomation.

Physical Examination Findings

Dogs

• Severe pain is the primary clinical sign.
• Progressive muscle fasciculations.
• Cramping of large muscle masses.
• Abdominal rigidity without tenderness.
• Marked restlessness, writhing, and contorted spasms.
• Hypertension and tachycardia anticipated.
• May note bronchorrhea, hypersalivation, hyperesthesia, lymph node tenderness, regional numbness, facial swelling and spasm (referred to as *Latrodectus* facies).
• Rhabdomyolysis possible.

Cats

• Early, marked paralysis.
• Severe pain—manifested by howling and loud vocalizations.
• Excessive salivation and restlessness.
• Vomiting—not unusual to vomit up the spider.
• Diarrhea.
• Muscle tremors and cramping.
• Ataxia and inability to stand—becomes adynamic and atonic.
• Respiratory collapse.
• Death without antivenin.

CAUSES & RISK FACTORS

• Very young or old age—increased risk.
• Systemic hypertension—increased risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Intervertebral disc disease.
• Acute abdomen.

CBC/BIOCHEMISTRY/URINALYSIS

• Leukocytosis.
• High creatine kinase—with severe muscle spasms.
• Albuminuria.

OTHER LABORATORY TESTS

Normal hemoccult test.

DIAGNOSTIC PROCEDURES

N/A

TREATMENT

• Inpatient—supportive care.
• Monitor respiratory status.

MEDICATIONS

DRUG(S) OF CHOICE

• Antivenin (Lyovac [*Latrodectus*], equine origin—Merck) 1 vial mixed with 100 mL crystalloid solution IV given slowly with monitoring of the inner ear pinna for evidence of hyperemia (indicator of allergic response); this dose is usually sufficient for response within 30 minutes; with proper use, reactions are rare. Variable availability. If allergic reaction occurs—stop antivenin; administer diphenhydramine; after 5–10 minutes, restart antivenin at a slower rate.
• New antivenin (Aracmyn; Instituto Bioclon, Mexico—managed by Rare Disease Therapeutics in the United States) has completed human phase III clinical trials but not yet approved for human use. It is an equine origin Fab2 product and should be much less likely to trigger an allergic response.
• There are multiple latrodectus antivenoms worldwide which have crossreactivity with black widow spider venom, including Australian red back spider antivenom (Commonwealth Serum Laboratories), South Africa (SAFR) brown widow antivenom, and the Yugoslavian widow spider antivenom.
• Studies suggest benzodiazepines are more effective than muscle relaxants for treatment of muscle pain related to black widow spider envenomation.
• Muscle spasms and severe pain are controlled by careful IV administration of narcotics or benzodiazepines at lowest effective dosage to avoid respiratory depression; methocarbamol relieves muscle spasms but has no effect on hypertension or respiratory depression.
• Intractable hypertension—sodium nitroprusside.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

IV fluids with hypertension.

FOLLOW-UP

• Weekly monitoring of the wound site until healed.
• Prognosis—uncertain for days; cats, usually fatal without antivenin.
• Weakness, fatigue, and insomnia—may persist for months.

S

SPIDER VENOM TOXICOSIS—BROWN RECLUSE

BASICS

OVERVIEW

- Brown recluse family—*Loxosceles* spp. (11 species indigenous to United States); 8–15 mm in body size; legs 2–3 cm long; violin-shaped pattern on cephalothorax with the neck of the fiddle extending caudally; 6 eyes (3 paired diads) as opposed to other spider species with 8 eyes; active at night.
- Distribution—found throughout the Midwest from the Gulf Coast of the United States and up the Mississippi River valley to southern Iowa. Some species are found in eastern southern California, western Arizona, and southern New Mexico.
- 60% of "brown recluse" spider bites in humans are misdiagnosed as they occur in areas with no endemic spider populations. See extensive Differential Diagnosis.
- Bites usually occur when spider becomes trapped in bedding; induce, necrotic arachnidism, an indolent dermatonecrotic lesion mediated by the venom enzyme sphingomyelinase D, direct hemolysis of erythrocytes, platelet aggregation, renal failure, coagulopathy, and death.
- Currently no consensus on treatment and multiple therapies have been used, including antihistamines, corticosteroids, dapsone, hyperbaric oxygen, surgical excision, and antivenom.
- Antivenom currently unavailable in United States (available only in Argentina, Brazil, and Mexico).

SIGNALMENT

Dogs and cats.

SIGNS

- Clinical signs are not completely defined in canine and feline envenomations.
- In humans:
  - Local pain and stinging (may last 6–8 hours); followed by pruritus and soreness.
  - Classic target lesion—ischemic area with a dark central eschar on an uneven erythematous background; after 2–5 weeks, central eschar may slough, leaving a deep, nonhealing ulcer that usually spares muscle tissue.
  - Not all skin lesions develop necrosis.
  - Less common—hemolytic anemia with hemoglobinuria in the first 24 hours; secondary renal complications.
  - Skin lesion severity and hemolysis are not linked.
  - Other possible systemic manifestations within the first 2–3 days after envenomation: fever; chills; rash; weakness; leukocytosis; nausea; arthralgia.
  - Envenomations to fatty areas develop more significant lesions; those occurring in loose tissue more likely to be edematous.

CAUSES & RISK FACTORS

Brown recluse spider bite (genus *Loxosceles*).

DIAGNOSIS

- Brown recluse spider bite is frequently misdiagnosed in regions of the country that do not have endemic populations of the spider.
- Epidemiologic history of bite including site of lesion, progression timeline of signs, and visualization of small puncta assist with diagnosis.

DIFFERENTIAL DIAGNOSIS

- Bacterial or mycobacterial infection; methicillin-resistant *Staphylococcus aureus* by a large margin in humans.
- Decubitus ulcer.
- Third-degree burn.
- Hemolytic anemia.
- Jaundice.
- Necrotizing vasculitis.
- Thrombocytopenia.
- Ehrlichiosis.
- Red blood cell parasitism.
- Vascular occlusive/venous disease.

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia.
- Leukocytosis.
- Thrombocytopenia.
- Hemoglobinuria.

OTHER LABORATORY TESTS

- BUN and creatinine.
- Coagulation profile—may reveal prolonged clotting times.

DIAGNOSTIC PROCEDURES

N/A

TREATMENT

- Routine wound care—may need aggressive supportive care.
- Supportive care—may include fluid therapy; secondary infections are infrequent; blood transfusion (rarely).
- Mild, local envenomation—usually responds to cool compresses as sphingomyelinase D activity is temperature dependent.
- Necrotic lesions—may need debridement after erythema has subsided.
- Severe envenomation—may require skin grafting after the lesion reaches full maturity.

MEDICATIONS

DRUG(S) OF CHOICE

- Tetracycline can be applied topically as a matrix metalloproteinase inhibitor.
- Hyperbaric oxygen—some evidence indicates that hyperbaric oxygen treatment may be beneficial for reducing size of the skin lesion.
- Dapsone—mixed results in various studies; 1 mg/kg q8h orally for 10 days; for dermatonecrotic lesions; leukocyte inhibitor; proposed to minimize inflammatory component of envenomation; repeat if needed. Efficacy against brown recluse envenomation has not been studied in the dog and cat.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Do not use heat—exacerbates condition.
- Dapsone—may cause hypersensitivity and methemoglobinemia in patients with glucose-6-phosphate dehydrogenase deficiency.
- Early surgical excision may cause larger defect than supportive care alone.
- Antihistamines, colchicine, anticoagulants, topical nitroglycerine, high doses of vitamin C, electric shock, and steroids have been proposed for treatments, but subsequently have been demonstrated to be ineffective.

FOLLOW-UP

Monitor wound site weekly until healed.

SPINAL DYSRAPHISM

BASICS

OVERVIEW

- Abnormal development of the embryonic spinal cord along the dorsal plane leading to a variety of structural anomalies (e.g., spina bifida, hydromyelia, duplicated or absent central canal, syringomyelia, aberrations in the dorsal median septum and ventral medial fissure, tethered cord).
- Thoracic and lumbar spinal segments most commonly affected.
- 'Dysraphism' suggests an abnormality in closure of the neural tube; the term 'myelodysplasia' (not to be confused with myelodysplastic syndrome) may be preferable when discussing anomalies with alternate pathogenesis.

SIGNALMENT

Nonprogressive

- Dog and cat.
- Reported in Rhodesian ridgeback, Weimaraner, English bulldog, pug, boxer, Victorian bulldog, golden retriever, Rottweiler, shih tzu, boerboel, chow chow, Siberian husky, English springer spaniel, Yorkshire terrier, Pyrenees mountain dog, Chinese crested dog, Swedish vallhund, and English cocker spaniel, Samoyed, Dalmatian, English setter; Manx cat, Burmese cat.
- Hereditary in the Weimaraner.
- Manx cat and brachycephalic breeds overrepresented, especially screw-tailed individuals.
- No sex predilection.
- Signs apparent by 3–6 weeks of age and become more obvious as animal matures. In mild cases, patient may not be presented for evaluation until several months of age.

Progressive

- Adult cavalier King Charles spaniels with syringomyelia resulting from occipital bone malformation (Chiari-like malformation; caudal occipital malformation syndrome [COMS]).
- Described in an adult Pomeranian with cervical syringomyelia and hydrocephalus.
- Described in an adult fox terrier with progressive paresis in the left pelvic limb, a 1-year-old English cocker spaniel with a 9 months history of progressive paresis in the right pelvic limb.

SIGNS

Vary in severity. Normal neurologic examination does not rule out spinal dysraphism.

Dogs

- Associated physical exam findings include indentation of the epaxial muscles, abnormal hair streams in the dorsal cervical area (a desired trait in the Rhodesian ridgeback), kinking of the undocked tail, scoliosis, and koilosternia (depression of the sternum).
- In the Weimaraner, gait is characterized by simultaneous flexion and extension of pelvic limbs (bunny hopping). Proprioceptive deficits, base wide stance, and crouched pelvic limb posture are also often present.
- In animals with syringomyelia (e.g., cavalier King Charles spaniel with COMS), any combination of neck or head pain, progressive forelimb weakness, paraparesis, imbalance, paroxysmal involuntary flank or neck scratching may be present.

Cats

In affected Manx cats, pelvic limb paresis or paralysis, urinary and fecal retention, abnormal or absent caudal vertebrae, and structural abnormalities in the sacrum may be present.

CAUSES & RISK FACTORS

- Missense mutation in the *NKX2-8* gene in the Weimaraner. Homozygous condition lethal; heterozygotes clinically affected.
- Autosomal dominant trait controlling number and structure of caudal vertebrae in the Manx cat. Prevalence increased by breeding for absence of tail.
- *In utero* spinal cord damage caused by infection, trauma, vascular compromise, drugs (antifungals, chemotherapeutics).
- Idiopathic in isolated patients.
- Syringomyelia may be acquired as result of infection, trauma, or neoplasia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Intervertebral disc disease, myelitis, arachnoid cysts, and neoplasia must be differentiated from progressive causes of syringomyelia.

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal.

IMAGING

- Spinal radiographs may show concurrent vertebral column anomalies and spinal cord compression in some patients.
- In patients with COMS, defects in the occipital bone may be appreciated on skull radiographs.
- MRI is necessary for definitive diagnosis of syringomyelia. Imaging shows attenuation of fourth ventricle, overcrowding of brainstem in caudal fossa, and cerebellar vermal herniation (COMS, Chiari-like malformation). Hydrocephalus may also be evident.
- One report of tethered cord in an English cocker spaniel in which conus medullaris was visibly caudodorsally displaced.
- CT reveals hydrocephalus, if present, with COMS.
- Without sophisticated imaging techniques, an antemortem diagnosis may be impossible except in Weimaraner and Manx cat.

TREATMENT

- Mildly affected animals may be acceptable pets.
- Severely affected, nonsurgical animals may benefit from a canine cart; consider euthanasia.
- Surgical options include foramen magnum remodeling (with occipital malformation) or ventriculoperitoneal shunt placement; laminectomy, ± syringo-subarachnoid shunting. These procedures may reduce pain or lead to improvement in neurologic signs. However, sensory disturbances such as scratching infrequently resolve, and recurrence is possible.

MEDICATIONS

DRUG(S) OF CHOICE

- Antibiotics—for urinary tract infection. Treat based on culture and sensitivity of urine.
- Corticosteroids—to improve signs in COMS by reducing CSF production and edema formation. Prednisone 0.25–0.5 mg/kg q12h or dexamethasone 0.025–0.05 mg/kg PO q12h; taper to alternate-day prednisone or twice-weekly dexamethasone.
- Carbonic anhydrase inhibitors—may alleviate signs in COMS by decreasing CSF production and allow for a reduction of steroid dosage. Acetazolamide 3.5–7.5 mg/kg q8–12h, methazolamide 5 mg/kg q8–12h, or furosemide 5 mg/kg PO, IM, SC q12h.
- Omeprazole—decreases CSF production and may alleviate signs in COMS and allow for a reduction of steroid dosage. Clinical data on use and effectiveness currently lacking; 0.5–1 mg/kg PO q24h.
- Gabapentin—recommended for management of neuropathic pain; 10 mg/kg q8–12h or pregabalin (Lyrica) 4 mg/kg PO q12h.
- Nonsteroidal anti-inflammatory drugs (NSAIDs)—may help manage neuropathic pain. Meloxicam (Metacam) 0.2 mg/kg once then 0.1 mg/kg q24h in dogs; carprofen (Rimadyl) 2.2 mg/kg PO q12h or 4.4 mg/kg PO q24h in dogs.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Avoid prolonged administration of NSAIDs, simultaneous use of of NSAIDs and acetaminophen, simultaneous use of NSAIDs and steroids, use of NSAIDs in patients with gastrointestinal or renal disease. Doing so

S

decreases risk of gastrointestinal ulceration and renal pathology.
• Do not use NSAIDs in cats.

FOLLOW-UP

PATIENT MONITORING

• Disorders of micturition predispose patients to secondary urinary tract infection.
• Avoid decubitus ulcers and urine and fecal scalds by properly caring for recumbent patients.

PREVENTION/AVOIDANCE

• Discourage breeding for absence of tail in Manx cats.
• Do not breed Weimaraners that have produced affected puppies (codominant inheritance).

MISCELLANEOUS

ASSOCIATED CONDITIONS

Congenital vertebral arch (e.g., spina bifida) and vertebral body–disc malformation (e.g., hemivertebra and block vertebra). These conditions alone often do not cause clinical signs.

ABBREVIATIONS

• COMS = caudal occipital malformation syndrome.
• CSF = cerebrospinal fluid.
• CT= computed tomography
• MRI = magnetic resonance imaging
• NSAID = nonsteroidal anti-inflammatory drug.

SPLENIC TORSION

BASICS

OVERVIEW
- May occur as a separate entity or in association with gastric dilatation and volvulus (GDV) syndrome.
- Acute or chronic.
- Pathophysiology—unknown.
- Systems affected—hemic/lymphatic/immune and cardiovascular.
- Isolated splenic torsion uncommon.

SIGNALMENT
- More common in large-breed, deep-chested dogs, such as the German shepherd dog and Great Dane. English bulldogs are also predisposed.
- No sex predilection.

SIGNS

Historical Findings
- Acute—cardiovascular collapse and abdominal pain.
- Chronic—intermittent anorexia, vomiting, weight loss, and possibly hemoglobinuria.

Physical Examination Findings
- Pale mucous membranes, tachycardia, weak femoral pulses, other signs of hypoperfusion.
- Palpable abdominal mass (spleen).
- Irregular heart rate or dropped pulses if arrhythmias present.

CAUSES & RISK FACTORS
- Large-breed and deep-chested dogs.
- Prior stretching of gastrosplenic, phrenicosplenic, and splenocolic ligaments (e.g., prior GDV).
- Historical gastric dilatation.
- Excessive exercise, rolling, and retching may contribute.
- Nervousness and anxiety have been associated with an increased risk of GDV but not of isolated splenic torsion.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other splenic disease (e.g., neoplasia, thrombosis, immune-mediated disease).
- Acute gastrointestinal disease with abdominal pain (acute abdomen).

CBC/BIOCHEMISTRY/URINALYSIS
- Anemia.
- Thrombocytopenia.
- Leukocytosis.
- Elevated liver enzyme activities.
- Pigmenturia/hemoglobinuria.

OTHER LABORATORY TESTS
Coagulation testing—prolongation of activated partial thromboplastin time (aPTT) or both prothrombin time (PT) and aPTT, with thrombocytopenia may indicate disseminated intravascular coagulation (DIC).

IMAGING

Abdominal Radiography
- Cranial or midabdominal mass may be seen.
- Spleen may be abnormally located.

Abdominal Ultrasonography
- Splenic congestion/lack of blood flow to spleen.
- Dilated splenic veins.
- Splenic infarction.

DIAGNOSTIC PROCEDURES
Electrocardiogram (ECG)—may show ventricular arrhythmias.

PATHOLOGIC FINDINGS
Splenic congestion and infarction.

TREATMENT
- Surgical emergency.
- After adequate cardiovascular stabilization, a splenectomy should be performed *without* untwisting the splenic pedicle.
- A permanent gastropexy should also be performed because of the association with GDV syndrome.
- A representative splenic specimen should be submitted for histopathologic examination.
- IV fluid support and cardiovascular monitoring are indicated after splenectomy.

MEDICATIONS

DRUG(S) OF CHOICE
- No specific drugs required.
- Postoperative pain relief advised.
- Plasma transfusion may be considered if DIC or coagulopathy are present.
- Antiarrhythmic drugs (e.g., lidocaine) may be indicated in the perioperative period.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
None

FOLLOW-UP
Surgical correction considered curative. Prognosis is good; mortality has been associated with preexisting septic peritonitis, hemorrhage or postoperative development of respiratory distress.

MISCELLANEOUS

SEE ALSO
- Acute Abdomen.
- Disseminated Intravascular Coagulation.
- Gastric Dilation and Volvulus Syndrome.

ABBREVIATIONS
- aPTT = activated partial thromboplastin time.
- DIC = disseminated intravascular coagulation.
- ECG = electrocardiogram.
- GDV = gastric dilation and volvulus.
- PT = prothrombin time.

SPLENOMEGALY

BASICS

DEFINITION
Enlargement of the spleen; characterized as either diffuse, focal, or nodular.

PATHOPHYSIOLOGY
• Splenic functions—removal of senescent and abnormal erythrocytes; filtration and phagocytosis of antigenic particles such as microorganisms, degraded cellular material, macromolecules; production of lymphocytes and plasma cells; antibody production, reservoir for erythrocytes and platelets; iron metabolism and storage, hematopoiesis, as required. • Many disorders affect function of spleen.

Diffuse Splenomegaly

Four General Pathologic Mechanisms
• Inflammation (splenitis)—associated with infectious agents; classified according to cell type (e.g., suppurative, necrotizing, eosinophilic, lymphoplasmacytic, and granulomatous-pyogranulomatous). • Lymphoreticular hyperplasia—increased proliferation of mononuclear phagocytes and lymphoid elements (in response to antigens); accelerated erythrocyte destruction. • Congestion—associated with impaired venous drainage.
• Infiltration—involves cellular invasion of the spleen or deposition of abnormal substances.

Focal or Nodular lesions
Associated with neoplastic (benign or malignant) or non-neoplastic disorders (infection, hyperplasia/regeneration, or inflammation).

SYSTEMS AFFECTED
Disorders of the spleen may also be associated with changes in the liver and lymph nodes.

SIGNALMENT
• Dog and cat; certain conditions maybe more prevalent in specific breeds or sizes of dog.
• Splenic torsion—overrepresented in large, deep-chested breeds (e.g., German shepherd dog, Great Dane). • Hemangiosarcoma—middle-aged dogs; large breeds; predilection in German shepherd dog, golden retriever, Labrador retriever, and boxer. • Prominent spleen—may be normal in certain breeds (German shepherd dog).

SIGNS

General Comments
• Splenic enlargement—often nonspecific.
• Frequently reflects an underlying disorder rather than primary disease of the spleen.

Historical Findings
• Vomiting, diarrhea, anorexia—can be seen with infiltrative diseases such as lymphoma, mast cell tumor, feline infectious peritonitis (FIP), lymphoplasmacytic enteritis (cats).
• Lethargy, anorexia, vomiting, vague abdominal pain (in acute cases pain can be severe), mild to moderate abdominal dogs (Great Dane, German shepherd dog overrepresented)—associated with splenic torsion (with or without concurrent gastric dilatation and volvulus [GDV]). • Weakness, lethargy, collapse (can be episodic), abdominal distention—can indicate a hemoabdomen secondary to bleeding/ruptured splenic tumor (hemangiosarcoma most common) or benign conditions such as a hematoma.

Physical Examination Findings
• Prominent spleen on abdominal palpation or cranial/mid-abdominal mass; nonpalpable spleen does not preclude splenomegaly.
• Dogs—smooth or irregular surface.
• Cats—usually diffuse, uniform enlargement.
• Pallor, poor capillary refill time, poor peripheral pulses and tachycardia if splenic hemorrhage or splenic torsion. • Abdominal distention if massive splenomegaly or splenic rupture (effusion). • Petechia and ecchymosis if coagulopathy secondary to primary splenic disorder or underlying disease. • Concurrent hepatomegaly, thickened intestines, and/or mesenteric lymphadenopathy imply infiltrative (neoplastic) or inflammatory (immune-mediated or infectious) disease.
• Peripheral lymphadenomegaly—suggests lymphoma/leukemia or histiocytic sarcoma.
• Cardiac arrhythmias—can be seen with primary cardiac disease affecting the spleen (congestion) or can be associated with primary splenic disorders.

CAUSES

Dogs

Inflammation (Splenitis)
• Inflammatory cell type can help prioritize differentials. • Suppurative (neutrophilic)—bacterial infections associated with penetrating abdominal wound; migrating foreign body; endocarditis; sepsis; infectious complication of splenic torsion. • Necrotizing—most commonly associated with anaerobic infections (often secondary to splenic torsion), or neoplasia.
• Eosinophilic—eosinophilic gastroenteritis, hypereosinophilic syndrome.
• Lymphoplasmacytic—subacute or chronic infectious disorders; pyometra; coexistent inflammatory bowel disease.
• Granulomatous—fungal or protozoal disease most common. • Pyogranulomatous—bacterial or fungal infections most common cause.

Hyperplasia
• Infection—chronic bacteremia (bacterial endocarditis; discospondylitis; *Brucella*).
• Immune-mediated disease—any; hemolytic anemia or thrombocytopenia, systemic lupus erythematosus (SLE).

Congestion
Tranquilizers; barbiturates; portal hypertension; right-sided heart failure; splenic torsion.

Infiltration
• Neoplasia—lymphoma; acute and chronic leukemia; (hemophagocytic) histiocytic sarcoma; multiple myeloma; systemic mastocytosis;
• Extramedullary hematopoiesis (EMH)—immune-mediated hemolytic anemia or thrombocytopenia; chronic anemia; infectious disease; malignancy; SLE. • Amyloidosis – part of systemic amyloidosis.

Cats

Inflammation
• Suppurative—penetrating wound or migrating foreign body; septicemia; salmonellosis. • Necrotizing—salmonellosis.
• Eosinophilic—hypereosinophilic syndrome.
• Lymphoplasmacytic—lymphoplasmacytic enteritis; hemotropic mycoplasmas; pyometra.
• Granulomatous—histoplasmosis; mycobacteriosis. • Pyogranulomatous—FIP, *Mycobacterium*.

Hyperplasia
• Infection—hemotropic mycoplasmosis.
• Immune-mediated—any; hemolytic disorders, SLE.

Congestion
Portal hypertension, congestive heart failure.

Infiltration
• Neoplasia—mast cell tumor, lymphoma; lympho- or myeloproliferative diseases; multiple myeloma; histiocytic sarcoma (rare); hemangiosarcoma (rare). • Non-neoplastic—amyloidosis, EMH.

RISK FACTORS
• Cats—feline leukemia virus (FeLV), FIP.
• Dogs—breed/age.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Other cranial organomegaly or masses.

CBC/BIOCHEMISTRY/URINALYSIS

Dogs
• Regenerative anemia secondary to splenic bleeding or hemolytic disease. • Nucleated red blood cells (RBCs)—may accompany EMH, indicates splenic dysfunction. • Spherocytes—hemolysis, microangiopathic shearing.
• Schizocytes (aka schistocytes) – disseminated intravascular coagulation (DIC), hemangiosarcoma. • Acanthocytes- hemangiosarcoma.
• Leukocytosis with a left shift—may indicate infectious or inflammatory conditions, marked regenerative response, or EMH.
• Thrombocytopenia—from increased consumption (DIC or bleeding) secondary to hemangiosarcoma or other neoplasia, increased destruction (immune-mediated), sequestration, or decreased production in the bone marrow.
• Hypercalcemia may be associated with neoplasia, especially lymphoma.
• Hyperglobulinemia may be associated with neoplasia, *Ehrlichia* infections.
• Hemoglobinemia and hyperbilirubinemia—associated with hemolysis and may occur with microangiopathic anemia, splenic torsion,

SPLENOMEGALY (CONTINUED)

Cats

• Direct RBC examination for hemoparasites. • Regenerative anemia and splenomegaly—may indicate hemotropic mycoplasmosis. • Macrocytosis and nonregenerative anemia—suggests retroviral infection or myeloproliferative disease. • Eosinophilia—suggests hypereosinophilic syndrome, systemic mastocytosis, or lymphoma. • Circulating blast cells—suggest lympho- or myeloproliferative disorder. • Nucleated RBCs—may accompany EMH and splenic dysfunction. • Thrombocytopenia—from increased consumption (DIC), increased destruction (immune-mediated), sequestration, or decreased production in the bone marrow.

OTHER LABORATORY TESTS

• FeLV and feline immunodeficiency virus testing. • Coagulation panel—DIC commonly seen with hemangiosarcoma (includes prolonged clotting times, hypofibrinogenemia, and increased fibrin degradation products [FDPs]); D-dimers not specific for clinical application in differential diagnoses).

IMAGING

Abdominal Radiography

• Confirms or detects splenomegaly. • Mass effect may appear in the (left) midcranial abdomen. • May provide evidence of an underlying cause—concurrent hepatomegaly may indicate infiltrative disease or right-sided heart disease; splenic torsion secondary to GDV. • Effusion—may indicate hemorrhage from splenic rupture (hemangiosarcoma, hematoma) or portal hypertension influencing splenic perfusion. • Visualization of the splenic tail along the ventral body wall on lateral radiographs of cats supports the diagnosis of splenomegaly.

Thoracic Radiography

• Three views (right and left lateral and dorsal–ventral views)—screen for metastasis and underlying disease in thoracic cavity and effusion. • Evaluate sternal lymph nodes—these drain the abdominal cavity, reflecting disorders causing lymphadenomegaly. Evaluate for signs of congestive heart failure (size of the cardiac silhouette and pulmonary veins and evidence of pulmonary edema or pleural effusion).

Abdominal Ultrasonography

• Distinguishes between diffuse and focal/nodular parenchymal patterns. • Diffuse enlargement with normal parenchyma—may occur with congestion or cellular infiltration. • In cats splenic masses greater than 1 cm suggestive of malignancy. • Hypoechogenicity may occur with splenic torsion, splenic vein thrombosis, hematopoietic neoplasia or infectious agents. • Complex, mixed echogenic mass—common with hemangiosarcoma or hematoma. • Can identify concurrent abdominal diseases—liver, kidneys, intestines, and lymph nodes. • Cannot differentiate between benign and malignant splenic disorders. • Doppler color flow interrogation of splenic vasculature may detect splenic vein thrombi or splenic torsion.

Echocardiography

Evaluate for cardiac dysfunction or cardiac tumors causing splenic congestion (based on other physical exam/imaging findings).

DIAGNOSTIC PROCEDURES

Fine-Needle Aspiration

• Assess coagulation status before any aspiration. Procedure—patient in right lateral or dorsal recumbency; using ultrasound guidance, use a 22- or smaller gauge, 2.5–3.75 cm (1–1.5 in.) length needle depending on the size of the patient. • Non-aspiration method (needle-only method) results in higher yield of nucleated cells relative to the amount of blood than aspiration method. • Specimens—evaluate cytologically for infectious agents (often found in macrophages); identify predominant inflammatory or infiltrative cell type. • Neoplastic infiltrates—classified as epithelial, mesenchymal, or round cell. • Aspiration of cavitated masses may cause rupture and is not recommended.

Bone Marrow Aspiration

• Indicated with cytopenias before splenectomy (spleen may be supporting hematopoiesis). • May yield infectious disorder (e.g., ehrlichiosis, mycosis, toxoplasmosis, leishmaniosis) or hematopoietic neoplasia.

TREATMENT

• Depends on underlying cause; supportive nursing care as needed. • Important to determine if splenomegaly is appropriate for systemic conditions. • Treatment and prognosis after splenectomy—based on histopathologic features: submit the entire spleen for histopathologic evaluation (hemangiosarcoma may be missed in some tumors owing to regional necrosis with diagnosis rendered of hematoma).

SURGICAL CONSIDERATIONS

Splenectomy

• With anemia or leukopenia—rule out bone marrow aplasia/hypoplasia before surgery; spleen may be the source of hematopoiesis. • Indicated for splenic torsion, splenic rupture, isolated splenic masses considered likely to be neoplastic, and mast cell infiltration (cats only). • Exploratory laparotomy—permits direct evaluation of all abdominal organs.

MEDICATIONS

DRUG(S) OF CHOICE

Depend on underlying disease.

FOLLOW-UP

PATIENT MONITORING

Ventricular arrhythmias (dogs)—associated with splenic mass lesions or torsion; may occur before, during, and up to 3 days post splenectomy; evaluate (auscultation and electrocardiogram) surgical candidates before anesthesia; continuous cardiac monitoring during surgery and post-operatively.

POSSIBLE COMPLICATIONS

• Asplenic patient—increased risk of infection and red cell parasitism. • Postoperative sepsis—uncommon complication. • Antibiotics—indicated in asplenic patients receiving immunosuppressive therapy, if any sign of infection apparent.

MISCELLANEOUS

AGE-RELATED FACTORS

Neoplastic causes more likely in geriatric animals.

ZOONOTIC POTENTIAL

A variety of infectious diseases may involve the spleen.

SEE ALSO

See Causes.

ABBREVIATIONS

• DIC = disseminated intravascular coagulation. • GDV = gastric dilatation and volvulus. • EMH = extramedullary hematopoiesis. • FDP = fibrin degradation product. • FeLV = feline leukemia virus. • FIP = feline infectious peritonitis. • RBC = red blood cell. • SLE = systemic lupus erythematosus.

SPONDYLOSIS DEFORMANS

BASICS

OVERVIEW

- Degenerative, noninflammatory condition of the vertebral column that occurs in response to intervertebral disc degeneration.
- Often an incidental finding, rarely clinically important.
- Characterized by the production of osteophytes along the ventral, lateral, and dorsolateral aspects of the vertebral endplates. Radiographically, appears as smooth, ventral bridging bone.
- Most common location in dogs is the thoracolumbar spine in the area of the anticlinal vertebra and the upper lumbar vertebrae; in cats, the thoracic vertebrae.

SIGNALMENT

- Dog and cat.
- Females > males.
- Dogs—commonly seen in large breeds, especially German shepherd dog; also boxer, Airedale terrier, and cocker spaniel.
- Occurrence increases with age. Present in 50% of dogs by 6 years and 75% by 9 years. May be radiographically evident in young dogs with an inherited predisposition.
- Boxers—positive correlation between spondylosis deformans and hip dysplasia. Both heritable traits are detectable in predisposed animals by radiographic examination at 1 year.
- Cats—present in 68% of asymptomatic cats.

SIGNS

General Comments

- Patients are typically asymptomatic; lesions are of minor if any clinical importance.
- Pain may follow fracture of bony spurs or bridges.

Historical Findings

- Stiffness.
- Restricted motion.
- Spinal pain.

Physical Examination Findings

Neurologic deficits are uncommon. If present, referable to compression of the spinal cord or nerve root.

CAUSES & RISK FACTORS

- Repeated microtrauma.
- Major trauma.
- Inherited predisposition.
- Acromegaly.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Discospondylitis—differentiated by radiographic evidence of endplate lysis.
- Spinal osteoarthritis—degeneration of articular facet joints.
- Neoplasia—may have irregular, ventral, nonbridging bone.

CBC/BIOCHEMISTRY/URINALYSIS

Normal

Radiographic Findings

Spinal radiography initially shows osteophytes as triangular projections several millimeters from the edge of the vertebral body. With progression, osteophytes appear to bridge the intervertebral space. True ankylosis is rare.

DIAGNOSTIC PROCEDURES

In uncommon presentations, MRI, CT, or CT myelography can be used to demonstrate an atypical dorsal osteophyte compressing the spinal cord or nerve roots or encroaching on critical soft tissue structures.

TREATMENT

- Typically not needed. Inform client that the condition is usually an asymptomatic, incidental finding, and is likely not responsible for any clinical signs that may be present.
- Treat spondylosis on an outpatient basis with strict rest and analgesia, possibly acupuncture.
- If overconditioned, recommend weight-reduction program.
- Acupuncture—dry needle or electroacupuncture treatment at weekly or biweekly interval and tapered to as-needed basis can be very effective in relief of pain. Useful in animals who do not tolerate medication or when clients prefer an alternative treatment modality.

MEDICATIONS

DRUG(S) OF CHOICE

Use only when the patient is exhibiting signs.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

- In dogs, NSAIDs are preferable to steroids (fewer side effects) unless patient has neurologic deficits or concomitant disease prohibits use. Administer with food.
- Carprofen (Rimadyl) 2.2 mg/kg PO q12h or 4.4 mg/kg PO q24h in dogs.
- Meloxicam (Metacam) 0.2 mg/kg once then 0.1 mg/kg q24h in dogs.
- Deracoxib (Deramaxx) 1–2 mg/kg PO q24h in dogs.
- Firocoxib (Previcox) 5 mg/kg PO q24h in dogs.
- Grapiprant (Galliprant) 2 mg/kg PO q24h in dogs.
- If gastrointestinal sensitivity, use in combination with an antacid (famotidine 0.5–1 mg/kg q24h or omeprazole 0.5–1 mg/kg q24h) or a gastrointestinal protectant (misoprostol at 3–5 µg/kg PO q6–8h or sucralfate 0.5–1 g q8h) to reduce the possibility of ulceration.

Non-NSAID Analgesics

- Use may enable reduction of dose or frequency of anti-inflammatory medications.
- Tramadol 2–5 mg/kg PO q8–12h in dogs; 1–4 mg/kg q12h in cats.
- Gabapentin 10 mg/kg PO q8–12h in dogs or cats.
- Buprenorphine 0.01–0.03 mg/kg PO q8h in cats.
- Acetaminophen 5 mg/kg POq12h in dogs.

Corticosteroids

- Only use in patients with neurologic deficits.
- Prednisone 0.25–0.5 mg/kg PO q12h; or dexamethasone 0.025–0.05 mg/kg PO q12h.
- Taper to alternate-day prednisone or twice-weekly dexamethasone.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Acetaminophen and NSAIDs—do not use in cats.
- Avoid prolonged administration of NSAIDs, simultaneous use of of NSAIDs and acetaminophen, simultaneous use of NSAIDs and steroids, use of NSAIDs in patients with gastrointestinal (GI) or renal disease. Doing so decreases risk of GI ulceration and renal pathology.

FOLLOW-UP

PATIENT MONITORING

- If signs are present, restrict activity and gradually return the animal to normal activity after signs have subsided for several weeks.
- Relapse can occur with strenuous activity.
- With prolonged use of analgesic medications, periodic biochemistry testing is warranted.

PREVENTION/AVOIDANCE

Boxers—given genetic correlation between spondylosis deformans and hip dysplasia and potential for early radiographic detection, dogs should be screened and selectively bred.

MISCELLANEOUS

ABBREVIATIONS

- CT= computed tomography.
- GI = gastrointestinal.
- MRI = magnetic resonance imaging.
- NSAID = nonsteroidal anti-inflammatory drug.

Romatowski J. Spondylosis deformans in the dog. Compend Contin Educ Pract Vet 1986, 8:531–536.

Authors Richard J. Joseph and Anne E. Buglione

SPOROTRICHOSIS

BASICS

OVERVIEW
- Zoonotic fungal disease affecting the integument, lymphatics, or generalized.
- Caused by inoculation of the ubiquitous dimorphic fungus *Sporothrix schenckii* into subcutaneous tissue.

SIGNALMENT
Cat and dog (less common).

SIGNS
- Dogs (cutaneous form)—numerous nodules that may drain or crust; most lesions located on the head, dorsal muzzle; occasionally on the chest, or disseminated on the body and on the limbs.
- Cats (cutaneous form)—lesions appear initially as wounds or abscesses mimicking wounds associated with fighting.
- Cutaneolymphatic form—usually an extension of the cutaneous form through the lymphatics, resulting in the formation of new nodules and draining tracts or crusts; lymphadenopathy is common.
- Disseminated form—systemic signs including lameness, respiratory symptoms (nasal discharge, sneezing, stertorous breathing), anorexia and weight loss also reported in dogs.

CAUSES & RISK FACTORS
- Dogs—hunting dogs from puncture wounds associated with thorns or splinters.
- Cats—intact male outdoor cats: Healthy cats may have a minor role in sporotrichosis transmission
- Animals exposed to soil rich in decaying organic debris.
- Exposure to infected animals or clinically healthy cats sharing a household with an affected cat.
- Immunosuppressive disease.

DIAGNOSIS

Caution: This is a zoonotic disease and proper precautions should be taken to prevent exposure; the absence of a break in the skin does not protect against the disease. Cats may act as reservoirs for *S. schenckii* and can transmit the infection to humans by a bite or scratch.

DIFFERENTIAL DIAGNOSIS
- Infectious—bacterial (deep) and fungal infection (e.g., cryptococcosis, blastomycosis, feline leprosy, histoplasmosis).
- Neoplasia.
- Granulomas caused by foreign bodies.
- Parasites—*Demodex*, *Pelodera*, *Leishmania*.

CBC/BIOCHEMISTRY/URINALYSIS
None unless associated with generalized disease.

OTHER LABORATORY TESTS
- Cultures of affected tissue preferred; swab culture may be adequate
- *Caution*: This is a zoonotic disease; laboratory personnel must be warned of the potential differential diagnosis.
- Serologic testing and PCR assays are available.

DIAGNOSTIC PROCEDURES
- Cytology of exudates—cigar- to round-shaped yeast found intracellularly or free in the exudates with pyogranulamatous inflammation.
- Biopsy—organisms usually numerous, especially in cats; fungal stains (periodic acid–Schiff or Gomori's methamine silver) may aid in the diagnosis; the absence of demonstrable organisms in tissues from dogs does not preclude diagnosis; pyogranulomatous inflammation with few mast cells, eosinophils, and plasma cells. Radiographs—evidence of irregular periostal proliferation.
- Immunohistochemistry might be useful for an early diagnosis of sporothricosis in cats. High sensitivity reported with immunohistochemistry to diagnose sporothricosis in dogs.
- ELISA— screening tool for the detection of specific *S. schenckii* antibodies in cats with sporotrichosis.

TREATMENT

Zoonotic; outpatient therapy may be a consideration but increases the potential for human exposure.

MEDICATIONS

DRUG(S) OF CHOICE
- Dogs—ketoconazole 5–15 mg/kg PO q12h, itraconazole 5–10 mg/kg PO q24h, terbinafine 30–40 mg/kg PO q24h given with food, administered until 1 month after clinical resolution; resolution usually occurs within 3 months. Disseminated disease—combination of amphotericin B and itraconazole is recommended; terbinafine may also be effective.
- Cats—itraconazole 5–15 mg/kg PO q24h or divided q12h for a minimum of 1 month beyond clinical cure; compounded formulations of itraconazole are not recommended due to inconsistent absorption.

FOLLOW-UP

PATIENT MONITORING
Reevaluation, including assessment of liver enzymes, recommended every 2–4 weeks.

PREVENTION/AVOIDANCE
N/A

EXPECTED COURSE AND PROGNOSIS
- Failure of response to therapy possible.
- Fluconazole and terbinafine remain relatively untested but may show promise for treatment.

MISCELLANEOUS

ZOONOTIC POTENTIAL
- *Caution*: This is a zoonotic disease.
- Client education is of paramount importance.
- Absence of a break in the skin does not protect against the disease.
- Reports of zoonotic transmission from bites and scratches from rodents, parrots, cats, dogs, horses, and armadillos.
- Clinically healthy cats sharing a household with an infected cat may be a source of infection.

ABBREVIATIONS
- ELISA = enzyme-linked immunosorbent assay.

SQUAMOUS CELL CARCINOMA, DIGIT

BASICS

OVERVIEW
- Locally invasive malignant tumor usually arising from subungual epithelium.
- Cats—metastasis to one or multiple digits from primary pulmonary site.
- Dogs—most common digital tumor (~50%); up to 25% metastatic rate, up to 22% multiple digits affected (multicentric disease).
- Forelimb more commonly affected than hind limb.
- Organ systems—skin/endocrine, musculoskeletal.

SIGNALMENT
- Dog and rarely cat.
- Median age—dogs and cats 10 years; reported in dogs as young as 3 years old.
- Large breeds (>75%) and black/dark-coated dogs (>90%) predisposed; breeds include standard poodle, Labrador retriever, giant schnauzer, Rottweiler, dachshund, flat-coated retriever, and possibly Beauceron, Briard, and miniature poodle.

SIGNS
- Swollen digit or digital mass which fails to heal.
- Lameness.
- Ulceration.
- Fractured or missing nail.
- Multiple digits affected in up to 22% of dogs; may present in one digit and develop additional digital tumors later.
- Multiple digits commonly seen in cats (30%); due to lung–digit syndrome.
- Regional lymphadenomegaly of the sentinel draining lymph node (uncommon at time of diagnosis).

CAUSES & RISK FACTORS
Risk factors (dogs)—hereditary; dark skin/hair pigmentation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Nailbed infection (paronychia).
- Trauma.
- Other tumors (dog)—melanoma; soft tissue sarcomas; mast cell tumor; osteosarcoma.
- Benign lesions—epithelial inclusion cyst, keratoacanthoma.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

IMAGING
- Thoracic radiography—to evaluate for metastatic disease (develops in up to 25% of dogs) and rule out a primary pulmonary carcinoma (cats).
- Limb radiography—lysis of the third phalanx of the affected digit in 80% of patients with potential secondary extension proximally to phalanx 2 and 1.
- Abdominal ultrasonography—for hind limb lesions, evaluate intra-abdominal lymph nodes for presence of metastatic disease.

DIAGNOSTIC PROCEDURES
- Cytology—diagnostic utility limited if there is severe inflammation or secondary infection (common), or the tumor is well differentiated.
- Biopsy of lesion—may be needed to confirm diagnosis.
- Cytology of regional lymph nodes to evaluate for metastasis.

TREATMENT
- Amputation of the affected digit at the level of the metacarpal or metatarsal phalangeal joint.
- In cats with a primary pulmonary tumor, amputation of a single affected digit may provide local palliative care and confirm diagnosis, however multiple digits on multiple limbs are often affected.
- Palliative radiation can be considered for single digits if metastatic disease present or in the setting of multicentric/multiple digits affected.
- Analgesics for pain control, antibiotics for secondary bacterial infections may be indicated.
- Benefit of chemotherapy has not been established; however in patients with advanced stage of disease chemotherapy useful for squamous cell carcinoma of other sites could be considered.

MEDICATIONS

DRUG(S) OF CHOICE
Piroxicam—dogs, 0.3 mg/kg PO q24h for analgesia/antineoplastic effects; cats, 0.3 mg/kg PO q24–48h has been used for other carcinomas.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
None

FOLLOW-UP

PATIENT MONITORING
Physical exam, thoracic radiographs, lymph node evaluation, ± abdominal ultrasound at 1–2 months, then every 3 months after treatment (complete surgical excision).

EXPECTED COURSE AND PROGNOSIS
- Complete surgical excision of the primary lesion and no evidence of metastasis; additional treatment may not be required.
- Survival time following complete surgical excision depends upon location of the tumor on the digit; squamous cell carcinoma (SCC) originating from subungual epithelium: 95% 1-year and 74% 2-year survival; SCC originating in other parts of the digit: 60% 1-year and 44% 2-year survival.
- In one study 1- and 2-year survival was 50% and 18%, respectively, while in two other studies only 20–45% of dogs died of SCC (multicentric or metastatic) and the median survival time was not reached.
- Development of multicentric disease (multiple affected digits) in dogs appears more common than lymph node or pulmonary metastasis.
- Surgery to amputate affected digit, regardless of presence of metastases, provides positive impact on survival in the dog.
- Histologic grading does not appear predictive of development of multicentric or metastatic disease in dogs.
- Prognosis for cats is poor with median survival times of 2–3 months if metastatic from pulmonary carcinoma.

MISCELLANEOUS

SEE ALSO
- Melanocytic Tumors, Skin and Digit.
- Squamous Cell Carcinoma, Skin.

ABBREVIATIONS
- SCC = squamous cell carcinoma.

SQUAMOUS CELL CARCINOMA, EAR

BASICS

OVERVIEW
• Malignant tumor of squamous epithelium occurring on the pinna, external ear, and/or middle ear (less common).
• Pinna—most common location in cats; tumors of the pinna in dogs are rarely squamous cell carcinoma.
• Organ system—skin/endocrine.

SIGNALMENT
• Cat and dog.
• Tumors of the pinna—common in cats with light pigmentation, average 12 years.
• Ear canal tumors—seen in older dogs and cats.
• Cocker spaniels overrepresented for benign and malignant ear canal tumors in one study.

SIGNS
• Tumors of the pinna:
  ○ Slowly developing lesions of the edge of the pinna.
  ○ Precancerous stage—crusty eczematous lesions (actinic dermatitis).
  ○ Cancerous phase—proliferation and/or ulceration progresses.
  ○ Multiple cutaneous lesions (about 10–15% of cats) occur in haired skin (multicentric squamous cell carcinoma *in situ*).
• Tumors of the ear canal:
  ○ Often unilateral, arise from the external ear canal.
  ○ Mass lesion (raised, ulcerated, broad-based).
  ○ Malodorous aural discharge.
  ○ Pruritis.
  ○ Pain.
  ○ Vestibular signs/Horner's syndrome (facial nerve paralysis, head tilt, circling) in ~10% of dogs; more common in cats with ear canal tumors.
  ○ Difficulty opening jaw.
  ○ Cervical lymphadenomegaly (retropharyngeal, mandibular).

CAUSES & RISK FACTORS
• Pinna—UV exposure in cats with white fur, light skin.
• Ear canal—chronic inflammation may be a risk factor.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Cats
• Pinna:
  ○ Trauma.
  ○ Vasculitis.
  ○ Cryoglobulinemia.
• Ear canal/middle ear:
  ○ Inflammatory/nasopharyngeal polyp (middle ear).
  ○ Other neoplasia (ceruminous gland adenocarcinoma, other).

Dogs
• Pinna:
  ○ Other neoplasia (mast cell tumor, histiocytoma, sebaceous gland tumor).
  ○ Trauma.
• Ear canal/middle ear:
  ○ Chronic otitis.
  ○ Other neoplasia (ceruminous gland adenoma or adenocarcinoma, papilloma).
  ○ Nasopharyngeal polyps (rare).

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

IMAGING
• Thoracic radiography—evaluate for pulmonary metastasis (rare with pinnal lesions).
• CT—shows extent of disease and provides surgical planning; 57–67% locally invasive into surrounding tissues.

DIAGNOSTIC PROCEDURES
• Cytology may confirm diagnosis; however, ulceration, inflammation, and secondary infection may limit diagnostic utility.
• Biopsy of pinna/aural mass to confirm diagnosis via histopathology; video otoscopy may aid in visualization of mass lesion and biopsy.
• Lymph node cytology of draining lymph nodes to assess for metastatic disease.

TREATMENT
• Pinna:
  ○ Appropriate surgical excision may require pinnectomy and possibly vertical ear canal ablation; must remove lesion with margin of normal tissue.
  ○ Alternatives include photodynamic therapy (less predictable; multiple treatments may be required), cryosurgery (for small, superficial lesions), strontium plesiotherapy (superficial radiation therapy), electrochemotherapy with bleomycin, or curettage/diathermy.
• Ear canal/middle ear:
  ○ Total ear canal ablation and bulla osteotomy is usually needed to achieve complete excision; lateral ear canal resection rarely achieves adequate control.
  ○ Radiation therapy may be used for palliation of nonresectable tumors or postoperatively for microscopic disease.

MEDICATIONS

DRUG(S) OF CHOICE
• Pinna (cat):
  ○ Imiquimod 5% cream—apply topically q24-48h.
  ○ Etretinate 0.75–1 mg/kg PO q24h; can prevent progression of precancerous lesions; may not be commercially available.
  ○ Acitretin 1 mg/kg PO q24h can be used in place of etretinate.
  ○ Vitamin E 400–600 IU PO q12h; may be beneficial to prevent or delay progression of precancerous lesions.
• Ear canal tumors:
  ○ Systemic chemotherapy—benefit not yet established; anecdotal benefit.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Women who are pregnant or planning to become pregnant should not handle acitretin.

FOLLOW-UP

PATIENT MONITORING
• Pinna—physical examination at 1 month, then every 3 months after treatment (complete surgical excision).
• Ear canal—physical examination, thoracic radiographs, lymph node evaluation, and possible CT every 3 months after treatment.

PREVENTION/AVOIDANCE
• Limit sun exposure.
• Tattoos on nonpigmented areas may be helpful.

EXPECTED COURSE AND PROGNOSIS
• Pinna—prognosis good with complete surgical excision; survival >1.5 years with complete pinnectomy.
• Ear canal tumors locally invasive (57–67%) and can recur locally despite surgery; prognosis is guarded.
• Dogs—median survival 5.3 months with bulla involvement compared to >58 months without.
• Cats—median survival 3.8 months; worse prognosis with bulla involvement; median survival 1.5 months with neurologic signs.

MISCELLANEOUS

SEE ALSO
• Ceruminous Gland Adenocarcinoma, Ear.
• Squamous Cell Carcinoma, Skin.

SQUAMOUS CELL CARCINOMA, GINGIVA

BASICS

OVERVIEW
- Malignant tumor of squamous epithelium.
- Rapid progression, locally invasive, highly osteo-invasive (77%).
- Most common oral malignancy in cats; one of most common oral malignancies in dogs.
- Approximately 10–20% metastasis in dogs and cats with potential involvement of draining lymph nodes (most common) and lung parenchyma.

SIGNALMENT
- Mean age (dogs/cats) 10.5 years.
- More common in medium and large-breed dogs.

SIGNS

Historical Findings
- Mass effect.
- Ptyalism.
- Dysphagia.
- Halitosis.
- Bloody saliva.
- Weight loss.
- Hyporexia or avoidance of hard foods/toys.
- Poor grooming (cats).

Physical Examination Findings
- Erythematous, ulcerated, fleshy lesion.
- Loose teeth.
- Facial swelling or deformity.
- Exophthalmos.
- Pain on opening jaw.

CAUSES & RISK FACTORS
Potential risk factors in cats include flea collars, canned food (tuna), and tobacco smoke.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other oral malignancy—fibrosarcoma in cats; melanoma, fibrosarcoma, osteosarcoma in dogs.
- Epulis (acanthamatous, fibrous, ossifying).
- Tooth root abscess.
- Benign growth or polyp.
- Gingival hyperplasia (breed, e.g., boxer, or drug-induced, e.g., cyclosporine).
- Eosinophilic granuloma complex.

IMAGING
- Skull radiography—evaluate potential bone involvement.
- High-detail dental radiography—more sensitive in evaluating local disease than skull radiography; best with mandibular masses.
- CT—ideal to evaluate soft tissue extension, bone invasion, regional lymph nodes, and for surgical planning.
- Thoracic radiography—evaluate for pulmonary metastasis (uncommon in dogs, rare in cats).

DIAGNOSTIC PROCEDURES
- Cytology—fine-needle aspirate samples can be sufficient, though ulceration, inflammation, and secondary infection may limit diagnostic utility.
- Deep tissue biopsy—beneficial to differentiate from other oral malignancies via histopathology.
- Cytology of regional lymph nodes to assess for regionally metastatic disease.

TREATMENT

Dogs
- Radical surgical excision required (e.g., hemi-mandibulectomy); usually well tolerated; margins of at least 2 cm necessary.
- Radiation therapy—effective for long-term control; curative-intent treatment used alone or in combination with surgery or chemotherapy.
- Chemotherapy—alone or in combination with other treatment modalities; toceranib phosphate (Palladia) exerts single-agent activity in a substantial fraction (biologic response) of dogs treated.
- Piroxicam may have some antineoplastic effects.
- Cryosurgery or electrochemotherapy—indicated for small lesions with no bone involvement.
- Photodynamic therapy—adjunct to surgery may be effective for local control of small tumors.
- Analgesics for pain or antibiotics for secondary bacterial infections may be indicated.

Cats
- Surgery—most tumors are inoperable; small rostral lesions may be excised with wide 2–3 cm margins; cats do not tolerate aggressive oral surgery as well as dogs.
- Palliative treatments include coarse-fraction radiation therapy (<50% response).
- Metastasis less of a concern as most cats succumb to local disease progression.
- Bisphosphonates—used to palliate bone pain.
- Analgesics for pain or antibiotics for secondary bacterial infections may be indicated.

MEDICATIONS

DRUG(S) OF CHOICE
- Toceranib phosphate (Palladia)—dogs and cats, 2.5–3.25 mg/kg PO q48h.
- Cisplatin—dogs only, 60–70 mg/m^2 IV once q3–4 weeks for 4 treatments.
- Carboplatin—dogs, 300 mg/m^2 q3 weeks IV; cats, 180–240 mg/m^2 q3–4 weeks for 4–5 treatments.
- Mitoxantrone—cats, 5–6 mg/m^2 q3 weeks IV for 4–5 treatments.
- Piroxicam—dogs, 0.3 mg/kg PO q24h; cats, q48–72h.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Cisplatin—never in cats. Nephrotoxic in dogs, cannot combine with NSAIDs.

FOLLOW-UP

PATIENT MONITORING
Physical exam, lymph node evaluation, and thoracic radiographs at 1–2 months, then every 3 months after treatment.

POSSIBLE COMPLICATIONS
Postoperative complications—tumor recurrence, ptyalism, mandibular drift causing malocclusion, difficulty prehending food, inability to groom.

EXPECTED COURSE AND PROGNOSIS

Dogs
- Negative prognostic factors—caudal or maxillary location, >2 cm diameter, older age, incomplete excision.
- Surgical excision—median survival 15–16 months, 34 months combined with radiation therapy; mandibulectomy better outcome than maxillectomy.
- Combination carboplatin and piroxicam with or without surgery—median survival >18 months (7 dogs).
- Piroxicam—17% response rate with a median progression-free interval of 3.5–6 months.

Cats
- 1-year survival rate is 10% for multimodal therapy.
- In rare cases where surgery is an option, median survival 1 year.

MISCELLANEOUS

SEE ALSO
- Melanocytic Tumors, Oral.
- Squamous Cell Carcinoma, Tongue.
- Squamous Cell Carcinoma, Tonsil.

Consulting Editor Timothy M. Fan
Acknowledgment The author and editors acknowledge the prior contribution of Jackie M. Wypij.

SQUAMOUS CELL CARCINOMA, LUNG

BASICS

OVERVIEW
- Primary tumor of bronchial epithelium with squamous metaplasia.
- High metastatic potential to regional lymph nodes, pleural surface (carcinomatosis), pulmonary parenchyma, less commonly distant organs.
- Organ system—respiratory.

SIGNALMENT
- Dog and cat—mean age 11–12 years.
- Persian cats may be overrepresented for pulmonary carcinomas.

SIGNS
- May be incidental finding on radiographs.
- Harsh, nonproductive cough.
- Dyspnea, tachypnea.
- Lethargy, exercise intolerance.
- Hemoptysis.
- Cachexia, weight loss.
- Vomiting, regurgitation, diarrhea (cats).
- Lameness:
  - Distal limb swelling, pain (hypertrophic osteopathy).
  - Digital lesions (cats).

S

CAUSES & RISK FACTORS
- Urban environment, second-hand smoke suspected.
- Laboratory dogs trained to smoke cigarettes develop lung cancer.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other primary lung neoplasia—adenocarcinoma, bronchoalveolar carcinoma, histiocytic sarcoma.
- Metastatic pulmonary neoplasia.
- Fungal granuloma.
- Abscess.
- Aspiration pneumonia.

CBC/BIOCHEMISTRY/URINALYSIS
Often unremarkable.

IMAGING
- Thoracic radiography (3-view):
  - Most often in caudal lung lobes.
  - Often a solitary mass, well-circumscribed margins.
  - May identify tracheobronchial lymphadenomegaly, pulmonary metastatic lesions, pleural effusion.
  - May displace/compress trachea or mainstem bronchi.
- CT:
  - Determines surgical resectability.
  - Solitary, well-circumscribed, bronchocentric mass with internal air bronchograms; mild–moderate heterogeneous contrast enhancement.
  - More sensitive than radiographs in detecting pulmonary and lymph node metastasis.
- Limb radiography:
  - Digit metastases—bony lysis in the distal phalanx (cats, lung–digit syndrome).
  - Hypertrophic osteopathy—periosteal proliferation, long bones.

DIAGNOSTIC PROCEDURES
- Cytology:
  - Transthoracic fine-needle aspiration of peripheral lesions; ultrasound or CT guidance may be needed.
  - Pleural effusion or intrathoracic lymph node aspirates if primary lesion is not amenable to aspiration.
  - Endoscopic bronchial brushing may be useful for centrally located lesions.
  - Bronchoalveolar lavage and transtracheal wash: rarely diagnostic.
- Biopsy necessary for definitive diagnosis; may be obtained via keyhole biopsy, thoracoscopy, or thoracotomy.
- Potential complications of diagnostic procedures—pneumothorax, hemothorax, pleural effusion, infection, and iatrogenic tumor seeding (rare).

TREATMENT
- Surgery—wide and complete resection of affected lung lobe; biopsy lymph nodes even if they appear normal; lymph node extirpation when possible. In select cases, thoracoscopic surgery may be considered.
- Chemotherapy—potentially beneficial in adjuvant or palliative setting, intracavitary (IC) chemotherapy may be useful for carcinomatosis/pleural effusion.
- Palliative medications—cough suppressants and antibiotic therapy for secondary bacterial infections.

MEDICATION

DRUG(S) OF CHOICE
- Doxorubicin—dogs >10 kg, 30 mg/m^2 IV; dogs <10 kg and cats, 1 mg/kg IV q2–3 weeks for 5 treatments.
- Carboplatin—dogs, 300 mg/m^2 IV q3–4 weeks; cats, 180–250 mg/m^2 IV q3–4 weeks for 4–5 treatments.
- Mitoxantrone—dogs and cats, 5–6 mg/m^2 q3 weeks; can give IV, IC (if pleural effusion present), or split total dose: half IV, half IC for 4–5 treatments.
- Vinorelbine—dogs, 15 mg/m^2 IV weekly for 4 weeks then every other week for 4 treatments.
- Cisplatin—dogs only, 60 mg/m^2 IV q3–4 weeks for 4 treatments.
- Toceranib phosphate (Palladia)—dogs and cats, 2.5–3.25 mg/kg PO q48h.
- Metronomic chemotherapy—cyclophosphamide 15 mg/m^2 PO q24h, piroxicam 0.3 mg/kg PO q24h.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Cisplatin—never use in cats; nephrotoxic in dogs.

FOLLOW-UP

PATIENT MONITORING
Postoperatively, consider chemotherapy options; recheck thoracic radiographs and/or CT scan in 1–2 months, then every 3 months.

EXPECTED COURSE AND PROGNOSIS
- Of the primary pulmonary carcinomas, squamous cell carcinoma (SCC) and undifferentiated carcinoma carries the worst prognosis.
- Survival if untreated or with evidence of metastatic disease—usually <3 months.
- Median survival with treatment for SCC—8 months (dogs).
- Cats—median survival of pulmonary carcinomas surgically excised is 64–156 days.
- Negative prognostic factors (all lung tumors)—large size, enlarged lymph nodes, metastasis, pleural effusion, high histologic grade/poorly differentiated, or respiratory signs at diagnosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Paraneoplastic hypertrophic osteopathy, lung–digit syndrome (cats).

SEE ALSO
Adenocarcinoma, Lung.

SQUAMOUS CELL CARCINOMA, NASAL AND PARANASAL SINUSES

BASICS

OVERVIEW
- Local invasion of neoplastic squamous epithelium from the nasal cavity and/or paranasal sinuses.
- Slowly progressive (months) and commonly bilateral.
- Low metastatic rate.
- Prevalence—15–17% of nasal neoplasia in cats and dogs.

SIGNALMENT
- More common in dog than in cat.
- Dogs—median age, 9–10 years, male predilection; cats—median 10–12 years, male predilection.
- Dogs—predilection for sinonasal tumors in medium and large breeds.

SIGNS

Historical Findings
- Intermittent, progressive unilateral to bilateral epistaxis and/or mucopurulent nasal discharge.
- Epiphora.
- Sneezing.
- Halitosis.
- Anorexia.
- Dyspnea.
- Seizures secondary to cribriform plate invasion.

Physical Examination Findings
- Nasal discharge (epistaxis, mucopurulent, and/or serosanguinous).
- Facial deformity.
- Ocular—epiphora, decreased retropulsion, elevated third eyelid, exophthalmus.
- Pain on nasal/paranasal sinus palpation.
- Obstructed nasal airflow.

CAUSES & RISK FACTORS
Dolicocephalic breed, urban environment, and tobacco smoke exposure speculated to be risk factors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other intranasal neoplasia—adenocarcinoma, undifferentiated carcinoma, lymphoma (cats), sarcomas (dogs).
- Tooth root abscess.
- Viral infection—cats.
- Cryptococcosis—cats.
- Aspergillosis.
- Foreign body.
- Trauma.
- Oronasal fistula.
- Coagulopathy.
- Hypertension.
- Bacterial sinusitis—uncommon.
- Lymphocytic—plasmacytic rhinitis.
- Inflammatory polyps (cats).

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

OTHER LABORATORY TESTS
If epistaxis, perform coagulation profile and blood pressure to rule out hypertension and coagulopathy prior to intranasal biopsy.

IMAGING
- Skull radiography—asymmetrical osteolysis of caudal turbinates; superimposition of soft tissue mass; fluid density in the frontal sinuses; loss of teeth; displacement of midline structures; involvement of hard palate.
- Thoracic radiography—detect pulmonary metastasis (uncommon).
- CT scan—recommended imaging modalities for the identification of soft tissue density mass, loss of turbinate detail, soft tissue/fluid opacity in sinus; best method for assessing tumor invasiveness, including bony invasion, invasion of cribriform plate or orbit.

DIAGNOSTIC PROCEDURES
- Rhinoscopy—mass effect, may be obscured by exudates.
- Cytology—obtained by aspiration or squash preparation; may be limited by inflammation or secondary infection.
- Biopsy with histopathology—necessary for definitive diagnosis; methods include nasal hydropulsion, transnostril blind biopsy with forceps or bone curette, fiberoptic-guided biopsy, percutaneous biopsy of facial deformities; biopsy via dental extraction site, rhinotomy.
- Precautions must be taken to minimize risk of penetrating the cribriform plate.
- Cytology and/or biopsy of regional lymph nodes—detect metastatic disease (uncommon).

TREATMENT
- Definitive radiotherapy—best clinical control in dogs and cats; exenteration does not add benefit.
- Coarse-fraction radiotherapy beneficial in dogs and cats for palliation.
- Adjunctive chemotherapy—responses in dogs reported; recommended for palliation of clinical signs, metastasis, and as an adjuvant to radiation therapy.
- Analgesics for pain control.
- Anecdotally, nasal hydropulsion may palliate clinical signs.

MEDICATIONS

DRUG(S) OF CHOICE
- Cisplatin—dogs only, 60–70 mg/m^2 IV q3 weeks for 4 treatments.
- Carboplatin—dogs, 300 mg/m^2 IV q3 weeks; cats, 180–250 mg/m^2 IV q3–4 weeks for 4–5 treatments.
- Mitoxantrone—dogs/cats, 5–6 mg/m^2 IV q3 weeks for 4–5 treatments.
- Toceranib phosphate (Palladia)—dogs/cats, 2.5–3.25 mg/kg PO q48h.
- Piroxicam—0.3 mg/kg PO q24h (dogs), q48h (cats).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
- Cisplatin—never use in cats; nephrotoxic in dogs—do not administer with NSAIDs.

FOLLOW-UP

PATIENT MONITORING
Physical examination, thoracic radiographs, lymph node evaluation, ±CT scan every 3 months after treatment or when signs recur.

POSSIBLE COMPLICATIONS
Acute or late side effects from radiation therapy.

EXPECTED COURSE AND PROGNOSIS
- Untreated carcinomas (all types)—median survival 3 months; epistaxis carries a worse prognosis.
- Definitive radiotherapy (all carcinomas)—median survival 12–18 months (dogs and cats); 10.4 months with stereotactic radiotherapy.
- Coarse-fraction radiation therapy (all tumor types)—improved clinical signs in ~90% of dogs; median survival 4.8–10 months; median survival 10–12 months (cats).
- Local recurrence with extension to the brain can occur.
- Re-irradiation is possible, reduces clinical signs, extends survival time.

SQUAMOUS CELL CARCINOMA, NASAL PLANUM

BASICS

OVERVIEW
- Malignant tumor of squamous epithelial cells of the nasal planum.
- Locally invasive and rarely metastasizes.
- Organ systems—skin/exocrine, respiratory.

SIGNALMENT
- Common in cat; rare in dog.
- Mean age—cats, 8.5–12.1 years; dogs, 9–10 years.
- More likely to develop in animals with a lightly pigmented nose (cats).
- No reported sex or breed predilection in cats.
- Dogs—overrepresentation of males and Labrador retrievers in one study.

SIGNS
- Cats—slowly progressive lesion; may begin as superficial crusting and scabbing, progress to carcinoma *in situ*, and develop into superficial and then invasive erosive carcinoma; other cutaneous sites may be affected (cats—multicentric squamous cell carcinoma *in situ* [MSCCIS]).
- Dogs—sneezing; epistaxis; swelling and ulceration of planum, proliferative lesion.

CAUSES & RISK FACTORS
- Exposure to ultraviolet light (UVB).
- Absence of protective pigment (cats).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Infection/abscess.
- Trauma.
- Dermatitis (allergic, other).
- Eosinophilic granuloma complex (cats).
- Immune-mediated disease.
- Cutaneous lymphoma.
- Mast cell tumor.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

IMAGING
- Thoracic radiography—to evaluate for metastasis (rare).
- CT scan—evaluate soft tissue extension and bone invasion prior to surgical planning, essential for canine tumors in which extensive underlying structures are often involved.

DIAGNOSTIC PROCEDURES
- Cytology—fine-needle aspirate of primary lesion may confirm diagnosis; however, ulceration, inflammation, and secondary infection may limit diagnostic utility.
- Biopsy and histopathology—a deep wedge or punch biopsy is often needed to definitively diagnose squamous cell carcinoma. Multiple samples recommended as lesion may have a spectrum of actinic changes ranging from squamous metaplasia to invasive carcinoma.
- Cytology or histopathology of regional lymph nodes screening for regional metastasis (rare in cats, occasional in dogs).

PATHOLOGIC FINDINGS
Lesions may vary in appearance depending on stage of disease in cats; typically ulcerative in cats; more likely proliferative in dogs.

TREATMENT
- Superficial tumors—surgery, cryosurgery, irradiation (strontium-90 plesiotherapy), photodynamic therapy, electrochemotherapy with bleomycin, or curettage/diathermy.
- Invasive tumors—require radical surgical excision and adjunctive external beam radiotherapy (cats); dogs not as responsive to radiotherapy.
- Immediate postoperative nutritional support may be required, especially for cats.
- Analgesics for pain control and antibiotics for secondary bacterial infections as indicated.

MEDICATIONS

DRUG(S) OF CHOICE
- Etretinate—cats, 0.75–1 mg/kg PO q24h; synthetic retinoid; may be useful for early precancerous lesions; may not be commercially available.
- Acitretin—cats, 1 mg/kg PO q24h can be used in place of etretinate.
- Imiquimod 5% cream for nasal planum lesions associated with MSCCIS—apply topically to affected lesions q24–48h; most cats respond but develop new lesions in other sites; these lesions often subsequently respond to topical therapy.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Women who are pregnant or planning to become pregnant should not handle etretinate, acitretin, or imiquimod.

FOLLOW-UP

PATIENT MONITORING
- Physical examination at 1 month, then every 3 months after treatment.
- Biopsy any new suspicious lesion.

PREVENTION/AVOIDANCE
- Limit sun exposure.
- Tattoos on nonpigmented areas may be helpful.

EXPECTED COURSE AND PROGNOSIS
- Prognosis—good for small, noninvasive tumors; guarded for invasive tumors.
- Survival with radiotherapy alone (cats)—mean 17.7 months; 1 year, 61.5% with 81.8% recurrence.
- Surgery (cats, nosectomy)—median survival >22 months.
- Strontium-90 plesiotherapy (cats, superficial)—98% response rate; median progression-free interval of 4.5 years; median survival >8 years.
- Photodynamic therapy (cats, superficial)—96% response rate; often need multiple treatments; does not appear as effective as other therapies long term.
- Electrochemotherapy with bleomycin—risk of recurrence; many achieve complete remission.
- Curettage and diathermy—excellent response; risk of recurrence.
- Dogs (superficial tumors)—surgery alone may be curative.
- Dogs (invasive tumors)—in one study of 8 dogs, average survival time was 5.4 months; in another study of 17 dogs treated with surgery and/or radiation therapy, 70% of tumors recurred with a median survival time of 3–6 months.

SQUAMOUS CELL CARCINOMA, SKIN

BASICS

OVERVIEW
- Malignant tumor of squamous epithelium.
- Multicentric squamous cell carcinoma *in situ* (MSSCIS)- also called Bowen's-like disease or Bowenoid carcinoma *in situ* (cats).
- Local disease may progress from carcinoma *in situ* to invasive carcinoma.
- Metastasis is uncommon—most common sites are regional lymph nodes and lungs.
- Systems affected—skin/exocrine.
- Represents 9–25% of all skin tumors in cats; 4–18% in dogs.
- Solar-induced (actinic) SCC is more prevalent in sunny climates and high altitudes.

SIGNALMENT
- Cats, mean age 9–10 years; often have light/unpigmented skin.
- Dogs, mean age 8 years; Scottish terrier, Pekingese, boxer, poodle, Norwegian elkhound, Dalmatian, beagle, whippet, and white English bull terrier may be predisposed.

SIGNS
- Proliferative or erosive skin lesions.
- Solar-induced lesions in cats—nasal planum, eyelids, lips, and pinna.
- MSCCIS may occur in any site, unrelated to sun exposure or skin pigmentation; may note 2–30+ lesions on the head, digits, neck, thorax, shoulders, and ventral abdomen; hair in the lesion epilates easily; crusts cling to the epilated hair shaft.
- Dogs—most commonly affects toes, scrotum, nose, legs, and anus.

CAUSES & RISK FACTORS
- Ultraviolet irradiation (actinic form).
- Papillomaviruses may play a role.
- Light/nonpigmented skin.
- Previous thermal injury.
- Risk factors for MSCCIS in cats are undetermined but may be associated with immunosuppression.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Infection/abscess.
- Dermatophytosis.
- Trauma.
- Dermatitis.
- Eosinophilic granuloma complex.
- Immune-mediated disease.
- Cutaneous lymphoma.
- Mast cell tumor.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

IMAGING
- Thoracic radiography—may detect lung metastasis (rare).
- Abdominal ultrasonography—evaluate and monitor sublumbar lymph nodes if skin disease involves the caudal half of the patient.

DIAGNOSTIC PROCEDURES
- Cytology or histopathology of lesion—ulceration, inflammation, and secondary infection may limit diagnostic utility of cytology. A deep wedge or punch biopsy is often needed to definitively diagnose cutaneous SCC. Multiple samples recommended as actinic form may encompass spectrum from actinic changes to carcinoma.
- Cytology of lymph nodes to identify presence of regional metastasis.

TREATMENT
- Superficial tumors suspected to be solar-induced—wide surgical excision may be locally curative; other treatment options include cryosurgery, photodynamic therapy, or strontium-90 plesiotherapy.
- Invasive tumors—require aggressive surgical excision, external-beam radiation therapy has shown effectiveness.
- MSCCIS may be treated with curative-intent surgery for local control; however, most cats develop new lesions in other sites; treatment with immune-modulating drugs (imiquimod) may be most effective.
- Adjunctive chemotherapy—recommended with incomplete surgical excision, nonresectable mass, and metastasis.
- Electrochemotherapy (bleomycin) and curettage with diathermy may be effective.

Nursing Care
- Analgesics as needed.
- Antibiotic therapy if secondary skin infections.

Client Education
- Discuss UV risk factors associated with the development of the tumor.
- Most cats with MSCCIS will develop new lesions in other sites.

MEDICATIONS

DRUG(S) OF CHOICE
- Imiquimod 5% cream for MSCCIS—topically to affected lesions q24–48h; most cats respond but develop new lesions in other sites.
- Cisplatin—dogs, 60 mg/m^2 IV q3 or 4 weeks for 4 treatments.
- Carboplatin—dogs, 300 mg/m^2 IV q3 weeks; cats, 200–250 mg/m^2 IV q3–4 weeks for 4–5 treatments.
- Mitoxantrone—dogs and cats, 5–6 mg/m^2 IV q3 weeks for 4–5 treatments.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Cisplatin—never use in cats; nephrotoxic in dogs.

Alternative Drug(s)
Topical synthetic retinoids (e.g., tretinoin)-may be useful for early solar-induced superficial lesions; may be irritating to skin.

FOLLOW-UP

PATIENT MONITORING
- Physical examination 1 month after resolution of tumor, then every 3 months after treatment.
- Thoracic radiography and lymph node evaluation at each 3-month recheck examination; abdominal ultrasound if the lesion is on the caudal portion of the patient.

PREVENTION/AVOIDANCE
- Limit sun exposure.
- Tattoos on nonpigmented areas may be helpful.

EXPECTED COURSE AND PROGNOSIS
Prognosis—good with superficial lesions that receive appropriate treatment; guarded with invasive lesions, advanced stage of disease, or recurrent lesions.

Client Education Handout available online

SQUAMOUS CELL CARCINOMA, TONGUE

BASICS

OVERVIEW
- Malignant tumor of squamous epithelium.
- Rare tumor that occurs more commonly in cats than in dogs.
- Usually grows rapidly.
- Cats—most common lingual neoplasia, often progresses locally prior to clinical evidence of metastasis.
- Dogs—one of most common malignant lingual neoplasias (25–32%); variably metastatic by way of lymphatic vessels to regional lymph nodes and lungs (0–43%).
- Organ system—gastrointestinal.

SIGNALMENT
- Cats—middle-aged or older (>7 years).
- Dogs—average 10–11 years; female large-breed dogs most commonly affected.

SIGNS

Historical Findings
- Ptyalism.
- Halitosis.
- Dysphagia.
- Oral bleeding.
- Decreased appetite.
- Weight loss.
- Poor grooming (cats).

Physical Examination Findings
- Incidental finding.
- Tongue mass—variable appearance, often nodular and ulcerated.
- Intramandibular swelling (cats).
- Cervical lymphadenomegaly—occasionally.

CAUSES & RISK FACTORS
Potential increased risk of feline oral squamous cell carcinoma (SCC) associated with flea collars, canned food (particularly tuna), and possibly exposure to tobacco smoke.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other lingual malignancy (melanoma, sarcoma, mast cell tumor, plasmacytoma, lymphoma, hemangiosarcoma, granular cell tumor).
- Trauma.
- Ulcerative glossitis.
- Benign lesion (papilloma).
- Infection/abscess.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

IMAGING
- Advanced imaging with CT or MRI provides greatest information regarding extent of disease.
- Thoracic radiography—three-view required to evaluate lungs for metastasis; more common in dogs.

DIAGNOSTIC PROCEDURES
- Cytology—fine-needle aspirate or impression smear from incisional biopsy (wedge); may yield diagnosis; however, ulceration, inflammation, and secondary infection may limit diagnostic utility.
- Deep wedge tissue biopsy—necessary for definitive diagnosis.
- Cytology and/or lymph node biopsy to evaluate for regional metastasis; more common in dogs.

TREATMENT
- Surgical—generally inoperable in cats; aggressive excision warranted in dogs; function of the tongue after recuperation is usually acceptable in dogs, but will require changes in husbandry practices.
- Postsurgical care (e.g., esophagostomy) by owner often required.
- Partial glossectomy—may be performed on the rostral half (mobile tongue) or longitudinal half of the tongue (40–60% removed); ~35–50% of patients have incomplete surgical margins.
- Subtotal glossectomy may be considered in select cases.
- Other surgical methods (e.g., electrocautery and cryosurgery) do not offer additional advantage to conventional excision.
- Response to radiotherapy—poor (<7 weeks); may be used adjunctively on microscopic disease postoperatively.
- Systemic therapies—chemotherapy agents or toceranib phosphate effective in oral SCC may exert anticancer activities for lingual SCC.
- Piroxicam may have antineoplastic activity in some patients.
- Supportive/palliative medications for analgesia and antibiotics for secondary bacterial infections may be indicated.

MEDICATIONS

DRUG(S) OF CHOICE
- Carboplatin—dogs, 300 mg/m^2 IV q3–4 weeks; cats, 180–250 mg/m^2 IV q3–4 weeks for 4- 5 treatments.
- Piroxicam—dogs, 0.3 mg/kg PO q24h; cats, 0.3 mg/kg PO q48h.
- Toceranib phosphate (Palladia)—dogs and cats, 2.5–3.25 mg/kg PO q48h.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

PATIENT MONITORING
After complete surgical resection, recheck at 1–2 months and then every 3 months with physical examination and evaluation for metastasis (lymph node palpation/aspiration and thoracic imaging).

POSSIBLE COMPLICATIONS
Possible complications postoperatively—long-term difficulty prehending food, local recurrence.

EXPECTED COURSE AND PROGNOSIS
- Prognosis—poor, owing to extensive local disease (cat) and local recurrence (28% for all lingual tumors) and moderate rate of metastasis (dog).
- After surgical excision (subtotal glossectomy, dogs)—median survival 216 days, <25% survive 1 year.
- Negative prognostic factors (dogs)—caudal location, incomplete excision, recurrence, larger size (>2 cm); histologic grade, metastatic disease.
- Piroxicam—17% response rate in oral SCC with a median progression-free interval of 3.5–6 months; one partial response in 3 dogs with lingual SCC.
- Prognosis in cats similar to other oral sites of SCC; median survival ~3 months with multimodal therapy.

MISCELLANEOUS

SEE ALSO
- Melanocytic Tumors, Oral.
- Squamous Cell Carcinoma, Gingiva.
- Squamous Cell Carcinoma, Tonsil.

ABBREVIATIONS
- SCC = squamous cell carcinoma.

Suggested Reading

SQUAMOUS CELL CARCINOMA, TONSIL

BASICS

OVERVIEW
- Rapid and progressive invasion of neoplastic squamous epithelium arising from the tonsillar fossa into tonsillar lymphoid tissue.
- More common in dogs than cats—comprises 9% of canine oral tumors.
- Highly locally invasive into soft tissues.
- Early metastasis—70–90% eventually metastasize regardless of local control.

SIGNALMENT
- Dog and cat; median age 10 years.
- No known breed or sex predilection.

SIGNS

Historical Findings
- Cough.
- Enlarged lymph nodes.
- Dysphagia.
- Ptyalism.
- Retching.
- Halitosis.
- Weight loss.
- Anorexia.
- Lethargy.

Physical Examination Findings
- Enlarged tonsil(s).
- Widening or "fullness" of oropharyngeal space.
- Cervical lymphadenomegaly.
- Pain on opening jaw.

CAUSES & RISK FACTORS
Exact cause unknown; however, 10 times more common in animals living in urban environments vs. those in rural environments.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Lymphoma (generally associated with lymphadenomegaly and bilateral disease).
- Abscess.
- Metastatic neoplasm (oral melanoma, sarcoma).
- Tonsillitis.
- Tonsillar crypt foreign body.
- Salivary gland tumor.
- Thyroid carcinoma.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

IMAGING
- Thoracic radiography—three-view to detect lung metastasis; 5–20% positive for metastasis at presentation; 60–85% metastasis at death.
- CT—evaluate local extension of primary tumor as well as mandibular and retropharyngeal lymph node involvement; recommended prior to surgery or radiation therapy.
- Abdominal ultrasound—evaluate abdominal organs; 20% disseminated metastasis to multiple organs at death (dogs).

DIAGNOSTIC PROCEDURES
- Cytology—inflammation and secondary infection may limit diagnostic utility of fine-needle aspirate samples but should still be attempted.
- Histopathology—deep tissue biopsy may be needed to differentiate from other oral malignancies.
- Cytology and/or biopsy of regional lymph nodes to evaluate for metastatic disease; in dogs 20–55% metastasis at diagnosis.

TREATMENT
- Surgery—many are inoperable; tonsillectomy, when done, should be bilateral.
- Postoperative care (esophagostomy or gastrotomy tube) by owner may be needed.
- Other surgical methods (electrocautery and cryosurgery)—no advantage over conventional excision.
- Regional radiation therapy is effective for local control and palliation of clinical signs.
- Chemotherapy—anecdotal reports of cisplatin, carboplatin, doxorubicin being used with limited success.
- Piroxicam and/or toceranib phosphate (Palladia) may have antineoplastic effects in canine carcinomas.
- Analgesics for pain control; antibiotics for secondary bacterial infections may be indicated.

MEDICATIONS

DRUG(S) OF CHOICE
- Carboplatin—dogs, 300 mg/m^2 IV q3–4 weeks; cats, 180–240 mg/m^2 IV q3–4 weeks for 4–5 treatments.
- Mitoxantrone—dogs and cats, 5–6 mg/m^2 IV q2–3 weeks for 5 treatments.
- Piroxicam—dogs, 0.3 mg/kg PO q24h, toceranib phosphate (Palladia) 2.75–3.25 mg/kg PO q48h.
- Doxorubicin—dogs >10 kg, 30 mg/m^2 IV; dogs <10 kg and cats, 1 mg/kg q2–3 weeks for 5 treatments.
- Cisplatin—dogs, 60–70 mg/m^2 IV q3–4 weeks for 4 treatments.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Cisplatin—never use in cats; nephrotoxic in dogs.

FOLLOW-UP

PATIENT MONITORING
Most patients euthanized within months for local progression or metastasis; patients with curative-intent therapies should be rechecked with physical examination and evaluated for metastasis (thoracic radiographs/CT) at 1–2 months, then every 3 months.

POSSIBLE COMPLICATIONS
Postoperative complications—tumor recurrence, may need feeding tubes postoperatively.

EXPECTED COURSE AND PROGNOSIS
- Prognosis—poor owing to extensive local disease and high rate of recurrence (tongue, pharynx, lymph nodes) and metastasis.
- Minimal information in cats; however, appear to carry a grave prognosis as with most oral squamous cell carcinomas in cats.
- Dogs: 11–40% 1-year survival (survival times increased if unilateral and no metastasis at diagnosis).
- Untreated (dogs) median survival 1–2 months vs. treated median survival 7–8 months.
- Surgery alone has limited benefit—median survival 2–4 months (dogs).
- Palliative radiotherapy or chemotherapy (dogs)—75% response rate, 2–9 months median survival.
- Surgery, radiation therapy, and chemotherapy (dogs)—median survival 9–12 months.
- Piroxicam alone—17% response rate for all oral squamous cell carcinoma with a median progression-free interval of 3.5–6 months; 3 of 5 dogs with tonsillar SCC exhibiting a partial remission or stable disease.

MISCELLANEOUS

STAPHYLOCOCCAL INFECTIONS

BASICS

OVERVIEW

- *Staphylococcus*—Gram-positive, nonmotile, facultatively anaerobic, spherical bacteria (cocci); *staphyle* (Greek "bunch of grapes") form characteristic microscopic arrangement in clusters.
- Results in variety of infections characterized by pus formation.
- Can produce toxins (superantigens) that exert profound systemic signs (fever, hypotension, shock, multiorgan failure, death).
- Ubiquitous; live free in environment and as commensal parasites of skin and upper respiratory tract.
- Pathogenic and nonpathogenic strains; wide spectrum of virulence, host range, and site specificities; not strictly host- or site-specific.
- Pathogenic strains—possess extracellular toxins and enzymes (e.g., coagulase, staphylokinase, hemolysin, epidermolysins); staphylocoagulase in more pathogenic strains (e.g., *S. pseudintermedius*, *S. aureus*).
- Coagulase-negative staphylococci are less virulent (e.g., *S. felis*, *S. epidermidis*).
- Methicillin-resistant staphylococci, which are increasingly isolated from dogs and cats, is an emerging problem due to multidrug resistance phenotype which limits treatment options and challenges infection control measures. When a methicillin-resistant strain expresses co-resistance to at least two additional antimicrobial classes then it is called multidrug resistant (MDR).

SIGNALMENT

- Dogs and cats.
- Very young—susceptible because of incomplete, developing immunity.
- Old, debilitated—susceptible because of impaired host defenses.
- Immunocompromised—more susceptible.

SIGNS

- Abscesses and infections of the skin, eyes, ears, respiratory system, genitourinary tract, skeleton, and joints.
- Dogs—pyoderma, otitis externa, cystitis, prostatitis, pneumonia, abscesses, osteomyelitis, discospondylitis, arthritis, mastitis, bacteremia, endocarditis, wound infections, toxic shock syndrome.
- Cats—abscesses, oral infections, otitis externa, conjunctivitis, metritis, cholangiohepatitis, cystitis, bacteremia.
- Fever.
- Anorexia.
- Pain.
- Pruritus.
- Can affect every organ system.

CAUSES & RISK FACTORS

- Opportunistic pathogens depending on virulence factors:
  - Adhesion expression (binds bacteria to cells and extracellular matrix).
  - Toxins (cytolytic, exfoliative, enterotoxigenic, superantigen toxins).
  - Expression of factors to evade the host's immune response (e.g., coagulase).
  - Formation of biofilms which protect the bacterium from the immune response.
- Disease—from disturbance of the natural host–parasite equilibrium when local and general defense mechanisms are significantly lowered (e.g., chronic debilitating diseases).
- Secondary infection—allergies (atopy, food, fleas); endocrinopathies (hypothyroidism, hyperadrenocorticism); parasites (demodicosis); seborrhea.
- Burns or wounds—complications.
- Biofilms (extracellular polysaccharide networks) support infection of implants and invasive devices (e.g., IV catheters).
- Transmission—airborne organisms, carriers, direct contact (droplet nuclei).
- *S. pseudintermedius*—most common staphylococcal species isolated from dogs, commensal organism on skin and mucous membranes of dog and cat (although much lower prevalence in cats). Methicillin-resistant *S. pseudintermedius* (MRSP) is a clinically important pathogen causing antibiotic resistant infections in dogs and cats (see Multidrug Resistant Infections).
- *S. aureus*—does not colonize dogs as often as *S. pseudintermedius*; colonizes skin and mucosal membranes of humans where it is one of the most common community-acquired and hospital-acquired pathogens of people. Methicillin-resistant *S. aureus* (MRSA) infections uncommonly diagnosed in dogs and cats.
- *S. schleiferi*—coagulase variable species; rarely isolated from healthy skin of dogs or cats but commonly isolated from skin and ear canal infections of dogs with history of prior antimicrobial exposures.
- Risk factors for methicillin-resistant staphylococcus in dogs include previous antibiotic therapy, previous hospitalization, urban environment, older age.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Dermatitis—allergies, seborrhea, parasites, immune-mediated.
- Other infectious causes—viruses, bacteria, fungi, *Rickettsia*, protozoa.
- Neoplasia.
- Immune-mediated diseases.

CBC/BIOCHEMISTRY/URINALYSIS

- Normal or high white blood cells (WBCs) consisting of neutrophilia ± left shift.
- Biochemistry—may suggest predisposing cause.
- Urinalysis—pyuria (with or without bacteruria) with cystitis.

OTHER LABORATORY TESTS

- Direct microscopy.
- Gram stain.
- Cytology—neutrophils and cocci singly or in pairs, short chains, or irregular clusters.
- Culture—avoid superficial contamination; collect samples by aspiration, wash, or biopsy; do not overinterpret a positive isolation; organisms can be isolated from normal animals
- Organisms survive up to 48 hours in clinical specimens when kept cool (4°C/40°F), particularly on swabs containing a holding medium.
- Antibiotic susceptibility testing (very important due to methicillin-resistant and multidrug-resistant staphylococci).
- Pulsed-field gel electrophoresis molecular typing.

IMAGING

Radiology—osteolytic and osteoproliferative lesions with osteomyelitis; interstitial or alveolar pulmonary pattern with pneumonia; radiodense uroliths (struvite). Endocarditis lesions may be visible by echocardiography. Ultrasonography may identify abscesses.

DIAGNOSTIC PROCEDURES

Cerebrospinal fluid tap—if meningitis or discospondylitis suspected; discospondylitis lesions may be fine-needle aspirated using CT or ultrasound guidance.

PATHOLOGIC FINDINGS

Characteristic abscess lesion—necrotic tissue, fibrin, and a large number of neutrophils.

TREATMENT

- Identify and manage predisposing cause to minimize selection for antibiotic-resistant staphylococci.
- Properly handle and dispose of contaminated objects, practice good hand hygiene and wear personal protective equipment (PPE) when handing patient with known or suspected methicillin-resistant staphylococcus infection.
- Topical antibacterial cleaning of wounds and pyoderma—chlorhexidine, benzoyl peroxide shampoos.
- Known or suspected methicillin-resistant staphylococcus-infected animals should be isolated.

MEDICATIONS

DRUG(S) OF CHOICE

- Antibiotic resistance—great propensity owing to production of β-lactamase, which

inactivates penicillins; may carry plasmids (segments of genetic material that may carry genes for antimicrobial resistance) that can be transferred to other strains of staphylococci or species of bacteria.
• History of previous antimicrobial therapy for staphylococcal infection—culture and antibiotic susceptibility testing indicated: choose drugs below based on this testing.
• Use topical therapy when possible.
• Non-penicillinase-producing strains:
  ○ Penicillin G 10,000–20,000 U/kg IM, SC q12–24h, penicillin V 8–30 mg/kg PO q8h.
  ○ Amoxicillin 22 mg/kg PO q6–8h or ampicillin 22–30 mg/kg IV, IM, SC q6–8h.
• Penicillinase-producing strains:
  ○ First-generation cephalosporins—cephalexin at 22 mg/kg PO q8h; cefadroxil at 22 mg/kg PO q8–12h.
  ○ β-Lactamase-resistant synthetic penicillins—clavulanic acid-potentiated amoxicillin 20–25 mg/kg PO q8–12h, oxacillin 22–40 mg/kg PO q8h, dicloxacillin 10–25 mg/kg PO q8h).
• Gentamicin 2–4 mg/kg IV, IM, SC q8h or amikacin 15 mg/kg IV q24h.
• Trimethoprim-potentiated sulfonamides—30 mg/kg IV, PO q12h.
• Chloramphenicol—40–50 mg/kg IV, IM, SC, PO q8–12h.
• Methicillin-resistant staphylococci express *mecA* gene which encodes an altered penicillin-binding protein (PBP-2a) which has a low affinity for all β-lactam drugs (penicillins, cephalosporins, and carbapenems).
• In patients with penicillin allergy—try cephalosporin, clindamycin, enrofloxacin, or vancomycin (although this is strongly discouraged to reserve vancomycin for treatment of serious MRSA infections in humans).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Avoid immunosuppressive drugs.

FOLLOW-UP

As appropriate for location of infection

MISCELLANEOUS

ZOONOTIC POTENTIAL

• Possible; MRSA is also potential anthropozoonosis.
• Most people and pets carry their own pathogenic staphylococcal flora; disease is not caused by mere exposure; however, transfer from dogs to humans is possible, and vice versa.
• Bite infections contain a mix of aerobes and anaerobes from both the skin of the patient and the mouth of the animal, including *Staphylococcus*.
• Hand hygiene (proper washing/drying and use of alcohol-based hand sanitizers) and use of PPE is an integral part of the prevention of the spread of MRSA/MRSP between animals and MRSA between animals and humans.
• Owners of dogs and cats with MRSA infection should be educated to wash their hands after handling their pets, to clean and disinfect surfaces that might become contaminated, and to not let their pet lick their face or open wounds. If owners have concerns about their health or the health of others in their household then they should be instructed to talk to their health care provider.

ABBREVIATIONS

• MDR = multidrug resistant.
• MRSA = methicillin-resistant *Staphylococcus aureus*.
• MRSP = methicillin-resistant *Staphylococcus pseudintermedius*.
• PPE = personal protective equipment.
• WBC = white blood cell.

STEROID-RESPONSIVE MENINGITIS-ARTERITIS—DOGS

BASICS

OVERVIEW
- May be acute or protracted.
- Lesions—most impressive in CNS, affecting meninges and meningeal arteries; sometimes peracute bleeding; vascular changes in the heart, liver, kidney, and gastrointestinal system.
- Genetic factors—play a role in different breeds such as beagles and Nova Scotia duck tolling retrievers.
- Worldwide occurrence.

SIGNALMENT
- Dog.
- Beagle, Bernese mountain dog, Nova Scotia duck tolling retriever, and boxer predisposed; any breed can be affected.
- Mostly young adult dogs of both sexes; age range 5–18 months.

SIGNS
- Classical (acute)—hyperesthesia; cervical rigidity; stiff gait; fever up to 42°C (107.6°F).
- Protracted—neurologic deficits, usually reflecting a spinal cord or multifocal lesion.

CAUSES & RISK FACTORS
- Cause unknown.
- Pathologic findings, laboratory data, and marked response to steroids—suggest an immune-mediated disease related to a dysregulation of IgA production and a Th17-skewed immune response.
- Epidemiologic observations—altered immune response may be triggered by an environmental factor, possibly of infectious nature; genetic predisposition.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Acute—bacterial meningitis; meningeal tumors; discospondylitis.
- Protracted—bacterial meningitis; meningeal tumors (histiocytosis, meningioma, lymphosarcoma); other infectious encephalitides; meningoencephalomyelitis of unknown origin.

CBC/BIOCHEMISTRY/URINALYSIS
- Acute—leukocytosis with neutrophilia and left shift.
- Protracted—CBC noncontributory.

OTHER LABORATORY TESTS
IgA levels (serum and CSF)—usually high; high serum C-reactive protein (CRP) levels.

IMAGING
Radiographs to exclude discospondylitis; MRI to exclude differential diagnoses.

DIAGNOSTIC PROCEDURES

Cerebrospinal Fluid Analysis
- Acute—mild-to-moderate elevation of protein; moderate-to-marked pleocytosis, predominantly polymorphonuclear cells.
- Protracted—normal, or mild elevation of protein; mild-to-moderate pleocytosis with mixed cell population, or with a predominance of mononuclear cells.

PATHOLOGIC FINDINGS

Acute
- Marked meningitis with macrophages, plasma cells, lymphocytes, and varying numbers of polymorphonuclear cells mostly in the cervical region.
- Lesions of the meningeal arteries—degenerative with perivascular inflammation.

Protracted
- Marked fibrous thickening and focal mineralization of the leptomeninges.
- Arterial walls—thickened and stenotic from cellular proliferation of the intima and fibrosis.

TREATMENT
- Inpatient—at onset, fluid therapy and ice packs useful for high body temperature.
- After initial treatment, managed as outpatient.
- Regular follow-ups—inform client about side effects of long-term steroid treatment.

MEDICATIONS

DRUG(S) OF CHOICE
- Initial signs with mild CSF pleocytosis—nonsteroidal anti-inflammatory drugs (NSAIDs); carefully monitor the patient.
- First relapse, or symptoms become worse with marked CSF pleocytosis—start long-term treatment (6 months) with prednisolone 4 mg/kg PO q24h for 1–2 days; then taper slowly; reexamine patient (CSF collection, blood profile or CRP) every 4–6 weeks after initiation of therapy.
- Neurologic examination and CSF become normal, normal serum CRP levels—reduce steroid dose.
- Persistent pleocytosis—continue same steroid dosage.
- Treatment may be stopped after about 6 months.
- Immunosuppressive drugs if patient does not respond well to prednisolone alone; used in combination.
- Consider gastrointestinal protector to avoid ulcer.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Corticosteroids—high-dose treatment can lead to severe complications; non-life-threatening side effects (polyuria, polydipsia, polyphagia, and weight gain); not tolerated in about 5% of dogs.

FOLLOW-UP

PATIENT MONITORING
Control examinations—every 4–6 weeks; include blood examination and CSF collection; measurement of serum CRP levels until steroids discontinued.

PREVENTION/AVOIDANCE
Strictly control treatment schedule to prevent frequent relapses. No reliable predictive indicator available for relapse.

POSSIBLE COMPLICATIONS
- Subarachnoid bleed—may result in acute tetra- or paraplegia.
- Hypoxic lesions of spinal cord or brain.
- Side effects of immunosuppressive treatment.

EXPECTED COURSE AND PROGNOSIS
- Acute—prognosis relatively good in young dogs with early therapy.
- Protracted cases with frequent relapses—prognosis guarded; controlled studies note about 60% of dogs are cured after immunosuppressive treatment. Relapses occur in about 32% of the dogs.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Polyarthritis

AGE-RELATED FACTORS
Old animals do not tolerate long-term steroid treatment well, but condition rare in dogs >5 years of age.

SYNONYMS
- Aseptic meningitis.
- Canine juvenile polyarteritis syndrome.
- Corticosteroid-responsive meningomyelitis.

ABBREVIATIONS
- CRP = C-reactive protein.
- NSAID = nonsteroidal anti-inflammatory drug.

Author Andrea Tipold

S

STERTOR AND STRIDOR

BASICS

DEFINITION
• Abnormally loud sounds that result from air passing through a narrowed nasopharynx, pharynx, larynx, or trachea.
• Discontinuous sounds heard without a stethoscope.
• Stertor—low-pitched snoring sound that usually arises from the vibration of flaccid tissue or fluid; usually arises from nasal or pharyngeal airway obstruction.
• Stridor—higher pitched sounds that result when relatively rigid tissues are vibrated by the passage of air; result of partial or complete obstruction of the larynx or cervical trachea.

PATHOPHYSIOLOGY
• Airway obstruction causes turbulence as air travels through a narrowed passage; with worsening obstruction or increasing airflow velocity, the amplification of airway sounds occur due to increased turbulence and vibration of tissue, secretions, or foreign bodies.
• Obstruction sufficient to increase the work of breathing augments respiratory muscle effort and exacerbates turbulence; inflammation and edema of tissues in the region of the obstruction may develop, further reducing the airway lumen and further increasing the work of breathing, creating a vicious cycle.
• Complete airway obstruction will result in the lack of sounds.
• Obesity further increases respiratory effort and exacerbates airway obstruction.

SYSTEMS AFFECTED
Respiratory

GENETICS
• Brachycephalic obstructive airway syndrome is heritable in many breeds, including English and French bulldogs, pugs, Boston terriers, shih tzus, and other brachycephalic breeds.
• Congenital laryngeal paralysis has been identified in bouvier des Flandres, bull terriers, Siberian huskies, Alaskan Malamutes, and white-coated German shepherd dogs. Dalmatians, Rottweilers, Leonbergers, and Pyrenees mountain dogs.
• Older large breed dogs (e.g., Labrador retrievers) commonly develop laryngeal paralysis as part of a geriatric-onset laryngeal paralysis polyneuropathy complex.

INCIDENCE/PREVALENCE
Common

GEOGRAPHIC DISTRIBUTION
Worldwide

SIGNALMENT
Species
Dog more than cat.

Breed Predilections
• Common in brachycephalic dogs and less so cats
• Acquired laryngeal paralysis—overrepresented in certain giant breeds (e.g., Saint Bernard and Newfoundlands) and large breeds (e.g., Irish setters, Labrador retrievers, and golden retrievers).
• Cats of any breed due to nasopharyngeal polyps, inflammatory or neoplastic laryngeal diseases, or laryngeal paralysis (the latter far less common in cats than dogs).

Mean Age and Range
• Affected brachycephalic animals and dogs or cats with inherited laryngeal paralysis are typically younger than 1 year of age when owners detect a problem.
• Acquired laryngeal paralysis typically occurs in older dogs and cats.

Predominant Sex
No sex predilection for any cause, although inherited laryngeal paralysis has a 3:1 male predominance.

SIGNS
• Change or loss of voice.
• Partial obstruction—produces an increase in airway sounds before producing an obvious change in respiratory pattern or gas exchange.
• Owners may indicate that the sound has existed for as long as several years.
• Breath sounds audible from a distance without a stethoscope—suspect narrowing of upper airway.
• Nature of the sound—ranges from abnormally loud to obvious fluttering to high-pitched squeaking, depending on the degree of airway narrowing.
• Stress or exercise may amplify the sound or induce respiratory distress.
• May note increased respiratory effort and paradoxical respiratory movements (chest wall collapses inward during inspiration and springs outward during expiration) when the effort is extreme; respiratory motions often accompanied by obvious postural changes (e.g., abducted forelimbs, extended head and neck, and open-mouth breathing).

CAUSES
• Brachycephalic airway syndrome (stenotic nares, elongated soft palate, everted laryngeal saccules, laryngeal collapse).
• Laryngeal paralysis—inherited or acquired.
• Laryngeal neoplasia—benign or malignant.
• Granulomatous/inflammatory laryngitis.
• Tracheal collapse, stenosis, obstruction, neoplasia, foreign body.
• Nasopharyngeal polyp, stenosis, foreign body.
• Cervical bite wounds.
• Acromegaly.
• Neuromuscular dysfunction.
• Anesthesia or sedation—only if predisposing anatomy exists.
• Cleft palate.
• Aplasia of soft palate.
• Redundant pharyngeal mucosal folds.
• Soft palate mass.
• Edema or inflammation of the palate, pharynx, and larynx (including everted mucosal lining of the laryngeal ventricles)—secondary to coughing, vomiting or regurgitation, turbulent airflow, upper respiratory infection, and hemorrhage.
• Secretions (e.g., pus, mucus, and blood) in the airway lumen.

RISK FACTORS
• High ambient temperature or humidity.
• Fever.
• High metabolic rate—as occurs with hyperthyroidism or sepsis.
• Exercise.
• Anxiety or excitement.
• Any respiratory or cardiovascular disease that increases ventilation.
• Turbulence caused by the increased airflow can lead to swelling and worsen the airway obstruction.
• Hypothyroidism or polyneuropathy.
• Obesity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Systematically auscultate over the nose, pharynx, larynx, and trachea to identify the point of maximal intensity of any abnormal sound and to identify the phase of respiration when it is most obvious.
• Important to identify the anatomic location from which the abnormal sound arises and to seek exacerbating causes (see Risk Factors; e.g., a chronic airway obstruction may become manifest when the patient is exposed to extremely high ambient temperatures).
• Must differentiate sounds of pharyngeal, laryngeal, and tracheal narrowing from sounds arising elsewhere in the respiratory system.
• Nasal and tracheal narrowing and severe or extensive narrowing of the bronchi—can cause increased respiratory sounds.
• If the sound persists when the patient opens its mouth, a nasal cause can virtually be ruled out.
• If the owner describes a change in voice, the larynx is the likely abnormal site.

OTHER LABORATORY TESTS
Arterial blood gases—help characterize the degree of respiratory compromise (e.g., degree of hypoxemia, hypercapnia, or acid–base disturbances).

IMAGING
• Lateral radiographs of the head and neck—may help identify abnormal soft tissues of the airway (e.g., elongated soft palate or a nasal polyp); limited use for identifying laryngeal paralysis, although experienced radiographers can identify abnormally dilated or swollen laryngeal saccules; cartilaginous destruction is suggestive of neoplasia or granulomatous laryngitis; may detect external masses compressing the upper airway.

STERTOR AND STRIDOR (CONTINUED)

• Radiography and fluoroscopy—important for assessing the cardiorespiratory system; rule out other or additional causes of respiratory difficulty; such conditions may add to an underlying upper airway obstruction, causing a subclinical condition to become clinical.
• Ultrasound can be used to assess laryngeal structure and function, can also be used to document cervical tracheal collapse but air is a poor acoustic window.
• CT can be used to provide additional anatomic detail.

DIAGNOSTIC PROCEDURES

Laryngoscopy

• Definitive diagnostic tests for direct visualization of pharyngeal or laryngeal changes.
• Requires sedation that preserves laryngeal function. Recommend propofol 4–8 mg/kg IV to effect.
• The patient's ability to use muscles to open the airway is compromised by anesthesia; be prepared to correct any lesions found, at a minimum, be prepared to intubate.
• If correctable conditions are not identified and corrected—patient's recovery from anesthesia can be complicated by severe airway obstruction; must be prepared to perform a tracheotomy if airway is obstructed and a definitive surgical remedy cannot be pursued immediately.
• Assess timing and degree of movement of the arytenoids during light anesthesia—laryngeal paralysis results in lack of abduction of the arytenoids during inspiration. Use doxapram 1–2 mg/kg IV to stimulate respiration if needed.
• Normal palate—thin; just barely overlaps the tips of the epiglottis; easily displaced dorsally using the blade of the laryngoscope.
• Overlong soft palate—thick; usually inflamed; may lie 1 cm or more past the tip of the epiglottis.

TREATMENT

APPROPRIATE HEALTH CARE

• Inpatient management required for surgical treatment.
• Closely monitor effects of sedatives; sedatives can relax the upper airway muscles and worsen the obstruction; be prepared with emergency methods for securing the airway if complete obstruction occurs.
• In cases of suspected laryngeal paralysis resulting in respiratory distress and partial obstruction in dogs, sedation with butorphanol 0.2–0.3 mg/kg and acepromazine 0.025–0.05 mg/kg with oxygen supplementation and active cooling measures if hyperthermic may be indicated.
• If available, use of high-flow oxygen nasal cannulation has been successful to treat partial airway obstruction.
• Severe or complete airway obstruction—attempt an emergency intubation; if obstruction prevents intubation, emergency tracheostomy or passage of a tracheal catheter to administer oxygen may be the only available means for sustaining life; a tracheal catheter can briefly sustain oxygenation while a more permanent solution is sought.

NURSING CARE

• Treatment requires removal of obstruction, supplemental oxygen is variably helpful.
• IV fluids may be required, particularly if hyperthermia develops from increased work of breathing.
• Active cooling measures (ice packs in axilla and groin region, alcohol on foot pads, chilled IV fluids) helpful in alleviating hyperthermia but not indicated for fever.

ACTIVITY

Keep patient cool, quiet, and calm—anxiety, exertion, and pain lead to increased ventilation, potentially worsening the obstruction.

DIET

• NPO if anesthesia is planned.
• Dietary management to avoid obesity, a known risk factor for developing airway obstruction and associated stertor or stridor.

CLIENT EDUCATION

Inform client that the patient can make the transition from being a noisy breather to having an obstructed airway in a few minutes or even seconds.

SURGICAL CONSIDERATIONS

• Laryngoscopy and bronchoscopy for foreign body retrieval and biopsy of laryngeal region and tracheal lumen. Use of small balloon catheters passed beyond the foreign body prior to expansion may be useful in removing some objects.
• Take particular care when inducing general anesthesia or when using sedatives in any patient with upper airway obstruction.
• Surgery—indicated to obtain a diagnosis through biopsy with histopathology, to manage obstruction while awaiting histopathology results or resolution of inflammation/infection (e.g., tracheotomy), or to resolve disease by excision, correction of obstructive lesion, and removal of foreign bodies.

MEDICATIONS

DRUG(S) OF CHOICE

• Medical approaches—appropriate only if the underlying cause is infection, edema, inflammation, or hemorrhage; anatomic or neurologic causes are not amenable to medical treatment.
• Steroids—may be indicated if edema or inflammation is thought to be an important contributor; effect with IV administration of a short-acting glucocorticoid such as dexamethasone sodium phosphate (1 mg/kg prednisone equivalent) should be apparent in the first several hours. Single dose may be sufficient, or a tapering dose might be required. Inflammatory laryngitis often requires higher doses administered over a longer dosing schedule with taper of

PRECAUTIONS

Sedatives, analgesics, and anesthetics—avoid excessive suppression of laryngeal movement and respiratory suppression to avoid aspiration in animals with laryngeal disease.

FOLLOW-UP

PATIENT MONITORING

Respiratory rate and effort need to be closely monitored. When owner chooses to take an apparently stable patient home, or if continual observation is not feasible, inform client that complete obstruction could occur.

PREVENTION/AVOIDANCE

Advise client to avoid exercise, high ambient temperatures, and extreme excitement.

POSSIBLE COMPLICATIONS

Serious complications may occur without therapy to relieve the obstruction; these include airway edema, pulmonary edema (may progress to life-threatening acute lung injury), and hypoventilation; may require tracheotomy and/or artificial ventilation.

EXPECTED COURSE AND PROGNOSIS

• Varies with underlying cause.
• Even with surgical treatment, some degree of obstruction may remain for 7–10 days due to swelling.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Peripheral neuropathy often associated with laryngeal paralysis.

SYNONYMS

Snoring

SEE ALSO

• Brachycephalic Airway Syndrome.
• Hypothyroidism.
• Laryngeal Diseases.
• Myasthenia Gravis.
• Nasal and Nasopharyngeal Polyps.
• Tracheal Collapse.

STOMATITIS AND ORAL ULCERATION

BASICS

DEFINITION

- Stomatitis—an inflammation of the tissues of the oral cavity, more specifically defined below.
- Ulceration—focal or multifocal loss of mucosal integrity of the superficial epithelial layers in specific areas of the oral cavity.
- American Veterinary Dental College Nomenclature—oral and oropharyngeal inflammation is classified by location as:
  - Stomatitis—inflammation of the mucous lining of any of the structures in the mouth; in clinical use the term should be reserved to describe widespread oral inflammation (beyond gingivitis and periodontitis) that may also extend into submucosal tissues (e.g., marked caudal mucositis extending into submucosal tissues may be termed caudal stomatitis).
  - Gingivitis—inflammation of gingiva.
  - Periodontitis—inflammation of nongingival periodontal tissue (i.e., the periodontal ligament and alveolar bone).
  - Alveolar mucositis—inflammation of alveolar mucosa.
  - Sublingual mucositis—inflammation of mucosa on the floor of the mouth.
  - Labial/buccal mucositis—inflammation of the lip/cheek mucosa.
  - Caudal mucositis—inflammation of mucosa of the caudal oral cavity.
  - Contact mucositis and contact mucosal ulceration ("contact ulcers" and "kissing ulcers")—lesions in susceptible individuals that are secondary to mucosal contact with a tooth surface bearing the responsible irritant, allergen or antigen.
  - Palatitis—inflammation of mucosa covering the hard and/or soft palate.
  - Glossitis—inflammation of mucosa of the dorsal and/or ventral tongue surface.
  - Cheilitis—inflammation of the lip (including the mucocutaneous junction area and skin of the lip).
  - Osteomyelitis—inflammation of the bone and bone marrow.
  - Tonsilitis—inflammation of the palatine tonsil(s).
  - Pharyngitis—inflammation of the pharynx.

PATHOPHYSIOLOGY

- Metabolic:
  - Diabetes mellitus.
  - Hypothyroidism.
  - Renal disease—uremia.
- Nutritional:
  - Protein-calorie malnutrition.
  - Riboflavin deficiency.
- Neoplastic:
  - Dog—malignant melanoma; squamous cell carcinoma; fibrosarcoma.
  - Cat—squamous cell carcinoma; fibrosarcoma; malignant melanoma.
- Immune-mediated:
  - Pemphigus vulgaris—90% have oral involvement.
  - Bullous pemphigoid—80% have oral involvement.
  - Systemic lupus erythematosus—50% have oral involvement.
  - Discoid lupus erythematosus.
- Drug-induced—toxic epidermal necrolysis, erythema multiforme.
- Infectious:
  - Retrovirus—feline leukemia virus/feline immunodeficiency virus (FeLV/FIV).
  - Calicivirus—cat.
  - Herpesvirus—cat.
  - Leptospirosis—dog.
  - Periodontal disease—dog and cat.
- Traumatic:
  - Foreign body—bone or wood fragments.
  - Electric cord shock.
  - Malocclusion.
  - Gum-chewer's disease—chronic chewing of cheek or sublingual mucosa.
- Chemical/toxic:
  - Acids—etching gels for dental procedures (37% phosphoric acid).
  - Bases: hypochlorite, cleaning solutions.
  - Thallium.
- Idiopathic:
  - Eosinophilic granuloma—cats, Siberian huskies, Samoyeds.
  - Feline stomatitis—cats; feline chronic gingivostomatitis (FCGS).
  - Canine ulcerative stomatitis—dogs; allergic, hypersensitivity reaction to plaque.
  - Idiopathic osteomyelitis—dogs.

SYSTEMS AFFECTED

Gastrointestinal (oral).

INCIDENCE/PREVALENCE

Variable

SIGNALMENT

Species

Dogs and cats of any age and either sex.

Breed Predilections

- Breed predilection for canine ulcerative stomatitis (aka chronic ulcerative paradental stomatitis [CUPS])—Maltese, cavalier King Charles spaniels, cocker spaniels, bouvier des Flandres.
- Feline stomatitis—FCGS may have predilection for Somali and Abyssinian cats.
- Idiopathic osteomyelitis—may have predilection for cocker spaniels; complication associated with canine ulcerative stomatitis.

Mean Age and Range

Any age.

Predominant Sex

Either gender.

SIGNS

Historical Findings

- History and oral examination—foreign bodies; malocclusions; chemical, toxic, and electrical burns.
- Idiopathic conditions—clinical signs; history; breed predispositions; response to therapy.
- Anorexia.
- Behavior changes secondary to oral sensitivity.
- *Note*: In canine ulcerative stomatitis, occasionally these signs will start following a routine dental cleaning on a previously "normal" patient; probably would have occurred eventually, just exacerbated by manipulation in the oral cavity.

Physical Examination Findings

- Halitosis.
- Gingivitis.
- Pharyngitis.
- Buccitis/buccal mucosal ulceration.
- Hypersalivation (thick, ropey saliva).
- Pain.
- Contact mucosal ulceration or contact mucositis—"kissing ulcers" common in canine ulcerative stomatitis.
- Plaque—with or without calculus.
- Exposed, necrotic bone—with alveolar osteitis and idiopathic osteomyelitis.
- Scar formation on lateral margins of tongue—with canine ulcerative stomatitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

See Causes.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC, biochemistry, urinalysis, and thyroxine (T_4)—diabetes mellitus, renal disease, hypothyroidism, infections, and for preoperative considerations.
- Chronic conditions may have elevated serum total protein and elevated globulin levels due to chronic antigen stimulation; T_4 may be decreased secondarily.

OTHER LABORATORY TESTS

- Serology—FeLV/FIV test; titers for specific infections.
- Cultures—usually nonspecific; oral flora contaminants.

IMAGING

Radiography—helps determine bony involvement, and other conditions such as periodontal disease or tooth resorption, and extent of idiopathic osteomyelitis.

DIAGNOSTIC PROCEDURES

Biopsy/cytology—neoplasia, immune-mediated disease, and chronic inflammation result in predominant lymphocytes and plasmocytes (in canine ulcerative stomatitis and feline stomatitis).

PATHOLOGIC FINDINGS

See definitions above.

STOMATITIS AND ORAL ULCERATION (CONTINUED)

TREATMENT

APPROPRIATE HEALTH CARE
Underlying metabolic or other disease—treat systemic illness appropriately.

NURSING CARE
Supportive therapy—soft diet; fluids; hospitalization in severe cases.

DIET
- Nutritional support—via pharyngostomy or esophagostomy feeding tube.
- May consider hypoallergenic diet.

CLIENT EDUCATION
- Canine ulcerative stomatitis—continuous, meticulous home care to prevent plaque accumulation; dental cleaning initially and frequently; periodontal therapy; extraction of diseased teeth.
- Warn client that prognosis is guarded, response to therapy depends on underlying cause, and prolonged treatment and/or further extractions may be necessary.
- In canine ulcerative stomatitis or feline stomatitis, any level of home care that can be provided is encouraged (brushing or topical antimicrobials).

S

SURGICAL CONSIDERATIONS
- Select extractions (partial, caudal, or full mouth)—may be indicated for chronic idiopathic conditions (e.g., canine ulcerative stomatitis and feline stomatitis) to remove the source of reaction (plaque/teeth).
- Removal of entire tooth structure is important.
- Removal of necrotic/avascular bone, gingival flap closure, and broad-spectrum antibiotics—indicated for idiopathic osteomyelitis; monitor for recurrence.

MEDICATIONS

DRUG(S) OF CHOICE
- Antimicrobials—treat primary and secondary bacterial infections; may be used intermittently between cleanings for therapeutic assistance, but the owner must be cautioned that chronic use could lead to antibiotic resistance; clindamycin 11 mg/kg PO q12h; amoxicillin–clavulanate 12.5–25 mg/kg PO q12h; tetracycline 10–22 mg/kg PO q8h.
- Anti-inflammatory/immunosuppressive drugs—the comfort of the patient must be weighed against potential long-term side effects of corticosteroid usage; prednisone 0.5–1.0 mg/kg q12–24h PO, taper dosage:
  - For eosinophilic granuloma—prednisolone 2–4.4 mg/kg PO once a day; for chronic cases use 0.5–1.0 mg/kg PO every other day.
  - Cyclosporine 5 mg/kg PO q24h. Therapeutic serum levels after 6 weeks if no response to therapy.
- Mucosal protectants—for chemical insults; sucralfate 1 g/25 kg q8h PO; cimetidine 5–10 mg/kg q8–12h PO.
- Analgesics—carprofen 0.5 mg/kg PO q12–24h; hydrocodone 0.22 mg/kg q8–12h; tramadol 2.2–4.4 mg/kg PO q6–12h; gabapentin 5–10 mg/kg PO SID.
- Topical therapy—chlorhexidine solution or gel (antibacterial); zinc gluconate/ascorbic acid; stabilized chlorine dioxide for halitosis.
- Appropriate antimicrobial and pain management therapy when indicated.
- Appropriate patient monitoring and support during anesthetic procedures.

CONTRAINDICATIONS
Corticosteroids are contraindicated in patients with systemic fungal infections.

PRECAUTIONS
- Some antimicrobials may upset the gastrointestinal tract.
- Avoid corticosteroids in patients that may already be immunocompromised (i.e., those with FeLV or FIV).
- Do not use these medications in patients with known hypersensitivities.

FOLLOW-UP

PREVENTION/AVOIDANCE
Optimal home care and regular professional cleaning and treatment is essential.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Idiopathic osteomyelitis may occur in some canine ulcerative stomatitis patients (see above).

ZOONOTIC POTENTIAL
N/A, unless immunocompromised individuals.

SYNONYMS
- Chronic ulcerative paradental stomatitis (CUPS).
- Ulcerative stomatitis.
- Gingivostomatitis.
- Vincent's stomatitis.
- Necrotizing stomatitis.

SEE ALSO
Feline Stomatitis—Feline Chronic Gingivosomatitis (FCGS).

ABBREVIATIONS
- CUPS = chronic ulcerative paradental stomatitis.
- FCGS = Feline chronic gingivostomatitis.
- FeLV = feline leukemia virus.
- FIV = feline immunodeficiency virus.
- T_4 = thyroxine.

STREPTOCOCCAL INFECTIONS

BASICS

OVERVIEW

- *Streptococcus*—Gram-positive, nonmotile, facultatively anaerobic spherical bacteria (cocci):
  - Commensal organisms; normal flora of the upper respiratory tract, oropharynx, lower genital tract, and skin.
  - Under appropriate conditions, capable of infecting all areas of body; frequent secondary invader of body tissues.
- Classified by ability to hemolyze red blood cells on blood agar plates:
  - α-Hemolytic (green zone of partial hemolysis).
  - β-Hemolytic (clear zone of hemolysis); usually more pathogenic than α-hemolytic, which is more pathogenic than nonhemolytic strains.
  - γ-Hemolytic (no change; nonhemolytic).
- Hemolytic strains further subdivided by differences in cell walls (Lancefield serogroups A–H and K–T); some groups more likely to be associated with disease:
  - Group G is associated with cats and dogs; group A with humans).
  - Many group D streptococci reclassified as enterococci.
- Produce exotoxins—streptolysins (hemolysins), streptokinases, deoxyribonucleases, and hyaluronidases.
- Adhesins to bind extracellular matrix proteins.

SIGNALMENT

- Dogs and cats.
- Very young—more prone to infection because of incomplete immunity; particularly kittens born to primiparous queen.

SIGNS

- Vary with site of infection and host immunocompetence. Sites of infection can include abscesses, genitourinary tract, ears, septicemia (e.g., toxic shock syndrome), joints, lungs, heart valves, lymph nodes, CNS, wounds (e.g., necrotizing fasciitis), tonsil/pharynx, or skin, and may result in abortion, fading puppies/kittens, or bitch/queen sterility.
- Weakness.
- Coughing.
- Dyspnea.
- Fever.
- Hematemesis.
- Hematuria.
- Lymphadenopathy.
- Pain.

CAUSES & RISK FACTORS

- Age, exposure, and immune response determine disease severity.
- Virulence—depends on specific organism.
- Opportunistic—surgical or traumatic wounds, viral infections, atopic dermatitis, immunosuppressive conditions.
- Coinfection with canine influenza virus increases disease severity. Other predisposing conditions—feline leukemia virus, feline infectious peritonitis, immunodeficiency, respiratory viral infections, feline lower urinary tract disease.
- Maternal antibodies generally protect neonates.
- Carrier state occurs.
- Bacterial superantigens may contribute to toxic shock syndrome and necrotizing fasciitis; enrofloxacin-induced bacteriophages may enhance superantigen expression.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other infectious causes—viruses, bacteria, fungi, *Rickettsia,* protozoa.

CBC/BIOCHEMISTRY/URINALYSIS

- Normal or high leukocytes with neutrophilia and left shift or degenerative left shift.
- Cocci—in circulating neutrophils if overwhelming sepsis.
- Biochemistry—suggests predisposing conditions.
- Urinalysis—pyuria (with or without bacteruria).

OTHER LABORATORY TESTS

- Direct microscopy.
- Gram stain—of exudates; Gram-positive cocci in chains or singlets.
- Culture and susceptibility testing —affected tissues, exudate or needle aspirates.
- PCR.

IMAGING

Radiographs—interstitial or alveolar pulmonary pattern (pneumonia); radiodense uroliths (struvite).

PATHOLOGIC FINDINGS

- Acute inflammation—gross or microscopic abscesses.
- Septicemia—omphalophlebitis, peritonitis, hepatitis, pneumonia, myocarditis.

TREATMENT

- Good nursing care.
- Rehydrate.
- Drain and flush abscess.
- Debride necrotic tissue.

MEDICATIONS

DRUG(S) OF CHOICE

- Ampicillin 22–30 mg/kg IV, IM, SC, PO q8h; combined with aminoglycoside (gentamicin or amikacin) for group B.
- Amoxicillin 22 mg/kg PO q8–12h.
- Amoxicillin–clavulanate 22 mg/kg PO q12h.
- Penicillin—penicillin G 10,000–20,000 U/kg IM, SC q12–24h or penicillin V 8–30 mg/kg PO q8h.
- Erythromycin 10–20 mg/kg IV, SC, PO q8h.
- Clindamycin 10–15 mg/kg PO, IV, SC q12h.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Avoid immunosuppressive drugs; aminoglycosides contraindicated with renal disease.
- Enrofloxacin—contraindicated for necrotizing fasciitis.

FOLLOW-UP

PREVENTION/AVOIDANCE

- Avoid overcrowding, maintain clean feeders and environment, segregate infected animals.
- Newborns—dip navel and umbilical cord in 2% tincture of iodine, consider prophylactic antibiotic treatment of kittens born to primiparous queens.

MISCELLANEOUS

ZOONOTIC POTENTIAL

- Animals may show no clinical signs with group A streptococci but may serve as reservoir for human infection.
- Streptococci isolated from people are usually of human, not animal, origin.
- *S. canis* infections in people reported from dog bites and wounds in contact with dogs.

STUPOR AND COMA

BASICS

DEFINITION
• Stupor—unconscious but arousable with noxious stimuli. • Coma—unconscious, not arousable with noxious stimuli.

PATHOPHYSIOLOGY
Any severe pathologic change (anatomic or metabolic) of the ascending reticular activating system (network of neurons situated in the core of the brainstem) and/or arousal system for the cerebral cortex can lead to depression, stupor, or coma.

SYSTEMS AFFECTED
• Nervous. • Cardiovascular. • Neuromuscular. • Ophthalmic. • Respiratory.

SIGNALMENT
• Dog and cat. • No breed, age, or sex predilection.

SIGNS
Historical Findings
• Possibility of trauma or unsupervised roaming. • Past medical problems of significance—diabetes mellitus, insulin therapy; hypoglycemia; cardiovascular problems; hypoxic episodes; renal failure; liver failure; neoplasia. • Patient's environment—possible heatstroke; hypothermia; drowning; exposure to drugs, including owner's medications, narcotics, toxins (e.g., ethylene glycol, lead, anticoagulants). • Onset may be acute or slowly progressive, depending on underlying cause.

Physical Examination Findings
• Evidence of external or internal trauma. • Severe hypo- or hyperthermia. • Evidence of hypoxia or cyanosis, ecchymosis or petechiation, cardiac or respiratory insufficiency—warrants investigation for metabolic causes. • Palpate for evidence of neoplasia. • Retinal hemorrhages or distended vessels—hypertension. • Papilledema—cerebral edema. • Retinal detachment—infectious, neoplastic, or hypertensive causes. • Chorioretinitis—infectious causes (distemper, feline leukemia virus [FeLV]-related diseases, toxoplasmosis, cryptococcosis, or coronavirus). • Sustained bradycardia (with normal serum potassium)—midbrain, pontine, or medullary lesion.

Neurologic Examination Findings
• Differentiate cerebrum–diencephalic lesion from brainstem lesion (better vs. worse prognosis). • Determine level of consciousness and if patient arousable. • Pupillary light reflexes—small responsive pupils: cerebral or diencephalic lesion; dilated unresponsive pupils (unilateral or bilateral) or fixed in midposition: midbrain or severe medullary lesions. • Oculocephalic reflex (when cervical manipulation possible)—loss of physiologic vestibular nystagmus: brainstem involvement. • Respiratory patterns—Cheyne-Stokes respiration: severe, diffuse cerebral or diencephalic lesion; hyperventilation: midbrain lesion; ataxic or apneustic breathing: pons or medulla lesion. • Cranial nerve (CN)—deficits with lesion of cerebrum–diencephalon: CN I, II; deficits of CN III: midbrain lesion; deficits of CN V–XII: pons and medulla lesions. • Postural changes—decerebrate rigidity: midbrain lesion.

CAUSES
• Drugs—narcotics, anesthetics, depressants, ivermectin. • Anatomic—hydrocephalus. • Metabolic—severe hypoglycemia, hyperglycemia, hyperosmolar syndromes, hypernatremia, hyponatremia, hepatic encephalopathy, hypoxemia, hypercarbia, hypothermia, hyperthermia, hypotension, coagulopathies, renal failure, lysosomal storage disease, severe hypothyroidism. • Nutritional—hypoglycemia, thiamine deficiency. • Neoplastic (primary)—meningioma, astrocytoma, gliomas, choroid plexus papilloma, pituitary adenoma, others. • Metastatic—hemangiosarcoma, lymphoma, mammary carcinoma, others. • Inflammatory noninfectious—granulomatous meningoencephalomyelitis. • Infectious—bacterial, viral (distemper, feline coronavirus [FCoV]), parasitic (aberrant larva migrants), protozoal (neosporosis, toxoplasmosis), fungal (cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis, actinomycosis), tick-borne diseases. • Idiopathic—epilepsy (post status epilepticus). • Immune-mediated—brain edema, vasculitis and thrombocytopenia leading to hemorrhage. • Trauma—most common cause. • Toxins—ethylene glycol, lead, rodenticides, others. • Vascular—hemorrhage (bleeding disorders, hypertension), infarction (feline ischemic encephalopathy, hypercoagulable disease, microfilaria, or migrating adult heartworm).

RISK FACTORS
• Diabetes mellitus—insulin therapy. • Hepatic failure. • Insulinoma. • Severe heat or cold exposure without protection. • Free-roaming animals—trauma. • Young and unvaccinated animals. • Hypertension.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Acute onset—most commonly caused by toxins, drugs, trauma, or vascular accidents. • Slow progression of neurologic signs without systemic abnormalities—suggests primary neurologic disorders of inflammatory, neoplastic, or anatomic causes. • Bilateral diffuse cortical signs—metabolic diseases, toxins, systemic infection, drugs, and nutritional causes. • Brainstem signs—trauma, inflammation, neoplasia, vascular accidents, or progression of cerebral disease causing tentorial herniation.

CBC/BIOCHEMISTRY/URINALYSIS
CBC
• Lead toxicity—may show nucleated red blood cells or basophilic stippling. • Severe infection—inflammatory hemogram. • Severe anemia—suggests hypoxemia.

Biochemistry
May see hypoglycemia, hyperglycemia, hypernatremia, azotemia, hyperosmolarity, and other metabolic derangements.

Urinalysis
• Diabetes mellitus—glycosuria. • Renal failure—isosthenuria, granular casts. • Immune-mediated disease or severe infection—proteinuria. • Hepatic encephalopathy—ammonium biurate crystals. • Ethylene glycol toxicity—calcium oxalate or hippurate crystals.

OTHER LABORATORY TESTS
• Serum ethylene glycol level and osmolar gap—acute onset. • Serum ammonia concentration and preprandial and postprandial bile acids—high levels indicate hepatic encephalopathy. • Serum and CSF titers—suspected infectious disease. • Arterial blood gases—evidence of hypoxemia; severe pH changes; hypo- and hypercarbia. • Coagulogram—including prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen, fibrin degradation product, D-dimer, platelet count, antithrombin, buccal bleeding time, thromboelastography; suspected intracranial bleeding or thrombosis. • Serologic testing—FeLV, feline immunodeficiency virus (FIV), FCoV, protozoal and heartworm disease. • Serum toxicity levels (e.g., lead, macrolide, other toxins). • Thyroid panel.

IMAGING
• Survey radiographs (thorax and abdomen)—evidence of heavy metal, organ enlargement, infiltration, or neoplasia. • Skull radiographs—fractures in trauma cases, lytic lesions, masses. • CT—excellent for detecting acute hemorrhage within calvaria; depressed fractures; lytic lesions, penetrating foreign bodies. • MRI with contrast—demonstrates cerebral edema, hemorrhage, mass, infiltrative diseases, vascular interruption.

DIAGNOSTIC PROCEDURES
• CSF—cytology, protein and immunoglobulin concentrations, and titers for infectious diseases; perform only when no evidence of trauma, increased intracranial pressure, coagulopathies, or metabolic disease. • Brainstem auditory-evoked response—determine brainstem function. • ECG, echocardiogram—determine cardiac

dysfunction; abnormalities may contribute to stupor or coma or may be caused by brain disease. • EEG—detect nonclinical seizure activity that can prolong stupor and coma.

PATHOLOGIC FINDINGS

Cerebral edema, hemorrhage, infarct, ischemia, inflammation, neoplasia, herniation, laceration, contusion, hematomas, skull fracture, necrosis, and apoptosis.

TREATMENT

APPROPRIATE HEALTH CARE

Poor Perfusion

• Small-volume fluid resuscitation technique; a combination of hydroxyethyl starch with balanced isotonic crystalloids. • Use peripheral veins, leaving the jugular vein blood flow unobstructed; shifting blood volume into the jugular veins is an important compensatory mechanism during high intracranial pressure (ICP). • Maintain systolic BP >90 mmHg; avoid hypertension. • Hydration—maintain with a balanced electrolyte crystalloid solution. • The head and neck should be leveled with the body or elevated to a 20° angle. • Oxygen supplementation—avoid a cough or sneeze reflex during intubation or nasal cannula placement; administer lidocaine (dogs, topical and/or 1–2 mg/kg IV) before intubation to blunt the gag and cough reflex. • Pa_{O_2} must be >50 mmHg to maintain cerebral blood flow autoregulation in normal brain tissue.

Ventilation

• Protect airway with intubation. • Pa_{CO_2}—maintain between 35 and 45 mmHg.

Reduce Increase In ICP

• Prevent thrashing, seizures, or any other form of uncontrolled motor activity that can elevate ICP; diazepam infusion 0.5–1 mg/kg/h, midazolam 0.2–0.4 mg/kg, or propofol 3–6 mg/kg IV titrated to effect; then 0.1–0.6 mg/kg/min CRI; levetiracetam 20 mg/kg IV/IM/rectal q8h if seizure activity. • Ensure systolic BP >90 mmHg. • 7% hypertonic saline (2–4 mL/kg IV); can reduce fluid volume needed to reach resuscitation endpoints; can combine with colloid. • Furosemide 0.75 mg/kg IV; may decrease CSF production. • Mannitol 0.5–1 g/kg IV bolus repeated at 2-hour intervals 3 or 4 times in dogs, and 2 or 3 times in cats; repeated doses must be given on time; improves brain blood flow and lowers ICP. • Hyperventilation (Pa_{CO_2} 32–35 mmHg) for 48 hours using mechanical ventilation; requires intensive monitoring. • Ventriculostomy for CSF drainage if critical elevation of ICP nonresponsive to medical treatment. • Consider surgical decompression and exploration—if cerebral dysfunction is progressing to midbrain signs with a history of trauma or bleeding (tentorial herniation); high ICP not responsive to medical therapy (if monitoring instrumentation available); depressed skull fracture fragments; penetrating foreign body; requires intensive monitoring.

NURSING CARE

• Prevent secondary complications of recumbency—eye lubrication; aseptic technique with catheters; turning; rehabilitation exercises. • Prevent urine/fecal scalding. • Careful nasogastric tube feeding for early trickle flow feeding; cisapride 0.5 mg/kg PO q8–12h and metoclopramide 1–2 mg/kg/day may promote gastrointestinal motility.

MEDICATIONS

DRUG(S) OF CHOICE

Underlying Disease

• Glucocorticosteroids—inflammatory, immune-mediated and space-occupying intracranial abnormalities. • Lactulose enemas, flumazenil 0.02 mg/kg IV and fluid support—hepatic encephalopathy. • Fluid diuresis, dialysis—renal failure. • Rehydration and insulin—diabetes mellitus with hyperosmolality; lower glucose slowly. • Glucose supplementation—hypoglycemia. • Support IV volume; cool—hyperthermia. • Support IV volume; warm to ≥98°F/36.5°C—hypothermia. • Gastric lavage and instillation of activated charcoal with a cathartic. • Dialysis—low-molecular-weight toxins. • Antibiotics—use agents that cross the blood–brain barrier for suspected bacterial infections (e.g., trimethoprim-sulfa, clindamycin, doxycycline, metronidazole). • Adjust crystalloid fluid selection to correct electrolyte disorders. • Thiamine (cat, 5–50 mg; dog, 1–20 mg IV)—possible thiamine deficiency.

PRECAUTIONS

• Avoid hypo- and hypertension, hypo- and hyperglycemia. • Avoid IV volume overload.

FOLLOW-UP

PATIENT MONITORING

• Serial neurologic examinations—detect deterioration that warrants aggressive therapeutic intervention. • BP—keep fluid therapy adequate for perfusion while avoiding hypertension. • Blood gases—assess need for oxygen supplementation or ventilation; monitor P_{CO_2} when hyperventilating. • Blood glucose—ensure adequate level to maintain brain functions while avoiding hyperosmolality. • ECG—detect arrhythmias that may affect perfusion, oxygenation, and cerebral blood flow. • ICP—detect marked elevations; track success of therapeutics. • Electrolytes—detect hypernatremia and hypokalemia.

PREVENTION/AVOIDANCE

• Keep pets confined or leashed. • Prevent exposure to toxins or in-home medications. • Routine healthcare program to minimize infectious and metabolic disease complications.

EXPECTED COURSE AND PROGNOSIS

• Short-term prognosis poor, other than related to hypoglycemia. • Pathology of brainstem worse than pathology of cerebral cortex. • Modified Glasgow Coma Score can provide prognostic information.

MISCELLANEOUS

ABBREVIATIONS

• CN = cranial nerve.
• CSF = cerebrospinal fluid.
• ECG = electrocardiogram.
• EEG = electroencephalogram.
• FCoV = feline coronavirus.
• FeLV = feline leukemia virus.
• FIV = feline immunodeficiency virus.
• ICP = intracranial pressure.
• Pa_{CO_2} = partial pressure of carbon dioxide in arterial blood.
• Pa_{O_2} = partial pressure of arterial oxygen.
• PT = prothrombin time.
• PTT = partial thromboplastin time.

SUBARACHNOID CYSTS (ARACHNOID DIVERTICULUM)

BASICS

DEFINITION
Subarachnoid cysts refer to dilation of the subarachnoid space causing compression of the underlying brain or spinal cord. The use of the term "cyst" is misleading, as most do not have a defined cyst wall with an epithelial lining and the term subarachnoid diverticulum is frequently used when the lesion is spinal in location. This term is also problematic in cases in which arachnoid scarring simply causes dilation of the subarachnoid space.

PATHOPHYSIOLOGY
• There are several proposed etiologies of subarachnoid cysts. • Any disease process that causes arachnoiditis has the potential to cause adhesions that result in the formation of one-way valves through which CSF flows, but cannot return, causing accumulation of CSF. • Congenital forms of the disease may result from abnormal splitting of the arachnoid membrane during development.

SYSTEMS AFFECTED
Nervous—spinal cord and brain (quadrigeminal cistern).

S

GENETICS
Certain breeds appear to be predisposed (e.g., pug, Rottweiler for spinal cord, Pekingese, shih tzu for brain). There are no data confirming heritability or a mode of inheritance at this time.

INCIDENCE/PREVALENCE
No specific data.

SIGNALMENT

Species
Dog and cat.

Breed Predilections
• Spinal—pug, Rottweiler, French bulldog. • Brain—small brachycephalic breeds.

Mean Age and Range
Dogs <3 years, range 2.5 months–13 years.

Predominant Sex
Male > female.

SIGNS

Historical Findings

Spinal

• Owners report a slowly progressive ataxia and paresis involving all or just the pelvic limbs. • Fecal incontinence—common early sign of thoracolumbar diverticula, with urinary incontinence developing shortly after. • Owners do not usually report that the pet is in pain. In a study of 122 cases, 19% of the dogs had pain. • There may be prior history of previous spinal cord injury (due to trauma, intervertebral disc disease, or fibrocartilagenous embolism). • There may be concurrent vertebral malformations at the site of the diverticula.

Brain

• Cerebellar signs. • Seizures.

Physical Examination Findings
Usually normal, although possible secondary consequences of the myelopathy include abrasions of the dorsal aspect of the toes, wearing of the nails, and urinary tract infections.

Neurologic Examination Findings

Spinal

• Neurologic signs reflect lesion localization—hindlimb involvement for thoracolumbar cysts and all limbs for cervical cysts. • Ataxia frequently characterized by hypermetria. • Paresis. • Proprioceptive placing deficits. • Fecal and/or urinary incontinence; urine retention (due to defective voiding). • Spinal reflexes may be reduced if the lesion is at the brachial or lumbosacral intumescence but otherwise are normal or increased. • Spinal pain is rarely elicited.

Brain

• Quadrigeminal cysts are frequently an incidental finding. However, extremely large cysts can produce compression of the cerebellum and brainstem. • Signs of cerebellar disease—hypermetria, intention tremor, wide-based stance. • Signs of brainstem compression—tetraparesis, head tilt. • Seizures (the relationship between the cyst and the presence of seizures is unclear).

CAUSES
• Several proposed etiologies. • Congenital malformation of the arachnoid mater (dilated septum posticum; in young dogs). • Secondary to traumatic injury to the arachnoid, causing adhesions and development of one-way valves for CSF flow. • Secondary to chronic microtrauma to the arachnoid, causing adhesions and development of one-way valves for CSF flow. This mechanism has been proposed for pugs with caudal thoracic subarachnoid cysts. Affected dogs may have hypoplasia of their articular facets leading to chronic instability.

RISK FACTORS
• Traumatic spinal cord injury that damages the arachnoid mater. • Hypoplastic articular facets associated with subarachnoid diverticulae in certain dog breeds (pugs).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Distinctive features—slowly progressive, nonpainful paresis and ataxia with a hypermetric gait, and presence of fecal and/or urinary incontinence in an animal that is still ambulatory. • Any cause of focal myelopathy could cause the same neurologic presentation. • Intervertebral disc herniation. • Neoplasia. • Trauma. • Inflammatory or infectious myelitis. • Congenital vertebral/spinal malformation. • Intraspinal vascular malformation.

CBC/BIOCHEMISTRY/URINALYSIS
Urinalysis may show evidence of urinary tract infection (pyuria, hematuria, proteinuria, and bacteriuria).

OTHER LABORATORY TESTS
Aerobic urine culture if evidence of urinary tract infection.

IMAGING
• Thoracic radiography—in older patients to rule out metastatic neoplasia. • Spinal radiography—should be performed in all patients; typically unremarkable in patients with subarachnoid diverticulae. However, some patients may have evidence of spinal fractures, and occasionally there is evidence of a vertebral malformation (articular facet hypoplasia, spina bifida, hemivertebra, or block vertebra) colocalizing with the neurologic signs. • Myelography—focal dilation of the subarachnoid space most commonly located dorsally but sometimes located ventrally; the dilation may be multilobed. • CT myelography—further delineates the dilated subarachnoid space in transverse section; without intrathecal contrast, will not demonstrate the lesion. • MRI—dilation of the subarachnoid space in sagittal and transverse section on T2-weighted images. T2-HASTE images provide even more definition of the CSF accumulation. The presence of active arachnoiditis can be detected on pre- and-postcontrast T1-weighted images.

DIAGNOSTIC PROCEDURES
CSF—to rule out a primary inflammatory process; may show mild inflammation as secondary consequence of the subarachnoid cyst.

PATHOLOGIC FINDINGS
• At surgery, adhesions may be evident in the subarachnoid space. Occasionally a thin cyst wall is apparent (this is unusual). • Histopathology of excised arachnoid—may show fibrosis or mild inflammation. • Histopathology of the spinal cord shows chronic compressive injury—loss of gray and white matter, Wallerian degeneration, demyelination.

TREATMENT

APPROPRIATE HEALTH CARE
• Patients with mild signs can be managed medically; surgery recommended for young dogs with moderate, progressive signs. • Nonambulatory patients should be

(CONTINUED) # SUBARACHNOID CYSTS (ARACHNOID DIVERTICULUM)

hospitalized for diagnostic workup and possible surgical decompression as soon as possible.

NURSING CARE

• Patients that have incomplete micturition should have their bladders manually expressed 3–4 times a day. If this is not possible, their bladders should be catheterized in a sterile fashion once or twice a day. • Appropriate maintenance fluids should be administered in the immediate postoperative period. • Postoperative pain should be assessed regularly (q6h) and treated as needed with opiates and nonsteroidal anti-inflammatory drugs. • Surgical incisions should be ice packed for 5–10 minutes three times a day for 24 hours after surgery and then should be hot packed for a similar period for an additional 2–5 days. • Rehabilitation is important; a patient-specific rehabilitation program should be developed to include gait training and improvement of strength.

ACTIVITY

• Paretic and ataxic patients need to be restricted to nonslip, flat surfaces to avoid falling. • Exercise should be restricted to walking on a leash to avoid falling, but controlled exercise is important in maintaining muscle strength and joint integrity. • Postoperatively, patients need to be restricted to a small, well-padded space (crate) to ensure that they do not fall while the laminectomy site is healing. Limited controlled exercise should be performed during this period.

CLIENT EDUCATION

• Clients need to be educated on the implications of a chronic compressive myelopathy; permanent damage to the spinal cord has already occurred and may not be reversible. The primary aim of treatment is to prevent further deterioration, with a hope of also producing a clinical improvement. • There may be an initial deterioration immediately postoperatively; there is a small chance that this deterioration could be permanent. • Incontinence, if present, is likely to be permanent. • The disease may recur in spite of surgical therapy.

SURGICAL CONSIDERATIONS

• Surgical decompression of spinal subarachnoid cysts is recommended in young dogs and can be attempted in older animals. • Marsupialization of the meninges may reduce the chance of a recurrence. • Surgical treatment of quadrigeminal cysts is only recommended if there are clear signs of compression of adjacent cerebellum and cerebral cortex. Direct surgical exploration and decompression or shunt placement can be attempted.

MEDICATIONS

DRUG(S) OF CHOICE

• Anti-inflammatory doses of prednisone (0.5 mg/kg orally once to twice a day) may improve signs and reduce inflammation. If there is no improvement, prednisone should be tapered and discontinued. • Omeprazole may reduce CSF production rate and improve signs. If there is no improvement it should be discontinued. • Treatment with antiepileptic drugs should be initiated in dogs with more than 1 seizure a month or cluster seizures. Choice of antiepileptic drug depends on a number of patient and client factors. Phenobarbital (starting at 2 mg/kg q12h), zonisamide (starting at 5–10 mg/kg q12h) and levetiracetam (starting at 20 mg/kg q8h) are all appropriate choices for first-line therapy.

PRECAUTIONS

Corticosteroids should be used with caution if the patient has urinary tract infection.

FOLLOW-UP

PATIENT MONITORING

• If response to prednisone is being assessed, the patient's gait and postural reactions should be reassessed in 1–2 weeks. The owner's assessment of continence is also important. • If there is a positive response to medical management, the patient should be monitored every 8–12 weeks for maintenance of the improvement over the next 6 months and then every 6–12 months. The owner should be instructed to call if deterioration in clinical signs is detected. • Surgical treatment—patient reassessed at 7–10 days for suture removal, evaluation of incision, and to ensure that there is no deterioration in gait, level of pain, continence; reassessment at 1–3 months and every 6–12 months subsequently. Telephone updates are acceptable if the patient is doing well.

POSSIBLE COMPLICATIONS

• Clients may encounter fecal and urinary incontinence.
• If incontinent, there is a predisposition to urinary tract infections.
• Signs may recur at any time.

EXPECTED COURSE AND PROGNOSIS

Spinal Diverticulae

• Surgical decompression produces a good long-term outcome (more than 1 year) in approximately 66% of dogs with spinal disease. • Age at onset of signs and duration of signs are associated with outcome. Dogs less than 3 years of age and with a short duration of signs (less than 4 months) are more likely to have a good long-term outcome. • There are limited data on the prognosis with medical management, but anecdotally the author can report a good long-term outcome in old dogs with mild signs when treated with prednisone and rehabilitation alone.

Quadrigeminal Cysts

Data on prognosis of quadrigeminal cysts managed medically or surgically are limited but suggests that a positive outcome can be attained with both treatment strategies.

MISCELLANEOUS

AGE-RELATED FACTORS

Cervical cysts are more common in dogs <3 years of age and thoracolumbar cysts are common in old pugs.

PREGNANCY/FERTILITY/BREEDING

N/A

SYNONYMS

Arachnoid diverticula, arachnoid cyst, meningeal or leptomeningeal cyst.

SUBINVOLUTION OF PLACENTAL SITES

BASICS

OVERVIEW
- Failure or delay of normal postpartum uterine involution (normally requires 12–15 weeks to complete).
- Failure of eosinophilic masses of collagen at placental sites to slough at 3–4 weeks postpartum.
- Failure of fetal trophoblastic cells to regress (normally occurs within 2 weeks); instead, they invade the maternal deep glandular endometrium and myometrium.
- Cause—unknown; hormonal or uterine basis not suspected based on coexistence of unaffected and subinvoluted placental sites in the same uterus.

SIGNALMENT
- Bitch <3 years most common.
- Higher incidence in first litter.
- No breed predilections.

SIGNS

Historical Findings
- Patient presented >12 weeks postpartum.
- Serosanguineous vulvar discharge beyond 12 weeks postpartum.
- Typically no systemic signs; rare occurrence of hypovolemic shock from hemorrhage.

Physical Examination Findings
- Serosanguineous vulvar discharge.
- Firm, spherical structures within uterus on abdominal palpation.

CAUSES & RISK FACTORS
Unknown; thought unlikely to be hormonal because only some of the placental sites may be involved. Also thought unlikely to be uterine disease because of high first litter prevalence.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Metritis—differentiated by vaginal cytology and physical examination.
- Vaginitis—differentiated by vaginal cytology.
- Vaginal neoplasia—differentiated by vaginal cytology and vaginal endoscopy.
- Uterine neoplasia—differentiated by ultrasonography or exploratory laparotomy.
- Cystitis—differentiated by vaginal cytology and urinalysis obtained by cystocentesis.
- Coagulopathy—differentiated by clotting times, platelet count.
- Trauma.
- Endogenous estrogen stimulation—bitch with an extremely shortened interestrous interval.
- Exogenous estrogen stimulation—oral medication or contact with topical hormone replacement product on human skin, bedding, or clothing.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

OTHER LABORATORY TESTS
- Serology for *Brucella canis* negative.
- Serum progesterone <2 ng/mL

IMAGING
Uterine ultrasonography—focal uterine wall thickening; possible echogenic fluid in the lumen

DIAGNOSTIC PROCEDURES
- Vaginal cytologic examination—key for diagnosis; reveals erythrocytes and parabasal epithelial cells; may note pathognomonic trophoblastic cells (polynucleated, heavily vacuolated).
- Guarded anterior vaginal or transcervical uterine culture—if vaginal cytologic examination or hemogram supports a diagnosis of secondary metritis.

PATHOLOGIC FINDINGS
- Gross—sites characterized by a thickened, hemorrhagic area that may be nodular.
- Histopathologic—definitive diagnosis; eosinophilic collagen masses with trophoblasts extending into the myometrium.

TREATMENT
- Usually outpatient.
- Spontaneous remission—occurs in most patients before or at next cycle; medical therapy is generally not warranted.
- Medical—for rare development of anemia, metritis, or peritonitis.
- Severely affected patients—may require blood transfusion (rare).
- Warn owner of the rare possibility of excessive hemorrhage; instruct owner to monitor mucous membrane color.
- Ovariohysterectomy—curative; treatment of choice if future breeding not desired.
- Surgical curettage of subinvoluted sites—may also be performed; effectiveness unknown.

MEDICATIONS

DRUG(S) OF CHOICE
- Oxytocin generally not successful.
- Ergonovine 10–30 µg/kg IM once; do not use if uterus friable.
- Small study showed response to megestrol acetate 0.1 mg/kg PO q24h for 1 week, then 0.05 mg/kg PO q24h daily for 1 week; 5 of 6 treated bitches were successfully bred, with normal parturition and puerperal periods.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
- Ecbolics—may cause uterine rupture.
- Progestational drugs—increase the risk of metritis, which may mimic pyometra or induce cystic endometrial hyperplasia.

FOLLOW-UP

PATIENT MONITORING
- Mucous membrane color and amount of discharge.
- Packed cell volume or hematocrit—if anemia is a concern.
- Changes in discharge color or odor and vaginal cytologic examination and culture—diagnose secondary infection.

POSSIBLE COMPLICATIONS
Infection, blood-loss anemia, or uterine rupture—rare.

EXPECTED COURSE AND PROGNOSIS
- Spontaneous resolution—the usual outcome in the majority of cases.
- Recurrence—not expected, occurs rarely.
- Prognosis for future reproduction—excellent with spontaneous resolution.

SUBMISSIVE AND EXCITEMENT URINATION—DOGS

BASICS

OVERVIEW
- Excitement and submissive urination occur as distinct behavioral presentations but may overlap in some patients.
- Submissive urination is related to fearful responses—animal perceives potential threat or danger during interaction and displays submissive behavior, including urination, as appeasement gesture to abort potential escalation of aggressive interactions.
- Generally seen in interaction with people; however, submissive urination may occur during interactions with other animals, especially conspecifics.

SIGNALMENT
- Onset as puppy in dogs of either sex: generally <1 year old.
- Anecdotally higher incidence in some small breeds, e.g., dachshund, cocker spaniel.
- Not observed in cats.

SIGNS
- Excitement—loss of urine control in situations of high arousal, e.g., greeting people, anticipation of activities such as walks or car rides; no actual urination posturing seen—urine is expelled while dog is engaged in activities such as jumping up or play; dog does not necessarily show submissive behavior.
- Submissive/fear—expelling small amounts of urine during interactions with people or other animals or in frightening situations; partial or full squatting position; dog may lift one hind leg partially for inguinal presentation.
- Dogs may be excited and aroused yet also submissive or fearful during greeting—when there are competing motivations this might therefore be described as conflict induced; the approach may be active with tail wagging and crouching/low body posture.

CAUSES & RISK FACTORS
- Administration of medications that reduce urethral competence or increase urine production (e.g., corticosteroids, sedatives).
- Domineering training styles or interaction patterns.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Incontinence, ectopic ureter, patent urachus.
- Cystitis.
- Disorders of urethral competence (which may increase severity or frequency of urination during submissive or excitement urination).
- Disorders causing polyuria/polydipsia may decrease pet's ability to maintain bladder control.

CBC/BIOCHEMISTRY/URINALYSIS
Indicated only to rule out medical disorders.

IMAGING
Indicated only to rule out medical disorders.

DIAGNOSTIC PROCEDURES
Indicated only to rule out medical disorders.

TREATMENT

Excitement Urination
- Avoid arousing situations.
- Do not greet dog when aroused/excited—greet dog away from front door and several minutes after arrival only after dog is calm.
- When entering home, toss treats away to redirect and distract pet; over time gradually transition to tossing treats closer to person and eventually hand treats to pet when pet sits calmly on cue.
- Avoid high-pitch excited speech around pet; avoid eye contact if it arouses/excites the pet.
- Teach owner to reinforce calm behavior and teach behaviors incompatible with high arousal, e.g., sit or lie down for greetings and before walks.
- Owners should interact with pet in emotionally neutral, low-key manner.

Submissive/Fear Urination
- Avoid threatening or confrontational interactions; do not lean over pet; do not punish or raise voice with pet; avoid eye contact.
- Avoid confrontational training styles/interactions.
- Avoid deep, loud, or high-pitch excited speech while around or interacting with the pet.
- Move slowly and calmly around pet to avoid potential startling or threatening movements.
- Squat down or greet/interact with pet while sitting in chair or on floor with the body turned partially away from the dog.
- Redirection or distraction with food treats or toys; toss treats away to redirect and distract pet; over time can gradually transition to tossing treats closer to person and eventually hand treats to pet when pet sits calmly on cue.
- Teach behaviors with positive reinforcement that are incompatible with submissive posturing using positive reinforcement (food treats)—pet sitting upright with head and ears up and forward; eye contact.
- Owner should recognize and identify triggers and turn and walk away or back away if pet begins to show submissive posturing.

MEDICATIONS
- Medications generally not indicated but could consider:
  - Phenylpropanolamine 12.5–50 mg PO up to q8h temporarily to increase urethral sphincter tone while behavior modification is taking effect.
  - Imipramine 2.2–4.4 mg/kg PO q12h or clomipramine 1–3 mg/kg PO q12h to increase urinary retention through anticholinergic effects; serotonin and norepinephrine properties can help reduce excitement or fear that contribute to urinating.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Prognosis is good if owners can follow simple behavior modification steps; a number of pets will improve with maturity alone.

SUPERFICIAL NECROLYTIC DERMATITIS

BASICS

OVERVIEW
- Uncommon in dogs; rare in cats.
- Usually a cutaneous marker for advanced liver disease with or without concurrent diabetes mellitus.

SYSTEMS AFFECTED
- Skin/exocrine.
- Endocrine/metabolic.
- Hepatobiliary.

SIGNALMENT
- Shih tzu, Shetland sheepdog, West Highland white terrier, cocker spaniel overrepresented.
- Older dogs.

SIGNS
- Skin—lesions may precede clinical evidence of internal disease by weeks or months; erythema, crusts, and erosions/ulcerations affecting the muzzle, mucocutaneous areas of the face, pinna, distal limbs (especially elbows and hocks), feet, perineum, perianal area, and external genitalia.
- Footpads—hyperkeratotic with fissures and ulcerations; pain when walking.
- Pruritus absent to severe.
- Secondary bacterial and/or yeast infection.
- Feline—alopecia and scaling of the limbs and trunk (two cases); erythema, ulceration, crusting, and alopecia of the limbs and trunk (one case); crusts and hyperkeratosis of paw pads (one case).

CAUSES & RISK FACTORS
- Specific cause unknown.
- Cutaneous nutritional deprivation—probably hypoaminoacidemia and/or deficiencies in essential fatty acids and zinc; due to metabolic abnormalities caused by hyperglucagonemia, liver dysfunction, or a combination.
- Usually associated with advanced liver disease with or without concurrent diabetes mellitus.
- Rarely associated with pancreatic or extrapancreatic glucagon-secreting tumor, ingestion of mycotoxins, or long-term phenobarbital and phenytoin therapies.
- Feline—one case each of pancreatic carcinoma, hepatic carcinoid, hepatopathy, and hepatopathy and intestinal lymphoma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Pemphigus foliaceus.
- Zinc-responsive dermatosis.
- Toxic epidermal necrolysis.
- Drug eruption.
- Feline exfoliative skin diseases—thymoma-associated exfoliative dermatitis and cutaneous epitheliotropic lymphoma.

CBC/BIOCHEMISTRY/URINALYSIS
- Red blood cell abnormalities—microcytosis, polychromasia, anisocytosis, poikilocytosis, target cells.
- Alkaline phosphatase, alanine aminotransferase, and aspartate aminotransferase—significant elevation.
- Total bilirubin—variably high.
- Albumin—frequently low.
- Borderline or frank hyperglycemia—common.

OTHER LABORATORY TESTS
- Bile acid levels—variably high.
- Liver biopsy—vacuolar hepatopathy with parenchymal collapse and nodular hyperplasia.
- Elevated plasma glucagon levels—present with glucagon-secreting tumors; variable with chronic liver disease.
- Hypoaminoacidemia—common.
- Aminoaciduria.
- High insulin levels may be noted.
- Sulfobromophthalein retention—typically increased.

IMAGING
- Ultrasonography—"honeycomb" liver pattern in advanced hepatopathy.
- Usually unremarkable with pancreatic or extrapancreatic glucagon-secreting tumor unless large enough to visualize.

DIAGNOSTIC PROCEDURES
Skin biopsy—sample early lesions; include crusts and avoid eroded/ulcerated lesions.

PATHOLOGIC FINDINGS
- Parakeratotic hyperkeratosis with high-level intracellular and intercellular epidermal edema; irregular epidermal hyperplasia and mild-to-severe superficial perivascular dermatitis.
- Chronic lesions—marked parakeratotic hyperkeratosis and epidermal hyperplasia.

TREATMENT
- Supportive care for systemic signs.
- Surgical excision of glucagon-secreting tumors—can be curative if no metastasis.
- Oral nutritional support—high-quality protein diet or protein supplement for non-encephalopathic cases; 3–6 cooked whole eggs or yolks per day.
- Hydrotherapy and shampoos—remove crusts; lessen pruritus and pain.

MEDICATIONS

DRUG(S) OF CHOICE
- Specific treatment—attempt to correct the underlying disease if possible.
- Nonspecific therapy—antibiotics and antifungal drugs for secondary skin infections.
- Amino acid hyperalimentation—IV administration of a 8.5–10% crystalline amino acid solution (e.g., Aminosyn®) 25 mL/kg, administered over 6–8 hours; repeated weekly or as needed for symptom relief (≥10 infusions may be required). Oral amino acid therapy may be beneficial.
- IV lipid infusion—may improve outcome when combined with IV amino acid therapy (7 mL/kg of 20% Intralipid®).
- Octreotide (somatostatin analogue) 2–3.2 µg/kg SC q6–12h as maintenance therapy for patients with nonresectable glucagon-secreting tumors.
- Glucocorticoids—can improve skin lesions; use carefully; encourages development of diabetes mellitus.
- Colchicine 0.03 mg/kg/day may be beneficial in advanced liver disease.
- Zinc methionine 2 mg/kg/day—adjunctive therapy.
- Essential fatty acids—adjunctive therapy.

FOLLOW-UP

POSSIBLE COMPLICATIONS
- Diabetes mellitus.
- Bacterial and/or yeast skin infections.
- Metastasis of glucagon-secreting tumors.

EXPECTED COURSE AND PROGNOSIS
- Prognosis poor; survival time reported as 6 months after development of skin lesions.
- Rare incidence of recovery if hepatic/metabolic insult resolves.

SUPRAVENTRICULAR TACHYCARDIA

BASICS

DEFINITION
Repetitive supraventricular premature depolarizations that originate from a site other than the sinus node, such as the atrial myocardium or atrioventricular (AV) nodal tissue.

ECG Features (Figure 1)
• Heart rate—rapid, 180–350 bpm in dogs. • Rhythm usually very regular (constant R-R interval) and may be sustained, but there can be frequent or infrequent short runs of supraventricular tachycardia (SVT), so-called paroxysmal SVT. Rarely, the rhythm will be irregular, suggesting abnormal automaticity as the etiology. • Usually QRS complexes typical of normal sinus complexes, i.e., narrow with a normal mean electrical axis. In some cases a coexisting bundle branch block or aberrant ventricular conduction makes it difficult, if not impossible, to differentiate an SVT from a ventricular tachycardia by examining the ECG. • P waves can be normal or abnormal and typically differ in configuration from the sinus P waves. P waves may be buried in the previous T wave and therefore not visualized. • AV conduction is usually normal (1:1), but various levels of functional second-degree AV block may occur at higher atrial rates (2:1, 3:1, 4:1, etc.).

PATHOPHYSIOLOGY
• SVT may be primary (idiopathic) or secondary to other cardiac diseases, generally those creating atrial enlargement. • May result from a reentrant mechanism or from abnormal automaticity in an ectopic focus. Reentrant SVT typically produces a very regular rhythm; SVT due to an automatic focus in atrial myocardium can produce an irregular rhythm. • Most cases in dogs respond to drugs that specifically alter conduction and refractoriness in the AV nodal tissue, suggesting AV nodal reentry as the mechanism. • Recent electrophysiologic studies revealed that some SVT in dogs is related to a congenital accessory pathway between the atria and ventricles, allowing electrical impulses to travel freely between the atria and ventricles without traversing the AV node and without conduction delay; in these cases, the SVT is caused by reentry through the accessory pathway and the AV node.

SYSTEMS AFFECTED
• Cardiovascular—congestive heart failure (CHF) may develop secondary to progressive myocardial failure associated with a chronically high heart rate (so-called tachycardia-induced myocardial failure). • Neuromuscular—syncope or generalized episodic weakness due to reduced cardiac output and oxygen delivery.

SIGNALMENT
Species
Dog and rarely cat.

SIGNS
General Comments
• Clinical signs may relate to the underlying cause. • Dogs with slow SVT or infrequent paroxysmal SVT may exhibit no clinical signs. • Dogs with fast SVT (heart rate usually >300 bpm) generally exhibit episodic weakness or syncope.

Historical Findings
• Owners are generally unaware of the arrhythmia. • Coughing or breathing abnormalities in dogs with CHF. • Episodic weakness or syncope.

Physical Examination Findings
• Rapid, usually regular heart rhythm. However, in dogs with paroxysmal SVT, rhythm may be normal and regular during the physical exam. • May have evidence of poor peripheral perfusion—pale mucous membranes, prolonged capillary refill time, and weak pulses. • May have no signs other than rapid heart rate. • Findings may reflect underlying cardiac condition (e.g., heart murmur).

CAUSES
• Chronic valvular disease. • Cardiomyopathy. • Congenital heart disease. • Cardiac neoplasia. • Systemic disorders. • Ventricular preexcitation. • Electrolyte imbalances. • Digoxin toxicity. • Idiopathic.

RISK FACTORS
Heart disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Sinus tachycardia. • Atrial flutter. • Atrial fibrillation. • Ventricular tachycardia (SVT with right bundle branch block or aberrant conduction can look like ventricular tachycardia; resolution of arrhythmia after lidocaine administration usually confirms ventricular tachycardia).

IMAGING
• Echocardiography (including Doppler studies) may help characterize the type and severity of underlying cardiac disorders. Echocardiography is also important for assessing myocardial function in patients with idiopathic SVT. • When viewed on an echocardiogram during bursts of SVT, the left ventricle has a normal end-systolic diameter and a small end-diastolic diameter, resulting in a decreased shortening fraction because of inadequate filling. • Usually left or right atrial enlargement in dogs with SVT secondary to other cardiac disorders.

DIAGNOSTIC PROCEDURES
• Long-term ambulatory (Holter) recording of the ECG may detect paroxysmal SVT in cases of unexplained syncope. This is generally only helpful if syncope is occurring regularly within a 24- to 48-hour period.

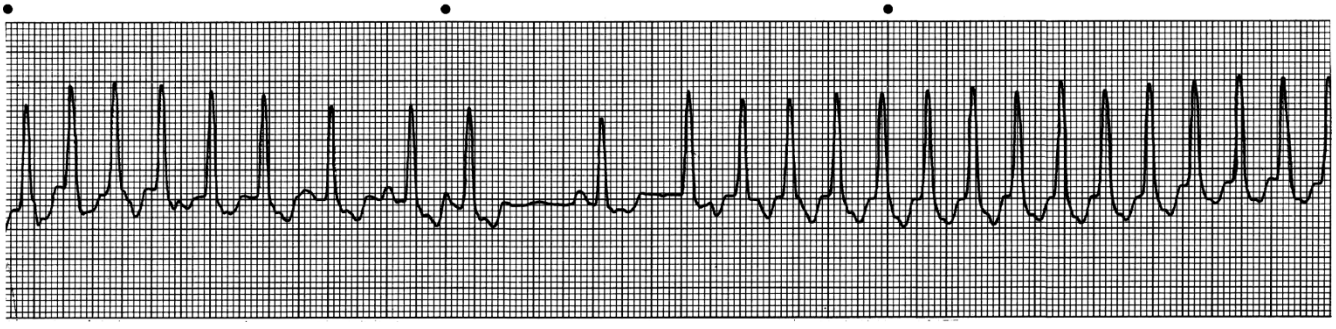

Figure 1.

Sinus with an atrial premature complex and paroxysmal SVT. Abrupt initiation and termination of the tachycardia help distinguish it from sinus tachycardia (lead II, 50 mm/s, 1 cm = 1 mV). (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

(CONTINUED) # SUPRAVENTRICULAR TACHYCARDIA

Holter monitors may also help characterize the rate and frequency of sustained SVT and are useful in evaluating the efficacy of therapy. • Event (loop) recorders may detect paroxysmal SVT in patients with infrequent episodes of syncope (<q24–48h). • Sustained SVT must be distinguished from sinus tachycardia because the two arrhythmias have different implications and treatment. A precordial thump may help differentiate sinus tachycardia from SVT when the heart rate is in the 150–250 bpm range; it will usually stop an SVT for at least 1 or 2 beats, while a sinus tachycardia will not slow. A vagal maneuver (e.g., ocular pressure or carotid sinus massage) may break an SVT abruptly but only gradually slows sinus tachycardia.

TREATMENT

APPROPRIATE HEALTH CARE

• Asymptomatic patients can be managed on an outpatient basis; patients with a sustained SVT or signs of CHF should be hospitalized until stable. • SVT is a medical emergency in dogs that exhibit weakness and collapse; nonpharmacologic interventions that may break an SVT include vagal maneuvers, precordial thump, and electrical cardioversion. • Vagal maneuvers are often unsuccessful but may be used initially because of their ease of administration and noninvasive nature. • Delivering a precordial thump can successfully (>90% of the time) terminate an SVT in dogs, but this maneuver may break the rhythm for only a brief period. At other times the rhythm remains converted. To perform a precordial thump, the dog is placed on its right side and the left apex beat is located. This region is then "thumped" with a fist while recording the ECG. • Emergency medical therapy is required in patients in which a precordial thump is unsuccessful (see below).

NURSING CARE

Treat CHF and correct any underlying electrolyte or acid–base disturbances.

ACTIVITY

Restrict until arrhythmia has been controlled.

DIET

Mild to moderate sodium restriction if in CHF.

CLIENT EDUCATION

Owners should observe patients closely for signs of low cardiac output such as weakness and collapse.

SURGICAL CONSIDERATIONS

Consider transvenous catheter ablation for patients with accessory pathways.

MEDICATIONS

DRUG(S) OF CHOICE

Emergency Therapy

• Administer one of the following: ◦ Calcium channel blockers—diltiazem 0.05–0.25 mg/kg IV over 5–15 minutes or verapamil 0.05 mg/kg boluses IV over 3–5 minutes up to 3 times; verapamil more likely to cause hypotension. ◦ β-Adrenergic blockers—esmolol 0.25–0.5 mg/kg slow IV bolus administration followed by a CRI of 50–200 µg/kg/min; moderate-to-severe myocardial failure is a relative contraindication to the administration of β-adrenergic blockers. ◦ Electrical cardioversion or intracardiac electrophysiologic pacing methods may be considered in extreme cases.

Long-Term Therapy

• Digoxin—administer at either maintenance oral dose or double the maintenance dose for the first day to produce a therapeutic serum concentration more rapidly; contraindicated in patients with accessory pathways.
• β-Adrenergic blocker—atenolol 0.2–1 mg/kg PO q12–24h as long as there is no underlying moderate-to-severe myocardial failure.
• Diltiazem is the calcium channel blocker of choice for long-term control of SVT; dose required to control SVT has not been reported in the dog. Diltiazem used more frequently to control ventricular rate in patients with atrial fibrillation at a dosage of 0.5–1.5 mg/kg PO q8h. In our clinic, we generally start in this range but almost always need to increase the dose to 2–3 mg/kg PO q8h to effectively control SVT. • Class I antiarrhythmic agents such as quinidine and procainamide can be tried when the aforementioned drugs are ineffective or when SVT is thought to be due to an automatic, rather than a reentrant, rhythm. SVT caused by an automatic atrial focus may produce an irregular rhythm and may be refractory to conventional drug therapy. When SVT is due to an accessory pathway, these drugs are more effective.

CONTRAINDICATIONS

Avoid calcium channel blockers in combination with beta-blockers; clinically significant bradyarrhythmias can develop.

PRECAUTIONS

Calcium channel blockers and β-adrenergic blockers have negative inotropic properties and should be used cautiously in dogs with documented myocardial failure.

ALTERNATIVE DRUG(S)

Emergency Treatment

• Adenosine 1–12 mg IV rapidly—very expensive and short-lived. • Propranolol 0.02 mg/kg slow IV boluses up to a total dose of 0.1 mg/kg—long half-life after IV administration, also significant β_2-blocking effects and is generally not recommended unless no other alternative is available.

FOLLOW-UP

PATIENT MONITORING

Serial ECG or Holter monitoring.

POSSIBLE COMPLICATIONS

Syncope and CHF.

EXPECTED COURSE AND PROGNOSIS

Most are controlled effectively with medication.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Accessory pathways in some patients.

AGE-RELATED FACTORS

In young dogs without evidence of structural heart disease, suspect a reentrant tachycardia involving an accessory pathway.

SYNONYMS

Atrial tachycardia, junctional tachycardia.

SEE ALSO

Atrial Fibrillation and Atrial Flutter.

ABBREVIATIONS

• AV = atrioventricular. • CHF = congestive heart failure. • ECG = electrocardiogram. • SVT = supraventricular tachycardia.

SYNCOPE

BASICS

DEFINITION
Temporary loss of consciousness and vascular tone associated with loss of postural tone, followed by spontaneous recovery.

PATHOPHYSIOLOGY
Inadequate cerebral perfusion and delivery of oxygen and metabolic substrates leads to loss of consciousness and motor tone; impaired cerebral perfusion can result from changes in vasomotor tone, cerebral disease, and low cardiac output caused by structural heart disease or arrhythmias.

SYSTEMS AFFECTED
- Cardiovascular.
- Nervous.

SIGNALMENT

Species
Dog and cat.

Breed Predilections
- Sick sinus syndrome—cocker spaniel, miniature schnauzer, West Highland white terriers, pug, dachshund.
- Ventricular arrhythmias—boxer, German shepherd dog.

Mean Age and Range
More common in old animals.

CAUSES

Cardiac Causes
- Bradyarrhythmias—sinus bradycardia, sinus arrest, second-degree atrioventricular (AV) block, complete AV block, atrial standstill.
- Tachyarrhythmias—ventricular tachycardia, supraventricular tachycardia, atrial fibrillation.
- Low cardiac output (nonarrhythmic)—cardiomyopathy, degenerative valve disease, subaortic stenosis, pulmonic stenosis, pulmonary hypertension, heartworm disease, pulmonary embolism, cardiac tumor, cardiac tamponade.

Neurologic and Vasomotor Instability
- Vasovagal syncope—emotional stress and excitement may cause heightened sympathetic stimulation, leading to transient tachycardia and hypertension, which is followed by a compensatory rise in vagal tone, leading to excessive vasodilation without a compensatory rise in heart rate and cardiac output; bradycardia often occurs.
- Situational syncope refers to syncope associated with coughing, defecation, urination, and swallowing.
- Carotid sinus hyperactivity may cause hypotension and bradycardia—often the cause of syncope when one pulls on a dog's collar.

Miscellaneous Causes
- Drugs that affect blood pressure and regulation of autonomic tone.
- Hypoglycemia, hypocalcemia, and hyponatremia (rare).
- Hyperviscosity syndromes (e.g., polycythemia and paraproteinemia) cause sludging of blood and impaired cerebral perfusion (rare).

RISK FACTORS
- Heart disease.
- Sick sinus syndrome.
- Drug therapy—vasodilators (e.g., calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, hydralazine, and nitrates), phenothiazines (e.g., acepromazine), antiarrhythmics, and diuretics.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Differential Signs
- Must differentiate from other altered states of consciousness, including seizures and narcolepsy (a sleep disorder).
- Seizures are often associated with prodromal and postictal periods; syncope occurs without warning, and animal usually has rapid, spontaneous recovery. Unlike syncope, seizure activity is usually associated with tonic–clonic muscle activity rather than flaccidity.
- Like syncope, narcolepsy occurs suddenly, results in muscle flaccidity, and resolves spontaneously. Unlike syncope, narcolepsy can last for minutes and can be terminated by loud noises or harsh external stimuli.
- Must differentiate from other causes of collapse such as musculoskeletal disease and neuromuscular disease (e.g., myasthenia gravis), which are not associated with loss of consciousness.

Differential Causes (Figure 1)
- Syncope with excitement or stress suggests vasovagal syncope.
- Syncope with coughing, urination, or defecation suggests situational syncope.
- Syncope with exercise suggests low-output states associated with arrhythmias or structural heart disease.
- A murmur supports heart disease but does not confirm cardiac cause for syncope.

CBC/BIOCHEMISTRY/URINALYSIS
- Usually normal.
- Hypoglycemia or electrolyte disturbance in some animals.

OTHER LABORATORY TESTS
- If animal is hypoglycemic, measure insulin concentration on same blood sample. Calculate an amended insulin: glucose ratio to rule out insulinoma.
- If animal is hyponatremic or hyperkalemic, consider an adrenocorticotropic hormone (ACTH) stimulation test.
- If low cardiac output is suspected, rule out occult heartworm disease.

IMAGING
- Radiography may detect structural heart disease, evidence of pulmonary embolism, or vascular changes supportive of heartworm disease.
- Echocardiography may detect structural heart disease (including tumors) or pericardial disease that could lower cardiac output.
- Doppler echocardiography may aid in the diagnosis of pulmonary hypertension.
- Pulmonary angiography may detect pulmonary embolism.
- CT and MRI may detect pulmonary embolism or heart-based and carotid body masses.
- Ventilation perfusion scintigraphy may detect pulmonary embolism.

DIAGNOSTIC PROCEDURES
- Have client monitor heart rate during any syncopal episode.
- Electroencephalogram, CT of the head, cerebrospinal fluid tap if CNS origin suspected.

Electrocardiogram
- Post-exercise ECG may reveal intermittent arrhythmia.
- Holter monitoring (24-hour ECG recording) or use of an ECG event (loop) recorder—useful for evaluating arrhythmic causes.
- Carotid sinus massage with ECG and blood pressure monitoring useful in evaluating carotid sensitivity.

TREATMENT

APPROPRIATE HEALTH CARE
- Avoid or discontinue medications likely to precipitate syncope.
- Treat as outpatient unless important heart disease is evident.

CLIENT EDUCATION
- Minimize stimuli that precipitate episodes.
- Low cardiac output—minimize activity.
- Vasovagal—minimize excitement and stress.
- Cough—remove collar.

SURGICAL CONSIDERATIONS
Pacemaker implantation for sick sinus syndrome, advanced AV block, and persistent atrial standstill.

MEDICATIONS

DRUG(S) OF CHOICE

Bradyarrhythmias
- Correct metabolic causes.

SYNCOPE (CONTINUED)

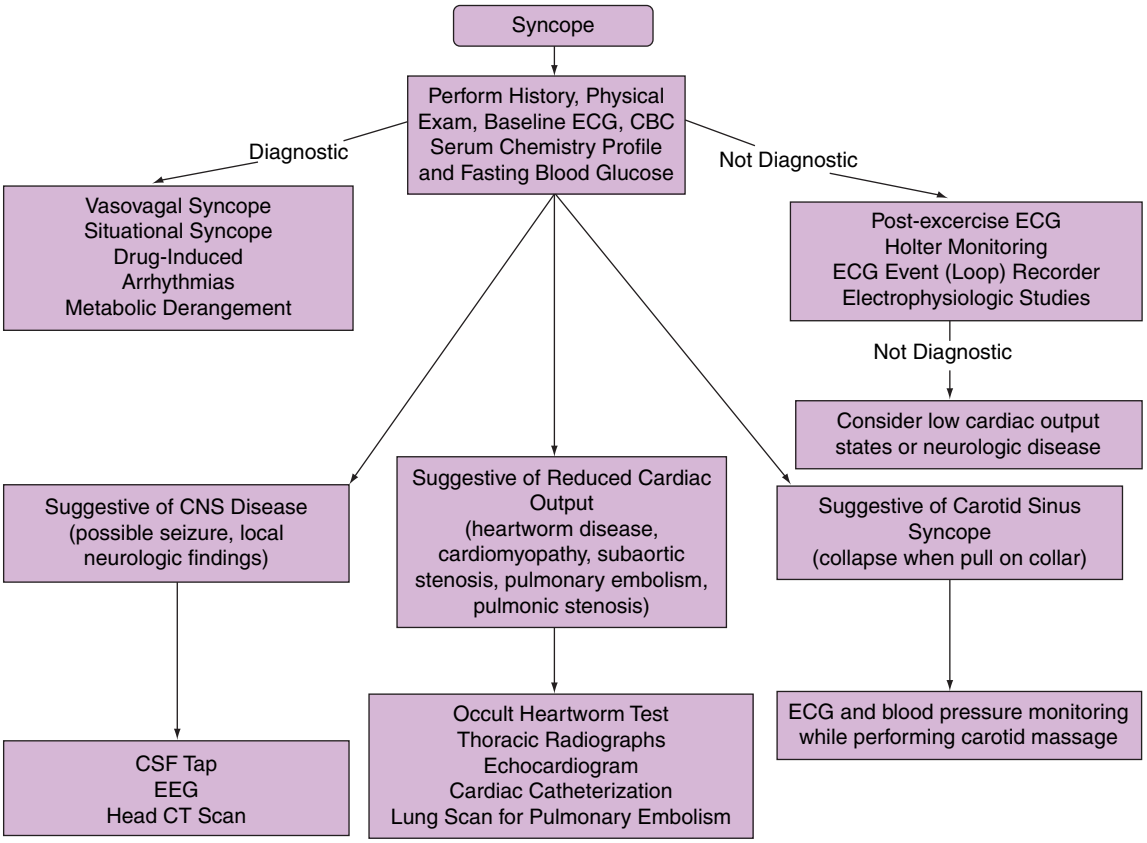

Figure 1.

Algorithm for syncope.

S

- Anticholinergics (e.g., atropine, propantheline bromide, hyoscyamine sulfate).
- Sympathomimetics (e.g., isoproterenol, bronchodilators).
- Phosphodiesterase III inhibitor (i.e., cilostazol) may be beneficial in sick sinus syndrome
- Pacemaker implantation in some patients.

Tachyarrhythmias

- Atrial arrhythmias—administer digoxin, beta-blocker, or diltiazem.
- Ventricular arrhythmias—administer lidocaine, mexiletine, sotalol, or beta-blocker.

Low Cardiac Output

Institute treatment to improve cardiac output, which varies according to specific cardiac disease.

Vasovagal

- Theophylline or aminophylline—sometimes helpful; mechanism of action in this setting is unclear.
- Beta-blockers (e.g., atenolol, propranolol, and metoprolol) may indirectly prevent vagal stimulation by blocking the initial sympathetic response.
- Anticholinergics may blunt the vagal response.

FOLLOW-UP

PATIENT MONITORING

ECG or Holter monitoring to assess efficacy of antiarrhythmic therapy.

POSSIBLE COMPLICATIONS

- Death.
- Trauma when collapse occurs.

EXPECTED COURSE AND PROGNOSIS

Most noncardiac causes are not life-threatening; cardiac causes may be treated, but syncope in patients with cardiac disease may suggest higher mortality risk.

MISCELLANEOUS

SEE ALSO

- Myasthenia Gravis.
- Narcolepsy and Cataplexy.
- Seizures (Convulsions, Status Epilepticus)—Cats.
- Seizures (Convulsions, Status Epilepticus)—Dogs.

ABBREVIATIONS

- ACE = angiotensin-converting enzyme.
- ACTH = adrenocorticotropic hormone.
- AV = atrioventricular.
- ECG = electrocardiogram.

SYNOVIAL CELL SARCOMA

BASICS

OVERVIEW
• Synovial sarcoma (or synovial cell sarcoma) is a malignant neoplasm arising from type B synoviocytes of the joint capsule or tendon sheath.
• Synovial sarcomas are locally aggressive and have moderate metastatic potential. At diagnosis up to 32% of dogs have metastases with the most common sites being the local lymph node and lungs.
• The disease is seen most commonly in the appendicular skeleton, specifically affecting the elbow, stifle, and shoulder joints. Synovial sarcoma must be differentiated via immunohistochemistry from other types of joint tumors, namely histiocytic sarcoma, which has a more aggressive biologic behavior and a worse prognosis.

SIGNALMENT
• Dog—often large-breed dogs of either sex, predisposition of flat-coated and golden retrievers, mean age of 9 years.
• Cat—rarely reported.

SIGNS
• Slowly progressive lameness.
• Palpable mass.
• Weight loss.
• Anorexia.
• Clinical course may be protracted over months to years.

CAUSES & RISK FACTORS
Unknown

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Other primary neoplasia (e.g., histiocytic sarcoma, chondrosarcoma, osteosarcoma).
• Metastatic neoplasia.
• Other bone or joint diseases (e.g., osteoarthritis, osteomyelitis).

CBC/BIOCHEMISTRY/URINALYSIS
No consistent abnormalities.

OTHER LABORATORY TESTS
N/A

IMAGING
• Radiographs of the affected joint often demonstrate both bone and joint involvement with periarticular soft tissue swelling and periosteal reaction or multiple punctate osteolytic changes in adjacent bone.
• Thoracic radiographs should be obtained to screen for metastatic disease.
• Abdominal ultrasonography should be performed to evaluate intra-abdominal lymph nodes in animals with tumors on the pelvic limbs.

DIAGNOSTIC PROCEDURES
• Regional lymph nodes should be palpated and fine-needle aspirates performed.
• Biopsy and immunohistochemistry to differentiate from histiocytic sarcoma (histiocytic sarcoma is CD18+).

TREATMENT
Limb amputation; forequarter, coxofemoral disarticulation or hemipelvectomy to minimize risk of local recurrence.

MEDICATIONS

DRUG(S) OF CHOICE
• The role of chemotherapy for synovial sarcomas is not known; however, doxorubicin is commonly utilized for the treatment of sarcoma histologies.
• Pain management with analgesic drugs as necessary.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

PATIENT MONITORING
Monitor for local recurrence and pulmonary metastatic disease every 2–3 months for the first year; every 6 months thereafter.

EXPECTED COURSE AND PROGNOSIS
• Localized disease at diagnosis—prognosis is excellent; median survival time >36 months. Lesser dose of surgery (i.e., marginal excision) is associated with poorer prognosis compared to limb amputation.
• Metastatic disease at diagnosis—prognosis is poor; median survival time <6 months. High-grade tumors (high mitotic rate, high percent tumor necrosis, high nuclear pleomorphism) also confer a worse prognosis.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING
Do not breed animals that are receiving chemotherapy.

SYRINGOMYELIA AND CHIARI-LIKE MALFORMATION

BASICS

DEFINITION
• Chiari-like malformation (CM) is characterized by overcrowding of the craniocervical junction (CCJ) and obstruction of CSF channels (brachycephalic obstructive CSF channel syndrome [BOCCS]); may be associated with behavioral and clinical signs of pain (CM-P).
• In syringomyelia (SM), fluid-filled cavities (syringes/syrinxes) develop within the spinal cord; it is a potential consequence of BOCCS.
• Myelopathy can develop with wide SM and, if the dorsal horn is involved, phantom scratching and torticollis.

PATHOPHYSIOLOGY

CM
A complex disorder associated with brachycephaly involving skull base shortening, craniofacial hypoplasia, and CCJ abnormalities including increased proximity of the atlas to skull and increased odontoid angulation. There may a relative increase in parenchymal volume; for example, cavalier King Charles spaniels (CKCS) have greater cerebellar volume compared to other breeds. The reduced cranial capacity results in rostrotentorial neuroparenchymal crowding with rostral forebrain flattening, small and ventrally orientated olfactory bulbs, displacement of the neural tissue to give increased height of the cranium and further reduction of the functional caudotentorial space with hindbrain herniation. CM is often compared to human chiari type I and 0 malformation, however it is more similar to complex craniosynostosis syndromes (premature fusion of multiple skull sutures).

SM
In addition to the above brachycephalic changes, dogs with SM are more likely to have CCJ abnormalities, including rostral displacement of the atlas with increased odontoid angulation, causing craniospinal junction deformation and medulla oblongata elevation. The most accepted theory of SM pathogenesis is that obstruction to CSF flow results in a mismatch in timing between the arterial and CSF pulse peak pressure. If peak CSF pressure is high when spinal arteriole and perivascular space pressures are low then the perivascular spaces act as a one-way valve, drawing in CSF which collects in, then expands and disrupts, the spinal cord central canal and ultimately a syrinx develops.

SYSTEMS AFFECTED
• Nervous.
• Ophthalmic.

GENETICS
• CM has moderately high hereditability ($H^2 = 0.37$).
• Critically relevant SM-associated CM has high hereditability ($H^2 = 0.81$).
• Quantitative trait loci (QTL) study in the Brussels griffon identified two novel genomic regions associated to CM. One region contains a single gene, *SALL-1*, involved in skull development.
• Genome-wide linkage studies in CKCS identified a haplotype, inferring protection against SM associated with CM.
• QTL in CKCS identified two loci on *Canis familiaris* autosome 22 (CFA 22) and CFA 26 associated with SM maximum transverse diameter linked to reduced volume of caudal cranial fossa:
  ◦ Loci on CFA22 contained a single gene, *PCDH17*, a CNS cell adhesion molecule and strongest candidate gene.
  ◦ Loci on CFA26 contained a single gene, *ZWINT*, expression of which is associated with neuropathic pain.

INCIDENCE/PREVALENCE
• In some brachycephalic toy breeds, most notably the CKCS, prevalence of CM approaches 100%.
• SM prevalence increases with age with 25% CKCS affected at 1 year, rising to 70% of CKCS >6 years.
• Studies in the Brussels griffon suggest 42–52% have SM.
• Prevalence of clinically relevant CMSM is difficult to determine as pain is subjective and difficult to measure directly.
• One study suggested 15.4% prevalence of clinically relevant SM in 6-year-old CKCS.

SIGNALMENT

Species
Dog and cat.

Breed Predilections
• Brachycephalic toy breeds and crosses (e.g., cavapoo).
• CKCS, King Charles spaniel, Brussels griffon, affenpinscher, Yorkshire terrier, Maltese, Chihuahua, Pomeranian, Boston terrier, papillon, French bulldog, pug.
• CM but not SM is observed in the Persian and other brachycephalic cats.

Mean Age and Range
From 6 months; however, dogs that do not have clinical signs at 6 years old are less likely to ever develop clinical signs.

Predominant Sex
No sex predisposition.

SIGNS

General Comments
• CM and SM may be clinically relevant. In the CKCS, clinically relevant SM is associated with syrinx transverse width ≥4 mm.
• Signs of CM-P may be intermittent and/or exacerbated by excitement, exercise, weather conditions, and time of day (night/morning).

Historical Findings
CM-P
• Vocalization—spontaneous; on changing position especially when recumbent; being picked up; during defecation.
• Head/ear scratching/rubbing with or without vocalization.
• Reduced activity (walking, playing).
• Refusal to climb stairs or jump.
• Change in emotional state/behavior (timid, anxious, withdrawn or aggressive).
• Disrupted sleep.
• Signs suggesting head/neck pain (aversion to touch/grooming; abnormal head position when awake/asleep; facial expression suggesting pain; squinting/avoiding light).

SM
• Rhythmic scratching action—(phantom scratching) without skin contact with curvature of the body and neck towards foot; induced by rubbing a defined area of skin, typically on neck and/or leash walking.

Physical Examination Findings
CM-P
• Yelping when lifted under sternum.
• Spinal pain—thoracolumbar > cervical > lumbar.
• Exotropia—ventrolateral strabismus when gazing to the ipsilateral side.
• Thoracic limb hypermetria.

SM
• Scratching action induced by rubbing dermatome corresponding to spinal cord dorsal horn damage by syrinx.
• Cervicothoracic torticollis (shoulder deviated ipsilateral; head tilt contralateral to spinal cord dorsal horn damage by syrinx).
• Weakness—thoracic limbs > epaxial/hypaxial muscles > pelvic limbs.
• Proprioceptive deficits—thoracic limbs > pelvic limbs.

CAUSES
• SM develops secondary to CSF channel obstruction.
• Degenerative—constrictive myelopathy in pug and screw tail breeds associated with arachnoid adhesions, facet hypoplasia, vertebral malformation, and secondary ligamentous hypertrophy and intervertebral disc disease (IVDD).
• Anomalous—CM, spinal arachnoid diverticulum/web.
• Neoplastic—mass causing obstruction of CSF channels and/or cerebellar herniation.
• Inflammatory/infectious—meningoencephalomyelitis of unknown origin (MUO), feline infectious peritonitis,
• Traumatic—sequel of spinal cord injury and arachnoid adhesions.

(CONTINUED) # SYRINGOMYELIA AND CHIARI-LIKE MALFORMATION

RISK FACTORS
Brachycephalicism and miniaturization.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Spinal Pain/Weakness/Ataxia
- IVDD—acute-onset, persistent localized pain in dogs >18 months.
- MUO—pain with rapidly progressive neurologic signs.
- Atlantoaxial subluxation—tetraparesis and pain especially on cervical flexion.
- Discospondylitis—pyrexia and neutrophilia at onset; pain constant.
- Degenerative myelopathy—nonpainful progressive pelvic limb weakness and proprioceptive deficit in dogs >8 years.

Scratching
Skin and ear disease—generalized, tail head, abdominal and digital pruritus is not a feature of CM/SM. In CM/SM the scratching is localized to the head/ears (CM-P) and neck/shoulder/sternum (SM).

Abnormal Head Position
- Rule out vestibular dysfunction due to inner ear, cranial nerve VIII, or intracranial disease.
- Rule out brachycephalic obstructive airway syndrome (BOAS) if sleeping with head elevated (with BOAS often wake coughing).

CBC/BIOCHEMISTRY/URINALYSIS
N/A

IMAGING

Skull and Cervical Radiographs
Limited value; can suggest CM (short basicranium, minuscule frontal sinus, flattened supraoccipital bone, close proximity of the atlas to the skull). In severe SM may have widening of cervical spinal canal and remodeling and scalloping of C2. Dynamic cervical images to assess for atlantoaxial subluxation.

CT
Useful for defining CCJ abnormalities and should be performed if a vertebral malformation is suspected and to facilitate planning of implanted surgical fixation.

MRI
- Aim to establish cause of SM, i.e., CM or other causes of CSF obstruction. Specialized imaging (e.g., balanced steady-state free precession sequences) may be required.
- Assess if radiological findings are consistent with neurological localization and severity, e.g., seizures (forebrain) cannot be attributed to SM (spinal cord).

CM-P
- There is no objective measure of CM-P on MRI. Diagnosis is suggested by appropriate historical, clinical and MRI findings and eliminating other causes of pain.
- MRI features—effacement/narrowed subarachnoid spaces (reduced definition of the sulci); ventriculomegaly; small, ventral olfactory bulbs; rostral forebrain flattening; dorsocaudal displacement of rostrotentorial neuroparenchyma contributing to hindbrain herniation; cerebellum invaginated under occipital lobes; flattening/indentation of the cerebellum by the supra-occipital bone/occipitoatlantal ligament. Atlas closer to the skull and craniospinal junction flexed over odontoid peg.

SM
- MRI features as for CM-P, often with more pronounced CCJ changes.
- Image entire spinal cord to determine extent of syrinx and any spinal cord tethering.
- Clinically relevant disease is more likely with SM width ≥4 mm (CKCS).
- "Active" syrinx indicated by a cavity which expands spinal cord, has asymmetrical shape on transverse images, and fluid signal-void sign (indicates turbulent flow).
- "Quiescent" syrinx indicated by a cavity which is elliptical on sagittal images, symmetrical and circular/ovoid on transverse images, and does not alter spinal cord outline.

DIAGNOSTIC PROCEDURES
CSF—to rule out MUO; however CSF analysis in CM/SM may reveal mild inflammatory changes.

PATHOLOGIC FINDINGS
- Gross—cerebellar herniation, ventriculomegaly, spinal cord cavitation.
- Histopathologic—dogs with clinically relevant SM have asymmetrical syrinx with altered dorsal horn structure and altered expression of pain-related neuropeptides, substance P, and calcitonin gene-related peptide.

TREATMENT

NURSING CARE
- Raise food bowls.
- Avoid neck collars if phantom scratching.
- Complementary therapy, e.g., acupuncture may be useful.

ACTIVITY
- Exercise encouraged to within own limits.
- Grooming may be poorly tolerated.
- Hydrotherapy may improve strength if SM-associated weakness.

DIET
Obesity positively correlated with a reduced quality of life but not greater neuropathic pain.

CLIENT EDUCATION
Periodic exacerbations of pain common, requiring "top-up" medication.

SURGICAL CONSIDERATIONS
- Craniocervical decompression (CCD) most common surgical procedure—establishing a CSF pathway via the removal of majority of supraoccipital bone and dorsal arch of C1; may be combined with a durotomy, with or without patching with a suitable graft material and with or without cranioplasty.
- Successful in reducing pain and improving neurologic deficits in ~80% cases; ~45% cases have satisfactory quality of life 2 years post-operatively. SM persists postoperatively.
- Clinical improvement probably attributable to reduction in CM-P; most cases require additional medical management.
- Atlantoaxial stability should be assessed prior to CCD.

MEDICATIONS

DRUG(S) OF CHOICE

CM-P
- Nonsteroidal anti-inflammatory drugs (NSAIDs)—at data sheet dosage.
- First-line adjuvant analgesics—gabapentin 10–20 mg/kg q12h/q8h; or pregabalin 5 mg/kg q12h/q8h.
- Second-line (add-on) adjuvant analgesics—topiramate 10 mg/kg q8h; or amitriptyline 0.25–2 mg/kg q12–24h (titrate up to effective dose); or memantine 0.3–1 mg/kg twice daily (titrate up to effective dose); or amantadine 3–5 mg/kg q24h.
- "Top up" analgesia—acetaminophen 10 mg/kg PRN up to q8h and/or opioids at data sheet dosage.

SM-Associated Phantom Scratching
Gabapentin or pregabalin as above.

SM-Associated Weakness and Postural Deficits
- Drugs that may reduce CSF pressure—proton pump inhibitors (omeprazole 0.5–1.5 mg/kg q24h); or H_2-receptor antagonists (cimetidine 5–10 mg/kg q8h); or diuretics (furosemide 1–2 mg/kg q12h; acetazolamide 4–8 mg/kg q9–12h).
- Corticosteroids—as last resort and lowest possible dose that controls signs, starting with 0.5 mg/kg prednisolone or methylprednisolone daily; withdraw NSAIDs.

CONTRAINDICATIONS
Amitriptyline should not be combined with drugs metabolized by cytochrome P450 2D6, e.g., cimetidine.

PRECAUTIONS
- Furosemide may activate renin-angiotensin aldosterone system which may be deleterious in dogs predisposed to myxomatous mitral valve disease (MVD).

S

SYRINGOMYELIA AND CHIARI-LIKE MALFORMATION (CONTINUED)

• Long-term acetazolamide or corticosteroids not recommended due to potential adverse effects.

POSSIBLE INTERACTIONS

CM/SM does not increase risk of anesthesia unless there is syringobulbia (syrinx in brainstem).

FOLLOW-UP

PATIENT MONITORING

• Periodic review of pain management and neurologic status.
• Serial MRI may be useful.
• Periodic CBC/biochemistry if receiving medication.

PREVENTION/AVOIDANCE

Purchase from a breeder that is health screening and can provide appropriate health certificates.

EXPECTED COURSE AND PROGNOSIS

• Approximately three-quarters of CM-P/SM-affected CKCS deteriorate on medical management. However, many dogs maintain acceptable quality of life.
• 15–20% of CM-P/SM-affected CKCS are euthanized.
• 25–47% of CM-P/SM-affected dogs having surgical management have recurrence or deterioration of signs within 0.2–3 years of surgery.

S

MISCELLANEOUS

ASSOCIATED CONDITIONS

CKCS have high prevalence of unrelated comorbidities, including BOAS, sleep disordered breathing, MVD, pancreatic disorders, biliary tree calcification, epilepsy, myoclonus, fly-catching behavioral disorder, gastroesophageal reflux, otitis media with effusion, deafness, macrothrombocytopenia, keratoconjunctivitis sicca, idiopathic facial nerve paresis, idiopathic vestibular disease.

AGE-RELATED FACTORS

Older brachycephalic toy breeds are more likely to have comorbidities such as MVD. Head and neck myoclonus is extremely common in older CKCS.

PREGNANCY/FERTILITY/BREEDING

• Official health schemes exist in many countries (e.g., the British Veterinary Association CM/SM scheme).
• Breeding recommendations based on SM status and age available.

SYNONYMS

• BOCCS.
• Caudal occipital malformation syndrome.
• Syringohydromyelia.

ABBREVIATIONS

• BOAS = brachycephalic obstructive airway syndrome.
• BOCCS = brachycephalic obstructive CSF channel syndrome.
• CCD = craniocervical decompression.
• CCJ = craniocervical junction.
• CFA = *Canis familiaris* autosome.
• CKCS = cavalier King Charles spaniel.
• CM = chiari-like malformation.
• CM-P = chiari-like malformation-associated pain.
• CSF = cerebrospinal fluid.
• IVDD = intervertebral disc disease.
• QTL= quantitative trait loci.
• MVD = myxomatous mitral valve disease.
• MUO = meningoencephalomyelitis of unknown origin.
• NSAID = nonsteroidal anti-inflammatory drug.
• SM = syringomyelia.

SYSTOLIC ANTERIOR MOTION

BASICS

OVERVIEW

Systolic anterior motion (SAM) is paradoxical dynamic movement of the mitral valve apparatus or some of its individual components in an anterior direction toward the left ventricular outflow tract (LVOT) and interventricular septum during systole. When the chordae tendineae are the sole component of the valve apparatus displaced anteriorly, the term chordal anterior motion (CAM) is sometimes used.

Pathophysiology

- When SAM was first recognized it was believed to be specific to the setting of hypertrophic cardiomyopathy (HCM) however, it has since been identified to occur under any circumstances that alter the dynamic geometry of the left ventricle (LV).
- There are multiple factors that can contribute to the development of SAM which can broadly be broken down into three main groupings: structural abnormalities, altered ventricular kinetics, and altered ventricular geometry (see Causes).
- Clinical manifestations occur on a spectrum of severity ranging from clinically silent changes to severe dynamic LVOT obstruction (LVOTO).
- Significant LVOTO can result in a pressure overload on the LV, resulting in myocardial hypertrophy; if severe enough, myocardial ischemia and ventricular arrhythmias may ensue.
- Cardiac output is also reduced with severe LVOTO and may result in weakness or collapse.

Systems Affected

Cardiovascular

Genetics

N/A, but certain underlying conditions have a genetic basis in certain breeds (e.g., HCM, subvalvular aortic stenosis [SAS]).

Incidence/Prevalence

True prevalence is unknown. One study identified SAM in 5.8% of apparently normal cats, of which 91.1% had HCM.

SIGNALMENT

Species

Dog and cat.

Breed Predilections

N/A, but certain breeds may be predisposed to certain underlying conditions (e.g., SAS in Newfoundlands; HCM in Maine coons).

Mean Age and Range

Unknown

SIGNS

Historical Findings

- Most animals are asymptomatic.
- Signs are often attributable to underlying disease process.
- Weakness, lethargy, or collapse may be observed with severe LVOTO.
- Patients with advanced underlying cardiac disease may have signs of left-sided or right-sided congestive heart failure (CHF) (e.g., tachypnea, dyspnea, cough, ascites).

Physical Examination Findings

- Systolic murmur which may be static, intermittent, or labile, i.e., variable in intensity from moment to moment.
- Diastolic gallop sounds may be present in patients with underlying cardiomyopathies.
- Femoral pulse quality may be reduced in patients with severe LVOTO.
- Arrhythmias may be appreciated (may be a direct sequela of severe LVOTO or may be due to the underlying disease process).

CAUSES & RISK FACTORS

Causes

SAM is a complex and dynamic condition that may arise from interactions of one or more of the following factors:

- Structural abnormalities:
  - Papillary muscle displacement.
  - Anterior and/or posterior mitral leaflet redundancy.
  - Abnormal chordae tendineae.
  - Bulging of the interventricular septum.
  - Small LV.
- Altered ventricular kinetics:
  - Hyperdynamic LV (generalized or regional).
- Altered ventricular geometry:
  - Reduced distance between septum and mitral coaptation point.
  - Mitral apparatus displaced anteriorly.
  - Decreased anterior:posterior length ratio.
  - Decreased mitro-aortic angle.

Risk Factors

- Any condition or intervention that alters left ventricular geometry or loading conditions.
- HCM.
- SAS.
- Systemic hypertension.
- Hypovolemia.
- Right ventricular systolic hypertension (e.g., pulmonic stenosis, tetralogy of Fallot, pulmonary hypertension).
- Stress/excitement.
- Mitral valve dysplasia.
- Thyrotoxicosis.
- Excess catecholamines.
- Positive inotropic drugs (e.g., dobutamine).
- Surgical mitral valve repair is identified as a risk factor in humans.
- SAM may occasionally be observed in completely healthy animals.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Must differentiate SAM from other causes of murmurs.
- It can be diagnostically challenging to distinguish if LVOTO due to SAM is the cause or the effect of myocardial hypertrophy.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

Echocardiography

- Paradoxical systolic motion of the anterior mitral leaflet/mitral apparatus toward the interventricular septum is identified on 2D and m-mode echocardiography, and is often best seen from right-parasternal five-chamber views that highlight the LVOT.
- Color-flow Doppler assessment of the LVOT identifies turbulent blood flow.
- The degree of LVOTO, if present, can be quantified via continuous-wave ± pulsed-wave Doppler interrogation. Doppler flow profiles in the setting of SAM are typically characterized by late systolic acceleration through the LVOT resulting in a "scimitar-shaped" profile.
- Mitral regurgitation is often identified; this is usually mild, with an eccentric jet that is posteriorly directed.
- Myocardial hypertrophy may be present (can be both a cause and an effect of SAM with significant LVOTO).
- Subvalvular ridge may be present in the LVOT of patients with SAS.
- Underfilling of the LV may be appreciated in some patients with SAM.
- Other echocardiographic findings, depending on the type and severity of underlying conditions.

Radiography

- May be normal.
- Radiographic changes, if present, usually reflect the underlying cause.
- Evidence of left- or right-sided cardiomegaly ± CHF may be present on thoracic radiographs.

DIAGNOSTIC PROCEDURES

ECG

- May be normal.
- Atrial or ventricular arrhythmias may be present, depending on underlying pathology.
- Evidence of left- or right-sided cardiomegaly may be present, depending on underlying cause and severity.

SYSTOLIC ANTERIOR MOTION (CONTINUED)

• May see evidence of myocardial ischemia (e.g., S-T segment elevation/depression) with severe LVOTO.

PATHOLOGIC FINDINGS
Gross or histopathologic findings reflect any underlying conditions, if present.

TREATMENT
Treat or remove underlying cause(s)

MEDICATIONS

DRUG(S) OF CHOICE
• Only as needed to manage an underlying condition or CHF, if present.
• Therapy with beta-blocker drugs (e.g., atenolol) is controversial. Beta-blockers are empirically used by some clinicians to reduce the severity and/or the effects of SAM/LVOTO, however evidence of efficacy or any survival benefit is lacking.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
• The use of positive inotropic drugs (e.g., dobutamine, pimobendan) in the setting of SAM with significant LVOTO is theoretically concerning and thus warrants prudence. Hypotension has been reported in a cat with SAM that received pimobendan for the treatment of heart failure, however a recent study of pimobendan administration in cats with HCM showed no difference in the incidence of LVOTO between treatment and placebo groups.
• Beta-blockers may reduce systolic function and should be used cautiously in patients with known systolic dysfunction.

FOLLOW-UP

PATIENT MONITORING
Type and frequency depends on any underlying disease processes.

PREVENTION/AVOIDANCE
N/A

POSSIBLE COMPLICATIONS
N/A

EXPECTED COURSE AND PROGNOSIS
• Depends on the nature and severity of underlying cause.
• In a study of cats with HCM, cats with SAM had longer survival times than those without. It is speculated that this may be due to SAM allowing earlier identification of the disease due to the presence of a murmur.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
N/A

PREGNANCY/FERTILITY/BREEDING
Certain underlying causes (e.g., HCM, SAS) may be heritable.

SYNONYMS
• Chordal anterior motion.
• CAM.
• Dynamic LVOTO.
• When LVOTO due to SAM is present concurrently with a HCM phenotype, the term hypertrophic obstructive cardiomyopathy is used.

SEE ALSO
• Aortic Stenosis.
• Cardiomyopathy, Hypertrophic—Cats.

ABBREVIATIONS
• CAM = chordal anterior motion.
• CHF = congestive heart failure.
• HCM = hypertrophic cardiomyopathy.
• LV = left ventricle.
• LVOT = left ventricular outflow tract.
• LVOTO = left ventricular outflow tract obstruction.
• SAM = systolic anterior motion.
• SAS = subvalvular aortic stenosis.

TAPEWORMS (CESTODIASIS)

BASICS

OVERVIEW
- Infection of small intestine with adult tapeworms of *Taenia* (especially *T. pisiformis* of dogs and *T. taeniaeformis* of cats), *Dipylidium caninum*, *Echinococcus* spp., *Mesocestoides*, *Diphyllobothrium*, or *Spirometra*.
- Infection by ingestion of intermediate host containing tapeworm larvae.
- Most cause no apparent harm to host other than perianal pruritus; *Spirometra* may cause diarrhea, weight loss, vomiting.
- Peritoneal larval cestodiasis (PLC)—potentially fatal peritoneal infection in dogs (accidental intermediate hosts) caused by *Mesocestoides* larvae.

SIGNALMENT
Dog and cat.

SIGNS
- Motile or dried, white to cream-colored, single proglottids or chains of square or rectangular proglottids of *Taenia* and barrel-shaped proglottids of *Dipylidium* visible on perineum or in feces; *Mesocestoides* proglottids are club-shaped, smaller, more numerous; *Echinococcus* proglottids too small to see.
- Dragging or rubbing anus on ground (pruritus).
- Diarrhea, weight loss—possible with *Spirometra*.
- PLC—abdominal distension (ascites), anorexia, lethargy.

CAUSES & RISK FACTORS
- *Taenia*, *Echinococcus*, *Mesocestoides*—eating viscera of intermediate hosts (birds, reptiles, rabbits, rodents, sheep).
- *Dipylidium* infections—eating fleas, lice.
- *Spirometra*—ingesting copepods; uncooked amphibians, reptiles, birds, mammals.
- *Diphyllobothrium*—eating uncooked fish.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Anal sac disease.
- Other causes of diarrhea.
- PLC—causes of ascites.

CBC/BIOCHEMISTRY/URINALYSIS
PLC—leukocytosis, hypoalbuminemia.

OTHER LABORATORY TESTS
N/A

IMAGING
PLC—abdominal ultrasonography, radiography.

DIAGNOSTIC PROCEDURES
- Fecal flotation to detect eggs; false negatives if eggs not released from proglottids; crush minced segments between two glass slides to release eggs, add drop of water, examine microscopically.
- *Dipylidium*—press adhesive cellophane tape to perianal skin, then apply tape to microscope slide; packets contain multiple pale yellow eggs ~50 µm in diameter with hexacanth embryo with three pairs of hooks.
- *Taenia*, *Echinococcus*—individual spherical brown eggs ~30–35 µm in diameter with hexacanth embryo.
- *Mesocestoides*—individual oval thin-shelled eggs with hexacanth embryo.
- PLC—detect larvae in peritoneal fluid by microscopy or PCR-restriction fragment length polymorphism.
- *Diphyllobothrium*/*Spirometra*—individual eggs with operculum; contain fully developed coracidium.

TREATMENT
- Outpatient anthelmintic treatment.
- Flea (or louse) control (*Dipylidium*).
- PLC—anthelmintic treatment, may require peritoneal lavage or surgery to remove larvae.

MEDICATIONS

DRUG(S) OF CHOICE
- Fenbendazole 50 mg/kg PO q24h for 3 days.
- Praziquantel 5 mg/kg PO, SC once:
  - Resistance to praziquantel in *Dipylidium* is emerging issue.
  - 7.5 mg/kg PO for 2 days for *Diphyllobothrium* (dogs, extra-label).
- Praziquantel/pyrantel pamoate—label dose (cats).
- Praziquantel/pyrantel pamoate/febantel—label dose (dogs).
- Epsiprantel 5.5 mg/kg PO (dogs), 2.8 mg/kg PO (cats) for *Taenia*, *Dipylidium*; 7.5 mg/kg PO (dogs) for *Echinococcus*.
- Emodepside 3 mg/kg/praziquantel 12 mg/kg, topically for *Taenia*, *Dipylidium* (cats).
- Canine PLC—praziquantel 5 mg/kg SC, repeat in 2 weeks; fenbendazole 50–100 mg/kg PO q24h for 4–8 weeks (extra-label; clinical remission, often not curative).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Do not use praziquantel or epsiprantel in animals <4 weeks old.

FOLLOW-UP

PATIENT MONITORING
- Post-treatment examination for tapeworm segments or eggs; incompletely removed adult *Mesocestoides* can repopulate by asexual multiplication.
- PLC—ultrasonography, abdominocentesis to detect recurrence; larvae difficult to eliminate (repopulate by asexual multiplication).

PREVENTION/AVOIDANCE
- Flea (or louse) control to prevent *Dipylidium* infection.
- Prevent hunting, scavenging, eating of intermediate hosts.

EXPECTED COURSE AND PROGNOSIS
- Anthelmintic treatment eliminates adult *Taenia*, *Echinococcus*, *Dipylidium*; reinfection often occurs.
- Incomplete removal of adult *Mesocestoides* can result in recurrence without reinfection.
- PLC treatment provides clinical remission, often not curative.

MISCELLANEOUS

ZOONOTIC POTENTIAL
- Children at risk for *Dipylidium* infection by ingestion of fleas; tapeworm segments have been mistaken for pinworms.
- Ingestion of *Echinococcus* eggs can cause hydatid disease in humans.
- Strict sanitation should be practiced when taeniid eggs observed due to similar egg morphology of *Taenia* and *Echinococcus*.
- Human infection with *Mesocestoides* can occur by ingestion of intermediate hosts.
- Human infections can occur by ingestion of uncooked fish (*Diphyllobothrium*), copepods (*Spirometra*), or vertebrate intermediate hosts.

ABBREVIATIONS
- PLC = peritoneal larval cestodiasis.

T

TEMPOROMANDIBULAR JOINT DISORDERS

BASICS

OVERVIEW
• Disorders of the temporomandibular joint (TMJ) alter masticatory function due to mobility and functional changes of the joint.
• Genetic, traumatic, degenerative, or idiopathic causes may result in pain, occlusal dysfunction, joint laxity, chronic arthritis, or open-mouth locking.

SIGNALMENT
• Dog and cat.
• No breed, sex, or age predisposition in most TMJ disorders.
• Open-mouth mandibular locking—basset hounds; Irish setters.
• Genetic predisposition in certain breeds (e.g., basset hounds) to develop TMJ disorders.

SIGNS
General Comments
• Difficulty opening mouth.
• Difficulty closing mouth.
• Laxity or excessive lateral movement of the mandible.
• Pain and/or crepitation when masticating, yawning, and/or vocalizing.

Specific
• TMJ luxation/subluxation—history of trauma or mouth locked open; radiographic evidence of luxation.
• Open-mouth mandibular locking—mandibular coronoid process buccal to the ventral surface of the zygomatic arch; locked in that position; large bulge palpated on affected side.
• Traumatic injury—evidence of trauma; mouth dropped open; mobility of mandible (may have multiple fractures); radiographs indicate fracture.
• Osteoarthritis/chronic post-traumatic changes—crepitation and pain when eating or if mandible is forced to move; radiographs may show osseous reaction indicative of arthritic changes.

CAUSES & RISK FACTORS
• Patients at a higher risk to experience injuries—young; free roaming.
• Trauma with fractures or a luxation resulting in immediate problems, and future degenerative problems.
• Mandibular neuropraxia—carrying heavy objects by mouth.
• Masticatory muscle myositis (MMM)—adult; large-breed (e.g., German shepherd dogs).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Craniomandibular osteopathy.
• Mandibular neuropraxia—motor nerve branches of masticatory muscles stretched when carrying heavy objects; mandible hangs open but is easily closed.
• MMM—autoimmune disease of type 2M myofibers of masticatory muscles supplied by trigeminal nerve; trismus progresses to total inability to open jaws.

CBC/BIOCHEMISTRY/URINALYSIS
Typically within normal limits.

OTHER LABORATORY TESTS
• Serum autoantibodies to type 2M myosin—to rule out MMM.
• Cytology of fluid aspirated from TMJ—inflammation from polyarthropathy.

IMAGING
• Skull radiography—essential to perform proper radiographic technique to visualize the TMJ.
• MRI—gold standard for imaging the TMJ.

DIAGNOSTIC PROCEDURES
• Usually none.
• Muscle biopsy—rule out MMM.

TREATMENT
• Eliminating or altering the etiologic factor responsible for the disorder, as well as correcting the problem.
• TMJ luxation—traumatic: luxation often occurs in a rostral–dorsal direction; in acute cases, place a "dowel" (pencil) across the mouth between the carnassial teeth; gently close the rostral portion of the mouth with a gentle "push" to reduce the luxation (push caudally for a rostral luxation); chronic luxation may not reduce and may require surgery. Digital manipulation may also be effective.
• Open-mouth mandibular locking—immediate attention; sedate animal, open the mouth further and apply gentle pressure on the bulging coronoid process to allow it to slip back under the zygomatic arch; surgical management: excise ventral portion of the zygomatic arch and/or a dorsal portion of the coronoid process to relieve future locking.
• Injury or fracture at TMJ—depends on extent of damage; fixation is difficult; condylectomy sometimes necessary.
• Chronic osteoarthritis or ankylosis—if severe, condylectomy may be needed.
• "Dropped jaw" (trigeminal [mandibular] neuropraxia)—conservative treatment: rest, anti-inflammatory drugs.
• MMM—immunosuppressant medications.

MEDICATIONS

DRUG(S) OF CHOICE
• Analgesics—for painful disorders, both acute and long-term management.
• Anti-inflammatory drugs—for post-operative pain and chronic inflammation.
• Muscle relaxants—help prevent increased muscle activity due to chronic pain response.

FOLLOW-UP

PATIENT MONITORING
Each case should be carefully followed because of the progressive changes that may occur in the TMJ, especially after traumatic injury.

PREVENTION/AVOIDANCE
Avoid situations that allow for trauma (pets running loose).

POSSIBLE COMPLICATIONS
In many cases after surgical treatment involving TMJ disorders, arthritis may develop later.

EXPECTED COURSE AND PROGNOSIS
Depends on the disorder afflicting the TMJ and the degree to which it is affected.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING
Avoid contraindicated medications.

SEE ALSO
Maxillary and Mandibular Fractures.

ABBREVIATIONS
• MMM = masticatory muscle myositis.
• TMJ = temporomandibular joint.

TESTICULAR DEGENERATION AND HYPOPLASIA

BASICS

OVERVIEW

• Degeneration—histologic changes occurring in the testes after puberty; may be differentiated from hypoplasia by increased thickness of basement membrane or by recognizing a space-filled gap between tail of epididymis and caudal pole of testicle.
• Hypoplasia—a variety of histologic lesions thought to be congenital (although often not obvious until after puberty) or heritable.

SIGNALMENT

• Dog—any age or breed; hypoplasia, generally young; degeneration, generally old.
• Tortoiseshell cat—may be fertile; usually linked with sex chromosome abnormalities (see Sexual Development Disorders).

SIGNS

• Infertility.
• Hypoplasia (dogs)—rarely any physical signs other than small testes.
• Degeneration (dogs)—history of scrotal or testicular insult may be relevant, reduced testicular size and loss of normal turgidity.
• Oligospermia (low numbers of spermatozoa in the ejaculate) or azoospermia (no spermatozoa in the ejaculate).

CAUSES & RISK FACTORS

Degeneration

• Heat.
• Irradiation.
• Increasing age.
• Arterial sclerosis.
• Epididymal occlusion.
• Incisional testicular biopsies.
• Any previous scrotal or testicular lesion may be related.
• Metals—lead salts, cadmium, organic mercurial compounds.
• Orchitis—infectious (such as brucellosis) or noninfectious (autoimmune).
• Some medications—cimetidine, ketoconazole, nitrofurans, flutamide.
• Steroid hormones—estrogen: secreted by a Sertoli cell tumor or exogenous exposure.
• Other hormonal abnormalities—hypothyroidism, hypocortisolism, hyperadrenocorticism.

Hypoplasia

• Klinefelter (XXY) syndrome.
• XX sex reversal—disorder of sexual development with the absence of *SRY* region (dogs).
• Hypogonadotropic hypogonadism—may be acquired from traumatic or neoplastic lesion of the pituitary.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Degeneration—azoospermia or severe oligospermia in previously fertile dogs having small testes.
• Hypoplasia—azoospermia with no history of proven fertility in dogs with small testes.
• Spermatocele.
• Sperm granuloma.
• Orchitis.
• Neoplasia.
• Ejaculatory failure—retrograde ejaculation, incomplete ejaculation.

OTHER LABORATORY TESTS

Alkaline phosphatase (ALP) concentration of seminal plasma—rule out incomplete ejaculation; samples with ALP <5,000 U/L consistent with incomplete ejaculation or bilateral epididymal obstruction.

IMAGING

Ultrasonography—testicular size (document decreasing values over time, comparison between testicles); heterogenous echogenicity of parenchyma, with or without calcification (chronic).

DIAGNOSTIC PROCEDURES

• Semen evaluation.
• Testicular biopsy (for azoospermia)—Tru-Cut (tissue plug): most complete histopathologic diagnosis; fix tissue for sectioning in Bouin's or formalin solutions.
• Karyotype—(hypoplasia) identify extra X chromosome or other numerical or structural chromosome anomaly.

PATHOLOGIC FINDINGS

• Normal spermatogenesis on biopsy—indicates obstruction in azoospermic dogs.
• Basement membrane thickness—differentiates hypoplasia from degeneration (thickness increased).

TREATMENT

• Removal of inciting cause, if possible; degeneration linked to adenohypophysis, adrenal gland, thyroid gland, or other metabolic disruption.
• No specific diagnosis—may try gonadotropic hormones; rare anecdotal reports of success.

MEDICATIONS

DRUG(S) OF CHOICE

• Gonadotropin-releasing hormone (GnRH) therapy successful in men with hypogonadotropic hypogonadism; no controlled studies in domestic animals:
  ◦ GnRH 1 µg/kg SC, with or with human chorionic gonadotropin (hCG) 1,600 IU, IM.
  ◦ hCG 500 IU SC, 2 times/week.

FOLLOW-UP

PATIENT MONITORING

Suspected testicular degeneration (dogs)—a repeat semen analysis performed at least 70 days after correcting any identified underlying cause is needed before long-term prognosis can be assessed.

EXPECTED COURSE AND PROGNOSIS

• Hypoplasia (dogs)—prognosis for fertility poor.
• Degeneration (dogs)—prognosis for sustained fertility depends on cause and duration of ejaculate quality and accuracy of breeding management (see Breeding, Timing).

MISCELLANEOUS

SEE ALSO

• Brucellosis.
• Infertility, Male—Dogs.
• Sexual Development Disorders.
• Spermatocele/Sperm Granuloma.
• Spermatozoal Abnormalities.

ABBREVIATIONS

• ALP = alkaline phosphatase.
• GnRH = gonadotropin-releasing hormone.
• hCG = human chorionic gonadotropin.

T

TETANUS

BASICS

OVERVIEW

• *Clostridium tetani*—an obligate anaerobic spore-forming Gram-positive rod found in soil and as part of normal bacterial flora of the intestinal tract of mammals; predilection for contaminated necrotic anaerobic wounds.
• Germinating spores—in wounds, produce potent exotoxin tetanospasmin (tetanus toxin); resistant to disinfectants and to effects of environmental exposure.

SIGNALMENT

Dogs, rarely cats.

SIGNS

Historical Findings

• Signs appear days to months after spores enter wound.
• Wound—often necrotic; but skin may have healed and not visible to owner.

Physical Examination Findings

The most common *initial* clinical signs in affected dogs are ocular and facial abnormalities.

Localized

• Mild rigidity of muscles or leg nearest the site of spore inoculation (wound).
• Stiffness of (hind) limbs; stilted gait; mild weakness and incoordination.
• Can resolve spontaneously—reflects partial immunity to tetanospasmin.
• Can be prodromal to generalized disease—when enough toxin gains access to CNS.

Progressive/Generalized

• Tail—stretches out; progressive tetany of muscles to point of sawhorse appearance.
• Convulsions (clonic)—limbs; whole body (opisthotonus); pain during contractions.
• Dyspnea.
• Difficulty opening jaws—trismus (lockjaw).
• Dysphagia, dysphonia.
• Eyes—lids retract (risus sardonicus, also includes wrinkled forehead and grinning appearance); third eyelid prolapses when head is touched; eyeballs recede into orbit (enophthalmos).
• Erect ears.
• Salivation.
• Fever, painful urination (dysuria), and constipation—may be seen.
• Tetanic muscle spasms—from stimulation (sudden movement, sound, touch).
• Death—during spasm of laryngeal and respiratory muscles (fatal acute asphyxia).

CAUSES & RISK FACTORS

• Unattended wounds (e.g., puncture wounds with foreign body, surgical wounds, compound bone fractures, tooth eruptions/fractures, foot injury or trauma)—portal of entry for spores.
• Outdoor activities provide opportunities for trauma/exposure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Intoxications— strychnine, bromethalin, metaldehyde poisoning.
• Dystonic reaction to neuroleptic drugs (acepromazine, prochlorperazine).
• Rabies.
• Meningitis–encephalitis.
• Immune-mediated polymyositis.
• Spinal trauma.
• Hypocalcemia.

CBC/BIOCHEMISTRY/URINALYSIS

• Initial leukopenia; then moderate leukocytosis; then return to reference range.
• Aspartate aminotransferase (AST) and creatine phosphokinase—some increased activity due to muscle damage (tremors).
• Urinalysis—possible myoglobinuria from muscle damage.

OTHER LABORATORY TESTS

• Venous or arterial blood gas analysis—assess adequacy of ventilation (P_{CO_2}).
• Serology—antitetanus antibody often undetectable in serum.
• Culture—wounds; usually unrewarding; must use anaerobic transport medium (do not refrigerate).
• Serum—to detect toxin (by mouse neutralization).
• CSF and blood cultures for bacterial pathogens of meningitis.

TREATMENT

• Inpatient—constant nursing care important; supportive care for prolonged period (3–4 weeks).
• Feeding—patients often have difficulty prehending food; gastrotomy tube may be necessary; force feeding may exacerbate tetanic state (not advised).
• Hydration—maintain with oral water; if inadequate give a balanced IV fluid.
• Keep patient in darkened quiet area; do not disturb.
• Keep patient on soft bedding; prevent decubital ulcers; rotate stabilized patients cautiously, q4–6h.
• Airway and ventilation—assess; may be necessary to perform endotracheal intubation; tracheostomy may be necessary; monitor blood gas for evidence of hypoventilation.

MEDICATIONS

DRUG(S) OF CHOICE

Sedation

• To control reflex spasms and convulsions.
• Chlorpromazine 0.1–0.5 mg/kg IM, IV, PO q6–12h, also acepromazine 0.01–0.1 mg/kg IV, IM, SC q6–8h; 1–3 mg/kg PO q8h.
• Benzodiazepines—may be administered CRI or intermittent dosing:
  ◦ Midazolam 0.25 mg/kg IV, IM q4–6h or 0.2–0.5 mg/kg/h IV CRI.
  ◦ Diazepam 0.5–1 mg/kg PO (dog), IV, IM q8h or 0.1–1 mg/kg//h IV CRI.
• Phenobarbital 1–4 mg/kg PO, IV q12h.
• Propofol—may be considered if unable to stop tremors; endotracheal intubation necessary.

Tetanus Antitoxin

• Binds only toxin that is free or unbound, does not eliminate already bound toxin.
• First test for hypersensitivity reaction (0.1 mL SC and observe).
• Human tetanus immunoglobulin—administer 500–3,000 U IM at multiple sites, especially proximal to wound; or use equine tetanus antitoxin 100–1,000 U/kg IV; may also be given SC or IM. Maximum dose 20,000 U/kg.
• Administer adsorbed tetanus toxoid intramuscularly.

Antibiotics

• Kill vegetative bacteria to reduce formation of additional toxin; this has no effect against toxin already bound to nerves.
• Metronidazole 10 mg/kg PO, IV q8–12h, preferred.
• Penicillin G 20,000–100,000 IU/kg q6–12h for 10 days; use sodium/potassium salt (IV) on the first day and procaine penicillin (IM) thereafter.
• Glycopyrrolate 0.005–0.01 mg/kg IV, IM q4–6h can be used to treat bradycardia associated with severe tetanus.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

• Avoid glucocorticoids and atropine.
• Use caution with narcotics—depress respiratory center.
• Avoid oral diazepam in cats due to hepatotoxicity.

FOLLOW-UP

PATIENT MONITORING

• Monitor for decubital ulcers and peripheral nerve palsies.
• Monitor blood pressure and ECG.
• Aspiration possible.

T

• Constipation possible.

PREVENTION/AVOIDANCE

• Vaccinate—tetanus toxoid; not typically used in dogs and cats.
• Prevent skin wound trauma—clear runs and yards of wire, glass, etc.
• Wound management—early and thorough irrigation; debridement and drainage, especially in tetanus-prone wounds.

EXPECTED COURSE AND PROGNOSIS

• Younger dogs with tetanus may be more likely to develop severe clinical signs.
• The prognosis for survival in dogs with tetanus is good if abnormalities in heart rate or blood pressure values do not develop.
• Prognosis—depends on number of factors; poorer prognosis has been associated with more toxin bound to nerves, wounds closer to the head, shorter interval between injury and first tetanic spasm, and development of aspiration pneumonia.
• Course of recovery—slow; requires rehabilitation to regain full use of limbs; most recover in 1 week; some have a course of 3–4 weeks; unattended disease can be fatal if it progresses to generalized disease (vs. localized tetanus).

MISCELLANEOUS

ZOONOTIC POTENTIAL

None, but tetanus spores ubiquitous in environment.

ABBREVIATIONS

• AST = aspartate aminotransferase.

TETRALOGY OF FALLOT

BASICS

OVERVIEW

• A congenital cardiac malformation that consists of a ventricular septal defect (VSD), pulmonic stenosis (PS), an overriding aorta, and right ventricular (RV) hypertrophy (Figure 1). The essential developmental abnormality is probably cranial deviation of the infundibular (outlet) septum; the other defects are secondary. • Hemodynamics are determined primarily by the size of the VSD (typically large, i.e., equals or exceeds area of the open aortic valve) and the severity of RV outflow tract obstruction (RVOTO). A large VSD allows equilibration of left and RV pressures, with shunt direction determined by the relationship between peripheral vascular resistance and the resistance to RV ejection. Severe RVOTO results in a right-to-left shunt with cyanosis and compensatory erythrocytosis as prominent clinical features. • An uncommon congenital defect, but the most common congenital cardiac malformation that causes cyanosis in dogs and cats.

SIGNALMENT

• Dog and cat—uncommon in both.
• English bulldog and keeshond predisposed.

T

SIGNS

Historical Findings

• Weakness. • Syncope. • Shortness of breath.

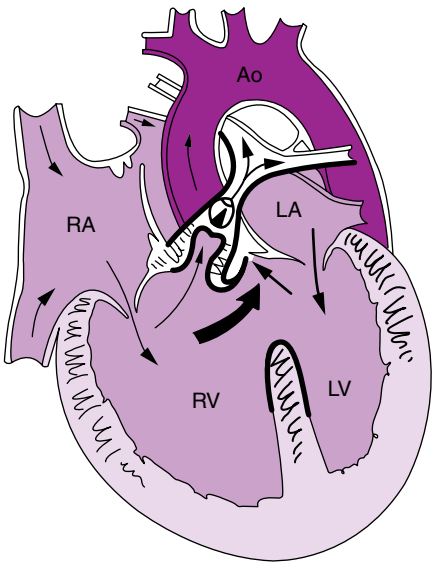

Figure 1.

Classic tetralogy of Fallot. RA = right atrium, LA = left atrium, RV = right ventricle, LV = left ventricle, Ao = aorta. (Source: Roberts W., Adult Congenital Heart Disease. Philadelphia, © 1987 F.A. Davis Company.)

Physical Examination Findings

• Systolic left basilar ejection murmur, caused by RVOTO in most patients; some with hyperviscosity and severe pulmonary stenosis do not have murmurs. • Cyanosis—most patients; degree of cyanosis depends on the direction and volume of shunt. If RVOTO is mild, direction of the shunt may be left-to-right; in this case, cyanosis is absent and the pathophysiology is that of an isolated VSD. • Arterial pulses usually normal. • Congestive heart failure rare, possibly because the right ventricle can unload into the left ventricle, preventing the development of suprasystemic RV pressures.

CAUSES & RISK FACTORS

Congenital; a continuum of conotruncal defects that includes tetralogy of Fallot inherited in keeshonden; the mode of transmission likely oligogenic. Genetic factors probably etiologically important when tetralogy of Fallot observed in patients of other breeds.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Aortic stenosis, PS, VSD, and atrial septal defect can all cause left basilar ejection murmurs. • Patients with severe PS and a right-to-left atrial-level shunt may have similar findings on physical examination. • Other anatomic right-to-left shunts (patent ductus arteriosus [PDA] or VSD with high pulmonary vascular resistance) do not typically cause murmurs; differential cyanosis (cranial mucous membranes are pink; caudal mucous membranes are cyanotic) is observed if a PDA shunts right-to-left.

CBC/BIOCHEMISTRY/URINALYSIS

Compensatory erythrocytosis if the shunt is right-to-left.

IMAGING

Thoracic Radiography

• Variable RV enlargement. • Ascending aorta may be prominent. • Pulmonary vessels are small.

Echocardiography

• RV hypertrophy. • Large VSD visualized directly. • Aortic overriding of the VSD. • Narrow infundibulum and/or abnormal pulmonic valve. • Doppler evidence of PS. • Contrast echocardiography typically delineates a right-to-left shunt.

Angiocardiography

• Reveals VSD, RV hypertrophy, PS, and shunt direction. • Nonselective angiography may confirm diagnosis in patients <10 kg.

DIAGNOSTIC PROCEDURES

Electrocardiography

RV hypertrophy pattern in most dogs and cats.

Oximetry

Used to confirm peripheral desaturation of hemoglobin.

TREATMENT

• Most treated as outpatients. • Exercise restriction recommended. • Treat erythrocytosis by periodic phlebotomy to maintain a PCV of 62–68%. • Palliative surgical procedures that enhance pulmonary blood flow have been performed. • Definitive surgical correction requires cardiopulmonary bypass.

MEDICATIONS

DRUG(S) OF CHOICE

Nonselective β-adrenergic antagonists such as propranolol may be palliative; they act as negative inotropes, thereby limiting dynamic RVOTO, and also prevent the physiologic drop in peripheral vascular resistance that occurs during exercise. These hemodynamic effects serve to limit right-to-left shunting. Propranolol may also favorably affect the oxyhemoglobin dissociation curve.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Vasodilators contraindicated.

FOLLOW-UP

• Monitor PCV every 1–3 months. • Do not breed affected animals. • Bacterial endocarditis, neurologic complications associated with erythrocytosis, arrhythmias, and sudden death are potential sequelae. • Prognosis generally poor; median age at death in one study was 23.4 months.

MISCELLANEOUS

ABBREVIATIONS

• PDA = patent ductus arteriosus.
• PS = pulmonic stenosis. • RVOTO = right ventricular outflow tract obstruction.
• VSD = ventricular septal defect.

THIRD EYELID PROTRUSION

BASICS

DEFINITION
Abnormal protrusion (elevation) of the third eyelid.

PATHOPHYSIOLOGY
- Dogs—movement of the third eyelid is passive.
- Cats—partial sympathetic nervous control of the third eyelid.
- May be primary (conformational) or secondary (exophthalmos, enophthalmos, sympathetic denervation, painful eye).

SYSTEMS AFFECTED
- Nervous—autonomic nervous system.
- Ophthalmic—third eyelid(s); orbit; globe.

SIGNALMENT
See Causes.

SIGNS
- Primary—often none; occasionally conjunctivitis and tearing.
- Secondary—associated with the underlying condition.
- Unilateral or bilateral—depending on cause.

CAUSES

Unilateral

Blepharospasm
- Painful ocular condition—corneal ulcer; glaucoma; uveitis; foreign body.
- Active retraction of the globe results in secondary third eyelid elevation.

Exophthalmos
- Increase in orbital volume—pushes the eye and third eyelid forward.
- Abscess or cellulitis—generally young patients; acute onset; painful on palpation.
- Neoplasm—generally older patients; gradual onset; frequently not painful.
- Salivary gland inflammation/mucocele—variable age; may be secondary to trauma; frequently not painful (see Orbital Diseases (Exophthalmos, Enophthalmos, Strabismus)).

Enophthalmos
- Globe—recedes into the orbit, causing third eyelid to appear elevated.
- Unilateral—may be caused by trauma, orbital fat atrophy, neoplasia, and inflammation.
- Horner's syndrome—clinical signs develop after sympathetic denervation; elevated third eyelid; enophthalmos; ptosis (drooping upper eyelid); miosis (see Horner's Syndrome).

Microphthalmos or Phthisis Bulbi
- Small globes—cause the third eyelid to appear elevated.
- Microphthalmos—congenital; idiopathic or may be inherited in specific breeds (many reported); other intraocular abnormalities may be present. May result from toxin ingestion (griseofulvin in pregnant cats).
- Phthisis bulbi—acquired; severe damage to the globe (uveitis, glaucoma, or trauma); ciliary body fails to produce aqueous humor; diminished; small, fibrotic globe.
- Other
- Neoplasia of the third eyelid—slow growing; usually older patients. Most common: adenocarcinoma of the gland of the third eyelid; hemangioma/hemangiosarcoma, melanoma and squamous cell carcinoma and others may involve the eyelid.
- Cherry eye—see Prolapsed Gland of the Third Eyelid (Cherry Eye).
- Everted or scrolled cartilage of the third eyelid—primarily large and giant breeds; the T-shaped cartilage of the third eyelid is rolled away from the surface of the eye instead of conforming to the corneal surface.
- Symblepharon—post-inflammatory adhesions between the third eyelid and cornea or conjunctiva. Common in cats who had ocular surface inflammation before the eyelids opened.
- Foreign body.
- Previous injury.
- Facial nerve paralysis—patient will retract the globe and "flash" the third eyelid.

Bilateral

Exophthalmos
- Space-occupying lesions of both orbits.
- Usually caused by immune-mediated inflammatory lesions (e.g., eosinophilic myositis, extraocular muscle polymyositis).

Conformational
- Breed-specific—primarily large-breed dogs.
- Deep orbits and prominent third eyelids.
- Not pathologic.
- No treatment needed.

Plasmoma
- Immune-mediated thickening and hyperemia of the leading edge of the third eyelid due to infiltration of plasma cells and lymphocytes; follicle formation; depigmentation.
- Primarily in German shepherd dogs; other breeds reported.
- May be associated with chronic superficial keratitis (pannus).

Other
- Blepharospasm (active retraction of globe).
- Enophthalmos—caused by dehydration, bilateral orbital fat atrophy secondary to severe cachexia, and chronic masticatory muscle myositis.
- Haw's syndrome (cats)—idiopathic bilateral elevation of the third eyelids; primarily young cats with history of diarrhea; ophthalmic examination otherwise normal; self-limiting; usually resolves in 3–4 weeks without treatment.
- Dysautonomia (Key-Gaskell syndrome)—bilateral elevated third eyelids; dilated nonresponsive pupils; keratoconjunctivitis sicca (KCS); dry mucosal surfaces; anorexia; lethargy; regurgitation; megaesophagus; bradycardia; megacolon; distended bladder (see Dysautonomia (Key-Gaskell Syndrome)).
- Tranquilizers—many (e.g., acepromazine) cause bilateral third eyelid elevation.
- Fatigue—transient third eyelid elevation, especially in dogs prone to ectropion.
- Cannabis intoxication.
- Tetanus—eyelids retract; third eyelid prolapse; enophthalmos; secondary to hypertonicity of extraocular muscles (see Tetanus).

Rabies—reported ocular signs include dilated pupils; anisocoria; third eyelid prolapse; uveitis (see Rabies).

RISK FACTORS
Depends on cause.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Most common causes of acute onset of unilateral condition—ocular pain (e.g., corneal ulcer, uveitis); orbital inflammation (e.g., orbital abscess, cellulitis).
- Middle-aged or older patient with unilateral, nonpainful condition—third eyelid or orbital neoplasm likely.
- All patients—must rule out a small eye (microphthalmos or phthisis bulbi) and Horner's syndrome.
- Likely causes of bilateral condition—systemic illness (e.g., dehydration, cachexia, dysautonomia); associated with conformational abnormalities.
- Prolapsed gland of the third eyelid—medial aspect of the third eyelid swollen; the third eyelid itself usually normal.
- Lightly pigmented third eyelid margin—normal conformation; may be falsely identified as an elevated third eyelid.

CBC/BIOCHEMISTRY/URINALYSIS
- Leukocytosis and a left shift—with orbital inflammatory processes.
- Blood work—generally normal despite differing causes.

OTHER LABORATORY TESTS
Dysautonomia—confirmed by measuring urine and plasma catecholamine concentrations and pharmacologic testing of the autonomic nervous system.

IMAGING
- Thoracic radiography—all patients with Horner's syndrome to rule out intrathoracic cause of sympathetic denervation, evaluate for metastatic disease.
- Orbital ultrasound—recommended to help localize suspected orbital mass and define its nature (e.g., solid or cystic).

THIRD EYELID PROTRUSION (CONTINUED)

• CT or MRI—further define suspected or known orbital mass.
• Skull radiographs—rarely show signs of orbital disease unless lesion is very large and destructive.

DIAGNOSTIC PROCEDURES
• Thorough ophthalmic examination utilizing a source of magnification.
• All patients with unilateral condition—examine both surfaces of the third eyelid and the conjunctival cul-de-sac carefully for a foreign body or symblepharon.
• Pharmacologic testing—localize lesion with Horner's syndrome (see Horner's Syndrome).
• Exploratory surgery and biopsy—may be only means to make a definitive diagnosis for a suspected orbital or third eyelid mass.

Cytology
• For suspected mass lesions:
  ◦ Unguided fine-needle aspiration—only if the mass is anterior to the equator of the eye.
  ◦ Ultrasound-guided fine-needle aspiration—for masses posterior to the eye; help avoid delicate retrobulbar structures.
• Third eyelid scrapings—German shepherd dogs with suspected plasmoma reveal plasma cells and lymphocytes.

TREATMENT
• Depends on cause.
• Painful condition—remove the cause of the irritation (e.g., foreign body); treat the primary ocular condition.
• Orbital cellulitis and abscess—orbital drainage and systemic antibiotics.
• Orbital neoplasms—usually require wide surgical excision via an orbital exenteration; may require adjunct therapeutic modalities if excision is incomplete.
• Microphthalmic eyes—usually none required; enucleation if painful or subject to recurrent conjunctivitis.
• Blind traumatized eyes—enucleate if painful and to prevent formation of intra-ocular sarcomas (cats).
• Horner's syndrome—treat cause, if known (~50% of dogs and cats); otherwise may resolve without treatment in 4–12 weeks.
• Surgical removal of the entire third eyelid—indicated for third eyelid neoplasia; may require adjunct therapeutic modalities if the surgical margins are not free of neoplasm.
• Radiotherapy around the eye—may result in severe keratitis, dry eye, and cataracts; discuss enucleation with the client before initiating treatment if eye will be in the radiation field.
• Orbital exenteration—may be warranted if the mass extends into the orbit.
• Plasmoma—usually controlled with topical medications; not cured; life-long therapy needed; topical corticosteroids (0.1% dexamethasone or 1% prednisolone acetate q6h, reduced to q24h when appears resolved); topical 1% cyclosporine q12h also effective.
• Haw's syndrome—usually self-limiting without treatment.
• See Dysautonomia (Key-Gaskell Syndrome), tetanus, or rabies.

MEDICATIONS
DRUG(S) OF CHOICE
See Treatment.

CONTRAINDICATIONS
Topical corticosteroids—never use in patients with corneal ulceration.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP
PATIENT MONITORING
Malignant neoplasia—thoracic radiographs and full physical exam q3–6 months to monitor for metastatic disease.

POSSIBLE COMPLICATIONS
• Neoplasm—extension to or involvement of adjacent orbital structures (e.g., eye, orbit, orbital sinuses, and cranial cavity) possible; metastasis to distant sites (usually thorax or liver) possible (approximately 90% are malignant).
• Vision loss—from the lesion itself, from elevation, or from treatment (e.g., radiotherapy and exenteration).

THROMBOCYTOPATHIES

BASICS

OVERVIEW

- Acquired or hereditary defects that affect platelet function, including procoagulant activity. Defects are in two categories: intrinsic and extrinsic.
- Intrinsic platelet defects originate within platelets; extrinsic platelet defects affect platelet function indirectly (e.g., von Willebrand disease [VWD]).
- Affected animals typically have normal platelet counts but have spontaneous or excessive bleeding; mucosal or postoperative bleeding are most common.
- Thrombocytopenic animals with concurrent thrombocytopathia will bleed more excessively than expected for the platelet count.

SIGNALMENT

- Acquired defects are the most common thrombocytopathias in companion animals. They occur in all breeds and at all ages.
- Hereditary platelet function defects may be diagnosed at any age but commonly appear in young animals with the loss of deciduous teeth, causing excessive bleeding.
- Hereditary defects are rare disorders that have been described in the following breeds/species:
  - VWD—Doberman pinschers, German shorthair pointers, many other pure and mixed- breed dogs.
  - Type I Glanzmann thrombasthenia—otterhound and great Pyrenees dogs
  - Storage pool diseases—Persian cats, American cocker spaniels, grey collie dogs.
  - CalDAG-GEFI thrombocytopathia—basset hound, spitz, and Landseer dogs.
  - Scott syndrome—German shepherd dog.
  - *P2Y12* (ADP) receptor mutation—greater Swiss mountain dog.

SIGNS

- Often mild spontaneous mucocutaneous bleeding (e.g., epistaxis, petechiation, gingival bleeding). Petechiae are not necessarily seen in animals with adequate circulating platelet number.
- Prolonged bleeding in some animals during or following diagnostic or surgical procedures.
- In Scott syndrome, postoperative hemorrhage is the most common sign.
- Bleeding diathesis can be more severe in acquired systemic conditions, as other components of coagulation can be affected as well.

CAUSES & RISK FACTORS

Acquired—Drugs

- Nonsteroidal anti-inflammatory drugs (NSAIDS; e.g., aspirin) inhibit platelet function by preventing the formation of thromboxane A_2. More selective cyclooxygenase 2 (COX-2) antagonists (e.g., meloxicam, deracoxib) have less effect on platelet function.
- Thienopyridine prodrugs (e.g. clopidogrel) inhibit the platelet P2Y12 ADP receptor.
- Hydroxyethyl starch (HES) solutions suppress platelet function in dogs in addition to other anticoagulant effects, but increased risk of bleeding is variable and prolonged with HES of higher molecular weight and higher molar substitution.
- *n*3 fatty acids have a mild thrombocytopathic effect in dogs that is not associated with clinical bleeding.
- Penicillins, tetracyclines, potentiated sulfonamides, anesthetic/sedative agents, and antihistamines cause mild platelet function defects in humans. Adverse effects of carbenicillin and ticarcillin have been documented in dogs and have not been investigated in cats.

Acquired—Secondary to Systemic Disease

Disseminated intravascular coagulation (DIC), uremia, anemia, liver disease (cholestasis and acquired or inherited shunts), ehrlichiosis, leishmaniasis, heart disease, immune-mediated thrombocytopenia, and neoplastic disorders (both hematopoietic and nonhematopoietic neoplasms) may alter platelet function.

Hereditary

- VWD (Doberman pinschers, German shorthair pointers, many other breeds)—a deficiency (type I and III) or qualitative defect (type II) of von Willebrand factor (VWF) prevents platelet adhesion to areas of vascular injury.
- CalDAG-GEFI hereditary thrombocytopathia (basset hound and Landseer dogs)—mutations in signal transduction in platelets, preventing platelet activation.
- Type I Glanzmann thrombasthenia (otterhound and great Pyrenees dogs)—platelet defect caused by a mutation in glycoprotein IIb–IIIa (fibrinogen receptor) on the platelet surface.
- Bernard Soulier syndrome (English cocker spaniel)—mutation in glycoprotein IX (VWF receptor complex) on the platelet surface prevents platelet adhesion.
- Chediak-Higashi syndrome, cyclic hematopoiesis, and dense granule defect (Persian cats, grey collie dogs, and American cocker spaniels, respectively)—deficiency (Chediak-Higashi syndrome, cyclic hematopoiesis) or functional defect (dense granule defect) of delta-granules in platelets results in inability to activate additional platelets at site of vascular injury.
- Scott syndrome (German shepherd dog)—platelet procoagulant deficiency resulting in failure to externalize phosphatidylserine, generate microparticles, and support effective assembly of coagulation complexes, caused by a *TMEM16F* mutation.
- *P2Y12* receptor mutation (greater Swiss mountain dog)—multifactorial defect; platelets are not activated by ADP.

DIAGNOSIS

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia, if bleeding is severe.
- Platelet counts typically normal in dogs with inherited thrombocytopathies, but thrombocytopenia seen following hemorrhage; bizarre and giant platelets may be seen.
- Biochemical profile—no specific changes.
- Urinalysis—hematuria.

OTHER LABORATORY TESTS

- Platelet function testing— may be used to diagnose hereditary and acquired defects, and to monitor effects of antiplatelet drugs:
  - Performed in specialized laboratories; requires freshly collected blood samples.
  - Platelet function analyzer-100, -200—sensitive to decreased platelet function, VWD, and anemia.
  - Aggregometry (light transmittance or impedance)—measures platelet response to different agonists (stimulants), using platelet-rich plasma or whole blood. Sensitive to specific drug effects (e.g., clopidogrel), receptor defects (e.g., ADP receptor).
  - Plateletworks—measures percent aggregation using whole blood platelet counting by routine impedance or optical hematology analyzers, and is available to some general practices.
  - Platelet indices (e.g., mean platelet volume, platelet volume distribution width, mean platelet component concentration)—variables helpful in characterizing platelet size, shape and activation (provided with some optical based hematology analyzers).
- Flow cytometry—for the detection of surface markers (e.g., glycoproteins), such as the fibrinogen receptor, P-selectin, or phosphatidylserine. Sensitive to Scott syndrome, fibrinogen receptor defects. Remote testing (P-selectin) shows promise for testing drug-effect (clopidogrel).
- VWF antigen by immunoassay—in animals suspected of VWD.
- Coagulation tests (prothrombin time [PT], activated partial thromboplastin time [aPTT], thromboelastography) [TEG]—to eliminate coagulopathy as a cause of hemorrhage; aPTT may be prolonged in some animals with VWD (due to decreased factor VIII–VWF binding, causing decreased factor VIII stability).
- Blood type: for animals who will require blood transfusion. There is no association of

THROMBOCYTOPATHIES (CONTINUED)

blood type with platelet function, however, some platelet products may contain red blood cells.
• Genetic testing of carrier animals.

DIAGNOSTIC PROCEDURES

Buccal mucosal bleeding time (BMBT)—to generally assess platelet function. Sensitive to platelet function defects and VWD, but also prolonged by thrombocytopenia. Measured using a spring-loaded lancet that makes a 5 mm long by 1 mm deep incision in the buccal (dog) or oral (cat) mucosa. The incision is observed until bleeding stops by the formation of a platelet plug. Normal BMBTs are less than 4–5 minutes in dogs and less than 2–3 minutes in cats. The BMBT can also be affected by hematocrit and blood viscosity, and results can vary between operators.

TREATMENT

• Transfusion—20 mL/kg (minimum of 10 mL/kg) platelet-rich plasma, or 1 unit/10 kg (minimum 1 unit/30 kg) cryoprecipitate, or 5.5 × 10^{10} platelets/10 kg body weight given as fresh platelet concentrate (may be available in some areas).
  ◦ DMSO-stabilized cryopreserved and lyophilized platelets are available in some countries; these products have less functional activity than fresh platelets but may be useful for correcting hemorrhage.
• Whole blood or packed red blood cell transfusion to correct anemia or if other platelet-containing products are not available. Fresh packed red blood cells also contain platelets in the sedimented pellet, and may be given for patients where volume overload is a concern.
• Cryoprecipitate—for elective surgeries in dogs with VWD, cryoprecipitate should be administered prior to the procedure and continued through to the postoperative period (see above).
• In animals with acquired platelet function disorders, treat the underlying disease process or withdraw the offending agent.
• Elective surgical procedures should be avoided or accompanied by appropriate transfusion products.
• Restrict activity during a bleeding episode.

MEDICATIONS

DRUG(S) OF CHOICE

• Desmopressin (DDAVP):
  ◦ 1 µg/kg SC, or IV diluted in 20 mL saline and administered over 10 minutes to dogs with VWD during a bleeding episode or in dogs with VWD requiring emergency surgery.
  ◦ 3 µg/kg SC in dogs with thrombocytopathia due to aspirin, liver disease, and a consideration in dogs with other thrombocytopathias.
• Antifibrinolytic agents (aminocaproic acid, tranexamic acid)—prevents clots from rapid breakdown, more commonly used to treat coagulopathies. The injectable preparations of each drug can be used topically in areas of bleeding (e.g., oral mucosa). Empirical data are lacking for dogs and cats. Both drugs are contraindicated in DIC, and should be used cautiously in cats:
  ◦ Aminocaproic acid 50–100 mg/kg PO, IV q6h; or 100 mg/kg IV followed by 30 mg/kg/h IV.
  ◦ Tranexamic acid 20 mg/kg PO, IV q8h, given over 30 minutes to minimize emesis.

FOLLOW-UP

• Take special precautions when performing surgical procedures on these animals. Have type-specific blood and cryoprecipitate available if indicated.
• Make owner aware that animals with hereditary platelet function defects may have recurring bleeding episodes. Fatal episodes are uncommon.
• If a hereditary defect is identified, the animal should not be used for breeding.

MISCELLANEOUS

SEE ALSO

• Chediak-Higashi Syndrome.
• Cyclic Hematopoiesis.
• Thrombocytopenia.
• Von Willebrand Disease.

ABBREVIATIONS

• aPTT = activated partial thromboplastin time.
• BMBT = buccal mucosal bleeding time.
• DDAVP = 1-desamino-8-D-arginine vasopressin.
• DIC = disseminated intravascular coagulation.
• NSAID = nonsteroidal anti-inflammatory drug.
• PT = prothrombin time.
• TEG = thromboelastography.
• VWD = von Willebrand disease.
• VWF = von Willebrand factor.

T

THROMBOCYTOPENIA

BASICS

DEFINITION
Platelet count below the reference interval, which varies by laboratory and methodology.

PATHOPHYSIOLOGY
- Platelets are produced by bone marrow megakaryocytes and released into the blood, where they normally circulate for 5–10 days.
- Thrombocytopenia is caused by one or more of: decreased production, increased sequestration, utilization, or destruction of platelets.
- Thrombocytopenia may result in spontaneous or excessive hemorrhage.

SYSTEMS AFFECTED
Hemorrhage may occur into any organ system. Clinical hemorrhage is most commonly recognized in the skin (petechiae, ecchymoses) and from mucosal surfaces of the gastrointestinal, renal/urologic, and respiratory systems; less commonly recognized in the ophthalmic, nervous, and reproductive systems.

INCIDENCE/PREVALENCE
- Thrombocytopenia is a common hematologic abnormality.
- Severe hemorrhage due to thrombocytopenia is uncommon to rare.

SIGNALMENT

Species
Dogs and cats.

Breed Predilections
Asymptomatic thrombocytopenias may be present in cavalier King Charles spaniels (see Pseudomacrothrombocytopenia [Inherited Macrothrombocytopenia]), greyhounds, Polish ogar dogs, Akitas.

SIGNS

General Comments
- Mild, moderate, and severe risk of spontaneous clinical hemorrhage at platelet counts of <25,000/µL, <10,000/µL, and <5,000/µL, respectively. These figures are guidelines only because of variation in methods of platelet counting, imprecision of low platelet counts, and individual animal variation.
- Concurrent platelet function defect, von Willebrand disease, coagulopathy, vasculitis, or sepsis increases risk of hemorrhage.

Historical Findings
- Spontaneous or excessive bleeding, generally from mucosal surfaces.
- Lethargy and collapse.
- Dyspnea and coughing (respiratory tract hemorrhage).
- Neurologic signs.
- Clinical signs of the primary disease.

Physical Examination Findings
- Petechiae and ecchymoses.
- Persistent bleeding from wounds and venipuncture sites.
- Melena/hematochezia/hematemesis.
- Hematuria.
- Ocular hemorrhage/hyphema.
- Splenomegaly, hepatomegaly.
- Pale mucous membranes.
- Weakness, collapse.
- Dyspnea, hemoptysis, epistaxis.
- Heart murmur (anemia).
- Neurologic abnormalities.

CAUSES
- Decreased production of platelets (may occur alone or with other cytopenias).
- Increased sequestration of platelets (splenomegaly, hypothermia).
- Increased utilization of platelets (e.g., DIC).
- Increased destruction of platelets (see Thrombocytopenia, Primary Immune-Mediated)—may be primary, or secondary to neoplasia, infectious agents, inflammation, drugs.
- Increased loss—volume resuscitation after massive bleeding.

RISK FACTORS
- Potentially any noninfectious inflammation, e.g., vasculitis, neoplasia.
- Potentially any infection—associated with feline leukemia virus (FeLV), feline immunodeficiency virus, distemper, parvoviruses, *Ehrlichia* spp., *Anaplasma* spp., *Rickettsia rickettsia*, leptospirosis, *Borrelia burgdorferi*, histoplasmosis, *Cytauxzoon felis*, *Babesia* spp., *Rangelia* spp., *Hepatozoon canis*, *Leishmania* spp., *Theileria* spp., heartworm, *Angiostrongylus vasorum*, and *Cuterebra* spp. (especially small dogs).
- Potentially any neoplasm.
- Large-field radiation therapy, cytotoxic drug therapy.
- Potentially any drug, especially sulfa-containing drugs, estrogens, gold compounds, phenylbutazone, phenobarbital (dogs); chloramphenicol, griseofulvin, propylthiouracil, methimazole and carbimazole (cats).
- Toxins and venoms—crotalid envenomation, zinc, autumn crocus, mycotoxins, xylitol.
- Hyperthermia (heat stroke).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Measurement error due to platelet clumping—more likely with traumatic venipuncture and in cats.
- Von Willebrand disease.
- Coagulopathy—petechiae, gastrointestinal hemorrhage, and epistaxis unusual; subcutaneous swellings, intracavity hemorrhage may be present.
- Trauma.

CBC/BIOCHEMISTRY/URINALYSIS
Confirm analyzer thrombocytopenia by examination of a blood smear; inspect feathered edge for platelet clumps; estimate platelet count from red cell monolayer; each platelet-per-oil immersion field represents 15,000–25,000/µL.
- Plateletcrit (analogous to hematocrit) reflects platelet mass; decreased with thrombocytopenia; normal in dogs with macrothrombocytopenia.
- Abnormalities on biochemistry profile and urinalysis reflect primary disease or effects of hemorrhage.

OTHER LABORATORY TESTS
- Von Willebrand factor antigen.
- Coagulation analysis (prothrombin [PT] and activated partial thromboplastin [aPTT] times, activated clotting time): prolonged results increase likelihood of disseminated intravascular coagulation (DIC); normal PT rules out vitamin K antagonism.
- D-dimers—positive result increases likelihood of DIC or local thrombosis.
- Serologic and PCR tests for infectious organisms.
- Fecal flotation and Baermann tests for parasitic larvae.
- Antiplatelet/antimegakaryocyte antibody tests—negative results help rule out immune-mediated thrombocytopenia (ITP).
- Coombs' test—positive result increases likelihood of concurrent immune-mediated hemolytic anemia.

IMAGING
Abdominal and thoracic radiographs, ultrasound, or 3D imaging can be useful in elucidating the underlying etiology.

DIAGNOSTIC PROCEDURES
Bone marrow aspirate or core biopsy—rule out reduced platelet production due to neoplasia, histoplasmosis, maturation arrest, bone marrow aplasia, myelofibrosis, and bone marrow necrosis. There is no specific finding that rules in or out immune-mediated megakaryocytic hypoplasia. Not contra-indicated in severe thrombocytopenia.

PATHOLOGIC FINDINGS
Secondary to hemorrhage.

TREATMENT

APPROPRIATE HEALTH CARE
- Treatment of primary disorder.
- Platelet transfusion—20 mL/kg (minimum 10 mL/kg) fresh whole blood or platelet-rich plasma, or 1 unit/10 kg (minimum 1 unit/30 kg) platelet concentrate (fresh, room-temperature stored, cryopreserved, or lyophilized products are all commercially available). While platelet

THROMBOCYTOPENIA (CONTINUED)

concentrate may increase platelet count, fresh whole blood is unlikely to cause a change in platelet numbers, although the transfused platelets may be enough to stop critical bleeding. Transfuse if critical hemorrhage is noted and consider prophylactic transfusion if platelet count <5,000–10,000/μL, especially if invasive procedures are planned. Transfusions may be needed q1–3 days if severe thrombocytopenia persists.
• Whole blood or packed red blood cell transfusion to correct anemia—bleeding due to thrombocytopenia is worse in the presence of anemia.
• Do not drain hematomas unless causing a problem (e.g., tracheal compression).

NURSING CARE
Minimize injections. Apply extended pressure after IV injection/catheterization and invasive procedures. Avoid jugular venipuncture and urine acquisition by cystocentesis.

ACTIVITY
Restrict activity in animals with moderate-to-severe thrombocytopenia.

DIET
Avoid hard foods and toys to minimize possibility for gingival bleeding.

SURGICAL CONSIDERATIONS
Extensive perioperative transfusion may be needed.

T

MEDICATIONS

DRUG(S) OF CHOICE
• See specific chapters for treatments of diseases causing thrombocytopenia.
• Acepromazine and trazadone have negligible effects on platelet function in dogs and cats and may be used to sedate animals to reduce risk of hemorrhage associated with excessive activity.

CONTRAINDICATIONS
• Opioids and gabapentin are preferred analgesic agents; if nonsteroidal anti-inflammatory drug (NSAID) use is required, selective cyclooxygenase-2 inhibitors (e.g., deracoxib) should be used to minimize effects on platelet function.
• Clopidogrel.
• *n*3 fatty acids have a mild negative effect on platelet function.

PRECAUTIONS
• Heparin may aggravate hemorrhage due to thrombocytopenia.
• Corticosteroid or other immunosuppressive therapy may promote infection and gastrointestinal ulceration.

POSSIBLE INTERACTIONS
• Antibiotics have negligible effects on platelet function in dogs and cats (see Thrombocytopathies).
• Gastroprotectants have negligible effects on platelet function.
• Common anesthetic agents have negligible effects on platelet function.
• Corticosteroids are generally considered to be prothrombotic.

ALTERNATIVE DRUG(S)
• Thrombopoietic stimulants—oprelvekin—50 μg/kg SC q24h for maximum of 2 weeks (to avoid risk of neutralizing antibody formation); most useful when thrombocytopenia caused by cytotoxic therapy; expensive.
• Fibrinolysis inhibitors—aminocaproic acid, tranexamic acid; contraindicated in DIC.
• Vincristine—0.02 mg/kg IV, once: may transiently increase platelet count in dogs with ITP; not indicated for other etiologies of thrombocytopenia, may cause leukopenia.
• Melatonin and 5-methoxytryptamine.
• Lithium is not recommended.

FOLLOW-UP

PATIENT MONITORING
• Amount of bleeding—control of clinical hemorrhage is most important parameter to monitor to judge effectiveness of treatment.
• Serial platelet counts using same method.
• Serial coagulation profiles if DIC is suspected.

PREVENTION/AVOIDANCE
Varies with cause.

POSSIBLE COMPLICATIONS
• Hemorrhagic shock.
• Uveitis.
• Neurologic abnormalities if hemorrhage in CNS.
• Dyspnea if hemorrhage into respiratory tract.

EXPECTED COURSE AND PROGNOSIS
Varies with cause. If the underlying cause of severe thrombocytopenia cannot be treated, prognosis is poor.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• If thrombocytopenia is due to reduced platelet production, other cytopenias may be present.
• ITP may be solitary or associated with other immune-mediated disorders.

AGE-RELATED FACTORS
Varies with cause—e.g., FeLV in younger cats, ITP in middle-aged dogs, neoplasia in older dogs.

ZOONOTIC POTENTIAL
None specifically, although some causes of thrombocytopenia (e,g, leptospirosis) may be due to a zoonosis.

SEE ALSO
• Disseminated Intravascular Coagulation.
• Hyphema.
• Pancytopenia.
• Petechia, Ecchymosis, Bruising.
• Pseudomacrothrombocytopenia (Inherited Macrothrombocytopenia).
• Splenomegaly.
• Thrombocytopathies.
• Thrombocytopenia, Primary Immune-Mediated.
• Vasculitis, Systemic (Including Phlebitis).
• Von Willebrand Disease.
And specific chapters for infectious diseases.

ABBREVIATIONS
• aPTT = activated partial thromboplastin time.
• DIC = disseminated intravascular coagulation.
• FeLV = feline leukemia virus.
• ITP = immune-mediated thrombocytopenia.
• NSAID = nonsteroidal anti-inflammatory drug.
• PT = prothrombin time.

THROMBOCYTOPENIA, PRIMARY IMMUNE-MEDIATED

BASICS

DEFINITION
• Immune-mediated destruction of platelets with no identifiable cause.
• In secondary immune-mediated thrombocytopenia (ITP), infectious diseases, neoplasia, vaccination, or drugs (e.g., sulfonamides, cephalosporins, phenobarbital, nonsteroidal anti-inflammatory drugs [NSAIDs]) trigger the production of antibodies.

PATHOPHYSIOLOGY
• Antiplatelet autoantibodies result in premature platelet destruction by splenic macrophages.
• In secondary ITP, platelet-bound antibodies can be antibodies bound to platelet antigens altered during course of disease or antibodies bound to foreign antigens or immune complexes.
• Autoantibodies can be directed against megakaryocytes.
• Antibody-mediated impairment of platelet function possible.

SYSTEMS AFFECTED
• Nervous.
• Gastrointestinal.
• Ophthalmic.
• Respiratory.
• Skin/exocrine.
• Renal/urologic.

GENETICS
Autoimmunity is frequently recognized in particular dog breeds and is often familial, suggesting a genetic influence.

PREVALENCE
Approximately 6% of dogs and 3% of cats with thrombocytopenia.

SIGNALMENT

Species
• Dog.
• Rare in cat.

Breed and Familial Predilections
Cocker spaniel, Maltese, bearded collie, poodle, Old English sheepdog, Irish setter.

Mean Age and Range
• Middle-aged dogs.
• Reported age range in dogs: 0.3–15 years (mean 5 years); in cats: 0.7–12 years (mean 6 years).

Predominant Sex
Female dogs.

SIGNS

Historical Findings
• Acute-onset mucosal hemorrhage.
• Chronic, low-grade blood loss.
• Lethargy, weakness, inappetence.
• Asymptomatic.
• Recent drug administration, vaccines, travel to tick-endemic area.

Physical Examination Findings
• Mucosal and cutaneous petechiae/ecchymoses.
• Melena, hematemesis, hematochezia.
• Epistaxis.
• Ocular hemorrhage, hyphema.
• Hematuria.
• Neurologic signs due to CNS bleeding.
• Dyspnea if bleeding into respiratory tract.
• Prolonged hemorrhage after trauma or venipuncture, hematoma formation.
• Hemorrhagic shock—pale mucous membrane, tachycardia, weak pulses.
• Fever.
• Palpably enlarged spleen.

DIAGNOSIS
• Severe thrombocytopenia (generally <20,000 platelets/μL).
• Careful exclusion of underlying diseases or potential triggers.
• Response to immunosuppressive therapy.

DIFFERENTIAL DIAGNOSIS
• Measurement error due to platelet clumping; especially in cats.
• Pseudomacrothrombocytopenia of cavalier King charles and English toy spaniels, Cairn and Norfolk terriers.
• Decreased production—infectious diseases, irradiation, primary bone marrow disorders (myelopthisis or myelofibrosis).
• Sequestration in the spleen.
• Increased utilization or consumption:
  ◦ Neoplasia, disseminated intravascular coagulation (DIC), thrombosis, vasculitis/vascular damage, infectious diseases.
  ◦ Severe hemorrhage or thrombosis may result in mild to moderate thrombocytopenia.

CBC/BIOCHEMISTRY/URINALYSIS
• Thrombocytopenia often severe (<20,000–30,000/μL), high risk of spontaneous bleeding.
• Blood smear examination—to confirm low platelet count; to identify potential causes for secondary ITP.
• Anemia may be present.
• Leukogram can be normal; mild to moderate leukocytosis in 30% of dogs.
• Concurrent neutropenia may indicate primary bone marrow or infectious disease.
• Coagulation testing generally normal; if abnormal consider secondary ITP, DIC.
• Chemistry results unspecific for ITP. Hypoproteinemia and hypoalbuminemia due to blood loss, hyperbilirubinemia due to hematoma resorption (rare), hyperglobulinemia may indicate underlying infectious disease (e.g., ehrlichiosis, leishmaniosis, feline infectious peritonitis [FIP]).
• Hematuria.

OTHER LABORATORY TESTS
• Infectious disease testing—secondary ITP reported in association with anaplasmosis, ehrlichiosis, Rocky Mountain spotted fever, bartonellosis, babesiosis, leishmaniosis, dirofilariasis, *Angiostrongylus* infection, distemper, infectious hepatitis, and bacterial infections in dogs; feline leukemia virus, feline immunodeficiency virus, and FIP in cats.
• Platelet-bound antibody detection—flow cytometric assay in specialized laboratories.
• Adjunct immunodiagnostic testing such as Coombs' test or antinuclear antibody titer if systemic lupus erythematosus is suspected.

IMAGING
• Splenomegaly, rarely hepatomegaly.
• Radiography and ultrasonography to exclude other causes of thrombocytopenia (e.g., neoplasia) or internal bleeding.

DIAGNOSTIC PROCEDURES
• Bone marrow evaluation not indicated with response to therapy; indicated if unexplained cytopenias or poor treatment response.
• Number of megakaryocytes increased unless immune reaction targeted against megakaryocytes.

TREATMENT

APPROPRIATE HEALTH CARE
• Uncomplicated cases with low bleeding risk and good owner compliance may be treated as outpatients.
• Patients with severe thrombocytopenia have very high risk of bleeding and warrant strict confinement.
• Management of hypovolemia with crystalloid solutions (colloids may impair platelet function).
• Packed red blood cells or whole blood to correct anemia.
• Transfusion of platelet products: 10–20 mL/kg fresh whole blood, 1 unit per 10 kg body weight of whole blood-derived platelet-rich plasma (containing approximately 8×10^{10} platelets/L) (minimum dose of 1 unit/30 kg) in animals with critical hemorrhage (caution if risk of hypervolemia). Platelet concentrates (lower total volume) if available. Platelets may be destroyed rapidly but may protect against catastrophic hemorrhage. DMSO-stabilized and lyophilized platelet concentrates are commercially available in the United States.

NURSING CARE
• Limit IM or SC injections. Apply extended pressure after IV injections. Avoid cystocentesis and jugular venipuncture. Bone marrow aspiration is safe.
• Intensive nursing care in patients with moderate to severe hemorrhage, hypovolemia, CNS abnormalities.
• Avoid hard foods, chew toys.

THROMBOCYTOPENIA, PRIMARY IMMUNE-MEDIATED (CONTINUED)

SURGICAL CONSIDERATIONS

- Splenectomy is a controversial option for refractory cases not responding to medical therapy.
- High risk of bleeding in dogs with severe thrombocytopenia.
- May need extensive peri- and intraoperative transfusions with red blood cells and platelets.

MEDICATIONS

DRUG(S) OF CHOICE

- Immunosuppression:
  - Corticosteroids—methyl prednisolone 10 mg/kg IV once or dexamethasone 0.2–0.3 mg/kg q24h, IV until able to take oral medication; prednisolone or prednisone (dogs 1 mg/kg PO q12h; cats 1.5–2 mg/kg PO q12h initially).
  - Additional or long-term therapy, usually in combination with corticosteroid (initial dosages)—cyclosporine 5 mg/kg PO q12h (dogs), mycophenolate mofetil 8–10 mg/kg PO q12h (dogs/cats), can also be given in the acute setting at 7–10 mg/kg IV q12h, azathioprine 2 mg/kg PO q24h (dogs), leflunomide 2–3 mg/kg PO q24h (dogs), chlorambucil 0.1–0.2 mg/kg PO q24h (cats).
- Other acute management—vincristine 0.02 mg/kg IV once (dogs) or human IV immunoglobulin (hIVIG) 0.5–1 g/kg over 6–8h once (dogs/cats).
- Antibiotics—consider doxycycline 5 mg/kg PO q12h if tick-borne disease is possible.
- Gastrointestinal protectants—sucralfate 20–50 mg/kg PO q6–8h or proton pump inhibitors (omeprazole 1 mg/kg PO q12h; pantoprazole 1 mg/kg IV/PO q12h).
- Once the platelet count is within the reference interval, the initial prednis(ol)one dose should be tapered by approximately 1/4 to 1/5 every 2 weeks, finally switching to alternate-day therapy. This and other therapies should be tapered slowly over approximately 6 months if no relapse.

PRECAUTIONS

- Discontinue any unnecessary medications.
- Corticosteroids—gastrointestinal ulceration; iatrogenic hyperadrenocorticism.
- Immunosuppression—predisposes to opportunistic infections, mycophenolate associated with gastrointestinal upset.
- Cytotoxic medications (azathioprine, mycophenolate mofetil, chlorambucil, vincristine)—bone marrow suppression.
- Dose tapering too rapidly after remission may predispose to recurrence.

FOLLOW-UP

PATIENT MONITORING

- Hematocrit measurements and physical examination as indicated in cases with severe hemorrhage.
- Measure platelet count daily until >50,000/µL; then every few days until platelet counts normalize. Then every 1–3 weeks during the period of drug dose tapering.
- CBC and biochemistry every 2–4 weeks.
- Urinalysis every 4–6 weeks due to risk of secondary infections.

PREVENTION/AVOIDANCE

Use vaccines judiciously. Role in recurrence is uncertain.

POSSIBLE COMPLICATIONS

- Spontaneous bleeding in specific areas (CNS, lungs) can be fatal.
- Side effects of medications.

EXPECTED COURSE AND PROGNOSIS

- Platelet counts will usually increase >50,000/µL a few days after starting treatment.
- Vincristine or hIVIG in addition to prednisone led to a shorter hospital stay or more rapid increase to 50,000 platelets/µL (median 2.5–4 days), respectively.
- Most dogs achieve normal platelet counts.
- Failure to respond to therapy should prompt diagnostic reconsideration.
- 5 of 19 dogs (26%) relapsed after 19–286, median 66 days; causes for relapse were dose reduction of immunosuppression, lack of owner compliance.
- If relapses occur, add a second immunosuppressive drug.
- Survival to discharge in recent studies—84–97% (dogs); prognosis is more favorable with intensive therapy including blood/platelet products if needed.
- Mortality rate in cats is 15% (2/13).

MISCELLANEOUS

ASSOCIATED CONDITIONS

Evans syndrome describes a rare occurrence of immune-mediated hemolytic anemia with ITP.

SYNONYMS

- Autoimmune thrombocytopenia.
- Idiopathic/autoimmune thrombocytopenic purpura.

SEE ALSO

- Disseminated Intravascular Coagulation.
- Lupus Erythematosus, Systemic (SLE).
- Pseudomacrothrombocytopenia (Inherited Macrothrombocytopenia).
- Thrombocytopenia.

ABBREVIATIONS

- DIC = disseminated intravascular coagulation.
- FIP = feline infectious peritonitis.

Client Education Handout available online

THROMBOCYTOSIS

BASICS

OVERVIEW

- Platelet count above the upper limit of the reference interval, which varies with the method of individual reference laboratories and methodologies.
- Reference intervals may be shifted upwards at high altitudes.

Pathophysiology

- Platelets are produced by megakaryocytes in the bone marrow and circulate for approximately 5–7 days. Approximately 30% of the circulating platelet mass resides transiently in the spleen and may be released suddenly with splenic contraction.
- Platelet production is stimulated by thrombopoietin (TPO).
- Thrombocytosis can be physiologic or reactive. Causes include physiologic redistribution, inflammation, and neoplasia.
- In humans, specific gene mutations have been associated with the development of essential thrombocytosis.

Systems Affected

- Hematologic—high circulating platelet count may impair ordinary hemostatic processes (especially von Willebrand factor-mediated platelet adhesion).
- Cardiovascular—thrombosis or hemorrhage: uncommon.

Incidence/Prevalence

Reactive thrombocytosis is common in cats and dogs.

SIGNALMENT

Cats and dogs.

SIGNS

Historical and physical exam findings are related to underlying causes associated with the thrombocytosis or sequelae of micro or macrovascular thrombosis (e.g., organ failure, ischemic events) or hemorrhage.

CAUSES & RISK FACTORS

Physiologic Thrombocytosis

Occurs secondary to redistribution of platelets from the spleen into circulation, secondary to splenic contraction associated with stress, exercise, or excitement.

Reactive Thrombocytosis

Occurs secondary to other conditions and may be short- or longstanding. Platelet elevations are typically mild to moderate and do not generally pose a risk for thrombosis. Causes of reactive thrombocytosis include:

- Inflammation secondary to infection, immune-mediated disease, surgery, trauma, or neoplasia. Inflammatory cytokines (e.g., interleukin-6) stimulate TPO production, which stimulates platelet production. The most common inflammatory diseases resulting in thrombocytosis in dogs are immune-mediated, gastrointestinal, and hepatobiliary in nature. In cats, gastrointestinal illness (involving intestinal, hepatobiliary and/or pancreatic diseases) is the most common disease category associated with thrombocytosis.
- Iron deficiency is a common but inconsistent cause of thrombocytosis.
- Recovery from thrombocytopenia (rebound thrombocytosis). This occurs most commonly:
  - Post splenectomy (thrombocytosis may be marked and may persist for weeks).
  - Following withdrawal of myelosuppression.
  - During recovery from immune-mediated thrombocytopenia.
  - Following blood loss.
- Hypercortisolemia secondary to hyperadrenocorticism or corticosteroid administration in dogs. In cats, hyperthyroidism may be a cause.
- Nonhemic malignant neoplasia (paraneoplastic secondary to cytokines stimulating thrombopoiesis)—carcinoma is the most common neoplasm associated with thrombocytosis.

Drug-Induced

- Epinephrine.
- *Vinca* alkaloids (vincristine, vinblastine).

Hemic Neoplasia/Myeloproliferative Disease

- Chronic myeloproliferative diseases are uncommon and include essential thrombocythemia.
- Acute megakaryocytic leukemia—>30% of nucleated cells in bone marrow are megakaryoblasts; myelofibrosis may be present, and neoplastic megakaryoblasts may be present in circulation or other organs.
- Markedly elevated platelet counts have been reported with essential thrombocythemia and acute megakaryocytic leukemia ($1–5 \times 10^6$ platelets/μL).

Pseudothrombocytosis

An artifactual increase in machine-based platelet count caused by red or white blood cell fragments and lipid particles associated with marked hyperchylomicronemia. A microscopic blood smear exam is required to properly identify this phenomenon.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Measurement error (pseudothrombocytosis) secondary to presence of cellular fragments or clerical error—a microscopic blood smear exam should be performed to confirm thrombocytosis when reported.

CBC/BIOCHEMISTRY/URINALYSIS

- Confirm thrombocytosis reported by a hematology analyzer by microscopic blood smear review.
- Hyperkalemia—an artifactual increase in serum potassium concentration can occur secondary to thrombocytosis due to release of intraplatelet potassium during clotting. Measurement of potassium using heparinized plasma is preferred to avoid this artifact.

OTHER LABORATORY TESTS

Use to identify underlying causes of reactive or neoplastic thrombocytosis. A diagnosis of essential thrombocytosis is generally one of exclusion.

DIAGNOSTIC PROCEDURES

Bone marrow examination—aspiration and core biopsy may be indicated with sustained extreme thrombocytosis to identify morphologic abnormalities that may be consistent with hemic neoplasia, dysplasia, or myelofibrosis.

TREATMENT

N/A

MEDICATIONS

DRUG(S) OF CHOICE

- If micro- or macrovascular thromboembolic complications are suspected, antiplatelet agents (e.g., clopidogrel, aspirin) may be indicated, although their use in humans with thrombocytosis has been associated with more severe hemorrhagic complications. Consultation with a veterinary specialist is highly recommended to determine if and which therapy may be indicated.
- Hydroxyurea is a chemotherapy drug that is used for cytoreductive therapy in humans with essential thrombocytosis. Published dosage recommendations for veterinary species vary widely. It is generally myelosuppressive, however, and will affect all cell lines. Consultation with a veterinary specialist is recommended regarding the administration and dosage of this drug. A comprehensive CBC every 1–2 weeks is recommended while taking hydroxyurea until platelet count stabilizes. Regular assessment of a serum biochemical profile is also recommended if using this drug.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Caution is recommended for the use of hydroxyurea in patients with anemia, preexisting bone marrow depression, history of urate stones, current infection, impaired

THROMBOCYTOSIS (CONTINUED)

renal function, or with previous chemotherapy or radiation therapy.

Adverse Effects

- Gastrointestinal effects of hydroxyurea may include anorexia, vomiting, or diarrhea.
- Additional adverse effects include stomatitis, sloughing of toenails, loss of fur, and dysuria.
- Bone marrow supression (anemia, thrombocytopenia, leukopenia) and lung damage (pulmonary fibrosis) are the most serious potential adverse effects of hydroxyurea. Therapy should be discontinued until values return to normal.
- Life-threatening methemoglobinemia has been reported in cats given high dosages (>500 mg) of hydroxyurea.

Precautions

- Concurrent use of hydroxyurea with other bone marrow depressant drugs may cause additive myelosuppression; use with caution.
- Hydroxyurea is a chemotherapy drug and a teratogen and contact may be hazardous to other animals and people that come in direct contact with it.

FOLLOW-UP

PATIENT MONITORING

Serial monitoring of comprehensive CBC for reassessment of thrombocytosis.

MISCELLANEOUS

ABBREVIATIONS

- TPO = thrombopoietin.

THUNDERSTORM AND NOISE PHOBIAS

BASICS

DEFINITION
Thunderstorm phobia is a disorder in which there is persistent and exaggerated fear of storms or the stimuli associated with storms. Fears of noises other than thunder also occur, such as fireworks or gunshots.

PATHOPHYSIOLOGY
Pathophysiology involves physiologic, emotional, and behavioral components. Overactivation of noradrenergic activity in the locus ceruleus is likely to be involved.

SYSTEMS AFFECTED
- Behavioral—avoidance or escape attempts, pacing, freezing, contact-seeking, vocalization.
- Cardiovascular—tachycardia.
- Endocrine/metabolic—increased cortisol levels, stress-induced hyperglycemia.
- Gastrointestinal (GI)—inappetence, GI upset, hypersalivation.
- Musculoskeletal—self-induced trauma.
- Nervous—trembling, adrenergic/noradrenergic overstimulation.
- Respiratory—tachypnea.
- Skin—self-directed or accidental trauma, displacement grooming.

GENETICS
Familial patterns have been observed in dogs with noise phobias but the exact mechanisms of inheritance have not been established.

PREVALENCE
Fear responses to noises affect 23–50% of the canine population with storms, fireworks, vacuum cleaners and gunshots most commonly reported.

SIGNALMENT
- Occurs in dogs and cats but dogs more often presented for treatment. Cats with noise aversion might present with redirected aggression.
- No association with sex or neuter status.
- Any breed can be affected. In one study, thunderstorm phobias were most prevalent in herding breeds.
- Dogs may begin exhibiting signs as puppies but may not be presented until adulthood.

SIGNS

Historical Findings
- One or more of the following occurs during storms, or when exposed to the eliciting noise: panting, pacing, trembling, remaining near owner, hiding, salivating, destructiveness, vocalization, self-inflicted trauma, escape attempts and inappropriate elimination.
- Stimuli that can elicit fear during storms include rain, lightning, thunder, wind, and possibly static electricity and changes in barometric pressure.

Physical Examination Findings
Unremarkable, except self-inflicted or escape-related injuries.

CAUSES
May include combinations of the following:
- Lack of exposure to storms or noises early in development.
- Highly aversive experience, such as exposure to a violent storm.
- Genetic predisposition for emotional reactivity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Conditions causing similar behavioral responses include separation anxiety, barrier frustration, and other phobias.
- Medical conditions that present with similar signs include metabolic, cardiac, neurological, dermatologic, GI, or any condition that causes significant discomfort or pain.

CBC/BIOCHEMISTRY/URINALYSIS
Results should be within normal ranges.

OTHER LABORATORY TESTS
Tests for thyroid or adrenal disease may be indicated.

IMAGING
N/A except if indicated to rule out medical cause (e.g., pain).

DIAGNOSTIC PROCEDURES
- N/A except to rule out medical cause.
- Electrocardiogram prior to tricyclic antidepressant use if suspected cardiac conduction abnormalities.

TREATMENT

APPROPRIATE HEALTH CARE
Outpatient treatment. Supervision may be necessary to prevent self-injury and destructive behavior.

NURSING CARE
Wound care for self-trauma or any physical trauma sustained during escape attempts.

ACTIVITY
Avoid crate confinement if not comfortably adapted or if risk of injury.

CLIENT EDUCATION

Behavior Management
Minimize, mute, or avoid exposure to stimuli by:
- Housing to a room or confinement area where the pet is comfortable and settled including safe haven confinement training to prevent, reduce, or mute stimuli.
- Avoid crate confinement if risk of injury or increased anxiety.
- Stimuli might be masked or muted with window shutters, sound baffling, white noise, fan, music or products such as ear covers (e.g., Mutt Muffs, headphones) or eye covers (ThunderCap, Doggles).
- Distraction from stimuli with favored toys, play, or highly valued rewards.

Behavior Modification
- Training and behavior modification to help calm the pet and change the association with the stimulus from one that is negative to one that is positive. Any confrontation, corrections or punishment in training must be avoided as it will further add to fear, anxiety and negative associations with the stimulus.
- Desensitization involves exposure to a recording of the stimulus or the stimulus muted or at sufficient distance that the volume does not elicit fear. The volume is gradually increased only if the pet remains relaxed.
- Counterconditioning is the pairing (association) of a positive outcome with each exposure to the stimulus. Operant counter-conditioning involves teaching a response (sit, relax) that is incompatible with the fear response (e.g., go to bed/mat, sit/focus, or touch). Favored food rewards are often used to facilitate learning.
- Audio recordings of noises or storms are commercially available. Other noises or sounds might be reproduced for desensitization and counterconditioning (e.g., gunshots, vacuum cleaners, traffic noise) by controlling exposure with distance, location, or with sound muting/baffling.
- Improper use of these exercises can worsen the condition.
- Exercises will be ineffective if the animal does not react to recorded thunderstorm sounds.

MEDICATIONS

DRUG(S) OF CHOICE
- With the exception of dexmedetomidine oromucosal gel, use of medications is considered extra-label. Imepetoin is also approved for use for noise aversion but not yet available.
- Azapirones, tricyclic antidepressants (TCAs), and selective serotonin reuptake inhibitors (SSRIs) require 2–4 weeks for effect and must be given daily during storm season to control anxiety. They can be used in combination with faster acting medications.

Medications for Acute, Short-Term Control of Anxiety

Alpha-2 Adrenergic Agonists
- Dexmedetomidine oromucosal gel—dogs, 125 μg/m^2 onto oral mucosa PRN, can repeat

T

THUNDERSTORM AND NOISE PHOBIAS (CONTINUED)

dosing up to q2–3h up to 5 times per noise event.
• Clonidine—dogs, 0.01–0.05 mg/kg PO q6–24h PRN.

Benzodiazepines
• Alprazolam—dogs, 0.02–0.1 mg/kg PO q4–12h PRN.
• Clonazepam—dogs, 0.05–0.25 mg/kg q8–12h PRN.
• Diazepam—dogs, 0.5–2 mg/kg PO q4–12h PRN.
• Lorazepam—dogs, 0.02–0.2 mg/kg PO q8–24h PRN.

Serotonin-2 Antagonist Reuptake Inhibitors (SARIs)
• Trazodone—dogs, 5–10 mg/kg PO PRN to q8–12h.

GABA Agonists
• Gabapentin—dogs, 20–30 mg/kg PO PRN to q12h; cats, 10–30 mg/kg PO PRN q24h.
• Imepitoin—partial GABA agonist—dogs, 20–30 mg/kg twice daily (begin up to 2 days in advance).

Phenothiazine Tranquilizers
• Acepromazine—dogs, 0.1–1 mg/kg PO q6–8h.
• Poor antianxiety properties.
• Use *only for* further sedation in conjunction with anxiolytic if needed to prevent injury.

T

Medications Used Daily or Throughout Thunderstorm Season

SSRIs
• Fluoxetine—dogs, 0.5–2 mg/kg PO q24h; cats, 0.5–1 mg/kg PO q24h.
• Paroxetine—dogs, 0.5–2 mg/kg PO q12h; cats, 0.5–1 mg/kg PO q24h.
• Side effects—inappetence and irritability.

TCAs
• Clomipramine—dogs, 1–3 mg/kg PO q12h; cats, 2.5–5 mg/cat PO q24h.
• Side effects—sedation, GI, and anticholinergic effects, and cardiac conduction disturbances.

GABA Agonists
Gabapentin—dogs 10–20 mg/kg PO q12h; cats, 5–10 mg/kg PO q12h.

CONTRAINDICATIONS
• Avoid using TCAs and phenothiazines in breeding males, patients with seizure disorders, cardiac disease, diabetes mellitus, glaucoma, or thyroid disease.

PRECAUTIONS
• Use benzodiazepines with caution in cats due to risk of hepatic necrosis.
• Use benzodiazepines with caution in aggressive dogs—disinhibition of aggression possible.
• Decrease dose or avoid use of these medications in geriatric patients and patients with impaired hepatic or renal function.

POSSIBLE INTERACTIONS
• TCAs, SSRIs, SARIs, and phenothiazines should never be combined with monoamine oxidase inhibitors.

ALTERNATIVE DRUG(S)
For adjunctive therapy in combination with drugs, environmental management and counterconditioning, natural therapeutic options that may aid in reducing anxiety including L-theanine alone or in combination with product containing whey protein, and *Phellodendron amurense* and *Magnolia officinalis*, alpha-casozepine alone or in diets combined with L-tryptophan, melatonin. Also for cats: feline F3 facial pheromone. Also for dogs: dog appeasing pheromone, *Souroubea* and *Plantanus*, a calming probiotic, aromatherapy (e.g., with lavender), pressure wraps or the Calmz anxiety relief system.

FOLLOW-UP

PATIENT MONITORING
With medication use, CBC and biochemistry profiles should be monitored periodically.

PREVENTION/AVOIDANCE
Puppies and kittens should be exposed to a variety of stimuli under benign conditions, including puppy and kitten classes.

POSSIBLE COMPLICATIONS
Severe injuries and property damage.

EXPECTED COURSE AND PROGNOSIS
Prognosis depends on severity, duration, and the ability to prevent injuries. The condition can progress if left untreated.

MISCELLANEOUS

SEE ALSO
Fears, Phobias, and Anxieties—Dogs.

ABBREVIATIONS
• GI = gastrointestinal.
• SARI = serotonin-2 antagonist reuptake inhibitor.
• SSRI = selective serotonin reuptake inhibitor.
• TCA = tricyclic antidepressant.

Author Lynne M. Seibert
Consulting Editor Gary M. Landsberg

THYMOMA

BASICS

OVERVIEW
- Originates from thymic epithelium, rarely metastasizes.
- Infiltrated with mature lymphocytes.
- May be associated with paraneoplastic syndromes (myasthenia gravis, hypercalcemia of malignancy).
- Classified as invasive (malignant) or noninvasive (benign).

SIGNALMENT
- Rare in dog and cat.
- Most common in medium- and large-breed dogs (especially Labrador and golden retrievers).
- Dogs—mean age 9.5 years.
- Cats—mean age 10 years.

SIGNS
- From physical presence of tumor—coughing, tachypnea, dyspnea.
- Secondary to obstruction of cranial vena cava—swelling of the head, neck, or forelimbs (dependent edema).
- Paraneoplastic syndromes (hypercalcemia or immune-mediated disease).
- Muscle weakness and megaesophagus caused by myasthenia gravis (~20%), hypercalcemia (causing polyuria/polydipsia), polymyositis, skin disease (especially in cats: exfoliative dermatitis and pemphigus vulgaris), hypergammaglobulinemia.
- Myasthenia gravis most often pre-op in dogs but can develop post-op in cats.

CAUSES & RISK FACTORS
N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Lymphoma (main rule-out).
- Branchial cyst.
- Ectopic thyroid carcinoma.
- Chemodectoma.
- Various subtypes of sarcoma.
- Mesothelioma.
- Non-neoplastic granuloma, abscess, or cyst.

CBC/BIOCHEMISTRY/URINALYSIS
- Lymphocytosis—occasionally (<5%).
- Intermittent basophilia—one case report.
- Hypercalcemia ~30%.

OTHER LABORATORY TESTS
- Antibody titers to acetylcholine receptors to confirm myasthenia gravis.
- Ultrasound-guided fine-needle aspiration and cytology of the mass—characterized by small lymphocytes, scattered mast cells, often with plasma cells and up to 60% will have an epithelial population (vs. a pure population of lymphoblasts with lymphoma). Thymomas can be cavitated/cystic, whereas lymphoma is usually homogeneous upon sonographic evaluation.
- Biopsy may be needed to confirm diagnosis and immunohistochemical stains (cytokeratin, lymphocyte CD markers) can be used.
- Flow cytometry of mass aspirate can confirm as a minimally invasive test (usually polyclonal CD4+ and CD8+ whereas lymphoma usually not); consider PCR for antigen receptor rearrangements to rule out lymphoma.

IMAGING
- Thoracic radiography—typically reveals a cranial mediastinal mass with dorsal deviation of the trachea, and may show pleural effusion or megaesophagus.
- CT scan or MRI can be used prior to thoracotomy for surgical planning, though cannot predict ease of resection.

DIAGNOSTIC PROCEDURES
Tensilon test—evaluate for myasthenia gravis in patients with signs of muscle weakness, dysphagia, or regurgitation.

TREATMENT
- Inpatient.
- Surgical excision—treatment of choice, and possible in 70% of cases; use an intercostal approach for small masses and a sternotomy for large masses. Recurrence ~17%, median survival time 635 days overall not considering prognostic factors (compared to 76 days without surgery).
- Dogs with myasthenia gravis and aspiration pneumonia have a poorer prognosis with surgery. Myasthenia gravis and megaesophagus are not necessarily poor prognostic factors, but require more intensive husbandry practices.
- Radiotherapy—potentially beneficial by reducing the lymphoid component of the mass (50-75% of cases benefit); median survival time 248 days in dogs (though 75% alive at 1 year in one series) and 720 days in cats. Can be used after surgery if excision incomplete.

MEDICATIONS

DRUG(S) OF CHOICE
- Prednisone 20 mg/m^2 PO q48h and cyclophosphamide 50–100 mg/m^2 PO q48h—used in a very limited number of patients, two of which had a partial remission likely associated with lymphodepleting effects.
- Myasthenia gravis—treat with prednisone and anticholinesterase drugs until the tumor can be removed.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Immunosuppressive drugs—do not use to treat myasthenia gravis if aspiration pneumonia present.

FOLLOW-UP
- Thoracic radiography—every 3 months; monitor for recurrence.
- Cure—possible if tumor is surgically resectable; greater than 80% alive at 1 year if resectable and no associated megaesophagus; median survival >1800 days for cats and 800 to >1000 days for dogs; 10–20% recur and may respond favorably to a second surgery.
- Prognosis—stage affects outcome after surgery: if invading adjacent organs, disseminated in thorax, or metastatic, then guarded (median 224 days). Prolonged survival despite no/minimal therapy might result from the indolent nature of the tumor.
- Patients with high lymphocyte proportion in tumor have a more favorable prognosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Concurrent nonthymic tumors (27%), polymyositis, and other autoimmune diseases— variable, from less than 10% and up to 40% of patients.

SEE ALSO
Myasthenia Gravis.

Consulting Editor Timothy M. Fan

TICK BITE PARALYSIS

BASICS

DEFINITION
Flaccid, lower motor neuron tetraparesis to tetraplegia caused by salivary neurotoxins from certain species of female tick.

PATHOPHYSIOLOGY
- Presynaptic disorder—tick injects salivary neurotoxin that interferes with the depolarization/acetylcholine release from the presynaptic nerve terminal of the neuromuscular junction; this effect is probably associated with an interruption of the calcium flux across axonal membranes.
- Australian *Ixodes holocyclus* tick—neurotoxin (holocyclotoxin) effects are more pronounced at higher temperatures; one adult tick is sufficient to cause neurologic signs, but infestation with *I. holocyclus* larvae or nymphs can also induce signs; holocyclotoxin also interferes with acetylcholine release at the autonomic nerve terminals.
- Signs—5–9 days after initial tick attachment.
- Not all infested animals develop tick paralysis; not all adult female ticks produce the toxin.

SYSTEMS AFFECTED
- Nervous—peripheral nervous system and neuromuscular junction most affected; cranial nerves can become involved, including the vagus and facial nerves with the North American ticks and, in addition, the trigeminal nerves and sympathetic nervous system with the Australian *Ixodes* tick.
- Respiratory—may see paralysis of the intercostal muscles and diaphragm; caudal brainstem respiratory center may be affected (rare with North American ticks; more common with Australian *Ixodes* ticks).

GENETICS
No genetic basis.

INCIDENCE/PREVALENCE
- North America—somewhat seasonal (more prevalent in the summer months); in the warmer areas (southern United States) may become a year-round problem.
- Australia—distinctly seasonal, up to 75% of cases occur during southern hemisphere spring season (September–November).
- Overall incidence—low in the United States; higher in Australia.

GEOGRAPHIC DISTRIBUTION
- United States—*Dermacentor variabilis*: wide distribution over the eastern two-thirds of the country, California, and Oregon; *D. andersoni*: from the Cascades to the Rocky Mountains; *Amblyomma americanum*: from Texas and Missouri to the Atlantic Coast; *A. maculatum*: Atlantic and Gulf of Mexico seaboards.
- Australia—*I. holocyclus*: coastal areas of the east; *I. cornuatus,* southern Australia (Tasmania).
- Other—cases with apparent tick paralysis have been described in South Africa (*Rhipicentor nuttalli*), southern Italy (*Rhipicephalus sanguineus*), and Iran (*Ornithodorus lahorensis*).

SIGNALMENT

Species
- Australia—dogs and cats.
- United States—dogs; cats appear to be resistant.

Breed Predilections
None

Mean Age and Range
Any age.

Predominant Sex
N/A

SIGNS

Historical Findings
- Patient exposed to ticks (wooded area) approximately 1 week before onset of signs.
- Onset—gradual; starts with weakness in the pelvic limbs, progresses to the thoracic limbs within 12–72 hours.

Neurologic Examination Findings
North American Ticks
- Neurologic signs—rapidly ascending, flaccid generalized lower motor neuron tetraparesis to tetraplegia.
- Patient becomes extremely weak to recumbent in 1–3 days, with hyporeflexia to areflexia and hypotonia to atonia.
- Pain sensation preserved, no hyperesthesia.
- Cranial nerve dysfunction—uncommon; may note facial weakness and reduced jaw tone; sometimes dysphonia and dysphagia early in the course; megaesophagus uncommon.
- Urination and defecation usually normal.
- No cardiovascular effects.
- Respiratory paralysis—uncommon in the United States; may occur if ticks are not removed; death may occur in 1–5 days.

Australian Ticks
- Neurologic signs—much more severe and rapidly progressive; ascending motor weakness can progress to tetraplegia within a few hours.
- Sialosis, depressed gag reflex, dysphonia, megaesophagus, vomiting/regurgitation.
- Sympathetic nervous system—mydriatic and poorly responsive pupils (common in cats); hypertension; tachyarrhythmias; pulmonary edema.
- Urinary bladder dysfunction may be present.
- Caudal medullary respiratory center involvement—progressive reduction in respiratory rate and increased respiratory effort.
- Respiratory muscle paralysis—much more prevalent; dogs and cats progress to dyspnea, cyanosis, and respiratory paralysis within 1–2 days if not treated.

CAUSES

United States
- *D. variabilis*—common wood tick.
- *D. andersoni*—Rocky Mountain wood tick.
- *A. americanum*—lone star tick.
- *A. maculatum*—Gulf Coast tick.

Australia
- *I. holocyclus*—far more potent neurotoxin than that of the North American species.
- *I. cornuatus*—southern paralysis tick, occasionally causes paralysis in southern Australia.

RISK FACTORS
- Environments that harbor ticks.
- Australia—higher risk during spring, and in areas with higher rainfall, containing tree cover and areas of water; higher risk of death if dog <6 months old or a toy breed.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Botulism.
- Acute polyneuropathy.
- Acute polyradiculoneuritis (coonhound paralysis).
- Distal denervating disease.
- Fulminant myasthenia gravis.
- Generalized (diffuse) or multifocal myelopathy.
- Intoxications (coral snake, black widow spider, lasalocid, blue and green algae).

CBC/BIOCHEMISTRY/URINALYSIS
Normal

OTHER LABORATORY TESTS
Arterial blood gases—severely affected patients may show hypoventilation and respiratory acidosis (low Pao_2, high $Paco_2$, low pH).

IMAGING
Thoracic radiography (*Ixodes* ticks)—megaesophagus, aspiration pneumonia, pulmonary edema.

DIAGNOSTIC PROCEDURES
- History of exposure to ticks.
- Thoroughly search for a tick—head, neck, body and limbs, ear canals, mouth, rectum, vagina, prepuce, and in between the digits and footpads; clipping the entire fur may be needed; immediately remove tick.
- In some cases the offending tick may have dropped, a negative finding does not exclude tick paralysis.
- Electrodiagnostics—electromyogram; normal insertional activity without spontaneous myofiber activity; lack of motor unit action

(CONTINUED) TICK BITE PARALYSIS

potentials; motor nerve stimulation shows a dramatic decrease in amplitude or a complete absence of compound muscle action potentials; decrease in motor nerve conduction velocities; normal sensory conduction and repetitive nerve stimulation.

PATHOLOGIC FINDINGS
Pulmonary histopathologic findings in dead/euthanized dogs include diffuse bronchopneumonia, congestion, and alveolar edema.

TREATMENT

APPROPRIATE HEALTH CARE
- Inpatient—neurologic dysfunction suggesting tick paralysis; hospitalize until either a tick is found and removed or appropriate treatment to kill a hidden tick is performed.
- Remove tick with forceps, applying steady pressure, taking care to remove mouth parts.

NURSING CARE
- Inpatient supportive care—essential until patient begins to show signs of recovery.
- Oxygen cage—hypoventilation ($Paco_2$ <45 mmHg) and hypoxia.
- Mechanical ventilation—respiratory failure ($Paco_2$ >45 mmHg).
- IV fluid therapy—if patient unable to eat/drink due to dysphagia, vomiting/regurgitation.
- Prevention of aspiration pneumonia—elevated feedings if megaesophagus present.

ACTIVITY
- Keep patient in a quiet environment.
- *Ixodes* tick paralysis—keep patient in a cool, air-conditioned area (toxin is temperature sensitive).

DIET
Withhold food and water if patient has dysphagia or vomiting/regurgitation.

CLIENT EDUCATION
- Non-*Ixodes* tick—inform client that good nursing care is essential, although the patient's recovery is rapid (within 24–72 hours) after removal of ticks.
- *Ixodes* tick—warn client that cranial nerve signs and weakness often continue to worsen for 24–48 hours even after tick removal; inform client that aggressive treatment to neutralize the toxin must be undertaken, and that patient death may ensue even if appropriate therapy is initiated.

MEDICATIONS

DRUG(S) OF CHOICE
- United States—if the tick cannot be found, topically apply a systemic insecticide such as fipronil or, alternatively, dip the patient in an insecticidal bath; often the only treatment needed.
- Australia—in addition to tick removal and use of topical acaricides, treatment often includes the use of commercially available tick antitoxin hyperimmune serum (TAS) to neutralize circulating toxin (0.5–1 mg/kg IV), depending on severity of clinical signs; adverse reactions to TAS administration can be reduced by premedication with atropine; if severe sympathetic signs, use of phenoxybenzamine, an α-adrenergic antagonist (1 mg/kg IV diluted in saline and given slowly over 20 minutes) can be beneficial.

CONTRAINDICATIONS
Drugs that interfere with neuromuscular transmission (e.g., tetracycline, aminoglycosides, procaine penicillin).

PRECAUTIONS
Ixodes tick—administer IV fluids at a slow rate to avoid further complications of pulmonary edema.

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
- Non-*Ixodes* tick—reassess neurologic status daily after tick removal; should see rapid improvement in muscle strength.
- *Ixodes* tick—monitor neurologic status, respiratory and cardiovascular functions intensively even after tick removal, because of the residual effect of neurotoxin.

PREVENTION/AVOIDANCE
- Vigilantly check for ticks up to 5–9 days after exposure.
- Frequent search for ticks in endemic areas during spring/summer months.
- Routine topical application of acaricidal solution/collar, or weekly insecticidal baths.
- Short-term acquired immunity develops after exposure to *Ixodes* neurotoxin.

POSSIBLE COMPLICATIONS
No long-term complications if the patient survives the acute effects of the toxin.

EXPECTED COURSE AND PROGNOSIS
- Non-*Ixodes* tick—prognosis good to excellent if ticks are removed; recovery in 1–3 days.
- *Ixodes* tick—prognosis often guarded; recovery prolonged; removal of tick does not always result in improvement; respiratory paralysis main cause of death; death in 1–2 days without treatment; 5% mortality rate reported in affected dogs, fatality rate in affected cats appears lower.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
Although humans can acquire the disease by being bitten by the same ticks (especially in Australia), tick paralysis is not transmitted to humans from affected pets.

PREGNANCY/FERTILITY/BREEDING
Unknown

T

TICKS AND TICK CONTROL

BASICS

DEFINITION
• Arachnids, arthropod ectoparasites feed on the blood of their hosts.
• Most ticks are not host specific; divided into argasid (soft) and ixodid (hard) ticks.
• Argasid are more primitive, more commonly parasitize birds; one of importance in dogs and cats is spinous ear tick (*Otobius megnini*).
• Ixodid ticks are more specialized and highly parasitic, both sexes are bloodsuckers; *Rhipicephalus sanguineus* and *Dermacentor variabilis* are common in dogs and cats.

PATHOPHYSIOLOGY
• Blood-loss anemia—from heavy infestations.
• Damage to the integument—local irritation and infection may occur; tick adaptations suppress host response and allow feeding for up to 1 week.
• Salivary secretions—neurotoxins; other pharmacologically active compounds cause impaired hemostasis and immune suppression at the tick-feeding site.
• Pathogens—acquired when ticks feed on infected reservoir hosts (often rodents and small feral mammals); transmitted while feeding on dogs and cats.

T

Tick Biology
• Hard ticks—four life stages: egg, larva, nymph, and adult; larvae and nymphs feed to repletion before detaching and molting; after detachment, females lay thousands of eggs and die; various tick stages may survive over winter, tolerate long starvation, low humidity, as well as water deprivation. Completion of life cycle requires three hosts; some species pass all stages on the same mammal.
• Transovarial transmission—organisms disseminate to the ticks' ovaries; infected eggs hatch and produce infected larvae.
• Trans-stadial transmission—immature ticks become infected while feeding on reservoir hosts and maintain infection through the molt from one life stage to the next, transmitting organisms to the new host when next stage feeds.
• Ticks generally acquire hosts by a passive ambush process; when a suitable host brushes against vegetation harboring questing ticks, they transfer to the host.
• *Amblyomma americanum* can be an active hunter and traverse distances of up to 18 m to attack a suitable host.
• Symbiotic relationship—*Ixodes scapularis* infected with *Anaplasma phagocytophylum* express an antifreeze glycoprotein gene that enhances survival of the tick in cold weather.

SYSTEMS AFFECTED
• Skin/exocrine.
• Hemic/lymphatic/immune.
• Musculoskeletal.
• Nervous.

GEOGRAPHIC DISTRIBUTION
• Strong geographic specificities exist for some tick species and their associated pathogens, producing geographic prevalence of associated diseases.
• Ranges of ticks are expanding, therefore the geographic incidence of tick parasitism and infections vectored by them are expanding.
• Emergence of new tick-borne infections and coinfection (due to coinfected vector ticks or parasitism of hosts by ticks of more than one species).
• *I. scapularis* and *I. pacificus*—midwest, northeast, southeast, and south-central United States and west coast, respectively.
• *R. sanguineus*—throughout the continental United States; *R. sanguineus* is unique among hard ticks; it can survive and establish its life cycle inside dwellings and kennels at (low) household humidity (common name "kennel tick").
• *D. variabilis*—eastern seaboard and west coast of United States.
• *A. americanum*—found throughout the midwest, south-central, southeast, and parts of the northeast United States with strong range expansion.
• *Amblyomma maculatum*—gulf coast states of United States with range expansion.

SIGNALMENT

Species
• Dog and cat.
• Cats are efficient at removing ticks; tick attachment and tick-vectored diseases including Lyme disease, anaplasmosis, and cytauxzoonosis have been diagnosed in domestic felines.

SIGNS
• Attached ticks or tick-feeding cavities may be seen on the skin.
• Irritation secondary to bite.
• Petechia secondary to infectious organisms (*Rickettsia*, *Anaplasma platys*).
• Blood-loss anemia (direct effect); thrombocytopenia, anemia, inclusion bodies in neutrophils, monocytes, red blood cells secondary to transmitted infectious organisms.
• Limb/joint abnormalities secondary to infectious organisms (*Borrelia burgdorferi* and other organisms implicated in oligo- and polyarthritis).
• Cardiac—Lyme carditis (*B. burgdorferi*), manifests typically as atrioventricular block; rare and poorly documented in dogs.
• Renal—unique, generally fatal protein-losing nephropathy in dogs infected with *B. burgdorferi* linked to immune complexes associated with antigen and antibody from infection.
• Rocky Mountain Spotted Fever—vague or non-specific symptoms of fever, lethargy, joint pain, gastrointestinal symptoms, focal hemorrhages (Rickettsia rickettsii).
• Paralysis—neurotoxins secreted from tick salivary glands produce ascending weakness and paralysis.
• Pyogranulomatous myositis, periosteal reaction, neutrophilia, antigenic stimulation, and amyloid deposition in viscera in *Hepatozoon americanum* infection in which the dog serves as the intermediate and reservoir host following tick ingestion.
• Weight loss, anemia, lethargy, fever, neutrophilia, hyperglobulinemia and hypoalbuminemia in *Hepatozoon canis* infection. Infection occurs by digesting the tick (*A. americanum*), which is the definitive host.

CAUSES
Ticks—attracted to hosts by warmth, presence of carbon dioxide, physical contact, and host-associated odors.

RISK FACTORS
• Domestic animals—can be in close contact with ticks due to invasion of ticks into suburban environments and expansion of suburban environment into surrounding forests, prairies, and coastline areas.
• Travel—increases risk for exposure.
• Risk is expanding as new cycles for maintenance of infectious organisms are emerging (and being discovered).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
N/A

OTHER LABORATORY TESTS
• Vector-borne disease (VBD) panels provide clinicians the ability to test blood for multiple agents by using serology and/or PCR.
• IDEXX Snap 4DxPlus Test—in-office rapid screening test for multiple VBD; detects antibodies (C_6 ELISA) against *B. burgdorferi*, *E. canis*, *E. ewingii, A. phagocytophilum*, *A. platys*, and *Dirofilaria immitis* antigens in canine serum, plasma, or whole blood.
• ABAXIS VetScan FLEX4 Rapid T—detects antibodies against *A. phagocytophilum*, *A. platys*, *B. burgdorferi*, *E. canis*, *E. chaffeensis*, *E. ewingii*, and *Dirofilaria immitis* antigens in canine whole blood, serum or plasma.
• Tests are sensitive and specific; *B. burgdorferi* test does not crossreact with vaccine-induced antibodies.

TREATMENT

APPROPRIATE HEALTH CARE
• Outpatient after removal of ticks.
• Removal—as soon as possible to limit time available for pathogen or neurotoxin transmission; grasp ticks close to the skin with fine-pointed tweezers and gently pull free.

(CONTINUED) TICKS AND TICK CONTROL

NURSING CARE
Wash feeding cavity with soap and water; generally sufficient to prevent local inflammation or secondary infection.

CLIENT EDUCATION
Application of hot matches, petrolatum jelly, or other materials not only fails to cause tick detachment but allows for longer periods of attachment and feeding.

MEDICATIONS

DRUG(S) OF CHOICE
See Prevention/Avoidance.

FOLLOW-UP

PREVENTION/AVOIDANCE
- Perimeter control and avoiding environments that harbor ticks.
- Frequent tick checks and tick removal.
- Year-round tick prevention.
- Tick control does not always equal control of tick-borne diseases: Products should quickly kill or prevent attachment and feeding by the tick.
- Tick-borne pathogens—may be transmitted very rapidly (viruses) or require several hours (*R. rickettsii*), less than 1 day (*A. phagocytophilum*), 1–2 days (*B. burgdorferi*), or 2–3 days (*Ehrlichia* species and *B. canis*).
- Ingestion of infected ticks makes tick control problematic for prevention of infection with *Hepatozoon* species.

Insecticides and Acaricides
- Acaricides meant only for dogs must not be applied to cats.
- Acaricidal collars—amitraz, deltamethrine, and flumethrin (Preventic, Seresto, and Scalibor, respectively).
- Spot-on treatments—fipronil, permethrin, flumethrin, etofenprox.
- Oral treatments—isoxazolines: fluralaner, afoxolaner, lotilaner, and sarolaner. Fluralaner is also available as a spot-on for dogs and cats. Sarolaner combined with selamectin is available as a spot-on for cats.
- Disease transmission interruption studies have been published for products containing fipronil, amitraz, isoxazolines, permethrin, and synthetic pyrethroids; rapid killing and clinical repellence are essential to prevent or interrupt tick feeding.

POSSIBLE COMPLICATIONS
Tick-borne diseases or tick paralysis.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- Canine babesiosis—*B. canis*.
- Rocky Mountain spotted fever—*R. rickettsia*.
- Canine monocytic ehrlichiosis—*E. canis* or *E. chaffeensis*.
- Cyclic thrombocytopenia—*A. platys*.
- Granulocytic anaplasmosis—*A. phagocytophilum* and *E. ewingii*.
- Lyme disease—*B. burgdorferi*.
- American canine hepatozoonosis—caused by protozoa *H. americanum*, following ingestion of an infected *tick*.
- Canine hepatozoonosis— caused by *H. canis* following ingestion of an infected *tick*.
- Tick paralysis—caused by a neurotoxin; affects acetylcholine synthesis and/or liberation at the neuromuscular junction of the host animal; ascending flaccid paralysis initially affects the pelvic limbs 5–9 days after tick attachment.

VACCINES
Currently for Lyme disease there are three types for dogs: (1) whole-cell, killed bacterin: LymeVax, Duramune Lyme, and Nobivac Lyme, (2) outer surface protein A (OspA): Recombitek Lyme, and (3) chimeric recombinant (OspA and 7 types of OspC): Vanguard crLyme. Efficacy studies which duplicate natural exposure are lacking.

ZOONOTIC POTENTIAL
- Ticks may parasitize wildlife, domestic animals, or humans at different stages in their developmental cycles; infections acquired in early life stages may be transmitted when ticks feed again in the next stage.
- Humans, if parasitized, may be exposed to organisms in infected ticks. *B. burgdorferi*, *A. phagocytophilum*, *R. rickettsia*, and *E. chaffeensis* are also human pathogens.

SYNONYMS
Acariasis

SEE ALSO
- Babesiosis.
- Ehrlichiosis and Anaplasmosis.
- Lyme Borreliosis.
- Rocky Mountain Spotted Fever.

ABBREVIATIONS
- IFA = immunofluorescent antibody assay.

TOAD VENOM TOXICOSIS

BASICS

OVERVIEW

• Two species of primary concern in North America—Colorado River toad (*Incilius alvarius*) and marine/cane toad (*Rhinella marina*); marine toad more toxic; both can be fatal. • *I. alvarius* found in Arizona, New Mexico, Texas, and Colorado; *R. marina* found in Florida, Texas, and Hawaii. Both species have body lengths up to 23 cm; easily distinguishes them from other toad species. Active during periods of high humidity (monsoon season—late summer Arizona, New Mexico, Texas, and Colorado for Colorado River toads); most encounters occur during evening, night, or early morning. • Toxin—produced in parotid glands; defensive; rapidly absorbed across the victim's mucous membranes; contains several major components: indole alkyl amines (similar to the street drug LSD), cardiac glycosides, and noncardiac sterols. On average 590 mg of crude secretions released from a single *R. marina*—100 mg of crude bufotoxin lethal to 10–15 kg dog. Sublingual/buccal absorption—bypasses gastrointestinal tract; first pass metabolism allows systemic exposure to unmetabolized bufogens. Rapidly absorbed across gastrointestinal mucosa and quickly eliminated. Crosses blood–brain barrier readily (rapid CNS effects).

SIGNALMENT

Primarily dogs; rarely cats.

SIGNS

General Comments

• Rapid onset. • A cane toad sitting in a water dish for several hours can leave enough residual toxins to kill dogs. • Salivation primary sign—*excessive* within seconds of exposure. • Toxicity varies with species, size and geographical location. If not in one of the regions cited above, *unlikely* to contain highly toxic secretions.

Historical Findings

• Crying/pawing at the mouth. • Frothing at mouth. • Ataxia—stiff gaited. • Seizures. • Animal found dead with toad in mouth.

Physical Examination Findings

• Profuse hypersalivation. • Hyperexcitability/vocalization. • Brick red buccal mucous membranes. • Hyperthermia. • Collapse. • Marked cardiac ventricular arrhythmia—less common with Colorado River toad. • Cyanosis. • Dyspnea. • Mydriasis. • Nystagmus. • Pulmonary edema. • Neurological signs. • Shock.

CAUSES & RISK FACTORS

• Living in indigenous geographic region for species and in close proximity to toads. • Moist, warm, outside environment. • Outdoor animal.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Caustics or other oral irritants. • Hyperthermia. • Heat stroke. • Hypocalcemia. • Hypoglycemia. • Serotonin syndrome. • Organophosphate or carbamate pesticides.

CBC/BIOCHEMISTRY/URINALYSIS

• May note hypercalcemia or hyperkalemia. • Elevated serum glucose. • Elevated urea nitrogen.

OTHER LABORATORY TESTS

Magnesium level—ventricular cardiotoxicity cases.

DIAGNOSTIC PROCEDURES

Electrocardiogram—ventricular arrhythmias.

TREATMENT

• Marine toad intoxication—medical emergency; death common. • Decontamination—flush mouth for 5–10 minutes with copious quantities of water. • Hyperthermia (>40.6°C/105°F)—provide a cool bath; remove from bath once temperature reaches 39.4°C (103°F). • Maintain airway. • Rapid evaluation of cardiac function. • Supportive therapy—correct electrolytes; acid–base imbalances. • Ingested toad—may require endoscopic removal or surgery. • Seizure potential—*high* with the truly toxic toads; emesis only performed by DVM who understands this concept.

MEDICATIONS

DRUG(S) OF CHOICE

• Atropine 0.04 mg/kg (1/4 of dose IV, remainder IM or SC)—reduces salivation; helps prevent aspiration; use with bradycardia, heart block, or other sinoatrial node alterations as a result of the digitalis-like effect of the toxin; not recommended if severe tachycardia present. • Esmolol or propranolol—esmolol is very short acting and may be used as a test dose. If arrhythmia responds to treatment, propranolol is used because the duration of action is much longer (hours; see Contraindications/Possible Interactions); rapid administration may be required to combat tachyarrhythmias; may be repeated in 20 minutes or require continuous IV infusion for persistent arrhythmias: ○ Esmolol 0.05–0.1 mg/kg IV q5min—maximum dosage of 0.5 mg/kg. ○ Propranolol 0.02 mg/kg IV slowly as needed—maximum dosage of 1 mg/kg. • Digoxin-specific Fab fragments (Digoxin Immune Fab) have been used successfully to treat toad venom induced cardiotoxic effects. • Anticonvulsant therapy—diazepam 0.5–1.0 mg/kg IV. • Lipid emulsion (20%)— anecdotally, IV intralipids may reduce bufadienolide (very lipophilic) toxicity.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

• Cardiac disease or bronchial asthma—patient may not tolerate the use of beta-blockers such as esmolol and propranolol. Use a test dose of esmolol (very short duration of action) and monitor closely before using propranolol (much longer duration of action). • Anesthetics (e.g., pentobarbital)—may depress function of an already compromised myocardium; use with caution.

FOLLOW-UP

• Continuous electrocardiographic monitoring—recommend until patient is fully recovered. • Colorado River toad intoxication—patients usually normal within 30 minutes of onset of treatment; death uncommon if treated; do not underestimate the risk of secondary heatstroke. • Marine toad intoxication—medical emergency; death common.

TOOTH—MISSING

BASICS

OVERVIEW

- Absence of tooth or teeth due to developmental conditions, not to trauma or extraction:
  - Total anodontia—absence of all teeth due to failure in development.
  - Partial anodontia—failure in development of part of the dentition (hypodontia, oligodontia—some teeth missing).
  - Edentulous—"without teeth" but primarily due to tooth loss (e.g., end-stage periodontal disease).
- In dogs, premolars or distal molars are the most common missing teeth.
- If a deciduous tooth is missing, its permanent successor will probably not develop as well.
- If a permanent tooth is missing, and the deciduous tooth is still present (persistent), if root structure is stable, that deciduous tooth might stay functional for a long time; lack of permanent tooth should be documented.

SIGNALMENT

- Any breed, size or gender, but smaller breeds predominate.
- Some familial tendencies, breed prevalence.

SIGNS

- Tooth not present (crown and root).
- Alveolar bone and gingival margin at site is regular, smooth, even slightly "scalloped" appearance.
- No tooth structure present radiographically.

CAUSES & RISK FACTORS

- Dog/cat.
- Total and partial anodontia—typically hereditary and may be associated with ectodermal dysplasia (Chinese crested dogs).
- Bilateral patterns of missing teeth may be indicative of a genetic or familial tendency, as opposed to a single missing tooth.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Delayed eruption.
- Unerupted teeth (see Dentigerous Cyst).
- Invulsed tooth.
- Extracted or lost due to periodontal disease or trauma.
- Fusion tooth—if two teeth have fused, there will be reduction in the tooth number (see Tooth Formation/Structure, Abnormal).

CBC/BIOCHEMISTRY/URINALYSIS

Typically not affected.

IMAGING

- Intraoral radiographs essential.
- Determine if teeth are truly missing, and/or if permanent teeth are present, if deciduous teeth are persistent/retained.
- Pre-purchase full-mouth radiographs on 8- to 10-week-old puppies can identify if permanent tooth structures are present (though there is no guarantee they will erupt).

DIAGNOSTIC PROCEDURES

- Complete oral examination.
- Appropriate preoperative diagnostics when indicated prior to procedure.

TREATMENT

SURGICAL CONSIDERATIONS

- Appropriate antimicrobial and pain management therapy when indicated.
- Appropriate patient monitoring and support during anesthetic procedures.
- None indicated unless an unerupted or involved tooth is found radiographically.

MEDICATIONS

DRUGS OF CHOICE

None indicated.

FOLLOW-UP

None needed.

MISCELLANOUS

- If multiple teeth are missing or they are missing bilaterally, there could be a familial tendency; consider removing from breeding stock.
- In some breeds (Doberman pinscher, Rottweiler) or Schutzhund trained dogs, any missing teeth may be considered a serious fault, and pre-purchase radiographs on puppies may be helpful.

SEE ALSO

- Dentigerous Cyst.
- Tooth Formation/Structure, Abnormal.

Suggested Reading

Author Heidi B. Lobprise
Consulting Editor Heidi B. Lobprise

TOOTH FORMATION/STRUCTURE, ABNORMAL

BASICS

OVERVIEW

Variation in Tooth Size

- Macrodontia—crown oversized, root normal.
- Microdontia—crown normal shape, but small.
- Peg tooth—small, cone-shaped tooth with a single cusp.

Variation in Tooth Structure/Shape

- Fusion—two separate tooth buds joined to form an entire single tooth or joined at the roots by cementum and dentin.
- Gemination—developing tooth bud undergoes an incomplete split, resulting in two crowns with a common root canal.
- Dilacerated—distorted or malformed tooth (crown or root)—a general term that may be used for many different presentations.
- Dens-in-dente (tooth within a tooth)—external layers invaginate into internal structures with varying severity.
- Shell teeth—crown present, but little to no root development.
- Amelogenesis imperfecta—hereditary reduction in the amount of developed enamel matrix.

Pathophysiology

- Stress or stimulus (trauma) at time of development can alter tooth formation.
- Infection, trauma to tooth buds, or traumatic extraction of deciduous teeth during permanent tooth formation can significantly alter the structure.
- Genetic or familial tendencies not known for most conditions.

SIGNALMENT

Dog/cat.

SIGNS

- Fusion—fused crown will be larger than a single tooth. There will be a reduced number of teeth (two counted as one).
- Gemination tooth—actual number of teeth will be unaltered, but one tooth will be larger, with duplication of part of the crown (and possibly roots radiographically); "Siamese twin."
- Dilacerated teeth:
  - Any variation in structure or form—extra root, curved root.
  - Each tooth must be evaluated for integrity of the pulp system, as any disruption in the continuity of the crown and roots may result in exposure of the pulp to the external environment.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Trauma to tooth structures.
- Developmental abnormalities.

IMAGING

- Discontinuity between crowns and roots.
- Possible pulp exposure and pulp stones.
- Roots are convergent with wide canals (nonvital pulp).
- Periapical/root abscessation with extensive bone loss.

DIAGNOSTIC PROCEDURES

- Complete oral examination.
- Intraoral radiographs.
- With any abnormal structure (dilaceration), pulpal integrity and the potential for crowding must be evaluated.
- Appropriate preoperative diagnostics when indicated prior to procedure.

TREATMENT

- Abnormal development of mandibular first molars in small-breed dogs.
  - Dilaceration is more common, sometimes described as dens-in-dente.
  - As one of the first permanent teeth to form, there may be a mechanical challenge (lack of space) in small dogs that impedes proper crown–root development.
  - Invagination of the enamel and/or cementum at the neck of the tooth, often with some degree of gingival recession.
- Fusion teeth—no treatment is necessary unless the groove between the two teeth and/or crowns extends to the gingival margin or below (nidus for periodontal disease).
- Gemination tooth—if tooth crowding results, extraction may be necessary.
- Dilacerated tooth—if there is pulpal exposure or compromise, extraction is generally necessary. In some cases, endodontic and restorative therapy may allow preservation of the tooth.

MEDICATIONS

DRUG(S) OF CHOICE

- Appropriate antimicrobial and pain management therapy when indicated.
- Appropriate patient monitoring and support during anesthetic procedures.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Good prognosis on teeth with moderate changes (peg teeth, fusion teeth, gemination tooth).
- Guarded prognosis on dilacerated teeth with pulpal compromise, though extraction typically successful.

TOOTH ROOT ABSCESS (APICAL ABSCESS)

BASICS

OVERVIEW

- An abscess is a localized collection of pus in a cavity formed by the disintegration of tissues.
- An abscess spreads along the pathway of least resistance from the tooth apex, resulting in osteomyelitis:
  - If this infection perforates through the cortex of the bone in which the tooth is encased, it can result in a cellulitis that can burst through the skin to create a cutaneous draining tract.
  - The drainage can also occur through the alveolar mucosa, above the mucogingival line (parulis).
- Can involve any teeth; the maxillary fourth premolars are most commonly affected, followed by the canines and mandibular first molars.
- Periodontal disease can extend down the root of the tooth to the apex, infecting the pulp and resulting in endodontic involvement (perio-endo lesion).
- Systemic spread of bacteria (bacteremia and pyemia) and the persistence of inflammation can affect other organ systems.
- A tooth root abscess can have an acute or chronic phase:
  - Phoenix abscess—acute exacerbation of a chronic periapical abscess.
- Can arise without the presence of bacteria (sterile abscess).

SIGNALMENT

- Dogs (primarily) and cats.
- Any age:deciduous or permanent teeth can be involved.
- Usually occurs in active animals that bite or chew a lot.

SIGNS

- Tooth is visibly broken with or having near pulpal exposure—90% of cases.
- Tooth may appear discolored.
- Tooth is not sensitive to percussion or cold or hot liquids or foods—note: acute tooth fracture with pulp exposure would be sensitive.
- Facial swelling—usually localized but can spread, resulting in a cellulitis.
- Cutaneous sinus (draining tract) exuding pus—suppurative apical periodontitis:
  - Suborbital abscess due to maxillary fourth premolar involvement is a common presentation.
- On oral examination, especially of the maxilla, there may be a red, raised lesion (parulis) at the anticipated location of the tooth apex. Often present where the attached gingiva meets the alveolar mucosa (mucogingival line) or above.
- Facial sensitivity may be slight but could be extensive if there is no draining.
- Tooth may be clinically asymptomatic, yet inflammation and bacteremia may be present.
- Tooth may be asymptomatic for a long time but will be affected eventually—subclinically or even years later.
- In the absence of a fractured tooth with an exposed canal, a deep periodontal pocket may extend to the apex of one or more roots, resulting in a similar abscess.
- May present as a jaw fracture, especially if the abscess affects the lower canine teeth or lower first molar. Slight trauma can cause a pathologic fracture of the mandible.
- Tooth may be loose and painful on palpation.
- May have facial lymphadenitis.
- Animal does not want to chew, especially on the affected side (plaque and calculus may accumulate), or will bite, but release quickly instead of holding on.
  - Some animals stop eating, the great majority do not.
- Sinusitis—maxillary sinus is most commonly affected.
- Sense of smell (olfactory capabilities) may be affected, especially with drug, bomb, or food-sniffing working dogs.

CAUSES & RISK FACTORS

- Any pulpal trauma—direct blow with fracture of crown; chewing hard objects (carnassial teeth); defense (fighting—canine teeth); malocclusive trauma; tug-of-war; bone plating that damaged roots.
- Advanced periodontal disease—a deep periodontal pocket can involve the apex where bacteria can enter the pulp system, especially at the palatal root of a small dog.
- Bacteria—the pulp can be affected by bacteria from dental caries, exposed dentinal tubules, or extension into endodontic system.
- Thermal heat resulting in pulpal necrosis—electrical cord burns, iatrogenic caused by use of electrocautery for gingival surgery, overpolishing during an oral hygiene procedure or use of rotary burs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Normal radiographic anatomy—chevron effect and mental formina.
- Tooth resorption—radiographs show no apical lucency or abscessation, but rather a disintegration of the root and/or crown with the loss of the periodontal ligament.
- Oral tumor.
- Squamous cell carcinoma and fibrosarcoma (rapidly growing and invasive) and ameloblastoma (slowly enlarges). These tumors can displace teeth, which often become mobile.
- Cementomas—radiographically show enlarged apical roots with a thin radiolucent zone continuous with the periodontal ligament.
- Cysts—radiographs usually show a very large lytic area involving any part of the root and/or unerupted crown:
  - Radicular cysts, apical periodontal granulomas.
  - Dentigerous cyst—occurs from the follicular cyst of an impacted or embedded tooth (usually the first mandibular premolars in dogs); in which case the radiograph show a tooth within the cyst.
- Periapical scar—usually occurs on an endodontically treated tooth where there has been no further increase in the radiographic apical lucency after a 6-month post-treatment period.
- Normal anatomy—mental foramens can be mistaken for apical lucencies on radiographic interpretation (the middle mental foramen just apical to second mandibular premolar).

CBC/BIOCHEMISTRY/URINALYSIS

CBC may show a leukocytosis and/or a mild regenerative anemia.

IMAGING

- Intraoral radiographs are the most commonly utilized diagnostic aid; demonstrates thickening of the apical periodontal ligament space; ill-defined radiolucency; shows bone loss at the apex as the lesion becomes chronic.
- As the lesion progresses, radiographic lesions consistent with osteomyelitis and cellulitis occur.
- Must be differentiated from chevron effect:this is evident radiographically in the small teeth that commonly develop a tooth root abscess.

DIAGNOSTIC PROCEDURES

- If fistulization has occurred, can place a gutta percha cone into the sinus tract and take a radiograph to identify the affected tooth.
- Transillumination with a strong fiber-optic light can help the clinician by distinguishing between a vital and necrotic pulp (compare to similar tooth on contralateral side).

PATHOLOGIC FINDINGS

- Apical area has a central area of liquefaction necrosis containing disintegrating neutrophils and cellular debris, surrounded by macrophages, lymphocytes, and plasma cells; can see bacteria.
- Extension of the lesion into cancellous bone results in inflammation of the periapical bone and resorption.
- Chronic changes may develop tracts that can be lined with epithelium; osteomyelitis or cellulitis lesions may become fibrotic with a capsule (radicular cyst and/or a periapical periodontal granuloma).

TREATMENT

- Must surgically drain and remove the focus of infection.
- Extraction of the tooth involved, with curettage of the apical infected area.

T

TOOTH ROOT ABSCESS (APICAL ABSCESS) (CONTINUED)

• Chronic conditions require surgical removal of the granulation tissue and curettage of the tract.
• Endodontic treatment of the involved tooth (surgical root canal if apical legion large).
• Medical management can be instituted temporarily until surgery can be performed.
• After treatment, cold packs on the area will help reduce inflammation.
• Following extraction, oral rest is recommended: soft diet, no hard chew toys, until the gingiva is healed.

MEDICATIONS

DRUG(S) OF CHOICE

• Broad-spectrum antibiotics recommended preoperatively to help prevent systemic spread of infection and improve tissue quality.
• Broad-spectrum antibiotic postoperatively for 7–10 days.
• Due to its ability to penetrate bone, clindamycin is recommended at a minimum of 5.5–11 mg/kg twice daily for dogs and once daily for cats.
• Second choice is amoxicillin/clavulanic acid 12.5–25 mg/kg orally twice daily.
• Analgesics preoperatively, intraoperatively, and postoperatively for 3–4 days.
• If a surgical endodontic treatment or an extraction was performed, a protective collar may be required.

FOLLOW-UP

• For extractions—recheck the site 10–14 days postoperatively. Soft diet and remove chew toys until healed gingiva is confirmed at recheck appointment.
• Recheck in 6–12 months with intraoral radiographs.
• Avoid traumatic injuries (e.g., letting the dog chase cars, hard chew toys, stop fighting).
• Curtail bite work—avoid handler sleeves that have tears or hole in them and avoid torsion movements.
• Check the mouth regularly for any trauma to additional teeth.

TORSION OF THE SPERMATIC CORD

BASICS

OVERVIEW
- Testicular torsion (also known as torsion of the spermatic cord) results from twisting of the spermatic cord which leads to occlusion of venous outflow from the testis.
- Prolonged occlusion leads to ischemia, infarction, and necrosis.
- Abdominally retained testes are at greater risk of torsion, thought to be because of increased range of motion as compared to testes confined to the scrotum.
- Neoplastic testes, with increased weight, also have a greater likelihood of undergoing torsion.
- Torsion of descended (scrotal) testes has also been described.
- Systems affected—reproductive.

SIGNALMENT
- Intact male animals.
- Higher incidence in cryptorchid males.
- Rare in dogs.
- Very rare (but reported) in cats.
- Mean age 6–8 years (dogs).
- Cases of testicular torsion in both young (<10 months) and old (>10 years) dogs have been reported.

SIGNS
- Abdominal pain.
- Hyporexia/anorexia.
- Vomiting.
- Lethargy.
- Hind limb lameness.
- Pyrexia.
- Dysuria.
- Hematuria.
- Diarrhea.
- Scrotal edema.
- Inguinal swelling.
- Bilateral symmetric alopecia (secondary to Sertoli cell tumor).
- Feminization (secondary to Sertoli cell tumor).

CAUSES & RISK FACTORS
- Cryptorchidism.
- Testicular neoplasia (most commonly Sertoli cell tumors and seminomas).
- High physical exertion.
- Exuberant libido and expression of sexual behaviors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Gastrointestinal disorder.
- Renal disease.
- Peritonitis.
- Abdominal trauma.
- Splenic torsion.
- Prostatic disease.
- The results of laboratory testing and imaging will aid in ruling in or out the above.

CBC/BIOCHEMISTRY/URINALYSIS
Nonspecific results in cases of testicular torsion, but useful in differentiating between other possible conditions.

IMAGING

Abdominal Ultrasonography
- Secondary to torsion, the affected testis typically appears hypoechoic in comparison to the contralateral (unaffected) testis.
- The diameter of the spermatic cord may be enlarged.
- The affected testis may be spherical in shape, as opposed to ovoid.
- Color Doppler ultrasound is very useful to visualize blood flow (or lack thereof).

Abdominal Radiographs
Nonspecific for diagnosing testicular torsion but valuable in assessing differential diagnoses.

TREATMENT
- Surgical removal of affected testis on an emergent basis
- Inpatient care for immediate postoperative monitoring
- In theory, if torsion of a scrotal testis is rapidly identified and detorsion occurs quickly, this testicle could be salvaged. No such cases are reported in the literature. In a canine experimental model of testicular torsion, ultrasonographic changes occurred in all subjects by one hour after torsion, which were seen before irreversible histological lesions were induced.

MEDICATIONS

DRUG(S) OF CHOICE
None specifically indicated other than routine postoperative pain control and antimicrobial coverage as indicated by the particular case.

FOLLOW-UP

PREVENTION/AVOIDANCE
Removal of undescended testes prior to development of neoplasia and/or torsion.

EXPECTED COURSE AND PROGNOSIS
Good prognosis for recovery following surgery in cases of uncomplicated testicular torsion.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- Cryptorchidism (generally accepted to be a heritable, sex-limited autosomal recessive trait).
- Testicular neoplasia (Sertoli cell tumor and seminoma most commonly, with an increased rate of occurrence in retained testes).

PREGNANCY/FERTILITY/BREEDING
If a retained testis is removed and a descended testis preserved, the ethical considerations of using the animal for breeding and potential for hereditary cryptorchidism should be impressed upon owner. Bilateral orchiectomy is the most commonly recommended course of treatment in literature reports.

Hecht S, King R, Tidwell AS, Gorman SC. Ultrasound diagnosis: intra-abdominal torsion of a non-neoplastic testicle in a cryptorchid dog. Vet Radiol Ultrasound 2004, 45:58–61.

Author Karen A. Von Dollen
Consulting Editor Erin E. Runcan

TOXOPLASMOSIS

BASICS

DEFINITION
Toxoplasma gondii—obligate intracellular coccidian protozoan parasite that infects nearly all mammals. Felids are the definitive hosts and all other warm-blooded animals serve as intermediate hosts.

PATHOPHYSIOLOGY
• Three main modes of transmission: (1) congenital, (2) ingestion of bradyzoites encysted in tissue of intermediate hosts, or (3) ingestion of sporulated oocysts within feces of felids.
• Most cats infected via ingestion of intermediate hosts; release bradyzoites in gastrointestinal tract that invade enteroepithelium; ultimately undergo sexual reproduction and oocyte formation; oocysts require 1–5 days to sporulate and become infectious after being passed in feces.
• Acute disseminated infection—organisms spread via blood or lymph; tachyzoites rapidly divide within extraintestinal tissues; causes focal necrosis, granulomatous inflammation; can be fatal.
• Following acute infection, slowly dividing bradyzoites encyst in host tissue, usually not clinically apparent unless immunosuppression or concomitant illness allows organism to reactivate to tachyzoite stage.
• Infection acquired during pregnancy—possible placentitis and transplacental transmission of tachyzoites to fetus; can induce abortion or clinical disease (kittens).

SYSTEMS AFFECTED
• Multisystemic.
• Ophthalmic—~ 80% of affected cats have uveitis.

INCIDENCE/PREVALENCE
• ~30% of cats and up to 50% of people serologically positive for *T. gondii*.
• Most animals asymptomatic.

GEOGRAPHIC DISTRIBUTION
Worldwide

SIGNALMENT
Species
Cats more commonly symptomatic than dogs.

Mean Age and Range
Mean age 4 years; range 2 weeks–16 years.

Predominant Sex
More common in male cats.

SIGNS
General Comments
• Determined by site and extent of organ damage.
• Acute—at time of initial infection, rapid clinical course.
• Chronic—reactivation of encysted infection due to immunosuppression, slower clinical course.

Historical Findings
• Lethargy, depression, anorexia.
• Weight loss.
• Fever.
• Ocular discharge, photophobia, miotic pupils (cats).
• Respiratory distress.
• Neurologic—ataxia, seizures, tremors, paresis/paralysis, or cranial nerve deficits.
• Digestive tract—vomiting, diarrhea, abdominal pain, and/or jaundice.
• Stillborn kittens.

Physical Examination Findings
Cats
• Transplacentally infected kittens may be stillborn or die before weaning; surviving kittens—anorexia, lethargy, high fever.
• Signs reflect necrosis/inflammation of lungs (dyspnea, increased respiratory noises), liver (icterus, abdominal enlargement from ascites), and CNS (encephalopathy).
• Postnatal exposure.
• Respiratory and gastrointestinal abnormalities most common—anorexia, lethargy, high fever, dyspnea, weight loss, icterus, vomiting, diarrhea.
• Ocular abnormalities common—uveitis (aqueous flare, hyphema, mydriasis), iritis, detached retina, iridocyclitis, and/or keratic precipitates.
• 10% of patients show neurologic abnormalities—blindness, stupor, incoordination, circling, torticollis, anisocoria, or seizures.

Dogs
• Puppies—generalized infection; fever, weight loss, anorexia, tonsillitis, dyspnea, diarrhea, vomiting.
• Adults—localized infections associated with neural and muscular systems.
• Neurologic manifestations variable; result of diffuse neurologic inflammation—seizures, tremors, ataxia, paresis, paralysis, muscle weakness.
• Ocular inflammation—rare.
• Cardiac involvement—usually subclinical.

CAUSES
T. gondii

RISK FACTORS
• Ingestion of intermediate hosts, environment contaminated with cat feces.
• Immunosuppression—may predispose to infection or reactivation: feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), feline infectious peritonitis (FIP), hemotropic mycoplasma, canine distemper, glucocorticoids, chemotherapy, postrenal transplant.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Cats
• Anterior uveitis—FIP, FeLV, FIV, other infectious, immune-mediated, trauma; lens-induced, corneal ulceration, lymphoma.
• Dyspnea—asthma, cardiogenic, pneumonia, neoplasia, heartworm disease, pleural space disease, diaphragmatic hernia, trauma.
• Meningoencephalitis—viral, fungal, parasitic, bacterial, idiopathic (feline polioencephalomyelitis).

Dogs
• Neurologic abnormalities—infectious, inflammatory, toxic, metabolic.

CBC/BIOCHEMISTRY/URINALYSIS
CBC (Cats)
• Normocytic normochromic anemia.
• Leukopenia—50% of patients with severe disease; primarily lymphopenia.
• Neutropenia with degenerative left shift.
• Leukocytosis during recovery.

Biochemistry
• Alanine aminotransferase and aspartate aminotransferase—increased enzyme activities.
• Hypoalbuminemia.
• Hyperbilirubinemia (25% of cats).

Urinalysis (Cats)
• Mild proteinuria.
• Bilirubinuria.

OTHER LABORATORY TESTS
Serology
• IgM—serologic titer of choice for diagnosis of active infection; elevated 2 weeks post infection (usually with onset of clinical signs) and persists for up to 3 months:
  ◦ Prolonged titer—reactivation or delay in antibody class shift to IgG (due to immunosuppression).
• IgG—titers rise 2–4 weeks post infection, persist >1 year; single high titer not diagnostic for active infection; 4-fold increase over a 3-week period suggests active infection.
• Serum antigen—positive 1–4 weeks post infection; remains positive during active or chronic infections (not helpful to determine infection type).
• PCR—to verify presence of *T. gondii* in biologic specimens:
  ◦ Prudent choice in suspect cases since many protozoa are morphologically similar and difficult to distinguish histopathologically.

(CONTINUED) TOXOPLASMOSIS

IMAGING
Radiographs—mixed pattern of patchy alveolar and interstitial pulmonary infiltrates; pleural and abdominal effusions and hepatomegaly may be present.

DIAGNOSTIC PROCEDURES
- Bronchoalveolar lavage, pulmonary fine-needle aspirate (cats with respiratory disease)—organism can be identified cytologically.
- Effusion cytology—organism rarely detected during acute infection.
- Cerebrospinal fluid (patients with encephalopathy)—high leukocyte count (both mononuclear cells and neutrophils) and protein.
- Fecal—active fecal oocyte shedding occurs for 1–3 weeks after infection in the cat and usually not during clinical disease; not recommended for determining whether or not an individual cat is infected with *T. gondii*. Oocysts may be detected on routine examination in asymptomatic cats but are morphologically indistinguishable from *Hammondia* spp. and *Besnoitia*.

PATHOLOGIC FINDINGS
- Potentially no gross lesions.
- Necrotic foci—up to 1 cm; most often in liver, pancreas, mesenteric lymph nodes, lungs; necrosis of brain (1 cm areas of discoloration).
- Ulcers and granulomas—in stomach and small intestine.

TREATMENT

APPROPRIATE HEALTH CARE
- Usually outpatient.
- Inpatient—severe disease; patient cannot maintain adequate nutrition or hydration.
- Confine—patients with neurologic signs.

NURSING CARE
Dehydration—IV fluids.

CLIENT EDUCATION
- Cats—prognosis guarded in patients needing therapy; response to therapy is inconsistent.
- Poorer prognosis for neonates and immunocompromised animals.

MEDICATIONS

DRUG(S) OF CHOICE
- Clindamycin 12.5–25 mg/kg PO, IV, IM q12h; continue at least 2 weeks after clinical resolution.
- 1% prednisone drops—q8h for uveitis.

PRECAUTIONS
Clindamycin—anorexia, vomiting, and diarrhea (dose-dependent).

ALTERNATIVE DRUG(S)
- Sulfadiazine 30 mg/kg PO q12h in combination with pyrimethamine 0.5 mg/kg PO q12h for 2 weeks; can cause depression, anemia, leukopenia, and thrombocytopenia, especially in cats.
- Folinic acid 5 mg PO q24h or brewer's yeast 100 mg/kg PO q24h—correct bone marrow suppression caused by above therapy.

FOLLOW-UP

PATIENT MONITORING
- Examine 2 days after treatment initiation for resolution of clinical signs; uveitis should resolve within 1 week.
- Neuromuscular deficits take longer to resolve, should see partial resolution within 2 weeks (some deficits may be permanent).
- Examine 2 weeks after resolution of clinical signs to determine if treatment may be discontinued.

PREVENTION/AVOIDANCE
Cats
- Diet—prevent ingestion of raw meat, bones, viscera, or unpasteurized milk (especially goat's milk), or mechanical vectors (flies, cockroaches). Only well-cooked meat should be fed.
- Behavior—prevent free-roaming to hunt prey (birds, rodents) or to enter buildings where food-producing animals are housed.

EXPECTED COURSE AND PROGNOSIS
- Prognosis—guarded; varied response to drug treatment.
- Acute—prompt and aggressive therapy often successful.
- Residual deficits (especially neurologic) cannot be predicted until course of therapy is completed.
- Ocular disease—usually responds to appropriate therapy.
- Severe muscular or neurologic disease—usually chronic debility.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- Young dogs—distemper.
- Cats—renal transplant recipients, FeLV, FIP, FIV; FIV infection does not affect clinical outcome or the ability of the animal to mount a protective immune response to subsequent reinfection.

AGE-RELATED FACTORS
Disease worse in neonates.

ZOONOTIC POTENTIAL
- Of most concern is infection of pregnant women or immunocompromised individuals. Pregnant women should avoid contact with cats excreting oocysts in feces, contact with soil and cat litter, and should not handle or eat raw meat (to kill organism, cook to ≥66°C/150°F):
  - Young cats are most likely to be shedding oocysts.
  - *Important*: oocysts need to be sporulated to be infectious. Unsporulated oocysts are shed in the feces and require at least 24 hours to sporulate; daily cleaning of litter box should reduce risk of exposure to infectious form.
- Cats—healthy animals with a positive antibody titer pose little danger to humans; animal with no antibody titer at greater risk of becoming infected, shedding oocysts in the feces, and constituting a risk to humans.
- Avoid contact with oocysts or tissue cysts—do not feed raw meat; wash hands and surfaces (cutting boards) after preparing raw meat; boil drinking water if source is unreliable; keep sandboxes covered to prevent cats from defecating in them; wear gloves when gardening; wash hands and vegetables before eating; empty cat litter boxes daily; disinfect litter boxes with boiling water; control stray cat population.
- *T. gondii* causes abortion in sheep; prevent cats from ingesting placenta or aborted fetuses and keep cats from defecating in sheep feed to break the life cycle.

PREGNANCY/FERTILITY/BREEDING
- Parasitemia during pregnancy—spread of organism to fetus; probably does not happen unless first-time infection of dam occurs during pregnancy (as with humans).
- Placental transmission rare.

ABBREVIATIONS
- FeLV = feline leukemia virus.
- FIP = feline infectious peritonitis.
- FIV = feline immunodeficiency virus.

T

TRACHEAL COLLAPSE

BASICS

DEFINITION
• Static or dynamic reduction in the luminal diameter of the large conducting airway with respiration. • Can involve the cervical trachea, the intrathoracic trachea, or both segments. • Airway collapse (bronchomalacia) refers to collapse of lobar bronchi and smaller airways, which can be seen in conjunction with tracheal collapse (tracheobronchomalacia) or alone. • Compression of the trachea or bronchi due to hilar lymphadenopathy or external mass lesions—not considered part of this condition.

PATHOPHYSIOLOGY
• Hypocellular tracheal cartilage in the cervical region identified historically in some small-breed dogs. • Lack of chondroitin sulfate and/or decreased glycoproteins within the cartilage matrix results in a reduction in bound water and loss of rigidity in the cartilage. • Causes of bronchomalacia not established—cartilage abnormalities could include a mechanism similar to cervical tracheal collapse, defects in chondrogenesis, nutritional deficiencies, or degenerative changes caused by chronic airway disease. • Collapse—weak tracheal cartilage allows flattening of the normal ring structure; trachea collapses in a dorsoventral direction when pressure fluctuates within the airway lumen. During inspiration, intrapleural pressure becomes more negative leading to a drop in intra-airway pressure. Atmospheric pressure exceeds airway pressure in the cervical region and lack of cartilage support results in cervical collapse. During forced expiration, intrapleural pressure becomes positive and exceeds intrathoracic intra-airway pressure. When cartilaginous airway walls are weakened by bronchomalacia, intrathoracic airway collapse occurs, on expiration. • Increased tension on the trachealis dorsalis muscle or neurogenic atrophy of the muscle causes stretching of the dorsal tracheal membrane with protrusion into the airway lumen. • Coughing—mechanical trauma to the tracheal mucosa from collapse of the dorsal tracheal membrane exacerbates airway edema and inflammation. • Upper airway obstruction worsens clinical signs, and chronic increases in respiratory effort could lead to secondary abnormalities in laryngeal structure and function. • Small airway disease augments the trans-airway pressure gradient and potentiates collapse in the intrathoracic region.

SYSTEMS AFFECTED
• Respiratory—chronic airway irritation. • Cardiovascular—pulmonary hypertension. • Nervous—can be involved when syncope develops from hypoxia or a vasovagal reflex associated with cough.

GENETICS
Under investigation. Tracheal collapse common in small toy breed dogs. Bronchomalacia seen in large and small breeds.

INCIDENCE/PREVALENCE
Common clinical entity.

GEOGRAPHIC DISTRIBUTION
Worldwide

SIGNALMENT
Species
Primarily dog, rarely cat.

Breed Predilections
Tracheal collapse—miniature poodles, Yorkshire terriers, Chihuahuas, Pomeranians, other small and toy breeds. Bronchomalacia—all breeds.

Mean Age and Range
• Middle-aged to elderly—onset of signs at 2–14 years of age. • Severely affected animals <1 year of age.

SIGNS
Historical Findings
• Usually worsened by excitement, heat, humidity, exercise, or obesity. • Dry honking cough. • Often have a chronic history of intermittent coughing or difficulty breathing. • Retching—often seen due to attempts to clear respiratory secretions from the larynx. • Tachypnea, exercise intolerance, and/or respiratory distress—common. • Cyanosis or syncope—seen in severely affected individuals.

Physical Examination Findings
• Increased tracheal sensitivity—virtually always seen. • Respiratory distress—inspiratory with cervical collapse; expiratory with intrathoracic collapse. • Stridor or musical sounds ausculted over narrowed cervical trachea. • An end-expiratory snap—heard when a large intra-thoracic airway collapses during forceful expiration then reopens. • Crackles—due to small airway collapse (inspiratory or expiratory) or chronic bronchitis. • Expiratory wheezes suggest concurrent bronchitis. • Mitral insufficiency murmurs—often found concurrently in small-breed dogs. • Normal to low heart rate and/or marked respiratory arrhythmia. • Loud second heart sound—suggests pulmonary hypertension. • Hepatomegaly—cause unknown.

CAUSES
• Unknown etiology—congenital, nutritional, or familial defects of chondrogenesis suspected. • Chronic airway inflammation suggested to contribute to bronchomalacia but relationship not clearly established. Seen with chronic bronchitis or eosinophilic bronchopneumopathy.

RISK FACTORS
• Obesity. • Airway infection or inflammation. • Upper airway obstruction. • Endotracheal intubation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Infectious tracheobronchitis. • Tracheal or laryngeal obstruction or foreign body. • Chronic bronchitis. • Pneumonia—viral, bacterial, fungal, parasitic, eosinophilic. • Bronchiectasis.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC—can show an inflammatory leukogram secondary to chronic stress or concurrent infection. • Increased liver enzymes common.

OTHER LABORATORY TESTS
Elevated bile acids—mechanism unclear.

IMAGING
Thoracic Radiography
• Airway collapse evident on a lateral thoracic radiographic in a large percentage of dogs with airway collapse, however, the location of collapse on static radiographs agreed with the site determined by fluoroscopy in <50% of cases. • Inspiratory radiographs—show primarily cervical collapse and collapse at the thoracic inlet. • Expiratory radiographs—show intrathoracic tracheal collapse; can also note collapse at the carina, ballooning of the cervical trachea, and cranial herniation of the lung lobe through the thoracic inlet. • Right-sided heart enlargement—can be seen secondary to chronic pulmonary disease and cor pulmonale, or heart can be artifactually enlarged due to obesity or breed conformation.

Fluoroscopy
Dynamic collapse of the cervical or intra-thoracic trachea and/or dorsal tracheal membrane can be visible during tidal respirations—usually more easily identified after induction of cough. Cranial lung herniation through the thoracic inlet is common.

DIAGNOSTIC PROCEDURES
Caution is warranted in anesthetizing and intubating dogs with tracheal collapse because endotracheal tube irritation can worsen clinical signs. Loss of respiratory drive from anesthetic drugs or excess excitement on recovery can precipitate airway obstruction.

Tracheal Wash
Use oral intubation (rather than the transtracheal approach) with a small endotracheal tube and a sterile catheter when obtaining samples for cytologic examination and bacterial culture/susceptibility.

Bronchoscopy
• Grade the severity of collapse: Grade I—slight protrusion of the dorsal tracheal membrane into the airway lumen; diameter reduced by <25%, Grade II—reduction of

(CONTINUED) TRACHEAL COLLAPSE

the tracheal lumen by 50%, Grade III—reduction of the tracheal lumen by 75%, Grade IV—tracheal rings flattened; <10% of the tracheal lumen can be seen; in some cases (particularly Yorkies), a double lumen trachea is observed, where tracheal rings have bowed dorsally to contact the trachealis muscle.
• Identify small airway disease—collapse or inflammation. Submit airway samples for cytologic examination and bacterial/susceptibility; specific culture for *Mycoplasma* is recommended.

Cytology

• Unremarkable in uncomplicated tracheal or bronchial collapse. • Neutrophilia without intracellular bacteria or marked bacterial growth—indicates airway inflammation.
• Lymphocytic inflammation is also common.
• Sepsis and suppuration along with marked bacterial growth of a pathogen—suggests pulmonary infection.

PATHOLOGIC FINDINGS

• Dorsal trachealis muscle—elongated.
• Cartilage rings—flattened. • Tracheal mucosal inflammation in some cases.
• Hypocellularity of the cartilage with low glycoproteins and chondroitin sulfate—can be noted via histopathologic examination or electron microscopy. • Can also see changes associated with chronic inflammatory airway disease.

TREATMENT

APPROPRIATE HEALTH CARE

• Outpatient—stable patients. • Inpatient—oxygen therapy and sedation for severe respiratory distress. Sedation and cough suppression—butorphanol 0.1–0.4 mg/kg SC or IV; addition of acepromazine 0.01–0.04 mg/kg SC or IV can enhance sedative effects and further reduce the cough reflex.

NURSING CARE

Monitor respiratory effort.

ACTIVITY

• Severely limited until patient is stable.
• During management of disease—gentle exercise recommended to encourage weight loss.

DIET

• Many affected dogs improve after losing weight. • Institute weight-loss program with restriction of caloric intake; use a gradual weight-loss program (1–2% weight loss per week).

CLIENT EDUCATION

• Warn client that weight gain, overexcitement, and humid conditions can precipitate a crisis. • Advise client to use a harness instead of a collar. • Advise owners that tracheal collapse is irreversible and that treatment strategies are designed to lessen triggers of cough. • For surgical candidates, advise owner of the likelihood of complications after surgery (e.g., persistent cough, respiratory distress, or laryngeal paralysis); some patients can require a permanent tracheostomy. For stent candidates, advise owners of need for extensive follow-up to avoid stent fracture, migration, or granulation tissue formation.

SURGICAL CONSIDERATIONS

• Treatment of upper airway obstructive disorders (elongated soft palate, everted laryngeal saccules)—can reduce signs due to tracheal collapse. • The presence of mainstem bronchial collapse worsens prognosis.
• Placement of extraluminal C-shaped rings by a skilled surgeon in selected patients with cervical collapse will enhance quality of life and reduce clinical signs when adequate stabilization of the airway can be achieved and when bronchomalacia does not limit resolution of clinical signs. Postoperative laryngeal paralysis is a potential complication.
• Intraluminal stents are life-saving in selected cases with intrathoracic airway collapse that fail aggressive medical management. Aspiration pneumonia is common after placement.

MEDICATIONS

DRUG(S) OF CHOICE

• Narcotic cough suppressants (butorphanol 0.5–1 mg/kg PO q4–8h or hydrocodone 0.22 mg/kg PO q4–8h) used to break the cycle of cough; reduce dose rate to the least frequent administration that controls signs. Use after infection or inflammation has been managed. • Reduction of tracheal inflammation—prednisone 0.5 mg/kg PO q12h then 0.25 mg/kg q12h for a total of 5–7 days may help. Inhaled steroids given via facemask and spacing chamber are preferred to avoid systemic effects of panting and weight gain. • Sustained-release theophylline 10 mg/kg PO q12h—thought to reduce the pressure gradient in small airways and decrease cough in dogs with intrathoracic airway collapse or bronchomalacia—bronchodilators have no effect on tracheal diameter. • Bacterial infection uncommon but doxycycline 3–5 mg/kg PO q12h is sometimes beneficial, perhaps through reduction in bacteria within the airway or reduction of inflammation.

PRECAUTIONS

Avoid long-term steroid use because of the propensity for weight gain and diseases associated with immunosuppression.

POSSIBLE INTERACTIONS

Theophylline metabolism—increased by concurrent treatment with ketoconazole or phenobarbital, which results in inadequate plasma concentration; decreased by fluoroquinolones (e.g., enrofloxacin), erythromycin, cimetidine, steroids, beta-blockers, mexiletine, and thiabendazole, which results in toxic plasma concentration and gastrointestinal upset, nervousness, or tachycardia; adjust dosages when concurrent use is necessary.

ALTERNATIVE DRUG(S)

Over-the-counter cough suppressants—rarely reduce cough.

FOLLOW-UP

PATIENT MONITORING

• Body weight. • Exercise tolerance. • Pattern of respiration. • Incidence of cough.

PREVENTION/AVOIDANCE

• Avoid obesity in breeds commonly afflicted.
• Avoid heat and humidity. • Use harness rather than leash.

POSSIBLE COMPLICATIONS

Intractable respiratory distress leading to respiratory failure or euthanasia.

EXPECTED COURSE AND PROGNOSIS

• Combinations of medications along with weight control can reduce clinical signs, but dogs will likely cough throughout life and can suffer recurrent exacerbations of disease.
• Surgery—benefits dogs severely affected with cervical collapse. • Stent placement—benefits some dogs, primarily those with respiratory difficulty rather than cough and those with intrathoracic collapse. Medications usually required post procedure.
• Prognosis—based on bronchoscopic evidence of airway obstruction and development of complications.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Chronic bronchitis. • Laryngeal paralysis.
• Pulmonary hypertension. • Breeds of dogs that develop tracheal collapse also commonly have mitral insufficiency.

SEE ALSO

• Bronchitis, Chronic. • Canine Infectious Respiratory Disease.

T

TRANSITIONAL CELL CARCINOMA

BASICS

DEFINITION
Malignancy arising from the transitional epithelium within the kidney, ureters, urinary bladder, urethra, prostate, or vagina.

PATHOPHYSIOLOGY
The underlying etiology of transitional cell carcinoma (TCC) remains unclear. It is possible that an environmental carcinogen may initiate or promote the malignant transformation of the transitional epithelium.

SYSTEMS AFFECTED
• Renal/urologic—the most common site affected is the trigone of the urinary bladder. Local invasion of the distal ureter is not uncommon and may lead to postrenal azotemia. The apex of the urinary bladder is more often affected in cats, although because of late detection the entire bladder is often involved by the time of diagnosis.
• Reproductive—the vagina is a possible site of primary TCC. The prostate may be involved through local invasion, or as the primary site of TCC. • Other systems may be affected through metastases (e.g., most commonly regional lymph nodes and lungs; other sites include bone, brain, eye) or paraneoplastic syndromes (hypertrophic osteopathy has been reported secondary to TCC of the urinary bladder).

GENETICS
N/A

INCIDENCE/PREVALENCE
• <1% of all reported malignancies in dogs.
• Rare in cats.

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
Middle-aged to old, spayed female, small-breed dogs most commonly reported with the disease.

Species
Dog and cat.

Breed Predilections
• Scottish terriers are at 18 times the risk compared to other breeds. • West Highland white terriers, Shetland sheepdogs, beagles, American Eskimo dogs, dachshunds. • May occur in any breed. • No breed predisposition in cats.

Mean Age and Range
Dogs—8 years, range 1 to 15+ years.

Predominant Sex
Female

SIGNS
General Comments
• Signs are similar to those of bacterial urinary tract infection or urolithiasis.
• Consider TCC in animals showing temporary or no response to appropriate antibiotic therapy.

Historical Findings
• Complaints of recurrent stranguria, pollakiuria, hematuria, dysuria, urinary incontinence, or any combination of the above signs should initiate a search for TCC.
• Signs may temporarily respond to antibiotic therapy.

Physical Examination Findings
• Often normal. • Occasionally, urethral thickening can be appreciated on digital rectal examination or a mass might be palpable in the caudal abdomen/urinary bladder region.
• Urethral/vaginal/prostatic TCC may be palpable on rectal examination. • Enlarged intrapelvic or sublumbar lymph nodes can be palpable on rectal examination.

CAUSES
• Dogs—reported risk factors include obesity, environmental carcinogens, chronic exposure to organophosphates or carbamates, and (rarely) long-term or a large bolus dose of cyclophosphamide. • Cats—unknown.

RISK FACTORS
Dogs—Scottish terrier breed, obesity, exposure to organophosphates or carbamates, cyclophosphamide therapy.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Non-neoplastic—bacterial urinary tract infection, urolithiasis, urethritis, vaginitis, prostatitis. • Neoplastic—other primary neoplasia (e.g., squamous cell carcinoma, transmissible venereal tumor), or metastatic neoplasia (e.g., locally infiltrative prostatic carcinoma).

CBC/BIOCHEMISTRY/URINALYSIS
• CBC and biochemistry usually within normal limits. • Biochemistry profile may show signs of renal and/or postrenal azotemia if ureteral or urethral obstruction exists.
• Urinalysis may reveal epithelial cells with criteria of malignancy—caution should be exercised if the sample is inflammatory as epithelial cells may exhibit criteria of malignancy in the presence of inflammation.

OTHER LABORATORY TESTS
• A DNA-based strategy for the detection of canine TCC is commercially available (CADET®). The assay is run on a urine sample and detects a mutation in the *BRAF* gene that is highly specific for TCC. • Urine culture and sensitivity are indicated, as concurrent urinary tract infection is common; however, caution is advised when performing cystocentesis on patients suspected to have TCC as tumor seeding along the needle tract may occur. • Biopsy (surgical, traumatic catheter, or cystoscopic) is gold standard for definitive diagnosis. Even with a low yield of tissue samples of some traumatic catheterizations, typically enough cells are obtained to get a cytologic diagnosis.

IMAGING
Thoracic Radiography
Metastatic patterns include multiple, well-defined interstitial nodules, increased interstitial pattern, and alveolar infiltrates.

Abdominal Radiography
• Unlikely to reveal specific urinary bladder disease unless the mass is mineralized (rare).
• May reveal sublumbar lymphadenomegaly or bony metastasis.

Double Contrast Cystography
• Dogs—space-occupying lesion, usually at trigone of the urinary bladder. • Cats—space-occupying lesion, may be at the apex of the urinary bladder. • Depending on the primary site, IV pyelography, voiding urethrogram, or vaginogram may be indicated.

Ultrasonography
• 2D ultrasonography is a highly sensitive imaging modality, helpful in identifying location and extent of disease; however, not a reliable method for monitoring response to therapy. • 3D ultrasonography is a more accurate tool for monitoring tumor volume and response to therapy.

CT
CT imaging of TCC is the most accurate way to measure tumor volume.

DIAGNOSTIC PROCEDURES
Exploratory Laparotomy
• Used to obtain biopsies of the primary tumor and regional lymph nodes. • Surgical cure very unlikely due to the infiltrative nature of the tumor. • Because tumor seeding is recognized with TCC, change surgical gloves and instruments after handling the tumor.

Cystoscopy
A less invasive way to identify and biopsy TCC within the urinary bladder or urethra.

Traumatic Catheterization
Use a polypropylene catheter to traumatically obtain small tissue samples for histologic or cytologic diagnosis.

Ultrasound-Guided Biopsy
Not recommended, as seeding of the biopsy tract with viable tumor cells is a highly possible sequela.

PATHOLOGIC FINDINGS
• Irregular to diffuse thickening of the urinary bladder mucosa. • Metastasis to regional lymph nodes, lungs, and bones (i.e., vertebra, pelvis) possible.

(CONTINUED) TRANSITIONAL CELL CARCINOMA

TREATMENT

APPROPRIATE HEALTH CARE
Radiotherapy with treatment units that allow for intensity modulation may provide long-term tumor control.

Inpatient vs. Outpatient
- Initial workup and diagnosis takes 1–2 days.
- Stable patients need not be hospitalized.

ACTIVITY
Normal

DIET
Normal, unless concurrently in renal failure.

CLIENT EDUCATION
• Long-term prognosis poor. • Palliation often attainable. • Trigonal location of the disease within the bladder makes complete surgical resection in dogs difficult.

SURGICAL CONSIDERATIONS
• TCC is highly exfoliative and highly transplantable—multiple reports of surgically induced seeding of TCC exist. • All surgical instruments and gloves should be replaced after contacting the tumor. • Partial cystectomy (ideally full-thickness resection of gross disease) combined with piroxicam therapy may result in improved outcomes compared to dogs treated with medical therapy only. • Tube cystostomy placement or urethral stenting may prolong survival times by bypassing or relieving urethral obstruction.

MEDICATIONS

DRUG(S) OF CHOICE
• Piroxicam 0.3 mg/kg PO q24h with food—reported to have activity in 21% of cases with a median survival of 244 days. • Deracoxib 3 mg/kg PO q24h with food—reported to have activity in 17% of cases with a median survival of 323 days. • A variety of chemotherapy drugs used at traditional maximally tolerated doses have activity against TCC, including mitoxantrone 5 mg/m^2 IV q21d, vinblastine 3 mg/m^2 IV q14d, cisplatin 50 mg/m^2 IV q21d, carboplatin 300 mg/m^2 IV q21d, and gemcitabine 800 mg/m^2 IV q7d. • Metronomic (continuous, low-dose) chemotherapy with chlorambucil 4 mg/m^2 PO q24h may play a role in the management of this disease.

CONTRAINDICATIONS
• Piroxicam—do not use in animals with known gastrointestinal erosions or ulcers; do not use in animals with renal insufficiency. • Piroxicam—do not combine with cisplatin. • Piroxicam therapy appears to be tolerated in cats, but at a reduced dosing frequency (q48h) in comparison to dogs.

PRECAUTIONS
• Animals with TCC may have renal damage either due to hydroureter, hydronephrosis, or pyelonephritis secondary to chronic urinary tract infection associated with the tumor. • Dogs being treated with chemotherapy should be monitored for myelosuppression. • Seek advice before initiating therapy if unfamiliar with cytotoxic drugs.

POSSIBLE INTERACTIONS
Cisplatin should not be used concurrent with other nephrotoxic drugs (e.g., aminoglycoside antibiotics).

ALTERNATIVE DRUG(S)
Antibiotics—antibiotic therapy should be administered as necessary.

FOLLOW-UP

PATIENT MONITORING
• Contrast cystography or ultrasonography every 6–8 weeks to determine disease status. • Thoracic radiographs and abdominal ultrasound every 2–3 months to monitor for metastatic disease.

PREVENTION/AVOIDANCE
Advise client regarding frequent urination following cyclophosphamide therapy to minimize contact time with the urinary bladder mucosa.

POSSIBLE COMPLICATIONS
• Urethral or ureteral obstruction and renal failure. • Metastatic disease to regional lymph nodes, lungs, or bone. • Recurrent urinary tract infection. • Urinary incontinence. • Myelosuppression of gastrointestinal toxicity secondary to chemotherapy. • Gastrointestinal ulceration secondary to piroxicam therapy.

EXPECTED COURSE AND PROGNOSIS
• Long-term prognosis is guarded. • Progressive disease likely. • Median survival—no therapy: 4–6 months; with therapy: 6–12+ months.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Recurrent urinary tract infections. • Postrenal azotemia. • Paraneoplastic hypertrophic osteopathy.

T

TRANSMISSIBLE VENEREAL TUMOR

BASICS

OVERVIEW
• Sexually, or other direct contact, transmitted, naturally occurring tumor.
• Appears to be more common in temperate areas and large cities.

SIGNALMENT
Predisposition in intact dogs of either sex, however, routes of nonsexually contact transmission permits disease manifestation in neutered and spayed dogs.

SIGNS
• Red, friable, lobulated mass on the mucosa of the vagina, penis or other nonreproductive organ mucous membranes.
• Oral and nasal mucosa may be affected.
• Owners may report blood dripping from the affected area or excessive licking of the genital area.
• Proliferative or exophytic tumor protrusion may be noticed.

CAUSES & RISK FACTORS
• Direct transplantation of tumor cells onto abraded mucosa, either by coitus, oral, or nasal transmission.
• Intact, free-roaming dogs are at greater than average risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Other neoplasia (e.g., squamous cell carcinoma, cutaneous lymphoma).
• Vaginal hyperplasia or pseudo-estrus.

CBC/BIOCHEMISTRY/URINALYSIS
• Usually unremarkable.
• Urinalysis (free-catch) reveals hematuria and abnormal round cell populations in some patients if the tumor is within the urogenital tract.

OTHER LABORATORY TESTS
N/A

IMAGING
• Thoracic radiographs, although this tumor type is rarely metastatic.
• Abdominal ultrasonography to evaluate mesenteric lymph nodes.

DIAGNOSTIC PROCEDURES
• Careful palpation of regional lymph nodes, and perform aspirates with cytology when clinically indicated.
• Examination of impression smears or aspirates of the tumor reveals homogenous sheets of round to oval cells with prominent nucleoli, scant cytoplasm, and multiple clear cytoplasmic vacuoles.
• Biopsy offers definitive diagnosis.

TREATMENT
• May spontaneously regress with appropriate immunologic response, treatment is recommended as spontaneous remissions are not reliable.
• Surgical excision of tumors is often followed by recurrence.
• Radiotherapy alone may be curative.
• Medical therapy is often curative.

MEDICATIONS

DRUG(S) OF CHOICE
• Vincristine sulfate 0.5–0.7 mg/m^2 IV once weekly for 2 weeks beyond complete resolution of gross disease.
• If only partial or no remission, doxorubicin 30 mg/m^2 IV every 3 weeks may have activity.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
• Myelosuppression secondary to vincristine or doxorubicin administration.
• Doxorubicin may be cardiotoxic, use with caution once a cumulative dose of 150 mg/m^2 is reached.
• Tissue sloughing if either vincristine or doxorubicin is administered perivascularly.
• Seek advice before initiating therapy if unfamiliar with cytotoxic drugs.

FOLLOW-UP

PATIENT MONITORING
CBC and platelet count before each chemotherapy treatment.

PREVENTION/AVOIDANCE
• Neuter animals.
• Prevent animals from roaming free in endemic areas.

POSSIBLE COMPLICATIONS
• Tumor recurrence possible following incomplete surgical excision or reexposure.
• Metastatic disease uncommon, but reported to occur in regional lymph nodes, eye, and spinal cord.

EXPECTED COURSE AND PROGNOSIS
Most cases of transmissible venereal tumor have an excellent response to therapy (primarily chemotherapy or radiotherapy) and an excellent prognosis.

MISCELLANEOUS

ZOONOTIC POTENTIAL
None

PREGNANCY/FERTILITY/BREEDING
• Pregnant animals should not be treated with chemotherapy.
• Animals may be infected with transmissible venereal tumor during coitus.

TRAUMATIC DENTOALVEOLAR INJURIES (TDI)

BASICS

DEFINITION
• Traumatic dentoalveolar injuries (TDI) may be broadly categorized into two major groups: (1) dental fractures and (2) luxation injuries.
• Dental fractures include enamel infraction, enamel fracture, enamel–dentin (uncomplicated) fracture, enamel–dentin–pulp (complicated) fracture, crown–root fracture (with or without pulpal involvement) and root fracture.
• Luxation injuries include concussion, subluxation, luxation (lateral, intrusive and extrusive) and avulsion and are often associated with a fracture of the alveolar process.
• An avulsion is an injury in which the tooth has been completely displaced out of its socket.

PATHOPHYSIOLOGY
• Untreated pulpal exposure invariably leads to pulpitis, pulpal necrosis and periapical pathology.
• Pulpitis and pulpal necrosis may also occur with enamel–dentin fractures, if the fracture line is close to the pulp chamber, which exposes a large number of dentinal tubules that may allow microbial contamination.
• Concussion injuries may also lead to pulpitis and pulpal necrosis.

SYSTEMS AFFECTED
Endodontic infection may cause systemic complications.

INCIDENCE/PREVALENCE
• 26.2% of dogs and cats had at least 1 TDI with a mean of 1.45 TDI per patient.
• The prevalence of TDI in dogs and cats with concurrent maxillofacial fractures increases to near 70%.

SIGNALMENT
Species
Dogs and cats.

Mean Age and Range
Juveniles tend to have more TDI associated with maxillofacial fractures, though TDI prevalence tends to increase throughout adolescence and peaks between 3 and 6 years of age.

SIGNS
Crown Fractures
• Clinical loss of tooth crown substance; enamel only, or enamel and dentin.
• Enamel–dentin fractures with the fracture line close to the pulp chamber—pale pink pulp is visible through the dentin.
• In enamel–dentin–pulp fractures, the pulp chamber is exposed.
• Acute enamel–dentin–pulp fractures may be associated with hemorrhage from the pulp.

Crown–Root Fractures
• Fracture line may be visible as it extends into the gingival sulcus.
• The "slab" fracture of the maxillary fourth premolar tooth extends subgingivally into the root.

Root Fractures
• At any point along the length of the root.
• Fracture line transverse or oblique; segments may remain aligned or be displaced.
• Abnormal mobility of a periodontally sound tooth may raise suspicion of a root fracture.

Luxation Injuries
• Severely concussed teeth may take on a blue/pink/purple/gray discoloration often referred to as intrinsic (endogenous) staining.
• Intrusive luxation—tooth appears shorter than normal; no tooth mobility detected.
• Extrusive luxation—tooth appears longer than normal and is mobile both vertically and horizontally.
• Lateral luxation—tooth crown is displaced in either a labial or palatal/lingual direction.
• Avulsion—the tooth has been completely displaced out of the socket. The tooth may or may not remain attached to the gingiva.
• Luxations and avulsions are often accompanied by gingival lacerations.

CAUSES
• Altercations with other animals, motor vehicle accidents, falls from height, contact with a moving object, or simply sustained during playful activity, collision with another animal or object or even during chewing/mastication.
• Since these injuries often occur during unsupervised activities, the mechanism of injury is often unknown.

RISK FACTORS
• Free-roaming behavior increases risk of trauma.
• The maxillary canine tooth is the most commonly luxated/avulsed tooth.
• Advanced periodontitis will predispose to luxations and avulsions.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Crown fracture—attrition, abnormal tooth formation.
• Root fracture—luxation; severe periodontitis. Imaging needed.
• Luxation—root fracture where the coronal segment is displaced.
• Avulsion—tooth exfoliated due to severe periodontitis.

CBC/BIOCHEMISTRY/URINALYSIS
• Noncontributory.
• Unaffected by tooth fracture.

IMAGING
General
• Intraoral radiography is mandatory.
• CT with appropriate protocol for the dentition may be beneficial for identifying some root fractures.

Radiographic Findings
• The presence of relatively wide root canal space (halted dentinogenesis) and/or periapical lucency (periapical periodontitis) is indicative of pulpal necrosis.
• Radiographic indicators of disease may not be present in concussion and subluxation injuries.
• Intrusive luxation—narrowing of the periodontal ligament space in the apical region.
• Extrusive luxation—widening of the periodontal ligament, especially in the apical region.
• Lateral luxation—widening and narrowing of the periodontal ligament space and fracture of the alveolar process.

DIAGNOSTIC PROCEDURES
• Percussion, thermal pulp testing, electric pulp testing are subjective methods that rely on patient feedback and, thus, are unreliable.
• Pulse oximetry has shown mixed results for determining pulpal vitality. This method should currently be considered unreliable.

PATHOLOGIC FINDINGS
Untreated pulpal exposure invariably leads to pulpitis and eventual pulpal necrosis and periapical pathology.

TREATMENT

APPROPRIATE HEALTH CARE
Depends on extent and severity of trauma to the patient.

NURSING CARE
Depends on extent and severity of trauma to the patient.

ACTIVITY
Restrict as indicated by nature of trauma.

DIET
In the immediate postoperative period (24–72 hours), moistening the patient's dry food may help decrease the chance of traumatizing any suture lines or splints.

CLIENT EDUCATION
A series of treatments may be necessary.

SURGICAL CONSIDERATIONS
Enamel–Dentin Fractures
Remove sharp and unsupported enamel/dentin edges with a bur and seal the exposed dentin with a suitable restorative material.

Enamel–Dentin–Pulp Fractures
• Requires endodontic therapy or extraction.

TRAUMATIC DENTOALVEOLAR INJURIES (TDI) (CONTINUED)

• For recent fractures in the mature tooth: (1) vital pulpotomy and restoration or (2) conventional root canal therapy and restoration.
• In most cases, vital pulpotomy should be carried out within 48 hours of the injury in order to prevent pulpal necrosis.
• Generally, vital pulpotomy is reserved for younger patients.
• Teeth treated with vital pulpotomy may require standard root canal treatment at a later date.
• Standard root canal therapy is the treatment of choice in older patients, when the injury is chronic or when the pulp is already necrotic.

Crown–Root Fractures

• Treatment of crown–root fractures follows the same principles as for crown fracture, though additional periodontal health concerns should be considered.
• Can the tooth be restored in a manner that can maintain periodontal health?
• Fractures that do *not* extend more than 4–5 mm below the gingival margin may be restored with dental composites or full metal crown in order to maintain periodontal health.
• Fractures that extend further along the root or deeply into the furcation of a multirooted tooth may necessitate extraction of the tooth.

T

Root Fractures

• The level of the fracture along the root length determines the treatment.
• Midroot and apical fractures may heal if the tooth is immobilized with a dental splint.
• Healing may occur by means of a dentinocemental callus, a fibrous union, or an osteofibrous union.
• Fractures in the apical 1/3 of the root carry best prognosis for healing.
• Fractures in the coronal 1/3 of the root usually require tooth extraction.

Luxations

• For lateral and extrusive luxations, reposition the tooth in its normal position and ensure appropriate occlusion; immobilize with a semi-rigid splint for 2–3 weeks.
• If luxation is accompanied by an alveolar process fracture, maintain the splint for 1–2 additional weeks.
• Since the vascular supply at the apex is typically compromised, root canal therapy is typically necessary and is performed 7 days after application of the splint.
• Any gingival lacerations should be sutured.
• The prognosis for intrusive luxations is generally considered poor; as such, extraction is generally recommended.

Avulsions

• The most important factor determining the result of treatment is the vitality of the periodontal ligament, which is dictated largely by the amount of time the tooth has been out of the socket.
• Optimal results are achieved if the tooth is replanted within 30-60 minutes of avulsion.
• Advise client to place the tooth in saline or milk and bring the affected animal in for treatment as quickly as possible.
• Avoid handling the tooth root and rinse gently with sterile saline solution.
• It is essential not to remove the periodontal ligament from the root; a viable periodontal ligament is necessary for healing.
• Replace the tooth in the socket and ensure normal position and occlusion.
• To immobilize the tooth, a semi-rigid splint is applied and left in place for 2–3 weeks.
• Root canal therapy is required in 7 days, but should not be performed at the time of reimplantation.
• Contraindications for replanting avulsed teeth are deciduous teeth, severe periodontitis, caries, or tooth resorption.

MEDICATIONS

DRUG(S) OF CHOICE

• A broad-spectrum bactericidal antibiotic drug for 5–7 days may be used (e.g., when longstanding infection is present) but is generally not indicated.
• Daily rinsing with 0.12% chlorhexidine gluconate solution will diminish the need for prolonged administration of antibiotics.
• Appropriate analgesic regime—usually nonsteroidal anti-inflammatory drug for 3–5 days.

FOLLOW-UP

PATIENT MONITORING

• Check a vital pulpotomy with postoperative radiographs after 6 and 12 months, or at intervals determined by clinical signs, to detect pulp death and consequent periapical changes indicating the need for root canal treatment.
• Check the outcome of conventional root canal therapy radiographically 6–12 months postoperatively; evidence of periapical pathology at this time indicates the need for further endodontic retreatment of the tooth.
• Monitor root fractures radiographically 3–6 months postoperatively.
• Monitor enamel–dentin fractures with radiography at 4–6 months after treatment to assess pulpal health.

PREVENTION/AVOIDANCE

Avoid situations in which teeth are likely to be damaged; keep animal from chewing on hard objects such as rocks.

POSSIBLE COMPLICATIONS

• Untreated pulpal exposure invariably leads to pulpitis and eventual pulpal necrosis and periapical pathology.
• Arrested development of immature teeth.

MISCELLANEOUS

AGE-RELATED FACTORS

The most appropriate treatment will vary with age.

ABBREVIATIONS

• TDI = traumatic dentoalveolar injuries.

TREMORS

BASICS

DEFINITION
Rhythmic, oscillatory, involuntary, abnormal, or normal movement of all or part of the body.

PATHOPHYSIOLOGY
Abnormal or normal movement caused by the alternate or synchronous contraction of reciprocally innervated, antagonistic muscles.

SYSTEMS AFFECTED
- Nervous.
- Endocrine/metabolic.
- Musculoskeletal—muscle weakness or pain.
- Behavioral—fear.

GENETICS
The role of genetics in tremor syndromes is largely unknown with the exception of X-linked hypomyelination in male springer spaniels.

INCIDENCE/PREVALENCE
N/A

SIGNALMENT
- Dog and cat.
- In general, any dog or cat may develop tremors. However, certain tremor syndromes have specific signalment.
- Corticosteroid-responsive tremor syndrome (generalized tremor syndrome, white shaker syndrome)—small to medium-size breed (<15 kg), young adult dogs (<5 years), regardless of coat color. A similar syndrome has recently been observed in 2 cats.
- Idiopathic head tremors (head bobbing)—Doberman pinschers, English bulldogs, French bulldogs, boxers, and Labrador retrievers are overrepresented.
- Orthostatic tremors—young, adult, giant-breed dogs.
- Benign pelvic limb tremors in older dogs—terriers predisposed.
- Hypomyelination—puppies; chow chows, springer spaniels, Samoyeds, Weimaraners, and Dalmatians.

SIGNS
- Localized or generalized.
- Localized—most often involves the head or the pelvic limbs.

CAUSES

Tremors Primarily Affecting the Head
- Cerebellar lesions leading to intention tremors—degenerative; congenital; metabolic; infectious; immune-mediated; neoplastic; traumatic; toxic causes; vascular.
- Idiopathic head tremors (head bobbing)—unknown cause.

Tremors Primarily Affecting the Limbs
- Orthostatic tremors—unknown cause. Seen in the thoracic and pelvic limbs of young, adult, giant-breed dogs. Tremors are present when standing and disappear in ambulating and recumbent animals.
- Compressive lesions of the spinal cord or nerve roots—lumbosacral stenosis; intervertebral disc disease; neoplasia; discospondylitis.
- Neuromuscular disease—peripheral neuropathy; neuromuscular junction abnormality; myopathy.
- Metabolic disorder causing weakness—hypoglycemia, hypoadrenocorticism, hypocalcemia, magnesium imbalance. Metabolic causes of tremors may also present as generalized tremors.
- Benign pelvic limb tremors in older dogs—unknown cause.

Generalized Tremors
- Corticosteroid-responsive tremor syndrome (generalized tremor syndrome, white shaker syndrome)—believed to be immune-mediated.
- Hypomyelination: specific defect in myelin formation unknown.
- Intoxications—metaldehyde (snail bait); mycotoxins (penitrem A and roquefortine); organophosphates; hexachlorophene; bromethalin; ivermectin; moxidectin; pyrethrins/pyrethroids; lead; 5-fluorouracil; macadamia nuts; theobromine; anatoxin-a; marijuana; zolpidem; clozapine, dysautonomia (although toxin is suspected, exact toxin is unknown); castor beans (*Ricinus communis*); carbon monoxide; mirtazapine, alfaxalone, diphenhydramine, many others.
- Degenerative neurologic disease—storage disease; Lafora disease; spongiform encephalopathy.
- Behavioral—fear.
- Hypothermia.

RISK FACTORS
- Presence of concurrent metabolic diseases that can cause tremors (hypoglycemia, hypoadrenocorticism, hypocalcemia, magnesium imbalance).
- Exposure to a known tremorgenic toxin.
- Exposure to fear-producing or hypothermia-inducing situations.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Differentiate tremor from constant repetitive myoclonus, seizures, and myokymia/neuromyotonia.
- Constant repetitive myoclonus—rhythmic contractions usually involving one or more pelvic limb muscles and/or muscles of mastication. Seen most often with distemper virus infection.
- Seizures—may be associated with autonomic disturbances (e.g., urination, defecation, and salivation) and alterations of consciousness.
- Myokymia/neuromyotonia—characteristic vermicular skin rippling caused by muscle contraction and often brought on by excitement or excessive stimulation.

Tremors Primarily Affecting the Head
- Assess for additional neurologic deficits suggesting cerebellar disease; intention tremors are a clinical sign of cerebellar disease; intention tremors worsen when the patient attempts to move the head in a goal-oriented manner; ataxia and dysmetria help determine the neuroanatomic diagnosis.
- Idiopathic head tremors (head bobbing)—patient usually young at onset; sporadic; up-and-down (yes) or side-to-side (no) direction; anatomic origin unknown; no other neurologic deficits present and mentation is not affected.

Tremors Primarily Affecting the Limbs
- Diseases of the lumbosacral spinal cord, cauda equina, and associated peripheral nerves; musculoskeletal diseases.
- Metabolic diseases (may also cause generalized tremors)—hypoglycemia, hypoadrenocorticism, hypocalcemia, magnesium imbalance.
- Neuromuscular disease—peripheral neuropathy; neuromuscular junction abnormality; myopathy.

Generalized Tremors
- Young dog (6–8 weeks)—congenital myelination abnormality; check breed incidences.
- Young adult dog—assess history for toxin exposure; consider corticosteroid-responsive tremor syndrome (generalized tremor syndrome, white shaker syndrome) in young, small-breed dogs.

CBC/BIOCHEMISTRY/URINALYSIS
- Usually normal with associated primary brain disease.
- Assess for metabolic disease; may find hypoglycemia, hypocalcemia, magnesium imbalance, pattern consistent with hypoadrenocorticism.
- Some myopathies are characterized by high creatine kinase, aspartate aminotransferase, and alanine aminotransferase.

OTHER LABORATORY TESTS
If tremors are affecting the limbs and weakness is suspected, consider testing for hypoadrenocorticism (adrenocorticotropic hormone stimulation test) and myasthenia gravis (acetylcholine receptor antibody titer).

IMAGING
- Localized to the pelvic limbs—survey radiography, CT, and/or MRI of the vertebral column and spinal cord from L4 to S3.
- Generalized tremors—in hypomyelination, MRI may reveal lack of myelin; in corticosteroid-responsive tremor syndrome (generalized

TREMORS (CONTINUED)

tremor syndrome, white shaker syndrome) MRI usually normal.
• Intention tremor—MRI of the brain, with special attention to the cerebellum.

DIAGNOSTIC PROCEDURES
• CSF analysis—sensitive but nonspecific; in corticosteroid-responsive tremor syndrome (generalized tremor syndrome, white shaker syndrome) mild mononuclear pleocytosis, but CSF may also be normal; in other encephalitides involving the cerebellum, results vary with cause of disease and duration.
• Electromyography of hind limb muscles—may help diagnosing neuromuscular disease if pelvic limb tremor.

PATHOLOGIC FINDINGS
Dependent on underlying cause of tremor.

TREATMENT
• Treat the underlying primary disease.
• Outpatient, unless surgical treatment is indicated (lumbosacral disease that requires decompression and stabilization).
• Avoid excitement and exercise—may worsen many tremors.
• Degenerative neurologic diseases (e.g., storage disease, spongiform encephalopathy)—no treatment available.
• Hypomyelination—generally not treatable; some breeds improve with maturity (e.g., chow chows).
• Idiopathic head tremors (head bobbing)—no effective treatment available; benign tremor that occurs sporadically; has few health consequences.
• Suspected intoxication—remove patient from further exposure; consult with a poison control center for possible antidote.

MEDICATIONS
DRUG(S) OF CHOICE
• Usually do not respond to antiepileptic drugs (e.g. phenobarbital or diazepam).
• Tremors associated with some toxicities, especially metaldehyde (snail bait), may be treated with methocarbamol (dogs: 50–150 mg/kg IV, maximum dose 330 mg/kg in 24h) and appropriate decontamination.
• Corticosteroids—immunosuppressive dose to treat corticosteroid-responsive tremor syndrome (generalized tremor syndrome, white shaker syndrome)
• Antibiotics—for discospondylitis; choose on the basis of culture and sensitivity of the lesion, blood, or urine.
• Cerebellar diseases—depends on the underlying etiology.
• Gabapentin 5–20 mg/kg up to q8h may be helpful in treatment of some tremors.

CONTRAINDICATIONS
Sympathomimetic drugs—may worsen condition.

FOLLOW-UP
PATIENT MONITORING
• Monitor the primary disease.
• Corticosteroid-responsive tremor syndrome (generalized tremor syndrome, white shaker syndrome)—monitor weekly initially to assess response to treatment.

PREVENTION/AVOIDANCE
Prevent reexposure in the cases of toxicity.

EXPECTED COURSE AND PROGNOSIS
• Idiopathic head tremors (head bobbing)—excellent prognosis, no treatment needed.
• Orthostatic tremors—slowly progressive; disappear when patient ambulates or when patient is recumbent.
• Benign pelvic limb tremors in older dogs—can be slowly progressive; disappear when patient ambulates or when patient is recumbent.
• Hypomyelination—may stabilize and even improve as animal ages.
• Corticosteroid-responsive tremor syndrome (generalized tremor syndrome, white shaker syndrome)—most respond to corticosteroid therapy; some may need low-dose corticosteroid therapy indefinitely.

TRICHOMONIASIS

BASICS

OVERVIEW

- Enteric, pear-shaped, motile (flagellated) protozoa similar to *Giardia*—inhabits large intestine of cats; similar organisms live in intestinal tract of many mammals
- *Tritrichomonas foetus* (sometimes referred to as *T. blagburni*) causes diarrhea in cats:
  - Transmitted via fecal–oral route, ingestion of trophozoites via grooming.
  - Parasites colonize terminal ileum, cecum, and colon leading to large bowel diarrhea.
- Coinfection with *Giardia*—common.

SIGNALMENT

Young, often purebred cats—usually under 1 year (range 3 months–13 years); particularly high prevalence in catteries.

SIGNS

Cats

- May or may not have symptoms of infection.
- Intermittent large bowel diarrhea, malodorous, occasionally contains blood and mucus.
- Anus—may become edematous, erythematous, and painful in kittens.
- Rectal prolapse—if anal irritation becomes severe.
- Diarrhea—improves with antibiotic treatment but reoccurs following course of treatment; may also show waxing and waning course without treatment.
- Median length of time of diarrhea is about 9 months, with resolution in most cats by 2 years; number of cats cohabitating will impact duration of clinical signs.
- Persistence of infection after resolution of diarrhea is common.

CAUSES & RISK FACTORS

- *Tritrichomonas foetus*—causes diarrhea in cats, infertility and abortion in cattle.
- *T. foetus* —high prevalence in purebred cats and densely housed populations such as catteries, show cats, shelters; but very low in feral or indoor cats.
- Pathogenic factors leading to infected cats developing diarrhea—endogenous bacterial flora, adherence of parasite to host epithelium, and cytotoxin and enzyme elaboration.
- *Pentatrichomonas* spp. (family Trichomonads)—inhabit large intestine of cats, dogs, humans; nonpathogenic in dogs and cats, except very rarely when it may become an opportunistic pathogen.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Cats

Dietary indiscretion, inflammatory bowel disease, neoplasia (especially gastrointestinal lymphoma), drugs (antibiotics), toxins (lead), parasites (cryptosporidiosis, *Giardia*, hookworms, roundworms), bacterial agents (salmonellosis, intestinal bacterial overgrowth, clostridia), systemic organ dysfunction (renal, hepatic, pancreatic, cardiac), and metabolic (hyperthyroidism).

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal—may reflect diarrhea.

OTHER LABORATORY TESTS

- Direct fecal smear—very low sensitivity:
  - Method—dilute fresh feces 50:50 in saline, cover slip, examine at 40× objective with condenser lowered to increase contrast.
  - Distinguish from *Giardia* (concave ventral disc, spiral forward motion)—*T. foetus* has jerky forward motion, spindle-shaped, undulating membranes.
- *T. foetus* trophozoites not seen on fecal flotation, will not survive refrigeration.
- Fecal protozoal culture—use commercial media in 37°C incubator (e.g., InPouch® TF); inoculate with 0.05 g fresh feces, examine for motile trophozoites daily for 12 days:
  - *Giardia* and *P. hominis*—do not grow after 24 hours in InPouch system.
- PCR (feces)—more sensitive than fecal culture.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

TREATMENT

- Rule out coexisting disease (cryptosporidiosis, giardiasis, bacterial), especially if diarrhea persists after specific treatment.
- Treatment may decrease the severity of diarrhea but may also prolong time to resolution.

MEDICATIONS

DRUG(S) OF CHOICE

- No approved treatments.
- *T. foetus*—poor treatment responses are common.
  - Ronidazole 30 mg/kg PO q24h for 14 days; currently preferred treatment.
  - Metronidazole 30–50 mg/kg PO q12h, 3–14 days.
- *P. hominis*—metronidazole 20 mg/kg PO q12h for 7 days.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Glucocorticoids may exacerbate clinical disease.
- High doses of metronidazole (usually >30 mg/kg) for extended periods may cause neurologic abnormalities (e.g., vestibular disease).
- Ronidazole may cause reversible neurotoxicity (similar to that seen with metronidazole treatment); doses above 30 mg/kg should not be used in cats, treatment should be discontinued if adverse effects occur.
- Resistance to ronidazole and metronidazole have been reported.

FOLLOW-UP

- Most cats spontaneously resolve their diarrhea but may take years (range 4 months–2 years).
- Relapses of diarrhea are common and often precipitated by dietary changes, stress, treatments of other conditions.

MISCELLANEOUS

ZOONOTIC POTENTIAL

T. foetus is not considered a zoonotic agent; possible zoonotic transmission for *Pentatrichomonas*.

TRIGEMINAL NEURITIS, IDIOPATHIC

BASICS

OVERVIEW
Sudden bilateral paralysis of trigeminal mandibular branches resulting in inability to close the mouth. Lesions are characterized by extensive nonsuppurative trigeminal neuritis, demyelination, and rare axonal degeneration affecting all portions of the trigeminal nerve and ganglion without brainstem involvement.

SIGNALMENT
- Primarily adult dogs.
- Rare in cats.

SIGNS
- Acute onset of a dropped jaw.
- Inability to close the mouth.
- Drooling.
- Difficulty in prehending food, messy eating.
- Swallowing is intact when food and water are placed in the caudal portion of the mouth.
- Approximately one-third of affected dogs will exhibit decreased facial sensation.
- Few dogs have sympathetic involvement of the head (Horner's syndrome).
- Long-term muscle atrophy depending on degree of axonal involvement.

CAUSES & RISK FACTORS
Unknown; autoimmune disorder suspected.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Musculoskeletal disorders of the temporomandibular joints and jaw—differentiated by history of trauma, pain, and physical examination findings.
- Rabies—always initially consider until there is sufficient evidence to rule it out.
- Encephalitis involving the motor nuclei of bilateral trigeminal nerve.
- Neoplasia—involvement of both mandibular nerves with myelomonocytic leukemia, lymphoma, and neurofibrosarcoma reported; usually does not have an acute onset.
- Masticatory muscle myositis—presentation excludes this condition characterized by trismus and difficulty/inability to open the mouth ("locked jaw").

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

IMAGING
MRI—diffuse enlargement of affected nerves that appear isointense to hyperintense on T2-weighted images if edema is present; contrast enhancement on post-contrast T1-weighted images.

DIAGNOSTIC PROCEDURES
- No specific test.
- Skull radiography, MRI, CSF, and muscle biopsy—to rule out differentials.

TREATMENT
- Recovery within 2–3 weeks of onset. Supportive treatment necessary during this period.
- Outpatient if owner is able to help the patient eat and drink.
- Patient cannot prehend or move food and water to the throat but can swallow if the bolus is placed in the caudal portion of the mouth and the jaw is manually held closed. Water and slurry food can also be placed, with a syringe, in the corner of mouth with the head slightly elevated.
- Fluids—subcutaneously if oral support insufficient.
- Esophagostomy or gastrostomy tubes—rarely necessary to maintain adequate food intake.

MEDICATIONS

DRUG(S) OF CHOICE
Corticosteroids not indicated as there is no evidence that they improve recovery. Furthermore, side effects (polyuria and polydipsia) can make management difficult.

FOLLOW-UP
- Self-limiting disorder.
- Full recovery in 2–3 weeks.
- Bilateral symmetrical masticatory muscle atrophy but without trismus.

MISCELLANEOUS

SYNONYMS
- Dropped jaw.
- Trigeminal neuropathy.
- Mandibular paralysis.

Suggested Reading

Author Mylène-Kim Leclerc

TULAREMIA

BASICS

OVERVIEW

- *Francisella tularensis*—small Gram-negative coccobacillus, principally found in wild lagomorphs and rodents; facultative intracellular parasite that survives and grows in the liver, resulting in granulomas and/or abscesses:
  - Type A is more virulent and found in rabbits and ticks, type B is waterborne and found in rodents and ticks.
  - In United States most cases found in Missouri, Alaska, Oklahoma, South Dakota, Tennessee, Kansas, Colorado, Illinois, Utah, Maine, New York, and New Jersey.
  - Increasing number of tularemia outbreaks in regions of Europe outside the classic endemic areas in recent years.
  - Absent from United Kingdom, Africa, South America, Australia.
- Tularemia infection in cats follows a bimodal seasonal incidence curve with peaks in spring and late summer–fall, and may reflect the seasonality of the disease in the rabbit.
- Infection—ingestion of tissue or body fluids of an infected mammal or contaminated water, bitten by blood-sucking arthropod (tick), flies, mites, midges, fleas, or mosquitoes; few bacteria needed to infect cats through skin, airways, or conjunctiva; larger number required to infect through gastrointestinal tract:
  - Skin contact—organism multiplies locally (papule) 3–5 days after contact; ulcerates 2–4 days later; spreads via lymphatics to regional lymph node (LN) and bloodstream; results in septicemia (lung, liver, spleen, LN, bone marrow).
  - Ingestion—may involve lymphadenopathy of cervical and mesenteric LN followed by septicemic spread; distribution of lesions to face, oral cavity, tonsils, intestines, and LN.
- Acute disease—2–7 days after contact with organism.
- Has high aerosol-related infection rate, low infectious dose, and ability to induce fatal disease.
- *F. tularensis* is considered a potential biologic warfare agent; occurrence of clusters of cases in companion animals may indicate potential human risk.

SIGNALMENT

- Cat—occasionally.
- Dog—rarely.

SIGNS

- Sudden onset of anorexia, lethargy, fever (104–106°F/40–41°C).
- Enlarged submandibular and cervical LN.
- Tender abdomen, palpable mesenteric LN, hepatomegaly—depending on stage of disease.
- Multifocal white patches or ulcers along glossopalatine arches and tongue.
- Icterus.

CAUSES & RISK FACTORS

- Organism— *Francisella tularensis*; all *Francisella* biogroups may infect cats but differ in virulence.
- Hunting or outdoor cats in endemic areas .
- Infected wildlife in the area of hunting activity.
- Exposure to infected blood-sucking parasites.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Pseudotuberculosis (*Yersinia pseudotuberculosis*)—usually vomiting and diarrhea.
- Babesiosis (*Babesia/Theileria*) (dogs and cats).
- Calicivirus (cats).
- Feline immunodeficiency virus.
- Toxoplasmosis (cats).

CBC/BIOCHEMISTRY/URINALYSIS

- Initially severe panleukopenia; then leukocytosis with left shift, toxic neutrophils, thrombocytopenia.
- Hyperbilirubinemia, bilirubinuria.
- Hyponatremia.
- Hypoglycemia.
- Alanine aminotransferase activity increased.
- Hematuria.

OTHER LABORATORY TESTS

Serology with tube agglutination or ELISA—reference laboratory; all animals do not necessarily respond serologically to infection (false negatives possible).

DIAGNOSTIC PROCEDURES

- *Caution*: use extreme care when working with infected specimens or isolates.
- Direct smear—lesion or biopsy; difficult to see organism on Gram staining.
- Culture—by reference laboratory only; blood, pleural fluid, LN aspirate onto cysteine- or cystine-containing media; not recoverable on routine laboratory media.
- Direct fluorescent antibody testing—clinical materials or tissues; rapid assay of infection status.
- Molecular testing of tissues in laboratories with validated diagnostic protocols.

PATHOLOGIC FINDINGS

- Multifocal white patches or ulcers along glossopalatine arches and tongue.
- Oral, tonsillar ulceration.
- Lymphadenopathy of cervical, retropharyngeal, or submandibular LN with abscessation.
- Diffuse intestinal lesions.
- Mesenteric lymphadenopathy, hepatosplenomegaly, icterus.

TREATMENT

- Inpatient with good nursing care; infection control protocols (personal protective gear) *very* important due to low infectious dose/zoonotic nature of disease.
- Early treatment important to prevent high mortality; treatment often unsuccessful.
- Treat for ectoparasites.

MEDICATIONS

DRUG(S) OF CHOICE

Treat all cases empirically until laboratory confirmation obtained.

- Little information available on the efficacy of antimicrobials; *high mortality if patient not treated early*.
- Early treatment with amoxicillin 22 mg/kg PO q8h for 5–7 days or 22 mg/kg IM, SC q12h for 5 days, in combination with gentamicin 4.4–6 mg/kg IV, IM, SC q24h for 7 days has been successful.
- Enrofloxacin 10 mg/kg PO, IV q24h (dog), 5 mg/kg PO, IV q24h (cat) may be effective.

FOLLOW-UP

PATIENT MONITORING

- Monitor for disseminated intravascular coagulation—may occur late in the infection.
- Monitor renal function during gentamicin therapy.

PREVENTION/AVOIDANCE

- Avoid travel to endemic areas.
- Endemic areas—confine animals to limit exposure to and ingestion of wildlife and ectoparasites (ticks); ectoparasite control by periodic spraying or dusting of animal and pastures.
- Neuter cats—limit hunting behavior, wildlife exposure.
- Take precautions to limit contamination of food and water with carcasses of infected wildlife.

EXPECTED COURSE AND PROGNOSIS

Prognosis poor if not treated early; prognosis poor if mesenteric LN palpable.

TULAREMIA (CONTINUED)

MISCELLANEOUS

ZOONOTIC POTENTIAL

- Extremely high.
- Human cases related to direct dog contact via bite, scratch or face snuggling/licking, direct contact with dead animals retrieved by domestic dogs, contact with infected ticks; dogs with oral contact with diseased wildlife or carcasses may act as "living fomites" to contaminate humans.
- All personnel in contact with patient or body fluids must use face mask, gloves, and gowns to avoid infection.
- Isolate patients.
- In emerging disease areas, cat ownership is a disease risk for humans.
- Bites and scratches pose a risk for humans.
- Do not mistake for plague or bite abscess in cats.

SYNONYMS

- Rabbit fever.
- Deerfly fever.
- Market men's disease.

ABBREVIATIONS

- LN = lymph node(s).

UNRULY BEHAVIORS: JUMPING, PULLING, CHASING, STEALING—DOGS

BASICS

DEFINITION

• Jumping—standing on rear legs with front legs on a person or object or leaping in the air with or without landing against the person. • Pulling—to exert force on the leash to cause motion towards the source of the force (the dog). • Chasing—pursuing a moving person, animal, or object. • Stealing—the taking of an item not intended to be used by the dog.

PATHOPHYSIOLOGY

• May be within the range of normal dog behaviors. • Insufficient outlets for normal activities may contribute. • Jumping up may be associated with excessive greeting but can be associated with separation anxiety or social anxiety. • Pulling can be associated with different motivational states including but not limited to fear, anxiety, excitement, and predatory behavior. • Pathologic hyperactivity and anxiety disorders may rarely be a contributing factor.

SYSTEMS AFFECTED

• Behavioral.
• Gastrointestinal.

SIGNALMENT

Species

Dogs

Breed Predilection

Herding and hunting breeds may be more likely to chase.

Mean Age and Range

More common in younger dogs but occurs at any age.

SIGNS

Historical Findings

• Jumping up on people occurs more commonly in association with arrivals, departures, or other greetings; also associated with exploring countertops or tables.
• Pulling may be more likely in the beginning of a walk or when seeing, hearing, or perhaps smelling a stimulus (e.g., person, other dog, object of interest) but can occur at any point.
• Items displaced, damaged, chewed, or ingested are common complaints in stealing.

Physical Examination Findings

• Usually unremarkable unless underlying medical problems. • Nails worn down.

CAUSES

• Jumping up is normal greeting and play behavior. Excitement, encouragement of the behavior, or inadvertent rewarding perpetuates it. Separation anxiety may result in excessive jumping on owners when returning home or leaving. Social anxiety may cause overly exuberant greeting of visitors, with jumping.
• Pulling can occur when a dog is not taught how to walk on loose leash or due to different motivational states. A dog may pull toward or away from something it is afraid of (avoidance) or toward something that is fear-evoking (aggression) or that it is excited about greeting. • Stealing is a normal acquisitive behavior. It can be an attention-seeking behavior or motivated by the appeal of the odor, texture, or taste of an item with which to chew, eat, or play. Stealing can occasionally be comfort-seeking or related to separation anxiety, in which the dog may steal an item when anxious as the owner is preparing to leave or when the dog is separated from the owner but the owner is still in the house.
• Chasing is a normal behavior, as part of herding, hunting, play, and defense.

RISK FACTORS

• Inadequate exploratory or social enrichment.
• Stealing food—restricted or weight-reduction diets, phenobarbital, benzodiazepines, glucocorticoids, hyperadrenocorticism, and diabetes mellitus. • Chasing—common in herding breeds.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Separation anxiety—escapes or attempts escape from confined areas in the owner's absence. Often occurs at entrances or when confined. Usually associated with other signs consistent with separation anxiety, including vocalization, urination, defecation, destruction, or salivation, in the owner's absence.
• Other anxiety or phobia (e.g., thunderstorm, fireworks).

CBC/BIOCHEMISTRY/URINALYSIS

• Usually unremarkable.
• May have abnormalities consistent with system affected.

OTHER LABORATORY TESTS

As indicated to rule out source of pain or endocrine disease (low-dose dexamethasone suppression test [LDDST], urine cortisol:creatinine ratio [UC:Cr ratio], bile acids).

IMAGING

Not indicated unless suspicion of foreign body or to rule out medical causes.

TREATMENT

APPROPRIATE HEALTH CARE

Outpatient management.

ACTIVITY

Increase the dog's daily exercise, opportunities for mental stimulation including food-related enrichment (food-filled toys, search and find games). If problem related to anxiety, must address underlying anxiety as well.

DIET

Review energy requirements, amount fed, and number of meals per day in food-stealing cases.

CLIENT EDUCATION

Jumping

• During training, prevention of jumping up is essential. • A head collar and leash can facilitate training by preventing jumping up or gently guide the dog away from jumping.
• Greeting visitors outside might diminish jumping behavior. The dog's access to the situation can be restricted by confinement (e.g., other room, crate) or on leash with owner until the visitor is seated, which may also reduce the arousal associated with jumping up. • Teach "Sit," "Stay," or "Place/mat" as an alternative desirable method to greet people, using highly valued rewards (food treats, toys) in areas of the home where the dog is calm and tractable. • Food rewards should be used consistently for desirable outcomes. • Add the word "Stay" when the duration of sitting is a few seconds; take a step away, return to the dog, and give the food reward. Build up the time away from the dog to 3–5 minutes. • Repeat exercises near the door and then with leaving and returning. • Next ask the dog to sit for a food reward when returning from gradually longer absences. • Family members and familiar visitors can enter, ask the dog to sit, and give a food reward. • If the dog has difficulty sitting related to pain or discomfort it can be taught "Touch" for greeting. The "Look" cue could also help in getting a dog's attention away from the person entering. • Dogs that like to retrieve and are too excited to sit may do better if a ball is tossed as a visitor enters.
• The owner should walk calmly to the door and speak in a quiet voice to avoid increasing the dog's excitement. • Avoid rewarding the jumping with any form of attention, including pushing the dog off. Do not acknowledge or interact with the dog; hold arms against the body, and look away or turn away from the dog. The person disengaging from the dog facilitates the dog listening to an owner's request to sit for a treat.
• Stepping on the dog's toes, squeezing the paws, and any type of punishment must be avoided as they cause fear, may lead to aggression, and negatively impact the human–animal bond.

UNRULY BEHAVIORS: JUMPING, PULLING, CHASING, STEALING—DOGS (CONTINUED)

Pulling

• A dog's natural walking speed may be faster than their owner's. • A no-pull harness or head collar can be helpful and may be all that is needed. • A brief play session in a fenced in yard before a walk may decrease initial energy and decrease pulling (although some dogs get more aroused immediately after exercise).
• Pulling related to fear, anxiety, or excitement requires desensitization (gradual exposure) and training/reinforcement of an alternative response as discussed under Chasing below.
• With proper application of positive reinforcement pulling can be resolved. • Use food to lure and reward the dog for walking next to a person. Have highly desirable small treats in the hand on the same side as the dog; initially give every few seconds. If the dog pulls, stop, call the dog's name and/or ask it to "Look" (see Chasing), reward the behavior and resume walking. Over time decrease the frequency of giving the treat until it is every minute or two. Many dogs learn to come to the owner for a treat when they learn the "Look" command.
• A second method is to stop walking as soon as the dog starts to pull. When the dog stops moving call the dog's name and/or ask it to "Look" and reward the behavior and continue walking when the leash is slack. If the dog pulls again repeat the process. • All punishment including leash corrections should be avoided as it does not train what is desirable and can condition fearful associations. Sharp jerking or turning suddenly may cause pain and injury to the neck and trachea.

Chasing

• A no-pull harness or head collar can be helpful in controlling the dog and reorienting it toward the owners in the presence of the chase stimulus. Herding breeds exhibit a phenotypic behavior that may respond better to control and management than to treatment. • Dogs that chase should be desensitized and counter-conditioned to the stimulus. • The owner should practice the same sit-and-stay exercises as described above, with the addition of a "Look" command using a treat brought up to the owner's eye. This will help get the dog's attention and focus it on the owner when it sees the moving stimulus. • Initially work with the dog inside without distractions, to train, sit, stay, and look. • Next work in a quiet yard with the dog on a leash, have the dog sit, stay, step away, return, look, and give the food reward. When the dog is successful, the process can be repeated in different parts of the yard with gradually more intense distractions.
• Training should begin without the chase stimulus present. If the owner is able to keep the dog's attention, the owner should then stage the chase stimulus (such as a bike or person jogging) to pass by at a sufficient distance and slow enough speed while training and rewarding sit, stay, and look. Over future sessions, the intensity of the stimulus can be gradually increased. • When the dog is able to ignore the chase stimulus in the yard, the owner can incorporate the same exercises in a park or on a walk while maintaining sufficient distance from the stimuli. When the owner sees the chase stimulus, he or she should ask the dog to sit, stay, and look, and then reward the dog.

Stealing

• The dog's investigative behavior and attempts to initiate play and chase may result in stealing. If the result is enjoyable the behavior is rewarded. • Adequate attention, exercise, and toys before times of inattention (e.g., making dinner, working, watching TV) will help to decrease the motivation for stealing. • If the dog steals, the owners should ignore the dog, walk away, get a treat, and call the dog. As the dog drops the item, the owner can say "Drop," "Good dog," and give the dog the treat or click and treat if the dog is clicker trained. The dog is being rewarded for relinquishing the item. • The owner might also need to use a stay and give a second treat or a chew toy to be able to retrieve the dropped item. Another option is to scatter a number of treats for the dog to pick up while the item is removed. • If the dog retreats under furniture, the owner should not pursue. If the dog feels threatened or cornered, it may defend itself aggressively. If it is imperative that the item be retrieved, the client may need to lure the dog out of hiding with even higher value treats or offer a walk or favored game. The owner should keep a log of when and what the dog steals, where they were at the time, and what they were doing to determine when and why the dog is stealing. Prior to, or at these times the dog can be engaged in desirable alternative activities (social play, chews, or food-filled toys). In addition, the owners should video-record the dog to see its response during their absence. See separation anxiety for more details. • For food stealing, food needs to be kept out of the dog's reach, since acquiring food is highly rewarding. Confinement training or gating the dog out of food preparation and dining areas may be necessary. Feeding from food puzzles and toys provides enrichment and engages the dog in alternative acceptable outlets for exploration. • If the dog steals food because it is on a diet, a protein source such as plain cooked chicken or other meat or low-calorie foods such as raw or cooked vegetables can be added to help increase the feeling of fullness.

MEDICATIONS

DRUG(S) OF CHOICE

None

FOLLOW-UP

PATIENT MONITORING

Every 2–3 weeks initially.

PREVENTION/AVOIDANCE

Close supervision, exercise, and exposure to varied stimuli as a young puppy and attending puppy classes and ongoing training can help to prevent and manage unruly behaviors.

POSSIBLE COMPLICATIONS

Injury as a result of escaping a fence, chasing a stimulus, or ingesting an inappropriate item.

EXPECTED COURSE AND PROGNOSIS

Generally good response to treatment for jumping, pulling, and stealing if the owner is consistent. Guidance and support of a force-free reward-based trainer may help to improve success. Chasing behaviors may be more difficult and resistant.

MISCELLANEOUS

AGE-RELATED FACTORS

Younger dogs need more activity than many owners anticipate.

SEE ALSO

• Aggression—Food and Resource Guarding Dogs.
• Fears, Phobias, and Anxieties—Dogs.
• Puppy Behavior Problems.
• Separation Anxiety Syndrome.

ABBREVIATIONS

• LDDST = low-dose dexamethasone suppression test.
• UC:Cr = urine cortisol:creatinine ratio.

U

URETEROLITHIASIS

BASICS

OVERVIEW
Occurrence of a urolith within a ureter; most originate in the renal pelvis and commonly occur with nephroliths. If the uroliths pass through the ureters into the lower urinary tract, patient may be asymptomatic or have silent hematuria. If both ureters become totally obstructed, without treatment death will occur in within 5 days.

SIGNALMENT
- Dog and cat.
- Breed, age, and sex predispositions vary with type of ureterolith.

SIGNS
- May be asymptomatic initially.
- Pain (ureteral colic) during passage of ureteroliths or acute ureteral obstruction.
- Renomegaly if obstruction leads to hydronephrosis.
- "Big kidney, little kidney syndrome"—obstruction of one ureter has previously occurred, resulting in a shrunken end-stage kidney; signs of uremia and renomegaly occur due to obstruction of the remaining functional kidney.
- Unilateral ureteral obstruction results in azotemia and uremic clinical signs only when the contralateral kidney has reduced function.
- Signs referable to a lower urinary tract infection (UTI) or septicemia may be present with ureterolithiasis.
- Ureteral rupture may occur, resulting in urine accumulation in the retroperitoneum.
- Cats with distal ureteral obstruction may have signs of dysuria and pollakiuria.

CAUSES & RISK FACTORS
- For a list of causes, see chapters on each urolith type.
- Most ureteroliths are calcium oxalate. Dogs may form struvite nephroliths and subsequent ureteroliths from urease-producing bacterial UTI. Cats may have ureteroliths composed of dried solidified blood clots.
- Circumcaval ureters (more commonly in right ureter) may predispose cats to obstruction by ureteroliths and secondary ureteral stricture formation.
- Prior treatment of nephroliths by extracorporeal shock wave lithotripsy (ESWL) or medical dissolution may be additional risk factors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Consider in cases of acute kidney injury (AKI), rapid progression of chronic kidney disease (CKD), renomegaly, abdominal pain, or fluid accumulation in the retroperitoneal space. Obstruction to urine outflow of both kidneys may not produce the same magnitude of renomegaly as unilateral obstruction because the patient may succumb to uremic complications before severe dilation occurs.
- Radiopacities detected by abdominal radiography that may be confused with ureteroliths include fecal material in the colon, nipples, peritoneoliths, calcified lymph nodes, and mineralization of the renal pelvis.
- Radiolucent ureteroliths may be difficult to differentiate from blood clots. Other causes of ureteral obstruction include intraluminal tumors, ureteroceles, ureteral strictures, and extraluminal compression. Hydroureter and hydronephrosis may occur because of ureteral ectopia, pyelonephritis, ureterovesical stenosis, and obstruction of the ureteral opening at the trigone (most commonly due to urothelial carcinoma).

CBC/BIOCHEMISTRY/URINALYSIS
CBC in patients with pyonephrosis secondary to obstructive ureteroliths may have leukocytosis, immature neutrophilia, and thrombocytopenia. Ionized calcium concentration, urinalysis, and urinary excretion of electrolytes may permit estimation of urolith composition pending results of definitive analysis.

OTHER LABORATORY TESTS
- Submit all retrieved ureteroliths for quantitative analysis to determine appropriate preventive strategies.
- Blood pressure should be monitored; hypertension is common with CKD or AKI secondary to ureteral obstruction.

IMAGING
- Radiography—radiopaque ureteroliths may be visualized. If obstruction and hydronephrosis have occurred, renomegaly may be apparent. If ureteral rupture occurs, contrast in the retroperitoneal space may be lost. Small ureteroliths may not be visualized.
- Ultrasonography—valuable for detecting hydronephrosis or hydroureter. Changes suggesting pyelonephritis may also be detected by ultrasound. The dilated proximal ureter may be traced to the ureteroliths. Ureteroliths are not observed ultrasonographically in up to 25% of cats with ureteroliths. Ultrasound-guided pyelocentesis can be used to confirm ureteral obstruction, although this is usually performed during surgical placement of subcutaneous ureteral bypass (SUB) or ureteral stents.
- CT before and after IV contrast can be used to confirm obstructive ureteroliths if they are suspected but not confirmed by other imaging modalities. This is not required for surgical planning for SUB or stent placement.

DIAGNOSTIC PROCEDURES
Nuclear scintigraphy alone should not be used to determine whether or not to preserve or surgically remove a kidney.

PATHOLOGIC FINDINGS
Progressive dilation of the pelvis and calyces; in advanced cases, the kidney may be transformed into a thin-walled sac with only shell of atrophic cortical parenchyma; ureteral dilation proximal to the site of obstruction is often present.

TREATMENT
- For small nonobstructive ureteroliths, allowing time for the ureteroliths to spontaneously pass down the ureter to the bladder may eliminate the need for intervention.
- Remove or bypass ureteroliths that are causing obstruction.
- Ureteroliths in dogs have been successfully treated with ESWL. Efficiency of ESWL fragmentation of ureteroliths is improved with prior ureteral stent placement. Calcium oxalate uroliths from cats are intrinsically resistant to fragmentation via ESWL. ESWL is not recommended for cats.
- Surgical techniques recommended for removal of ureteroliths vary, depending on the site of obstruction, species, the presence or absence of UTI, and the degree of function of the associated kidney.
- SUB placement is effective for relief of ureteral obstruction in cats and is often the preferred surgical procedure for cats.
- Ureteroneocystotomy may be performed for ureteroliths in the middle and distal ureter: the ureter proximal to the obstruction is excised and reimplanted into the bladder. Ureteroliths in the proximal ureter may be removed by ureterotomy. Performance of ureterotomy or ureteroneocystotomy in cats requires microsurgical expertise. When the contralateral kidney functions normally and severe end-stage hydronephrosis is present, ureteronephrectomy may be appropriate.
- Ureteral stent placement to bypass obstructive ureteroliths relieves the obstruction and causes passive ureteral dilation. Ureteral stents may be placed endoscopically in dogs and surgically in dogs and cats. Ureteral stent combined with medical dissolution effectively resolves struvite ureteroliths in dogs.

MEDICATIONS

DRUG(S) OF CHOICE
- Medical dissolution is only effective for struvite ureteroliths when combined with

URETEROLITHIASIS (CONTINUED)

ureteral stent placement. Medical dissolution requires culture-guided antibiotics and dissolution diet.
• Therapy aimed at prevention of recurrent disease is imperative following relief of obstruction.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Attempts to prevent one type of urolith may promote formation of a second type.

FOLLOW-UP

PATIENT MONITORING
• Following SUB placement, routine sampling of the SUB for urinalysis and culture along with flushing the SUB is performed every 3 months.
• Instillation of tetra-EDTA solution into the SUB is recommended with SUB flushes.
• Following successful removal of ureteroliths, recheck every 3–6 months for recurrence of uroliths and to ensure owner compliance with preventive measures; urinalysis, imaging, and urine culture.

PREVENTION/AVOIDANCE
• Elimination of predisposing factors.
• Specific therapy depends on the mineral composition of the urolith.

POSSIBLE COMPLICATIONS
Hydronephrosis, CKD, AKI, recurrent UTI, pyelonephritis, sepsis, ureteral rupture, ureteral stricture, hypertension.

EXPECTED COURSE AND PROGNOSIS
Highly variable; if unilateral disease is present, the opposite kidney retains adequate function, and recurrence is prevented, the prognosis is good. Prognosis is good for cats with SUB or ureteral stent placement that recover renal function to stage 1–2 CKD. Prognosis is good for dogs with obstructive ureteroliths that recover renal function to stage 1–2 CKD.

MISCELLANEOUS

ABBREVIATIONS
• AKI = acute kidney injury
• CKD = chronic kidney disease.
• ESWL = extracorporeal shock wave lithotripsy.
• SUB = subcutaneous ureteral bypass.
• UTI = urinary tract infection.

URETHRAL PROLAPSE

BASICS

OVERVIEW
- Prolapse of the mucosal lining of the distal urethra through the external urethral orifice.
- Prolapsed urethra appears as a congested, pea-shaped mass protruding from the distal end of the penis and is often associated with hemorrhage. Excessive licking may result in further traumatic damage to the exposed urethral mucosa.

SIGNALMENT
- Reported in male dogs and extremely rare in male cats.
- Most common in English bulldog, Boston terrier, and Yorkshire terrier.
- Mean age 18 months; range 4 months–5 years.

SIGNS
- Intermittent or persistent bleeding from the urethra.
- Intermittent or persistent licking of penis.
- Dysuria and pollakiuria caused by concomitant disorders.

Physical Examination Findings
- Persistent or intermittent urethral prolapse.
- Pale mucous membranes if anemic.
- Necrosis of the prolapsed urethra secondary to drying or self-induced trauma from licking.
- Uroliths may be palpable in the urinary bladder or urethra.

CAUSES & RISK FACTORS
- May result from sexual excitement and/or unrelated disorders (e.g., infections, uroliths, neoplasia) of the lower urinary tract.
- Increased intra-abdominal pressure secondary to dysuria associated with urocystoliths.
- Proposed causes include abnormal development of the urethra with increased intra-abdominal pressure as a consequence of brachycephalic airway syndrome, dysuria, or sexual activity. Increased intra-abdominal pressure could impair venous return of blood through the pudendal veins, predisposing susceptible dogs to engorgement of the corpus spongiosum surrounding the distal urethra.
- Breed predisposition (bulldogs and Boston terriers).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Prostatic disease.
- Persistent penile frenulum.
- Fracture of the os penis.
- Balanoposthitis.
- Urethritis.
- Urethroliths.
- Coagulopathy.
- Urethral neoplasia.

CBC/BIOCHEMISTRY/URINALYSIS
- CBC—may reveal regenerative anemia.
- Serum biochemistries—usually normal.
- Hematuria may be absent in urine collected by cystocentesis, but present in voided urine.
- Urine culture and sensitivity.

OTHER LABORATORY TESTS
Coagulation profile may rule out coagulopathy.

IMAGING
- Survey radiographs—useful to find some uroliths and evaluate the prostate size.
- Contrast cystourethrography—useful to rule out radiolucent uroliths, urethral disorders, and prostatic disease.
- Abdominal ultrasonography—useful to evaluate the prostate and urinary bladder.

DIAGNOSTIC PROCEDURES
- Ejaculation—useful to evaluate urethra during penile erection; some urethral prolapses are present only during penile erection.
- Evaluation of ejaculate may show evidence of prostatic disease.
- Enlarged images obtained with a surgical microcamera associated with a flexible endoscope may be necessary to diagnose urethral prolapse in cats.

TREATMENT
- May not be required if asymptomatic or only associated with episodic bleeding.
- If present only during penile erection, consider castration prior to attempting surgical removal of prolapsed tissue; diethylstilbestrol given for 3–6 weeks after surgery may reduce frequency of erections. If cause is unknown, castration status may not affect prolapse recurrence.
- Consider surgery for patients with excessive bleeding, pain, or extensive ulceration or necrosis of the prolapsed tissue, or if refractory to medical management.
- Satisfactory results have been obtained by manual reduction of the prolapse followed by urethropexy.
- CO_2 laser surgical technique may improve hemostasis, visualization, and accuracy of the surgeon, and decrease postoperative swelling.
- A surgical microscope may be necessary for adequate visualization to perform urethroplasty in cats.
- Postoperative hemorrhage and prolapse recurrence may be reduced with a simple continuous suture pattern and administration of postoperative sedation.

MEDICATIONS

DRUG(S) OF CHOICE
- Bacterial urethritis warrants use of appropriate antibiotics.
- Consider using diethylstilbestrol for 3–6 weeks after surgery to reduce frequency of erections.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
Consider risk of bone marrow suppression before giving estrogens, especially in anemic patients.

FOLLOW-UP

PATIENT MONITORING
Reevaluate 7–10 days following surgery for hemorrhage or recurrence of urethral prolapse.

PREVENTION/AVOIDANCE
If urethral prolapse is associated with penile erection, prevent contact with female dogs or situations likely to cause erection.

POSSIBLE COMPLICATIONS
- Most common postoperative complication was hemorrhage (39%).
- Prolapse recurred in 57% of dogs, but was less common when postoperative butorphanol or acepromazine were given.
- Recurrence of the prolapse may occur, especially if an underlying cause has not been detected and eliminated or controlled.

EXPECTED COURSE AND PROGNOSIS
- Prolapse may persist without significant sequelae. Some dogs may not require therapy.
- Some may not have problems after castration and/or surgical correction of a prolapsed urethra.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Urolithiasis and urinary tract infection.

URINARY RETENTION, FUNCTIONAL

BASICS

DEFINITION
Failure of the urethral smooth and/or striated muscle relaxation as the detrusor muscle contracts at the beginning of urination. Thought to be due to dysfunction of the reflex arc allowing urethral sphincter relaxation as the detrusor muscle contracts at the beginning of urination.

PATHOPHYSIOLOGY
This is a disorder of the emptying phase of micturition due to functional obstruction of the outflow tract and urethra. While the pathophysiology is not completely understood, it is thought that the neurologic lesion is located within the reticulospinal tract, Onuf nucleus, or caudal mesenteric ganglion. The loss of inhibitory signals to the pudendal and hypogastric nerves may also be involved. Involvement of a more local lesion (peripheral nerves, neuromuscular junction, striated and smooth muscles of the sphincters, etc.) is unknown. It is unclear whether anxiety and other behavior disorders may contribute to the disorder.

SYSTEMS AFFECTED
- Urinary tract.
- Typically have otherwise normal neurologic assessment.

U

INCIDENCE/PREVALENCE
Unknown. The literature suggests increasing incidence which may be related to increased awareness and thus diagnosis in male dogs.

SIGNALMENT
Dogs (cats can be affected). Most common in middle-aged male dogs (mean age of 4.9 years). Females are also affected although rarely. Large- to giant-breed dogs most commonly affected.

CAUSES
- Neurologic dysfunction due to spinal cord lesions cranial to the sacral segment resulting in upper motor neuron bladder signs with simultaneous detrusor and urethral contraction.
- Damage to the reflex arc impairing urethral sphincter relaxation during detrusor contraction.
- Urethral spasm of the smooth or striated muscles.
- Controversial behavioral/anxiety-driven component in some patients.

RISK FACTORS
- Large- to giant-breed dogs (25–64 kg).
- Young adults.
- Intact males—sexual excitement in the presence of intact females.
- Cauda equina syndrome.
- Urinary tract infections or urethritis resulting in urethral spasm.
- Surgery in the area of the bladder neck.
- Urethral and prostatic tumors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Diagnosis of a functional urethral obstruction is presumptive. These animals exhibit a typical pattern of urination in which they often start with a normal stream that quickly weakens and may stop completely. The affected animal may posture multiple times attempting to urinate without ever fully emptying their bladder. A large residual urine volume (>1 mL/kg) is typically noted. A mechanical obstruction should be ruled out; passing a urinary catheter is typically easy in dogs with functional obstruction.
- As a result of urine retention, overflow incontinence may occur. This can make it difficult for owners to distinguish it from storage disorders (e.g. urethral sphincter mechanism incompetence).
- This condition can share some similarities with upper motor neuron bladders seen in dogs with intervertebral disc disease.
- Other causes of urine obstruction must be ruled out. These include urolithiasis, neoplasia, benign prostatic hyperplasia, prostatitis, foreign body, and urethral strictures.

CBC/CHEMISTRY/URINALYSIS
Typically unremarkable though evidence of urinary tract infections may be noted on the urinalysis (pyuria, bacteriuria).

OTHER LABORATORY TESTS
None

IMAGING
Contrast urethrography studies in these dogs are often normal, though narrowing of the urethra may be noted due to urethrospasm. Ultrasound can be used to assess the ureters and renal pelvises to look for dilation secondary to obstruction from urolithiasis or vesicoureteral reflux.

DIAGNOSTIC PROCEDURES
Dogs with functional urethral obstruction are typically easily catheterized. A large residual urine volume is typically noted. A normal residual urine volume in dogs is 0.1–3.4 mL/kg (0.2 mL/kg mean). Urethroscopy may be indicated in individuals that fail to respond to medical therapy. This will allow for identification of strictures or other anatomic abnormalities. Urodynamic evaluation does not typically show increased urethral pressure unless the animal is actively voiding.

TREATMENT

Treatments are directed at addressing the relaxation of the smooth and striated muscles of the urethral sphincter (see drugs listed under Medications). Owners can also be instructed how to intermittently pass sterile catheters at home to address residual urine volume. If present, urinary tract infections should be treated based on culture and susceptibility testing. In cases of chronic functional urethral obstruction, bladder atony may occur secondary to prolonged bladder distension. In these cases treatment of bladder atony may be necessary. This should only be initiated once the functional obstruction has been relieved. Urethral stenting and cystostomy tubes are considered a salvage procedure and should only be considered in the most refractory cases. Intact males should be castrated.

MEDICATIONS

DRUG(S) OF CHOICE
- Alpha-1 adrenergic antagonists (give on an empty stomach):
  - Prazosin 0.5 mg/kg PO q12h; 1 mg/15 kg PO q8–12h.
  - Tamsulosin 0.1 mg/10 kg PO q24h; 0.4 mg/dog PO q24h (may increase to q12h).
- Benzodiazepines (anxyiolytic and muscle relaxant):
  - Diazepam 2–10 mg/dog PO q8h.
- Phenothiazine sedative/tranquilizer:
  - Acepromazine maleate 0.55–2.2 mg/kg PO q6–12h.
- Muscle relaxant:
  - Methocarbamol 132 mg/kg/day PO divided q8–12h, then 61–132 mg/kg/day divided q8–12h. If no response in 5 days, discontinue.
- Cholinergic:
  - Bethanechol chloride 2.5–25 mg/dog q8h (some respond to q12h).
- Pro-motility agent:
  - Cisapride 0.1–0.5 mg/kg PO q12h (up to 1 mg/kg PO q8h).
- Behavioral modification agents and anxiolytics may also provide some benefit.

CONTRAINDICATIONS
- Alpha-agonists.
- Testosterone or other androgens—avoid anything that may result in increased prostate size.
- Do not administer any medications that will promote detrusor muscle activity (i.e., bethanechol) until urethral obstruction (functional or mechanical) has been relieved.

PRECAUTIONS
- Prazosin may cause hypotension, CNS signs such as lethargy or dizziness, weakness, syncope, and gastrointestinal upset.
- Tamsulosin may cause hypotension though the safe dosage range is quite wide and severe hypotension is less likely than with other drug choices.
- Acepromazine may cause sedation and hypotension as well as cardiovascular collapse

from bradycardia and hypotension, decreased tear production may occur in cats.
• Diazepam can cause sedation, increased appetite, changes in behavior such as agitation or aggression have been reported. Dogs may also show ataxia. Avoid use in cats due to risk of liver toxicity.
• Methocarbamol may cause sedation, increased salivation, vomiting, along with lethargy, weakness and ataxia.
• Bethanechol's adverse effects are typically minimal when administered orally. Gastrointestinal effects such as hypersalivation, vomiting, diarrhea and anorexia may be seen but are typically mild. Cardiovascular and respiratory effects unlikely with oral dosing.
• Cisapride may cause vomiting, abdominal discomfort or diarrhea. The cardiovascular effects seen in humans are not documented in cats and dogs.

POSSIBLE INTERACTIONS

• Prazosin should not be used in conjunction with beta-blockers, sildenafil, or verapamil/nifedipine due to concerns for increased risk of hypotension.
• Tamulosin should not be used with other alpha-1 adrenergic antagonists or sildenafil/tadalafil as they may have cumulative hypotensive effects. Cimetidine, charithromycin, erythromycin, ketoconazole, and terbinafine may all result in increased plasma levels of tamulosin.
• Acepromazine may have adverse effects when administered in conjunction with a number of drugs. Be careful when administering with other drugs that may cause CNS effects or hypotension.
• Diazepam should be used with caution when administered concurrently with other CNS-depressant medications. There are also several classes of drugs that may increase or decrease plasma levels of diazepam when administered concurrently.
• Methocarbamol should be used with caution when other CNS-depressant medications are also prescribed.
• Bethanechol should not be used with other cholinergic or anticholinergic medications due to synergistic or antagonistic effects, respectively.
• Cisapride's effects may be decreased when given with anticholinergics. When given with benzodiazepines the sedative effects may be enhanced.

FOLLOW-UP

PATIENT MONITORING

Monitoring of residual urine volume as well as routine screening for urinary tract infections should be performed.

POSSIBLE COMPLICATIONS

If left untreated, chronic bladder distension can result in bladder atony and dysfunction of the detrusor muscle. Urine retention puts these dogs at risk of developing urinary tract infections.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING

Castrate male dogs.

SYNONYMS

• Detrusor-urethral dyssynergia.
• Detrusor-sphincter dyssynergia.

URINARY TRACT OBSTRUCTION

BASICS

DEFINITION
Restricted flow of urine from the kidneys through any point of the urinary tract to the external urethral orifice.

PATHOPHYSIOLOGY
Physical or functional obstruction of the urinary tract resulting in partial or complete cessation in renal excretory function. Luminal pressure is transmitted to the level of the kidney and its functional units (nephrons). As tubular pressure exceeds filtration pressure, glomerular filtration rate (GFR) ceases. Pathophysiologic consequences depend on site, degree, and duration of obstruction. The resulting uremia, acidemia, and hyperkalemia creates the clinical signs and progression.

SYSTEMS AFFECTED
- Renal/urologic.
- Cardiovascular, nervous, and respiratory systems also affected relative to duration of obstruction and severity of metabolic derangement.

SIGNALMENT
- Dog and cat.
- More common in males than females.

SIGNS

Historical Findings
- Pollakiuria and stranguria.
- Diminished to absent urine stream.
- Vocalizing, frequent trips to the litter box (cats).
- Gross hematuria.
- Systemic signs associated with complete (or nearly complete) urinary tract obstruction—lethargy, reduced appetite, and vomiting.

Physical Examination Findings
- Excessive (i.e., overly large or turgid) or inappropriate (i.e., remains after voiding efforts) distended urinary bladder, especially in conjunction with lower urinary tract signs.
- Abdominal distention/discomfort.
- Uroliths maybe be palpable in the distal urethra of obstructed male dogs, or on rectal exam of female dogs.
- Signs of severe uremia—dehydration, weakness, hypothermia, and/or bradycardia with moderate hyperkalemia, altered mentation, or sinus tachycardia from pain/stress.

CAUSES

Intraluminal Causes
- Urolithiasis—most common in male dogs.
- Urethral plugs—most common in male cats.
- Idiopathic—no overt intraluminal physical obstruction; may involve functional obstruction.

Intramural Causes
- Neoplasia of the bladder neck or urethra—more common in dogs.
- Prostatic disorders (neoplasia, prostatitis, etc.) in male dogs.
- Edema, hemorrhage, or spasm at sites of obstruction and/or associated with inflammation. Can contribute to persistent or recurrent obstruction following catheterization.
- Stricture at a site of prior injury or inflammation.
- Ruptures, lacerations, and punctures—usually caused by traumatic incidents.

Miscellaneous Causes
- Displacement of the urinary bladder into a perineal hernia.
- Neurogenic (see Urinary Retention, Functional).

RISK FACTORS
- Urolithiasis, particularly in males.
- Feline lower urinary tract disease, particularly in males.
- Prostatic disease in male dogs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Owners may have difficulty distinguishing urinary obstruction from constipation.
- Signs of feline idiopathic cystitis can be difficult to distinguish from obstruction, especially if there are no signs of systemic illness. Determination of bladder size (large/firm with obstruction, small with cystitis) can help distinguish.
- Animals whose urinations are not routinely observed by owners can present for signs referable to systemic illness rather than concern for obstruction.
- Evaluation of any azotemic patient, in conjunction with history and physical exam, should include consideration of possible postrenal causes (e.g., urinary obstruction).

CBC/BIOCHEMISTRY/URINALYSIS
- Hemogram is usually normal; a stress leukogram or hemoconcentration may be seen.
- Biochemical analysis may reveal azotemia, hyperphosphatemia, metabolic acidosis, hyperkalemia, and hypocalcemia proportional to duration of obstruction.
- Hematuria and proteinuria are common. Crystalluria may be associated with urolithiasis, though can be present in the absence of stones. There may be evidence of bacteriuria (dogs) and pyuria. Atypical epithelial cells may be seen in patients with neoplasia.

OTHER LABORATORY TESTS
- Urine culture may be beneficial if suspicion for urinary tract infection (UTI) in obstructed dogs (especially secondary to uroliths). Obstructed cats are unlikely to have bacterial cystitis, and presenting urine culture is not recommended unless recently catheterized.
- Uroliths passed or retrieved should be sent for crystallographic analysis.

IMAGING

Abdominal Radiography
- Uroliths—often demonstrated by survey radiography; but may be missed because of their size, composition, or location. Ensure entire lower urinary tract is included.
- Positive- or double-contrast cystourethrography may detect lesions of the urethra and urinary bladder.

Abdominal Ultrasonography
Ultrasonography is highly sensitive in detecting lesions of the bladder, proximal urethra, prostate, and upper urinary tract.

DIAGNOSTIC PROCEDURES
- Electrocardiography may detect abnormalities due to hyperkalemia, including tall T waves, prolonged PR interval, widened QRS complexes, loss of P waves, and bradycardia.
- Transurethral catheterization and contrast studies may determine the location and nature of obstructing material. Animals that cannot urinate despite being readily catheterized likely either have intramural lesions or functional urinary retention.
- Cystoscopy can be helpful to identify lesions not observed on contrast study or ultrasound.

TREATMENT
- Complete obstruction is a medical emergency that can be life-threatening; treatment should be started immediately.
- Initial goals are addressing metabolic derangements, especially significant hyperkalemia, and establishing urinary patency.
- IV administration of isotonic crystalloid based on degree of cardiovascular compromise, dehydration, and potential for post-obstructive diuresis.
- Severe hyperkalemia (K^+ >8 mmol/L, significant bradycardia/ECG changes)—administer calcium gluconate (1 mL/kg over 3–5 minutes, titrated based on ECG changes), regular insulin 0.1–0.2 U/kg IV once, and 50% dextrose bolus 1 mL/kg IV, diluted, over 5 minutes. May need continued dextrose infusion (2.5–5%) for 4–6 hours to avoid hypoglycemia. Terbutaline 0.01 mg/kg IM or IV can also be given. For more severe derangements (K^+ >10 mmol/L, pH <7.1) consider sodium bicarbonate 1 mL/kg IV over 5–10 minutes.
- Decompressive cystocentesis may allow relief of intravesicular pressure, resumption of GFR, and decreased back-pressure for

catheterization. Based on available studies, risk of complications appears to be very low.
• Urethral catheterization under heavy sedation or general anesthesia (see below) to relieve physical obstruction and establish urethral patency.
• Flushing urinary bladder until clear effluent, attach to sterile collection system.
• Post-obstructive management geared toward nursing care, maintaining fluid balance, correction of metabolic derangements, and sedation/analgesia.
• Rate of fluid administration should be determined based on clinical picture. Some patients can experience a post-obstructive diuresis, with significant urinary losses. It is important to keep up with these losses to avoid dehydration. This can be achieved by matching fluid rate to urine output.
• Hyperkalemia should resolve within hours after de-obstruction, and potassium may eventually need to be supplemented. Azotemia should also significantly decrease within 12–24 hours.
• Patients with obstructive urolithiasis often require a separate procedure for stone removal.

MEDICATIONS

DRUG(S) OF CHOICE
• Sedation/analgesia/anesthesia for catheter placement should be dictated by patient stability. Acepromazine plus an opioid if stable; opioid plus benzodiazepine if unstable. Ketamine and a benzodiazepine is a common combination. Alfaxalone may also be considered. General anesthesia may be indicated as it gives the most urethral relaxation, especially for obstructed dogs.
• In the post-obstructive period, continued sedation and analgesia is beneficial.
• Urethral relaxants (e.g., acepromazine and/or prazosin) may be beneficial for post-obstructive cats or patients with neurogenic urine retention.
• Antibiotics may be indicated with strongly suspected or documented evidence of infection (such as cytology or positive culture). Antibiotics should not be administered to prevent UTI while a urinary catheter is in place. This is not effective and can promote bacterial resistance.
• Nonsteroidal anti-inflammatory drugs have failed to improve speed of resolution or the frequency of reobstruction.

CONTRAINDICATIONS
• Corticosteroids are contraindicated while a urinary catheter is in place. This can predispose to the development of UTI.
• Nonsteroidal anti-inflammatory medications should be initially avoided in more metabolically compromised patients.

PRECAUTIONS
Avoid drugs that reduce blood pressure (e.g., acepromazine) or induce cardiac dysrhythmia (e.g., ketamine) until dehydration and hyperkalemia are resolved. Avoid excessive force during catheterization attempts.

FOLLOW-UP

PATIENT MONITORING
• Continuous ECG monitoring to guide treatment and evaluate response is warranted if there were significant changes initially.
• Assess urine production and hydration status frequently, and adjust fluid administration rate accordingly.
• Monitor renal values and electrolytes. Sicker patients may require more frequent monitoring (q6–12); once daily for more stable patients.
• The urinary catheter can be removed once metabolic derangements and urine output has normalized, and the urine appears to be clear of gross debris, clots, etc.
• After urinary catheter removal, monitor ability to urinate closely for at least 12–24 hours.
• Cats may benefit from continued pain medication and urethral relaxation for 5–7 days at home, as well as recommendations (increased water intake, environmental enrichment) to help decrease risk of re-obstruction.

POSSIBLE COMPLICATIONS
• Death.
• Injury to the excretory pathway (e.g., urethral tear) while trying to relieve obstruction.
• Hypokalemia during post-obstructive diuresis.
• Recurrence of obstruction (estimated at 15–40%).

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Bradycardia secondary to hyperkalemia.
• Azotemia, hyperphosphatemia, and metabolic acidosis.

SYNONYMS
Urethral obstruction.

SEE ALSO
• Azotemia and Uremia.
• Feline Idiopathic Lower Urinary Tract Disease.
• Hyperkalemia.
• Urinary Retention, Functional.

ABBREVIATIONS
• GFR = glomerular filtration rate.
• UTI = urinary tract infection.

URINARY TRACT PARASITES

BASICS

OVERVIEW

Dioctophyma renale (Giant Kidney Worm)

In North America, cases are frequently encountered in Mississippi, Louisiana, Minnesota, Wisconsin, Michigan, and the central and eastern provinces of Canada. Humans are accidental hosts; because of the aquatic portion of its life cycle, water is an essential element of the habitat of *D. renale*. Minks are the most commonly infected mustelids, and are the principal definitive host in North America.

Life Cycle

- To complete the life cycle, both males and females must be located in the same kidney of the host, and the urinary tract must be the patent. Fertile eggs are passed with urine voided by the host, and then embryonate in water. First-stage larvae are produced after 1–7 months. The definitive hosts become infected by ingesting the infective larvae in annelids.
- Definitive hosts are infected by ingesting raw fish, frogs, other paratenic hosts, or *Lumbriculus variegatus*. After ingestion, the infected larvae penetrate the walls of the stomach or intestines and migrate to the submucosa. After approximately 5–7 days, they migrate to the liver and remain there for about 50 days. Migration to the right or the left kidney and invasion of the renal pelvis follows.
- *D. renale* have been found more frequently in the right kidney than in the left. Finding encysted *D. renale* around liver is associated with larval penetration at the lesser curvature of the stomach. On occasion, *D. renale* have been encountered in the urinary bladder and/or ureters. Infective larvae become mature gravid females in the definitive host after 3.5–6 months. The entire life cycle requires approximately 2 years.

Pathophysiology in the Kidney

- Adult parasites have attained substantial size by the time they penetrate the kidney. The exact mechanisms involved with gaining access to the renal pelvis is unknown, but probably results from the effects of enzymes released by the parasite.
- Available evidence does not support the theory that adult *D. renale* slowly devour the renal tissue of the host, reducing it to a hollow sack. Although the exact mechanism(s) of destruction is not known, obstruction caused by the growing adult parasite(s) and secondary hydronephrosis (or pyonephrosis) plays a major role. Examination of the kidneys from dogs with unilateral renal infection reveals changes typical of advanced hydronephrosis (i.e., obliteration of the majority of renal tubules surrounded by chronic inflammatory tissue and persistence of the structural architecture of many glomeruli).
- Ova of *D. renale* may be observed in the renal parenchyma adjacent to the renal pelvis. The urothelium lining the renal pelvis is often hyperplastic.
- If only one kidney is affected with *D. renale* the host retains adequate renal function due to compensatory hypertrophy and hyperplasia of the remaining kidney. If both kidneys are parasitized, or if one kidney is parasitized and the opposite kidney has substantial comorbid dysfunction, varying stages of renal failure and uremia may occur. Eggs that are released by female worms pass through the urinary tract and provoke inflammation in the mucosa of the ureter and urinary bladder.

Pathophysiology in the Peritoneal Cavity

- In dogs, viable parasites located in the abdominal cavity and/or between lobes of the liver have been incidental findings during ovariohysterectomy.
- Eggs present in the peritoneal cavity can trigger development of chronic peritonitis. Examination of the abdominal viscera from dogs with *D. renale* in the peritoneal cavity revealed hemorrhage, granulomatous inflammation, and fibrosis frequently involving the omentum, the surface of the liver, and the surface of the spleen. Viable adult males have been found in the peritoneal cavity of dogs without an associated inflammatory response.
- Ascites may occur in dogs with peritoneal *D. renale* colonization. The fluid detected in the abdominal cavity is usually hemorrhagic.

Pearsonema (Capillaria)

- *Pearsonema* and *Capillaria* are used interchangeably and appear to be identical in taxonomy and biologic behavior.
- *Pearsonema (Capillaria) plica* are small, thread-like, yellowish parasites that invade the mucosa or submucosa of the bladder and rarely the renal pelvis and ureter, causing a mild inflammatory response.
- *P. plica* in dogs and cats and *P. feliscati* in cats have been uncommonly associated with signs of lower urinary tract disease.
- *P. plica* passes ova with bipolar plugs in urine. When earthworms ingest embryonated ova, the parasite develops into the infective stage. Ingestion of an infective earthworm results in a patent infection in dogs in 58–88 days.
- The life cycle of *P. feliscati* is poorly understood.

SIGNALMENT

D. renale

- Dogs and cats.

Pearsonema

- Dogs—no predilection reported.
- Cats—affected cats almost always >8 months old.

SIGNS

D. renale

- Feeding *L. variegatus* infected with *D. renale* to dogs typically induces vomiting due to effects of the parasite on the gastric mucosa.
- If only one kidney has been invaded with *D. renale*, signs are often absent.
- Silent hematuria may be the first indication of an abnormality.
- Palpation of the abdomen may reveal an enlarged and/or misshapen hydronephrotic kidney.
- If both kidneys are parasitized, clinical signs attributable to renal failure or uremia may occur. The host will typically die before extensive hydronephrosis of both kidneys has time to develop. The degree of renal dysfunction is influenced by (1) number of parasites in the kidney, (2) duration of infection, (3) number of kidneys parasitized, and (4) presence and severity of comorbid renal disease.

Pearsonema

- Usually none.
- Pollakiuria, hematuria, stranguria, and dysuria in heavily infected animals.

CAUSES & RISK FACTORS

D. renale

See Overview.

Pearsonema

Dogs

- High prevalence of infection (up to 50%) in the natural hosts (e.g., foxes, raccoons) in the southeastern United States may predispose animals in this geographic region.
- In kennels, high infection rates associated with contaminated soil surfaces.

Cats

Rare in United States; infection prevalence of 18–34% is reported in Australia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

D. renale

Any cause of hydronephrosis or renomegaly.

Pearsonema

Consider other, more common causes of lower urinary tract disease, such as urolithiasis, urinary tract infection, trauma, and neoplasia.

CBC/BIOCHEMISTRY/URINALYSIS

D. renale

- When gravid female worm is present in the kidney that has a patent track to the exterior, microscopic examination of urine usually reveals ova of *D. renale*.
- Hematuria, pyuria, and proteinuria with or without eggs are indicative of an inflammatory response.

U

(CONTINUED) URINARY TRACT PARASITES

• Findings typical of chronic kidney disease when both kidneys are parasitized.

Pearsonema

• Colorless, slightly pitted ova with bipolar plugs in urine sediment are diagnostic.
• Consider fecal contamination of urine with *Trichuris vulpis* or other morphologically similar ova if free-catch urine specimens are used, or if inadvertent rectal puncture and aspiration of feces with *T. vulpis* occurs during cystocentesis.
• Urine contamination of feces can produce false fecal examination findings.
• Symptomatic infections are usually associated with evidence of hematuria, pyuria, and proteinuria. Bacterial urine cultures are typically sterile.

OTHER LABORATORY TESTS

N/A

IMAGING

D. renale

• Radiography may reveal renomegaly. If IV urography is performed, it may be characterized by inability of the parasitized kidney to excrete the contrast agent.
• Ultrasonography may reveal the affected kidney to be hydronephrotic and find characteristic hypoechoic loops associated with one or more of these parasites in the renal pelvis. Transverse plane sonography of the affected kidney may reveal a thin hyperechoic rim that contains multiple circular structures of uniform diameter. The outer layers of these parasites are hyperechoic; the inner portions are hypoechoic. If parasites are in the peritoneal cavity, sonography may reveal hyperechoic curvilinear bands in the region of the right caudal lobe of the liver and/or the cranial pole of the right kidney. Serially performed studies may reveal movement of the parasite from one location to another.
• CT and MRI scans may also be used to detect *D. renale* in the renal pelvis of one or both kidneys, in the peritoneal cavity, or in varying positions between the lobes of the liver.

Pearsonema

N/A

DIAGNOSTIC PROCEDURES

N/A

TREATMENT

D. renale

Nephrectomy is usually the treatment of choice when only one kidney is affected and the opposite kidney is capable of sustaining homeostasis. Parasites that are incidental findings in the peritoneal cavity during celiotomy may be removed without further morbidity.

Pearsonema

• Infection is usually self-limiting in cats and dogs.
• If infected dogs are isolated, after 10–12 weeks ova are no longer detectable in the urine sediment.
• Replacing soil surfaces with sand, gravel, or concrete may reduce prevalence of infection in kennels contaminated with *P. plica* and *P. feliscati*.

MEDICATIONS

DRUG(S) OF CHOICE

D. renale

N/A

Pearsonema

• Consider anthelmintic therapy if clinical signs are present and persist; monitor therapeutic success by examining urine sediment for ova and observing status of clinical signs.
• Multiple courses of treatment may be necessary to eliminate the infection.
• Fenbendazole 50 mg/kg PO q24h for 3 days.
• Ivermectin 0.2 mg/kg SC once has been suggested as an alternative therapy, but objective information on its efficacy in this disease is limited.
• Oral treatment with albendazole 50 mg/kg PO q12h for 30 days was reported to be effective in dogs.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

D. renale

Dogs and cats should not be fed raw fish or fish viscera, especially in areas where *D. renale* is known to exist and should not be given access to lake or pond water likely to contain infective stages of *D. renale*.

Pearsonema

Monitor treatment success by examining urine sediment for ova and observing status of clinical signs. In the absence of reinfection, urinary capillariasis may be self-limiting. Isolation of dogs and cats from earthworms should be sufficient to eliminate a *Capillaria* bladder infection in 90 days.

MISCELLANEOUS

ZOONOTIC POTENTIAL

Capillaria spp. pose no known public health risks.

U

UROLITHIASIS, CALCIUM OXALATE

BASICS

DEFINITION
Formation of calcium oxalate (CaOx) uroliths within the urinary tract and associated clinical conditions (e.g., urinary obstruction, idiopathic hypercalcemia, chronic kidney disease).

PATHOPHYSIOLOGY
Presence of hypercalciuria, hyperoxaluria, hypocitraturia, and defective crystal growth inhibitors.

Hypercalciuria
In dogs, normocalcemic hypercalciuria may result from intestinal hyperabsorption of calcium (so-called absorptive hypercalciuria: type 1—dietary independent, type 2—dietary dependent, and type 3—phosphaturic induced hypervitaminosis D) or reduced renal tubular reabsorption of calcium (renal leak hypercalciuria). Hypercalcemic hypercalciuria results from excessive glomerular filtration of mobilized calcium, which overwhelms normal renal tubular reabsorptive mechanisms (called resorptive hypercalciuria, since bone resorption is associated with high serum calcium concentrations).

Hyperoxaluria
In humans, hyperoxaluria is associated with inherited abnormalities of excessive oxalate synthesis (primary hyperoxaluria types I, II, and III), excess consumption of foods containing high quantities of oxalate or oxalate precursors, pyridoxine deficiency, and disorders associated with fat malabsorption (i.e., fat complexes with intestinal calcium augmenting intestinal absorption of oxalate). Lack of oxalate-degrading bacteria in the intestine can increase the quantity of oxalate absorbed from the diet and the quantity excreted in urine.

Hypocitraturia
Urine citrate inhibits CaOx urolith formation. By complexing with calcium ions to form the relatively soluble salt calcium citrate, citrate reduces the quantity of calcium available to bind with oxalate. In normal dogs, acidosis is associated with low urinary citrate excretion, whereas alkalosis promotes urinary citrate excretion.

Defective Crystal Growth Inhibitors
Large-molecular-weight proteins in urine, such as Tamm-Horsfall mucoprotein, nephrocalcin, and osteopontin, have a profound ability to enhance solubility of CaOx. Urine from dogs with CaOx uroliths revealed that nephrocalcin had fewer carboxyglutamic acid residues than nephrocalcin isolated from normal dog urine.

Feeding Diets Promoting Urine Acidification
Diets designed to promote aciduria are a common risk factor in cats and dogs. In several species, acidic urine is associated with hypercalciuria (bone mobilization of calcium, increased glomerular filtration of calcium, and decreased renal tubular reabsorption of calcium) and hypocitraturia (increased renal tubular reabsorption).

SYSTEMS AFFECTED
Renal/urologic

INCIDENCE/PREVALENCE
In dogs, CaOx accounts for approximately 40% of the uroliths removed from the lower urinary tract and 45% of those removed from the upper urinary tract. In cats, CaOx accounts for approximately 40% of the uroliths removed from the lower urinary tract and 90% of those retrieved from the upper urinary tract.

SIGNALMENT

Species
Dog and cat.

Breed Predilections
- Dogs—reported in many breeds. Six breeds represent 60% of cases: miniature schnauzer, Lhasa apso, Yorkshire terrier, bichon frisé, shih tzu, and miniature poodle.
- Cats—Himalayan, Scottish fold, Persian, ragdoll, and Burmese are at greater risk.

Mean Age and Range
- Dogs—8.5 ± 3 years; 60%, 6–11 years.
- Cats—97% >2 years; 53%, 7–15 years.

Predominant Sex
Mostly male dogs (73%) and male cats (55%).

SIGNS

General Comments
- Asymptomatic in some animals.
- Depend on location, size, and number of uroliths.
- Animals with nephroliths are typically asymptomatic but may have persistent hematuria.
- Ureteral obstruction associated with contralateral microrenale, ipsilateral hydronephrosis, and acute onset of uremia occurs frequently in cats with chronic kidney disease.

Historical Findings
- Typical signs of urocystoliths or urethroliths include pollakiuria, dysuria, and hematuria. Some may present for urethral obstruction.
- Nephroureteroliths common (45%) in cats with chronic kidney disease.

Physical Examination Findings
- Detection of urocystoliths are by abdominal or urethral palpation; failure to palpate uroliths does not exclude them from consideration.
- Large urinary bladder with complete urethral obstruction (more common in cats).
- Urocystoliths with irregular contours rarely cause complete urethral obstruction.

CAUSES
See Pathophysiology.

RISK FACTORS
- Oral calcium supplements given independent of meals.
- Feeding acidifying foods that promote formation of aciduria (pH <6.6 in dogs and <6.25 in cats) was associated with CaOx urolithiasis. In normal cats, alkaline urine was associated with the lowest saturation for CaOx.
- Aciduria was a risk factor for first-time CaOx urolith formation in dogs.
- In healthy cats, urinary undersaturation for CaOx was achieved by inducing alkaluria via dietary formulation with potassium citrate.
- Excessive dietary protein, sodium (>1.2% DMB or 350 mg/100 kcal) and vitamin D promote hypercalciuria.
- Additional dietary oxalate (e.g., chocolate and peanuts) and ascorbic acid promote hyperoxaluria.
- Glucocorticoids and furosemide promote hypercalciuria.
- Vitamin B6-deficient diets (e.g., homemade) promote hyperoxaluria.
- Consumption of dry diets has a higher risk for CaOx urolith formation than consumption of high-moisture canned diets.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Urethral obstruction, urinary tract infection, urinary tract neoplasia, and idiopathic feline lower urinary tract disease.
- Other common radiodense uroliths are magnesium ammonium phosphate, calcium phosphate, and silica.

CBC/BIOCHEMISTRY/URINALYSIS
- Hematological and serum profile results are usually unremarkable.
- Urinalysis may reveal CaOx crystals, but absence of crystalluria does not exclude uroliths as a possibility.
- Hypercalcemia (rare in dogs, more common in cats) should be further evaluated to determine its cause and contribution to urolith formation.

OTHER LABORATORY TESTS
Quantitative mineral analysis of uroliths.

IMAGING
- CaOx uroliths ≥2 mm in diameter are radio-opaque and easily detected by survey radiography. IV urography, contrast pyelography, or ultrasonography may be needed to verify ureteral obstruction.

• Urinary tract mineralization may resemble uroliths.

TREATMENT

APPROPRIATE HEALTH CARE

• CaOx uroliths are not amenable to medical dissolution.
• Small stones that can pass through the urethra (<3 mm in most dogs >5 kg) should be removed by voiding urohydropropulsion or basket retrieval. Percutaneous cystolithotomy or routine cystotomy can be used to remove stones in smaller dogs and male cats.
• Consider laser lithotripsy, percutaneous cystolithotomy, or routine cystotomy to remove larger stones from the urinary bladder.
• Urethral surgery is discouraged. Retrograde urohydropropulsion is an effective procedure to flush urethral stones back into the urinary bladder prior to their removal from the urinary bladder.
• Persistently obstructed ureters require urgent intervention to minimize progressive kidney damage. See Ureterolithiasis.
• Removal of unobstructing nephroliths is usually unnecessary.

ACTIVITY

Reduce during the period of tissue repair after surgery.

DIET

• Studies support feeding high moisture foods that promote formation of less acidic urine (pH >6.3–6.6) to minimize formation of CaOx.
• Hypercalcemia in cats without evidence of hyperparathyroidism or malignancy is sometimes minimized by feeding Hill's Prescription Diet Feline w/d.

CLIENT EDUCATION

• Urolith removal does not alter the factors responsible for urolith formation; eliminating or minimizing risk factors is necessary to minimize recurrence.
• 50% of dogs reform uroliths within 2–3 years; 1/3 of cats reform uroliths in 2 years.
• Patients with hypercalcemia typically reform uroliths at a faster rate.

SURGICAL CONSIDERATIONS

• Consider surgical removal of lower tract uroliths that cannot be removed by minimally invasive procedures (voiding urohydropropulsion, basket retrieval, intracorporeal laser lithotripsy, percutaneous cystolithotomy).
• Avoid performing disfiguring urethrostomies and urethrotomies by using retrograde urohydropropulsion to flush urethroliths into the bladder or using lithotripsy to fragment urethroliths.
• Shock wave lithotripsy is an alternative to surgery for removal of nephroliths and ureteroliths in dogs.
• To minimize urolith reformation over suture nidus, minimize surgical procedures to remove uroliths and use absorbable suture and patterns that minimize suture exposure in the lumen of the urinary tract.
• Only surgeons trained in ureteral surgery should attempt ureterolithotomy. Ureteral stents in dogs and subcutaneous ureteral access devices or stents in cats should be considered.
• Consider parathyroidectomy for patients with primary hyperparathyroidism.

MEDICATIONS

DRUG(S) OF CHOICE

• No available drugs effectively dissolve CaOx uroliths in the urinary tract. *In vitro* dissolution is seen with alkaline solutions (pH ≥8) of 2% or greater EDTA.
• Potassium citrate used to promote alkaluria should not contain cranberry supplements.

PRECAUTIONS

Steroids and furosemide promote calciuria.

FOLLOW-UP

PATIENT MONITORING

• Postsurgical radiographs are essential to verify complete urolith removal.
• To prevent the need for repeated surgery, evaluate abdominal radiography every 9–12 months to detect urolith recurrence early. Small uroliths are easily removed by voiding urohydropropulsion or stone basket retrieval.

PREVENTION/AVOIDANCE

• Even with appropriate therapy, CaOx urolith recurrence is common (up to 50% in dogs and 33% in cats in 2–3 years). Regular monitoring and compliance check-ins are essential to adjust therapy to extend the interval between recurrences.
• Only recommend high-moisture foods (e.g., can, loaf, gravies). Feeding dry foods, combining dry and wet foods, or adding water to dry food is not effective in maintaining low urinary concentrations (specific gravity <1.020 in dogs and <1.030 in cats) of calculogenic minerals.
• Feeding high-sodium foods (≥300 mg/100 kcal) should not be recommended as a substitute for feeding high-moisture foods. Their efficacy to promote low urine specific gravity appears to be short-lived (3–6 months) and their use is contraindicated in kidney or heart disease.
• Avoid feeding diets that promote urine acidification. A linear increase in urine pH was associated with a linear decrease in urine CaOx saturation in normal cats.
• Commercially manufactured diets have been designed to prevent CaOx recurrence, but they may not be ideal for all patients.
• Hill's Prescription Diet c/d multicare has been shown to decrease calcium and oxalate excretion in dogs with CaOx urolithiasis. This food has lower levels of sodium and protein.
• Hill's Prescription Diet i/d Kiw Fat and has been recommended for dogs with CaOx urolithiasis and fat/lipid intolerance or fat/lipid responsive diseases (e.g., dogs with a history of pancreatitis). Because this diet promotes formation of acidic urine, administer potassium citrate to promote a more favorable urine pH >6.5.
• Royal Canin SO has been shown to decrease CaOx relative supersaturation in urine of urolith-forming dogs collected by owners. Because this diet promotes acidic urine, concomitant administration of potassium citrate is necessary to achieve a more favorable urine pH (>6.5). Because of its high sodium, this food may be inappropriate for small breeds at risk for degenerative mitral valve disease.
• Avoid supplements with vitamins C and D.
• Reevaluate patients 2–4 weeks after initiation of diet therapy to verify appropriate reduction in specific gravity (<1.020 for dogs and <1.030 for cats), appropriate urine pH (≥6.5), and amelioration of crystalluria. Do not use inappropriately collected or stored urine samples (e.g., urine collected by owners, refrigerated, or contaminated with debris) to monitor therapeutic efficacy. To promote dilute urine, feed canned or gravy formulations of food or add additional water to all types of food. If urine is acidic, consider administration of potassium citrate 75 mg/kg PO q12h; adjust dosage to achieve a pH between 6.5 and 7.5. Potassium citrate medications formulated with cranberry are not recommended because cranberry is a source of vitamin C; vitamin C supplementation should be discouraged because of its ability to increase urine oxalate.
• Vitamin B6 2–4 mg/kg PO q24–48h may help minimize oxalate excretion, especially for animals fed homemade or pyridoxine-deficient diets.
• If dietary changes are inadequate at slowing the rate of recurrence, consider hydrochlorothiazide diuretics (dog, 2 mg/kg and cat, 1 mg/kg q12–24h).
• If the patient is hypercalcemic, correct underlying cause.
• *Oxalobacter formigenes* is an intestinal bacterium that ingests oxalate as its sole nutrient. By metabolizing dietary oxalate in the intestine, less oxalic acid is available for absorption and less is excreted in urine. To preserve healthy populations of intestinal *Oxalobacter*, avoid indiscriminant or prolonged use of antimicrobics.

UROLITHIASIS, CALCIUM OXALATE (CONTINUED)

POSSIBLE COMPLICATIONS

- Urocystoliths can pass into and obstruct the urethra.
- Dogs that do not consume their daily requirement of some urolith prevention foods may develop various degrees of protein calorie malnutrition.
- Diet-associated hyperlipidemia develops in some patients consuming foods with higher fat content. Miniature schnauzers with hereditary hyperlipidemia are predisposed to pancreatitis when consuming some prevention foods.
- When treating multiple conditions (obesity, diarrhea, etc.) consider diets that are indexed to also prevent CaOx.

EXPECTED COURSE AND PROGNOSIS

- Approximately 50% of dogs and 33% of cats reform uroliths in 2–3 years. Treatment to minimize recurrence is helpful.
- Patients with persistent hypercalcemia typically reform uroliths at a faster rate.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Conditions predisposing to hypercalciuria: hyperadrenocorticism, acidemia, hypervitaminosis D, and hyperparathyroidism; or hyperoxaluria: vitamin B6 deficiency, hereditary hyperoxaluria, and ingestion of chocolate and peanuts.

AGE-RELATED FACTORS

Rare in young (<1 year old) animals.

PREGNANCY/FERTILITY/BREEDING

Diets used to prevent CaOx uroliths are not appropriate.

SYNONYMS

Oxalate urolithiasis.

SEE ALSO

Crystalluria.

ABBREVIATIONS

- AAFCO = Association of American Feed Control Officials.
- CaOx = calcium oxalate.

Client Education Handout available online

UROLITHIASIS, CALCIUM PHOSPHATE

BASICS

OVERVIEW

• Calcium phosphate (CP) uroliths within the urinary tract and associated clinical conditions. • Forms of CP identified in dogs and cats include: calcium phosphate apatite (CAP), calcium phosphate carbonate (CPC), calcium hydrogen phosphate dihydrate (brushite), and uncommon minerals—tricalcium phosphate (whitlockite) and octacalcium phosphate. • CP uroliths represent a small fraction (dogs <1.0%, cats <0.5%) of all uroliths submitted to the Minnesota Urolith Center (MUC) from 1981 to 2018 (Table 1). • More CP uroliths are found in the upper tract (kidney and ureter) (2.5% cats, 3.5% dogs), than in the lower tract (bladder and urethra). • CP uroliths (excluding brushite) do not have a characteristic shape. Brushite uroliths are typically round and smooth. • CP uroliths are usually cream or tan in color. Blood clots mineralized with CP are typically black.

SIGNALMENT

• Dog and cat.
• Rarely detected in animals <1 years old.
• CPC uroliths occur primarily in female dogs (72%).

SIGNS

• Depend on location, size, and number of uroliths. • Pollakiuria, dysuria, hematuria, and urethral obstruction. • Nephroureteroliths—typically asymptomatic but may have persistent hematuria or signs referable to concomitant renal failure (primarily cats).

CAUSES & RISK FACTORS

• CPC—commonly a minor component of struvite and calcium oxalate uroliths.
• Pure CP uroliths—usually associated with metabolic disorders, e.g., primary hyperparathyroidism, renal tubular acidosis, and excessive dietary calcium and phosphorus.
• Urinary tract infections—increased calcium excretion in combination with urinary tract infection with urease producing bacteria may be risk factors favoring CPC. • Nephroliths, urocystoliths, and urethroliths composed of blood clots mineralized with CP suggest dystrophic mineralization of tissue, in contrast to metastatic mineralization reflecting abnormal calcium and phosphorus metabolism. • Other risk factors—see Urolithiasis, Calcium Oxalate.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Other common causes of hematuria, dysuria, and pollakiuria, with or without urethral obstruction, include urinary tract infection and urinary tract neoplasia. • Other radiodense uroliths—magnesium ammonium phosphate, calcium oxalate, and silica. • Metastatic or dystrophic mineralization of urinary tract parenchyma may resemble uroliths.

CBC/BIOCHEMISTRY/URINALYSIS

• Usually unremarkable. • Hypercalcemia or azotemia rarely detected; postrenal azotemia in some animals with complete urinary outflow obstruction. • Urinary sediment analysis—amorphous crystals in some patients; brushite (calcium hydrogen phosphate dihydrate) forms are elongated, rectangular, lath-shaped crystals.

OTHER LABORATORY TESTS

• Quantitative analysis of retrieved uroliths is necessary to confirm their mineral composition. • Serum concentrations of parathyroid hormone, parathyroid hormone–related peptide, and hydroxycholecalciferol may help establish underlying causes.

IMAGING

• CP uroliths are radiodense (as dense as bone) and are often detected by survey radiography.
• CP uroliths may be detected by ultrasonography.

DIAGNOSTIC PROCEDURES

CP uroliths in the urethra and bladder may be detected by cystoscopy.

TREATMENT

• Medical dissolution of CP uroliths remains a goal for the future. • Consider surgical removal of lower tract uroliths that cannot be removed by minimally invasive procedures (e.g., voiding urohydropropulsion, basket retrieval, intracorporeal lithotripsy, laparoscopic cystotomy). • Avoid performing disfiguring urethrostomies by using basket retrieval to remove urethroliths, retrograde urohydropropulsion to flush urethroliths into the bladder or using lithotripsy to fragment urethroliths. • Shock wave lithotripsy is an alternative to surgery for removal of nephroliths, ureteroliths, and urocystoliths in dogs.
• Correction of hyperparathyroidism or other causes of hypercalcemia should minimize further urolith formation.

MEDICATIONS

DRUG(S) OF CHOICE

No effective medications available for dissolving CP uroliths.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Vitamin D supplements, other mineral supplements, glucocorticoids.

FOLLOW-UP

PATIENT MONITORING

• Radiography after surgery to verify complete urolith removal is a standard of practice.
• Abdominal radiography or ultrasonography every 3–5 months to enhance early detection of urolith recurrence and prevention of the need for repeated surgery. • Small uroliths are easily removed by voiding urohydropropulsion or catheter retrieval.

PREVENTION/AVOIDANCE

• A high-moisture (canned) diet formulated to prevent formation of calcium oxalate uroliths may help prevent recurrence. • Foods for older dogs that are lower in protein, phosphorus, and calcium, and which do not promote acidic urine are usually associated with decreased calcium and phosphorus excretion. Hill's Prescription Diet canned g/d is one example. • Because of the high moisture content of canned foods and their tendency to promote dilute urine, canned diets are more effective than dry diets in preventing recurrence. • Avoid excessive acidification or alkalinization of urine.

MISCELLANEOUS

SYNONYMS

Apatite uroliths.

ABBREVIATIONS

• CAP = calcium phosphate apatite.
• CP = calcium phosphate.
• CPC = calcium phosphate carbonate.
• MUC = Minnesota Urolith Center.

Authors Hasan Albasan and Jody P. Lulich

U

Table 1

Calcium phosphate uroliths submitted to the Minnesota Urolith Center (MUC) in 2013.

	Dog (n = 70,481)	Cat (n = 17,245)
Calcium phosphate carbonate form (CPC)	0.58%	0.09%
Calcium phosphate apatite form (CAP)	0.10%	0.17%
Calcium hydrogen phosphate dihydrate (Brushite)	0.32%	0.02%

UROLITHIASIS, CYSTINE

BASICS

OVERVIEW

- Formation of uroliths composed of cystine.
- Cystinuria—an inborn error of metabolism caused by defective tubular reabsorption of cystine, ornithine, lysine, and arginine (COLA) leading to cystine urolith formation.
- Cystine is freely filtered by glomeruli; however, most is actively reabsorbed in the renal proximal tubules.
- Impaired intestinal absorption of these amino acids has not been associated with any nutritional deficiency states in dogs, presumably because these are non-essential amino acids. However, cystine may be semi-essential amino acid and as a precursor of taurine, excessive cystine loss may affect taurine availability.
- Unless protein intake is severely restricted, cystinuric dogs have no detectable abnormalities associated with amino acid loss. Excessive loss of arginine in urine predisposes cats to hyperammonemic encephalopathy. Some cystinuric dogs may have carnitinuria.
- Cystinuric dogs have been classified into three different types: type 1 autosomal recessive *SLC3A1* mutations found in Newfoundlands, Landseer, and Labrador retrievers; type 2 autosomal dominant *SLC3A1* and *SLC7A9* identified in Australian cattle dogs and European miniature pinschers, and type 3, which has sex-limited inheritance (androgen dependence) and has been identified in mastiffs, English and French bulldogs, Scottish deerhounds, and Irish terrriers.
- Not all cystinuric dogs and cats form uroliths; cystinuria is a predisposing rather than a primary cause of cystine urolithiasis. Cystine is relatively insoluble in acid urine and is more soluble in alkaline urine.
- This disease is genetically heterogeneous (*SLC3A1* and *SLC7A9*) in cats as it is in dogs and humans.

SIGNALMENT

- Dogs—primarily adult (mean age 5 years; range 3 months–14 years) intact males, but may also affect females. It occurs in excess of 100 breeds, including dachshunds, English bulldogs, Newfoundlands, Labrador retrievers, Chihuahuas, pit bulls, and French bulldogs. May be detected in male and female Newfoundland and Labradors <1 year of age.
- Cats—primarily adult (mean age at diagnosis, 3.5 years; range, 4 months–12 years) males and females; most common in the domestic shorthair and Siamese breeds.

SIGNS

- Depend on location, size, and number of uroliths; affected animals may be asymptomatic.
- Urocystoliths—include pollakiuria, dysuria, and hematuria.
- Urethroliths—include urethral obstruction, pollakiuria, dysuria, and sometimes voiding of small smooth uroliths. Complete outflow obstruction may result in postrenal azotemia that may progress to uremia.
- Nephroliths—typically asymptomatic; may be associated with manifestations of hydronephrosis and renal insufficiency.

CAUSES & RISK FACTORS

- Inherited defects in renal tubular transporters of cystine.
- Breed predisposition.
- In young and middle-aged dogs with previous history of cystine urolithiasis—recurrence within 6–12 months following surgery unless prophylactic therapy is given.
- Urolith formation—enhanced by acidic, concentrated urine, incomplete and infrequent micturition.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Uroliths mimic other causes of pollakiuria, dysuria, hematuria, and/or outflow obstruction.
- Differentiate from other types of uroliths by urinalysis, radiography, and quantitative analysis of voided or retrieved uroliths.
- Urate uroliths and sterile struvite uroliths are of similar radiodensity.

CBC/BIOCHEMISTRY/URINALYSIS

- Cystine crystals are six-sided; insoluble in acetic acid.
- Positive urine cyanide-nitroprusside test.

OTHER LABORATORY TESTS

- Urinary amino acid profiles—reveal abnormal quantities of cystine and, in some dogs and cats, ornithine, lysine, arginine, and other amino acids.
- Quantitative mineral analysis of uroliths.
- DNA test.
- To diagnose androgen-dependent cystinuria in breed without a genetic text, calculate the urine cystine to creatine ratio before and 3 to 6 months after castration. A marked and persistent reduction is consistent with resolution of cystinuria via castration.

IMAGING

- Radiography—the radiodensity of cystine uroliths is similar to that of sterile struvite and silica, less than that of calcium oxalate and calcium phosphate, and greater than that of ammonium urate.
- Ultrasonography—can detect cystine uroliths, but does not provide reliable information about the radiodensity, shape, or number present.

DIAGNOSTIC PROCEDURES

- Urethrocystoscopy—used to detect cystine urethroliths and urocystoliths.
- Quantitative mineral analysis of uroliths.

TREATMENT

Measures to minimize urolith formation include changing the diet to reduce cystine excretion (lower methionine protein consumption), diluting urine to a lower cystine concentration, and alkalinizing the urine to improve cystine solubility.

Dogs

- Medical dissolution of uroliths by a combination of *N*-(2-mercaptopropionyl)-glycine (2-MPG) and dietary therapy; Hill's Prescription Diet Canine u/d reduces urinary excretion of cystine, promotes formation of alkaline urine, and reduces urine concentration; it is used in conjunction with 2-MPG for urolith dissolution and maybe effective alone in preventing recurrence of cystine uroliths.
- In one study, castration reduced recurrence of cystine uroliths in dogs identified with type 3, sex-limited inheritance.
- Other diets are available to prevent cystine, but lack published results of efficacy.

Cats

Diets designed for renal insufficiency and geriatric cats may be suitable to minimize formation. Give enough potassium citrate 40–75 mg/kg PO q12h to maintain a urine pH of 7.5. Choose a moist formulation diet to help reduce urine concentration. Dissolution with 2-MPG has been studied in a small number of cats at an oral dose of 12–20 mg/kg q12h. Frequency of recurrence was minimized in these cats without adverse side effects.

Dogs and Cats

Remove urocystoliths unable to be dissolved by voiding urohydropropulsion, basket retrieval, lithotripsy, or surgery.

MEDICATIONS

DRUG(S) OF CHOICE

Urine Alkalinizers

- For patients that have acidic urine despite dietary therapy.
- Data from cystinuric humans suggest that dietary sodium may enhance cystinuria; thus potassium citrate may be preferable to sodium bicarbonate as a urine alkalinizer. Give enough potassium citrate 40–75 mg/kg PO q12h to maintain a urine pH of 7.5.

(CONTINUED) UROLITHIASIS, CYSTINE

Thiol-Containing Drugs

- 2-MPG decreases urine concentration of cystine by combining with cysteine to form cysteine-2-MPG, which is more soluble than cystine.
- With status as an orphan drug, Thiola™ is only available from the distributor Retrophin. Generic 2-MPG (Tiopronin) may be obtained from compounding pharmacies. In dogs: 2-MPG may be given at a dosage of 15–20 mg/kg PO q12h to dissolve canine cystine uroliths in conjunction with dietary therapy. In our hospital, mean dissolution time was 78 days (range 11–211 days).
- 2-MPG may be given at a lower dosage (5–10 mg/kg PO q12h) to prevent recurrent canine cystine uroliths.
- In cats: 2-MPG has been studied in a small number of cats at an oral dose of 12–20 mg/kg q12h. Frequency of recurrence was minimized in these cats without adverse side effects. Drug-induced adverse events associated with 2-MGP are uncommon in dogs; they include reversible Coombs'-positive spherocytic anemia, thrombocytopenia, glomerular proteinuria, myopathy, aggressiveness, and increased hepatic enzyme activity.
- 2-MPG should be used with caution in cats, as the efficacy and safety of 2-MPG has not been thoroughly evaluated in normal or cystinuric cats.
- In mouse models, L-cystine methyl esters have effectively disrupted cystine crystal growth. Future studies hope to show that efficacy and safety profiles are superior to current thiol-binding drugs.

FOLLOW-UP

- Minimize recurrence with dietary management or 2-MPG.
- Monitor urolith dissolution at 30-day intervals by urinalysis, survey or contrast radiography, or ultrasonography.
- Although cystine uroliths tend to recur, recurrence does not affect all cystinuric dogs and cats.
- In some older dogs, the rate of recurrence declines as a consequence of a reduction in the magnitude of cystinuria and urine specific gravity.

MISCELLANEOUS

ABBREVIATIONS

- 2-MPG = *N*-(2-mercaptopropionyl)-glycine.

UROLITHIASIS, PSEUDO (DRIED BLOOD, OSSIFIED MATERIAL)

BASICS

OVERVIEW
Pseudo-uroliths are concretions of noncrystalline material that form within the urinary tract. They include dried solidified blood and ectopic bone. Pseudo-uroliths can be located in upper or lower sections of the urinary tract (renal pelvis, ureter, bladder, and urethra).

SIGNALMENT
Pseudo-uroliths are primarily a disease of cats.
- Dried solidified blood pseudo-uroliths comprise 1% or less of feline uroliths. They are 2–3 times more common in male than female cats. The mean age of affected cats is 9 years old (range 1–15 years).
- Ectopic bone pseudo-uroliths are rare, with few cases reported.

SIGNS
- Urinary tract obstructions (ureteral or urethral) are common. Obstructions can result in uremia with anorexia, vomiting, weakness, and, if hyperkalemia is present, bradycardia. Urethral obstructions can also cause nonproductive stranguria and a palpably enlarged, firm bladder.
- Other signs include hematuria, dysuria, and pollakiuria.

CAUSES & RISK FACTORS
- Dried solidified blood pseudo-uroliths are associated with hematuria, but mechanisms underlying their formation are unknown. Concurrent urinary tract infections are occasionally present.
- Ectopic bone forms due to ossification of the urothelium. Trauma and inflammation are risk factors in humans, but their role in veterinary species has not been determined.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Consider more common lower urinary tract diseases, such as feline idiopathic lower urinary tract disease, other types of urolithiasis (e.g., calcium oxalate and struvite), urethral plugs, urinary tract infection, and urinary tract neoplasia.

CBC/BIOCHEMISTRY/URINALYSIS
Hematuria, proteinuria, and, if obstruction is present, azotemia and hyperkalemia.

OTHER LABORATORY TESTS
- Quantitative analysis (polarized light microscopy and infrared spectroscopy).
- Urine culture to rule out concurrent infection.

IMAGING
Radiographic Findings
- Dried solidified blood is often radiolucent. Bladder distension will be present in the case of urethral obstruction. Pyelography can aid in the diagnosis of ureteral obstruction, but dried solidified blood pseudo-uroliths are infrequently identified even with this modality.
- Ectopic bone is radio-opaque and can be visualized with plain radiography.

Ultrasonographic Findings
- Patients with dried solidified blood pseudo-uroliths frequently have evidence of ureteral obstruction on ultrasound, including renal pelvic dilation with or without ureteral dilation. The pseudo-urolith is often not identified.
- Ectopic bone appears hyperechoic with distal acoustic shadowing.

DIAGNOSTIC PROCEDURES
Cystoscopy can characterize the appearance and number of pseudo-uroliths in the lower urinary tract.

PATHOLOGIC FINDINGS
- Dried solidified blood pseudo-uroliths are often black in color. Unlike blood clots, they are not malleable and crack with pressure. On histopathology, they consist of a conglomeration of red blood cells that lack distinct borders.
- Ectopic bone is grossly adhered to the urothelium but can easily be detached. Other mineralization, such as calcium oxalate, may also be present.

TREATMENT
- Urethral obstructions are treated as emergencies. Retrograde urohydropropulsion can relieve the obstruction; decompressive cystocentesis prior to placement of a urinary catheter may more rapidly reduce intravesicular pressure. Cystotomy or basket-retrieval is performed to remove pseudo-uroliths from the bladder. Voiding urohydropropulsion can be considered for those measuring <3 mm in diameter in female cats or ≤1 mm in male cats.
- Ureteral obstructions should also be managed immediately. Subcutaneous ureteral bypass or ureteral stenting is recommended. Traditional surgery is performed when these procedures are not available.

MEDICATIONS

DRUG(S) OF CHOICE
Neither dried solidified blood nor ectopic bone pseudo-uroliths are reported to be susceptible to medical dissolution.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A.

FOLLOW-UP

PATIENT MONITORING
Routine urinalysis to identify hematuria and serum renal biomarkers (BUN, creatinine, SDMA) to assess renal function.

PREVENTION/AVOIDANCE
Increased fluid intake is recommended as a general mechanism to decrease concretions of material within the urinary tract. Preventative strategies should be followed for any concurrent diseases, such as renal disease, urinary tract infection, or calcium oxalate urolithiasis.

POSSIBLE COMPLICATIONS
Obstruction can result in renal damage and, in severe cases, fatality. Calcium oxalate uroliths can form on ectopic bone within the urinary tract.

EXPECTED COURSE AND PROGNOSIS
Recurrence rates are unknown.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Ectopic bone pseudo-uroliths can serve as a nidus for calcium oxalate uroliths.

UROLITHIASIS, STRUVITE—CATS

BASICS

DEFINITION
Struvite uroliths and urethral plugs have physical and etiopathogenic differences; these terms should not be used as synonyms. Struvite uroliths are polycrystalline concretions composed primarily of magnesium ammonium phosphate (MAP) and small quantities of matrix. Struvite urethral plugs are composed of large quantities of matrix mixed with crystals (especially MAP), while others are composed primarily of organic matrix, sloughed tissue, blood, and/or inflammatory reactants.

PATHOPHYSIOLOGY
- See Urolithiasis, Struvite—Dogs.
- Most urethral plugs contain large quantities of matrix in addition to minerals, especially struvite. Risk factors associated with formation of MAP crystals contained in urethral plugs are similar to those associated with formation of struvite uroliths. Prevention or control of these risk factors should minimize the recurrence of the struvite component of urethral plugs.

SYSTEMS AFFECTED
Renal/urologic—upper and lower urinary tract.

INCIDENCE/PREVALENCE
- From 1981 to 2002, the prevalence of struvite uroliths has decreased and while that of calcium oxalate (CaOx) uroliths has increased. In 2015, struvite comprised 49% and CaOx comprised 36% of feline uroliths.
- Currently, struvite makes up ~50% of all types of uroliths in the lower urinary tract. Of these, 95% are sterile.
- Struvite has been detected in approximately 8% of feline nephroliths.
- Struvite has remained the most common (~90%) mineral in matrix-crystalline urethral plugs.

SIGNALMENT

Species
Cat (see Urolithiasis, Struvite—Dogs).

Mean Age and Range
- Mean age at time of diagnosis is 7 years (range, <1–22 years).
- Sterile struvite uroliths do not affect immature cats; infection-induced struvite may occur in immature (<1 year) and senior cats (>10 years).

Predominant Sex
- Struvite uroliths are more common in female cats (55%) than in males.
- Struvite urethral plugs primarily affect males.

SIGNS

General Comments
- Affected cats may be asymptomatic.
- Depend on location, size, number, and cause of uroliths.

Historical Findings
- Typical signs of urocystoliths include pollakiuria, dysuria, periuria, hematuria, and sometimes voiding of small, smooth uroliths.
- Signs of renal dysfunction (polyuria and polydipsia) are found in some cats with nephroliths.
- Signs of outflow obstruction (e.g., dysuria, large painful urinary bladder, and postrenal azotemia) are found with struvite urethral plugs.

Physical Examination Findings
- A thickened, firm, contracted bladder wall may be appreciated.
- Palpation is insensitive and unreliable for detection of urocystoliths.
- Urethral plugs or urethroliths may be detected by examination of the distal penis.
- Outflow obstruction results in an enlarged urinary bladder and signs of postrenal azotemia.

CAUSES
See Pathophysiology.

RISK FACTORS
- Sterile struvite uroliths—mineral composition, energy content, and moisture content of diets; urine-alkalinizing metabolites in diets; quantity of diet consumed; *ad libitum* vs. meal-feeding schedules; formation of concentrated urine; and retention of urine.
- Infection-induced struvite urolithiasis—urinary tract infection (UTI) with urease-producing bacteria, abnormalities in local host defenses that allow bacterial UTIs, and the quantity of urea excreted in urine.
- The small diameter of the male distal urethra predisposes to obstruction with plugs and urethroliths.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Uroliths mimic other causes of pollakiuria, dysuria, periuria, hematuria, and/or outflow obstruction.
- Differentiate struvite uroliths and urethral plugs from other types of uroliths by signalment, urinalysis, urine culture, radiography, ultrasonography, cystoscopy, and quantitative analysis of uroliths or plugs.

CBC/BIOCHEMISTRY/URINALYSIS
- Complete outflow obstruction may cause postrenal azotemia.
- MAP crystals typically appear as colorless, orthorhombic (having three unequal axes intersecting at right angles), coffin-like prisms. They often have 3–8 sides.

OTHER LABORATORY TESTS
- Pretreatment urine cultures (preferably obtained by cystocentesis) can detect primary infections with urease-producing microbes causing infection-induced struvite uroliths and differentiate them from infections acquired as a sequelae to urolithiasis.
- Quantitative mineral analysis should be performed on all uroliths and plugs.
- Bacterial culture of inner portions of uroliths retrieved from patients with urease-positive UTI may be of value.

IMAGING

Radiography
- Struvite uroliths—radiodense, single or multiple, rough or smooth, round or faceted, sometimes disc-shaped; some struvite urethral plugs may be detected by survey radiography.
- The size and number of uroliths are not a reliable index of probable efficacy of dissolution therapy.
- Contrast urethrocystography helps identify the site of urethral obstruction and strictures.

Ultrasonography
- Detects location and approximate size and number of uroliths. Tends to overestimate stone size and underestimate stone number.
- Does not indicate degree of radiodensity or shape of uroliths.

DIAGNOSTIC PROCEDURES
Cystoscopy reveals location, number, size, and shape of urethroliths and urocystoliths.

PATHOLOGIC FINDINGS
Urethral plugs may contain red blood cells, white cells, transitional epithelial cells, bacteria, and/or viruses in addition to matrix and minerals.

TREATMENT

APPROPRIATE HEALTH CARE
- Retrograde urohydropropulsion to eliminate urethral stones; lavage to remove urethral plugs.
- Voiding urohydropropulsion to eliminate small bladder and urethral stones.
- Medical dissolution of struvite uroliths is an outpatient strategy.

DIET
- Medical dissolution is the standard of practice for elimination of struvite uroliths.
- Treatment with a dedicated struvite calculolytic diet (e.g., Hill's Prescription Diet Feline s/d) results in dissolution within 2–4 weeks of therapy.
- Treatment with urinary therapeutic foods designed for struvite dissolution and CaOx prevention are effective but may require longer treatment times.
- Infection-induced struvite urocystoliths may be dissolved by feeding a calculolytic diet and an appropriate antimicrobic.
- Continue diet therapy for 1 month after radiographic evidence of urolith dissolution.

UROLITHIASIS, STRUVITE—CATS (CONTINUED)

• Struvite crystalluria may be minimized by feeding magnesium-restricted urine-acidifying diets.
• Canned foods help to reduce urine concentration of calculogenic metabolites and promote increased frequency of voiding.

CLIENT EDUCATION
• If dietary management is used, limit access to other foods and treats.
• Short-term (weeks to months) treatment with a calculolytic diet and antibiotics as needed is effective in dissolving infection-induced struvite uroliths.
• Owners of cats with infection-induced struvite urocystoliths must comply with dosage schedule of antibiotics.
• Avoid feeding calculolytic diets to immature cats.

SURGICAL CONSIDERATIONS
• Ureteroliths cannot be dissolved. For persistent ureteroliths associated with morbidity, consider subcutaneous ureteral bypass, ureteral stents, or traditional surgery.
• Urethroliths cannot be medically dissolved. Consider voiding urohydropropulsion to remove urethroliths or urethral plugs. Alternatively, move urethroliths into the bladder by retrograde urohydropropulsion.
• Immovable urethroliths, recurrent urethral plugs, or strictures of the distal urethra may require perineal urethrostomy.
• Consider laser lithotripsy for urocystoliths and/or urethroliths.
• Consider surgical correction if uroliths are obstructing urine outflow and/or if correctable abnormalities predisposing to recurrent UTI are identified by radiography or other means.
• Radiographs should be obtained immediately following surgery to verify that all uroliths were removed.

MEDICATIONS

DRUG(S) OF CHOICE
• Dissolution of infection-induced urocystoliths requires appropriate antibiotics, chosen on the basis of bacterial culture and antimicrobial susceptibility tests. Give antibiotics at therapeutic dosages until the UTI is eradicated and there is no radiographic evidence of uroliths.
• Buprenorphine may be used to alleviate discomfort (15 µg/kg via buccal transmucosal administration q8–12h).
Tolteridine may be considered as an anticholinergic and antispasmodic to minimize hyperactivity of the bladder detrusor muscle and urge incontinence (0.05 mg/kg PO q12h).

CONTRAINDICATIONS
Do not give urine acidifiers to azotemic patients or immature cats.

PRECAUTIONS
Azotemic patients are at increased risk for adverse drug events.

FOLLOW-UP

PATIENT MONITORING
Check rate of urolith dissolution monthly by urinalysis, urine culture, survey or contrast radiography, or ultrasonography.

PREVENTION/AVOIDANCE
• Recurrent sterile struvite uroliths may be prevented by using acidifying, magnesium-restricted diets or urine acidifiers. Do not administer urine acidifiers with acidifying diets.
• For patients whose urine has been acidified, carefully monitor them for CaOx crystalluria. Change management protocol if persistent CaOx crystalluria develops.
• In patients at risk for both struvite and CaOx crystalluria, focus on preventing CaOx uroliths. Struvite uroliths can be medically dissolved; CaOx uroliths cannot be dissolved.
• Infection-induced struvite urolithiasis can be prevented by eradicating and controlling UTIs. Use of magnesium-restricted, acidifying diets is not required if the urease-positive microbes can be eradicated.

POSSIBLE COMPLICATIONS
• Urocystoliths may pass into and obstruct the urethra, especially if the patient is persistently dysuric. Urethral obstruction may be managed by retrograde urohydropropulsion.
• An indwelling transurethral catheter increases the risk for iatrogenic bacterial UTI and urethral stricture.

EXPECTED COURSE AND PROGNOSIS
Mean times for dissolution of sterile urocystoliths ranged from 13 to 36 days. Mean times for dissolution of infection-induced struvite urocystoliths ranged from 21 to 44 days. Most struvite uroliths located in the urinary bladder can be safely dissolved with a low risk of adverse effects, including urethral obstruction.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Any disease that predisposes to bacterial UTI.

AGE-RELATED FACTORS
Infection-induced struvite is the most common urolith in immature cats. Sterile struvite is rare in immature cats.

SYNONYMS
Feline lower urinary tract disease.

SEE ALSO
• Crystalluria.
• Lower Urinary Tract Infection, Bacterial.
• Lower Urinary Tract Infection, Fungal.
• Nephrolithiasis.
• Urolithiasis, Struvite—Dogs.

ABBREVIATIONS
• CaOx = calcium oxalate.
• MAP = magnesium ammonium phosphate.
• UTI = urinary tract infection.

Client Education Handout available online

U

UROLITHIASIS, STRUVITE—DOGS

BASICS

DEFINITION
Formation of polycrystalline concretions (i.e., uroliths, calculi, or stones) composed of magnesium ammonium phosphate hexahydrate (MAP, struvite) in the urinary tract.

PATHOPHYSIOLOGY

Infection-Induced Struvite
- Urine must be supersaturated with MAP for struvite uroliths to form. MAP supersaturation of urine is often associated with urinary tract infections (UTIs) with urease-producing microbes.
- UTIs caused by urease-producing microbes (*Staphylococcus*, *Proteus*, and *Ureaplasma*) and urine containing sufficient urea favors formation of uroliths containing struvite, carbonate apatite, and calcium apatite.
- Consumption of dietary protein exceeding the daily requirement results in formation of urea from catabolism of amino acids.
- Metabolic and anatomic abnormalities may indirectly induce struvite uroliths by predisposing to UTIs.

Sterile Struvite
- In dogs, this type of struvite is uncommon.
- Dietary or metabolic factors may be involved in the genesis of sterile struvite uroliths in dogs.
- Microbial urease is not involved in formation of sterile struvite uroliths.

SYSTEMS AFFECTED
Renal/urologic.

GENETICS
- The high incidence of struvite uroliths in some breeds such as miniature schnauzers suggests a familial tendency. Susceptible miniature schnauzers may inherit an abnormality of local host defenses of the urinary tract that increases their susceptibility to UTI.
- Sterile struvite uroliths were found in a family of English cocker spaniels.

INCIDENCE/PREVALENCE
Struvite uroliths account for approximately 40% of stones affecting the canine lower urinary tract and 23% of stones affecting the upper urinary tract.

GEOGRAPHIC DISTRIBUTION
Ubiquitous

SIGNALMENT

Species
Dog

Breed Predilections
- Miniature schnauzer, shih tzu, bichon frise, miniature poodle, cocker spaniel, and Lhasa apso.
- Any breed may be affected.

Mean Age and Range
- Mean age, 6 years (range <1 to >19 years).
- Most uroliths in immature (<12 months old) dogs are infection-induced struvite.

Predominant Sex
More common in females (~85%) than males (~15%), which may be related to the greater propensity for females to develop bacterial UTI.

SIGNS

General Comments
- Some dogs are asymptomatic.
- Signs depend on location, size, and number of uroliths and virulence of bacteria.

Historical Findings
- Typical signs of urocystoliths include pollakiuria, dysuria, and hematuria; sometimes small, smooth uroliths are voided.
- Typical signs of urethroliths include pollakiuria and dysuria; sometimes small, smooth uroliths are voided, and some medium size uroliths are associated with urethral obstruction.
- Nephroliths may be associated with manifestations of renal insufficiency. Obstruction to urine outflow with bacterial UTI may result in generalized pyelonephritis and septicemia.

Physical Examination Findings
- Uroliths may be palpated in the urinary bladder and urethra (by rectal exam).
- Urethral obstruction may cause enlargement of the urinary bladder.
- Ureteral obstruction may cause enlargement and pain of the associated kidney.
- Complete urine outflow obstruction combined with bacterial infection may cause ascending UTI and signs of renal failure and septicemia.

CAUSES
- Urinary tract disorders that predispose to infections with urease-producing bacteria, fungal pathogens, or ureaplasma in patients whose urine contains a large quantity of urea.
- Specific causes of sterile struvite uroliths are unknown.

RISK FACTORS
- Exogenous or endogenous exposure to high concentrations of glucocorticoids predispose to bacteriuria.
- Abnormal retention of urine.
- Alkaline urine decreases the solubility of struvite.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Uroliths mimic other causes of pollakiuria, dysuria, hematuria, and/or outflow obstruction.
- Differentiate from other types of uroliths by signalment, rectal exam, urinalysis, urine culture, radiography, and quantitative analysis of uroliths.

CBC/BIOCHEMISTRY/URINALYSIS
- Complete outflow obstruction can cause postrenal azotemia and hyperphosphatemia.
- MAP crystals typically appear as colorless, orthorhombic, coffin-like prisms. They may have 3–6 or more sides and often have oblique ends.

OTHER LABORATORY TESTS
- Quantitative bacterial culture of urine, preferably collected by cystocentesis.
- Bacterial culture of inner portions of infection-induced struvite uroliths.
- Quantitative mineral analysis of urolith.

IMAGING
- Struvite uroliths are radiodense and may be detected by survey radiography.
- Ultrasonography can detect uroliths, but provides no information about their density, shape, or size.
- Determine precise location, size, and number of uroliths; the size and number are not a reliable index of probable efficacy of dissolution therapy.

TREATMENT

APPROPRIATE HEALTH CARE
- Medical dissolution with antimicrobials and therapeutic food is preferred treatment for non-obstructing struvite uroliths.
- Ureteral stenting facilitates medical dissolution of obstructing nephroureteroliths.
- Appropriate antimicrobic administration is the cornerstone of treatment for infection-induced struvite dissolution and prevention.
- Voiding urohydropropulsion, laser lithotripsy, percutaneous cystolithotomy, and/or surgery require short periods of hospitalization.

DIET
- Infection-induced and sterile struvite urocystoliths and nephroliths may be dissolved by feeding a calculolytic food (Hill's Prescription Diet Canine c/d, s/d, Royal Canin® and others).
- Continue calculolytic diet therapy for 1 month beyond survey radiographic evidence of urolith dissolution.
- Avoid use of the protein restricted diet in patients with protein-calorie malnutrition. Some calculolytic diets are designed for short-term (weeks to months) dissolution therapy, rather than long-term (months to years) prophylactic therapy. Monitor the patient for evidence of protein malnutrition. Consider dissolution diets meeting maintenance nutritional requirements in immature dogs. Avoid high sodium foods in dogs with cardiac valvular disease or heart failure.

CLIENT EDUCATION
- If dietary management is used, limit access to other foods and treats.

UROLITHIASIS, STRUVITE—DOGS (CONTINUED)

• Short-term (2–3 months) treatment with a calculolytic food and administration of antibiotics is effective in dissolving struvite uroliths.
• Comply with dosage schedule for antibiotic and diet therapy.

SURGICAL CONSIDERATIONS

• Ureteroliths and urethroliths may be difficult to medically dissolve because they are minimally immersed in urine.
• Consider ureteral stenting or shock-wave lithotripsy for persistent ureteroliths associated with morbidity. Ureteral stenting may allow for renal decompression and allow time for stone dissolution.
• Consider voiding urohydropropulsion if urethroliths are likely to pass through the urethra. Alternatively, consider laser lithotripsy or move urethroliths into the bladder by retrograde urohydropropulsion.
• Consider surgical correction if uroliths are obstructing urine outflow and minimally invasive procedures are ineffective or not available. Immovable urethroliths may require urethrotomy or urethrostomy.

MEDICATIONS

DRUG(S) OF CHOICE

• Dietary dissolution of infection-induced urocystoliths or nephroliths requires oral administration of appropriate antibiotics, chosen on the basis of quantitative bacterial culture and antimicrobial susceptibility tests. Give antibiotics until there is no radiographic evidence of uroliths and there is eradication of UTI.
• In most cases, antimicrobics need to be administered for the entire dissolution period. Shorter duration may be successful if they sterilize the urolith (e.g., small uroliths).

PRECAUTIONS

• Diet-induced polyuria will reduce the concentration of antimicrobial drugs in urine; consider this fact when calculating antimicrobic dosages.

FOLLOW-UP

PATIENT MONITORING

Monitor rate of urolith dissolution at 4 to 6 week intervals by urinalysis, urine culture, and imaging (ultrasonography, and/or survey or contrast radiography).

PREVENTION/AVOIDANCE

• Infection-induced struvite urolithiasis may be prevented by eradicating and controlling infections by urease-producing bacteria.
• Recurrent sterile struvite uroliths may be prevented by use of acidifying, magnesium-restricted diets (Hill's Prescription Diet Canine c/d and others) or urine acidifiers.
• Monitor patients whose urine has been acidified for calcium oxalate crystalluria. Change management protocol if persistent calcium oxalate crystalluria develops.
• In patients at risk for both struvite and other urolith types, focus dietary prevention of metabolic uroliths (e.g., calcium oxalate, urate, cystine)— and UTI prevention for struvite uroliths.

POSSIBLE COMPLICATIONS

• Benefits and risks are associated with feeding low protein-high fat struvitolytic diets. Potential contraindications include those with (1) abnormal fluid accumulation, (2) chronic kidney disease, and (3) predispositions to pancreatitis (especially miniature schnauzers with hyperlipidemia).
• Urocystoliths may pass into and obstruct the urethra. Urethral obstruction can be managed by retrograde urohydropropulsion or lithotripsy.
• Dysuria may be minimized by antimicrobic treatment of bacterial UTIs and oral administration of anticholinergic drugs.
• Diet-associated polyuria will result in voiding increased urine volume. This may be associated with varying degrees of urinary incontinence in neutered female dogs with a predisposition to incontinence. Allow frequent opportunity to urinate to minimize inappropriate housesoiling.

EXPECTED COURSE AND PROGNOSIS

• The mean time for dissolution of all infection-induced urocystoliths was 3 months (range 2 weeks–7 months), whereas nephroliths took 6 months (range 2–10 months). The mean dissolution time of sterile struvite urocystoliths was 6 weeks (range 4–12 weeks).
• When feeding Hills Prescription Diet s/d, compliance with dietary recommendations is verified by a reduced concentration of urea in serum (approximately 10 mg/dL) and a low urine specific gravity (1.004–1.014).
• If uroliths increase or fail to decrease in size after approximately 6–8 weeks of appropriate management, alternative methods should be considered. Difficulty in inducing complete dissolution of uroliths should prompt consideration that (1) the wrong mineral component was identified, (2) the nucleus of the uroliths has a different mineral composition than other portions of the urolith, and (3) the owner is not complying with therapeutic recommendations. With the addition of high sodium dissolution foods lacking protein reduction, the proportion of calcium phosphate carbonate associated with infection-induced struvite has increased. Struvite uroliths with high percentages of calcium phosphate carbonate appear less amenable to medical dissolution.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Any disease that predisposes to bacterial UTI.

AGE-RELATED FACTORS

Infection-induced struvite is the most common form of urolith in immature dogs. The uroliths develop as a result of microbial UTI.

PREGNANCY/FERTILITY/BREEDING

• The calculolytic foods are not designed to sustain pregnancy.

SYNONYMS

• Phosphate calculi.
• Infection stone.
• Urease stone.
• Triple-phosphate stone.

ABBREVIATIONS

• MAP = magnesium ammonium phosphate.
• UTI = urinary tract infection.

UROLITHIASIS, URATE

BASICS

DEFINITION
Uroliths composed of uric acid, sodium urate, or ammonium urate.

PATHOPHYSIOLOGY
• Impaired conversion of uric acid to allantoin (see Figure 1) causes high concentration of uric acid in serum and urine. • Patients with portosystemic shunts may develop ammonium urate uroliths because of impaired hepatic metabolism of uric acid and ammonia.

GENETICS
Dalmatians have a breed predisposition to forming urate urolithiasis.

INCIDENCE/PREVALENCE
Approximately 5–8% of uroliths retrieved from dogs and cats.

SIGNALMENT

Species
Dog and cat.

Breed Predilections
Dalmatians, English bulldogs, Black Russian Terriers (due to mutation in SLC2A9 gene), and breeds predisposed to portosystemic shunts (e.g., Yorkshire terriers).

Mean Age and Range
• Mean age in patients without portosystemic shunts is 3.5 years (range 0.5 to >10 years). • Mean age in patients with portosystemic shunts is <1 year (range 0.1 to >10 years).

Predominant Sex
• More common in male dogs without portosystemic shunts. • No sex predilection in dogs with portosystemic shunts or cats.

SIGNS

Historical Findings
Hematuria, dysuria, pollakiuria. Possible hepatic encephalopathy in patients with portosystemic shunts.

Physical Examination Findings
• Urethral obstruction. • Asymptomatic in some patients. • Stunted growth and copper-colored irises (cats) in patients with portosystemic shunts.

CAUSES
Rule out portosystemic shunt.

RISK FACTORS
• High purine intake (glandular meat).
• Persistent aciduria in a predisposed animal.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Other causes of lower or upper urinary tract disease.

CBC/BIOCHEMISTRY/URINALYSIS
• Aciduria, urate crystalluria, azotemia in patients with urinary outflow obstruction. • Low BUN and microcytosis in patients with portosystemic shunts; reduced production of urea by the liver may mask hypoglycemia, hypoalbuminemia, and increased hepatic enzyme activities in patients with more severe hepatic dysfunction.

OTHER LABORATORY TESTS
• Liver function tests such as postprandial serum bile acids have abnormal results in patients with portosystemic shunts. • Genetic testing for mutation in SLC2A9 gene, which encodes for a carrier protein necessary for uric acid metabolism, can be performed in dogs without portosystemic shunts who are at high risk or who have formed urate uroliths (performed at University of California Davis and Embark).

IMAGING
• Urate uroliths may be radiolucent; may need IV pyelogram to detect nephroliths or double contrast cystography to detect urocystoliths. Microhepatica in patients with portosystemic shunts. • Ultrasonography may reveal radiolucent uroliths. Patients with a portosystemic shunt may also have microhepatica, bilateral renomegaly, and a portosystemic vascular anomaly identified with ultrasound.

DIAGNOSTIC PROCEDURES
Liver biopsy; bile acids, blood ammonia; advanced imaging to identify portosystemic shunt.

PATHOLOGIC FINDINGS
In patients with portosystemic shunts, liver biopsy may reveal hepatic atrophy and/or dysplasia.

TREATMENT

APPROPRIATE HEALTH CARE
Urethral or ureteral obstruction may require inpatient treatment. Urate uroliths can be dissolved on outpatient basis.

NURSING CARE
Fluid therapy to correct dehydration.

ACTIVITY
Usually not restricted, except after surgery.

DIET
For dissolution and prevention, a high moisture, low-purine, urine-alkalinizing diet.

CLIENT EDUCATION
Recurrence of uroliths is possible. A plan to minimize recurrence should be developed.

SURGICAL CONSIDERATIONS
• Minimally invasive techniques such as cystoscopic stone basket removal, percutaneous cystolithotomy or lithotripsy are preferred over cystotomy, urethrotomy, and nephrotomy to remove uroliths. • Portosystemic shunt ligation.

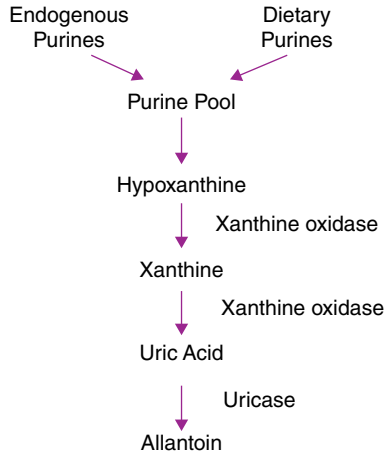

Figure 1.

MEDICATIONS

DRUG(S) OF CHOICE
Allopurinol 15 mg/kg PO q12h, a xanthine oxidase inhibitor, for dissolution (see Figure 2).

CONTRAINDICATIONS
Glucocorticoids and other immunosuppressive drugs may promote hyperuricosuria.

PRECAUTIONS
Allopurinol is contraindicated in animals with renal failure and is not effective in animals with portosystemic shunts.

POSSIBLE INTERACTIONS
Skin eruption with use of allopurinol and ampicillin.

FOLLOW-UP

PATIENT MONITORING
See Figure 3.

PREVENTION/AVOIDANCE
• High-moisture, low-purine, urine-alkalinizing diet. • Some dogs require allopurinol administration (5.0–7.5 mg/kg PO q12h). • Low uric acid excreting Dalmatians (those without SLC2A9 mutation) should be at lower risk due to decreased urinary uric acid excretion.

POSSIBLE COMPLICATIONS
• Urethral obstruction. • Uroliths likely to recur if no preventive measures.

EXPECTED COURSE AND PROGNOSIS
• Medical dissolution takes an average of 4 weeks, if there is good compliance. • Medical dissolution usually not successful with portosystemic shunt.

UROLITHIASIS, URATE (CONTINUED)

MISCELLANEOUS

ASSOCIATED CONDITIONS
Portosystemic shunt.

PREGNANCY/FERTILITY/BREEDING
Low-protein/purine diet is not recommended for pregnant or lactating animals.

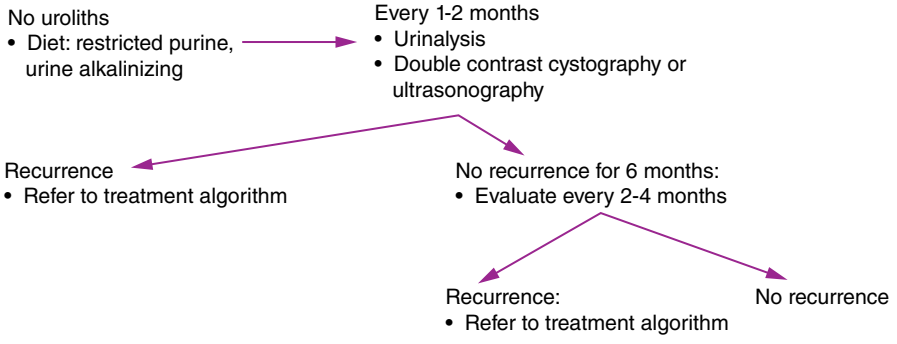

Figure 3.
Algorithm for prevention of urate urocystolithiasis.

U

UROLITHIASIS, XANTHINE

BASICS

OVERVIEW

• Xanthine, a product of purine degradation, is converted to uric acid by xanthine oxidase. Naturally occurring or drug-induced impairment of xanthine oxidase results in hyperxanthinemia and xanthinuria.
• Naturally occurring xanthinuria is likely caused by a familial or congenital defect in xanthine oxidase activity. In cavalier King Charles spaniels, an autosomal recessive mode of inheritance has been found.
• Acquired xanthinuria is a complication of allopurinol therapy. High-purine diets increase the risk of xanthinuria in these patients.
• Xanthine is the least soluble purine excreted in urine.

SIGNALMENT

• Dog and cat. Naturally occurring xanthinuria is more common in cats.
• Naturally occurring xanthinuria and xanthine uroliths have occurred in young cavalier King Charles spaniels.
• Cats—adult males (66%) and females (33%) (mean age 3.3 years; range 2 months–13 years). Most common in the domestic shorthair and domestic longhair breeds.

SIGNS

• Dependent on stone location, size, and number; may be asymptomatic.
• Pollakiuria, dysuria, hematuria, and voiding of small, smooth, yellow uroliths. Complete outflow obstruction may result in azotemia.
• Nephroliths may be associated with hydronephrosis and renal insufficiency.

CAUSES & RISK FACTORS

• Xanthinuria.
• Genetic inheritance in some breeds.
• Cats—uroliths often recur unless prophylactic therapy is initiated.
• Approximately 11% of cats have reoccurrence of xanthine uroliths. Urolith formation enhanced by aciduria, highly concentrated urine, and incomplete and infrequent micturition.
• In animals given excessive allopurinol, xanthinuria is enhanced by failure to appropriately restrict dietary purine precursors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Other causes of pollakiuria, dysuria, hematuria, or outflow obstruction.
• Differentiate from other urolith types by urinalysis, radiography, and quantitative stone analysis.

CBC/BIOCHEMISTRY/URINALYSIS

Xanthine crystals cannot be distinguished from urate by light microscopy; both are usually yellow-brown and may form varying sized spherules.

OTHER LABORATORY TESTS

• Infrared spectroscopy, X-ray diffraction, or other quantitative techniques are required to differentiate xanthine from ammonium urate, sodium urate, and uric acid.
• High-pressure liquid chromatography of urine to detect xanthine, hypoxanthine, and other purine metabolites.
• Genetic testing for xanthinuria type 2a, which involves a mutation in molybdenum cofactor sulfurase (performed at University of Minnesota).

IMAGING

• Radiography—similar density to soft tissue; stones cannot be reliably detected.
• Ultrasonography, double contrast cystography, and IV urography aid in detecting uroliths and their location.

OTHER DIAGNOSTIC PROCEDURES

• May be detected by urethrocystoscopy.
• Uroliths may be retrieved by aspiration via a transurethral catheter or voiding urohydropropulsion.

TREATMENT

• Medical dissolution protocols for xanthine uroliths have not been developed.
• Remove small urocystoliths by voiding urohydropropulsion.
• Minimally invasive surgery can remove larger active uroliths from the lower urinary tract.
• Minimize further growth of existing uroliths by reducing dietary risk factors. Discontinue or reduce allopurinol dosages.
• Consider canned renal-failure diets to increase urine volume, minimize purine precursors, and prevent aciduria in cats.
• Consider perineal urethrostomy for recurrent urethral obstruction in male cats.

MEDICATIONS

DRUG(S) OF CHOICE

Urine Alkalinizers

• Consider in aciduric patients despite dietary therapy.
• Potassium citrate or sodium bicarbonate—target urine pH of 7.0–7.5.

Allopurinol

• Adjust dosage of allopurinol in context of urine concentration of uric acid, and quantity of dietary purines (see Urolithiasis, Urate).
• Allopurinol-induced uroliths may dissolve by discontinuing allopurinol therapy and feeding a low-purine diet.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Do not use allopurinol to treat naturally occurring xanthine uroliths.

FOLLOW-UP

• Monitor dissolution every 30 days by urinalysis, contrast radiography, or ultrasonography.
• Recurrence does not occur in all patients.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Urate urolithiasis.
• Nephrolithiasis.

SEE ALSO

• Crystalluria.
• Urolithiasis, Urate.

UTERINE INERTIA

BASICS

OVERVIEW
Failure to expel fetuses of normal size, presentation and posture through a normal birth canal at the normal end of gestation.

Primary Uterine Inertia
- Multifactorial—failure to establish a normal, progressive myometrial contraction pattern.
- Seen in bitches with fewer than 3 puppies in the litter—failure to initiate parturition at term.
- Occurs with large litter sizes—overstretching of the uterus.

Secondary Uterine Inertia
- Occurs following initiation of parturition where some or all of the litter is not expelled.
- Can be secondary to dystocia or large litter.

SIGNALMENT
Queens and bitches of any breed and age.

SIGNS
- Primary—failure to initiate parturition at the end of gestation; dam is typically asymptomatic except for vaginal discharge (uteroverdin) following placental separation.
- Secondary—uterine contractions cease despite normal contractions initially; may deliver part of litter and then stop. Some primiparous queens may initiate parturition, and then pause for as long as 48 hours prior to resuming birth.

CAUSES & RISK FACTORS
- Primary—inadequate stimulation from fetuses to initiate cascade of events leading to parturition (small litters); abnormal or inadequate hormones or receptors; systemic disease; obesity; tocolytic administration; hypocalcemia; uterine infection; inadequate or unbalanced nutrition.
- Secondary—follows exhaustion of uterine muscle during normal parturition of large litters; occurs in bitches fed diet with poor calcium:phosphorus ratio; occurs during dystocia after prolonged periods of uterine contraction and eventual uterine fatigue; can occur with uterine torsion and trauma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Primary—inaccurate predicted parturition date; false pregnancy; nonviable pregnancy.
- Secondary—normal parturition; parturition already complete.

CBC/BIOCHEMISTRY/URINALYSIS
- Normocytic, normochromic anemia (normal in pregnancy).
- Low total calcium or low ionized calcium (iCa).
- Hypoglycemia.

OTHER LABORATORY TESTS
Serum progesterone <2 ng/mL for 48 hours prior to parturition in most cases.

IMAGING
- Ultrasonography findings—fetal heart rates sustained <160–170 bpm indicate stress and need for intervention; separation of the placenta from the uterus—need for immediate intervention to optimize fetal survival.
- Radiographic findings—evaluate for presence; size; and abnormalities of presentation, position, and posture of fetus(es).

DIAGNOSTIC PROCEDURES
Digital vaginal examination to evaluate for presence of fetus within caudal birth canal and abnormal anatomy causing narrowed birth canal.

TREATMENT
- Inpatient—if live fetus(es) are present and fetal stress is documented, cesarean section advisable to optimize fetal survival; surgery is the only option for primary uterine inertia when fetal survival is desired.
- Fluid therapy as needed to support hydration and vascular volume.
- Medical—for secondary uterine inertia with nonobstructive dystocia and no evidence of fetal distress.

MEDICATIONS

DRUG(S) OF CHOICE
- 10% calcium gluconate 1 mL/5 kg SC q4–6h or 0.2 mL/kg IV slowly.
- 2.5–5% dextrose-containing fluids if hypoglycemic (can also give bolus of dextrose 0.5 g/kg, diluted to 10% or lower, IV).
- Oxytocin typically not effective as sole treatment—give 15–30 minutes after calcium administration at 0.5–4 IU/bitch SC or IM or 0.5–1 IU/queen SC or IM. Do not administer to animals with obstructive dystocia.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
- Bradycardia with calcium treatment; monitor electrocardiogram and discontinue treatment if noted.
- Contractions may resume with calcium treatment and rehydration alone.
- Delaying surgery while pursuing medical management may decrease fetal survival rate.
- Uterine rupture (rare).

FOLLOW-UP

PATIENT MONITORING
- Serial assessment of blood iCa concentration in hypocalcemic cases (see Eclampsia).
- Monitor dam's temperature and character of vaginal discharge daily for 5–7 days following dystocia or cesarean section—concern for metritis.

PREVENTION/AVOIDANCE
- Consider elective cesarean section in cases of very small or vary large litters.
- Breed females in good body condition and monitor nutrition during pregnancy.
- Utilize tocodynamometry (Veterinary Perinatal Specialties, Wheatridge, CO) to identify and manage secondary uterine inertia.
- Remove females with repeated primary uterine inertia from breeding stock.

POSSIBLE COMPLICATIONS
- Fetal death if too much time elapses before intervention.
- Primary inertia thought to be heritable in some breeds of dogs and cats.

EXPECTED COURSE AND PROGNOSIS
- Primary uterine inertia—idiopathic cases may recur on subsequent pregnancies.
- Secondary uterine inertia—will not necessarily recur if due to fetal factors such as large litter size, poor nutrition, or dystocia due to malpresentation.

MISCELLANEOUS

SEE ALSO
- Dystocia.
- Eclampsia.

ABBREVIATIONS
- iCa = ionized calcium.

UTERINE TUMORS

BASICS

OVERVIEW
- Rare tumors arising from the uterine smooth muscle and epithelial tissues.
- Comprise 0.3–0.4% of tumors in dogs and 0.2–1.5% in cats.
- Dogs—usually benign; leiomyomas, 85%–90%; leiomyosarcoma, 10%; other types (e.g., carcinoma, fibroma, fibrosarcoma, lipoma, extramedullary plasma cell tumor, mast cell tumor, hemangiosarcoma) rare.
- Cats—usually malignant (adenocarcinoma); include leiomyoma, leiomyosarcoma, fibrosarcoma, fibroma, lipoma, and Mullerian tumor (adenosarcoma).
- Metastasis—may occur with malignant forms.

SIGNALMENT
- Dog and cat.
- No breed predilection reported.
- Middle-aged to older animals usually affected.
- Birt-Hogg-Dube syndrome in German shepherd dogs has been associated with uterine leiomyomas, renal cystadenocarcinomas, and nodular dermatofibrosis.

SIGNS
- Dogs—often clinically silent and discovered incidentally; vaginal discharge; pyometra, infertility; abdominal organ compression or secondary metastatic signs (site specific).
- Cats—vaginal discharge (may be hemorrhagic); abnormal estrous cycles; polyuria; polydipsia; vomiting; abdominal distention, infertility, uterine prolapse; signs related to metastatic disease (site specific).

CAUSES & RISK FACTORS
- Intact sexual status (hormonal influence).
- Nulliparous bitches have an increased risk of uterine pathology.
- Mutated *BHD* gene in German shepherd dogs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Pyometra.
- Endometriosis.
- Other mid-caudal abdominal masses.

CBC/BIOCHEMISTRY/URINALYSIS
No specific abnormalities.

OTHER LABORATORY TESTS
N/A

IMAGING
- Abdominal radiography—may detect a mid-caudal abdominal mass.
- Thoracic radiography—recommended; assess for distant pulmonary metastasis.
- Ultrasonography—may reveal uterine mass, masses in uterine horns may be difficult to definitely identify at uterine.
- Abdominal CT/MRI—further delineation of mass, assess for metastatic disease.

DIAGNOSTIC PROCEDURES
- Cytologic evaluation—however, tumors might be poorly exfoliative, especially if mesenchymal in origin; improved cytologic yield with epithelial malignancies (carcinoma).
- Imaging unable to differentiate between histologic subtypes.
- Histopathologic examination—necessary for definitive diagnosis.

TREATMENT
Ovariohysterectomy—treatment of choice.

MEDICATIONS

DRUG(S) OF CHOICE
Doxorubicin, cisplatin, carboplatin, epirubicin—rational choices for palliation of malignant or metastatic disease.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
- Doxorubicin—carefully monitor patients with underlying cardiac disease; consider pretreatment and serial echocardiograms and ECG.
- Cisplatin—do not use in dogs with preexisting renal disease; do not use without appropriate and concurrent diuresis; do not use in cats (fatal).
- Chemotherapy may be toxic; seek advice if unfamiliar with these agents.

FOLLOW-UP

PATIENT MONITORING
- Malignant—consider thoracic radiographs and abdominal ultrasonography every 3 months.
- CBC, biochemical profile, and urinalysis (if using cisplatin)—perform before each chemotherapy treatment.

EXPECTED COURSE AND PROGNOSIS
Prognosis—excellent (cure) if benign; guarded if malignant; poor if metastases present; after chemotherapy, unknown.

MISCELLANEOUS

ASSOCIATED CONDITIONS
BHD syndrome in German shepherd dogs has been associated with uterine leiomyomas.

ABBREVIATIONS
- BHD = Birt-Hogg-Dube.

UVEAL MELANOMA—CATS

BASICS

OVERVIEW
- Also called feline diffuse iris melanoma.
- The most common intraocular tumor in cats.
- Usually arise from the anterior iridal surface with extension to the ciliary body and choroid.
- Tend to be flat and diffuse, not nodular (unlike intraocular melanomas in dogs).
- Initially has a benign clinical and histologic appearance.
- Unique feature—may develop metastatic disease up to several years later.
- Metastatic rate may be 8.1–63%.
- Secondary glaucoma may increase the risk for metastasis.

SIGNALMENT
- No sex or breed predisposition.
- Average age is 9.5 years, although can affect any adult cat.

SIGNS

Historical Findings
- Iris color change.
- Secondary glaucoma leading to mydriasis or buphthalmia, resulting in blindness.

Physical Examination Findings
- Iris surface—thickened, irregular, usually pigmented, though can be nonpigmented.
- Lesions—focal to diffuse; usually flat; slowly progressive; may involve one or both eyes.
- Advanced disease—often see pigmented tumor cells in the aqueous; homogeneously thickened iris, black, velvety appearance.
- May note drainage angle infiltration, which may result in secondary glaucoma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Freckles (nevi) on the surface of the iris that do not appear to change over time—may be benign pigmented lesions; more likely melanocytoma, a benign lesion.
- Heterochromia irides—congenital, nonprogressive alteration in iridal pigmentation.
- Diffuse iridal color change that results from chronic anterior uveitis. Differs from uveal melanoma by the history of chronic anterior uveitis.
- Iris atrophy—the anterior iris stroma is lost, increasing visualization of the heavily pigmented posterior iris tissue. Iris thinning is seen as full-thickness holes in the iris or as retroillumination defects in the iris when light is bounced off the tapetum back through the iris.
- Limbal melanomas—benign behavior; usually focal, superiorly located, flat to slightly raised limbal masses that do not invade the uveal tract unless they are very large.

CBC/BIOCHEMISTRY/URINALYSIS
Normal

IMAGING
- Thoracic radiographs and abdominal ultrasonography for extensive lesions—help determine presence and extent of metastatic disease.
- Recommended presurgically and every 6 months after the diagnosis if histopathologic diagnosis indicates extensive disease.

DIAGNOSTIC PROCEDURES
- Complete ophthalmic examination, including tonometry and gonioscopy.
- Iridal biopsy—may be performed, not beneficial for staging the disease.
- Melanocytes in the iridocorneal angle and ciliary vessels suggest metastatis may have occurred, but these may not be evident until years later.

TREATMENT
- Varies with age of cat, extent and speed of progression, doctor's preference, and client's level of concern about the potential for malignancy.
- Old cat with slow progression—consider only periodic examinations and serial photography to monitor the progress of the lesion(s).
- Younger cat with rapidly progressive disease—consider enucleation.
- Small, isolated, freckle-like lesions have been apparently successfully treated with laser (diode) photoablation, although controlled or long-term follow-up studies are lacking.
- Mild to moderate diffuse iridal involvement—most ophthalmologists prefer a conservative approach of periodic examinations and serial photography to monitor the growth progress of the lesion(s). Enucleation is an alternative if progression can be documented or the owner is highly concerned about the potential for malignancy.
- Extensive iridal involvement resulting in changes in pupil shape or mobility, extra-iridal extension, invasion into the drainage angle, or secondary glaucoma—enucleation is suggested.
- Cats with iridal thickening and iridocorneal angle involvement, with and without glaucoma, however, had similar survival times when compared with unaffected age-matched control cats.
- Advanced lesions consisting of infiltrative iris involvement including the posterior epithelium and ciliary body had decreased survival times, presumably as a result of metastatic disease.

MEDICATIONS

DRUG(S) OF CHOICE
N/A

FOLLOW-UP

PATIENT MONITORING
- Intraocular pressure (IOP)—quarterly monitoring if surgical options are declined; mild IOP elevation may be treated with oral or topical carbonic anhydrase inhibitors (e.g., dorzolamide or brinzolamide at 1 drop to affected eye q8h, or methazolamide at approximately 6.25 mg per cat PO q12–24h); secondary glaucoma due to melanoma is best controlled by enucleation.
- Common metastasis sites—liver, lungs, regional lymph nodes; monitor periodically.

EXPECTED COURSE AND PROGNOSIS
- One long-term study shows that patients with early iris melanoma have no increased risk of life-threatening metastasis compared to controls, but patients with advanced lesions have dramatically shortened survival times.
- Lesions—focal, multifocal to diffuse; usually flat; pigmentation over months to years (i.e., variable); may involve one or both eyes.
- Advanced disease—often see pigmented tumor cells in the aqueous; homogeneously thickened iris causing abnormal pupil shape and change in pupil mobility.
- Prognosis—guarded, even with enucleation; metastasis may not become apparent for several years or may be diagnosed on necropsy.

MISCELLANEOUS

SYNONYMS
- Feline diffuse iris melanoma.
- Iris melanoma.

ABBREVIATIONS
- IOP = intraocular pressure.

UVEAL MELANOMA—DOGS

BASICS

OVERVIEW
- Melanomas of anterior uvea (e.g., iris and ciliary body) and posterior uvea (choroid).
- Most common primary intraocular neoplasm in dogs.
- Usually benign and unilateral; often destructive to the eye but also can be very slow-growing.
- Most often affects anterior uvea. In a retrospective study of 1842 enucleated eyes with uveal melanoma, 79.2% were benign and 20.8% malignant.
- Anterior uveal—4% rate of vascular metastasis to lungs and viscera, but rare for malignant uveal melanoma to metastasize.
- Choroidal—rarely metastasize.

SIGNALMENT
- No breed or sex predilection.
- Anterior uveal—average age 8–10 years.
- Choroidal melanoma—average age 6.5 years.
- Range—2 months–17 years.

SIGNS

Anterior Uveal
- Pigmented scleral or corneal mass.
- Pigmented mass visible in anterior chamber or posterior to pupillary margin.
- Irregular pupil.
- Uveitis.
- Glaucoma.
- Hyphema.
- No vision loss—unless mass obstructs pupil or glaucoma has developed.

Choroidal
- Often missed because of tumor location; usually incidental finding.
- Posterior segment mass on funduscopy.
- Very slow-growing; rarely require enucleation.
- Rare.

CAUSES & RISK FACTORS
- Idiopathic.
- Potential transformation of flat, pigmented iris freckles into melanomas.
- Labrador retrievers—presumed autosomal recessive inheritance.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Non-neoplastic uveal proliferations—iris freckles are not raised.
- Diffuse iris hyperpigmentation secondary to chronic uveitis, particularly in golden retrievers (golden retriever pigmentary uveitis) and boxers.
- Ocular melanosis (Cairn terriers).
- Uveal cysts—transilluminate and move freely within the eye, unlike melanomas.
- Granulomatous masses.
- Iris bombé.
- Ocular perforation with uveal prolapse.
- Other ocular neoplastic conditions, especially conjunctival melanoma, which could be misinterpreted as extrascleral extension of uveal melanoma. Conjunctival melanoma is usually malignant and aggressive in dogs.
- Outward scrolling of pupillary margin due to uveitis (ectropion uvea).

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal.

OTHER LABORATORY TESTS
N/A

IMAGING
Ocular ultrasonography—may help determine extent of mass.

DIAGNOSTIC PROCEDURES
- Slit-lamp biomicroscopy—determine size and location of mass.
- Transillumination of mass.
- Tonometry.
- Indirect ophthalmoscopy—with or without concomitant scleral indentation.
- Gonioscopy—evaluate drainage angle for tumor extension.
- Ocular ultrasonography—if cornea opaque and cannot visualize deeper ocular structures, or suspect ciliary body mass hidden by iris.

PATHOLOGIC FINDINGS
- Restricted to enucleated globe; biopsy not practical in most patients.
- Two cell types usually seen—plump cells filled with melanin, spindle cells.
- Mitotic index—most reliable criterion for malignancy:
  - <2 mitotic figures per 10 HPF: benign.
  - 4 mitotic figures per 10 HPF: clinically malignant tumors.
- Veterinary ocular pathologist should evaluate globe.

TREATMENT
- Usually benign, may opt to monitor q3–6 months.
- Young Labrador retrievers—aggressive growth, need surgery.
- Counsel client about enucleation; surgery often causes client emotional distress:
  - Emphasize unilateral condition, sparing of fellow eye, and that one-eyed animals function very well.
- Indications for enucleation—rapid size increase, eye cannot be salvaged, mass spread diffusely within eye, visual function significantly impaired, extraocular invasion, secondary complications (e.g., glaucoma, pain, hemorrhage).
- Enucleation—use gentle surgical technique to prevent showering of tumor cells into circulation, avoid tension on optic chiasm (could blind fellow eye), exenterate entire orbital contents if extrascleral extension.
- Sector iridectomy for discrete small masses—infrequently used.
- Laser treatment of small iris tumor.
- Melanoma vaccine efficacy unknown; likely ineffective without enucleation. Consider vaccine if malignant melanoma is present, to try to prevent metastasis.

MEDICATIONS

DRUG(S) OF CHOICE
Reseveratrol, a potent antioxidant derived from grapes, inhibited uveal tumor growth of uveal melanoma *in vitro*, but grape skins may be toxic to dogs. Grapeseed extract is a safe alternative that may support ocular health of affected dogs.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
N/A

FOLLOW-UP
- Postoperative thoracic and abdominal radiography or ultrasonography—at 6 and 12 months if mitotic index is high or patient has extrascleral, vascular, or optic nerve extension.
- Evaluate enucleation site for tumor recurrence.

UVEODERMATOLOGIC SYNDROME (VKH)

BASICS

OVERVIEW
- Rare canine syndrome similar to Vogt–Koyanagi–Harada (VKH) in humans.
- Chronic granulomatous inflammatory condition of unknown etiology.
- Affects the meninges, eyes then skin.
- Clinical signs reflect melanin as the target of inflammation.

PATHOPHYSIOLOGY
Likely an autoimmune process against antigenic components of melanocytes, suspected tyrosinase and related proteins; involves T-cells and macrophages for skin lesions and B-cells and macrophages for ocular lesions.

SYSTEMS AFFECTED
- Ophthalmic.
- Skin/exocrine.
- Nervous (rarely).

SIGNALMENT
- Akita, Samoyed, Siberian husky, Alaskan Malamute, old English sheepdog, and chow chow predisposed.
- Other breeds and mixed breeds reported.
- Suspected heritability: canine leukocyte antigen DLA-DQA1*00201 has been associated with an increased risk for uveodermatological syndrome.
- No sex predilection.
- Mean age of onset 6 months–6 years.

SIGNS
- Ophthalmic signs almost always precede dermatologic signs.
- Sudden-onset uveitis (photophobia, blepharospasm, conjunctival inflammation, pain).
- Secondary changes include glaucoma, cataracts, bullous retinal detachment, and progression to blindness.
- Unilateral uveitis may be seen in dogs with heterochromic irides.
- Concurrent or subsequent leukoderma of the nose, lips, and eyelids.
- Depigmented nasal planum may develop crusting and ulceration.
- Concurrent or subsequent striking leukotrichia of the muzzle and periorbital regions.
- Footpads, scrotum, vulva, anus, and oral cavity (hard palate) may also depigment.
- Neurologic symptoms (meningoencephalitis,) possible, but very rare.

CAUSES & RISK FACTORS
- Exact cause is unknown.
- Most likely an inherited autoimmune disorder.
- Skin trauma or infectious agent (e.g., virus) are possible triggers.
- Exposure to sunlight can exacerbate the symptoms.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Pemphigus foliaceus/erythematosus.
- Discoid/systemic lupus erythematosus.
- Mucocutaneous pyoderma (severe).
- Vitiligo.
- Neoplasia—epitheliotropic lymphoma.
- Numerous inflammatory and infectious dermatoses can cause depigmentation.
- Ocular—any cause of uveitis or glaucoma including neoplasia, trauma, infection and idiopathic causes.

CBC/BIOCHEMISTRY/URINALYSIS
Normal

OTHER LABORATORY TESTS
ANA—negative.

DIAGNOSTIC PROCEDURES
- Skin biopsy necessary for diagnosis, especially when correlated with ocular disease.
- Examination by veterinary ophthalmologist strongly recommended.

PATHOLOGIC FINDINGS
Lichenoid to interface dermatosis consisting of mostly histiocytic inflammation; macrophages containing granular melanin pigment; pigmentary incontinence.

TREATMENT
- Aggressive and rapid initiation of immunosuppressive therapy required to prevent formation of posterior synechiae and secondary glaucoma, cataracts, or blindness.
- Retinal exams are the most important means of monitoring progress; improvement in dermatologic lesions may not reflect continued retinal pathology.
- Bilateral enucleation can improve patient comfort and attitude when eye condition worsens and medical treatment is unsuccessful.
- Management by a veterinary ophthalmologist is strongly recommended.

MEDICATIONS

DRUG(S) OF CHOICE
- Initial high doses of prednisone 1.1–2.2 mg/kg PO q12–24h.
- Cases may improve with use of prednisone alone, but delaying aggressive therapy risks irreversible progression of disease: concurrent treatment options should include:
  - Azathioprine 1.5–2.5 mg/kg PO q24h in resistant cases; the dosage and frequency should be tapered to q48h for maintenance of remission.
  - Doxycycline 10 mg/kg q24h with niacinamide (250 mg patients <10 kg; 500 mg patients >10 kg q24h).
  - Cyclosporine (modified) 5 mg/kg PO q24h; the dosage and frequency may be tapered for maintenance of remission.
- Topical or subconjunctival steroids and cycloplegics may be indicated if anterior uveitis is present.

FOLLOW-UP

PATIENT MONITORING
- Weekly retinal examinations and lab work (based on medications prescribed). Dermatologic lesions may not mirror improvement in retinal lesions.
- Tapering of drugs should be based on improvement of ocular lesions.
- Severe opportunistic infections may occur with long-term use of combination immunosuppressive agents.

EXPECTED COURSE AND PROGNOSIS
- Generally good for dermatologic symptoms.
- Guarded to poor for vision unless treatment is quickly instituted and is effective.
- Some breeds (e.g., Akita or Siberian husky) may respond more poorly to treatment.

MISCELLANEOUS

SEE ALSO
- Dermatoses, Depigmenting Disorders.
- Lupus Erythematosus, Cutaneous (Discoid).
- Lupus Erythematosus, Systemic (SLE).
- Lymphoma, Cutaneous Epitheliotropic.
- Pemphigus.

ABBREVIATIONS
- ANA = antinuclear antibody.
- VKH = Vogt–Koyanagi–Harada syndrome.

VAGINAL DISCHARGE

BASICS

DEFINITION
Any substance emanating through the vulvar labia.

PATHOPHYSIOLOGY
- Dependent on underlying cause of vaginal discharge.
- Discharge may originate from uterus, vagina, vestibule, clitoris, clitoral sinus, perivulvar dermis, or urinary tract.

SYSTEMS AFFECTED
- Reproductive.
- Renal.
- Skin.
- Urinary.

INCIDENCE/PREVALENCE
- Unknown as there are many causes.
- Considered a common reason for seeking veterinary care.

SIGNALMENT
- Healthy bitch <6–12 months of age (prepubertal)—juvenile (puppy) vaginitis and congenital anomalies more common.
- Nonpregnant bitch that has undergone at least one estrous cycle—normal estrus, persistent estrus (cystic ovarian disease or granulosa cell tumor), pyometra, neoplasia
- Bitch bred in the last 30–70 days—normal parturition (50–70 days) or abortion (<50 days).
- Bitch that has recently whelped—normal lochia or postpartum metritis more common, subinvolution of placental sites.
- Ovariectomized bitch—vaginal stricture or estrogen-responsive urinary incontinence more common; neoplasia.

SIGNS

Historical Findings
- Discharge from the vulva.
- Licking, scooting, and spotting.
- Attracting male dogs.
- Parturition—with postpartum discharge.
- Recent estrus—with pyometra.
- Hemorrhagic discharge >8 weeks postpartum—subinvolution of placental sites.
- Vomiting, anorexia—may be seen with metritis and pyometra.

Physical Examination Findings
Vaginal discharge that may be serosanguinous, purulent, lochial, hemorrhagic, mucoid, or urinous.

CAUSES

Normal Physiologic Conditions
- Proestrus.
- Estrus.
- Diestrus.
- Late pregnancy.
- Parturition.
- Normal lochia.

Pathologic Conditions
See specific chapters for further information.
- Cystic ovarian disease (persistent estrus).
- *Brucella canis* infection.
- Metritis.
- Pyometra.
- Retained placenta or fetuses.
- Subinvolution of placental sites (hemorrhagic discharge postpartum ≥8 weeks).
- Neoplasia—uterus, vagina, urinary tract (including transmissible venereal tumor), ovary (granulosa cell tumor/persistent estrus).
- Vaginitis.
- Estrogen-responsive urinary incontinence.
- Coagulopathy.
- Congenital defects of the distal genital tract—intersex conditions, imperfect embryologic fusion of the Müllerian ducts (vagina), joining of the genital folds (vestibule) and genital swellings (vulvar lips), ectopic ureters.
- Trauma.
- Foreign body.

RISK FACTORS
- Prophylactic antibiotics—may alter normal vaginal flora and predispose to secondary infection.
- Exogenous estrogen—predispose to pyometra in the intact bitch.
- Exogenous androgens—may cause clitoral hypertrophy.
- Exogenous or endogenous progesterone—predispose to pyometra or stump pyometra.
- Obesity—excess skin folds around vulva.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Healthy intact bitch <6–12 months of age—juvenile vaginitis (prepubertal), normal estrous cycle, urogenital trauma or neoplasia, foreign body, coagulopathy, ectopic ureter(s), congenital abnormalities of the perineum or distal genital tract, intersex conditions, urinary tract disease.
- Nonpregnant bitch that has undergone at least one estrous cycle—normal estrus, pyometra, split heat, foreign body, urogenital trauma, neoplasia, coagulopathy, cystic ovarian disease (follicular cysts).
- Bitch bred in the last 30–70 days—abortion, pyometra, normal parturition (>57 days from breeding), fetal/embryonic death, split heat, *Brucella canis* infection.
- Bitch that has recently whelped—lochia (normal up to 6–8 weeks postpartum), subinvolution of placental sites (hemorrhagic discharge ≥8 weeks postpartum), postpartum metritis, vaginal trauma, retained placenta or fetus.
- Ovariectomized bitch—vaginal stricture, foreign body, neoplasia, polyps, stump pyometra due to exogenous or endogenous progesterone, exogenous estrogens (exposure to owner's hormone replacement therapy), perivulvar dermatitis, ovarian remnant syndrome, estrogen-responsive urinary incontinence.

CBC/BIOCHEMISTRY/URINALYSIS
- Regenerative anemia—may be normal in pregnancy or during estrus.
- Urinalysis—may indicate urinary tract infection.

OTHER LABORATORY TESTS
- Progesterone—determine if bitch is in luteal phase, which increases likelihood of pyometra. Progesterone, 17-hydroxyprogesterone may be secreted in animals with adrenal cortex disease.
- Adrenocorticotropic hormone (ACTH) stimulation test—to diagnose adrenocortical disease.
- *Brucella canis* serology—screen with rapid slide agglutination test; agar gel immunodiffusion test confirmatory.
- Bacterial culture of whole blood or lymph node aspirate for *B. canis*.
- PCR for *B. canis* available, best to use on abortive discharge (Kansas State Veterinary Diagnostic Laboratory).

IMAGING

Radiography
- Detect enlarged uterus or ovary, pregnancy.
- Evidence of fetal death—presence of gas around fetus or misalignment and/or collapse of fetal skeleton.

Ultrasonography
- Determine contents of uterus; free fluid in the uterus is characteristic of pyometra, hydrometra, and mucometra.
- Pregnancy diagnosis and embryonic/fetal wellbeing—heartbeat may be seen as early as the 20th day of diestrus, heart rate <180 bpm indicates fetal stress.
- Masses—neoplasia, granulomas, cystic ovarian disease, granulosa cell tumor, or foreign body; saline distention of the vagina may help visualization.

Contrast Radiography—Vaginogram/Urethragram/Cystogram/Excretory Urography
- Identify abnormal conformation or structure (i.e., neoplasia or foreign body) within the vagina.
- Rule out vestibulovaginal strictures, rectovaginal and urethrovaginal fistulas.
- Rule out differentials and help localize the problem.
- Pronounced folds (rugae) of vagina during estrus will cause filling defects (normal).

VAGINAL DISCHARGE (CONTINUED)

DIAGNOSTIC PROCEDURES

Vaginal Cytology

- Determine nature of discharge—inflammatory, hemorrhagic, purulent.
- Evaluate epithelial cells —superficial (cornified) cells present under the influence of estrogen.
- Always performed in order to interpret vaginal cultures (inflammation should accompany infection).

Vaginal Culture and Sensitivity

- Performed prior to other diagnostic procedures.
- Use guarded swab to sample cranial vagina.
- The vagina is not a sterile environment and culture of normal bitches results in growth of normal vaginal flora; use of vaginal cytology and other diagnostic tools is essential for interpretation of culture results.
- Most common organisms in the microbiome (commensals and potential pathogens) are *Escherichia coli*, *Streptococcus* spp., *Pasteurella* spp., and *Staphylococcus* spp.
- Other organisms which can be commensals include *Mycoplasma* spp., *Enterobacter* spp., *Pseudomonas* spp., *Klebsiella* spp.
- Normal microbiome consists of numerous opportunistic pathogens, e.g., *E. coli* and *Mycoplasma* spp.

Vaginoscopy

- Rigid cystourethroscope or ureteroscope, pediatric gastroscope or proctoscope, or flexible endoscope used to visualize vagina.
- Identify source of vaginal discharge—uterine, vaginal, vestibular, or urethra.
- Visualize anomalies, persistent hymen, neoplasia, foreign body, trauma, abscess, and evaluate the vaginal and vestibular mucosa.
- Removal of foreign body or biopsy of vaginal mass.

Other

- Digital examination of vestibule, vaginovestibular junction, and distal vagina.
- Biopsy and histopathology of mass lesions.
- Cystocentesis—urine culture and sensitivity.
- Coagulation profile, platelet count.

TREATMENT

- Based on diagnosis.
- No treatment for normal causes of vaginal discharge.

SURGICAL CONSIDERATIONS

- Ovariectomy or ovariohysterectomy (OHE) is treatment of choice for neoplastic conditions.
- Cystic ovarian disease can be medically managed or ovariectomy/OHE performed.
- Removal of foreign body or surgical excision of mass(es).
- Surgical excision or radiation therapy are options for transmissible venereal tumor (TVT).

MEDICATIONS

DRUG(S) OF CHOICE

- Antibiotic—choice based on guarded cranial vaginal culture and sensitivity.
- Dopamine agonist—may be used in addition to PGF2α for luteolysis via suppression of the luteotropic hormone prolactin—bromocriptine 10 µg/kg PO or cabergoline 5 µg/kg PO q8–24h until serum progesterone level <2.0 ng/mL.
- Supportive care including IV fluids as indicated.

CONTRAINDICATIONS

Certain antibiotics may be contraindicated during pregnancy and nursing.

PRECAUTIONS

Dopamine agonists—side effects include vomiting and nausea; can be controlled with antiemetics.

ALTERNATIVE DRUG(S)

Aglepristone (Alizin®) 10 mg/kg SC, 2 doses given 24 hours apart—progesterone receptor antagonist that may be used alone or concurrently with prostaglandin therapy for treatment of pyometra (currently not widely available in the United States without special authorization).

FOLLOW-UP

PATIENT MONITORING

Subinvolution of Placental Sites

Monitor hematocrit or packed cell volume (PCV)—may have significant blood loss.

PREVENTION/AVOIDANCE

- Puppy vaginitis—delay elective OHE until after first estrous cycle in cases of juvenile vaginitis; may avoid chronic vaginitis.
- Addition of probiotics to daily diet.
- Avoid exogenous steroids (estrogens, progestins, androgens).

POSSIBLE COMPLICATIONS

Endotoxemia and septicemia may occur with pyometra or metritis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Pyometra and cystic endometrial hyperplasia.

AGE-RELATED FACTORS

- Increased risk for pyometra after each estrous cycle.
- Neoplasia more common in older bitches.

ZOONOTIC POTENTIAL

- *Brucella canis*—fluids and fetal tissue during abortion are highly contaminated with organisms.
- Immunocompromised people are at highest risk. Animal caretakers and pathologists are at risk due to high exposure.

PREGNANCY/FERTILITY/BREEDING

- Neoplasia—poor prognosis for future fertility.
- TVT—sexually transmitted disease; breeding should be avoided.
- *Brucella canis*—sexually transmitted disease and grave prognosis for resolution of disease and normal fertility; should not be used for breeding.

SEE ALSO

- Abortion, Spontaneous (Early Pregnancy Loss)—Cats.
- Abortion, Spontaneous (Early Pregnancy Loss)—Dogs.
- Brucellosis.
- Ovarian Remnant Syndrome.
- Pyometra.
- Retained Placenta.
- Sexual Development Disorders.
- Subinvolution of Placental Sites.
- Transmissible Venereal Tumor.
- Vaginal Malformations and Acquired Lesions.
- Vaginitis.

ABBREVIATIONS

- ACTH = adrenocorticotropic hormone.
- OHE = ovariohysterectomy.
- PCV = packed cell volume.
- TVT = transmissible venereal tumor.

Client Education Handout available online

VAGINAL HYPERPLASIA AND PROLAPSE

BASICS

OVERVIEW

- Protrusion of spherical or donut-shaped mass from vulva during proestrus or estrus, rarely during gestation, parturition, or after administration of estrogenic drugs:
  - Type I—slight eversion of vaginal floor cranial to the urethral orifice but no protrusion through vulva.
  - Type II—vaginal tissue prolapses through vulvar opening (tongue-shaped mass).
  - Type III—donut-shaped eversion of the entire circumference of vaginal wall, including the urethral orifice, seen ventrally on the prolapsed tissue.
- Exaggerated response of vaginal mucosa to estrogen; some affected animals have follicular cysts.
- Despite the name, the change seen histopathologically is edema rather than hyperplasia or hypertrophy if occurring during proestrus or estrus.
- Severe prolapse—may occlude urethra and prevent normal urination.
- True vaginal prolapse without hyperplasia or edema occurs rarely pre- or postpartum and may include uterine body and horns.

SIGNALMENT

- Young (most 18–22 months, range 6 months–4.6 years), large-breed bitches.
- Predisposed breeds—large and brachycephalic breeds (boxer, mastiff, English bulldog, Saint Bernard); Labrador and Chesapeake Bay retrievers; German shepherd dog; English springer spaniel; Walker hound; Airedale terrier; American pit bull terrier.
- Hereditary component probable—increased incidence in some family lines.

SIGNS

Historical Findings

- Onset of proestrus or estrus.
- Although rare, can be seen during diestrus or at parturition (8–12% of cases occur at parturition); or after administration of estrogenic drugs or exposure to exogenous estrogens.
- Licking of vulvar area.
- Failure to allow copulation.
- Dysuria.
- Previous occurrence.

Physical Examination Findings

- Protrusion of round, tongue-shaped, or donut-shaped tissue mass from the vulva.
- Vaginal examination—locate lumen and urethral orifice; types I and II: vaginal lumen is dorsal to the prolapse; type III: lumen is central to the prolapse; urethral orifice is ventral to the prolapse with all three types.

CAUSES & RISK FACTORS

- Estrogen stimulation.
- Genetic predisposition.
- Dystocia.
- Increased abdominal pressure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Vaginal polyp—differentiated by vaginal examination.
- Vaginal neoplasia—transmissible venereal tumor and leiomyoma; differentiated by signalment, stage of cycle, and vaginal examination.
- Clitoral hypertrophy; differentiated by physical examination.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Biopsy—differentiate from neoplasia.

TREATMENT

- Outpatient; unless urethral obstruction.
- Breeding—possible by artificial insemination (discuss potential heritability).
- Prolapsed tissue—keep clean and lubricated with sterile water-soluble lubricant.
- Use of sugar or a 50% dextrose solution on edematous tissue may help to shrink prolapse.
- Elizabethan collar and clean indoor environment—minimize tissue trauma.
- Instruct client to monitor patient's ability to urinate.
- If urethral obstruction present, place indwelling urinary catheter.
- Regression—usually begins in late estrus; should be resolved during early diestrus.
- Recurrence rate—66–100% at next estrous cycle.

Surgical Considerations

- Ovariohysterectomy—prevents recurrence; may hasten resolution.
- Severe condition—requires surgical reduction or resection; identify and catheterize urethra, 25% recurrence at next cycle after surgery.
- With dystocia, cesarean section required, ovariohysterectomy may be necessary.
- When occurring during pregnancy, both resection of prolapse and surgical reduction with accompanying hysteropexy have been successfully reported. Vaginal delivery with concurrent vaginal prolapse has been reported; close monitoring for obstructive dystocia is recommended.

MEDICATIONS

DRUG(S) OF CHOICE

Gonadotropin-releasing hormone (GnRH) 2.2 µg/kg IM or human chorionic gonadotropin (hCG) 1,000 IU IM—if breeding not planned that cycle; may hasten ovulation and resolution by a couple of days; not effective if given after ovulation (progesterone >8–10 ng/mL).

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Avoid progestational drugs, they can induce pyometra.

FOLLOW-UP

PATIENT MONITORING

Monitor health of prolapsed tissue and the ability to urinate.

PREVENTION/AVOIDANCE

Ovariohysterectomy—recommended owing to genetic component and likelihood of recurrence.

POSSIBLE COMPLICATIONS

Type III—may affect urethra and prevent normal urination.

EXPECTED COURSE AND PROGNOSIS

- Medical treatment—prognosis for recovery good, except with urethral involvement.
- Surgical intervention for type III—prognosis good.

MISCELLANEOUS

ABBREVIATIONS

- GnRH = gonadotropin-releasing hormone.
- hCG = human chorionic gonadotropin.

VAGINAL MALFORMATIONS AND ACQUIRED LESIONS

BASICS

DEFINITION
Altered anatomic architecture due to congenital anomalies (imperforate hymen, dorsoventral septum, hymenal constriction, rectovaginal fistula, segmental aplasia, cysts, conformational defects of the vulva) and acquired conditions (vaginal hyperplasia, foreign bodies, strictures, adhesions, fistulas, and neoplasia).

PATHOPHYSIOLOGY

Congenital
- Normal embryologic development—paired paramesonephric (Müllerian) ducts fuse to form uterine body, cervix, and vagina; urogenital sinus forms the vestibule, urethra, and urinary bladder; hymen (composed of epithelial linings of paramesonephric ducts and urogenital sinus and an interposed layer of mesoderm) normally disappears by birth.
- Errors during embryonic development—imperforate hymens; dorsoventral septae; hymenal constrictions (including vestibulovaginal stenoses); vaginal diverticulum (double vagina, vaginal pouch); cysts.

Acquired
- Vaginal scarring—from trauma (mating, dystocia, sexual abuse) or inflammation; may note adhesions or strictures, which narrow vaginal diameter.
- Vaginal hyperplasia (dogs)—exaggerated response of the vaginal mucosa to estrogen; actually edema (vs. hyperplasia or hypertrophy).
- Neoplasia—extraluminal leiomyoma most common; usually old patients; no influence of ovarian status.

SYSTEMS AFFECTED
- Reproductive—interference with natural mating and whelping; frequently concurrent vaginitis.
- Renal/urologic—urinary tract infections; urinary incontinence with congenital malformations of hymenal area.
- Skin/exocrine—perivulvar dermatitis secondary to vaginitis, recessed vulva (redundant perivulvar folds or hypoplastic vulva), or urinary incontinence.

GENETICS
Congenital—heritable component suspected; no direct evidence.

INCIDENCE/PREVALENCE
- Incidence (congenital)—unknown; conditions may be asymptomatic, especially if female never used for breeding.
- Prevalence (vaginal septa)—in one study, 0.03%.

SIGNALMENT

Species
Dog and cat.

Breed Predilections
- Congenital—none identified.
- Vaginal hyperplasia—large and brachycephalic breeds (boxer, mastiff, English bulldog, Saint Bernard); Labrador and Chesapeake Bay retrievers; German shepherd dog; English springer spaniel; Walker hound; Airedale terrier; American pit bull terrier.

Mean Age and Range
- Congenital lesion—young (<2 years of age) intact or spayed females.
- Vaginal hyperplasia—young (<2 years of age) intact females.
- Acquired lesion (adhesions and strictures)—post-pubertal females of any age.
- Neoplasia—mean age 10 years; ovarian status has no effect.

SIGNS

Historical Findings
- Vulvar discharge.
- Excessive licking of vulva.
- Pollakiuria, stranguria.
- Dyschezia.
- Urinary incontinence.
- Attractive to males.
- Refuses mating.

Physical Examination Findings
- Usually normal.
- Evidence of vaginal discharge, perivulvar dermatitis, or mass.
- Recessed or hypoplastic vulva (occasional).

CAUSES
- Congenital.
- Inflammatory.
- Hormonal.
- Traumatic.
- Neoplastic.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Vaginitis—concurrent with many malformations; differentiated by vaginoscopy and vaginography.
- Urinary tract infection—differentiated by vaginal cytology and urinalysis (cystocentesis sample).
- Pyometra—differentiated by physical exam, abdominal ultrasonography.

CBC/BIOCHEMISTRY/URINALYSIS
- Usually normal.
- Urinalysis—possible urinary tract infection.

IMAGING

Positive-Contrast Vaginography, Excretory Urography
- Defines vaginal vault to cervix, urethra, cranial vestibule, and urinary bladder.
- Defines cervical canal and uterine lumen in intact patient during estrus.
- Identifies strictures, septae, persistent hymens, masses, rectovaginal fistulas, urethrovaginal fistulas, vaginal rupture, and diverticulae.
- Procedure:
  - Patients should be fasted for 24 hours; give enema 2 hours before procedure.
  - Performed under sedation or general anesthesia.
  - Pass Foley catheter into vestibule, inflate balloon, infuse aqueous iodinated contrast media (1 mL/kg). Avoid overdistension and underdistension.
- Vestibulovaginal stenoses—ratio of maximal height of vagina to smallest height of vestibulovaginal junction—normal >0.35, mild 0.26–0.35, moderate 0.20–0.25, severe <0.20.
- Urinary incontinence—excretory urography to indentify ectopic ureters or intrapelvic bladder neck.

Abdominal Ultrasonography
- Much of vagina not visible because of pelvis.
- Cranial vaginal masses may occasionally be imaged.
- Infusion of saline into vagina before examination helps differentiate luminal from transmural or extraluminal lesions.

DIAGNOSTIC PROCEDURES
Sequence of procedures is important; recommended order:
- Vaginal cytology—identify stage of estrous cycle; reveal inflammatory or neoplastic cells (see Breeding, Timing).
- Digital examination of vestibule and caudal vagina—measure diameter; identify caudal strictures or masses; note size and conformation of vulva.
- Vaginoscopy—identify strictures, adhesions, septa, diverticula, masses, and foreign bodies; may use a variety of specula; a long (16–20 cm), hollow, rigid-type (e.g., infant proctoscope) with light source recommended; match speculum diameter to size of patient; post-cervical fold (normal) obscures visualization of external os of cervix; rigid cystoscopes (used for transcervical insemination) adequate for many anomalies, need vaginal distension (under general anesthesia) with saline or air to visualize some anomalies or lesions.
- Imaging—see above.
- Urethrocystoscopy—identify ectopic ureters, other abnormalities.

PATHOLOGIC FINDINGS

Congenital
- Imperforate hymen—thin fenestrated membrane, dorsoventral band(s), or a thick membrane at vestibulovaginal junction; most common defect; remainder of genital tract normal.
- Dorsoventral septum—oriented dorsoventrally in vagina, cranial to vestibulovaginal junction; may note a double cervix

(CONTINUED) # VAGINAL MALFORMATIONS AND ACQUIRED LESIONS

(most common variant), double vagina, or divided uterine fundus (rare).
• Hymenal constriction or vestibulovaginal stenosis—moderate to severe constriction at vestibulovaginal junction.
• Vaginal hypoplasia or vaginal aplasia—vagina, cervix, uterus, vulva may be absent or hypoplastic.

Acquired

• Strictures and adhesions—may be identified anywhere in vagina or vestibule; result of trauma or inflammation; persistent vaginitis, refusal to mate, dystocia, or problems with micturition are common sequelae.
• Vaginal hyperplasia and prolapse.
• Vaginal neoplasia—usually extraluminal leiomyoma in wall of vestibule; leiomyosarcomas; transmissible venereal tumors; lipomas; mast cell tumors; epidermoid carcinomas; squamous cell carcinomas; fibromas; fibrosarcomas; and invasive urinary tract carcinomas reported.
• Foreign bodies—plant material, sticks, and swabs.

TREATMENT

APPROPRIATE HEALTH CARE

• Usually outpatient, until nature of defect is ascertained.
• Inpatient—for positive contrast vaginography.
• Manual dilation (bougienage)—digitally or with smooth rigid object:
  ◦ Attempt in patients with imperforate hymen or mild vestibulovaginal stenosis.
  ◦ Perform in sedated patient gradually over a course of several treatments.
  ◦ May be performed in anesthetized patient at one time to maximal dilation.
  ◦ Typically leads to reduction, but not complete resolution, of clinical signs; unlikely to resolve moderate or severe stenoses.

NURSING CARE

As appropriate for condition.

SURGICAL CONSIDERATIONS

• Resection, transection, excision—many minor congenital (e.g., imperforate hymen, small dorsoventral septa) and acquired lesions (small strictures, masses, or adhesions in caudal portion of vagina).
• Episiotomy—usually required for adequate surgical access.
• T-shaped vaginoplasty—described for vestibulovaginal stenoses; resection appears to provide best odds of resolution, although results are variable.
• Complete ring resection—vaginal stenosis.
• Vulvoplasty—excessive vulvar fold (redundant perivulvar skin fold) with or without increased perivulvar fat deposition; recessed vulva; reserved for patients with concurrent chronic vaginitis, vaginovulvar discharge, perivulvar dermatitis.
• Transendoscopic laser ablation—one report for correcting a dorsoventral septum in an English bulldog that subsequently bred and delivered 4 pups vaginally.
• Ovariohysterectomy—patient has no breeding value; exhibits signs only during estrus.
• Vaginal ablation (vaginectomy cranial to external urethral orifice) and ovariohysterectomy—patient has no breeding value; concurrent severe, refractory vaginitis at all stages of estrous cycle; severe vaginal stenosis; broad-based vaginal tumors.

MEDICATIONS

DRUG(S) OF CHOICE

• Concurrent vaginitis—appropriate local and antibiotic therapy (see Vaginitis).
• Stenotic lesions—manual dilation in conjunction with corticosteroids (prednisone 1 mg/kg PO q24h) in an attempt to prevent recurrence; high recurrence rates with or without steroids.

FOLLOW-UP

PREVENTION/AVOIDANCE

Congenital lesions—for a familial line with a high number of affected individuals, recommend sterilization of affected individuals and their sire and dam.

POSSIBLE COMPLICATIONS

• Dystocia, urinary tract infections, incontinence, and vaginitis—with vaginal malformations; with patients that fail to respond to treatment.
• Strictures and adhesions—may be postoperative complications of corrective surgical procedures.

EXPECTED COURSE AND PROGNOSIS

• Depends on severity of lesion and degree of inflammation after treatment.
• Prognosis after treatment for imperforate hymens, short dorsoventral bands, or caudal strictures or adhesions—fair to good for improvement of clinical signs; fair to guarded for complete resolution of signs and normal fertility.
• Prognosis for hymenal constrictions, vaginal hypoplasia or severe cranial strictures or adhesions—guarded to poor for complete resolution of signs and normal fertility; with concurrent severe vaginitis, best recommendation is vaginal ablation.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Urinary tract infections.
• Vaginitis.
• Urinary incontinence.

AGE-RELATED FACTORS

• Congenital—more likely in young bitches of any ovarian status.
• Vaginal hyperplasia—more likely in young intact bitches.
• Neoplasia of vagina or vestibule—more likely in old bitches of any ovarian status.

PREGNANCY/FERTILITY/BREEDING

• Some patients may be bred by artificial insemination; possibility for a vaginal delivery is unlikely without correction of the anomaly.
• Warn owner that an elective cesarean section may be required.

SEE ALSO

• Breeding, Timing.
• Transmissible Venereal Tumor.
• Vaginal Discharge.
• Vaginal Hyperplasia and Prolapse.
• Vaginal Tumors.
• Vaginitis.

VAGINAL TUMORS

BASICS

OVERVIEW
• Second most common reproductive tumor, comprising 1.9–3% of all tumors in dogs.
• Dogs—83% benign smooth muscle tumors, often pedunculated (e.g., leiomyoma, fibroleiomyoma, and fibroma); less common differentials include lipoma, transmissible venereal tumor, mast cell tumor, squamous cell carcinoma, leiomyosarcoma, hemangiosarcoma, osteosarcoma, or extension of primary urinary tract carcinomas also reported.
• Dogs—may be an incidental finding at necropsy.
• Cats—extremely rare; usually of smooth muscle origin.
• Hormonal influence—may play a role in the development of leiomyomas, fibromas, or polypoid tumors.

SIGNALMENT
• Dog—mean age 10.2–11.2 years, boxers, nulliparous bitches more commonly affected.
• Cat—no data available.

SIGNS
Dogs
• Extraluminal—slow-growing perineal mass; vulvar discharge; dysuria; pollakiuria; vulvar licking; dystocia.
• Intraluminal—mass protruding from the vulva (often at estrus if sexually intact); vulvar discharge; stranguria; dysuria; tenesmus.

Cats
• Firm mass in the perineal region.
• Constipation.

CAUSES & RISK FACTORS
• Intact sexual status (hormonal influence).
• Nulliparous bitches more commonly affected.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Vaginal prolapse.
• Urethral neoplasia.
• Uterine prolapse.
• Clitoral hypertrophy.
• Vaginal polyp.
• Vaginal abscess/granuloma.
• Vaginal foreign body.
• Vaginal hematoma.

CBC/BIOCHEMISTRY/URINALYSIS
No consistent abnormalities.

OTHER LABORATORY TESTS
N/A

IMAGING
• Thoracic radiography—recommended; assess for pulmonary metastatic disease (uncommon).
• Abdominal radiography—may detect cranial extension of a mass.
• Ultrasonography, vaginography, and urethrocystography—may help delineate mass.
• CT/MRI—definitive delineation of tumor, assess for surgical feasibility, assess for metastatic disease within abdominal visceral organs.

DIAGNOSTIC PROCEDURES
• Vaginoscopy with cytologic examination of an aspirate—may help determine cell type. Often cytology is nondiagnostic given the mesenchymal nature (poorly exfoliative) of most vaginal tumors.
• Biopsy with histopathologic examination—often necessary for definitive diagnosis.

PATHOLOGIC FINDINGS
• Intraluminal—vestibular wall; protruding into the vulva; may occur singularly or as multiple masses.
• Extraluminal—vestibular roof; causing a bulging of the perineum.

TREATMENT

• Surgical excision and concurrent ovariohysterectomy—treatment of choice.
• Subtotal and total vaginectomy described for extensive disease.
• Postoperative radiotherapy—may be of benefit for sarcoma and incompletely resected benign tumors.

MEDICATIONS

DRUG(S) OF CHOICE
• Postoperative therapy—no standard established.
• Doxorubicin 30 mg/m^2, cisplatin 60 mg/m^2, or carboplatin 300 mg/m^2—rational choice to palliate malignant or metastatic disease in dogs.
• Piroxicam 0.3 mg/kg PO SID may be useful especially for those dogs with primary urinary tumors extending into the vagina and carcinomas.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
• Doxorubicin—carefully monitor with underlying cardiac disease; consider pretreatment and serial echocardiograms and ECG.
• Cisplatin—do not use in cats (fatal); do not use in dogs with renal disease; always use appropriate and concurrent diuresis.
• Chemotherapy may be toxic; seek advice if you are unfamiliar with chemotherapeutic drugs.
• Piroxicam should not be used with other nonsteroidal anti-inflammatory drugs (NSAIDs) or prednisone and should be avoided in animals with underlying renal or hepatic disease. Should not be used in conjunction with cisplatin.

FOLLOW-UP

PATIENT MONITORING
• Thoracic radiography and abdominal ultrasonography—consider every 3 months if tumor is malignant.
• CBC (doxorubicin, cisplatin, carboplatin), biochemical profile (cisplatin, piroxicam), urinalysis (cisplatin, piroxicam)—perform before each chemotherapy treatment.

EXPECTED COURSE AND PROGNOSIS
• Prognosis—good with complete excision; guarded if incomplete excision; poor with metastatic disease; poor with carcinoma or squamous cell carcinoma.
• Recurrence—15% (leiomyoma) without concurrent ovariohysterectomy.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Cats—reported concurrent cystic ovaries and mammary gland adenocarcinoma.

ABBREVIATIONS
• NSAID = nonsteroidal anti-inflammatory drug.

VAGINITIS

BASICS

DEFINITION
Inflammation of the vagina.

PATHOPHYSIOLOGY
• Juvenile vaginitis—unknown, possibly due to imbalances of juvenile vaginal mucosal glandular epithelium. • Primary adult-onset vaginitis—*Brucella canis* or canine herpesvirus. • Secondary adult-onset vaginitis—sequela to congenital anomaly, vaginal atrophy following ovariohysterectomy (OHE), drug therapy, foreign body, neoplasia, urinary tract infection, urinary incontinence, systemic disease.

SYSTEMS AFFECTED
Reproductive

INCIDENCE/PREVALENCE
• 0.7% of dogs in one study. • Primary vaginitis—very rare.

SIGNALMENT

Species
Dog

Mean Age and Range
• Juvenile vaginitis—less than 1 year of age, ranging from 8 weeks to 1 year, prepubertal animals. • Adult-onset vaginitis—over 1 year of age, ranging from 1 to 16 years of age.

SIGNS

Historical Findings

Juvenile Vaginitis
• May have no significant history. • Vulvar discharge—seen most often following urination. • Vaginal irritation. • Crusting of the hair coat in the vulvar region. • Scooting. • Excessive vulvar licking. • Perivulvar pruritus. • Inability to housetrain.

Adult-Onset Vaginitis
• Vulvar discharge. • Excessive vulvar licking. • Pollakiuria. • Pain during urination. • Polyuria and polydypsia. • Pruritus. • Urinary incontinence. • Infertility.

Physical Examination Findings
• Vulvar discharge—mucoid to purulent, scant to copious. • Vulvar hyperemia. • Vestibular hyperemia. • Perivulvar dermatitis. • Digital examination—strictures and hymens identified at vagino-vestibular junction, granular irregularity of mucosa, especially wall opposite urethral papilla. • Vaginoscopy—diffuse hyperemia of vaginal and vestibular mucosa, prominent lymphoid follicles, luminal exudates, erythema of the urethral papilla or clitoral fossa; presence of foreign body, neoplasia, or congenital abnormalities.

CAUSES
• Prepubertal vagina. • Infantile vulva. • Urinary tract infection. • Urinary or fecal incontinence. • Foreign body. • Neoplasia—transmissible venereal tumor, leiomyoma. • Bacterial—*Brucella canis, Escherichia coli, Streptococcus* spp., *Staphylococcus intermedius, Pasteurella* spp., *Chlamydia*, *Pseudomonas* spp., *Mycoplasma* spp. • Viral—canine herpesvirus. • Congenital anomalies including vagino-vestibular strictures, inverted vulva. • Systemic disease—diabetes mellitus. • Zinc toxicity. • Exogenous or endogenous androgens.

RISK FACTORS
• Alteration of normal vaginal flora by antibiotics. • Clitoral hypertrophy secondary to exogenous or endogenous (hermaphrodites) androgens. • Inverted or recessed vulva. • Obesity. • Abnormal conformation. • Vaginal trauma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Normal—hemorrhagic or serosanguinous discharge during proestrus, continuing into estrus. • Normal—slight purulent exudate in early diestrus; neutrophils and parabasal epithelial cells present. • Normal—mucus discharge during pregnancy. • Normal—postpartum discharge for up to 6–8 weeks; odorless dark brown or hemorrhagic discharge; substantial amounts are normal for up to 4 weeks. • Subinvolution of the placental sites—hemorrhagic discharge lasting longer than 8 weeks postpartum. • Cystourethritis. • Foreign body. • Pyometra. • Metritis. • Retained placenta(s). • Clitoral hypertrophy. • Embryonic or fetal death. • Urine or feces contamination secondary to congenital anomaly (e.g., ectopic ureter) or acquired condition (e.g., incontinence secondary to hypoestrogenism). • Perivulvar dermatitis. • Sexual differentiation disorder. • Vaginal neoplasia, trauma, hematoma, abscess. • Ovarian neoplasia. • Zinc toxicity.

CBC/BIOCHEMISTRY/URINALYSIS
• Usually normal. • Adult onset—pyuria, bacteriuria, hematuria, or systemic disease.

OTHER LABORATORY TESTS
• *B. canis* serology—rapid slide agglutination test, agar gel immunodiffusion test, bacterial culture of whole blood or lymph node aspirate. • Serum progesterone concentration—determine if patient is in estrus or luteal phase (≥2 ng/mL).

IMAGING

Ultrasonography
• Rule out uterus as source of discharge. • Detection of masses; saline distention of the vagina may help visualization.

Contrast Radiography—Vaginogram/Urethragram/Cystogram/IV Pyelogram
• Identify abnormal conformation or structure within vagina. • Rule out vestibulovaginal strictures, rectovaginal and urethrovaginal fistulas.

DIAGNOSTIC PROCEDURES

Vaginal Culture and Sensitivity
• Use guarded swab to sample cranial vagina. • 74% of adult-onset cases positive for bacterial growth: ○ Most common organisms are E. coli, Streptococcus spp., and Staphylococcus intermedius. ○ Others include Mycoplasma, Pasteurella, Pseudomonas spp., Chlamydia. • Vagina is not a sterile environment; culture of normal bitches results in growth of normal vaginal flora; use of vaginal cytology is essential for interpretation of culture results.

Vaginal Cytology
• Performed in conjunction with vaginal culture. • Juvenile vaginitis: usually polymorphonuclear leukocytes ± bacteria. • Adult-onset vaginitis—usually septic inflammation. • Evaluate epithelial cells for cornification—cornification present under the influence of estrogen. • Determine nature of discharge—inflammatory, blood, presence of fecal material.

Vaginoscopy
• Using rigid cystourethroscope, ureteroscope, pediatric gastroscope, proctoscope, or flexible endoscope. • Identify anatomic anomalies, evaluate vaginal mucosa. • Identify source of vaginal discharge. • Remove foreign body, biopsy masses. • The vaginal wall can be thin in ovariectomized bitches—exercise care when using rigid cysto-urethroscope and ureteroscope.

Other
• Digital vaginal examination—identify strictures in posterior tract. • Histopathology of vaginal masses. • Urine culture and sensitivity.

TREATMENT

APPROPRIATE HEALTH CARE
• Correction/removal of underlying cause. • Generally outpatient. • Surgical management may be necessary for foreign bodies, masses, or correction of structural anomalies. • Elizabethan collars to prevent self-mutilation.

ACTIVITY
Not altered.

DIET
Not altered.

CLIENT EDUCATION

General
• *B. canis*-positive patients should be isolated. Euthanasia recommended due to zoonotic potential and lack of effective treatment. • Exogenous estrogens and androgens must be removed from the environment.

V

VAGINITIS (CONTINUED)

Juvenile Vaginitis

• Generally resolves without treatment. • Should resolve after first estrous cycle, if not before. Patient may need to go through one estrous cycle prior to elective OHE.

Adult-Onset Vaginitis

• Usually occurs secondary to underlying cause, and resolves after correction. • If no primary cause identified, high likelihood of spontaneous recovery without treatment.

SURGICAL CONSIDERATIONS

• Correction of structural anomaly. • Removal of foreign body. • Removal/biopsy of vaginal mass. • Episioplasty. • Vaginectomy may be performed in refractory cases.

MEDICATIONS

DRUG(S) OF CHOICE

Juvenile Vaginitis

• Antibiotic therapy warranted in patients with excessive discomfort (pain or excessive vulvar licking) and/or urinary tract infections. • Antibiotic selection based on culture and sensitivity combined with vaginal cytology. • Probiotics—helpful to restore normal vaginal flora.

Adult-Onset Vaginitis

• Systemic antibiotics (type based on cranial vaginal culture and sensitivity); treat for 4 weeks. • Nonsteroidal anti-inflammatory drugs (NSAIDs) or anti-inflammatory dose of corticosteroids to decrease inflammation. • Diethylstilbestrol (DES)—for idiopathic or recurrent vaginitis in spayed bitches; restores normal mucosal integrity, increases vaginal epithelial cornification; use lowest effective dose: 0.5 mg, PO for dogs weighing <9 kg or 1 mg PO for dogs >9 kg q24h for 7 days, then taper dose over 2–4 weeks and maintain at lowest effective dose. Potential lifelong therapy: ○ Incurin® (estriol) used as above. • Probiotics—to restore normal vaginal flora. Potential lifelong therapy.

CONTRAINDICATIONS

• Antibiotic therapy in patients may result in alteration of normal flora, development of infection secondary to treatment, or foster drug-resistant bacteria. • Vaginal douches with antibiotic/antiseptic agents may be irritating to the vaginal mucosa and worsen the condition. • Corticosteroid administration may worsen concurrent infections.

PRECAUTIONS

Estrogen administration may increase risk of pyometra in intact animals.

POSSIBLE INTERACTIONS

Effects of hydrocortisone may be potentiated with concurrent estrogen therapy.

ALTERNATIVE DRUG(S)

• Juvenile vaginitis may be treated with DES to induce estrus in refractory cases, but long-term effects are not documented. • Moist towelettes/baby wipes may be used to clean the perivulvar area.

FOLLOW-UP

PATIENT MONITORING

Juvenile Vaginitis

• Reevaluate if symptoms become more severe or intolerable. • Reevaluate after first estrous cycle.

Adult-Onset Vaginitis

• Recheck if symptoms do not resolve after removal of underlying cause. • Reculture 5–7 days after cessation of antibiotic therapy or if symptoms continue despite therapy.

PREVENTION/AVOIDANCE

• Delay elective OHE until after first estrous cycle in dogs with juvenile vaginitis. • Avoid using antibiotics if unwarranted. • Maintain good body weight and condition. • Avoid vaginal douching. • Avoid exogenous androgen therapy.

EXPECTED COURSE AND PROGNOSIS

• Juvenile vaginitis—onset at 6 weeks to 6–12 months of age; duration is days to months but typically intermittent; usually resolves with time or after first estrous cycle. • Adult-onset—normally resolves after removal/treatment of inciting cause; antibiotic therapy may hasten resolution in some cases, NSAIDs may help resolve inflammation.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Perivulvar dermatitis. • Atopy.

AGE-RELATED FACTORS

Juvenile vaginitis may be present in prepubertal dogs, usually <1 year of age.

ZOONOTIC POTENTIAL

Brucella canis—uncommon cause but should be ruled out.

PREGNANCY/FERTILITY/BREEDING

• Vaginitis during pregnancy is rare but may result in ascending infection and subsequent abortion. Resolution of vaginitis should result in a good prognosis for fertility if underlying cause does not affect fertility. • Structural anomalies such as persistent hymen may prevent natural mating to occur, or could predispose to a dystocia if artificially inseminated. • Scarring secondary to trauma may result in excessive fibrous tissue and decreased distensibility of the vagina.

SEE ALSO

• Brucellosis.
• Metritis.
• Pyometra.
• Retained Placenta.
• Sexual Development Disorders.
• Subinvolution of Placental Sites.
• Vaginal Malformations and Acquired Lesions.

ABBREVIATIONS

• DES = diethylstilbestrol.
• NSAID = nonsteroidal anti-inflammatory drug.
• OHE = ovariohysterectomy.
• TVT = transmissible venereal tumor.

VASCULAR RING ANOMALIES

BASICS

OVERVIEW

Right Aortic Arch

- Entrapment of the esophagus by a persistent right fourth aortic arch (PRAA) on the right and dorsally, the base of the heart and pulmonary artery ventrally, and ductus or ligamentum arteriosum on the left and dorsally.
- Causes megaesophagus cranial to the obstruction at the base of the heart.

Double Aortic Arch

- Entrapment of the esophagus by a functional aortic arch on the right, an atretic aortic arch on the left, the base of the heart and pulmonary artery ventrally, and ductus or ligamentum arteriosum on the left and dorsally.
- Causes megaesophagus cranial to the obstruction at the base of the heart; also causes some tracheal compression.

SIGNALMENT

- Dog and cat.
- Seen most commonly in German shepherd dogs, Irish setters, Great Danes, and Boston terriers.

SIGNS

- Regurgitation of undigested solid food in animals <6 months old.
- Malnourishment in many animals.
- Time between eating and regurgitation varies.
- Signs of aspiration pneumonia (e.g., cough, tachypnea, or dyspnea) in some animals.

CAUSES & RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Congenital megaesophagus.
- Stricture, diverticulum, or esophageal foreign body.
- Esophageal motility disorder in shar-peis.

CBC/BIOCHEMISTRY/URINALYSIS

- Results usually normal.
- High white blood cells in some animals with aspiration pneumonia.

OTHER LABORATORY TESTS

N/A

IMAGING

- Thoracic radiography—shows food-filled cranial esophagus or signs of aspiration pneumonia in some animals.
- Contrast esophagography—confirms megaesophagus extending to the heart base.
- Fluoroscopy—may be used to differentiate esophageal motility disorders.
- Angiography—may be needed to differentiate between specific vascular ring anomalies.

OTHER DIAGNOSTIC PROCEDURES

Esophagoscopy can be used to differentiate esophageal motility disorders.

TREATMENT

- Surgical correction of the vascular entrapment is indicated—can be performed thoracoscopically or by thoracotomy with similar results.
- Medical management of concurrent aspiration pneumonia may be necessary.
- Feeding procedures for megaesophagus may also be necessary for a prolonged period.
- Supportive care with oxygen may be needed in animals with aspiration pneumonia.

MEDICATIONS

DRUG(S) OF CHOICE

Broad-spectrum antibiotics, such as enrofloxacin 2.5 mg/kg q12h and amoxicillin 10–15 mg/kg q12h should be instituted in animals with aspiration pneumonia.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Prognosis for resolution of the problem, even after surgery, is guarded. However, the majority of dogs that survive longer than 2 months post repair of PRAA have a good to excellent outcome.
- Complications of malnourishment and aspiration pneumonia are common and can be severe.
- Esophageal function may be permanently compromised.

MISCELLANEOUS

ABBREVIATIONS

- PRAA = persistent right fourth aortic arch.

Author Jean M. Betkowski

Consulting Editor Michael Aherne

VASCULITIS, CUTANEOUS

BASICS

OVERVIEW
- Inflammation of blood vessel walls.
- Pathophysiology—primarily type III (immune complex), but type I and type II reactions possible.
- Systems affected—skin/exocrine and renal/urologic in some greyhounds.
- Genetics—familial pyogranuloma and vasculitis of Scottish terriers possibly autosomal dominant; proliferative arteritis in St. Bernards (unknown mode of inheritance).

SIGNALMENT

Species
Dog and cat (rare).

Breed Predilections
Chinese Shar-Pei, dachshund, collie, Shetland sheepdog, German shepherd dog, and Rottweiler predisposed.

SIGNS

Historical Findings
Anorexia, depression, pyrexia possible.

Physical Examination Findings
- Focal alopecia with scarring and scaling (especially vaccine-induced)—lesions over location of vaccination and pinnal apices.
- Necrosis and punctate ulcers, palpable purpura, hemorrhagic bullae or urticaria.
- Acrocyanosis.
- Extremities (paws, pinnae, lips, tail, and oral mucosa) may be painful.
- Pitting edema of the extremities, polyarthropathy, and myopathy possible.

CAUSES & RISK FACTORS
- Idiopathic.
- Drug-induced.
- Vaccine-induced.
- Adverse food reaction.
- Tick-borne diseases (e.g., *Rickettsia rickettsii*).
- Infectious.
- Underlying metabolic process (e.g., diabetes).
- Autoimmune.
- Neoplasia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Deep pyoderma.
- Ear margin seborrhea.
- Chemical and thermal burn.
- Hypersensitivity reaction.
- Dermatomyositis.
- Cryoglobulinemia.
- Toxic epidermal necrolysis.
- Erythema multiforme.
- Eosinophilic dermatitis.
- Systemic lupus erythematosus.
- Bullous pemphigoid.
- Pemphigus vulgaris.
- Sepsis.

CBC/BIOCHEMISTRY/URINALYSIS
Normal unless due to underlying metabolic process or infection.

OTHER LABORATORY TESTS
- Serologic testing for parasitic and infectious disease.
- Immunodiagnostics—antinuclear antibody (ANA) titer, Coombs' test, and cold agglutinin tests.

DIAGNOSTIC PROCEDURES
- Skin scrapings—demodicosis.
- Biopsy of early lesion—neutrophilic (leukocytoclastic/non-leukocytoclastic), lymphocytic, eosinophilic, or granulomatous mixed cells in and around the vessels; vascular necrosis and fibrin thrombi may be prominent; perivascular hemorrhage and edema may occur.
- Representative cultures (e.g., blood, urine, skin) if suspicious of infectious issues.
- Subtle findings suggestive of follicular, dermal, and/or epidermal hypoxia may be seen in mild cases or late-stage tissue samples.

PATHOLOGIC FINDINGS
- May vary with stage and etiology.
- Intramural inflammation of vessels, endothelial cell swelling, pale collagen, faded hair follicles, hemorrhage, and edema of surrounding tissue.

TREATMENT
- Adequate wound care may be necessary for cases with severe and extensive ulceration.
- No limitation in activity unless infectious agent suspected.
- Isolate if contagious or zoonotic agent suspected.
- Individual (focal) lesions may be surgically excised; otherwise, dependent on underlying etiology.

MEDICATIONS

DRUG(S) OF CHOICE
- Based on underlying disease; if drugs or drug-like substances are suspected, they should be discontinued.
- Immune-mediated disease with concurrent vasculitis—prednisolone 0.5–4 mg/kg q24h, taper with response.
- Pentoxifylline 10–20 mg/kg PO q8–12h.
- Cyclosporine 5 mg/kg q24h.
- Tetracycline and niacinamide each 500 mg q8h for dogs >10 kg or 250 mg PO q8h for dogs <10 kg or doxycycline 5 mg/kg PO q12h with niacinamide as with tetracycline.

Alternative Drugs
- Chlorambucil 0.1–0.2 mg/kg every 1–2 days PO initially and taper according to response.
- Azathioprine 1–2 mg/kg every 1–2 days PO initially and taper according to response.
- Dapsone 1 mg/kg PO q24h or sulfasalazine 15–22 mg/kg PO q8–12h.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Precautions
- Do not use any medications suspected of causing hypersensitivity.
- Do not administer tetracycline/doxycycline to pregnant or young animals.

FOLLOW-UP

PATIENT MONITORING
- Monitor appropriately during treatment of specific etiology.
- Pentoxifylline—may decrease blood pressure; may cause excitation; monitor blood pressure if concerned.
- Doxycycline or tetracycline—possible increased liver enzymes, possible esophageal strictures in cats (doxycycline); monitor liver chemistries.
- Patients receiving prednisolone, azathioprine, chlorambucil, sulfasalazine, or dapsone—monitor appropriately with CBC, chemistry screen, and urinalysis.
- Sulfasalazine or dapsone—may decrease tear formation; Schirmer tear test every 2 weeks initially and then routinely.
- Immunosuppressive therapies should be reduced to the lowest possible therapeutic dose.

POSSIBLE COMPLICATIONS
Sepsis and death from primary cause and/or sequelae if severe.

EXPECTED COURSE AND PROGNOSIS
If no underlying disease is found, vasculitis may be difficult to treat and the prognosis is guarded.

MISCELLANEOUS

PREGNANCY/FERTILITY/BREEDING
- Corticosteroids, sulfasalazine, tetracycline/doxycycline, and dapsone—do not use in pregnant animals.
- All drugs should be used with caution in pregnant and breeding animals.

ABBREVIATIONS
- ANA = antinuclear antibody.

Suggested Reading

Author Karen A. Kuhl
Consulting Editor Alexander H. Werner Resnick

VASCULITIS, SYSTEMIC (INCLUDING PHLEBITIS)

BASICS

DEFINITION
• Heterogeneous group of disorders causing inflammation secondary to endothelial damage of blood vessel walls, leading to tissue necrosis.
• Characterized by histological evidence of inflammation, destruction of blood vessels and ischemic changes.
• Phlebitis is associated with, and is a complication of, IV therapy with the tunica intima of the vascular endothelial wall becoming inflamed.

PATHOPHYSIOLOGY
• Endothelial damage by an infectious agent, parasite infestation, endotoxin, or immune complex deposition that initiates local inflammation, neutrophil chemotaxis, and complement activation, sensitizing the vascular endothelium causing release of vasoactive substances that cause vasoconstriction, increase vascular permeability, and activate coagulation systems.
• End result is endothelial cell activation, necrosis of the vessel wall with subsequent thrombosis which may cause hemorrhage and extravasation of proteins into surrounding tissue, leading to swelling and edema.
• Thrombosis obstructs blood flow and may cause palpable thickening or vascular cord, which may progress to irreversible vascular sclerosis.
• Leukocyte pyrogens may cause systemic inflammation and fever.

SYSTEMS AFFECTED
• Skin—local inflammation/infection.
• Cardiovascular—altered vascular permeability and blood flow.
• Hemic/lymphatic/immune—bacteria, inflammatory mediators and emboli can cause systemic inflammatory response and organ dysfunction.
• Renal/urologic—systemic inflammatory response and type III hypersensitivity reaction. causing proteinuria and glomerulonephritis, respectively.
• Ophthalmic—uveitis due to systemic inflammatory response.
• Musculoskeletal—systemic inflammatory response and type III hypersensitivity reaction.
• Respiratory—deep venous thrombophlebitis may cause pulmonary embolism.

INCIDENCE/PREVALENCE
• Unknown—vascular inflammation is a common cause of dermatologic disease in humans and animals. More often seen in dogs than in cats.
• 20–80% of hospitalized patients receiving peripheral IV therapy develop phlebitis with superficial thrombophlebitis most common (10–12% may progress to deep venous thrombosis).

SIGNALMENT

Species
• Dog and cat.
• No known specific age or gender predisposition in veterinary medicine.

Breed Predilections
• Collies and Shetland sheepdogs (familial canine dermatomyositis).
• German shepherd dog—autosomal recessive.
• Scottish terrier—suspect autosomal dominant.
• Shar-pei—familial vasculitis.
• St. Bernard and giant schnauzer—dermal arteritis of nasal philtrum.
• Jack Russell terrier.
• Greyhound—idiopathic cutaneous and renal vasculopathy.

SIGNS

Historical Findings
• Provocative drug (e.g., cephalexin, sulfonamides, itraconazole, and hydralazine) given to sensitized animal.
• Recent vaccination history.
• Exposure to ticks.
• Poor dirofilariasis prophylaxis in endemic areas.

Physical Examination Findings
• Swelling.
• Palpable purpura, plaques, hemorrhagic bullae alone or in combination with edema.
• Ulceration.
• Necrosis of affected skin, especially mucous membranes, mucocutaneous junctions, pinnae edges, and footpads.
• Systemic signs reflecting organ involvement (e.g., hepatic, renal, gastrointestinal and CNS).
• Systemic signs of illness (e.g., lethargy, anorexia, lymphadenopathy, pyrexia, generalized pain, and weight loss).
• Juvenile polyarteritis in beagles characterized by recurring episodes of fever (>40°C) and neck pain persisting for 3–7 days.
• Cutaneous lesions of polyarteritis nodosa (subcutaneous nodules—less common in dogs than in people).
• Signs associated with underlying infectious or immune-related disease (e.g., thrombocytopenia and polyarthropathy).
• Ophthalmologic examination—anterior uveitis, scleral injection, hyphema.

CAUSES

Infectious
• Parasitic—Dirofilaria immitis, Angiostrongylus vasorum, Leishmania spp., Babesia gibsoni.
• Viral—e.g., feline infectious peritonitis, canine coronavirus, and canine circovirus infection.
• Rickettsial—e.g., Rocky Mountain spotted fever and ehrlichiosis.
• Protozoal—e.g., Toxoplasma.
• Bacterial—sepsis.

Iatrogenic
• Mechanical injury from IV catheter size/stiffness/integrity/duration, traumatic placement, previous venipuncture, high fluid infusion rates.
• Chemical injury—IV catheter material, drugs, fluids of extreme osmolality or pH, parenteral nutrition, other vesicant solutions.
• Obstructed blood flow—large-bore catheter, vasoconstriction, and hypotension.

Idiopathic
Approximately 50% of cases.

Immune-Related
• Systemic lupus erythematosus.
• Rheumatoid arthritis-like arthropathy.
• Lupus-like drug reaction.
• Type III hypersensitivities (e.g., to food, cephalexin, sulfonamides, fenbendazole, and penicillin).
• Juvenile polyarteritis in beagles.
• Wegener's granulomatosis (rare).
• Polyarteritis nodosa.
• Neoplasia.
• Uremia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Cutaneous signs developing after administration of medication/vaccine implicate drug reaction (usually not immediate, may develop after days or weeks).
• Vasculitis associated with systemic signs (e.g., polyarthropathy, myositis, pyrexia) implicates immune or infectious cause.
• Cold hemagglutinin disease suggested by distribution of cyanotic or necrotic lesions (nose, ears, toes, tail tip, prepuce) and history of exposure to cold.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC changes consistent with degree of systemic inflammatory response and platelet consumption.
• Biochemistry and urinalysis changes may be applicable with organ involvement (e.g., hepatic, renal, portal, caval, gastrointestinal, cerebral, cardiac, and pulmonary).

OTHER LABORATORY TESTS
• Tissue, blood, and urine cultures if sepsis suspected.
• Serologic tests may aid diagnosis of infectious (i.e., rickettsial, *Leishmania*) disease.
• Antinuclear antibody (ANA) titer positive in patients with systemic lupus erythematosus (SLE); may also be positive in patients with other systemic illnesses.
• Occult heartworm test positive in patient with dirofilariasis.
• *Angiostrongylus* infestation diagnosed by fecal examination and cytologic examination of tracheal wash.

VASCULITIS, SYSTEMIC (INCLUDING PHLEBITIS) (CONTINUED)

• Coagulation—may see alterations in prothrombin time (PT), partial thromboplastin time (PTT), D-dimer, antithrombin, protein C, thromboelastography.

IMAGING

Thoracic Radiographs

Nonspecific abnormalities that may be seen include infiltrates, nodules, patchy consolidation, pleural effusion, and cardiomegaly.

Abdominal Imaging

• CT (with angiogram) or MRI— Provide valuable information regarding diagnosis of deep tissue embolism and thickening of the vessel wall when suspected based on organ damage or dysfunction.
• B-mode ultrasonography to assess venous patency, character, and blood flow.

DIAGNOSTIC PROCEDURES

• Doppler assessment—inexpensive test of venous patency and blood flow.
• Skin biopsy specimen from active edges of developing lesions is definitive for vasculitis but may not reveal cause.
• Immunofluorescence test of skin biopsy specimen may rule out pemphigus and pemphigoid diseases.
• If allergic response is suspected, resolution of signs upon discontinuation of suspect medication or food supports diagnosis.

PATHOLOGIC FINDINGS

• Inflammation and destruction of blood vessels with secondary ischemic/hypoxic changes from thromboembolic occlusion of vessels.
• Inflammatory infiltrate may be neutrophilic (major), eosinophilic, or lymphocytic.
• Damage to blood vessels may lead to the development of hemorrhage and edema within affected tissue.
• Epidermal lesions such as exudation, crusting, and ulceration may also develop secondary to ischemia.

TREATMENT

APPROPRIATE HEALTH CARE

• Based upon individual patient, history, clinical findings, identification of the inciting cause, and whether or not disease is progressive.
• Remove suspected inciting cause (IV catheter, drugs, or xenobiotic substances) and avoid in the future.
• Minimally affected dogs require little management.
• Moderate to severe cases require pharmacologic intervention and wound care to prevent secondary bacterial infection and sepsis.
• If untreatable or unknown underlying condition—glucocorticoid, immunosuppressive (e.g., cyclophosphamide, azathioprine), and other drugs (e.g., dapsone and sulfasalazine) are occasionally effective, but clinical trials of efficacy have not been reported in animals.
• If caustic infiltration suspected for phlebitis, terminate infusion and leave cannula in place temporarily to aspirate residual catheter fluid and instill specific antidotes into affected tissue when applicable.
• Intermittent warm moist compress or hydrotherapy; some extravasated substances require cold therapy.
• Photobiomodulation (low-level light therapy [LLLT]) can be used directly over affected areas to reduce inflammation, activate stem cells, and promote blood flow and tissue repair.
• Avoid stagnant blood flow and thromboembolism by promoting mobility (i.e., physical therapy and/or compression therapy).

NURSING CARE

• Supportive therapy (e.g., IV fluids, oxygen, nutrition) for systemic illness secondary to vasculitis (e.g., hepatic, renal, pulmonary, gastrointestinal, cerebral, cardiac).
• IV catheter placement and maintenance—use strict aseptic technique and sterile dressing with IV catheters being regularly checked for patency, line integrity, and associated swelling (every 1–2 hours) with continuous infusions. Change peripheral catheters every 3–4 days, or within 24 hours if placed under emergency situation.

ACTIVITY

• Soft/cushioned bedding and protective footwear can be used when the pads are eroded/ulcerated.
• Minimal rough play with other dogs as may exacerbate skin damage.

DIET

• Nutritional support appropriate to treatment of underlying illness(es).
• Consider glycemic control if sepsis or risk of sepsis.

CLIENT EDUCATION

• Advise clients of IV catheter risks and complications, especially in patients with predisposing factors.
• Clients should be trained in and continue physical therapy and basic nursing care at home.

SURGICAL CONSIDERATIONS

• Infected catheter sites and/or extensive tissue damage may require surgical debridement and delayed closure.
• Surgical ligation or stripping of the corded vessels may be indicated to avoid deep vein thrombosis.

MEDICATIONS

DRUG(S) OF CHOICE

• Infectious or immune-related—treat underlying disease (see specific condition); supportive care.
• Lupus-like drug reactions and type III hypersensitivity—discontinue drug; supportive care.
• Methylxanthine derivative—pentoxifylline 20 mg/kg three times daily improves microcirculatory peripheral blood flow, tissue blood oxygenation, and decreases inflammation.
• Glucocorticoids—prednisolone 0.5–1 mg/kg with progressive disease and no underlying trigger identification; continue until clinical remission achieved then slowly taper by 25% every 14 days.
• Other immunomodulators—cases refractory to glucocorticoids (e.g., cyclosporine, azathioprine, chlorambucil).
• Antioxidants—e.g., vitamin E 200–800 IU q12h anecdotally provide a protective effect against ischemic dermatopathies.
• Leukocyte-specific anti-inflammatory—tetracycline and niacinamide combination used for milder cases of vasculitis; exact mechanism incompletely understood.
• Sulfonamide drugs—e.g., sulfasalazine 25 mg/kg three times daily for refractory neutrophilic vasculitis.
• Antibiotics (if infection/sepsis suspected)—use empirical therapy, based on location and potential contaminants if no culture and sensitivity available.

CONTRAINDICATIONS

• Avoid caustic, irritating, or immunogenic topicals or infusions.
• Do not administer sulfasalazine to patients sensitive to sulfonamides.
• Multiple myelosuppressive/immunosuppressive drugs may be additive and increase risk of infection.

PRECAUTIONS

• Avoid use of systemic nonsteroidal anti-inflammatory drugs (NSAIDs) if renal, hepatic, or gastrointestinal dysfunction.
• Corticosteroids, unless used as an appropriate pretreatment for chemotherapy, are associated with delayed wound healing and may predispose to infection.
• Pentoxifylline may reduce blood pressure.

POSSIBLE INTERACTIONS

Use of NSAIDs with concurrent anti-inflammatory or immunosuppressive dose corticosteroid therapy.

ALTERNATIVE DRUG(S)

• Topical dermatitis creams (e.g. silver-sulfadiazine) may help reduce irritation and prevent infection.

(CONTINUED)

VASCULITIS, SYSTEMIC (INCLUDING PHLEBITIS)

• Topical tacrolimus for focal lesions may help reduce inflammation.

FOLLOW-UP

PATIENT MONITORING

• Patients being treated with sulfonamide drugs (e.g., dapsone) or immunosuppressants–regular monitoring of CBC, serum chemistry profile and urinalysis for side effects (e.g., myelosuppression, hepatopathy, and other blood dyscrasias).
• Patients receiving sulfasalazine—monitor for keratoconjunctivitis sicca with Schirmer tear test (every 2 weeks for first 2 months).
• Hardness, skin pallor, black discoloration, or eschar formation occur with tissue necrosis.
• Persistent or progressive redness, swelling, pain, or heat—adjust antibiotic therapy based on most current culture and sensitivity results.

PREVENTION/AVOIDANCE

• Tick prevention and regular monitoring of serum titers for tick-borne diseases in endemic areas.
• Avoidance/elimination of optional/minimizing of the number of vaccines given at any one time.
• Discontinue and avoid suspected inciting triggering factors.
• Avoid use of phlebotic veins for IV therapy or blood collection until completely healed.
• Consider using submicron IV catheter filters, which may reduce incidence by removing particulates, endotoxin, and other soluble mediators of morbidity.

POSSIBLE COMPLICATIONS

• Dependent on severity.
• Tissue necrosis.
• Organ damage (e.g., hepatic, renal, portal, caval, gastrointestinal, cerebral, cardiac, pulmonary).
• Thromboembolism.
• Lymphangitis.
• Septicemia.
• Extension to deep venous system.

EXPECTED COURSE AND PROGNOSIS

• Mild phlebitis cases self-limiting (1–3 days) with removal of catheter. For severe local lesions, resolution can take 3–4 weeks and may result in loss of function/permanent tissue damage. Poor prognosis when associated with pulmonary thromboembolism and/or sepsis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Pulmonary thromboembolism.
• Infection/cellulitis/sepsis.
• Immune-mediated disease (e.g., SLE).

AGE-RELATED FACTORS

• Neonatal and geriatric patients may be predisposed to infection.
• Delayed wound healing in geriatric patients.

ZOONOTIC POTENTIAL

N/A

PREGNANCY/FERTILITY/BREEDING

• Pregnancy may predispose to thromboembolism.
• Incidence of fetal complications with phlebitis is unknown.

SYNONYMS

• Thrombophlebitis.
• Necrotizing vasculitis.
• Vasculitis.

SEE ALSO

• Lupus Erythematosus, Systemic.
• Pulmonary Thromboembolism.
• Sepsis and Bacteremia.

ABBREVIATIONS

• ANA = antinuclear antibody.
• LLLT = low-level light therapy.
• NSAID = nonsteroidal anti-inflammatory drug.
• PT = prothrombin time.
• PTT = partial thromboplastin time.
• SLE = systemic lupus erythematosus.

V

VENTRICULAR ARRHYTHMIAS AND SUDDEN DEATH IN GERMAN SHEPHERDS

BASICS

OVERVIEW
Inherited disorder resulting in ventricular arrhythmias in otherwise healthy young German shepherd dogs. The phenotypic spectrum is wide, with some dogs having infrequent single premature ventricular complexes while others have frequent and rapid ventricular tachycardia (VT) that is associated with sudden death. The pattern of inheritance is complex, depending heavily on background genetics. Siblings of dogs that have died suddenly should be tested for this disorder.

SIGNALMENT
• Most dogs develop arrhythmias at approximately 12 weeks of age (identified as young as 6 weeks). Number and severity of arrhythmias tend to peak between 5–9 months. By approximately 18–24 months most dogs have only a few arrhythmias.
• No sex predilection.

SIGNS
• Signs are very rare (e.g., in >500 dogs examined only 1 had syncope) since VT is often nonsustained until, in some dogs, it degenerates into ventricular fibrillation resulting in death (usually between 5 and 9 months of age).
• Arrhythmias often detected during routine examination before neutering. • Death is associated with sleep, rest after exercise, or excitement after sleep, particularly in early morning.

CAUSES & RISK FACTORS
• Genetic mutation(s) responsible has not been identified. • Multiple electrophysiologic abnormalities have been identified—early and delayed afterdepolarizations, heterogeneous and altered action potential duration, as well as changes in ion channel current density, calcium cycling, and sympathetic innervation.
• VT tends to be most frequent with slow heart rates (drug-induced [e.g. fentanyl] or during sleep).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Rule out myocarditis.

CBC/BIOCHEMISTRY/URINALYSIS
Results of routine laboratory tests are unremarkable.

OTHER LABORATORY TESTS
Troponin concentration—to rule out myocarditis. Dogs with inherited arrhythmias have normal troponin levels.

IMAGING
• Thoracic radiographs—normal.
• Echocardiography—usually normal.

DIAGNOSTIC PROCEDURES
24-Hour Ambulatory Electrocardiogram (Holter Monitor)
• Required for diagnosis and classification of severity. • Arrhythmias identified most commonly are rapid (rates >400 bpm) polymorphic VT with single premature complexes that are most commonly of a left ventricular origin pattern (negative in lead II). Though nonsustained rapid polymorphic VT is most characteristic, approximately 15% of dogs will have slower monomorphic and more sustained VT. • Some dogs will have thousands of singlet ventricular premature complexes (VPCs) with no VT; extensive periods of ventricular bigeminy have been found in others. • After 6 months of age, runs of VT are more common after pauses.

PATHOLOGIC FINDINGS
Routine gross and histopathologic examination is within normal limits.

TREATMENT
• Limited studies have shown cardiac pacing to keep the heart rate above 120 bpm decreased the frequency of the arrhythmias but did not prevent sudden death.
• Implantation of cardioverter defibrillators may be helpful, but proper programming of these devices in young dogs is complicated.
• Avoid drugs that slow heart rate.
• Anesthesia is not contraindicated as long as anticholinergic drugs are used to prevent bradycardia during the age range when the arrhythmias exist. • Treatment is required only for dogs with VT. Afflicted dogs with only VPCs do not die. However, if a young dog is identified with this disorder, repeated Holter monitoring is advised to be sure that the phenotype of that particular dog does not include VT (e.g., particularly if the peak affectedness of that dog has not yet occurred).

MEDICATIONS

DRUG(S) OF CHOICE
• Ventricular arrhythmias usually are easily suppressed with lidocaine 2 mg/kg IV.
• Control of the arrhythmias with oral medication is more problematic. • Sotalol alone can be proarrhythmic and should not be used. • Sotalol 2–3 mg/kg PO q12h combined with mexiletine 4–8 mg/kg PO q8h suppresses the ventricular arrhythmias, but response in individual dogs is highly variable.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS
• Avoid drugs that slow heart rate until dogs are older than 18–24 months.
• Drugs that slow or prolong action potential duration such as sotalol, phenylephrine, or fentanyl are proarrhythmic.

FOLLOW-UP

PATIENT MONITORING
• Repeat Holter monitoring to assess drug efficacy. • After 18–24 months of age the Holter monitoring is again repeated. If the number of ventricular ectopic complexes is <2,000 singles with no VT, the dog's risk of death is very low and medications may be stopped. • Although occasional dogs may have a dramatic drop in the arrhythmia count and severity during treatment, most do not. Therefore, absence of arrhythmias on Holter recordings after 18–24 months of age indicates a change in the disorder rather than an antiarrhythmic effect.
• Lifelong treatment is not required.

EXPECTED COURSE AND PROGNOSIS
• Approximately 50% of affected dogs with >10 runs of VT/24 hours will die suddenly before 1 year of age. If a dog does not have VT identified by 24-hour electrocardiographic monitoring, the probability of death is very low. • Even severely affected dogs that have reached the age of 2 years with documented absence of arrhythmia have lived a normal lifespan >12 years.

MISCELLANEOUS

AGE-RELATED FACTORS
Since identification of affected dogs depends on the determination of arrhythmias before the age of 1 (ideally 4–9 months) to 2 years (at most), afflicted dogs can easily be missed because the only clinical sign is sudden death with no evidence of a cause found on routine post-mortem examination.

ABBREVIATIONS
• VPC = ventricular premature complex.
• VT = ventricular tachycardia.

VENTRICULAR FIBRILLATION

BASICS

DEFINITION
• A ventricular rhythm of disorganized electrical activity resulting in nonproductive ventricular muscle quivering (i.e., fibrillation). • Also known as V-fib or VF and is considered the most severe cardiac rhythm disturbance.

PATHOPHYSIOLOGY
Loss of organized ventricular activity results in acute and profound drop in cardiac output, systemic blood pressure, and organ perfusion, eventually leading to death.

SYSTEMS AFFECTED
• Cardiovascular. • All organ systems affected by loss of perfusion.

GENETICS
• Not recognized in veterinary patients. • However, there are known ventricular arrhythmias with modes of inheritance in the dog.

INCIDENCE/PREVALENCE
Unknown

SIGNALMENT
Species
Dog and cat.

Breed Predilections
None

Mean Age and Range
Unknown, but probably more common in geriatric animals.

SIGNS
Historical Findings
• Severe systemic illness. • Severe cardiac disease. • Previously documented cardiac arrhythmias.

Physical Examination Findings
• Collapse. • Loss of consciousness (i.e., syncope). • Cardiac arrest. • Death.

CAUSES
Cardiac
• Cardiac surgery/interventional procedure. • Cardiomyopathy. • Myocardial injury. • Myocarditis. • Subaortic/aortic stenosis.

Extracardiac
• Anoxia. • Autonomic imbalances, especially high sympathetic tone or administration of catecholamines. • Circulatory shock. • Drug reactions—e.g., anesthetic agents, especially halothane and ultrashort-acting barbiturates, digoxin. • Electrical shock. • Electrolyte and acid–base imbalances. • Hypothermia.

RISK FACTORS
Any severe systemic illness or cardiac disease.

DIAGNOSIS

ECG Features (Figures 1 and 2)
• Rapid, chaotic, irregular rhythm with bizarre waves or oscillations. • Oscillations may be large (coarse fibrillation) or small (fine fibrillation). • Absent P waves. • Absent QRS complexes.

DIFFERENTIAL DIAGNOSES
• Check for pulse. • Rule out ECG artifact. • Reapply ECG clips and ensure good skin contact and adequate gel (or alcohol) applied to leads. • If there is possibility of using defibrillator to shock patient, do *not* use alcohol as it is a flammable substance.

CBC/BIOCHEMISTRY/URINALYSIS
The abnormalities generally relate to the underlying metabolic problem that causes ventricular fibrillation.

OTHER LABORATORY TESTS
Cardiac troponin I may be elevated in case of severe arrhythmia, cardiac ischemia, or myocarditis.

IMAGING
• Can utilize point of care ultrasound to visualize heart chamber activity. • Avoid alcohol and utilize gel whenever possible (see above).

PATHOLOGIC FINDINGS
Vary depending on histopathologic findings on post-mortem examination.

TREATMENT

APPROPRIATE HEALTH CARE
• Rapidly fatal rhythm requiring immediate, aggressive treatment. • Outcome is often death without use of electrical cardioversion (defibrillation).

Direct Current Defibrillation
• Immediate defibrillation is recommended when the duration of cardiopulmonary arrest caused by ventricular fibrillation is 4 minutes or less. • Otherwise, a 2-minute cycle of chest compressions before defibrillation is recommended. • The dose of energy for initial defibrillation is 2–4 J/kg (biphasic defibrillator) or 4–6 J/kg (monophasic defibrillator). • If an initial shock is not successful, CPR is resumed for 2 minutes before defibrillation is attempted again. • A 50% escalation in the energy delivered may be considered for subsequent defibrillation attempts.

Precordial Thump
To be used if no access to an electrical defibrillator. • Apply a sharp blow with the ulnar aspect of a closed fist to the chest wall over the heart. • Rarely successful in conversion to sinus rhythm. • This technique is *not* recommended for other rhythms as a thump can also cause more malignant arrhythmias.

NURSING CARE
Treat any identified conditions such as hypothermia, electrolyte disturbances, and acid–base disorders.

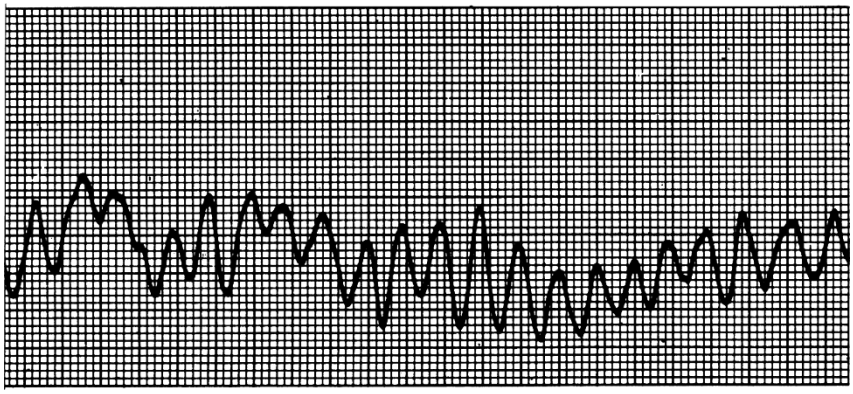

Figure 1.

Coarse ventricular fibrillation. (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

VENTRICULAR FIBRILLATION (CONTINUED)

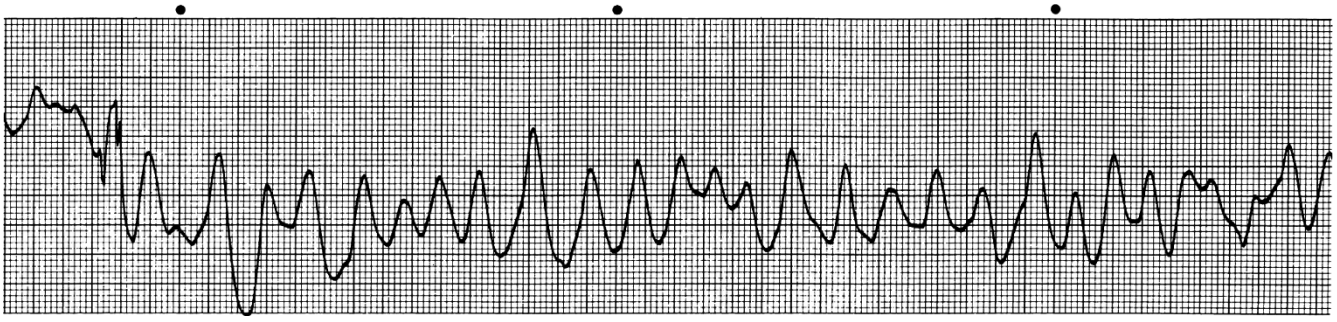

Figure 2.

Ventricular flutter–fibrillation in a cat with severe myocardial damage from an 11-story fall. The complexes are very wide, bizarre, tall, and rapid. (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

CLIENT EDUCATION

If the patient is converted back to a sinus rhythm, warn the owner that the patient is at high risk for recurrence of the arrhythmia in the immediate post-resuscitation period.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUG(S) OF CHOICE

• Institute cardiopulmonary cerebral resuscitation. • Epinephrine—low dose (0.01 mg/kg) of epinephrine is recommended as high-dose therapy has not been associated with increased survival. A shortcut to calculate low-dose epinephrine volume for administration is 0.1 mL/10 kg. The dose may be repeated at 3- to 5-minute intervals. • Vasopressin—there is evidence that this drug may be equivalent to or even superior to epinephrine is some situations. The dose of vasopressin is 0.8 units/kg (dogs and cats), and the dose may be repeated at 3- to 5-minute intervals. • Once the animal is successfully converted, administer IV lidocaine or amiodarone to lower the risk of refibrillation or development of ventricular tachycardia. • Lidocaine 2 mg/kg (dogs, IV, IO, IT); a shortcut to calculate the dose for the 2% (20 mg/mL) solution is 1 mL/10 kg. • Amiodarone (Nexterone®) 2–5 mg/kg (dogs, IV). Do NOT use amiodarone with polysorbate 80; this has been shown to cause anaphylaxis in dogs. Hypotension is a common occurrence during amiodarone administration.

PRECAUTIONS

• Lidocaine raises the fibrillation threshold but makes defibrillation more difficult. • Lidocaine and amiodarone have the potential to be proarrhythmic. • There is currently no evidence for improved outcome with use of these medications in patients with VF.

ALTERNATIVE DRUG(S)

• Magnesium (chloride or sulfate) is commonly administered (0.3 mEq/kg IV) for antiarrhythmic treatment. Magnesium is not known to have any proarrhythmic effect. There is no supportive evidence for its use in VF. • Chemical conversion can be attempted if no access to electrical defibrillator. Administer 1 mEq potassium/kg and 6 mg/kg acetylcholine IC. This approach is rarely successful.

FOLLOW-UP

PATIENT MONITORING

• CBC, biochemistry profile, urinalysis, arterial blood gases with acid–base analysis. • If primary cardiac disease is suspected—echocardiogram, cardiac troponin, and thoracic radiographs. • Continuous ECG monitoring.

PREVENTION/AVOIDANCE

Careful monitoring of critically ill patients to prevent and correct acid–base disturbances, hypotension, and hypoxemia.

POSSIBLE COMPLICATIONS

• Recurrence of VF. • Death. • Disseminated intravascular coagulation. • Multiorgan failure.

EXPECTED COURSE AND PROGNOSIS

Most patients die because of either the arrhythmia or the underlying disease.

MISCELLANEOUS

AGE-RELATED FACTORS

May be more likely in patients of advanced age.

PREGNANCY/FERTILITY/BREEDING

V

VENTRICULAR PRE-EXCITATION AND WOLFF–PARKINSON–WHITE SYNDROME

BASICS

DEFINITION

• Ventricular pre-excitation occurs when impulses originating in the sinoatrial node or atrium activate a portion of the ventricles prematurely through an accessory pathway without going through the atrioventricular (AV) node; the remainder of the ventricles are activated normally through the usual conduction system. • Wolff–Parkinson–White (WPW) syndrome consists of ventricular pre-excitation with episodes of paroxysmal supraventricular tachycardia (Figures 1 and 2).

ECG Features of Ventricular Pre-excitation

• Normal heart rate and rhythm. • Normal P waves. • Short PR interval (dogs, <0.06 seconds; cats, <0.05 seconds). • Widened QRS (small dogs, >0.05 seconds; large dogs, >0.06 seconds; cats, >0.04 seconds), often with slurring or notching of the upstroke of the R wave (delta wave).

ECG Features of Ventricular Pre-excitation with WPW Syndrome

• Extremely rapid heart rate (dogs, often >300 bpm; cats, approaching 400–500 bpm). • P waves may be difficult to recognize. • QRS complexes may be normal, wide with delta wave, or very wide and bizarre, depending on the circuit. • Conduction is usually 1:1 (i.e., 1 P wave for every QRS complex).

PATHOPHYSIOLOGY

• Can be associated with congenital or acquired cardiac defects in dogs or cats. • May be associated with hypertrophic cardiomyopathy in cats. • Hemodynamic compromise during episodes of supraventricular tachycardia with WPW syndrome. • WPW syndrome results from a developmental abnormality of the atrioventricular groove. During normal cardiogenesis, direct continuity between the atrial and ventricular myocardium is lost by growth of the annulus fibrosis. Defects in the annulus leave muscular connections called accessory pathways or Kent bundles between the atria and ventricular myocardium. By bypassing the AV node, these pathways can lead to pre-excitation of the ventricles. • The accessory pathways typically have an "all or none" conduction properties. They may only conduct from the atria to the ventricles (called anterograde or antegrade conduction), only from the ventricles to the atria (called retrograde conduction), or in both directions.

SYSTEMS AFFECTED

Cardiovascular

INCIDENCE/PREVALENCE

Unknown

SIGNALMENT

Species

Dog and cat.

SIGNS

Historical Findings

• None in patients with ventricular pre-excitation. • Syncope in patients with WPW syndrome.

Physical Examination Findings

• None in animals with ventricular pre-excitation. • Rapid heart rate in animals with WPW syndrome.

CAUSES

Congenital Heart Disease

• Congenital defect limited to the conduction system. • Atrial septal defect in dogs or cats. • Tricuspid valvular dysplasia in dogs.

Acquired Heart Disease

Hypertrophic cardiomyopathy in cats.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Ventricular pre-excitation—differentiate from other causes of short PR intervals (e.g., fever, hyperthyroidism, and anemia); these conditions do not cause delta waves. • Narrow complex WPW syndrome—differentiate from other supraventricular arrhythmias (e.g., atrial tachycardia, atrial flutter, and atrial fibrillation); WPW syndrome is most easily recognized after conversion to normal heart rate and rhythm. • Alternating WPW syndrome should not be confused with ventricular bigeminy. • Wide complex WPW syndrome must be differentiated from ventricular tachycardia. • Short PR interval may be correlated with a normal QRS complex if the anomalous pathway bypasses the AV node and connects to the bundle of His (i.e., Lown-Ganong Levine syndrome).

CBC/BIOCHEMISTRY/URINALYSIS

Normal

OTHER LABORATORY TESTS

Normal

IMAGING

Echocardiography may show structural heart disease.

DIAGNOSTIC PROCEDURES

Electrocardiography

PATHOLOGIC FINDINGS

• Pathologic findings vary with underlying cause. • Possibility of no organic heart lesions.

V

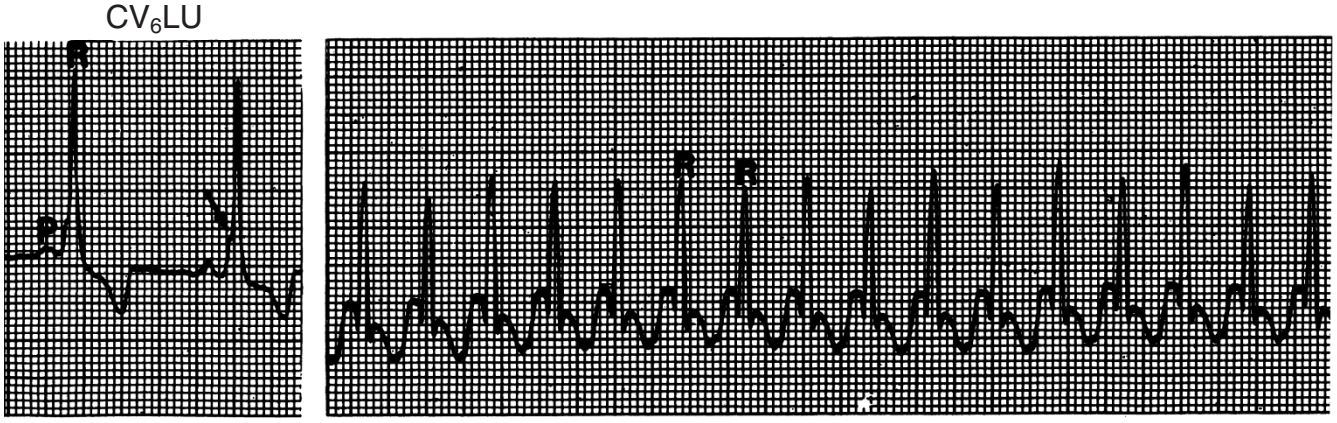

Figure 1.

Wolff–Parkinson–White syndrome (canine). Ventricular pre-excitation represented by the short PR interval, wide QRS complex, and delta wave (arrow) in CV_6LU. Paroxysms of supraventricular tachycardia are represented in the long lead II rhythm strip. (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

VENTRICULAR PRE-EXCITATION AND WOLFF–PARKINSON–WHITE SYNDROME (CONTINUED)

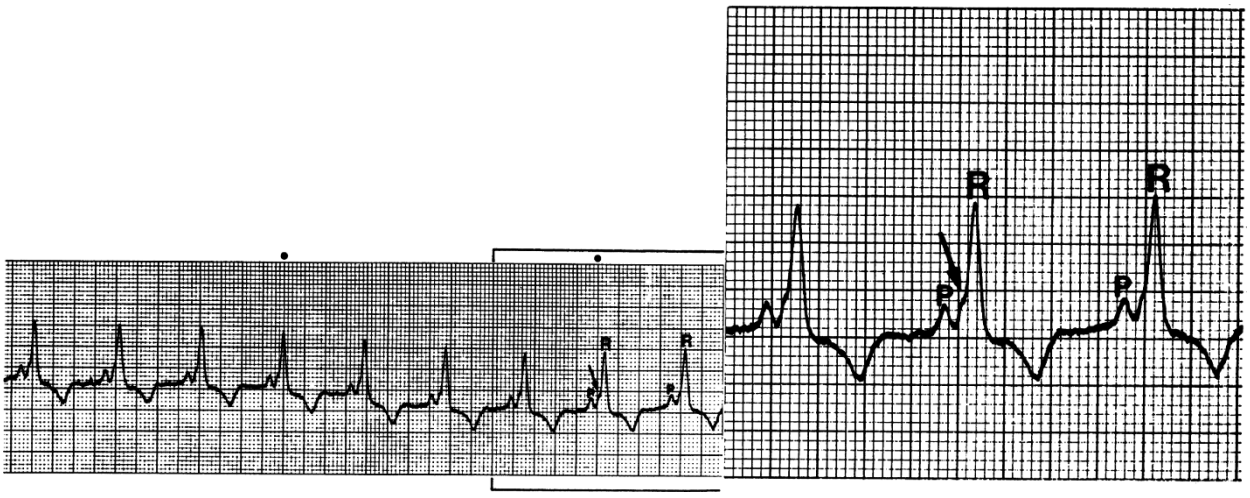

Figure 2.

Ventricular pre-excitation in a cat with episodes of fainting. The P waves are normal, the PR interval is short, and the QRS complex is wide; delta waves (arrow) are present. (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

TREATMENT

APPROPRIATE HEALTH CARE

• Ventricular pre-excitation without tachycardia—no treatment needed. • WPW syndrome requires conversion by ocular or carotid sinus pressure, direct current shock (the most effective treatment), or drugs.

ACTIVITY

May need to be limited with WPW until supraventricular tachycardias are controlled.

CLIENT EDUCATION

WPW—explain the need to identify and treat the underlying cause in addition to therapy for supraventricular tachycardia.

SURGICAL CONSIDERATIONS

Catheter ablation with radiofrequency current—a relatively recent technique that allows accessory pathways to be destroyed or ablated by a transvenous catheter positioned at the site of the pathway; can be preferred alternative to lifelong therapy with drugs.

MEDICATIONS

DRUG(S) OF CHOICE

• A variety of drugs are used in humans; opinions differ on agents of choice.
• Lidocaine 2 mg/kg IV bolus followed by 25–75 mg/kg/min CRI IV drip (dogs only). • Esmolol 50–100 mg/kg bolus, 50–200 mg/kg/min CRI (dogs and cats). • Propranolol 2.5–5 mg PO q8–12h (cats); 0.2–1 mg/kg PO q8h (dogs) or atenolol 6.2–12.5 mg PO q24h (cats); 0.25–1 mg/kg PO q12h (dogs). • Diltiazem may be effective—1–2.5 mg/kg PO q8h (cats); 0.5–1.5 mg/kg PO q8h (dogs). • Procainamide IV may be used acutely because it decreases conduction over the accessory pathway and is safe if anterograde accessory pathway conduction is present in atrial fibrillation.

CONTRAINDICATIONS

• Digitalis, verapamil, and propranolol may be contraindicated—by slowing conduction through the AV node, these drugs may favor conduction through the anomalous pathways. • Cats—propranolol and atenolol are the drugs of choice.

FOLLOW-UP

PATIENT MONITORING

Serial ECG.

POSSIBLE COMPLICATIONS

None expected.

EXPECTED COURSE AND PROGNOSIS

Depends on severity of the underlying cause; most WPW patients respond to therapy for supraventricular tachycardia—favorable prognosis.

MISCELLANEOUS

ABBREVIATIONS

• AV = atrioventricular.
• WPW = Wolff–Parkinson–White.

VENTRICULAR PREMATURE COMPLEXES

BASICS

DEFINITION
Single cardiac impulse initiated within the ventricles instead of the sinus node.

ECG Features
• QRS complexes typically wide and bizarre (see Figures 1 and 2). • P waves dissociated from the QRS complexes.

PATHOPHYSIOLOGY
Mechanisms include increased automaticity, reentry, and delayed afterdepolarizations.

SYSTEMS AFFECTED
Cardiovascular—secondary effects on other systems because of poor perfusion.

GENETICS
• Polygenic in German shepherd dogs—inherited ventricular arrhythmia. • Likely autosomal recessive, possibly autosomal dominant with incomplete penetrance in Rhodesian ridgebacks—inherited ventricular arrhythmia.

INCIDENCE/PREVALENCE
Unknown

SIGNALMENT

Species
Dog and cat.

Breed Predilections
• Common in large-breed dogs with cardiomyopathy, especially boxers (arrhythmogenic right ventricular cardiomyopathy) and Doberman pinschers. • Inherited ventricular arrhythmia in German shepherd dogs and Rhodesian ridgebacks. • Common in cats with cardiomyopathy; occasionally seen in cats with hyperthyroidism.

Mean Age and Range
Seen in all age groups.

SIGNS

Historical Findings
• Weakness. • Exercise intolerance. • Syncope. • Sudden death. • Often asymptomatic.

Physical Examination Findings
• Irregular rhythm associated with pulse deficits; may auscult splitting of the first or second heart sound. • May be normal if arrhythmia is intermittent and absent during examination. • May observe signs of congestive heart failure (CHF) (e.g., dyspnea, cough) or murmur, depending on the cause of arrhythmia.

CAUSES
• Cardiomyopathy. • Congenital defects (especially subaortic stenosis). • Degenerative valve disease. • Gastric dilation and volvulus. • Traumatic myocarditis (dogs). • Digitalis toxicity. • Hyperthyroidism (cats). • Cardiac neoplasia. • Myocarditis. • Pancreatitis.

RISK FACTORS
• Hypokalemia. • Hypomagnesemia. • Acid–base disturbances. • Hypoxia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Supraventricular premature beats with bundle branch block. • Look for P waves associated with the wide QRS complexes; an atrial premature complex with aberrant conduction has an associated P wave. • An atrial premature complex is usually followed by a noncompensatory pause in which the R-R interval of the two sinus complexes enclosing an atrial premature complex (APC) is less than the R-R interval of three consecutive sinus complexes. • A ventricular premature complex is usually followed by a compensatory pause in which the R-R interval of two sinus complexes enclosing a ventricular premature complex (VPC) is greater than or equal to the R-R interval of three consecutive sinus complexes.

CBC/BIOCHEMISTRY/URINALYSIS
• Hypokalemia and hypomagnesemia predispose animals to ventricular arrhythmias and blunt the response to class I antiarrhythmic drugs (e.g., lidocaine, procainamide, mexiletine, and quinidine). • High amylase and lipase if condition is secondary to pancreatitis.

OTHER LABORATORY TESTS
• High T_4 (cats) if condition is secondary to hyperthyroidism. • Increased cardiac troponin I, a biomarker for possible acute myocardial injury may suggest an underlying cardiac condition.

IMAGING
Echocardiography may reveal structural heart disease.

DIAGNOSTIC PROCEDURES
Long-term ambulatory (Holter) recording of the ECG to detect transient ventricular arrhythmias in patients with unexplained syncope or weakness.

PATHOLOGIC FINDINGS
Vary with underlying cause.

TREATMENT

APPROPRIATE HEALTH CARE
Generally outpatient basis.

ACTIVITY
Restrict if the arrhythmia is accompanied by clinical signs or evidence of structural heart disease.

CLIENT EDUCATION
Alert owner to potential for the arrhythmia worsening and syncope or sudden death.

SURGICAL CONSIDERATIONS
• Continuous ECG monitoring recommended while anesthetized. • Premedicating the patient with acepromazine 0.02–0.05 mg/kg raises the threshold for ventricular fibrillation. • Mask inductions not recommended; sympathetic release during mask induction can aggravate arrhythmia. • Avoid anticholinergics unless bradycardia develops.

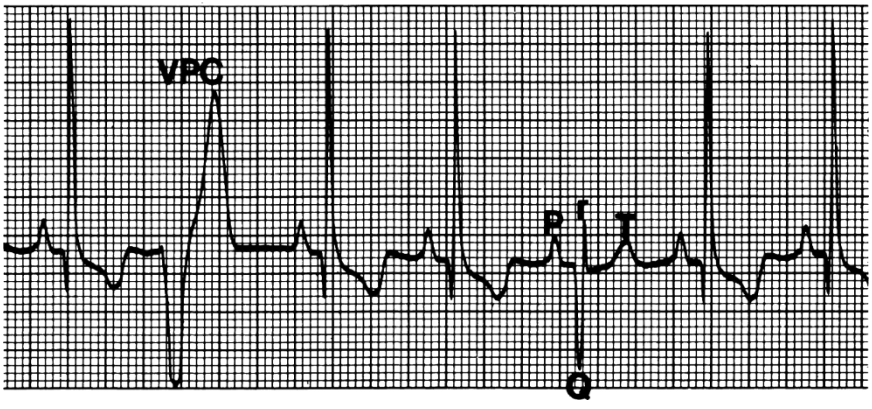

Figure 1.

VPC and a fusion complex (fifth complex) in a dog with myocarditis from pancreatitis. A fusion complex is the simultaneous activation of the ventricle by impulses

VENTRICULAR PREMATURE COMPLEXES (CONTINUED)

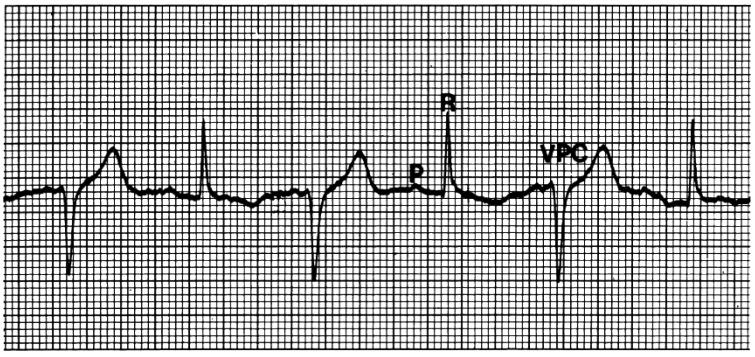

Figure 2.

Ventricular bigeminy. Every other complex is a VPC from the same focus. Each is coupled (interval the same between it and the adjacent sinus complex) to the preceding normal complex. (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

MEDICATIONS

DRUG(S) OF CHOICE

General Comments

• Correct any hypokalemia or hypomagnesemia. • Drug therapy in the absence of clinical signs—controversial; studies in humans with asymptomatic VPCs and myocardial infarction demonstrated a high incidence of sudden death when treatment was initiated with class I antiarrhythmic agents; no similar studies have been conducted in veterinary patients. • The author generally does not prescribe antiarrhythmic drugs unless there is evidence of clinical signs of low cardiac output (e.g., episodic weakness or syncope) or the belief that the patient is at high risk of sudden death, based on presence of R on T phenomenon or breed association with VPCs and sudden death (e.g., boxers and Doberman pinschers). • If antiarrhythmic therapy is initiated in an attempt to lower the risk of sudden death, the author usually chooses a beta-blocker or sotalol (except in German shepherd dogs [see below]); no studies have been done to confirm efficacy of beta-blockers for prevention of sudden death in dogs or cats.

Dogs

• Patient not in CHF or hypotensive—initiate therapy with a beta-blocker such as propranolol 0.2–1 mg/kg PO q8h, atenolol 0.2–1 mg/kg q12h, or metoprolol 0.2–1 mg/kg PO q8–12h or class III agent sotalol 1–3.5 mg/kg PO q12h.
• Patient in CHF or hypotensive—initiate therapy with a class I antiarrhythmic agent such as mexiletine 5–8 mg/kg PO q8h or procainamide 8–20 mg/kg PO q6–8h. • Combine a class I antiarrhythmic drug with a beta-blocker or sotalol if arrhythmia persists; especially in boxers.
• Sotalol monotherapy may have proarrhythmic effect in German shepherd dogs.

Cats

Atenolol 6.25–12.5 mg PO q12h.

CONTRAINDICATIONS

PRECAUTIONS

• Use beta-blockers cautiously in animals with CHF; they initially depress myocardial contractility.
• Use digoxin cautiously; it can potentially aggravate ventricular arrhythmias. • Drugs that prolong the action potential (e.g., sotalol) may worsen arrhythmia in German shepherd dogs with inherited ventricular arrhythmia.

POSSIBLE INTERACTIONS

Quinidine and amiodarone raise serum digoxin levels.

ALTERNATIVE DRUG(S)

• Consider amiodarone 5–10 mg/kg PO q12h for refractory arrhythmias in dogs (generally reserved for ventricular tachycardia); may not want to use in Doberman pinschers.
• Consider sotalol 10–20 mg/cat PO q12h or procainamide 3–8 mg/kg PO q6–8h for cats that do not tolerate beta-blockers.

FOLLOW-UP

PATIENT MONITORING

• Holter monitoring preferred for monitoring severity of the arrhythmia and efficacy of antiarrhythmic therapy; the goal of antiarrhythmic therapy is to reduce the frequency of ventricular ectopy by >85%. • Serial ECGs are not as useful as Holter monitoring—VPCs and paroxysmal ventricular tachycardia can occur sporadically through the day. • Serum digoxin levels in patients receiving that medication.

PREVENTION/AVOIDANCE

• Correct predisposing factors such as hypokalemia, hypomagnesemia, myocardial hypoxia, and digoxin toxicity. • Do not breed affected German shepherd dogs or Rhodesian ridgebacks with inherited ventricular arrhythmias.

POSSIBLE COMPLICATIONS

Syncope, sudden death.

EXPECTED COURSE AND PROGNOSIS

• If cause is metabolic—condition may resolve with good prognosis. • If condition is associated with cardiac disease—prognosis is

MISCELLANEOUS

SEE ALSO

• Chagas Disease (American Trypanosomiasis). • Digoxin Toxicity. • Myocarditis.
• Ventricular Tachycardia.

ABBREVIATIONS

• APC = atrial premature complex. • CHF = congestive heart failure. • T_4 = thyroxine.
• VPC = ventricular premature complex.

VENTRICULAR SEPTAL DEFECT

BASICS

DEFINITION
An anomalous communication between the two ventricles. Numerous classification schemes have been proposed; briefly, the defect may be in the outlet, muscular, or membranous septum. Most ventricular septal defects (VSDs) in small animals are perimembranous, such that the defect is subaortic and has a right ventricular orifice that is beneath the septal leaflet of the tricuspid valve.

PATHOPHYSIOLOGY
- A VSD results in an interventricular communication—direction and volume of the shunt are determined by the size of the defect, the relationship of the pulmonary and systemic vascular resistances, and the presence of other anomalies.
- Most VSDs in dogs and cats are small and therefore restrictive (i.e., sufficiently small that the difference between left and right ventricular pressures is maintained). Moderate-sized VSDs are only partially restrictive and result in various degrees of right ventricular hypertension. Large VSDs have an area that is as large as or larger than the open aortic valve; they are nonrestrictive, so that left and right ventricular pressures are necessarily equal. Only moderate and large defects impose a pressure load upon the right ventricle (Figure 1).
- In a patient with normal resistance to right ventricular ejection, the direction of the shunt is left-to-right, which increases pulmonary venous return and imposes a volume load on the left atrium and ventricle. With large shunts, congestive failure can develop.
- Unless the defect is of moderate or large size, the right ventricle is spared.

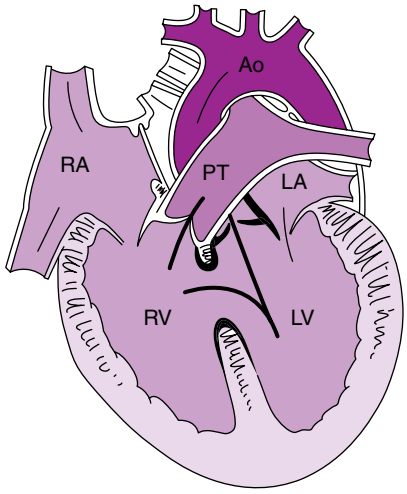

Figure 1.

Ventricular septal defect. In this schematic, the defect results in an unobstructed communication and therefore, right ventricular hypertrophy and pulmonary hypertension are shown. Left-to-right shunting is shown. RA = right atrium, LA = left atrium, RV = right ventricle, LV = left ventricle, Ao = aorta, PT = pulmonary trunk. (Source: Roberts W., Adult Congenital Heart Disease. Philadelphia, © 1987 F.A. Davis Company.)

SYSTEMS AFFECTED
- Respiratory—if pulmonary edema develops.
- Cardiovascular—a large shunt can result in pulmonary vascular disease, pulmonary hypertension, and shunt reversal (i.e., Eisenmenger's syndrome). This is uncommon in small animals; if shunt reversal occurs, it seems to do so early in life.

GENETICS
Breed predispositions recognized; genetic transmission has not been established.

INCIDENCE/PREVALENCE
One of the most common congenital cardiac malformations in cats, comprising 50% of cases with congenital cardiac defects in one study. Less common in dogs, reported to occur in 7.5–14.4% of cases with congenital cardiac disease.

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT
Species
Dog and cat.

Breed Predilections
English bulldog, English springer spaniel, basset hound, Akita, West Highland white terrier, Lakeland terrier.

Mean Age and Range
Most defects detected during routine examination of puppies and kittens.

Predominant Sex
N/A

SIGNS
Historical Findings
- Usually asymptomatic.
- Clinical signs of left ventricular failure include dyspnea, exercise intolerance, syncope, and cough.

Physical Examination Findings
- A restrictive VSD results in a systolic murmur that typically is loud, band-shaped, and heard best over the right hemithorax. A diastolic decrescendo murmur may result if the VSD undermines anatomic support of the aortic valve, causing aortic regurgitation. Patients with right-to-left shunts generally do not have murmurs.
- Split second heart sound in some patients.
- Femoral pulses usually normal.
- Mucous membranes—pink, unless pulmonary vascular disease causes a right-to-left shunt and arterial hypoxemia.
- Tachycardia, dyspnea, and crackles may be evident if left ventricular failure occurs.

CAUSES
Congenital; may have a genetic basis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other congenital cardiac malformations that cause systolic murmurs include atrioventricular valve dysplasia, aortic or pulmonary stenosis, and complex malformations such as tetralogy of Fallot.
- The "to-and-fro" murmur, consisting of distinct systolic and diastolic murmurs, which results when aortic valve regurgitation complicates a VSD must be distinguished from the continuous murmur of patent ductus arteriosus.
- Generally, diagnosis of congenital cardiac malformations requires echocardiographic evaluation including Doppler studies.

CBC/BIOCHEMISTRY/URINALYSIS
- Results usually normal.
- Uncommon right-to-left shunting results in compensatory erythrocytosis.
- Patients with severe congestive heart failure (CHF) may have prerenal azotemia.

OTHER LABORATORY TESTS
N/A

IMAGING
Thoracic Radiography
- Radiographic appearance is determined by the size and direction of the shunt. Thoracic radiographs may be normal if the VSD is small. Larger defects cause various degrees of left or even generalized cardiac enlargement. Pulmonary hyperperfusion with prominence of the main pulmonary artery segment may be apparent. CHF is manifest as pulmonary edema.
- Patients with right-to-left shunts have right-sided cardiomegaly; the pulmonary arteries are large proximally but distally attenuated, and the pulmonary veins are small because of reduced pulmonary perfusion.

Echocardiography
- Two-dimensional echocardiography may demonstrate left atrial enlargement with left ventricular dilation and hypertrophy. Systolic myocardial function is usually preserved. Right ventricular hypertrophy is apparent only if the defect is moderate or large in size, or if the VSD is one aspect of a complex malformation such as tetralogy of Fallot. Careful study usually demonstrates the defect. Evaluate echocardiographic images critically; the artifact of "septal drop-out" is very common.
- The diagnosis is confirmed by Doppler interrogation of the interventricular septum. If the defect is restrictive, spectral Doppler reveals a high-velocity systolic jet. The shunt may be seen directly by color-flow Doppler.

VENTRICULAR SEPTAL DEFECT (CONTINUED)

Contrast echocardiography may help in the diagnosis of a right-to-left VSD.
• Infrequently, VSDs spontaneously close. The mechanism of closure is usually adherence of a part of the septal tricuspid valve leaflet to the interventricular septum resulting in the echocardiographic appearance of "septal aneurysm," which is an incidental echocardiographic finding.

Cardiac Catheterization
Selective cardiac catheterization allows visualization of the defect by contrast angiocardiography and calculation of the shunt fraction (QP/QS) and pulmonary vascular resistance.

DIAGNOSTIC PROCEDURES

Electrocardiography
• Evidence of left atrial enlargement, left ventricular hypertrophy, or even right ventricular hypertrophy in some animals.
• Right ventricular enlargement pattern in most animals that have a right-to-left shunt because of pulmonary vascular disease or pulmonic stenosis.

PATHOLOGIC FINDINGS
Size of the defect determines the degree of chamber enlargement and hypertrophy; pulmonary edema and possibly ascites are seen in patients with CHF.

TREATMENT

APPROPRIATE HEALTH CARE
Clinical signs are related to CHF; most patients can be treated as outpatients.

NURSING CARE
N/A

ACTIVITY
Restrict if animal has CHF; need not restrict asymptomatic patients with small defects.

DIET
Moderate sodium restriction recommended for patients with CHF.

CLIENT EDUCATION
Definitive surgical correction is not widely available; if CHF develops, it is terminal, even with palliative care.

SURGICAL CONSIDERATIONS
• Only a minority of VSDs are sufficiently large to warrant repair.
• Consider definitive surgical repair of the defect during cardiopulmonary bypass for defects associated with a large shunt. Cardiopulmonary bypass is presently performed at a small number of veterinary centers. Consider pulmonary artery banding as a palliative procedure for patients with moderate or large shunts and CHF.
• Some VSDs are amenable to transcatheter closure using purpose-designed metallic occluder devices.

MEDICATIONS

DRUG(S) OF CHOICE
Furosemide, enalapril, pimobendan, and, in some circumstances, digoxin—recommended for animals with CHF (see Congestive Heart Failure, Left-Sided).

CONTRAINDICATIONS
Vasodilators—contraindicated or used only with great caution in patients with complex malformations.

PRECAUTIONS
ACE inhibitors and digoxin must be used cautiously if patient has renal dysfunction.

FOLLOW-UP

PATIENT MONITORING
Periodic echocardiographic or radiographic evaluation suggested for patients without clinical signs.

PREVENTION/AVOIDANCE
Breeding affected animals is not recommended.

POSSIBLE COMPLICATIONS
• Left ventricular CHF.
• Bacterial endocarditis.
• Pulmonary hypertension.
• Arrhythmias.

EXPECTED COURSE AND PROGNOSIS
• Patients with small shunts generally have a normal lifespan; isolated, restrictive VSDs usually do not cause clinical signs.
• Concurrent anomalies such as pulmonic stenosis or aortic insufficiency worsen the prognosis.
• Patients with overt CHF may live 6–18 months with medical treatment.
• The development of pulmonary hypertension and shunt reversal is uncommon but generally associated with a poor prognosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• VSD may be one component of complex malformations such as tetralogy of Fallot.
• Most VSDs are perimembranous and therefore, subaortic. As a result, aortic valve insufficiency resulting from a poorly supported aortic valve complicates the condition in some patients.
• VSD may be associated with an atrial septal defect as part of an atrioventricular septal defect.

AGE-RELATED FACTORS
The murmur of VSD becomes apparent shortly after birth, when pulmonary vascular resistance decreases.

ZOONOTIC POTENTIAL
N/A

PREGNANCY/FERTILITY/BREEDING
High risk in patients with large defects; breeding affected animals is not recommended.

SYNONYMS
Interventricular septal defect.

SEE ALSO
• Congestive Heart Failure, Left-Sided.
• Tetralogy of Fallot.

ABBREVIATIONS
• ACE = angiotensin-converting enzyme.
• CHF = congestive heart failure.
• VSD = ventricular septal defect.

VENTRICULAR STANDSTILL (ASYSTOLE)

BASICS

DEFINITION
Absence of ventricular complexes on the ECG or absence of ventricular activity (electrical–mechanical dissociation).

ECG Features
Ventricular asystole can result from severe sinoatrial block or arrest or by third-degree atrioventricular (AV) block without a junctional or ventricular escape rhythm; ECG features include:
- P waves present if patient has complete AV block (Figure 1).
- P waves absent during asystole if patient has severe sinoatrial block or arrest.
- No QRS complexes.
- Electrical–mechanical dissociation—a recorded ECG cardiac rhythm (P-QRS-T) and no effective cardiac output or palpable femoral pulse.

PATHOPHYSIOLOGY
Ventricular asystole represents cardiac arrest; if the ventricular rhythm is not restored in 3–4 minutes, irreversible brain injury can occur.

SYSTEMS AFFECTED
- Cardiovascular.
- All organ systems affected by loss of perfusion.

GENETICS
N/A

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
None

SIGNALMENT

Species
Dog and cat.

Breed Predilections
None

Mean Age and Range
Unknown

SIGNS

Historical Findings
- Severe systemic illness or cardiac disease in many patients.
- Other cardiac arrhythmias in some.
- Syncope.

PHYSICAL EXAMINATION FINDINGS
- No ventricular pulse can be palpated.
- Cardiac arrest.
- Collapse.
- Death.

CAUSES
- Complete AV block with absence of ventricular or junctional escape rhythm.
- Severe sinus arrest or block.
- Hyperkalemia (Figure 2).

RISK FACTORS
- Any severe systemic illness (e.g., severe acidosis and hyperkalemia) or heart disease.
- Hypoadrenocorticism causing hyperkalemia.
- Urinary tract rupture or obstruction, resulting in hyperkalemia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Rule out ECG artifact; reapply ECG clips and make sure skin contact is good and adequate alcohol is applied to leads.

CBC/BIOCHEMISTRY/URINALYSIS
Severe hyperkalemia is a possible cause.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

DIAGNOSTIC PROCEDURES
Systemic blood pressure—readable pressure absent.

PATHOLOGIC FINDINGS
N/A

TREATMENT

APPROPRIATE HEALTH CARE
- Asystole is a frequently fatal rhythm requiring immediate aggressive treatment.
- Artificial pacing with a transvenous or transthoracic pacemaker may succeed if myocardium is mechanically responsive.
- DC electrical conversion is not effective unless the rhythm can first be converted to ventricular fibrillation with medications.

NURSING CARE
Treat any treatable problems such as hypothermia, hyperkalemia, and acid–base disorders.

ACTIVITY
N/A

DIET
N/A

CLIENT EDUCATION

SURGICAL CONSIDERATIONS
None

MEDICATIONS

DRUG(S) OF CHOICE
- Institute cardiopulmonary resuscitation.
- Epinephrine 0.2 mg/kg IV, intratracheal (IT), or intralingual (IL) (double the dose for IT administration and deliver with equal volume of saline).
- Atropine 0.05 mg/kg IV, IT, or IL (double the dose for IT administration and deliver with equal volume of saline).
- Sodium bicarbonate 1 mEq/kg IV for each 10 minutes of cardiac arrest.
- Dexamethasone and dopamine may be helpful in patients with electrical–mechanical dissociation.

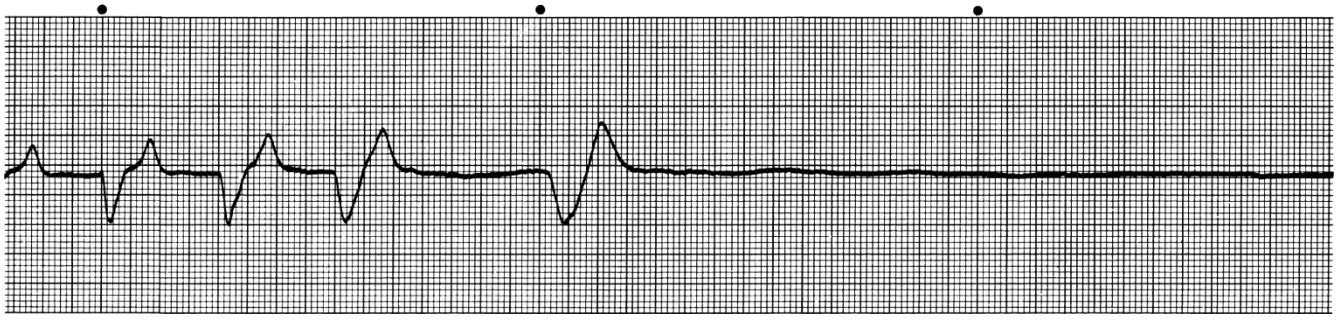

Figure 1.

Ventricular asystole in a dog with severe complete AV block. Only P waves (atrial activity) are present; there is no ventricular activity. Lead II, 50 mm/s, 1 cm = 1 mV. (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

VENTRICULAR STANDSTILL (ASYSTOLE) (CONTINUED)

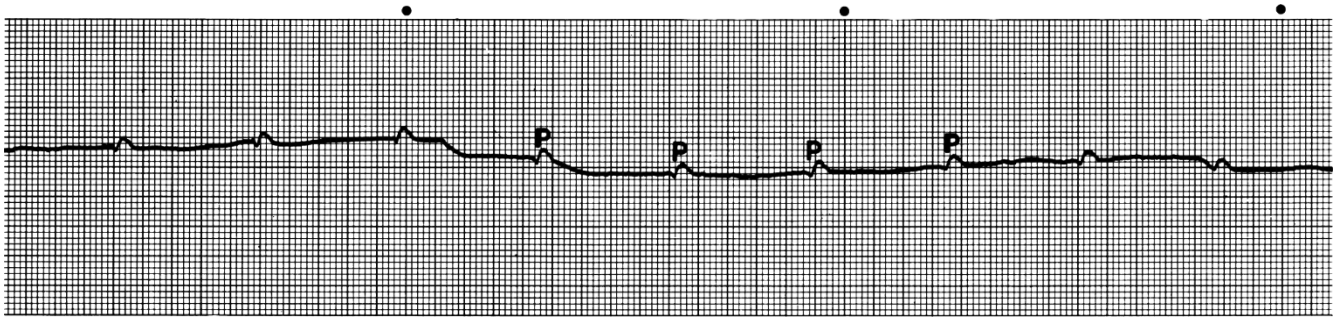

Figure 2.

Ventricular asystole in a cat with severe hyperkalemia (11 mEq/L) from urethral obstruction. No P waves or QRS complexes are seen after four wide and bizarre QRS complexes (atrial standstill with delayed ventricular conduction). Lead II, 50 mm/s, 1 cm = 1 mV.) (Source: From Tilley LP. Essentials of Canine and Feline Electrocardiography, 3rd ed. Baltimore: Williams & Wilkins, 1992. Reprinted with permission of Wolters Kluwer.)

CONTRAINDICATIONS
Drugs that depress sinus node or AV node conduction in patients with sinus arrest or heart block (e.g., beta-blockers, calcium channel blockers, digoxin).

PRECAUTIONS
None

POSSIBLE INTERACTIONS
None

ALTERNATIVE DRUG(S)
Calcium gluconate—patients with ventricular standstill and hyperkalemia.

V

FOLLOW-UP

PATIENT MONITORING
- If animal is resuscitated—evaluate CBC, biochemical analysis, and urinalysis.
- If animal survives and primary cardiac disease is suspected—echocardiogram and thoracic radiographs.
- ECG—closely and frequently.

PREVENTION/AVOIDANCE
Careful monitoring of critically ill patients to prevent and correct acid–base and electrolyte disturbances, hypotension, and hypoxemia.

POSSIBLE COMPLICATIONS
- Death.
- Disseminated intravascular coagulation (DIC) and multiorgan failure.

EXPECTED COURSE AND PROGNOSIS
Usually death. If sinus rhythm reestablished, prognosis still usually guarded to poor as not uncommon to arrest again.

VENTRICULAR TACHYCARDIA

BASICS

DEFINITION
Ventricular tachycardia (VT) may occur in structurally normal hearts (hereditary arrhythmias) or may be a manifestation of myocardial abnormalities associated with cardiomyopathy, significant valvular disease, myocarditis, infiltrative disease or electrolyte abnormalities. To date, no available medical therapy is known to prevent sudden death (SD) in animals afflicted with VT.

PATHOPHYSIOLOGY
Severity of VT depends both on the hemodynamic consequences (hypotension) and on the electrical instability of a rhythm, i.e. its potential to degenerate into ventricular fibrillation (VF), resulting in SD. In Dobermans, SD due to VT–VF occurs in about 30–50% of cases. In boxers with arrhythmogenic right ventricular cardiomyopathy (ARVC), 33% are syncopal due to VT and 30% have SD due VT–VF. Similarly, 13% of English bulldogs with inherited ARVC experience SD. Underlying mechanisms of VT include increased automaticity, reentry, and triggered activity.

ECG Features (Figure 1)
- QRS complexes—typically wide and bizarre.
- Three or more ventricular premature contractions in a row.
- May be intermittent (paroxysmal) or sustained; heart rate usually >150 bpm with a regular or irregular rhythm.
- P waves, if visible, are dissociated from the QRS complexes.
- Breed-specific ECG changes—VT in boxers is characteristically positive in the ventrocaudal leads (leads II, III, and aVF), thus manifests a "left bundle branch block pattern." VT in Doberman pinschers and German shepherd dogs has both polymorphic and monomorphic characteristics.

SYSTEMS AFFECTED
Cardiovascular system, with secondary effects on other systems due to poor perfusion.

GENETICS
- In boxers, ARVC is inherited as autosomal dominant trait with adult onset of disease. Some boxers have a mutation in the striatin gene, but the disease is manifested with incomplete penetrance (i.e., even if a boxer has the genetic mutation, it may not lead to the development of arrhythmias in that dog) and it is likely that there is more than one mutation in boxers that may lead to the disease in some lines. Striatin is a desmosomal protein (scaffolding protein) located in the intercalated disc region of the cardiomyocyte and colocalizes with desmosomal proteins such as plakophilin-2 and other known proteins that are mutated in human ARVC. DNA test results can indicate if a dog is heterozygous or homozygous for the genetic striatin deletion. Homozygous dogs are more likely to show disease and should not be used for breeding.
- English bulldogs also appear to harbor a form of inherited ARVC manifest with VT and SD in 13% of dogs. Genetic mode of inheritance is undetermined. There is 2.9:1 male to female ratio of affectedness. Unlike boxers with ARVC, the majority of English bulldogs appear to present with signs of CHF at the time of arrhythmia detection.
- Dilated cardiomyopathy with VT in Doberman pinschers is inherited as an autosomal dominant trait with adult onset of disease. In Dobermans there are two genetic mutations associated with dilated cardiomyopathy (DCM) and VT identified in the pyruvate dehydrogenase kinase 4 (PDK4) gene (*PDK4/NCSU/DCM1*) and the titin gene (*NCSU DCM2*). Dogs with both mutations are at the highest risk of getting DCM, although dogs with a mutation in either gene can develop the disease as well.
- Inherited VT and SD, considered primarily an "electrical disorder" (since no underlying structural heart disease is identified), is found in young German shepherd dogs and English springer spaniels. They have been shown to have inherited channelopathies, resulting in repolarization abnormalities. In springer spaniels a mutation in the *KCNQ1* gene, responsible for a repolarizing K channel, was found to exhibit QT interval prolongation on ECG and SD. In German shepherd dogs, the mode of inheritance is polygenic due to an abnormality in a major gene with modifiers.
- Young Rhodesian ridgebacks have been found to be affected with severe ventricular arrhythmias and SD. It is inherited in an autosomal recessive mode and linked to a genetic mutation, likely associated with mitochondrial alterations.

INCIDENCE/PREVALENCE
Common in dogs; uncommon in cats.

GEOGRAPHIC DISTRIBUTION
None

SIGNALMENT

Species
Dog and cat.

Breed Predilections
Commonly seen in large-breed dogs with cardiomyopathy, especially boxers and Doberman pinschers, also in German shepherd dogs and Rhodesian ridgebacks.

Mean Age and Range
- All age groups, if not breed-specific VT.
- Boxers with ARVC usually present at 4–6 years of age; frequency and severity of the arrhythmia usually increase over time.
- Doberman pinschers with occult cardiomyopathy typically develop ventricular arrhythmias beginning at 3–6 years of age, but it also can occur much later in life; frequency and severity usually increase over time.
- German shepherd dogs develop ventricular arrhythmias at 12–16 weeks of age and the frequency and severity of the arrhythmias increase until 24–30 weeks of age. After 8 months of age the arrhythmia severity stabilizes or starts to decrease.
- The Rhodesian ridgeback's most severe arrhythmias are found between 6 and 30 months of age, after which many dogs appear to outgrow the problem.
- Bulldogs with ARVC have a mean age of 9.2 years at time of presentation for arrhythmias.

SIGNS

Historical Findings
- Syncope.
- Weakness.
- Exercise intolerance.
- SD.
- May be asymptomatic.

Physical Examination Findings
- May be normal if arrhythmia is paroxysmal and absent during examination.
- Paroxysmal or sustained tachycardia may be ausculted.
- Femoral pulses may have variable pulse intensity or be weak during runs of VT.
- Signs of CHF or a murmur may be present, depending on cause of arrhythmia.

CAUSES
- Cardiomyopathy.
- Inherited channelopathies.
- Congenital defects (especially subaortic stenosis).
- Chronic degenerative valve disease.
- Traumatic or infectious myocarditis.
- Cardiac neoplasia.
- Gastric dilation and volvulus.
- Splenic neoplasia/hemorrhage.
- Hyperthyroidism (cats).
- Digitalis toxicity.
- Pancreatitis.
- VT can also be found in dogs affected with noncardiac disease states including electrolyte abnormalities (potassium), or systemic diseases where imbalance of cardiac autonomic modulation may elicit VT. The VT occurring secondary to those circumstances may occur at heart rates similar to the sinus rate (in this scenario the rhythm is termed "accelerated idioventricular rhythm" rather than VT since the heart rate is normal), thus considered less malignant, and are often self-limiting with correction or resolution of the underlying cause.

RISK FACTORS
- Hypokalemia, hyperkalemia.
- Hypomagnesemia.
- Acid–base disturbances.
- Hypoxemia.
- Neoplasia (e.g., cardiac or splenic hemangiosarcoma).
- Anemia.

VENTRICULAR TACHYCARDIA (CONTINUED)

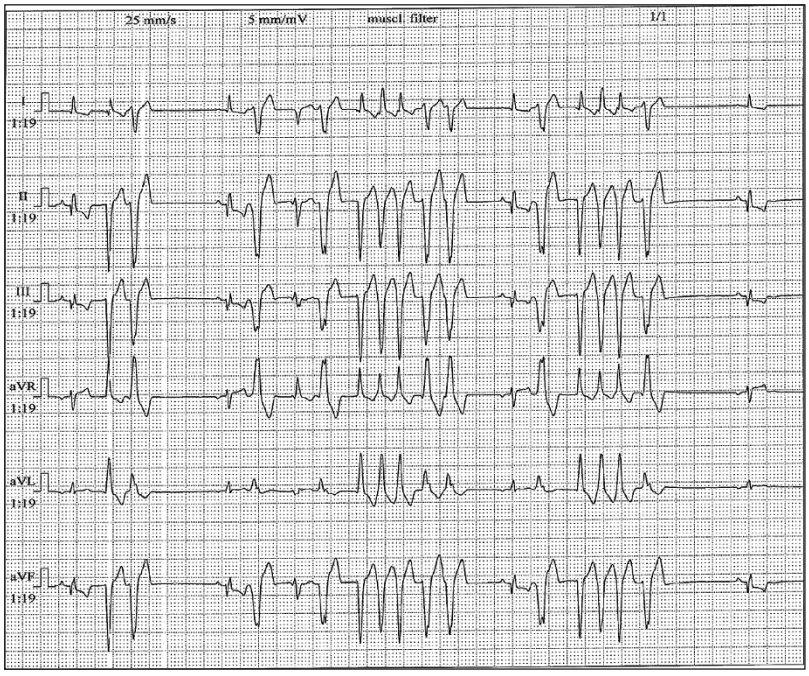

Figure 1.

Ventricular tachycardia. 6-lead ECG demonstrating the wide and bizarre QRS complexes that occur in runs of up to 6 beats in a Doberman pinscher with DCM. Ventricular tachycardia should be treated as soon as possible. Acid–base and electrolyte abnormalities should always be corrected.

V

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Supraventricular tachycardia with bundle branch block. If P waves can be identified, look for association between P waves and QRS complexes. If there is a consistent PR interval, then the rhythm is supraventricular with bundle branch block. If there is no association between P waves and QRS complexes, the rhythm is probably VT. If P waves cannot be identified due to a fast rate (P buried in preceding T wave), lidocaine administration may result in slowing of the VT rate and P waves may be identified if present. Termination of a tachyarrhythmia after administration of lidocaine supports diagnosis of VT. If no effect with lidocaine, esmolol administration may result in slowing of a supraventricular tachycardia with bundle branch block, so that P waves associated with QRS complexes can be identified.

CBC/BIOCHEMISTRY/URINALYSIS

- Hypokalemia and hypomagnesemia predispose to VT and blunt response to class I antiarrhythmic drugs (e.g., lidocaine, procainamide, mexiletine, and quinidine).
- High amylase and lipase if arrhythmia is secondary to pancreatitis.
- Inflammatory changes may occur on CBC such as increased neutrophil count if arrhythmia secondary to myocarditis.

OTHER LABORATORY TESTS

- Increased cardiac troponin I (cTnI) with myocarditis.
- High T_4 (cats) if arrhythmia is secondary to hyperthyroidism.
- Lyme or tick titers in myocarditis.
- Genetic testing is available at NC State (https://cvm.ncsu.edu/genetics/) for arrhythmias originating due to boxer ARVC, Doberman DCM and Rhodesian ridgeback inherited arrhythmias.
- Increased trypsin-like immunoreactivity and pancreatic lipase immunoreactivity if suspect pancreatitis is a cause for the VT.

IMAGING

Echocardiography may reveal underlying structural heart disease.

DIAGNOSTIC PROCEDURES

ECG and long-term ambulatory (Holter) or event recording of the ECG—for detection of intermittent VT in patients with unexplained syncope or weakness.

PATHOLOGIC FINDINGS

Vary with underlying cause.

TREATMENT

APPROPRIATE HEALTH CARE

- Most patients with intermittent VT can safely be evaluated for underlying diseases (echocardiogram, lab work) and it is ideal to establish a true baseline of the arrhythmia quantity and quality by a 24-hour Holter prior to initiating therapy.
- If unstable (laterally recumbent, weak, or frequent syncope), immediate IV treatment in a hospital setting with continuous ECG monitoring may be required. Once the arrhythmia is controlled and patient is hemodynamically stable, oral medication should be instituted. A follow-up 24-hour Holter is required to evaluate efficacy and possible pro-arrhythmic effects of antiarrhythmic therapy.

NURSING CARE

Varies with underlying cause.

ACTIVITY

Boxers tend to have an increased incidence of VT during excitement, so in some cases owners should know what specific situations to avoid. In humans with ARVC, exercise has been shown to exacerbate arrhythmia incidence and risk of SD.

(CONTINUED) VENTRICULAR TACHYCARDIA

DIET
Dogs with diet-associated (boutique, exotic-ingredient, or grain-free [BEG] diets) DCM may have an increased incidence of VT and risk of SD.

CLIENT EDUCATION
Alert the owner to the potential for SD.

SURGICAL CONSIDERATIONS
- When possible, determine the cause of the arrhythmia and treat it prior to inducing general anesthesia.
- Assess if VT is correctable with a test dose of lidocaine; if it is, treat as necessary with lidocaine, either using IV boluses or CRI.
- Premedication with acepromazine 0.02–0.05 mg/kg raises the threshold for VF.
- Avoid proarrhythmic drugs such as alpha-2 agonists (xylazine, medetomidine) and thiopental.
- Mask induction is not recommended in inadequately sedated patients with ventricular arrhythmias because increased sympathetic tone during mask induction will aggravate the arrhythmia.
- Continuous ECG monitoring during anesthesia.

MEDICATIONS

DRUG(S) OF CHOICE
Correct any hypokalemia or hypomagnesemia, if possible, prior to instituting medical therapy.

Dogs

Acute Life-Threatening VT
- Administer lidocaine slowly in 2 mg/kg IV boluses (up to 8 mg/kg total) to convert to sinus rhythm; follow with lidocaine CRI, 30–80 µg/kg/min.
- If lidocaine fails—administer procainamide 5–15 mg/kg slow IV bolus (may cause vomiting or hypotension due to negative inotropic effect), followed by 25–50 µg/kg/min IV CRI.
- In cases of refractory VT, lidocaine and procainamide CRIs can be combined.
- If no response to lidocaine or procainamide, amiodarone (Nexterone®) can be administered as a 2 mg/kg IV bolus infused over 10 minutes, followed by a CRI of 0.8 mg/kg/h for 6 hours, then decrease to 0.4 mg/kg/h or alternatively try slow IV boluses of esmolol (a short-acting beta-blocker) at 0.05–0.1 mg/kg q5min to a cumulative dose of 0.5 mg/kg, or as a 50–200 µg/kg/min CRI.
- If there is inadequate response to the various IV therapies, then PO medication may be administered. Sotalol 1.5–2.5 mg/kg PO q12h may convert dangerous VT within 1–3 hours in such situations, even when the usual IV medications failed. It can be administered in a "loading protocol" (1.5–2.5 mg/kg PO q4h or q6h), for the first 2 doses, depending on the severity of the VT and myocardial function.

Chronic VT in a Stable Patient
- Sotalol 1–2.5 mg/kg PO q12h.
- Mexiletine monotherapy is not very effective, but combination of mexiletine 4–8 mg/kg PO q8h with a beta-blocker such as atenolol 0.25–1 mg/kg PO q12h or sotalol 1–2.5 mg/kg PO q12h may be more effective for refractory VT, especially in boxers.
- Amiodarone may be used for refractory VT in dogs with poor myocardial function (loading dosage of 5–15 mg/kg PO q12h for 2–14 days, maintenance dosage of 6–15 mg/kg PO q24h). Requires regular monitoring due to the risk for serious side effects in dogs (hepatotoxicity, neutropenia, thyroid dysfunction). Signs of toxicity include anorexia, vomiting, lethargy, and hepatic enzyme elevation. Amiodarone hepatopathy is reversible after reduction of dosage or discontinuation of the drug. Overt clinical signs of toxicity generally resolve within a few days of stopping amiodarone. Monitoring of serial serum chemistries is recommended, since increases in liver enzyme activities usually precede the onset of clinical signs of amiodarone toxicity. Liver enzymes should be measured after 7 days of drug loading and once monthly during maintenance therapy.
- Amiodarone can be combined with atenolol 0.5–1.0 mg/kg twice a day to enhance antiarrhythmic effects.
- In German shepherd dogs the combination of mexiletine and sotalol is the most effective therapy for VT. Sotalol monotherapy should be avoided due its proarrhythmic effects in this breed.

Cats
- Use lidocaine cautiously and only for sustained VT; neurotoxicity (seizures) is common in cats. Use one-tenth of the dosage used for dogs.
- For oral maintenance therapy of severe VT in cats use sotalol 10 mg/cat q12h or atenolol 6.25–12.5 mg PO q12h.

CONTRAINDICATIONS
Avoid atropine, catecholamines (e.g., epinephrine, dopamine) until arrhythmia is controlled.

PRECAUTIONS
- Use beta-blockers cautiously in animals with CHF. Monitoring by echocardiogram is recommended to check for worsening of myocardial function due to beta blockade.
- Sotalol, when used as a sole agent, and other drugs that prolong action potential duration may worsen VT in German shepherd dogs with inherited ventricular arrhythmias.

POSSIBLE INTERACTIONS
Quinidine and amiodarone raise digoxin levels.

FOLLOW-UP

PATIENT MONITORING
- Holter monitoring is preferred for assessment of severity of the arrhythmia and efficacy of antiarrhythmic therapy; the goal of antiarrhythmic therapy is to reduce the frequency of ventricular ectopy by >85%.
- Serial ECG and telemetry can be used alternatively—but not as meaningful as Holter monitoring because ventricular premature complexes and paroxysmal VT can occur sporadically throughout the day.

PREVENTION/AVOIDANCE
- Correct predisposing factors such as hypokalemia, hypomagnesemia, myocardial hypoxia, and digoxin toxicity.
- In boxers, limit significant stress or excitement as the increase in sympathetic tone may exacerbate the arrhythmia.

POSSIBLE COMPLICATIONS
- Syncope.
- SD.

EXPECTED COURSE AND PROGNOSIS
- If cause is metabolic—condition may resolve with a good prognosis.
- If condition is associated with cardiac disease—prognosis is guarded because the underlying heart disease is likely chronic and progressive and therefore the arrhythmias may also worsen over time; presence of significant VT increases the risk of SD.
- If VT associated with hemangiosarcoma (cardiac or splenic)—the long-term outcome is grave due to the poor prognosis of the underlying disease.
- Approximately 50% of German shepherd dogs with more than 10 runs of VT/24 hours die suddenly.
- Doberman pinschers with VT and DCM may die suddenly during their first syncopal episode.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
If German shepherd dogs reach the age of 18 months, the probability of SD decreases, similarly in Rhodesian ridgebacks, after 30 months of age.

ZOONOTIC POTENTIAL
None

VERTEBRAL COLUMN TRAUMA

BASICS

DEFINITION
• Vertebral column trauma are caused by the application of exogenous forces to the vertebrae, intervertebral discs, tendons, ligamentous support structures, and the spinal cord.
• The clinical signs may include spinal hyperesthesia, limb paresis and/or proprioceptive ataxia, para- or tetraplegia, loss of nociception, urinary retention, and fecal incontinence.

PATHOPHYSIOLOGY
• In the normal vertebral column, passive (bones, ligaments, discs), active (tendons, muscles), and neural systems are responsible for stability.
• Compression, lateral bending, torsion, and sheer forces may result in failure of these systems, leading to vertebral fracture or subluxation.
• In some instances, significant spinal cord injury (SCI) such as traumatic disc herniation, penetrating injuries and post-traumatic vascular myelopathy, can be present without instability or fracture.
• SCI is the result of primary and secondary injuries.
• Primary injury results from initial mechanical events (spinal cord compression, contusion). The secondary injury is the biochemical cascade (combination of oxidative stress, inflammation, vascular injury) that follows and causes extension of the primary injury.

SYSTEMS AFFECTED
• Nervous.
• Musculoskeletal.
• Others possible due to exogenous trauma.

INCIDENCE/PREVALENCE
• Vertebral fractures and luxations represented 6% of all feline myelopathies and 7% of all canine neurology cases in two studies.
• The incidence of traumatic SCI without fracture/luxation is unknown.

SIGNALMENT

Breed Predilections
Medium- and large-breed dogs are more commonly affected.

Mean Age and Range
Most affected dogs and cats are young (median 2 years of age; range 0.25–15 years in one study).

Predominant Sex
Males appear overrepresented.

SIGNS

General Comments
• The majority of dogs with vertebral column trauma have SCI.
• Concurrent peripheral (e.g., brachial plexus trauma) or CNS injuries (e.g., head trauma) can occur.
• Abnormalities associated with other body systems are frequently identified.

Historical Findings
• Acute-onset paresis and ataxia or para-/tetraplegia.
• Clinical signs suggestive of hyperesthesia (vocalization, reluctance to move, arched back).

Neurologic Examination Abnormalities
• Focal SCI (affecting C1–C5, C6–T2, T3–L3, or L4–S3 spinal cord segments) is most common.
• Gait abnormalities—in >90% of animals; may include proprioceptive ataxia, paresis, and loss of voluntary movement.
• Abnormalities in spinal reflexes and postural reactions are common and usually reflect the spinal cord segment(s) injured.
• Decreased spinal reflexes can also be secondary to spinal shock (acute, transient, loss of spinal reflexes, commonly withdrawal reflexes, after SCI).
• Regional hyperesthesia.
• Animals with severe SCI may have absent nociception.
• Absence of deep nociception is a negative prognostic indicator, with the proportion of animals ambulating following thoracolumbar vertebral fracture/luxation considered <5%.

Physical Examination Abnormalities
• Pulmonary contusions and rib fractures.
• Pelvic and appendicular bone fractures.
• Cutaneous wounds.
• Traumatic brain injury.
• Abdominal organ injury.

CAUSES
• Automobile accident is the most common cause of vertebral column trauma.
• Other etiologies include fall, animal bites, and gunshot wounds.

RISK FACTORS
Animals housed outdoors, walked off lead, or unsecured in the cabs of pickup trucks are likely overrepresented.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Other neurologic diseases such as acute disc herniation, fibrocartilagenous embolic myelopathy, acute noncompressive nucleus pulposus extrusion, meningomyelitis, discospondylitis, and neoplasia, should be considered.
• Orthopedic injuries such as appendicular fracture or ligamentous injuries may occasionally be mistaken for vertebral column trauma.

CBC/BIOCHEMISTRY/URINALYSIS
• Abnormalities may be present if significant injury has occurred to other body systems.
• Anemia, findings consistent with dehydration, elevated creatinine kinase, and hematuria are all commonly seen.

IMAGING

Radiography
• 70% sensitive and highly specific for detecting vertebral fracture/luxation.
• Do not permit visualization of the spinal cord and have poor soft tissue detail.

Myelography
Can define extradural spinal cord compression but invasive and does not allow direct visualization of spinal cord parenchyma; may not detect lateralized spinal cord compression and lacks the tissue detail of advanced imaging studies.

Advanced Imaging
• CT—gold standard for evaluating the bones of the vertebral column and for visualizing mineralized disc material and extradural hemorrhage.
• MRI—can allow visualization of the bony vertebral column, but provides more soft tissue details than CT; it is the only means to exclude certain differential diagnoses, such as fibrocartilaginous embolism, and can provide prognostic information concerning recovery.

DIAGNOSTIC PROCEDURES
• CSF—often unremarkable or not etiology-specific; in some severe cases, CSF total protein, nucleated count, and red blood cell count may be increased.
• CSF is collected as an adjunct and not as a substitute to advanced imaging.
• Caution should be taken with CSF collection as positioning for cisternal or lumbar tap can exacerbate spinal cord injury by destabilizing a vertebral fracture or luxation.

PATHOLOGIC FINDINGS
• Gross findings may include evidence of vertebral luxation/fracture, extradural hemorrhage, disc extrusion, spinal cord swelling, dural/subarachnoid erythema/hemorrhage, and myelomalacia.
• Histopathologic abnormalities within the spinal cord may include necrosis, demyelination, infarction, parenchymal hemorrhage.

TREATMENT

APPROPRIATE HEALTH CARE
• Emergency intensive care management is recommended for all animals immediately following injury.
• Surgical management is needed if imaging suggests significant spinal cord compression and/or vertebral column instability.

VERTEBRAL COLUMN TRAUMA (CONTINUED)

• Medical management may be selected for animals that lack evidence of instability/compression.

NURSING CARE

• Prior to imaging, animals should be immobilized on a back board. Animals with suspected cervical lesions should ideally be placed in a neck brace that does not impair their breathing.
• Animals with imaging that suggests vertebral column instability should be immobilized until surgical stabilization.
• Non-ambulatory dogs require padded bedding, frequent turning, and urinary bladder evacuation.
• Fluid therapy is required in the event of dehydration and to maintain adequate blood pressure and perfusion to the spinal cord.
• Pain management is also required.
• Sedation can be considered to avoid exacerbation of the signs in anxious and frantic animals.
• Physical rehabilitation consisting of range of motion exercises, active weight bearing, and underwater treadmill may be beneficial but significant mobilization should only be performed after any vertebral column instability is addressed.

ACTIVITY

• Strict exercise restriction for 4 weeks for all animals following vertebral column surgery. Animals with fractures and instability may require 6–8 weeks of rest.
• Medically managed animals lacking vertebral column instability/fracture may require shorter periods of rest.

SURGICAL CONSIDERATIONS

• Surgery is recommended for animals with advanced imaging that supports significant spinal cord compression or vertebral column instability (e.g., subluxation, violation of multiple vertebral unit compartments).
• Spinal stapling, pins, and methylmethacrylate, and various plates can be used to stabilize the vertebral column.
• Decompression may be needed with or without stabilization in cases with significant extradural hemorrhage or disc material.
• Rapid surgical intervention (within 48 hours) is usually recommended to relieve spinal cord compression and limit permanent damage.

MEDICATIONS

DRUG(S) OF CHOICE

• Opioid analgesics—commonly used for pain management; fentanyl 2–5 µg/kg CRI, hydromorphone 0.05–0.1 mg/kg IV q6h).
• NSAIDs provide analgesia and anti-inflammatory effects and may be beneficial if hydration status, kidney, and liver functions are normal. Carprofen 2.2 mg/kg PO q12h commonly used.
• Gabapentin 10 mg/kg q8–12h can be beneficial for neuropathic pain.
• Alpha receptor antagonists can relax the internal urethral sphincter and facilitate urinary voiding in upper and lower motor neuron bladder dysfunction. Prazosin 1 mg/15 kg PO q8–12h.

CONTRAINDICATIONS

Glucocorticoids—methylprednisone sodium succinate (MPSS) and other glucocorticoids have not been shown to be beneficial in dogs with SCI.

PRECAUTIONS

• NSAIDs may result in gastric ulcers and kidney injury.
• Glucocorticoids may cause gastric or colonic ulceration, vomiting, and urinary tract infections (especially dexamethasone).
• Alpha-antagonists may result in hypotension and gastrointestinal signs.

POSSIBLE INTERACTIONS

Glucocorticoids and NSAIDs should not be combined as this increases the risk of gastrointestinal adverse effects.

ALTERNATIVE DRUG(S)

N/A

FOLLOW-UP

PATIENT MONITORING

Daily physical and neurologic examination is strongly suggested to monitor progression.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

• Chronic ataxia/paresis as well as failure to regain voluntary ambulation are possible.
• Some animals may have urinary/fecal incontinence, especially if they are non-ambulatory.
• Non-ambulatory animals are at risk for skin ulcers and urinary tract infection.

EXPECTED COURSE AND PROGNOSIS

• Animals with intact nociception have a good prognosis for ambulatory recovery if appropriate treatment is undertaken.
• Animals with absent nociception that have vertebral fracture or luxation have a very poor prognosis for regaining voluntary ambulation (<5%).

MISCELLANEOUS

ASSOCIATED CONDITIONS

Animals that have traumatic SCI often have injury to other body systems.

AGE-RELATED FACTORS

Younger animals are more commonly affected.

PREGNANCY/FERTILITY/BREEDING

SCI may affect ability to achieve pregnancy and carry fetuses to term.

SYNONYMS

Traumatic myelopathy.

SEE ALSO

• Myelopathy—Paresis/Paralysis—Cats.
• Paralysis.

ABBREVIATIONS

• MPSS = methylprednisone sodium succinate.
• NSAID = nonsteroidal anti-inflammatory drug.
• SCI = spinal cord injury.

VESICOURACHAL DIVERTICULA

BASICS

OVERVIEW
- A common congenital anomaly of the urinary bladder that occurs when a portion of the urachus (i.e., a fetal conduit that allows passage of urine from the bladder to the placenta) located at the bladder vertex fails to close; the result is a blind diverticulum of variable size that protrudes from the bladder vertex.
- Other characteristics include congenital microscopic diverticula (microscopic lumens that may persist at the bladder vertex).
- Acquired macroscopic diverticula develop after the onset of concurrent but unrelated acquired lower urinary tract diseases; presumably, urethral obstruction or detrusor hyperactivity induced by inflammation causes high intraluminal pressure and subsequent enlargement of microscopic diverticula.
- Congenital macroscopic diverticula, most likely caused by impaired urine outflow, develop before or soon after birth and persist indefinitely.

SIGNALMENT
- Dog and cat.
- Frequently encountered in cats with acquired lower urinary tract diseases; twice as common in male cats as in female cats.
- No breed or age predisposition.

SIGNS
Depend on concomitant disorders predisposing to formation of macroscopic vesicourachal diverticula.

CAUSES & RISK FACTORS
- Persistent congenital microscopic diverticula—cause unknown.
- Congenital microscopic diverticula—risk factors for acquired macroscopic diverticula.
- Diseases associated with increased bladder intraluminal pressure (e.g., bacterial urinary tract infection, uroliths, urethral plugs, and idiopathic disease)—risk factors for acquired macroscopic diverticula.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Persistent (or patent) urachus; rare—characterized by inappropriate loss of urine through the umbilicus.
- Persistent urachal ligaments are nonpatent fibrous remnants of the urachus, connecting the bladder vertex to the umbilicus.
- Urachal cysts are focal accumulations of fluid in isolated segments of the urachus. They may be aseptic or septic.

CBC/BIOCHEMISTRY/URINALYSIS
- Abnormal findings are related to the underlying disorder that causes vesicourachal diverticula, unless complicated by concurrent acquired lower urinary tract diseases.
- Abnormal findings related to secondary urinary tract infection.

IMAGING
- Congenital and acquired macroscopic diverticula—best identified by positive-contrast urethrocystography.
- Radiographs obtained with the bladder completely then partially distended with contrast medium may facilitate detection of small diverticula.

DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
- Extramural macroscopic diverticula appear as convex or conical luminal projections from the bladder vertex.
- Intramural microscopic diverticula appear as transitional epithelium-lined lumens persisting at the bladder vertex from the level of the submucosa to subserosa.

TREATMENT
- Many macroscopic diverticula in cats (and probably dogs) are acquired and self-limiting if the underlying disease is eliminated.
- Direct treatment efforts toward eliminating underlying cause(s) of lower urinary tract disease.
- Consider diverticulectomy if a macroscopic diverticulum persists in a patient with persistent or recurrent bacterial urinary tract infection despite appropriate antimicrobial therapy.

MEDICATIONS

DRUG(S) OF CHOICE
N/A

FOLLOW-UP

PATIENT MONITORING
If bacterial urinary tract infection persists or recurs despite proper antimicrobial therapy, the status of the diverticulum should be reevaluated by contrast radiography.

PREVENTION/AVOIDANCE
Avoid diagnostic procedures or treatments that alter normal host urinary tract defenses and predispose to urinary tract infection.

POSSIBLE COMPLICATIONS
Persistent congenital macroscopic diverticula are risk factors for recurrent bacterial urinary tract infection.

EXPECTED COURSE AND PROGNOSIS
- Congenital microscopic diverticula are usually clinically silent unless complicated by concurrent lower urinary tract disease.
- Acquired macroscopic diverticula typically heal in 2–3 weeks after amelioration of clinical signs of lower urinary tract disease.
- Diverticulectomy and appropriate antimicrobial therapy usually associated with resolution of recurrent urinary tract infections in patients with persistent congenital macroscopic diverticula.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- Persistent congenital macroscopic diverticula are potential risk factors for recurrent bacterial urinary tract infections.
- Acquired macroscopic diverticula are typically encountered in patients with concurrent lower urinary tract diseases.

SEE ALSO
- Lower Urinary Tract Infection, Bacterial.
- Lower Urinary Tract Infection, Fungal.

VESTIBULAR DISEASE, GERIATRIC—DOGS

BASICS

DEFINITION
Acute-onset nonprogressive disturbance of the peripheral vestibular system in older dogs.

PATHOPHYSIOLOGY
- Unknown.
- Suspected abnormal flow of the endolymphatic fluid in the semicircular canals of the inner ear secondary to disturbance in production, circulation, or absorption of the fluid.
- Possible intoxication of the vestibular receptors or inflammation of the vestibular portion of the vestibulocochlear nerve (cranial nerve VIII).
- Often incorrectly referred to as a stroke, geriatric vestibular disease is neither central in location nor suspected to be vascular or ischemic in origin.

SYSTEMS AFFECTED
Nervous—peripheral vestibular system.

GENETICS
N/A

INCIDENCE/PREVALENCE
Common, sporadic, acquired disease of older dogs.

SIGNALMENT

Species
Dog

Breed Predilections
- None reported.
- Seems to occur more frequently in medium to large breeds.

Mean Age and Range
Geriatric; patients usually >8 years old.

Predominant Sex
N/A

SIGNS

General Comments
- Signs of acute onset peripheral vestibular dysfunction usually unilateral but occasionally bilateral.
- If vestibular signs are severe, do not incorrectly attribute the signs (especially the gait) to a central (i.e., CNS) location.

Historical Findings
- Sudden onset of imbalance, disorientation, reluctance to stand, and (usually) head tilt and irregular eye movements.
- May be preceded or accompanied by nausea and vomiting.

Physical Examination Findings
- Head tilt—mild to marked; directed toward the side of the lesion; occasionally disease is bilateral with erratic side-to-side head movements either without a head tilt or with a mild tilt in direction of the more severely affected side.
- Abnormal (resting) nystagmus common in early stages; either horizontal or rotatory with the fast phase always in the direction opposite to the head tilt; with bilateral disease, abnormal nystagmus usually mild or not present and physiologic nystagmus or conjugate eye movements diminished to absent.
- Mild to marked disorientation and vestibular ataxia with tendency to lean or fall in the direction of the head tilt.
- Strength and proprioception normal; with severe disease, patient may be reluctant/unable to stand and may have other issues (e.g., hip dysplasia), making assessment of gait difficult; with bilateral disease, may have base-wide stance.

CAUSES
Unknown

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Primarily distinguished from other causes of vestibular deficits by the acute onset and usually rapid improvement without specific treatment.
- Otitis media and interna—may have concurrent ipsilateral facial nerve (cranial nerve VII) paresis or paralysis, deafness, and/or Horner's syndrome; otitis externa with ruptured tympanic membrane may be present with otitis media and interna.
- Ototoxic drugs—eliminated by history.
- Trauma—may cause similar acute changes; differentiated by history, results of physical examination.
- Hypothyroid neuropathy—usually not as acute in onset or as severe; may be associated with clinical signs of hypothyroidism and possible cranial nerve VII deficit.
- Neoplasia—either affecting CN VIII peripherally or in a central location; signs usually not as acute in onset as geriatric vestibular disease and signs persistent and usually progressive in nature.

CBC/BIOCHEMISTRY/URINALYSIS
- Generally normal.
- Hemoconcentration secondary to dehydration may be present.
- Unrelated concurrent disorders (e.g., renal and hepatic disease) associated with geriatric state may cause laboratory abnormalities.

OTHER LABORATORY TESTS
N/A

IMAGING
- Usually none required.
- Radiographs of tympanic bullae: normal radiographs do not rule out bulla disease.
- CT or MRI (preferred over radiographs)—may be required to rule out other causes such as otitis media and interna, central causes (e.g., ischemic event, neoplasia, inflammatory disease).

DIAGNOSTIC PROCEDURES
- Brainstem auditory evoked response—to assess cochlear portion of cranial nerve VIII; may help to evaluate for otitis media and interna since only the vestibular portion of cranial nerve VIII is affected with geriatric vestibular disease.
- Deafness may, however, be present as an unrelated aging change.

PATHOLOGIC FINDINGS
None reported.

TREATMENT

APPROPRIATE HEALTH CARE
- Mild disease—usually can manage as outpatient.
- Severe disease—patients that cannot ambulate or require IV fluid support should be hospitalized during the initial stages.

NURSING CARE
- Treatment supportive, including rehydration by IV fluids if required.
- Keep recumbent patients warm and dry using soft, absorbent bedding and, if required, urinary catheter.
- Severe disease—physical therapy, including passive manipulation of limbs and moving body to alternate sides, may be required initially.

ACTIVITY
Restrict activity as required by the degree of disorientation and vestibular ataxia.

DIET
- No modification usually required.
- Nausea, vomiting, and severe disorientation—initially withhold oral intake, then supervised feeding.

CLIENT EDUCATION
Reassure client that although the initial signs can be alarming and incapacitating, the prognosis for rapid improvement and recovery is excellent.

MEDICATIONS

DRUG(S) OF CHOICE
- Sedatives—for severe disorientation and ataxia; diazepam 2–10 mg/dog PO or IV q8h, acepromazine 0.02–0.05 mg/kg IM, SC, IV to maximum of 2 mg, dexmedetomidine 1–2 µg/kg IV.
- Antianxiety—trazodone approximately 5 mg/kg PO q8–24h.

(CONTINUED) VESTIBULAR DISEASE, GERIATRIC—DOGS

• Antiemetic drugs or drugs against motion sickness—questionable benefit; dimenhydrinate 4–8 mg/kg PO, IM, IV q8h, meclizine HCl 25 mg PO q24h, maropitant 1 mg/kg SC q24h for up to 5 days or 2 mg/kg PO q24h for up to 5 days.
• Glucocorticoids—not recommended since do not alter course of the disease; may exacerbate concurrent issues (e.g., dehydration).
• Antibiotics—recommended when otitis media and interna cannot be ruled out; trimethoprim-sulfa 15 mg/kg PO q12h or 30 mg/kg PO q12–24h; first-generation cephalosporin (e.g., cephalexin 10–30 mg/kg PO q12h); amoxicillin–clavulanic acid 12.5 mg/kg PO q12h, enrofloxacin 5–20 mg/kg PO q24h or divided q12h.

CONTRAINDICATIONS
N/A

FOLLOW-UP

PATIENT MONITORING
• Neurologic examination of outpatient—repeat 2–3 days later to confirm stabilization and initial improvement.
• Discharge inpatient when able to ambulate and resume eating and drinking.

PREVENTION/AVOIDANCE
N/A

POSSIBLE COMPLICATIONS
• Fluid and electrolyte imbalances and decompensation of preexistent renal insufficiency may follow vomiting and/or insufficient fluid and food intake.
• Pressure sores/abrasions.

EXPECTED COURSE AND PROGNOSIS
• Improvement of clinical signs usually starts within 72 hours with gradual resolution of vomiting and improvement of nystagmus and vestibular ataxia.
• Head tilt and ataxia—significant improvement usually occurs over 7–10 days; if no improvement other causes of peripheral vestibular disease should be pursued; mild head tilt may persist.
• Most patients return to normal within 2–3 weeks.
• Recurrence—repeat episodes of geriatric vestibular disease can occur on the same or opposite side but are uncommon; brief return of signs may occur with stress (e.g., anesthesia).

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Geriatric dogs affected (mean age suggested 12.5 years).

ZOONOTIC POTENTIAL

V

VESTIBULAR DISEASE, IDIOPATHIC—CATS

BASICS

DEFINITION
Acute-onset nonprogressive disturbance of the peripheral vestibular system of cats.

PATHOPHYSIOLOGY
- Unknown.
- Suspected abnormal flow of the endolymphatic fluid in the semicircular canals of the inner ear, secondary to a disturbance in the production, circulation, or absorption of the fluid.
- Possible intoxication of the vestibular receptors or inflammation of the vestibular portion of the vestibulocochlear nerve (cranial nerve VIII).

SYSTEMS AFFECTED
Nervous—peripheral vestibular system.

INCIDENCE/PREVALENCE
- Sporadic acquired disease.
- None reported.

SIGNALMENT

Species
Cat

Mean Age and Range
Any age; rare in cats <1 year of age.

SIGNS

General Comments
Limited to signs associated with peripheral vestibular disturbance.

Historical Findings
Sudden onset of severe disorientation, falling, rolling, leaning, vocalizing, and crouched posture; tendency to panic when picked up.

Physical Examination Findings
- Head tilt—always toward the side of the lesion; occasionally disease is bilateral with wide, side-to-side excursions of the head either without a head tilt or with a mild tilt toward the more severely affected side.
- Resting nystagmus—usually horizontal, but may be rotatory with the fast phase always in direction opposite to the head tilt; with bilateral disease, the abnormal nystagmus is usually mild or not present, and physiologic nystagmus or conjugate eye movements are diminished to absent.
- Vestibular ataxia with tendency to roll and fall toward the side of the head tilt.
- Preservation of strength and normal proprioception; with bilateral disease, patient may be reluctant to ambulate, preferring to stay in a crouched posture and possible wide-based stance.

CAUSES
- Unknown.
- Previous upper respiratory tract infection—suspected in some patients; relationship not confirmed; in limited necropsy data no evidence of inflammation.

RISK FACTORS
May be an increase in cases in the summer and early fall, possibly after outbreaks of upper respiratory disease; disease can occur throughout the year.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Diagnosis made on the basis of acute-onset peripheral vestibular signs that improve relatively rapidly without specific treatment.
- Otitis media and interna (e.g., bacterial, parasitic)—may have concurrent ipsilateral facial nerve (cranial nerve VII) paresis or paralysis, Horner's syndrome, deafness, ruptured tympanic membrane, otitis externa, and/or imaging changes in tympanic bulla; signs usually not self-limiting.
- Nasopharyngeal polyp(s)—may cause unilateral or, much less commonly, bilateral peripheral vestibular signs; may have concurrent tympanic bulla involvement; signs usually not as acute and severe at onset and are not self-limiting.
- Neoplasia—e.g., squamous cell carcinoma; signs usually not acute in onset; may have concurrent cranial nerve VII deficit and/or ipsilateral Horner's syndrome; signs not self-limiting.
- Blue-tailed lizard ingestion—southeastern United States; thought to produce a similar acute, unilateral, peripheral vestibular syndrome; vomiting, salivation, irritability, and trembling also noted; most patients recover without specific treatment.
- Aminoglycoside toxicity, especially streptomycin—may cause acute unilateral or bilateral peripheral vestibular syndrome and/or hearing loss; differentiated by history of drug use.
- Trauma—overzealous ear flushing; usually occurs when cleaning performed under general anesthesia or sedation; signs follow immediately upon recovery from anesthesia/sedation.

CBC/BIOCHEMISTRY/URINALYSIS
Normal

IMAGING
- None usually necessary.
- Radiographs of tympanic bullae: normal radiographs do not rule out bulla disease.
- CT or MRI—occasionally required to rule out other causes such as otitis media and interna, nasopharyngeal polyp(s) and neoplasia.

DIAGNOSTIC PROCEDURES
Brainstem auditory evoked response—may help rule out other causes (e.g., otitis media and interna; nasopharyngeal polyp(s), neoplasia); with idiopathic vestibular disease hearing not affected since disease limited to the vestibular portion of cranial nerve VIII.

PATHOLOGIC FINDINGS
None reported.

TREATMENT

APPROPRIATE HEALTH CARE
- Usually outpatient.
- Inpatient—severely affected patient may require hospitalization for supportive care.

NURSING CARE
- Mild disease—treatment supportive only.
- Severe disease—may require IV or subcutaneous fluids; maintain patient in quiet, well-padded cage.

ACTIVITY
Restricted according to the degree of disorientation and ataxia.

DIET
Patient may initially be reluctant to eat and drink because of disorientation and/or nausea.

CLIENT EDUCATION
Reassure client that, despite initial alarming and often incapacitating signs, the prognosis for rapid and complete recovery is excellent.

MEDICATIONS

DRUG(S) OF CHOICE
- Sedatives—for severe disorientation and rolling; diazepam 1–5 mg/cat PO q8–12h, acepromazine 0.02–0.05 mg/kg IM, SC, IV.
- Antiemetic drugs and drugs against motion sickness—questionable benefit; e.g., meclizine HCl 12.5 mg PO q24h, maropitant 1 mg/kg q24h PO, SC.
- Glucocorticoids—not recommended since do not alter course of the disease.
- Antibiotics—recommended if otitis media and interna cannot be ruled out; trimethoprim-sulfa 15 mg/kg PO q12h; first-generation cephalosporin (e.g., cephalexin 15–20 mg/kg PO q12h); drug of choice is amoxicillin/clavulanic acid (Clavamox 62.5 mg/cat PO q12h, Clavaseptin 12.5 mg/kg PO q12h).

FOLLOW-UP

PATIENT MONITORING
- Neurologic examination of outpatient—repeat in approximately 72 hours to confirm stabilization and initial improvement.

V

• Inpatient—discharge patient when able to ambulate and resume eating and drinking.

EXPECTED COURSE AND PROGNOSIS

• Marked improvement, especially in resting nystagmus starting within 72 hours, with progressive improvement of gait and head tilt.
• Patients usually normal within 2–3 weeks.
• Head tilt—final sign to resolve; mild residual tilt may remain.
• If signs do not improve rapidly, other causes of vestibular disease should be pursued.
• Rarely recurs.

VOMITING, CHRONIC

BASICS

DEFINITION
Persistent vomiting lasting longer than 5–7 days or vomiting that occurs intermittently several days/week. This condition is usually nonresponsive to symptomatic treatment.

PATHOPHYSIOLOGY
- Vomiting occurs when the vomiting center, located within the medulla oblongata, is activated by the humoral or neural pathway.
- There are four main components to the vomiting reflex: (1) visceral receptors within the gastrointestinal (GI) tract; (2) vagal and sympathetic afferent neurons; (3) chemoreceptor trigger zone (CRTZ); and (4) vomiting center.
- The humoral pathway is mediated via activation of the CRTZ and is affected by bloodborne triggers such as uremic toxins, drug toxicity, and endotoxemia.
- The neural pathway is mediated via activation of the vomiting center and is affected by disorders associated with obstruction, distension, or inflammation of the GI tract.
- All causes of vomiting (including the vestibular apparatus and cerebrum) are ultimately mediated via the vomiting center.

SYSTEMS AFFECTED
- Endocrine/metabolic—dehydration, electrolyte and acid-base imbalances.
- Cardiovascular—hypovolemia; electrolyte or acid–base imbalances can cause arrhythmias.
- GI—esophagitis and subsequent esophageal stricture.
- Respiratory—aspiration pneumonia.
- Nervous—altered mentation.

SIGNALMENT
- Dog and cat.
- Young animals are more likely to ingest foreign bodies; linear foreign bodies are more common in cats.
- Confirmed or suspected breed predispositions—brachycephalic breeds are prone to pyloric outflow obstruction secondary to mucosal hypertrophy; basenji, German shepherd dog, and shar-pei are prone to inflammatory bowel disease (IBD); Rottweiler are prone to eosinophilic IBD; Airedale terrier prone to pancreatic carcinoma; beagle, Bedlington terrier, cocker spaniel, Doberman pinscher, Labrador retriever, Skye terrier, and standard poodle are prone to chronic hepatitis. Yorkshire terrier predisposed to intestinal lymphangiectasia.

SIGNS
Historical Findings
- Hematemesis, decreased appetite or anorexia, and melena, may suggest gastric disease.
- Diarrhea and profound weight loss may suggest intestinal disease.
- Signs such as weakness, polyuria, or jaundice may relate to other underlying metabolic diseases.

Physical Examination Findings
- Weight loss and poor hair coat may indicate chronic malnutrition.
- Abdominal palpation may reveal abdominal distention, pain, thickened bowel loops, lymphadenopathy, or mass effects.
- Tacky mucous membranes and prolonged skin tenting if dehydration is present; pale membranes if patient is anemic.
- Oral examination may reveal uremic ulcerations or sublingual string foreign bodies.
- Rectal examination may detect diarrhea, hematochezia, or melena.

CAUSES
Esophageal Disease
- Hiatal hernia (more commonly associated with regurgitation).
- Gastroesophageal reflux (more commonly associated with regurgitation).

Infectious Disease
- *Helicobacter*-related gastritis.
- Histoplasmosis.
- Pythiosis.
- Small intestinal bacterial overgrowth.
- Gastric or intestinal parasites.

Metabolic Diseases
- Renal disease.
- Hepatobiliary disease.
- Hypoadrenocorticism.
- Chronic pancreatitis.
- Diabetic ketoacidosis (DKA).
- Electrolyte abnormalities—hypo-/hyperkalemia, hyponatremia, hypercalcemia.

Inflammatory Bowel Disease
- Lymphocytic, plasmacytic, eosinophilic, or granulomatous.
- Gastritis, enteritis, or colitis.

Obstructive GI Disease
- Foreign body.
- Chronic hypertrophic pyloric gastropathy.
- Intussusception.

Neoplastic Disease
- GI lymphoma, adenocarcinoma, fibrosarcoma, GI stromal cell tumor.
- Pancreatic adenocarcinoma.
- Gastrin-secreting tumor (gastrinoma).
- Mast cell tumor.

Neurologic
- Cerebral edema.
- CNS tumors.
- Encephalitis/meningoencephalitis.
- Vestibular disease.

Motility Disorders
- Postgastric dilatation.
- Postsurgical—gastric, duodenal.
- Electrolyte imbalances.
- Ileus.

Miscellaneous
- Drugs (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], glucocorticoids, chemotherapeutics, antibiotics, antifungals).
- Food sensitivity.
- Toxicity.

Additional Causes
- Parasitic (cats)—dirofilariasis, *Ollulanus tricuspis*.
- Inflammatory—cholecystitis, cholangiohepatitis.
- Metabolic—hyperthyroidism.
- Functional—constipation/obstipation.

RISK FACTORS
Breed-associated disease (see Signalment).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Vomiting must first be differentiated from regurgitation.
- Regurgitation is a passive process and occurs without an abdominal component, thus localizing disease to the esophagus.
- Vomiting is a centrally mediated reflex often preceded by prodromal signs of restlessness, nausea, salivation, and repeated swallowing.

CBC/BIOCHEMISTRY/URINALYSIS
- Chronic GI bleeding can cause a non-regenerative anemia, often with characteristics of iron deficiency (microcytosis, hypochromasia, thrombocytosis).
- Non-regenerative anemia may also occur secondary to chronic metabolic or inflammatory diseases.
- Inflammatory conditions may cause neutrophilic leukocytosis and monocytosis.
- Eosinophilia can occur from eosinophilic IBD, hypoadrenocorticism, and GI parasitism.
- Thrombocytopenia has been reported with IBD.
- Dehydration increases the packed cell volume and total protein.
- Electrolyte and acid–base imbalances reflect severity of losses and can help to localize disease.
- Hypochloremic metabolic alkalosis, often with hypokalemia, suggests gastric outflow obstruction.
- Hyperkalemia suggests hypoadrenocorticism or oliguric/anuric renal failure; occasionally, enteritis caused by trichuriasis or bacterial infection (salmonellosis) mimics hypoadrenocorticism.
- Metabolic acidosis is common in patients with dehydration, renal failure, DKA, and severe gastroenteritis with diarrhea.

• Increased liver enzyme activity, hypoalbuminemia, hyperbilirubinemia, hypoglycemia, or low urea nitrogen concentration suggest hepatic disease.
• Persistent hyperglycemia and glucosuria is consistent with diabetes mellitus.
• Hyperglobulinemia may indicate chronic inflammation or infection.
• Hypoproteinemia, hypocholesterolemia, lymphopenia, and hypomagnesemia occur secondary to a protein-losing enteropathy caused by infiltrative intestinal diseases such as lymphocytic plasmacytic gastroenteritis, neoplasia, histoplasmosis, or intestinal lymphangiectasia.
• Urinalysis is used to rule out renal failure and DKA.
• Aciduria in the hypokalemic, hypochloremic, alkalotic patient suggests gastric outflow obstruction.

OTHER LABORATORY TESTS

• Resting cortisol to screen for hypoadrenocorticism. A resting cortisol <2 µg/dL should be followed with an ACTH stimulation test.
• Pancreatic lipase immunoreactivity assay may help confirm pancreatitis together with supportive history, physical exam findings, and ultrasound.
• Serum cobalamin and folate as indicators of intestinal absorption.
• Pre- and postprandial bile acids to screen for hepatobiliary dysfunction.
• Fecal testing for GI parasitism.

IMAGING

• Survey radiographs of the abdomen help identify foreign bodies, GI distension with fluid or gas, and displacement, malposition, shape, and/or size changes of abdominal organs.
• Survey radiographs of the thorax are used to evaluate for pulmonary metastases, gross esophageal abnormalities, or infectious disease.
• A barium upper GI series can be used to identify foreign bodies, GI wall masses or infiltrative disease, mucosal ulceration, delayed gastric emptying, and motility disorders; however, the procedure is relatively insensitive for detection of mucosal ulceration.
• Abdominal ultrasonography to identify abnormalities of the liver, gallbladder, kidneys, pancreas, GI tract, and mesenteric lymph nodes.
• CT and MRI further evaluate for abnormalities of abdominal organs.

DIAGNOSTIC PROCEDURES

• Gastroduodenoscopy—allows direct inspection of the gastric and intestinal lumen to identify gross mucosal lesions and foreign bodies and provides a minimally invasive method of biopsy to evaluate for microscopic disease. Limitations of endoscopy include the working length of the endoscope (unable to access the jejunum in large-breed dogs) and depth of the biopsies.
• Laparoscopy or exploratory laparotomy is used for more extensive diagnostic and therapeutic procedures.

TREATMENT

APPROPRIATE HEALTH CARE

Specific treatment should be aimed at eliminating the underlying cause in conjunction with supportive therapy. Care may be inpatient or outpatient depending on the case.

NURSING CARE

• If vomiting is intractable, stop oral intake of food and water for 12–24 hours or until the vomiting episodes are better controlled with antiemetics.
• Use crystalloid fluid therapy to replace deficits and to provide for maintenance and ongoing losses.
• Supplement potassium if hypokalemia is present; 20 mEq of KCl/L of fluid can be safely added for replacement and maintenance; use higher concentrations if severe hypokalemia is present.

DIET

• Debilitated patients and those in poor nutritional condition may need supplemental parenteral or enteral nutrition.
• Dietary therapy for patients with suspected food allergy or with IBD should use an elimination diet containing a single, novel protein source or a hydrolyzed diet.

CLIENT EDUCATION

Dependent on underlying disease.

SURGICAL CONSIDERATIONS

Use surgical treatment if uncontrolled hemorrhage, obstruction, or perforation is suspected.

MEDICATIONS

DRUG(S) OF CHOICE

• Antisecretory drugs such as H_2-receptor blockers (e.g., famotidine, ranitidine) or proton pump inhibitors such as omeprazole (more potent)—famotidine 0.5–1 mg/kg PO, IV, or SC q12h; ranitidine 1–2 mg/kg PO, IV q12h; omeprazole 0.7–1.5 mg/kg PO q12h.
• Protectants such as sucralfate 0.25–1 g/dog PO q6–12h or 0.25 g/cat PO q6–12h to accelerate gastric mucosal healing; can be used with antisecretory drugs for patients with evidence of upper GI bleeding (e.g., hematemesis or melena).
• Antibiotics—indicated for treatment of *Helicobacter*-associated gastritis, small intestinal bacterial overgrowth (SIBO), and as an adjunct to corticosteroids in the treatment of IBD.
• Metronidazole—may be used at 10 mg/kg PO q12h in conjunction with corticosteroids to treat IBD, although evidence of direct benefit of this approach is currently lacking.
• Antibiotic-responsive enteropathy (tylosin-responsive enteropathy)—tylosin is the drug of choice administered at 10–40 mg/kg q12h for 8–12 weeks. Alternative option is metronidazole 10 mg/kg q12h for 8–12 weeks, although tylosin may be superior for this disorder.
• Use corticosteroids in conjunction with dietary changes to treat biopsy-confirmed IBD; azathioprine, chlorambucil, or cyclosporine can also be used in patients with poor response to corticosteroids alone or to decrease the dosage of steroids required to control symptoms. Avoid the use of more than two immunomodulatory drugs given concurrently.
• Prokinetic drugs (e.g., metoclopramide, cisapride, or erythromycin) are used to treat delayed gastric emptying not associated with obstructive disease. Metoclopramide 0.2–0.5 mg/kg IV, IM, PO q6–8h; more effective as a CRI of 1–2 mg/kg q24h in hospitalized patients.
• Pyrantel pamoate is effective for *Physaloptera*; fenbendazole is effective for *Ollulanus*.
• Iron supplementation for animals with chronic GI bleeding that develop microcytic hypochromic anemia.
• Surgery and/or chemotherapy for neoplasia, depending on the tumor type and location.
• Paraneoplastic hypersecretion of gastric acid, as occurs with mastocytosis and gastrin-secreting pancreatic tumors, is best treated with antisecretory drugs (e.g., omeprazole).
• Reserve antiemetics for patients with persistent vomiting unresponsive to treatment of the underlying disease. Maropitant 1 mg/kg SC q24h, 2 mg/kg PO q24h. Chlorpromazine 0.5 mg/kg SC, IM q6–8h. Ondansetron 0.2–0.5 mg/kg SC, IV q8–12h, 0.5–1.0 mg/kg PO q12h.
• Vomiting caused by chemotherapy is best treated with ondansetron 0.5–1 mg/kg IV, PO given 30 minutes before chemotherapy.

CONTRAINDICATIONS

N/A

PRECAUTIONS

• Do not give α-adrenergic blockers such as chlorpromazine to dehydrated patients as they can cause hypotension.
• Use antiemetics with caution, as they can mask the underlying problem.
• Metoclopramide can cause lethargy, restlessness, agitation, and other behavioral changes, particularly in cats.
• Corticosteroids are immunosuppressive and are a risk factor for development of GI

VOMITING, CHRONIC (CONTINUED)

ulceration; use caution when treating IBD with corticosteroids at high dosages or for long periods.
• Azathioprine and chlorambucil are myelotoxic; monitor CBCs for neutropenia and thrombocytopenia every 2 weeks for the first month of treatment and monthly thereafter.
• Cyclosporine can exacerbate vomiting and diarrhea when used at high dosages; use with caution in patients with renal disease.
• Do not use anticholinergics as antiemetics, as they can exacerbate vomiting by causing gastric atony and gastric retention.
• Metoclopramide and cisapride are contraindicated in patients with GI obstruction.

POSSIBLE INTERACTIONS
Ranitidine interferes with hepatic metabolism of theophylline, phenytoin, and warfarin, and should not be used concurrently with these drugs. Avoid use of cimetidine because it is a weak H_2-receptor antagonist and is a potent inhibitor of the cytochrome P450 enzyme pathway.

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
• Frequency of vomiting.
• Body weight; body condition score.

PREVENTION/AVOIDANCE

V

VON WILLEBRAND DISEASE

BASICS

DEFINITION
• Primary hemostatic defect caused by a quantitative or functional deficiency of von Willebrand factor (VWF).
• Clinical expression varies from a mild to severe bleeding diathesis.

PATHOPHYSIOLOGY
• VWF is an adhesive plasma protein required for platelet binding at sites of small vessel injury. In addition, plasma VWF is a carrier protein for coagulation factor VIII.
• A lack of VWF impairs platelet adhesion and aggregation, especially at vascular sites under high shear stress (e.g., arterial vessels). The largest molecular weight (MW) forms of VWF demonstrate highest reactivity in supporting platelet–collagen interactions.

SYSTEMS AFFECTED
• VWF deficiency may cause spontaneous hemorrhage, prolonged post-traumatic hemorrhage, and ultimately blood-loss anemia.
• Spontaneous hemorrhage—typically manifests as bleeding from mucosal surfaces.

GENETICS
• An autosomal trait; both males and females express and transmit the defect with equal frequency.
• Expression pattern of severe forms (types 2 and 3 von Willebrand disease [VWD]) is recessive; the milder form (type 1 VWD) appears to be recessive or incomplete dominant.

INCIDENCE/PREVALENCE
• The most common hereditary hemostatic defect in dogs.
• Rarely reported in cats.

GEOGRAPHIC DISTRIBUTION
None

SIGNALMENT

Breed Predilections
• Three type classifications are found in dogs; a single type predominates within each affected breed.
• Type 1 VWD (mild to moderate signs)—quantitative deficiency. Low VWF concentration (VWF:Ag)with proportionate decrease in VWF function. Type 1 is the most common classification:
  ◦ Breeds—Airedale terrier, Akita, basset hound, Bernese mountain dog, dachshund, Doberman pinscher, German shepherd dog, golden retriever, greyhound, Irish wolfhound, Manchester terrier, miniature pinscher, Pembroke Welsh corgi, poodle, and sporadic cases in other purebred and mixed-breed dogs.
• Type 2 VWD (severe signs)—quantitative and functional protein defect; low VWF:Ag with profound lack of activity due to absence of high MW multimers:
  ◦ Breeds—German wirehaired and shorthaired pointers.
• Type 3 VWD (severe signs)—complete lack of plasma VWF:
  ◦ Breeds—Chesapeake Bay retriever, Dutch kooiker, Scottish terrier, Shetland sheepdog, and sporadic cases in dogs of other breeds.

Mean Age and Range
• Severe (types 2 and 3 VWD) typically manifests by 3–6 months of age.
• Milder forms typically demonstrate abnormal bleeding after surgery or trauma, or in association with another condition that impairs hemostasis.

SIGNS

Physical Examination Findings
• Hemorrhage from mucosal surfaces—epistaxis, gastrointestinal hemorrhage, hematuria, vaginal hemorrhage, gingival hemorrhage.
• Prolonged bleeding after surgery or trauma.
• Blood loss and/or iron-deficiency anemia, if prolonged hemorrhage.
• Petechiae rarely present.

CAUSES
Hereditary VWD is caused by mutations that impair VWF synthesis, release, or stability.

RISK FACTORS
Acquired disease conditions or drug therapy that impair platelet function may exacerbate clinical signs of VWD.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
• Thrombocytopenia.
• Acquired coagulation factor deficiency (often associated with liver disease, vitamin K deficiency, or disseminated intravascular coagulation [DIC]).
• Acquired platelet function defects (often associated with drug therapy, uremia, hyperproteinemia).
• Hereditary coagulation factor deficiencies (see Coagulation Factor Deficiency).
• Hereditary platelet function defects (see Thrombocytopathies).

CBC/BIOCHEMISTRY/URINALYSIS
• Regenerative anemia develops after blood loss.
• Platelet count is normal unless the patient has experienced acute, massive bleeding.

OTHER LABORATORY TESTS
• Coagulation screening tests (activated clotting time, activated partial thromboplastin time, prothrombin time, thrombin clot time, fibrinogen concentration)—within reference intervals.
• Clinical diagnosis based on specific measurement of plasma VWF:Ag:
  ◦ VWF:Ag <50% indicates VWF deficiency, but clinical signs of abnormal bleeding typically develop in animals with VWF:Ag < 25%.
  ◦ Types 1 and 2 VWD are characterized by low VWF:Ag, whereas type 3 VWD is defined as a complete absence of detectable protein (VWF:Ag <0.1%).
• Types 1 and 2 VWD are differentiated with functional and/or structural VWF analyses:
  ◦ Von Willebrand factor collagen binding assay (VWF:CBA) is a functional measure of VWF/collagen affinity. Dogs with type 2 VWD have a relative lack of VWF:collagen binding activity (CBA) compared to VWF:Ag, resulting in a protein concentration to function ratio >2:1. Dogs with type 1 VWD have proportionate protein concentration and function.
• VWF multimer structure is visualized on Western blots. Dogs with type 2 VWD lack the highest MW forms.

DIAGNOSTIC PROCEDURES
• Buccal mucosal bleeding time (BMBT) and the platelet function analyzer-100 are point-of-care screening tests whose endpoints are prolonged in patients with platelet aggregation defects or VWF deficiency. Prolongation is also found in patients with thrombocytopenia, anemia, or changes in blood viscosity.
• BMBT (expected values 2–4 minutes)—typical values for type 1 VWD = 5–10 minutes, types 2 and 3 VWD >12 minutes.
• PFA-100 closure times (expected ADP/collagen closure time <120 seconds): typical values for type 1 VWD = 150–300 seconds, types 2 and 3 VWD >300 seconds.

PATHOLOGIC FINDINGS
Hemorrhage is the only associated abnormality. Morbidity and mortality are caused by blood loss or hemorrhage into critical sites (i.e., CNS, respiratory tract).

TREATMENT
• Transfusion of fresh whole blood, fresh plasma, fresh frozen plasma, and cryoprecipitate will supply VWF.
• Component therapy (fresh frozen plasma, 10–12 mL/kg, IV) or cryoprecipitate (1 unit per 10 kg body weight, IV) is best for surgical prophylaxis and non-anemic patients, to prevent red cell sensitization and volume overload.
• Patients with severe VWD may require repeated transfusions to control or prevent hemorrhage.

VON WILLEBRAND DISEASE (CONTINUED)

SURGICAL CONSIDERATIONS

• Preoperative transfusion should be given just before the procedure. Peak VWF is obtained immediately after transfusion, with values falling to baseline by 24 hours after a single dose.
• Cage rest and close monitoring (serial HCT and examination of surgical site) for 24 hours after surgery are ideal to confirm adequate hemostasis. Management of severe VWD typically requires at least one postoperative transfusion.

MEDICATIONS

DRUG(S) OF CHOICE

• Desmopressin acetate (DDAVP) is a vasopressin analogue that can be given preoperatively to dogs with mild to moderate type 1 VWD to enhance surgical hemostasis. Dosage is 1 µg/kg SC, given 30 minutes before surgery.
• Response is variable; transfusion should be available if DDAVP alone does not prevent bleeding.

CONTRAINDICATIONS

Avoid drugs with anticoagulant or antiplatelet effects: NSAIDs, sulfonamide antibiotics, heparin, wafarin, hetastarches, estrogen, cytotoxic drugs.

FOLLOW-UP

PATIENT MONITORING

Observe closely for hemorrhage associated with trauma or surgical procedures.

PREVENTION

• Screen dogs preoperatively to determine baseline VWF:Ag in breeds or lines with high prevalence of VWD. The risk of abnormal bleeding is greatest for dogs with VWF:Ag <25%.
• Clinically affected dogs should not be bred. Carriers of VWD can be identified based on low VWF:Ag (<50%). However, values for carrier and clear dogs may overlap at the low end of the reference interval (50–70% VWF:Ag). Commercial laboratories offer genetic tests to detect specific VWF mutations in several breed-variants of VWD. Dogs that are heterozygous for a specific mutation are considered VWD "carriers" and homozygotes are considered VWD "affected."
• Selective breeding practices can reduce or eliminate VWD from an affected pedigree. Breeding two clear parents is ideal because all offspring are expected to be clear. Breeding one clear and one carrier parent may be acceptable, with the clear pups produced from these matings used for subsequent breeding. Carrier-to-carrier matings are inadvisable because they are most likely to produce clinically affected offspring.

EXPECTED COURSE AND PROGNOSIS

• Most dogs with mild to moderate VWD have good quality of life and require minimal or no special treatment.
• Dogs with more severe forms require transfusion for surgery and should be transfused if supportive care fails to control a spontaneous bleed. Most of these dogs can be maintained comfortably in pet homes.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• The development of any disease condition that impairs platelet function may exacerbate the bleeding tendency of VWD. Common conditions include thrombocytopenia, endocrinopathy (hypothyroidism, hypoadrenocorticism), hyperproteinemia, and uremia.
• Acquired VWD occurs in humans with aortic stenosis, and features of type 2 VWD have been reported in cavalier King Charles spaniels with mitral valve disease.

PREGNANCY/FERTILITY/BREEDING

See Prevention for breeding recommendations.

SYNONYMS

VWF protein was formerly referred to as factor VIII-related antigen.

ABBREVIATIONS

• BMBT = buccal mucosal bleeding time.
• DDAVP = deamino-8-D-arginine vasopressin.
• DIC = disseminated intravascular coagulation.
• HCT = hematocrit.
• MW = molecular weight.
• NSAID = nonsteroidal anti-inflammatory drug.
• PFA = platelet function assay.
• VWF = von Willebrand factor.
• VWF:Ag = von Willebrand factor antigen.
• VWF:CBA = von Willebrand factor collagen binding assay.

WEIGHT LOSS AND CACHEXIA

BASICS

DEFINITION
• Weight loss—loss of body weight (BW) resulting from reduction in fat mass and/or lean body mass.
• Lean body mass (LBM)—tissues other than adipose tissue (muscle, organs, bone); skeletal muscle is most dynamic component.
• Simple starvation—acute or chronic decrease in food intake below caloric requirements in an otherwise healthy animal; adaptive responses allow loss of fat mass over LBM.
• Cachexia—weight loss and tissue wasting secondary to underlying disease (e.g., cancer, heart failure, inflammatory conditions). Hallmark is loss of LBM; fat mass is variably affected.
• Sarcopenia—age-related muscle loss and decline in muscle quality. Can occur without loss of BW.

PATHOPHYSIOLOGY

Weight Loss and Simple Starvation
• Decreased caloric intake or increased energy expenditure results in negative energy balance.
• In otherwise healthy animals, compensation such as reduced metabolism and a shift toward lipid-based energy production reduce protein catabolism by up to two-thirds.

Cachexia
• Occurs secondary to acute or chronic disease (see Causes).
• Pathophysiology better evaluated in humans than dogs and cats:
  ◦ Upregulation of inflammatory cytokines (e.g., interleukin-6 [IL-6], tumor necrosis factor-α [TNF-α]), catecholamines, neurohormones and cortisol.
  ◦ Increases in oxidative stress; activation of catabolic pathways (e.g., ubiquitin-proteasome system).
  ◦ Decreases in anabolic factors (e.g., growth hormone [GH], insulin-like growth factor I [IGF-1]).
• Results in dysregulation of appetite, insulin resistance, increased muscle catabolism, and impaired tissue synthesis.
• Increased basal metabolic rate and metabolic inefficiencies contribute to tissue wasting.
• Secondary anorexia aggravates malnutrition and muscle catabolism.

Sarcopenia
• Occurs during normal aging in the absence of disease; may occur alongside cachexia.
• Inflammation, oxidative stress, and catabolic pathway upregulation likely contribute to LBM loss similarly to cachexia.

SYSTEMS AFFECTED
• Musculoskeletal—progressive loss of LBM causes weakness, fatigue, and exercise intolerance.
• Hemic/lymphatic/immune—serous atrophy of fat can rarely cause bone marrow hypoplasia and pancytopenia.
• Underlying diseases leading to cachexia can affect all body systems.

GENETICS
N/A

INCIDENCE/PREVALENCE

Weight Loss
• Congestive heart failure (CHF)—42.5% of dogs; 34% of cats.
• Cancer—5.5–69% of dogs; 60% of cats.
• Chronic kidney disease (CKD)—28.9–55% of dogs; 36–81% of cats.

Cachexia
• CHF—48.3–54% of dogs; unknown in cats.
• Cancer—35% of dogs; 91% of cats.
• CKD—28.9% of dogs (weight loss/cachexia); 81% of cats.

GEOGRAPHIC DISTRIBUTION
N/A

SIGNALMENT

Species
Dog and cat.

Breed Predilections
N/A

Mean Age and Range
Risk of sarcopenia and cachexia increases with age.

Predominant Sex
None

SIGNS

General Comments
• Body Condition Score (BCS)—palpation/observation of fat deposits over ribs, lumbar spine, abdominal fat pad (cats), and tail base:
  ◦ Scored 1 (severe fat loss) to 9 (obesity).
• Muscle Condition Score (MCS)—palpation/visualization of muscle of spine, skull, scapulae, and wings of the ilia:
  ◦ Graded as none, mild, moderate, or severe muscle wasting.
• BCS and MCS *must* be evaluated separately, as loss of LBM can occur without loss of fat or change in BW.

Historical Findings
• Appetite may be normal, increased, decreased, or absent depending on cause.
• History should focus on identifying underlying disease (see Causes).

Physical Examination Findings
• Decreased BW compared to historical weights (corrected for hydration changes, fluid accumulation, etc.).
• Decreased absolute or relative BCS (fat loss) and/or MCS (LBM loss).
• Other physical examination findings may indicate underlying disease process (see Causes).

CAUSES

Physiologic Negative Energy Balance
• Simple starvation.
• Competition in a multi-pet household.
• Increased physical activity.
• Prolonged or extreme cold environment.
• Pregnancy or lactation.

Anorexia/Pseudoanorexia
• Inability to smell, prehend, or chew food.
• Dysphagia.
• Nausea.
• Regurgitation.
• Vomiting.
• Pain or anxiety.
• Iatrogenic (e.g., drug side effects).

Maldigestive/Malabsorptive
• Inflammatory bowel disease.
• Intestinal neoplasia (lymphoma, carcinoma, sarcoma).
• Lymphangiectasia.
• Age-related decreases in digestive function.
• Exocrine pancreatic insufficiency.

Infectious
• Severe intestinal parasitism.
• Infiltrative fungal disease (e.g., histoplasmosis).
• Protozoal (e.g., *Toxoplasma gondii*, *Neospora caninum*).
• Feline leukemia virus/feline immunodeficiency virus (cats).

Metabolic
• Organ failure (e.g., cardiac, hepatic, or renal failure).
• Hypo- or hyperadrenocorticism.
• Hyperthyroidism (cats).
• Cancer.
• Diabetes mellitus.

Excessive Nutrient Loss or Consumption
• Protein-losing enteropathy.
• Protein-losing nephropathy.
• Extensive skin lesions (e.g., burns).
• Chronic effusive disease (e.g., chylothorax).
• Increased catabolism (e.g., fever, infection, inflammation, cancer).

Neuromuscular
• Lower motor neuron disease.
• Myopathy/myositis.
• CNS disease—usually associated with anorexia or pseudoanorexia.

RISK FACTORS
• Age.
• See Causes.

DIAGNOSIS
Evaluate BW, BCS, and MCS (compare to historical values).

DIFFERENTIAL DIAGNOSIS
• See Causes.
• Increased appetite may indicate physiologic, maldigestive/malabsorptive, or metabolic cause.

WEIGHT LOSS AND CACHEXIA (CONTINUED)

• Fever may indicate inflammatory or infectious cause.

CBC/BIOCHEMISTRY/URINALYSIS
• Laboratory tests may indicate underlying cause.
• Low hematocrit, low albumin, increased BUN, and increased BUN to creatinine ratio may be associated with malnutrition.

OTHER LABORATORY TESTS
• Determined by most likely differential diagnoses (see Causes).
• Serum T_4 in any cat >5 years old.
• Rule out infectious (parasitic, protozoal, viral, and fungal) causes:
  ◦ Fungal antigen testing, FeLV/FIV, fecal centrifugal flotation, etc.
• Serum trypsin-like immunoreactivity (TLI), cobalamin and folate for maldigestive/absorptive disease.
• Fecal alpha-1 protease inhibitor level for protein-losing enteropathy.
• ACTH stimulation test for hypoadrenocorticism.
• Pre- and postprandial serum bile acids for hepatobiliary disease.
• Urine protein:creatinine ratio for protein-losing nephropathy.

IMAGING
• Thoracic/abdominal radiographs, abdominal ultrasound, CT, and/or echocardiography may help identify underlying cause.
• Ultrasound, CT, or dual energy x-ray absorptiometry (DEXA) might be used to approximate LBM.

W

DIAGNOSTIC PROCEDURES
Vary per suspected underlying cause.

PATHOLOGIC FINDINGS
Histopathology—cachexia may cause preferential atrophy of type II myofibers.

TREATMENT
Treat the underlying disease and provide appropriate nutritional support.

APPROPRIATE HEALTH CARE
• Depends on hemodynamic stability, voluntary food intake, and underlying disease type/severity.
• Anorexic patients refractory to supportive care should be hospitalized or managed as outpatients with a feeding tube.

NURSING CARE
• Nursing needs depend on underlying disease.
• Daily cleaning, regular flushing, and monitoring of feeding tubes to prevent infection/clogging.
• Debilitated patients with severe cachexia should have adequate padding and be rotated frequently to prevent decubital ulcers.

ACTIVITY
• Physical therapy, exercise, and rehabilitation may slow cachexia/sarcopenia progression:
  ◦ Increase caloric intake appropriately.

DIET
• Resting energy requirements (RER) = 70 kcal × kg $BW^{0.75}$; may need to exceed RER in cachectic patients, if tolerated:
  ◦ Maintenance energy requirement [MER] for neutered adult dog: 1.6 × RER, but may exceed 2.0–3.0 × RER in individual patients.
  ◦ MER for neutered adult cat: 1.2 × RER, but may be higher in individual patients.
• Unless contraindicated, exceed Association of American Feed Control Officials (AAFCO) protein minimum in cachectic patients:
  ◦ Dogs—4.5 g/100 kcal; cats—instead of: 6.5 g/100 kcal.
  ◦ Most critical care, performance, and growth diets are high in protein and fat.
  ◦ Kitten foods may be suitable for adult cats; cat foods may be suitable for dogs.
• Prolonged anorexia—deliver 25–33% of RER on day 1; gradually increase to 100% RER over 3–5 days, if tolerated:
  ◦ Monitor serum potassium, phosphorus, and magnesium during refeeding; supplement if needed.

Oral Nutrition
• Preferred if patient is physically able to ingest, digest and absorb nutrients.
• To increase voluntary food intake, offer palatable food several times daily; offer the patient's usual food; offer moist food unless dry is preferred; offer food warmed to body temperature.
• Consider diets enriched with eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) for cachectic patients or those with inflammatory conditions (e.g., therapeutic diets for arthritis or dermatologic conditions):
  ◦ Most diets provide less than recommended EPA/DHA amounts (see below); additional supplementation may be beneficial.
• If underweight patients refuse therapeutic diets (e.g., renal diet), try alternate brand or texture, add broth or other palatability enhancer:
  ◦ Adequate intake of a maintenance diet is typically preferable to inadequate intake of a therapeutic diet.
• Consider appetite stimulants (see Medications).
• Forced feeding is rarely effective and is not recommended due to high risk of aspiration.

Enteral Nutrition
• Preferred if patient is anorexic/pseudoanorexic but can digest and absorb nutrients.
• Place feeding tubes as far proximal in the GI tract as tolerated.
• Nasoesophageal or nasogastric tubes (5–12Fr) can be used temporarily. Due to small tube size, only liquid diets can be used.
• Esophagostomy (12–18Fr) or gastrostomy tubes (16–24Fr) are semi-permanent:
  ◦ Preferred over nasogastric tubes for outpatient management.
  ◦ Allow higher caloric-density slurry diets, therapeutic diets, medication, and oral water administration.
• Liquid/slurry feedings q6–8h; initial feedings <10 mL/kg/feeding.
• Jejunostomy or gastro-jejunostomy tubes (5–8Fr) are more difficult to place and manage, and require liquid diets fed via chronic infusion:
  ◦ Rarely indicated.

Parenteral Nutrition
• Only if enteral feeding is contraindicated.
• If required, recommend referral to an appropriate tertiary facility.

CLIENT EDUCATION
• Feeding tube management and expectations, if considering placement.
• See Expected Course and Prognosis.

SURGICAL CONSIDERATIONS
• If surgery is indicated, consider placing a feeding tube at that time.
• Severe cachexia or weight loss (especially if albumin is low) may prolong healing.

MEDICATIONS

DRUG(S) OF CHOICE
• Appropriate medications for underlying cause (if identified).
• Therapies targeting catabolic pathways are currently being investigated.

Appetite Stimulants
• Adjust selection and dosage based on underlying disease.
• Mirtazapine: 7.5 and 15 mg tablets; 2% transdermal suspension (cats):
  ◦ Cats: 1.88 mg/cat PO q24–48h; 2 mg/cat transdermally q24–48h.
  ◦ Dogs: 1–30 mg/dog PO q8–24h; recommend 1 mg/kg PO q8–12h.
• Capromorelin: 30 mg/mL oral suspension:
  ◦ Dogs: 3 mg/kg PO q24h.
  ◦ Extra-label dose not established in cats (6 mg/kg tolerated).
  ◦ Also increases IGF-1 secretion.

Omega-3 Fatty Acids
• Fish oil, krill oil, omega-3 supplements:
  ◦ Vary widely in EPA and DHA content; check each supplement individually.
• Dogs and cats—40 mg/kg/day EPA + 25 mg/kg/day DHA:
  ◦ Avoid fish oil supplements with vitamins A and D if using at this dose.

CONTRAINDICATIONS
N/A

PRECAUTIONS
Treatments for underlying diseases may cause anorexia, nausea.

POSSIBLE INTERACTIONS
Mirtazapine can cause serotonin syndrome if combined with multiple other medications, including selective serotonin reuptake inhibitors (e.g., fluoxetine) and monamine oxidase inhibitors (e.g., selegeline).

ALTERNATIVE DRUG(S)
N/A

FOLLOW-UP

PATIENT MONITORING
- Appropriate monitoring for underlying disease (see Causes).
- *Precisely* monitor food intake and BW to ensure daily intake of RER/MER.
- Serial monitoring of BW, BCS, MCS *at every visit*.

PREVENTION/AVOIDANCE
- Early recognition of loss of BW and/or LBM and early intervention are key in preventing debilitation:
  - Perform thorough nutritional assessment at each visit and implement nutritional interventional plan when necessary.
  - Perform diagnostic workup to identify underlying cause of unintended weight loss.
- Aggressive management of diseases associated with cachexia.

POSSIBLE COMPLICATIONS
Tube feeding—infection, vomiting, regurgitation and/or diarrhea; tube displacement; aspiration; peritonitis (gastrostomy or jejunostomy tubes).

EXPECTED COURSE AND PROGNOSIS
- Provision of nutrition to cachectic patients without addressing the underlying cause is rarely successful in correcting the loss of body tissues.
- Weight loss, LBM loss, or poor body or muscle condition are associated with shorter survival in veterinary cardiac, CKD and cancer patients.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Cachexia and sarcopenia are more common in geriatric patients.

ZOONOTIC POTENTIAL
N/A

PREGNANCY/FERTILITY/BREEDING
Lactation and pregnancy may cause weight loss due to increased calorie expenditure.

SYNONYMS
- Emaciation.
- Debilitation.

SEE ALSO
See Causes.

ABBREVIATIONS
- AAFCO = Association of American Feed Control Officials.
- ACTH = adrenocorticotropic hormone.
- BCS = body condition score.
- BW = body weight.
- CHF = congestive heart failure.
- CKD = chronic kidney disease.
- DEXA = dual energy x-ray absorptiometry.
- DHA = docosahexaenoic acid.
- EPA = eicosapentaenoic acid.
- GH = growth hormone.
- GI = gastrointestinal.
- IGF-1 = insulin-like growth factor I.
- IL-6 = interleukin-6.
- LBM = lean body mass.
- MER = maintenance energy requirement.
- MCS = muscle condition score.
- RER = resting energy requirements.
- TLI = trypsin-like immunoreactivity.
- TNF-α = tumor necrosis factor-α.

WEST NILE VIRUS INFECTION

BASICS

OVERVIEW

- Acute to inapparent viral disease with neurologic manifestations caused by West Nile virus (WNV), a member of the family Flaviviridae, genus *Flavivirus*.
- Geographic distribution of virus is North, Central, South America, Africa, Asia, southern Europe, and Australia (Kunjin virus).
- Natural route of infection is through bite of numerous species of mosquitoes depending upon geographic location. Infection produces a low-level viremia, insufficient for dogs to be an amplifying host; antibody detectable by day 7 post infection.

SIGNALMENT

- Natural infections not limited by species or age.
- Seroprevalence varies widely with geographic region (3–96%).

SIGNS

- High percentage of dogs show no clinical signs—no experimentally infected dogs have shown clinical signs.
- Incubation period 2–4 days post infection.
- Febrile response 104–108°F (40.3–42.2°C) 3–6 days post infection.
- In the rare affected dog, common signs are ataxia, depression, anorexia, tremors, conscious proprioceptive deficits, seizures, weakness, flaccid paralysis; polyarthritis and myocarditis also reported.

W

CAUSES & RISK FACTORS

- Neurologic disease caused by WNV.
- Outdoor dogs much greater odds of being seropositive than indoor dogs; high seroprevalence in coyotes.
- Stray dogs at greater odds of being seropositive than owned dogs.
- Lineage 1 virus more neurovirulent (all North American isolates) than lineage 2 (Africa).
- Yearly fluctuation of infections linked to density of mosquito populations.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- On an individual basis, signs of WNV-induced neurologic disease are indistinguishable from signs associated with various "arbovirus" infections, e.g., eastern equine encephalitis (EEE), Venezuelan equine encephalitis (VEE), La Crosse.
- Other considerations—rabies, canine distemper, neosporosis, toxoplasmosis, pseudorabies, encephalomyocarditis virus, meningoencephalitis of unknown etiology (MUE).

CBC/BIOCHEMISTRY/URINALYSIS

- Generally normal.
- Serial sampling may show drop in leukocytes but may remain within normal.

DIAGNOSTIC PROCEDURES

- Minimal viremia makes detection of agent in acute phase unlikely; test of choice is reverse transcriptase PCR (RT-PCR) for WNV specifically or for arboviruses in general; urine may be PCR positive for a longer period post infection than whole blood.
- Acute and convalescent serum samples should be collected for IgM ELISA test and/or virus neutralization assays.
- For post-mortem testing—RT-PCR and/or immunohistochemistry.
- CSF—no significant findings (one report).

PATHOLOGIC FINDINGS

- Gross lesions not present in limited number of dogs necropsied (one had epicarditis).
- Histologic lesions in brain—mild, multifocal, nonsuppurative meningoencephalitis (lymphocytic to lymphohistiocytic perivascular infiltrates predominantly in gray matter).

TREATMENT

Supportive therapy for neurologic abnormalities.

MEDICATIONS

- Antiviral drugs have not been tested for efficacy.
- Antipyretics may decrease fever.
- Anticonvulsant medications, as indicated.

FOLLOW-UP

PREVENTION/AVOIDANCE

Vaccines available for horses, have not been approved for dogs.

MISCELLANEOUS

ZOONOTIC POTENTIAL

- West Nile virus can infect numerous species including humans; however, the insect vector is generally necessary for transmission and the viremia is too low in infected dogs to serve as host for infecting feeding mosquitoes.
- Care should be taken if necropsy is done, as infectious viral particles may be present in tissue samples.

RISK TO OTHER ANIMALS

Virus is not transmitted from infected dog to other animals. Clinical case of WNV should be noted as indicative of infected mosquitoes in the area.

ABBREVIATIONS

- EEE = eastern equine encephalitis.
- MUE = meningoencephalitis of unknown etiology.
- RT-PCR = reverse transcriptase polymerase chain reaction.
- VEE = Venezuelan equine encephalitis.
- WNV = West Nile virus.

WHIPWORMS (TRICHURIASIS)

BASICS

OVERVIEW
- The whipworm, *Trichuris*, infects the cecum of dogs (*T. vulpis*) and cats (*T. campanula* and *T. serrata*); feline trichuriasis is extremely rare in continental United States.
- Life cycle is direct; infection is acquired by ingestion of larvated eggs; infective eggs can persist in environment for months to years.
- Infection can be asymptomatic or cause bloody diarrhea and large bowel inflammation.
- Clinical signs can occur before patency, i.e., before eggs are shed in feces; prepatent period is approximately 70–90 days.
- No extraintestinal migration occurs.

SIGNALMENT
- Dogs and cats.
- No age, breed, or sex predilections.

SIGNS
- Range from asymptomatic to severe.
- Intermittent large bowel diarrhea often containing mucus and fresh blood (hematochezia).
- Bloody diarrhea with dehydration, anemia, and weight loss in severe cases.
- Signs can occur before eggs detectable in feces.
- Acute to chronic debilitation.

CAUSES & RISK FACTORS
- Ingestion of infective (larvated) eggs from fecally contaminated environment.
- Eggs accumulate in environment and remain infective for months to years, especially in soil in moist, shady areas.
- Return of dog to an environment contaminated with infective eggs after anthelmintic treatment will result in reinfection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Bacterial (spirochaetal) infections of cecum.
- Hookworm infection—identify eggs in feces; signs include anemia, pale mucous membranes, melena rather than hematochezia.
- Inflammatory bowel disease.
- Gastrointestinal ulcers.
- Dietary indiscretion.
- Capillarid infections (*Pearsonema*, *Eucoleus*)—eggs similar in appearance but smaller with roughened surface; infect urinary or respiratory tracts, respectively, rather than gastrointestinal tract; usually asymptomatic.
- Secondary pseudo-hypoadrenocorticism in severe trichuriasis with metabolic acidosis, hyponatremia, hyperkalemia, and dehydration; adrenocorticotropic hormone (ACTH) stimulation response is normal in cases of trichuriasis.

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal; hyponatremia, hyperkalemia, and metabolic acidosis can occur in severe cases.

OTHER LABORATORY TESTS
ACTH stimulation test in severe cases with electrolyte disturbances to differentiate trichuriasis from hypoadrenocorticism.

IMAGING
N/A

DIAGNOSTIC PROCEDURES
- Centrifugal flotation of feces in sugar solution (specific gravity >1.2) preferred method.
- Differentiate *Trichuris* eggs (brown, ovoid or lemon-shaped with prominent bipolar plugs, smooth shell, single cell within egg, ~90 × 45 µm) from similar capillarid eggs (smaller, roughened shell surface).
- ELISA for whipworm antigen in feces—commercial test detects antigen produced by male and female adult and immature worms, can detect prepatent infection; combine with microscopy as above.

TREATMENT
- Outpatient treatment with anthelmintic for most cases.
- Severe cases with dehydration and electrolyte disturbances require inpatient fluid therapy in addition to anthelmintic.

MEDICATIONS

DRUG(S) OF CHOICE
- Fenbendazole—50 mg/kg PO q24h for 3 days; repeat monthly 3 times; extra-label in cats.
- Febantel/praziquantel/pyrantel pamoate—label dose PO in dogs.
- Milbemycin oxime—0.5 mg/kg PO q30 days in dogs.
- Moxidectin/imidacloprid—label dose in dogs.

FOLLOW-UP

PATIENT MONITORING
Repeat fecal examination for trichurid eggs and/or retreat with anthelmintic at 3 weeks and at 3 months following initial treatment or once a month for 3 months to detect and eliminate recently matured adults.

PREVENTION/AVOIDANCE
- Prompt removal and disposal of feces to prevent environmental contamination with infective eggs.
- Anthelmintic treatment of infected dogs to prevent shedding of eggs and contamination of environment.

EXPECTED COURSE AND PROGNOSIS
Good prognosis following treatment and implementation of preventive measures.

MISCELLANEOUS

ZOONOTIC POTENTIAL
Relatively rare cases of human infection with *T. vulpis* have been diagnosed based on morphologic differences between eggs of the human whipworm, *T. trichiura,* and those of *T. vulpis*.

ABBREVIATIONS
- ACTH = adrenocorticotropic hormone.

XYLITOL TOXICOSIS

BASICS

OVERVIEW

- Xylitol—a 5-carbon sugar alcohol used most commonly as a sweetener; present in many sugar-free gums, candies, toothpastes, mouthwashes, chewable over-the-counter medications and supplements, nasal sprays, liquid medications, specialty foods, and baked goods. It is also available as a granulated powder for cooking and baking.
- Ingestion by dogs can cause vomiting, weakness, ataxia, seizures, hypokalemia, and hypoglycemia due to excess insulin release.
- Mild to moderate elevations of alanine aminotransferase (ALT) can be seen within 4 hours of ingestion.
- Dosages >0.1 g/kg may cause hypoglycemia.
- Hepatic failure may occur at dosages >0.5 g/kg, with secondary coagulopathy possible due to hepatic necrosis.

SIGNALMENT

- Dogs—no breed, age, or sex predilection.
- Cats—toxicity not expected.

SIGNS

- Vomiting may develop within 15–30 minutes of exposure.
- Hypoglycemia may develop in as little as 2 hours after ingestion, with signs including progressive lethargy, weakness, ataxia, collapse, and seizures.
- Hepatic failure with signs of icterus as well as possible hemorrhage including petechiae, ecchymosis, and gastrointestinal and abdominal bleeding may be seen within 24–48 hours after ingestion.
- Hypoglycemia may not occur prior to onset of hepatic failure.

CAUSES & RISK FACTORS

Ingestion of xylitol or xylitol-containing products.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Hypoglycemia

- Insulin overdose.
- Sulfonylurea antihyperglycemic agents.
- Insulinoma (pancreatic β-cell tumor).

Acute Hepatic Failure

- Acetaminophen.
- Sago palm (*Cycad* spp.).
- Aflatoxin.
- Blue-green algae.
- Amanita and similar hepatotoxic mushrooms.
- Iron.
- Leptospirosis.

CBC/BIOCHEMISTRY/URINALYSIS

- Hypoglycemia.
- Hypokalemia.
- Elevated ALT initially.
- Bilirubinemia.
- Elevated aspartate aminotransferase (AST), alkaline phosphatase (ALP) less consistent.

OTHER LABORATORY TESTS

Prothrombin time/partial thromboplastin time (PT/PTT)—use if evidence of hepatic failure is present to monitor for development of secondary coagulopathy resulting in prolonged values.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Severe acute periacinar and midzonal hepatic necrosis with periportal vacuolar degeneration.
- Petechiae and ecchymotic lesions suggestive of coagulation abnormalities.

TREATMENT

- Decontamination—emesis up to 6 hours post ingestion is valid for gum exposures, if patient is asymptomatic; activated charcoal has poor binding to xylitol and not likely to be beneficial.
- Monitor blood glucose every 2–4 hours for hypoglycemia and every 6–8 hours for hypokalemia and correct as needed.
- Monitor liver enzymes every 12 hours for 48 hours with ingestions >0.5 g/kg.

MEDICATIONS

DRUG(S) OF CHOICE

- Dextrose—0.5–1 g/kg IV followed by a 2.5–5% CRI for hypoglycemia. Consider starting for ingestions >1 g/kg for hepatoprotection.
- Potassium chloride—supplement in fluids if potassium value <2.5 mmol/L.
- *N*-Acetylcysteine—if hepatic enzyme elevations occur; or ingestions >1 g/kg; 140 mg/kg PO or IV (extra-label) followed by 70 mg/kg every 6 hours for 7–17 doses, depending on the degree of hepatic enzyme changes.
- *S*-Adenosylmethionine (SAM-e)—PO daily for ingestions >0.5 g/kg. Administer for 2 weeks if no to mild liver enzyme elevations occur and continue for 4 weeks if significant elevations occur.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

None

FOLLOW-UP

- Monitor glucose levels for at least 8–10 hours.
- Monitor hepatic enzymes for 48 hours. If hepatic failure occurs, continue to monitor until values begin to decrease and again 4 weeks post ingestion.
- Prognosis good for uncomplicated hypoglycemia with mild to moderate elevations of ALT; guarded to poor if severe hepatic necrosis occurs and early intervention is not initiated.
- Patients who recover are not expected to have long-term negative effects.

MISCELLANEOUS

SEE ALSO

- Hepatic Failure, Acute.
- Hypoglycemia.
- Poisoning (Intoxication) Therapy.

ABBREVIATIONS

- ALP = alkaline phosphatase.
- ALT = alanine aminotransferase.
- AST = aspartate aminotransferase.
- PT = prothrombin time.
- PTT = partial thromboplastin time.
- SAM-e = *S*-adenosylmethionine.

ZINC TOXICOSIS

BASICS

OVERVIEW

• Toxicity results from the ingestion of zinc-containing material. • Many zinc compounds: zinc carbonate and zinc gluconate (dietary supplements), zinc chloride (deodorants), zinc pyrithione (shampoos), zinc acetate (throat lozenges), zinc oxide (sunblock, Desitin, calamine lotion), zinc sulfide (paints), metallic zinc (coins).
• Causes gastrointestinal (GI) inflammation and intravascular hemolytic anemia; may cause multiple organ failure (e.g., renal, hepatic, pancreatic, and cardiac), disseminated intravascular coagulation (DIC), and cardiopulmonary arrest.

SIGNALMENT

Most frequently reported in small-breed dogs less than 30 pounds (small pylorus retains zinc object or dose response); can occur in all species, all sizes.

SIGNS

• Onset of signs varies depending on the form of zinc, stomach acidity, and nutritional status of the patient. • Initial signs due to the irritant nature of the zinc chloride salts on the GI mucosa, causing vomiting, diarrhea, anorexia and lethargy. • Later signs associated with intravascular hemolysis and potential pancreatic, hepatic and renal damage; may include continued vomiting/diarrhea/anorexia, pale or icteric mucous membranes, dehydration, tachypnea, pigmenturia, abdominal discomfort, orange-tinged feces, melena.

CAUSES & RISK FACTORS

• Toxic doses not well defined; unreferenced median lethal oral dose of "zinc salts" is 100 mg/kg. • Toxicities result from ingestion of zinc-containing material: US pennies minted after 1982 (most common source), hardware (e.g., nuts, bolts), staples, galvanized metal (e.g., nails), boardgame pieces, zippers, toys, jewelry, holiday garland, bra clasps and hooks, animal identification tags, fixtures, buttons.
• Brass—alloy of copper and zinc. • Organic forms of zinc (e.g., zinc oxide) generally cause GI inflammation and self-limiting vomiting.
• Stomach acidity promotes rapid leaching of zinc from the ingested substance, allowing zinc to be absorbed.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• GI upset—viral, bacterial, parasitic, immune-mediated, foreign body, liver or renal disease, pancreatitis. • Intravascular hemolysis—immune-mediated hemolytic anemia, *Babesia*, *Allium* spp. (onion, garlic, chive, leek, shallot), copper, mothball toxicosis (naphthalene), caval syndrome, acetaminophen, coral snake venom, pit viper venom, brown recluse spider venom, mushrooms, overhydration, skunk spray, propylene glycol.

CBC/BIOCHEMISTRY/URINALYSIS

• Hemolytic anemia, with possible Heinz body formation (30% of cases)—PCV drops rapidly. • Regeneration will occur if enough time. • Target cells. • Spherocytosis—mild and often inconsistent (20% of cases).
• Hemoconcentration due to dehydration (prior to hemolysis). • Leukocytosis with neutrophilia. • Hemoglobinemia.
• Bilirubinemia. • High AST, ALP; less common elevations in GGT and ALT.
• Elevated amylase and lipase. • Proteinuria, granular casts. • Pigmenturia. • Azotemia—(prerenal or renal).

OTHER LABORATORY TESTS

• Serum zinc levels often >5 ppm (normal dog/cat range: 0.70–2 ppm). Use non-zinc-contaminated blood tubes for collection.
• Coagulation panel: may indicate DIC.
• Frequent monitoring of PCV.

IMAGING

• Abdominal imaging: *may* reveal metallic object(s) in the GI tract. • Often the zinc object has passed by the time the patient is admitted.

DIAGNOSTIC PROCEDURES

ECG—may reveal arrhythmias and ST-segment abnormalities.

TREATMENT

• Rapid removal of the zinc object by endoscopy or laparotomy/gastrotomy.
• IV fluid therapy—maintain hydration and diuresis. • Severe intravascular hemolysis may require blood transfusion(s)/packed RBCs/oxygen-carrying substances.

MEDICATIONS

DRUG(S) OF CHOICE

• Chelation therapy should *not* be warranted once the source of the zinc is removed. Zinc levels drop fairly rapidly (few to several days) via excretion into bile, pancreatic secretions, and urine. • CaEDTA 100 mg/kg diluted in 5% dextrose SC, divided into 4 doses per day (as for lead poisoning) if clinical improvement or reduced serum zinc is not accomplished by removal of zinc objects. Not commonly used and is potentially nephrotoxic. • Penicillamine 110 mg/kg/day PO q6–8h for 5–14 days (as for lead poisoning) if clinical improvement or reduced serum zinc is not accomplished by removal of zinc objects. Safer chelator to use. • Heparin 150 U/kg SC q6h, for DIC. • H_2-receptor antagonists (e.g., cimetidine, ranitidine, famotidine), proton pump inhibitors (e.g., omeprazole), sucralfate, and antacids used alone or in combination may help reduce irritation and stomach acidity and the rate of release and absorption of zinc.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

Avoid aminoglycoside antibiotics and other potential nephrotoxins due to added risk of developing acute renal failure.

FOLLOW-UP

PATIENT MONITORING

• ECG—monitor for evidence of arrhythmias, ST-segment alterations. • Coagulation profile, PCV, RBC, amylase, lipase, BUN, creatinine, ALP, AST, and ALT—monitor for the first 72 hours after removal of zinc source.
• Monitor serum zinc levels.

CLIENT EDUCATION

Educate clients on zinc hazards.

EXPECTED COURSE AND PROGNOSIS

• Multiple organ failure (e.g., kidney, liver), DIC, pancreatic disease, cardiopulmonary arrest are not common but potential outcomes. • Rapid removal of zinc source may provide progressive improvement over 48–72 hours; complete recovery possible.

MISCELLANEOUS

ABBREVIATIONS

• ALP = alkaline phosphatase. • ALT = alanine aminotransferase. • AST = aspartate aminotransferase. • DIC = disseminated intravascular coagulation. • GGT = gamma-glutamyltransferase. • GI = gastrointestinal.
• PCV = packed cell volume. • PT = prothrombin time. • PTT = partial thromboplastin time. • RBC = red blood cells.

APPENDIX II

ENDOCRINE TESTING

Table II-A

Endocrine function testing protocols

ADRENAL GLAND DISORDERS

ACTH STIMULATION TEST

Screening for Hyperadrenocorticism (in dogs; test not recommended for diagnosis of HAC in cats)

• Administer 5 µg/kg (up to 250 µg/dog) synthetic ACTH (cosyntropin; Cortrosyn, Organon Pharmaceuticals, West Orange, NJ), IV or IM. Serum samples should be obtained before and 1 hour after injection of ACTH for cortisol assay.
• Alternatively, but less ideal, 2.2 IU/kg ACTH gel may be given IM, and serum samples obtained before and 1 and 2 hours post injection.

Interpretation

An exaggerated response to ACTH is consistent with Cushing's disease. High normal cut-off values differ slightly between laboratories.

Screening for hypoadrenocorticism

• Administer 1 µg/kg (dogs) or 5 µg/kg (cats) cosyntropin, IV. Serum samples should be obtained before and 1 hour after injection of ACTH for cortisol assay.
• The use of ACTH gel for the diagnosis of Addison's is not recommended.

Interpretation

Pre- and post-cortisol determinations <2 µg/dL (55 nmol/L) are consistent with hypoadrenocorticism.

Monitoring mitotane and trilostane administration in dogs

• Administer 1 µg/kg (dogs) or 5 µg/kg (cats) cosyntropin, IV. Serum samples should be obtained before and 1 hour after injection of ACTH for cortisol assay.
• Test should be started 3–4 hours after administration of trilostane.

Interpretation

• Monitoring mitotane therapy for hyperadrenocorticism: Pre- and post-cortisol values are between 1 and 5 µg/dL.
• Monitoring trilostane therapy for hyperadrenocorticism: Post-ACTH cortisol values between 2 and 6 µg/dL are acceptable, but this range is controversial. Results must be interpreted in light of clinical signs.

LOW-DOSE DEXAMETHASONE SUPPRESSION TEST (LDDST)

Dogs

Administer 0.01 mg/kg dexamethasone IV. Obtain serum samples before and 4 and 8 hours after injection of dexamethasone for cortisol assay.

Cats

Administer 0.1 mg/kg dexamethasone IV. Obtain serum sample before and 4 and 8 hours after injection of dexamethasone for cortisol assay.

Interpretation

Three basic patterns:
• Lack of suppression: All cortisol values remain above 1.4 µg/dL (40 nmol/L). This pattern is consistent with Cushing's disease.
• Suppression: Cortisol values fall below 1.4 µg/dL (40 nmol/L) at 4 and 8 hours. This pattern suggests that the animal does not have Cushing's disease.
• Escape from suppression: Cortisol value falls below 1.4 µg/dL (40 nmol/L) at 4 hours and rises above 1.4 µg/dL at 8 hours. This pattern is consistent with pituitary-dependent Cushing's disease.

HIGH-DOSE DEXAMETHASONE SUPPRESSION TEST (HDDST)

Administer 0.1 mg/kg dexamethasone IV. Obtain serum samples before and 4 and 8 hours after injection of dexamethasone for cortisol assay.

Interpretation

Any cortisol determination that falls below 1.4 µg/dL (40 nmol/L) at any point during the 8-hour testing period is considered suppression. Suppression after a high dose of dexamethasone is consistent with pituitary-dependent Cushing's disease. Lack of suppression (all cortisol values remain above 1.4 µg/dL) is diagnostic of a pituitary or adrenal tumor.

THYROID GLAND DISORDERS

TSH STIMULATION TEST

Administer 0.5 U/kg TSH (maximum dose 5 U) IV. Obtain serum samples before and 6 hours after injection of TSH for T_4 determination.

Interpretation

Post-TSH T_4 levels <3 µg/dL (35 nmol/L) are consistent with hypothyroidism.

TRH STIMULATION TEST

Administer 0.1 mg/kg TRH IV. Obtain serum samples before and 4 hours after TRH injection for T_4 determination.

Interpretation

An increase in T_4 concentration <50% after TRH administration is consistent with hypothyroidism.

T_3 SUPPRESSION TEST

Obtain a blood sample for determination of T_4 and T_3. The serum is removed and kept refrigerated or frozen. Administer T_3 (Cytomel, SmithKline Beecham, Philadelphia, PA) PO at a dosage of 25 µg/cat q8h for 2 days. On the morning of the third day, administer 25 µg of T_3, and 2–4 hours later obtain a second blood sample for T_3 and T_4 determinations. The basal (day 1) and post-oral T_3 serum samples should be submitted to the laboratory together to avoid interassay variation.

Interpretation

Serum T_4 concentration after administration of T_3 >1.5 µg/dL (20 nmol/L) is consistent with hyperthyroidism.

SEX HORMONE DISORDERS

GNRH STIMULATION TEST

Administer 0.5–1.0 µg of GnRH/kg IM. Obtain blood samples before GnRH administration and 1 hour later. Assay blood samples for testosterone.

Interpretation

Normal dogs have baseline testosterone levels between 0.5 and 5 ng/mL, and after administration of GnRH the testosterone levels rise above 5 ng/mL. Animals with hypoandrogenism have lower values.

HCG STIMULATION TEST

Administer 44 IU of hCG/kg IM. Obtain blood samples before hCG administration and 4 hours later. Assay blood samples for testosterone.

Interpretation

Normal dogs have baseline testosterone levels between 0.5 and 5 ng/mL, and after administration of hCG, the testosterone levels rise above 5 ng/mL. Animals with hypoandrogenism have lower values.

DIABETES INSIPIDUS

MODIFIED WATER DEPRIVATION TEST

Note: This is not recommended due to morbidity and potential complications; ADH supplementation trial preferred.

Rule out other causes of polyuria and polydipsia (especially hyperadrenocorticism).

ENDOCRINE TESTING (*CONTINUED*)

Table II-A

Endocrine function testing protocols (*continued*)

Begin water restriction 3 days before abrupt water deprivation.
- Day 1: 130–165 mL/kg/day.
- Day 2: 100–125 mL/kg/day.
- Day 3: 65–70 mL/kg/day (normal maintenance requirement).

The morning of the fourth day, discontinue food and water. Start the test. Weigh the patient and empty the bladder. Weigh and measure PCV/TP, USG, BUN, and Na^+ at 1- to 2-hour intervals. *Monitor carefully for dehydration and depression and discontinue the test if the patient becomes dull, azotemic, or hypernatremic*. When 5% of body weight is lost (or azotemia, hypernatremia, or dullness develop), empty the bladder and check urine specific gravity.

Interpretation

If the urine specific gravity is >1.025 (dogs) or >1.030 (cats), stop the test. The patient does not have diabetes insipidus. If the urine specific gravity is not >1.025 (dogs) or >1.030 (cats), administer 0.55 U/kg aqueous vasopressin IM (maximum dose 5 U). Empty the bladder and check urine specific gravity at 30, 60, and 120 minutes post administration. If urine specific gravity increases <10%, nephrogenic diabetes insipidus is indicated; if it increases 10–50%, partial central diabetes insipidus is indicated; if it increases 50–800%, complete central diabetes insipidus is indicated.

DDAVP (desmopressin), 5 µg/dog SQ may be used in place of aqueous vasopressin, with specific gravity assessed at 2 and 4 hours.

Following the test, water should be offered in small amounts initially (to avoid vomiting), and slowly increased back to the dog's daily intake.

Table II-B

Tests of the endocrine system*

†	*Unit*	*Dogs*	*Cats*
Adrenocorticotropic hormone, basal (ACTH, plasma)	pmol/L	2–15	1–20
Aldosterone† (plasma)			
Basal	pmol/L	14–957	194–388
Post-ACTH	pmol/L	197–2103	277–721
Cortisol (serum or plasma, urine)			
Basal	nmol/L	25–125	15–150
Post-ACTH	nmol/L	200–550	130–450
Post–low-dose dexamethasone (0.01 or 0.015 mg/kg)	nmol/L	≤ 40	≤ 40
Post–high-dose dexamethasone (0.1 or 1.0 mg/kg)‡	nmol/L	≤ 40	≤ 40
Urinary cortisol-creatinine ratio	$\times 10^{-6}$	8–24,† 10§	—
Insulin, basal (serum)	pmol/L	35–200	35–200
Intact parathormone† (serum)	pmol/L	2–13	0–4
Progesterone (serum or plasma, female)	mmol/L	≤ 3.0 in anestrus, proestrus 50–220 in diestrus, pregnancy	≤ 3.0 in anestrus, proestrus 50–220 in diestrus, pregnancy
Testosterone (serum or plasma, male)	nmol/L	1–20	1–20
Thyroxine (T_4, serum)			
Basal	nmol/L	12–50	10–50
Post–thyroxine-stimulating hormone (TSH)	nmol/L	> 45	> 45
Triiodothyronine (T_3) suppression*	nmol/L	—	≤ 20
Triiodothyronine, basal (T_3, serum)	nmol/L	0.7–2.3	0.5–2.0

*Prepared with the assistance of ME Peterson, The Animal Medical Center, New York, NY. Unless indicated otherwise, values in this table are adapted from Kemppainen RJ, Zerbe CA. Common endocrine diagnostic tests: normal values and interpretations. In: Kirk RW, ed., Current Veterinary Therapy X. Philadelphia: Saunders, 1989, pp. 961–968. Hormone determinations are variable between laboratories. The laboratory performing the analysis should provide reference values. Before submitting samples for hormone determinations, consult the laboratory for sample specifications, use of anticoagulants, and sample preservation. General sampling conditions are discussed in Reimers TJ. Guidelines for collection, storage, and transport of samples for hormone assay. In: Kirk RW, ed., Current Veterinary Therapy X. Philadelphia: Saunders, 1989, pp. 968–973. Factors that affect serum thyroid and adrenocortical hormone concentrations in dogs are discussed in Reimers TJ, Lawler DF, Sutaria PM, et al. Effects of age, sex, and body size on serum concentrations of thyroid and adrenocortical hormones in dogs. Am J Vet Res 1990, 51:454.

†Provided by RF Nachreiner, Animal Health Diagnostic Laboratory, Endocrine Diagnostic Section, Michigan State University.

‡This test is used after adrenocortical hyperfunction has been confirmed. It is used to differentiate adrenal tumor (where no suppression is seen) from pituitary-dependent cases (where suppression occurs but is variable).

APPENDIX III

APPROXIMATE NORMAL RANGES FOR COMMON MEASUREMENTS IN DOGS AND CATS

	Dog	*Cat*
Heart rate (bpm)	60–180	140–220
Capillary refill time	1.5–2 sec	1.5–2 sec
Body temperature	99.5–102.5°F	100.5–102.5ºF
	37.5–39.2°C	38.1–39.2ºC
Mean arterial pressure (mm Hg)	90–120	100–150
Blood volume (mL/kg)	75–90	47–66
Cardiac output		
(mL/kg/min)	100–200	167 ± 39
(L/M^2/min)	4.72 ± 1.09	
Systemic vascular resistance		
(mm Hg/mL/kg/min)	1600–2500 dynes.sec.cm^{-5}	
(dynes/sec/cm)	2162 ± 458	
Mean pulmonary arterial pressure (mm Hg)	14±3	
Central venous pressure (cm H_2O)	3±4	
Urine output	1–2 mL/kg/hr	1–2 mL/kg/hr
Breathing rate (breaths/min)	10–30	24–42
Minute ventilation (mL/kg/min)	170–350	200–350
Oxygen delivery		
(mL/kg/min)	29 ± 8	
(mL/M^2/min)	815 ± 234	
Oxygen consumption		
(mL/kg/min)	4–11	3–8
(mL/M^2/min)	198 ± 53	
Arterial Po_2 (mm Hg)	85–105	100–115
Arterial So_2	> 95	> 95
Arterial Pco_2 (mm Hg)	30–44	28–35
Arterial pH	7.36–7.46	7.34–7.43
Bicarbonate (mEq/L)	20–25	17–21
Base deficit (mEq/L)	0 to –4	–1 to –8
Total plasma proteins (g/dL)	6.0–8.0	6.8–8.3
Albumin (g/dL)	2.5–3.5	2.4–3.8
Packed cell volume (%)	37–55	29–48
Hemoglobin (g/dL)	12–18	9–15.1
Sodium (mEq/L)	145–154	146–157
Potassium (mEq/L)	3.9–4.9	3.6–4.9
Chloride (mEq/L)	105–116	113–121
Total CO_2 (mEq/L)	16–26	15–21

APPENDIX IV

NORMAL VALUES FOR THE CANINE AND FELINE ELECTROCARDIOGRAM

Rate			
	Dog		60–140 beats/min for giant breeds 70–160 beats/min for adult dogs Up to 180 beats/min for toy breeds Up to 220 beats/min for puppies
	Cat		Range: 120–240 beats/min Mean: 197 beats/min
Rhythm			
	Dog		Normal sinus rhythm Sinus arrhythmia Wandering sinoatrial pacemaker
	Cat		Normal sinus rhythm Sinus tachycardia (physiologic reaction to excitement)
Measurements (lead II, 50 mm/sec, 1 cm = 1 mV)			
	Dog	P wave	Width: maximum, 0.04 second; 0.05 second in giant breeds Height: maximum, 0.4 mV
		PR interval	Width: 0.06–0.13 second
		QRS complex	Width: maximum, 0.05 second in small breeds maximum, 0.06 second in large breeds Height of R wave*: maximum, 3.0 mV in large breeds maximum, 2.5 mV in small breeds
		ST segment	No depression: not more than 0.2 mV No elevation: not more than 0.15 mV
		T wave	Can be positive, negative, or biphasic Not greater than one-fourth amplitude of R wave Amplitude range ± 0.05–1.0 mV in any lead
		Q-T interval	Width: 0.15–0.25 second at normal heart rate; varies with heart rate (faster rates have shorter Q-T intervals and vice versa)
	Cat	P wave	Width: maximum, 0.04 second Height: maximum, 0.2 mV
		PR interval	Width: 0.05–0.09 second
		QRS complex	Width: maximum, 0.04 second Height of R wave: maximum, 0.9 mV
		ST segment	No depression or elevation
		T wave	Can be positive, negative, or biphasic—most often positive Maximum amplitude: 0.3 mV
		Q-T interval	Width: 0.12–0.18 second at normal heart rate (range 0.07–0.20 second); varies with heart rate (faster rates have shorter Q-T intervals and vice versa)
Mean Electrical Axis (frontal plane)			
	Dog		+40 to +100 degrees
	Cat		0 to + 160 degrees (not valid in many cats)
Precordial Chest Leads (values of special importance)			
	Dog		CV_5RL (rV_2): T wave positive, R wave not greater than 3.0 mV CV_6LL (V_2): S wave not greater than 0.8 mV, R wave not greater than 3.0 mV* CV_6LU (V_4): S wave not greater than 0.7 mV, R wave not greater than 3.0 mV* V_{10}: negative QRS complex, T wave negative except in Chihuahuas
	Cat		CV_6LL (V_2): R wave not greater than 1.0 mV CV_6LU (V_4): R wave not greater than 1.0 mV V10: T wave negative, R/Q not greater than 1.0 mV

*Not valid for thin, deep-chested dogs under 2 years of age.

APPENDIX V

ANTIDOTES AND USEFUL DRUGS: METHODS OF TREATMENT

Antidotes and Useful Drugs	*Toxicant/Indication for Use*	*Dosage*
Acepromazine	Amphetamine and other stimulant drugs with agitation and excitation; serotonin syndrome	Dogs and cats: 0.02–0.1 mg/kg IV, IM, SC. May cause hypotension.
Antivenin, crotalids	*Crotalus* and *Sistrurus* (rattlesnake); *Agkistrodon* (cottonmouth and copperhead) venom	Several products available. Follow the manufacturer's guidelines for dilution and administration. Dose varies from 1 to 5 vials IV depending on severity of symptoms. 95% of cases controlled with a single vial.
Antivenin, elapids	*Micrurus fulvius, Micrurus tenere, Micruroides euryxanthus* (coral snakes) venom	Extremely limited availability. The manufacturer's guidelines for dilution and administration should be followed closely.
Atipamezole	Medetomidine, dexmedetomidine reversal. Used off-label to reverse other alpha-2-adrenergic agonists, including amitraz, clonidine, and xylazine	Dogs: 50–100 μg/kg IM Cats: 25–50 μg/kg IM or IV (slow)
Atropine	Anticholinesterase pesticide muscarinic signs (OPs and carbamates); also cholinergic agents and clitocybe and inocybe (muscarinic) mushrooms	Dogs and cats: 0.2–2 mg/kg. One quarter of the dose should be given IV and the remainder IM or SC. The dose will likely need to be repeated; heart rate and secretions should be used to guide redosing.
Barbiturates	Strychnine and other seizure-producing drugs	Dogs: Phenobarbital at 5–8 mg/kg IV q4–6h. Cats: Phenobarbital at 3 mg/kg IV, repeat every 20 minutes to maximum of 24 mg/kg/24 hours.
Calcitonin salmon	Hypercalcemia; vitamin D and analogs	4–6 IU/kg, SC q8–12h. Rarely used.
Calcium gluconate or chloride	Fluoride and hydrofluoric acid; oxalic acid and oxalates; beta and calcium channel antagonists; others	Calcium gluconate 10% 0.54–1.61 mL/kg IV slowly; calcium chloride 10% 0.18–0.56 mL/kg IV slowly.
Calcium disodium EDTA (CaEDTA or calcium disodium versenate)	Heavy metals, primarily lead and zinc. Also chelates cadmium, chromium, copper, cobalt, iron, manganese, nickel, plutonium, thorium, uranium, yttrium, and vanadium	Dilute product in 5% dextrose to a final concentration of 2–4 mg/mL prior to use. Give 25 mg/kg IV or SC q6h. Maximum recommended daily dose of 2 g/day. Treat for 5 days; rest for 5–7 days; and repeat if needed. Do not use if metal still present in GIT.
Cyproheptadine	Drugs that cause serotonin syndrome (selective serotonin reuptake inhibitors, tricyclic antidepressants, 5-hydroxytryptophan)	Dogs: 1.1 mg/kg PO or rectally q4–8h PRN. Cats: 2–4 mg *total* dose PO or rectally q4–8h PRN.
D-penicillamine	Heavy metals, primarily lead; but also cadmium, copper, inorganic mercury, and zinc	Dogs (home therapy after $CaNa_2EDTA$ lead treatment): 110 mg/kg/day PO divided q6–8h for 1–2 weeks. Cats (home therapy after $CaNa_2EDTA$ lead treatment and in the presence of elevated blood levels): 125 mg *total* dose, PO q12h for 5 days. Do not use if metal still present in GI tract.
Dantrolene	Hops *(Humulus lupulus)* intoxication and black widow spider envenomation *(Latrodectus mactans)*	Dogs: Black widow spider: 1 mg/kg IV followed by 1 mg/kg PO q4h as needed. Hops: 2–3 mg/kg IV or 3.5 mg/kg PO.
Deferoxamine	Iron	Dogs and cats: 40 mg/kg IM q4–8h. In critical situations, an IV infusion of 15 mg/kg/hour can be used, but the cardiovascular system must be monitored closely during this time. The excreted complex turns the urine pink or salmon colored and is sometimes referred to as the "vin rose" of iron poisoning. Continue treatment until the urine is clear or serum iron levels are within normal limits.
Digoxin immune Fab fragments	Digoxin, *Rhinella* sp. *(Bufo)* toad toxins, and some cardiac glycoside-containing plants	If serum digoxin level is available: number of vials = serum digoxin level (ng/mL) × BW (kg)/100. If serum digoxin level is **not** available or if treating a *Rhinella (Bufo)* toad or cardiac glycoside-containing plant toxicosis, start therapy with 1–2 vials and reassess as needed.

(*Continued*)

ANTIDOTES AND USEFUL DRUGS: METHODS OF TREATMENT (*CONTINUED*)

Antidotes and Useful Drugs	*Toxicant/Indication for Use*	*Dosage*
Dimercaprol (BAL)	Heavy metals, primarily arsenic. Also used to chelated lead and mercury	Arsenic toxicosis: 5 mg/kg IM × one dose followed by 2.5 mg/kg IM q4h for 2 days, q8h for 1 day, and q12h until recovered. Lead toxicosis: 2.5–5 mg/kg IM as 10% solution q4h on days 1 and 2, then q6h on day 3.
Ethanol	Ethylene glycol	Preferred method: using 7% ethanol (70 mg/mL), load with 8.6 mL/kg (600 mg/kg) slow IV × 1 dose and follow with 1.43 mL/kg/hour (100 mg/kg/hour) IV CRI for 24–36 hours or until ethylene glycol (EG) test is negative.
Flumazenil	Benzodiazepine (clonazepam, diazepam, lorazepam, others); CNS depression or coma	Dogs and cats: 0.01 mg/kg IV. Short half-life and may need to repeat in 1–3 hours. Doses 10–20× labeled dose have been used in some animals but there is currently no scientific data to support them.
Fomepizole	Ethylene glycol	Dogs: 20 mg/kg IV over 15–20 minutes as loading dose; 15 mg/kg IV at 12 and 24 hours; 5 mg/kg IV at 36 hours. Repeat EG test. If positive, continue 5 mg/kg IV every 12 hours until negative. Cats: 125 mg/kg slow IV as a loading dose; 31.25 mg/kg IV at 12, 24, and 36 hours.
Glucagon	Insulin and oral hypoglycemic agent-induced hypoglycemia; beta and calcium channel blockers and tricyclic antidepressants bradycardia, AV block, and hypotension.	50 ng/kg IV bolus in 0.9% sodium chloride followed by 10–15 ng/kg/min CRI. May need to increase up to 40 ng/kg/min to maintain euglycemia.
Hydroxycobalamin (vitamin B12a; B12 precursor)	Cyanide	75–150 mg/kg IV
Intravenous lipid emulsion (ILE); also referred to as intravenous fat emulsion (IFE)	Some lipophilic (fat-soluble) drugs including baclofen, barbiturates, ivermectin and moxidectin, propranolol, tricyclic antidepressants, verapamil, and others.	Standard protocol: 1.5 mL/kg IV bolus of 20% solution over 5–15 minutes, followed immediately with CRI of 0.25 mL/kg/min over 1–2 hours. May repeat dose in several hours if signs of toxicity return and serum is not lipemic. Suggested protocol: 1.5–4 mL/kg IV bolus of 20% over 1 minute, followed by CRI of 0.25 mL/kg/min over 30–60 min. Individual boluses may be repeated as needed up to 7 mL/kg.
Leucovorin	Methotrexate; pyrimethamine trimethoprim, ormetoprim, others	Dogs and cats: Methotrexate: Varies depending on methotrexate serum concentrations (25–200 mg/m^2 IV, IM q6h for up to 8 doses). Pyrimethamine, trimethoprim: 0.1–0.3 mg/kg PO q24h.
Methocarbamol	Metaldehyde, permethrin, strychnine, tremorgenic mycotoxins, other toxicants that cause tremors	Dogs: 55–220 mg/kg slow IV. Labeled not to exceed 330 mg/kg/day but higher doses may be used in severe poisonings as long as the dog is monitored for CNS and respiratory depression. Cats: 44 mg/kg slow IV, up to 330 mg/kg/day. Labeled not to exceed 330 mg/kg/day but higher doses may be needed in severe poisonings. Monitor for CNS and respiratory depression when using high doses.
Methylene blue	Aniline dyes, local anesthetics, naphthalene, nitrates and nitrites-induced methemoglobinemia	Cats: Use with extreme caution or not at all. Dogs: 1–1.5 mg/kg as 1% solution IV over several minutes; may be repeated once in 30 min.

ANTIDOTES AND USEFUL DRUGS: METHODS OF TREATMENT (*CONTINUED*)

Antidotes and Useful Drugs	*Toxicant/Indication for Use*	*Dosage*
N-acetylcysteine (NAC)	Acetaminophen; less often *Amanita phalloides* mushroom, sago palm, and xylitol intoxication	Dogs and cats: 140 mg/kg IV or PO × 1 dose, then 70 mg/kg IV or PO q 6 hours for 7 doses. The product should be diluted to a 5% solution prior to use. IV administration preferred in cats due to low oral bioavailability (20%). A variety of other doses have been suggested; most based on extrapolation from human literature. Some recommend higher doses (280 mg/kg) and others additional doses (up to 17 doses) for massive ingestions. Emesis frequently occurs with oral dosing, especially after the initial dose, and an antiemetic may be required prior to starting NAC therapy.
Pamidronate	Cholecalciferol, calcipotriene, and calcitriol-induced hypercalcemia and hyperphosphatemia	Dogs and cats: 1.3–2 mg/kg diluted in 250–500 mL 0.9% NaCl, IV slowly over several hours. Monitor serum calcium levels q12–24h and adjust ancillary treatment as needed. If hypercalcemia is still present, a repeated dose of pamidronate may be necessary 5–7 days after the initial dose. Very large overdoses of cholecalciferol may require a second dose in 3–4 days.
Naloxone	Opioid and opiate-induced respiratory and CNS depression	Dogs and cat: 0.01–0.04 mg/kg, IV, IM, SC; may need to use 0.04 mg/kg with larger overdoses. IM and SC route result in slower onset of action (5 minutes). Short half-life and may need to repeat in 1–3 hours.
Phytonadione (vitamin K1)	Anticoagulant rodenticides, warfarin tablets	2–5 mg/kg PO q24h or divided twice a day.
Pralidoxime (2-PAM)	Organophosphates (nicotinic signs)	Dose (dogs and cats): 20 mg/kg IM or slow IV (over 30 min) for first dose. Repeat dose q8–12h, IM or SC. Rapid IV administration has resulted in tachycardia, neuromuscular blockade, laryngospasm, muscle rigidity, and death.
Protamine sulfate	Heparin	Dogs and cats: 1 mg protamine sulfate IV per 100 units heparin to be inactivated. Give slowly, no faster than 50 mg per over 10 minutes. Decrease amount of protamine sulfate by 50% for every 30–60 minutes that has passed since heparin overdose given.
Pyridostigmine	Anticholinergic plants (*Cestrum* spp., *Datura* spp., *Solanum* spp, etc.), atropine, avermectin and ivermectin, botulism, some elapid snake bites, and nondepolarizing neuromuscular blocking agents (curare, pancuronium, etc.)	0.01–0.03 mg/kg/hour CRI. Longer half-life than other similar drugs.
Pyridoxine	Isoniazid	71 mg/kg as 5–10% infusion over 30–60 minutes; if total amount of isoniazid consumed is known can give on a mg per mg (1:1) ratio.
Succimer (2-3 dimercaptosuccinic acid)	Lead	Dogs and cats: 10 mg/kg PO or rectal q8h × 10 days; retreat only if clinical signs are present. Monitor renal values closely in cats.
Trientine (TETA)	Copper hepatopathy in dogs	Dogs: 10–15 mg/kg PO 1–2 hours before meals. Useful in dogs unable tolerate vomiting associated with D-penicillamine.
Yohimbine	Xylazine and other alpha-2-adrenergic agonists (amitraz, clonidine, xylazine)	Dogs and cats: 0.11 mg/kg IV slowly. Shorter half-life than atipamezole.

Abbreviations: Standard

Comments:

Specific antidotes are not free of side effects and should be used with knowledge and forethought. Many toxicants lack a true antidote, and symptomatic and supportive care, including many of the useful drugs found in this table, is imperative for survival of the poisoned patient. Other drugs may be needed and the reader is directed to the references below for further information.

APPENDIX VI

LYNN R. HOVDA

TOXIC HOME AND GARDEN HAZARDS FOR PETS

Table VI-A

Toxic plants and their clinical signs—antidotes and treatment

Plant and Characteristics	*Clinical Signs*	*Antidotes and/or Treatment*
Air plant, cathedral bells (*Kalanchoe* spp.) Bright red-orange to pink blooms; umbel flower pattern. Plant contains cardiotoxins similar to azalea and rhododendrons, concentrated mainly in flowers	Cardiac glycoside causes acute signs 1–3 hours after ingestion. Signs include depression, salivation, diarrhea, bradycardia, heart block, tachypnea, ataxia, tremors, and paralysis	Preventive emesis and/or activated charcoal early after ingestion. Treat as a cardiac glycoside (see Cardiac Glycoside Plant Toxicosis)
Aloe, octopus plant, candelabra plant (*Aloe* spp.) Succulent plant, used in folk and herbal medicine. Toxic fraction is anthraquinone glycoside; disrupts water and electrolyte balance in large intestine	Anorexia, depression, vomiting, colic, diarrhea, tremors (uncommon), and change in urine color. Generally mild in nature	Drugs for abdominal pain/diarrhea. Protect airway, treat locally for pharyngitis associated with oxalate crystals (rare)
Autumn crocus (*Colchicum autumnale*) Houseplant, garden plant. Typically blooms in fall, different from most other bulbs. Dosages above 6 g/kg BW considered lethal. Although the whole plant is toxic, the toxin (colchicine) is highest in bulbs.	Acute onset 2–12 hours post ingestion. Initial signs are nausea, salivation, vomiting, colic, diarrhea, incoordination, and weakness. Multiple organ systems (heart, lungs, and kidneys) also may be involved. Potential for coagulopathy and elevated serum enzymes	Induce emesis if not vomiting. Activated charcoal if early. Evaluate CBC and serum chemistries, including prothrombin, LDH, CK. IV fluids, analgesics, anticonvulsants as needed
Baneberry, doll's eye, cohosh (*Actea* spp.) Toxic principal is protoanemonin glycoside, as well as irritant essential oils	Clinical response ranges from dermatitis and blistering of skin to oral irritation, drooling, pawing at face or mouth, emesis, diarrhea, and hematuria. Neurologic and cardiovascular signs are occasionally reported	Cleanse mouth thoroughly with water; apply appropriate local demulcents; control emesis and diarrhea as necessary; monitor for organ dysfunction, especially renal damage
Belladonna lily (*Amaryllis* spp.) Potted plant, bulbs are most toxic, Contains both lycorine alkaloid (systemic effects) and insoluble oxalates (local pharyngitis)	Nausea, vomiting, diarrhea, hypotension, depression. Oxalate crystals can cause direct pharyngeal irritation	Gastric lavage, activated charcoal, fluids, and supportive treatment
Bittersweet (*Celastrus* spp.) Weed, vine with red berries. Immature fruits are toxic. Toxins are sesquiterpene alkaloids (celapanine, celastrine, paniculatine)	Gastric irritation, vomiting, diarrhea	Fluids, supportive care as needed
Bleeding heart (*Dicentra* spp.) Garden, woods, potted plant. Roots more toxic than leaves. Toxins are isoquinoline alkaloids (apomorphine, cularine, protoberberine)	Vomiting, diarrhea, muscle tremors, convulsions or paralysis	Fluids and seizure control
Castor bean (*Ricinus communis*) Garden shrub or ornamental grows to 2 m. Seeds are 1 cm, dark and light mottled, and highly toxic; chewing the seed greatly increases toxicity. Toxin is ricin	Severe, dangerous if seeds chewed before swallowing. Latent period 6–48 hours. Emesis, severe and hemorrhagic diarrhea, colic, muscle tremors, sudden collapse. Dehydration, hypotension, hemolysis and/or hemoglobinuria	Emesis for recent exposure: sorbitol if diarrhea not present; charcoal, fluids, and electrolytes. Monitor electrolytes, liver, kidney, adrenal function up to 6 days; H2 blockers for GI signs; diazepam for seizures; Antibiotics, lactulose, SAM-e for liver damage

TOXIC HOME AND GARDEN HAZARDS FOR PETS (*CONTINUED*)

Table VI–A

Toxic plants and their clinical signs—antidotes and treatment (*continued*)

Plant and Characteristics	*Clinical Signs*	*Antidotes and/or Treatment*
Chinaberry tree (*Melia azedarach*) Other common names are Persian lilac, white cedar, Texas umbrella tree. Ornamental tree in temperate to subtropical areas: southern coastal states, Mexican border. Berry is most toxic. Toxins are meliatoxins	Salivation, anorexia, vomiting, diarrhea. May be followed by weakness, ataxia, excitement or seizures. Fatalities have occurred, generally within 2 days post ingestion	Early emesis, GI lavage and charcoal are considered beneficial. Fluid and electrolyte replacement, anticonvulsants, and supportive care
Christmas rose (*Helleborus niger*) House and garden plant; entire plant is toxic, but fruits are most dangerous. Small amounts considered dangerous. Contains several toxins including ranunculin that is converted to protoanemonin when chewed, cardenolides, and bufadienolides	Hypersalivation, vomiting, anorexia, diarrhea followed by cardiac arrhythmias, heart block with premature beats, premature beats, slow irregular pulse. Potent cardenolide action is greatest risk	Gastric lavage or emesis; activated charcoal or saline cathartics to decontaminate the GI tract. Atropine may be helpful as for other cardenolide plants such as *Digitalis* spp.
Daphne (*Daphne mezereum*) Landscape shrub; evergreen or deciduous. Entire plant is toxic. Bitter or acid taste discourages consumption, may reduce toxic effects. Toxins are tricyclic daphnane and diterpenes	Vesication and edema of the lips and oral cavity associated with ingestion. Signs progress to salivation, thirst, abdominal pain, emesis, hemorrhagic diarrhea	Analgesics to control pain. General GI detoxification, medical treatment for vomiting and diarrhea. Fluid and electrolyte replacement as needed. Monitor body fluids and electrolytes
Delphinium/larkspur (*Delphinium* spp.) and pheasant's eye, yellow oxeye (*Adonis* spp.) Outdoor perennial, gardens, mountains; tall with blue, purple, or pinkish flowers. Seeds more toxic than leaves. Toxin is a diterpenoid alkaloid	Small animal poisoning unlikely unless by access to seeds. Early signs are vomiting, colic and diarrhea. May progress to trembling, ataxia, weakness, lateral recumbency	GI detoxification; demulcents and anti-diarrheal for GI signs; physostigmine to treat muscarinic signs
English holly (*Ilex* spp.) Landscape plant; glossy green leaves with marginal spicules. Fruit (drupe) white, yellow, black, red, orange. Occurs in forested areas of eastern N. America; elsewhere as an ornamental. Fruit is most likely portion consumed. Fruit and leaves contain potentially toxic saponins	Nausea, vomiting, diarrhea most common from consumption of berries. Some animals may be depressed. Clinical response most often mild/moderate and transient	Relief of digestive distress, activated charcoal may be helpful. Fluid and electrolyte replacement as needed
English ivy (*Hedera helix*), also known as Atlantic ivy, Irish ivy, common ivy Houseplant, or in mild climates used as a ground cover. Occurs as a woody, climbing or creeping vine. Commonly grown throughout North America. Toxins are triterpenoid saponins.	Salivation, thirst, emesis, gastroenteritis, diarrhea, dermatitis. Relatively few reported cases, most are moderate GI irritation. Often moderate or mild	Symptomatic relief of GI distress; supportive care for vomiting and diarrhea
Golden angel's trumpet (*Brugmansia* spp.) Non-native ornamental, similar to jimsonweed. Large pendulous flowers, similar to angel's trumpet. Toxin similar to jimsonweed (tropane alkaloid scopolamine) causes anticholinergic effects	Typical anticholinergic effects are restlessness, dilated pupils, tachycardia, dyspnea, dry mouth, GI atony, rarely seizures. Rarely lethal	Treat similar to *Datura* spp. (see Thorn apple below.)

(*Continued*)

TOXIC HOME AND GARDEN HAZARDS FOR PETS (*CONTINUED*)

Table VI–A

Toxic plants and their clinical signs—antidotes and treatment (*continued*)

Plant and Characteristics	*Clinical Signs*	*Antidotes and/or Treatment*
Horse chestnut or Ohio buckeye (*Aesculus* spp.) Landscape or forest tree; palmate leaves. Native range is Midwest, east to Appalachian mountains, south into Texas. Planted as ornamental/landscape tree as well. Nuts and twigs most toxic; very early green foliage in spring. Horse chestnut highly toxic; Ohio buckeye very low toxicity. Contain several toxins including saponins, anthraquinones, and a coumarin glycoside	Gastroenteritis, diarrhea, dehydration, electrolyte imbalance. Neurologic signs possible, including incoordination, hypermetria, staggering. Usually transient, rarely fatal. Recovery usual within 24–48 hours	Fluid and electrolyte replacement, demulcents, and therapy for gastroenteritis. Confine animals during neurologic phase
Iris or blue or yellow flag (*Iris* spp.) Perennial garden flower, very commonly available. Rootstock (rhizome) most toxic; most risk at transplantation. Close to soil surface, may be dug up by dogs. Advise clients of potential risk. Rootstock contains purgative toxin known as irisin	Hypersalivation, vomiting, colic, diarrhea which may be hemorrhagic. Occasionally irritation of the lips and muzzle	GI decontamination early. Fluid and electrolyte therapy as needed
Irish potato (*Solanum tuberosum*) Vegetable garden plant. Vines, green skin, and sprouts are toxic. Toxins vary but are solanine and other glycoalkaloids	Vomiting, diarrhea, depression, rapid heart rate, mydriasis, muscle tremors. Signs may vary from atropine like to cholinesterase inhibition. Use antidotes accordingly and with caution	GI decontamination. If atropine-like signs predominate: use physostigmine. If salivation and diarrhea are present: use atropine cautiously
Jerusalem cherry, Winter cherry (*Solanum pseudocapsicum*) Common ornamental houseplant. Toxin is the glycoalkaloid solanine, similar to other plants of the nightshade (Solanaceae) family	Severe GI irritation characterized by drooling, vomiting, diarrhea, ulceration, depression, and sometimes seizures	GI decontamination if exposure is recent. If salivation and diarrhea are present and severe, use atropine cautiously. Provide fluid therapy based on condition of patient and results of laboratory tests
Lantana (*Lantana camara*) Occurs wild and in gardens in mild temperate to tropical areas. Naturalized in southeastern coastal states of the USA. Bright orange, yellow, red, purple, or pink flowers. Foliage and immature berries are most toxic. Toxins are pentacyclic triterpenoid lantadenes A, B, and C	Weakness, lethargy, vomiting, diarrhea, mydriasis, dyspnea. Continued ingestion can lead to chronic disease. Advanced signs: cholestasis, hyperbilirubinemia. Liver changes predispose to photosensitization	GI decontamination, activated charcoal for acute exposures. Provide fluids and respiratory support. Protect from sunlight and treat for hepatic insufficiency
Lily of the valley (*Convallaria majalis*) Ornamental garden plant. Prefers moist, shaded areas. Blossoms nodding/drooping on stem. Toxic principal (cardenolides) persists in dried plants; highest concentration in roots	Multi-organ failure. Tremors, thirst, vomiting, diarrhea, cardiac arrhythmia/bradycardia, weakness, shock. Monitor for cardiac arrhythmias, shock and hyperkalemia	Emesis or gastric lavage. Control dehydration, maintain electrolytes; control diarrhea; monitor ECG and serum potassium
Lupin, bluebonnet (*Lupinus* spp.) Common garden ornamental throughout USA; wild plants abundant in some regions, primarily western USA. Seeds more toxic than leaves, but plant, seeds, and pods are toxic. Toxin is lupine	Signs begin 1–24 hours post exposure. Salivation, ataxia, mydriasis, depression or seizures, disorientation, dyspnea. Liver and kidney damage may develop from continued ingestion. Lupines are teratogenic in ruminants. Risk in small animals is not well known	GI decontamination with activated charcoal for acute exposure. Anticonvulsants may be needed if neurologic signs are severe

TOXIC HOME AND GARDEN HAZARDS FOR PETS (*CONTINUED*)

Table VI–A

Toxic plants and their clinical signs—antidotes and treatment (*continued*)

Plant and Characteristics	*Clinical Signs*	*Antidotes and/or Treatment*
Mexican breadfruit, Swiss cheese plant, hurricane plant (*Monstera deliciosa*) Stems and leaves contain insoluble calcium oxalate spicules (raphides)	Chewing on the plant releases oxalate spicules into mouth, tongue and lips. Response is immediate irritation, pain, salivation, and inflammation. Signs include pawing at face, drooling, and vomiting; potential interference with upper airway	Cleanse mouth thoroughly with water. Apply local and/or systemic anti-inflammatory agents based on clinical condition of patient
Mistletoe (*Phoradendron* spp.) Access to pets in homes at holiday time. Oval evergreen leaves with white berries. Leaves, stems, and berries are moderately toxic, contain toxic amines and proteins	Vomiting, GI pain, diarrhea; ataxia, hypotension, occasional seizures, cardiovascular failure. Principal risk may be from use during holiday season	Fluid and electrolyte replacement; demulcents for gastroenteritis
Monkshood (*Aconitum* spp.) Perennial garden ornamental. Entire plant is toxic, contains diterpene alkaloids that are primarily neurotoxic	Interferes with inactivation of Na+ channels in nerves. Salivation, vomiting, diarrhea. Muscle tremors, weakness, cardiac arrhythmia and/or heart failure; respiratory depression	GI decontamination, fluid and electrolyte replacement. Manage similar to digitalis glycoside overdose, with caution for potassium administration
Morning glory (*Ipomoea purpurea* and *Ipomoea tricolor*) Garden annual, potted plant. Seeds most toxic. Increased risk when seeds are pre-soaked, consumed by dogs. Indole alkaloid toxin similar to ergot alkaloids; abused as hallucinogen	Nausea, mydriasis, ataxia, muscle tremors, hallucinations, decreased reflexes, diarrhea, hypotension	Dark, quiet surroundings; tranquilization as needed. GI decontamination is not routinely recommended
Mountain laurel (*Kalmia* spp.) Native of eastern and southeastern woods, mountains. Both leaves and flowers are toxic. Honey from nectar also toxic. Toxins are diterpenoids, in particular grayanotoxins I and II	Oral irritation, salivation, projectile vomiting, diarrhea, weakness, impaired vision, bradycardia, hypotension, AV block	Activated charcoal, fluid replacement, and respiratory support as needed
Narcissus, daffodil, jonquil (*Narcissus* spp.) Garden ornamental bulb. Bulb is most toxic. Contains lycorine alkaloid	Nausea, vomiting, salivation, hypotension, diarrhea. Prolonged signs may cause dehydration	Gastric lavage, activated charcoal, fluid replacement, supportive treatment for gastroenteritis
Nettle (*Urtica* spp.) Garden or waste area weed. Hairs on leaves contain toxin that enters skin on contact. Most common in hunting or outdoor free-roaming dogs. Toxins are biogenic amines (acetylcholine, histamine, etc.)	Oral irritation and pain, hypersalivation, swelling and edema of nose and periocular areas or other areas of skin contact	Antihistamines and analgesics. Local or systemic anti-inflammatory supportive therapy to treat affected contact areas
Persian violet, sowbread (*Cyclamen persicum*) Popular florists' plant; widely available. Irritant saponins in all parts of the plant, especially tubers or roots	Chewing plant parts causes oral irritation with drooling, vomiting and diarrhea. Occasional hemoglobinuria may color urine red-brown. Large amounts may cause cardiac arrhythmias, seizures and rarely mortality	Control vomiting and diarrhea if severe; administer fluids as needed. Monitor urine for color and/or hemoglobin. Control seizures and cardiac arrhythmias as needed

(*Continued*)

TOXIC HOME AND GARDEN HAZARDS FOR PETS (*CONTINUED*)

Table VI–A

Toxic plants and their clinical signs—antidotes and treatment (*continued*)

Plant and Characteristics	*Clinical Signs*	*Antidotes and/or Treatment*
***Philodendron* spp.** Very common indoor ornamental vine. Toxic principal is insoluble oxalate	Chewing on the plant releases oxalate spicules into mouth, tongue and lips. Response is immediate irritation, pain, salivation, and inflammation. Signs include pawing at face, drooling, and vomiting; also potential interference with upper airway	Cleanse mouth thoroughly with water. Apply local and/or systemic anti-inflammatory agents based on clinical condition of patient
Poinsettia (*Euphorbia pulcherrima*) Garden or potted plant, especially during Holiday season. Sap of stem and leaves mild irritant. Contains a variety of diterpenoid euphorbol esters	Irritation of mouth: may cause vomiting, diarrhea, and dermatitis. Usually transient and not life-threatening	Demulcents for local lesions; fluids to prevent dehydration
Rosary pea, precatory bean (*Abrus precatorius*) Native of Caribbean islands. Seeds (when broken or chewed) are highly toxic. Seeds used in ornamental jewelry in some countries. Illegal to import into USA. Toxin is abrin	Signs may be delayed up to 2 days after ingestion. Early signs are nausea, vomiting, diarrhea (often hemorrhagic) followed by weakness, tachycardia, possible renal failure, coma, death	Emesis or lavage followed by activated charcoal, demulcents, fluids, and electrolytes. Early and thorough detoxication is important for survival
Thorn apple, jimsonweed (*Datura stramonium*) Annual weed, some species are ornamental (*Datura metel*). Entire plant is toxic, but seeds are most toxic and available. Toxins are tropane alkaloids (hyoscyamine and scopolamine) with effects similar to atropine	Thirst, disturbances of vision, delirium, mydriasis, tachycardia, hyperthermia, GI atony/constipation. Commonly described as "Hot as a pistol, blind as a bat, red as a beet, mad as a hatter"	GI decontamination if early after ingestion. Parasympathomimetic drug (e.g., physostigmine)
Tulip (*Tulipa* spp.) and Hyacinth (*Hyacinthus* spp.) Poisoning usually occurs when dogs consume available bulbs or dig up freshly planted bulbs. Toxic principal includes allergenic lactones and similar alkaloids	Signs reflect direct irritation and include drooling, nausea, vomiting, diarrhea, dyspnea, tachycardia, and hyperpnea	GI decontamination if early after ingestion. Apply local and/or systemic anti-inflammatory agents based on clinical condition of patient. Monitor and control gastrointestinal effects; medicate as needed for tachycardia and dyspnea
Tobacco (*Nicotiana tabacum*) Garden plant, weed, cigarettes. Entire plant toxic. Nicotine alkaloid is toxic principal	Rapid onset of salivation, nausea, emesis, tremors, incoordination, ataxia, collapse and respiratory failure	Assist ventilation, provide vascular support. Gastric lavage with activated charcoal
Wisteria (*Wisteria* spp.) Woody vine or shrub with bluish purple to white legume flowers. Entire plant is toxic. Toxin is a glycoprotein lectin	Nausea, abdominal pain, prolonged vomiting; diarrhea. Signs may persist 2–3 days	Antiemetics and fluid replacement therapy
Yellow jessamine (*Gelsemium sempervirens*) Mild temperate to subtropical climates; mainly SE United States. Yellow trumpet-shaped flowers grow on evergreen vines. Neurotoxic alkaloids and sempervirine, an indole, are toxins	Weakness, ataxia, clonic/tonic seizures, paralysis, respiratory failure	GI decontamination early in course of toxicosis. Symptomatic and supportive therapy for respiration. Fluid replacement therapy as needed

TOXIC HOME AND GARDEN HAZARDS FOR PETS (*CONTINUED*)

Table VI-B

Herbal toxicities						
Class	*Toxic Principle*	*Genus Species*	*Common Names*	*Clinical Signs*	*Treatment Overview*	*Popular Usage*
Allergenic	Arabinogalactan	*Echinacea purpurea*	Purple coneflower	Vomiting, diarrhea	Symptomatic/supportive care.	Cold/flu support Immune stimulant
Alpha-2 adrenergic blocking agent	Yohimbine Corynanthine (rauhimbine) Raubasine (δ-yohimbine)	*Pausinystalia johimbe*	Yohimbine	Hyperactivity, agitation, tremors, seizures, vomiting, diarrhea, abdominal pain, tachycardia, hypertension followed by profound hypotension, hypoglycemia	Decontamination; monitor CNS and CV signs; control agitation, tremors, seizures; monitor blood glucose; IV fluids; dextrose PRN	Hypertension Angina "Herbal Viagra"
Anticoagulant	Hydroxycoumarin, bisabolol	*Matricaria recutita*, *Chamaemelum nobile*	Chamomile	Vomiting, diarrhea, lethargy, rarely epistaxis, hematoma (cats)	Monitor coagulation, symptomatic and supportive care, very rarely blood transfusion	Sedative Gastrointestinal ulcers
Cationic detergents	Quaternary ammonium compounds	*Citrus* × *paradisi*	Grapefruit seed extract (GSE)	Drooling, vomiting ± blood, weakness, anorexia, hyperthermia, oral/esophageal irritation or ulceration, dermal erythema, pain, ulceration	Dilution, carafate slurries, H2 blocker or PPI, fluids, nutritional support, broad-spectrum antibiotic, pain control	Disinfectant Antifungal
Essential oils	Melaleuca oil, pulegone, menthofuran	*Melaleuca alternifolia*, *Mentha pulegium*	Tea tree oil, Pennyroyal oil	Orally: vomiting, diarrhea, CNS depression, hepatotoxicity, aspiration pneumonia. Dermally:transient paresis	Dermal: bathe in liquid dish soap. Oral: fluids, *N*-acetylcysteine, monitor liver enzymes. Pain control, thermoregulation PRN	Germicidal Fungal infections Antiseptic Flea control
	Methyl salicylate		Liquid potpourri Oil of wintergreen Oil of sweet birch	Clinical signs are dependent on the type of essential oil and route of exposure. May include GI signs, corrosive oral lesions, drooling, vomiting, ataxia, coma, respiratory distress, hypothermia or hyperthermia, hypotension, acute liver failure	Dermal: bathe in mild liquid dish soap. Oral: Do not induce emesis or give activated charcoal. Irrigate the oral cavity. Fluids, anti-emetic, GI protectants, nutritional support, thoracic radiographs if indicated, monitor liver and kidney values in large exposures, broad-spectrum antibiotics and hepatoprotectants if indicated	Insecticides Aromatherapies Room/air fresheners Personal care products Massage oils Antibacterials Flavorings Herbal remedies Cleaners—citrus oils
	d-Limonene Terpenic oils Benzyl alcohol, benzyl acetate, benzyl benzoate		Citrus oil Pine oils Ylang ylang oil			
	Menthol Alcohols and aldehydes		Peppermint oil Cinnamon oil			
GABA Inhibitor	4-Methoxypyridoxine (MPN)	*Ginkgo biloba*	Gingko, maidenhair tree Dietary supplements pose less risk than fruit/seeds due to lower concentration	Anorexia, vomiting, diarrhea, agitation, clonic tonic seizures	Decontamination (emesis, activated charcoal), GI protectants, anticonvulsants Antidote: Pyridoxal phosphate/ pyridoxine (active form of vitamin B6)	Antitussive Expectorant Cognitive function (although no scientific proof)

Table VI-B

Herbal toxicities (*continued*)

Class	*Toxic Principle*	*Genus Species*	*Common Names*	*Clinical Signs*	*Treatment Overview*	*Popular Usage*
Hypoglycemics	Alpha lipoic acid (ALA) Cinnamon Xylitol	 *Cinnamomum cassia* 	Thioctic acid Cinnamon Xylitol	Hypersalivation, vomiting, hypoglycemia, increased hepatic and/or renal enzymes, death (ALA)	Decontaminate, IV fluids, monitor blood glucose, manage hypoglycemia, monitor liver enzymes, hepatoprotectants (NAC-Mucomyst, Denamarin)	Diabetic treatment Sugar substitute *Amanita* Mushroom poisoning (ALA)
MAO inhibitor	Hypericin	*Hypericum perforatum*	St. John's wort	Depression, vomiting, diarrhea, rarely tremors, seizures	Decontamination, symptomatic and supportive care, cyproheptadine for serotonin syndrome	Antidepressant Insomnia
Methylxanthines	Caffeine, theobromine	*Camellia sinensis*, *Paullinia cupana*, *Cola acuninata*, *Theobroma cacao*	Epigallocatechin gallate or ECGC (green tea), guarana, cocoa, cola, kola nut, chocolate	Agitation, hyperactivity, polyuria, polydipsia, cardiac arrhythmias, tremors, seizures	Decontamination, fluid diuresis, monitor CV and CNS, manage arrhythmias, tremors, seizures, symptomatic and supportive care	Weight loss, Herbal "NoDoz"
Polysulfated glycosamino-glycan (PSGAG)	PSGAG manganese	Glucosamine Chondroitin sulfate	Adequan®, Cosequin®, Dasuquin® Many other brands	Oral: vomiting, diarrhea, polydipsia, hepatopathy. IM: transient dose-dependent prolongation of PT, aPTT, reduced platelet aggregation, diathesis	Manage vomiting and diarrhea, baseline liver enzymes if large ingestion. Coagulopathies only expected with injectable overdoses or if significant liver enzyme elevations occur, monitor clotting parameters	Arthritis Chondroprotective
Salicylates	Methyl salicylate Salicin Salicylic acid	*Gaultheria procumbens* 	Wintergreen extract Willow bark	GI upset, GI ulcers, hyperthermia, hepatoxicity, coagulopathies, coma	Decontamination, GI protectants, fluids, monitor for acidosis, monitor liver and kidney values, liver protectants, monitor clotting parameters	Anti-inflammatory Analgesic
Sedative	Valpotriates	*Valeriana officianalis*	Valerian	Lethargy, sedation	Generally home care, prevent injury	Sedative Sleep aid
Serotonin syndrome	5-Hydroxytryptophan (5-HTP) *Caution*: chewables may also contain xylitol	*Griffonia simplicifolia*	5-HTP Oxitriptan	Vomiting, diarrhea, tremors, seizures, ataxia, hyperesthesia, tachycardia, hyperthermia, mydriasis, transient blindness, depression	Decontamination, IV fluids, acepromazine or chlorpromazine for agitation, methocarbamol for tremors; phenobarbital or propofol for seizures. Avoid benzodiazepines. Cyproheptadine for serotonin syndrome. Monitor for DIC if significantly hyperthermic	Antidepressant Appetite suppressant Sleep aid
Sympathomimetics	Ephedrine Pseudoephedrine Synephrine	*Ephedra sinica*	Ma huang	Hyperthermia, hypertension, tachycardia, tremors, seizures, hallucinations, agitation, serotonin syndrome	Decontamination, monitor CV/CNS signs. Acepromazine for agitation. Cyproheptadine for serotonin syndrome. Beta blockers for tachycardia. Avoid benzodiazepines	Weight loss Body building Herbal "ecstasy" Decongestants

APPENDIX VI

TABATHA REGEHR

TOXIC HOME AND GARDEN HAZARDS FOR PETS (*CONTINUED*)

Table VI-C

Household cleaners, disinfectants, and solvents—products, clinical signs, and treatment

Products	*Toxicity and Clinical Signs*	*Treatment*
SOAPS, DETERGENTS, AND CLEANING AGENTS		
Soaps (fatty acid salts)—includes commercial bar soaps, some liquid hand soaps, laundry bar soaps, homemade soaps, some baby and infant products	Low order toxicity	Generally dilution with water and observation is all that is required. Can typically be managed by pet owner. Fluids and electrolytes should be used to replace fluid loss from excessive vomiting and diarrhea. If vomiting has not yet occurred, emesis should be induced in noncorrosive bar soap ingestions >20 g soap/kg BW. Eyes should be irrigated with tepid water or isotonic saline for 10–15 minutes and observed for signs of irritation. Any exposed skin and hair coat should be rinsed with tepid water for 15 minutes.
Anionic detergents (sulfonated or phosphorylated straight-chain hydrocarbons)—includes most laundry detergents, some automatic dishwashing detergents, and some shampoos. Common detergents include alkyl sodium sulfate, alkyl sodium sulfonate, dioctyl sodium sulfosuccinate, linear alkyl benzene sulfonate, sodium lauryl sulfate, others. Hard water "boosters" or "builders" such as sodium carbonate, sodium phosphate, and sodium silicate are often added	Generally slight to moderate toxicity with high alkaline (pH >12) and potentially corrosive automatic dishwashing detergents, including pods or complete packs, the exception. Irritation to the GI tract with discomfort, vomiting, and diarrhea the most common signs. Absorption occurs through the GI tract and irritated skin; IV hemolysis has been reported. Repeated dermal exposure may result in irritation. Ocular exposure may cause conjunctivitis and irritation; ocular exposure to automatic dishwashing detergents may result in corneal erosion and opacity. Laundry pods or complete packs have caused more serious problems than expected based on the ingredients. The reason is unknown but may be related to increased amounts ingested due to a concentrated product package	Depends on specific product and amount ingested. With most products, dilution with water and replacement of fluid and electrolyte losses secondary to vomiting and diarrhea are all that are required. GI protection as needed. Serum should be monitored for hemolysis. Skin and hair coat should be rinsed well with tepid water for 15 minutes to prevent exposure, especially those animals that are known to self-groom. Eyes should be irrigated well for 10–15 minutes with tepid water or isotonic saline and monitored closely for irritation. Animals exposed in any manner to automatic dishwashing detergents or laundry pods should be examined and monitored for corrosive type injuries and aspiration pneumonia
Cationic detergents (quaternary ammonium compounds with aryl or alkyl substituent groups, often a very long hydrophobic carbon chain with a halogen such as chloride or iodide is attached)—includes fabric softeners, sanitizers, germicides. Compounds such as benzethonium chloride, benzalkonium chloride, and cetyl pyridinium chloride are used as cationic detergents. Liquid potpourris, covered elsewhere, are also in this group	Highly toxic compounds. Effects are concentration dependent with 1% concentrations causing irritation and damage to mucous membranes and 7.5% concentrations resulting in corrosive burns to the mouth, tongue, pharynx, and esophagus. Cats can develop lesions at 2% concentration. GI signs at high concentration include profuse salivation, and vomiting ± blood. Other signs include shock at any stage of exposure, muscle weakness, fever, CNS and respiratory depression, seizures, collapse and coma Dermal effects are concentration dependent. Hair loss and skin ulceration are frequently seen in cats and inflammatory lesions on the paws in dogs. Ocular signs after exposure are concentration dependent and range from irritation and discomfort to corneal damage and ulceration	Depends on the concentration of the product and route of exposure. Animals ingesting product should be given frequent drinks of water if stable. Vomiting should not be induced, especially when the concentration is greater than 7.5%. Activated charcoal is not typically indicated. The mouth and oropharynx should be examined for lesions and those animals with continued profuse salivation, stridor, or dysphagia should undergo endoscopic examination for analysis of mucosal damage. Supportive care includes IV fluids as needed, attention to respiratory effort, adequate caloric intake, seizure medication as needed, and close monitoring for shock. GI protection indicated with all exposures. Ancillary therapies may include pain control and repeated wound lavage. Exposed skin and hair coat should be washed with tepid water and mild soap for at least 15 minutes and monitored for irritation and ulceration. The eyes should be thoroughly evaluated and irrigated with isotonic saline for 20 minutes followed by a slit lamp examination. Further treatment depends on the examination results

TOXIC HOME AND GARDEN HAZARDS FOR PETS (*CONTINUED*)

Table VI–C

Household cleaners, disinfectants, and solvents—products, clinical signs, and treatment (*continued*)

Products	*Toxicity and Clinical Signs*	*Treatment*
Nonionic detergents (uncharged aqueous solutions)—includes hand dishwashing detergents, shampoos, few laundry detergents. Alkyl ethoxylate, alkylphenoxy polyethoxy ethanol (alcohol ethoxylates), and polyethylene glycol stearate are examples	Primarily of low toxicity after ingestion. Ocular exposure may result in irritation	Dilution with water and observation normally all that is required. Can typically be managed by pet owner. IV fluids and electrolytes may be used to replace fluid losses from excessive vomiting and diarrhea. GI protection may be needed. Eyes should be irrigated with tepid water or isotonic saline for 10–15 minutes and observed for signs of continued irritation. Any exposed skin and hair coat should be rinsed well with tepid water to prevent reexposure
CORROSIVES		
Acids (pH <7; strong acids pH <2.5–3)—includes rust removers, drain and toilet bowl cleaners, car battery acid, gun barrel cleaning fluids, other metal cleaners, hair wave neutralizers, some swimming pool cleaning agents. Hydrochloric acid (muriatic acid), sulfuric acid, nitric acid, oxalic acid, phosphoric acid, and sodium bisulfite (sodium acid sulfate) are all acid corrosives. Hydrofluoric acid, a rust remover product, carries a special warning	Signs are concentration and time dependent although in general these are highly toxic substances when below a pH of 2.0. Acids typically have a localized necrotic effect and rarely cause full-thickness mucous membrane lesions. Exposure in animals results in immediate, intense pain which typically limits further exposure. Corrosive mucous membranes burns are initially gray to milky white, turning black as an eschar forms. Stricture formation may follow in several weeks. The animal may vocalize or become lethargic; excessive panting may indicate pain and inability to swallow may be noted. Other effects are hematemesis, abdominal pain, polydipsia, epiglottal edema with secondary respiratory distress, and shock. Secondary pneumonitis results from aspiration or exposure to acid vapors. Serious burns result from ocular or dermal exposure. Pain is severe. Acids tend to penetrate the eye more slowly than bases and may result in a delayed corneal damage including corneal and conjunctiva necrosis. Hydrofluoric acid (HF) penetrates tissues and poisoning can occur through ingestion, inhalation, or skin or eye exposure. Signs are often delayed and pain may not be immediately evident. Once systemic, HF binds with calcium ions producing insoluble calcium fluoride. Severe pain and swelling as well as hypocalcemia result. In severe exposures death from cardiac arrest may occur	All exposures should be diluted immediately with water. Attempts to neutralize the burn with other chemicals are contraindicated as is emesis or gastric lavage. Activated charcoal is ineffective in binding acid corrosives and should not be administered. GI protection indicated with all exposures. Ancillary therapies may include pain control and repeated wound lavage. and pain control as needed. Supportive care including IV fluids may be indicated. Therapy for shock may be required as uncorrected circulatory collapse can lead to renal failure, ischemic lesions in vital organs, and acute death. The presence of severe pharyngeal edema indicates the need for an endotracheal or tracheostomy tube. Esophageal complications are less common with acid exposures than alkali ingestions. If necessary, endoscopy should be carefully performed 12–24 hours after exposure to determine the extent of injury. The procedure should be stopped at the first sign of mucosal damage. Radiographic examination is another alternative. Affected skin and hair coat should be irrigated for at least 15 minutes with copious amounts of tepid water and monitored for lesions. Affected eyes should be irrigated for 20–30 minutes with isotonic saline followed by an examination with a slit lamp. Further treatment depends on the result of the examination. Any deterioration in the animal's signs necessitates a second examination. Hydrofluoric acid exposures require immediate attention even though they may not show any signs. Caretakers should take precautions to protect themselves when bathing or applying medications. Exposed areas should be washed well with cool water and ice packs/cold compresses applied to slow diffusion of the fluoride ion. Calcium gluconate gel applied liberally to the affected area will help bind fluoride. If calcium gluconate gel is not readily available, the area can be soaked in any magnesium hydroxide containing antacid product until the gel is located

(*Continued*)

TOXIC HOME AND GARDEN HAZARDS FOR PETS (*CONTINUED*)

Table VI–C

Household cleaners, disinfectants, and solvents—products, clinical signs, and treatment (*continued*)

Products	*Toxicity and Clinical Signs*	*Treatment*
Bases (pH >7; strong base pH >11.5–12; some references state >10)—includes drain and oven cleaners, cleaning agents, toilet bowl cleaners, washing products. Lye (sodium or potassium hydroxide or caustic soda), sodium carbonate (washing soda or soda ash), sodium metasilicate, and ammonium hydroxide are alkaline ingredients present in many of these products	Rapid liquefaction necrosis on contact with deep, penetrating ulcers. Ingestion may result in full thickness esophageal burns with secondary stricture formation. Little pain on contact so animals are not repelled allowing for a more significant exposure to occur. The remaining signs are similar to those found under corrosive acids	All exposures should be diluted immediately with water. Attempts to neutralize with other chemicals are contraindicated as is emesis or gastric lavage. Activated charcoal is ineffective in binding and should not be administered. Supportive care includes IV fluids and adequate nutrition. GI protection indicated with all exposures. Corticosteroids have been recommended to decrease stricture formation, but their use is controversial. Antibiotics should be used in animals with known perforations or infections. Therapy for shock may be required as uncorrected circulatory collapse can lead to renal failure, ischemic lesions in vital organs, and acute death. The presence of severe pharyngeal edema indicates the need for an endotracheal or tracheostomy tube. Endoscopy should be carefully performed 12–24 hours after exposure to determine the extent of injury. The procedure should be stopped at the first sign of mucosal damage. Radiographic examination is another alternative. Affected skin and hair coat should be flushed for at least 15 minutes with copious amounts of tepid water and monitored for lesions. Affected eyes should be irrigated for 20–30 minutes with isotonic saline followed by an examination with a slit lamp. Further treatment depends on the results of the examination. Any deterioration in the animal's signs necessitates a second examination
DISINFECTANTS		
Bleaches—includes common household bleach (3–6% sodium hypochlorite); industrial or swimming pool bleach (up to 50% sodium hypochlorite); powdered bleach (calcium hypochlorite, sodium dichloroisocyanurate), non-chlorine or colorfast bleach (sodium carbonate peroxide, hydrogen peroxide, sodium perborate)	The toxicity of chlorine bleach depends on the pH and concentration of the hypochlorite ion. Exposed animals may smell like chlorine and their exposed hair coat bleached. Household chlorine bleach products are mild to moderate irritants and generally not associated with significant tissue destruction. Common clinical signs secondary to ingestion include oral irritation, salivation, abdominal pain, and vomiting. Inhalation of fumes may result in coughing, gagging and retching. Systemic reactions are rare. Oral, pharyngeal, esophageal, and gastric burns have been reported from household chlorine bleach ingestions but are rare. The more concentrated hypochlorite solutions and bleach powders can produce corrosive effects. Non-chlorine bleach products are of low order toxicity with gastric irritation and vomiting the most commonly reported signs. Borate containing products decompose to peroxide and borate resulting in a more alkaline and potentially irritating product	All oral exposures should be diluted with water. Exposed skin and hair coat should be washed with a mild soap and copious amounts of water; eyes should be irrigated with isotonic saline for 15 minutes. Animals inhaling chlorine bleach fumes should be moved to fresh air. The incidence of esophageal damage is low so endoscopy is not routinely recommended. Animals with dysphagia, dyspnea, or severe oropharnyngeal burns should undergo careful endoscopic examination and treated as needed for corrosive injuries. Ancillary therapies may include gi protection, pain control, and repeated wound lavage. Affected skin and hair coat should be flushed for at least 15 minutes with copious amounts of tepid water and monitored for lesions

TOXIC HOME AND GARDEN HAZARDS FOR PETS (*CONTINUED*)

Table VI–C

Household cleaners, disinfectants, and solvents—products, clinical signs, and treatment (*continued*)

Products	*Toxicity and Clinical Signs*	*Treatment*
Phenols (coal tar-derived aromatic alcohols)—chlorophenols, phenylphenols in a variety of concentrations and products; some concentrated commercial products contain up to 50% pure phenol. Found in household cleaning products, medicated shampoos, disinfectants, and scents	Considered highly toxic and a medical emergency due to rapid absorption by inhalation, ingestion, or dermal exposure. Cats are more sensitive than dogs. The LD_{50} of pure phenol in dogs is 0.5 g/kg BW (orally) and cats 80 mg/kg BW (unknown route). Concentrations 1–5% may cause tissue irritation and dermal burns, 5–10% dermal, oral and gi burns are possible, and at >10% corrosive damage to all tissues are expected. Oral exposure causes burns to the mouth, oropharynx, and esophagus. Hypersalivation, panting, agitation, and vomiting progress to tremors, cardiac arrhythmias, shock, and coma. Methemoglobinemia, respiratory alkalosis, and renal and hepatic damage may develop. Dermal and ocular exposure results in a short period of intense pain followed by local anesthesia. Necrotic skin areas are white followed in a few days by a dry, gray black eschar. Ocular exposure results in severe corneal burns and erosions	Oral dilution is recommended as soon as possible but choice diluent is considered controversial. Dilute with water or milk at home prior to obtaining veterinary care. Some sources recommend mineral oil for dilution. Emesis is contraindicated and anti emetic should be administered promptly. The mouth and oropharynx should be examined carefully for evidence of mucosal damage prior to gastric lavage. If present gastric lavage is contraindicated. If there is no mucosal damage, activated charcoal with a cathartic may be administered. Further care is supportive and includes monitoring of renal and hepatic function, acid-base status, and respiratory effort. Shock and respiratory depression are complicating factors. *N*-Acetylcysteine (NAC) and SAMe may be used to limit hepatic and renal toxicity. Individuals treating dermal exposures should protect themselves prior to animal treatment. Polyethylene glycol (PEG) or glycerol is recommended for the initial dilution and removal of phenolic compounds followed by washing with a mild soap and water. Oil-based creams and ointments should be avoided as they may increase phenol absorption. Affected eyes should be irrigated for 20–30 minutes with isotonic saline and a slit lamp examination performed. Medications and further therapy depend on exam results
Pine oils (terpene alcohols) and turpentine (mixture of terpenes derived from pine oil)—concentration of pine oil in disinfectants varies from 0.3% to 60%. Turpentine is used to thin oil-based paints. May also be found in equine hoof dressings	Moderate to severe toxicity risk is concentration dependent. The oral LD_{50} of pine oil varies from 1 to 2.7 mL/kg BW but much lower doses may result in severe toxicosis. Cats are more susceptible than dogs. Pine oil products are direct irritants to mucous membranes resulting in erythema in contact areas (mouth, oropharynx, skin). Ingestion results in profuse salivation, abdominal pain, and vomiting ± blood. Systemic effects include respiratory depression, CNS depression, weakness, ataxia, and hypotension. Aspiration during ingestion or emesis or chemical pneumonitis secondary to systemic absorption results in pulmonary toxicity. Myoglobinuria and acute renal may develop with massive ingestions. Dermal exposure causes redness and irritation. Ocular signs include photosensitivity, blepharospasm, epiphora, and conjunctival and scleral erythema	All oral exposures should be diluted with water. Induction of emesis is contraindicated, and gastric lavage carries a risk. Activated charcoal is not indicated. Further treatment is symptomatic and includes close monitoring of renal perfusion, electrolytes, and acid base status. Affected skin should be washed well with a mild soap and copious amounts of water. Ocular exposures should be irrigated for at least 15 minutes with isotonic saline and monitored for further signs

Table VI–C

Household cleaners, disinfectants, and solvents—products, clinical signs, and treatment (*continued*)

Products	*Toxicity and Clinical Signs*	*Treatment*
SOLVENTS AND ALCOHOLS		
Acetone—found in nail polish remover, glues and rubber cement, paint thinner, varnish.	The oral LD_{50} in dogs is 8 mL/kg BW but doses as low as 2–3 mL/kg BW may be toxic. The odor of acetone and presence of elevated urinary ketones indicate exposure. Clinical signs associated with a mild exposure include CNS depression, ataxia, and vomiting; stupor and coma occur with larger amounts. Hyperglycemia and ketonemia may be present	Emesis followed by activated charcoal with a cathartic has been suggested but is controversial due to rapid absorption of acetone and poor binding of activated charcoal. It may be useful if performed within 15–30 minutes of ingestion. Further therapy is symptomatic and supportive and may need to be continued for several days due to the long plasma half-life
Isopropanol—found in model engine fuel, deicers, windshield washer fluid, fuel additives, and varnish and stain removers	The toxic dose of 70% isopropanol is 2 mL/kg BW but doses as low as 0.5 mL/kg BW may be toxic. Signs occur rapidly, generally within 30–60 minutes, and include vomiting ± blood, stupor, and ataxia which may progress to CNS and respiratory depression, severe hypotension, and coma. Mild acidosis may occur	The rapid onset of signs prevents most forms of decontamination. Emesis may be induced in asymptomatic animals if the ingestion occurred with 15–30 minutes. Activated charcoal is not recommended as it does not readily bind alcohols. Further treatment includes IV fluids and monitoring of acid-base and electrolyte status. Hemodialysis may be useful in animals with severe hypotension and coma
Methanol (methyl or wood alcohol, "denatured alcohol")—found in windshield wiper solutions, antifreeze products for door locks	The lethal dose of oral methanol in dogs is 4–8 mL/kg BW. Clinical signs include CNS and respiratory depression, ataxia, hypothermia, vomiting, and coma. Metabolic acidosis is rare. Blindness only occurs in humans and primates	Treatment is similar to isopropanol toxicosis
Ethanol—found in certain mouthwashes, alcohol for consumption (see individual entry), perfumes, cologne, hand sanitizers	The lethal dose of oral methanol in dogs is 5–8 mL/kg BW. Clinical signs are similar to those associated with methanol exposures. Metabolic acidosis more likely than with a methanol exposure	Treatment is similar to isopropanol toxicosis

APPENDIX VII

LEIGH A. LAMONT, KURT A. GRIMM, AND WILLIAM J. TRANQUILLI

PAIN MANAGEMENT

Table VII-A

Recommended parenteral opioid dosages and indications

Opioid	*Dose/Route/Duration*	*Indications*	*Comments*
Butorphanol (injectable)	Dog: 0.2–0.4 mg/kg IM, IV, or SC Cat: 0.2–0.4 mg/kg IM, IV, or SC Duration: 1–3 h	Mild to moderate pain	Mild or no sedation; mild ventilatory depression
Buprenorphine (injectable)	Dog: 0.005–0.03 mg/kg IM, IV Cat: 0.005–0.03 mg/kg IM, IV or transmucosal Duration: 3–8 h Cat: 0.12–0.24 mg/kg SC once daily for up to 3 days for post-operative pain (SIMBADOL) Duration: 24 h	Mild to moderate pain	May be difficult to antagonize, onset of effect 15–30 minutes
Morphine (injectable)	Dog: 0.2–1.0 mg/kg IM or SC; 0.05–0.5 mg/kg IV Cat: 0.05–0.2 mg/kg IM or SC Duration: 3–6 h	Moderate to severe pain	Sedation; respiratory depression; bradycardia; nausea; hypothermia; dysphoria in cats without pain or with large dosage; rapid IV injection may cause histamine release
Methadone (injectable)	Dog: 0.25–0.5 mg/kg IV, IM or SC Cat: 0.1–0.25 mg/kg IV, IM or SC Duration 3–4 h	Moderate to severe pain	Sedation; dysphoria, vomiting, and constipation are reportedly less than with morphine
Hydromorphone (injectable)	Dog: 0.05–0.2 mg/kg IM, IV, or SC Cat: 0.05–0.2 mg/kg IM, IV, or SC Duration: 3–6 h	Moderate to severe pain	Similar side effects as those observed with morphine, but less vomiting and minimal histamine release. May be associated with hyperthermia in cats
Fentanyl (injectable)	Dog: 0.002–0.01 mg/kg IV Cat: 0.001–0.005 mg/kg IV Duration: 20–30 min	Moderate to severe pain; CRI necessary for long-term analgesia	Sedation; respiratory depression; bradycardia; nausea; inadequate duration of analgesia from single IV bolus or IM injection

Table VII-B

Recommended dispensable opioid dosages and indications

Opioid	*Dose/Route/Duration*	*Indications*	*Comments*
Codeine (tablets)	Dog: 1.0–2.0 mg/kg PO Cat: 0.1–1.0 mg/kg PO Duration: 4–8 h	Mild to moderate pain	Minimal side effects; when dosed with acetaminophen, avoid in dogs with liver disease or Heinz body anemia; do not use in combination with acetaminophen in cats
Butorphanol (tablets)	Dog: 0.5–1.0 mg/kg PO Cat: 0.5–1.0 mg/kg PO Duration: 2–4 h	Mild to moderate pain	Mild or no sedation; mild ventilatory depression.
Tramadol (immediate-release tablets)	Dog: 2–10 mg/kg PO q8–12h Cat: 2–5 mg/kg PO q8–12h	Mild to moderate pain	Sedation, anxiety, urinary retention

PAIN MANAGEMENT (*CONTINUED*)

Table VII-C

Recommended parenteral local anesthetic dosages and indications

Local Anesthetic	*Dose/Route/Duration*	*Indications*	*Comments*
Lidocaine (inject able)	Dog: 6–10 mg/kg infiltrate/nerve block; 4 mg/kg epidural; 1–2mg/kg IV bolus followed by 0.05–0.1 mg/kg/min IV CRI Cat: 3–5 mg/kg infiltrate/ nerve block; 4 mg/kg epidural Duration: 1–1.5 h	Moderate to severe pain	CNS and cardiac toxicity with inadvertent IV injection causing excessive plasma concentrations
Bupivacaine (injectable)	Dog: 2 mg/kg infiltrate/nerve block; 1 mg/kg epidural Cat: 1–1.5 mg/kg infiltrate/nerve block; 1 mg/kg epidural Duration: 3–10 h	Moderate to severe pain	Cardiac and CNS toxicity with inadvertent IV injection causing excessive plasma concentrations
Bupivacaine (liposome injectable suspension)	Dog: 5.3 mg/kg infiltrated into tissue layers during incisional closure of cranial cruciate ligament surgery (NOCITA) Cat: 5.3 mg/kg infiltrated in each forelimb for peripheral nerve block for onychectomy (NOCITA) Duration: 48–72 h	Moderate to severe pain	Cardiac and CNS toxicity with inadvertent IV injection causing excessive plasma concentrations; incisional inflammation/ discharge in small number of dogs; hyperthermia in small number of cats

Table VII-D

Recommended parenteral NSAID dosages and indications

NSAID	*Dose/Route/Duration*	*Indications*	*Comments*
Carprofen (injectable)	Dog: 2–4 mg/kg IV, SC q24h Cat: 1.0 mg/kg SC only once	Mild to moderate pain	Primarily used perioperatively before switching to oral formulation; GI irritation and altered renal function
Meloxicam (injectable)	Dog: 0.2 mg/kg initially IM, IV, or SC; 0.1 mg/kg thereafter SC Cat: 0.1–0.2 mg/kg initially IM, SC (single dose only per label) Duration: 24 h	Mild to moderate pain	Can be mixed with food; GI irritation and altered renal function
Ketoprofen (injectable)	Dog: 1.0–2.0 mg/kg initially IM, IV, or SC; 0.5–1.0 mg/kg thereafter SC Cat: 1.0–2.0 mg/kg initially IM, IV, or SC; 0.5–1.0 mg/kg thereafter SC Duration: 24 h	Mild to moderate pain; approved in Canada for dogs and cats and in the US for horses	GI irritation and altered renal function. Dosing should not exceed 5 days for dogs and 3 days for cats
Robenacoxib (injectable)	Dog: 2.0 mg/kg SC q24h for up to 3 days; PO administration as per Table VII-E thereafter Cat: 2.0 mg/kg SC q24h for up to 3 days	Mild to moderate postoperative pain and inflammation	

PAIN MANAGEMENT (*CONTINUED*)

Table VII-E

Recommended dispensable NSAID dosages and indications

NSAID	*Dosage/Route/Duration*	*Indications*	*Comments*
Carprofen (tablets and chewables)	Dog: 4.4 mg/kg PO q24h or divided q12h Cat: 1.0 mg/kg PO (1 dose only) Duration: 12–24 h	Mild to moderate pain; approved for use in dogs with osteoarthritis or perioperative pain	Toxicity associated with chronic use in cats due to variable half-life; may cause GI irritation and altered renal function in some patients
Deracoxib (chewable tablets)	Dog (post-operative pain): 3.0–4.0 mg/kg PO q24 h as needed for 7 days Dog (osteoarthritis): 1–2 mg/kg PO q24h for long-term treatment over 7 days Cat; not used Duration: 24 h	Pain and inflammation associated with osteoarthritis. Post-operative pain and inflammation associated with orthopedic surgery in dogs with osteoarthritis	GI irritation and altered renal function
Firocoxib (chewable tablets)	Dog: 5 mg/kg PO q24h Cat: not used Duration: 24 h	Pain and inflammation associated with osteoarthritis and perioperative pain	GI irritation and altered renal function
Etodolac (tablets)			
Grapiprant (tablets)	Dog: 2 mg/kg PO q24h; cannot be dosed accurately in dogs weighing less than 3.6 kg Cat: not used Duration: 24 h	Pain and inflammation associated with osteoarthritis	Non-COX inhibiting-NSAID; most common adverse reactions are vomiting, diarrhea, decreased appetite, decreased albumin/serum protein; give on an empty stomach to optimize oral bioavailability
Aspirin (tablets)	Dog: 10–25 mg/kg PO Cat: 10–15 mg/kg PO Duration: 8–12 h for dogs, 24–72 h for cats	Mild to moderate pain and inflammation	GI irritation and altered renal function; more likely at higher doses
Meloxicam (oral liquid suspension, tablets)	Dog: 0.2 mg/kg initially PO; 0.1 mg/kg thereafter PO Cat: 0.1–0.2 mg/kg initially PO; 0.05–0.1 mg/kg thereafter PO (reduce to minimum effective dose) Duration: 24 h	Mild to moderate pain	GI irritation and altered renal function; can be mixed with food. Cats should not be given meloxicam for > 5 days
Robenacoxib (oral tablets)	Dog: 2.0 mg/kg PO q24h for up to 3 days Cat: 1 mg/kg PO q24h for up to 3 days Duration: 24 h	Mild to moderate postoperative pain and inflammation	GI irritation and altered renal function
Ketoprofen (tablets)	Dog: 1.0–2.0 mg/kg initially PO; 0.5–1.0 mg/kg thereafter PO Cat: 1.0–2.0 mg/kg initially PO; 0.5–1.0 mg/kg thereafter PO Duration: 24 h	Mild to moderate pain; approved in Canada for dogs and cats and in the US for horses	GI irritation and altered renal functions. Limit administration to 5 days for both dogs and cats
Acetaminophen (tablets and oral liquid suspension)	Dog: 10–15 mg/kg PO Cat: contraindicated Duration (in dogs): 8–12 h	Mild to moderate pain; low anti-inflammatory action	Toxic to cats; often given in combination with codeine to dogs

PAIN MANAGEMENT (*CONTINUED*)

Table VII-F

Dosages and indications for selected drugs used to treat neuropathic pain

Drug	*Dosage/Route*	*Duration (PO)*	*Comments*
Ketamine (NMDA antagonist)	Dog: 0.1–1.0 mg/kg IM, SC, or PO Cat: 0.1–1.0 mg/kg IM or SC	4–6 h 4–6 h	Low doses potentiate postoperative analgesics. Do not use with intracranial hypertension
Amantadine (NMDA antagonist)	Dog: 3.0–5.0 mg/kg PO Cat: 3.0–5.0 mg/kg PO	24 h 24 h	Used to potentiate or prolong analgesia. Efficacious when combined with an NSAID for management of osteoarthritis-associated pain in dogs
Amitriptyline (tricyclic antidepressant)	Dog: 1.0 mg/kg PO Cat: 2.5–10.0 mg/cat PO	12–24 h 24 h	Used to potentiate or prolong analgesia.
Gabapentin (antiepileptic)	Dog: 2–10 mg/kg PO q8–12h; dose can be titrated up to 20 mg/kg q8–12h if necessary Cat: 1–8 mg/kg PO q8–12h	24 h 24 h	Usually associated with few side effects other than sedation, and, occasional ataxia in cats. Has shown good results in human and animal studies

To select and administer an adjuvant analgesic properly, the veterinarian should be aware of the drug's clinical pharmacology. The following information about the drug is necessary: (1) approved indication, (2) unapproved indication (e.g., as an analgesic) widely accepted in veterinary medical practice, (3) common side effects and potentially serious adverse effects, (4) pharmacokinetic features, and (5) specific dosing guidelines for pain.

APPENDIX VIII

DAVID DYCUS, CANNY FUNG, AND MATHIEU GLASSMAN

MEDICATIONS AND SUPPLEMENTS FOR OSTEOARTHRITIS

This appendix has been provided to act as a quick reference for supplements and medications commonly used to treat animals with joint pain and osteoarthritis (OA). The contraindications, precautions, and interactions include all of the most common concerns for these categories. For a comprehensive list of warnings, we recommend referring to one of the many veterinary drug reference that are available.

The authors have also included a subjective evaluation of the level of evidence-based, peer-reviewed research that is available to support the use of these medications and supplements in clinical practice to support animals with osteoarthritis and inflammation:
- NONE—No evidence to support use in the clinical veterinary patient.
- WEAK—Evidence that shows minimal benefit to the veterinary patient clinically or *in vitro*. There may be human literature that could be inferred to the veterinary patient.
- MODERATE—Evidence that shows *in vitro* and/or *in vivo* benefit for OA and joint pain.
- STRONG—Compelling evidence that shows benefit for OA and joint pain support in the clinical veterinary patient.

Table VIII-A

Anti-inflammatories and pain medications

Category	*Dosage*	*Mechanism of Action*	*Contraindications*	*Precautions*	*Interactions*	*Evidence-Based Support in the Literature*
Amitriptyline (tricyclic antidepressant [TCA])	Dog: 1.0 mg/kg PO Cat: 2.5–10.0 mg/cat PO	TCAs inhibit serotonin and norepinephrine reuptake and possible actions at opioid receptors and nerve transmission, complete MOA unknown	Patients with renal or hepatic or thyroid or cardiac disorders	May reduce seizure threshold Sedation at higher doses Anticholingeric properties (constipation and urinary retention) Taper when discontinuing	Concurrent administration with monoamine oxidase inhibitors, anipryl, SSRIs due to potential of serotonin syndrome	NONE—for OA management
Antiepileptic (gabapentin)	Dog: 2–10 mg/kg PO q8–12h; dose can be titrated up to 20 mg/kg	GABA analogue, therapeutic action on neuropathic pain is thought to involve voltage-gated N-type calcium ion channels, complete MOA unknown	Patients with renal or hepatic insufficiency may require less frequent dosing or lower doses	Sedation at higher doses Abrupt discontinuation can lead to severe rebound pain, tapering the dose is recommended	Concurrent administrations with oral antacids can reduce absorption from GI tract	NONE—for OA management
NMDA antagonist (amantadine)	Dog: 3.0–5.0 mg/kg PO Cat: 3.0–5.0 mg/kg PO	NMDA receptor antagonist, complete MOA unknown. Best used when combined with another analgesic such as an NSAID	Patients with hypersensitivity to it. Reduce dose in face of renal dysfunction	Use caution in patients with seizure disorders or patient on medications that lower the seizure threshold GI upset	Concurrent administrations with urinary acidifiers may increase excretion or anticholinergic drugs and TMS may enhance effects/decrease excretion	MODERATE

(*Continued*)

MEDICATIONS AND SUPPLEMENTS FOR OSTEOARTHRITIS (*CONTINUED*)

Table VIII-A

Anti-inflammatories and pain medications (*continued*)

Category	*Dosage*	*Mechanism of Action*	*Contraindications*	*Precautions*	*Interactions*	*Evidence-Based Support in the Literature*
NSAIDs (various)	See Table VIII-C	Inhibit prostaglandin synthesis through cyclooxygenase enzymes. Inhibition of EP4 receptor-specific	NSAIDs must not be given with steroids	NSAIDs may cause gastric ulceration or upset COX-2 selective drugs may interfere with liver function when used outside of dosage range When switching NSAIDs wait 3 days for washout before starting new drug When switching from aspirin to NSAID 7 days for washout is required	Steroids with NSAIDs	STRONG
Opioids (various)	See Tables VIII-A and VIII-B	Natural opioid prodrug with suspected metabolism to active metabolites including morphine. Efficacy reflects the agonistic action of mu opioid receptors	None	Use caution in patients with head trauma	May decrease the effects of diuretics in patients with CHF	MODERATE

To select and administer an adjuvant analgesic properly, the veterinarian should be aware of the drug's clinical pharmacology. The following information about the drug is necessary: (1) approved indication, (2) unapproved indication (e.g., as an analgesic) widely accepted in veterinary medical practice, (3) common side effects and potentially serious adverse effects, (4) pharmacokinetic features, and (5) specific dosing guidelines for pain.
NMDA = N-methyl-d-aspartate; GI = gastrointestinal; NSAID = nonsteroidal anti-inflammatory drug.

Table VIII-B

Recommended parenteral NSAID dosages and indications

NSAID	*Dose/Route/Duration*	*Indications*	*Comments*
Carprofen (injectable)	Dog: 2–4 mg/kg IV, SC q24h Cat: 1.0 mg/kg SC only once	Mild to moderate pain	Primarily used perioperatively before switching to oral formulation; GI irritation and altered renal function.
Ketoprofen (injectable)	Dog: 1.0–2.0 mg/kg initially IM, IV, or SC; 0.5–1.0 mg/kg thereafter SC Cat: 1.0–2.0 mg/kg initially IM, IV, or SC; 0.5–1.0 mg/kg thereafter SC Duration: 24 h	Mild to moderate pain; approved in Canada for dogs and cats and in the US for horses	GI irritation and altered renal function. Dosing should not exceed 5 days for dogs and 3 days for cats.
Meloxicam (injectable)	Dog: 0.2 mg/kg initially IM, IV, or SC; 0.1 mg/kg thereafter SC Cat: 0.1–0.2 mg/kg initially IM, SC (single dose only per label) Duration: 24 h	Mild to moderate pain	Can be mixed with food; GI irritation and altered renal function

GI = gastrointestinal; NSAID = nonsteroidal anti-inflammatory drug.

MEDICATIONS AND SUPPLEMENTS FOR OSTEOARTHRITIS (*CONTINUED*)

Table VIII-C

Recommended oral NSAID dosages and indications

NSAID	*Dosage/Route/Duration*	*Indications*	*Comments*
Acetaminophen (tablets and oral liquid suspension)	Dog: 10–15 mg/kg PO Cat: contraindicated Duration (in dogs): 8–12 h	Mild to moderate pain; low anti-inflammatory action	Toxic to cats; often given in combination with codeine to dogs
Aspirin (tablets)	Dog: 10–25 mg/kg PO Cat: 10–15 mg/kg PO Duration: 8–12 h for dogs, 24–72 h for cats	Mild to moderate pain and inflammation	GI irritation and altered renal function; more likely at higher doses. Not commonly used as there are better options available today
Carprofen (tablets and chewables)	Dog: 4.4 mg/kg PO q24h or divided q12h Cat: 1.0 mg/kg PO (1 dose only) Duration: 12–24 h	Mild to moderate pain; approved for use in dogs with OA or perioperative pain	Toxicity associated with chronic use in cats due to variable half-life; may cause GI irritation and altered renal function in some patients
Deracoxib (chewable tablets)	Dog (postoperative pain): 3.0–4.0 mg/kg PO q24h as needed for 7 days Dog (OA): 1–2 mg/kg PO q24h for long-term treatment over 7 days Duration: 24 h	Pain and inflammation associated with OA. Post-operative pain and inflammation associated with orthopedic surgery in dogs with OA. Postoperative ≥ 1.8 kg	GI irritation and altered renal function
Etodolac (tablets)	Dog: 10–15 mg/kg PO Cat: not used Duration: 24 h	Mild to moderate pain	Hypoproteinemia; GI irritation and altered renal function. Associated with KCS in a small number of dogs Not commonly used as there are better options available today
Firocoxib (chewable tablets)	Dog: 5 mg/kg PO q24h	Pain and inflammation associated with OA and perioperative pain	GI irritation and altered renal function
Gapriprant (tablets)	Dog: 2mg/kg PO q24h Cat: up to 15mg/kg/day for 28 days	Pain and inflammation associated with OA	GI irritation. No safety evaluation in dogs younger than 9 months of age or weighing less than 3.6 kg. FDA approved in dogs
Ketoprofen (tablets)	Dog: 1.0–2.0 mg/kg initially PO; 0.5–1.0 mg/kg thereafter PO Cat: 1.0–2.0 mg/kg initially PO; 0.5–1.0 mg/kg thereafter PO Duration: 24 h	Mild to moderate pain; approved in Canada for dogs and cats and in the US for horses	GI irritation and altered renal functions. Limit administration to 5 days for both dogs and cats. Not commonly used as there are better options available today
Meloxicam (oral liquid suspension, tablets)	Dog: 0.2 mg/kg initially PO; 0.1 mg/kg thereafter PO Cat: 0.1–0.2 mg/kg initially PO; 0.05–0.1 mg/kg thereafter PO (reduce to minimum effective dose) Duration: 24 h	Mild to moderate pain	GI irritation and altered renal function; can be mixed with food. Cats should not be given meloxicam for >5 days
Robenacoxib (oral tablets and injectable in some countries)	Dog: 2 mg/kg SC once prior to surgery, 1 mg/kg PO q24h for up to 12 days Cat: 1 mg/kg PO up to 3 days in US Duration: 24 h	Mild to moderate pain; not approved for dogs in US	GI irritation and altered renal function. Only FDA-approved NSAID for cats
Tepoxalin (tablets)	Dog: Load 20 mg/kg, then 10 mg/kg PO q24h	Pain and inflammation associated with OA	GI irritation. Give with food. Caution in patients with hepatic, cardiac and renal dysfunction No safety evaluation in dogs younger than 6 months of age or weighing less than 3 kg

Table VIII-D

Disease-Modifying Drugs (DMOADs)

Category	*Dosage*	*Mechanism of Action*	*Contraindications*	*Precautions*	*Interactions*	*Evidence-Based Support in the Literature*
Avocado Soybean unsaponifiables (ASU)	300 mg/day	Stimulates aggrecan production and restored aggrecan production after IL-1β treatment and decreased MMP-3 production and stimulated TIMP-1 production	None	None	None	STRONG
Chondroitin	800 mg/day	Stimulates synthesis of GAGs and inhibit degradative enzymes	None	Large variation in products	None	WEAK
Glucosamine	1000 mg/day	Used in the synthesis of disaccharide units of GAGs and proteoglycans. May have anti-inflammatory properties and may stimulate GAGs , proteogylcan and collagen synthesis, may scavenge oxygen-derived free radicals, stimulate hyaluronic acid synthesis	None	Large variation in products	None	WEAK
Green-lipped mussel extract	20–49 mg/kg/day; 4 (dogs <40 kg BW)–6 (dogs >40 kg BW) capsules/day for 10 days then continuing with half of the loading dose	May have chondroprotective and anti-inflammatory properties	None	None	None	STRONG
Omega-3 fatty acid	Eicosapentaenoic acid (EPA), Dochosahexaenoic acid (DHA) (150–175 mg/kg of DHA and/or EPA daily; canine	Competes with omega-6 fatty acids in particular arachadonic acid to minimize the inflammatory cascade, in addition can cause the inhibition of release of cyclooxygenase and lipoxygenase	None	Use cautiously in patients prone to pancreatitis, high dosages of omega-3 fatty acids without incorporation of diet and daily exercise will lead to weight gain	None	STRONG
Polysulfated glycosaminoglycans (Adequan)	(2 mg/lb IM twice weekly for 4 weeks; Canine) Off label usage for SC route, for felines, and for monthly maintenance	Not completely known suspected to inhibit serine proteinases, prostaglandin E2 synthesis, and metalloproteases. May stimulate synthesis of protein, collagen, proteoglycan, and hyaluronic acid	None	Use caution in patients with underlying clotting or platelet pathology	None	STRONG
T-Relief	Dogs: 1–3 tablets PO q8h Newborn puppies: ½ tablet PO q24h Weaned puppies: 1 tablet PO q8h Cats: 1 tablet PO q8h	Unknown; homeopathic ingredients including arnica Montana and belladonna to help with minor injuries	None	None	None	WEAK

GAGs = glycosaminoglycans; MMP = matrix metalloproteinsases; IL-1 = interleukin-1; TIMP = tissue inhibitors of metalloproteinase.

APPENDIX IX

CHRISTOPHER L. MARIANI

GLOSSARY OF TERMINOLOGY FOR SEIZURES AND EPILEPTIC DISORDERS

GLOSSARY OF TERMINOLOGY FOR SEIZURES AND EPILEPTIC DISORDERS

There is no formally approved classification system for seizures or epilepsy in veterinary medicine and authors proposing such systems in the past have largely adapted human classification schemes (1–5). This proposed glossary is no different and is based mainly on publications sanctioned by the International League Against Epilepsy (ILAE) (6–11). Terms have been added, changed or eliminated to better reflect the seizure types seen in veterinary patients and the challenges inherent with the interpretation of such events in animals. This glossary is adapted from a more detailed proposal of terminology for veterinary patients (12), and interested readers are referred to this work for more details on seizure description and semiology, background on ILAE classification and adaptations for animals, and rationale for the currently proposed terms.

GENERAL TERMS AND DEFINITIONS

Seizure: a discrete episode suspected to be epileptic in origin. Synonym: ictus.

Epileptic seizure: manifestation(s) of excessive and/or hypersynchronous activity of neurons in the brain; usually self-limiting.

Epilepsy: a chronic neurologic condition characterized by recurrent seizures; has an intracranial origin.

Focal seizure: a seizure whose initial signs indicate, or are consistent with, initial activation of only part of one cerebral hemisphere. Synonym: partial.

Generalized seizure: a seizure whose initial signs indicate, or are consistent with, more than minimal involvement of both cerebral hemispheres.

CLASSIFICATION OF EPILEPTIC SEIZURES

1. Motor Seizures: involving somatic musculature in any form. May consist of an increase (positive) or decrease (negative) in muscle contraction to produce a movement.

1A. Elementary Motor: a single type of contraction of a muscle or group of muscles that is usually stereotyped.

- **Tonic**: a sustained increase in muscle contraction lasting a few seconds to minutes.
- **Myoclonic:** sudden, brief (< 100 ms), involuntary single or multiple contractions of muscles or muscle groups of variable topography (axial, proximal limb, distal limb, facial).
  - **Clonic:** myoclonus that is regularly repetitive, involves the same muscle groups, at a frequency of approximately 2–3 per second, and is prolonged.
- **Tonic-clonic:** a sequence consisting of a tonic followed by a clonic phase.
  - **Generalized tonic-clonic seizure:** bilateral symmetric tonic contraction and then bilateral clonic contractions of somatic muscles, usually associated with autonomic phenomena and loss of consciousness. Synonyms: grand mal seizure, bilateral tonic-clonic seizure, major motor seizure.
- **Atonic:** sudden loss or diminution of muscle tone without an apparent preceding myoclonic or tonic event lasting greater than 1–2 seconds and involving the head, trunk, jaw or limb musculature.
- **Astatic:** loss of erect posture that results from an atonic, myoclonic or tonic mechanism. Synonym: drop attack.

1B. Automatism: a more or less coordinated, repetitive, motor activity usually occurring when cognition is impaired. Often resembles a voluntary movement. Examples might include chewing, licking, aimless running, or vocal utterances (e.g., barking, meowing, whining or growling).

2. Non-motor Seizures

Aura: an ictal phenomenon that may precede an observable seizure or if occurring alone, constitutes a sensory seizure.

Sensory seizure: a perceptual experience not caused by appropriate stimuli in the external world.

Note: Although sensory seizures almost certainly occur in animals, documenting their existence is obviously very difficult without the ability of the patient to describe sensory phenomena. Therefore, we are left to observe the behavior that the suspected sensory seizure produces. Some potential sensory phenomena include visual events (e.g., flashing or flickering lights, or other objects or patterns; the animal may bite or snap in response ["fly biting"]), somatosensory events (tingling, numbness or electric-shock sensations; the animal may bite or lick itself or run frantically during episode), auditory, olfactory, gustatory and affective events (e.g., fear, depression, joy or anger; the animal may become aggressive towards people or other animals).

Dyscognitive seizure: events in which disturbance of cognition is the predominant or most apparent feature.

Note: In the ILAE glossary, cognition is composed of perception, attention, emotion, memory and executive function (which includes decision making and initiation of motor activity) (8). In animals, without a description from the patient it may again be difficult to prove that certain dyscognitive seizure types exist or differentiate them from sensory seizures. However, certain examples (e.g., events where animals suddenly stop what they are doing and stare into space, often with a lack of appropriate responsiveness to external stimuli ["behavioral arrest"]) might be best classified here.

3. Autonomic Seizures: an objectively documented and distinct alteration of autonomic nervous system function involving cardiovascular, pupillary, gastrointestinal, sudomotor, vasomotor, and thermoregulatory functions.

MODIFIERS AND DESCRIPTORS OF SEIZURE TIMING

Duration: time between the beginning of initial seizure manifestations and the cessation of observed seizure activity. Does not include prodrome or postictal states but might include aura.

Cluster seizures: two or more seizures within a 24-hour period. Synonyms: acute repetitive seizures, serial seizures

Status epilepticus: 1) a seizure that persists for greater than 5 minutes or 2) recurrent seizures without interictal resumption of baseline central nervous system function.

Prodrome: a pre-ictal phenomenon. A subjective or objective clinical alteration (e.g., agitation, attention-seeking) that heralds the onset of an epileptic seizure but does not form part of it.

Note: It may be quite challenging or impossible to differentiate a prodrome (pre-ictal period) from an aura (start of ictus) in many veterinary patients although videotaping of the episodes, close observation and/or ictal electroencephalography may be helpful in this regard.

Postictal phenomenon: a transient clinical abnormality of central nervous system function that appears or becomes accentuated when clinical signs of the ictus have ended. May manifest as impaired mentation, altered behavior or motor or sensory deficits.

Provocative factor: transient and sporadic endogenous or exogenous element capable of augmenting seizure incidence in animals with chronic epilepsy or evoking seizures in susceptible individuals without epilepsy.

- **Reactive:** occurring in association with transient systemic perturbation or illness such as some metabolic conditions (e.g., hypoglycemia, electrolyte disorders) or intoxications.
- **Reflex:** objectively and consistently demonstrated to be evoked by a specific afferent stimulus or by activity of the patient. Examples include stimuli such as light flashes, certain noises or startling and activities such as specific motor movements or more complex behaviors.

CLASSIFICATION OF EPILEPSY

Epilepsy is defined here as a chronic neurologic disorder that causes recurrent seizure activity, and that has an intracranial

etiology. As stated by the ILAE Classification Core Group in 2006, "the diagnosis of epilepsy implies a persistent epileptogenic abnormality of the brain that is able to spontaneously generate paroxysmal activity. This is in contrast to a brain that has an acute seizure as a natural response to a transient insult or loss of homeostasis" (10). Thus, seizures caused by extracranial disorders such as metabolic conditions (e.g., hypoglycemia, electrolyte abnormalities) or toxins are not considered to be epilepsy, even when repetitive seizures occur over time (e.g., with hypoglycemia secondary to an insulinoma). These seizures are termed reactive seizures (see definition under "provocative factor" above). Note however that such a disorder might secondarily cause structural damage to a previously normal brain (e.g., through necrosis or excitotoxicity) and result in true epilepsy. An explanation of the term "idiopathic epilepsy" is also warranted here, as veterinarians use the word "idiopathic" in various ways. Some use this term to imply epilepsy of genetic or heritable origin (as it was originally intended for use in humans), while others use "idiopathic" to mean "cause unknown." The following classification is proposed to replace those previously used in veterinary medicine and has been adapted from a 2010 ILAE report (11).

Genetic epilepsy: Epilepsy as a direct result of a known or strongly suspected genetic defect or defects in which seizures are the core sign of the disorder. Generally, genetic epilepsies have no identifiable structural brain lesion or other neurologic signs, and have an age-dependent onset. Synonyms: Primary, inherited, idiopathic (for some).

Structural epilepsy: Epilepsy as a result of one or more identifiable structural lesions of the brain. Synonyms: Symptomatic, secondary. Structural epilepsies include disorders such as brain tumors, encephalitis, and cerebrovascular accidents. Note that some disorders that may have a genetic cause or that are strongly heritable may still be best classified here; these include anomalous disorders such as hydrocephalus, lissencephaly, degenerative disorders such as ceroid lipofuscinosis, and others.

Unknown epilepsy: The underlying cause of the epilepsy is unknown. This may be the result of a subtle structural lesion that is undetectable with currently available diagnostic technologies or an as yet unrecognized genetic disorder. Synonyms: Cryptogenic, probably symptomatic, idiopathic (for some).

APPENDIX X

COMMON PROCEDURES AND TESTING PROTOCOLS

ABDOMINOCENTESIS AND FLUID ANALYSIS

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection.

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Abdominocentesis is the percutaneous removal of peritoneal fluid for diagnostic and/or therapeutic purposes.
- Characterization of abdominal fluid may help determine primary disease process or pathophysiologic mechanism responsible for fluid accumulation.
- Blind abdominocentesis is easily performed when a large amount of fluid is present; ultrasound-guided abdominocentesis is useful when fluid volume is limited or localized.
- Diagnostic peritoneal lavage (DPL) is most often considered if abdominocentesis has failed to yield any fluid and undiagnosed intra-abdominal disease is suspected.
- Therapeutic abdominocentesis may improve quality of life in conjunction with medical management of chronic ascites.

INDICATIONS
- Peritoneal fluid suspected based on physical examination (abdominal distention, fluid wave) or diagnostic imaging.
- Blunt or penetrating abdominal trauma (e.g., dog bite, gunshot wound, motor vehicular accident).
- Suspicion of ruptured bowel, peritonitis, or postoperative GI dehiscence.
- Acute abdominal pain.
- Shock without apparent cause.
- DPL—with suspicion of undiagnosed intra-abdominal disease in face of negative abdominocentesis.
- Therapeutic abdominocentesis—when increased intra-abdominal pressure causes respiratory distress, decreased blood flow to visceral organs, or discomfort.

CONTRAINDICATIONS
- Abdominocentesis should be performed with caution or is contraindicated in presence of:
  - Dilated hollow abdominal viscus (stomach and intestines), generalized ileus.
  - Organomegaly.
  - An enlarged uterus because of pregnancy or pyometra.
  - Coagulopathy, thrombocytopenia.
- An uncharacterized large intra-abdominal mass is contraindication for blind abdominocentesis.
- Avoid DPL if diaphragmatic hernia suspected.

POTENTIAL COMPLICATIONS
- Hemorrhage from a punctured vessel or lacerated abdominal organ.
- Perforation of a hollow viscus (bowel, bladder) and iatrogenic peritonitis.
- Spread of infection, especially from a localized lesion (e.g., abscess, pyometra).
- Tearing of a fenestrated over-the-needle catheter in the abdomen during removal.
- Large-volume abdominocentesis may cause rapid fluid shifts and electrolyte changes:
  - Avoid removing large volumes from animals that have serum albumin of ≤2 g/dL.
- In addition to the above, DPL may result in subcutaneous hematoma or leakage of lavage fluid.

CLIENT EDUCATION
- Abdominocentesis is a minimally invasive diagnostic procedure that is generally easy to perform and associated with minimal risk and discomfort.
- Abdominocentesis is usually performed in awake patients, but sedation and/or analgesia may be necessary.

BODY SYSTEMS ASSESSED
- Hepatobiliary.
- Urinary.
- Gastrointestinal.
- Vascular (as with hemoabdomen).

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
Consider emptying a distended urinary bladder prior to abdominocentesis or DPL.

Anesthesia or Sedation
Patients should be restrained either manually or with sedation/analgesia to prevent unwanted motion that could result in complications. Prior to drug administration, consider patient's general and cardiovascular condition (e.g., shock) and procedure being performed (sedation and local analgesia almost always indicated for DPL).

Patient Positioning
Patient in left lateral recumbency (to prevent splenic puncture) or can remain standing to improve gravity-dependent fluid retrieval. Patient positioning may be altered based on visualization of fluid using ultrasound guidance.

Patient Monitoring
Blood pressure, pulse oximetry, and heart rate/ECG should be monitored as indicated by patient's clinical status. Patients should be monitored for signs of pain or discomfort.

Equipment or Supplies
- Clippers.
- Surgical scrub.
- Sterile gloves.
- Syringes of various sizes (3, 5, or 10 mL).
- 2% Lidocaine (injectable).
- Glass slides.
- EDTA and serum tubes and culturettes.

For Abdominocentesis
- Hypodermic needle: 18- through 22-gauge, 1- to 1½-inch or over-the-needle IV catheter of similar size. Butterfly catheters may be used in small or thin patients.
- Consider addition of fenestrations in large gauge (14–18 gauge) over-the-needle catheters using a sterile scalpel blade. Fenestrations should be small and smooth and should not be directly opposite each other, as this may lead to catheter weakening and possible kinking or tearing within abdomen.
- Optional: extension set.
- For therapeutic abdominocentesis, a three-way stopcock, 20- to 60-mL syringe, and collection vessel.

For DPL
- A commercially available peritoneal dialysis catheter or alternatively a 20- to 14-gauge, over-the-needle, 1–2 inch IV catheter, fenestrated as described previously.
- A bag of warmed sterile isotonic saline solution with an administration set.
- 3- to 12-mL syringes.
- A three-way stopcock attached to an extension set (optional).

TECHNIQUE

Closed or Open Needle Abdominocentesis
- Abdominocentesis site is just caudal to umbilicus, on ventral midline or slightly lateral to the right (2–3 cm in mid-sized dogs). In a standing patient, site is at most dependent part of abdomen.
- A 10 × 10 cm area should be clipped, and skin prepared aseptically.
- Lidocaine 2% local anesthetic may be infused at the abdominocentesis site.
- Needle is inserted through skin and abdominal wall; if using an over-the-needle catheter, catheter is fed off stylet once in the abdomen (typically fluid visible in hub):
  - If needle or catheter is not attached to a syringe, collect the fluid into a sterile tube as it drips from the hub (this technique may introduce air into abdomen).
  - If needle or catheter is attached to syringe or extension set and syringe, apply gentle suction; vigorous suction may result in false-negative result.
- Collect fluid aseptically, perform cytologic analysis, bacteriologic culture, other diagnostics as indicated.
- For therapeutic abdominocentesis, extension set and 3-way stopcock are mounted on needle or catheter and attached to a syringe.

(CONTINUED) ABDOMINOCENTESIS AND FLUID ANALYSIS

• When using an over-the-needle catheter with added fenestrations, take care to remove it completely by gently rotating it or dissecting it from subcutaneous tissue.

Four-Quadrant Abdominocentesis

• Divide ventral surface of abdomen into 4 quadrants by an imaginary line that bisects linea alba and through the umbilicus.
• Wide surgical prep centered at umbilicus.
• Insert needles, one at a time, in each quadrant until fluid is retrieved.
• Fluid should flow through needle into sampling tubes.
• False-negative results more likely if suction applied.

Ultrasound-Guided Abdominocentesis

• Locate small volume or localized effusion with ultrasonography.
• Clip hair on a 10 × 10 cm area and prepare aseptically.
• Mount needle on syringe or extension set attached to syringe, insert under ultrasound guidance into pocket of fluid and gently aspirate.

Diagnostic Peritoneal Lavage (Closed Technique)

• Consider imaging (abdominal radiographs, CT, or ultrasound) prior to DPL as this procedure will alter results.
• DPL site is 1–3 cm caudal to umbilicus, on midline or just right from midline.
• Wide surgical prep centered at umbilicus.
• Infiltrate skin and abdominal wall with local anesthetic at puncture site.
• Make a stab incision through skin with a number 11 scalpel blade at site of local anesthetic infusion.
• Introduce catheter with stylet into abdomen through stab incision.
• Slide catheter off stylet dorsocaudally into abdomen.
• Once catheter is in abdomen, attach syringe and aspirate gently. If fluid is retrieved, there is no need to proceed with lavage.
• In the absence of fluid, infuse 20–22 mL/kg of warm sterile 0.9% saline solution through catheter using an IV infusion set with rapid gravity flow.
• After completing infusion, have patient walk around (if able) or roll patient gently from side to side to disperse fluid, taking care not to dislodge catheter.
• Aspirate catheter gently with a syringe to remove fluid sample. Most often, only a small portion of instilled fluid is retrieved; remaining fluid will be reabsorbed by peritoneum.
• Collect lavage fluid aseptically and analyze.

SAMPLE HANDLING

• Inspect fluid macroscopically for clarity and color.
• Divide fluid into aliquots:
  ◦ EDTA tube for cytologic evaluation, including red blood cell and nucleated cell counts and differential (*not* for culture).
  ◦ A serum tube for biochemical analysis as indicated (may need concurrent analysis on peripheral blood; see below).
  ◦ A culturette or an additive-free glass tube, for aerobic and anaerobic bacterial culture, depending on laboratory preference.
• Determine specific gravity and total solids (TS) by refractometry.
• Direct microscopic cytologic evaluation: smear small drop of fluid across a slide, air-dry, and apply Romanovsky-type stain (Diff-Quik, Hema III, Giemsa, or Wright stain). For hypocellular fluids (2,000–50,000 cells/µL), a drop from the resuspended pellet of a centrifuged sample can be evaluated. Cytospin preparation may be necessary for very hypocellular (<2,000 cells/µL) samples.
• Measure packed cell volume (PCV) and TS of hemorrhagic effusions. Consider the following paired biochemical tests based on differential diagnoses:
  ◦ Uroabdomen: creatinine, potassium.
  ◦ Bile peritonitis: bilirubin.
  ◦ Pancreatitis: lipase, amylase, cPLI.
  ◦ Chyloabdomen: triglycerides, cholesterol.
  ◦ Septic peritonitis: glucose, lactate.
  ◦ FIP: protein electrophoresis.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring

Usually none, but should be tailored to patient's general condition (e.g., shock, pain).

Nursing Care

None

Dietary Modification

None

Medication Requirements

Analgesia might be required.

Restrictions on Activity

Cage rest, as needed, depending on patient's clinical signs.

Anticipated Recovery Tme

N/A

INTERPRETATION

NORMAL FINDINGS OR RANGE

• Absence of free intra-abdominal fluid.
• In normal dogs, lavage fluid WBC count is <500–1,000 cells/µL.
• Postsurgery lavage fluid WBC count can be up to 10,000 cells/µL. Cytologic characteristics are more meaningful than cell count in differentiating septic vs. nonseptic peritonitis in these cases.

ABNORMAL VALUES

• Presence of free intra-abdominal fluid.
• Lavage fluid with >1,000 WBCs/µL or that is grossly abnormal (e.g., hemorrhagic, greenish, cloudy, purulent).
• Depending on macroscopic appearance, specific gravity, protein content, cellularity, and cytologic findings, abdominal effusion is classified as pure transudate, modified transudate, and exudate (septic and nonseptic). Its etiology can sometimes be determined.

Additional Results for Specific Conditions

• Chyloabdomen—concentration of abdominal fluid triglycerides higher than serum triglyceride concentration; triglyceride concentration often >100 mg/dL.
• FIP—abdominal fluid albumin/globulin ratio <0.8 suggests FIP.
• Hemoabdomen—if PCV of abdominal fluid is greater than peripheral PCV, organ or large vessel laceration or disruption is suspected. Hemodilution may occur in cases of uroabdomen with concurrent hemorrhage or after DPL. Because DPL fluid cannot be compared with peripheral PCV, a PCV >5% in DPL fluid is indicative of hemorrhage.
• Uroabdomen—abdominal fluid creatinine concentration higher than serum creatinine concentration (>2:1), potassium concentration in effusion greater than serum potassium (>1.4:1). BUN is not reliable for diagnosis of uroabdomen (rapidly equilibrates across peritoneum).
• Bile peritonitis—fluid bilirubin concentration higher than that of serum, extra- or intracellular bile pigment usually found on cytologic examination.
• Pancreatitis—higher fluid amylase and lipase concentrations than serum suggest pancreatitis. Peritoneal fluid canine-specific pancreatic lipase (cPL) concentration is very sensitive in dogs as an aid in diagnosis of acute pancreatitis.
• Peritonitis—>1,000 WBCs/µL in lavage fluid.
• Septic peritonitis—intracellular bacteria (± extracellular bacteria), presence of degenerate neutrophils are diagnostic for septic effusion. Additionally, the fluid lactate concentration is higher in septic vs. nonseptic effusions. In dogs, a fluid lactate concentration >2.5–4 mmol/L and a blood-to-fluid lactate difference of >2 mmol/L has good sensitivity and specificity for diagnosing septic effusion. This may be less reliable in cats. A blood-to-fluid glucose difference of >37 mg/dL is sensitive and specific for septic peritoneal effusion in dogs and cats.
• Eosinophilic effusion—>10% eosinophils in fluid.
• Aberrant cestodiasis—the presence of *Mesocestoides* spp.

ABDOMINOCENTESIS AND FLUID ANALYSIS (CONTINUED)

CRITICAL VALUES

• After adequate cardiovascular resuscitation, the following conditions need immediate attention and might require exploratory celiotomy:
  ◦ Septic peritonitis.
  ◦ Uroabdomen.
  ◦ Bile peritonitis.
  ◦ Hemoabdomen.

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure

Avoid sedative agents that induce splenomegaly.

Conditions That May Interfere with Performing the Procedure

• If there is abdominal distention, differentiate between organomegaly, intra-abdominal fat, and fluid accumulation before abdominocentesis.
• Adhesions from previous surgeries may interfere with DPL.
• Insufficient fluid quantity for technique used.
• Flocculent or fibrinous fluid.
• Fluid localized in a difficult to access space (e.g., cranial to liver).
• Negative abdominocentesis is possible in a patient with an acute disease process. Repeat imaging and/or abdominocentesis can be considered if indicated based on clinical signs and increased suspicion of intra-abdominal disease.
• A negative abdominocentesis is possible in a patient with severe dehydration or hypovolemia; repeat imaging and abdominocentesis following IV fluid resuscitation.

Procedure Techniques or Handling That May Alter Results

• Vigorous suction can result in needle or catheter blockage by omentum or viscera.
• In the absence of coagulopathy, blood from traumatic sampling will usually clot when exposed to an artificial surface, whereas peritoneal effusion will not.
• Degenerate neutrophils and intracellular bacteria are signs of septic peritonitis; while bacteria and debris may be present if a loop of bowel is aspirated, typically degenerate neutrophils are absent.

Influence of Signalment on Performing and Interpreting the Procedure

Species
None

Breed
None

Age
None

Gender
None

Pregnancy
Relative contraindication because of an enlarged uterus.

Clinical Perspective
• Many different diseases may manifest with peritoneal effusion; cytologic and fluid analysis are indicated for every effusion.
• Use of a fenestrated catheter vs. a needle may increase likelihood of fluid retrieval.
• DPL may provide superior diagnostic accuracy but is much more time intensive to perform, and samples are diluted.

MISCELLANEOUS

ANCILLARY TESTS

• CBC, serum biochemistry, and urinalysis.
• Abdominal ultrasonography: assess parenchymal integrity, identify small fluid volume.
• Any additional testing to determine primary etiology of abdominal effusion (nonexhaustive list; see Ascites):
  ◦ Thoracic radiography, echocardiogram, and ECG (right-sided heart failure, pericardial effusion, metastatic neoplasia).
  ◦ Excretory urography or contrast cystourethrogram if uroabdomen is suspected.
  ◦ Serum bile acids if hepatic failure/portal hypertension is suspected.

SYNONYMS

• Abdominal tap.

SEE ALSO

Ascites.

ABBREVIATIONS

• DPL = diagnostic peritoneal lavage.
• PCV = packed cell volume.
• TS = total solids.

ARTHROCENTESIS WITH SYNOVIAL FLUID ANALYSIS

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection.

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
Synovial fluid is normally a clear, viscous fluid essential in the mechanical function of joints. Synovial fluid analysis is integral in the diagnosis and characterization of joint disease in canine and feline patients. Joint disease can involve one or more joints and can be due to infectious, inflammatory or noninflammatory etiologies. Synovial fluid analysis can differentiate inflammatory vs. noninflammatory arthropathies and can aid in determination of the underlying cause. Arthrocentesis is a safe, quick, and relatively easy procedure to perform in most clinical settings and involves fine-needle aspiration of joint fluid. The equipment needed is minimal and inexpensive, and the techniques are not difficult to learn, requiring only basic knowledge of joint anatomy.

INDICATIONS
- Joint pain or effusion.
- Lameness/stiffness or gait abnormality.
- Fever of unknown origin.
- Undefined lethargy or nonspecific pain.

CONTRAINDICATIONS
- No absolute contraindications.
- Caution with coagulopathy.
- Caution with severe thrombocytopenia (<20,000/µL).

POTENTIAL COMPLICATIONS
- Sedation-associated complications.
- Iatrogenic joint infection.
- Hemarthrosis.

CLIENT EDUCATION
- Patients will need to be sedated.
- Patients will need to have multiple joints shaved.

BODY SYSTEMS ASSESSED
Musculoskeletal

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
None

Anesthesia or Sedation
- Adequate sedation required.
- Opioids for pain control:
  - Hydromorphone 0.05–0.1 mg/kg IM or IV.
  - Methadone 0.1–0.3 mg/kg IM or IV.
  - Fentanyl 3–5 µg/kg IV.
- Dexmedetomidine 3–10 µg/kg IM or IV to effect.
- General anesthesia often not required.

Patient Positioning
Lateral recumbency.

Patient Monitoring
Standard for sedation protocol.

Equipment or Supplies
- Clippers.
- Surgical prep—chlorhexidine scrub/betadine scrub.
- Alcohol prep.
- Sterile gloves.
- Sterile hypodermic needles.
- 22-Gauge 1-inch needles (for cats and small dogs):
  - Most commonly used.
- 22-Gauge 1½-inch needles (may be needed for large dogs).
- Sterile 3-mL syringes.
- A culturette or culture transport vial.
- Glass microscope slides.
- EDTA tubes.

TECHNIQUE
- Prior to starting the procedure, have all equipment in place and familiarize yourself with the anatomy of the selected joint (Figures 1–5).
- It is recommended to sample three or more joints.
- Clip overlying hair and aseptically prepare the chosen joint.
- It is essential to appropriately prepare sites to avoid iatrogenic joint infection.
- Don sterile gloves.
- An assistant opens the syringe and needles, aseptically placing them on the sterile field. The needle should be mounted on the syringe.
- Flex the joint using the nondominant hand (now nonsterile) and palpate the appropriate landmarks for the specific joint to be tapped with the dominant hand (sterile).
- Holding the syringe, pass the needle through the skin, joint capsule, and synovial membrane, into the joint cavity. Avoid the articular cartilage. If bone is encountered, pull back slightly and redirect the needle into the joint space.
- Gently aspirate. Unless the joint is severely distended, only a few drops of fluid may be obtained in the hub of the needle. As soon as fluid appears in the hub of the needle, release negative pressure and remove the needle from the joint. If the joint is very distended, a larger volume of fluid may be removed from the joint space. If blood is seen in the hub of the needle at any point in the procedure, immediately release pressure and remove the needle.
- Ensure that the negative pressure (the plunger) is released prior to withdrawing the syringe from the point to avoid contamination of the fluid with peripheral blood.
- A large amount of blood makes cytologic evaluation too difficult, and tapping a new joint space is advisable. A small amount of blood may be in the joint space as part of the disease process.

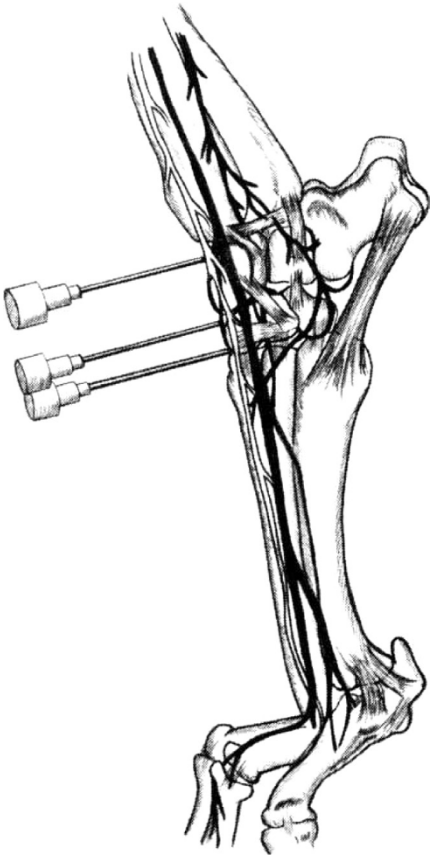

Figure 1.

Schematic representation of landmarks for the carpal joint.

Note: The following discussion about individual joints is presented in order of increasing difficulty:

Carpal Joint
- With the nondominant hand, flex the joint to achieve a maximum amount of open joint space.
- Palpate the space between the radius and proximal carpal bones, the proximal carpal bones and distal carpal bones, and the carpal and metacarpal bones.
- The radiocarpal joint is the most common joint space to tap due to the larger space.
- Identify and avoid the dorsal common digital artery and accessory cephalic vein.
- Holding the syringe, insert the needle from the cranial surface through the skin and joint capsule and into the joint space.

Stifle Joint
- Due to its large size, this joint is frequently aspirated.
- The stifle may be approached from either the medial or lateral aspect.

ARTHROCENTESIS WITH SYNOVIAL FLUID ANALYSIS (CONTINUED)

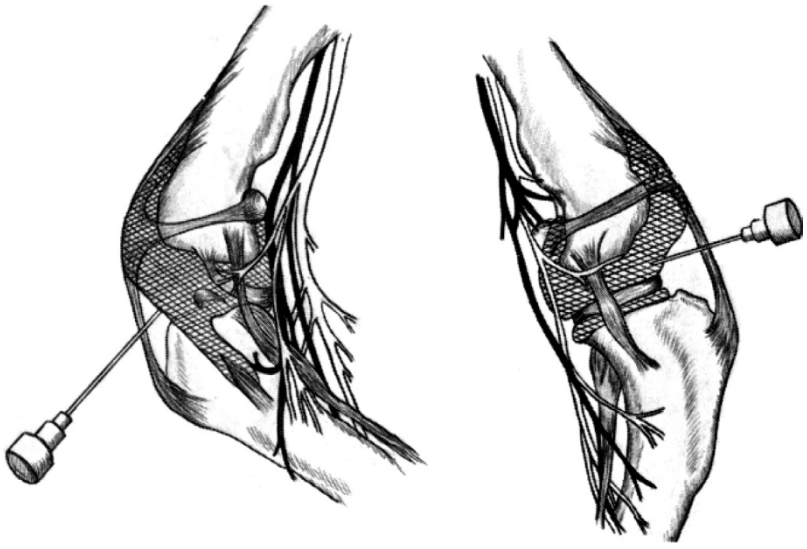

Figure 2.

Schematic representation of landmarks for the stifle joint.

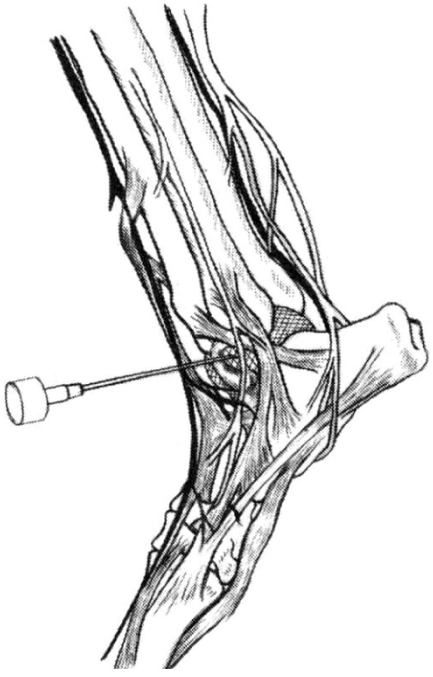

Figure 3.

Schematic representation of landmarks for the tarsal joint.

- Flex the stifle joint to open the joint space.
- Insert the needle from the cranial aspect, lateral or medial to the patellar ligament. The needle should enter the joint approximately halfway between the patella and tibial tuberosity.
- Direct the needle caudally and obliquely toward the intercondylar space.
- It may be helpful to apply digital pressure to the opposite side of the patellar ligament to cause joint fluid to collect toward the approach. A fat pad is present that may interfere with obtaining fluid. If fluid is not obtained initially, back up the needle, redirect, and aspirate.

Tarsal Joint

- Two small joint spaces can be tapped in the tarsus.
- One approach is to flex the joint slightly and palpate the cranial space between the tibia and tibiotarsal bone. Insert the needle from the cranial and lateral aspect and direct it medially. This joint is shallow and the needle will not be advanced very far.
- The second approach is from the distal aspect and is accomplished by flexing the tarsal joint more fully to open the space between the distal fibula, tibia, and calcaneus bones. Palpate this space and insert the needle from a caudolateral position. The needle should be advanced parallel to the calcaneus distally and slightly medially.

Elbow

- The elbow is flexed moderately to an approximately 45 degree angle. This opens the space between the humerus and the ulna.
- The joint is entered from the caudolateral aspect.
- Insert the needle between the olecranon process and the lateral condyle of the humerus and advance it distally and slightly medially, following the cranial surface of the ulna.

Scapulohumeral Joint

- Flex the joint slightly to widen the space. Palpate the greater tubercle and the acromion process of the scapula.
- Approach the joint from the lateral aspect and insert the needle slightly cranial and distal to the acromion process and just caudal to the greater tubercle. The needle should be directed in a caudal-medial and slightly downward direction.
- The joint space can be approached also from a cranial direction. Insert the needle medial to the greater tubercle and ventral to the supraglenoid tubercle, angling it in a cranial-caudal direction.

SAMPLE HANDLING

- Joint fluid should be evaluated grossly for color, turbidity, viscosity, quantity, and ability to clot. A change in the color or viscosity of the joint fluid can indicate disease or blood contamination.
- If the sample is contaminated with blood by a traumatic tap, the blood usually does not mix evenly, whereas blood from ongoing hemorrhage into the joint appears evenly distributed.
- Viscosity is assessed by expelling one to two drops of fluid from the syringe onto a slide. If the fluid is easily expelled, the viscosity is low. Formation of a string of fluid as it leaves the needle is consistent with normal viscosity.
- Many taps yield only a few drops of fluid, and complete fluid analysis may be difficult. Slides should always be submitted for cytologic evaluation because determining the type of cells in the fluid is the most helpful piece of information in defining the disease process.
- If enough fluid can be obtained, a small amount of the sample should be placed in an EDTA tube for fluid analysis.
- Culture and microbial sensitivity testing should performed. The probability of bacterial infection is greater in patients that have monoarthropathies and purulent-appearing joint fluid.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring

- Standard for sedation protocol
- Monitor for increased joint pain or swelling.

(CONTINUED) ARTHROCENTESIS WITH SYNOVIAL FLUID ANALYSIS

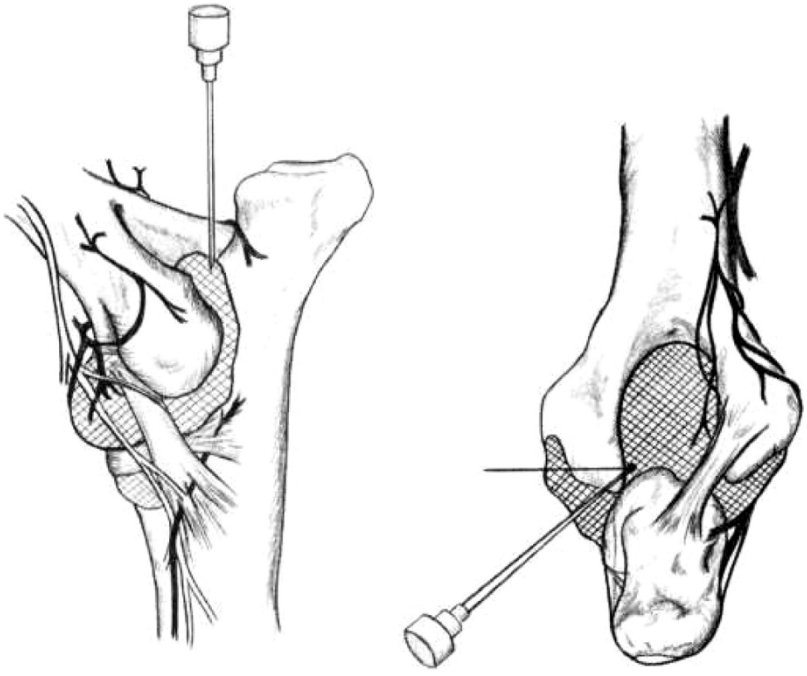

Figure 4.

Schematic representation of landmarks for the elbow joint.

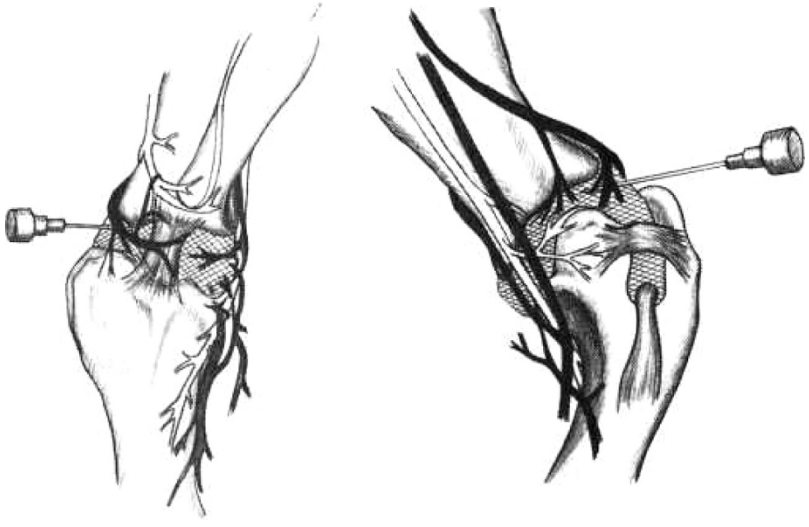

Figure 5.

Schematic representation of landmarks for the shoulder joint.

Nursing Care
None

Dietary Modification
- In some cases, weight reduction is recommended.
- Specific diets are available for dogs with joint disease.

Medication Requirements
Dependent on primary disease process.

Restrictions on Activity
- Allow patient to dictate activity level.

Anticipated Recovery Time
Immediate after recovery from sedation.

INTERPRETATION

NORMAL FINDINGS OR RANGE
See Table 1.

CRITICAL VALUES
None

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure
None

Conditions That May Interfere with Performing the Procedure
- Coagulopathy.
- Severe skin disease or infection.

ARTHROCENTESIS WITH SYNOVIAL FLUID ANALYSIS (CONTINUED)

Table 1

Abnormal values.

Variable	*Normal*	*Trauma/Hemarthrosis*	*Degenerative Arthropathy*	*Inflammatory Arthropathy*
Appearance	Clear-to-straw colored	Clear-to-red	Clear-to-yellow	Yellow-to-bloody, hazy/cloudy
Protein	<2.5 g/dL	Variable	<2.5 g/dL	Often >2.5 g/dL
Viscosity	High	Decreased	Normal/decreased	Decreased
Nucleated cell count (cells/μL)	<3,000	Increased RBCs	1,000–10,000	5,000 to >100,000
Neutrophils	<5%	Relative to blood	<10%	>10–100%
Mononuclear cells	>95%	Relative to blood	>90%	10–<90%
Comments	Small volume of fluid	Erythophagia	Macrophages	Wide variation

Procedure Techniques or Handling That May Alter Results

Traumatic tap with blood contamination.

Influence of Signalment on Performing and Interpreting the Procedure

Species

- Feline chronic progressive polyarthropathy has been documented in male cats.
- Bacterial L-form infection can cause a severe, erosive polyarthritis in cats.
- Calicivirus (both by natural infection and by vaccination) can cause a transient polyarthritis in young kittens.

Breed

- Arthrocentesis may be more difficult to perform in small-breed dogs.
- An erosive polyarthropathy has been documented in young greyhounds.
- Swollen hock syndrome occurs in shar-peis.

Age

None

Gender

None

Pregnancy

None

CLINICAL PERSPECTIVE

- An accurate medical history noting trauma and travel history and drug and toxin (e.g., NSAID, anticoagulant) exposure should be taken.
- Physical examination should include a thorough musculoskeletal and neurologic examination to differentiate joint disease from primary orthopedic or neurologic problems. Although careful attention must be paid to evaluating joints for effusion and pain with flexion or extension, it is extremely important to note that significant joint disease can be present despite a lack of abnormalities on joint palpation.
- Initial diagnostic testing that should be considered before joint taps are performed include a CBC, serum biochemistry analysis, urinalysis with a urine culture, and radiographs of affected and corresponding nonaffected joints. Vector-borne disease testing should be performed. A coagulation panel can be submitted if hemarthrosis secondary to toxicity or inherited disease is suspected. Further studies, such as additional serologic testing for infectious disease and systemic testing for immune-mediated disease, should be considered when appropriate historical or clinical signs are present. Blood cultures may also be performed to look for a systemic infectious cause of joint inflammation/infection.
- Occasionally (especially in cats), fever and lethargy are the sole presenting signs in animals with polyarthritis.
- It may be difficult to obtain good samples from cats and small dogs.
- Cell counts in normal synovial fluid are low and predominantly contain lymphocytes and mononuclear cells; increased neutrophil count is indicative of disease.
- Once an inflammatory process is defined, there is considerable overlap in cytologic findings between the specific causes of inflammation:
  - In general, inflammatory disease is characterized by increased numbers of neutrophils and a variable increase in large, mononuclear cells in the joint fluid. Septic joints tend to have very high numbers of neutrophils, which may also exhibit degenerative changes. Bacterial organisms are usually not seen; *Ehrlichia* sp. morulae are seen infrequently. Increased numbers of nondegenerate neutrophils are generally seen with an immune-mediated process. A more complete review of cytologic changes in joint disease can be found in the Suggested Reading section.
- Rheumatoid arthritis, an erosive disease of the distal joints in small dogs, is extremely rare. Radiographs are helpful in making this diagnosis. Rheumatoid factor analysis is not necessary in the majority of cases.
- Reactive polyarthritis may be seen secondary to systemic infectious disease, drugs, neoplasia, or any chronic inflammatory condition.
- With proper technique, significant complications are very rare.

MISCELLANEOUS

ANCILLARY TESTS

- Radiographs: affected and unaffected joint.
- Infectious disease testing (Lyme, *Ehrlichia*, heartworm, *Leishmania*, *Toxoplasma*).
- Antinuclear antibody serology.
- Urine protein/creatinine ratio.
- Rheumatoid factor.

SYNONYMS

Joint tap.

SEE ALSO

- Arthritis (Osteoarthritis).
- Arthritis, Septic.

BACTERIAL CULTURE AND SENSITIVITY

BASICS

TYPE OF SPECIMEN
Blood
Fluid
Tissue
Urine
Feces

TEST EXPLANATION AND RELATED PHYSIOLOGY
Culture and sensitivity testing to aid in diagnosis of infectious disease is one of the most common tests in the diagnostic laboratory. Proper specimen selection and collection are crucial to proper diagnosis. In addition, it is important to distinguish normal flora from infectious agents. When possible, samples for bacterial culture should be collected prior to the initiation of antimicrobial therapy as systemic antibiotic administration can impair microbial growth *in vitro*.

Different methodologies may be used to determine antimicrobial susceptibility. Kirby-Bauer disc diffusion and serial antibiotic dilution to determine minimum inhibitory concentrations (MICs) are two of these methods. In addition to susceptibility data, it is important to understand the physiology of the location of infection as this can also affect antimicrobial selection.

INDICATIONS
To identify bacteria causing infection and determine the most appropriate therapy

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
None

BODY SYSTEMS ASSESSED
Dependent on location of infection.

SAMPLE

SAMPLE COLLECTION
The sample depends on the site of potential infection.
- Swab the site (e.g., ear, discharge) by using a sterile swab. Swabs tipped with inert, nontoxic rayon are preferred.
- Fine-needle aspirate—aseptic preparation of the aspiration site is important to prevent contamination of sample with normal skin flora.
- 0.5–1.0 mL of urine—cystocentesis is the method of choice. Aseptic catheterization can also be used, although quantitiative urine culture is preferred for these samples. Voided urine is not preferred due to potential contamination from the external urinary tract, and results must be interpreted in the context of quantitative data.
- 0.5–1.0 mL of effusion.
- Material aspirated from a lesion (e.g., abscess).
- Venous blood—sample size determined by manufacturer of the culture bottle and patient size, but larger sample volumes are preferred.
- Feces.
- Tissue biopsy.
- Wash fluid (tracheal wash, nasal flush, prostatic wash).

SAMPLE HANDLING
Aseptically prepare the skin prior to any percutaneous aspiration. Wounds should be cleaned and lavaged prior to collection of culture sample. For skin lesions, remove surface exudate by wiping with sterile saline or 70% alcohol prior to sample collection.

Aerobic Culture
- Sterile swab—swabs should be placed into some type of microorganism collection and transport container (e.g., BactiSwab, Remel, Lenexa, KS; BBL CultureSwab, Becton-Dickinson, Franklin Lakes, NJ). These containers typically consist of a round-bottomed sleeve designed to protect the sample. Some transport systems contain medium designed to enhance survival of any microorganisms present. When using a transport container with media, ensure that swab is completely immersed in culture medium.
- Submit fluids (urine, effusion, aspirated material, wash solutions) in a sterile tube with or without media. Plain red-top tubes are acceptable, but the use of serum separator tubes or plastic red-top tubes with clot activator should be avoided.
- Biopsy—place sample in a sterile container and add several drops of sterile 0.9% saline to keep tissue moist.
- Catheter tip—5 cm of the distal tip is sterilly cut and placed into a sterile container for transport.

Anaerobic Culture
- Tissue or aspirates of deep material are always superior to superficial swab specimens.
- If a swab must be used, pass it deep into the base of the lesion.
- Biopsy—place the sample in sterile container and add several drops of sterile saline to keep the tissue moist.
- If sample processing will be delayed >2 hours, place sample into a specific anaerobic transport tube or vial. Anaerobic transport medium is a mineral salt-base soft agar with reducing agents designed to maintain an anaerobic environment for an extended period, maintaining viability of more fastidious microorganisms.
- Swabs of material are plunged deep into the agar so that even though material at the top of the tube is exposed to oxygen, material at the bottom of the tube remains anaerobic.
- Transport fluids in an anaerobic transport vial. After cleaning the rubber stopper with alcohol, push the needle through the septum and inject the fluid on top of the anaerobic transport medium.
- Samples in anaerobic transport medium can generally be used for both aerobic and anaerobic cultures.

Fecal Culture
Use fecal transport medium when submitting for culture of *Salmonella*, *Shigella*, *Campylobacter*, and other fecal pathogens.

Mycoplasma Culture
Semen or mucus from respiratory tract can be submitted in a sterile container. Material can also be collected on a sterile swab and submitted in a microorganism transport container that contains Amies transport medium without charcoal, although this is not an optimal method.

Blood Culture
- Aseptically prepare venipuncture site.
- Remove the plastic cap covering each of 2 blood culture bottles and decontaminate each rubber stopper with 70% alcohol. It is best to have both aerobic and anaerobic types of vials, however, venting anaerobic vials to make them aerobic can be done.
- Collect blood using sterile needle and syringe. A minimum of 4 mL of blood (2 mL for each bottle) is necessary:
  - Better results may be achieved with larger sample volumes.
  - Sampling volume should be based on the manufacurer's recommendation for the blood culture bottles being used, the number of samples to be collected, and patient size.
- Change the needle prior to introducing sample into each bottle and divide sample between the two blood culture bottles; mix well:
  - Blood should be sampled at 2 or 3 time points, 30–60 minutes apart. Each collection should occur from a different location/vein if possible.

SAMPLE STORAGE
- To increase viability of organisms and prevent overgrowth, refrigerate samples for routine aerobic culture until shipped.
- Specimens for anaerobic culture, blood culture, and fecal culture should be maintained at room temperature:
  - All samples should be submitted/plated for culture as soon as possible to maximize results.

BACTERIAL CULTURE AND SENSITIVITY (CONTINUED)

SAMPLE STABILITY

Aerobes
Refrigerate for ≈2 days.

Anaerobes
- Stable in an anaerobic transport tube for 1–2 days (depends on organism).
- Stable in a red- top tube or standard microorganism collection and transport system for ≤2 hours.
- Refrigeration decreases viability.

PROTOCOL
None

INTERPRETATION

NORMAL FINDINGS OR RANGE
- No growth of bacteria in culture from sterile fluids/sites.
- Growth of normal flora only, but no pathogenic organisms from nonsterile locations.

ABNORMAL VALUES
- Growth of pathogenic organisms.
- Kirby-Bauer microbial susceptibility results for antimicrobials are reported as either susceptible or resistant.
- Some antimicrobial susceptibility results are reported with an MIC, which is the lowest concentration of antibiotic that inhibits the growth of a given strain of bacteria. When using MICs to select an appropriate antimicrobial, three criteria are important:
  1. The MIC on the clinical microbiology report.
  2. The antimicrobial's normal range used to establish susceptibility. This represents the concentration of antibiotic that is reasonably achievable.
  3. The breakpoint of the antimicrobial—the dilution where the bacteria begin to show resistance.
- The breakpoint and the normal range differ by drug and bacterial species. Therefore, comparing antimicrobial MICs is based on differences between the breakpoint and the normal range for each antimicrobial. The further the MIC is from the breakpoint in its normal range, the more susceptible that organism is to the antimicrobial.

CRITICAL VALUES
None

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology
Systemic antibiotic administration can inhibit *in vitro* microbial growth.

Drugs That Alter Physiology
None

Disorders That May Alter Results
None

Collection Techniques or Handling That May Alter Results
- Specimens that are 2 days old may lose viability.
- Inappropriate containers:
  - EDTA is bacteriostatic.
  - The clot activator in serum-separator tubes and plastic red-top tubes may affect results.
  - Samples for anaerobic cultures have limited viability if not transported in specific anaerobic transport tubes.

Influence of Signalment

Species
None

Breed
None

Age
None

Gender
None

Pregnancy
None

LIMITATIONS OF TEST
- *Mycobacterium* sp. and *Nocardia* sp. are difficult to culture and must be specifically requested.
- MIC is just one of the criteria used to select an antimicrobial. Antimicrobial selection also depends on the location of infection, what dose and route of administration will achieve adequate concentrations at that site, and how long the infection needs to be treated.

Sensitivity, Specificity, and Positive and Negative Predictive Values
None

Valid If Run in a Human Lab?
Yes, although human laboratories may not be able to perform susceptibility testing for veterinary-only approved antimicrobials.

CLINICAL PERSPECTIVE
- In cultures from a mucosal surface (e.g., tracheal wash, nasal swab, vaginal discharge, urine collected by catheter or free catch), interpretation must consider the presence of normal flora:
  - Large numbers of a single microorganism in almost pure culture suggests a pathogenic process.
  - A mixture of ≥4 different organisms in light to moderate numbers suggests growth of normal flora.
  - Light growth from a sample submitted in enrichment broth suggests normal flora (or suppression of growth by antimicrobial therapy).
- Specific anaerobic transport containers are more expensive than routine microorganism collection and transport containers (and may not be provided gratis by diagnostic laboratories), but can be readily obtained from commercial distributors of microbiology supplies and improve the likelihood of documenting an anaerobic infection.
- Chances of documenting bacteremia are increased by submitting 2 sets of blood cultures collected from different venipuncture sites or from the same site 15–30 minutes apart.

MISCELLANEOUS

ANCILLARY TESTS
Dependent on the site of infection.

SYNONYMS

BLOOD GAS INTERPRETATION

BASICS

TYPE OF SPECIMEN
Blood

TEST EXPLANATION AND RELATED PHYSIOLOGY
- Used to evaluate the acid–base status of patients:
  - Arterial samples may be used to evaluate the adequacy of oxygenation and ventilation.
  - Venous blood samples are not adequate for evaluation of oxygenation but may provide information about ventilation as long as perfusion is adequate.
- Normal physiologic reactions within the body occur at a specific pH value.
- Major variables evaluated when assessing acid–base status include the pH, HCO_3^- concentration, P_{CO_2} (partial pressure of CO_2), and base excess (or deficit). Abnormalities within acid–base status are typically classified as acidosis, alkalosis, or mixed disorders.
- Each disorder may be caused by metabolic and/or respiratory abnormalities:
  - The term *metabolic* implies a net gain or loss of HCO_3^-
  - The term *respiratory* implies a net gain or loss of CO_2.
- P_{CO_2} and pH are inversely proportional, whereas there is a direct relationship between HCO_3^- concentration and pH.
- To interpret acid–base balance:
  - Evaluate pH first—determine whether it is too high (alkalosis), too low (acidosis), or normal.
  - Alkalosis is classified as metabolic if due to elevated HCO_3^- concentration (>24 mmol/L) and respiratory if associated with a decreased P_{CO_2} (<36 mmHg).
  - Acidosis is classified as metabolic if associated with a decreased HCO_3^- concentration (<20 mmol/L), and respiratory if associated with an increased P_{CO_2} (>40 mmHg).
  - With mixed acid–base disorders, two problems may either exacerbate the disorder (e.g., concurrent respiratory and metabolic acidosis) or mask the problem, producing a normal pH if the two disorders have opposite effects (e.g., concurrent metabolic acidosis and respiratory alkalosis).
- Generally, an acid–base disturbance is accompanied by compensation by either the respiratory system or the kidneys. This compensation attempts to return the pH to an overall normal range, but it is important to note that full compensation never occurs:
  - Respiratory compensatory efforts occur immediately, whereas metabolic compensation will not reach its full level for 2–3 days because changes in renal handling of HCO_3^- require time. In severe metabolic alkalosis, respiratory compensatory attempts will be limited by the hypoxemia that accompanies hypoventilation.
- Hypoxemia is a partial pressure of oxygen (P_{aO_2}) <90 mmHg at sea level. Hypoxemia has five potential underlying pathologies:
  - Low inspired oxygen concentration—may occur at altitude or with anesthetic machine malfunction
  - Ventilation–perfusion mismatch—reflects an altered balance between ventilated and perfused lung regions.
  - Pure shunt—caused by cardiac defects (e.g., tetralogy of Fallot)
  - Diffusion impairment—includes diseases that thicken the alveolar–capillary membrane.
  - Hypoventilation (i.e., a P_{CO_2} >50 mmHg).
- When assessing the oxygenation status of patients, it is prudent to consider not only the P_{aO_2} value but also to calculate the alveolar–arterial (A-a) gradient. The normal range is <15:
  - A-a gradient is calculated by subtracting the measured P_{aO_2} from the calculated ideal alveolar oxygen partial pressure (P_{AO_2}) by using this formula:

$$P_{AO_2} = [\%\ \text{inspired}\ O_2 \times (\text{atmospheric} - \text{water-vapor pressure})] - (P_{aCO_2}/0.8)$$

  - For example, breathing room air at sea level, normal dogs with a P_{aO_2} of 95 mmHg and a P_{CO_2} of 40 mmHg, the P_{AO_2} will be [0.21(760 – 47)] – (40/0.8) = 150 – 50 = 100. The measured P_{aO_2} of 95 mmHg is subtracted from this value to get an A-a gradient of 5.
  - This formula is particularly useful if a patient has marked hyper- or hypoventilation.
  - For example, a dog with a P_{aO_2} of 84 and a P_{CO_2} of 22 is hyperventilating. However, calculation of the A-a gradient gives a value of 38.5, which is elevated, suggesting that increased respiratory rate is compensating for primary lung disease.
  - Conversely, in a dog with P_{aO_2} of 65 and a P_{CO_2} of 59, the A-a gradient is 11.25, which is normal, which indicates that hypoventilation, and subsequent hypoxemia, is caused by some disorder other than primary lung disease.
  - At increasing inspired-oxygen concentrations, the A-a gradient becomes less accurate. Thus, if the concentration of inspired oxygen is directly known, a ratio of the P_{aO_2} to the fractional inspired oxygen concentration (F_{iO_2}) may be calculated. The normal value for the P_{aO_2}/F_{iO_2} is 100:0.21 or 476. In people and dogs, acute lung injury is present at a ratio <300 and acute respiratory distress syndrome at a ratio <200.

INDICATIONS
- Assessment of acid–base balance.
- Assessment of oxygenation (arterial samples only).

CONTRAINDICATIONS
- Avoid arterial collection when patients have severe coagulopathy.
- Avoid arterial collection when patients have cellulitis or open infection at the collection site.

POTENTIAL COMPLICATIONS
- Hematoma at the sampling site.
- Collection of a venous sample instead of intended arterial sample and subsequent inappropriate patient management decisions.

CLIENT EDUCATION
None

BODY SYSTEMS ASSESSED
- Cardiovascular.
- Endocrine and metabolic.
- Renal and urologic.
- Respiratory.

SAMPLE

SAMPLE COLLECTION
- Venous or arterial blood.
- Typically, heparinized blood samples are analyzed. Self-filling syringes are commercially available and routinely used for arterial samples.

SAMPLE HANDLING
- Samples should be collected under anaerobic conditions for the most accurate P_{CO_2} and HCO_3^- values.
- Samples should be processed immediately to prevent altered values.
- Samples exposed to room air will have an increased P_{aO_2} and decreased P_{CO_2}.

SAMPLE STORAGE
If immediate analysis is not possible, samples may be stored anaerobically on ice for 4 hours.

SAMPLE STABILITY
For 4–6 hours if kept on ice.

PROTOCOL
None

INTERPRETATION

NORMAL FINDINGS OR RANGE
- pH: 7.36–7.44.
- P_{CO_2}: 36–40 mmHg.
- HCO_3^-: 20–24 mEq/L (or mmol/L).
- Base excess: ±4.

BLOOD GAS INTERPRETATION (CONTINUED)

- Po_2: 90–100 mmHg (at sea level, breathing room air [21% oxygen]).
- Reference intervals may vary, depending on sea level, laboratory, and assay.

ABNORMAL FINDINGS
Values above or below the reference range.

CRITICAL VALUES
- pH: <7.2 or >7.5.
- Pco_2: <20 or >55 mmHg.
- Po_2: <60 mmHg (arterial sample).
- HCO_3^-: <13 or >33 mmol/L.
- Base excess (or deficit): >12.

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology
None

Drugs That Alter Physiology
Supplemental oxygen, bicarbonate infusions, carbonic anhydrase inhibitors.

Disorders That May Alter Results
None

Collection Techniques or Handling That May Alter Results
- Difficulty in arterial puncture may result in either a fully or partially deoxygenated (venous) sample.
- Prolonged storage at room temperature will affect results.
- Administration of excessive heparin will dilute the sample and may result in altered values.
- Exposure of the sample to room air for an extended period of time (>1 minute).

Influence of Signalment

Species
Arterial blood–gas collection is very challenging in cats. Cats are thought to have a lower Pco_2 than other species.

Breed
Brachycephalic dogs may have a lower Pao_2, but this may reflect the relative difficulty of restraining them for sampling.

Age
Whereas in people, decreased Pao_2 accompanies aging, this has not been found to be true in one study in dogs. A-a gradient may increase slightly with age.

Gender
None

Pregnancy
Advanced pregnancy in humans may cause an altered respiratory pattern that produces respiratory alkalosis with a compensatory metabolic acidosis. Pao_2 is unchanged. This effect might be observed in late pregnancy in companion animals.

LIMITATIONS OF TEST

Sensitivity, Specificity, and Positive and Negative Predictive Values
N/A

Valid If Run in a Human Lab?
Yes.

CAUSES OF ABNORMAL FINDINGS
See Table 1.

Table 1

Causes of abnormal findings.

Analyte	*High Values*	*Low Values*
HCO_3^-	Metabolic alkalosis	Metabolic acidosis
	High GI obstruction	Poor perfusion (lactic acidosis)
	Profound hypokalemia	Renal failure
	Iatrogenic	Diabetic ketoacidosis
		Ethylene glycol intoxication
	Compensation for respiratory acidosis	Compensation for respiratory alkalosis
Pco_2	Respiratory acidosis	Respiratory alkalosis
	Severe respiratory failure	Panting
		Fever
	Cervical lesion	Pain
	Opioid overdose	Iatrogenic
	Large dog placed in lateral recumbency	
	Compensation for metabolic alkalosis	Compensation for metabolic acidosis
Po_2	Not significant	Hypoxemia
		Pulmonary disease
		Edema
		Contusions
		Pneumonia
		Pleural space disease
		Pneumothorax
		Pleural effusion
		Diaphragmatic hernia
		Cardiovascular shunts (e.g., tetralogy of Fallot)
		Hypoventilation
		Pain
		Respiratory depressants
		Intracranial disease
		Cervical disease

(CONTINUED) BLOOD GAS INTERPRETATION

CLINICAL PERSPECTIVE

- Determine whether appropriate compensation is occurring or if two disorders are present. Guidelines for compensation are the following:
  - Metabolic acidosis—each 1 mEq/L decrease in HCO_3 will decrease Pco_2 by 0.7 mmHg.
  - Metabolic alkalosis—each 1 mEq/L increase in HCO_3 will increase Pco_2 by 0.7 mmHg.
  - Respiratory acidosis.
    - Acute—each 1 mmHg increase in Pco_2 will increase HCO_3 by 0.15 mEq/L.
    - Chronic—each 1 mmHg increase in Pco_2 will increase HCO_3 by 0.35 mEq/L.
- Respiratory alkalosis:
  - Acute—each 1 mmHg decrease in Pco_2 will decrease HCO_3 by 0.25 mEq/L.
  - Chronic—each 1 mmHg decrease in Pco_2 will decrease HCO_3 by 0.55 mEq/L.
- Severe acidosis is common with ethylene glycol intoxication.
- All assessments of oxygenation should include assessment of the Pco_2 and, if warranted, calculation of the A-a gradient or Pao_2/Fio_2.
- It is crucial to recognize that an arterial blood gas merely provides objective evidence as to degree of impairment, but it is not specific for the cause.

MISCELLANEOUS

ANCILLARY TESTS

- Serum biochemistry profile and urinalysis.
- Ethylene glycol test.
- Thoracic radiographs to look for cardiopulmonary disease.
- Echocardiography if heart may be affected.

SYNONYMS

- Oxygen (O_2) saturation.
- Partial pressure of carbon dioxide in blood (Pco_2).

BLOOD PRESSURE DETERMINATION: NONINVASIVE AND INVASIVE

BASICS

TYPE OF PROCEDURE
Blood pressure measurement.

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Blood pressure (BP) is the product of cardiac output and systemic vascular resistance. BP is indirectly related to organ perfusion, and the maintenance of normal BP is vital to maintaining organ function.
- Elevated (hypertension) and decreased (hypotension) BP can be seen in small animal patients:
  - Hypertension most commonly occurs secondary to concurrent diseases (e.g., renal disease, hyperthyroidism, hyperadrenocorticism, hyperaldosteronism, diabetes mellitus, obesity, and pheochromocytoma). Older cats may be hypertensive without a clear cause.
  - Hypotension can occur as a result of shock (e.g., anaphylaxis, hypovolemia, sepsis, cardiac failure), as well as with the administration of certain medications (e.g., anesthetics, arterial vasodilators).
- Indirect BP is measured using two main methodologies: Doppler ultrasonic flow probe and oscillometric:
  - Doppler can be used in cats and dogs, and readings can be obtained over a wide range of pressures, with variable heart rates. The Doppler measurement is likely between the systolic and mean arterial blood pressures, and should be interpreted as the systolic blood pressure to avoid misdiagnosis of hypotension.
  - Oscillometric devices record mean arterial BP and calculate diastolic and systolic blood pressure as well. They are less accurate in patients with extreme brady- or tachycardias, and may be difficult to use in small patients. They are easy to use and lend themselves well to screening exams.
- BP can be measured directly (also called invasively) by introducing a catheter into an artery and then connecting this catheter to an external pressure transducer. Direct BP measurement requires expertise for arterial catheter placement, as well as for obtaining reliable readings, and is generally not suited for routine use in awake patients.

INDICATIONS
- When signs of end-organ damage from hyper or hypotension are present, such as retinal hemorrhage and/or detachment, cardiac hypertrophy, or neurologic abnormalities.
- Part of full workup in patients with diseases known to cause hypertension.
- In patients with emergent clinical signs or those requiring critical care.
- Anesthetized patients.
- Patients receiving medications known to affect BP.

CONTRAINDICATIONS
- Indirect BP—none.
- Direct BP—patients who cannot be sedated or anesthetized, lack of appropriate skill or equipment.

POTENTIAL COMPLICATIONS
Indirect BP
None

Direct BP
- Hematoma formation at the puncture site.
- Pain related to venipuncture (can use local anesthetic block or place under sedation/anesthesia).
- Thrombosis and potentially distal necrosis; feline metatarsal catheters should be removed within 6–8 hours of placement.
- Infection of the puncture site.

CLIENT EDUCATION
None

BODY SYSTEMS ASSESSED
Cardiovascular

PROCEDURE

PATIENT PREPARATION
Pre-Procedure Medication or Preparation
None required for indirect measurement. With direct measurement, the site of arterial puncture should be clipped and sterilely prepared.

Anesthesia or Sedation
May affect measured BP. If direct BP readings are to be taken in a conscious patient, infiltration of local anesthetics can facilitate placement of the arterial line. Local anesthetic will also minimize arterial spasm in sedated or anesthetized patients.

Patient Positioning
- It is ideal to have the site where BP is being measured at the level of the heart.
- For oscillometric BP devices, the extremity with the cuff should not bear weight when the reading is taken.

Patient Monitoring
None for indirect. With direct BP measurement, the patency of the catheter needs to be maintained, and movement of the limb with the catheter should be minimized.

Equipment or Supplies
- Indirect BP measurement: oscillometric or Doppler device, cuff, and sphygmomanometer
- Direct BP measurement: pressure transducer, non-compliant tubing, multiparameter monitor

TECHNIQUE
Indirect
Doppler (Figure 1)
- Clip the area where BP is to be measured (the area just below the metacarpal or metatarsal pads, ventral aspect of tail).
- Apply ultrasound gel to the transducer.
- Apply the cuff to the area above the transducer (the width of cuff should be 30–40% of limb circumference) attached to the sphygmomanometer.
- Position the transducer so that a good arterial signal is heard.
- Inflate the cuff until the signal is no longer audible and then slowly deflate the cuff until the signal returns. The pressure at which the signal returns is considered to be systolic pressure.
- Repeat the measurement; wait at least 3–5 minutes between readings.

Oscillometric
- Apply the cuff to appropriate site (between the elbow and the carpus, above the elbow, at the tail base, at the distal hind limb).
- Activate the machine to start automatic inflation and measurement. The heart rate reported by the machine should match the patient's heart rate; if not, the measurement is incorrect.
- Repeat the measurement.

Direct
- Clip and surgically prepare the puncture site. Most common site is the dorsal pedal (metatarsal) artery; the tail artery can be used, and rarely the femoral artery.
- An over-the-needle peripheral catheter (22 or 20 gauge) is inserted into the area where the artery is palpated (femoral arterial catheters usually require a cut-down procedure).
- Once blood has flashed into the catheter, the catheter is advanced into the artery and capped with an injection port or t-set. The catheter is flushed with heparinized saline and taped or sutured in place.
- The t-port is attached to noncompliant tubing that is filled with heparinized saline from a pressurized bag (pressure prevents blood from backing up into the arterial catheter). If a cap is left on the catheter, a needle attached to the noncompliant tubing may be used to pierce the injection port and the pressure may be monitored that way.
- The tubing is attached to a calibrated pressure transducer. The pressure transducer is then attached to appropriate monitoring equipment.
- If an automatic flush is not incorporated in the pressure monitoring setup, the tubing and catheter should be flushed with heparinized saline frequently to maintain patency.

SAMPLE HANDLING
N/A

APPROPRIATE AFTERCARE
Post-Procedure Patient Monitoring
- Indirect—none.
- Direct—following removal of the catheter, a tight bandage should be placed for 1–2 hours, and after removal, monitor the arterial puncture site for indications of hemorrhage.

Nursing Care
- Indirect—none.
- Direct—apply a pressure bandage to the arterial puncture site upon removal of the

(CONTINUED) BLOOD PRESSURE DETERMINATION: NONINVASIVE AND INVASIVE

Medication Requirements
N/A

Restrictions on Activity
None

Anticipated Recovery Time
None

INTERPRETATION

NORMAL FINDINGS OR RANGE

- Normal ranges depend on the method used to measure BP, age, breed, and, to some degree, operator factors (experienced vs. novice).
- An average value for BP in awake dogs is around 133/75 (systolic/diastolic) measured with an oscillometric monitor, giving a mean arterial pressure of 94 mmHg.
- In awake cats, normal BP has been found to be 125/90 (mean of 101 mmHg) via direct methods.

ABNORMAL VALUES

Hypotension is considered to be present in most cases where mean arterial blood pressure is less than 70 mmHg.

CRITICAL VALUES

- Critical hypotension is present with a mean arterial BP <60 mmHg or a systolic or Doppler pressure <80 mmHg.
- Critical hypertension is present with a systolic BP >180 mmHg and/or a diastolic BP >120 mmHg.

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure

- Most anesthetics will alter BP. Generally, pressure is decreased (e.g., propofol, isoflurane, sevoflurane); however, α_2-adrenergic agonists can cause an increase by increasing systemic vascular resistance.
- Beta-blockers, nitroprusside, and calcium-channel blockers may decrease BP.
- Ocular medications may affect BP; timolol can decrease BP and phenylephrine can increase it.
- Adrenergic agents (epinephrine, norepinephrine, dopamine) will increase BP.

Conditions That May Interfere with Performing the Procedure
N/A

Procedure Techniques or Handling That May Alter Results

Indirect

- Anything that leads to patient stress can lead to white-coat hypertension and thereby inaccurate BP readings.
- The width of the cuff should be 30–40% of limb circumference. Cuffs that are too large may give falsely low readings, whereas cuffs that are too small can cause falsely elevated readings.

Direct

- Blood clots or air bubbles in the tubing may cause inaccurate readings for direct BP.
- Inappropriate tubing (using regular tubing vs. noncompliant) can fail to transmit the pressure wave appropriately, damping the signal.
- Excessively long tubing or kinking of tubing will cause erroneous readings.

Influence of Signalment on Performing and Interpreting the Procedure

Species
Cat and dog normal ranges are similar.

Breed
No breed-related differences have been noted in cats. Among dogs, sighthounds tend to have higher BPs than other breeds.

Age
BP increases with age.

Gender
Males will have higher BPs than females; on average, the difference is <10 mmHg.

Pregnancy
Unknown

CLINICAL PERSPECTIVE

- There are many indications for BP measurement, to detect both hypotension and hypertension.
- All anesthetized animals should have serial blood pressure measurements.
- In older animals, BP screening is indicated at regular visits.
- For general practice, indirect methods are best suited for screening patients.
- Direct BP measurement is ideal where continuous BP measurement is needed, especially in critical cases.

MISCELLANEOUS

ANCILLARY TESTS

If hypertension is found, appropriate laboratory tests are indicated to identify whether an underlying cause exists.

SYNONYMS

None

BLOOD SAMPLE COLLECTION

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
The procedure involves using a syringe with attached hypodermic needle to aspirate blood percutaneously through a vessel wall into the syringe to a desired amount. For arterial blood collection, a heparinized syringe with an attached needle is used. Blood samples may also be obtained through newly placed peripheral catheters, or central venous catheters.

INDICATIONS
To obtain a blood sample for test analysis.

CONTRAINDICATIONS
- Severe coagulopathy (nonperipheral vessels).
- If a patient struggles or stresses to the point where it can further injure itself or the restrainers.

POTENTIAL COMPLICATIONS
- Complications are rare.
- Excessive bleeding can cause a hematoma in patients with a coagulopathy. A pressure wrap over the venipuncture area can prevent of minimize this problem.
- Multiple venipunctures of the same vein and area could cause bruising, phlebitis, or thrombosis of the vein.

CLIENT EDUCATION
Clients should be warned that there might be an area of hair clipped at the site and a small bandage applied, which should remain in place for 1 hour after the procedure. Mild bruising or irritation of the skin may be present.

BODY SYSTEMS ASSESSED
All

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
- None.
- For arterial blood collection, oxygen therapy should be discontinued for 10 minutes before sample collection if assessment of a patient breathing room air is desired.

Anesthesia or Sedation
- Generally no sedatives are required.
- If a patient is fractious, a mild sedative may be needed.

Patient Positioning
- Proper positioning for the procedure is vital for a positive outcome.
- For venous blood collection, the patient will need to be restrained as needed for the vein being accessed and the vein compressed proximal to the planned site of puncture. For jugular venipuncture, it is best to have the patient in a sitting position with the head held high and slightly turned to the opposite side. For saphenous venipuncture, the vein is best viewed with the patient in lateral recumbency. Cephalic veins are best accessed when the patient is in sternal recumbency with the leg extended.
- For arterial blood collection, the patient will need to be restrained in lateral recumbency with the lower pelvic limb held out by the restrainer, being careful not to compress the artery and disrupt arterial blood flow. If a patient's dyspnea worsens when in lateral recumbency, it may be necessary to perform this procedure with the patient standing or sitting.

Patient Monitoring
- None.
- Dyspneic patients should be monitored closely for signs of increased dyspnea. If this occurs during the procedure, oxygen should be administered, and the patient allowed to sit calmly.

Equipment or Supplies
- An appropriately sized syringe, generally not larger than the amount of blood needed.
- A needle—use the smallest to cause the least trauma and pain to the patient but large enough to easily draw the volume of blood needed (e.g., 22 or 20 gauge × 1 inch). Larger needles are preferred if coagulation testing is planned.
- An alcohol swab.
- Appropriate collection tubes in which to place blood.
- A heparinized syringe for arterial blood collection (1- or 3-mL syringe with a 22 or 25 gauge needle). Draw heparin into syringe and then push all of the heparin back into the heparin vial, leaving just enough to coat the inside of the syringe. Preheparinized, self-filling syringes are also available for arterial blood sampling.
- If drawing blood from a central venous catheter, a three-syringe technique should be used: a 3-mL syringe, filled with 0.5 mL of heparinized saline, is first filled to 3 mL as a "pre-sample." Subsequently, the appropriate amount of blood for diagnostic sampling is obtained. The pre-sample is then reinfused back into the patient (the heparin in the saline prevents clotting), and the catheter is then flushed with heparinized saline to clear the catheter. Technically, the pre-sample should be 3–5 times the priming volume of the catheter lumen.

TECHNIQUE
Prior to patient restraint, gather all supplies needed.

Venous Blood Collection
- Based on the amount of blood needed and the quality of the available veins, a vein will be selected by the venipuncturist. Typically, the jugular vein is used when more than 2 mL of blood is needed, and a coagulopathy is not present. An alternative to this is the lateral saphenous vein in dogs and the medial saphenous vein in dogs and cats, which works well if a patient is struggling. If a small amount of blood is needed (<2 mL), the cephalic vein may be used.
- The patient should be restrained, preferably on an examination table. The site is swabbed with alcohol. The vein is compressed proximal to the site to allow the vein to engorge. The needle is advanced through the skin and then into the vein lumen, and the syringe plunger pulled back to aspirate the appropriate amount of blood. Compression of the vein is released. The syringe and needle are then withdrawn as a unit and blood placed into appropriate collection tubes. The restrainer applies pressure directly to the venipuncture site for 15–20 seconds then checks the site; if there is still bleeding, a bandage can be applied.

Arterial Blood Collection
- If a self-filling arterial blood syringe is used, pull the plunger back to the desired amount of blood needed (0.4 mL is adequate for most blood gas analyzers). The patient should be restrained with its bottom leg held out. The restrainer should put a hand behind the patient's hock to keep its leg extended without compressing the artery.
- Preferred site is the pedal (metatarsal) artery, which courses over the metatarsal bones and courses into the hock joint. The tail, femoral, and lingual arteries have also been used to collect samples under varying conditions:
  - The artery is identified by palpation with a finger of the nondominant hand (which may also hold the paw to keep the leg extended). The needle is then directed into the artery directly below the palpated pulse. The artery will generally exhibit some fremitis when the needle is near.
  - If using a regular syringe, once the needle has penetrated the skin, negative pressure is created with the plunger of the syringe and the needle is directed to puncture the arterial wall. A flash of blood back into the syringe will usually be seen after arterial puncture. Allow the syringe to fill to the amount of blood needed, withdraw the syringe and needle, and have the restrainer place pressure over the site for several minutes. A small pressure wrap may be needed.

(CONTINUED) BLOOD SAMPLE COLLECTION

- If using a self-filling syringe, once the artery is punctured, arterial blood pressure will fill the syringe until the porous filter of the plunger is reached, at which point the syringe contains an anaerobic blood sample.
- For both syringes, following sample acquisition, the syringe contents should be protected from room air. The needle may be placed into a rubber stopper or eraser, or the needle removed and the syringe capped with a specialized stopper (usually provided with the self-filling syringes).
- Due to proximity of the nerve to the artery, arterial puncture may be associated with pain, and the animal may pull the leg back during the procedure.

SAMPLE HANDLING

- Venous samples should be placed into appropriate collection tubes immediately to prevent clot formation. The tubes containing anticoagulant should be filled before the clot tubes. Invert the tubes at least 5 times to mix the samples thoroughly with the anticoagulant.
- Arterial samples for blood gas analysis should be assayed immediately.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring

Remove the pressure wrap 1 hour after the procedure and verify lack of continued bleeding or hematoma.

BLOOD SMEAR MICROSCOPIC EXAMINATION

BASICS

TYPE OF SPECIMEN
Blood smear (see Blood Smear Preparation).

TEST EXPLANATION AND RELATED PHYSIOLOGY
- Cell counts derived from an automatized hematology analyzer must be correlated to findings in a manual examination of a peripheral blood smear:
  - Confirm cell counts.
  - Identify unusual cell types (including neoplastic cells).
  - Identify morphological changes such as toxic change or left shifts, reactive lymphocytes, polychromatic cells, nucleated erythrocytes (nRBC), and immature platelets.
  - Identify parasites.

INDICATIONS
- With every complete blood count (CBC).
- To confirm results from an automated hematology analyzer.
- To characterize erythrocytes and classify anemia.
- To diagnose inflammation, hematopoietic neoplasia, and bone marrow disease.
- To evaluate platelets, especially if automated counts are low.
- To identify circulating parasites.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
12-hour fasting samples are preferred to prevent lipemia, which can interfere with RBC morphology evaluation.

BODY SYSTEMS ASSESSED
Hematologic, lymphatic, and immune.

SAMPLE

SAMPLE COLLECTION
Previously prepared blood smear (see Blood Smear Preparation).

SAMPLE HANDLING
- Slides should not be exposed to formalin or formalin fumes.
- Slides should be protected from breakage.
- Do not scratch or refrigerate slides.
- If slides do not have a coverslip, oil should be gently blotted away rather than wiped.

SAMPLE STORAGE
Store slides in shatterproof containers at room temperature.

SAMPLE STABILITY
- Air-dried slides can be stored at room temperature indefinitely. They are stable months to years if fixed, stained, and not exposed to dust, light, or heat.
- For long-term storage, a permanent coverslip is recommended.

PROTOCOL
- Smears should be evaluated systematically:
  - Gross examination of slide quality.
  - Evaluate all cell lines at low-(10× objective), medium (40–50× objective), and high-power (100× oil objective) magnification.
  - Evaluate number and morphology of neutrophils, banded neutrophils (bands), lymphocytes, eosinophils, monocytes, and basophils.
  - Unusual cells that can be seen include immature granulocytes, lymphoblasts, mast cells, and nRBC.
  - A nucleated cell differential should be performed, platelet numbers and presence/absence of clumping should be estimated, morphological changes of red blood cells (RBCs) and white blood cells (WBCs) should be noted, and presence of parasites (e.g., microfilaria) or inclusions should be determined.

Macroscopic Evaluation
- Confirm patient identity (slide label).
- Evaluate the quality of the blood smear. If the quality is poor, make a new blood smear (see: Blood Smear Preparation):
  - Smear should be shaped like a parabolic cone (similar to the flame of a candle) with a blunt base, almost parallel sides, and a gently curved feathered edge at the nose.
  - Smear should cover 1/3 to 2/3 of the slide, however the quality of the monolayer and feathered edge are more important than the overall surface area.
  - The stain quality should be adequate for proper cell identification.

Low Power Evaluation
- At low power (10× objective), scan the entire smear.
- A monolayer where erythrocytes are closely opposed without overlapping should be present near a gently feathered edge (see Figure 1):
  - With experience, a marked decrease or increase in RBC number can be detected.
  - Anemic samples have a larger monolayer with increased space between cells extending into the smear base, while polycythemic samples have a minimal to absent monolayer.
  - Perform a reticulocyte count if anemia is suspected.
- Identify potential RBC agglutination and differentiate from rouleaux. If agglutination is suspected, perform a saline agglutination test.
- At the feathered edge, search for microfilaria and large unusual cells (e.g., mast cells, lymphoblasts, other leukemic cells).
- Identify and evaluate the severity of platelet and leukocyte clumping at the feathered edge or base.
- WBCs are unevenly distributed in a smear; heavier and larger cells are more abundant at the base and feathered edges. Lymphocytes are more abundant than neutrophils in the thinner parts of the center and monolayer. Evaluate all areas of the slide for a more representative assessment.
- In the main body of the smear, estimate overall WBC count with a 10× objective. Average cells/field × 100 = approximate cells/μL:
  - When counting WBCs, include at least 1 field in the base and feathered edge when determining the average to compensate for uneven leukocyte distribution. Moving from feathered tip to base is helpful.

Medium Power Evaluation
- If the slide is coverslipped, evaluate with a 40× objective. If the slide is not, use a 50× oil objective.
- Begin at the feathered edge to identify larger uncommon cells (mast cells, lymphoblasts, etc.), then move to the monolayer to perform a leukocyte differential:
  - Due to uneven distribution of leukocytes, systematically move from edge to edge, a zig-zag, or alternating squares/Greek key pattern (Figure 2) to perform the differential.
  - Classify 100 nucleated cells as neutrophils, bands, lymphocytes, monocytes, eosinophils, basophils, or other/unclassifiable (blasts, immature granulocytes, mast cells, etc.). Count nRBCs separately (do not include in the differential):
    - If there is a leukocytosis (>30,000 cells/μL) or >2% other cells, count 500 cells. Multiply your total WBC count (estimated or automatized hematology analyzer results) by the differential to calculate absolute cell counts.
  - If there is >2% nRBC, calculate a corrected WBC count. The formula is:

    Corrected WBC = (Measured WBC × 100)/(100 + # nRBC seen)

  - Note morphological changes to leukocytes such as neutrophil toxic change, reactive lymphocytes, monocyte vacuolation, viral inclusions, and presence of parasites.
- Perform an initial evaluation of erythrocytes for polychromasia, anisocytosis, poikilocytes, parasites, and inclusions including Heinz bodies, Howell-Jolly bodies, basophilic stippling, and iron (siderotic) inclusions.

(CONTINUED) **BLOOD SMEAR MICROSCOPIC EXAMINATION**

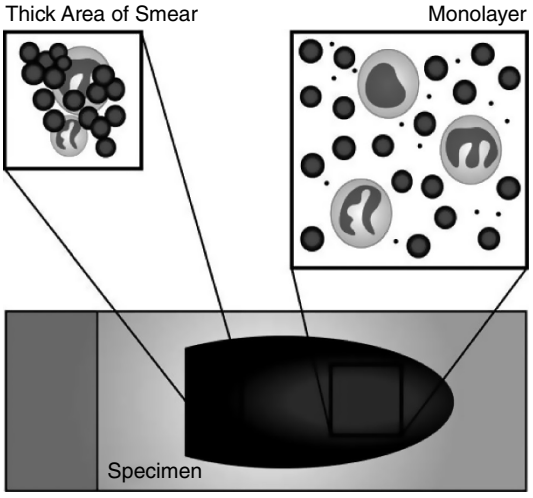

Figure 1.

This drawing of a blood smear illustrates how cell morphology is optimal in the monolayer just behind the feathered edge, where RBCs are evenly distributed. Cells in thicker areas, toward the back of the smear, are less flattened and appear smaller and darker and are more difficult to identify. The overlap of cells, in thicker portions of the smear, further obscures and distorts their morphologic features.

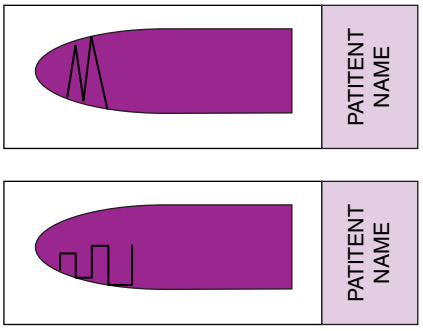

Figure 2.

Perform a leukocyte differential using a zig-zag or alternating squares/Greek key pattern.

- Note location (cytoplasmic, nuclear, epicellular) and type of cell affected by parasites and inclusions.
- Roughly evaluate number and size of platelets, looking for smaller clumps.

High Power Evaluation

- Evaluate both the monolayer and feathered edge with a 100× oil objective, focusing on cell morphology, parasites, and inclusions.
- Perform a close evaluation of erythrocytes for variation in cell size, color, inclusions, and shape abnormalities including spherocytes, echinocytes, keratocytes, schistocytes, acanthocytes, leptocytes, stomatocytes, and codocytes:
  - Quantify morphologic RBC changes using the following grading scheme:
    - Rare = <1 per 100× objective fields
    - Occasional = 1–3 per 100× objective field
    - Few or mild = 4–10 per 100× objective field
    - Moderate = 10–25 per 100× objective field
    - Many or marked = >25 per 100× objective field
- Search again for erythroid parasites and inclusions; some are not visible below 100×.
- Perform a closer evaluation of morphological changes to leukocytes (listed above).
- Count platelets at 100× in the monolayer, in a minimum of 10 fields, and evaluate for abnormal morphology and microclumping. Average platelets per 100× oil field × 20,000 = approximate platelets/µL.

INTERPRETATION

NORMAL FINDINGS OR RANGE

- Adjacent erythrocytes that barely touch or rarely overlap in the monolayer, 1–2 polychromatic cells per 100× objective field, mild anisocytosis, few poikilocytes, and no inclusions.

BLOOD SMEAR MICROSCOPIC EXAMINATION (CONTINUED)

• Approximately 5–15 WBCs per 10× objective field, with 60–80% mature neutrophils and no morphologic abnormalities.
• Approximately 10–25 platelets per 100× objective field in the monolayer without clumping.
• No parasites.

ABNORMAL FINDINGS

• Tightly packed or widely spaced RBCs.
• Absolute WBC or platelet numbers above or below the reference interval.
• Morphological abnormalities in any cell line.
• Parasites present.

CRITICAL VALUES

• Less than 1–3 neutrophils per 10× objective field suggests marked neutropenia and increased risk of infection.
• Less than 1–3 platelets per 100× objective field, without clumps present, suggests thrombocytopenia severe enough to cause bleeding.

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology
None

Drugs That Alter Physiology
• Glucocorticoids can cause leukocytosis, neutrophilia, lymphopenia, and variable monocytosis.
• Epinephrine can cause neutrophilia, lymphocytosis, and variable thrombocytosis.
• Heinz bodies (see Anemia, Heinz Body) are caused by oxidative damage from numerous drugs including acetaminophen, benzocaine, phenazopyridine, propofol, and vitamin K.
• Most chemotherapeutic agents can cause pancytopenia (see Pancytopenia), as can many other medications including chloramphenicol (feline), estrogen (canine), griseofulvin, methimazole (feline), phenobarbital, phenylbutazone (canine), and trimethoprim-sulfa.
• Chloramphenicol and phenylbutazone can cause neutrophilic vacuolation.

Disorders That May Alter Results

• Hemolysis causes a thick pink background that distorts cells.
• Lipemia can cause RBC smudging.
• Hyperglobulinemia causes a thick blue background that distorts RBCs and causes pseudo-agglutination.

Collection Techniques or Handling That May Alter Results

• Poorly mixed blood can produce a thin smear, and misrepresent the WBC count and differential.
• Clotted blood artificially decreases platelet, RBC, and WBC numbers.
• Samples collected in sodium citrate anticoagulant have decreased platelet counts than those with EDTA anticoagulation (multiply count by 1.1 to account for dilution from liquid citrate anticoagulant).
• Poor blood smear preparation prevents accurate evaluation (see Blood Smear Preparation).
• Aged blood has increased platelet clumps and altered cell morphology including nuclear pyknosis, nuclear hypersegmentation in neutrophils, and cytoplasmic vacuolation.
• Epicellular parasites can detach over time and may be missed if smears are not made immediately after collection.
• Old stain or poor washing produces stain precipitate that can be mistaken for bacteria or parasites.

Influence of Signalment

Species
• Canine RBCs have a prominent zone of central pallor with little anisocytosis, while feline RBCs are smaller without obvious central pallor and more anisocytosis.
• Cat RBCs are more susceptible to Heinz bodies.
• Canine eosinophils (except in sighthounds, see below) have rounded granules while feline eosinophils have smaller granules shaped like rice grains—this can be used to differentiate mislabeled samples.
• Basophils have more indistinct granules in dogs and cats relative to other species.

Breed
• Higher RBC counts have been reported in German shepherd dogs, boxers, greyhounds, and dachshunds.
• Decreased RBC size (microcytosis) is reported in Akitas, chow chows, Chinese shar peis, and shiba inus.
• Akitas with high and low RBC potassium phenotypes have different erythrocyte parameter findings.
• Hereditary macrocytosis is reported in poodles.
• Congenital stomatocytosis is reported in Alaskan malamutes, Drentse partrijshonds, and miniature schnauzers.
• Lower WBC counts are reported in greyhounds, Belgian tervurens, and border collies.
• Gray eosinophils in sighthounds such as greyhounds, Italian greyhounds, and whippets can be difficult to detect and missed by automated analyzers.
• Marked lymphopenia is reported in basset hounds and Jack Russell terriers with severe combined immunodeficiency syndrome (SCID).
• Increased eosinophils have been reported in Bernese mountain dogs, Brittanys, rottweilers, and German shepherd dogs.
• Lower platelet counts are reported in sighthounds including North American Scottish deerhounds and greyhounds, and also in the Polish hound (ogar Polski).
• Lower platelet counts with large platelets (macrothrombocytopenia) is an autosomal recessive trait present in cavalier King Charles spaniels and Norfolk and Cairn terriers.
• Cyclic hematopoiesis in gray collies can cause various waxing and waning cytopenias.

Age

BLOOD SMEAR PREPARATION

BASICS

TYPE OF PROCEDURE
Diagnostic sample preparation

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Preparation of a good-quality air-dried blood smear is necessary for accurate evaluation.
- Smears should have a feathered edge and a monolayer with even cell distribution for a reliable WBC differential, visualization of cell appearance, and adequacy for parasite identification.
- Sample aging impacts leukocyte morphology and platelet couns, therefore immediate preparation of a good-quality blood smear is necessary.
- Prepared slides should be submitted with the corresponding anticoagulated blood for all complete blood counts (CBCs) sent to a referral laboratory.

INDICATIONS
Every time an in-house CBC is performed, and when a CBC is sent to a referral laboratory.

CONTRAINDICATIONS
Results are inaccurate if blood clots are present in the sample. A fresh blood sample should be taken if clots are present. Slides should be protected from exposure to formalin fumes.

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
12-hour fasting samples are preferred to prevent lipemia, which can interfere with RBC morphology evaluation.

BODY SYSTEMS ASSESSED
Hematologic, lymphatic, and immune.

PROCEDURE

PATIENT PREPARATION

Preprocedure Medication or Preparation
- Sterilize the venipuncture site with alcohol. The site may be shaved if needed.
- Collect blood (see Blood Sample Collection) and transfer into an anticoagulant tube; EDTA (purple top) is preferred for most species but lithium heparin (green top) may provide better cell morphology for some birds, reptiles, and amphibians:
  - Heparin is sometimes used in small animals with small blood volume in order to have sufficient plasma for biochemical tests.
  - Sodium citrate anticoagulant can also be used but counts should be multiplied by 1.1 to account for dilution.

Anesthesia or Sedation
Not required but may be helpful for clean venipuncture in fractious animals.

Patient Positioning
Varies with preferred venipuncture site.

Patient Monitoring
Observe venipuncture site for hemorrhage, bruising, or hematoma formation.

Equipment or Supplies
- New glass slides.
- Pencil for labeling slide.
- Microhematocrit tube or 22–25G needle.
- Stain (for in-clinic evaluation).

TECHNIQUE
- Label glass slide with patient name, using a pencil. Markers and pens wash off with some stains.
- Gently mix anticoagulated blood for even distribution of cellular constituents. A tube rocker can be used or the tube manually inverted 5 times.
- A small droplet of blood should be placed near the edge of a new glass slide. Droplets can be applied with a microhematocrit tube or needle.
  - The most common error in slide preparation is too large a drop. Reduce the size of the drop and repeat if a good monolayer and feathered edge are not obtained.
- Use a second clean glass slide to spread the drop. Begin by placing the second slide at a 30-45° angle to the first where the blood will be spread (see Figure 1).
- Back the spreader slide into the drop. Let the blood migrate along the contact edge and toward the periphery (~5 seconds).
- When the blood has spread close to the edges of the slide, gently float the top slide away from the drop towards the end of the lower slide without applying downward pressure.
- Air-dry rapidly by waving the slide in the air or placing under a table fan (do not blow on slides).
- Stain with a Romanovsky-type stain (e.g., Diff-Quick, Wright-Giemsa, etc.) if evaluating in-house. Slides sent to external laboratories should be unstained.
- Package in appropriate shatterproof containers for transportation to external laboratories.

SAMPLE HANDLING
- Do not scratch or refrigerate slides.
- Air-dried slides can be stored at room temperature indefinitely. They are stable months to years if fixed, stained, and not exposed to dust, light or heat.
- For long-term storage, a permanent coverslip is recommended.
- Avoid exposure to any formalin, even formalin fumes from a nearby biopsy specimen.

INTERPRETATION

NORMAL FINDINGS OR RANGE
- See Blood Smear Microscopic Examination.
- A good smear is shaped like a parabolic cone (similar to the flame of a candle) with a blunt base, almost parallel sides, and a gently curved feathered edge at the nose.
- A monolayer where erythrocytes are closely opposed without overlapping should be present near a gently feathered edge.
- The smear should cover 1/3 to 2/3 of the slide; however a large smear is not the goal. The quality of the monolayer and feathered edge are more important than the overall surface area. If either are not present, make a new smear.

Causes of Abnormal Values
See Tables 1 and 2.

CRITICAL VALUES
None

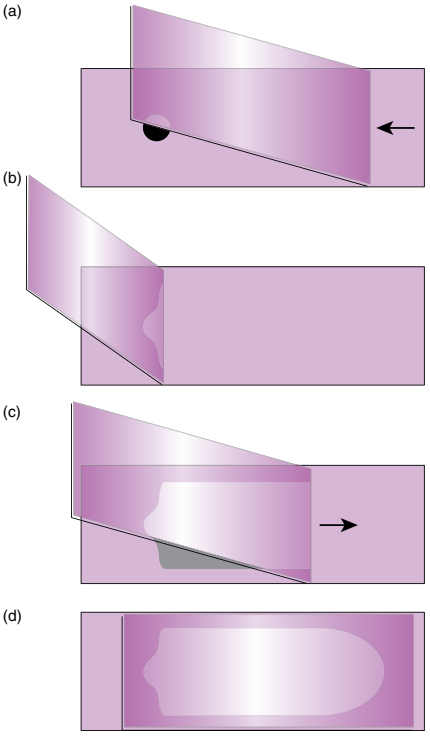

Figure 1.

Proper technique for blood smear preparation.

(CONTINUED) BLOOD SMEAR PREPARATION

Table 1

Common staining mistakes.

Problem	*Appearance*	*Probable Causes*	*Solution*
Bacterial growth in stain	Scattered extracellular bacteria, sometimes on a different plane of focus	Stain used for nonsterile procedures (e.g., skin lesions).	Use separate stain for cytology and hematology. Replace stain frequently
Poor coloration	Pale colors or insufficient contrast	Insufficient time in dye or fixative, wrong pH water rinse, evaporated solutions	Standardize time per dip using a stopwatch. Use pH buffered distilled water to rinse. Tightly cap stains
Stain precipitate	Darkly basophilic dots, sometimes aggregated, on a different plane of focus	Aged staining solution, evaporated solutions, or inadequate rinsing of slides	Filter or replace stain. Tightly cap stain when not in use. Rinse with distilled rather than tap water
Water artifact	Moth-eaten cells, refractile "inclusions"	Too much water in fixative	Replace fixative

Table 2

Common smear preparation mistakes.

Problem	*Probable Causes*	*Solutions*
Blunt end (not arced)	Spreader slide lifted abruptly	Lift spreader slide gently. Smaller drop may be needed
Blood reaches far edge	Too large a drop, spreader slide too low or moved too slowly	Use smaller drop. Raise the angle of the spreader slide or spread faster
Mono layer absent (thick smear)	Too large a drop, spreader slide too high, apolycythemia	Use smaller drop and/or lower the angle of the spreader slide
Striations (chatter)	Spreader slide moved too slowly or inconsistently	Move spreader slide faster and/or more gently. Reduce downward pressure
Abnormal shape	Spreader slide corner lifted	Move spreader slide more gently and smoothly
Rough feathered edge	Unclean spreader slide, large platelet clumps	Use a clean slide. Remix blood. Repeat with lower angle

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation

None

Conditions That May Interfere with Performing the Procedure

Marked polycythemia causes increased blood viscosity that can prevent smooth distribution of cells, preventing the formation of a monolayer and distorting leukocyte morphology. Lowering the spreader slide angle may help.

Collection Techniques or Handling That May Alter Results (see Tables 1 and 2)

- Blood aging prior to slide preparation will cause platelet clumping and altered leukocyte morphology including nuclear pyknosis, nuclear hypersegmentation in neutrophils, and cytoplasmic vacuolation. Slides should be made as soon as possible after blood collection.
- Poorly mixed samples can cause a thinner smear mimicking anemia and misrepresentation of the leukocyte differential.
- Clots in the blood sample will decrease the presence of platelets on the smear and may alter the leukocyte differential.
- An inadequate feathered edge will interfere with detection of platelet clumps and abnormal cells.
- Any exposure to formalin fumes fixes the slides, preventing adequate cytological staining. leukocytes cannot be accurately identified. Slides exposed to formalin should not be evaluated.

Influence of Signalment on Performing and Interpreting the Procedure

Species

The choice of EDTA, lithium heparin, or sodium citrate as an anticoagulant varies by species for best cellular morphology balanced with the need for collection of plasma or minimizing blood collection volume. Research species prior to selecting an anticoagulant.

Breed

None

Age

None

Sex

None

Pregnancy

None

CLINICAL PERSPECTIVE

- Slide quality matters; it is easier to made smooth smears on better quality slides. Use new glass slides, preferably with a negative charge.
- Sample aging changes leukocyte morphology and platelet counts—make slides immediately.
- Fresh smears may be necessary to identify RBC parasites including hemotropic *Mycoplasma* spp.
- Some erythroid parasites, such as *Babesia*

MISCELLANEOUS

BLOOD TYPING

BASICS

TYPE OF SPECIMEN
Blood

TEST EXPLANATION AND RELATED PHYSIOLOGY
- Blood types are genetic markers on the surface of red blood cells (RBCs):
  - Species-specific and antigenic (immune system can recognize and potentially produce antibodies against them).
  - A set of 2 or more alleles at 1 gene locus makes up a blood group system.
  - An individual lacking a given blood type may develop antibodies against it, either naturally (e.g., AB system in cats) or following sensitization via a mismatched transfusion.
  - In dogs and cats, blood-typing methods are mostly based on agglutination reaction in which a species-specific antiserum or a lectin is directed against specific RBC antigens.
- In dogs, an international standardization proposed seven blood groups, referred to as Dog Erythrocyte Antigen (DEA), followed by a number. Since then, two new canine blood groups have been recognized:
  - The *Dal* blood group was discovered following blood incompatibility in a previously-transfused anemic Dalmatian. Dal-negative dogs are rare and at high risk of transfusion incompatibility if they are to receive multiple blood transfusions, considering the fact that all blood donors tested to date are Dal positive.
  - Two additional canine blood types, Kai 1 and Kai 2 have recently been identified, but their clinical significance remains unknown.
- For each blood group, a dog may be either positive or negative, so an individual dog's RBCs can have several of these blood groups on their membranes. Flow cytometry analysis of the DEA 1 antigen using a monoclonal antibody revealed that the expression of DEA 1 is a continuum of reactions ranging from negative to strongly positive, i.e., that all the alleles of the DEA 1 system have a similar epitope. Consequently, the historical nomenclature DEA 1.1, 1.2, 1.3, and DEA 1.1 negative is now simplified to DEA 1 positive and DEA 1 negative.
- Dogs do not have clinically significant naturally occurring alloantibodies; however, they may become sensitized after receiving a blood type-mismatched transfusion. DEA 1 is the most antigenic blood group in dogs. For this reason, blood typing for DEA 1 is desirable prior to transfusions to avoid sensitization.
- In cats, the AB blood group system is the predominant system, consisting of three blood types: A, B, and AB. The *a* allele is dominant over the *b* allele. The rare *ab* allele, causing the blood type AB, is separately inherited, being (co)-dominant to *b* and recessive to the *a* allele:
  - Although most cats are type A in North America (>95% of domestic shorthairs), significant geographic and breed-associated differences exist in the frequencies of these blood types.
  - Cats possess naturally occurring alloantibodies against the blood type they are lacking.
    - Type B cats have very strong anti-A alloantibodies, such that transfusion of type A blood into a type B cat will produce a life-threatening acute transfusion reaction.
    - Approximately 1/3 of type A cats have detectable weak anti-B alloantibodies, which may cause shortened survival of transfused B cells in type A cats.
  - In 2007, a blood type called *Mik was* identified outside of the feline AB blood group and found to be capable of causing a hemolytic transfusion reaction. Unfortunately, blood typing for Mik is no longer possible.
- Easy-to-use blood-typing kits are commercially available for in-practice determination of canine DEA 1, and feline A, B or AB blood types.
  - The RapidVet-H canine and feline blood-typing cards (DMS Laboratories, Flemington, NJ) provide results in approximately 2 minutes. The animal blood type is indicated by visible RBC agglutination. The level of agglutination depends on the amount of antigen expressed on RBC membranes. This test is difficult to use in animals exhibiting RBC auto-agglutination.
  - The Alvedia Quick Test DEA 1 and Alvedia Quick Test A+B blood-typing kits (Alvedia, Villeur banne, France) are based on immunochromatography; RBCs migrate on a membrane and interact with monoclonal antibodies to produce a visible line. A second control line appears if the test was performed correctly.
  - RapidVet-H IC Feline uses immunochromatography for feline blood typing.
- Several automated blood typing analyzers are now commercially available.
- Typing services and/or polyclonal antisera are also available for DEA 1, 4, 5 and 7, as well as the feline AB system. There is limited accessibility to DEA 3, 5 and *Dal* reagents and a complete lack of accessibility to DEA 6, DEA 8 and Mik reagents.
- Several genetic variants associated with the B and the AB blood groups have been identified, representing a promising molecular diagnostic scheme to genotype cats for the AB blood group system and to differentiate type A, B and, more recently, AB cats.

INDICATIONS
- Screening blood donors and recipients to assure blood compatibility prior to transfusion.
- Screening breeding cats to ensure blood-compatible mates and avoid neonatal isoerythrolysis.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
None

BODY SYSTEMS ASSESSED
Hemic, lymphatic, and immune.

SAMPLE

SAMPLE COLLECTION
A 1–2 mL venous blood sample.

SAMPLE HANDLING
EDTA anticoagulant.

SAMPLE STORAGE
Refrigerate for short-term storage.

SAMPLE STABILITY
The physical integrity of RBCs is critical for correct results. Ideally, samples should be blood typed within 2–3 days of blood collection.

PROTOCOL
None

INTERPRETATION

NORMAL FINDINGS OR RANGE
- Dogs—roughly 50% are DEA 1 positive, with various degree of antigenic expression (Table 1).
- Cats—in North America, most are type A (>95% of domestic shorthairs); <5% are type B, and <1% are type AB.

ABNORMAL VALUES
None

CRITICAL VALUES
None

INTERFERING FACTORS
Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology

Recent blood transfusion (packed RBCs or whole blood).

Drugs That Alter Physiology

None

(CONTINUED) BLOOD TYPING

Table 1

Normal findings in dogs.

Canine Blood Types	*% Positive*	*% Negative*
DEA 1	33–65	35–67
DEA 3	5–24	76–95
DEA 4	87–100	0–13
DEA 5	8–51	49–92
DEA 7	8–82	18–92

Table 2

Cats—type B frequency in North America.

Breeds	*Type B Frequency in North America (%)*
Siamese, Burmese, Tonkinese, Russian blue, Ocicat, Oriental shorthair	0
Maine coon, Norwegian forest, DSH/DLH	<5
Abyssinian, Himalayan, Birman, Japanese bobtail, Persian, Somali, Sphinx, Scottish fold	5–25
Exotic and British shorthair, Cornish rex, Devon rex	25–50

Disorders That May Alter Results

- Severe anemia may cause false-negative results because the number of RBCs may be insufficient to agglutinate in response to antiserum; this may be circumvented by centrifuging the blood sample and removing some plasma to concentrate the RBCs prior to blood typing.
- Autoagglutination, such as in immune-mediated hemolytic anemia, precludes typing by agglutination-based methods because such blood samples will always appear positive. To some limits, this may be circumvented by washing the RBCs prior to blood typing.
- Marked rouleaux can be mistaken for a weak positive reaction with the Rapid Vet-H canine and feline blood-typing cards.

Collection Techniques or Handling That May Alter Results

Hemolysis of the blood may not allow blood typing, because the physical integrity of the RBCs is critical for correct results.

Influence of Signalment

Species

- Dogs—DEA 1, 3, 4, 5, 6, 7 and 8, and *Dal*.
- Cats—feline AB blood groups (type A, B or AB) and *Mik*.

See comments above concerning limited availability of some typing reagents.

Breed

- Dogs—breed-associated differences in the frequency of blood types are mostly documented for DEA 1 (surveys mostly among large breed dogs, i.e., canine blood donors). In addition to Dalmatians, dogs with the rare Dal-negative blood types were identified in Doberman pinschers and shih tzus.
- Cats—significant geographic and breed-associated differences in the frequencies of these blood types have been found. Type B domestic cats are uncommon in some countries like the United States and Switzerland, however, in other countries such as Australia, Greece, and Turkey, their prevalence can reach up to 36% of the non-pedigree feline population (see Table 2).

Age

None

Gender

None

Pregnancy

None

LIMITATIONS OF THE TEST

Sensitivity, Specificity, and Positive and Negative Predictive Values

N/A

Valid If Run in a Human Lab?

No

CLINICAL PERSPECTIVE

- It is strongly recommended to blood type canine blood donors and patients for DEA 1 prior to transfusion to limit sensitization by transfusion, because DEA 1 is the most antigenic and clinically significant blood type.
- Dal blood typing, in addition to standard DEA 1 typing, is recommended in Dalmatians, Doberman pinschers and shih tzus, especially in previously transfused dogs.
- A canine patient negative for a given blood type can become sensitized and produce specific antibodies against this blood type if transfused with positive blood. A subsequent transfusion of positive blood may lead to an immediate hemolytic transfusion reaction. Such transfusion reactions have been documented against DEA 1, 4, *Dal*, and one common antigen.
- The sensitization (i.e., the production of antibodies in negative dogs) against DEA 4 or the *Dal* antigen is particularly challenging because finding compatible blood may be extremely difficult given the high prevalence of those blood types in the canine population.
- Because of naturally occurring alloantibodies, feline donors and recipients should always be blood typed prior to transfusion. As little as 1 mL of type A blood can lead to a fatal hemolytic transfusion reaction if given to a type B cat.
- Type A and AB kittens born to type B queens are at risk of developing neonatal isoerythrolysis caused by the presence of strong anti-A alloantibodies in the colostrum of type B queens. The disease is characterized by a severe hemolytic anemia and possible nephropathy, as well as other organ failures. To avoid neonatal isoerythrolysis, it is recommended to blood type breeding mates, particularly in breeds with a high incidence of type B cats.
- All previously transfused dogs and cats (>4 days) should be crossmatched, in addition to standard blood typing, to look for the presence of antibodies before receiving additional blood.

BONE MARROW ASPIRATE AND BIOPSY

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Cytologic examination of samples collected via bone marrow aspiration (BMA) is necessary to assess the presence or absence, quantity, and ratio of precursors of the red blood cell (RBC), platelet, and white blood cell (WBC) lines.
- Cytologic examination is also used in staging patients with hematologic and certain other malignancies, where bone marrow involvement is associated with a higher stage of disease.
- Histologic examination of samples collected via bone marrow biopsy (BMB) provides information regarding tissue architecture within the bone marrow and is an important step in evaluating primary bone marrow disorders, such as aplastic anemia, nonregenerative anemia, myelodysplasia and myelofibrosis.
- Poorly prepared smears or inadequately harvested core biopsy samples can make interpretation difficult.

INDICATIONS
- BMA:
  - Identify cell types, quantity, and ratio of precursor cells within the bone marrow (e.g., when peripheral cytopenias are noted).
  - Identify the presence of suspected infectious agents.
  - Assess bone marrow involvement in neoplastic conditions.
  - Provides information on the cell types present but no information on bone marrow structure.
- BMB:
  - Indicated for animals with suspected structural bone marrow abnormalities (aplastic anemia, non-regenerative anemia, myelodysplasia, myelofibrosis).

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
Hemorrhage is a risk but not expected to be clinically significant.

CLIENT EDUCATION
- The procedure has minimal risk.
- Mild discomfort associated with the procedure can be alleviated through the use of a local anesthetic and heavy sedation or anesthesia. If indicated, analgesic agents may be provided following the procedure.

BODY SYSTEMS ASSESSED
Hemic, lymphatic, and immune.

PROCEDURE

PATIENT PREPARATION
Pre-Procedure Medication or Preparation
Hair clipping and aseptic skin preparation are indicated prior to BMA or BMB.

Anesthesia or Sedation
Local anesthesia (lidocaine) in conjunction with heavy sedation or anesthesia.

Patient Positioning
- Palpate the desired site of sample collection (amenable locations include the head of the humerus, iliac crest, and trochanteric fossa; the sternum may also be used in some animals) and position the animal accordingly.
- Humerus—lateral recumbency with the patient's foreleg rotated externally and extended caudally 45°, keeping the leg parallel to the table or floor.
- Iliac crest—sternal recumbency with the patient's legs extended forward, rounding the lumbosacral area.
- Trochanteric fossa—lateral recumbency.

Patient Monitoring
- Monitor for adequate analgesia and level of sedation.
- Monitor for bleeding at the aspiration or biopsy site following sample collection.
- If patient is hevily sedated or anesthetized, monitors such as pulse oximetry, blood pressure, ECG, and capnography may be indicated.

Equipment or Supplies
- Surgical scrub.
- Sterile gloves.
- Sterile 4 × 4-inch gauze.
- A no. 11 scalpel blade.
- 1 mL of 2% lidocaine (maximum of 2 mg/kg, can be diluted to 1% if more volume is needed).
- BMA:
  - A Rosenthal or Illinois BMA needle
  - A 6- or 12-mL syringe
  - EDTA solution
  - A watchglass or glass petri dish
  - Pipette or hematocrit tubes
  - Glass slides
- BMB:
  - A Jamshidi infant needle or pediatric BMB needle
  - A 6- or 12-mL syringe
  - A jar containing 10% buffered formalin for sample
  - A cartridge to hold small samples in the formalin jar

TECHNIQUE
- BMA or BMB generally requires 2–3 people: 1–2 to position the animal, monitor sedation or anesthesia, and assist with sample handling, and the other to collect the sample.
- Clip hair from an approximately 5 cm^2 area over the desired site and perform a surgical scrub. After surgical preparation of the site, infiltrate the area with 0.5–1.0 mL of local anesthetic (e.g., 2% lidocaine), making sure to also block the periosteum. Follow with a final surgical scrub.
- Make a small stab incision with the no.11 scalpel blade.

Bone Marrow Aspiration
- Insert the bone marrow needle through the stab incision made in the skin and subcutaneous tissues. Position the needle on the periosteum.
- Holding the instrument closely between the thumb and index finger and within the closed palm, begin to rotate the instrument back and forth with gentle pressure until it is solidly within the marrow cavity:
  - Care must be taken to keep the needle and instrument in line; avoid rocking the needle during its advancement.
  - Firm adequate placement can be determined by the ability to move the limb by moving the inserted instrument gently side to side.
- Once positioned in the marrow cavity, the cap and stylet are removed and a 6- or 12-mL syringe (containing 0.5 mL of EDTA, if available) is attached to the needle and used to aspirate with negative pressure.
- As soon as marrow is seen within the syringe, negative pressure is released to minimize dilution or contamination of the sample with peripheral blood.
- The syringe is then detached and its contents emptied in single small drops onto a series of glass slides, placing 1 drop per slide (alternatively, the contents may be emptied into a watchglass or glass petri dish containing 0.5–1.0 mL of EDTA; this technique reduces the risk of clotting prior to slide preparation).
- Working quickly to avoid clotting of the sample, the bone marrow drops are smeared onto each of the slides (see Fine-Needle Aspiration for slide preparation technique).
- Alternatively, if a watchglass containing EDTA is used, individual bone marrow particles (identified by a spicule shape) may be collected using a pipette or hematocrit tube, transferred to the slides, and the sample then smeared along the length of the slide.

Bone Marrow Biopsy
- Insert the biopsy instrument through the stab incision made in the skin and subcutaneous tissues. Position the needle on the periosteum.
- Holding the instrument so the plastic handle rests in the palm and the needle extends between the index and middle fingers, begin to rotate instrument back and forth with gentle pressure until it penetrates the outer cortex and enters the marrow cavity.

BONE MARROW ASPIRATE AND BIOPSY (CONTINUED)

• Once securely positioned within through the outer cortex, remove the stylet and advance the needle 1–2 cm within the marrow by continuing to rotate the instrument back and forth with gentle pressure. At this point, a core of bone marrow should be lodged within the hollow needle.
• To break off the core within the needle and ensure it is removed along with the instrument, sharply twist the instrument several times in a clockwise direction, followed by several twists in a counterclockwise direction, and then firmly rock the instrument in a circular motion in one direction and then the other. Finally, attach a 6- or 12-mL syringe to the end of the instrument and apply a single burst of negative pressure. The instrument can then be removed from the bone by rotation and steady traction.
• Once the instrument is removed, use the "shepherd's crook" stylet inserted retrograde though the needle to push the bone marrow core biopsy gently out through the top of the instrument and place the sample in formalin. Small samples should be placed in a tissue cassette prior to inserting in formalin jar.

SAMPLE HANDLING

• BMA—air-dried samples can be stored at room temperature, though samples should be fixed and stained as soon after collection as possible (within 3–7 days) for optimal assessment of cellular morphology.
• BMB—collected samples should be placed in 10% buffered formal for submission to a histopathology laboratory.
• A peripheral blood sample should be collected and submitted at the time of either BMA or BMB.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring
• Monitor for evidence of mild superficial hemorrhage at the BMA or BMB site.
• Monitor for evidence of discomfort at the BMA or BMB site or lameness on the sampled leg.

Nursing Care

Anticipated Recovery Time
Immediate

INTERPRETATION

NORMAL FINDINGS OR RANGE

• Bone marrow should be evaluated by a trained pathologist.
• Sample should be evaluated for:
  ◦ Cellularity (normal range, 25% fat and 75% cells to 75% fat and 25% cells; varies according to age).
  ◦ Megakaryocyte series (normal range, approximately 4–50 megakaryocytes per spicule).
  ◦ Erythrocyte series (abundance, proportions, morphology).
  ◦ Granulocytic series (abundance, proportions, morphology).
  ◦ Myeloid/erythroid ratio (normal range, 0.75:1 to 2:1).
  ◦ Presence of organisms (e.g., *Histoplasma capsulatum, Leishmania donovani, Toxoplasma gondii, Cytauxzoon felis, Ehrlichia* spp.)
  ◦ Presence of erythrophagocytosis, plasmacytosis, iron-containing pigments, neoplastic cell infiltration, and myelofibrosis.

ABNORMAL VALUES

• Decreased overall cellularity.
• Increases or decreases in megakaryocyte numbers.
• Abnormal numbers, proportions, or morphology of erythrocyte or granulocyte series.
• Presence of infectious organisms.
• Evidence of erythrophagocytosis, plasmacytosis, or decreased iron-containing pigments.
• Neoplastic cell infiltration.

CRITICAL VALUES

None

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure
• Administration of immunosuppressive therapies (as for suspected immune-mediated cytopenias) prior to sample collection may alter interpretation.
• Administration of corticosteroids or other chemotherapeutic agents prior to sample collection may alter the presence or number of neoplastic cells.

Conditions That May Interfere with Performing the Procedure
None

Procedure Techniques or Handling That May Alter Results
• Inadequate sample collection; animals with myelofibrosis may have underwhelming BMA and difficult to obtain BMB.
• Excessive aspiration with BMA may lead to dilution or contamination of the sample with peripheral blood.

Influence of Signalment on Performing and Interpreting the Procedure

Species
None

Breed
Some breed-related variability; for example, increased hematocrit, mild thrombocytopenia, mild leukopenia may be seen in greyhounds.

Age
Normal bone marrow cellularity decreases with age: samples from juvenile, adult, and geriatric animals contain approximately 25% fat and 75% cells, 50% fat and 50% cells, and 75% fat and 25% cells, respectively.

Gender
None

Pregnancy
None

CLINICAL PERSPECTIVE

• Cytologic examination of samples collected via BMA is an important step in assessing the presence or absence, quantity, and ratio of precursors of the RBC, platelet, and WBC lines in patients with increases or decreases in peripheral blood cell counts.
• Assessment can support a diagnosis and prognosis in animals with cytopenias and hematologic and certain other malignancies.
• BMB provides additional information regarding tissue architecture within the bone marrow.

MISCELLANEOUS

ANCILLARY TESTS

A CBC should be performed in conjunction with BMA and BMB.

SYNONYMS

None

SEE ALSO

• Anemia, Aplastic.
• Anemia, Immune-Mediated.
• Anemia, Nonregenerative.
• Bone Marrow Aspirate Cytology: Microscopic Evaluation (in Appendix X).
• Myelodysplastic Syndromes.
• Myeloproliferative Disorders.
• Thrombocytopenia.

ABBREVIATIONS

• BMA = bone marrow aspiration.
• BMB = bone marrow biopsy.

BONE MARROW ASPIRATE CYTOLOGY: MICROSCOPIC EVALUATION

BASICS

TYPE OF SPECIMEN
Tissue

TEST EXPLANATION AND RELATED PHYSIOLOGY
Bone marrow is the major hematopoietic organ of the mammalian body, and its examination aids in evaluating various hematologic disorders. The most common indication for its microscopic evaluation is a complete blood count (CBC) abnormality that cannot be readily explained by a good medical history or by physical examination, chemistry profile, and/or other diagnostic procedures. In addition, bone marrow evaluation may aid in monitoring disease progression or response to therapy, determination of disease prognosis, and staging of certain neoplasms. Finally, body iron stores can be estimated, particularly if special stains are used, and occult infectious agents may be identified. A CBC collected within 24 hours of marrow collection is imperative for accurate interpretation of findings.

In young animals, active hematopoiesis occurs throughout the skeleton in both the long bones (e.g., humerus, femur) and flat bones (e.g., ribs, pelvis). However, active hematopoiesis in normal adult animals is restricted to the flat bones and extremities of the long bones (e.g., proximal humerus or femur); the central area of the long bones is composed predominantly of adipose tissue. Furthermore, even the hematopoietically active regions of adult animals contain a higher percentage of fat compared to these areas in young animals. Knowledge of the age-related anatomic distribution of hematopoietic tissue is imperative so that an appropriate, representative specimen is collected.

Active hematopoietic tissue is highly vascular and the spaces between vascular sinuses are filled with hematopoietic cells. The hematopoietic areas are bordered by the endothelium lining the vascular sinuses and are given structural scaffolding by adventitial cells. Hematopoietic tissue is predominantly composed of megakaryocyte, erythrocyte, granulocyte, and monocyte cell precursors in various stages of maturation. Low numbers of resident macrophages, lymphocytes, plasma cells, and mast cells, as well as a variable amount of adipose tissue, are also normally present.

Collection of both aspirates and core biopsy specimens is technically simple (see Bone Marrow Aspirate and Biopsy). Aspirate specimens allow detailed analysis of cell populations, individual cell identification, and morphologic evaluation and are more amenable to cytochemical staining and immunocytochemistry. However, aspirates do not preserve architecture and may not be representative of the marrow as a whole. Myelofibrosis, regardless of the cause and, to a certain extent, the severity, often exfoliates poorly and may yield an insufficient specimen, so a core biopsy is crucial in these instances. Core biopsies have a longer turnaround time and are more expensive, but their utility lies in the preservation of tissue architecture and more accurate impression of overall cellularity. Additionally, cell arrangement, necrosis, infiltrative patterns, myelofibrosis, absolute megakaryocyte numbers, and quantification of iron stores can be better assessed in a core biopsy sample.

Prior to laboratory submission, a slide should be stained to assess whether it contains an adequate number of well-preserved hematopoietic unit particles or spicules. Spicules grossly appear as fatty streaks on unstained preparations and as intensely staining blue areas on stained preparations. If the slide is satisfactory, the stained and, preferably, additional unstained slides may then be sent to a diagnostic laboratory. Bone marrow aspirates collected into EDTA may also be submitted to the lab so that additional slides may be prepared.

INDICATIONS
- Peripheral blood abnormalities.
- Unexplained, persistent decreases in cell counts, including non- or poorly regenerative anemia, neutropenia, or thrombocytopenia.
- Unexplained, persistent elevations in cell counts.
- Atypical cells in peripheral blood.
- Clinical staging of malignancy.
- Unexplained hyperproteinemia or monoclonal gammopathy.
- Unexplained hypercalcemia.
- Fever of unknown origin, especially in searching for occult disease, including infectious agents.
- Assessment of body iron stores.
- Suspicion of osteomyelitis or infiltrative or proliferative bone marrow disease as may or may not be suggested by diagnostic imaging.
- A bone marrow core biopsy is indicated when repeated aspiration attempts, particularly if different sites are sampled, fail to yield adequate marrow samples.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
- Risks related to heavy sedation or anesthesia necessary for procedure.
- Fracture of bone already compromised by infiltrative disease or other pathology.

CLIENT EDUCATION
- Interpretation of findings typically contingent upon CBC collected within 24 hours.
- Inherent pathology such as myelofibrosis can result in yield of insufficient sample (biopsy preferred to aspirate).

BODY SYSTEMS ASSESSED
Hemic/lymphatic/immune

SAMPLE

SAMPLE COLLECTION
Marrow from proximal humerus or femur, wing of ilium, or sternum. Can be collected into EDTA, or directly prepared onto glass microscope slides.

SAMPLE HANDLING
Transport slides at room temperature in an appropriate protective slide container. Marrow collected into EDTA should be maintained chilled as with CBC blood samples.

SAMPLE STORAGE
Store slides at room temperature, protected from light. Avoid exposure to extreme temperatures, humidity, and formalin fumes (submit bone marrow core biopsies in separate specimen bag). Retain unstained slides for possible ancillary testing.

SAMPLE STABILITY
- Stained slides are stable for months to years.
- Unstained slides are stable for 1 week or more.

PROTOCOL
- Subjective evaluation of the marrow begins with a low-power (40– 100×) magnification of overall cellularity, megakaryocyte numbers, and iron content.
- Evaluate cellularity—identify multiple large, intact particles and compare the proportion of dark blue-staining hematopoietic tissue to the proportion of colorless adipose tissue within the particle to determine a rough percentage. Estimates of cellularity will be inaccurate if the number of particles on the slide is low. Good-quality bone marrow core biopsies typically give a more accurate assessment.
- Assess megakaryocytes—approximately 2–7 megakaryocytes are normally associated with each particle, although the exact number varies by species and the technique used to make the cytologic preparation. Megakaryocytes are the largest of the hematopoietic cells and are easily seen at low-power magnification. Mature megakaryocytes should predominate; they have abundant pale basophilic cytoplasm with fine magenta granules and 8 or more nuclei fused into a dense, lobulated mass.

BONE MARROW ASPIRATE CYTOLOGY: MICROSCOPIC EVALUATION (CONTINUED)

• Assess iron stores—a few small clumps of brown to black material per particle representing iron stored in the form of hemosiderin are routinely identified in the bone marrow of normal dogs. Prussian blue reaction may be used to confirm the presence or absence of iron, but typically is not necessary. Stainable iron is usually absent in normal bone marrow from healthy cats.
• At high power (500– 1000× magnification), attempt a general assessment of cell distribution (M/E ratio).
• Erythroid precursors appear as smaller, darker cells. They generally have darker basophilic cytoplasm and round nuclei with condensed chromatin.
• Myeloid precursors are larger and paler with light blue cytoplasm that may contain magenta primary granules or secondary granules with a round, indented, or U-shaped nucleus. Secondary granules can be eosinophilic, basophilic, or nonstaining (i.e., in neutrophil precursors).
• In healthy animals, there are approximately equal numbers of erythroid and myeloid precursors that should be overwhelmingly predominated by the later stages.
• Other cells, such as macrophages, lymphocytes, plasma cells, and mast cells, are normally found in low numbers.
• If any single type of cell appears to predominate, or if unusual morphologies are encountered, evaluation by a board-certified pathologist is recommended.

INTERPRETATION

NORMAL FINDINGS OR RANGE

• Cellularity (adults)—33%–66% hematopoietic cells; remaining percentages consist of adipose tissue.
• Megakaryocytes—2–7 megakaryocytes per spicule; highly variable depending on the technique used to prepare the slide and overall sample yield (e.g., presence of spicules).
• M/E ratio—0.75–2.53 (dogs) and 1.21–2.16 (cats).

ABNORMAL FINDINGS

Values above or below the reference ranges.

CRITICAL VALUES

None

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology
None

Drugs That Alter Physiology
Some drugs have been associated with toxic effects on hematopoietic cells, including diethylstilbestrol, phenylbutazone, chloramphenicol (especially cats), sulfadiazine, methimazole, albendazole, phenobarbital, and griseofulvin.

Disorders That May Alter Results

• Low yield aspirates (e.g., overall poor cellularity or lacking sufficient spicules) may occur with hypocellular marrow, stromal reactions (e.g., myelofibrosis), and neoplasms resulting in myelophthisis (e.g., mesenchymal neoplasms).
• Chronic blood loss anemia may lead to megakaryocytic hyperplasia despite a normal platelet count.

Collection Techniques or Handling That May Alter Results

• Inappropriate collection site (i.e., area of bone not actively involved in hematopoiesis).
• Insufficient number of particles/low yield aspirate.
• Excessive pressure when preparing cytologic slides or delayed collection (>30 minutes) after animal's death may result in lysed cells.
• Delayed processing or exposure of cytology to formalin fumes will alter staining.
• Clotted aspirates will have reduced cellularity and skewed differential cell counts.

Influence of Signalment

Species
• Cats normally lack stainable iron, regardless of their age.
• Subtle variations in differential cell percentages (e.g., cats may have slightly more numerous lymphocytes than dogs).

Breed
None

Age
• Young animals have active hematopoietic tissue throughout long and flat bones. Adult animals exhibit the most active hematopoiesis in their flat bones and the extremities of their long bones. The central area of long bones contains abundant adipose tissue and very little active hematopoietic tissue.
• Older dogs often have abundant stainable iron, whereas younger dogs do not.

Gender
None

Pregnancy
None

LIMITATIONS OF THE TEST

Sensitivity, Specificity, and Positive and Negative Predictive Values

N/A

Valid If Run in a Human Lab?

Yes

CAUSES OF ABNORMAL FINDINGS

See Table 1.

CLINICAL PERSPECTIVE

• Cytologic findings must be interpreted in light of the medical history, clinical findings, CBC, and results from other diagnostic tests and procedures.
• A bone marrow aspirate cannot be adequately interpreted without a concurrent CBC, particularly with regard to assessment of the M/E ratio.

MISCELLANEOUS

ANCILLARY TESTS

• Concurrent CBC (obtained within the last 24 hours).
• Blood film morphologic assessment of circulating blood cells.
• Bone marrow core biopsy sample.
• Immunocytochemistry, immunophenotyping, and cytochemical stains to determine clonality and lineage of abnormal cells identified in marrow, including PARR and flow cytometry.
• FeLV IFA or PCR on bone marrow for occult FeLV infection if peripheral blood ELISA is negative.
• Serology or PCR testing for arthropod-vectored diseases (e.g., *Ehrlichia* spp.).
• Serum protein electrophoresis to assess hyperglobulinemia.

SYNONYMS

None

COMPLETE OPHTHALMOLOGIC EXAM

BASICS

TYPE OF PROCEDURE
Diagnostic examination

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Step-wise assessment of the adnexal and ocular components, their structural and neurological function, and their potential affects on ocular comfort and vision.
- Various diagnostic tests and equipment are used as part of the eye exam, and familiarity with the normal values and ocular anatomy will allow for recognition of early or subtle changes and assist in diagnosis and treatment of discrete ophthalmic conditions.

INDICATIONS
- Indicated as part of a wellness examination or as part of a health screening in breeding animals.
- Iindicated when the patient is presented for ocular discomfort, an abnormal ocular appearance, or changes in vision. As part of diagnostic testing for an unknown illness, an eye exam may reveal ocular manifestations of systemic disease.

CONTRAINDICATIONS
Individual steps of the eye exam may be contraindicated, such as pharmacological mydriasis in a patient with elevated intraocular pressure or tonometry in a patient with a fragile globe (deep corneal ulcer, perforation or laceration).

POTENTIAL COMPLICATIONS
- A complete eye exam is a noninvasive procedure; however, some of the ancillary diagnostic tests require direct contact with the cornea or application of ophthalmic drugs:
  - Risk of drug hypersensitivity to topical anesthetic or mydriatic agents, resulting in conjunctival hyperemia, chemosis, ocular pruritis, blepharospasm, or photophobia.
  - Contact with the cornea while performing tonometry or tear assessment could result in corneal epithelial erosions. While these complications are rare, they can cause ocular discomfort.

CLIENT EDUCATION
- The eye exam is important in determining the cause of ocular discomfort or changes in ocular appearance or vision, and may be a key component in recognition of local or systemic infection, inflammation or neoplasia.
- The need for a referral to a veterinary ophthalmologist for more extensive diagnostic testing, medical therapy, or surgical procedures may be indicated based on the findings.
- Detection of certain ocular abnormalities in breeding animals may suggest inherited conditions, and could affect reproductive decisions.

BODY SYSTEMS ASSESSED
Ocular and neuro-ophthalmic.

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication, Equipment or Supplies (Figure 1)
Prior to the eye exam, the following medications, instrumentation, and accessory diagnostic tools should be available:
- Topical ophthalmic anesthetic, such as proparacaine HCl 0.5% ophthalmic solution.
- Topical ophthalmic mydriatic, such as tropicamide 1% ophthalmic solution.
- Eye wash/eye irrigating solution.
- Schirmer tear test strips.
- Fluorescein stain ophthalmic strips or solution.
- Tonometer (rebound or applanation).
- Ophthalmoscope handle with direct lens attachment, including cobalt blue filter, and a Finoff transilluminator tip.
- Hand-held condensing lens (20D, 28D, 30D or 2.2 pan retinal lenses) for indirect ophthalmoscopy.
- Magnifying loupes, such as OptiVISOR.

Anesthesia or Sedation
Except in the case of an extremely fractious animal, sedation should be avoided. Most sedative agents will lower tear production, in addition to making examination of the eye more difficult due to elevation of the nictitating membrane and ventral rotation of the globe.

Patient Positioning
- Good restraint of the patient is key to a thorough eye exam. Ideally, the patient should be positioned on an exam table in sternal recumbency.
- Special attention to minimal manipulation of the eyelids is important when assessing the eyelid and globe position, and also when obtaining intraocular pressures to avoid falsely elevated readings.

TECHNIQUE
- The complete eye exam, similar to a physical exam, is performed in a step-wise fashion, typically in the same order each time to avoid missing subtle abnormalities.
- The initial part of the exam is performed from a distance and without touching the patient, while later steps require good restraint and minimal movement from the patient.
- A thorough patient medical and ocular history is important to obtaining an accurate diagnosis and appropriate treatment plan:

1. Observation of the patient prior to restraint may allow for detection of behaviors suggestive of visual deficits. Interactions between the pet and objects in the exam room may reveal hesitancy or loss of visual cues in an unfamiliar environment. If visual deficits are suspected, consider additional tests, such as maze testing using obstacles placed in the patient's path or cotton-ball tracking to investigate further. These tests can be done in both room lighting and dim lighting conditions to explore the possibility of decreased night vision or nyctalopia.
2. Once the patient has been adequately restrained, the face and eyes should be assessed for symmetry of adnexal and periocular structures (e.g. muscles of mastication, palpebral fissure size), in addition to globe size and position, and pupil symmetry. The Finoff transilluminator can be held at an arm's length, close to the examiner's eye, and retroillumination using the tapetal reflex will allow for good assessment of pupillary size and symmetry. Palpation of the tissues around the orbit may reveal muscle atrophy, boney proliferation or orbital cellulitis. The globe itself should easily retropulse into the orbit behind closed lids. Retropulsion may be important in helping to distinguish exophthalmia from buphthalmia. An oral exam is indicated for patients with suspected orbital disease.
3. The neuro-ophthalmic exam includes assessment of cranial nerves (CN) II–VII.
   a. The palpebral reflex is performed by gently touching at the temporal and then nasal canthus, and observing the eyelids to close. Incomplete blink may suggest either a decrease in sensation (CN V) or motor function (CN VII) or lagophthalmia, such as is seen in brachycephalic dogs.
   b. The menace response, a crude estimation of vision, assesses CN II and CN VII. This is a learned response present in animals older than 8–12 weeks of age. This test is performed by making a swift "menacing gesture" with a closed hand toward the eye and watching for a blink response ± slight withdrawal of the head. Be careful not create movements of air or brush against hairs around the eye that could stimulate a response that is tactile rather than visual. By covering each eye in turn, a more individual assessment of the contralateral eye can be performed.
   c. The pupillary light reflex (PLR) can be appraised after noting for symmetry in size, shape and position of the pupils (e.g., anisocoria, dyscoria). A bright

COMPLETE OPHTHALMOLOGIC EXAM (CONTINUED)

Figure 1.

From top left: Eye wash irrigating solution, proparacaine HCl 0.5% ophthalmic solution, tropicamide 1% ophthalmic solution, TonoPen Avia® applanation tonometer, TonoVet Plus® rebound tonometer, Volk 2.2 Pan Retinal hand-held condensing lens and case, direct ophthalmoscope head attachment, and ophthalmoscope handle with Finoff transilluminator attachment. Source: Lawrence P. Tilley

light from a Finoff transilluminator should stimulate a direct response (pupil constriction) in the ipsilateral eye and a slightly less robust consensual response in the contralateral eye. The PLR should be assessed for each eye, with notation of both direct and consensual responses. PLRs can be complete, incomplete, delayed, or absent. Any abnormal response may suggest pathology in the retina, optic nerve, or PLR pathway, including CN III or iris sphincter muscles. This test does not assess the visual pathways in the brain.

d. The dazzle reflex is also performed with a bright light directed towards each eye, with a reflexive response of blinking. This test assesses CN II, CN VII and the visual pathways in the brain. Although a positive test does not correlate directly with vision, a negative dazzle reflex does give a poor prognosis for return to vision.

e. The presence of strabismus or nystagmus or lack of ability to move the globe may indicate oculomotor (neurologic or extraocular muscle) deficits and could indicate either central or peripheral nervous system disorders or orbital disease. Mild esotropia and pronounced physiologic nystagmus are common in Siamese cats.

4. The accessory diagnostic tests are performed next.

a. The Schirmer tear test (STT) is a measurement of both basal and reflex tear production. This is performed by placing the notched end of STT strip into the conjunctival fornix in the lateral 2/3 of the lower lid. Care is taken not to handle this portion of the strip to avoid contamination with oil or debris from the examiners' fingers. Placement of a slight bend at the notch through the protective plastic sleeve may help to keep it in position. The strip should remain in the fornix for 60 seconds, removed, and immediately read out. A normal tear production in a dog is approximately 18 ± 3 mm/min. Tests reading below 15 mm/min in combination with clinical signs of keratoconjunctivitis (e.g., mucoid discharge, conjunctival hyperemia, corneal pigmentation or vascularization) may signal quantitative tear film abnormalities (keratoconjunctivitis sicca [KCS]). Normal STT readings with similar clinical signs may indicate a qualitative tear film abnormality.

b. Following the STT, the intraocular pressure (IOP) should be estimated. If an applanation tonometer is to be used, application of topical anesthetic 20–30 seconds prior to testing is necessary. A rebound tonometer does not require topical anesthetic. The examiner should be familiar with the instrument's requirement for calibration, instructions for use, and also understand the measurement confidence interval (CI 85–95%) for each reading. The patient should be gently restrained with minimal pressure on the neck and eyelids to allow for the most accurate readings. Tight muzzles may interfere with normal IOP readings. Most devices require 5-6 contacts with the cornea to calculate an average estimated IOP. Any reading with <95% CI or IOP >20 mmHg should be repeated to ensure accuracy. Consider additional testing if glaucoma is suspected.

c. Following IOP measurement, one drop of fluorescein stain can be applied to look for evidence of corneal epithelial erosions or ulceration. The stain should be gently rinsed with eye wash or saline, and the cornea should be evaluated with the cobalt blue filter of the ophthalmoscope head. Stain uptake will appear

(CONTINUED) COMPLETE OPHTHALMOLOGIC EXAM

bright green in the blue light, and indicates loss of the corneal epithelium. Corneal ulcers should be treated accordingly based on features such as chronicity, depth, and evidence of infection. With any deep corneal ulcer, the eye should be considered fragile and at risk of perforation.

d. If the eye exam is normal to this stage, a drop of tropicamide, an ophthalmic mydriatic agent, may be applied topically to dilate the pupil. Dilation will allow for a comprehensive examination of the lens and fundus. In patients with an elevated IOP, iris pigment changes, iris masses or marked irregularities, suspected lens instability, or PLR abnormalities, a consultation with an ophthalmologist may be recommended prior to dilation.

5. The next step in the eye exam is a survey of the adnexal structures- the eyelids, including the nictitating membrane, conjunctiva, and nasal-lacrimal system. The Finoff transilluminator can be used to examine these structures. Additional magnification in the form of magnifying loupes may be required.

a. The eyelids should be inspected for abnormalities in position or length (e.g. entropion/ectropion, ptosis), irregularities, thickening or discoloration (e.g. lid masses, blepharitis), or aberrant hairs (distichia, ectopic cilia, trichiasis). The eyelid margin should be smooth and in contact with the cornea help to evenly distribute the tear film. The meibomian gland openings should be apparent as gray dots along the lid margin, but should not be inflamed or have excess discharge.

b. The conjunctiva lines the eyelids (palpebral conjunctiva), the globe (bulbar conjunctiva) and nictitating membrane. The conjunctiva, a mucous membrane, should be smooth, pink and moist without excessive discharge. If conjunctivitis is suspected, additional testing can be considered.

c. Examination of the nictitating membrane is enhanced when the globe is gently retropulsed so that this third eyelid will passively elevate. If there is suspicion of foreign material in the eye, the leading edge of the nictitating membrane can be grasped with atraumatic forceps, such as von Graefe forceps, following the application of topical anesthetic. Any swelling or protrusion of the third eyelid, its gland or cartilage should be further investigated.

d. The lacrimal puncta are located near the medial canthus, just inside the eyelid margin of the upper and lower eyelids. The openings should lack discharge. Chronic epiphora or mucopurulent discharge may be suggestive of an obstruction of the nasal lacrimal system or dacryocystitis. A positive Jones test (a drop of fluorescein stain placed on the cornea observed exiting the ipsilateral nares) confirms patency of the nasal–lacrimal system.

6. Examination of the cornea can be performed with the Finoff transilluminator, but magnification using the direct ophthalmoscope is ideal for noting fine details. The corneal surface should be smooth and transparent, with a lustrous tear film, and no evidence of blood vessels, pigment, fibrosis, edema or other opacity. Commonly, tear film abnormalities are the cause of corneal changes in the dog. The STT is important in ruling out dry eye disease. The fluorescein stain test can assess for corneal ulceration. Keratitis, or inflammation of the cornea, is usually represented by vascularization, corneal infiltrate, or pigmentation, and can be ulcerative or non-ulcerative. Various corneal dystrophies, corneal degeneration or other keratopathies may also be present.

7. The anterior chamber should be evaluated for appropriate depth and clarity. The slit beam of the direct ophthalmoscope can be used to look for flare (protein or cellular debris) in the anterior chamber causing the Tyndall effect (scattering of light causing a hazy beam to appear in the normally clear aqueous). The slit beam should be focused on the cornea, and there should be no evidence of light between the cornea and iris face/anterior lens capsule in the normal eye. Any opacity in the anterior chamber should be further assessed, as anterior uveitis is most likely the cause. Strands of vitreous may be seen in the anterior chamber in patients with lens instability.

8. The iris is most easily examined prior to dilation. The direct ophthalmoscope can be used for magnification. The iris face is not completely smooth, and the major arterial circle runs along the periphery, close to the iris base. This is especially apparent in animals with light colored irides. Irregularities in the iris, such as excess pigment or pigment loss, abnormal blood vessels, fine strands of tissue (e.g. persistent pupillary membranes) or iridal masses should be noted prior to pharmacological dilation. The pupil margin should be smooth, although some patients have a slightly darker but normal "pupillary ruff." A moth-eaten or ragged edge to the pupil margin, especially in conjunction with decreased miosis during PLR assessment, may indicate iris atrophy. A patient with uveitis often has a miotic pupil at rest and may have evidence of fine blood vessels on the iris face (rubeosis iridis), in addition to flare in the anterior chamber.

9. The lens should be examined with the pupil dilated to allow for the most comprehensive assessment. The direct ophthalmoscope can be used for magnification to look at fine details in the lens, but the Finhoff transilluminator is good to assess the overall appearance. The lens and lens capsule should be smooth and transparent. Any opacity within the lens that blocks the tapetal reflex is considered a cataract, while nuclear sclerosis is simply the more densely compacted nuclear lens fibers noted in older animals. Nuclear sclerosis does not block the light passing through to the posterior segment or light bouncing off the tapetum during retroillumination, and a fundic exam can be easily performed in a patient with nuclear sclerosis; however, varying degrees of cataract may make the fundic exam more difficult or impossible. Any lens instability should be noted, as lens subluxation or luxation are a risk for development of glaucoma. With early lens instability, an aphakic crescent may be noted, when some of the zonules holding the lens in place are lost, allowing the lens to shift in position. This may appear as a brighter tapetal reflection along the equator of the lens. In a normal patient, the equator, or most peripheral aspect of the lens, should not be visible. Occasionally, vitreous can be seen coming forward into the anterior chamber in the region of the aphakic crescent.

10. The posterior segment exam can be performed with the direct ophthalmoscope, but a more panoramic view of the fundus is best achieved using indirect ophthalmoscopy.

a. First, using the Finoff transilluminator, the region just posterior to the lens should be surveyed for any opacity. Anterior vitreous changes causing opacities include vitreal degeneration (e.g., asteroid hyalosis, syneresis). Other changes in the vitreous could be due to congenital abnormalities, hemorrhage, or intraocular neoplasia.

b. For the best view of the fundus, including retinal blood vessels, tapetum and non-tapetum, and optic disc, a hand-held condensing lens (20D, 28D, 30D or 2.2 pan retinal lens) and Finoff transilluminator are used for indirect ophthalmoscopy. The examiner sits or stands at about one arm's length from the patient while an assistant stabilizes the head and gently retracts the eyelids. The Finoff light source is held close to the examiner's eye, directed at the patient's eye.

COMPLETE OPHTHALMOLOGIC EXAM (CONTINUED)

A bright tapetal reflex will help guide the examiner to the appropriate placement of the lens, about 5–6 cm from the patient's eye. The lens should be moved just slightly either towards the examiner or towards the patient until the fundic image is focused on the lens. The examiner should make slight adjustments with their own head and body rather than moving the light or lens to observe the entire fundus. The image created with this method is upside down and backwards, so the necessary movements to achieve a view of the entire fundus may not be intuitive. The fundus should be surveyed systematically in each quadrant (nasal and temporal tapetum and non-tapetum) and the optic disc should be evaluated for color, shape, loss of detail or changes in depth (e.g. raised or cupped). A raised and hyperemic optic disc may indicate optic neuritis, while a pale or dark and cupped disc may indicate chronic glaucoma. Changes in the position or contour of the retina, such as in retinal detachment or retinal dysplasia should also be noted. Subretinal infiltrates, such as inflammatory cells or blood, may be present with chorioretinitis.

c. The direct ophthalmoscope can also be used to examine the fundus. Although the image acquired is in the correct, upright orientation, the fundus is extremely magnified and may make interpretation of findings more difficult. For the direct fundic exam, the examiner's eye, direct ophthalmoscope, and patient's eye are very close to each other (2–3 cm), which may be dangerous with unruly patients. The direct ophthalmoscope is set to 0 diopters, and the examiner moves in closer to the patient's eye until retinal vessels are in focus. The same four quadrant survey and exam is performed, but this method makes the peripheral fundus more challenging to see than with the more panoramic indirect method.

11. Once the eye exam is completed, all abnormalities should be documented, and the changes correlated with patient history and clinical signs to develop a diagnosis and treatment plan. Visual deficits in the absence of significant ophthalmic abnormalities may be due to conditions such as sudden acquired retinal degeneration syndrome (SARDS), retrobulbar or optic tract neuropathy or optic neuritis, or central vision loss. Consultation with a veterinary ophthalmologist and/or neurologist may be appropriate depending on history and any other clinical signs or behavior changes. Additional diagnostic tests such as CT or MRI may be indicated with suspicion of orbital disease or central lesions. See Table 1 for a selection of abnormal findings and possible differential diagnoses.

APPROPRIATE AFTERCARE

Restrictions on Activity

Although most dogs and cats do not appear apprehensive following the use of mydriatic drugs, dilation of the pupils can lead to photophobia or discomfort in bright light. Additionally, some animals are sensitive to topical anesthetic drugs, such as proparacaine. Effects from these ophthalmic drugs can last up to several hours, so clients should be made aware of the potential for mild blepharospasm or conjunctival hyperemia after a complete eye exam.

INTERPRETATION

NORMAL FINDINGS OR RANGE

- STT ≥15 mm/min.
  - Dogs (normal range 18 ± 3 mm/min).
  - Cats* (normal range 17 ± 6 mm/min).

*Cats can reportedly have a STT as low as 0–5 mm/min due to a sympathetic stress response.

- IOP 8–20 mmHg in dogs and 10–25 mmHg in cats.

Table 1

Selection of abnormal findings and potentential differential diagnoses.

Exam component	*Abnormalities*	*Selection of Possible Diagnoses*
Observation	Vision deficits	Retinal disease, CNS disease (including optic nerve and visual tracts), glaucoma, uveitis, cataract, severe keratitis
Palpation	Decreased ocular retropulsion ± pain	Orbital disease
Neuro-ophthalmic examination	Absent PLR/fixed mydriasis with absent menace response	Retinal disease, optic neuritis, glaucoma
Schirmer tear test	<10–15 mm/min	Keratoconjunctivitis sicca (KCS), dry eye
Fluorescein stain	Positive	Corneal ulceration
Intraocular pressure	>20–25 mmHg (elevated)	Glaucoma (primary or secondary)
	<8 mmHg (decreased)	Anterior uveitis
Adnexal structures (eyelids, nictitating membrane, conjunctiva, nasal lacrimal system)	Swelling, hyperemia, increased ocular discharge	Blepharitis, conjunctivitis, Dacryocystitis Neoplasia
	Protrusion of third eyelid	Prolapsed gland of the third eyelid; neoplasia

(CONTINUED) # COMPLETE OPHTHALMOLOGIC EXAM

CRITICAL VALUES

- STT <10–15 mm/min—likely indicates quantitative tear film disorder (KCS).
- IOP >25 mmHg—likely indicates glaucoma.
- IOP <8 mmHg—may indicate uveitis.
- Positive fluorescein stain uptake, especially in conjunction with clinical signs indicating a corneal ulcer.

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure

- Mydriatic drugs, such as topical atropine or tropicamide, can suppress the PLR of the affected eye(s) and may have long-lasting effects.
- Some topical glaucoma medications, such as latanoprost, can cause extreme miosis, precluding the ability to perform a fundic exam.
- Systemic anesthetic and sedative agents will likely depress the STT results and can also blunt the menace response.

Conditions That May Interfere with Performing the Procedure

- Significant anterior segment changes such as marked corneal opacities or cataracts may prohibit a posterior segment examination.
- Patients that are systemically ill or those that have neurologic abnormalities (e.g., post-ictal changes or CNS disease) may not have a normal menace response or neuro-ophthalmic exam.

Procedure Techniques or Handling That May Alter Results

Improper restraint during IOP measurements may lead to falsely elevated readings. Tight muzzles, or excess pressure on the eyelids or neck can lead to increased intraocular pressure.

CROSSMATCH

BASICS

TYPE OF SPECIMEN
Blood

TEST EXPLANATION AND RELATED PHYSIOLOGY
• Performed to detect serologic incompatibility between a possible blood donor and recipient. In contrast with blood typing, which recognizes antigens on RBC membranes, a crossmatch evaluates plasma for the presence of antibodies.
• A major crossmatch, which is of greatest clinical significance, tests for alloantibodies in patient plasma against donor RBCs. The minor crossmatch looks for alloantibodies in donor's plasma against patient's RBCs. This is of lesser concern because the donor's plasma volume is small, particularly in packed RBC products, and is markedly diluted in recipients.
• A tube crossmatching procedure is most often used, with antibodies indicated by subsequent hemolysis or hemagglutination, but its interpretation is subjective and requires some expertise.
• Gel column technology (DiaMed AG, Cressier sur Morat, Switzerland, and Ortho Clinical Diagnostic, NJ, USA) is a simple, sensitive, and standardized crossmatch method, but accessibility is limited. Gel-based and immunochromatographic in-house crossmatching kits are now available for dogs and cats, which facilitates the procedure and the interpretation of results (DMS Laboratories, Flemington, NJ and Alvedia, Limonest, France).

INDICATIONS
Screening blood donors and recipients to assure blood compatibility

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
None

BODY SYSTEMS ASSESSED
Hemic, lymphatic, and immune.

SAMPLE

SAMPLE COLLECTION
• 1–2 mL of venous blood from donor and recipient.
• A segment from the tubing of the donor blood bag can be used.

SAMPLE HANDLING
• Collect the patient's (and possible donor's) blood into EDTA.
• Stored donor cells are often in citrated phosphate dextrose or citrated phosphate dextrose acetate-1 anticoagulant.

SAMPLE STORAGE
Refrigerate the sample for short-term storage.

SAMPLE STABILITY
• Whole blood in EDTA—crossmatch within 48–72 hours of blood collection.
• Properly preserved donor blood—stable for 4 weeks after collection if stored at 4°C.

PROTOCOL (STANDARD TUBE CROSSMATCH)
1. Centrifuge blood (1000 ×*g* for 5 minutes). Remove the plasma from each sample with a pipette, and transfer the sample to clean, labeled tubes. Note any hemolysis.
2. Wash RBCs 3 times with 0.9% saline—resuspend 0.25 mL of RBCs in 2–4 mL of saline. Centrifuge for 1 minute, remove the supernatant, repeat the procedure twice, and remove the supernatant.
3. Resuspend 0.10–0.25 mL of washed RBCs in ≈4.5 mL 0.9% saline to obtain a 3–5% RBC suspension.
4. For each donor, prepare three tubes labeled major, minor, and recipient autocontrol. Add to each tube 2 drops (50 µL) of plasma and 1 drop (25 µL) of RBC suspension as follows:
    a. Major—recipient plasma + donor RBCs.
    b. Minor—donor plasma + recipient RBCs.
    c. Autocontrol—recipient plasma + recipient RBCs.
5. Mix gently and incubate for 15–20 minutes at 37°C.
6. Centrifuge for 15 seconds.
7. Reading the results—examine the supernatant for hemolysis. Gently resuspend the RBC button by tapping tube and examine for agglutinating clumps. Grade positive hemagglutination reactions as 1+ (fine), 2+ (small), 3+ (large), or 4+ (1 large agglutinate).
8. If macroscopic agglutination is not observed, examine a drop of resuspended RBCs for microscopic agglutination (100× or 400×). This is of questionable importance.
9. A positive reaction in the control tube indicates autoantibodies, which complicate the interpretation of other tubes.

INTERPRETATION

NORMAL FINDINGS OR RANGE
Compatible crossmatch—the absence of hemolysis or hemagglutination.

ABNORMAL FINDINGS
Incompatible crossmatch—the presence of hemolysis or hemagglutination.

CRITICAL VALUES
None

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology
None

Drugs That Alter Physiology
Hydroxyethyl starch solution (hetastarch) can lead to rouleaux, which can be mistaken for agglutination. Rouleaux can be distinguished from true agglutination if RBC clusters disperse with the addition of saline.

Disorders That May Alter Results
Persistent autoagglutination, such as in immune-mediated hemolytic anemia, precludes crossmatching because such samples always appear incompatible.

Collection Techniques or Handling That May Alter Results
Severe hemolysis may preclude crossmatch testing.

Influence of Signalment

Species
• Dogs—first-time transfusions are considered safe without prior crossmatching since dogs do not have clinically significant naturally-occurring alloantibodies. Although mild immunologic incompatibilities have been documented in transfusion-naive dogs (crossmatch weakly incompatible), their clinical importance requires further investigation.
• Cats—both AB-blood typing and crossmatching are recommended in all cats, even with the first transfusion, as 15–19% of cats have naturally occurring antibodies against RBC antigens outside of the AB system, although their clinical importance is unclear.

Breed
• Dogs—previously transfused crossmatch-incompatible Dalmatian, Doberman pinschers and shih tzu are at great risk of Dal-incompatibility (due to an increased frequency of Dal-negative dogs in these breeds).
• Cats—because of the increased prevalence of type B cats in certain breeds (e.g., Abyssinian, Devon Rex, exotic shorthair), A-B incompatibility is more frequently encountered in those breeds.

Age
None

Gender
None

Pregnancy
• Dogs—unlike women, bitches do not become sensitized to RBC antigens, and subsequently produce alloantibodies, during gestation.
• Cats—unknown.

LIMITATIONS OF THE TEST

- A compatible crossmatch does not prevent sensitization or delayed transfusion reactions. It simply indicates that currently there are no significant antibodies against the RBCs.
- Crossmatching provides no information about leukocyte or platelet compatibility and, in some cases, may not be sensitive enough to detect anti-RBC antibodies.

Sensitivity, Specificity, and Positive and Negative Predictive Values

N/A

Valid If Run in a Human Lab?

Yes (excluding direct antiglobulin test).

CLINICAL PERSPECTIVE

Any dogs and cats that have been given a previous transfusion should be crossmatched before they receive additional blood even when the same donor is being used. Alloantibodies can develop within 4 days and may last for many years.

MISCELLANEOUS

ANCILLARY TESTS

Blood typing.

SYNONYMS

CYSTOCENTESIS

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Cystocentesis is the gold standard for sterile collection of urine for urinalysis and urine culture.
- Urinalysis is part of the minimum database when evaluating ill dogs and cats or when performing routine health screens. Urine culture should be performed in animals with clinical signs of lower urinary tract disease (e.g., pollakiuria, dysuria), in animals with active urine sediment, in animals with acute kidney injury, and in animals with diseases known to predispose them to urinary tract infections (e.g., diabetes mellitus, hyperadrenocorticism, renal failure).

INDICATIONS
- Routine collection of urine samples for urinalysis or urine culture.
- Immediate relief of bladder overdistention, and to facilitate bladder catheterization, in animals with urethral obstruction.

CONTRAINDICATIONS
- Coagulopathy.
- Thrombocytopenia.
- Pregnancy or pyometra.
- Suspected or confirmed transitional cell carcinoma.
- Severe and diffuse cutaneous disease of caudal abdomen (e.g., severe pyoderma, pemphigus complex).
- Insufficient volume of urine within the bladder.

POTENTIAL COMPLICATIONS
- Seeding of transitional cell carcinoma tumor cells into the abdomen or along the needle track.
- Transient hematuria (rare).
- Iatrogenic urinary tract infection (very rare).
- Bladder rupture (very rare).
- Aortic laceration (very rare).
- Vasovagal response (very rare).

CLIENT EDUCATION
None

BODY SYSTEMS ASSESSED
Renal/urologic

PROCEDURE

PATIENT PREPARATION

Preprocedure Medication or Preparation
- Typically, none is required. Uncooperative patients may require slight sedation for the procedure.
- In rare cases, where urine is required for urinalysis or culture, but frequent voiding or recent urination has hampered urine collection, a single dose of isotonic fluids can be administered, although this will affect urine specific gravity.

Anesthesia or Sedation
None is needed in most patients. Uncooperative patients may require slight sedation for the procedure. Alpha-2 agonists will increase urine flow and decrease urine specific gravity.

Patient Positioning
- For cystocentesis, the bladder is best palpated and isolated while the patient is in lateral recumbency (dogs and cats) or standing (dogs).
- Blind cystocentesis is performed with the patient in dorsal recumbency.

Patient Monitoring
None

Equipment or Supplies
- A 3- to 12-mL syringe.
- A 22-gauge needle (usually 1–1½ inches).
- 70% alcohol (ethyl or isopropyl) for skin preparation.

TECHNIQUE
- The bladder should be palpated prior to attempting cystocentesis. The bladder is normally present in the caudal abdomen; with increased urine volumes the bladder will move cranially, toward the ventral body wall.
- If the bladder can be palpated and contains enough urine to attempt cystocentesis, the bladder isolation technique should be used. In those dogs where the bladder is not easily palpated, ultrasound guidance or a blind aspiration technique can be attempted. Blind aspiration is more commonly associated with complications and is less likely to be successful.
- Attach the needle to the syringe.

Bladder Isolation Technique
- Restrain the patient in lateral recumbency. In some dogs, the bladder is more easily palpated with the patient standing.
- The individual palpating the bladder should isolate the bladder with one hand.
- Clean or spray the cystocentesis site with 70% alcohol.
- Keeping the bladder isolated, the needle should be inserted into the bladder without applying negative pressure.
- Alternatively, an assistant can attempt cystocentesis by inserting the needle and syringe between the fingers of the person who has isolated the bladder. This allows the bladder to be isolated by using two hands and may be easier in dogs. The individual palpating the bladder should guide the assistant as to how far to insert the needle.
- Once the needle has been inserted to the appropriate depth, the syringe plunger should be slowly drawn back, creating negative pressure. Negative pressure should not be applied until the person performing the procedure believes the bladder has been entered.
- When the desired volume of urine has been collected, negative pressure should be released and the syringe and needle removed.

Ultrasound Guidance Technique
- Restrain the patient in dorsal recumbency and using ultrasound identify the bladder on ventral midline of the caudal abdomen.
- Clean or spray the cystocentesis site with 70% alcohol.
- Insert the needle at an oblique angle to the probe where the bladder is visualized.
- When the needle is seen entering the bladder lumen, the syringe plunger should be slowly drawn back, creating negative pressure.
- When the desired volume of urine has been collected, negative pressure should be released and the syringe and needle removed.

Blind Aspiration Technique
- Restrain the patient in dorsal recumbency with the rear limbs extended.
- Spray 70% alcohol over the caudal ventral abdomen.
- The needle is inserted on midline at the site where alcohol pools. Alternatively, the bladder position can be estimated by determining where lines drawn between the last two sets of nipples theoretically cross (Figure 1). In male dogs, move the prepuce and penis to the side to enable insertion of the needle and syringe on the midline plane. The needle should be directed caudally at an approximately 30–45° angle.
- Once the needle has been inserted to the appropriate depth, the plunger of the syringe should be slowly drawn back, creating negative pressure. If urine is not obtained, remove the needle and re-attempt at a site just cranial or caudal.
- If GI tract content or blood is seen in the needle hub, release the negative pressure and then withdraw the needle and syringe. A fresh needle and syringe should be used if blind cystocentesis is reattempted.
- When the desired volume of urine has been collected, negative pressure should be released and the syringe and needle withdrawn.

Decompressive Cystocentesis for Animals with Urethral Obstruction
- Serially attach the needle to IV extension tubing, a three-way stopcock, and a 20- to 60-mL syringe.
- Restrain the patient in dorsal or lateral recumbency and identify the bladder via palpation or with ultrasound.
- Clean or spray the cystocentesis site with 70% alcohol.

(CONTINUED) CYSTOCENTESIS

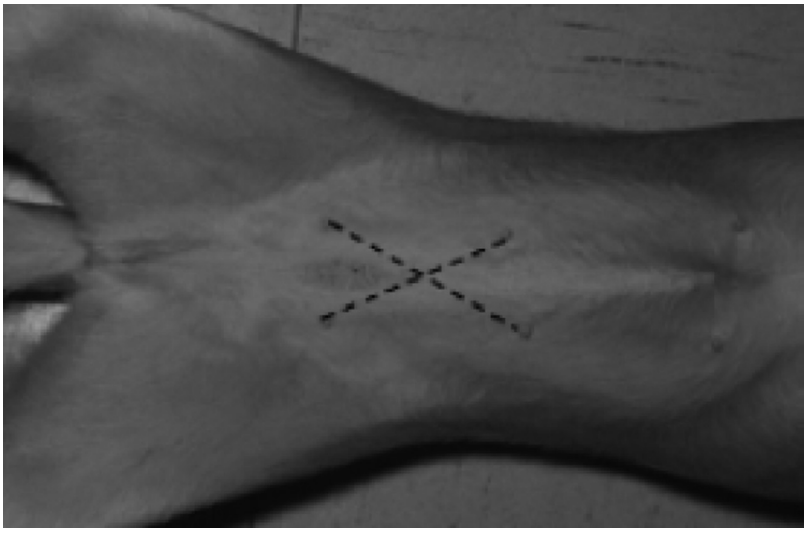

Figure 1.

A female dog in dorsal recumbency, with dotted lines drawn between the last two sets of nipples. In the blind aspiration cystocentesis technique, the needle should be inserted where the lines cross and the needle directed caudally at an approximately 30–45° angle. Source: Lawrence P. Tilley

• Insert the needle into the bladder at a 45° angle.
• Once the needle has been inserted to the appropriate depth, the plunger of the syringe should be slowly drawn back, creating negative pressure. If urine is obtained, continue aspiration to remove the maximal volume of urine possible.
• When the maximal volume of urine has been collected, negative pressure should be released and the needle withdrawn.

SAMPLE HANDLING

• Samples collected for urinalysis should be analyzed immediately, if possible, because refrigeration for later analysis can alter some dipstick and sediment findings.
• Urine samples collected for culture should be refrigerated or placed into bacteriostatic transport containers until plated onto appropriate media. The amount of urine to be submitted varies among diagnostic laboratories, but many microbiologists prefer at least 5 mL because this may increase the likelihood of isolation of infectious agents.

INTERPRETATION

NORMAL FINDINGS OR RANGE
N/A

ABNORMAL VALUES
N/A

CRITICAL VALUES
N/A

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure
• A number of drugs affect urinalysis findings. A thorough medical history is required for proper interpretation of results.
• Antibiotics may inhibit growth of bacteria if urine is submitted for culture.

Conditions That May Interfere with Performing the Procedure
• Cystocentesis may be difficult at times of low bladder urine volume (e.g., immediately after voiding; in pollakiuric patients). Urinary catheterization using sterile technique will allow small amounts of urine to be collected.
• Bladder rupture.

Procedure Techniques or Handling That May Alter Results
• Improper or delayed handling of urine after collection affects urinalysis results.
• Urine samples may be contaminated inadvertently with GI tract content if aspiration is performed prior to the needle entering the bladder. Partially digested food, feces, and bacteria cause a false-positive active urine sediment and positive urine culture.

Influence of Signalment on Performing and Interpreting the Procedure

Species
See Urinalysis Overview (Appendix X) for details regarding interpretation in dogs and cats. Some differences of note include these:
• Cat urine is typically more concentrated than dog urine, although the reference ranges in normal animals overlap significantly.
• Dogs may normally have a small amount of bilirubinuria, whereas bilirubinuria in cats is always a pathologic finding.
• Cats typically have more acidic urine than dogs; however, urine pH is significantly influenced by diet.
• Fat droplets are common in feline urine but rare in canine urine.

Breed
None

Age
• Neonatal puppies (<3 weeks old) have more dilute urine than pediatric or adult dogs.
• Transient proteinuria and glucosuria have been reported in neonatal puppies, although this is not a consistent finding in all studies.

Gender
Male dogs may have higher concentrations of urine bilirubin than female dogs.

CYSTOCENTESIS (CONTINUED)

Pregnancy
None

CLINICAL PERSPECTIVE

Cystocentesis should be considered the standard method for urine collection in all small-animal patients:
- Urine samples collected by catheterization or midstream free catch may be contaminated by microorganisms and inflammatory cells normally found in the distal urethra, prepuce, and vaginal vault. Results of urine sediment examination or culture from urine samples not collected by cystocentesis must be interpreted with caution, and there is a higher risk of artifactual bacterial contamination.
- Comparison of urinalysis findings from cystocentesis and free-catch midstream urine samples may assist in differentiating urethral or genital disease from bladder or upper urinary tract disease.
- Although cystocentesis of animals that may have transitional cell carcinoma of the urinary bladder may seed tumor cells into the abdomen or along the needle track, cystocentesis should still be routinely performed in dogs and cats unless a bladder mass has been confirmed by diagnostic imaging studies.

MISCELLANEOUS

ANCILLARY TESTS

ELECTROCARDIOGRAPHY

BASICS

TYPE OF PROCEDURE

Electrodiagnostic: heart electrical activity measurement

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY

- The electrocardiogram (ECG, EKG; Figure 1) captures the electrical fields generated by the pumping heart. Waveforms are a display of the electrical activity of the heart generated during depolarization and repolarization.
- The leads represent single planes of measurement of the electrical activity of the heart. Each lead has a positive and negative surface electrode setting. If energy is traveling away from the positive electrode, a negative orientation of the wave occurs on the ECG, and if the net direction of the electrical energy impulse is toward the positive electrode, a positive deflection occurs. If the impulses are at perpendicular, an isoelectric deflection occurs. Lead II is the most common lead used for initial evaluation of the ECG.
- The form of the ECG is characterized by deviations from baseline that are linked to specific events in the cardiac cycle (Figure 1):
  - Each cardiac cycle starts with an impulse that originates in the sinoatrial (SA) node, which is located in the right atrium. An impulse will travel through the myocardium of the atria, resulting in depolarization. This event generates the P wave on the tracing. The tracing is recorded when the atrium contracts, not when the original SA node fires, because the latter event is too small to trigger a recordable event.
  - As the impulse moves through the atrioventricular (AV) node, which is near the base of the right atrium, the PR interval is generated.
  - Once through the AV node, the conduction speed increases and the electrical activity fires through the bundle of His, the bundle branches, and the Purkinje system.
  - Rapid, widespread depolarization of the ventricles then occurs. This leads to the QRS complex. Subsequent ventricle contraction then occurs.
  - The Q wave represents the interventricular septum depolarization and thus is the first negative deflection. The Q wave may not always be easy to isolate on tracings.
  - The R portion is the ventricular myocardium depolarizing and the impulse traveling from the endocardium to the epicardium. It is a positive deflection and the most prominent waveform on the ECG.
  - The S wave is the basal ventricle posterior wall and interventricular septum activating. It is the first negative deflection following the R wave.
  - The repolarization of the ventricles is recorded as the T wave.
  - As repolarization occurs, the ST segment is generated.

INDICATIONS

- Diagnosis of cardiac arrhythmias, myocardial ischemia, changes in cardiac environment (e.g., pericardial effusion, pericarditis).
- Patients with the following clinical signs:
  - Tachycardia or bradycardia.
  - Dyspnea, cyanosis, syncope, or seizures.
  - Shock, acute emergency, or severe illness, such as pyometra, gastric dilatation and volvulus syndrome (GDV or bloat), uremia, pancreatitis, and toxic insults.
  - Electrolyte disturbances (especially potassium) or in chronic diuretic administration.
  - Cardiac murmurs.
- Also used in the context of patient monitoring:
  - During anesthesia and in the perioperative period.
  - Routine health monitoring of senior or chronically ill patients where prognosis may be affected by cardiac function.
  - Pharmacologic monitoring for agents with known cardiotoxicity (e.g., quinidine, digitalis, beta-blockers).
- In patients with an abnormal radiographic appearance of the heart or great vessels, in combination with other diagnostics (e.g., echocardiography).
- During diagnostic or therapeutic procedures, (e.g., pericardiocentesis).
- In patients with elevations in vagal tone (e.g., disease in the nervous system, respiratory system, GI system, use of potent opioids).

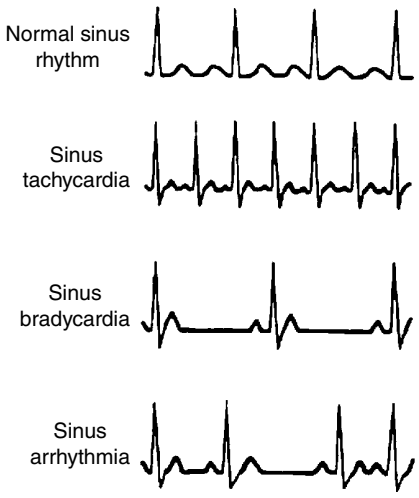

Figure 1.

Common examples of electrocardiograms.

ELECTROCARDIOGRAPHY (CONTINUED)

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
Caution in dyspneic patients.

CLIENT EDUCATION
- Inform clients that this is not a standalone test but interpreted in the context of the patient's medical history, clinical signs, and other database findings.
- Let them know that this is just a snapshot and that repeat ECG and Holter monitoring may be required to understand the problem more fully, especially with paroxysmal tachycardias and with conduction disturbances (e.g., AV block).

BODY SYSTEMS ASSESSED
Cardiovascular

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
- The number of leads measured depends on the equipment.
- Three bipolar leads is minimum, and three additional unipolar leads are usual.
- This type of procedure does require a quiet, calm environment (and animal) in order to optimize results. Distraction during the test may produce spurious results, so care should be taken to let the animal settle in before measurement begins.
- An experienced technician or veterinarian should run the test and, ideally, serial tests should be conducted and interpreted by the same individuals to help maintain consistency.
- Turn off fluorescent bulbs or electrical equipment (especially in older equipment) in the room, do not cross your limbs, and avoid contact with metal surfaces.
- Before recording begins, clips must be effectively placed. The right arm (RA) and left arm (LA) electrodes are best clipped to the proximal olecranon area or even halfway down the radius. The right leg (RL) and left leg (LL) electrodes are clipped over the patella ligament. Before applying a clip, remember to apply conductive gel or 70% isopropyl alcohol. The advantage of the latter is that it does not get gummed up in long hair. For longer term (e.g., intraoperative) monitoring, gel is better because alcohol evaporates too quickly. The precordial chest (V lead) electrode is applied for precordial unipolar chest leads.
- Muscle tremors may produce artifacts. Movements and purring can lead to vibrations along the baseline. A hand placed gently on the animal's chest wall may help to reduce its shivering.
- A wandering baseline is often caused by respiratory cycle movements because contact at the skin–clip interface can be poor. Panting or coughing may also cause the same thing. To resolve this issue, gently hold the muzzle closed for 4 seconds, as long as the patient is not dyspneic.

Anesthesia or Sedation
- Anesthesia is not required, and sedation is rarely required.
- Pediatric patients may require snug restraint to enable testing.

Patient Positioning
- Since reference levels originate from the right lateral recumbent position, that position would be ideal, but, realistically, if a pet is recalcitrant or dyspneic, any position that minimizes tremors, shivering, panting, or struggling will do. As an alternative, standing is preferred to sitting if right lateral recumbency is too stressful.
- Ideally, the forelimbs would be held apart and perpendicular to minimize interference, in amenable patients.
- If indicated, oxygen delivered by mask or flow-by techniques may be provided during the exam.
- For intraoperative monitoring, a patient's position is not critical.

Patient Monitoring
Monitor for sudden dyspnea or cyanosis or other signs that reflect decompensation.

Equipment or Supplies
- ECG equipment is relatively inexpensive and ranges from transtelephonic sets to integrated computer oscillometric recorders that can print and upload to the computerized patient record directly.
- A blanket or soft pad for the table.
- An ECG recording machine. The ECG apparatus should meet the requirements of the Committee on Electrocardiography of the American Heart Association. The amplifier is tied to a strip recorder, either on a computer screen or an oscilloscope, or by a stylus on wax paper. At a minimum, single-channel capture and an oscilloscope should be available. Three-channel equipment enables more detailed capture and analysis by enabling the tester to record three leads simultaneously.
- Contact gel or 70% isopropyl alcohol.
- Clippers if the hair is too thick to provide close clip contact.
- A printer or a computer or transtelephony device, depending on where the results are to be sent or how they are to be recorded.
- Separate the cables so they do not overlap. Usually, this is a set of five wires. Alligator clips are usually used for animals. Plate clips are better for electrical sensitivity but are more easily displaced by struggling animals:
  - The alligator clips, which should be copper, may be filed and bent so they pinch less. With very small animals, placing a plate inside the clip may help maintain the patient's comfort without loss of efficiency.
  - Alternatively, adhesive pads for human use may be applied to the patient for longer term ECG recording. Special clips may be used to attach to the button on the pad, or regular clips may be attached as well.

TECHNIQUE
- Run the standardization marker for sensitivity and increase speed to 50 mm/s before you start to record. If only using the ECG for periprocedural or in hospital monitoring, a speed of 25 mm/s is adequate unless the patient is very tachycardic.
- Switch leads to obtain 4-second segments approximately, with the goal to record a minimum of four good complexes in each lead to fully assess the electrical activity. Repeat as needed to cover available leads for the system.
- Finally, record a long strip of lead II for full rhythm assessment.
- A break will be needed if precordial leads are to be recorded, because the electrodes will need to be repositioned. Turn off the machine, turn it back on, and run the standardization again before recording.
- Turn off the record switch, turn off the machine, and clean the gel from the hair coat after gently removing the clips.
- For transtelephonic ECG, the portable preamplifier converts electrical signals into tones that can be sent over a phone line. Position the animal, attach two electrodes (moistened for good contact) to the forelimbs near the elbow, and then call the transtelephonic service.

SAMPLE HANDLING
- Sensitivity controls how tall the complexes are, with 1 mV being standard. This means 10 small boxes (1 cm) equals 1 mV.
- Change to 2 mV to increase the size of the complexes represented and to 0.5 mV to reduce the height of tall complexes.
- A marker must be done at the start of each strip to record the lead sensitivity. Newer models do this automatically.
- Position the baseline recording in the center of the paper strip for recording.
- Record at least 5–6 complexes for each lead and record a long strip especially if watching for arrhythmias. Check the polarity: If the R waves are not positive in lead I, check the hookup to see if it is still negative, which is abnormal for lead I.
- Placement of the grounding is not critical except that it should be far away as possible.

• If using a rhythm strip to monitor ECG during procedures, the specific lead is unimportant, as long as the observer can identify a P, QRS, and T complex in the tracing (i.e., lead II may be isoelectric following positioning for a surgery such as a forelimb amputation, but lead III may be adequate for rhythm monitoring).

INTERPRETATION

NORMAL FINDINGS OR RANGE

The findings can be divided into heart rate (HR), rhythm, analysis of complexes and intervals, electrical axis, and chest leads. (See an ECG text guide for interpretation details.) Abnormalities in rhythm, complexes and intervals, and waveforms, and disturbances in impulse conduction and mean electrical axis (MEA) can occur. Normal values for ECG analysis are listed in Appendix IV. An extensive review of ECG interpretation is beyond the scope of this chapter (see Suggested Reading), but some general tips to interpret ECG follow.

Heart Rate

• When ECG is run at 25 mm/s, each large box on the paper is equal to 1/5 of a second, and each set of five large boxes (usually indicated by a black mark at the base of the grid) is equivalent to 1 second of ECG.
• The rate is calculated by observing the number of QRS complexes in a 3-second interval.
• Multipy this number by 20 to calculate the beats per minute.
• At 50 mm/s, three sets of large boxes is equivalent to 1.5 seconds and the number of QRS complexes should be multiplied by 40.

Arrhythmia Analysis

See specific arrhythmia chapters for visual examples and therapeutic recommendations.
• First, calculate the rate.
• Note the regularity of the QRS complexes and characterize the rhythm as regular or irregular:
  ◦ Patients that have rhythmic variation due to breathing have a regularly irregular rhythm (i.e, irregular in a predictable way).
  ◦ Animals with atrial fibrillation have an irregularly irregular rhythm, without any discernible pattern.
• Evaluate the tracing for P waves. A P wave should precede every QRS complex:
  ◦ Evaluate the distance between the P wave and each QRS (should be the same).
  ◦ Patients with various AV blocks may not have a reliable P-R interval or P waves in general. Patients with ventricular or junctional arrhythmias will have QRS complexes without associated P waves.
• Verify that there is a QRS complex for every identified P wave. QRS complexes without P waves may originate from the ventricles or AV junction.

CRITICAL VALUES

Related to specific arrhythmias; diagnosis of ventricular tachycardia, ventricular fibrillation, third-degree AV block, sinus arrest (lack of P waves), and asystole require immediate intervention and further diagnostic testing.

INTERFERING FACTORS

• Environmental interference, interpretation error, interpretation without a proper minimum database, or overinterpretation.
• The ECG does not assess the heart itself, just the electrical activity of the myocardium, so an animal with advanced congestive heart failure (CHF) may have a normal ECG, and an animal with cardiac arrest may display normal activity for a period of time after the heart stops beating (the electrical activity is just not translated into muscular contraction).
• Since not all abnormalities are present all of the time, serial studies or Holter monitors may be needed.
• Breed and conformation may affect the tracings and interpretation.

Drugs That May Alter Results of the Procedure

Sedation (e.g., with alpha-2 agonist drugs) may cause artifactual arrhythmias, or mask the presence of others.

Conditions That May Interfere with Performing the Procedure

Electrical interference, stress, dyspnea, or an uncooperative patient.

Procedure Techniques or Handling That May Alter Results

A wandering baseline caused by movement, not adjusting the millivoltage or speed, improper patient position, contact with a metal surface, crossed wires or legs, or electrical interference.

Influence of Signalment on Performing and Interpreting the Procedure

Species
Interpretations of tracings are specific to species.

Breed
Clip placement is affected in deep-chested breeds.

Age
Young dogs.

Gender
None

Pregnancy
None

CLINICAL PERSPECTIVE

The ECG may be used for simple rhythm monitoring, or may provide specific insight into cardiac disease. A thorough understanding of the technique and the causes of the deflections on the final waveforms will completment other diagnostic results. Knowing your equipment, taking care to minimize stress, and developing a proper database of information against which to compare results before making an interpretation are important.

MISCELLANEOUS

ANCILLARY TESTS

FECAL DIRECT SMEAR AND CYTOLOGY

BASICS

TYPE OF SPECIMEN
Feces

TEST EXPLANATION AND RELATED PHYSIOLOGY
- Performed to examine the fecal microbiota and any nucleated cells that are present (epithelial, inflammatory), and to detect other pathogens that may be present (i.e., bacterial, fungal, protozoal, algal, oomycetal).
- Abnormalities detected by fecal cytology are often nonspecific, and may enable diagnosis of the primary cause of GI illness in some cases, although may more frequently represent findings associated with other underlying diseases or processes.
- Direct fecal smear cytology is not synonymous with a rectal scrape, which is a method of sampling the rectal mucosa by direct scraping of its surface with a swab or blunt spatula. Rectal scraping is typically required to identify some deeper infections (e.g., histoplasmosis, protothecosis).

INDICATIONS
- Diarrhea.
- Less commonly, other GI signs (e.g., vomition).

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
- This test may not reveal the primary cause of a patient's GI signs. Instead, abnormalities secondary to other underlying primary or secondary GI disease may be detected.
- Normal direct fecal smear cytology does not definitively exclude the possibility of GI disease, including underlying infection or inflammation.

BODY SYSTEMS ASSESSED
Gastrointestinal

SAMPLE

SAMPLE COLLECTION
Collect feces from the rectum by using a slightly moistened cotton-tipped applicator or use the feces present on one's gloved finger after a digital rectal exam.

SAMPLE HANDLING
- Smear or roll the feces onto a clean, glass microscope slide to form a thin film.
- Prepare a wet preparation by adding a few drops of saline and a coverslip. Do not make the wet preparation too thick; one should be able read newsprint through the wet prep. Adding a drop of iodine to the preparation may improve visualization of protozoa.
- Air-dry the thin film of feces:
  - Stain with a Romanowsky stain (e.g., Diff-Quik; Dade Behring, Newark, DE) for cytologic examination.
  - Use acid-fast stain if looking for *Cryptosporidium* sp.
  - Heat-fix prior to Gram staining.

SAMPLE STORAGE
- Wet preparations should be prepared and immediately examined.
- For other preparations, the sample should be processed within 2 hours or feces should be refrigerated.
- Store air-dried fecal smears at room temperature and protected from light.
- Fecal smear slides should not be refrigerated or frozen.
- Wet preparations should be read immediately and cannot be stored.

SAMPLE STABILITY
- Feces at room temperature: 2 hours.
- Refrigerated feces: variable stability, depending on abnormality of interest. Parasite ova are stable, but cellular deterioration and changes in bacteria flora occur over time.
- Wet preparations cannot be stored.
- Fixed-stain smears are stable indefinitely if protected from light and humidity.

PROTOCOL
- Examine the wet preparation for motile parasites or parasite ova.
- Examine the Romanovsky-stained smear for the following:
  - Background bacterial flora.
  - Noninflammatory cells (e.g., epithelial cells, neoplastic cells).
  - Inflammatory cells.
  - The number of spore-forming bacteria per 1,000× high-power field.
  - The presence of pathogens, such as the following (depending on geographic location):
    - Short spiral or gullwing-shaped bacteria (e.g., *Campylobacter*, *Helicobacter*, *Anaerobiospirillum*, treponeme-like bacteria, *Serpulina* spp.)
    - Protozoa (e.g., *Giardia*, *Tritrichomonas*, *Entamoeba*).
    - Dimorphic fungi (e.g., *Histoplasma*).
    - Other fungi (e.g., *Cryptococcus*, *Candida*, *Aspergillus*).
    - Algae (e.g., *Prototheca*).
    - Oomycetes (e.g., *Pythium*).

INTERPRETATION

NORMAL FINDINGS OR RANGE
- A polymorphic bacterial population of bacilli. Cocci should be absent or very rarely observed.
- A low number of well-differentiated epithelial cells.
- Amorphous material, representing digesta.
- A small amount of plant material.
- A small amount of extracellular yeast (e.g., *Cyniclomyces*; formerly known as *Saccharomycopsis*).

ABNORMAL FINDINGS
- Monomorphic bacterial microbiota.
- An increased number of cocci.
- The presence of inflammatory cells.
- The presence of abnormal noninflammatory cells (e.g., reactive epithelial cells, neoplastic cells).
- The presence of potential pathogens (e.g., protozoa, fungi, algae, oomycetes, gullwing-shaped bacteria).
- The presence of >10 spore-forming bacteria per 1,000× high-power field.
- Specifically, sporulated *Clostridium* has a safety-pin or tennis racket appearance because the spore produces an oval, colorless area.

CRITICAL VALUES
None

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology
None

Drugs That Alter Physiology
Prior antimicrobial administration may alter the GI microbiota, resulting in abnormal direct fecal smear cytologic results.

Disorders That May Alter Results
Prior GI procedures (e.g., surgery, enema) may alter GI flora, resulting in abnormal direct fecal smear cytologic results.

Collection Techniques or Handling that May Alter Results
Deeper scraping of the rectal mucosa will increase the number of epithelial cells observed in direct fecal smear cytology. Deeper scraping may be helpful when certain infections (e.g., histoplasmosis, protothecosis) are suspected.

Influence of Signalment

Species
None

Breed
None

Age
None

Gender
None

Pregnancy
None

LIMITATIONS OF TEST

Sensitivity, Specificity, and Positive and Negative Predictive Values
None

(CONTINUED) # FECAL DIRECT SMEAR AND CYTOLOGY

Table 1

Causes of abnormal findings.

Preparation	*Abnormal Finding*	*Possible Causes*
Wet preparation	Motile protozoa	*Giardia, Balantidium, Entamoeba, Tritrichomonas* trophozoites
	Parasite larvae	*Strongyloides, Aelurostrongylus, Filaroides*, saprophytic larvae caused by environmental contamination
	Parasite eggs	Coccidia (*Cystoisospora* spp.), *Toxocara, Trichuris, Ancylostoma, Uncinaria*
Romanowsky stain	Monomorphic population of bacteria	Bacterial overgrowth caused by primary or secondary GI disease or antibiotic treatment
	Sporulated bacteria	*Clostridium* overgrowth
	Short spiral or gullwing-shaped bacteria	*Campylobacter, Helicobacter, Anaerobiospirillum*
	White (colorless) rods in macrophages and free in background	*Mycobacterium*
	Neutrophils	Nonspecific sign of GI inflammation or suggests the presence of transmural colonic or rectal inflammation
	Eosinophils	Allergic hypersensitivity or parasitic infection
	Small lymphocytes, plasma cells	Lymphocytic, plasmacytic enteritis
	Monomorphic large lymphocytes	Lymphoma
	Teardrop-shaped protozoan organisms with 2 nuclei that "appear to be looking back at you"	*Giardia*
	Spindle-shaped protozoa with whiplike flagella and an undulating or wavy membrane	*Tritrichomonas*
	Ciliated protozoan with a large sausage-shaped macronucleus that surrounds a small micronucleus	*Balantidium*
	Round intracellular yeast (within macrophages), 3–5 μm diameter	*Histoplasma*
	Septate branching hyphae	*Aspergillus*, other fungus, or *Pythium*
	Round or oval algae with basophilic granular cytoplasm (3 × 16 μm)	*Prototheca*
Acid-fast stain	4–5 μm round magenta structures	*Cryptosporidia* sp.
	Intracellular magenta linear inclusions	*Mycobacterium*

Valid If Run in a Human Lab?
Yes, if the observer (i.e., pathologist or technician) is acquainted with veterinary species.

CAUSES OF ABNORMAL FINDINGS
See Table 1.

CLINICAL PERSPECTIVE
- Abnormal background bacterial microbiota is often an incidental finding associated with other primary or secondary GI diseases, with GI procedures, or with prior antimicrobial administration. In some cases, though, abnormal microbiota may be a factor contributing to diarrhea.
- Observation of inflammatory cells suggests the presence of transmural colonic or rectal inflammation. Fecal culture may be useful to exclude underlying infection by invasive bacteria (e.g., salmonellosis).
- Identification of atypical noninflammatory cells, such as abnormal epithelial cells, may indicate the presence of neoplasia or hyperplasia.
- The primary cause of diarrhea may be determined when pathogens (e.g., bacterial, protozoal, fungal, algal, oomycetal) or an increased number of spore-forming bacteria are observed.

MISCELLANEOUS

ANCILLARY TESTS
- Fecal culture and determination of antibiotic sensitivities are useful when inflammatory cells or pathogens are observed.
- Gram stain of the direct fecal smear is useful in evaluating the microbiota and potential bacterial pathogens.
- Warthin–Starry silver stain of the direct fecal smear is useful in evaluating potential bacterial pathogens (e.g., *Lawsonia*).
- Submission of direct fecal smear to a referral laboratory for cytologic evaluation is useful when abnormal noninflammatory cells (e.g., atypical epithelial cells) or when potential pathogens are observed.
- Other tests employed as part of routine GI diagnostic evaluation may include serum biochemistry, fecal flotation, fecal pathogen PCR, and radiography.

SYNONYMS
Fecal cytology

FECAL FLOTATION

BASICS

TYPE OF SPECIMEN
Feces

TEST EXPLANATION AND RELATED PHYSIOLOGY
- Designed to recover diagnostic stages of parasites that are shed in feces (e.g., eggs, oocysts, and cysts).
- Based on specific gravity (SG) of flotation solution.
- Parasite eggs, oocysts, and cysts will float in solutions of a higher SG than the parasitic life stage. The SG of most parasite eggs is between 1.05 and 1.23. Therefore, for parasite eggs to float, the SG of the flotation solution must be greater than that of the eggs.
- Flotation solutions are made by adding a measured amount of salt or sugar to water to produce a solution with the desired SG. Solutions may be made from scratch or bought premixed.
- Common flotation solutions include sugar (Sheather's solution; SG, 1.2–1.33), sodium nitrate ($NaNO_3$; SG, 1.2–1.3), and zinc sulfate ($ZnSO_4$; SG, 1.18–1.2).
- Most parasitology diagnostic and research laboratories routinely use Sheather's solution, which will float most common parasite eggs.
- Many commercially available kits supply sodium nitrate.
- Zinc sulfate is considered the gold standard for flotation of *Giardia* cysts.
- Sodium nitrate solution is widely used for fecal egg counts of large and production animals, and might an option for mixed practices.
- The SG of a flotation solution should be verified with a hydrometer and then checked on a routine basis (e.g., monthly) to detect SG changes caused by evaporation. If the SG is too high, it may rupture eggs, oocysts, or cysts.

INDICATIONS
- Routine health screening.
- Digestive upsets; vomiting and/or diarrhea.
- Respiratory signs such as chronic coughing or sneezing.

CONTRAINDICATIONS
None, other than insufficient fecal output.

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
- Because pets can have normal stools and still be infected with intestinal parasites, it is good medicine to perform routine fecal exams on all pets. The absence of diarrhea or visible worms in dog feces does not mean that the animal is not infected.
- Negative fecal flotation does not completely exclude the possibility of gastrointestinal or respiratory parasites. For example, tapeworm segments (or proglottids) may be seen in the feces, and the flotation may be negative for several reasons: eggs were not released from the segment, the SG of the solution used was not high enough to float the heavy taeniid-type eggs (i.e., *Taenia* and *Echinococcus*), or perhaps owners mistook grains of rice or fly larvae for tapeworm segments.
- All dogs and cats should receive regular heartworm preventives based on macrocyclic lactone drugs; however, these products may not treat or prevent infection by some intestinal worms or other parasites such as tapeworms, flukes, *Coccidia*, or *Giardia*.

BODY SYSTEMS ASSESSED
- Gastrointestinal.
- Respiratory.

SAMPLE

SAMPLE COLLECTION
Minimum of 1 g, ideally 2–3 g of fresh feces.

SAMPLE HANDLING
- Place the sample in an airtight container (e.g., screw-top jar, ziplock bag).
- Every sample must be appropriately labeled.
- The sample is best analyzed on the day of collection.
- If not possible, keep it cooled or refrigerated until processing, avoid freezing.

SAMPLE STORAGE
Refrigeration

SAMPLE STABILITY
The stability of organisms and life stages varies; e.g., *Giardia* cysts are very fragile and delicate, whereas ascarid eggs are very hardy.

EQUIPMENT
- Scale able to weigh up to 5 g.
- Light microscope with objectives of 10× and 40× magnification.
- Benchtop centrifuge (swinging-bucket or fixed-angle).

PROTOCOL
Fecal flotation with centrifugation has been shown to be the most accurate way to recover parasite diagnostic life stages and consistently recovers more of these stages than standing flotation methods (also known as simple flotation):

1. Weigh out 1–3 g of feces.
2. Mix feces with ≈15 mL of flotation solution in a cup until homogeneous.
3. Pour the mixture through a tea strainer into another fecal cup.
4. Pour the strained solution into a 15 mL centrifuge tube.
5. If you have a centrifuge with swing buckets, fill the tube with flotation solution until forming a slight positive meniscus. Do not overfill tube. Doing so will cause some floating diagnostic stages to be forced down the side of tube when the coverslip is placed.
6. Place a coverslip on the tube and put the tube in the centrifuge.

Note: Steps 5 and 6 are done only if the centrifuge has a swinging-bucket rotor (swing head). If the centrifuge has a fixed-angle head (fixed head), the tube is spun without being filled completely. After centrifuging, the tube is moved to a test-tube rack and filled with flotation solution until a slight positive meniscus forms. A coverslip is then placed on the tube, and the tube is allowed to stand for an additional 10 min before the coverslip is removed and examined.

7. Centrifuge at 1,200 RPM (280 ×*g*) for 5 minutes.
8. Allow centrifuge to stop without using the brake, as it may interfere with the flotation of the parasite diagnostic stages.
9. Remove the tube and let it stand for 5–10 minutes. (*Note*: 10 minutes would allow more parasite diagnostic stages, if present, to float.).
10. Remove the coverslip and place on a glass slide.
11. Systematically examine the entire area under the coverslip by using the 10× objective lens (100× magnification). The 40× objective lens can be used to confirm the diagnosis and make measurements; however, with practice, most identification can be made at 100× magnification.

INTERPRETATION

NORMAL FINDINGS OR RANGE
No parasitic eggs, oocysts, or cysts seen (or "no parasites seen)."

ABNORMAL FINDINGS
Parasitic eggs, oocysts, or cysts seen (or report of specific parasite genera/species seen).

CRITICAL VALUES
None

INTERFERING FACTORS
Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology
None

Drugs That Alter Physiology
None

Table 1

Common parasites of dogs and cats found in feces.

Parasite	*Life Stage*	*Location of Mature Life Stage*	*How Infection Happens*
Common parasites of dogs with stage of life cycle found in feces			
Toxocara canis	Large, dark, thick-shelled egg	Small intestine	*In utero* or ingestion of infected paratenic hosts or infective larvated eggs or nursing (milk)
Toxascaris leonina	Large, light, thick-shelled egg	Small intestine	Ingestion of infected paratenic hosts or infective larvated eggs
Physaloptera spp.	Thick-shelled, larvated egg	Stomach	Ingestion of infected intermediate hosts (e.g., insects) or paratenic hosts (e.g., frogs, mice)
Taenia spp.	Small egg, with hooks	Small intestine	Ingestion of metacestode stage in intermediate hosts (e.g., rabbits)
Dipylidium caninum	Egg packet	Small intestine	Ingestion of metacestode stage in intermediate hosts (fleas)
Ancylostoma caninum	Strongyle-type egg	Small intestine	Ingestion of L_3 from environment, nursing (milk), or skin penetration by L_3
Uncinaria stenocephala	Strongyle-type egg	Small intestine	Ingestion of L_3 from environment or rarely skin penetration by L_3
Eucoleus boehmi (formerly known as *Capillaria boehmi*)	Bioperculated egg	Nasal passages	Ingestion of larvated egg or infected intermediate host
Trichuris vulpis	Bioperculated egg	Cecum, large intestine	Ingestion of larvated egg
Eucoleus aerophilus (formerly known as *Capillaria aerophila*)	Bioperculated egg	Lungs	Ingestion of larvated egg or infected intermediate host
Strongyloides stercoralis	Larvae	Small intestine	Ingestion or skin penetration by L_3
Cystoisospora spp. (formerly known as *Isospora* sp.)	Oocyst	Small intestine	Ingestion of sporulated oocysts, or cysts in intermediate host
Giardia sp.	Cyst	Small intestine	Ingestion of cysts
Alaria sp.	Egg	Stomach, small intestine	Ingestion of mesocercaria in fish, frogs, or rodents
Common parasites of cats with diagnostic life stage found in feces			
Toxocara cati	Large, dark, thick-shelled egg	Small intestine	Ingestion of infected paratenic hosts or infective larvated eggs
Toxascaris leonina	Large, light, thick-shelled egg	Small intestine	Ingestion of infected paratenic hosts or infective larvated eggs
Physaloptera spp.	Thick-shelled, larvated egg	Stomach	Ingestion of infected intermediate hosts (e.g., insects, arthropods) or paratenic hosts (e.g., frogs, mice)
Taenia spp.	Egg	Small intestine	Ingestion of metacestode stage in intermediate hosts (e.g., rodents)
Dipylidium caninum	Egg packet	Small intestine	Ingestion of metacestode stage in intermediate hosts (fleas)
Ancylostoma tubaeforme	Strongyle-type egg	Small intestine	Ingestion of L_3 from environment, or skin penetration
Eucoleus aerophilus (formerly known as *Capillaria aerophila*)	Bioperculated eggs	Lungs	Ingestion of infective larvated egg or infected intermediate host
Cystoisospora spp. (formerly known as *Isospora* sp.)	Oocyst	Small intestine	Ingestion of sporulated oocysts, or cysts in intermediate host
Toxoplasma gondii	Oocyst	Small intestine	Ingestion of sporulated oocysts, tachyzoites, or bradyzoites in mice or other meat
Giardia sp.	Cyst	Small intestine	Ingestion of cysts
Aelurostrongylus abstrusus	Larvae (L_1)	Lungs	Ingestion of intermediate hosts (snails or slugs) or paratenic hosts (mice and birds)
Spirometra sp.	Egg	Small intestine	Ingestion of plerocercoid in intermediate host (reptile, mammals)
Alaria sp.	Egg	Stomach, small intestine	Ingestion of mesocercaria in fish, frogs, or rodents

Demodex, *Cheyletiella*, and *Otodectes* sp. mites may be seen in fecal flotations. *Echinococcus* sp. eggs are similar to *Taenia* sp.

FECAL FLOTATION (CONTINUED)

Disorders That May Alter Results
None

Collection Techniques or Handling That May Alter Results
- Insufficient sample size.
- Old samples: the presence of free-living nematodes and protozoa.

Influence of Signalment
Species
None

Breed
None

Age
Puppies and kittens should be checked for internal parasites and medicated according to the recommendations of the American Association of Veterinary Parasitologists, American Animal Hospital Association, and the Companion Animal Parasite Council.

Gender
None

Pregnancy
None

LIMITATIONS OF TEST
- Sample size can be an issue in anorexic or very small animals with minimal fecal output.
- Some eggs (*Trichuris vulpis*) and cysts (*Giardia* sp.) are shed in low numbers or intermittently. If suspicion is high, fecal flotation should be run on samples from 3 consecutive days.

Sensitivity, Specificity, and Positive and Negative Predictive Values
Note that centrifugal flotation is more sensitive and accurate than passive flotation.

Valid If Run in a Human Lab?
No. Few technicians are trained in the identification of animal parasite diagnostic life stages.

CAUSES OF ABNORMAL FINDINGS (SEE TABLE 1)
- Spurious eggs and oocysts of parasites of other animals may be passed in feces of dogs and cats when these fed on live animals or carcasses, or animal feces (e.g., oocysts of *Eimeria*, a coccidian of birds, rodents, and herbivores).
- Pseudoparasites are common findings in fecal flotations, and should not be mistaken with parasite diagnostic stages. In fact, pseudoparasites are structures of free-living organisms that may pass in feces or are product of environmental contamination (e.g., pollen grains, plant hair, mite eggs, grain mites).

CLINICAL PERSPECTIVE
- A good-quality microscope with a micrometer is required. A micrometer makes it possible to measure objects seen under the microscope, thus ensuring the accurate diagnosis of parasites.
- *Giardia* cysts are often mistaken for yeast, but *Giardia* cysts are all about the same size, whereas yeasts vary greatly in size and shape.
- Proper techniques are imperative for the accurate diagnosis of intestinal parasites.
- Due to coprophagy, strongyle-type eggs from horses or cows, or coccidia oocysts from ruminants, rabbits, or birds, may be found in canine feces. To determine whether these eggs are just passing through, confine the dog away from these animals for 24–48 hours and recheck.

MISCELLANEOUS

ANCILLARY TESTS
- Fecal sedimentation techniques to look for trematode (fluke) eggs.
- Baermann technique to look for larvae of lungworms (note that some worms that are found in the respiratory tract may shed eggs that can be seen in flotation, see Table 1).
- In animals with diarrhea, consider evaluating fecal cytology, cobalamin, folate, and trypsin-like immunoreactivity.

SYNONYMS
Fecal float.

FINE-NEEDLE ASPIRATION

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- For acquisition of samples of masses, lymph nodes, organ cellularity for the purposes of cytologic examination.
- Cytology may identify inflammatory and infectious processes and distinguish between neoplastic and nonneoplastic conditions.
- Poorly prepared smears can make interpretation difficult. Extremely thick smears, for example, can limit evaluation of individual cell characteristics.

INDICATIONS
- Evaluation of cutaneous, subcutaneous, intracavitary masses.
- Evaluation of lymphadenopathy.
- Evaluation of nodules, masses, or other changes within organs.

CONTRAINDICATIONS
- Fine-needle aspiration (FNA) is difficult to perform on very small masses or those that cannot be stabilized.
- FNA entails a risk of hemorrhage when used to assess cavitary masses.
- Patients with a condition that includes severe bleeding tendencies (e.g., thrombocytopenia or coagulopathy).

POTENTIAL COMPLICATIONS
- Bleeding, bruising.
- Release of bioactive substances (e.g., mast cell tumor).
- Potential spread of malignant neoplasia (rare).
- Pneumothorax (FNA of lungs).

CLIENT EDUCATION
While risks are minimal when FNA cytology of internal organs or masses is performed, clients should be advised of the potential for hemorrhage or pneumothorax in the case of lung aspiration.

BODY SYSTEMS ASSESSED
All

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
- None needed for external palpable masses.
- The use of an aseptic skin preparation is indicated prior to FNA of internal masses.

Anesthesia or Sedation
- Generally, none is needed for external palpable masses or lymph nodes.
- Mild to heavy sedation is beneficial for obtaining diagnostic ultrasound-guided or bone FNA.

Patient Positioning
Any that enables optimal access to the site being aspirated.

Patient Monitoring
For minor bruising or bleeding at the FNA site.

Equipment or Supplies
- A needle of appropriate gauge—a 22-gauge, 1-inch needle is appropriate for most cutaneous and subcutaneous masses. Longer needles may be used for intracavitary or ultrasound-guided aspirates.
- A 6- or 12-mL syringe.
- Glass microscopic slides.

TECHNIQUE

Sample Collection

Needle Only

The mass or tissue is stabilized as much as possible while the needle is inserted into it and vigorously moved in and out of it in several directions. The needle is then withdrawn, a syringe filled with air is attached to the needle hub, and pressure is applied to the plunger to empty the needle's contents onto a glass slide. If blood or liquid is observed in the hub of the needle during this procedure, the FNA should be discontinued and the slide prepared.

Needle and Syringe with Continuous Negative Pressure

The mass or tissue is stabilized as much as possible, and the needle with attached empty syringe is inserted into the mass or tissue. Negative pressure is then applied to the syringe and maintained while the needle is redirected several times within the mass or tissue. Negative pressure is then released, and the needle with attached syringe is withdrawn. The syringe is detached from the needle, filled with air, reattached to the hub of the needle, and pressure is applied to the plunger to empty the needle's contents onto a glass slide. If blood or liquid is observed in the hub of the needle during this procedure, the FNA should be discontinued and the slide prepared.

Needle and Syringe with Repeated Negative Pressure

The mass or tissue is stabilized as much as possible while the needle with attached empty syringe is inserted into the mass or tissue. Negative pressure is applied to the syringe and released several times. The needle can be redirected and negative pressure again applied and released several times. This can be repeated in several directions within the mass or tissue. Once the sample has been collected, negative pressure is released, and the needle with attached syringe is withdrawn. The syringe is detached from the needle, filled with air, reattached, and pressure is applied to the plunger to empty the needle's contents onto a glass slide. If blood or liquid is observed in the hub of the needle during this procedure, the FNA should be discontinued and the slide prepared.

Slide Preparation

Flat Spreader Slide Technique

A second slide is laid gently atop and perpendicular to the slide containing the sample and gently drawn down the length of the sample slide to achieve an even, thin layer of cells.

Angled Spreader Slide Technique

A second slide is positioned over the slide containing the sample and angled at 45° with the sample located in the small angle created between the two slides. The spreader slide is then drawn along the sample slide so that the cells are spread in an even layer down the latter slide's length. This technique, similar to that used for making a blood smear, may result in the rupture or breakage of cells from FNA.

SAMPLE HANDLING
- Air-dried samples can be stored at room temperature.
- Samples should be fixed and stained as soon after collection as possible (ideally within 3–7 days) for optimal assessment of cellular morphology.
- Once fixed and stained, FNA smears are stable for months to years, depending on storage conditions.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring
Generally, no post-procedure monitoring is required, although if FNA is performed on highly vascular internal masses or tissues, monitoring for evidence of hemorrhage (i.e., mucous membrane color, attitude, with or without PCV and total solids) should be performed in the hours after the procedure.

Nursing Care
None

Dietary Modification
None

Medication Requirements
None

Restrictions on Activity
None

Anticipated Recovery Time

FINE-NEEDLE ASPIRATION (CONTINUED)

INTERPRETATION

NORMAL FINDINGS OR RANGE
A bullet-shaped tissue smear that extends approximately one-half to two-thirds the length of the slide.

ABNORMAL VALUES
- Abnormal cell ratios, numbers, or types.
- The presence of infectious agents.
- The presence of neoplastic cells.
- The presence of abnormal inflammation.

CRITICAL VALUES
None

INTERFERING FACTORS
Drugs That May Alter Results of the Procedure
None

Conditions That May Interfere with Performing the Procedure
None

Procedure Techniques or Handling That May Alter Results
- Hemorrhage with numerous RBCs evident cytologically may limit interpretation.
- Failure to fix and stain slides within 1–2 weeks may alter cellular characteristics and limit value of interpretation.

Influence of Signalment on Performing and Interpreting the Procedure
Species
None

Breed
None

Age
None

Gender
None

Pregnancy
None

CLINICAL PERSPECTIVE
Cytologic examination of FNA samples is a first step in assessing masses, lymphadenopathy, and other organ changes. Examination of prepared slides can provide information on potential pathology affecting the tissue sampled, including hyperplastic, reactive, inflammatory, and neoplastic changes. Depending on results, a follow-up incisional or excisional biopsy may be indicated for definitive diagnosis.

MISCELLANEOUS

ANCILLARY TESTS
- A biopsy with a histopathologic diagnosis to confirm the FNA results if they are equivocal or if the biopsy is indicated for definitive diagnosis and grading.
- Coagulation testing if there is a concern for hemorrhage during the procedure.

SYNONYMS
Fine-needle aspiration biopsy.

SEE ALSO
- Blood Smear Preparation (in Appendix X).
- Impression Smear (in Appendix X).
- Ultrasound-Guided Mass or Organ Aspiration (in Appendix X).

ABBREVIATIONS
- FNA = fine-needle aspiration.

FLUID ANALYSIS

BASICS

TYPE OF SPECIMEN
Tissue

TEST EXPLANATION AND RELATED PHYSIOLOGY
The abdominal and thoracic cavities normally contain a small amount of fluid that is an ultrafiltrate of blood which serves to provide lubrication that enables frictionless movement of adjacent organ surfaces and the body cavity walls. An increased amount of fluid in any body cavity lined by mesothelial cells is termed an effusion. An effusion is not a disease itself but, rather, the result of a pathologic alteration in the process of fluid production and/or removal, or an accumulation from an ectopic source.

A comprehensive fluid analysis is a rapid, simple, inexpensive, and reasonably safe way of gaining useful information regarding disease processes that cause effusions. Classification schemes are designed to help clinicians generate a short list of differential diagnoses and characterize an effusion based on the primary underlying pathophysiologic mechanism.

Effusions are classified as a pure transudate, modified transudate, exudate, hemorrhagic effusion, or neoplastic effusion (see Table 1). Exudates are further divided into subcategories of septic or nonseptic exudates. The classification of these fluids is based on three parameters: total protein, nucleated cell counts (NCCs), and cytologic appearance.

Pure transudates usually form via a passive process resulting from decreased colloid osmotic pressure (vs. an alteration in capillary permeability). They most frequently form as a result of hypoproteinemia from either increased loss or decreased production of albumin (the primary contributor to plasma colloid osmotic pressure). Infrequently, transudates precede modified transudates before developing an increased NCC or protein concentration.

A modified transudate occurs when vascular fluids leak from normal, noninflamed vessels (e.g., via increased capillary hydrostatic pressure or lymphatic obstruction). This fluid is modified by the addition of protein or cells (compared to a pure transudate). A chylous effusion is a specialized type of modified transudate that results from leakage of noninflamed lymphatics into the thoracic and/or abdominal cavity.

Exudates are the result of increased vascular permeability and inflammation and are further classified as septic or nonseptic (sterile) depending on whether infectious agents are present in the fluid. Nonseptic exudates may result from conditions that cause longstanding modified transudates, as well as from other, more inflammatory disease conditions. Hemorrhagic effusions can be caused by ruptured vessels or organs.

Neoplasia is a common underlying cause of effusions in dogs and cats although neoplastic cells may not be identified on cytologic preparations (i.e., neoplastic cells may not exfoliate into the effusion). Furthermore, neoplasia may cause various effusions, including modified transudates, exudates, and hemorrhagic effusions. The term neoplastic effusion is reserved for fluids in which a neoplastic cell population is definitively identified. However, this determination is frequently difficult because neoplastic cells are absent or are present in low numbers, and reactive mesothelial cells often have cytologic criteria that mimic malignancy.

INDICATIONS
- Accumulation of fluid because of an unknown cause.
- Suspicion of neoplasia or sepsis.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
During acquisition of fluid (see Thoracocentesis and Fluid Analysis, Pericardiocentesis, and Abdominocentesis and Fluid Analysis):
- Hemorrhage.
- Infection.
- Trauma to surrounding viscera (i.e., perforation, laceration).

CLIENT EDUCATION
Sampling of cavitary effusions typically is minimally invasive with minimal associated risk and discomfort for the animal, and may have therapeutic benefits (e.g., pericardiocentesis).

BODY SYSTEMS ASSESSED
- Cardiovascular.
- Gastrointestinal.
- Hemic/lymphatic/immune.
- Hepatobiliary.
- Renal/urologic.

SAMPLE

SAMPLE COLLECTION
2–6 mL of fluid.

SAMPLE HANDLING
- Collect the sample into EDTA-containing tube to prevent clotting and to optimize preservation of cells.
- Place an aliquot into a sterile tube without EDTA if bacteriologic culture is anticipated (EDTA is bacteriostatic) or if biochemical testing is required.
- Prepare smears immediately if the sample will not be processed within 1–2 hours after collection.
- Transport the fluid sample chilled, with any accompanying slides at room temperature.

SAMPLE STORAGE
- Refrigerate fluid.
- Stores slides at room temperature, away from light or humidity.

SAMPLE STABILITY
- Fluid.
- Room temperature: 2–4 hours.
- Refrigerated (4°C): 24–36 hours.
- Unstained smears of fluid can be stored for 1 week or more. Stained slides can be stored for months to years.

PROTOCOL
In-house fluid analysis:
- Note the gross appearance of fluid including color and clarity.
- Prepare smears of fluid by using the same technique used to make blood smears. Smears should be thin enough to dry quickly. Be sure that the smear has a stainable feathered edge.
- Air-dry smears and stain with a Romanovsky-type cytology stain.
- Perform a NCC via hematology analyzer or hemocytometer.
- Centrifuge an aliquot of fluid and note the appearance of the supernatant.
- Determine the total protein of supernatant via refractometer.
- If the NCC is <3,000/µL, prepare additional smears of sedimented cellular material, using either a centrifuge (with resuspension of the pellet) or a cytospin device.

INTERPRETATION

NORMAL FINDINGS OR RANGE
No excess free fluid should be found in the pleural cavity, peritoneal cavity, and pericardium.

ABNORMAL FINDINGS
The presence of an abnormal, increased amount of fluid within a body cavity

CRITICAL VALUES
Evidence of septic peritonitis, uroabdomen, or bile peritonitis requires immediate intervention.

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology
None

FLUID ANALYSIS (CONTINUED)

Table 1

Classification of effusions.

Classification	*Gross Appearance*	*Protein (g/dL)*	*Cells/μL*	*Cell Types Present*
Pure transudate	Colorless; clear	<2.5	<1,500	Mixed (macrophages, nondegenerate neutrophils, mesothelial cells)
Modified transudate	White to red; variable turbidity	2.5–5.0	1,000–7,000	Mixed (nondegenerate neutrophils, macrophages, mesothelial cells, small lymphocytes)
Chylous effusion[a]	Milky white, tan, or pink	2.5–5.0	1,000–7,000	Predominantly small lymphocytes
Exudate[b]	Amber, white, or red; turbid or cloudy	>3.0	>7,000	Predominantly neutrophils
Hemorrhagic effusion[c]	Pink or red; cloudy or opaque	Variable	Variable	Similar to peripheral blood but lacks platelets and may have erythrophagia
Neoplastic effusion	Variable	Variable	Variable	Neoplastic cells present

[a] Chylous effusions have a triglyceride concentration of >100 mg/dL and a fluid cholesterol/triglyceride ratio of <1.0.

[b] Further classification of exudates depends on whether microorganisms are present (i.e., septic versus nonseptic).

[c] The PCV of fluid is ≥10–25% of the PCV of peripheral blood.

Drugs That Alter Physiology

- Corticosteroids may artifactually decrease the percentage and total number of neutrophils.
- Antibiotic administration greatly hinders the cytologic identification of bacteria, and can result in false-negative culture results. In patients that have received antibiotics that develop exudates characterized by degenerate neutrophils, a septic effusion should be a primary differential, even in the absence of intracellular microorganisms.

Disorders That May Alter Results

- High triglyceride concentration in chylous effusions, or other causes of turbidity, may artificially increase protein determination by refractometry. If possible, clear such samples prior to determining protein concentration by refractometer.
- The dilutional effect of urine in uroperitoneum may decrease the protein concentration and NCC.
- Peracute hemorrhagic effusions may not have detectable erythrophagocytosis.
- The protein concentration in an effusion can be affected by serum protein concentration (e.g., mildly increased with dehydration; decreased with protein-losing enteropathies or nephropathies) regardless of the effusion mechanism.

Collection Techniques or Handling That May Alter Results

- Excessive pressure when preparing cytologic preparations (e.g., direct or sediment smears) may lyse cells.
- Delayed processing may lead to *in vitro* artifacts such as erythrophagocytosis, lysed cells, and/or poor cellular preservation. Bacterial overgrowth may occur if a preservative is not used or the specimen is not refrigerated.

Influence of Signalment

Species
None

Breed
None

Age
None

Gender
None

Pregnancy
None

LIMITATIONS OF TEST

Sensitivity, Specificity, and Positive and Negative Predictive Values

N/A

Valid If Run in Human Lab?

Yes.

Causes of Abnormal Values

CLINICAL PERSPECTIVE

- Turbidity caused by lipids (e.g., chylous effusion) will not clear with centrifugation, unlike the turbidity caused by an increased NCC.
- Inadvertent venipuncture or aspiration of the spleen is possible at time of collection. True hemorrhagic effusions should have the same color and turbidity throughout the draw, whereas with accidental venipuncture and splenic aspirate samples usually change color and turbidity during collection. Splenic aspirates may also clot, while effusion generally will not, unless peracute.
- Lipid can be an irritant and chronic chylous effusions may have a mixed inflammatory cell population, including neutrophils (which may ultimately predominate) and macrophages, in addition to lymphocytes.
- If intracellular infectious agents are identified, the effusion is septic, regardless of protein concentration and NCC.
- If fluid collected by abdominocentesis has low cellularity, abundant mixed bacteria, ingesta, and/or intestinal parasite ova, consider accidental enterocentesis or acute intestinal perforation.
- The distinction between reactive mesothelial cells and a true neoplastic cell population (carcinoma or mesothelioma) is often difficult to impossible with cytology alone, since reactive mesothelial cells may exhibit significant atypia mimicking malignancy. Correlation with observation of a "mass effect" on imaging may assist in making this distinction, but additional diagnostics are often needed, such as cytopathologic/histopathologic evaluation of any masses.

MISCELLANEOUS

ANCILLARY TESTS

- Albumin.
- Creatinine (fluid)—a value of ≥2-fold serum creatinine and ≥1.4 fold serum potassium is diagnostic for uroperitoneum.
- Total bilirubin (fluid)—a value of ≥2-fold serum bilirubin is diagnostic for bile peritonitis. Bile crystals are frequently observed cytologically, as well.
- Triglycerides (fluid; for diagnosis of chylothorax)—greater than serum triglycerides
- Glucose (fluid)—a value of 38 mg/dL less than that for blood glucose has been suggested to be specific for sepsis, but low glucose may simply reflect the concurrent elevated NCC and subsequent utilization by leukocytes, and samples may be analyzer dependent.
- Microbial culture and sensitivity

Table 2

Causes of abnormal values.

Type of Effusion and Mechanisms	*Possible Causes*
Pure transudate	Decreased production of albumin
Decreased plasma colloidal osmotic pressure (i.e., hypoalbuminemia)—more common	Liver failure
	Maldigestion/malabsorption
Early cardiac disease or portal hypertension	Starvation
	Increased loss of albumin
	Protein-losing nephropathy
	Protein-losing enteropathy
	Other
	Iatrogenic overhydration
Modified transudate	Cardiac disease
Increased capillary hydrostatic pressure	Portal hypertension
Lymphatic obstruction	Neoplasia
	Acute organ torsion
Chylous effusion	Cardiac disease
Leakage of lymphatics from noninflamed vessels	Hernia
	Neoplasia
	Trauma
	Idiopathic
	Lung torsion
	Intestinal lymphangiectasia
	Mediastinal granuloma
Exudate	Uroperitoneum
Increased vascular permeability and inflammation caused by septic and nonseptic etiologies	Bile peritonitis
	Feline infectious peritonitis
	Inflammation and/or infection of internal organs
	Foreign bodies
	Neoplasia
Eosinophilic effusion	Neoplasia (e.g., mast cell tumor, lymphoma, carcinoma)
Eosinophils >10% of the NCC	Infection (e.g., fungus, parasite, protozoa)
Secretion of IL- 5 by sensitized T-lymphocytes, mast cells, or neoplastic cells	Other eosinophilic inflammatory process such as eosinophilic gastritis
Hemorrhagic effusion	Traumatic injury
Ruptured vessels	Rodenticide toxicity
Coagulopathies	Neoplasia
Neoplastic effusion	Lymphoma and other "round" cell tumors
Exfoliation of identifiable neoplastic cells into fluid	Carcinoma
	Mesothelioma
	Sarcoma (often poorly exfoliative)

SYNONYMS

Body cavity effusion

Consulting Editor Benjamin M. Brainard

GLUCOSE CURVE

BASICS

TYPE OF SPECIMEN
Whole blood.

TEST EXPLANATION AND RELATED PHYSIOLOGY
- A method of evaluating glucose control in diabetic dogs or cats.
- Serial blood glucose (BG) measurement enables assessment of the effect of food and medication (insulin or oral hypoglycemic drugs) on glucose control. The dose, and, if necessary, the type, of medication (e.g., intermediate-acting vs. long-acting insulin) can be altered, depending on results.
- The lowest (nadir) and highest BG concentrations should be noted, as well as the duration of action of insulin (the number of hours the glucose is in a desired range, provided the nadir is acceptable).
  - Hypoglycemia (a BG concentration of <60 mg/dL) or a rapid drop in glucose concentration can result in rebound hyperglycemia or the Somogyi phenomenon, whereby counterregulatory hormones, notably glucagon, epinephrine, and corticosteroids, cause a variable period of hyperglycemia after hypoglycemia occurs.
    - The occurrence of the Somogyi phenomenon is debatable and some internists prefer the term posthypoglycemic hyperglycemia or glucose variability because the link between hypoglycemia and hyperglycemia is uncertain.
- There is significant variation in BG curves from day to day even with no change in insulin dose or feeding. A curve should always be interpreted in conjunction with information on the patient's appetite, thirst, urinations and energy level.
- Control of clinical signs rather than glucose concentration is the overall goal with diabetic patients.

INDICATIONS
- To regulate a new diabetic patient.
- To investigate a poorly controlled diabetic patient.
- To diagnose transient diabetes mellitus, a temporary or permanent resolution of diabetes in cats.

CONTRAINDICATIONS
- Inappetence or illness on the day of the test.
- Hypoglycemia (a BG concentration of <60 mg/dL) on admission: In this case, cancel the BG curve analysis and recommend a 10–25% insulin-dose reduction.
- Stress hyperglycemia—if a patient, especially a cat, is very anxious, the curve may be meaningless. If glucose readings in an extremely stressed patient are normal, insulin overdosage may be suspected.

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
- The goal for diabetic management is to maintain daily BG concentrations between 100 and 300 mg/dL with an average glucose <250 mg/dL. Measurements outside that range may require a dose adjustment, an alternative insulin type, or further investigation or monitoring.
- Owners can monitor glucose at home by using lancets to obtain a small drop of blood from the marginal ear vein, metacarpal pad, foot pad, ventral medial pinna, buccal mucosa of a lip (dogs), or elbow calluses (dogs).
  - Warming the site first with a dry (to avoid diluting sample) warm cloth will improve sample size.
  - Glucose should be measured by using portable veterinary-specific glucometers that use the least amount of blood, such as the AlphaTRAK 2 (Zoetis, Parsippany, NJ).
  - Glucometers designed for human usage measure lower than the actual reading, which may result in falsely low BG readings.
- Owners need to be instructed carefully in the home use of glucometers and informed about calibration and coding of the devices according to the manufacturer's directions.
- Newer long-term interstital devices (e.g., freestyle Libre, Abbott, N. Chicago, IL) may allow generation of BG curve data at home, over longer periods of time (e.g., 14 days), using smartphone-based technology.

BODY SYSTEMS ASSESSED
Endocrine and metabolic.

SAMPLE

SAMPLE COLLECTION
- Generally, a very small amount of blood (<0.2 mL) is obtained by venipuncture, using an insulin syringe or pricking the skin with a lancet:
  - The goal is to be minimally invasive while enabling multiple sequential sample collections.
- When using a lancet, the glucometer with test strip inserted is held to the drop of blood, which is then drawn up by capillary action.
- For in-hospital curves a glucometer is typically used but if a larger amount of blood is obtained, glucose can be measured with a point of care machine, although the same machine should be used for analyzing all samples in the curve.

SAMPLE HANDLING
The sample should be analyzed immediately.

SAMPLE STORAGE
Immediate analysis is recommended.

SAMPLE STABILITY
If measuring serum glucose, the blood sample should be separated quickly to avoid spurious hypoglycemia.

PROTOCOL
- The patient is admitted to the hospital shortly after being fed and given insulin at home.
- The owner's feeding schedule should be followed for the remainder of the day.
- Appetite and stress level are noted during the day.
- BG concentration is measured every 2 hours for 10–12 hours. Collect blood from any easily accessible peripheral vein or pricking skin with lancet, using minimal restraint to avoid stress hyperglycemia.
- Measure glucose by using a portable glucose meter or a point-of-care analyzer.
- Note the BG nadir, duration of effect (number of hours BG concentration between 60–300 mg/dL), and highest BG concentration.
- BG curves are typically repeated 7–14 days following an insulin dose change. New diabetic patients may require 3–4 curves to determine an insulin dose that controls clinical signs. Cats going into remission also require multiple curves while they are tapered off insulin.

INTERPRETATION

NORMAL FINDINGS OR RANGE
- Dogs and cats—the ideal BG concentration range is 80–300 mg/dL with an average BG <250 mg/dL and a nadir of 80–150 mg/dL.
- Normal or below-normal BG concentration readings in cats with diabetes mellitus suggest transient diabetes, especially if normal findings are repeatable with dose reduction or discontinuation of insulin administration.

ABNORMAL FINDINGS
BG concentrations above or below ideal range require evaluation.

CRITICAL VALUES
- A BG concentration <60 mg/dL requires evaluation to ensure patient is not exhibiting clinical signs such as twitching, stumbling, or mental dullness (may need to treat with IV glucose or oral glucose if patient is able to eat). Recheck BG hourly until normal, consider potential insulin dose adjustment to avoid subsequent hypoglycemic events.

(CONTINUED) GLUCOSE CURVE

Table 1

Interpretation of curve.

Abnormal Finding	*Suggested Response*
Nadir and peak BG concentration are greater than the ideal	Increase the dose of insulin
The nadir is acceptable, but the effect of insulin was of insufficient duration	Switch to a longer acting insulin: Dogs: Switch from NPH (neutral protamine Hagedorn) insulin to lente insulin or insulin detemir Cats: If not already on a long acting insulin, switch to insulin glargine or insulin detemir
Hypoglycemia	Decrease the dose by 10–25% and, in cats, consider transient diabetes mellitus
Persistent hyperglycemia may be caused by insulin overdose (post hypoglycemic hyperglycemia) insulin underdose, or insulin resistance).	Consider increasing insulin dose, switching insulin type and if the insulin dose is >1.5 U/kg bid, evaluate for causes of the insulin resistance

• A persistently high BG concentration (>600 mg/dL) may be associated with hyperglycemic hyperosmolar syndrome.

INTERFERING FACTORS

• Glucometers are not designed to measure glucose in serum or plasma.
• Inaccurate readings can also occur with anemia, polycythemia, inadequate sample size, expired glucose strips, miscoded meters, contamination (e.g., sugar on skin of pet or human).
• A correction formula for the Alpha-TRAK 2 has been developed to account for variation in patient PCV:

Corrected glucose = glucose reading + ([1.6 × PCV(%)] − 81.3) (dogs)

Corrected glucose = glucose reading + ([1.17 × PCV(%)] − 50.2) (cats)

Drugs That May Alter Results or Interpretation

Drugs That Interfere with Test Methodology
None

Drugs That Alter Physiology
The administration of drugs such as corticosteroids and megestrol acetate cause insulin resistance that predisposes patients to diabetes or worsening glucose control.

Disorders That May Alter Results

Any underlying disease can make diabetes more difficult to regulate: especially hyperadrenocorticism, infection, pancreatitis, acromegaly, or thyroid disease, as well as diestrus.

Collection Techniques or Handling That May Alter Results

• Stress hyperglycemia in cats and, to a lesser degree, in dogs may inappropriately increase the BG concentration.
• Failure to separate serum promptly may falsely lower the BG concentration when the assay relies on serum sample.
• Sugary food on skin of patient or person obtaining blood sample may falsely increase glucose concentration.

Influence of Signalment

Species
None

Breed
None

Age
None

Gender
Intact females with diabetes are very difficult to regulate and should be spayed.

Pregnancy
The same as for gender.

LIMITATIONS OF TEST

• There is significant variation in BG curves from day to day even with no change in insulin dose or feeding. A curve should always be interpreted in conjunction with information on the patient's appetite, thirst, urinations and energy level.
• Control of clinical signs rather than glucose levels is the overall goal with diabetic patients.
• Handheld portable glucometers may overestimate or underestimate glucose levels when compared to reference methods. Veterinary-specific glucometers are more accurate and validated for dogs and cats, and strongly recommended.

Sensitivity, Specificity, and Positive and Negative Predictive Values

N/A

Valid If Run in a Human Lab?

Yes.

CAUSES OF ABNORMAL FINDINGS

See Table 1.

CLINICAL PERSPECTIVE

• BG curves are only one indicator of diabetic control, and results can vary from day to day, even when there is little change in the patient's status. Therefore, the results should be interpreted with the animal's clinical signs (e.g., presence of PU/PD, polyphagia, weight loss, neuropathy). If the patient appears well (no PU/PD, stable weight, active), then changes made may be small or the curve might be repeated.
• Other reasons for persistent hyperglycemia (BG concentrations >300 mg/dL) are mishandling of insulin, poor injection technique, inadequate absorption, and insulin resistance (e.g., infection, drugs, hyperadrenocorticism, diestrus, acromegaly, hypothyroidism, hyperthyroidism.
• It is important that portable glucometers be coded correctly and that the test strips are correct and in date.

MISCELLANEOUS

ANCILLARY TESTS

• Serial urine glucose testing can enable veterinarians to make some dose increases in new diabetic patients before fine-tuning with a BG curve.
• Measurement of serum fructosamine concentration can be used in addition to analysis of BG curves and, in fractious animals, may replace the analysis of a BG curve. If fructosamine is normal to low-normal in hypoglycemic patients, it supports insulin overdose and, in cats, potential remission.
• Continuous glucose monitoring using interstitial (subcutaneous) sensors (e.g., CGMS System Gold; Medtronic MiniMed,

GLUCOSE CURVE (CONTINUED)

Minneapolis, MN) enables continuous interstitial fluid glucose concentration to be measured for up to 14 days. The newer Libre Freestyle Flash glucose monitoring system is cost effective, easy to use, is accurate in diabetic dogs, and is being evaluated for use in diabetic cats.

IMPRESSION SMEAR

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection.

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Impression smears obtained from superficial lesions or from tissue biopsy samples may reveal cellular details not visible after collection and processing for histologic evaluation.
- Individual cell types, including infectious organisms and neoplastic cells, may be identified on impression smear cytology, which provides more rapid assessment than histologic examination.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
None

BODY SYSTEMS ASSESSED
All

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
None

Anesthesia or Sedation
None

Patient Positioning
None

Patient Monitoring
None

Equipment or Supplies
- A paper towel for blotting.
- A scalpel blade.
- Glass slides.

TECHNIQUE
Impression smears may be made directly from superficial ulcerated lesions or from harvested biopsy tissue.
- Directly from a lesion: An imprint is made by touching the center of a clean glass slide to the uncleaned lesion. After an initial impression smear, the lesion can be gently blotted and cleaned with saline solution and gauze and a second impression made.
- For a harvested biopsy tissue: A freshly cut surface is exposed by sectioning the tissue biopsy sample with a scalpel blade (this is not required if the sample being evaluated is freshly removed via needle or punch biopsy). An important aspect of obtaining diagnostic impression smears is blotting the tissue on a clean absorbent material, such as a paper towel, to remove excess blood, moisture, and tissue fluid prior to imprinting the tissue on a slide. The blotted tissue can be gently touched onto the middle of a clean glass slide and lifted off. Multiple impression smears may be made onto separate glass slides.

SAMPLE HANDLING
- Air-dried samples can be stored at room temperature.
- Samples should be fixed and stained as soon after collection as possible (ideally within 3–7 days) for optimal assessment of cellular morphology.

INTERPRETATION

NORMAL FINDINGS OR RANGE
- A blot of tissue centered on the glass slide.
- Identification of cells normally seen in sampled tissue.

ABNORMAL FINDINGS
- Abnormal ratios, numbers, or types of cells present.
- Infectious agents.
- Neoplastic cells.

CRITICAL VALUES
None

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure
None

Conditions That May Interfere with Performing the Procedure
None

Procedure Techniques or Handling That May Alter Results
- Failure to blot the sample adequately prior to making an impression smear may obscure evaluation.
- Failure to fix and stain slides within 3–7 days may alter cellular characteristics and limit the value of the interpretation.

Influence of Signalment on Performing and Interpreting the Procedure

Species
None

Breed
None

Age
None

Gender
None

Pregnancy
None

CLINICAL PERSPECTIVE
- Impression smears are simple to make and may reveal cellular details not visible following collection and processing for histologic evaluation.
- Even if submitting biopsy samples for histopathology, impression smear evaluation can give valuble clues to the origin of disease so that treatment may be started while waiting for histopahologic results.

MISCELLANEOUS

ANCILLARY TESTS
- Fine-needle aspiration and cytology.
- Biopsy with histopathologic evaluation.

SYNONYMS
- Touch prep.
- Touch prep cytology.

PERICARDIOCENTESIS

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection.

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Diagnostic and therapeutic procedure undertaken to relieve cardiac compression caused by pericardial effusion (PE):
  - PE may be neoplastic, idiopathic, traumatic, infectious, inflammatory, hemorrhagic, or metabolic in origin, or may result from late-stage congestive heart failure (CHF).
  - Chronic PE has gradual onset of clinical signs (weakness, ascites, pleural effusion) and a globoid cardiac silhouette radiographically.
  - Acute PE causes rapid onset of clinical signs (collapse, shock, sudden death).
- Cardiac tamponade is hemodynamic instability (cardiogenic shock) resulting from PE:
  - Occurs when effusion elevates intrapericardial pressure, exceeding right-sided diastolic intracardiac pressures.
  - Observed echocardiographically as partial collapse of the right heart in diastole.
  - Characterized clinically by shock (collapse, hypotension, tachycardia); necessitates emergency pericardiocentesis (PC).
  - Tamponade causes one ventricle to fill at the expense of the other, creating pulsus paradoxus, a decrease in peripheral pulse pressure on inspiration.
  - Intrapericardial pressure, not the effusion volume per se, determines clinical and hemodynamic severity.
- Medical therapies (e.g., diuretics) are relatively contraindicated (an exception is PE secondary to CHF), and PC is necessary to stabilize the patient.

INDICATIONS
- PE producing clinical signs of cardiac tamponade.
- Diagnostic sample acquisition.

CONTRAINDICATIONS
- An insufficient volume of PE such that the risk of PC outweighs potential benefit.
- Relative contraindications include PE secondary to coagulopathy or endocardial splitting where relief of pericardial pressure may perpetuate hemorrhage.
- Not indicated for distention of the pericardium by solid tumors or abdominal contents.

POTENTIAL COMPLICATIONS
- Minimize complications by careful preparation and technique.
- Puncture of cardiac chambers or great vessels.
- Ventricular arrhythmias.
- Coronary laceration causing myocardial ischemia or infarction.
- Exsanguination (more likely to occur from failure to confirm the correct catheter position resulting in evacuation of blood from a ventricular chamber, rather than from cardiac laceration).
- Death.
- Pulmonary laceration or hemorrhage.
- Pneumothorax.
- Failure to relieve cardiac tamponade or obtain a diagnostic PE sample.
- Infection.
- Constrictive or effusive-constrictive pericardial disease (late complication).

CLIENT EDUCATION
- Clients should be informed of potential risks and complications of the procedure.
- The cause of the PE may not be known at the time of PC. Hemangiosarcoma is a common cause with a poor long-term prognosis.
- PC may exacerbate hemorrhage of tumors and may worsen tamponade or precipitate cardiopulmonary arrest.
- Effusions may recur in the near or far future. Recurrences are cause dependent and difficult to predict.

BODY SYSTEMS ASSESSED
Cardiovascular

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
- Rapid IV fluid administration is indicated to treat hypovolemic shock (from hemorrhage or third space fluid losses due to right-sided heart failure), and this should be administered during preparation for PC. The more debilitated the patient is, the greater is the need for the procedure.
- An IV catheter facilitates fluid resuscitation, sedation, and treatment of ventricular arrhythmias.
- Echocardiographic diagnosis of small cardiac tumors may be facilitated by the presence of PE. Ultrasound examination of the heart should precede PC if patient is stable.

Anesthesia or Sedation
- The more debilitated the patient is, the lesser the need for sedation.
- The author prefers IV sedation with butorphanol (0.2 mg/kg). Avoid agents promoting hypotension (e.g., acepromazine).

Patient Positioning
Left lateral recumbency is preferred to facilitate directing of catheter toward the right ventral caudal aspect of the heart. Some localized PE may not accessible from this approach. With ultrasound guidance, sternal recumbency may allow an appropriate window.

Patient Monitoring
- ECG monitoring (for ventricular arrhythmias) by a designated assistant during the procedure.
- Once the first sample of PE is removed, it should be observed for coagulation; if the sample clots, the catheter is likely in the heart, rather than pericardial sac.

Equipment or Supplies (see Figure 1)
- A large-bore, over-the-needle catheter is typically used: 18–14 gauge, 2–5½ inches, depending on patient size.
- Small (3–6 mL) and large (10–50 mL) syringes.
- Three-way stopcock.
- Extension tubing.
- Collection: bowl, tubes for cytological evaluation (EDTA) and culture submission.
- No. 11 surgical blade.
- Sterile surgical gloves (see Figure 1).
- 2% Lidocaine for local anesthesia and for treatment of ventricular arrhythmias:
  - Calculate dose of lidocaine for antiarrhythmic therapy (2 mg/kg IV).

TECHNIQUE
- Default catheter entry location is at 5th–7th intercostal space of right ventral thorax, at the level of costal-chondral junction.
  - The hair is clipped, and the suitability of the site is confirmed using ultrasound.
- The site is aseptically prepared, and can be infiltrated deeply with lidocaine (0.5–3.0 mL, not to exceed 2 mg/kg).
- A no. 11 blade is used to create a small stab incision through skin at site of catheter entry.
- Catheter entry should be near the center of the rib space, erring toward the cranial aspect of the rib:
  - The catheter should intersect the pericardium at the right ventral aspect, so catheter is advanced dorsally and cranially (i.e., toward the opposite scapula) (see Figure 2).
  - Prior to insertion, the operator can attach a sterile 3-mL syringe to the catheter stylet.
    - Once catheter tip is through skin, a small amount of suction is applied to the syringe; this ensures that PE will be aspirated as soon as the stylet tip penetrates the pericardium.
  - ECG is monitored closely during catheter advancement. A burst of ventricular premature complexes suggests that the stylet tip has contacted the epicardium. The catheter should be retracted until arrhythmia abates.

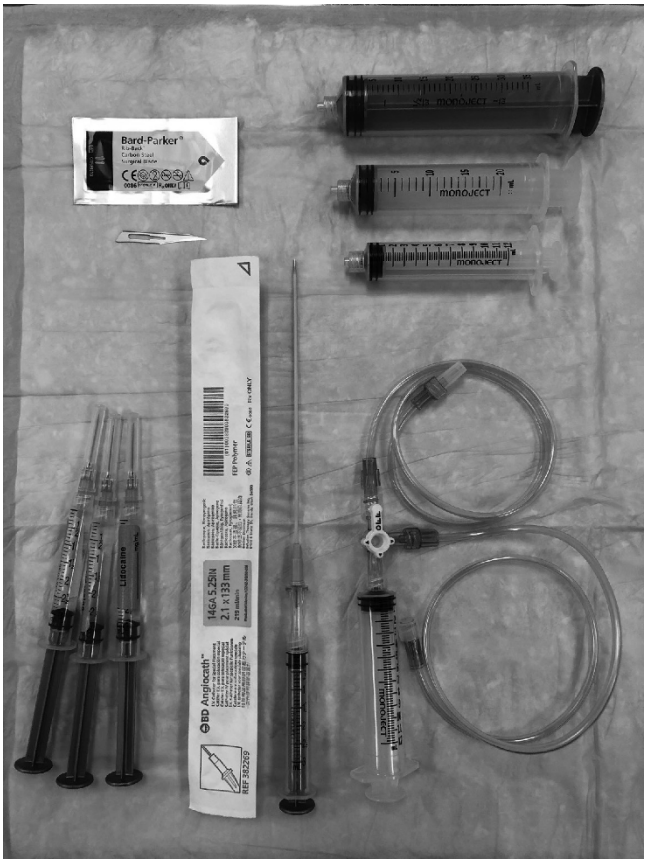

Figure 1.

Instrumentation used for PC. A no. 11 blade is ideal for creating a small stab incision into the skin at the entry site. A 14-gauge, 5.25-inch catheter and stylus are shown with a small syringe attached; i.e., configured to advance into the pericardial space. Extension tubing, three-way stopcock, and syringes for aspiration are shown. The sharp metal stylus is removed after the catheter is fully positioned, and the catheter is attached to the extension tubing. Three prepared and labeled doses of 2% lidocaine for IV bolus (2 mg/kg = 1 mL/10 kg) are shown.

- Contact of the catheter tip with pericardium may impart a scratchy sensation, which may alarm inexperienced operators.
- There may be a sensation of popping through the pericardium with the catheter.

• When PE is aspirated or observed in the hub of the stylet, the stylet is advanced a short distance (2–4 mm) further, after which the nondominant hand advances the flexible catheter off the stylet into pericardial space:
- A distended pericardium may shrink substantially during procedure, which will cause the catheter tip to exit the pericardial space if it is not advanced sufficiently or too short.

• Once the stylet is withdrawn, extension tubing is attached directly to catheter hub, leading to a large syringe and interposed three-way stopcock operated by an assistant.

• Aliquots from this initial syringe of PE should be placed into an EDTA tube for cytologic analysis, a tube without additive or culturette for culture, and a tube without additive to assess for clotting of the sample (to verify the catheter is not intracardiac).
• Verifying appropriate placement of catheter.
- Monitor sample for coagulation; most effusions (unless peracute) will be defibrinated, and will not clot, while a sample from ventricular lumen will clot.
- A small amount of presumptive PE (e.g., 5–20 mL) can be removed while heart rate is observed. With tamponade, even a small decompression of the pericardial space can demonstrably decrease heart rate. A continual decrease in heart rate throughout the procedure is suggestive of correct catheter placement, whereas increasing heart rates should prompt operator to suspend aspiration and reevaluate catheter position.
- The effusion PCV may be determined; it should be different from the peripheral blood, and supernatant is often xanthochromic.

• Once catheter positioning within the pericardium is confirmed, PE can be evacuated rapidly using the three-way stopcock to alternately aspirate and expel PE into a collecting bowl.
• The pericardial space should be evacuated as completely as possible (exceptions are atrial tears and bleeding disorder).
• Other considerations:
- At any time during the procedure, significant ventricular arrhythmias should prompt catheter repositioning (usually partial withdrawal) and consideration of treatment with lidocaine (2 mg/kg IV) if arrhythmia does not abate promptly.
- A scratchy sensation may be transmitted to the catheter as it rubs against the pericardium and epicardium, or stuttering

PERICARDIOCENTESIS (CONTINUED)

Figure 2.

Catheter positioning and orientation for PC from the right ventral approach. While stabilizing the catheter near the entry point with the nondominant hand, the catheter is advanced cranially and dorsally with the dominant hand, i.e., toward the opposite scapula. A small degree of suction is maintained with the syringe so that pericardial fluid is aspirated at the moment of pericardial penetration. Subsequently, the syringe and stylet are held in stationary while the flexible catheter is advanced well into the pericardial sac. The sharp metal stylet is withdrawn after the catheter is fully positioned, and the catheter is then attached to extension tubing leading to a three-way stopcock and aspiration syringe.

of the extension tubing caused by intermittent flow obstruction as the volume of PE decreases; at this point, the operator may slowly withdraw the catheter while the assistant maintains a small amount of suction with the syringe. Catheter withdrawal is paused at any location that results in additional aspiration of PE, and the process is repeated until catheter is completely withdrawn.
  - Catheter tip should be inspected to verify that it is intact after removal.
  - Cardiac motion may continue to expel PE into pleural space through catheter hole; this may result in lower than anticipated volumes of removed PE as well as pleural effusion following the procedure (there is no need to remove the pleural effusion).

SAMPLE HANDLING

- Pericardial fluid is placed in EDTA for cytologic examination and then in suitable sterile transport media for microbiological evaluation (bacterial and/or fungal).
- The hematocrit of presumed PE may be determined during the procedure, as noted above.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring

- Patients should be monitored for 12–24 hours. Monitoring should include serial heart and respiratory rates, cardiac ultrasounds (to evaluate return of PE), and ECG.
- Significant ventricular arrhythmias may develop.
- Iatrogenic pneumothorax is possible.
- Return of PE and clinical signs may be rapid.

Nursing Care

None specific to PC. Other care may depend on cause of PE.

Dietary Modification

N/A

Medication Requirements

- Ancillary medical treatments depend on the cause of the PE (e.g., neoplastic, infectious, idiopathic).
- Abdominal effusion stemming from tamponade-induced CHF typically does not require diuretics or treatments other than PC.
- Fluid therapy if hemorrhagic or third space fluid losses cause hypovolemia.

Restrictions on Activity

Judicious exercise restriction.

Anticipated Recovery Time

PC typically produces dramatic and immediate improvement in hemodynamic parameters. However, dogs may remain subdued for 1–2 days.

INTERPRETATION

NORMAL FINDINGS OR RANGE

N/A

ABNORMAL FINDINGS

- Cytologic evaluation of PE is notoriously nondiagnostic:
  - Most common causes of PE (neoplasia and idiopathic)—typically produce hemorrhagic effusions without identifiable cell types or features that identify causative conditions.
  - Unusual causes of PE that may be diagnosed cytologically include lymphoma, unusual tumors, and bacterial or fungal infections.

CRITICAL VALUES

- An increasing heart rate or clotting PE sample during PC. Do not aspirate further. Check to ensure correct catheter placement.
- Ventricular tachycardia (>180 bpm) or complex ventricular arrhythmia. Reposition (partially withdraw) the catheter and administer lidocaine (2 mg/kg IV).

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure

None

(CONTINUED) PERICARDIOCENTESIS

Conditions That May Interfere With Performing the Procedure

- A small (insufficient) volume of PE.
- Coagulopathy.

Procedure Techniques or Handling That May Alter Results

None

Influence of Signalment on Performing and Interpreting the Procedure

Species
Cats and small dogs may be more difficult for PC because of their small size.

Breed
N/A

Age
N/A

Sex
N/A

Pregnancy
N/A

CLINICAL PERSPECTIVE

- Rapid IV fluid administration should be administered to debilitated patients during preparation for PC.
- Complications are minimized by careful preparation and technique.
- Significant clinical improvement can occur with removal of even a small volume of effusion.
- Hemodynamically significant PE requires PC to stabilize the patient.

MISCELLANEOUS

ANCILLARY TESTS

- Echocardiography may provide a definitive diagnosis if an intrapericardial, right atrial, or heart base mass is present.
- Cytologic and microbiological examination of the PE.
- Further evaluation may include CBC and biochemical analysis, coagulation testing, toxoplasma titer (cats), thoracic radiographs and abdominal ultrasound in search of primary or metastatic neoplasia, histopathology, and thoracic exploration or thorascopic surgery for partial or complete pericardiectomy.
- In dogs with PE, elevation of plasma cardiac troponin I suggests an increased probability of hemangiosarcoma.

POINT OF CARE ABDOMINAL ULTRASONOGRAPHY

BASICS

TYPE OF PROCEDURE
Point of care ultrasound.

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Abdominal veterinary point of care ultrasound (VPOCUS) is an expansion of the original abdominal-focused assessment with sonography for trauma (A-FAST®) protocol published in 2004: a limited or focused technique that can be performed by nonspecialists to rapidly assess patients and help direct immediate diagnostic and therapeutic interventions.
- It requires minimal training, is performed during triage or during daily patient evaluation, does not compromise patient safety, is noninvasive, rapid, repeatable, and objective.
- Abdominal VPOCUS has been validated for both trauma and nontrauma patients, and is sensitive and specific for the detection of free abdominal fluid:
  - Mistakes are less likely, and learning is often facilitated, by asking simple binary questions (i.e., presence of free fluid yes/no).
  - Additional binary questions (beyond the detection of free fluid) that have been evaluated with abdominal VPOCUS include assessment of gastrointestinal (GI) motility, estimation of urine production, identification of gall bladder wall edema/thickening, and the detection of free abdominal air.

INDICATIONS
- Trauma patients.
- Unstable patients.
- Any patient as part of the triage exam.
- Post-surgery patients not recovering as expected.
- Routine daily assessment of hospitalized patients.
- To identify free abdominal fluid of any cause.
- Suspicion of pneumoperitoneum.
- Concern for adequate urine production.
- Suspicion of gastric retention or GI ileus.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
Abdominal VPOCUS is not a full ultrasonographic examination and does not replace comprehensive formal sonography, physical examination, or other diagnostic procedures, including radiographs. They are limited exams that answer specific questions in a very rapid fashion, often dictating the need for immediate therapy and further diagnostics, including comprehensive formal ultrasound examinations.

BODY SYSTEMS ASSESSED
Focused areas of the abdominal cavity to answer specific, often binary, questions.

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
- Do not compromise patient safety: bring the ultrasound machine to the patient and complete/continue any emergency stabilization and concurrent diagnostic efforts.
- Clipping of fur is unnecessary, although image quality may be improved with clipping.

Anesthesia or Sedation
Minimal restraint required, sedation rarely necessary.

Patient Positioning
- Left or right lateral recumbency. The patient can be rolled into sternal recumbency to assess the gravity dependent paralumbar region if necessary, once the other sites have been evaluated.
- Sternal or standing if lateral not possible.
- Consider gravitational effects and patient positioning for different pathologies (e.g., free fluid).
- Avoid dorsal recumbency in patients with respiratory or cardiovascular compromise.

Patient Monitoring
Serial VPOCUS monitors progression or resolution of underlying pathology.

Equipment or Supplies
- Ultrasound machine.
- Microconvex/curvilinear probe.
- Frequency: 5 MHz (patients >15 kg), 7.5 MHz (patients <15 kg).
- Gain adjusted to detect anechoic fluid.
- Depth adjusted to visualize the region of interest.
- Coupling agent: 70% isopropyl alcohol, part fur before applying. Ultrasound gel can also be used.

TECHNIQUE
- Five focused regions of the abdomen are systematically evaluated: subxiphoid (also called diaphragmatico-hepatic), urinary bladder (also called cysto-colic), right paralumbar (also called hepato-renal), left paralumbar (also called spleno-renal), and umbilical (see Figure 1).
- Fan and rock the probe through 45° angles in both longitudinal and transverse axis at all sites.

Key Structures
Key structures assessed at each site include:
- Subxiphoid: diaphragm, liver, gallbladder, ventral stomach, and the areas between these structures. The caudal vena cava, pleural space, and pericardial sac can also be evaluated at this site (not discussed in this chapter).
- Urinary bladder: urinary bladder, gravity and non-gravity-dependent body walls, and the areas between these structures.
- Right paralumbar: right caudal liver lobe, right kidney, body wall, duodenum, and the areas between these structures.
- Left paralumbar: spleen, left kidney, intestines, body wall and the areas between these structures.
- Umbilical (additional 5th view): gravity-dependent body wall, intestines, spleen and regions between these structures.

Correctly Locating and Evaluating Each Site

Subxiphoid
- Palpate the "V" at the xiphoid region and place the probe in long axis to the body.
- Rock the probe cranially until the liver is visible.
- Adjust depth to visualize the diaphragm beyond the liver.
- Fan the probe through all planes of the liver and rock the probe to assess the most ventral and cranial parts of the liver (small fluid accumulations often collect between the liver and diaphragm).
- The gallbladder is visualized to the right of midline and assessed for wall thickening or other abnormalities.
- By rocking the probe perpendicular to the spine and slowly fanning left and right the proximal stomach wall is identified and can be assessed for motility.
- The probe is then rotated into transverse axis and fanned and rocked through all planes.

Urinary Bladder
- The probe is placed in longitudinal axis to the body between the pelvic limbs.
- Pushing too hard can compress and displace the bladder.
- Adjust the depth to visualize both the dorsal and ventral bladder walls.
- Slide the probe to the non-gravity-dependent side of patient and angle the ultrasound beam through the bladder, while fanning, to identify fluid in deeper gravity-dependent sites along the body wall.
- Slide the probe cranially to locate the apex of the bladder and fan the probe through all planes at the bladder apex.

(CONTINUED) POINT OF CARE ABDOMINAL ULTRASONOGRAPHY

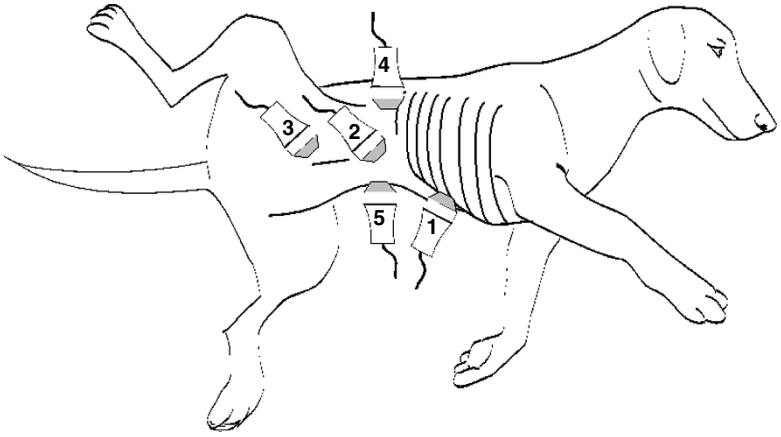

Figure 1.

Abdominal VPOCUS windows: (1) subxiphoid, (2) umbilical, (3) urinary bladder, (4) left paralumbar, and (5) right paralumbar. Each location is evaluated in longitudinal and transverse orientation with rocking and fanning of the probe to maximize the area evaluated and to ensure all target structures/sites are thoroughly evaluated. At the urinary bladder and umbilical sites the probe should be directed toward the gravity-dependent body wall areas where fluid is most likely to accumulate.

- Slide caudally to evaluate the caudal regions.
- Following thorough longitudinal scanning, rotate the probe to a transverse axis and repeat the scan.
- Bladder volume can be estimated in millimeters and monitored serially using the formula to calculate the volume of a sphere:
  - In longitudinal axis, a measurement of the length is taken. This is *L*. A depth measurement in longitudinal can be taken (D_L).
  - In transverse axis, a width measurement is taken. This is *W*. A depth measurement in transverse can be taken (D_T).
  - The formula is then as follows: $(L \times W \times (D_L + D_T)/2) \times 0.625$.

Right Paralumbar

- In smaller patients, the probe is placed in longitudinal axis to the body caudal to the last rib, just below the hypaxial/lumbar muscles.
- It may be necessary to place the probe between ribs to locate target structures.
- In dogs, if the liver is visualized first, the probe can be slid caudally until the kidney is located.
- The right kidney is often quite lateral (relative to midline).
- The probe is fanned and rocked in both longitudinal and transverse axis to assess the kidney.
- To locate the duodenum, place the probe at the level of the right kidney in longitudinal axis, and sweep medially towards midline until the largest small intestinal segment is found, which can be assessed for motility.

Left Paralumbar

- The probe is placed relatively lateral to midline to find the left kidney and spleen.
- The spleen is located cranial and often lateral to the left kidney.
- To find the left kidney, use your index finger to trace the last rib from the mid-abdominal region dorsally: the kidney is usually located where the last rib encounters the hypaxial muscles.
- The probe is fanned and rocked in both longitudinal and transverse axis to assess the kidney.
- It may be easier to find the spleen and slide the probe caudally until the left kidney is located.

Umbilical View

- The probe is placed over the umbilical region and directed towards the tabletop.
- The probe is then rocked and fanned through all planes and then changed from a longitudinal to transverse orientation and the procedure repeated.
- This allows localization of gravity-dependent abdominal effusion to be identified before the probe is slid under the patient to assess the gravity-dependent paralumbar site.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring

Serial examinations are useful to detect changes in patient pathology: frequency is dictated by changes to patient stability (heart rate, respiratory changes, or neurologic changes).

INTERPRETATION

ABNORMAL VALUES

- Free fluid appears as dark (anechoic or hypoechoic) uncontained triangles/sharp angles between organs and structures; be sure to thoroughly evaluate all key organs at all sites.
- Obtain fluid samples for in-house analysis (cytology, refractometer, parameters of sepsis or uroabdomen) which may dictate immediate interventions (surgery, antibiotics, transfusion, etc.). Consider sample submission to reference laboratory (cytology, culture) if indicated.
- Pneumoperitoneum in patients that have not undergone laparotomy is abnormal and hollow organ rupture should be ruled out. There are three key steps to help detect pneumoperitoneum:
  - Identify the peritoneal lining; this helps differentiate GI air from free air in the abdomen. Place the animal in lateral for a few minutes to allow air to rise to the non-gravity-dependent body wall. The peritoneal lining can be visualized directly or identified by locating structures in contact with it (e.g., liver, kidney, spleen, etc.). Free air can be detected between organs or within the wall of some structures, although this is more technically challenging.

POINT OF CARE ABDOMINAL ULTRASONOGRAPHY (CONTINUED)

- Identify the presence of reverberation artifact that originates at the peritoneal lining. This helps differentiates reverberation artifact contained within the GI tract. Free air reverberation artifact originating at the peritoneal lining often obliterates structures below it.
- Identify the enhanced peritoneal stripe sign. This sonographic finding occurs when free abdominal air comes in contact with the peritoneal lining, causing the peritoneal lining to become more hyperechoic. Reverberation artifact, if it is the result of free abdominal air, will originate from the enhanced peritoneal stripe sign.

• Ileus: Ileus is defined as a transient cessation of GI motility or an abnormal pattern of GI motility. The mean number of peristaltic contractions of the stomach and proximal duodenum are 4–5 contractions per minute. To measure the number of contractions per minute the total number of contractions is recorded over 3 minutes and divide by 3. If contractions are decreased to absent a diagnosis of decreased motility is made.
• Food within the GI tract is a strong stimulus for contraction; ileus is confirmed when food is present within the GI lumen in the absence of GI contractions.
• Gall bladder wall thickening/edema (halo sign) is not specific but anaphylaxis, fluid overload, right-sided heart failure, sepsis, and pericardial effusion should be considered in unstable patients.
• Oliguria/anuria: Although not 100% accurate, a lack of change in bladder volume despite appropriate IV fluid in a well-hydrated patient could be indicative of anuria or oliguria.

INTERFERING FACTORS

Conditions That May Interfere with Performing the Procedure

• Dehydration and hypovolemia may reduce the sensitivity of finding abdominal effusion; reassess once resuscitation procedures are undertaken.
• Gas-filled GI tract can obscure some structures.
• Empty or very distended bladders may be difficult to interpret.

Influence of Signalment on Performing and Interpreting the Procedure

Species
Large-breed dogs may be more difficult to image due to the depth and location of their organs.

Age
Very young healthy animals may normally have small quantities of free fluid present.

CLINICAL PERSPECTIVE

• Abdominal VPOCUS is a rapid, repeatable diagnostic tool that helps identify specific pathology.
• Requires minimal training or experience.

MISCELLANEOUS

SYNONYMS

Abdominal-focused assessment with sonography in trauma/triage (A-FAST®)

ABBREVIATIONS

• GI = gastrointestinal.
• VPOCUS = veterinary point of care ultrasound.

POINT OF CARE PLEURAL SPACE AND LUNG ULTRASONOGRAPHY

BASICS

TYPE OF PROCEDURE
Point of care ultrasound

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Pleural space and lung ultrasound (PLUS) is an expansion of thoracic focused assessment with sonography for trauma that includes lung ultrasound. Cardiovascular ultrasound is assessed separately as it involves the evaluation of both the abdomen (vascular) and heart (limited echocardiography):
  - Pathologies evaluated include pleural effusion, pneumothorax, alveolar interstitial syndrome (AIS), and lung consolidation.
  - A focused veterinary point of care ultrasound (VPOCUS) technique that can be performed by nonspecialists to rapidly assess patients and direct immediate diagnostic and therapeutic interventions.
    - Requires minimal training, is performed during triage or daily patient evaluation, does not compromise patient safety, is noninvasive, rapid, repeatable, and objective.
    - Accuracy is variable, and depends on the experience of the sonographer, underlying pathology, patient positioning, scanning protocol, and criteria used to identify the different pathologies.
  - In the authors' experience the most common clinical errors include failing to identify pneumothorax by not scanning the most caudal dorsal sites, missing smaller volume pleural effusions by not scanning the more ventral regions when patients are in sternal or standing positions, and confusing the curtain sign for lung pathology.
- Principles of PLUS that increase the chance of detecting pathology include the application of binary questions to keep scanners focused to techniques and questions within their skill sets, modifying protocols to evaluate areas of the pleura and lung where pathology is most likely to accumulate, and defining sonographically scannable thoracic borders:
  - If pleural effusion needs to be ruled out in a standing patient, then searching the most ventral borders between the lung and sternal muscles (where fluid accumulates) is important vs. a patient that is lateral (where fluid will accumulate at the widest, most gravity-dependent point of the thorax).
  - In a patient with severe dyspnea, the binary question (based on initial triage examination) dictates which part of the PLUS protocol is performed first (e.g., pneumothorax, pleural effusion, lung pathology). Once the patient is more stable, completion of the PLUS examination and other VPOCUS scans can be performed.
  - Defining sonographically scannable borders of the thorax on either side of the chest helps ensure sites where pathology are most likely to accumulate are evaluated.

INDICATIONS
- Dyspneic patients.
- Trauma patients.
- Part of the triage exam.
- Post-surgery patients not recovering as expected.
- Routine daily assessment.
- Suspected pneumothorax.
- Suspected pleural effusion.
- Suspected alveolar interstitial disease.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
PLUS is not a full ultrasonographic examination of the thorax and does not replace comprehensive formal sonography, physical examination, or other diagnostic procedures including thoracic radiographs. It is a focused exam that answers specific questions in a rapid fashion, often dictating the need for immediate therapy and further diagnostics, including comprehensive formal ultrasound examinations.

BODY SYSTEMS ASSESSED
Lungs and pleural space to answer specific questions.

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
- Do not compromise patient safety: bring the ultrasound machine to the patient and continue emergency stabilization and concurrent diagnostic efforts.
- Clipping of fur is unnecessary but may improve image quality.

Anesthesia or Sedation
- Minimal restraint required.
- Oxygen therapy and anxiolytics may calm patients, decreasing the respiratory rate and effort, making interpretation easier.

Patient Positioning
- Air accumulates at the highest gravity-independent areas; fluid at the most gravity-dependent areas, which varies with patient positioning.
- Dyspneic patients should be scanned in sternal/standing to avoid stress.
- More stable patients can be scanned in left or right lateral recumbency.
- Avoid dorsal recumbency in dyspneic or cardiovascularly compromised patients.

Patient Monitoring
Serial VPOCUS monitors progression or resolution of underlying pathology.

Equipment or Supplies
- Ultrasound machine.
- Microconvex/curvilinear probe.
- Frequency adjusted to make the pleural line appear grainy when assessing the glide sign (typically 5–7.5 mHz).
- Depth adjusted to 4–6 cm; pleural line should be located at roughly a third the distance of the ultrasound image.
- Coupling agent; alcohol, part fur before applying. Ultrasound gel can also be used.

TECHNIQUE
The following PLUS protocol has three objectives: assess for (1) pneumothorax, (2) lung pathology, and (3) pleural effusion. The order can be modified to rule out the most likely and life-threatening pathology first. It is intended for the sternal/standing patient. (The protocol is slightly modified when searching for pleural effusion and/or pneumothorax in laterally recumbent patients; see below.)

1. Place the probe on a region of the thorax where lung can be reliably identified, behind the thoracic limb, roughly between the 5th–6th intercostal space and half to two-thirds of the way up the thorax (see Figure 1). Starting at this location avoids accidental placement of the probe over the curtain sign, abdomen and sublumbar muscles, which can be confused for pathology. The probe can be placed perpendicular or parallel to the ribs. For beginners, the authors recommend placing the probe perpendicular to identify the BAT sign.
2. Normal structures are identified at this location (see Normal Findings or Range: BAT sign, pleural line, glide sign, A-lines, B-lines, curtain sign).
3. If a glide sign is seen, slide the probe caudally until the curtain sign is identified:
   - Patients with significant pneumothorax will not have a glide sign at this location and thoracentesis or a search for the lung point should be undertaken (see Abnormal Findings).
4. From the curtain sign, slide the probe dorsocaudally along the curtain sign until the hypaxial muscle–pleural space junction is identified. This is the most caudo-dorsal site of the thorax and the smaller volumes of pneumothorax are likely to be identified in a standing/sternal patient (see below):

POINT OF CARE PLEURAL SPACE AND LUNG ULTRASONOGRAPHY (CONTINUED)

(a)

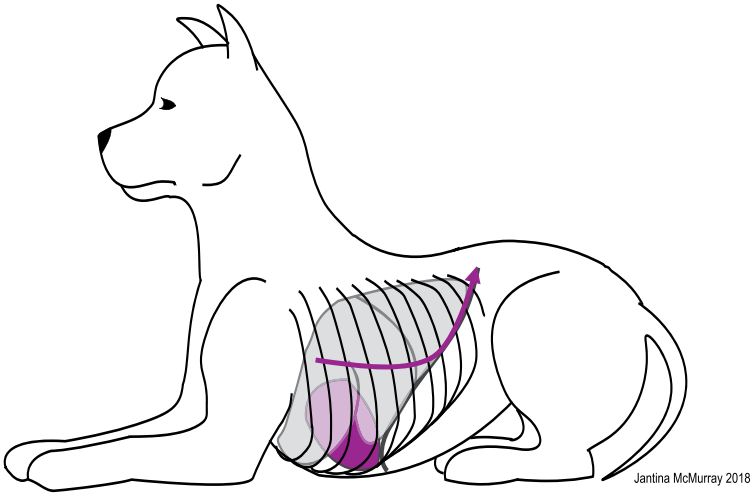

Figure 1a.

The probe is placed over lung, then slid caudally until the curtain sign is identified (caudal lung border). Then slide dorsally along the curtain sign, focusing on the pleural line, until the pleural line is lost in the hypaxial muscles. Return to the pleural line. This is the most caudal dorsal site, which can be rapidly identified with confidence in any patient. Source: From Boysen S, McMurray J and Gommeren K (2019) Abnormal Curtain Signs Identified With a Novel Lung Ultrasound Protocol in Six Dogs With Pneumothorax. Front. Vet. Sci. 6:291. doi: 10.3389/fvets.2019.00291. Public Domain.

(b)

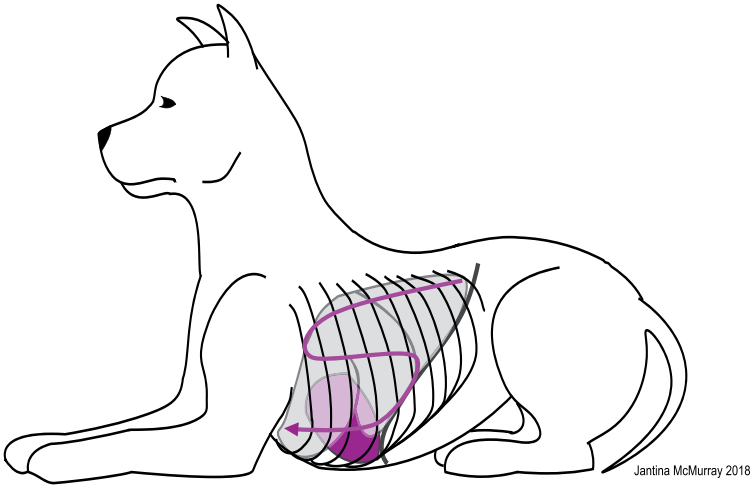

Figure 1b.

From the most caudal dorsal site, slide the probe in an "S"-shaped pattern, dividing the thorax into dorsal, middle, and ventral thirds to assess multiple lung regions for pathology. Source: From Boysen S, McMurray J and Gommeren K (2019) Abnormal Curtain Signs Identified With a Novel Lung Ultrasound Protocol in Six Dogs With Pneumothorax. Front. Vet. Sci. 6:291. doi: 10.3389/fvets.2019.00291. Public Domain.

- If a glide sign is seen here, pneumothorax is ruled out for this side of the thorax in the standing/sternal patient.
- If a glide sign is not seen here, and a pneumothorax cannot be ruled out based on clinical findings, then search for a lung point or return of the glide sign (see below).

5. If a glide sign was identified in step 4, and pneumothorax ruled out, continue scanning for lung pathology (AIS and lung consolidation) and pleural effusion; for AIS/lung consolidation slide the probe across the intercostal spaces in an "S" fashion to scan multiple lung regions. Pause and hold the probe stationary as necessary to better assess suspected areas for pathology:
   - From the most caudo-dorsal position, slide the probe across the dorsal border of the thorax as cranial as possible to the scapula/flexor muscles of the shoulder

(c)

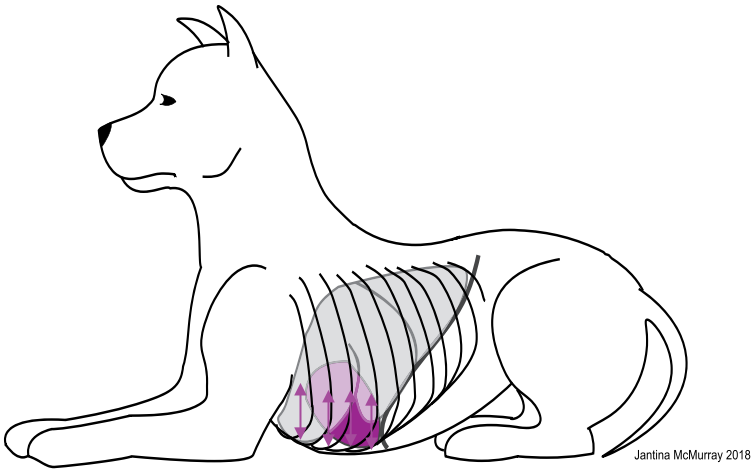

Figure 1c.

At the ventral regions of the thorax (level of the costochondral junction) the probe can be turned parallel to the ribs and slid ventrally until the sternal muscles are encountered. This ensures small volumes of pleural fluid that may not be seen with the probe perpendicular to the ribs at the level of the costochondral junction are not missed. From the sternal muscles, which are often in contact with the heart in the 4th–6th intercostal spaces, the probe can also be slid dorsally to ensure the ventral lung regions are assessed for pathology. Source: From Boysen S, McMurray J and Gommeren K (2019) Abnormal Curtain Signs Identified With a Novel Lung Ultrasound Protocol in Six Dogs With Pneumothorax. Front. Vet. Sci. 6:291. doi: 10.3389/fvets.2019.00291. Public Domain.

while continuing to visualize the pleural line for pathology:

- Once the cranial–dorsal border is reached, slide the probe ventrally to the mid-thorax, roughly at the heart base region, and then caudally toward the curtain sign while continuing to visualize the pleural line for pathology.
- At the curtain sign, slide the probe ventrally until the pericardio-diaphragmatic window is identified (where the heart and diaphragm are visible in the same sonographic window). This is a good window to differentiate pleural and pericardial fluid.
- The probe is then slid cranially until the thoracic inlet is reached (limited by the thoracic limb).
- To avoid missing smaller volumes of pleural effusion turn the probe parallel to the ribs at or just below the costochondral junction, roughly between the 3rd and 7th intercostal spaces, and slide the probe ventrally until the lung and sternal muscle are both visible in the same sonographic window. To also assess the ventral lung borders for pathology, the probe can be slid dorsally from the sternal–pleural junction, between the ribs at these same intercostal spaces (maintaining the probe parallel to the ribs), until lung is encountered.

6. The other side of the thorax should be scanned in a similar fashion.
7. The subxiphoid should also be included for assessment of pleural effusion and AIS/lung consolidation:
    - The probe can be placed in long and short axis to the body in the subxiphoid region. Palpate the "V" where the ribs connect ventrally and place the probe at this location. The probe is then rocked and fanned so that the ultrasound beams penetrate the thorax.
    - Once the thorax is visualized, the probe is fanned to visualize the entire region.
8. With the patient in lateral recumbency the protocol is similar, however it should be remembered that fluid will accumulate at the widest gravity-dependent location of the thorax and air will accumulate at the widest most non-gravity-dependent location. These sites should be considered and the protocol modified in light of patient positioning, the binary question to answer first, and the pathology in question.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring

Serial thoracic VPOCUS examinations are useful to follow resolution/progression of pathology, and should be repeated as dictated by changes to patient stability.

INTERPRETATION

NORMAL FINDINGS OR RANGE

Normal Structures

There are six key PLUS findings to identify in healthy animals, which should also be assessed in animals with suspected pathology.

1. BAT Sign (also termed the gator sign) (see Figure 2)

Using the BAT sign mnemonic—"the ultrasound beam will not traverse Bone or Air when the probe is Transverse to the ribs"—helps sonographers to orient.

- The ultrasound beam will not traverse beyond the proximal rib surface (smaller downward facing curvilinear white lines) or the pleural line (upward curving white line) in healthy animals, which means these structures are the last visible features the ultrasound beam can identify when the ultrasound probe is situated over lung and oriented perpendicular to the ribs: everything beyond the ribs and pleural line is artifact in healthy animals.
- The pleural line is essential to identify as all PLUS pathology originates from the pleural line: the first horizontal white line below the ribs that connects the rib shadows (body of the bat).

POINT OF CARE PLEURAL SPACE AND LUNG ULTRASONOGRAPHY (CONTINUED)

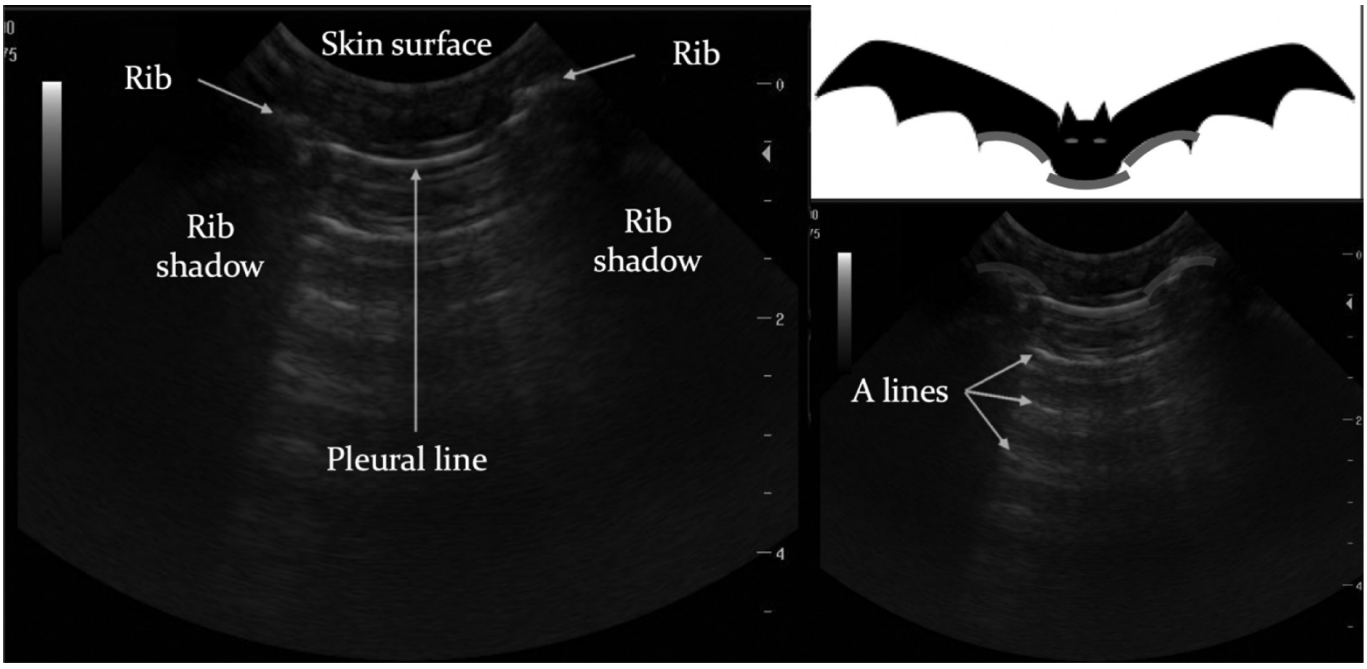

Figure 2.

Image depicting the BAT sign where the ultrasound beam encounters Bone (rib heads = wings of the bat) and Air (pleural line = body of the bat) with the probe Transverse (perpendicular) to the ribs. Horizontal A-lines are also shown.

2. Pleural Line

When the lung is in contact with the chest wall the pleural line indicates the parietal pleura and the visceral pleura are joined. In cases of pneumothorax or pleural effusion, the pleural line comprises only the parietal pleura (the visceral pleural is visible deep to pleural effusion and not visible with pneumothorax).

- All pleural space pathology (i.e., pleural effusion, pneumothorax, etc.) originates at the pleural line.
- All sonographically detectable lung pathology originates at the visceral pleura (lung surface), which will be at the pleural line when lung contacts the chest wall, and the visceral pleura when the lung is visibly separated from the chest wall (e.g., pleural effusion).

3. The Glide Sign

The to-and-fro shimmering visible along the pleural line that occurs as a result of lung sliding along the chest well during the respiratory cycle:

- The glide sign rules out pleural space pathology, particularly pneumothorax and pleural effusion.
- Two criteria must be present for a glide sign to occur: (1) the two pleura must be in contact; (2) the patient must breathe for the two pleura to glide across each other creating the visible shimmering.
- The glide sign can be made "grainier" and therefore easier to visualize by changing the angle the ultrasound beam strikes the pleural line (changing the angle from perpendicular), by placing the probe over a single rib head, and by decreasing the gain setting.
- The glide sign is difficult to identify in patients that are panting or have rapid shallow breathing.
- Keep your hand stationary and only interpret the glide sign when the patient is not moving (movement creates a false positive).

4. A-Lines

Horizontal white line artifacts occurring at equidistant intervals that project through the far field of the ultrasound image, decreasing in intensity with depth.

- A-lines are created when the ultrasound beam is bounced back and forth between the ultrasound probe and highly reflective structures such as the soft tissue–air interface that occurs at the pleural line.
- A soft tissue–air interface is present at the pleural line when air fills the lung and when air occupies the pleural space in cases of pneumothorax. Therefore A-lines are visible with both aerated lung and pneumothorax.

5. B-Lines (Figure 3)

Vertical white line artifacts that occur when air and fluid are in proximity to each other at the lung surface.

- They often have the following five criteria: (1) vertical white/hyperechoic projections; (2) originating from the lung surface at the pleural line; (3) extending through the far field without fading; (4) obliterating A-lines if present; and (5) swinging to-and-fro with the glide sign during respiration.
- Up to three B-lines in a single sonographic window, but only at 1 or two locations on either side of the thorax is considered normal and may be identified in 10–30% of healthy dogs and cats.
- More than three B-lines at a single site is associated with AIS/wet lung.
- The same differential diagnosis for AIS on ultrasound should be considered as an interstitial–alveolar pattern on thoracic radiographs.
- The number of B-lines correlates with the quantity of extravascular lung water, although prognosis varies with cause.

6. Curtain Sign

Sharply demarcated vertical edge artifact separating aerated lung from abdominal contents, (thoraco-abdominal border) (see Figure 4).

- When the ultrasound probe is positioned such that it is over both the thorax and the abdomen with the marker of the probe directed cranially, the cranial half of the image (thorax) will not allow the ultrasound beam to extend past the pleural line (produces A-lines), while the caudal half of the image (abdomen) allows the beam to be transmitted through the far field, permitting soft tissue structures to be visible.

(CONTINUED) POINT OF CARE PLEURAL SPACE AND LUNG ULTRASONOGRAPHY

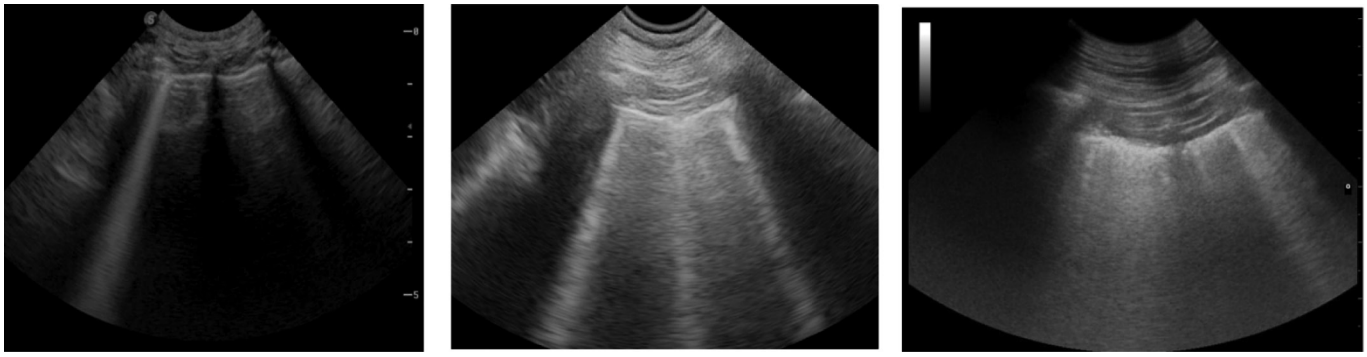

Figure 3.

Images depicting a single B-line (left), four B-lines (middle), and multiple to coalescing B-lines (right).

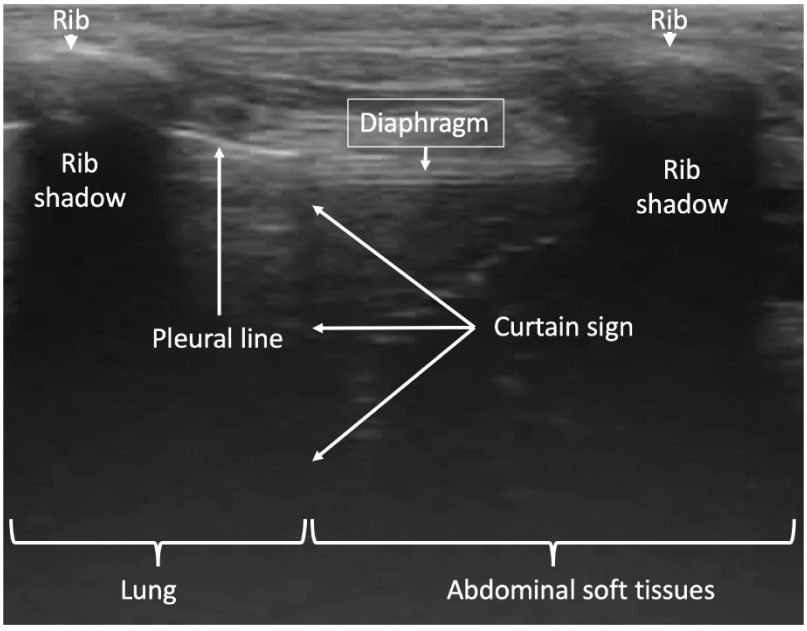

Figure 4.

Curtain sign, depicted as the sharp vertical line separating aerated lung from the soft tissue structures of the abdomen. The diaphragm is not visible once it curves away from the thoracic wall as interposed lung prevents its visualization.

• During inspiration, the vertical edge and abdominal contents move caudally, and during expiration the vertical edge and abdominal contents move cranially, in a synchronous manner.
• It is important not to confuse the curtain sign (back and forth movement of the diaphragm) with a glide sign.

Dry Lung

Dry lung at a probe location is identified when the following two criteria are present:
• The patient has a glide sign.
• There are ≤three B-lines in a single sonographic window, and/or the presence of only A-lines (not always visible).

ABNORMAL FINDINGS

Pneumothorax

• There are three key findings in deciding if a pneumothorax is present or not; two are exclusion criteria, one is an inclusion criteria:
  ◦ The presence of a glide sign rules out pneumothorax at the probe location with confidence. Lack of a glide sign should prompt consideration of pneumothorax, but a glide sign is not always easy to identify, even in healthy patients.
  ◦ The presence of B-lines extending from the pleural line excludes pneumothorax at that probe location because B-lines originate from the lung surface. B-lines are not always visible in healthy patients.
  ◦ Finding a lung point or the return of a glide sign confirms pneumothorax on that side of the thorax. If a glide sign is not seen and there is suspicion of a pneumothorax a search for the lung point should be undertaken.
• The lung point is defined as the site within the thorax where the lung recontacts the parietal pleura and creates an intermittent or partial glide sign within a section of the ultrasound image when the patient breathes. It is the exact point within the thorax where there is a return of the glide sign: movement of the probe from an area where there is no perceived glide sign, to an area where the glide sign

POINT OF CARE PLEURAL SPACE AND LUNG ULTRASONOGRAPHY (CONTINUED)

reappears within a region of the ultrasound window. Air in the pleural space (pneumothorax) tends to compress the lung cranially and ventrally: to identify the lung point slide the probe cranially–ventrally toward the elbow from the site where a glide sign was not visible. The lung point will not be seen if the lung fails to recontact the chest wall in cases of massive/complete pneumothorax.

Pleural Effusion

Pleural effusion appears as hypoechoic accumulations between the thoracic wall and lungs, and its appearance can vary depending on the cellularity of the effusion, probe location, patient positioning, the quantity of fluid and the presence of adhesions.

- Locating the pericardio-diaphragmatic window helps differentiate pleural effusion from pericardial effusion; pleural effusion is uncontained outlining and tracking along the diaphragm while pericardial effusion is contained and curves away from the diaphragm following the contour of the heart.
- The presence of fluid between the lung and ventral sternal muscles, with the probe parallel to the ribs creates a triangular shape of anechoic fluid similar to a sail. (the "sail sign").
- As fluid accumulates the lungs may become atelectatic, appearing as floating tissue-like structures termed the "jellyfish" sign in human medicine.

AIS

Lung ultrasound will only detect lung pathology if it reaches the lung surface. Most diseases that cause AIS (cardiogenic pulmonary edema, trauma-induced contusions, aspiration pneumonia, etc.) reach the lung surface. As stated above, three or more B-lines in any single sonographic window is considered indicative of AIS.

Lung Consolidation

Sonographically detected lung consolidation can occur as a result of atelectasis, bronchopneumonia, thromboembolism, neoplasia, and inflammatory conditions such as pulmonary contusions and acute respiratory distress syndrome.

- Criteria to diagnose lung consolidation:
  - Abnormal pattern should be differentiated from the liver, spleen and other soft tissue abdominal structures.
  - Abnormal pattern should arise from the pleural line.
  - There should be a tissue-like pattern (similar to liver echotexture).
  - Anatomic boundaries must be present:
    - Superficial boundary of consolidation.
    - At the pleural line in the absence of pleural effusion.
    - At the deep boundary of a pleural effusion if effusion present.
  - Deep boundary of the consolidation may be irregular (aerated lung boundary) or regular (if the whole lobe is consolidated).
  - When consolidation fails to traverse the entire lung lobe (partial consolidation) aerated lung is encountered deep to the consolidation which can create an irregular consolidation/air interface, called a "shred sign." At the consolidation/aerated lung interface a hyperechoic irregular border is seen that usually creates comet tail artifacts.
  - If the border between the consolidation and aerated lung is smooth and almost circular, it most likely represents a nodule.
  - Where consolidation extends through the entirety of the lung, from one surface to the other, translobar hepatization is seen.
  - Air bronchograms, if present, can be seen within lung consolidation as small white hyperechoic pointed foci or lines.

INTERFERING FACTORS

Conditions That May Interfere with Performing the Procedure

- Patient position affects where pathology may be found and is important to consider when scanning patients.
- Severe dehydration and hypovolemia may reduce the sensitivity of finding pleural effusion; patients should be reassessed with VPOCUS once resuscitation procedures are undertaken.

Influence of Signalment on Performing and Interpreting the Procedure

Large-breed dogs may be more difficult to image, especially at the subxiphoid region due to the depth of their pleural surface.

CLINICAL PERSPECTIVE

- PLUS examinations are a quick and repeatable diagnostic tool that can help identify pathology and direct further diagnostics and therapy.
- VPOCUS examinations require little training and experience.

MISCELLANEOUS

ANCILLARY TESTS

- Thoracocentesis.
- Pericardiocentesis.

SYNONYMS

TFAST®, VetBLUE®, lung ultrasound.

SEE ALSO

Point of Care Abdominal Ultrasonography (in Appendix X).

ABBREVIATIONS

- AIS = alveolar interstitial syndrome.
- PLUS = pleural and lung ultrasound.
- VPOCUS = veterinary point of care ultrasound.

RECTAL SCRAPING AND CYTOLOGY

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection.

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Quick, relatively noninvasive, technique that can be used to diagnose certain colonic or rectal diseases.
- Different from fecal cytologic evaluation, which looks for diversity of the fecal bacterial population.

INDICATIONS
- Chronic or very severe large-bowel disease (especially patients with hypoalbuminemia, weight loss, or both) in dogs that may have fungal disease (e.g., histoplasmosis), algal disease (i.e., protothecosis), neoplastic disease, and especially those with mucosal abnormalities on digital rectal palpation.
- Procedure is seldom indicated in cats.

CONTRAINDICATIONS
Severe coagulopathy.

POTENTIAL COMPLICATIONS
- Excessive bleeding (rare).
- Perforation if exceedingly improper technique is employed.

CLIENT EDUCATION
- Specific for certain infections but is insensitive—if the results are negative, you have not eliminated any diseases.
- It is appropriate to evaluate rectal cytology before performing endoscopy in dogs with suspected fungal, algal or neoplastic disease, especially if mucosal abnormalities are found on rectal examination.

BODY SYSTEMS ASSESSED
Gastrointestinal

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
None

Anesthesia or Sedation
Sedation with narcotics/neuroleptanalgesics or anesthesia with injectable propofol may be needed in animals that are in excessive pain during the rectal examination.

Patient Positioning
May be performed with the patient in any of several positions.

Patient Monitoring
None

Equipment or Supplies
- Examination gloves.
- A small curette or similar instrument.

TECHNIQUE
- A gloved finger is inserted into the rectum, and a complete digital rectal examination is performed.
- Next, a small curette is guided into the rectum with the finger, and the rectal mucosa is gently scraped to obtain epithelial cells:
  - The goal is to obtain mucosal epithelium, not feces.
  - Blood should not be obvious after the procedure.
- Spread epithelial cells on a glass slide, air-dry, and stain with new methylene blue, Diff-Quik, or modified Giemsa.
- In larger dogs, one may tape the cap of a syringe casing to the tip of the index finger and use it to scrape the rectal mucosa.

SAMPLE HANDLING
The slide is handled routinely as any cytologic slide.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring
None

Nursing Care
None

Dietary Modification
None

Medication Requirements
None

Restrictions on Activity
None

Anticipated Recovery Time
Immediate

INTERPRETATION

NORMAL FINDINGS OR RANGE
No fungal organisms, no algae, and no appreciable inflammation.

ABNORMAL FINDINGS
- Fungal organisms (e.g., histoplasmosis, typically found in macrophages).
- Algae (i.e., protothecosis).
- Substantial numbers of neutrophils or eosinophils.
- Malignant cells.

CRITICAL VALUES
None

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure
None known.

Conditions That May Interfere with Performing the Procedure
Excessive rectal or anal pain makes sedation or anesthesia necessary.

Procedure Techniques or Handling That May Alter Results
None

Influence of Signalment on Performing and Interpreting the Procedure

Species
This procedure is almost never performed in cats.

Breed
None

Age
None

Gender
None

Pregnancy
None

CLINICAL PERSPECTIVE
- Specific but not necessarily sensitive for diagnosis of colonic histoplasmosis, a disease that is common in select geographic areas of the United States.
- May help diagnose severe colitis by finding substantial numbers of neutrophils, but this is a nonspecific finding that can occur in numerous disorders.
- Care must be taken before diagnosing a malignancy based solely on cytologic analysis because epithelial dysplastic changes are common in many diseases.

MISCELLANEOUS

ANCILLARY TESTS
Colonoscopy and biopsy are required if rectal cytologic analysis is nonrevealing in a dog that is suspected of having colonic histoplasmosis, protothecosis, or rectal neoplasia.

SYNONYMS
Rectal scrape.

SEE ALSO
Histoplasmosis

SALINE AGGLUTINATION TEST

BASICS

TYPE OF SPECIMEN
Whole blood (anticoagulated with EDTA).

TEST EXPLANATION AND RELATED PHYSIOLOGY
- Performed when erythrocytes are aggregated (clusters of grapes) or stacked (similar to coins) on a blood smear. This finding indicates erythrocyte rouleaux or agglutination:
  - Rouleaux occurs due to interactions of red blood cells with plasma proteins such as fibrinogen.
  - Agglutination is caused by presence of antibodies (usually IgM) on surface of red cells, forming bridges between one another and spontaneously aggregating. Most commonly associated with immune-mediated hemolytic anemia (IMHA).
- When saline agglutination test is performed, rouleaux will disperse in the presence of saline but agglutination will not.

INDICATIONS
Differentiate erythrocyte rouleaux from antibody-mediated agglutination.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
Negative saline agglutination test does not rule out IMHA.

BODY SYSTEMS ASSESSED
Hemic/immune.

SAMPLE

SAMPLE COLLECTION
One drop of whole blood and 4 drops of sterile 0.9% saline are required.

SAMPLE HANDLING
- Saline should be between 23 and 37°C; collect blood into EDTA and observe for agglutination on microscope slide.

SAMPLE STORAGE
Test should be interpreted immediately.

SAMPLE STABILITY
- EDTA-anticoagulated blood:
  - Several hours at room temperature.
  - 1 day at 2–8°C (refrigerated).

PROTOCOL
- There is no standardized protocol for this test.
- Add a drop of whole blood to a microscope slide.
- Dilute this drop of blood by adding four drops of saline.
- Rock slide gently back and forth before examining it macroscopically and microscopically for agglutination. Cover slip recommended for microscopic evaluation.
- True agglutination will continue to form aggregates that appear similar to clusters of grapes in the presence of saline. Rouleaux will be dispersed by saline and no aggregation will be observed.
- Additional saline can be added if there is concern that an insufficient amount was added in order to rule out rouleaux.
- For inconclusive results, washing erythrocytes 3 times in a 1:4 ratio is recommended to confirm persistent aggregation.

INTERPRETATION

NORMAL FINDINGS OR RANGE
Lack of macroscopic or microscopic aggregation.

ABNORMAL FINDINGS
Persistent aggregation with addition of saline.

CRITICAL VALUES
None

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation
Treatment with corticosteroids may result in false-negative results.

Disorders That May Alter Results
- Animals occasionally have naturally occurring anti-erythrocyte antibodies, causing a positive result; however, these animals are not generally anemic and clinical history is important to differentiate normal from pathologic agglutination.
- Cold agglutinins may not precipitate at the temperature of test and result in false-negative result.

Collection Techniques or Handling That May Alter Results
- Inadequate amount of saline may not disperse rouleaux (false positive).
- Overdilution with saline may cause dispersion of agglutination (false negative).
- Letting dilution sit for too long before interpretation may result in false-negative results if antibodies are of low affinity.

Influence of Signalment

Species
Cats can exhibit more rouleaux in health than dogs; it is recommended to add more saline when performing this test in cats.

Breed
IMHA is more common in some dog breeds (e.g., cocker spaniels, English springer spaniels, Old English sheepdogs).

Age
None

Sex
None

Pregnancy
None

LIMITATIONS OF TEST
- Lack of standardized protocol makes interpretation and reproducibility difficult.
- Cannot always differentiate between rouleaux and autoagglutination, particularly if antibodies causing agglutination are of low affinity and easily dispersed.
- Rouleaux and agglutination may be present at the same time.

Valid If Run in Human Lab?
Yes

CAUSES OF ABNORMAL FINDINGS
- IMHA.
- Neoplasia.
- Infectious disease.
- Toxicities (e.g., bee sting envenomation).
- Drug reaction.
- Systemic lupus erythematosus.
- Alloimmune hemolytic anemia.

CLINICAL PERSPECTIVE
- Some clinical pathologists do not endorse this test due to lack of standardization of protocol and interpretation.
- Some cases of IMHA do not display macroscopic or microscopic agglutination.
- Not a standalone test for diagnosis of IMHA; requires proper interpretation of history, physical exam, complete blood count (CBC) with blood smear review, biochemical profile, ± Coombs' testing.

MISCELLANEOUS

ANCILLARY TESTS
A Coombs' test is not indicated if saline agglutination is positive as it would be expected to be positive as well.

SYNONYMS
Saline dispersion test.

(CONTINUED) **SALINE AGGLUTINATION TEST**

THORACOCENTESIS AND FLUID ANALYSIS

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection.

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Thoracocentesis or pleurocentesis can be performed for one of two purposes: diagnostic evaluation or therapeutic intervention:
  - Diagnostic thoracocentesis can be essential for diagnosing the presence of pleural space disease and evaluating the contents of the cavity, whether air or fluid. Pleural fluid can then be further evaluated grossly for color and consistency, and microscopically for cellularity and the presence of protein or organisms.
  - Therapeutic thoracocentesis is used to treat pleural effusion and pneumothorax resulting from a variety of causes. Typically, therapeutic thoracocentesis follows a positive diagnostic tap.

INDICATIONS
- When the presence of pleural air or fluid is suspected, especially in an animal with increased inspiratory effort and reduced breath sounds on thoracic auscultation.
- To sample/alleviate pleural air or fluid identified on an imaging study.
- Conditions leading to pleural space disease include trauma, hemorrhage, neoplasia, heart failure, chylothorax, spontaneous rupture of a pulmonary bulla, and infection.

CONTRAINDICATIONS
Thoracocentesis should be performed cautiously on patients with abnormal hemostasis.

POTENTIAL COMPLICATIONS
- Lung puncture or laceration producing pneumothorax. More likely to be serious in patients with pleural fibrosis.
- Hemorrhage, if the internal thoracic artery is lacerated.
- If the fenestrated catheter technique is used, and the fenestrations are not small and smooth, the catheter can get caught on the skin and break, with pieces remaining in the patient.
- Infection (pyothorax) can develop if sterile technique is not used.

CLIENT EDUCATION
Clients should be aware of the potential complications of the procedure and the potential severity of the underlying disease.

BODY SYSTEMS ASSESSED
- Cardiovascular.
- Hemic, lymphatic, and immune.
- Respiratory.

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
- Sedation may be necessary, especially in cats.
- Clip the hair over a large area of the lateral thorax. The point of needle insertion should be at the 7th–9th intercostal space, dorsal to the costochondral arch.
- To remove fluid, the needle should enter at the level of the costochondral junction. To remove air, it should enter where the chest wall is widest.
- Local anesthetic is generally not necessary for a diagnostic tap. However, local anesthesia is imperative for therapeutic thoracocentesis. Lidocaine (no more than 2 mg/kg) should be injected SC and infused into the intercostal muscles.
- Scrub the skin surface with povidone-iodine or chlorhexidine. Contact time should be at least 3 minutes and then wipe with alcohol.
- For emergency therapeutic thoracocentesis, full skin antisepsis may be abbreviated.

Anesthesia or Sedation
- Selection should be based on the individual patient.
- Often, butorphanol ± acepromazine or a benzodiazepine is sufficient.

Patient Positioning
- The patient should be in a comfortable position that does not compromise its respiration. Typically, the patient is in sternal recumbency or standing:
  - Sitting should be avoided because it interferes with accurate determination of landmarks.
- Supplemental oxygen may stabilize patient and improve comfort during centesis.

Patient Monitoring
Respiration, heart rate, and pulse should be monitored throughout procedure.

Equipment or Supplies
Diagnostic Tap
- A 3-mL syringe with a 22-gauge, 1-inch needle can be used for cats and most dogs, for large (>30 kg) or obese dogs, a 1½-inch needle may be needed.
- A butterfly needle can also be used in cats and small dogs.
- Serum and EDTA tubes, and culture swabs needed for fluid analysis.

Therapeutic Tap
- A 14- to 16-gauge, 3½- to 5¼-inch catheter for dogs.
- A 16- to 20-gauge, 2- to 3½-inch catheter for cats and small dogs *or* a butterfly needle.
- A no. 11 scalpel blade.
- Sterile gloves.
- A 3-mL syringe.
- A 12- to 60-mL syringe.
- An IV fluid-extension set.
- A three-way stopcock.
- A container for fluid.

TECHNIQUE

Diagnostic Thoracocentesis
- Locate the desired point of insertion by counting to the 7th–9th intercostal space. Begin counting in the caudal most intercostal space (12th space) and count cranially. Position the needle at the widest point of the thorax for air, and just dorsal to the costochondral arch for aspiration of fluid.
- Stabilize both hands on the animal so that the hands and the needle move with the chest wall. Insert the needle through the skin at the cranial aspect of the rib; once in the subcutaneous space, apply 1–2 mL of vacuum on the syringe. Slowly advance the needle perpendicular to the body wall while maintaining vacuum. Penetration of the pleura is indicated when the vacuum is suddenly lost (pneumothorax) or fluid enters the syringe (effusion):
  - Penetration of the pleura may cause discomfort to the patient, and should be palpated by the operator as a slight pop.
- Once the presence of pleural fluid or air is confirmed, withdraw the needle slightly to decrease the likelihood of lung laceration.

Butterfly Catheter Technique
- For diagnostic or therapeutic thoracocentesis.
- When using this technique, position the needle so that the bevel is facing cranially. Insert the catheter perpendicular to the chest wall and, once in the subcutaneous space, apply 1–2 mL of vacuum with the syringe attached to the catheter extension tubing.
- Once the vacuum is lost, the tip of the needle can be directed so that it is away from the lung, and advanced along the inner pleura. The wings of the catheter can be pressed against the cranial rib and used to direct the needle in the pleural space.

Therapeutic Thoracocentesis
- Locate the point of insertion by counting to the 7th–9th intercostal space as described above. Position the needle at the widest point of the throax for air, and just dorsal to the costochondral arch for aspiration of fluid.
- If fluid is suspected, a few small fenestrations can be made in the catheter, starting 1 cm proximal to the tip, to prevent clogging and increase yield:
  - Use a no. 11 blade and, while wearing sterile gloves, make small V-shaped holes by joining cuts at a 45° angle.

- These holes should be no more than 20% of the circumference of the catheter.
- Rotate the catheter 90° at each fenestration to maintain the integrity of the catheter (i.e., fenestrations should not be opposite each other).
- Do not scoop holes out; ensure that the edges are smooth to decrease the likelihood of the catheter getting caught on the skin and breaking.

• Lift the skin away from the body wall and make a stab skin incision that fully penetrates the dermis with the no. 11 blade.
• Attach the 3-mL syringe to the catheter–needle assembly.
• The nondominant hand is rested on the animal and used to advance the catheter–stylet assembly into the skin incision:
- The stylet is advanced by the fingers of the nondominant hand, which is resting on the chest wall.
- Once the needle has entered the subcutaneous space, the dominant hand applies 1–2 mL of vacuum using the syringe.
- While maintaining the vacuum, advance the stylet slowly along the cranial aspect of the rib until the vacuum is lost (or fluid is observed), indicating that the pleural space has been entered.

• Once the stylet has entered the pleural space, advance the entire assembly approximately ¼ inch:
- Hold the stylet hub stationary and advance the catheter ≈1 cm over the stylet.
- It is critical that the catheter is advanced and that the stylet is not pulled backward out of the pleural space.
- Holding the stylet stationary, advance the catheter cranially into the thorax, parallel to the spine (for air) or cranioventrally (for fluid).

• Remove the stylet and have an assistant attach the extension set that has been connected to the three-way stopcock and syringe and begin aspiration.

SAMPLE HANDLING

Aliquots of effusion samples may be placed in EDTA tubes for cytologic analysis and tubes without additive or culturettes for bacteriologic culture. A slide should also be made for immediate cytologic evaluation.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring

• The patient's respiration rate and effort should be monitored after thoracocentesis. Deterioration suggests that either the condition is worsening or that an iatrogenic pneumothorax has developed.
• Monitor the heart rate, pulses, and capillary refill time.
• Patients with recurrent pneumothorax after 2–3 thoracocenteses will likely benefit from thoracostomy tube placement and continuous pleural suction.

Nursing Care

No specific nursing care is necessary after the centesis.

Dietary Modification

N/A

Medication Requirements

Based on underlying disease.

Restrictions on Activity

The animal should remain quiet for a few hours after the thoracocentesis so that respiration rate and effort can be evaluated effectively. Further restrictions will be based on underlying disease.

Anticipated Recovery Time

The patient should recover as soon as the needle or catheter has been removed, and the sedation has worn off. Full recovery is based on the etiology of the underlying disease.

INTERPRETATION

NORMAL FINDINGS OR RANGE

A normal patient should not have any air or fluid in its pleural space.

ABNORMAL FINDINGS

• If air is found, this indicates a pneumothorax.
• If fluid is found, indicating pleural effusion, it can be due to a number of causes, which can often be distinguished from one another by fluid cytology (see Fluid Analysis):
- Transudates, modified transudates, and pseudochylous effusion can be found in patients with heart failure.
- The presence of intracellular bacteria or excessive numbers of neutrophils indicates a pyothorax.
- Chyle may be present and is defined by fluid analysis and comparison with serum.
- Neoplasia may be identified as well, although reactive mesothelial cells can have an appearance similar to neoplastic cells can caution is advised with diagnosis of neoplasia.

CRITICAL VALUES

If air is continuously being produced and removed with the catheter apparatus, or if the fluid is indicative of a pyothorax, a thoracostomy tube should be placed to evacuate the pleural space more effectively.

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure

None known

Conditions That May Interfere with Performing the Procedure

Inadequate sedation will prevent safe and adequate thoracocentesis.

Procedure Techniques or Handling That May Alter Results

• The fluid can be contaminated, invalidating the results of microbial culture, if the fluid is not handled aseptically.
• A fresh slide preparation should always be made, especially if there is delay in evaluating the EDTA sample.

Influence of Signalment on Performing and Interpreting the Procedure

Species
None

Breed
None

Age
None

Gender
None

Pregnancy
None

CLINICAL PERSPECTIVE

• If the clinician is unsure whether the patient has pleural space disease, a diagnostic thoracocentesis should first be performed, especially if the patient is not stable enough for radiography.
• If the results of the diagnostic thoracocentesis are positive, a therapeutic thoracocentesis is recommended if the animal has an increased respiratory effort.
• The catheter technique is safer than using a needle because it decreases the likelihood of lung laceration.
• Samples should be evaluated to guide the clinician on how to treat the patient properly.

MISCELLANEOUS

ANCILLARY TESTS

• Radiography or thoracic ultrasound can determine the need for thoracocentesis and post-procedure can assess the effectiveness of the thoracocentesis and identify underlying pathology.
• Samples should be evaluated using appropriate fluid analysis, including cytologic evaluation. Based on these results, microbial culture of the fluid sample may be appropriate.

TRACHEAL WASH

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection from the lower airway

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
Tracheal wash involves insertion of a catheter into the airway of a dog or cat, injection of sterile saline for culture and cytologic evaluation, and subsequent aspiration of the fluid that has contacted the airway lining. The catheter can be inserted through an oral approach using a sterile endotracheal tube (endotracheal wash [ETW]) or through a transtracheal approach by passing sterile tubing through a catheter that is inserted between tracheal rings (transtracheal wash [TTW]). The catheter terminates at the carina for collection of a global airway sample.

INDICATIONS
Acute or chronic cough.

CONTRAINDICATIONS
- Bleeding disorders.
- Anesthetic contraindications (for ETW).
- Markedly fractious animals (for the transtracheal approach).

POTENTIAL COMPLICATIONS
- Any anesthetic complication.
- Subcutaneous emphysema.
- Pneumomediastinum.
- Hemorrhage.
- Cartilage damage.

CLIENT EDUCATION
- Cough may be transiently worsened after the procedure.
- Subcutaneous emphysema can develop.

BODY SYSTEMS ASSESSED
Respiratory

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
- Preoxygenate the patient for 5 minutes prior to the anesthesia.
- In cats, administer terbutaline (0.01 mg/kg SC) immediately prior to the procedure to counteract bronchoconstriction. Repeat if tachypnea or hemoglobin desaturation develops.
- Dogs with marked expiratory effort might also benefit from administration of terbutaline prior to the procedure, although bronchoconstriction is not a component of their disease.

Anesthesia or Sedation
- Local anesthesia with lidocaine is typically sufficient for a TTW in compliant patients. Mild sedation with acepromazine, butorphanol, or a benzodiazepine can be required. A TTW is a good choice for animals that are poor candidates for anesthesia.
- To perform an ETW, a mild anesthetic protocol that enables intubation and 5–10 minutes of light anesthesia is necessary.

Patient Positioning
Sternal (some clinicians prefer positioning with the most affected side of the lungs ventrally for the transoral approach).

Patient Monitoring
- Pulse oximetry can be used throughout an ETW along with standard anesthetic monitoring.
- If SC emphysema or bleeding develops during a TTW, the procedure should be aborted and stabilization and monitoring procedures instituted.

Equipment or Supplies
- ETW—sterile endotracheal tube, sterile gloves, sterile catheter or tubing, syringes, and sterile saline.
- TTW—local anesthesia (lidocaine), through-the-needle catheter (e.g., Intracath, BD, Franklin Lakes, NJ) or over-the-needle catheter and sterile tubing, syringes, and sterile saline.
- If desired, a three-way stopcock and sterile container (e.g., mucous specimen trap) can be used in conjunction with house suction to facilitate retrieval of fluid.

TECHNIQUE
- A TTW is appropriate for use in dogs larger than 8–10 kg. This can be performed with an over-the-needle catheter (14–16 gauge) and 3.5 French urinary catheter, or a through-the-needle catheter (18 gauge, 8 or 12 inch):
  - The ventral portion of the neck is clipped and lightly scrubbed with antiseptic solution followed by alcohol wipes, and a more complete surgical preparation is performed after local anesthesia.
  - Lidocaine (0.25–0.5 mL, not to exceed 2 mg/kg) is instilled into the subcutaneous tissue down to the level of the tracheal rings.
  - The catheter is inserted into the skin with the bevel of the stylet facing downward. The stylet is withdrawn and the urinary catheter is passed through the short catheter down the trachea.
  - An aliquot of nonbacteriostatic saline (4–10 mL) is injected into the catheter followed by 2–3 mL of air and then aspirated back into the syringe. Stimulation of a cough or chest compression after instillation can facilitate retrieval of a sample.
  - Fluid instillation and aspiration can be repeated 2–3 times until an adequate sample has been retrieved (0.5–1.0 mL is usually sufficient for culture and cytologic evaluation).
  - The long catheter is removed followed by the short catheter and a light wrap is applied to the neck.
  - If a through-the-needle catheter is used, the needle is used to puncture the trachea and then the urinary catheter is fed into the trachea. Once the catheter is entirely within the trachea, the needle is backed out of the skin, and the syringe with saline may be attached to the inserted catheter hub. The remainder of the procedure is as described above.
- An ETW is appropriate for use in large and small dogs, pediatric patients, and in cats. A sterile endotracheal tube and a sterile polypropylene catheter (3.5–8.0 French) or red rubber catheter are needed:
  - The animal is anesthetized with a short-acting anesthetic agent (e.g., propofol or alfaxolone, with premedication).
  - The sterile endotracheal tube is passed into the trachea, taking care to avoid touching the oral mucosa or larynx with the end of the tube in order to limit contamination with oropharyngeal bacteria.
  - An assistant holds the tube in place, and a sterile polypropylene catheter or red rubber tube is passed to the level of the carina (approximately the 4th intercostal space).
  - An aliquot of nonbacteriostatic saline (4–10 mL) is instilled into the airway followed by 2–3 mL of air, and gentle suction from the syringe is used to retrieve the fluid and cells from the lower airway. Alternately, house suction can be utilized with a mucous specimen trap, which can be connected to a tracheal suction catheter with a chimney valve.

SAMPLE HANDLING
Airway samples are submitted for cytologic evaluation and for bacterial culture. Aerobic, anaerobic, and Mycoplasma culture or PCR should be considered for individual cases, and the laboratory should be consulted for guidelines on sample submission. Aerobic culture can generally be submitted in a sterile red-top tube; however, some laboratories require Amies or charcoal medium for *Mycoplasma* culture and an anaerobic culture tube to detect anaerobic bacteria.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring
- Monitor respiratory rate and effort.
- Watch for respiratory distress or appearance of SC emphysema.
- Monitor the TTW site for bleeding or swelling.

TRACHEAL WASH (CONTINUED)

Nursing Care
• Keep the animal quiet during recovery.
• If respiratory distress develops, placement in an oxygen-enriched environment can be helpful.

Dietary Modification
Any animal undergoing a tracheal wash should be fasted for 12–24 hours prior to the procedure, when possible.

Medication Requirements
None

Restrictions on Activity
• The use of leashes should be avoided for 1–3 days after a transtracheal wash.
• Normal activity levels can usually be resumed after 1 day.

Anticipated Recovery Time
1–2 hours

INTERPRETATION

NORMAL FINDINGS OR RANGE
• Normal animals should have ciliated respiratory epithelial cells present on cytologic evaluation and rare inflammatory cells or macrophages.
• Culture of airway fluid in normal dogs and cats can reveal light growth of various types of bacteria, including *Pasteurella*, *Streptococcus*, *Staphylococcus*, *Acinetobacter*, *Moraxella*, *Enterobacter*, *Pseudomonas*, *Escherichia coli*, and *Klebsiella*.

ABNORMAL FINDINGS
• Large numbers of neutrophils or eosinophils.
• Degenerate neutrophils and intracellular bacteria are typically found in infectious processes.
• Abnormal lymphocytes can be suggestive of lymphoma.
• Airway parasites or protozoa may be evident on cytologic evaluation.
• Rarely, neoplastic cells may exfoliate into tracheal wash fluid.
• Infection can be documented by growth of a single species of pathogenic bacteria or by moderate growth of a mixed number of bacterial species.
• Detection of *Mycoplasma* indicates infection.

CRITICAL VALUES
None

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure
• Corticosteroids will reduce the flux of inflammatory cells into the airways.
• Antibiotics will suppress bacterial growth on culture.
• Cough suppressants may make it difficult to obtain fluid from the airways.

Conditions That May Interfere with Performing the Procedure
• Severe tracheal sensitivity and tracheal or airway collapse can be worsened by trauma associated with tracheal wash.
• Airway collapse can result in poor return of fluid.
• In obese animals, a transtracheal wash can be difficult to perform because of an inability to palpate and stabilize the trachea.
• Room temperature saline may induce bronchoconstriction when infused in cats.

Procedure Techniques or Handling That May Alter Results
Upper airway contamination (indicated by the presence of squamous cells or Simonsiella bacteria on cytologic evaluation) influences culture results and increases the likelihood of growth of contaminating bacteria.

Influence of Signalment on Performing and Interpreting the Procedure
Species
• Dogs—TTW or ETW are appropriate, depending on size of the animal and ability to undergo anesthesia.
• Cats—ETW is appropriate.

Breed
• Caution should be employed when undertaking any respiratory procedure in brachycephalic animals.
• The size of animal will influence the decision to perform a TTW vs. ETW.

Age
Young dogs may be more likely to have *Bordetella* and/or *Mycoplasma* on culture than older dogs. Cartilage injury is more of a concern in younger animals.

Gender
None

Pregnancy
None

CLINICAL PERSPECTIVE
Tracheal wash procedures are relatively safe and easy to perform. Results of culture and cytologic evaluation provide valuable information on appropriate treatment of respiratory patients.

MISCELLANEOUS

ANCILLARY TESTS
If results are nondiagnostic, consider bronchoscopy with bronchoalveolar lavage.

SYNONYMS
None

ULTRASOUND-GUIDED MASS OR ORGAN ASPIRATION

BASICS

TYPE OF SPECIMEN
Ultrasonographic

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Percutaneous ultrasound-guided mass or organ aspiration is a technique that is commonly used to obtain material for cytologic examination as an aid in the diagnosis of a disease process:
  - Ultrasonography is typically sensitive but not specific for disease processes, and additional information such as that obtained from cytologic examination of cellular material is often helpful in determining a definitive diagnosis.
  - In addition, because needle placement can be directly visualized in real time, precise placement in an area of interest is possible.
- This procedure is commonly used to obtain cellular material from the liver, spleen, and kidneys with diffuse, infiltrative disease, as well as masses anywhere within the body.
- A prerequisite is that the area to be aspirated must be visible during ultrasonography, and an unobstructed path for the needle trajectory must be identified:
  - If there is gas or bone surrounding a lesion, then ultrasound guidance will likely not be possible.

INDICATIONS
Obtain a cellular or fluid sample for cytologic evaluation to further define or diagnose the etiology of an abnormality in an organ or mass.

CONTRAINDICATIONS
- Coagulopathy.
- Superimposed structures in the path of the needle trajectory.
- Patient noncompliance.
- Inability to visualize the lesion definitively with ultrasonography.

POTENTIAL COMPLICATIONS
- Hemorrhage, which is typically self-limiting unless a major vascular structure is damaged during the procedure or a severe coagulopathy is present.
- Sepsis or peritonitis if an abscess or infected lesion is sampled (rare).
- Possible seeding of neoplasia along the needle tract (rare).

CLIENT EDUCATION
Typically, the client should be apprised of the possible complications, but no additional education is necessary. If general anesthesia is required (because of patient noncompliance or a difficult-to-reach lesion), then typical preparation instructions should be given (e.g., withhold food).

BODY SYSTEMS ASSESSED
- Endocrine and metabolic.
- Gastrointestinal.
- Hemic, lymphatic, and immune.
- Hepatobiliary.
- Musculoskeletal.
- Renal and urologic.
- Reproductive.
- Respiratory.

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
- Withhold food and water as needed if anesthesia or sedation is necessary to accomplish the procedure.
- The skin in the area to be aspirated should be removed of hair (typically using clippers with a no. 40 clipper blade) and aseptically prepared.
- Alcohol may be used as an ultrasound-coupling agent to prevent any artifact that may occur in the cytologic preparation. (Ultrasound coupling gel can cause an artifact if it contaminates the slides during preparation.)
- To verify a safe needle trajectory, ultrasonography should be performed prior to the procedure.

Anesthesia or Sedation
- Some patients will tolerate this procedure without anesthesia, sedation, or the use of local anesthetics. The need for sedation should be anticipated for anxious or painful patients and for intercostal approaches in the abdomen or thorax.
- If anesthesia or sedation is necessary, standard regimens may be used that are appropriate for the patient.
- It should be noted that protocols that cause panting or excessive splenic enlargement may make the procedure more difficult. For example, pure opioids may cause excessive panting and make it difficult to guide the needle into deep or small lesions.

Patient Positioning
Patients should be positioned to enable an unobstructed approach and placement of both the needle and the transducer. Typically, patients will be positioned in lateral or dorsal recumbency, and they should be manually restrained if anesthesia is not used.

Patient Monitoring
None, except as indicated during sedation or anesthesia.

Equipment or Supplies
Typically, a 22-gauge needle of appropriate length attached to a syringe (6 or 12 mL) is used. Small needles (23, 25, or 27 gauge) may be used particularly if hemorrhage is felt to be a significant risk. However, nondiagnostic samples may be obtained with smaller gauge needles.

TECHNIQUE
- There are three methods used to perform a percutaneous ultrasound-guided mass or organ aspiration. In any case, the shortest trajectory between the skin surface and the lesion should be chosen. Only one body cavity should be penetrated at a time. In addition, choice of ultrasound transducer type can affect the ease of performing the procedure. Convex or sector-type transducers usually have a smaller footprint and thus are easier to manipulate when performing this procedure. A linear transducer may be difficult to use because it has a larger footprint:
  - Indirect technique: This technique involves using ultrasonography to identify the lesion to be sampled, and then the transducer is removed and the needle is passed blindly into the structure to be sampled. This technique may be used if the lesion is extremely large, and thus confirmation of needle placement is not necessary.
  - Freehand technique: This is the most commonly employed technique. The needle is held in one hand and the transducer is held in the other. The area of interest should be visualized, and the probe is manipulated such that the lesion is clearly visible. The needle should puncture the skin a few millimeters away from the transducer in order to facilitate needle visualization, as well as to protect against puncturing the transducer. The goal is to pass the needle within the plane of the ultrasound beam so that the needle is visible. Do not pass the needle in a plane perpendicular to the ultrasound plane, because the length will not be visible. The more acute the needle angle is to the ultrasound beam, the more difficult it is to visualize the needle. Therefore, the needle should form at least a 45° angle with the transducer to facilitate its visualization. The needle is passed through the skin and then into the lesion of interest.
  - Guided technique: The needle is held in place by using an attachable guide, which is coupled to the transducer (see Figure 1). The ultrasound machine will have software that will show the projected trajectory of the needle. The area of interest is visualized, and the transducer is manipulated such that the projected path of the needle is superimposed over the area to be sampled. The needle is then passed through the

ULTRASOUND-GUIDED MASS OR ORGAN ASPIRATION (CONTINUED)

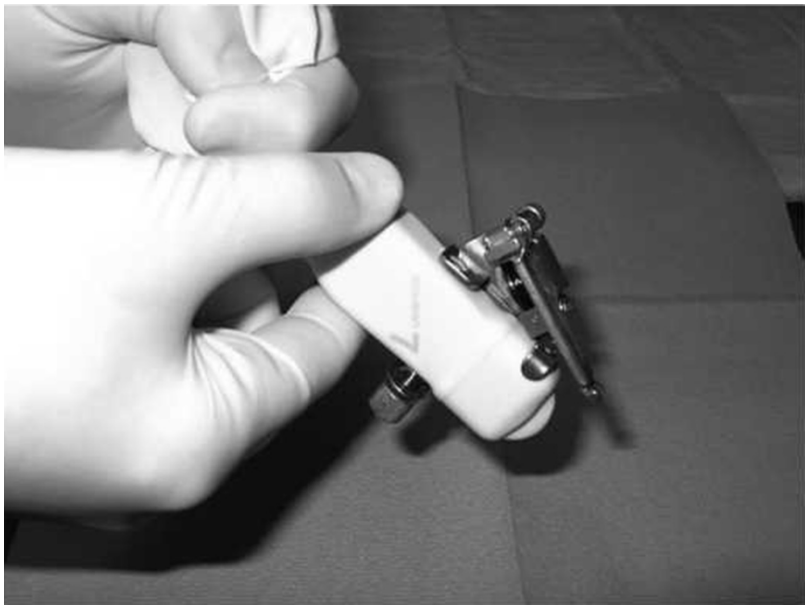

Figure 1.

A transducer with a needle guide attachment in place. The guide will maintain the needle in the plane of the ultrasound beam and, combined with the software program on the machine, will enable specific placement of a needle or biopsy instrument in the area of interest. Source: Lawrence P. Tilley

needle guide attached to the transducer and into the patient.

- If using either the freehand or the guided technique, improved needle visualization may be obtained either by moving the needle slightly, by moving the needle in and out of the tissue, or by minimally adjusting the transducer to bring the needle more into the plane of the ultrasound beam.
- Using any of the aforementioned methods, the sample may be obtained either through direct aspiration with active suction applied to the syringe while the needle tip is in the lesion or through a nonaspiration technique whereby the needle is moved up and down in the area of interest several times before the needle is withdrawn from the patient.
- Any organ or mass can be aspirated by using any of these techniques. If a diffuse disease is suspected in the liver, it is usually best to aspirate the left side of the liver to help prevent possible laceration of the gallbladder. In addition, the spleen is typically sampled by using a nonaspiration technique to help prevent hemodilution of the sample. It may be advantageous to obtain at least 1 sample by using an active aspiration technique and 1 sample by using a nonaspiration technique (in organs other than the spleen) to maximize the chance of obtaining a diagnostic sample. Active aspiration may disrupt fragile cells such as seen in lymphoma:
  - To practice aspiration or biopsy techniques, a biopsy phantom can be created. A biopsy phantom can improve the hand-to-eye coordination necessary to perform these techniques successfully, particularly the freehand technique, which requires more practice for proficiency (see Figure 2).
  - The simplest biopsy phantom uses a heavy plastic bag. (An empty IV saline bag works well.) Culinary gelatin is mixed at double the recommend concentration and poured into the bag. After 15–30 minutes of refrigeration, as the gelatin begins to set, targets are inserted into the middle of the gelatin. (Grapes, cherries, and chickpeas work well.) Care should be taken to not create any air bubbles. The gelatin is allowed to set completely, and then the bag is sealed. The outer surface can then be imaged and a needle passed easily through the bag to the target.

SAMPLE HANDLING

The cytologic sample should be placed onto a microscope slide. Disconnecting the needle from the syringe and filling it with air usually facilitates this (see Fine-Needle Aspiration). The needle is then reattached, and a rapid expulsion of the air in the syringe will force the cellular sample in the hub of the needle onto a microscope slide.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring

The patient should be monitored immediately after the procedure in order to verify that significant hemorrhage is not occurring. This may be more common in patients with ascites. The duration of monitoring is variable depending on the individual patient and its specific problems.

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure
The use of opioids and other drugs that cause splenomegaly should be avoided because they may compromise the procedure.

Conditions That May Interfere with Performing the Procedure
- A lesion that is surrounded by air or bone and cannot be visualized by using ultrasound.
- Patient noncompliance.

Procedure Techniques or Handling That May Alter Results
- Excessive hemodilution or rough handling of the cellular material may result in a nondiagnostic sample.
- If appropriate orientation of the needle with the ultrasound plane is not maintained, the needle might not be visualized in the ultrasound image and inappropriate sampling may occur.
- Fluid within a cavitated mass or cystic lesion may not contain diagnostic cells.

Influence of Signalment on Performing and Interpreting the Procedure
Species

Age
None

Gender
None

Pregnancy
None

CLINICAL PERSPECTIVE
- Percutaneous ultrasound-guided mass or organ aspiration should be used to help further define the etiology of an infiltrative process or mass.
- This procedure is quick and generally safe when performed by an experienced practitioner.
- Both active aspiration and nonaspiration techniques may be necessary to obtain a diagnostic sample.

MISCELLANEOUS

ANCILLARY TESTS
If the cytologic sample is nondiagnostic, then a needle biopsy sample may be obtained by using the same principles as for obtaining a cytologic sample. Typically, sedation or general anesthesia is required for this procedure.

URETHRAL CATHETERIZATION

BASICS

TYPE OF PROCEDURE
Diagnostic sample collection.

PROCEDURE EXPLANATION AND RELATED PHYSIOLOGY
- Urinalysis is part of the minimum database for evaluation of ill dogs and cats and for routine health screening of all patients:
  - Sterile sample collection is required for culture and sensitivity testing of urine when infectious cystitis is suspected.
  - In those cases where cystocentesis is contraindicated or unsuccessful at obtaining urine, urethral catheterization enables sterile urine samples to be collected with minimal risk to patients.
- Patients in need of exact calculation of urine output (e.g., those with anuric or oliguric renal failure), patients with functional or mechanical urethral obstruction, and many recumbent animals often require intermittent or indwelling urinary catheterization as part of their management plan.
- Urethral catheterization is required in order to perform other diagnostic procedures such as prostatic wash, cystourethrography, and voiding or catheter-assisted hydropropulsion of uroliths.

INDICATIONS
- Sterile urine collection when cystocentesis is contraindicated.
- Temporary relief of urethral obstructions.
- Collection of urine for fluid-output determination or metabolic testing (e.g., 24 hour collection of urine for calculation of electrolyte excretion).
- Management of recumbent patients.

CONTRAINDICATIONS
Severe vaginitis or balanoposthitis.

POTENTIAL COMPLICATIONS
- Iatrogenic bacterial or fungal cystitis.
- Urethral trauma (perforations or tears, stricture formation).

CLIENT EDUCATION
None

BODY SYSTEMS ASSESSED
Renal/urologic

PROCEDURE

PATIENT PREPARATION

Pre-Procedure Medication or Preparation
None

Anesthesia or Sedation
- Male dogs typically require minimal to no sedation.
- Female dogs and both male and female cats usually require heavy sedation or anesthesia.
- Hydropulsion of urethral obstructive materials is frequently most successful in a very relaxed animal; in difficult cases, the deepening of sedation or even general anesthesia may allow catheterization.

Patient Positioning
- Male dogs—lateral recumbency.
- Male cats—dorsal recumbency.
- Female dogs and cats—sternal recumbency with their legs tucked underneath or extended over the edge of a table.

Patient Monitoring
None

Equipment or Supplies
- Hair clippers.
- Diluted povidone-iodine (Betadine) or chlorhexidine solution: 1 part povidone-iodine or chlorhexidine solution to ≈200 parts sterile saline.
- A sterile 12-mL syringe.
- Sterile gloves.
- Sterile lubricating jelly.
- Two sets of 4 × 4-inch gauze sponges soaked in sterile saline and chlorhexidine or povidone-iodine solution.
- Povidone-iodine scrub should not be used on the genital mucous membranes.
- A sterile urinary catheter (Foley catheter, red rubber catheter (polyurethane or silicone), tomcat (polypropylene), or slippery sam (polytetrafluroethylene) catheter of appropriate size). If using a Foley catheter, inflate the balloon prior to catheterization to assess for leaks:
  - Polyurethane, silicone, and polytetrafluroethylene catheters are softer and likely to be better tolerated than the stiffer polypropylene catheters for long-term catheterization.
- In female dogs, if the visualization method is being used:
  - A disinfected vaginal speculum.
  - A light source.
- If the urinary catheter will be indwelling:
  - A closed collection system.
  - Materials for anchoring the catheter to the patient (e.g., bandage tape, suture material).

TECHNIQUE

Male Dogs
- For indwelling catheters, clip the hair on the distal one-third of the prepuce. Clipping the hair on the ventral abdomen around the preputial opening to a distance of 2–5 cm may also reduce the risk of iatrogenic infection.
- Flush the prepuce 3–5 times with 2–12 mL of dilute povidone-iodine solution (the volume depends on the size of dog) by using the sterile syringe.
- An assistant should exteriorize the penis. This is best done with the assistant standing at the dog's back (while the animal is in lateral recumbency), and the individual placing the catheter standing at the dog's ventrum.
- Clean the extruded penis with sterile 4 × 4-inch gauze sponges, alternating between chlorhexidine or povidone-iodine solution and sterile saline. A minimum of three scrubs should be performed with each solution.
- Flush the penis with 2–5 mL of dilute povidone-iodine solution.
- After donning sterile gloves, coat the distal catheter with lubricating jelly. Using sterile technique, insert the urinary catheter. The catheter should be gently advanced until urine is seen in the distal end of the catheter. Some resistance may be encountered when the catheter passes around the ischial arch, but gentle pressure is usually sufficient to overcome this. Care should be taken not to advance the catheter too far into the bladder because in rare cases the catheter may knot inside the bladder, making removal difficult.
- For patients with urethral obstruction, pulsative flushing of small volumes (1–2 mL) of sterile saline through the catheter may distend the urethra and retropulse the obstructive material into the bladder, facilitating catheterization.
- Red rubber catheters can be used for indwelling or intermittent catheters in male dogs, but Foley catheters are preferred for indwelling catheters:
  - If a Foley catheter is used, inflate the bulb with sterile saline after the catheter has been advanced to the bladder.
- Immediately connect a sterile, closed collection system to the indwelling catheter.
- Anchor the indwelling catheter as needed to prevent displacement:
  - Most common method is to place bandage tape around the catheter ≈2–4 cm cranial to the preputial opening, with tabs on either side. Sutures are then passed through the tabs and attached to the body wall.

Female Dogs
- Clip the hair around the vulva, including the perineal area, to a distance of 2–5 cm from the vulva.
- Scrub the vulva and perivulvar area with sterile 4 × 4-inch gauze sponges, alternating between chlorhexidine or povidone-iodine solution and sterile saline. A minimum of three scrubs should be performed with each solution.
- Flush the vaginal vault 3–5 times with 2–12 mL of dilute povidone-iodine or chlorhexidine solution (the volume depends on the size of dog) by using the sterile syringe.
- Sterile lidocaine jelly can be flushed into the vulva using a clean, lubricated syringe with the needle removed.
- Visualization technique:
  - After donning sterile gloves, insert the vaginal speculum with its handles pointing

URETHRAL CATHETERIZATION (CONTINUED)

dorsally. The speculum is then advanced dorsally and cranially over the pelvic brim and spread until the urethral papilla and urethral orifice are seen (see Figure 1).
  - Visualization is improved by use of a speculum with an attached light source or a headlamp or by an assistant who stands behind the individual placing the catheter and illuminates the vaginal vault with the light source.
  - The urethral papilla is on the ventral midline of the vaginal floor, distal to the cervix (Figure 1).
  - Coat the catheter with the lubricating jelly and then, using sterile technique, place the urinary catheter. Foley catheters are preferred for indwelling catheters. Red rubber catheters, though they can be used in female dogs, are easier to dislodge than in male dogs because a significantly shorter length of the catheter is inserted. Inflate the balloon if a Foley catheter is used and gently retract the catheter until the balloon is seated in the bladder trigone.
- Digital palpation technique:
  - After donning sterile gloves, lubricate the index finger of the nondominant hand and insert into the vaginal vault, advancing cranially and dorsally over the pelvic brim until the urethral papilla is palpated at the fingertip.
  - Coat the distal catheter with the lubricating jelly and then, using sterile technique, place the urinary catheter. The catheter should be advanced along the ventral aspect of the inserted index finger and then guided into the urethral orifice by palpation.
- A blind placement technique as described below for female cats may be necessary for very small dogs.
- Use of a stylet may increase rigidity of the catheter facilitating placement into the urethral orifice. If a stylet is used it should be kept fully within the catheter to prevent trauma to the urethra.
- For patients with urethral obstruction, pulsatile flushing of small volumes (1–2 mL) of sterile saline through the catheter may distend the urethra and retropulse the obstructive material into the bladder, facilitating catheterization.
- Anchor the urinary catheter to prevent displacement. Bandage tape can be used as described previously for male dogs, suturing the catheter to the body wall ventral to the vulva. Alternatively, if a Foley catheter was used, the balloon will anchor the catheter in the bladder, and the catheter/collection system may be stabilized using tape to the dog's tail, or to an area just above the hock, to avoid fecal contamination and inadvertent removal.

Male Cats

- A coccygeal epidural block may provide analgesia to the perineum, penis and urethra, and can facilitate catheterization in cats with urethral obstruction:
  - With the patient in sternal recumbency, palpate the space on dorsal midline between the sacrum and first coccygeal vertebrae. Moving the tail up and down may help to identify this landmark as the sacrum is immobile but the coccygeal vertebrae will be mobile when the tail is manipulated.
  - Clip the fur over this site and prepare it aseptically.
  - Wearing sterile gloves, palpate and reconfirm the location of the space between the sacrum and the first coccygeal vertebrae. Slowly insert a 25-gauge, 5/8-inch needle on midline at a 30–45° angle into the epidural space.
  - Attach a 1 mL slip-tip syringe and gently aspirate; if blood is aspirated the needle should be removed and repositioned.
  - If no blood is aspirated, slowly infuse 0.1 mL/kg of 2% lidocaine into the epidural space. If the needle was correctly positioned, little resistance should be noted.
  - Following injection, withdraw the needle and assess for relaxation of the rectum and tail.

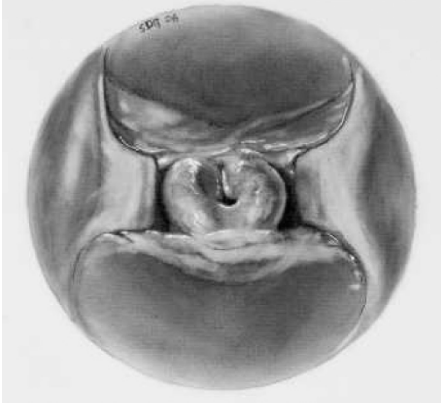

Figure 1.

The vaginal vault of a female dog, as viewed during urethral catheterization. The urethral papilla with central orifice is located on the ventral midline. Source: Lawrence P. Tilley

- A coccygeal epidural block is contraindicated in patients with thrombocytopenia, coagulopathy, hypotension, skin disease at the injection site, or when anatomic abnormalities are present.

• Clip the hair around the prepuce, including the perineal area, to a distance of 1–2 cm from the preputial opening.
• Tomcat catheters (open-ended) can be used for intermittent catheterization; open-ended catheters or catheters with a removable stylet are the preferred catheter for relieving urethral obstruction in male cats. Red rubber catheters or Foley catheters (close-ended) should be used for indwelling urinary catheters.
• An assistant should exteriorize the penis, which is best done with the assistant standing at the cat's head or side (while the animal is in dorsal recumbency).
• Proper exteriorizing of the penis is critical for successful passage of urinary catheters in male cats. Gentle pressure at the base of the prepuce will cause the penis to extrude.
• The penis should be completely exteriorized and pointed caudally, parallel to the spine. Attempting to pass the urinary catheter when the penis is not at the correct angle increases the risk of significant urethral trauma and will prevent the catheter from passing:
  - Clean the extruded penis with sterile 4 × 4-inch gauze sponges, alternating between chlorhexidine or povidone-iodine solution and sterile saline. A minimum of three scrubs should be performed with each solution.
  - After donning sterile gloves, coat the distal catheter with lubricating jelly.
  - Using sterile technique, place the urinary catheter. The catheter should be gently advanced until urine is seen in the distal end of the catheter, taking care not to advance the catheter too far into the bladder.
  - It may be necessary to grasp the prepuce and apply caudal traction while advancing the catheter to straighten the urethra to allow passage.
  - For patients with urethral obstruction, pulsatile flushing of small volumes (1–2 mL) of sterile saline through the catheter may distend the urethra and retropulse the obstructive material into the bladder, facilitating catheterization.
  - If the bladder is already distended due to obstruction, it may be necessary to perform cystocentesis to relieve back pressure and allow infusion of saline and placement of the catheter.
• Immediately connect a sterile, closed collection system for indwelling catheters.
• Anchor the catheter as needed to prevent displacement. In addition to this anchor, red rubber catheters are frequently secured with tape to the cat's tail ≈4–6 cm caudal to the anus.

Female Cats

• Clip the hair around the vulva, including the perineal area, to a distance of 1–2 cm from the vulva.
• Scrub the vulva and perivulvar area with sterile 4 × 4-inch gauze sponges, alternating between chlorhexidine or povidone-iodine solution and sterile saline. A minimum of three scrubs should be performed with each solution.
• Flush the vaginal vault 3–5 times with 0.5–2.0 mL of dilute povidone-iodine solution (the volume depends on the size of cat) by using the sterile syringe.
• Urethral catheterization of female cats is performed blindly.
• After donning sterile gloves, coat the distal catheter with the lubricating jelly. With the cat in sternal recumbency and its legs extended (which is most easily done with the legs allowed to dangle from the edge of a table), the catheter is inserted into the vulva and advanced slowly. The catheter usually enters the bladder without difficulty.
• For patients with urethral obstruction, pulsatile flushing of small volumes (1–2 mL) of sterile saline through the catheter may distend the urethra and retropulse the obstructive material into the bladder, facilitating catheterization.
• Tomcat catheters can be used for intermittent catheterization. Red rubber catheters should be used for indwelling urinary catheters due to the softer material.
• Anchor the catheter as needed to prevent displacement. The most common method is to place bandage tape around the catheter ≈2–4 cm cranial to the vaginal opening, with tabs on either side. Sutures are then passed through the tabs and attached to the body wall.

SAMPLE HANDLING

• Samples collected for urinalysis should be analyzed immediately if possible; refrigeration for later analysis can alter some dipstick and sediment findings.
• Urine samples collected for culture should be refrigerated, ideally in a culture transport vial, until plated onto appropriate media.

APPROPRIATE AFTERCARE

Post-Procedure Patient Monitoring

None

Nursing Care

Indwelling urinary catheters should be kept clean. The external portion of the catheter should be cleaned every 24 hours (or more frequently, as needed) with 4 × 4-inch gauze soaked in chlorhexidine or povidone-iodine solution and sterile saline.

Dietary Modification

None

Medication Requirements

• Prophylactic antibiotics for the prevention of urinary tract infection should not be administered to patients with indwelling urinary catheters. This practice increases the risk of hospital-acquired resistant infections and has not been shown to prevent infection.
• Animals with indwelling urinary catheters should have urine cultured at the time of catheter removal. Bacterial colonization of indwelling urinary catheters is possible, and therefore urine culture results drawn from indwelling catheters should be interpreted with caution.

Restrictions on Activity

Elizabethan collars should be placed on nonrecumbent patients with indwelling catheters.

Anticipated Recovery Time

Immediate

INTERPRETATION

NORMAL FINDINGS OR RANGE

N/A

ABNORMAL VALUES

N/A

CRITICAL VALUES

Urethral obstruction that cannot be relieved by urethral catheterization requires surgical intervention, although deeper anesthesia combined with cystocentesis may allow relaxation and catheterization.

INTERFERING FACTORS

Drugs That May Alter Results of the Procedure

Drugs that increase urethral tone (e.g., phenylpropanolamine, di-ethylstilbestrol) may theoretically make catheterization more difficult. However, this is likely not clinically significant.

Conditions That May interfere with Performing the Procedure

• Urethral obstruction by masses, inflammation, urethrospasm, urethroliths, matrix and mucous plugs, stricture, or extramural masses.
• Pelvic trauma.

Procedure Techniques or Handling That May Alter Results

Loss of sterility or contamination of the catheter during placement predisposes patients to development of iatrogenic urinary tract infection.

Influence of Signalment on Performing and interpreting the Procedure

Species

See the Technique section.

URETHRAL CATHETERIZATION (CONTINUED)

Breed
None

Age
Placement of urinary catheters in neonatal or pediatric patients can be very difficult. Red rubber catheters are ideal because they are less likely to cause iatrogenic trauma during placement.

Gender
See the Technique section.

Pregnancy
None

CLINICAL PERSPECTIVE

- Urethral catheterization is underused as a method for obtaining sterile urine samples, particularly in those patients where repeated cystocentesis attempts are unsuccessful at obtaining a urine sample.
- If urine is being collected for culture, the first 3–10 mL of urine drawn from the catheter should be discarded, after which the sample for culture is collected. This is recommended because the distal urethra and vaginal vault are not sterile environments and often cause some contamination of the catheter tip during placement and because indwelling catheters may have bacterial colonization of the catheter lumen.

URINALYSIS OVERVIEW

BASICS

TYPE OF SPECIMEN
Urine

TEST EXPLANATION AND RELATED PHYSIOLOGY
A urinalysis (UA) is a basic diagnostic screening test that is easy to perform, relatively inexpensive, and can be useful in evaluating renal/urologic and nonrenal conditions. A complete UA includes the following components:
- Physical characteristics: volume, odor, color, transparency, and solute concentration (e.g., urine specific gravity [USG]).
- Chemical characteristics: presence of bilirubin, blood, glucose, ketones, pH, and protein. Some tests available on dipsticks (e.g., urobilinogen, nitrite, leukocytes, esterase, USG) may be unreliable, of no value, or not validated for veterinary species.
- Microscopic evaluation of urine sediment: cells, crystals, casts, organisms, and other (e.g., sperm, lipid, mucus).

INDICATIONS
- UA, part of the minimum data base, is used in conjunction with complete blood count (CBC) and clinical chemistry to establish baseline for initial workup.
- Assessment of kidney function: concentrating ability of solutes (e.g., USG); filtering and resorptive handling of electrolytes, protein, glucose; and response to acid–base imbalance.
- Detection of hemorrhage, inflammation, infection, or neoplasia in the urinary or genital tract.
- Evaluation of systemic disorders or diseases.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
Hemorrhage or inadvertent enterocentesis can occur with cystocentesis.

CLIENT EDUCATION
If an owner collects urine, it should be put into a clean container free of any type of contaminant (e.g., detergents or disinfectants).

BODY SYSTEMS ASSESSED
- Endocrine and metabolic.
- Hemic, lymphatic, and immune.
- Hepatobiliary.
- Musculoskeletal.
- Renal and urologic.
- Reproductive.

SAMPLE

SAMPLE COLLECTION
5–10 mL of urine collected by free catch of a voided sample, manual expression of the urinary bladder, catheterization, or cystocentesis.

SAMPLE HANDLING
- Collect urine into a clean, dry container with a tight-fitting lid and free of potential contaminants (e.g., detergents, disinfectants). It should be labeled with appropriate information (e.g., patient and owner identification; date, time, and method of collection).
- Results are most accurate if urine is analyzed within 30–60 minutes after collection.
- The sample should be refrigerated if a delay in analysis is unavoidable.
- Refrigerated samples should be warmed to room temperature before analysis.

SAMPLE STORAGE
- Refrigeration can slow sample deterioration. The container should protect the sample from light and have a tight-fitting lid.
- Refrigeration may alter some results (e.g., increased crystal formation).
- Avoid freezing the urine because this will affect certain tests (e.g., urine sediment examination).
- Preservatives generally adversely affect chemical assays. No single preservative suits all testing requirements.

SAMPLE STABILITY
Components analyzed in urine sediment (i.e., cells, casts, crystals, bacteria) deteriorate rapidly (within 2–4 hours). Over time, CO_2 is lost from the stored sample, increasing pH, and bilirubin may degrade with exposure to light or spontaneously oxidize (stable for up to 12 hours refrigerated). Most other chemical tests are stable for 12 hours in a refrigerated sample.

PROTOCOL
- Mix the sample and transfer it to a centrifuge tube.
- Evaluate the physical features of the urine (i.e., volume, odor, color, turbidity).
- Determine the USG by using a refractometer.
- Measure urine analytes by using a reagent strip:
  - Immerse a reagent strip into well-mixed, room-temperature urine and turn the strip on its side, tapping away excess urine.
  - Examine the color change of each analyte at the time indicated by the manufacturer and compare the color change to the reference chart.
  - Confirmatory tests are affected less by urine color and may be warranted to confirm specific dipstick analyte results. Such tests include the Ictotest® (Siemens, Tarrytown, NY) for bilirubin, the K-CHECK® (Biorex Labs, Cleveland, OH) for ketones, and sulfosalicylic acid test (SSA) for protein.
  - Automated dipstick readers are available.
- Centrifuge the sample for 5–10 minutes at low RPM in a conical tube:
  - Ideally, the same volume of urine should be centrifuged each time, and reference values are based on 5 mL of urine. Analysis of smaller urine volume should be noted on the final report because that can result in less sediment.
  - The recommended RPM is quite variable (500–3,000 RPM) because it is actually gravitation force (*g*-force) that is important. A *g*-force of 450×*g* is recommended. See Internet Resources for a conversion program between RPM and *g*-force.
  - Excessively high-speed centrifugation can distort cells or fragment fragile elements such as casts.
- Use urine supernatant to measure protein by the SSA method. If urine is bloody or extremely cloudy, double check the USG by using supernatant.
- Decant the supernatant, leaving ≈0.5 mL of urine sediment.
- Resuspend the sediment and transfer a drop to a microscope slide.
- Coverslip and examine the sample microscopically at 10× and 40× (see Urine Sediment).

INTERPRETATION

NORMAL FINDINGS OR RANGE
- Fresh urine should be relatively clear, yellow, and have a slight ammonia odor. Intact male cat urine may have a strong odor.
- The USG should be evaluated based on the hydration status. In general, the urine concentration from a random urine sample is considered adequate if the USG is >1.035 and >1.040 in dogs and cats, respectively, although USG can vary significantly depending on the state of hydration in normal animals.
- Normal urine should have a pH between 6.0 and 7.5, and should be negative for protein, ketones, blood, bilirubin, and glucose. Some dogs with highly concentrated urine may show a trace to 1+ reaction for bilirubin and/or protein.

URINALYSIS OVERVIEW (CONTINUED)

• Urine sediment should contain few cells and crystals and no casts. Lipid is seen occasionally in cat urine.

ABNORMAL FINDINGS

• USG should be greater than 1.030 in patients with azotemia. Consistently isosthenuric urine in non-azotemic animals may reflect renal or nonrenal disease. Hyposthenuria (USG <1.008) indicates an inability to concentrate secondary to a nonrenal disease (e.g., diabetes insipidus) because a functional kidney must be present to dilute the urine below isosthenuria.
• Urine pH should mirror the blood pH; in academic patients with alkaline urine, consideration should be given to urinary bicarbonate loss (renal tubular acidosis) or urinary tract infection with urease-producing bacteria. Many drugs and prescription diets can either raise or lower the urinary pH, and a complete history should be taken to put urinalysis results into context.
• Urine glucose may be elevated due to persistent or paroxysmal hyperglycemia (see Hyperglycemia), and should be interpreted in concert with the serum glucose. Some renal tubular defects will also result in persistent glucosuria without hyperglycemia (e.g., Fanconi's syndrome).
• Urine ketones will be elevated in states of ketonemia, (e.g., diabetic ketoacidosis, starvation). Because the strip only detects acetoacetate and acetone, animals with beta-hydroxybutyrate ketonemia may generate a negative test.
• Urine protein in urine with inactive sediment may be indicative of glomerular or renal tubular disease or hereditary glomerulopathy. Proteinuria is an appropriate condition accompanying urinary tract inflammation or infection. Proteinuria in inactive urine samples should be further investigated through the measurement of a urine protein:creatinine ratio.
• Urine bilirubin is found in concentrated canine urine samples in small amounts, but should not be found in dilute canine urine or feline urine. Its presence generally indicates elevated serum bilirubin concentration and may be due to any systemic causes of hyperbilirubinemia (hepatic, prehepatic, or posthepatic).
• Urine heme protein is positive in the presence of hemoglobin, myoglobin, or red blood cells, and as such may indicate systemic disease or hemolysis, or urinary tract hemorrhage, which can result from thrombocytopenia, neoplasia, or cystitis, among other conditions. Pigmenturia may be differentiated from hematuria through centrifugation of a urine sample, wherein the red blood cells will be pelleted, while pigment will remain in the supernatant.

CRITICAL VALUES

Variable depending on assay; diabetic ketoacidosis requires emergency care, and animals with significant proteinuria and azotemia may be at risk for complications associated with protein-losing nephropathies. Pigmenturia/hematuria may be indicative of life-threatening coagulopathy, hemolysis, or other diseases associated with anemia or muscle damage (e.g., heat stroke, crotalid envenomation).

INTERFERING FACTORS

Drugs That May Alter Results or Interpretation

Drugs That Interfere With Test Methodology

Certain drugs or metabolites excreted into the urine may impart characteristic odors. Hydroxethyl starch and radiographic contrast agents can alter USG measurements; radiographic contrast agents can also interfere with some biochemical analytes or cause crystal formation. Cephalexin, tetracycline, and vitamin C therapy may be associated with false-positive readings for urine glucose.

Collection Techniques or Handling That May Alter Results

• Method of collection can influence findings:
  ◦ Voided and free catch samples or samples obtained by manual expression contain components from lower urogenital tract and may have increased bacteria, epithelial cells, or leukocytes.
  ◦ Cystocentesis samples may be contaminated with iatrogenic hemorrhage.
  ◦ Samples from catheterization can contain increased bacteria, and/or epithelial cells, reflect iatrogenic hemorrhage, or be contaminated with lubricant.
  ◦ Samples obtained from a surface (e.g., floor, examination table, cage) may contain bacteria, debris, or other environmental contaminants.
• Reagent strips should be stored at room temperature in the original container; protected from excessive light, moisture, and heat; not used past the expiration date; and discarded if any of the pads on the strips are discolored.

LIMITATIONS OF TEST

• The ketone reagent pad is only sensitive for detecting acetoacetate and acetone, so if a patient has beta-hydroxybutyrate ketonuria, this will not be detected, but can be measured in the blood using hand-held devices (See Diabetes Mellitus with Ketoacidosis).
• Pigmenturia of any cause may interfere with reading the colorimetric results.

Valid If Run in a Human Lab?

Yes.

MISCELLANEOUS

ANCILLARY TESTS

Urine protein:creatinine (UPC) ratio is indicated if proteinuria is observed with an inactive sediment (i.e., no hematuria, pyuria, or bacteriuria).

ABBREVIATIONS

• SSA = sulfosalicylic acid.
• UA = urinalysis.
• UPC = urine protein:creatinine ratio.
• USG = urine specific gravity.

URINE SEDIMENT

BASICS

TYPE OF SPECIMEN
Urine

TEST EXPLANATION AND RELATED PHYSIOLOGY
- Microscopic evaluation of urine is recommended on every urine sample, even when physical characteristics or the results from a urine dipstick are unremarkable.
- Components evaluated include cells, crystals, casts, organisms, and other elements (e.g., lipid, mucus):
  - Erythrocytes can enter the urine anywhere in the urologic tract (i.e., kidneys, ureters, bladder, urethra) or genital tract.
  - Neutrophils are the common leukocyte found in urine, but macrophages and lymphocytes can also be present.
  - Epithelial cells include renal tubular cells, transitional cells, and squamous cells. Neoplastic cells are sometimes detected.
  - Formation of crystals depends on urine pH and concentration (i.e., urine specific gravity [USG]) and the presence of oversaturated crystalogenic substances.
    - Diet and some drugs may also influence crystal formation.
    - The presence of crystals suggests an increased risk of urolithiasis, but it does not predict which animals may actually form uroliths or the type of urolith that may form.
  - Casts originate in the tubular lumen and are composed of mucoprotein, cells, and cellular debris. The presence of casts may indicate renal proteinuria (hyaline) or tubular degeneration (cellular and/or granular).

INDICATIONS
- Microscopic examination of urine sediment is part of a routine urinalysis (UA).
- Many of the chemical results (e.g., urine heme protein, protein) should be interpreted in conjunction with the sediment findings.
- Part of the workup in an animal exposed to a nephrotoxic substance or in those with stranguria or pollakiuria.

CONTRAINDICATIONS
None

POTENTIAL COMPLICATIONS
None

CLIENT EDUCATION
Urine sediment is critical in diagnosing urinary tract infections.

BODY SYSTEMS ASSESSED
- Hemic, lymphatic, and immune.
- Hepatobiliary.
- Renal and urologic.

SAMPLE

SAMPLE COLLECTION
- 5–10 mL of urine collected by free catch of a voided sample, manual expression of the urinary bladder, catheterization, or cystocentesis. The method of collection may affect sediment makeup.
- It is important that a consistent volume of urine is used for sediment evaluation. This will enable findings to be semiquantitative and compared with reference values, and enable monitoring of the animal's response to treatment.

SAMPLE HANDLING
- Collect the urine into a clean container free of additives, detergents, and chemicals.
- Ideally, the assay should be performed within an hour after collection.

SAMPLE STORAGE
- Refrigeration can aid in slowing cellular breakdown, but it enhances crystal formation. If refrigerated, sample should be warmed to room temperature before analysis.
- Do not freeze the urine.

SAMPLE STABILITY
Components analyzed in urine sediment (i.e., cells, casts, crystals, bacteria) do not hold up well in urine. Cells may lyse, and casts can break down. Crystals can dissolve or new crystals may form. Bacteria may die or multiply:
- Casts begin to deteriorate within 2 hours.
- Cells can lyse or lose morphologic characteristics within 2–4 hours, depending on urine osmolality.

PROTOCOL
- A standard volume of urine (usually 5 mL) is centrifuged at a slow speed.
- The supernatant is removed and saved for biochemical or other tests.
- The pellet is gently resuspended in a small amount of urine (≈1 mL), and a small drop is placed onto a glass slide with a coverslip.
- Microscopic examination is done at a low magnification (10× objective; low-power field [LPF]) and a high magnification (40× objective; high-power field [HPF]) with the condenser of the microscope lowered so that contrast is increased.
- Several components are quantified by the number per LPF (i.e., casts) or HPF (i.e., cells).
- Other components such as crystals, bacteria or other organisms, lipid, and mucus are either graded as present or absent or graded on a few (1+), moderate (2+), or many (3+) scale.
- Staining the urine sediment with a commercial, water-based stain or new methylene blue before examination may aid in identifying constituents and accentuate cellular detail.
- A cytologic preparation of urine sediment can be made by smearing a drop of sediment on a slide, allowing it to air-dry, and staining it with routine hematologic stains. This technique is useful in evaluating cells and identifying bacteria or other organisms.

INTERPRETATION

NORMAL FINDINGS OR RANGE
- Urine sediment is usually inactive, containing few microscopically visible components, but it is not uncommon to find low numbers of cells or certain types of crystals, depending on method of collection.
- The following may be seen in urine from healthy dogs or cats:
  - WBCs: <2–5/HPF.
  - RBCs: <2–5/HPF.
  - Epithelial cells: <2/HPF.
  - Casts: none or at most a few that are hyaline or granular.
  - Crystals: amorphous phosphate, bilirubin (dogs), calcium oxalate dihydrate, calcium phosphate, and struvite are common in healthy animals. Ammonium biurate, sodium urates, and uric acid crystals are occasionally seen in urine from healthy animals.
  - Bacteria: usually none. Low numbers occasionally are seen in voided samples with genital tract contamination or samples taken from floors, tabletops, or litterboxes.
  - Sperm (intact males).

ABNORMAL FINDINGS
The following are considered abnormal in dogs or cats:
- WBCs: >5/HPF.
- RBCs: >5/HPF.
- Epithelial cells: >5/HPF.
- Casts: the presence of > 1–2/LPF (hyaline, granular) or any cellular (epithelial, RBC, WBC), waxy, fatty, and/or broad casts.
- Crystals: the presence of calcium oxalate monohydrate, ammonium biurate, bilirubin, cholesterol, cystine, leucine, tyrosine, sodium urate, and/or uric acid (see Table 1).

CRITICAL VALUES
None

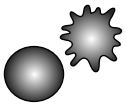
INTERFERING FACTORS
Drugs That May Alter Results or Interpretation
Drugs That Interfere with Test Methodology
Acidifiers or alkalinizers may modify crystal formation and composition.

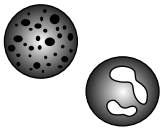
Drugs That Alter Physiology
Sulfadiazine and metabolites, ampicillin, allopurinol, and radiopaque contrast agents

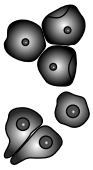
URINE SEDIMENT (CONTINUED)

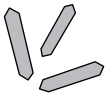
Table 1

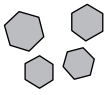
Causes of abnormal findings.

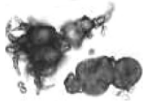


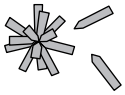












Element	*Reference Interval With Lesion Location*	*Etiology*
Cells		
RBCs (hematuria)	<2–5/HPF	May be normal
	>5/HPF	Bleeding or vascular damage associated with glomeruli or tubules, calculi, renal vein thrombosis, vascular dysplasia, trauma, infarct, inflammation, or infection
	Renal	
	Lower urinary tract	Acute or chronic infection, calculi, neoplasia, or hemorrhagic cystitis Voided urine sample from animals in estrus
	Genital tract	
	Iatrogenic	Vessel damage from cystocentesis or catheterization
	Coagulopathy	Thrombocytopenia, thrombocytopathia, von Willebrand disease, or hereditary or acquired coagulopathies
WBCs (pyuria)	<2–5/HPF	May be normal
	>5/HPF	Inflammation from noninfectious causes: pyelonephritis/nephritis, urolithiasis (calculi), neoplasia, or necrosis
	Renal	Inflammation from infectious causes: pyelonephritis/nephritis, bacteria, fungal, or parasitic
	Lower urinary tract	Acute or chronic cystitis (infectious or noninfectious), calculi, neoplasia Voided urine sample with contamination from the prostate, prepuce, or vagina
	Genital tract inflammation	
Epithelial cells	Squamous epithelial cells	Insignificant finding in voided or catheterized samples
	Transitional cells	May be normal or artifact of collection method
	<2/HPF	Hyperplasia secondary to inflammation, infection, or irritation, or due to cyclophosphamide administration
	>5/HPF	
	Neoplastic cells	Transitional cell carcinoma cells occasionally found in urine; caution advised if cellular atypia noted in the presence of inflammation (may be difficult to differentiate hyperplasia from neoplasia)
Crystals (crystalluria)	Type of crystal and typical conditions	Etiology
	Urine pH acidic or neutral	
	Amorphous urate	Formed from yellow precipitates of sodium, potassium, magnesium, or calcium urate salts; normal in dalmatians and English bulldogs; also seen with liver disease or portal vascular anomalies
	Bilirubin	May be seen in healthy dogs, common in dogs with bilirubinemia or abnormal bilirubin metabolism, and uncommon in cats
	Calcium oxalate monohydrate	Common with ethylene glycol toxicosis
	Calcium oxalate dihydrate	Found in healthy dogs and cats, found in animals with uroliths composed mostly of calcium oxalate, and occasionally seen with ethylene glycol toxicosis
	Cystine	Rare; congenital renal tubular defect in reabsorption of cystine from the renal filtrate; cystinuria may result in cystine store for formation
	Sodium urate	May be seen concurrently with ammonium urate crystals Associated with sulfonamide administration
	Sulfa	
	Uric acid	Considered normal in dalmatians and English bulldogs, rarely seen in other healthy animals, and can be seen with liver disease or portal vascular anomalies
Urine pH alkaline and/or neutral		
	Ammonium urate (ammonium biurate)	Portosystemic shunts or hepatic diseases with hyperammonemia, can be seen rarely in healthy animals but are common in dalmatians and English bulldogs
	Amorphous phosphate	Amorphous form of calcium phosphate crystals that resemble amorphous urates; may be

Table 1

Causes of abnormal findings (*Continued*)

Element	*Reference Interval With Lesion Location*	*Etiology*
	Calcium phosphate	Seen in healthy dogs and in dogs with persistently alkaline urine or with calcium phosphate uroliths
	Struvite (triple phosphate)	Common in cats and dogs with alkaline urine; composed of magnesium, ammonium, and phosphorus
Other crystals		
	Ampicillin	Associated with ampicillin administration
	Cholesterol	Uncommon; associated with cellular membrane deterioration, occasionally seen with some renal diseases, and may be seen in healthy dogs
	Leucine	Rare, ingestion of food contaminated with melamine
	Melamine	Rare; may suggest liver disease
	Tyrosine	Rare in dogs; can be associated with liver disease
	Xanthine	Rare; may be seen in animals treated with allopurinol
Casts (cylinduria)	Type of cast	Etiology
	Hyaline	A few can be normal with concentrated urine; >1–2/LPF associated with renal causes of proteinuria
	Cellular WBC	Associated with tubular inflammation, infection (e.g., bacterial pyelonephritis, leptospirosis), or acute tubular necrosis
	Epithelial	Associated with degeneration/necrosis of tubules (e.g., ischemia, toxins, infarct)
	RBC	Rare; associated with hemorrhage into tubules
	Granular	A few can be normal with concentrated urine; >1–2/LPF associated with degeneration/necrosis of tubules (e.g., ischemia, toxins, infarct)
	Fatty	Common in cats with renal tubular degeneration
	Waxy	Associated with chronic degeneration/necrosis of tubules (e.g., ischemia, toxins, infarct)
Bacteria (bacteriuria)		Infection of the urinary tract, infection of the genital tract (voided sample), *in vitro* growth with delayed sample analysis, or contamination (voided and some catheterized samples)
Other organisms	Yeast	Often Candida spp.
	Fungi (hyphae or budding)	Blastomyces spp., Cryptococcus spp., or Aspergillus spp. (German shepherd dogs can have a disseminated infection)
	Nematode ova	Dioctophyma renale or Capillaria plica
	Microfilariae	Seen with significant hematuria
	Algae	Prototheca spp. (dogs can have disseminated infection)
Lipids		No clinical significance; may be normal; a common finding in cats
Mucus		Genital secretions, suggestive of urethral irritation; mucous strands may form linear structures resembling casts
Contaminants	Pollen grains	Occasionally found in urine sediment, not significant but may be potentially confused with other constituents
	Sperm	

URINE SEDIMENT (CONTINUED)

(uncommon) have been associated with crystal formation in dogs and cats.

Disorders That May Alter Results

- Casts and cells, especially RBCs, may lyse in poorly concentrated (USG <1.008) or alkaline urine, especially if a sample is several hours old.
- RBCs usually are crenated in highly concentrated urine. This may cause difficulties with identification.

Collection Techniques or Handling That May Alter Results

- Voided samples may contain more cells, have bacterial contamination, or contain material from the genital tract.
- Catheterized samples may contain more RBCs or epithelial cells (transitional or squamous cells) or be contaminated with lubricant.
- Samples obtained by cystocentesis generally have the least potential of contamination but may contain increased RBCs if blood vessels are damaged during urine collection. Inadvertant enterocentesis is uncommon but can occur.
- Refrigeration enhances crystal formation.
- The use of certain urine preservatives may cause in vitro formation of tyrosine-like crystals.
- The use of stain can dilute sediment, lowering counts, and may introduce crystals and/or organisms (i.e., bacteria, yeast) that grow in stain.

Influence of Signalment

Species

- Lipid droplets are common in cats and are of no clinical significance.
- Low numbers of bilirubin crystals are sometimes seen in concentrated urine from healthy dogs.
- Cystinuria with cystine crystal formation is more common in dogs but occurs rarely in cats.

Breed

- Uric acid and ammonium biurate crystals are common in Dalmatians and English bulldogs.
- Cystinuria with cystine crystalluria has been reported in many breeds of dogs, including dachshunds, Newfoundlands, English bulldogs, Scottish deerhounds, mastiffs, and Scottish terriers.

Age

None

Gender

Sperm may be found only in the urine from intact males or recently bred intact females.

Pregnancy

None

LIMITATIONS OF TEST

- Crystals that form *in vitro* have no clinical significance.
- The number of casts is not an indication of the severity, duration, or potential reversibility of the underlying disease. The type of cast rarely denotes a specific diagnosis.
- A normal sediment does not rule out some type of urinary tract disease.

Sensitivity, Specificity, and Positive and Negative Predictive Values

N/A

Valid If Run in a Human Lab?

Yes.

CAUSES OF ABNORMAL FINDINGS

See Table 1.

CLINICAL PERSPECTIVE

- Urine sediment examination should always be part of a routine UA, even if physical and chemical characteristics are unremarkable.
- A standard volume of urine used for sediment examination should be established.
- Chemistry results (e.g., heme protein, protein) should be interpreted with knowledge of urine sediment.
- The urine pH can affect the type of crystals present, and the USG can affect urine sediment.
- The presence of crystals does not necessarily indicate the presence of a urolith, although high concentrations of crystals may predispose an animal to urolith formation. Clinical signs and hematuria may help identify those animals with uroliths.
- Cocci are difficult to identify unless in chains: Brownian movement of tiny particles of debris may resemble cocci. Suspected cocci should be verified by Gram staining an air-dried smear of sediment. Cocci will appear deep purple with a Gram stain, whereas debris/protein will be pink or perhaps colorless.
- Some sediment abnormalities (e.g., casts) can be an early sign of nephrotoxicity seen prior to the onset of serum chemistry abnormalities.
- The absence of pyuria or a failure to detect bacteria does not exclude an occult urinary tract infection. This is particularly common in conditions associated with dilute urine, such as diabetes mellitus and hyperadrenocorticism.

MISCELLANEOUS

ANCILLARY TESTS

- Serum biochemical profile.
- CBC.
- UA (including heme, protein, USG, pH).
- Urine culture.
- Urolith analysis.
- CadetBRAF assay (Antech diagnostics): if urinary tract neoplasia is suspected.

SYNONYMS

None

protein-losing enteropathy, 849, 1136
ptyalism, 1146
quadrigeminal cyst, 1177
seizures, 1227
spinal dysraphism, 1276
syringomyelia and Chiari-like malformation, 1312
tracheal collapse, 1348
urethral prolapse, 1365
urolithiasis/crystalluria, 348, 970, 1372, 1383
vomiting, 1426
Yucca schidigera, 537
Yugoslavian shepherd, lysosomal storage disease, 689
Yunnan baiyao
for hemangiosarcoma, 594, 597, 599
for nasal adenocarcinoma, 33
for pericardial disease, 1060

Z

Zaleplon toxicosis, 169
Zamia floridana, 1213
Zantedeschia spp., 775
Zeniquin. *See* Marbofloxacin
Zidovudine, 507, 515
Zinc
  for chronic hepatitis, 624–625
  for cirrhosis and fibrosis of liver, 281
  for copper associated hepatopathy, 330, 331
  for flatulence, 537
  for glucagonoma, 569
  for halitosis, 579
  for hepatic encephalopathy, 613
  for hepatocutaneous syndrome, 635
  for superficial necrolytic dermatitis, 1306
Zinc-responsive dermatosis (zinc deficiency), 372–373, 376
  blepharitis, 182
  nasal involvement, 956
Zinc toxicosis, 1437
Zoledronate, 29, 204
Zolpidem toxicosis, 169
Zonisamide
  for genetic epilepsy in dogs, 454–455
  for hepatic encephalopathy, 613
  for meningioma, 892
  for meningoencephalomyelitis of unknown origin, 898
  for quadrigeminal cyst, 1177
  for seizures/status epilepticus, 1226
  for subarachnoid cysts, 1303
Zygomatic mucocele/sialocele, 1002, 1214, 1215
Zylkene. *See* Alpha-casozepine
