Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

The goal of this first edition of *Canine and Feline Infectious Diseases* was to provide a text for veterinary students and clinicians with a strong clinical emphasis. Authorship has been limited to veterinarians who have had direct and considerable clinical experience with diagnosis and treatment of the diseases described. The chapters have been presented in a consistent and logical format with extensive use of tables, photographs, and line drawings, so that veterinarians and students can quickly find answers to questions they have that relate to infectious diseases in dogs and cats.

Organization

This book contains two parts and eight sections. The first part, *Basic Principles in the Diagnosis and Management of Small Animal Infection*, contains three sections: Laboratory Diagnosis of Infectious Diseases, Antiinfective Therapy, and Basic Principles of Infection Control. The second part, *Major Infectious Diseases and their Etiologic Agents*, systematically discusses specific infectious diseases of dogs and cats in a way that is practical and relevant to the veterinary clinician.

The first section, *Laboratory Diagnosis of Canine and Feline Infectious Diseases*, is co-authored by a small animal clinician and a clinical microbiologist. It aims to help practicing veterinarians select the best type of test for detection of an infectious disease, collect the most appropriate specimens for testing, optimally transport specimens to the laboratory, and most importantly, to interpret test results properly. The second section, *Antiinfective Therapy*, is co-authored by a clinician and a veterinary pharmacologist. The goal of this section is to help veterinarians use first principles to select the most appropriate drug for treatment of a suspected or confirmed infectious disease, understand the mechanisms of action and adverse effects of various antimicrobial drugs used in practice, and utilize treatment regimes that minimize development of antimicrobial resistance. The third section, *Basic Principles for Infection Control*, is co-authored by veterinary clinicians who have extensive practical experience with infectious disease control in veterinary hospitals. Practical protocols for the management of canine and feline patients suspected to have infectious diseases are provided, including handling, disinfection, isolation, and vaccination protocols.

The second half of this book addresses specific infectious diseases of dogs and cats, which are grouped into viral, bacterial, fungal, and protozoal diseases (Sections 1 through 4) as well as clinical syndromes (Section 5). A summary box at the beginning of the chapter provides an overview of the disease or diseases covered. Each chapter contains information on etiology and epidemiology, clinical signs and their pathogenesis; physical examination abnormalities, diagnosis, treatment and prognosis, immunity and vaccination, prevention, and public health implications. Some information on the equivalent disease in humans is provided whenever pertinent. Where relevant, maps and life cycle drawings are included, and chapters are illustrated with photographs of case material. All chapters contain a table that summarizes the performance, advantages and disadvantages of the major diagnostic assays available for each disease, and many chapters also contain a table that provides antimicrobial drug treatment recommendations and dosing. Key statements in the text are referenced in case the reader desires additional background information, although provision of an exhaustive list of references is not in the scope of this book. A few suggested readings are provided.

One (and occasionally two) case example(s) can be found in a standard format at the end of almost all of the chapters in the second half of the book. These cases are designed to emphasize key epidemiological and clinical aspects of the disease, the application of diagnostic assays, treatment, and prognosis. The cases were seen at the authors' institutions, and many include the results of full laboratory assessments, radiology, cytology, and histopathology reports. Unless otherwise specified, all urinalyses and urine cultures were performed on specimens collected by cystocentesis, and all thoracic radiographic studies consisted of left and right lateral and ventrodorsal views. Abdominal ultrasound examinations consisted of complete studies of intraabdominal structures. Because these are "real-world" examples, diagnosis, management, and outcomes are not always perfect or ideal. Nevertheless, this can provide insight into real-life problems that may confound accurate diagnosis and management of the disease, such as misdiagnosis when an infectious disease resembles other infectious or non-infectious diseases on the differential diagnosis list. Other problems illustrated include limitations of the sensitivity or specificity of diagnostic tests used, or hurdles imposed by the availability of client financial resources. A comment section at the end of the case provides the author(s') perspective on the case. It should be recognized that infectious diseases can vary widely in their clinical presentation and response to treatment, so each case just provides one "view" of the infectious disease described in the chapter.

Jane E. Sykes

Acknowledgments

I am incredibly grateful to the huge number of veterinarians, residents, and veterinary students worldwide who have encouraged me to write and edit this book. I would particularly like to acknowledge all of my colleagues at the University of California, Davis, who over the years provided a large number of the carefully collected and valuable images in this book. Special mentions go to Barbara Byrne, Patricia Pesavento, and Eileen Samitz who spent much additional time to prepare or provide material for photography for this book.

I would like to acknowledge the illustrator for the book, Ted Huff, who has performed the amazing task of converting a large number of complicated maps and life cycle drawings into crisp, clean diagrams that are easy to understand and remember. I have also been fortunate to work with a phenomenal team at Elsevier who were consistently encouraging, efficient, and made every effort to be accommodating. I would like to thank my internal medicine and infectious disease colleagues worldwide, many of whom contributed to chapters for this book, for inspiring me to have a passion for the study of small animal internal medicine and infectious diseases. Last but not least I would like to acknowledge my family, who cheered me on the whole way.

SECTION 1

Laboratory Diagnosis of Canine and Feline Infectious Diseases

Jane E. Sykes and Shelley C. Rankin

CHAPTER 1

Isolation in Cell Culture

Jane E. Sykes and Shelley C. Rankin

KEY POINTS

- With the increasing availability of nucleic acid–based testing, cell culture is decreasingly used for diagnosis of infections caused by obligate intracellular pathogens in dogs and cats.
- Cell culture remains an important technique for (a) confirmation of a diagnosis when the results of molecular testing or serology are unavailable or equivocal; (b) pathogen discovery; and (c) vaccine manufacture. For some pathogens, cell culture is the most sensitive and specific method for organism detection.
- Before collection of specimens, veterinary clinicians should communicate with the laboratory that is to perform the culture to discuss the patient signalment, history, immune status, travel history, nature of the suspected infection, and number of animals affected.
- Specimens are inoculated onto monolayers, and the infecting organism is identified based on the presence of characteristic cytopathic effect after a predictable incubation period, with or without confirmatory antigen staining, electron microscopy, or nucleic acid testing.
- False-negative results may occur as a result of inadequate specimen collection, deterioration of organisms during transport, or culture contamination with bacteria or fungi.
- Positive results do not imply that the organism detected is the cause of an animal's signs, because some organisms can be present without causing disease. This is especially the case for animals with respiratory or gastrointestinal disease.

INTRODUCTION

Cell culture refers to the culture of nucleated (eukaryotic) cells under controlled conditions within the laboratory. Infectious agents that require living host cells for replication can only be isolated in cell culture. With the advent of molecular diagnostic assays based on nucleic acid detection, cell culture is being used less often for routine clinical diagnostic purposes, because of the long turnaround times (days to weeks), cost, and requirement for significant technical expertise to perform cell culture and interpret results (Table 1-1). Nevertheless, isolation of viral and intracellular bacterial and protozoal pathogens in cell culture remains an important technique for the discovery of new pathogens, identification of organisms involved in disease when the results of molecular testing or serology are unavailable or equivocal, the propagation of isolates for research purposes, the generation of organisms for vaccination purposes, and the establishment of the efficacy of novel antimicrobial drugs. Vaccines for dogs and cats that are propagated in cell culture include those for canine distemper, canine adenovirus infections, parvovirus infections, rabies, and feline viral and chlamydial respiratory tract disease. Veterinary clinicians should remain aware of situations where cell culture may be the best technique to identify the presence of an infectious agent and the optimum methods for collection and submission of specimens. Knowledge of cell culture methods can help veterinary clinicians to submit the optimum specimens and to understand laboratory turnaround times, potential complications, and how to interpret results.

Specimen Collection and Transport

Although cell culture can be used to propagate intracellular bacteria and protozoa, it is most often used by clinicians for the diagnosis of viral infections. Active communication between the clinician and the laboratory that performs viral isolation is recommended. Successful detection of viruses is highly dependent on (a) collecting the appropriate specimens, (b) the timing of specimen collection, and (c) rapid and proper specimen

Ehrlichia canis	PCR, antibody detection

CSF, Cerebrospinal fluid; IFA, fluorescent antibody; IHC, immunohistochemistry; PCR, polymerase chain reaction; RT, reverse transcriptase.

transport and processing. Thus the actions of the veterinary clinician play a critical role in ensuring positive test results when a virus is present.

The clinician should discuss with the laboratory what types of viruses are suspected in light of the animal's clinical presentation. The patient signalment, history, clinical signs, immune status, travel history, and number of animals affected should be discussed to generate conclusions regarding the nature of the suspected infection (Box 1-1). Some viruses, such as feline coronavirus (FCoV), are difficult to isolate in cell culture or grow slowly, whereas others, such as feline calicivirus (FCV), replicate readily and rapidly in cell culture, and the sensitivity of cell culture is high. Viruses differ in respect to the cell type they prefer to replicate within. As a result, specimens should be sent to the laboratory with information on the specific viruses that are suspected.

BOX 1-1

Factors That Should Be Discussed with the Laboratory before Collection of Specimens for Pathogen Isolation in Cell Culture

Patient species, breed, age, and environment
Number of animals affected
History and clinical signs
Immune status of the patient
Geographic location and travel history
Suspected infectious agents
Timing of specimen collection
Type and amount of specimen to be collected
Transport conditions, including timing and method of transportation

The timing of specimen collection is particularly important for viral infections. Specimens should be collected as early as possible following the onset of clinical signs, optimally within the first week, because viral shedding may commence before the onset of signs and continue for only a few days. The duration of viral shedding depends on the type of virus and the anatomic site sampled. When multiple animals are affected, collection of specimens from more than one animal may increase the chance that an isolate will be obtained. If possible, antibody testing using acute and convalescent phase serology should be performed concurrently to help confirm the diagnosis (see Chapter 2).

Selection of the best specimen and collection site for culture is optimized based on knowledge of the pathogenesis of the infectious agent involved, because the optimum specimen collection site may not be the site where clinical signs are most severe. Attempts should be made during specimen collection to prevent contamination of the specimen with normal flora, although this is not always possible. Specimen size should also be maximized (for example, at least 5 mL of blood, body fluids, or lavage specimens, and ideally 8 to 10 mL of blood) to increase the chance of a positive isolation. In general, nasal or nasopharyngeal washes have been preferred over nasal swabs in human patients for isolation of respiratory viruses, but one study showed that nasal swab specimens were just as sensitive as nasopharyngeal washes for isolation of most respiratory viruses.[1] Nasal or oropharyngeal swab specimens are collected by placing a long-shafted swab in the area to be sampled, rotating the swab against the mucosa, and allowing the secretions to be absorbed for approximately 5 to 10 seconds.

Swabs and small tissue specimens for virus isolation should be placed in buffered virus transport medium, which contains antibiotics and protein. This can be obtained from the laboratory or purchased from other commercial sources. It is important that the medium used has not reached its expiry date.

VetBooks.ir

TABLE 1-2

Specimen Collection Guide for Diagnosis of Viral and Intracellular Bacterial Infections of Companion Animals

System Affected	Possible Agents	Specimen Type
Respiratory tract	Dogs: coronaviruses, canine adenovirus, influenza viruses, parainfluenza virus, CDV, canine herpesvirus Cats: FHV-1, FCV, influenza viruses, FCoV	Oropharyngeal swabs Nasal flushes, transtracheal wash or bronchoalveolar lavage specimens: ideally 5 to 10 mL of fluid Lung tissue obtained at biopsy or necropsy, including an area adjacent to affected tissue
Eye	Dogs: canine herpesvirus, canine adenovirus Cats: FHV-1, FCV, *Chlamydia felis*	Conjunctival swab, scraping or biopsy
Central nervous system	Dogs: CDV, West Nile virus, arboviruses	Cerebrospinal fluid: ideally at least 0.5 to 1 mL Blood: 8 to 10 mL Brain at necropsy
Gastrointestinal tract	Dogs: CDV, CPV, rotaviruses, canine coronavirus Cats: FCoV, FCV, FeLV, rotaviruses, toroviruses	Feces: ideally an olive-sized portion of formed feces or 10 mL of liquid stool Intestinal biopsies obtained using endoscopy or surgery, or intestinal tissue obtained at necropsy
Genital	Dogs: canine herpesvirus Cats: *Chlamydia felis*	Vesicle scrapings, vaginal swabs
Congenital and perinatal	Dogs: canine herpesvirus Cats: FHV-1, FeLV	Blood, tissues obtained at necropsy
Blood	Dogs: *Anaplasma phagocytophilum, Rickettsia rickettsii, Ehrlichia canis* Cats: FeLV, FIV, FCoV	Blood: ideally 8 to 10 mL

CDV, Canine distemper virus; CPV, canine parvovirus; FCoV, feline coronavirus; FCV, feline calicivirus; FeLV, feline leukemia virus; FHV-1, feline herpesvirus-1; FIV, feline immunodeficiency virus.

Liquid specimens such as blood, cerebrospinal fluid, and bronchoalveolar lavage fluid do not need to be placed in transport media. Blood samples should be collected using sterile technique, with antiseptic preparation of the site of venipuncture, and can be submitted in EDTA anticoagulant tubes.

All specimens should be refrigerated on collection and transported as quickly as possible (preferably within 24 hours) to the laboratory, because delayed transport can lead to loss of organism viability. If delays in excess of 2 to 3 days are anticipated, the specimen can be frozen. Freezing should be avoided whenever possible, as it may lead to dramatic loss of virus viability. If freezing is unavoidable, freezing at −70° C is preferable to freezing at −20° C, and shipping on dry ice is preferable, if possible. The laboratory's submission guide should be checked for specimen handling recommendations.

Table 1-2 provides a guide to the recommended specimen types for isolation of viruses or obligate intracellular bacteria from companion animals. Specimens should be labeled with the patient data, the site(s) from which the specimen(s) was collected, specific organisms suspected, and the time and date of specimen collection. Contained specimens should be placed inside leakproof triple packaging and transported on wet ice or cold packs to the laboratory, especially if transport is expected to take longer than 1 hour. Absorbent materials should be placed within the secondary container in order to absorb any spills. If specimens are to be shipped, the specimen must be labeled and handled according to governmental and International Air Transport Association (IATA) regulations for shipping materials known to contain infectious substances, which are categorized as Category A or Category B. Category A infectious substances are those capable of causing permanent disability or life-threatening or fatal disease in otherwise healthy animals and humans.[2] Most specimens submitted by veterinarians fall under Category B, which are those that do not fall under the criteria for inclusion in Category A. Updated documents providing guidance on regulations for the transport of infectious substances are provided online by the World Health Organization (WHO).[2] Import permits may be required for interstate and international transportation.

Diagnostic Methods

Maintenance of Cell Cultures in the Laboratory

In general, cells are grown as a monolayer on a plastic plate. The cells in the monolayer can be derived directly from an animal *(primary cell culture)*, which tend to have a limited life span, or they may be immortalized *(continuous cell lines)*. Primary cell cultures are needed for the isolation of some viruses, because the cells more closely resemble those present in vivo, and the replication of these viruses occurs more efficiently in primary cell lines than in continuous cell lines. Further subculture of primary cell lines often reduces their sensitivity to viral infection. Primary cell cultures are generated by placing tissues in cell culture media, often after treatment of the tissue with an enzyme such as trypsin or collagenase. Primary white blood cell cultures (such as peripheral blood mononuclear cell cultures) are generated by separation of the white cells from the other cellular elements using density gradient centrifugation, and adding them to a culture medium. Ficoll, a highly branched polysaccharide,

is an example of a medium used commonly for density gradient centrifugation. Primary cell cultures have been used widely for the isolation of intracellular pathogens of dogs and cats.[3-6]

Low-passage cell lines remain viable and sensitive to viral infections for 20 to 50 passages. *Continuous cell lines* are the type of cell line used most commonly for diagnostic, research, and commercial purposes. These are derived from cancer cells (such as the widely used HeLa cell line, derived from human cervical cancer cells of a patient named Henrietta Lacks),[7] or they result from experimental induction of cellular mutations (for example, using a carcinogen). Continuous cell lines representing a wide variety of cell types are available from commercial suppliers (Table 1-3). Laboratories that perform virus isolation for disease diagnosis may need to simultaneously inoculate multiple cell lines, because

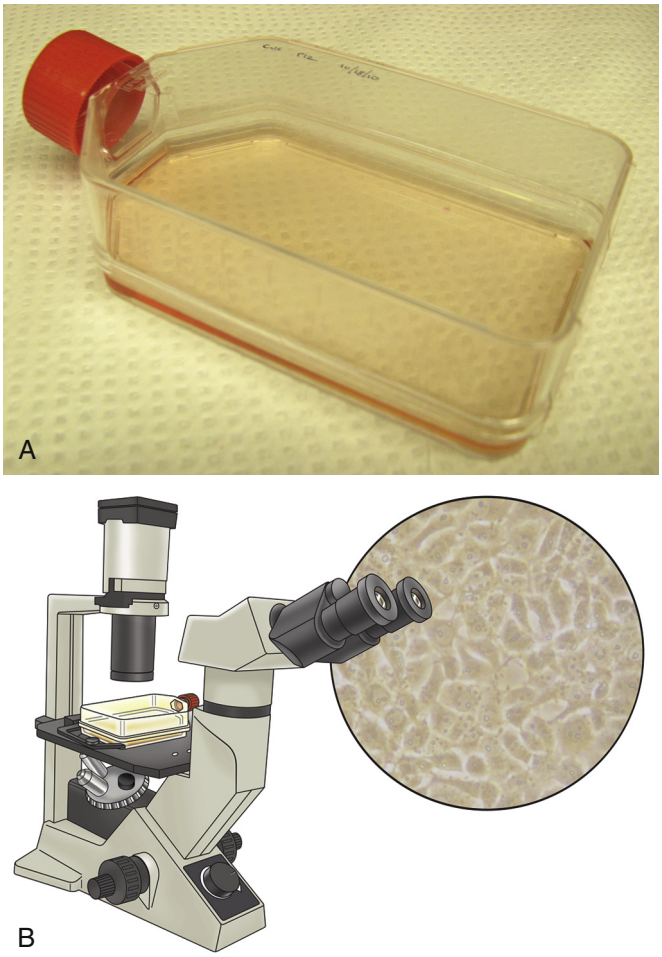

FIGURE 1-1 **A,** Plastic flask that contains cell culture medium. **B,** A confluent cell monolayer is present on the bottom of the flask and can be visualized through the top of the flask using a binocular inverted microscope.

different viruses prefer to replicate in differing cell types. Mixed cell cultures are also now available commercially to simultaneously facilitate isolation of multiple different viral pathogens.

Cells for cell culture are stored in the laboratory in liquid nitrogen tanks. The cells are thawed, dispersed in cell culture medium, and allowed to settle on the bottom of a plastic flask (Figure 1-1). The cell culture medium keeps the cells moist and provides the cells with nutrients. *Minimum essential medium* (MEM), also known as *Eagle's minimum essential medium*, and *Dulbecco's medium* are examples of widely used synthetic cell culture media. The cell culture medium contains a balanced salt solution, essential amino acids, glucose, vitamins, and a bicarbonate buffering system. Variations of MEM are available, some of which contain nonessential amino acids, the pH indicator phenol red, and the pH buffering agent HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid), which helps to maintain a physiologic pH despite an increasing concentration of CO_2 that is produced as a result of cellular respiration. The medium often requires supplementation with animal serum, most commonly fetal calf serum, which helps the cells to attach to and spread on the plate, although serum-free medium has also been used successfully for culture of canine and feline viruses.[8] Media for cell culture growth differ from media for maintenance of cells in culture, the former generally containing a higher concentration of animal serum (10% versus 2% for maintenance medium).

VetBooks.ir

To prevent bacterial or fungal contamination when viral pathogens are cultured, careful attention to sterile technique is required. Manipulation of cells in the flask is performed in a laminar flow hood, and the culture medium is sometimes supplemented with antibiotics (generally ampicillin or an aminoglycoside), with or without an antifungal agent (amphotericin B or nystatin). Cell culture flasks are placed in a humidified incubator that maintains temperature usually at 37°C, and a gas mixture that typically contains 5% CO_2.

The cell culture flasks are removed from the incubator and examined daily using an inverted binocular tissue culture microscope (see Figure 1-1), which allows examination of unstained cells through the bottom of the flask. The medium is replaced with fresh medium if the pH indicator suggests it is becoming too acidic. Once the cells have multiplied sufficiently to form a semiconfluent monolayer, the cells can either be passaged or be allowed to reach confluence before inoculation with specimen. In order to passage the cells, the medium is removed, and a small volume of trypsin or EDTA solution is added to the monolayer. The monolayer is incubated with the solution for several minutes, after which the cells detach from the flask and can be resuspended in medium, which is then added to new flasks.

Occasionally, cell lines become cross-contaminated with other cell lines. The HeLa cell line is an example of a prolific and hardy cell line that commonly contaminates other cultures. Major cell line repositories such as the American Type Culture Collection (ATCC) use genetic typing methods to verify the identity of the cells in their collection. Cell lines can also become easily contaminated with *Mycoplasma* spp., which pass through filters used to exclude other bacteria. The presence of contaminating *Mycoplasma* spp. can interfere with replication of other pathogens and cause alterations of cellular morphology. *Mycoplasma* contamination is detected using stains such as Hoechst stain, culture for *Mycoplasma*, and commercially available PCR assays that specifically detect *Mycoplasma* DNA for the purpose of cell culture quality assurance.[9]

Inoculation of Cell Cultures

Infection of a cell monolayer is accomplished by removal of overlying medium and inoculation of the monolayer with a suspension of viral or bacterial organisms. If tissue specimens are provided for culture, the specimens are homogenized in culture medium before they are inoculated onto the monolayer. Specimens may first be centrifuged to remove cell debris and bacteria. Passage through a filter can also be used before inoculation to remove bacteria. The inoculum is added to the monolayer. Organisms within the inoculum are then allowed to settle on the monolayer for approximately 1 hour before the residual inoculum is removed and fresh maintenance medium is added.

For isolation of virus, the monolayer is then examined daily for evidence of cytopathic effect (CPE). Medium is replaced weekly or biweekly. CPE refers to the cellular changes induced by viral replication in the cell culture monolayer and includes cell lysis or cell fusion (syncytium formation). The presence of a particular viral pathogen is indicated by the appearance of characteristic CPE for that pathogen after a predicted incubation period (Figure 1-2). For example, CPE induced by FCV is characterized by cell rounding and detachment that can occur within 24 hours, and within 16 hours for highly virulent strains.[10] The presence of CPE is confirmed through the comparison of inoculated cultures to uninoculated (control) cultures. Examination of the cell monolayer using light microscopy after fixation and staining can reveal additional diagnostic features, such as the presence of inclusion bodies and syncytium formation. Some viruses are relatively noncytopathogenic. In some cases, the presence of these viruses can be demonstrated by adding washed erythrocytes to the monolayer and examination of the monolayer for evidence of hemadsorption (see Figure 1-2, B). Hemadsorption results from incorporation of viral surface hemagglutinin molecules into the plasma membranes of the cell culture monolayer. Examples of hemadsorbing viruses that produce minimal CPE include influenza and parainfluenza viruses. Other, more sensitive and specific methods for identification of

an organism that has infected a cell culture monolayer include fixation and staining of the monolayer with fluorescent antibodies that are specific for certain viruses (Figure 1-3), use of nucleic acid detection techniques such as PCR, or use of electron microscopy.

For *spin-amplified cell culture*, the monolayer is centrifuged at low speed after inoculation. This can enhance recovery of certain viruses and intracellular bacterial pathogens such as chlamydiae. Either an entire plate of cell culture wells can be spun in a plate centrifuge, or *shell vials* can be used (also known as the *shell vial technique*). Shell vials are small, flat-bottomed bottles (Figure 1-4). A monolayer is grown on a glass coverslip at the bottom of the vial, and after inoculation, the vials are centrifuged at low speed. Using this method, fluorescent antibody staining for viral or chlamydial antigen is used to detect the pathogen before CPE occurs. After 48 to 72 hours, the coverslips are fixed, stained with virus-specific fluorescent-labeled antibodies, removed from the vials, and examined with a fluorescence microscope.

Plaque Assays

Overlay of the monolayer with agar or methylcellulose after inoculation with virus minimizes subsequent viral movement through the monolayer and restricts damage by each replicating viral particle to a small area. This results in the formation of "holes" in the monolayer, or *plaques* (Figure 1-5). The monolayer can then be stained and the number of plaques can be counted in order to obtain information regarding the amount of virus in the inoculum. Plaque assays are commonly used by researchers to assess the efficacy of antiviral treatments, through reduction of plaque formation.

Laboratory Safety Concerns That Relate to Cell Culture

The processing of specimens in a biological safety cabinet not only serves to protect cultures from contamination but also acts to protect the laboratory worker from laboratory-acquired infections. Most viruses grown in veterinary diagnostic laboratories are classified as biosafety level 2 (BSL 2) agents. Biosafety levels range from 1 through 4 (Table 1-4). In the United States, the Centers for Disease Control and Prevention (CDC) assigns these levels. It is important that veterinary clinicians be aware that isolation of hazardous pathogens can only be conducted in specially designed and accredited laboratories.

Interpretation of Results

Negative Results

Reasons for negative test results using virus isolation are numerous, so the clinician should not assume that a virus is not present when a negative test result is obtained (Box 1-2). Negative test results can occur as a result of inadequate specimen size, lack of viral shedding by the animal at the time of specimen collection, the binding of antibodies to viruses within the specimen,

VetBooks.ir

TABLE 1-4

Biosafety Levels Set for Diagnosis of Laboratory Practices

Level	Risk	Examples	Example Precautions
BSL 1	Minimal potential hazard to human health and the environment	Canine adenovirus-1 Nonpathogenic *Escherichia coli*	Gloves, facial protection. Standard microbiologic practices using bench-top techniques. Routine decontamination practices (hand washing, routine bench disinfection, autoclaving of infectious waste).
BSL 2	Moderate potential hazard to human health and the environment. Organisms cause mild disease or are difficult to contract as laboratory aerosols.	Most veterinary viruses, including influenza viruses	Access to the laboratory restricted when work is taking place; extreme precautions with sharp contaminated materials; use of appropriate biosafety cabinets when generation of aerosols possible. No requirement for directional airflow into the laboratory.
BSL 3	Dangerous agents that can be transmitted by aerosol within the laboratory but for which effective vaccines or treatments exist.	West Nile virus Equine encephalitis viruses *Rickettsia rickettsii* *Coxiella burnetii* *Mycobacterium tuberculosis*	Laboratory is located away from high-traffic areas. Restricted laboratory access when work in progress; double door entry, ventilation providing airflow into the room, exhaust air not recirculated; special practices and protective clothing for BSL 3, including biosafety cabinet use; special floor and ceiling materials specified.
BSL 4	Dangerous and exotic agents that pose a high risk of aerosol-transmitted laboratory infections, or which produce severe or fatal disease in humans	Ebola virus Marburg virus Smallpox	Hazmat suit and self-contained oxygen system, entrance containing multiple showers, a vacuum room, an ultraviolet light room, and multiple airlocked doors. Strict control of laboratory access to authorized personnel.

BOX 1-2

Reasons for Negative Test Results following Isolation of Viruses in Cell Culture

Virus not causing the disease
Virus causing the disease, but:
- Specimen size inadequate
- No viral shedding at the time of sampling
- No viral shedding at the site of sampling
- Antibody interference with viral infectivity for cell culture
- Inadequate organism numbers at the anatomic site of specimen collection
- Loss of organism viability during transportation to the laboratory
- Overgrowth of one viral pathogen by another
- Overgrowth by bacterial or fungal agents
- Lack of cell sensitivity for the virus (wrong cell type inoculated)
- Laboratory inexperience with techniques required for virus isolation and identification

inadequate organism numbers at the anatomic site of specimen collection, or loss of organism viability during transportation to the laboratory. Loss of viral viability is more likely to occur with enveloped viruses such as canine distemper virus than with non-enveloped, hardy viruses such as canine parvovirus or FCV.

Negative test results can also occur when the cell line inoculated is not sensitive to the virus present in the specimen. Low-passage cells may also lose their infectivity for viral infection if they have undergone multiple serial passages.

False negatives can also occur if the plates are overgrown by bacteria or fungi. Although treatment of the viral transport and culture media with antimicrobials can help prevent this, resistant bacteria or fungi may still be present. Sometimes, multiple viruses are present within a specimen, and one virus overgrows another. For example, this can occur with mixed infections with FCV and feline herpesvirus-1 (FHV-1) in cats with upper respiratory tract disease. FCV rapidly infects Crandell-Reese feline kidney cells and produces CPE, which obscures the concurrent presence of FHV-1.

Positive Results

It is imperative that veterinary clinicians be aware that the detection of a virus in a specimen does not always imply that the organism is the cause of the animal's clinical signs. This is especially true for specimens collected from the respiratory or gastrointestinal tracts, where multiple infectious agents may be present concurrently, and in many cases, viruses can replicate in these locations without causing clinical signs of illness. In some animals, the development of severe clinical signs is more likely when there is simultaneous presence of multiple infectious agents. As noted previously for specimens that test negative, the presence of one agent may also obscure the presence of another, more significant organism (such as with FCV and FHV-1 co-infections), which could result in the incorrect assumption that only one organism is the cause of an animal's disease.

CHAPTER 2

Immunoassays

Jane E. Sykes and Shelley C. Rankin

VetBooks.ir

KEY POINTS

- Immunoassays are commonly used in practice to detect antigen or antibody in body fluids.
- The term *serology* is most often used to refer to assays that detect antibody in serum.
- Immunoassays that detect antigen or antibody in dogs and cats suspected to have infectious diseases include direct and indirect immunofluorescent antibody (IFA), immunohistochemistry (IHC), ELISA, Western immunoblotting, agglutination tests, gel immunodiffusion assays, and serum neutralization.
- Positive immunoassay results do not always imply infection, and negative results do not rule out infection.
- When interpreting the results of immunoassays, veterinarians should consider what is being measured (antigen or antibody), the likelihood of antigen or antibody being present in relation to the onset of illness, whether the positive test result is consistent with the animal's clinical signs, and the animal's vaccination history and immune status. The possibility of false positives due to immunologic cross-reactivity, as well as the analytical sensitivity and specificity of the test used (i.e., the test's performance), must also be considered.
- Additional assays may be required to support immunoassay test results.

INTRODUCTION

Serology refers to the measurement of antigen-antibody interactions for diagnostic purposes, but is most often used to refer to the detection of antibodies in serum. In general, a blood sample is *seroreactive* (or *seropositive*) if it contains antibodies to a particular pathogen. Assays have been designed that detect different classes of antibodies in serum, most commonly IgG or IgM. Methods used to detect antibodies can also be applied to detect antigen. They can also be used on body fluids other than serum, such as urine, cerebrospinal fluid, and aqueous humor. Assays that measure antigen-antibody interactions for diagnostic purposes are most broadly referred to as *immunoassays*. Types of immunoassays include immunofluorescent antibody (IFA) tests, ELISAs, agglutination tests, gel immunodiffusion tests (AGID or gel ID tests), and Western blotting. Many of these assays involve the use of *polyclonal antibodies,* or, more commonly, *monoclonal antibodies,* which are commercially available. Polyclonal antibodies are produced in animals (e.g., rabbits or horses) as a normal antibody response to antigen exposure. Monoclonal antibodies are produced in almost unlimited amounts in tissue culture, and have a higher degree of antigenic specificity.

Some immunoassays, such as ELISA and IFA, provide quantitative results, expressed as optical density units (ODs) or titers (e.g., 1:800, or *reciprocal titer* = 800). Exposure to an infectious agent results in a rise in antibody titer over time (Figure 2-1). Usually, the first antibody class to be produced by plasma cells is IgM, after which IgG synthesis by plasma cells occurs. When exposure to a pathogen occurs for the first time, there is a lag phase of 5 to 7 days before IgM antibodies can be detected in the blood *(primary antibody response)*. The antibody titer increases, and if the infectious agent is cleared, there is a progressive decline in the titer over weeks to months. The speed and magnitude by which the antibody titer rises depends on host factors and the infectious agent involved. For some diseases, such as leptospirosis, a significant rise occurs within 3 to 4 days of the onset of clinical signs. In secondary, or anamnestic, immune responses, the lag phase is shorter, the antibody titer increases more rapidly and to a greater magnitude, and antibodies may persist for longer periods of time (months to years).

Serologic diagnosis of infectious diseases relies on an understanding of the timing of the antibody response in relation to development of clinical signs for different infectious diseases. The results of serologic testing are interpreted differently for acute infections than they are for chronic or persistent infections. *For infections with a short incubation period,* such as leptospirosis or Rocky Mountain spotted fever, antibody titers are often negative in the first week of illness. In general, an increase in antibody titers over a 2- to 4-week period then occurs. *Seroconversion* is consistent with recent infection, and at least a fourfold increase in titer is required for the change to be considered significant. Because serologic test results can differ between laboratories that perform the same assay, the same laboratory should be used to determine the acute and the convalescent titer. Ideally, to minimize interassay variation, an aliquot of the acute specimen should be stored, frozen, and assayed at the same time as the convalescent specimen, although in reality this is often not done. A fourfold decline in antibody titer may also be consistent with recent infection, depending on the stage of illness at which serologic testing is performed. *For chronic, persistent infections,* such as FIV infection or canine leishmaniosis, a single, positive antibody titer can indicate active infection. Titer increases do not occur when infection persists beyond 1 to 2 months, and so acute- and convalescent-phase serology is not useful for diagnosis of chronic infections.

Specimen Collection and Transport

Blood collected for antibody testing should be allowed to clot, and the serum separated immediately and then refrigerated or

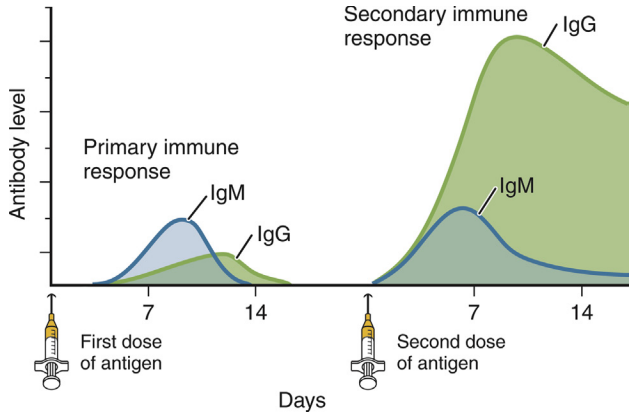

FIGURE 2-1 Time course of primary and secondary immune responses, showing relative amounts of IgM and IgG produced at different times after antigen exposure. (Modified from Tizard IR. Veterinary Immunology, 8 ed. St Louis: Saunders; 2008)

frozen. Specimens can be refrigerated for up to a week before they are shipped to the laboratory. If testing is to be delayed for longer than a week, specimens should be frozen at –20°C or –80°C. Specimens can be stored frozen for years without loss of antibody titer. For specimens collected for antigen testing, assay results may be more susceptible to variation with specimen storage. The laboratory should be contacted in order to determine specimen storage and handling requirements.

Diagnostic Methods

Immunofluorescent and Immunoperoxidase Antibody Assays

Direct IFA (also known as direct FA) detects *antigen* in clinical specimens. IFA involves the use of an antibody that has been tagged (*conjugated*) with a fluorescent label (such as fluorescein isothiocyanate) to detect the presence a specific antigen. IFA is performed directly on a glass slide, and fluorescence is detected by microscopy. The sensitivity of direct IFA is too low to detect individual virus particles or soluble antigen, so usually IFA detects antigen present in association with eukaryotic or bacterial cells. If the antigen is intracellular, pretreatment of the slide to permeabilize the cells may be necessary. The glass slide is then incubated with a solution that contains the fluorescent antibody, then washed to remove unbound antibody, and the cells are examined using a fluorescence microscope (Figure 2-2). Examples of the use of direct IFA in veterinary medicine include detection of *Giardia* oocysts, FeLV within monocytes in peripheral blood or bone marrow, or canine distemper virus within epithelial cells from a conjunctival scraping. Nonspecific fluorescence can result in false positives using these methods, but this can be overcome with the inclusion of proper controls and technical expertise. An alternative to the use of a fluorescein-conjugated antibody is the use of an antibody that has been conjugated to an enzyme such as horseradish peroxidase (immunoperoxidase). A substrate, most commonly 3,3′-diaminobenzidine (DAB), is then added to the slides. In the presence of hydrogen peroxide, DAB is converted to an insoluble brown precipitate, which can be visualized using conventional light microscopy. This technique is known as *immunocytochemistry*. The same method, when applied to tissue sections, is known as *immunohistochemistry* (IHC) (Figure 2-3).

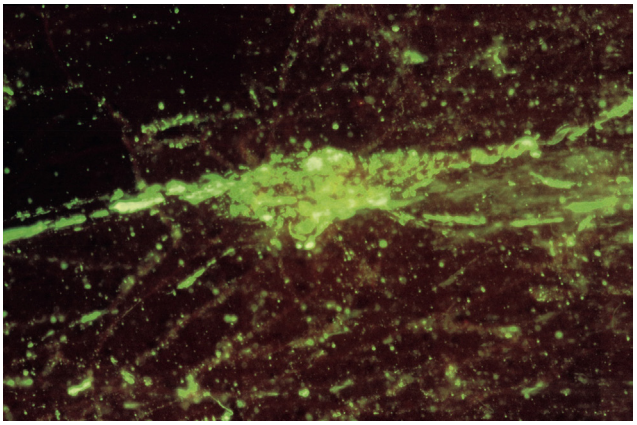

FIGURE 2-2 Direct fluorescent antibody stain of brain tissue for rabies virus. Frozen tissue sections were stained with a commercial reagent that contains three monoclonal antibodies specific for the rabies virus nucleocapsid. Antibodies were labeled with fluorescein. Positive staining is present in a Purkinje cell. (Courtesy of Galligan J. New York State Department of Health. In Maclachlan NJ, Dubovi EJ. Fenner's Veterinary Virology, 4 ed. New York: Elsevier; 2011.)

(Courtesy of Dr. Patricia Pesavento, School of Veterinary Medicine, University of California, Davis.)

Indirect IFA (also known as IFA testing, or IFAT) is generally used to establish a serum *antibody* titer to an infectious agent, but it can also be used to detect antigen. When used to detect antigen, it is more sensitive than direct IFA. For measurement of antibody titers, patient serum is serially diluted in the laboratory

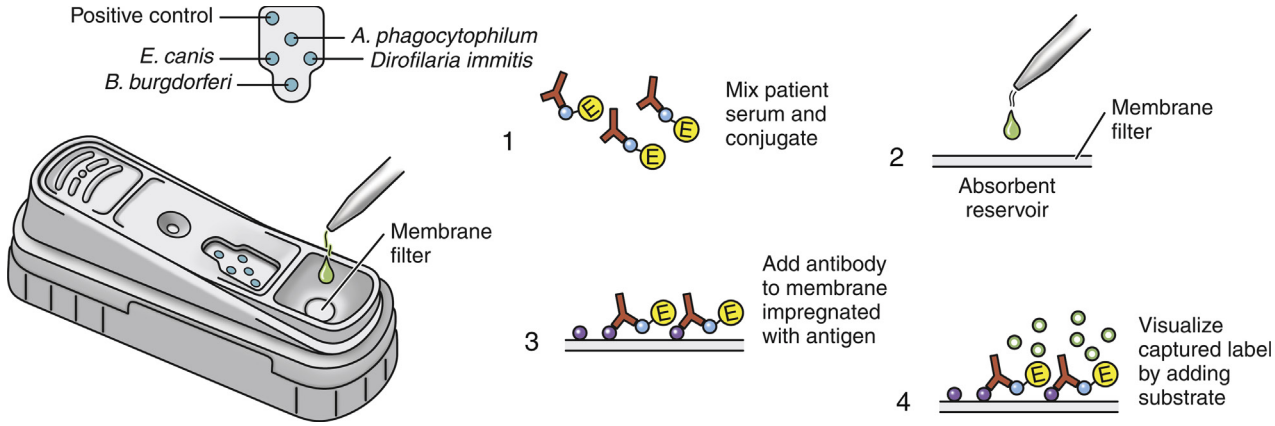

FIGURE 2-4 Flow-through immunoassay device (IDEXX Laboratories, Inc.). Specific antigen (for example, a recombinant protein) or antibody is immobilized on a membrane in the device in a spot or line. 1, Patient serum that may or may not contain target antigen or antibody is mixed with a solution that contains conjugated antibody or antigen. 2-3, The solution is allowed to flow through the device, where it becomes captured on the membrane. 4, The device is activated (snapped), which releases wash and substrate reagents within the device. A positive reaction appears as a colored bar, or in this case, a dot. Color development in designated spots on the membrane can indicate the presence of antibody to *Anaplasma* spp., *Ehrlichia canis,* and *Borrelia burgdorferi,* or the antigen of *Dirofilaria immitis.*

and reacted with a known antigen that has been fixed to glass slides. IFA slides are commercially manufactured for this purpose. Slides are then washed to remove unbound antibody. A *secondary antibody*, which is designed to react with the bound patient antibodies (e.g., dog IgG or dog IgM), is applied to the slides, which are then washed again. This secondary antibody has been conjugated to a fluorescent label. The slides are then examined using a fluorescence microscope. The highest dilution of serum that results in specific fluorescence is reported to the clinician as the antibody titer to the infectious agent of interest. Examples of the use of indirect IFA for serologic testing in dogs and cats include quantitative serology for some tick-borne infectious diseases (e.g., *Ehrlichia canis*, *Anaplasma* spp.).

More recently, veterinary immunofluorescence assays have been marketed that allow multiple antigen (or antibody) targets to be mounted on novel platforms, such as fluorescent beads or wells on the surface of a spinning silicon disc that resembles a compact disc. Automated silicon disc–based assays allow rapid and simultaneous analysis of hundreds of specimens, with dramatic reduction in labor associated with traditional IFA or ELISA assays, and reduced chance of false-positive or -negative assay results due to human error. A bead-based assay is currently available in the United States for detection of antibody to *Borrelia burgdorferi* (see Chapter 51). A silicon disc–based assay is available in the United States for detection of antibodies to *B. burgdorferi, E. canis,* and *Anaplasma phagocytophilum* and antigen to *Dirofilaria immitis* (Accuplex 4, Antech Diagnostics, Irvine, Calif). The performance of these assays in the field is under investigation.

Enzyme Linked Immunosorbent Assays

ELISA (also known as *enzyme immunoassay*) can be used to detect either antigen or antibody. In the laboratory, it is usually performed in a polystyrene microtiter plate. However, in-clinic modifications of the test, such as flow-through or lateral-flow ELISAs (e.g., SNAP, IDEXX Laboratories, Inc.), whereby antigen or capture antibody is immobilized on a membrane filter, are widely used in veterinary practices (e.g., for diagnosis of feline retroviral, heartworm, *Giardia*, *Leishmania*, and tick-borne infections) (Figure 2-4). For *antigen* detection, an unknown quantity of antigen in a clinical specimen is immobilized in the wells of the plate. The antigen is either bound directly to the surface of the plate or is bound through the use of a *capture antibody*, which is an antibody that is bound to the plate surface that specifically binds to the antigen of interest *(sandwich ELISA)*. The antigen is then detected with an antibody that is conjugated to an enzyme such as immunoperoxidase, and the substrate is added. This results in a color change, which can be read visually or using an ELISA plate reader (Figure 2-5). The plate reader records optical density of the wells in comparison to that of control wells, allowing assessment of the quantity of antigen present. The plates are washed with a detergent solution between steps, and this can be automated using an ELISA plate washer. Sandwich ELISAs have been used widely for detection of FeLV antigen in cat blood. In *competitive ELISA,* the test specimen (e.g., dog serum), which contains an unknown amount of antigen, is mixed with a known amount of labeled antigen. The mixture is added to wells that contain known amounts of a capture antibody, and the labeled and unlabeled antigens compete for antibody binding. The more labeled antigen that binds, the less antigen is present in the test specimen. Other variations of competitive ELISAs also exist.

For *antibody* detection, serial dilutions of patient serum can be added to a known amount of antigen fixed on a plate and detected using a secondary antibody.

Western Immunoblotting

Western immunoblotting, also known as *Western blotting,* is also used to detect antibodies to an infectious agent in patient serum. After physical and/or chemical disruption of an organism, the proteins are then separated on the basis of molecular mass using vertical sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE). The protein bands are then transferred *(blotted)* to a nitrocellulose membrane using an electric current. The membrane is cut into vertical strips, and each strip is probed with serial dilutions of patient serum. If there are antibodies in the serum to antigens from the organism of interest, the antibodies bind to the antigens on the strip. The antigen-antibody complexes can then be visualized as discrete bands using immunoperoxidase detection methods. The pattern of band reactivity is specific for an immune response to that organism (Figure 2-6). Western blotting is offered commercially

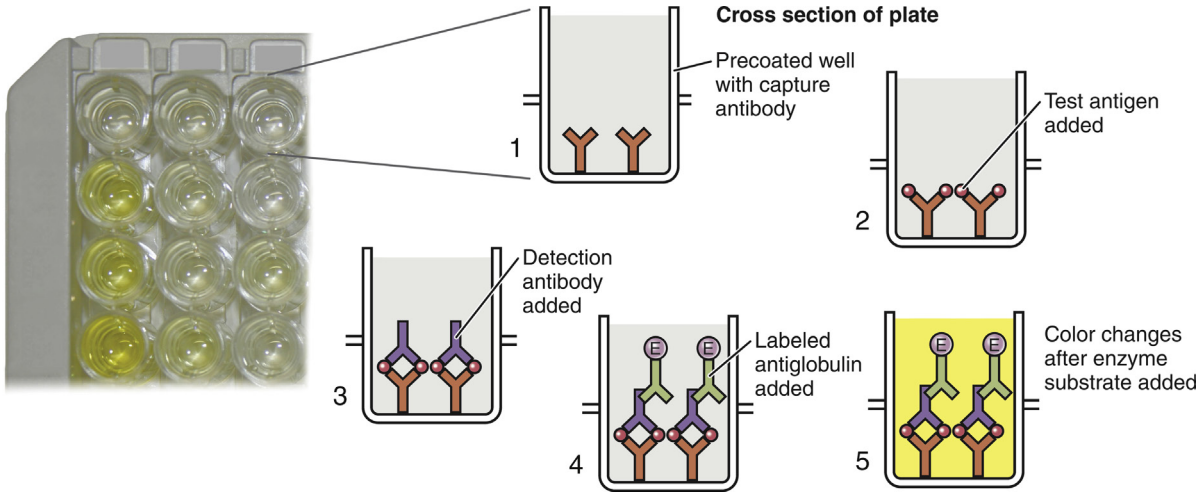

FIGURE 2-5 Sandwich ELISA. An antibody is immobilized in the plate, which binds antigen in a test specimen. The antigen is then detected using an antibody that is conjugated to an enzyme such as immunoperoxidase, and the substrate is added, which results in a color change. (Modified from Tizard IR. Veterinary Immunology, 8 ed. St Louis: Saunders; 2008.)

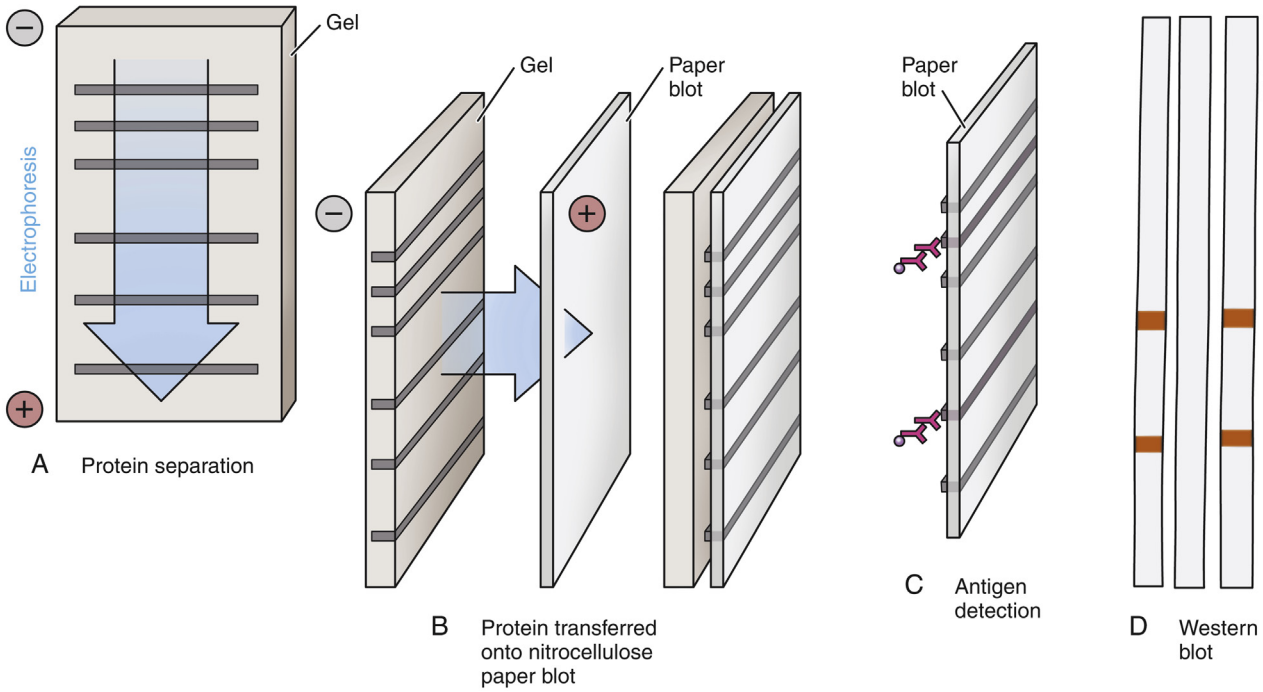

FIGURE 2-6 Western blotting (immunoblotting). Purified viruses or bacteria are disrupted and subjected to electrophoresis along the length of a polyacrylamide gel, so that the proteins are separated according to their molecular weight **(A)**. The bands are then transferred to a nitrocellulose paper membrane **(B)** and probed with patient serum **(C)**. The strip shown on the right is a Western blot that shows antibody reactivity to the antigens of FIV **(D)**. (Original blot courtesy of IDEXX Laboratories, Inc.)

for the diagnosis of FIV and *B. burgdorferi* infection and has been used in research laboratories as the gold standard for the detection of antibody responses to vector-borne pathogens such as *E. canis*. In the case of FIV infection, Western blotting has been used to confirm positive ELISA test results.[1] In the case of *B. burgdorferi* infection, Western blotting has been evaluated for its ability to differentiate between the response to vaccination and natural exposure.[2]

Agglutination Testing

Agglutination tests detect antibody or antigen and involve agglutination of bacteria, red cells, or antigen- or antibody-coated latex particles. They rely on the bivalent nature of antibodies, which can cross-link particulate antigens. Serial dilutions of serum are tested for their ability to cause or inhibit agglutination, and the highest dilution that causes or inhibits agglutination is reported as the antibody or antigen titer. IgM causes agglutination more effectively than IgG. If excess antibody is present, particles may become so coated with antibody that agglutination is actually inhibited. This is called the *prozone effect* and can result in false-negative test results if serum is not adequately diluted. Examples of agglutination tests that are used to diagnose infectious diseases of dogs and cats include the microscopic agglutination test (MAT) for serologic diagnosis of leptospirosis

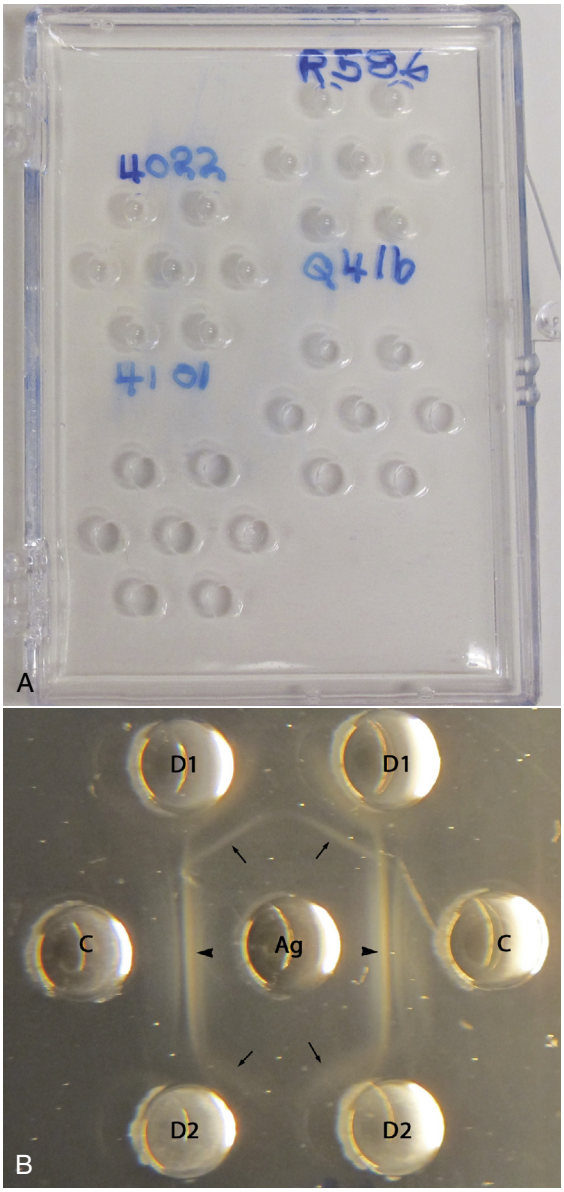

FIGURE 2-7 **A,** Gel immunodiffusion (or double diffusion) system used for detection of antibodies to *Aspergillus fumigatus, Histoplasma capsulatum, Blastomyces dermatitidis,* and *Coccidioides immitis* (Meridian Bioscience, Inc.). The kit consists of an agar diffusion medium in a small plastic tray that contains four arrays of six wells arranged around a central well. An antigen preparation for each of the fungal species is placed in the central well of each array. **B,** Positive gel immunodiffusion for *Aspergillus fumigatus*. The central well *(Ag)* contains a purified carbohydrate preparation from mycelial phase cultures of *Aspergillus fumigatus, Aspergillus niger,* and *Aspergillus flavus.* The top two wells *(D1)* and the bottom two wells *(D2)* contain serum from 2 dogs (dog 1 and dog 2) with nasal aspergillosis (performed in duplicate for each dog). After the wells are loaded, the plate is incubated at room temperature for 24 hours. Precipitin lines form when the antigen and antibody diffuse out of each well and form immune complexes. A light box is used to illuminate the plate so the precipitin bands are visible. Both dogs are positive for antibody to the *Aspergillus* species tested *(small arrows),* although the reaction is strongest for dog 1. The *arrowheads* are the precipitin lines generated by the positive control antibodies (in wells labeled *C*).

(agglutination of live leptospires) and the cryptococcal antigen latex agglutination test (agglutination of antibody-coated latex beads). Hemagglutination inhibition (HI) is used to determine antibody titers to canine parvovirus and canine influenza virus, and it evaluates the ability of serum to inhibit erythrocyte agglutination by these viruses.

Agar Gel Immunodiffusion

For *agar gel immunodiffusion* (AGID, gel ID or double diffusion) tests, round wells are cut in a layer of agar on a plastic plate using a punch. One well, usually the central well, is filled with a soluble antigen, and the other wells are filled with patient serum. A positive antibody control specimen is included in each assay. The reagents are allowed to diffuse into the agar, and when antibodies and antigen meet in optimal proportions (the *point of equivalence*), immune complexes form. This results in a visible line of precipitate between the antigen well and wells that contain positive serum (Figure 2-7). Immunodiffusion testing is most often used to detect antibodies to fungal pathogens in dogs, such as *Aspergillus fumigatus,*[3] *Coccidioides immitis,*[4] and *Blastomyces dermatitidis.*[5] It is also used to detect antibodies to *Brucella canis*.

Serum Neutralization

Serum neutralization is a technique used to determine the antibody titer to viruses. Serial dilutions of patient serum are mixed with a known quantity of virus particles. The mixture is incubated to allow the antibodies in the patient serum to bind to the virus particles, and the mixture is then added to a confluent cell monolayer. The highest dilution of patient serum that inhibits viral replication in the monolayer (as determined by examination for cytopathic effect or immunostaining) is the antibody titer reported by the laboratory. Serum neutralization can be used to detect antibodies to canine distemper virus and several respiratory viruses that infect dogs and cats.

Complement Fixation Testing

Complement fixation (CF) tests have largely been superseded by the use of ELISA tests. The CF test detects antibodies in patient serum. The serum is heat-treated to inactivate complement in the test specimen. The test uses sheep RBCs, anti–sheep RBC antibody, and unheated guinea pig serum as a source of complement. Under normal circumstances, when these three reagents are mixed, the result is hemolysis. Hemolysis occurs when complement binds to antibody-coated RBC and triggers formation of the membrane attack complex, with resultant pore formation. In the CF test, a known antigen is added to the heat-treated patient serum. When antibodies are present in the serum, the addition of this antigen leads to the formation of antigen-antibody complexes. Guinea pig complement is then added to the mixture and is consumed by the complexes. The resultant mixture is thus unable to lyse sensitized sheep RBCs. A lack of hemolysis indicates a positive CF test.

Interpretation of Results

To interpret the results of serology or immunoassay tests, the clinician first needs to consider whether the test was designed to detect antibody or antigen (Tables 2-1 and 2-2), and, if designed to detect antibody, whether it was IgM-specific (detects early antibody responses). The results also have to be interpreted in light of the pathogenesis of the infectious disease, specifically the timing of antigen and antibody appearance in the body fluid being tested. Finally, the sensitivity and specificity of the test itself need to be considered (i.e., the *analytical sensitivity and specificity*), which are determined during test validation (Table 2-3). For example, some immunoassays that detect antigen will not generate a positive result unless a large amount of antigen is present in the specimen provided (low analytical sensitivity). Test analytical sensitivity and specificity should be available from the laboratory that performs the test. False-positive test

VetBooks.ir

TABLE 2-1

Guidelines for Interpretation of Test Results Using Immunoassays That Detect Antigen

Antigen Test Result	Possible Explanation	Troubleshooting Suggestions
Negative	Pathogen of interest not present	Confirm with additional diagnostic test if necessary, (e.g., alternative antigen assay, antibody or PCR assay)
	Antigen present, but quantity below limit of detection	Consider an antibody or PCR assay
	Antigen present but complexed by antibody and not available for detection	Consider an antibody or PCR assay
	Technical error or reagent failure	Identified with inclusion of appropriate laboratory controls
Positive	Pathogen of interest present	Confirm with additional diagnostic test if necessary, especially in regions with a low prevalence of infection. Antigen presence may not imply that the pathogen is the cause of disease
	Antigen present but viable microbe absent	Confirm with additional diagnostic test
	Vaccine antigen present	Obtain vaccination history and consider a test that discriminates between vaccine and wild-type organisms, if available
	Cross-reactive antigen present from another substance or pathogen	Obtain history and consider the likelihood of infection with related agents
	Technical error	Identified with inclusion of appropriate controls by the laboratory
	Poor assay analytical specificity (prone to generate false-positives)	Use alternative assay

TABLE 2-2

Guidelines for Interpretation of Test Results Using Immunoassays That Detect Antibody

Antibody Test Result	Possible Explanation	Troubleshooting Suggestions
Negative	Exposure to pathogen of interest did not occur	Confirm with additional diagnostic test if necessary
	Too early in course of infection/illness	Obtain convalescent titer; consider an antigen or PCR test for early diagnosis
	Severe immunosuppression	Consider an antigen or PCR test
	Technical error	Identified with inclusion of appropriate controls by the laboratory
	Poor assay analytical sensitivity (prone to false-negatives)	Use alternative assay
Positive	Previous natural exposure to the pathogen of interest	If infection is chronic and persistent, positive test results may equal active infection.
	Previous immunization against the pathogen of interest	Obtain vaccination history; consider use of assays that discriminate between natural exposure and vaccine antibody, if available
	Immunologic cross-reactivity	Obtain history and consider the likelihood of previous exposure to related agents
	Technical error	Identified with inclusion of appropriate controls by the laboratory
	Poor assay specificity (prone to false-positives)	Use alternative assay. Consider the use of a confirmatory test, especially in regions with low disease prevalence

VetBooks.ir

TABLE 2-3

Sensitivity, Specificity, Positive and Negative Predictive Value

Test Attribute	Definition
Sensitivity	Number of truly positive animals that are identified as positive by the test, divided by the total number of animals that are truly positive (as determined by the gold standard assay) (%). A test with low sensitivity fails to detect many positive animals (many false-negative results).
Specificity	Number of truly negative animals that are identified as negative by the test, divided by the total number of animals that are truly negative (as determined by the gold standard assay) (%). A test with low specificity generates many false-positive test results.
Positive predictive value	The number of animals that are truly positive divided by the total number of animals that test positive (true positives plus false positives).
Negative predictive value	The number of animals that are truly negative divided by the total number of animals that test negative (true negatives plus false negatives).
Etiologic predictive value*	The proportion of animals with positive test results that truly have the disease of interest, as opposed to carriage of an organism in the absence of disease.

*Gunnarson, RK, Lanke J. The predictive value of microbiologic diagnostic tests if asymptomatic carriers are present. Statist Med 2002; 21:1773–1785.

results due to low analytical specificity are more likely when testing animals from populations where the prevalence of true positive test results is low. In this situation, a test has a *low positive predictive value,* and confirmatory testing may be required. A quality assurance program should be in effect within the laboratory to ensure that specimens submitted are of adequate quality, that sufficient technical expertise is present to perform the tests, and that appropriate control assays are included with each run to ensure proper assay performance.

Negative Results for Antigen Detection

Negative results for antigen will occur if the antigen is not present in the specimen being tested. They may also occur if the amount of antigen is below the limit of detection of the assay (e.g., low worm burden in heartworm disease). For some infectious agents, such as FIV, antigen testing is not performed because antigen levels during infection are typically extremely low. The amount of antigen present can also vary over the course of a particular infection. Finally, false-negative results may occur when antibody present in the specimen complexes antigen and makes it unavailable for detection by the immunoassay.

Positive Results for Antigen Detection

Positive results for antigen can indicate the presence of the suspected pathogen in the specimen. They do not necessarily imply that the pathogen is the cause of an animal's clinical signs. Antigen can also be present in the absence of intact, viable organisms. Positive results can follow recent vaccination with the pathogen of interest. For example, positive fecal parvovirus antigen tests can occasionally occur in fecal specimens obtained several days after attenuated live virus vaccination of kittens for feline panleukopenia virus.[6] False positives can occur as a result of antigenic cross-reactivity with some other substance or organism in the specimen. An example is positive serum and urine antigen assays for *Aspergillus* spp. in dogs treated with Plasmalyte infusions or those infected with other molds such as *Paecilomyces* spp.[7]

Negative Results for Antibody Detection

Negative results for antibody will occur if the patient has not been exposed to the infectious agent of interest. They may also occur if the patient has not yet had time to develop antibodies. For example, negative antibody tests early in the course of illness are common with leptospirosis and canine granulocytic anaplasmosis. In this situation, a convalescent titer is required for diagnosis using serology. Negative antibody test results can occur in severely immunosuppressed animals, such as in cats with advanced FIV infection that no longer can mount an immune response, or cats with advanced feline infectious peritonitis. Negative results may also occur because the test lacks sensitivity (i.e., low analytical sensitivity).

Positive Results for Antibody Detection

Positive results for IgG antibody suggest *previous exposure* to a pathogen and do not necessarily indicate active infection. Paired IgG titers are required to document recent infection. Single positive results for IgM-specific assays may indicate a recent infection or a chronic infection that continues to stimulate the immune system. Previous immunization may also result in positive results. If the infection is chronic and persistent, such as with FIV infection, positive results indicate active infection, provided there has been no history of previous FIV vaccination. False-positive results for antibody may also occur when antigenic cross-reactivity occurs. For example, dogs recovering from *Leptospira* infection have been shown to test positive on IFA for the related spirochete *B. burgdorferi*.

CHAPTER 3

Isolation and Identification of Aerobic and Anaerobic Bacteria

Jane E. Sykes and Shelley C. Rankin

KEY POINTS

- Because of the increasing prevalence of antimicrobial drug resistance among bacteria isolated from dogs and cats, culture and susceptibility is always recommended when a bacterial infection is suspected at a normally sterile anatomic site.
- Successful isolation of aerobic and anaerobic bacteria from a clinical specimen relies on collection of a sufficient quantity of material, from the correct location, and appropriate storage and transport of the specimen to the laboratory. Care should be taken to prevent specimen contamination during collection.
- The laboratory should be provided with an appropriate history if fastidious, anaerobic, or slow-growing bacterial organisms are suspected.
- Concurrent examination of a Gram-stained smear by the laboratory assists in assessment of specimen quality and interpretation of culture results.
- Antimicrobial susceptibility testing is most commonly performed using broth microdilution or agar diffusion testing and aims to determine the minimum concentration of an antimicrobial drug that inhibits growth of the organism in vitro (minimum inhibitory concentration, or MIC). The laboratory uses MIC breakpoints, which are established and revised regularly by national standards agencies, to assess the susceptibility of an organism to a particular antimicrobial drug.

INTRODUCTION

Factors that influence the detection of clinically relevant organisms in specimens collected from dogs and cats are:

1. An appropriate level of suspicion for the presence of a bacterial infection;
2. Development of a list of differential diagnoses that reflects the types of bacterial pathogens that might be the cause of clinical signs, because of the requirement of some bacteria for special transport conditions, culture conditions, or prolonged incubation;
3. Collection of a sufficient *amount* of specimen;
4. Collection of the *correct type* of specimen;
5. Specimen collection from the *correct anatomic location;* and
6. Proper handling, storage and transport of the specimen, which should be sent with a request for culture to the laboratory within acceptable time limits.

These factors cannot be overemphasized. Without them, time and money invested in collection of specimens and culture is wasted.

Given the increasing prevalence of multidrug resistance among bacteria that infect dogs and cats, veterinarians should make attempts to confirm a bacterial infection at a normally sterile site by requesting microscopic evaluation of direct smears and culture by a laboratory whenever possible before the choice is made to administer an antimicrobial drug.

The purpose of this chapter is to provide information in regard to the correct way to collect and handle specimens for culture before they are sent to the laboratory, and to outline bacteriologic procedures performed in the microbiology laboratory that are of relevance to the small animal clinician.

Specimen Collection and Transport

Veterinary clinicians should collect specimens for culture using an *appropriate method* from the *correct anatomic site*. Collection of a sufficient *amount* of specimen is very important. Table 3-1 suggests optimal specimen types for detection of bacteria from specific anatomic sites. Attempts should always be made to prevent contamination with commensal bacteria during specimen collection. When anaerobes are suspected, aspirates or biopsies should be obtained rather than swabs, and the specimen should be stored at room temperature and not refrigerated. This is because oxygen diffuses into cold specimens more rapidly than specimens held at room temperature.

Specimens should be transported to the laboratory immediately. As a general rule for aerobic culture, if transport requires longer than 2 hours, appropriate transport medium should be used or specimens should be refrigerated without transport medium. Although specimens can be held for up to 72 hours, culture of specimens older than 24 hours should be avoided, even if they have been refrigerated or placed in transport media, because of increased likelihood of false positive and false negative results with longer storage times. Transport medium for bacterial culture is usually supplied in a plastic tube with one or two swabs attached to the tube's cap (Figure 3-1). The medium is designed to maintain bacterial viability without causing significant growth. It usually consists of a small amount of agar, reagents that maintain pH, a colorimetric pH indicator that indicates whether oxidation has occurred, and specific factors that maintain the viability of certain pathogens. Some organisms, such as chlamydiae and leptospires, have specific transport medium requirements. Specimens that are placed in transport media should not be refrigerated.

Specimens should be labeled with the patient's name, patient number, source of specimen, and the date and time of collection, and should be labeled, packaged, and transported according to regional and national regulations (see Chapter 1). Specimens for anaerobic culture should preferably be transported in an oxygen-free container.

VetBooks.ir

TABLE 3-1

Suggested Specimen Types for Bacterial Culture from Selected Anatomic Sites and Likely Pathogens Present

Specimen Type	Suggested Volume for Culture	Likely Pathogens Present
Blood	≥10 mL for patients weighing >10 kg, or 1% of patient blood volume	Gram-positive and gram-negative aerobes. Common contaminants are coagulase-negative staphylococci, *Corynebacterium*, *Bacillus* spp., and propionibacteria (see Chapter 86)
CSF	≥0.5 mL	Gram-positive and gram-negative aerobes, anaerobes, *Brucella* spp. (dogs), *Nocardia*, *Actinomyces*,[1] *Mycoplasma* spp. (cats)[2] (see Chapter 90)
Middle ear	Aspirate of fluid or pus through tympanic membrane	Gram-positive and gram-negative aerobes, anaerobes, *Mycoplasma* spp., *Actinomyces* spp.[2,3] (see Chapter 84)
Skin	Swab from epidermal collarette or ruptured pustule (superficial pyoderma); biopsy from which dermis has been removed (deep pyoderma)	Gram-positive aerobes (especially staphylococci), rarely *Pseudomonas aeruginosa* (see Chapter 84)
External ear	Swab ear canal after removing debris and crusts from the canal	Gram-positive aerobes, *Pseudomonas aeruginosa* (see Chapter 84)
Cornea	Scrape or swab exposed corneal stroma and inoculate directly onto media. Referral to veterinary ophthalmologist recommended	Gram-positive aerobes, *Mycoplasma* spp., *Pseudomonas aeruginosa*[4]
Abdominal fluid	1-5 mL	Gram-negative and gram-positive aerobes, anaerobes, *Actinomyces* spp. (see Chapter 88)
Pleural fluid	1-5 mL	Gram-negative and gram-positive aerobes, anaerobes, *Actinomyces* spp., *Nocardia* spp., *Mycoplasma* spp. (see Chapter 87)
Feces	Fresh whole stools preferred. Avoid swabs or fecal loops containing fecal matter due to low specimen size. Submit in clean, dry leak-proof container.	*Escherichia coli*, *Salmonella*, *Clostridium perfringens*, *Clostridium difficile*, *Campylobacter* spp., *Anaerobiospirillum* (Chapters 45-49 and 88)
Urine	1-5 mL urine collected using cystocentesis	Gram-negative and gram-positive aerobes, *Corynebacterium urealyticum* (see Chapter 89)
Bronchoalveolar lavage specimens	1-5 mL	Gram-positive and gram-negative aerobes, anaerobes (aspiration pneumonia), *Mycoplasma* spp., rarely *Mycobacterium* spp. (see Chapter 87)

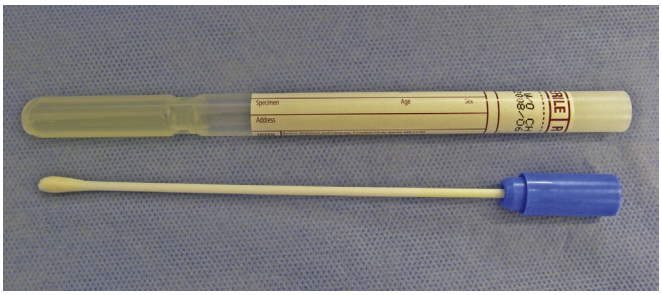

FIGURE 3-1 Swab system containing transport media for aerobic bacterial culture.

Diagnostic Methods

Microscopic Examination of Direct Smears

A Gram stain prepared from the specimen can permit the rapid preliminary diagnosis of infection and determine whether the organism(s) present are gram-positive or gram-negative (Box 3-1; Figure 3-2). This helps guide the clinician to select an appropriate empiric therapy, if necessary, while awaiting the results of culture and susceptibility testing. If sufficient material is available, examination of a direct smear also helps to determine whether a specimen is adequate for culture and aids interpretation of culture results. For swab or aspirate specimens, clinicians should consider providing a separate specimen for a direct smear in addition to a specimen for culture.

Acid-fast stains can be used on smears to assist in the identification of *Nocardia* and *Mycobacterium* spp., as well as on fecal smears to detect some parasitic oocysts, such as those of *Cryptosporidium*. These organisms stain magenta as a result of their high cell wall mycolic acid content, which in turn results in their resistance to decolorization after staining (which is often performed using an acid-alcohol solvent, hence the term *acid-fast*). Examples of acid-fast staining methods are the *Ziehl-Neelsen, Fite's,* and *Kinyoun* stains.

Other microscopic techniques used for bacterial identification in specialized laboratories include *darkfield microscopy*, *phase-contrast microscopy,* and *fluorescence microscopy* (see Chapter 2). Darkfield and phase contrast microscopy allow visualization of organisms without fixation and staining, so motility as well as structure can be assessed. In darkfield microscopy, the

BOX 3-1

Procedure for Gram Staining

Heat-fix specimen on the slide over a gentle flame or fix in 95% methanol for 2 min, and then air dry
Flood with crystal violet solution for 15 to 60 s (10 g of 90% dye in 500 mL absolute methanol)
Wash with water
Flood with iodine for 15 to 60 s (6 g of I_2 and 12 g of KI in 1800 mL of water)
Decolorize with acetone-alcohol (400 mL of acetone in 1200 mL of 95% ethanol)
Wash immediately
Counterstain with safranin for 15 to 60 s (10 g of dye in 1L of water)
Wash, blot dry, and examine using light microscopy

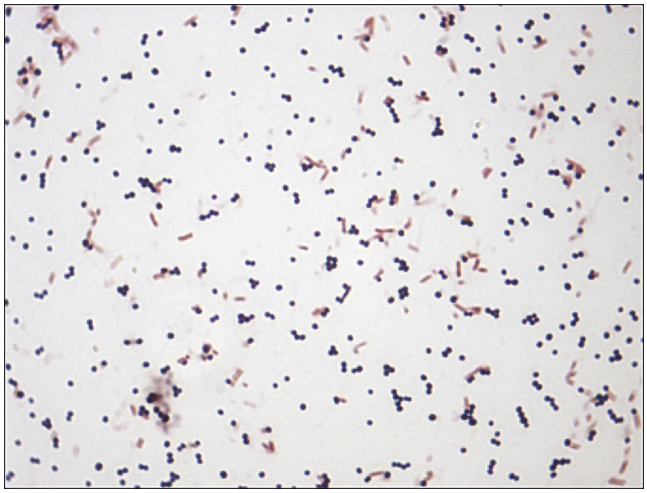

FIGURE 3-2 Gram-stained smear of gram-positive cocci *(dark blue)* and gram-negative rods *(red)* (1600× oil magnification).

condenser only permits light that bounces off an object to pass from below up into the objective, so the object appears bright against a dark background. Darkfield microscopy is used primarily for identification of fine spirochetes such as leptospires, which cannot be visualized using conventional microscopy (see Chapter 50). In phase-contrast microscopy, slowing and deflection of beams of light occur as they pass through an object.

Bacterial Culture

The performance of bacterial culture for diagnostic purposes requires appropriate laboratory facilities, proper biosafety level-2 containment, properly trained individuals, reference strains for quality control testing, and the use of standard protocols.[5] Media used for bacterial culture may be categorized as general-purpose, enriched, selective, differential, and specialized media (Table 3-2). Some media belong to more than one of these categories. For example, MacConkey agar is both a selective and a differential medium (Figure 3-3). Media for culture contains a nutrient source, most commonly peptones (hydrolyzed animal or vegetable substances), and is adjusted to a specific pH. Solid medium contains agar, which is derived from seaweed. Other nutrients may be added based on specific organism requirements. More than 100 different types of bacteriology media exist, most of which can be purchased as preprepared plates or broth.

Blood culture media contain the anticoagulant sodium polyanethol sulfonate (SPS), which is less inhibitory to bacterial growth than other anticoagulants. Some blood culture media (e.g., BD BACTEC Plus) contain resin beads that bind antimicrobial drugs in the patient's blood specimen, so they do not inhibit bacterial growth (Figure 3-4). The detection of bacterial growth in blood culture systems can be automated using instrumentation that measures emission of fluorescence or a colorimetric change in a sensor. The change occurs as CO_2 concentrations within the bottle increase, which indicates the presence of bacterial growth. Some instruments detect pressure changes in the head of the bottle. The culture is monitored at regular intervals by the instrument, to optimize early detection of bacterial growth. Positive blood culture bottles are then evaluated by performing a Gram stain of the broth, and subculture to appropriate media.

TABLE 3-2

Types of Media Used in Bacteriology

Medium Type	Attributes	Example
Transport	Nonnutritive liquid or semisolid medium. Promotes organism viability without allowing significant growth.	Amies transport medium
General-purpose	Allows growth of most aerobic and facultatively anaerobic organisms	Sheep blood agar
Enriched	Promotes growth of fastidious organisms that require specific nutrients, for example *Francisella*	Chocolate agar, which is enriched with heat-treated blood, which gives it a brown color
Selective	Selects for growth of certain organisms while inhibiting others	MacConkey agar, which selects for gram-negative bacteria
Differential	Aids in preliminary identification of organisms based on colony appearance	MacConkey agar, which promotes pink colony formation by organisms that ferment lactose
Specialized	Selects for a specific pathogen through the addition of specific nutrients	Anaerobic medium, which contains hemin, vitamin K, and reducing agents

Another blood culture system is the Isolator lysis centrifugation system (DuPont, Wilmington, DE) (See Figure 3-4, *B*). In this system, blood is added to a tube that contains anticoagulant and a reagent that induces RBC lysis. The tube is centrifuged, and the pellet is plated onto agar media and incubated. This method allows colony counts to be obtained. The tubes allow isolation not only of aerobes, but also some anaerobic bacteria.

In the laboratory, media for bacterial culture should be warmed to room temperature before inoculation, and damaged media, such as dehydrated medium or medium that has changed color, should not be used. Medium is stored in the dark at 2°C to 8°C and discarded when it reaches its expiration date. After plating, incubation is most commonly performed at 35°C to 37°C in air for a minimum of 2 days. Conditions vary for specific bacteria, and growth in 3% to 5% CO_2 is preferred by some fastidious organisms. The laboratory should be informed, by providing an adequate clinical history, when pathogens with special culture requirements are suspected, such as *Campylobacter, Mycoplasma, Actinomyces, Nocardia,* and *Mycobacterium* spp. These organisms require special media or prolonged incubation times (e.g., weeks). Specimens for anaerobic culture should be plated onto appropriate media immediately and incubated in an anaerobic environment. Anaerobic containers, which create an anaerobic environment through the use of gas-generating reagents, can be used for incubation (Figure 3-5). Because anaerobes grow more slowly than aerobes, anaerobic cultures should be held for 7 days before being reported as negative.

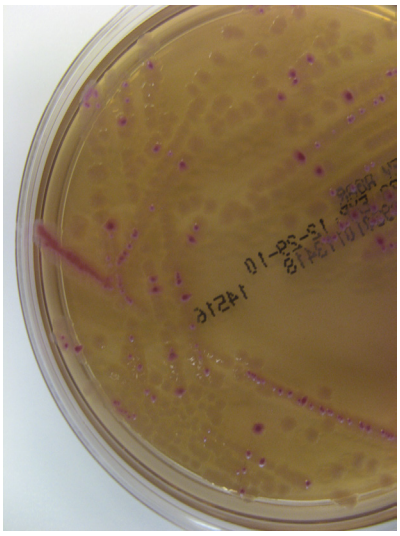

FIGURE 3-3 Growth of bacteria on MacConkey medium that shows the selective and differential qualities of the medium. The medium contains substances that inhibit the growth of gram-positive bacteria. By using the lactose available in the medium, bacteria such as *Escherichia coli*, *Enterobacter* spp., and *Klebsiella* spp. produce acid when they grow on the medium, which lowers the pH of the agar and results in the formation of red to pink colonies.

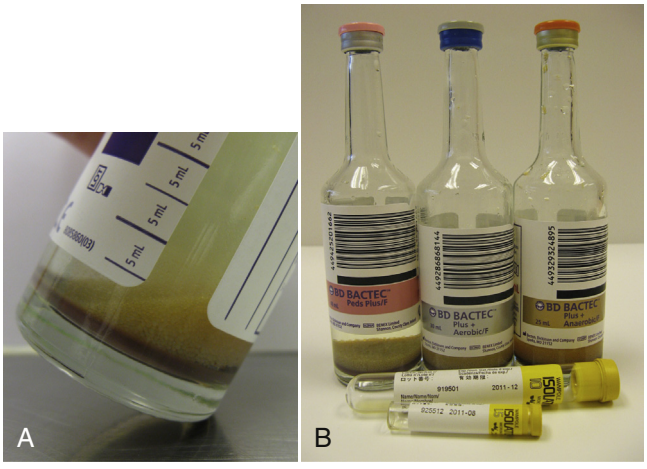

FIGURE 3-4 Blood culture systems. **A,** BACTEC system showing resin beads that bind antimicrobial drugs. **B,** Pediatric, aerobic, and anaerobic BACTEC systems for blood culture together with adult and pediatric WAMPOLE Isolator tubes (front) for lysis-centrifugation culture of blood.

Blood and Intravascular Catheters

Bacteremic animals may be continuously or intermittently bacteremic. Because of intermittent bacteremia, multiple, separate specimens, each containing greater than or equal to 10 mL of blood, are recommended. Pediatric bottles are available that can be inoculated with as little as 1.5 mL of blood, although the chance of a positive isolation increases as the blood volume drawn increases. Therefore, as much blood should be drawn as possible, provided that collection of a large volume of blood does not jeopardize the patient. Bottles should be held at room temperature and submitted immediately to the laboratory. Two, and ideally three, blood samples should be collected using meticulous sterile technique, and the timing of blood draws should depend on the severity of the animal's illness (Box 3-2). Inoculated bottles are incubated in aerobic conditions for 7 days before being reported as negative. Additional blood samples are not recommended, because they add cost without a significant increase in sensitivity.[6] The choice to inoculate anaerobic blood culture bottles is controversial. Studies in humans have shown that the prevalence of anaerobic bloodstream infections has decreased, and routine inoculation of anaerobic blood culture bottles may not be necessary. In one veterinary study, anaerobes were not identified in any of 33 dogs with endocarditis using

FIGURE 3-5 System for isolation of anaerobic and microaerophilic bacteria. The packets are opened, and the sachets inside are placed into the container with the inoculated plates. The container is sealed immediately. The sachets contain ascorbic acid. Atmospheric oxygen in the container is rapidly absorbed and replaced with carbon dioxide in an exothermic reaction process. After an appropriate incubation period, the container is opened and the plates inspected for growth. An anaerobic indicator can be placed within the box to ensure that the proper conditions are maintained.

VetBooks.ir

anaerobic culture of blood, but anaerobic bacteremia may be occur with other underlying causes of bloodstream infections.[6] Common blood culture contaminants include coagulase-negative staphylococci, *Bacillus* spp., corynebacteria, and propionibacteria. When only one blood culture is positive for one of these organisms, contamination is likely, but the presence of multiple positive blood cultures from separate sites suggests true bacteremia.

Culture of intravascular catheter tips is performed to determine whether a catheter is a source of bacteremia and should only be performed simultaneously with blood culture. The catheter is removed after cleaning the skin around the catheter site with alcohol, and the distal 5 cm is aseptically removed into a sterile tube and submitted immediately.[7] In the laboratory, the catheter tip is rolled onto an agar plate. The result of catheter culture alone should not change treatment. Therefore, in most situations, blood culture may be all that is required.

Skin

For dogs with superficial pyoderma, specimens for culture should ideally be collected from a pustule. No surface disinfection should be performed. The hair should be clipped using sterile scissors; clippers should be avoided. A pustule is lanced with a sterile narrow-gauge needle, and pus on the needle or exuding from the pustule is applied to a sterile swab, which can then be placed in transport medium for transport to the laboratory. If a pustule cannot be found, cultures can also be obtained by lifting crusts and swabbing beneath the crust, or rolling the swab across an epidermal collarette two to three times. Papules can be cultured by biopsy after surface disinfection with 70% alcohol, allowing the surface to dry, and use of a 3- to 4-mm punch and sterile surgical instruments to collect the biopsy, which is then submitted in transport medium or a small amount of sterile saline. The biopsy site can then be sutured closed.

For deep pyoderma, a biopsy of the lesion should also be obtained after surface disinfection with 70% alcohol. The dermis should be excised with a sterile blade and the biopsy submitted as just described.

For dogs and cats with wounds, aspirates and deep tissue biopsies after surgical dissection are always preferable to swab specimens. Swab specimens are often contaminated by surface microorganisms, contain only a small amount of material, and are not amenable to optimal anaerobic transport. For this reason, collection of pus from fistulous tracts using a swab should also be avoided. If an abscess is present, an aspirate of the abscess fluid should be collected and submitted for aerobic and anaerobic culture. For dogs and cats with cellulitis, an aspirate can be attempted by injecting a small volume of sterile saline into the lesion and aspirating back into a syringe, although bacterial yields may be low and biopsy may be required in some cases.

Body Fluids

Usually, 1 to 5 mL of body fluid is required for culture. Fluid can be inoculated into blood culture bottles in the laboratory or alongside the patient. Body fluids that have the potential to clot should be submitted to the laboratory in a tube that contains an appropriate ratio of anticoagulant. In the laboratory, body fluids with volumes that exceed 1 mL are generally concentrated using centrifugation and resuspension of the pellet in a smaller volume (e.g., 0.5 mL) of supernatant before they are inoculated onto agar.

For cerebrospinal fluid, the chance of organism isolation also increases when the volume submitted is maximized. If possible, at least 0.5 mL should be submitted for culture. Cerebrospinal fluid specimens should be immediately transported to the laboratory, preferably at room temperature.

Tissue Specimens

Attempts should be made to obtain as large a tissue specimen as possible for culture. The use of swabs to collect specimens for culture during surgical procedures is discouraged because of insufficient specimen size. Small pieces of tissue can be submitted in a small amount of sterile, nonbacteriostatic saline. In the laboratory, the tissue is minced using sterile procedures to release organisms before smears are prepared and media inoculated. Because an anaerobic environment can be maintained within pieces of tissue greater than or equal to 1 cm^3 in volume, these are suitable for anaerobic culture without oxygen-free transport. Such tissue specimens may be stored at room temperature for up to 24 hours.

Airway Specimens

Specimens from the upper respiratory tract are generally contaminated with commensal bacteria. Aerobic bacterial culture of a nasal wash specimen may be indicated in cats with chronic rhinosinusitis in which an antimicrobial resistant organism is suspected, in particular *Pseudomonas aeruginosa*. Isolation of *Bordetella bronchiseptica* may also have clinical significance in dogs and cats with nasal discharge. Growth of *Mycoplasma* spp. from the nasal cavity has uncertain clinical significance, because *Mycoplasma* spp. can be isolated from the nasal cavities of both healthy cats and cats with rhinosinusitis.[8-11]

BOX 3-2

Suggested Procedure for Obtaining Blood Cultures

Shave site.
Clean skin with 10% povidone iodine or 1-2% tincture of iodine, swabbing concentrically from the center; allow to dry (wait 1 min).
If a catheter must be used for specimen collection, clean access port with 70% alcohol and allow to dry. Avoid collection from a catheter if possible.
Clean stopper on top of the culture tube or bottle with 70% alcohol; allow to dry (wait 1 min).
Perform venipuncture using sterile gloves to palpate the vein.
Inoculate blood culture bottle without changing the needle.
Space cultures based on severity of illness, before starting antimicrobial therapy.

- Acute febrile illness: antimicrobials need to be changed or started immediately: two sets from separate sites, all within 10 minutes. Consideration could be given to drawing a third set using a resin bottle just before administering the second dose of antimicrobials (i.e., when trough drug concentrations are present)
- Acute endocarditis: 3 sets from 3 separate sites, within 1-2 hours
- Nonacute disease: 3 sets from separate sites within 24 hours, spaced at intervals of at least 3 hours

VetBooks.ir

Specimens from the lower respiratory tract may be collected using transtracheal, endotracheal, or bronchoalveolar lavage. Bronchial brush specimens may also be submitted for culture, after placing them in 1 mL of sterile nonbacteriostatic saline. The presence of intracellular bacteria on cytologic examination is consistent with a bacterial infection, rather than contamination. Anaerobic culture could be considered for animals with aspiration pneumonia or migrating plant awn foreign body pneumonia.

Feces

Whole stools or swabs that contain fecal matter should be processed within 1 to 2 hours or refrigerated as soon as possible after specimen collection and submitted within 24 hours. The specimens should not be contaminated with barium or urine. Rectal swabs that contain fecal material can be immersed in transport medium until processing. Testing of more than one sequential specimen may improve detection of fecal pathogens due to the low sensitivity of fecal culture methods. Selective media are required for isolation of *Salmonella* spp. Because *Clostridium perfringens* and *C. difficile* are commonly detected in normal stool specimens, toxin antigen testing may be more appropriate than culture to determine the role these organisms may be playing in diarrhea (see Chapter 48). Special medium is also required for isolation of *Campylobacter* (see Chapter 47).

Urine

Urine should be collected using cystocentesis whenever possible. Collection of urine via sterile catheterization in male dogs is acceptable when cystocentesis is not possible. Quantitative cultures should always be performed. For specimens obtained by cystocentesis, any level of bacterial growth is significant, although most urinary tract infections contain greater than or equal to 10^3 colony-forming units (CFU)/mL of bacteria. For urine specimens obtained via catheter from male dogs, bacterial growth of greater than or equal to 10^5 CFU/mL has been considered significant.[12] Only aerobic bacterial culture is routinely indicated. Anaerobic urine culture may be indicated when there is radiologic evidence of emphysematous cystitis. Urine specimens should be refrigerated and submitted to the laboratory as soon as possible. Special urine transportation tubes can be used to preserve bacteria within the specimen provided they are appropriate for the volume of urine collected (e.g., BD Vacutainer urine culture and sensitivity tube). Urine "paddles" are also available for in-house veterinary use. These allow inexpensive screening for the presence of absence of infection (Figure 3-6). The paddles have media impregnated on them, are designed to be incubated in the clinic, and can provide some information on the infecting bacterial species present and the number of CFU/mL. Positive paddles can then be submitted to the laboratory for culture and susceptibility testing, although this does not always permit accurate identification of all bacteria present in mixed infections (see also Chapter 89).

For animals with a urinary catheter in place and a suspected urinary tract infection, culture of the catheter tip is not recommended, because it is generally contaminated with commensal organisms from the urethra. Instead, a urine specimen should be obtained by aspiration from a new urinary catheter, or, if feasible, using cystocentesis. If a catheter is used to collect the specimen, several milliliters of urine should be removed and discarded first to clear the catheter. Urine culture should never be performed on collection bag specimens.

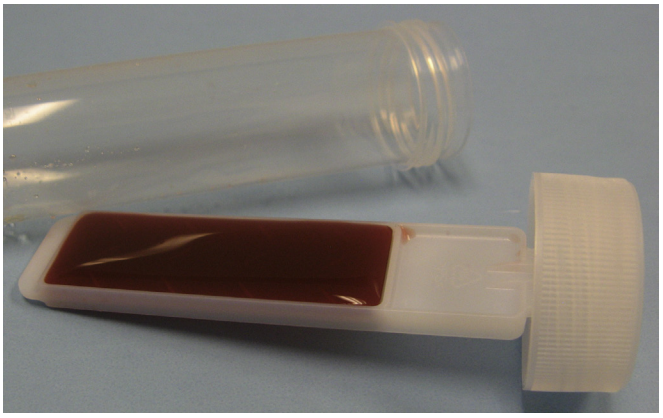

FIGURE 3-6 Media paddle available for screening urine for the presence of an aerobic bacterial infection. The paddle is impregnated on each side with selective and nonselective media (in this case eosin methylene blue medium, shown, and cysteine lactulose electrolyte-deficient media, on underside, respectively). The paddle is flooded with urine, incubated, and inspected for growth. Eosin methylene blue medium is red and selects for growth of gram-negative enteric organisms. Cysteine lactose electrolyte-deficient medium is initially green but turns yellow in the presence of lactose-fermenting organisms.

Fastidious and Unculturable Organisms

Some bacteria, such as *Bartonella* spp., *Borrelia burgdorferi*, and *Leptospira* spp., require special culture conditions (see Chapters 50 to 52). Others, such as hemotropic *Mycoplasma* species, are unculturable, and DNA amplification methods such as PCR are required for detection of these organisms. Cell culture is required to propagate certain bacteria. Examples include *Chlamydia felis* and tick-borne pathogens such as *Anaplasma phagocytophilum*.

Bacterial Identification

Following aerobic or anaerobic culture, presumptive bacterial identification can be made on the basis of colony morphology and microscopic morphology (e.g., Gram stain characteristics, rods or cocci). Further differentiation is generally based on a series of additional phenotypic tests, which are selected based on microscopic morphology and whether the organism is gram-negative, gram-positive, aerobic, or anaerobic. Microbiology laboratories use published methods to identify bacteria.[13] Preliminary tests used to identify gram-positive aerobes include the presence or absence of hemolysis on a blood agar plate (Figure 3-7), a positive or negative catalase test, and the production of coagulase. Identification of gram-negative aerobes relies on whether or not the organism ferments lactose, indole production, oxidase production, and the production of a variety of other enzymes. Assessment of motility and the ability to ferment carbohydrates are also used to differentiate bacteria. Biochemical test strips are available that allow multiple tests to be performed simultaneously (e.g., API Strips, bioMérieux) (Figure 3-8), so that identification can be made within 24 to 48 hours. Automated identification systems that consist of a 96-well microtiter tray that contains a variety of biochemical reagents (e.g., Sensititre, TREK Diagnostics, Cleveland) are also in use in some veterinary diagnostic laboratories.

Molecular methods such as 16S rRNA gene PCR and sequencing are now being used to identify organisms to the species level (see Chapter 5). Speciation of some mycobacteria requires analysis

VetBooks.ir

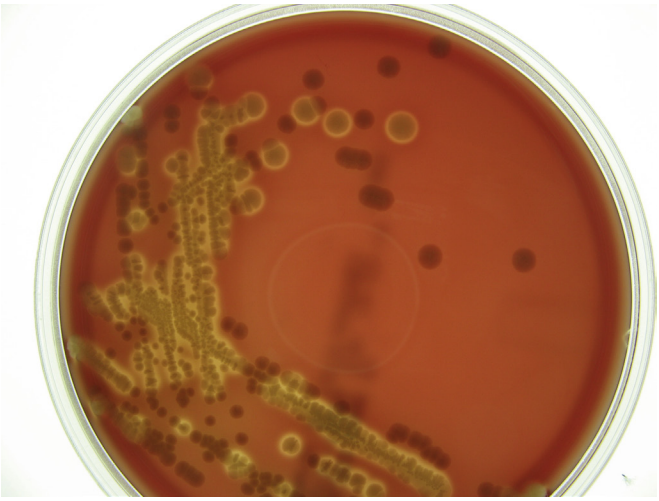

FIGURE 3-7 Mixture of beta-hemolytic and nonhemolytic enteric bacteria growing on blood agar. Beta-hemolysis is characterized by complete clearing of the agar around each colony.

of mycolic acid content using high-performance liquid chromatography. Recently, the availability of matrix-assisted laser desorption ionization time-of-flight mass spectrometry instrumentation (i.e. the Bruker Biotyper and VITEK MS systems) has revolutionized bacterial identification in the clinical microbiology laboratory. These systems use mass spectrometry to rapidly (on average in 6 minutes) and accurately (often >95%) identify organisms to the species level based on their chemical composition, provided a reference spectrum for the organism is available in the database used for comparison. Although the instrumentation is expensive, the ultimate cost is lower than with conventional biochemical methods, because of reduction in labor and reagent costs.[14]

Interpretation of Bacterial Culture Results

Specimens That Test Negative

Negative results (or lack of growth) using bacterial culture do not imply the absence of bacteria. Negative test results can occur as a result of inadequate specimen size (such as when swabs or aspirates are submitted), when there are inadequate organism numbers at the site of specimen collection, when overgrowth with commensal organisms occurs, or when there is loss of organism viability during transportation to the laboratory. The last is particularly problematic for anaerobic bacteria. In some situations, multiple bacterial species are present within a specimen, and one species (such as *Proteus* spp.) swarms the plate and obscures the presence of another. The identification of multiple bacterial types on a Gram-stained smear allows the laboratory to plan culture methods that maximize detection of all species present.

Negative test results can also occur when the organism is not inoculated onto the correct media or sufficient time is not allowed for growth. Clinicians must consider whether fastidious or slow-growing organisms might be present and inform the laboratory if they are suspected. Poor laboratory quality control procedures may also lead to false-negative test results. Use of an accredited laboratory can help minimize such problems.

Specimens That Test Positive

The detection of bacterial organisms within a specimen using culture does not imply that the organism is the cause of an animal's clinical signs. Contamination is the most common cause of false positive cultures. Isolation of only one or two colonies of coagulase-negative staphylococci, *Bacillus* spp., *Corynebacterium* spp., or propionibacteria suggests contamination. Isolation of large numbers of a single type of bacteria from a normally sterile site is usually clinically significant, especially when supported by cytologic evidence of bacteria within phagocytes.

Antimicrobial Susceptibility Testing

Importance of Antimicrobial Susceptibility Testing

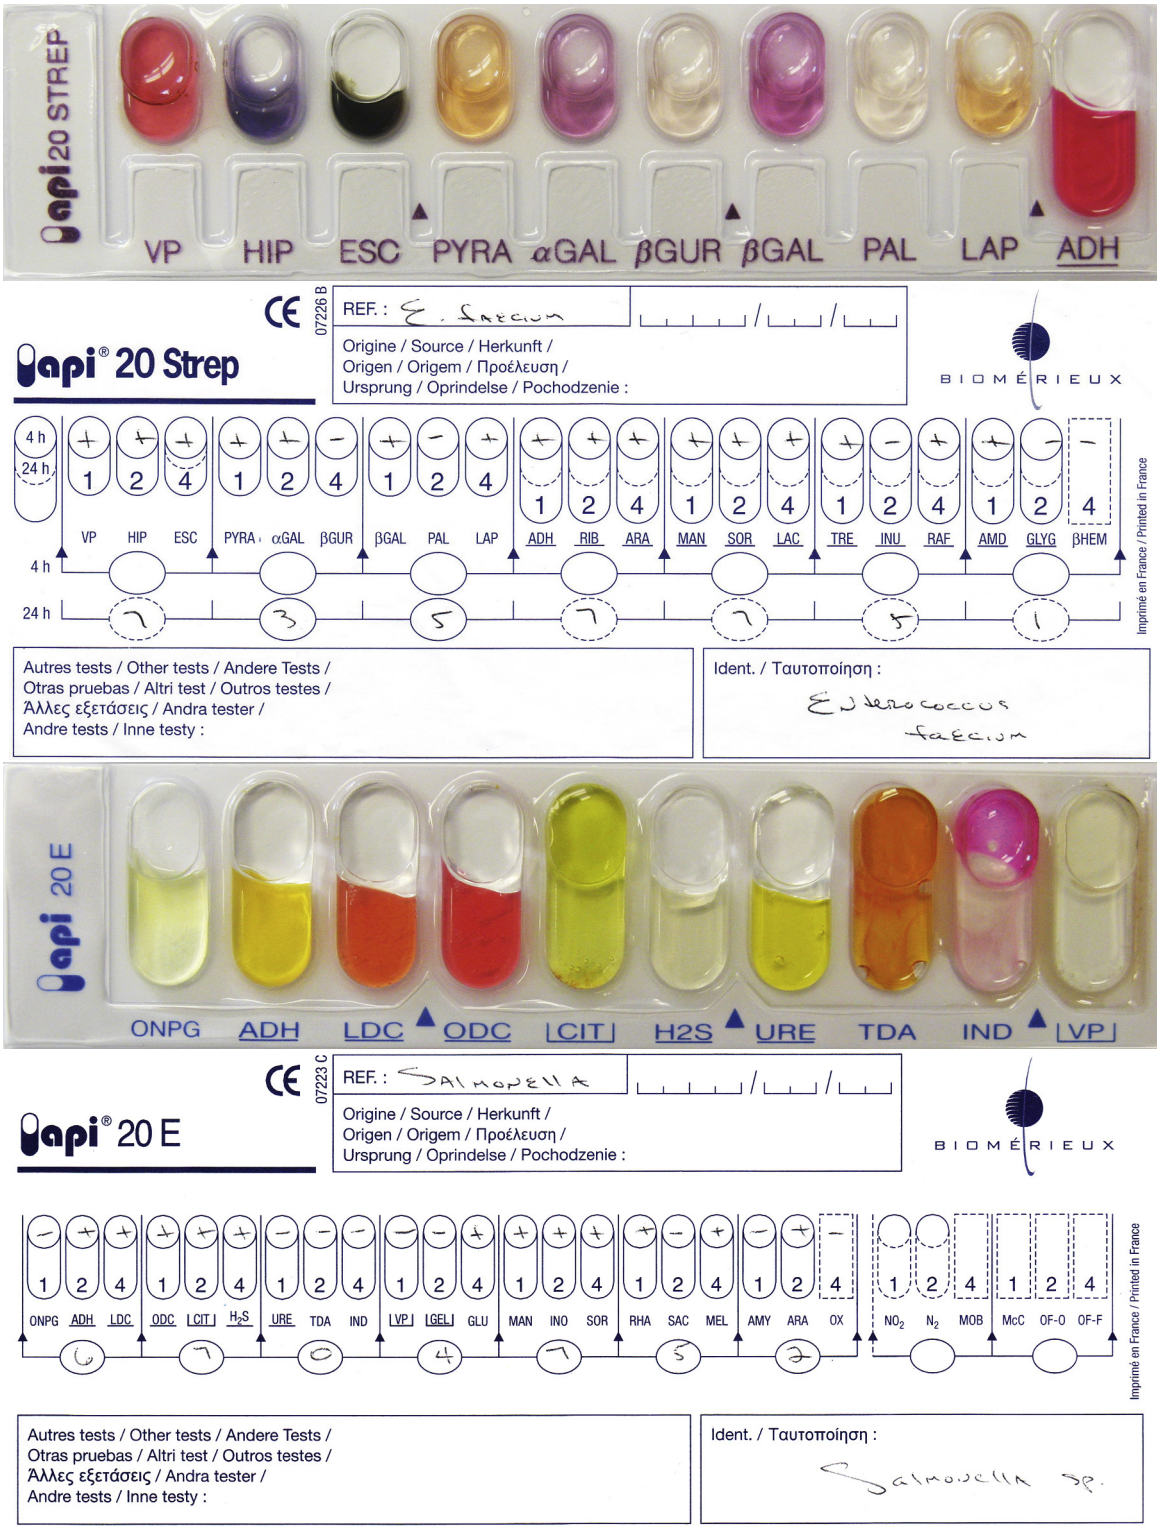
Given the increasing recognition of antimicrobial resistance among bacteria that are isolated from small animal patients, determination of antimicrobial susceptibility can be as or more important to the clinician than the identity of the infecting agent. The result of antimicrobial susceptibility testing is generally available 2 to 3 days after submission of a specimen for culture. In animals that are critically ill, empiric antimicrobial therapy may already have been initiated by the time this result is available. The susceptibility results may show that the organism is resistant to a drug being used, in which case the drug should be changed to one to which the organism is susceptible. The susceptibility pattern can help to identify an alternate drug when the patient does not tolerate the initial drug prescribed. Susceptibility testing may indicate that the organism is susceptible to a more narrow-spectrum (and generally less expensive) antimicrobial drug than the drug initially prescribed, in which case the spectrum should be narrowed to minimize the development of antimicrobial resistance.

Methods of Susceptibility Testing

Susceptibility testing can be performed using dilution methods or diffusion methods. The *minimum inhibitory concentration* (MIC) is the lowest concentration of antimicrobial drug that inhibits visible growth of an organism over a defined incubation period, most commonly 18 to 24 hours. The MIC is determined using dilution methods, which involve exposing the organism to twofold dilutions of an antimicrobial drug. The concentration range used varies with the drug and the organism being tested. In vitro factors that influence MIC include the composition of the medium, the size of the inoculum, incubation conditions, and the presence of resistant bacterial subpopulations within the inoculum. Standard protocols are published by the Clinical and Laboratory Standards Institute (CLSI) that specify medium composition and pH, inoculum size, inoculation procedures, agar depth, and incubation conditions, as well as quality control requirements.[13] Failure to comply with these protocols can lead to erroneous results, so laboratories that adhere to CLSI standards should be used whenever possible. MIC testing does not take into account in vivo factors such as postantibiotic effect and the effects of protein binding on antimicrobial drug activity (see Chapter 6).

Dilution Methods

Dilution methods include *broth macrodilution, broth microdilution,* and *agar dilution*. The most widely used method in North America is broth microdilution, whereby twofold dilutions of antimicrobials are made in a broth medium in a microtiter plate (Figure 3-9). Pre-prepared frozen or freeze-dried microtiter plates for inoculation are available



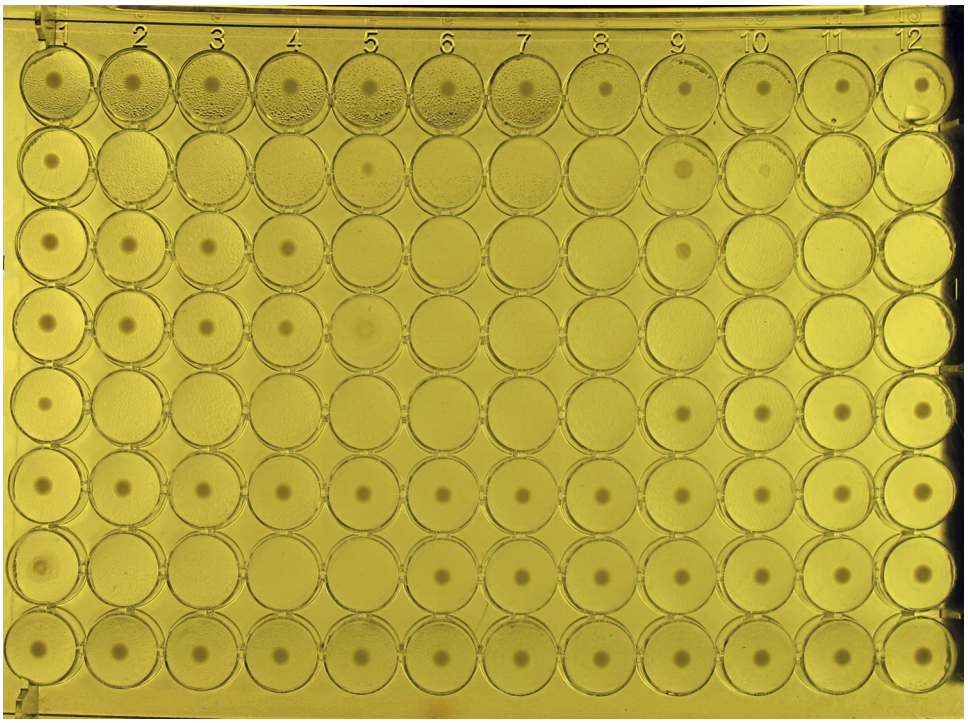


FIGURE 3-8 API bacterial identification strips. Only the left half of the reaction strip is shown. *Top (api20STREP): Enterococcus faecium. Bottom (api20E): Escherichia coli*. Positive reactions are assigned a numerical code on the handwritten strip. The codes in each three-well group are added to generate a new (seven-number) code that can be used to identify the organism.

commercially (e.g., Sensititre plates, TREK Diagnostic Systems, Cleveland). The results can be determined using visual examination of the plates for the inhibition of bacterial growth, or by the use of semiautomated or automated instrumentation. Dilutions can also be performed in agar, each dilution being poured onto a plate in a standardized fashion and allowed to set before inoculating it with the organism(s) of interest. Agar dilution can be used to perform susceptibility testing of fastidious bacteria with special medium requirements, such as *Campylobacter* spp.

The MIC for each antimicrobial drug tested against the organism is reported to the clinician on the susceptibility panel. It is the lowest concentration of antibiotic (usually in µg/mL) that inhibits growth of the organism in vitro. The lower the

FIGURE 3-9 Broth microdilution for determination of MICs. A series of wells contain an antimicrobial drug at twofold dilutions in a standard format. One custom plate format is shown (TREK Diagnostic Systems Sensititre Companion Animal MIC plate). A pellet of bacteria (in this case, *Escherichia coli* from an infected feline esophagostomy tube site) settles on the bottom of each well when growth fails to be inhibited by the antimicrobial drug concentration tested in that well. The cutoff MICs that define susceptibility versus resistance are published by the Clinical and Laboratory Standards Institute (CLSI) in the United States. This isolate was reported as resistant to ampicillin (>16 mg/mL), susceptible to amoxicillin-clavulanic acid (8 mg/mL), susceptible to amikacin (8 mg/mL), susceptible to cefoxitin (8 mg/mL), resistant to ticarcillin (>64 mg/mL), susceptible to cefpodoxime (≤2 mg/mL), susceptible to ticarcillin-clavulanic acid (16 mg/mL), resistant to trimethoprim-sulfamethoxazole (>2 mg/mL), susceptible to cefovecin (1 mg/mL), susceptible to cefazolin (≤4 mg/mL), susceptible to gentamicin (2 mg/mL), susceptible to imipenem (≤1 mg/mL), resistant to doxycycline (>8 mg/mL), resistant to enrofloxacin and marbofloxacin (both >2 mg/mL), and resistant to chloramphenicol (>16 mg/mL). The MIC for ceftiofur was ≤0.25 mg/mL, but because a breakpoint for this drug has not been published, only the MIC was reported, and not whether the isolate was susceptible or resistant. Results for some drugs tested, such as oxacillin, are not reported for gram-negative bacteria because these drugs are used to treat gram-positive bacterial infections.

MIC, the more potent is the antimicrobial at inhibiting bacterial growth.

Diffusion Methods

Diffusion methods include gradient diffusion (also known as Etest) and disc diffusion. The *Etest* involves use of a plastic strip coated with an antimicrobial gradient on one side and an MIC interpretive scale on the other side (Figure 3-10, *A*). An agar plate is inoculated with the organism of interest so that subsequent growth of the organism forms a "lawn," rather than individual colonies (i.e., *inoculation to confluence*). At the time of inoculation, the strips are applied to the surface of the plate. The antimicrobial drug diffuses into the medium, resulting in an elliptical zone of growth inhibition around the strip. The MIC is read at the point of intersection of the ellipse with the MIC scale on the strip. Although the strips are expensive, Etests have the advantage of being adaptable to use with fastidious organisms and anaerobes.

Disk diffusion, also known as Kirby-Bauer antibiotic testing, involves application of commercially available drug-impregnated filter paper discs to the surface of an agar plate that has been inoculated to confluence with the organism of interest. Commercially available, mechanical disk-dispensing devices can be used to apply several disks simultaneously to the surface of the agar. The drug diffuses radially through the agar, the concentration of the drug decreasing logarithmically as the distance from the disk increases. This results in a circular zone of growth inhibition around the disk, the diameter of which is inversely proportional to the MIC (see Figure 3-10, *B*). The zone diameters are interpreted on the basis of guidelines published by CLSI (see Definition of Breakpoints, next), and the organisms are reported as susceptible, intermediate, or resistant. Disk diffusion can only be used to test rapidly growing organisms that have consistent growth rates, for which criteria for interpretation of zone sizes are available.

Definition of Breakpoints

Once susceptibility testing has been performed, organisms are classified on the susceptibility panel report as "susceptible" (S), "resistant" (R), and, in some cases, of "intermediate" (I) susceptibility. *This refers to a predicted in vivo situation, rather than in vitro susceptibility.* The growth of "susceptible" isolates is predicted to be inhibited by antimicrobial drug concentrations that are usually achievable in blood and tissues using normal dosage regimens. "Intermediate" isolates have MICs that approach usually attainable blood and tissue levels and for which response rates may be lower than those of susceptible isolates. This category implies clinical efficacy in body sites where the drugs are normally concentrated (e.g., enrofloxacin and amoxicillin in urine) or when a higher-than-normal dose of a drug can be used. "Resistant" isolates are predicted to grow in the face of the usually achievable concentrations of the drug in blood and tissues.[15]

So why can the laboratory predict in vivo susceptibility on the basis of MIC determination, which is an in vitro test? In order to do this, the laboratory refers to *breakpoints*, or clinical cutoff MICs (or, for disc diffusion testing, cutoff zone diameters), which are established, published, and revised regularly by committees that are affiliated with standards agencies such as the CLSI. If the MIC determined in the microbiology laboratory is lower than a published breakpoint for that organism-drug combination, the organism is defined as susceptible. *The breakpoint is not reported to the clinician.* Breakpoints are established on the basis of multiple factors (Box 3-3), which include (1) a knowledge of MIC distributions and resistance mechanisms for each organism-drug combination (Figure 3-11),[16] (2) clinical response rates in humans and animal models, (3) how the drug is distributed and metabolized in the body (pharmacokinetics), and (4) whether the drug is concentration dependent or time dependent as it relates to antibacterial effect (pharmacodynamics) (see Box 3-3).[15] Zone diameter breakpoints for disc diffusion testing are determined by correlation with MIC values. For simplicity, breakpoints are established for antimicrobial drug

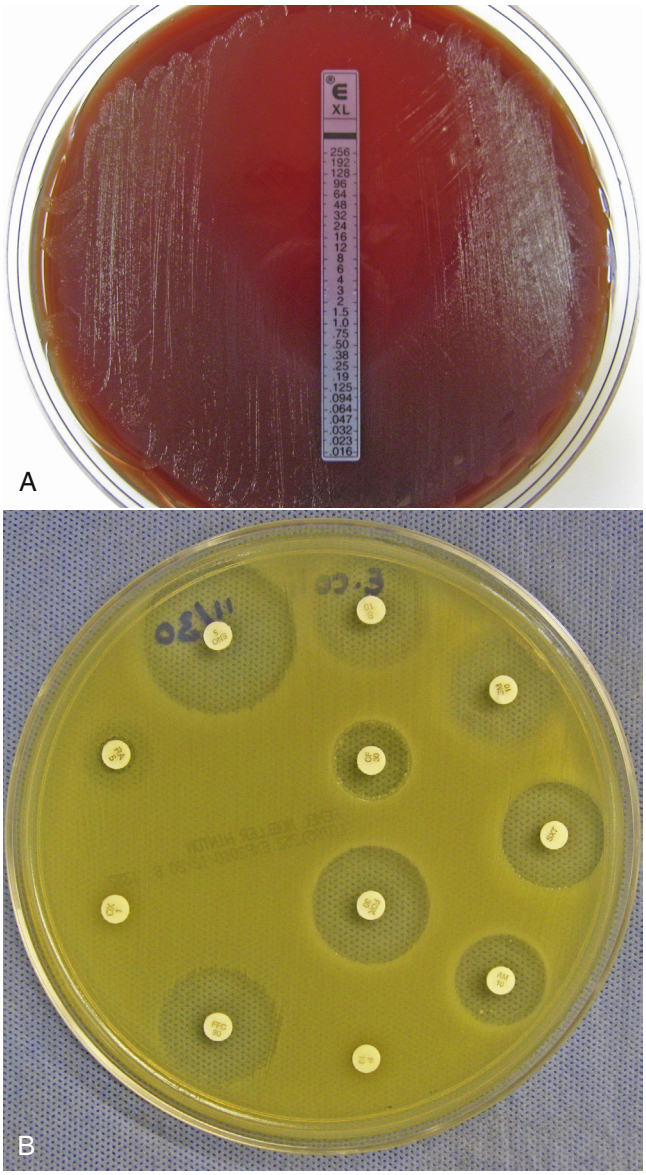

FIGURE 3-10 Alternatives to broth microdilution for antimicrobial susceptibility testing. **A,** Etest that shows susceptibility of a *Bacteroides fragilis* isolate to amoxicillin-clavulanic acid. The strip in the center is impregnated with a gradient of antimicrobial drug (in this case, amoxicill-clavulanic acid), with the highest concentration at the top of the strip. The MIC is read at the point where bacterial growth is no longer inhibited by the strip (0.19 mg/mL in this case). **B,** Disc diffusion (also known as Kirby-Bauer testing) for *Escherichia coli* showing varying degrees of resistance to different antimicrobial drugs, reflected by zones of growth inhibition around discs containing each antimicrobial drug.

concentrations in the bloodstream, and are based on a specific dosage regime for the antimicrobial drug tested. This dosage regime is selected by the standards agency involved. Because some antimicrobials are concentrated extensively in urine, some veterinary laboratories may offer urine MIC panels, which provide breakpoints for lower urinary tract infections. These breakpoints are higher than corresponding serum MIC breakpoints, so a greater proportion of organisms tested are classified as "susceptible." Urine MIC panels have been controversial because the possibility of concurrent pyelonephritis (tissue drug concentrations rather than urine concentrations) cannot always be ruled out. Breakpoints may be reevaluated when new mechanisms of resistance appear in bacteria or when new data are generated that improve understanding of the pharmacokinetics and pharmacodynamics of an antimicrobial drug.

For infections in sites such as the central nervous system, the clinician needs to consider whether or not (1) an antimicrobial will penetrate that site, (2) the drug is appropriate and safe, and (3) a higher dose is necessary to achieve adequate concentrations. The clinician must also consider factors such as immunosuppression and other concurrent illness or drug therapy when treating infections on the basis of antimicrobial susceptibility test results.

The bacterial species isolated determines which antimicrobials the laboratory selects for inclusion in susceptibility panels. For example, susceptibility to cephalosporins may not be reported for enterococci because of intrinsic resistance. Some antimicrobial drugs (e.g., vancomycin, linezolid, imipenem) should be reserved for treatment of multiple-drug resistant organisms that cause life-threatening infections. Consultation with a health professional with expertise in infectious diseases or antimicrobial pharmacology is recommended before these drugs are selected.

BOX 3-3

Factors Used by Standards Agencies to Establish Breakpoints for Antimicrobial Susceptibility Testing

Bacterial Factors
- Evaluation of MIC distributions for each bacterial species. These tend to be normally distributed (see Figure 3-10; available for different antimicrobial drugs at www.eucast.org).[15]
- Knowledge of bacterial resistance mechanisms, as determined using phenotypic or genetic testing (e.g., testing for altered penicillin binding proteins in staphylococci)

Pharmacokinetics of the antimicrobial drug when used at a specific dosage regime in the animal species of interest, including protein binding, taking into account variation among individuals

Pharmacodynamic indices (e.g., whether killing is concentration or time dependent) for the antimicrobial drug as they relate to organism killing (see Chapter 6)

Clinical response rates in humans and animal models, which are based on prospective, randomized controlled clinical studies with well-defined dosage regimes

Minimum and Serum Bactericidal Concentration

The *minimum bactericidal concentration* (MBC) is the minimum concentration of an antimicrobial drug that is bactericidal. It is determined by re-culturing *(subculturing)* broth dilutions that inhibit growth of a bacterial organism (i.e., those at or above the MIC). The broth dilutions are streaked onto agar and incubated for 24 to 48 hours. The MBC is the lowest broth dilution of antimicrobial that prevents growth of the organism on the agar plate. Failure of the organism to grow on the plate implies that only nonviable organisms are present. The use of MBCs has been advocated by some for treatment

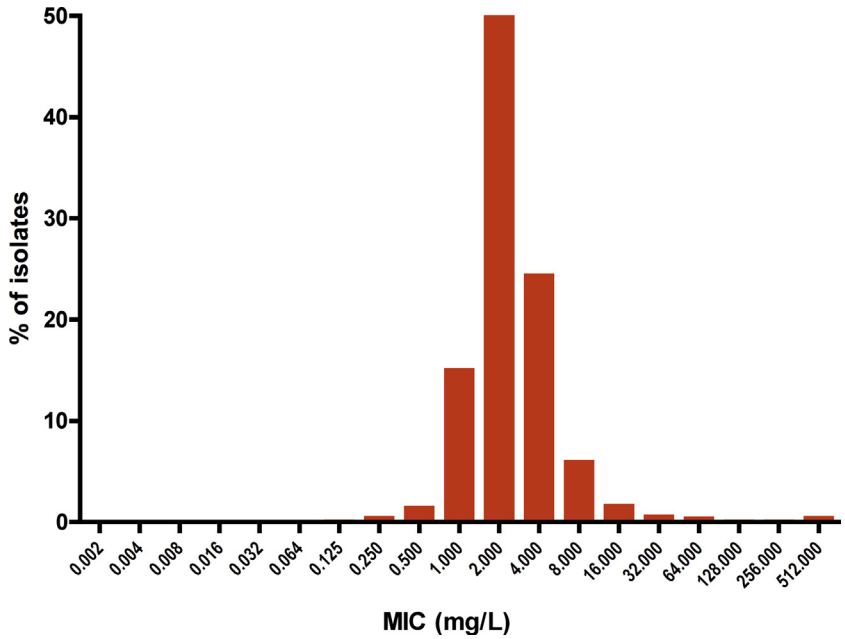

FIGURE 3-11 Histogram that shows the distribution of amikacin minimum inhibitory concentrations (MICs) for isolates of *Escherichia coli*. The MICs are normally distributed. (From www.eucast.org. Accessed May 11, 2012.)

VetBooks.ir

of serious infections (such as endocarditis) or for treatment of immunosuppressed patients. Their value has been controversial, and they are not widely performed in human or veterinary medicine.

Serum bactericidal testing (SBT) is performed in the same manner as the MBC test, but uses the serum of a patient that has been treated with an antimicrobial. Serum is usually collected at expected peak and trough serum concentrations. SBC can be used to determine whether a patient has been adequately dosed, and to ensure that the antimicrobial is having the desired effect on the organism. Some data are available to support specific peak and trough SBT results required for the optimal treatment of human endocarditis, osteomyelitis, and cancer chemotherapy patients.[17-20] The SBT has not been widely used or evaluated for infections in dogs and cats and remains controversial in human medicine.

Mutant Prevention Concentration

The *mutant prevention concentration* (MPC) is the lowest antimicrobial drug concentration required to block the growth of the least susceptible bacterial cell in high density bacterial populations.[21] It is the MIC of the most resistant bacterial strain in a mixed bacterial population. Concentrations of antimicrobial between the MIC and the MPC allow selective amplification of resistant mutants (also known as the *mutant selection window*).[22] This range is considered to be a "danger zone" for therapeutic drug concentrations. Minimizing the length of time that the antimicrobial drug concentration remains in the mutant selection window in vivo may reduce the likelihood for resistance selection during treatment.[22] The MPC cannot be extrapolated from the MIC. It is estimated using the standard agar dilution method used to estimate MIC, but with a larger inoculum ($\geq 10^9$ instead of 10^5 organisms), so as to include resistant subpopulations of bacteria. Administration of higher doses of antimicrobial drugs that exceed the MPC increases the chance of toxicity to the patient, but offsets the chance of selection for resistant organisms, even though infection may be cured with lower doses.[22,23] Although first evaluated for the fluoroquinolones, data is accumulating regarding the usefulness of the MPC for other drug classes. MPC estimations are currently not routinely performed in veterinary diagnostic laboratories.

CHAPTER 4

Isolation and Identification of Fungi

Jane E. Sykes and Shelley C. Rankin

KEY POINTS

- Fungi often grow more slowly than bacteria and can have specific culture media requirements. Some fungi are dangerous to culture because they produce airborne spores that may lead to laboratory-acquired infections.
- The clinician should tell microbiology laboratory personnel if a fungal infection is suspected. Providing a list of suspected pathogens facilitates safe and successful culture of pathogenic fungi. The animal's clinical abnormalities, travel history, history of immunosuppressive drug therapy, and the results of cytology or histopathology should be taken into account.
- Specimens should be collected and transported as for bacterial culture. Refrigeration inhibits growth of some fungi.
- Because of increasing drug resistance among pathogenic fungi, the demand for antifungal susceptibility testing has increased, and for some fungal pathogens, culture and susceptibility testing before beginning antifungal drug therapy may be advantageous.

INTRODUCTION AND DEFINITIONS

Fungi are eukaryotic microorganisms that secrete enzymes in order to digest organic material in the environment. The resultant nutrients are absorbed through a specialized fungal cell wall (known as *chemotrophic nutrition*). A basic understanding of fungal terminology facilitates communications between clinicians, microbiologists, and pathologists. Fungal organisms have two basic morphologic forms:

1. Molds—molds exist as filaments known as *hyphae,* which may be divided into cellular compartments *(septate hyphae).* A mass of filaments is known as a *mycelium.* A granule formed by a compacted mat of fungal filaments is a *eumycetoma* (as opposed to an *actinomycotic mycetoma;* see Chapter 42).
2. Yeasts—these are single-celled organisms that reproduce by budding. In some cases, buds do not detach from the parent cell, but instead form a chain. Elongated chains of buds may resemble hyphae. These are termed *pseudohyphae* (Figure 4-1).

Many pathogenic fungi exist as a mold in the environment, but in tissues convert to a yeast form. These fungi are called *dimorphic fungi*. An example of a dimorphic fungus is *Blastomyces dermatitidis*.

Fungi reproduce by producing *spores*. Spores can be produced following asexual or sexual reproduction. Asexual reproduction (through mitosis) generates spores that are identical to the parent cell. Sexual reproduction involves the fusion of haploid nuclei from two hyphal structures, which is followed by meiosis. The asexual stage of a fungus is known as an *anamorph*, whereas the sexual stage is known as a *teleomorph*. Many fungi have two different species names to reflect these stages. For example, the teleomorph of *Cryptococcus neoformans* is known as *Filobasidiella neoformans*. Formally, the teleomorph name is supposed to take precedence and can be used to describe both stages.[1] However, asexual reproduction predominates in most fungi, including during growth in culture. Thus, certain fungi, such as *C. neoformans*, are more widely known by their anamorph name. In addition, teleomorphs of some fungal organisms have not yet been described. Some organisms can exist in more than one asexual form, and therefore have more than two names. For example, *Pseudallescheria boydii* (teleomorph) has two asexual forms, *Graphium fruticola* and *Scedosporium apiospermum*. Currently, there is a move by mycologists to identify only a single name for a fungal organism ('one fungus = one name'). Throughout this book, the name most commonly used in the literature is used to refer to different fungal pathogens.

Specimen Collection and Transport

Isolation of fungal organisms from clinical specimens can be facilitated by the use of special media. For many fungal species, this may be hazardous to laboratory personnel. Submission of specimens for culture of dangerous organisms such as *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Histoplasma*

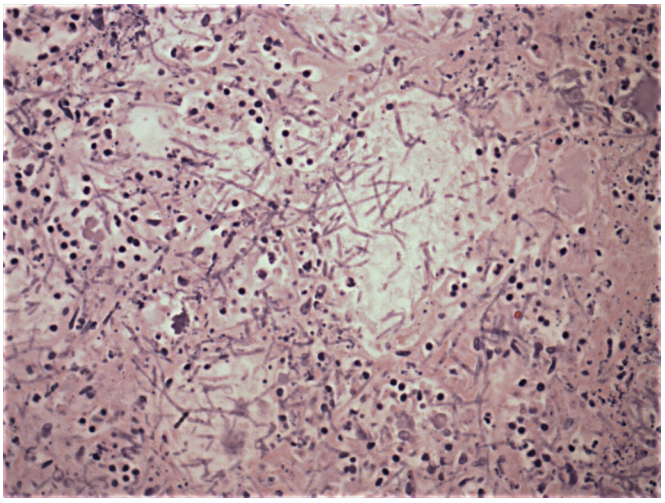

FIGURE 4-1 Histopathology of the thyroid gland from a 13-year old female spayed poodle mix with disseminated *Candida albicans* infection. The dog had been treated with prednisone, cyclosporin, and azathioprine for refractory immune-mediated hematologic disease. Note intralesional pseudohyphae. H&E stain, 400× magnification.

VetBooks.ir

capsulatum is discouraged if the diagnosis can be obtained using other methods such as cytology, histopathology, and serologic testing. These organisms exist as yeasts in tissues (at 37°C) that are minimally hazardous to clinicians and laboratory personnel, but grow as hyphae at lower temperatures and on culture medium, which generate spores that can be inhaled and cause disease.

Specimens that are commonly submitted for fungal culture include lower respiratory tract wash specimens, cerebrospinal fluid, urine, other body fluids, skin, eye, hair, or biopsy specimens from the nasal cavity, bone, or skin. Guidelines for specimen collection are the same as for bacterial culture (refer to Chapter 3). The clinician should inform the laboratory what fungal species are suspected, because different fungi have different media preferences and growth conditions. As large a specimen as possible should be collected. Care should be taken to avoid collection of contaminated specimens. Blood cultures may be useful for dogs and cats with disseminated fungal disease when lesions cannot be easily accessed. Detection of fungemia can sometimes be achieved using blood culture systems for bacterial isolation. Lysis-centrifugation methods (Isolator tubes, Wampole Laboratories) may be more sensitive for detection of dimorphic and filamentous fungi in blood. Mycobacterial blood culture media (such as MB/BacT, BioMérieux) may also offer increased sensitivity for detection of fungemia.[2]

For dermatophyte culture, 10 to 12 hairs should be plucked from the edge of the lesion using sterile forceps and submitted without refrigeration in a clean dry paper envelope or sterile glass or plastic tube. Paper envelopes are preferred to tubes because tubes retain moisture that can promote overgrowth of contaminants. Scrapings of crusts at the edges of the lesion can also be submitted. Claw clippings can be collected after cleaning them with 70% alcohol to remove contaminating bacteria and fungi. Crumbling material from under the claw may be the best specimen, or the entire claw can be submitted.

If transport requires longer than 2 hours, appropriate transport media should be used or specimens should be refrigerated. When rapid transport to the laboratory is possible, storage and transport at room temperature is preferred. Fungal culture of specimens that are more than 24 hours old is not recommended because of increased likelihood of false-positive and false-negative results. The laboratory should be informed if the patient is receiving antifungal drug treatment, which may interfere with the ability to culture fungus from the specimen.

Specimens should be labeled with the patient's name, patient number, and source of specimen, as well as the date and time of collection, and labeled, packaged, and transported according to regional and global regulations for shipping of infectious substances (see Chapter 1).[3] Careful packaging and transport is particularly important for specimens suspected to contain fungal pathogens. If dangerous organisms might be present, the laboratory should be warned in advance and the specimens marked appropriately.

Diagnostic Methods

Microscopic Examination of Direct Smears

Examination of a direct smear before culture allows rapid partial or complete identification of many fungi by the laboratory (Table 4-1, Figure 4-2). This can help the clinician make initial treatment decisions and guides media selection by the laboratory. Using Gram stain, yeasts generally stain gram positive and molds tend to be gram negative.[4] A potassium hydroxide (KOH) preparation may be performed to examine a specimen for dermatophyte hyphae and arthroconidia. The KOH clears keratinaceous and cellular debris, but fungal elements are left intact. If tissue granules are present, the laboratory will crush them, examine them for hyphae, and the granules can also be cultured. Fungal morphology may be altered in specimens from dogs and cats receiving antifungal drug treatment (Figure 4-4).

Special stains used in the laboratory for fungal identification include India ink, which is used to identify cryptococcal yeasts in cerebrospinal fluid (see Figure 62-8), and calcofluor white, which binds polysaccharides in the fungal cell wall and fluoresces when examined using fluorescence microscopy (Figure 4-5, *A*). Other stains, such as lactophenol cotton blue (see Figure 4-5, *B*), are also used to identify fungi after they have been grown in culture.

In some situations, fungi are observed in tissues with histopathology but a culture of the causative organism is not available, either because it has not been performed or because the organism has failed to grow. The morphology and staining characteristics of the organism on histopathology may also be useful for preliminary identification or allow full identification of the pathogen. Special stains used include Mayer's mucicarmine stain, which stains the cryptococcal polysaccharide capsule red; Gomori's methenamine silver stain, which stains fungal organisms black; and periodic acid–Schiff, which stains fungal elements dark pink (Figure 4-6). If the identity of the fungus remains in doubt, an additional specimen should be collected for culture if possible, and the microbiology laboratory should be made aware of the morphology of the organism and the differential diagnoses. Complete identification of the organism using culture is useful for proper treatment and prognostication.

Fungal Culture

Before culture, clinical specimens must be prepared for inoculation. For example, body fluids are usually first centrifuged by the laboratory to concentrate fungal organisms. The sediment is then resuspended in a smaller volume of supernatant and inoculated onto selective media. If biopsy specimens are submitted, the tissues are finely sliced, ground, or minced, which releases the organisms before they are inoculated onto the media.

Many types of media are available for isolation of fungi, and no single medium is optimal for all organisms. Many fungi grow on blood agar plates used for primary isolation of bacteria. Special media used for initial (primary) isolation of fungal organisms from tissues and body fluids are shown in Table 4-2. Other media are available for differentiation of fungal species (see Fungal Identification, later). Media that contain antibacterial agents (usually chloramphenicol or gentamicin) are used to culture specimens that might contain bacteria. Cycloheximide is added to dermatophyte test medium to inhibit the growth of contaminant saprophytic mold species. This allows selective isolation of dermatophytes such as *Microsporum canis*.

Plates for fungal culture are sealed with an air-permeable tape in order to prevent exposure of laboratory personnel to potentially dangerous spores and to minimize plate contamination with airborne fungal organisms. Plates that grow filamentous fungi are opened only in a biological safety cabinet. Laboratories prefer to use media in tubes or bottles to reduce occupational exposure to aerosolized fungal elements. Fungal cultures are incubated at room temperature (22°C to 25°C)

TABLE 4-1

Microscopic Descriptions of Some Common Fungal Pathogens of Dogs and Cats

Organism	Yeast or Hyphae	Diameter (μm)	Description	Geographic Distribution
Blastomyces dermatitidis	Yeast	8-15	Round with thick, often refractile cell wall and broad-based budding (see Figure 60-8).	Southeastern and south central United States, upper Midwest region
Histoplasma capsulatum	Yeast	2-5	Oval to round, often found in clusters within macrophages (see Figure 61-7).	Ohio and Mississippi river valleys, especially in southern United States. Also Central America
Cryptococcus spp.	Yeast	2-15	Round to oval, narrow-based budding, sometimes forming chains of organisms. Large capsule (see Figures 4-4 and 62-8). Poorly encapsulated variants are rarely encountered.	Worldwide, common in Australia and western North America
Coccidioides spp.	Spherule	10-200	Spherules vary in size and may contain endospores ("pomegranate-like"). Using cytology, they appear as empty and collapsed, deeply basophilic structures (see Figure 63-8).	Central California, Arizona, Nevada, Central and South America
Sporothrix schenckii	Yeast	2-6	Oval, round, or cigar-shaped, occasionally budding (see Figure 64-4). May be found intracellularly and extracellularly. Difficult to find in dogs but may be abundant in cats.	Temperate and tropical zones worldwide. Most common in South and Central America
Malassezia spp.	Yeasts and pseudohyphae	3-8 (yeast), 5-10 (pseudohyphae)	Round to oval; when budding, have the appearance of "footprints" (see Figure 59-2).	Worldwide
Candida spp.	Yeast and pseudohyphae	3-4 (yeast), 5-10 (pseudohyphae)	Usually yeasts with a single bud or pseudohyphae with multiple constrictions (see Figure 67-3).	Worldwide
Dermatophytes	Hyphae	3-15	Septate hyaline hyphae, arthroconidia may be visible along hair shafts (see Figure 58-8)	Worldwide
Aspergillus spp.	Hyphae	4-6	Septate hyaline hyphae with uniform diameter that branch at 45° angles (see Figure 4-2).	Worldwide
Scedosporium spp., *Paecilomyces* spp.	Hyphae	3-12	Septate hyaline hyphae that tend to branch at wider angles than *Aspergillus* spp. (45° to 90°) (see Figure 4-6).	Worldwide
Basidiobolus and *Conidiobolus* (zygomycosis)	Hyphae	10-30	Wide, non- or poorly septate irregular hyaline hyphae, branching at right angles, may be twisted or folded. Poorly stained using hematoxylin and eosin stain (see Figure 4-3).	Tropical and subtropical regions of the Americas, Africa, southeast Asia, and Australia
Phialophora, *Exophiala*, *Cladophialophora*, *Bipolaris* (phaeohyphomycosis or dematiaceous molds)	Hyphae	1.5-6	Pigmented hyphae, budding cells with single septa and chains of swollen round cells (see Figure 68-5). May form granules.	Worldwide
Pythium insidiosum	Hyphae	4-9	Sparsely septate, hyaline hyphae with 90° branches, detectable using hematoxylin and eosin stain	Tropical, subtropical, and some temperate regions of the world.

TABLE 4-2

Special Medium Types Used to Culture Fungi That Infect Dogs and Cats

Type of Medium	Additives	Indications
Sabouraud dextrose agar	None	Cultivation of all fungi.
Brain-heart infusion agar	None	Cultivation of all fungi.
Potato dextrose agar or potato flake agar	None	Cultivation of all fungi. Especially useful for opportunistic molds. Induces sporulation.
Inhibitory mold agar	Chloramphenicol, sometimes gentamicin	Cultivation of all fungi when bacterial contamination is suspected or possible.
Dermatophyte test medium	Chloramphenicol, gentamicin, cycloheximide	Dermatophyte isolation. Shows a color change when dermatophytes grow on the medium.

or 30°C, a lower temperature than that used for routine culture of bacteria. In general, cultures should be examined daily for 2 weeks and twice weekly for an additional 2 to 4 weeks, because the growth of some organisms may be very slow. In general, rapidly growing fungi grow in 1 to 3 days, those with intermediate growth in 5 to 9 days, and slow growers take up to 4 weeks. Yeast colonies are smooth and resemble bacterial colonies, and molds grow in colonies that are dry, wrinkled, or heaped (Figure 4-7).

Fungal Identification

After growth in culture, fungi are identified based on visual characteristics such as colony morphology and color. Light microscopy is useful to evaluate the microscopic morphology of yeasts and to determine the presence of septate or nonseptate hyphae and fruiting structures for molds (Table 4-3). Increasingly, DNA sequence information has been used to identify fungi (such as after PCR of D2 or ITS regions of the 23S rRNA gene). Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry holds considerable promise for identification of fungi in the future (see Chapter 3).[5] Molds that produce pigment are known as *dematiaceous* fungi (see Figure 4-7, *B*), and those that do not are known as *hyaline* fungi. A variety of broth or solid media are also used for fungal identification. For example, *Candida* species can be differentiated using *Candida* bromcresol green (BCG) agar, because each species has a specific colonial morphology and color on this medium. Test strips are commercially available that allow multiple biochemical identification tests for yeasts to be performed simultaneously (e.g., API 20C AUX Yeast Identification Kit, bioMérieux) (see Figure 3-8), so identification can be made within 1 to 2 days.

Interpretation of Fungal Culture Results

False-negative and false-positive results are very common with fungal culture, and results must be interpreted in light of the organism grown, the animal's clinical condition, and the results of cytology and histopathology.

Specimens That Test Negative

Negative test results can occur as a result of inadequate specimen size (such as when swabs or aspirates are submitted), when there are inadequate organism numbers at the site of specimen collection, when overgrowth with contaminating bacteria or saprophytic fungi occurs, or when there is loss of organism

VetBooks.ir

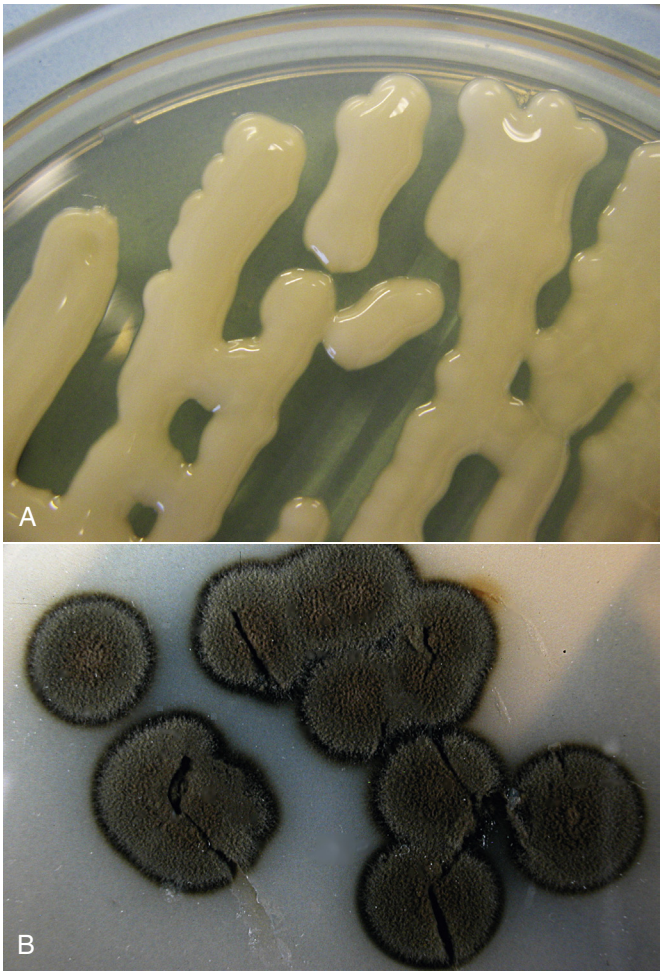

FIGURE 4-7 **A,** Growth of *Cryptococcus gattii* yeasts on potato flake agar. **B,** *Cladophialophora bantiana,* a pigmented (dematiaceous) mold, isolated from canine brain tissue on potato flake agar.

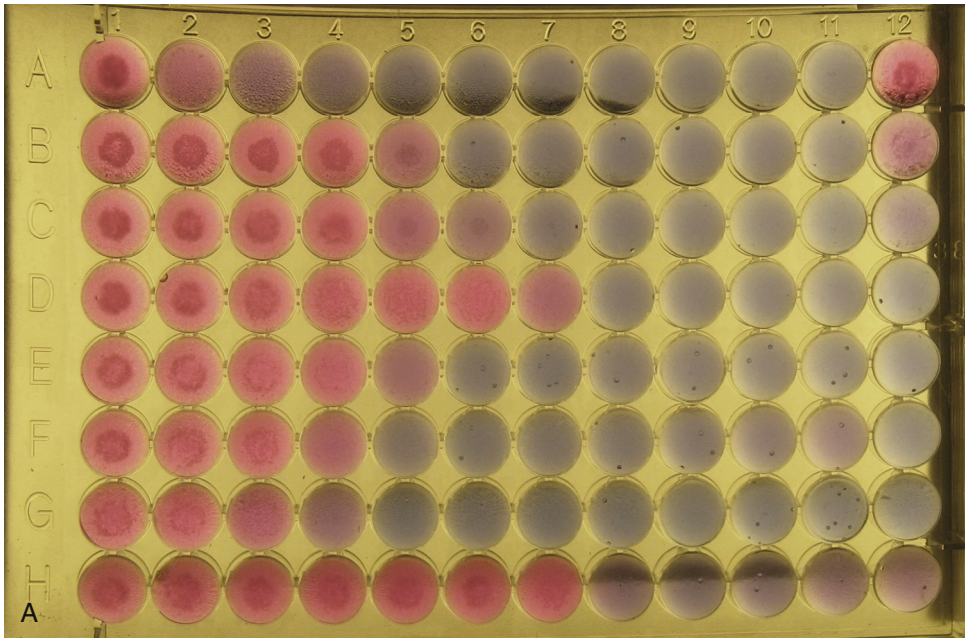
viability during specimen transportation. If the patient is receiving antifungal drugs but has not completely cleared the infection, culture may be negative.

False-negative test results also occur when the organism is not inoculated onto the correct media or sufficient time is not allowed for growth. It is critical that clinicians inform the laboratory if a fungal infection is suspected, and what organism might be involved. Poor laboratory quality control procedures may also lead to false-negative test results. Use of an accredited laboratory can help minimize such problems.

Specimens That Test Positive

The detection of fungal organisms within a specimen does not always imply that the organism is causing the animal's clinical signs. Contamination by saprophytic fungi, especially *Aspergillus*, is the most common cause of false-positive fungal cultures. Organisms are more likely to be clinically significant when cytologic examination of a stained smear also demonstrates the presence of fungal organisms.

Antifungal Susceptibility Testing



Increasing resistance to antifungal agents has been documented for a variety of fungal pathogens. This has led to an increased demand for antifungal susceptibility testing by clinicians. Fortunately, the reproducibility of antifungal susceptibility testing has improved greatly in recent years, and breakpoints (see Chapter 3) have been established for treatment of many fungal infections in human patients. Although breakpoints are still lacking for veterinary patients, antifungal susceptibility testing allows comparison of the activity of two or more antifungal drugs, and serial testing of isolates from a single patient allows the development of resistance to be monitored over time. Methods of susceptibility testing that have been adapted for yeast and mold infections include broth microdilution, the Etest, and disk diffusion (see Chapter 3).

TABLE 4-3

Classification of Fungi That Are Known to Infect Dogs and Cats

Phylum	Class	Example	Characteristics
Zygomycota	Zygomycetes	*Absidia, Rhizopus, Conidiobolus, Basidiobolus*	Aseptate hyphae. In asexual reproduction, spores are abundantly produced in a closed sac called a sporangium. Sexual reproduction results in a single, large thick-walled zygospore.
Basidiomycota	Basidiomycetes	*Cryptococcus, Malassezia*	Sexual reproduction leads to haploid production of basidiospores on a basidium.
Ascomycota	Archiascomycetes Hemiascomycetes Euascomycetes	*Pneumocystis* *Candida* spp. *Histoplasma, Blastomyces, Microsporum, Trichophyton* *Aspergillus* spp. *Fusarium* spp. *Pseudallescheria* spp. (teleomorph of *Scedosporium* spp.)	Sexual reproduction leads to haploid production of ascospores in a sac-like structure (ascus). Organisms are more commonly identified based on characteristics of asexual reproduction.

Common antifungal agents tested include amphotericin B, itraconazole, fluconazole, voriconazole, posaconazole, caspofungin, griseofulvin, and flucytosine (Figure 4-8). Limitations of antifungal susceptibility testing include the slow growth of fungal pathogens when compared to bacteria, and the fact that fungi may grow as yeasts or molds depending on media and incubation conditions. Partial inhibition of growth over a wide range of antifungal drug dilutions may also occur (a phenomenon known as *trailing*). Criteria have been set for interpretation of MICs in the presence of trailing for different antifungal drugs.[6] MALDI-TOF mass spectrometry can be used to determine antifungal drug susceptibility among fungal pathogens and in future may overcome some of the difficulties that currently exist.[7]

CHAPTER 5

Nucleic Acid Detection Assays

Jane E. Sykes and Shelley C. Rankin

VetBooks.ir

KEY POINTS

- Assays for detection of nucleic acid such as polymerase chain reaction assays are increasingly available commercially for diagnosis of companion animal infectious diseases.
- Molecular diagnostic assays include those that involve amplification (the copying of nucleic acid so that it can be more readily detected) or probe-based assays that do not involve nucleic acid amplification.
- Specimens for these assays should be collected using sterile technique in order to minimize contamination.
- Interpretation of the results of molecular diagnostic tests requires knowledge of the problems and pitfalls of each type of assay. The results of testing at one laboratory may differ from that at another because of variations in assay design.
- With increased automation, laboratory proficiency testing, improved quality assurance, and standardization of reporting, the availability and utility of molecular diagnostic tests for companion animal infectious diseases will increase.

INTRODUCTION

Assays that detect nucleic acid, also known as molecular diagnostic assays, include probe-based assays such as in situ hybridization, and methods that amplify DNA, such as the polymerase chain reaction (PCR).

DNA or RNA probes are short, single-stranded nucleic acids (usually <50 base pairs) that have a sequence that hybridizes to (i.e., is complementary to) a specific segment of DNA from the target microorganism (Figure 5-1). For in situ hybridization, the probe is labeled with a fluorescent or chemical tag so that the bound probe can be detected. The probe is reacted with a tissue specimen on a microscope slide in order to determine if the organism is present in the specimen. For PCR, two specific short (approximately 20 bases) DNA sequences called *primers*, which are complementary to the target microorganism's DNA, are used in conjunction with a machine called a *thermocycler* to amplify a specific segment of DNA from just one copy to millions of copies that can be more easily detected. In situ PCR is a combination of these two techniques.[1]

Nucleic acid detection methods are ideally suited to detection of organisms that are not easily found using cytology or histopathology, are slow-growing, or are difficult to culture, as well as when a rapid (<12 hours) diagnosis is required. Other applications are shown in Box 5-1.

The use of nucleic acid–based assays for diagnosis has increased dramatically in veterinary medicine over the past 10 years. Because of the exquisite sensitivity of some assays, especially those that involve DNA amplification, positive results may reflect contamination that occurs in the laboratory. Contamination problems have decreased with increased automation and the use of real-time PCR assays (see later). In human medicine, proficiency testing programs have helped to overcome quality assurance problems in laboratories that perform molecular diagnostic assays.[2] Not all PCR assays for a specific pathogen are equal, because the nucleic acid primers and probes and the equipment used to run each assay may be different. So a PCR assay for *Leptospira* performed in one laboratory may perform differently than an assay used in another laboratory.

A plethora of nucleic acid detection methods have been developed since the advent of PCR, many of which are commercially available for diagnosis of human infectious diseases but are not yet being widely used in veterinary medicine. These are described in detail elsewhere.[1,3,4] The purpose of this chapter is to outline (1) the indications for nucleic acid detection methods, (2) the best ways to collect and transport specimens for these assays, (3) the most commonly used methods in veterinary medicine, and (4) guidelines for their interpretation.

Specimen Collection and Transport

The recommendations for specimen collection and transport presented here are based on the guidelines published by the Clinical and Laboratory Standards Institute (CLSI).[5] These guidelines are updated on a regular basis and ensure that detection of nucleic acids within clinical specimens is optimal. In some instances, nucleic acid may be present and detectable in a specimen even when the specimen has not been handled in a manner that is consistent with the guidelines. Many laboratories publish their own specific guidelines for specimen collection and transport. Specimens should be properly packaged and labeled (see Chapter 3).

Nucleic Acid Probe Assays

In situ hybridization is generally performed on formalin-fixed, paraffin-embedded tissue specimens. Specimens that have been archived for several years may still be adequate, even for detection of RNA, which is more labile than DNA.[6,7] The optimum specimen for fluorescence in situ hybridization (see later for discussion) is tissue that has been snap frozen in liquid nitrogen after being embedded in optimal cutting temperature (OCT) medium.[5]

Polymerase Chain Reaction

When collecting specimens for PCR, the timing of collection relative to the course of disease and the best specimen type must be considered. For acute diseases, PCR is often most useful early in the course of disease. For chronic diseases, timing is less critical.

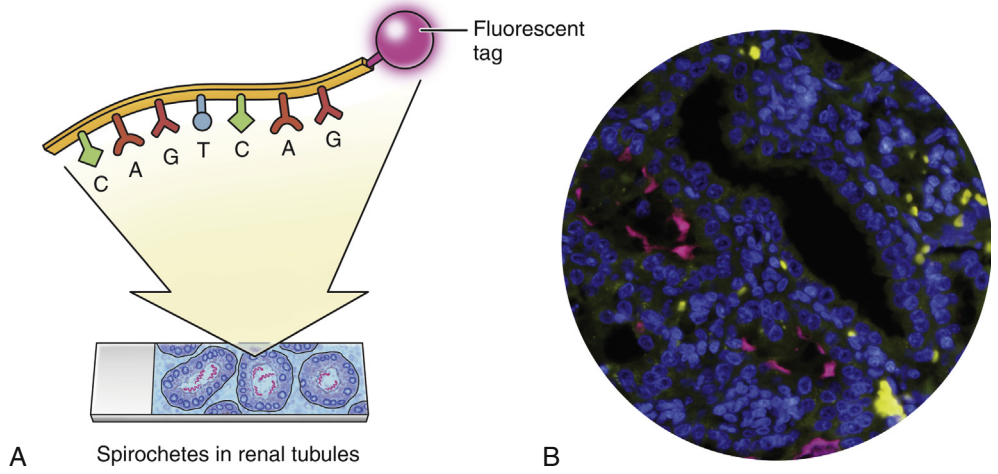

FIGURE 5-1 Fluorescence in situ hybridization (FISH). **A,** A nucleic acid probe that is complementary to a segment of leptospiral DNA is tagged with a fluorescent label and incubated with a tissue section on a slide. **B,** Unbound probe is washed away, and the section is examined using fluorescence microscopy. (*Leptospira* FISH image courtesy Dr. Richard Goldstein.)

BOX 5-1

Applications of Nucleic Acid Based Assays

Application	Examples
Detection of microbes that are not easily detected using light microscopic examination of tissues or smears	*Bartonella* spp., viral pathogens
Detection of microbes that are difficult or impossible to culture	Hemotropic mycoplasmas, *Bartonella* spp., *Mycobacterium* spp., *Brucella* spp.
Rapid detection of microbes to allow early institution of infection control measures	Influenza virus, hypervirulent FCV, rabies virus, *Mycobacterium tuberculosis*
Detection of microbes that are hazardous to culture in the laboratory	H1N1 influenza virus, *Francisella tularensis*
Detection of microbes in the face of inactivating substances such as antimicrobials or formalin	Retrospective identification of an infecting microorganism in formalin-fixed, paraffin-embedded tissues after histopathology
Detection of antimicrobial resistance genes	Possession of *mecA*, the gene for methicillin resistance, by staphylococci
Detection of novel pathogens using broad-spectrum PCR and sequencing	*Bartonella henselae*,* hemotropic mycoplasmas†
Monitoring organism load as a measure of disease progression or response to treatment	FIV viral load
Identification of a cultured organism to the species level	*Nocardia* and *Actinomyces* spp., many molds

†Willi B, Boretti FS, Cattori V, et al. Identification, molecular characterization, and experimental transmission of a new hemoplasma isolate from a cat with hemolytic anemia in Switzerland. J Clin Microbiol 2005;43:2581-2585.

Knowledge of organism shedding patterns can help to determine the most appropriate timing of specimen collection. For example, *Leptospira* organisms are primarily present in blood in the first week of acute illness, after which they may be shed in the urine.[8]

Because contamination can occur outside the PCR laboratory as well as within the laboratory, collection of specimens for nucleic acid testing should be performed aseptically. Gloves should be worn, and disposable instruments should be used (e.g., disposable blades, punch biopsy instruments).

In general, for detection of pathogens that contain DNA (i.e., all bacteria, fungi, some viruses), either fresh or frozen specimens should be submitted. In general, DNA is stable in tissue for up to 24 hours at 2°C to 8°C, at least 2 weeks at –20°C, and at least 2 years at –20°C or below –70°C.[5] Specimens held at room temperature should be submitted immediately and reach the laboratory within 24 hours. Specimens can also be refrigerated and submitted on wet ice within 72 hours. Provided the target of the assay is not an erythrocyte pathogen, erythrocytes should be removed before storage if possible. Specimens should not be stored in frost-free freezers, as these undergo repeated freeze-thaw cycling, which can be associated with DNA degradation.[9] Box 5-2 outlines recommendations based on specimen type.

BOX 5-2

Guidelines for Collection and Transport of Specimens for Polymerase Chain Reaction Assays

Specimen Type	Collection and Transport Recommendations
Whole blood and bone marrow	Use only EDTA or acid citrate dextrose (ACD) anticoagulant. Heparin inhibits PCR.* The use of hemolyzed specimens and frozen blood should be avoided if possible. DNA: Submit specimens held at room temperature within 24 hours of collection. Specimens can be stored at 2°C to 8°C for 72 hours, or at –20°C or ≤–70°C for prolonged storage (removal of erythrocytes recommended). RNA: Use stabilization solution or send immediately to the laboratory on wet ice. For storage, freeze serum, plasma, or buffy coat specimens at or below –70°C.
Tissue specimens	Optimal specimen is 1 to 2 g of fresh tissue. Rinse blood from tissue using sterile saline. Wrap in saline-moistened gauze or paper. Avoid excessive dilution. Formalin-fixed, paraffin-embedded tissues can be used when no other specimen is available but are not optimal. DNA: Transport fresh tissue immediately to the laboratory on wet ice. Any storage should be at or below –70°C, preferably after snap freezing in liquid nitrogen. RNA: Use stabilizing solution, process within 1 hour of collection, or snap freeze in liquid nitrogen and store at or below –70°C
Cerebrospinal fluid	DNA: Transport at 2°C to 8°C or freeze at –20°C or at or below –70°C RNA: Chill immediately on wet ice and deliver to the laboratory within 4 hours. Otherwise freeze immediately (removal of contaminating erythrocytes recommended) and ship on dry ice.
Bronchoalveolar lavage specimens	Transport at room temperature within 24 hours of collection. If a delay is anticipated, store for up to 72 hours at 2°C to 8°C or freeze at or below –70°C.
Urine	Minimize storage at room temperature. Storage and transport should be according to the specific assay performed.
Feces	Use preserved specimen transport container, or transport under refrigeration at 2°C to 8°C.

Adapted from the CLSI guidelines MM13-A.

RNA is highly susceptible to degradation during storage and transport. For detection of RNA viruses, some laboratories provide an RNA stabilizing solution into which specimens are collected to prevent RNA degradation. If stabilizing solution is not readily available at the time of specimen collection, swabs and body fluids should be immediately sent to the laboratory on wet ice. Tissue should ideally be snap frozen at –70°C within half an hour of collection and shipped on dry ice without being thawed in the interim. RNA is stable for at least 2 years at or below –70°C. Ribonucleases can continue to degrade RNA at –20°C.

For tissue specimens, the optimal amount is 1 to 2 g, although more or less may be required depending on the cellularity of the specimen.[5] Tissues stored in formalin, especially for prolonged periods, are suboptimal for PCR because the formalin cross-links the DNA in the specimen. Tissues fixed briefly in formalin and then paraffin-embedded are preferable to tissues stored in formalin, because the formalin is removed during the embedding process. Paraffin-embedded specimens should only be used when no other specimens are available.[5]

Although PCR can be performed on feces, its sensitivity may be lower than with other specimens because inhibitors of PCR are particularly abundant in fecal material.[10] The use of appropriate amplification controls by the laboratory facilitates detection of false negatives due to the presence of inhibitors.

Diagnostic Methods

Nucleic Acid Probes

A variety of nucleic acid probes are available commercially as kits for detection of microorganisms that infect humans. Some of these can also be used to detect the same pathogens in specimens from dogs or cats. Probes are available for use in the clinical microbiology laboratory to identify organisms that have grown in culture (e.g., Gen-Probe Inc., San Diego), and these probes are widely used in human clinical microbiology laboratories.

Probe hybridization can be performed on a nitrocellulose membrane *(solid-phase hybridization);* on formalin-fixed, paraffin-embedded sections mounted on a microscope slide (*in situ hybridization*); or in solution *(liquid-phase hybridization)*. For solid-phase hybridization, the probe is reacted with microorganism DNA that has been immobilized on the membrane. Unbound probe is washed away, and the bound probe is detected using fluorescence, chemiluminescence, radioactivity, or color development (in the same way that bound antibody or antigen is detected in an ELISA or immunofluorescent antibody assay). For in situ hybridization, formalin-fixed, paraffin-embedded specimens are sectioned and mounted on a special slide. The sections are deparaffinized, dried, and incubated with a solution that contains the probe, so both the presence and the location of the target pathogen within tissues can be identified. In situ hybridization assays that include a fluorescent-labeled probe are referred to as *fluorescence in situ hybridization* (FISH) assays (see Figure 5-1).

Because liquid-phase hybridization occurs in solution, unbound probe cannot be washed away. To overcome this problem, a chemiluminescent acridinium ester label is attached to the probe. A subsequent chemical hydrolysis step selectively degrades only unbound probe. On addition of peroxides, the intact (hybridized) probe then emits light.[11]

Although not yet widely used for veterinary applications, *peptide nucleic acid (PNA) probes* are now increasingly available to detect target DNA. PNA probes are uncharged peptides that mimic DNA and bind to complementary DNA sequences just as a nucleic acid probe would.[12,13] PNA probes lack the net negative charge of nucleic acid probes; therefore, the electrostatic repulsion that normally occurs when two negatively charged DNA strands hybridize does not occur. The result is a more stable and specific binding of the probe to its target, which in turn can be associated with increased assay sensitivity and specificity.

Branched DNA assays and *hybrid capture assays* are highly sensitive hybridization methods that include steps to intensify the signal generated from probe hybridization.[3,4] They are not yet widely used in veterinary medicine.

The Polymerase Chain Reaction

PCR allows the specific amplification of DNA sequences from just one copy to millions of copies, which can be more readily detected. The DNA from a clinical specimen is extracted using a commercially available DNA extraction kit. A pair of primers, roughly 20 nucleotides long, is then used to bracket a desired DNA sequence, which is subsequently copied using a DNA polymerase enzyme (Figure 5-2).

PCR assays are broadly divided into *conventional PCR assays* and *real-time PCR assays*. Conventional PCR assay is the simplest PCR method and although still widely for research purposes, its use for diagnostic purposes is decreasing. In conventional PCR, the PCR product is detected as a band on an agarose gel after agarose gel electrophoresis. In real-time PCR, a fluorescent signal is generated *as PCR products accumulate*, allowing them to be detected in "real time." A major advantage of real-time PCR methods is that the tube in which the PCR takes place does not need to be opened for detection of the PCR product. This greatly reduces the likelihood of contamination and false positive test results. Real-time PCR assays are amenable to automation, and reactions are generally loaded onto covered 96- or 384-well plates. This can be done robotically, further reducing the possibility of contamination and manual loading errors.

Regardless of the type of PCR assay, extracted DNA is added to aliquots of a PCR *mastermix*. The mastermix is a solution

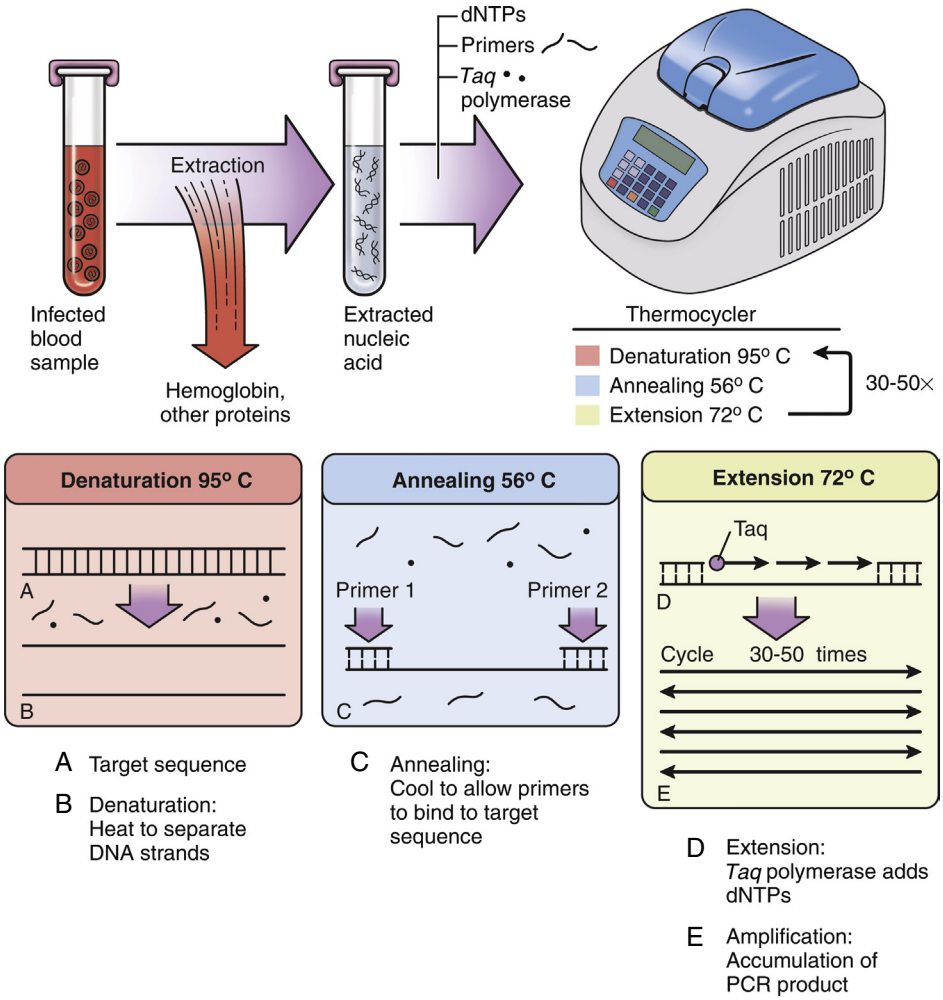

FIGURE 5-2 Basic PCR assay. Nucleic acid is extracted from a clinical specimen through removal of contaminating proteins such as hemoglobin. Two primers are added that hybridize at each end of a specific segment of a pathogen's DNA. Also present in the reaction mixture are the enzyme *Taq* polymerase (*dots*) and free nucleotides (dNTPs) for new DNA. A thermocycler is used to rapidly and repeatedly heat and cool the tubes through denaturation, annealing, and extension steps. Denaturation separates double-stranded DNA. Annealing occurs at a specific temperature that causes the primers to bind only to their target sequences. When the reaction mixture is then heated to 72°C, the *Taq* enzyme uses the primers as initiation points for DNA extension, and the target sequence is copied. The process is repeated 30 to 50 times, with logarithmic accumulation of the PCR product, so there are millions of copies of the target pathogen's DNA. These can then be detected using agarose gel electrophoresis (see Figure 5-3).

VetBooks.ir

that contains the two primers, dNTPs (G, T, A, and C) for making new DNA, and a DNA polymerase. The DNA polymerase used most commonly (*Taq* DNA polymerase) is a heat-stable polymerase derived from *Thermophilus aquaticus*, a bacterium that is adapted to live in hot springs. Typical PCR assay reaction volumes are 10 to 50 µL.

The next step is performed in a thermocycler, a machine that is programmed to heat and cool the tubes repeatedly, so that the DNA can be amplified (see Figure 5-2). Initially the DNA is heated to 95°C, which causes the paired strands of DNA to *denature*. Next, the tubes are cooled to a specific *annealing temperature* (usually around 50°C to 65°C), which allows the primers bind to their respective sequences. Finally, the tubes are heated to 72°C. This is the temperature at which the DNA polymerase adds dNTPs in the mastermix to the primers, extending the primers as it copies the sequence of the template DNA. The 3-step cycle is repeated 30 to 50 times, which results in logarithmic accumulation of a PCR product that is an exact copy of the segment of DNA between the two primers. The amplified segments of DNA are called *amplicons*.

Detection of the PCR Product: Conventional versus Real-time PCR

In conventional PCR, amplified DNA is loaded into wells in an agarose gel then passed through the gel using horizontal electrophoresis, stained with a DNA stain, and visualized using ultraviolet transillumination. The longer the PCR product, the more slowly it moves through the gel during electrophoresis. When a series of molecular weight markers are run alongside the end product of PCR, the size of the PCR product can be estimated (Figure 5-3). The true identity of the product can then be confirmed using sequencing or by transferring it to a membrane and performing DNA hybridization with a specific probe. The process of loading the PCR product in agarose wells requires that the PCR tubes be opened, which can lead to aerosolization of PCR amplicons. These amplicons can then contaminate reagents, equipment, and tubes that are used for running subsequent PCR assays. Unless proper controls are included, false positives resulting from such contamination may go unidentified and lead to erroneous reporting of results.

Two major types of real-time PCR assays are in use in veterinary medicine: fluorescent probe–based assays and SYBR Green PCR assays.

Fluorescent probe real-time PCR assays incorporate one or more specific DNA probes into the PCR mastermix, in addition to the two primers used in conventional PCR. The probe(s) are tagged with a dye that emits fluorescent light. Inclusion of a probe adds specificity to the test, because it is less likely that both primers *and* the probe will bind to DNA other than that of the target organism. Three types of probes may be used:

1. *TaqMan (5′ nuclease) probes*. Many veterinary laboratories that offer probe-based PCR assays use TaqMan probes. These are tagged with a fluorescent reporter dye at one end, and a quencher dye at the other end of the probe. The close proximity of the quencher dye to the reporter dye inhibits the reporter dye from emitting fluorescence. When the *Taq* DNA polymerase copies the section of DNA between the two primers, it encounters the probe and chops it into pieces, because it has inherent exonuclease activity. This causes the reporter dye to separate from the quencher dye. The reporter dye then emits fluorescence, which can be measured using a spectrophotometer (Figure 5-4, *A*).
2. *Molecular beacons*. A molecular beacon is a probe with fluorescent reporter and quencher dyes at each end, but when not bound to the target sequence, it forms a hairpin loop that brings each dye in close proximity and stops the reporter dye from emitting fluorescence. When the probe anneals, the dyes separate, and the reporter dye emits fluorescence (see Figure 5-4, *B*).
3. *FRET probes*. FRET (fluorescent resonance energy transfer) probe assays use two probes that are expected to lie next to one another on the target sequence. One of the probes is tagged at the 3′ end with a green fluorescent dye, the other at the 5′ end with a red fluorescent dye. When the two dyes come together during annealing, the green fluorescent dye transfers its energy to the red probe, causing it to emit fluorescence, which can then be detected (see Figure 5-4, *C*). Currently there are only rare reports of the use of this technology for diagnosis in veterinary medicine.

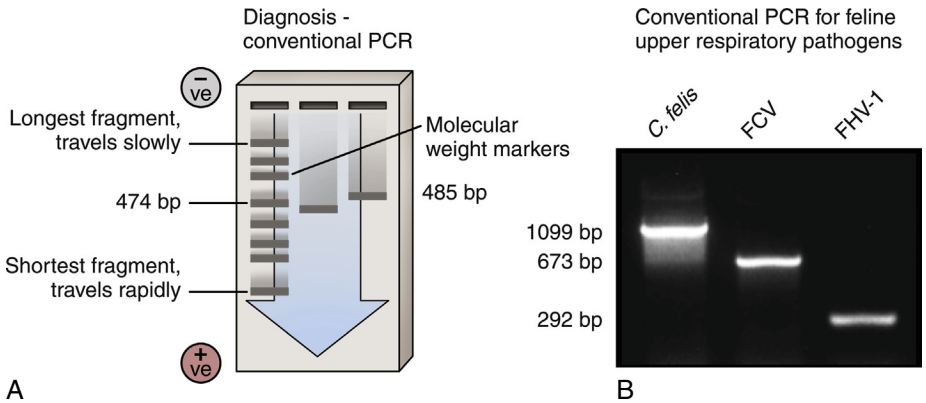

FIGURE 5-3 **A,** Detection of PCR products by agarose gel electrophoresis. At the end of the PCR process, the reaction mixture that results is loaded into wells at the top of an agarose gel. An electric current is applied across the gel, and because DNA is negatively charged, any amplified DNA in the reaction mixture migrates through the gel toward the positive terminal. The longer the DNA sequence that has been amplified, the more slowly it moves through the gel. Simultaneous electrophoresis of a molecular weight standard in an adjacent lane (*left* lane) allows estimation of the size of any PCR products amplified. The molecular weight standard contains DNA fragments of known size. After electrophoresis, the gel is stained with a DNA stain. If the target pathogen's DNA was successfully amplified, it appears as a band of an expected size (in this case, 485 base pairs [*bp*] long). Bands that are the wrong size ("aberrant PCR products") may represent nonspecific amplification of DNA from a different microorganism or host DNA (*middle* lane). **B,** Photograph of PCR products in an agarose gel after agarose gel electrophoresis and staining. DNA bands amplified from *Chlamydia felis*, feline calicivirus (*FCV*), and feline herpesvirus-1 (*FHV-1*) are shown. The primers were designed to amplify different-length products from each pathogen so that if multiple pathogens were present in a single specimen, they could be distinguished from one another.

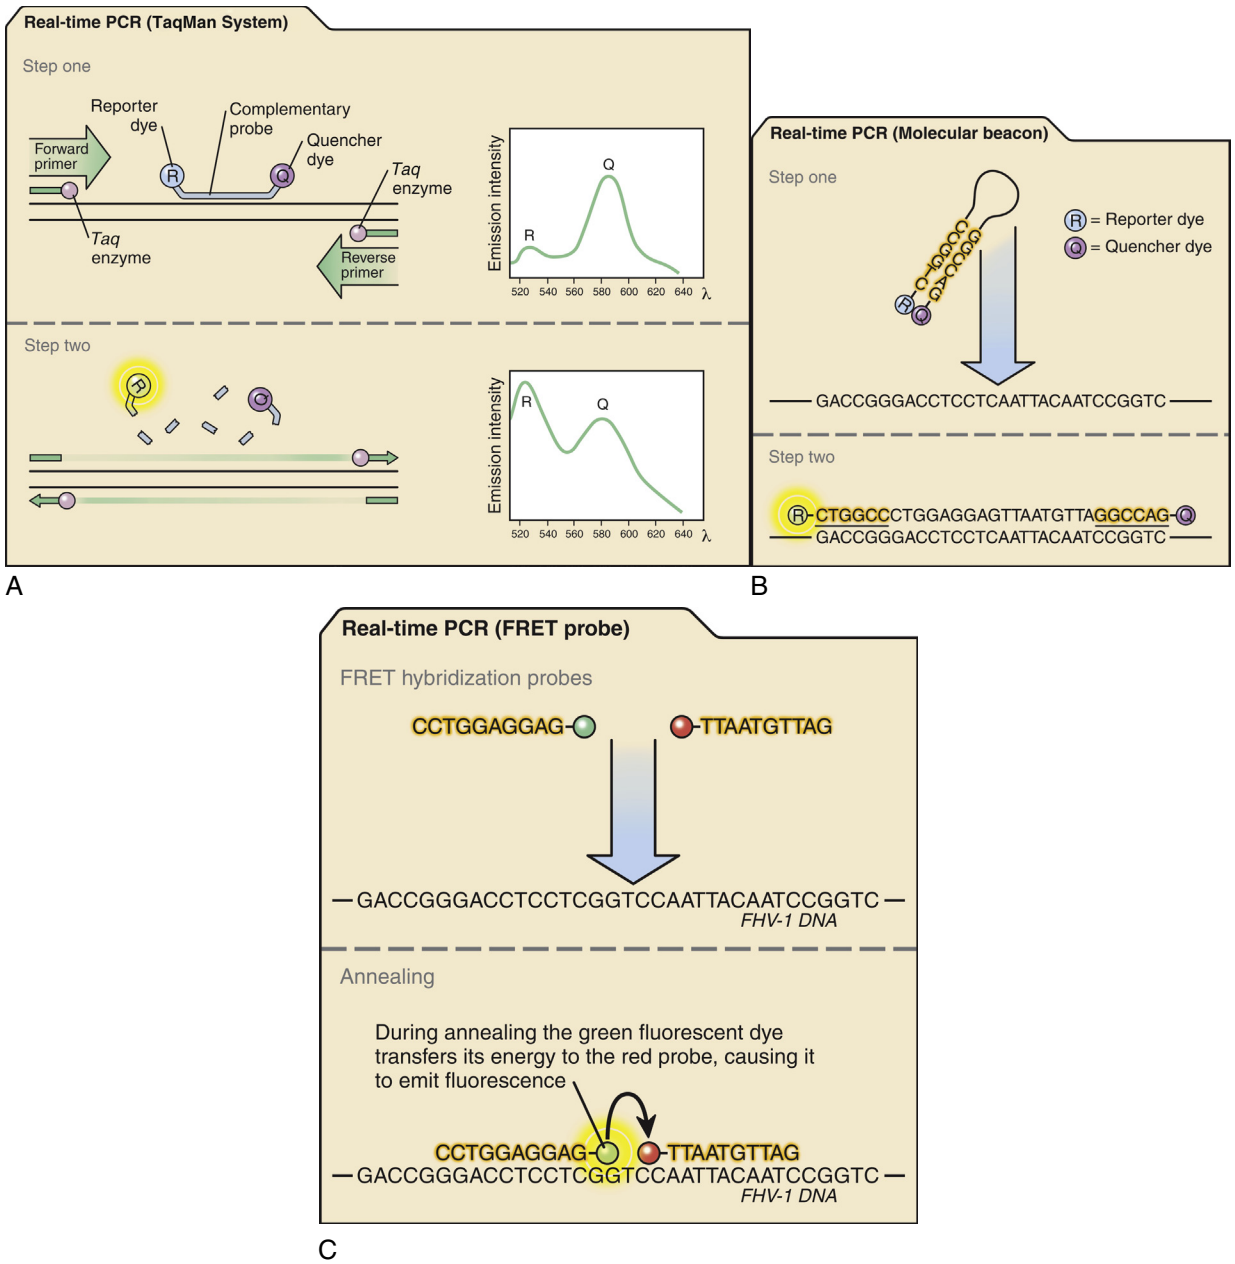

FIGURE 5-4 Probe-based real-time PCR assays. **A,** TaqMan probe PCR system. In addition to the forward and reverse primers used in conventional PCR, an additional short probe is used that binds specifically to the DNA of the pathogen of interest (step one). Emission of fluorescence by a reporter dye located at one end of the probe is quenched by another dye at the other end of the probe. When the *Taq* enzyme extends the primers, an inherent exonuclease activity of the enzyme results in the digestion of the probe. The quencher and reporter dyes separate, causing the quencher dye to emit fluorescence. Other probe-based real-time PCR assays include molecular beacon assays **(B)** and fluorescent resonance energy transfer probe assays **(C)**.

SYBR Green Real-time PCR assays use a double-stranded DNA binding dye (SYBR Green) that fluoresces when bound to double-stranded DNA as it forms during PCR amplification. Because there is no probe, carefully designed primers are required to ensure high assay specificity for the organism of interest.

The amount of fluorescence emitted during real-time PCR is proportional to the number of copies of template DNA in the specimen, so real-time PCR assays can be quantitative. A plot of PCR cycle number against fluorescence is generated by an attached computer and interpreted by the laboratory technician (Figure 5-5). The number of cycles that elapse before fluorescence is detectable above a certain threshold value is the CT (cycle threshold) value. Most laboratories run approximately 40 cycles, and so specimens that generate CT values less than 40 are considered positive. Said another way, if PCR proceeds to 40 cycles without emission of fluorescence (CT = 40), then the target DNA is not detectable in the specimen, and the result is reported as negative. The lower the CT value, the more target DNA (= organism load) is present in the sample, because fewer cycles elapse before fluorescence is detected. Because specimen size can vary, the CT value may be normalized to the number of host cells present in the sample. Knowledge of organism load may have prognostic value for some infections, can allow infection to be monitored over time with treatment, and may be useful to differentiate low-level colonization from active infection causing clinical signs (see Interpretation of Results, later). At the time of writing, organism loads are variably reported by veterinary diagnostic laboratories performing PCR assays.

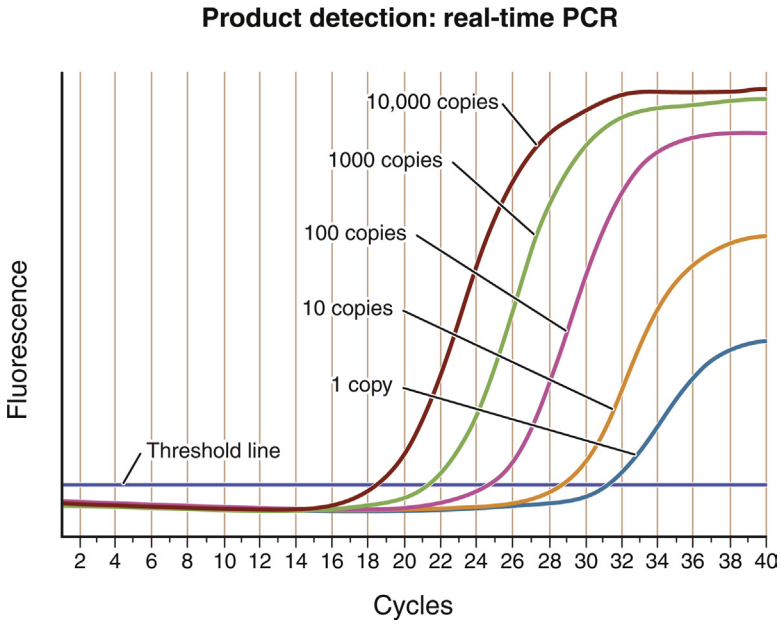

FIGURE 5-5 Plot that shows the emission of fluorescence during PCR product formation over time in real-time PCR as the number of cycles of denaturation, annealing, and extension increases from 0 to 40 (*x*-axis). The cycle threshold (CT) value is the number of PCR cycles required for the fluorescent signal (*y*-axis) to rise above a threshold value for fluorescence (threshold line). The more copies of target pathogen DNA that are present in a clinical specimen (which correlates with the number of organisms present), the earlier fluorescence is emitted and the lower the CT value. Thus, for example, if only one organism is present in a submitted specimen, the CT value for this particular PCR assay is 32, but if 10,000 organisms are present, the CT value is around 19.

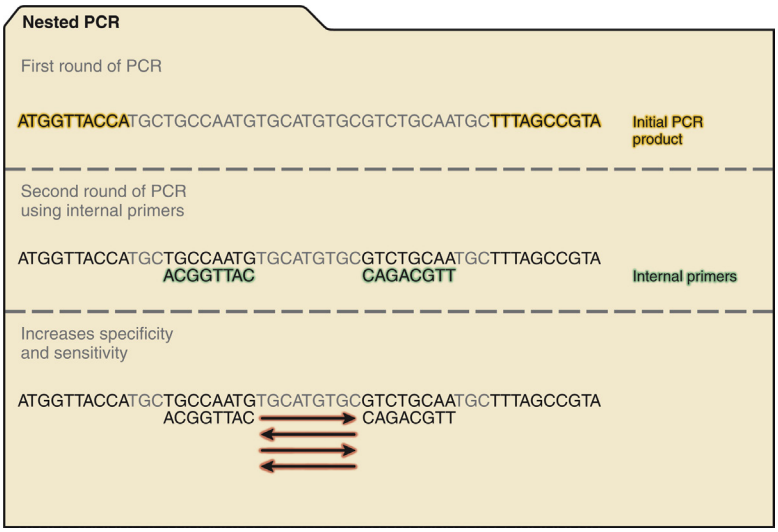

FIGURE 5-6 Nested PCR. After the first round of PCR amplification, a second set of internal primers *(green)* is used in yet another round of PCR amplification, which generates a second, shorter PCR product.

Rapid thermocyclers are available in several different formats. Special carousel thermocyclers have been developed that rapidly heat and cool the reactions, which are placed in specially designed glass capillaries. As a result, PCR assays can be completed in 45 minutes, instead of the usual 4 to 5 hours.[14]

Polymerase Chain Reaction Variations

Variations on the basic PCR assay include reverse-transcriptase PCR, nested PCR, and multiplex PCR.

Reverse-transcriptase PCR is used for RNA detection. After extraction of RNA from the clinical specimen using a commercial kit, the enzyme *reverse transcriptase* is added to the RNA, together with dNTPs that will be used to make DNA. The starting point for reverse transcription can be a single complementary DNA primer that binds to the RNA, or alternatively, *random hexamers*, which are a mixture of six-nucleotide primers that represent all possible combinations of dNTPs. The reverse transcriptase then uses the primers to make a DNA copy of the RNA (known as *cDNA*), which is subsequently subjected to PCR amplification.

For *nested PCR*, a small amount of amplified PCR product is subjected to a second round of conventional PCR using another set of internal primers (Figure 5-6). Having an additional set of primers increases the specificity of the PCR assay and also greatly increases its sensitivity.[15] Unfortunately, the increased sensitivity means that false positives due to contamination can be extremely problematic with this method, and it has lost popularity for diagnostic purposes.

VetBooks.ir

Multiplex PCR assays use multiple sets of primers *in the same reaction tube* to simultaneously detect multiple organisms (or multiple genes from the same organism). Duplex PCR assays can detect two organisms, and triplex PCR assays can detect three organisms. The potential downside of multiplex reactions is that if both organisms are present, and one organism is present in relative abundance, amplification of this organism can consume reagents, which reduces the sensitivity of the assay for the other target organism.

Verification of Polymerase Chain Reaction Assay Performance

Before being used for diagnostic purposes, PCR assays must be shown to be *sensitive, specific, reproducible,* and *efficient*.

For PCR, *the limit of detection* is the lowest number of copies of the target DNA or RNA sequence that the assay can detect. Serial dilutions of known amounts of the template DNA are tested using the PCR assay of interest, until template can no longer be detected.

From a diagnostic standpoint, a PCR assay may lack sensitivity (many false negatives) if the assay fails to detect all possible strains of a target organism. This can occur if the probe or primers are strain, rather than species-specific, and many strains of the target organism exist with variable sequences (as is the case with RNA pathogens such as feline calicivirus). As part of the verification process, the assay should be shown to detect as many strains as possible.

A PCR assay has poor analytical specificity if false positives occur as a result of contamination or because of manual loading error. Specificity may also be poor if the primers bind to and initiate amplification of DNA from unrelated organisms or the host animal (i.e., cat, dog, human DNA). Specificity is tested during the verification process by showing that the PCR assay fails to amplify DNA from specimens that contain organisms that are genetically related to the target organism, as well as organisms that may be expected to be contaminating normal flora.

The results of PCR assays must also be repeatable. Repeatability is determined for real-time PCR assays by determining whether the CT value varies significantly for the same specimen when tested multiple times. Usually intraassay (within the same run) and interassay (within different runs) variations are measured.

A real-time PCR assay that has an *efficiency* of 100% doubles the number of copies of template in every PCR cycle. Efficiencies below 90% are unacceptable for quantitative assays, and ideally efficiency should be greater than 95%. The efficiency is determined by testing serial dilutions of a target DNA standard and by creating a chart of copy number versus CT value. Ideally, this is compared with a similar chart using dilutions of the standard DNA spiked into a clinical specimen, to show that inhibitors within the specimen will not affect efficiency.

Prevention of Contamination and Quality Control

Prevention of PCR contamination relies on good laboratory practices, some of which are outlined in Box 5-3. Contamination can be difficult to eradicate once it occurs, so prevention of contamination is critical. Laboratories should include negative controls with every run, and a positive control should be included to ensure that the assay is working, preferably one that is put through the nucleic acid extraction process. The positive control should contain a low concentration of DNA, as abundant DNA in a positive control sample may be a source of contamination. Many laboratories run two separate negative controls. One of the negative controls contains mastermix and nuclease-free water in place of specimen DNA. The other consists of water or a known negative specimen that is placed through the extraction process to ensure that contamination does not occur during extraction (negative extraction control). When 96- or 384-well plate formats are used, negative control wells are interspersed among the test wells to monitor for plate contamination.

BOX 5-3

Methods That May Be Used to Minimize Contamination in Diagnostic Laboratories That Perform Nucleic Acid Amplification Assay

- Separation of rooms for DNA extraction, PCR, and PCR product detection
- Robotic DNA extraction
- Automated detection of PCR products (real-time PCR)
- Opening one specimen tube at a time
- Use of screw-top caps rather than snap-top tubes to prevent splashing
- Use of filter-plugged pipette tips
- Use of negative extraction controls and negative template controls in every run
- Routine monitoring for contamination using wipes
- Standard cleanup protocol that inactivates nucleic acids
- Use of positive control samples of low concentration
- Use of dUTP and uracil-*N*-glycosylase in the PCR mastermix

In order to prevent contamination, some laboratories use deoxyuracil triphosphate (dUTP) instead of deoxythymidine triphosphate (dTTP) in the PCR mastermix. The PCR products therefore contain uracil (U) in place of thymidine (T). The enzyme uracil-*N*-glycosylase (UNG) is also added to the mix. This enzyme destroys DNA amplicons that contain deoxyuracil residues, and eliminates any contaminating DNA amplicons from previous reactions before PCR amplification begins. When the specimen is heated in the initial denaturation step, the UNG is destroyed.

The presence of substances that inhibit the PCR assay can be detected using a *housekeeping gene* control PCR assay. This is performed on a separate aliquot of the specimen at the same time as the assay for the target pathogen. Housekeeping genes are host (dog or cat) genes that are expected to be present in the specimen. Examples of commonly used housekeeping gene PCR assays are those for canine or feline glyceraldehyde-3-phosphate dehydrogenase (GAPDH), histone, or 18S DNA. A negative housekeeping gene PCR assay result (or a high CT value for the assay, which is equivalent to a weak positive result) suggests that inhibitors may be present in the specimen, or that the DNA in the submitted specimen may have degraded during storage or transport. Some PCR assays use an *internal housekeeping gene control*, in which a housekeeping gene PCR is multiplexed with the PCR assay for the target microorganism.

Interpretation of Results

Because some PCR assays can detect as few as one or two organisms, and both viable and nonviable organisms are detected, it may be difficult to determine the significance of a positive PCR test result in light of an animal's disease. An understanding of the pathogenesis of infectious diseases and organism shedding patterns is crucial in interpreting positive PCR results. Correct interpretation of the results relies on knowledge of the methods used by a laboratory and their advantages and disadvantages.

VetBooks.ir

BOX 5-4

Factors That Should Be Considered When Interpreting Nucleic Acid Amplification Assay Results

Negative Test Result

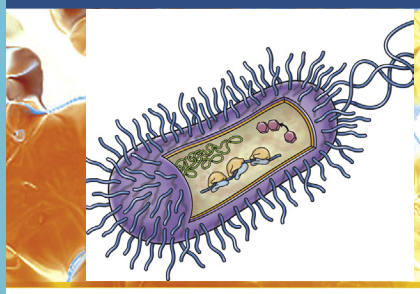
Organism not present
Too few organisms present
Insufficient specimen size
Wrong specimen type
Improper timing of specimen collection
Patient receiving antimicrobial therapy
Specimen degradation during storage or transport
Assay reagent failure
Assay inhibitors present or extraction failure
Reagents consumed in a multiplex assay
Assay does not detect all strains

Positive Test Result

Viable or nonviable organisms present and causing disease
Viable or nonviable organisms present but not causing disease
Vaccine organisms present
Contamination
Loading errors
Assay cross-reaction with other pathogens or host DNA in the sample

Specimens That Test Negative

Factors that lead to negative test results are shown in Box 5-4. An example of the use of the wrong specimen type would be submission of blood for a *Borrelia burgdorferi* PCR test, when *B. burgdorferi* is found predominantly in connective tissue.[16] Assay inhibition and specimen degradation can be identified by interpretation of housekeeping gene control assay results, which should be performed by the laboratory. Assay reagent failure is identified by the laboratory when the positive control tests negative.



Specimens That Test Positive

Factors that must be considered when interpreting positive test results are shown in Box 5-4. The most common reason for false-positive test results for assays that involve DNA amplification is contamination. Loading errors, in which specimens are inadvertently loaded into the wrong wells on a microtiter plate, may also lead to false-positive results and are reduced with the use of automated methods. Because of the exquisite sensitivity of PCR, it may be difficult to determine the significance of a true positive result. The organism may be part of the normal flora, carried subclinically (e.g., latent feline herpesvirus-1 in a nasal biopsy), or simply colonizing the anatomic site sampled. Several U.S. veterinary laboratories offer PCR "panels" for diagnostic purposes. Individual PCR assays for several different pathogens are performed on nucleic acid extracted from a single specimen. This high-throughput panel format allows assays to be offered at a substantial discount over the cost of multiple individual assays. This type of testing can result in unexpected positive test results, such as a positive result for the *Clostridium perfringens* toxin gene in a cat with diarrhea that is suspected to have trichomoniasis. As with any laboratory test, positive results need to be interpreted in light of the clinical history, clinical signs, and the pathogenesis of the disease in question.

A positive result can occur if an attenuated live vaccine for the target organism was recently administered. Because PCR detects both viable and nonviable organisms, PCR can be positive for days after antimicrobials have been administered, when culture is negative.[17-19] The duration of PCR positivity after treatment depends on the specimen type tested and the target pathogen.

SECTION 2

Antiinfective Therapy

Jane E. Sykes and Mark G. Papich

CHAPTER 6

Principles of Antiinfective Therapy

Jane E. Sykes and Mark G. Papich

KEY POINTS

- The use of antimicrobial drugs (AMDs) can lead to selection of resistant bacterial populations, within the targeted bacterial population and also other commensal bacteria.
- Bacterial mechanisms of drug resistance include production of enzymes that inactivate AMDs, drug exclusion through membrane alterations and efflux pumps, and modification of the site of action of the AMD.
- Strategies that minimize selection for drug resistance include (1) confirmation of the presence of infection before AMD treatment is commenced, (2) proper identification of the infecting organism, (3) selection of agents with activity specific to the pathogen present, (4) administration of an adequate dose of AMD, and (5) administration of AMD for the proper duration of time.
- Selection of an appropriate AMD should be based on the activity of the agent against the suspected pathogen; knowledge of drug pharmacokinetics, which includes bioavailability and tissue penetration; consideration of host factors such as concurrent illness, medications, or immunosuppression; and knowledge of drug pharmacodynamics, that is, whether the drug exhibits concentration- or time-dependent antibacterial effects.

INTRODUCTION

Antibiotics have been considered one of the greatest inventions of the 20th century. The modern era of antimicrobial drug (AMD) treatment began with the discovery of sulfonamides in 1935.[1] In the 1940s, the therapeutic value of penicillin and streptomycin was discovered, and by 1950, the "golden age" of AMD therapy was underway. With the increasing use of AMDs, there has been a transition to an era of widespread antimicrobial resistance among important veterinary and human pathogens. This has been compounded by a declining rate of development of new classes of AMDs.

Antimicrobial resistance genes have existed in microbes long before antimicrobial agents were used in therapy. Microbe populations generally consist of a mixture of genetically susceptible and resistant organisms. The use of AMDs exerts pressure that favors selection of the resistant microbes ("survival of the fittest"), within both the targeted bacterial population and other commensal bacteria (which have the potential to become pathogenic when host defenses are impaired). The chance that resistant bacterial populations will emerge depends on the ability of the population to rapidly acquire mutations, the ability of host defenses to eliminate resistant bacteria, and the AMD concentrations at the site of infection.

Guidelines for prudent antimicrobial use have been published by several professional veterinary organizations in order to reduce selection for resistant bacterial pathogens.[2-6] Individual hospitals are encouraged to develop antimicrobial guidelines based on evaluation of their local prevalence of AMD resistance. Strategies that minimize selection for antimicrobial resistance include documentation of the presence of infection; proper identification of the infecting organism; and the use of agents that are as specific for the pathogen as possible, at the proper dose and for the proper duration of time. These strategies are described in more detail in this chapter.

Identification of the Infecting Organism

The detection of fever or leukocytosis does not imply bacterial infection and the need for antibiotic treatment, especially given the relatively high prevalence of sterile inflammatory and immune-mediated diseases in dogs and viral infections in cats. Selection of the most appropriate AMD relies on knowledge of (1) the presence of an infectious agent, (2) the type of infectious agent present, and (3) the susceptibility of the agent to different AMDs. In some cases, treatment with antibiotics may not be necessary even though the cause of disease is bacterial. Some infections undergo spontaneous cures without the aid of an antibiotic. For example, a cat bite abscess can often be drained and resolved without the need to administer an antibiotic (see Chapter 57).

In some situations, collection of a specimen for cytology or histopathology permits a diagnosis of infection to be established.

VetBooks.ir

The identity of some infectious agents, such as rickettsial and fungal pathogens, may be presumptively identified to the genus or species level based on their morphology. If skin cytology from a dog reveals cocci (a Gram stain is not necessary to confirm the presence of gram-positive cocci), then the presence of *Staphylococcus pseudintermedius* is highly probable. If, on the other hand, cytology from an ear swab reveals rods, the possibility of *Pseudomonas aeruginosa* must be considered. In either case, this knowledge is valuable for selecting initial antibacterial therapy. The use of molecular diagnostic techniques, such as PCR assays, can also allow rapid identification of an infecting organism, which can help to guide antimicrobial drug selection. For example, identification of a vector-borne pathogen (e.g., *Rickettsia* spp., *Ehrlichia canis*) is helpful because doxycycline is usually the first drug of choice for the majority of these pathogens. Unfortunately, unless susceptibility to a particular AMD is predictable, these techniques do not typically provide information about AMD susceptibility. Given the emergence of widespread AMD resistance, especially among bacteria and some fungi, collection of specimens for culture and susceptibility before treatment with AMDs is commenced has become more and more important. Although there is an initial cost to the client for culture and susceptibility testing, long-term costs to the client may be reduced considerably because of decreased prescription of unnecessary or inappropriate AMDs, improved likelihood of rapid resolution of the underlying disorder with early diagnosis and appropriate treatment, and reduced need for more expensive, second- or third-line AMDs. Administration of AMDs without identification of the infectious agent can also decrease subsequent chances of successful culture and proper diagnosis if the disorder does not resolve.

In animals with life-threatening infections, institution of AMD treatment is necessary before the results of culture and susceptibility become available. The choice of treatment at this stage can be based on cytology and knowledge of the type of infections that most commonly occur at the anatomic site involved (also known as *bacteriologic statistics*). Because of the life-threatening nature of these infections, the practice of "de-escalation" (as opposed to "escalation") is employed. This is the practice of initially selecting a highly active agent that has a high probability of successful elimination of the pathogen; then once the infectious agent has been identified, the drug spectrum should be changed or narrowed according to culture and susceptibility results. If the infection is life threatening, highly active agents such as an aminoglycoside or fluoroquinolone with or without a β-lactam can be selected initially. Then, if culture and susceptibility show susceptibility to β-lactams, treatment should be continued with these agents alone.

Classification of Antimicrobial Drugs

Antimicrobial drugs may be classified based on their structure (e.g., β-lactams, fluoroquinolones), spectrum of activity (gram-positive versus gram-negative bacteria), mechanism of action (Table 6-1, Figure 6-1), whether they are *bacteriostatic* (inhibit or slow growth) or *bactericidal* drugs, and their pharmacodynamic properties (see Pharmacodynamics of Antimicrobial Drugs, later). Bactericidal drugs interfere with cell wall or nucleic acid synthesis, whereas bacteriostatic drugs inhibit protein synthesis or cause changes in bacterial physiology. When a bacteriostatic drug is removed, in the absence of host defense mechanisms, organism growth resumes, and any decline in bacterial numbers that occurs when the drug concentration drops below the minimum inhibitory concentration (MIC) reflects clearance by the host immune response. However, the line that separates bactericidal and bacteriostatic is not as precise as previously thought. Some bacteriostatic drugs become bactericidal when present in high concentrations at the site of infection, or if concentrations are maintained above the MIC for the entire dosing interval. Even macrolides and chloramphenicol, which are traditionally considered as bacteriostatic drugs, can be bactericidal against some organisms. A drug may be bactericidal against gram-positive cocci, but bacteriostatic against gram-negative bacilli. Therefore, from a clinical perspective, it is more useful to describe drugs as time versus concentration-dependent, rather than as bactericidal or bacteriostatic. This allows the clinician to consider the dosage regimen and dosing interval to optimize therapy. There are rare instances where a bactericidal agent is preferred over a bacteriostatic one. It may be preferable to prescribe a bactericidal drug to treat life-threatening infections (such as vegetations in endocarditis or in a systemically immunocompromised host).[7]

Antibacterial drugs have also been classified for veterinary use as first-line, second-line, or third-line drugs.[8] First-line drugs are those that could be used for empirical selection in the absence of or pending the results of culture and susceptibility testing, and include amoxicillin, cephalexin, doxycycline, and trimethoprim-sulfonamides. Second-line drugs are those to be used on the basis of culture and susceptibility testing and because of the lack of any appropriate first-line options. These include ticarcillin, piperacillin, amikacin, and third-generation cephalosporins. Fluoroquinolones were also included in this group because in human medicine, excessive fluoroquinolone use has been associated with emergence of antimicrobial resistance and treatment failures.[9] Fluoroquinolones could be considered as first-line drugs for dogs and cats suspected to have serious gram-negative bacterial infections that require treatment pending the results of culture and susceptibility testing. The use of third-line drugs, including vancomycin, linezolid, and carbapenems such as imipenem and meropenem, is usually reserved for situations when certain criteria are met[8]:

1. Infection must be documented based on clinical abnormalities and culture.
2. The infection is serious and has the potential to be life-threatening if left untreated.
3. Resistance is documented to all other reasonable first- and second-line options.
4. The infection is potentially treatable.
5. The clinician may seek advice from an infectious disease clinician or a clinical microbiologist to discuss antimicrobial susceptibility test results, and to discuss the use of these agents if there is unfamiliarity with their use. In some instances, there may be other viable options (e.g., topical therapy).

Pharmacodynamics of Antimicrobial Drugs

Pharmacokinetic and pharmacodynamic parameters (PK-PD exposure relationships) are important determinants of the efficacy of AMDs and serve as the basis for determination of clinically effective dosage regimens and susceptibility breakpoints and for the development of guidelines for AMD use for specific types of infections.[10]

The killing of microbes by AMDs may be classified as *concentration dependent* or *time dependent*. AMDs that exhibit

TABLE 6-1

Classification of Antimicrobial Drugs Based on Their Mechanism of Action

Mechanism of Action	Antimicrobial Drug	Examples
Inhibition of cell wall synthesis	β-Lactams, glycopeptides	Penicillin, cephalexin, meropenem, vancomycin
Protein synthesis inhibition	Tetracyclines, aminoglycosides, chloramphenicol, lincosamides, macrolides	Doxycycline, gentamicin, erythromycin, clindamycin, azithromycin
Inhibition of DNA replication	Fluoroquinolones	Enrofloxacin, marbofloxacin
Inhibition of folic acid metabolism	Trimethoprim-sulfonamides	Trimethoprim-sulfamethoxazole

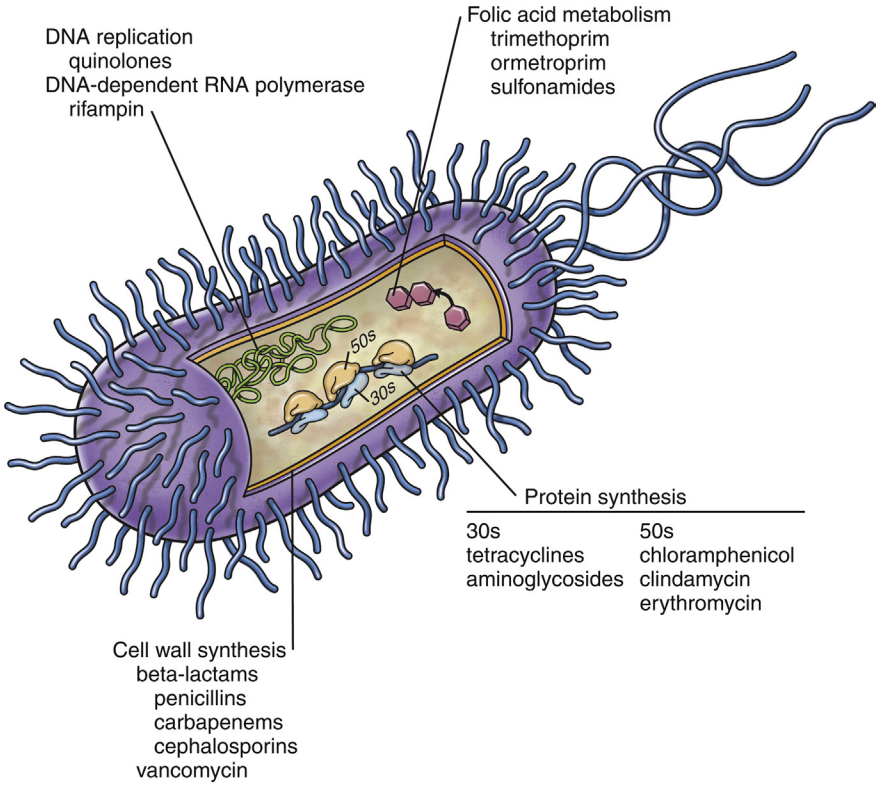

FIGURE 6-1 Sites of action of antimicrobial drugs within the bacterial cell.

concentration-dependent killing are fluoroquinolones and aminoglycosides. These drugs work optimally when the peak concentration in the plasma (C_{max}), or the area under the curve (AUC) exceeds the MIC by a defined factor (Figure 6-2). These are typically bactericidal agents and the ability to kill bacteria increases as the AMD concentrations increase. Target concentrations have been defined for laboratory animals and humans and have been extrapolated to veterinary patients. For example, the peak concentration to MIC ratio (C_{max}/MIC) should exceed 8 to 10 for optimum dosing of aminoglycosides. The AUC for a 24-hour interval to MIC ratio (AUC_{24}/MIC) should exceed 100 for fluoroquinolones. For some infections, a ratio of 125 is better, and in some patients (e.g., immunocompromised patients with life-threatening infections), a ratio of 250 may be desirable. Drugs that exhibit concentration-dependent killing also have *postantibiotic effect* (PAE). The PAE is the persistence of antimicrobial effects after drug concentrations at the site of infection fall below the MIC. The exact cause of the PAE varies with the drug, but it may result from irreversible binding of a drug to the target site. The duration of the PAE is influenced by the duration of antibiotic exposure, the drug concentration, the bacterial species present, and the class of antibiotic. For concentration-dependent antibiotics, administration of the total daily dose as a single dose every 24 hours is preferred to a smaller divided dose, in order to maximize C_{max} or AUC. For aminoglycosides, this also reduces drug toxicity.[7]

β-lactams (penicillins and cephalosporins), macrolides, and lincosamides (clindamycin) exhibit *time-dependent killing*. As concentrations of these drugs increase, bacterial killing plateaus, and outcome is correlated with the *time* that the AMD concentration spends above the MIC at the site of infection. This is usually expressed as the percent of time above the MIC during a 24-hour interval (T > MIC). For β-lactam drugs apart from carbapenems, PAEs are minimal. As a result, these drugs work best when administered multiple times a day or as continuous-rate infusions, in order to maintain drug concentrations at the site of infection. For some drugs (e.g., some

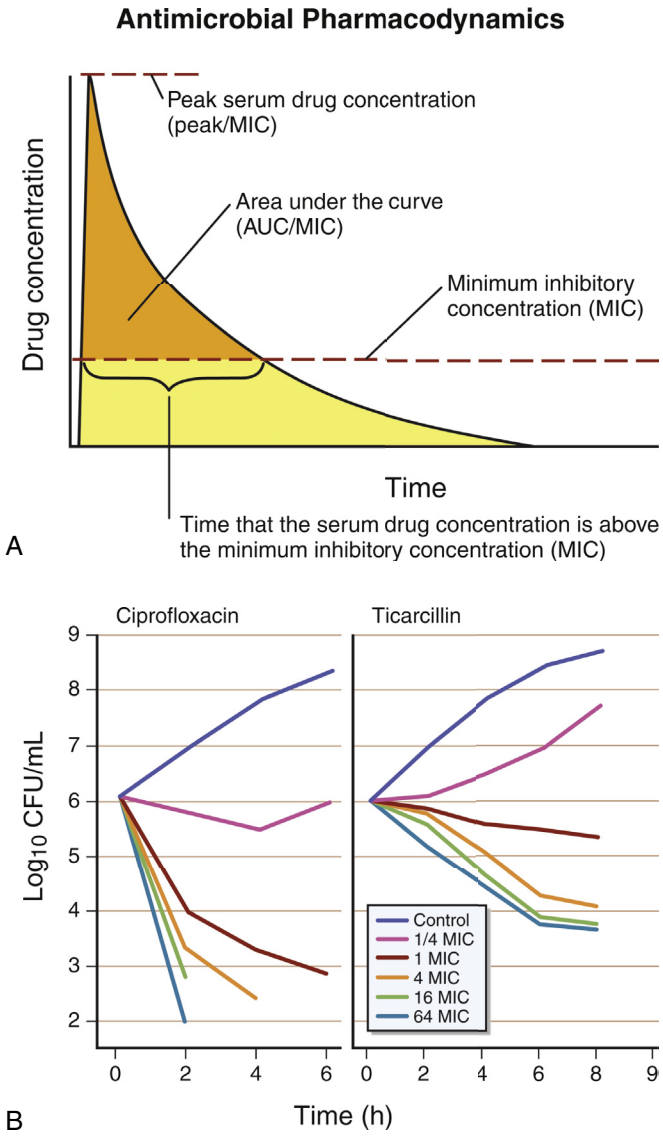

FIGURE 6-2 A, Antimicrobial drug (AMD) pharmacodynamics. Concentration-dependent drugs are most active when the peak concentration (C_{max}), or the area-under-the-curve (AUC) in the plasma exceeds the MIC by a defined factor. For time-dependent drugs, outcome is correlated with the time that the AMD concentration at the site of infection spends above the MIC. This is usually expressed as the percent of time above the MIC during a 24-hour interval (T > MIC). **B,** As AMD concentrations increase, the ability of concentration-dependent drugs such as fluoroquinolones (in this case, ciprofloxacin) to kill bacteria increases. As concentrations of time-dependent drugs such as β-lactam drugs (in this case, ticarcillin) increase, bacterial killing plateaus. MIC, minimum inhibitory concentration.

cephalosporins), a long T > MIC is achieved by virtue of a long half-life. The required time above the MIC for an AMD varies with the pathogen present, the drug, and the site of infection, but in general it should be 40% to 50% of the dosing interval.[7,10] Drug dosages that achieve concentrations in excess of an MIC for these periods can be calculated based on pharmacokinetic data. For time-dependent AMD with long half-lives (such as macrolides, clindamycin, and tetracyclines), efficacy is determined primarily by the extent to which the area under the curve exceeds the MIC. As the MIC of an organism increases, it becomes more difficult to achieve these PK-PD targets, and organisms are regarded as resistant.

In animals with renal failure, AMD clearance may be greatly diminished. In this case, T > MIC and AUC/MIC are achieved with a reduced dose or less frequent dosing. For β-lactam antibiotics, it is logical to increase the dose interval. For fluoroquinolones, it is better to decrease the dose.

Site of Infection

In general, the concentration of an AMD at the site of infection should at least equal the MIC for the infecting organism, but the exact concentration and the duration of the concentration at the site varies with the class of antimicrobial. For some AMDs, the serum or plasma total (bound and unbound) drug concentrations may not reflect the drug concentration in tissues. Examples are the highly lipophilic macrolide antibiotics (e.g., azithromycin) for which the tissue drug concentration greatly overestimates the plasma drug concentration. On the other hand, tissue concentrations greatly underestimate the plasma or serum drug concentration for poorly lipophilic agents such as aminoglycosides or β-lactams. Antimicrobial selection for different body sites is outlined in Box 6-1.

The concentration of an AMD at the site of infection is affected by factors such as lipid solubility, protein binding, and other factors reducing permeability, such as the presence of large amounts of pus, scar tissue, foreign material, devitalized tissue, and bone. Lipid-soluble drugs such as chloramphenicol, rifampin, fluoroquinolones, and trimethoprim are most adept at crossing membranes, including the blood-brain, alveolar, and prostatic barriers. In contrast, poorly lipophilic, polar drugs such as penicillins and aminoglycosides do not cross lipid membranes and will not achieve adequate tissue levels in tissues in which there is a barrier to penetration (e.g., prostate, brain, eye, or intracellular sites). In human patients, aminoglycosides and amphotericin B have been administered intrathecally to treat central nervous system infections.[11,12] In order to use β-lactam antibiotics to treat these infections, high doses are required because of a poorly penetrated blood-brain barrier. Even in the face of inflammation, the brain/blood concentration ratio of these drugs is low. Water-soluble AMDs that are excreted in active form by the liver and concentrated in bile, such as doxycycline and ampicillin, make excellent choices for susceptible hepatobiliary infections (see Chapter 88). Urinary tract infections are ideally treated with drugs such as amoxicillin and trimethoprim-sulfonamides, which are highly concentrated in the urine (see Chapter 89).

Other Host Factors

Other host factors that should be considered in AMD selection and route of administration include the following:

1. History of adverse drug reactions. These are most commonly gastrointestinal in dogs and cats, but may include hypersensitivity reactions.
2. Age. With the exception of doxycycline, the use of systemic tetracyclines is contraindicated in young animals because of the potential for teeth discoloration (see Figure 8-5). Fluoroquinolones have the potential to cause cartilage and joint toxicity in dogs between the ages of 7 and 28 weeks. The clinical significance of this has been questioned.[13,14]
3. Species. Dogs and cats differ in their susceptibility to adverse drug reactions. For example, dogs can develop severe cutaneous reactions to 5-flucytosine. Cats are susceptible to acute retinal degeneration following treatment with high doses of

BOX 6-1

Examples of Appropriate Initial Antimicrobial Drug Choices for Treatment of Bacterial Infections in Different Anatomic Sites*

Skin
Cephalexin
Amoxicillin-clavulanate
Clindamycin

Urinary Tract
Amoxicillin
Trimethoprim-sulfamethoxazole

Prostate
Trimethoprim-sulfamethoxazole

Respiratory tract
Doxycycline
Fluoroquinolones

Intestinal Tract (e.g., for animals with hepatic encephalopathy)
Ampicillin
Neomycin

Biliary Tree
Amoxicillin-clavulanate
Doxycycline
Fluoroquinolones

Brain
Metronidazole
Fluoroquinolones
Trimethoprim-sulfonamides

Bone
Clindamycin
Cephalosporins
Amoxicillin-clavulanate

*The identity of the pathogen present must also be used to guide antimicrobial drug selection.

enrofloxacin. Cats also are prone to esophageal ulceration from oral doxycycline hyclate or clindamycin unless the medication is administered with a bolus of water or food.

4. Breed. Doberman pinschers may be more susceptible to hypersensitivity reactions following trimethoprim-sulfonamide administration.
5. Gastric acidity. The absorption of some AMDs, such as ketoconazole and itraconazole, is impaired by medications that suppress gastric acid production.
6. Concurrent medications. Drug interactions, such as concurrent use of drugs that require metabolism using cytochrome P450 enzymes, can affect the choice or dose of AMD used. For example, chloramphenicol and ketoconazole are well-known P450 enzyme inhibitors, whereas rifampin is an enzyme inducer.
7. Pregnancy. Penicillins, cephalosporins, aminoglycosides, and macrolides are generally considered safe during pregnancy. The volume of distribution in pregnancy is greater, and so higher doses may be required to achieve equivalent serum concentrations.
8. Renal and hepatic function. The dose of AMDs that are dependent on renal elimination may require reduction in these animals with impaired renal function in order to minimize toxicity. For example, fluoroquinolones may be more likely to cause seizures or retinal toxicity in animals with renal failure. The use of nephrotoxic drugs such as amphotericin B or aminoglycosides may be relatively contraindicated in animals with renal dysfunction. Adverse effects may be more common when drugs that require hepatic metabolism, such as metronidazole or chloramphenicol, are administered to animals with impaired liver function.

Route of Administration

The most common routes of administration for AMDs in dogs and cats are topical, intravenous, intramuscular, subcutaneous, and oral. For localized infections of the skin, eye, or ear canal, topical administration has the advantage of delivering a high concentration of the AMD to the site, which may overcome bacterial resistance mechanisms, and avoid any systemic exposure to the drug. Parenteral administration, especially intravenous administration, provides maximum bioavailability and is recommended for (1) treatment of life-threatening infections, (2) systemic administration of antimicrobials with poor oral bioavailability (such as aminoglycosides), and (3) when gastrointestinal signs or malabsorption preclude effective drug administration via the oral route. Because parenteral AMDs are generally administered in hospital, compliance with this mode of administration is also likely to be greater. Absorption may be delayed after subcutaneous or intramuscular administration when perfusion of these tissues is impaired, and so these routes are not recommended for use when intravenous administration is possible. Peak plasma drug concentrations are achieved quickly after intravenous bolus administration. Therefore, bolus administration is an optimum approach for a concentration-dependent antimicrobial provided rapid injection does not produce toxicity (such as may occur with fluoroquinolones). For a time-dependent drug such as a β-lactam, a slow infusion (even a slow constant-rate infusion) optimizes the time-dependent activity.

Provided gastrointestinal function is healthy, administration of many oral AMDs results in acceptable bioavailability, even though many popular antimicrobials have oral absorption that is far less than 100%. Drugs with the highest oral bioavailability in dogs and cats are the fluoroquinolones; β-lactams have low and variable bioavailability. Nevertheless, once the animal can tolerate oral medications and its clinical condition becomes stable, a switch can be made from parenteral to oral antimicrobials. Peak plasma concentrations are always lower with oral administration than those achieved with intravenous administration, but for time-dependent drugs or for drugs that achieve efficacy on the basis of an AUC/MIC exposure relationship, this route is acceptable for a cure. Early switch from intravenous to oral therapy in human patients has gained increased favor in recent years because of reduced lengths of hospitalization, lowered costs, fewer intravascular catheter-related infections, and decreased selective pressure on nosocomial bacterial infections.[15,16] The oral bioavailability of some drugs can be maximized if they are administered with food (e.g., clavulanic acid-amoxicillin) or

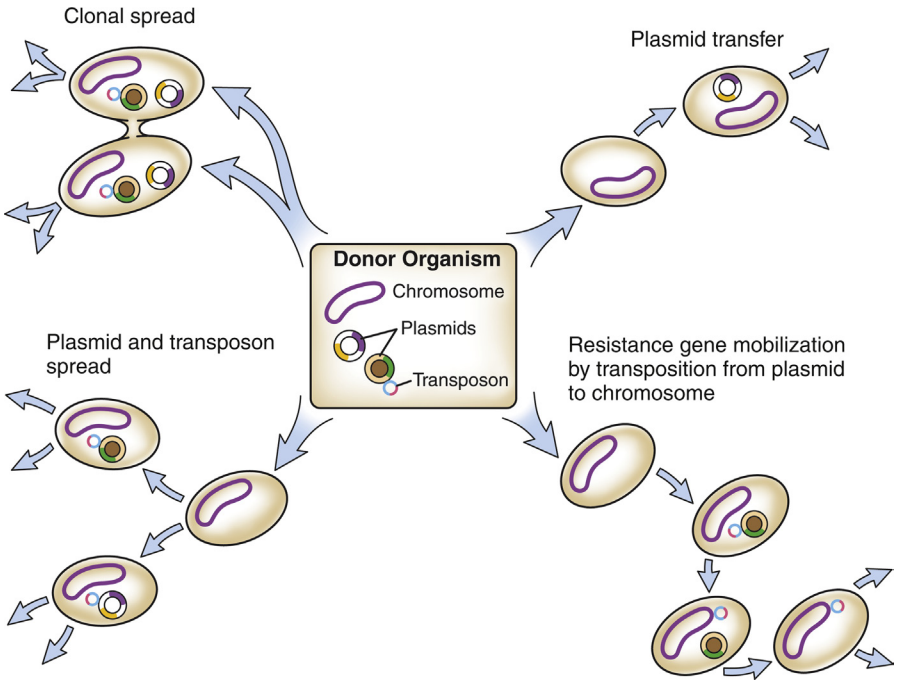

FIGURE 6-3 Genetic mechanisms of resistance in bacteria.

without food (e.g., azithromycin). Some drugs are simply not absorbed orally and must be administered parenterally or by the topical route. These drugs include penicillin G, piperacillin, ticarcillin, aminoglycosides, many cephalosporins (cefazolin, cefotaxime, cefoxitin), meropenem, imipenem, and vancomycin. Some drugs are not absorbed orally unless administered as a prodrug. An example is cefpodoxime proxetil. The proxetil portion of the molecule is cleaved off at the time of intestinal absorption to allow for adequate systemic concentrations.[17]

Antimicrobial Resistance

Infectious agents may be intrinsically resistant to an AMD, or be resistant as a result of genetic variations. *Intrinsic* or *innate resistance* refers to the innate ability of an organism to resist the effects of an AMD owing to structural or functional characteristics of that organism. For example, enterococci are intrinsically resistant to cephalosporins, because they lack the penicillin-binding proteins that bind these antibiotics.[18] Anaerobic bacteria are intrinsically resistant to aminoglycosides because oxygen is required for entry of the drug to the bacteria. The microbiology laboratory may "suppress" the results of susceptibility tests for antimicrobials to which organisms are intrinsically resistant (i.e., they are not listed in the susceptibility report to the clinician). Resistance can also be defined via pharmacokinetic-pharmacodynamic targets. For example, an organism may not express complete resistance to an antimicrobial, but the organism is effectively resistant when standard dosage regimens cannot reach a particular peak concentration or AUC.

Genetic resistance to an AMD may occur as a result of point mutations, DNA rearrangements, or acquisition of foreign DNA. Point mutations can result in alteration of the target site of an AMD, such as the susceptibility of bacterial DNA gyrase to fluoroquinolones.[19] DNA rearrangements may include inversions, deletions, duplications, insertions, or transpositions (including chromosome to plasmid) of large segments of DNA. The single most important mechanism of antibacterial resistance is acquisition of foreign DNA by horizontal transfer, especially that carried by plasmids and transposons.[20] Plasmids are circular, double-stranded DNA molecules that are capable of independent replication and can be transferred from one bacterial strain or species to another through the process of bacterial conjugation. Transposons are small, mobile segments of DNA that are flanked by inverted repeats and encode one or more resistance genes (Figure 6-3). They depend on the chromosome or plasmids for replication. Plasmid-associated genes that confer AMD resistance are frequently on transposons and can move from the plasmid to the bacterial chromosome. A single plasmid may contain resistance genes for more than five different AMDs.

Mechanisms of Antimicrobial Resistance

Antimicrobial Inactivation

Bacterial enzymes capable of inactivation of AMDs include β-lactamase enzymes, enzymes that modify aminoglycoside structure, chloramphenicol acetyltransferase, and erythromycin esterase. β-Lactamase production is the most important mechanism of resistance to β-lactam antibiotics among gram-negative bacteria.[20] A vast array of β-lactamase enzymes have been discovered, which have been extensively classified into groups.[21,22] Extended-spectrum β-lactamases (ESBLs) can hydrolyze not only penicillins and first-generation cephalosporins, but also extended-spectrum cephalosporins such as cefotaxime and ceftazidime (which contain an oximino group). To date, ESBLs have only been described in gram-negative bacilli and are most commonly produced by *Escherichia coli* and *Klebsiella pneumoniae*. ESBLs are often inhibited by β-lactamase inhibitors such as clavulanic acid. The ESBL with the most importance at the present time for small animals are the CTX-M β-lactamases, which hydrolyze cefotaxime and other third-generation cephalosporins. Other types of β-lactamase enzymes include AmpC β-lactamases, which are encoded by chromosomal genes, and metallo-β-lactamases.[20,23] These types of β-lactamase enzymes

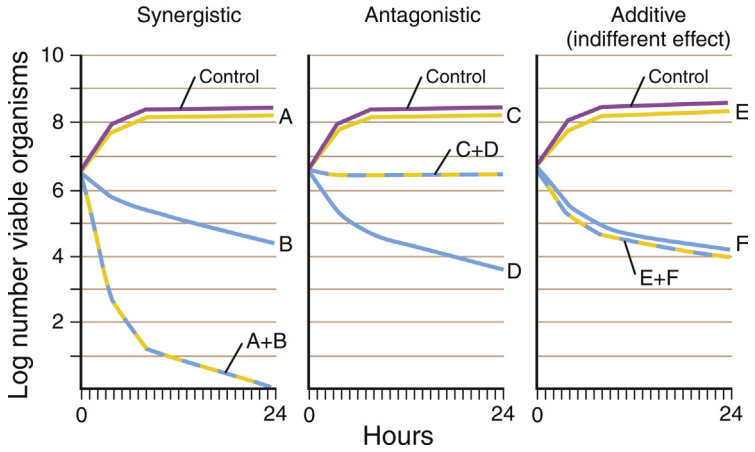

FIGURE 6-4 Synergistic, antagonistic, and additive effects of antimicrobial drug combinations. Drugs used are referred to using letters of the alphabet. Control = no drug.

are resistant to clavulanic acid. Metallo-β-lactamases can inactivate carbapenems such as meropenem and imipenem.

Membrane Alteration

Protein channels called *porins* facilitate the passage of hydrophilic AMDs into gram-negative bacteria. Acquisition of porin mutations can result in conformational changes of or reduced expression of porins. The result is exclusion of AMDs such as β-lactams and fluoroquinolones.[24]

Efflux Pump Induction

Expression of efflux pumps by bacteria allows them to exclude certain AMDs. This is a major mechanism of resistance to tetracyclines in gram-negative bacteria. A huge variety of efflux pumps have been described.[25] Efflux pumps may not be specific for one particular class of antimicrobial. Therefore, these have been termed "multidrug" efflux pumps and mediate multidrug resistance (MDR). The acquisition of MDR mechanisms greatly reduces the effective options for therapy. Multidrug-resistant organisms such as *Pseudomonas aeruginosa* and *Acinetobacter baumannii* can utilize multidrug efflux pumps in concert with a variety of other resistance mechanisms, including β-lactamase enzyme production, drug target alterations, and AMD modification enzymes.

Target Modification

Methylation of ribosomal targets by bacterial methyltransferases can lead to resistance to tetracyclines, lincosamides, aminoglycosides, and especially macrolide antibiotics. Expression of altered penicillin binding proteins (PBPs) is an important mechanism of resistance to β-lactam antimicrobials. Expression of PBP2a by staphylococci, which is encoded by the *mecA* gene, confers resistance to all β-lactam antimicrobials, including β-lactamase resistant penicillins such as methicillin and oxacillin (methicillin-resistant staphylococci). Mutations of DNA gyrase can confer resistance to fluoroquinolones.[20] Resistance to trimethoprim sulfonamides can result from altered dihydropteroate synthetase and dihydrofolate reductase enzymes.[26]

Novel Approaches to Antimicrobial Drug Resistance

With rapid spread of multidrug-resistant bacterial pathogens, alternatives to antibiotics have been investigated. One approach is bacteriophage therapy. Bacteriophages are viruses that infect bacteria, and because of their specificity for certain bacterial species, they can deliver targets to one type of organism without harming others.[27,28] Bacteriophage treatment may also be more successful than AMD treatment in the presence of biofilms, which impair antibiotic penetration. Other approaches that are under investigation include use of bacterial cell wall hydrolases, cationic antimicrobial peptides, and antisense antibiotics. Cationic antimicrobial peptides are derived from eukaryotic cells, have immunomodulatory properties, and rapidly kill a variety of bacteria.[29] Although it is difficult for bacteria to develop resistance to these peptides, multiple resistance mechanisms have been described. Antisense antibiotics are oligonucleotides that bind to the DNA of pathogenic microorganisms and inhibit gene expression.[30]

Antimicrobial Drug Combinations

When an infectious agent is suspected but has not yet been identified, the use of AMD combinations is tempting because of the added broad spectrum of coverage that they provide. However, use of AMD combinations does not necessarily reduce the chance of selection for a resistant organism, adds expense, and may predispose to drug toxicity. Theoretically, drug combinations may have additive, synergistic, or antagonistic effects (Figure 6-4). These properties are not as well established in clinical situations. For example, antagonism between a bacteriostatic antibiotic (such as tetracycline) and a bactericidal antibiotic that requires bacterial growth for efficacy (such as a β-lactam) is also theoretically possible, but there is only one clinical example of this occurrence, published in the 1950s.[31] Such antagonism has not been replicated since that time.

Several reasons have been suggested for the use of AMD combinations:

1. Some drugs must be administered in combination with other drugs because of rapid development of resistance to them when they are used as a sole agent. Examples are 5-flucytosine and rifampin.
2. If a polymicrobial infection is present, one drug may not have a sufficient spectrum of activity.
3. If the nature of an infection is not known and infection is life-threatening, it is reasonable to commence treatment with a broad-spectrum combination (such as a fluoroquinolone and a β-lactam), based on knowledge of the likely pathogen present and local prevalence of AMD resistance, pending the results of culture and susceptibility testing. Once the results

VetBooks.ir

of culture and susceptibility testing are available, deescalation should be performed.

4. Certain combinations of AMD are synergistic for treatment of specific infections. For example, the combination of a β-lactam and an aminoglycoside is synergistic for treatment of enterococcal endocarditis. The relatively slow bactericidal activity of the β-lactam is greatly enhanced by the addition of the aminoglycoside, such that shorter durations of treatment or extension of the dosing interval becomes possible without affecting outcome.[7]
5. Some drugs are not effective against anaerobic bacteria (e.g., fluoroquinolones with the exception of pradofloxacin). They should be combined with an agent active against anaerobes (e.g., clindamycin or metronidazole) when a mixed infection with anaerobic and aerobic bacteria is suspected.
6. When a vector-borne pathogen is suspected, doxycycline may be administered until the results of further diagnostic tests confirm or eliminate this suspicion. In these cases, patients are frequently administered doxycycline in combination with another active agent to treat alternative bacterial infections that have not yet been ruled out.

Monitoring the Response to Treatment

The response to antimicrobial treatment is best monitored based on clinical assessment, which includes follow-up cytologic examination or cultures. Therapeutic drug monitoring can be used to ensure adequate serum drug concentrations when treating with aminoglycosides, vancomycin, and azole antifungal drugs. It should be remembered that in some cases, infections resolve because of the host immune response alone.

CHAPTER 7

Antiviral and Immunomodulatory Drugs

Jane E. Sykes and Mark G. Papich

KEY POINTS

- Most antiviral drugs available for treatment of canine and feline viral infections are nucleoside analogues with greatest activity against herpesvirus and retrovirus infections.
- Because antiviral drugs also affect the function of host cell machinery, they have considerable potential for toxicity.
- Antiviral drugs are widely used in human medicine for treatment of herpesvirus, HIV and other viral infections. Much less is known about these medications in dogs and cats and there are few diseases of dogs and cats for which efficacy has been demonstrated.
- Because of important differences between human and animal virus infections, one should never assume that an antiviral agent used in people should be used in animals unless there is proof of safety and efficacy.
- Antiviral drugs used to treat feline herpesviral infections include famciclovir, idoxuridine, and cidofovir. Zidovudine is the only antiretroviral drug that has demonstrated efficacy for treatment of cats, primarily for FIV infections.
- Antiviral drugs can act synergistically with immunomodulators.
- Immunomodulators include microbial products, plant-derived immunomodulators, naturally occurring mammalian proteins, glucocorticoids, and synthetic compounds such as pentoxifylline and opioids. The effect of many of these drugs on outcome in dogs and cats with infectious diseases has not been fully evaluated using large, prospective, randomized, masked, controlled clinical trials.
- The parenteral use of natural or recombinant human protein immunomodulators in dogs and cats may result in the formation of neutralizing antibodies after 1 to 2 weeks of treatment, which can cross-react with endogenous proteins.

INTRODUCTION

The purpose of this chapter is to describe the mechanisms of action, spectrum of activity, and adverse effects of the major antiviral and immunomodulatory drugs that have exhibited utility or have potential for treatment of companion animal infectious diseases. An enormous number of different compounds have been considered or evaluated in vitro and in vivo with variable success. Only those currently in use for treatment of dogs and cats with naturally occurring infections, those that show considerable promise for the future, or those evaluated in controlled clinical trials are discussed in this chapter.

Antiviral Drugs

Antiviral agents interfere with virus-specific events in replication, including viral attachment, uncoating, assembly, and virus-directed macromolecular synthesis. As a result, antiviral agents typically have a restricted spectrum of activity. In contrast to most antibacterial drugs, antiviral drugs can also affect the function of host cell machinery and thus antiviral drugs have a greater risk of toxicity. In addition to acute toxicities such as marrow suppression, many antiviral agents are immunosuppressive, carcinogenic, and teratogenic. Many are given topically in order to minimize systemic toxicity. Antiviral agents are more likely to be effective when an intact host immune response is present. Combinations of antiviral drugs with different mechanisms of action and combinations of antiviral and immunomodulatory drugs are increasingly being used to treat human viral infections, especially HIV infection, with an associated decrease in toxicity and reduction in selection for drug-resistant mutants.

Although all antiviral drugs used to treat small animals were originally developed for treatment of human viral infections, the application of these drugs to treat viral infections of small animals has not proven straightforward. This relates to differences in the composition of human and companion animal viruses (which affect their susceptibility to inactivation by antiviral drugs), or problems relating to toxicity of human antiviral drugs in dogs and cats.

Antiviral drugs can be classified based on their spectrum of activity (i.e., family of viruses that are inhibited) and their mode of action. Antiviral drugs used in small animal medicine are primarily effective against herpesviruses or retroviruses, and most are *nucleoside analogues*. Nucleoside analogues resemble host nucleosides, which are nitrogenous bases with an attached sugar molecule used as a building block for the formation of DNA or RNA (Figure 7-1). Use of nucleoside analogues by viruses during replication leads to the formation of abnormal nucleic acids or termination of nucleic acid synthesis. Latent viral infections are not affected because the replication of latent virus is suspended. However, reactivation of these infections can be reduced in frequency or prevented. Examples of nucleoside analogues and their spectrum of activity are shown in Figure 7-1 and Table 7-1. Other antiviral drugs that have been used in clinical veterinary medicine include *amino acids* (L-lysine) and *neuraminidase inhibitors* (oseltamivir). The value of other treatments such as small inhibitory RNA molecules for viral infections of small animals is also under investigation.[1]

Antiherpesviral Drugs

The standard antiviral treatments for herpesviral infections in human patients are the nucleoside analogues acyclovir and

penciclovir, and their prodrugs valacyclovir and famciclovir, respectively. These drugs are activated by the herpesviral enzyme thymidine kinase (TK), which phosphorylates them to a monophosphate form. Host cell enzymes then phosphorylate the drugs further to triphosphate forms, which concentrate in virus-infected cells and interfere with viral DNA replication via inhibition of the viral DNA polymerase enzyme. Because the DNA polymerases of different herpesviruses are inhibited to varying degrees by acyclovir triphosphate, not all herpesviral infections are equally susceptible. Drug resistance results from reduced viral TK activity, altered viral TK, or altered viral DNA polymerase. The antiherpesviral drugs cidofovir, idoxuridine, trifluridine, and vidarabine are not dependent on viral TK for phosphorylation and so have greater host cell toxicity. In small animal medicine, these four drugs have been used topically to treat ocular feline herpesviral infections.

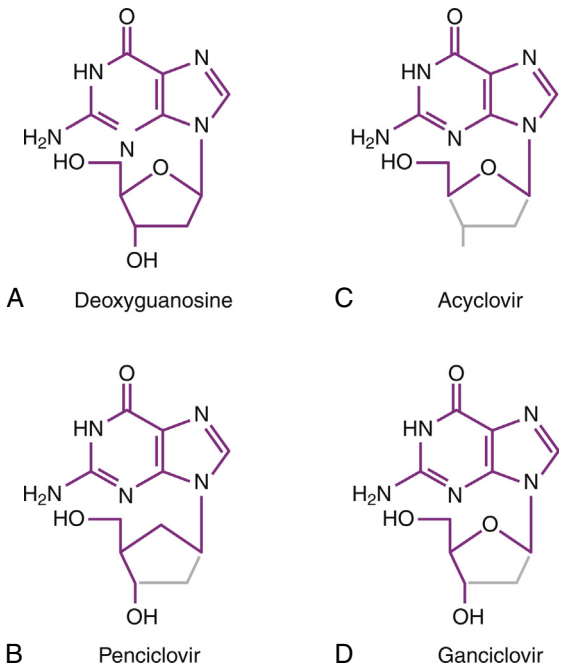

FIGURE 7-1 Chemical structures of deoxyguanosine (a nucleoside) and antiherpesviral nucleoside analogues. the grey portion is missing in the nucleoside analogues. **A,** Deoxyguanosine. **B,** Acyclovir. **C,** Penciclovir. **D,** Ganciclovir.

Acyclovir and Valacyclovir

Acyclovir is a synthetic analogue of the purine nucleoside deoxyguanosine (see Figure 7-1). In human patients, acyclovir is widely used to treat herpes simplex and varicella-zoster virus infections, both of which are α-herpesviruses. In small animal medicine, acyclovir has primarily been used to treat feline herpesvirus-1 (FHV-1) infections, although FHV-1 has a much lower susceptibility to the drug compared with the human herpesviruses.[2] Acyclovir has also been used to treat canine herpesvirus-1 (CHV-1) infections in puppies (see Chapter 16). Other nucleoside analogues (trifluridine, idoxuridine, cidofovir, ganciclovir, and penciclovir) show much greater activity than acyclovir against FHV-1 in vitro.[2-4]

Topical acyclovir has been used with limited success to treat feline herpetic dermatitis[5] and keratitis.[6] Topical treatment requires frequent (>4 times a day) application for beneficial effect.[6] The oral bioavailability of acyclovir is low in cats, and high doses are required to achieve adequate serum drug concentrations.[7] Valacyclovir, the prodrug for acyclovir, is rapidly converted to acyclovir by a first-pass effect after oral administration, and administration of the prodrug results in improved oral bioavailability of acyclovir. Unfortunately, administration of high doses of acyclovir or valacyclovir to cats has resulted in significant toxicity, including myelosuppression, renal tubular

TABLE 7-1

Antiviral Drugs in Use in Small Animals

Antiviral Drug	Mechanism of Action	Human Applications	Small Animal Applications
Acyclovir/ valacyclovir	Guanosine analogue; interferes with viral DNA polymerase and DNA synthesis. Activity requires viral TK.	Herpesviruses, especially HSV and varicella-zoster virus	Poorly effective against FHV-1
Penciclovir/ famciclovir	See acyclovir	Herpesviruses, especially HSV and varicella-zoster virus	FHV-1 infections
Cidofovir	Deoxycytidine monophosphate analogue. Activity independent of viral TK.	Systemically to treat cytomegalovirus retinitis; topically to treat papillomavirus infections	Topical treatment of FHV-1 ocular infections
Idoxuridine	Iodinated thymidine analogue. Interferes with viral DNA synthesis.	Topical treatment of HSV keratoconjunctivitis	Topical treatment of FHV-1 keratitis
Trifluridine	Fluorinated thymidine analogue. Interferes with viral DNA synthesis.	See idoxuridine	See idoxuridine
Vidarabine	Adenosine analogue. Interferes with viral DNA synthesis.	See idoxuridine	See idoxuridine
Zidovudine	Thymidine analogue. Interferes with viral DNA synthesis.	Systemic treatment of HIV infections	Systemic treatment of FIV and FeLV infections

FHV-1, feline herpesvirus-1; HSV, herpes simplex virus; TK, thymidine kinase.

VetBooks.ir

necrosis, and hepatic necrosis, without effective suppression of viral replication.[8] Thus the use of systemic acyclovir and valacyclovir to treat cats with herpesvirus infections is not recommended.

Penciclovir and Famciclovir

Of all antiviral drugs used to treat small animal patients, penciclovir and famciclovir have shown the greatest promise. Penciclovir is another guanosine analogue (see Figure 7-1). It is present at much higher concentrations and for longer duration in cells than is acyclovir, which permits less frequent dosing. In humans, the prodrug famciclovir is well absorbed orally and rapidly converted to penciclovir, leading to increased oral bioavailability of penciclovir. Most of the drug is eliminated unchanged in the urine, and so dose reduction may be required for animals with decreased kidney function. In human patients, the concurrent administration of food decreases peak plasma concentrations without affecting overall bioavailability. In humans with herpes simplex virus and herpes zoster infections, famciclovir is as effective as acyclovir. In contrast, penciclovir (and thus famciclovir) have been shown to be potent inhibitors of FHV-1 replication (which is not the case for acyclovir). Penciclovir-resistant mutants of FHV-1 with altered TK enzymes have been described.[9]

Administration of famciclovir to cats at dosages comparable to those used in other species results in much lower plasma concentrations and a longer time to development of peak plasma concentrations of penciclovir when compared with other animal species, which suggests altered absorption or metabolism of famciclovir in cats.[10] High doses of famciclovir have been required to achieve adequate plasma drug concentrations. Nevertheless, famciclovir is well tolerated when administered orally to cats at doses that produce clinical responses.[5,10,11] Treatment of cats with experimentally induced FHV-1 conjunctivitis with famciclovir at 90 mg/kg PO q8h for 21 days resulted in lower clinical and pathologic disease scores and decreased viral shedding when compared with placebo-treated cats.[11] Clinical responses also occur in naturally infected cats with both acute and chronic manifestations of disease with negligible adverse effects.[5] Because of saturation of the metabolism of famciclovir to penciclovir, equivalent serum and tear penciclovir concentrations can be achieved in cats with 40 or 90 mg/kg PO q8h of famciclovir, so 40 mg/kg PO q8h is considered equally efficacious.[12,13] Clinical improvement often occurs within a week of treatment.

Ganciclovir

Ganciclovir resembles acyclovir except that it has an additional hydroxymethyl group on its acyclic side chain (see Figure 7-1). In human patients, ganciclovir is widely used specifically for the treatment of human cytomegalovirus infections, which can be life threatening in the immunocompromised. Cytomegaloviruses are β-herpesviruses. Systemic administration of ganciclovir to human patients is associated with a high prevalence of adverse drug reactions, especially cytopenias and central nervous system (CNS) signs, and so the use of ganciclovir is limited to patients with life-threatening or sight-threatening infections. A topical ophthalmic gel formulation of ganciclovir (0.15%) is now available for treatment of keratitis caused by herpes simplex virus-1. Ganciclovir is highly inhibitory to FHV-1 replication in vitro.[4,14] Pharmacokinetic, safety, and efficacy studies in cats have not yet been performed, but topical ganciclovir holds promise for treatment of feline ocular herpesviral infections.

Cidofovir

Cidofovir is a nucleotide analogue of deoxycytidine monophosphate. Because the drug already has a monophosphate group, its metabolism to the active diphosphate form by host cellular enzymes is not dependent on viral TK, and so it has been used to treat acyclovir- and penciclovir-resistant infections. In human patients, cidofovir is primarily used to treat cytomegalovirus retinitis. Cidofovir also has efficacy against other DNA virus infections, such as poxvirus and papillomavirus infections, and has been used topically as a cream to treat viral warts in people. Because the oral bioavailability of cidofovir is extremely low (<5%), it is always administered intravenously, intravitreally, or topically. Cidofovir has a prolonged intracellular half-life, which enables infrequent parenteral dosing regimens in human patients (once weekly, and then every other week for maintenance therapy).

Like ganciclovir, cidofovir is highly active in vitro against FHV-1.[4,14,15] Twice-daily administration of a 0.5% cidofovir ophthalmic solution significantly decreases viral shedding and the severity of clinical disease in cats with experimentally induced ocular FHV-1 infection (Table 7-2).[16] Local irritation and scarring of the nasolacrimal duct has been reported with topical administration of cidofovir to humans and rabbits with keratoconjunctivitis.

Idoxuridine and Trifluridine

Idoxuridine and trifluridine are halogenated thymidine analogues that interfere with the replication of FHV-1 in vitro, although they are more potent inhibitors of herpes simplex virus replication.[2,14] They have been used to treat herpesviral keratitis in humans and in cats.[17] These drugs are highly toxic when given systemically, because host cell and viral DNA synthesis are equally affected. Frequent topical application is required (five to six times daily), and prolonged use can cause corneal irritation or ulceration. Trifluridine has better corneal penetration than idoxuridine and is available as a 1% ophthalmic solution. Unfortunately, trifluridine is expensive, and ocular administration of trifluridine is often extremely irritating to cats.[18] In contrast, topical idoxuridine administration is generally well tolerated.

Vidarabine

Vidarabine is an adenosine analogue that is phosphorylated by host cellular enzymes to vidarabine triphosphate, which interferes with DNA synthesis by both the virus and host cells. It is effective against idoxuridine-resistant herpesviral strains because its mechanism of action differs from that of idoxuridine. It is reportedly well tolerated by cats when administered five to six times daily to cats as a 3% ophthalmic ointment.[18]

Lysine

Lysine is an amino acid that interferes with herpesviral replication by a poorly understood mechanism. Antagonism of arginine may somehow be involved, because a high lysine-to-arginine ratio appears to be important for efficacy. However, arginine itself was also shown to interfere with the replication of herpes simplex virus in vitro.[19]

Lysine has shown efficacy when administered as tablets to cats with FHV-1 conjunctivitis[20] and, in another study, it reduced shedding of reactivated virus by latently infected cats.[21]

VetBooks.ir

TABLE 7-2

Antiviral Drugs Used for Treatment of Feline Herpesvirus Infections

Drug	Dose	Interval	Route	Comments
Famciclovir	62.5 mg/cat, 125 mg/cat, or 40-90 mg/kg	q8h	PO	Reduce dose for cats with renal insufficiency. Compound suspensions are bitter and poorly tolerated. Broken tablets are best administered in a gel cap. Safe in kittens.
Cidofovir	0.5% solution	q12h	Topical ophthalmic	Monitor for ocular irritation. Solution prepared from commercial 7.5% intravenous solution by dilution in sterile saline. Store diluted solution up to 6 months at 4°C, –20°C, and –80°C. Can also be obtained from compounding pharmacies.
Idoxuridine	0.1% solution or 0.5% ointment	5-6 times daily	Topical ophthalmic	Monitor for ocular irritation and ulceration. Compounding may be required.
Trifluridine	1% solution	5-6 times daily	Topical ophthalmic	May be poorly tolerated.
Vidarabine	3% ointment	5-6 times daily	Topical ophthalmic	Well tolerated. Compounding may be required.
Lysine	250 mg (kittens) 500 mg (cats)	q12h	PO	Questionable efficacy. Bolus administration preferred to dietary supplementation.
Zidovudine	5 to 15	q12h	PO, SC	Monitor CBC weekly during treatment for the first month, then monthly. Use low end of the dose range in renal failure. Use higher dose with caution.

When administered as tablets to cats in a shelter, there was no reduction in upper respiratory tract disease.[22] There was concern that the stress of tablet administration may have contributed to disease in these cats. However, in two other studies, dietary supplementation with lysine was not effective for management of upper respiratory tract disease in a shelter.[23,24] In fact, cats that received the lysine-supplemented diet had more severe disease and more frequent viral shedding than cats that received a non-supplemented ration, despite having increased plasma lysine concentrations. The lysine-supplemented diet did not affect plasma arginine concentration, so altered arginine levels did not appear to contribute to the increased severity of disease.

Antiretroviral Drugs

All antiviral drugs used to treat cats with retrovirus infections have been nucleoside analogues, which inhibit the DNA polymerase function of the retroviral reverse transcriptase (RT) enzyme. Unfortunately, many drugs used for treatment of HIV infections (such as protease inhibitors) are not effective for treatment of feline retrovirus infections, because they only act on HIV enzymes. The only antiretroviral that has shown benefit in naturally infected cats is zidovudine (AZT). At the time of writing, an integrase inhibitor known as raltegravir has shown early promise for treatment of FeLV infections both in vitro and in vivo.[25,26] Many drugs that have activity against feline retroviruses in vitro, such as ribavirin and adefovir (PMEA), are toxic when given to cats, which limits their use in practice.

Zidovudine and Fozivudine

Zidovudine (azidothymidine; AZT; Retrovir) is a thymidine analogue and was one of the first drugs shown to be effective against HIV. Inside host cells, it is converted to the active triphosphate form. AZT inhibits the replication of FIV, reduces plasma viral load, improves stomatitis, and increases CD4/CD8 ratios in cats naturally infected with FIV.[27,28] Some FIV isolates are resistant as a result of mutations in the RT enzyme. Although AZT is active against FeLV in vitro, when compared with FIV-infected cats, it has not performed as well for treatment of naturally infected, sick cats with chronic FeLV infection. Nevertheless, improvement in stomatitis, reduced antigenemia, and reduction in development of lymphoma have been reported in studies of naturally and experimentally FeLV-infected cats that were treated with AZT.[28,29]

AZT is available as a10 mg/mL syrup and a 10 mg/mL injection. It has good oral bioavailability and is well distributed to tissues, including the CNS. It is metabolized to an inactive form by the liver and excreted by the kidneys. Dosage reduction has been recommended for cats with renal failure. Unfortunately, some cats treated with AZT can develop dose-related hematologic adverse effects, most commonly nonregenerative anemia and neutropenia, so the CBC must be monitored during treatment. Adverse effects may be confused with retrovirus-induced cytopenias. In human patients with HIV infection, cytopenias are more likely to occur when disease is advanced.

Fozivudine is a thioether lipid-zidovudine conjugate that undergoes intracellular cleavage to zidovudine monophosphate and subsequent phosphorylation to the active triphosphate form. Cleavage preferentially occurs in lymphocytes and monocytes compared with RBC and marrow stem cells, and so hematologic toxicity is less likely to occur. Fozivudine reduces viremia in cats experimentally infected with FIV, without significant adverse effects.[30] Further study is required to evaluate this drug for treatment of chronic FIV and FeLV infections in cats.

VetBooks.ir

Lamivudine

Lamivudine (3TC), a cytidine analogue, is synergistic when combined with AZT for treatment of HIV infection, and the combination is in common use in human medicine. AZT/3TC prevented FIV infection when given to cats shortly after experimental inoculation, but did not appear to be beneficial for treatment of cats with chronic FIV infection.[31] In addition, severe hematologic adverse effects and fever occurred in some cats.

Other Antiretroviral Drugs

Raltegravir inhibits the retroviral integrase enzyme. Integrase incorporates transcribed viral DNA into the host chromosome. In human patients, raltegravir is approved for treatment of HIV infections and is used in combination with other antiretroviral drugs. Although expensive, raltegravir has shown great promise for treatment of FeLV infections in vitro and also in vivo.[25,26] Other drugs that have shown promise in vitro for treatment of FeLV infections, with no evidence of toxicity to cell cultures, are the nucleoside analogues tenofovir, decitabine, and gemcitabine.[26] Tenofovir is used as part of combination therapy to treat HIV infections. It is administered as a prodrug. Decitabine and gemcitabine are cytidine analogues used in human patients to treat myelodysplastic syndromes and carcinomas, respectively. The use of combinations of gemcitabine and carboplatin to treat carcinomas in cats has been reported, but cytopenias and gastrointestinal toxicity occurred in some of the cats.[32]

Plerixafor is a bicyclam derivative that selectively blocks the chemokine receptor, CXCR4. This receptor is used by FIV to enter cells (see Chapter 21). In a placebo-controlled, masked clinical trial, administration of plerixafor to cats with FIV infection for 6 weeks reduced proviral load but did not lead to improvement in clinical or immunologic variables.[33]

Antiinfluenza Viral Drugs

The main drugs used in human medicine to treat influenza virus infections are neuraminidase inhibitors, such as oseltamivir and zanamivir, and the tricyclic amines amantadine and rimantadine, which inhibit the M2 ion channel protein that is present in influenza A viruses (Figure 7-2). Only oseltamivir has been used to any great extent in small animals. Amantadine, which also has antagonistic effects at the NMDA (*N*-methyl-D-aspartate) receptor, has been used to treat osteoarthritis in animals in combination with other drugs.[34]

Oseltamivir

Oseltamivir (Tamiflu) is the prodrug of oseltamivir carboxylate (GS4071), a potent inhibitor of influenza virus neuraminidase. Oseltamivir was developed because of the poor oral bioavailability of zanamivir, a neuraminidase inhibitor that is structurally similar to GS4071. Neuraminidase is a surface glycoprotein of both influenza A and influenza B viruses (see Figure 7-2). The viral neuraminidase cleaves sialic acid residues on the surface of infected cells, which allows new virus particles to be released from host cells. It also prevents aggregation of virus particles after they are released and facilitates spread of the virus through the mucus of the respiratory tract by cleaving sialic acid residues in mucin.

In humans and dogs, oseltamivir has high oral bioavailability.[35] Esterase enzymes in the liver then convert oseltamivir to its active form, which is well distributed to most body fluids, including surface epithelial cells throughout the upper and lower respiratory tract. Elimination of the drug relies on renal excretion. The drug is well tolerated in humans, with gastrointestinal signs being the most frequently reported adverse effects.

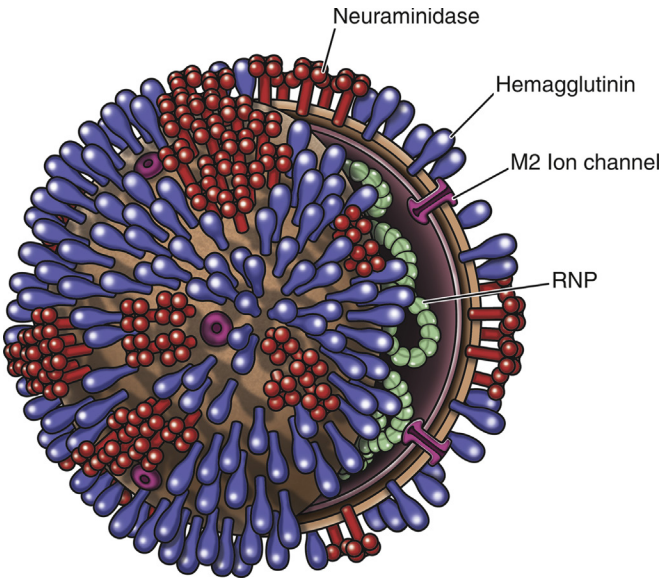

FIGURE 7-2 Structure of an influenza virus. The M2 protein, which is only present in influenza A viruses, is inhibited by tricyclic amines such as amantadine. Oseltamivir inhibits the viral neuraminidase.

The prevalence of resistance to oseltamivir among influenza virus isolates is generally low (<5%). High-level resistance results from mutations in the viral neuraminidase. Neuraminidase inhibitors could play a critical role in prevention of mortality in human influenza virus pandemics, so strategies that minimize the selection of resistant mutants are important. The Centers for Disease Control and Prevention recommends prioritizing antiviral treatment to human patients at risk of complications of influenza, such as the very young and very old.[36]

Oseltamivir has been used to treat canine parvovirus (CPV) enteritis in puppies, with anecdotal reports of improved outcome. A single prospective, randomized, masked, placebo-controlled trial of 35 dogs with CPV enteritis showed that dogs treated with oseltamivir (2 mg/kg PO q12h) had no significant drop in their white blood cell count, whereas untreated dogs had a significant drop in their white blood cell count in the first 5 days of hospitalization.[37] Treated dogs also gained weight during hospitalization, whereas untreated dogs lost weight. However, there was no difference in hospitalization time, treatments needed, clinical scores, morbidity, or mortality between the two groups, and the number of dogs in each group was small. No significant adverse drug effects were observed, but oseltamivir was administered as a 1:1 dilution with water, in order to reduce reactions to the taste of the drug and vomiting shortly after drug administration. The authors acknowledged that there were potential concerns that related to administration of an oral medication to dogs with enteritis, with variability in drug absorption.

As CPV has no neuraminidase, it was hypothesized that oseltamivir instead may act on the neuraminidases of bacteria that are normally responsible for secondary bacterial infections in CPV enteritis, which are primarily those of the gastrointestinal tract. The role of bacterial neuraminidases in the pathogenesis of enteric bacterial infections and bacterial translocation is unknown. Bacterial neuraminidase enzymes may play a role in biofilm formation and help bacteria to invade mucin layers of the respiratory tract.[38] It has been suggested that gut bacteria

VetBooks.ir

may use neuraminidase enzymes to cleave sialic acid residues on gastrointestinal epithelial cells, which exposes receptor sites for bacterial adherence.

A major concern that relates to treatment of CPV enteritis with oseltamivir is the possibility of selection for resistant mutants among influenza viruses if widespread use of the drug occurs in veterinary clinics. Given the restrictions on the use of this drug for treatment of human influenza virus infections, further investigation is required before the use of oseltamivir can be recommended for treatment of CPV enteritis.

Other Antiviral Drugs

Although not useful for treatment of cats because of toxicity, the nucleoside analogue ribavirin has shown promise in vitro for treatment of canine distemper virus (CDV) infections. Another drug, 5-ethynyl-1-beta-D-ribofuranosylimidazole-4-carboxamide (EICAR), has also shown activity against CDV in vitro[39] and for treatment of measles virus, which is closely related to CDV.[40] Ribavirin is primarily used to treat hepatitis C virus infections in humans. The pharmacokinetics and toxicity of ribavirin and EICAR in dogs require further study.

Nelfinavir is a protease inhibitor used to treat HIV infection. It also limits the replication of severe acute respiratory syndrome (SARS) coronavirus in vitro,[41] but its mode of action against coronaviruses is poorly understood. Nelfinavir was not effective in a mouse model of SARS.[42] Although nelfinavir alone was not completely effective, a combination of nelfinavir and *Galanthus nivalis* agglutinin (GNA) inhibited the replication of feline coronavirus in vitro and may have application for the treatment of feline infectious peritonitis (FIP).[43] GNA appears to bind the viral outer envelope glycoproteins and prevent cellular entry. The use of nelfinavir was reported in a few cats with naturally occurring coronavirus infections,[43,44] but the toxicity and pharmacokinetics of nelfinavir and GMA in cats and efficacy of these drugs for treatment of FIP remains unknown.

Immunomodulators

An immunomodulator is any drug that alters immune system function. Immunomodulators are also referred to as *biologic response modifiers*. Their use for treatment of infectious diseases may be beneficial when compromise of the immune system impairs effective antimicrobial drug treatment. Alternatively, immunomodulators can be used to dampen an excessive host inflammatory response.

A variety of immunomodulators have been used to treat feline retroviral infections, FIP, FHV-1 infections, and canine and feline parvoviral enteritis (Table 7-3). Immunomodulators used in veterinary medicine can be divided into six main groups: (1) microbial products; (2) plant-derived biologic response modifiers; (3) naturally occurring cytokines, such as colony-stimulating factors, and interferons; (4) immunoglobulins; (5) glucocorticoids; and (6) synthetic compounds with immunomodulatory activity, such as pentoxifylline.

Treatment of canine and feline viral infections with immunomodulators has frequently been associated with disappointing results, and data from large, prospective, controlled clinical trials are generally not available. Frequently, an immunomodulator shows antiviral activity in vitro but this does not correlate with treatment responses in vivo. Sometimes, mild to moderate clinical improvement is observed, but treatment does not result in cure. The use of human recombinant cytokines beyond 1 or 2 weeks of treatment has been associated with the development of antibodies against the cytokines, which have the potential to cross-react with endogenous cytokines. In the absence of data from randomized, placebo-controlled clinical trials to support their use, immunomodulators should be used with caution, because they may have the potential to accelerate disease. This may occur for viruses that are dependent on rapidly dividing cells for replication (such as parvovirus) or those that replicate only in activated lymphocytes (such as FIV). Promotion of an inflammatory response may also have detrimental effects if immune-mediated processes play an important role in the pathogenesis of disease (such as for FIP).

Microbial Products

Microbial products with immunomodulatory activity include bacillus Calmette-Guérin extract (a mycobacterial cell wall extract from *Mycobacterium bovis*), purified staphylococcal protein A, killed *Propionibacterium acnes* (ImmunoRegulin, ImmunoVet), *Staphylococcus aureus* phage lysate (Staphage Lysate, Delmont Laboratories, USA), *Serratia marcescens* abstract, and inactivated poxviruses (Baypamun, Bayer). To date, controlled clinical trials with these products have not demonstrated significant efficacy for treatment of viral infections in dogs and cats. Staphylococcal phage lysate, which contains components of *S. aureus* and a bacteriophage, and *Propionibacterium acnes* immunotherapy have shown efficacy for treatment of pyoderma in dogs and are available commercially for this purpose (see Table 7-3; also see Chapter 84).[45]

Plant-Derived Biologic Response Modifiers

Acemannan (Carrisyn, Carrington Laboratories, Irving, TX) is a mucopolysaccharide derived from aloe vera plant leaves that induces cytokine production and dendritic cell maturation. It stimulates macrophages to secrete a variety of cytokines, including IFN-γ, TNF-α, prostaglandin E2, Il-1, and Il-6. It has been used to treat FIV and FeLV infections, either by oral or parenteral administration,[46,47] and a veterinary product is available for treatment of canine and feline fibrosarcomas. Controlled trials are needed to understand the efficacy of this treatment in naturally infected cats.

Polyprenyl immunostimulant (Sass & Sass, Inc., Oakridge, TN) is a plant-derived investigational veterinary biological that is made up of phosphorylated, linear polyisoprenols. In vitro, it upregulates synthesis of Th1 cytokines and has antiviral properties. Cats with experimentally induced FHV-1 infection had a decreased severity and duration of upper respiratory tract signs when treated with polyprenyl immunostimulant, in comparison to placebo-treated cats.[47a] Long-term (>2 years) survival has been reported in a few cats with noneffusive FIP that were treated with polyprenyl immunostimulant. The response in cats with effusive FIP has been disappointing.[48]

Naturally Occurring Mammalian Proteins

Colony-Stimulating Factors

Colony-stimulating factors (CSFs) are naturally occurring glycoproteins that stimulate production, differentiation, survival, and activation of white blood cells. Examples include erythropoietin; thrombopoietin; Il-5 (which stimulates eosinophil and basophil production); Il-3; stem cell factor; and macrophage CSF, granulocyte CSF (G-CSF), and granulocyte-macrophage CSF (GM-CSF). Recombinant G-CSF has been used most

TABLE 7-3

Commercially Available Immunomodulators That May Have Benefit for Treatment of Infectious Diseases of Dogs and Cats

Drug	Dose	Interval	Species	Route	Comments
Acemannan	2 mg/kg	Weekly	C	SC	For treatment of fibrosarcomas, efficacy unclear for FIV and FeLV infections
Feline recombinant interferon omega	1 million U/kg	q24h for 5 consecutive days on days 0, 14, and 60	C, D	SC	For FeLV infections
	0.1 million U/kg	q24	C	Oromucosal	For refractory caudal stomatitis associated with FCV infection
Filgrastim	5 µg/kg	q24h	C, D	SC	Monitor CBC weekly during treatment. Long-term use (>2 weeks) can lead to development of neutralizing antibodies.
Lactoferrin	200 mg powder or 40 mg/kg solution	q24h	C	Topical	For refractory gingivitis and stomatitis. Must be purchased from chemical suppliers
Lymphocyte T-cell immunomodulator	1 mL	Weekly	C	SC	For treatment of FeLV and FIV infections
Human recombinant interferon alpha	10^4 to 10^6 U/kg	q24h	C	SC	Monitor CBC weekly during parenteral treatment. Long-term parenteral use can lead to development of neutralizing antibodies
	1 to 50 U/cat	q24h		PO	
Pentoxifylline	15 mg/kg	q8h	D	PO	Benefits for treatment of FIP unclear. Co-administration of cytochrome P450 inhibitors may increase serum drug concentrations
	¼ of a 400 mg tablet	q8h	C		
Polyprenyl immunostimulant	3 mg/kg	Three times weekly	C	PO	Possible benefit for treatment of noneffusive FIP
Prednisolone	1 to 2 mg/kg	q24h	C	PO	For FIP
Propionibacterium acnes, killed	0.1 mg dogs <7 kg 0.2 mg 7-20 kg 0.4 mg 20-34 kg 0.8 mg > 34 kg	Twice weekly. After 14 d, weekly until remission, and monthly thereafter to maintain remission	D	IV	For pyoderma. Available as a 0.4 mg/mL solution
Staphylococcus aureus phage lysate	0.5 mL	Once or twice weekly	D	SC	For pyoderma

C, Cats; *D*, dogs.

widely in veterinary medicine as an immunomodulator. The use of these drugs may be limited by their cost and immunogenicity.

Granulocyte colony-stimulating factor. Granulocyte CSF stimulates growth and differentiation of the neutrophil cell line. It also stimulates neutrophil function, including chemotaxis, phagocytosis, antibody-dependent cellular cytotoxicity, and superoxide production. Nonglycosylated, recombinant human G-CSF is available under the trade name Neupogen. Pegfilgrastim (Neulasta) is a pegylated form with a long half-life and single-dose administration. Lenograstim is a glycosylated form available outside the United States. These three forms have similar efficacy and adverse effects in humans. G-CSF is approved for use in humans for treatment of chemotherapy-induced myelosuppression, for treatment of severe chronic neutropenia, for mobilization and collection of peripheral blood stem cells for bone marrow transplantation, and to accelerate myeloid reconstitution after hematopoietic stem cell transplantation.[49] G-CSF and GM-CSF have been used to treat pneumonia and severe sepsis in humans without neutropenia, but significant benefit has not been identified.[50,51]

When G-CSF is administered as a daily subcutaneous injection to dogs and cats, the neutrophil count increases over several days. This results from an enhanced rate of granulopoiesis and a shortened neutrophil maturation time. Slight increases in monocyte and lymphocyte counts can also occur.[52] Counts return to normal 5 days after discontinuation of treatment.

VetBooks.ir

In veterinary medicine, filgrastim has been used to treat chemotherapy-induced neutropenia and cyclic neutropenia in gray collies. Filgrastim was not effective for treatment of leukopenia in experimentally induced CPV infection.[53,54] Repeated administration of filgrastim to dogs and cats has been associated with development of antibodies to the protein within 2 to 3 weeks of treatment, which can cross-react with endogenous G-CSF. Thus, although it can increase neutrophil counts in some FIV-infected cats, long-term use of filgrastim is not recommended.[55] Recombinant canine G-CSF (rcG-CSF) may be safer for long-term use in dogs, and possibly also cats. One recombinant canine formulation mobilized neutrophils in dogs within 24 hours of administration.[56] Recombinant canine G-CSF reduces the severity and duration of bone marrow suppression induced by cyclophosphamide in dogs.[57] In a prospective, non-randomized clinical trial for treatment of CPV infection, neutrophil counts were higher and hospital times were shorter in dogs treated with rcG-CSF, but survival times were decreased.[58] Treatment of canine and feline parvovirus infections with G-CSF might cause harm, because the increased cell turnover induced by the drug might promote parvovirus replication. Further studies are required to evaluate the utility of rcG-CSF for treatment of neutropenias associated with canine parvoviral enteritis, feline retrovirus infections, and chronic canine monocytic ehrlichiosis.

In dogs and cats, exogenous G-CSF is well tolerated. In human patients, the main adverse effects of treatment are bone and musculoskeletal pain, headache, anemia, thrombocytopenia, and splenomegaly. Long-term use in humans can be associated with osteopenia as a result of upregulation of osteoclast activity. Rare complications in people include splenic rupture and exacerbation of autoimmune disorders.

Granulocyte-macrophage colony-stimulating factor. GM-CSF stimulates growth and function of neutrophils, monocytes, and eosinophils. Commercial GM-CSF formulations available for treatment of hematologic disorders in human patients include sargramostim, molgramostim, and regramostim, which vary slightly in amino acid sequence and degree of glycosylation. When used to treat cats with FIV, viral load increased,[59] and so the use of GM-CSF is not recommended for treatment of FIV-induced cytopenias. Interestingly, sargramostim has been used to treat some human patients with AIDS-associated opportunistic infections, which include oropharyngeal candidiasis and disseminated mycobacterial infections. Administration of recombinant human GM-CSF to dogs was associated with antibody development after 10 days.[60]

Interferons

Interferons are cytokines with antiviral properties. IFN-α, IFN-β, and IFN-ω are type I interferons, which are produced by leukocytes and fibroblasts in response to a viral infection. Type I interferons activate natural killer (NK) cells, increase expression of major histocompatibility complex (MHC) class I molecules, and have antitumor activity. IFN-γ is the only type II interferon and is produced by T lymphocytes and NK cells in response to antigenic stimulation. IFN-γ plays a critical role in the clearance of intracellular pathogens by macrophages. Recombinant human IFN-γ has been used to treat chronic granulomatous disease in humans as well as chronic infections caused by intracellular bacteria and fungi, but recombinant veterinary preparations are not available.

Interferon alpha. Naturally occurring IFN-α represents a group of more than 20 molecules that vary slightly in composition and inhibit viral nucleic acid and protein synthesis. A variety of recombinant human and natural IFN-α preparations are available, including pegylated forms that have prolonged biologic half-lives. In human patients, IFN-α is used in conjunction with antiviral drugs to treat hepatitis B and hepatitis C virus infections, papillomavirus infections, and HIV-associated Kaposi's sarcoma. It is generally administered for 24 or 48 weeks.

Recombinant human IFN-α (rhIFN-α) has been administered parenterally and orally to cats for treatment of feline retroviral infections, feline upper respiratory viral infections, and FIP. It inhibits replication of FeLV, FIV, FHV-1, and feline coronavirus in vitro. Unfortunately, mixed results have been obtained after parenteral and oral administration to cats with retrovirus infections, and parenteral IFN-α was not effective for treatment of FIP.[61] Parenteral administration can lead to the development of neutralizing antibodies and apparent loss of activity after 3 or 7 weeks.[62]

Oral administration of a low dose of rhIFN-α to treat viral infections of animals has been controversial because of proteolytic degradation of rhIFN-α by gastric acid. Nevertheless, beneficial outcomes have been reported in some cats with FHV-1, FeLV, and FIV infections, presumably because immunomodulation follows mucosal absorption of the drug. Topical application of rhIFN-α to the eye has been used to treat FHV-1 keratitis, but controlled studies using this treatment are lacking. With the availability of more effective antiviral drugs such as famciclovir, it is likely that the use of these antiviral drugs may take precedence over, or be used in combination with, treatment with IFN-α.

Feline recombinant interferon-omega. IFN-ω is a Type 1 interferon closely related to IFN-α. It is secreted by virus-infected leukocytes. Its precise mechanism of action is not known. In dogs it increases macrophage and NK cell activity, and it has antiviral activity against several feline viruses in vitro, including FeLV, FHV-1, feline calicivirus (FCV), canine and feline parvoviruses, and feline coronavirus. It also has antitumor activity.[63] A recombinant feline formulation of IFN-ω produced in silkworms is available in Europe and Canada for veterinary use (rfIFN-ω, Virbagen omega, Virbac). Because it has similar activity in canine and feline cells, it has potential for treatment of both canine and feline viral infections. The optimal dosing regimen is unknown, but the manufacturer recommends three cycles of treatment, on days 0, 14, and 60, for 5 consecutive days.

Preliminary data suggested that treatment of cats with FIP with rfIFN-ω might increase survival times,[64] but a randomized, placebo-controlled study of naturally infected cats demonstrated no improvement in quality of life or survival time.[65] When cats with naturally occurring FeLV-related disease were treated with rfIFN-ω in a placebo-controlled trial, survival time over a 2-month follow-up period increased.[66] Improvement in clinical scores and laboratory parameters was also documented in some sick cats that were naturally infected with FeLV and FIV, despite no significant changes in viral load.[67] The drug also has been used topically, orally, and parenterally to treat FHV-1 infections, and subcutaneously to treat refractory FCV-associated stomatitis.[68-71] Oromucosal administration of rfIFN-ω to cats with refractory FCV-associated stomatitis led to significant clinical improvement when compared with placebo.[68] Treatment of puppies with naturally and experimentally induced CPV enteritis with rfIFN-ω in a number of placebo-controlled trials was associated with reduced disease severity and, in some studies, significantly reduced mortality. In contrast, there was no improvement in survival in cats from a cattery with feline panleukopenia virus infection that were treated with rfIFN-ω when compared with an untreated control group.[72]

Recombinant fIFN-ω is well tolerated by dogs and cats. Transient lethargy, fever, vomiting, mild diarrhea, and anorexia have been documented in some treated cats, especially at higher doses (2.5×10^6 U/kg). Mild neutropenia, eosinophilia, and reversible increases in the activity of serum AST have also been described following treatment.[73] Additional studies of the efficacy and safety of rfIFN-ω in larger numbers of sick cats with retroviral infections and cats and dogs with other viral infections are required.

Lymphocyte T-cell Immunomodulator

Lymphocyte T-cell immunomodulator (T-cyte Therapeutics, Inc.) is a protein derived from thymus epithelial cells. According to the product brochure, LTCI upregulates Il-2 production in vitro and regulates CD4 T-cell function. It was also reported to stimulate platelet production in mice with chemotherapy-induced thrombocytopenia. LTCI has been conditionally approved by the U.S. Department of Agriculture as an aid for treatment of FIV and FeLV infections, and for the associated signs of cytopenias and opportunistic infections. Controlled independent studies of the efficacy of LTCI in cats are required.

Immunoglobulins

In human patients, human intravenous immune globulin (IVIG) has been used for treatment of immunodeficiencies, as well as autoimmune disorders (Figure 7-3). A single infusion of human IVIG has been used successfully to treat immune-mediated thrombocytopenia in dogs,[74] but repeated administration to animals may lead to transfusion reactions. Intravenous immunoglobulin preparations have been commercially available for passive immunization of cats or dogs in Europe. These contain antibodies to FPV, FHV-1, and FCV (Feliserin, IDT Biologika GmbH, Rodelben, Germany), or CDV, canine adenovirus, and CPV (Stagloban, IDT Biologika GmbH). The efficacy of these preparations has not been reported. Subcutaneous and intraperitoneal administration of adult cat serum to kittens with failure of passive transfer can provide IgG concentrations equivalent to those in kittens that suckle normally.[75] In general, when given parenterally in high doses, specific immunoglobulins are only effective for prevention, and not treatment of an infectious disease.[76] Oral administration is not effective. Passive administration of antitoxins is also used to treat tetanus (see Chapter 54) and for neutralization of snake venom components. Passive immunization may be associated with allergic reactions, which can be severe, and it has the potential to interfere with subsequent active immunization attempts. Administered antibodies are generally eliminated over a period of 2 to 3 weeks.

Lactoferrin

Bovine lactoferrin is a glycoprotein with immunomodulatory properties that is normally present in exocrine secretions and neutrophils. It reduces cytokine secretion by mononuclear cells and lymphocyte activation in cats infected with FIV. In vitro, bovine lactoferrin has antiviral activity against FCV and FHV-1.[77,78] Topical application (40 mg/kg q24h for 14 days) to the mouth of a small number of FIV-positive and FIV-negative cats with stomatitis was associated with improved appetite and reduced oral inflammation, salivation, and pain, and increased neutrophil phagocytic activity.[79] Chronic oral administration of bovine lactoferrin to a dog with β_2-integrin-related neutrophil dysfunction was associated with increased neutrophil function and recovery from opportunistic infections.[80]

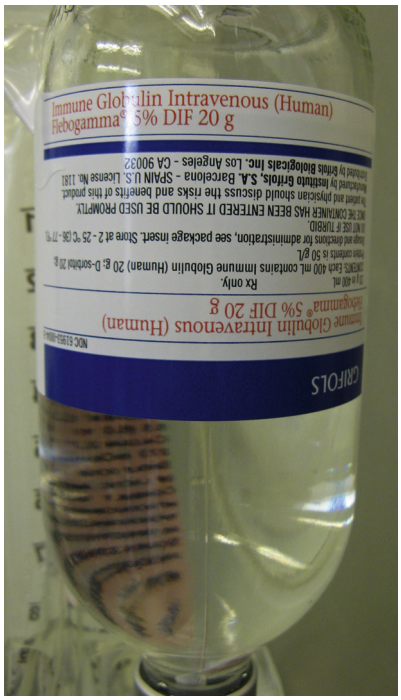

FIGURE 7-3 Human intravenous immune globulin solution (inverted for administration).

Glucocorticoids

In animals and humans with infectious diseases, treatment with glucocorticoids is sometimes used to dampen an overzealous immune response that contributes to the pathology of infection. Glucocorticoids have potent antiinflammatory and immunosuppressive properties. They suppress cytokine synthesis, decrease antibody production, cause lymphocytolysis and eosinopenia, decrease neutrophil margination, interfere with cyclooxygenase-2, and reduce the activity of phospholipase A2, and thus initiation of the arachidonic acid cascade. However, glucocorticoid administration also has the potential to worsen outcome through excessive immune suppression, so their use has been advocated only for specific infectious diseases under certain circumstances. Glucocorticoids can also contribute to development of secondary infections even when they are used to treat another disease. For example, it is not unusual in dogs or cats for a latent infection to emerge, or for a secondary infection to develop (e.g., demodicosis, staphylococcal pyoderma, dermatophytosis, systemic mycoses) when glucocorticoids are used to produce immunosuppression.

An example of the beneficial effect of glucocorticoids for treatment of an infectious disease is in FIP, where inflammation plays a major role in pathogenesis. Although controlled clinical trials comparing prednisone treatment with a placebo have not been performed, for many cats, treatment with prednisolone (1 to 2 mg/kg PO q24h) is associated with transient complete or partial remission and as a result is generally accepted as the standard of care for treatment of FIP (see Chapter 20).[65]

A short course of prednisolone using immunosuppressive doses (1 mg/kg PO q12h) has also been used to suppress secondary immune-mediated hemolysis in cats infected with *Mycoplasma haemofelis*,[81] but given that glucocorticoids can reactivate hemoplasma infections, additional studies are needed to determine whether this practice improves outcome. Similarly, glucocorticoid treatment has been used to suppress

VetBooks.ir

immune-mediated consequences of infection with the tick-borne pathogens *Ehrlichia canis* and *Babesia* spp, when antimicrobial treatment alone is not followed by complete resolution of clinical abnormalities. Adjunctive glucocorticoid treatment did not worsen outcome in dogs with Rocky Mountain spotted fever.[82] In contrast, glucocorticoid administration may have a negative impact in dogs with Lyme arthritis.[83] There are anecdotal reports of improved outcome for dogs with suspected Lyme glomerulonephritis that are treated with methylprednisolone sodium succinate in conjunction with other immunosuppressive drugs, such as mycophenolate mofetil or azathioprine (see Chapter 51).

Many large human studies have assessed the role of glucocorticoid treatment in septic shock (see Chapter 86). Treatment with high doses of hydrocortisone for less than 5 days is contraindicated because of secondary infection and gastrointestinal bleeding. Treatment with physiologic doses of glucocorticoids has been advocated to overcome relative adrenal insufficiency, which occurs in severe septic shock in both humans and dogs.[84] Recent consensus guidelines for human patients with septic shock recommend adjunctive hydrocortisone treatment in patients who are unresponsive to fluid resuscitation and treatment with vasopressors.[85]

Infections that generate inflammation within the eye and CNS are frequently treated with anti-inflammatory doses of topical or systemic glucocorticoids, respectively, in conjunction with antimicrobial drugs. The goal of such treatment is to minimize or prevent loss of vision or deterioration of neurologic status, especially when organism death is followed by a profound inflammatory response. For CNS infections, the effect of concurrent glucocorticoid treatment may depend on the specific pathogen present and the immune response of the infected individual. Prospective studies that evaluate outcome after adjunctive glucocorticoid treatment in CNS infections of dogs and cats are lacking. In a retrospective study, treatment of dogs and cats with CNS cryptococcosis with antiinflammatory doses of glucocorticoids increased survival in the first 15 days after starting antifungal drug treatment.[86]

Other

Pentoxifylline

Pentoxifylline is a synthetic methylxanthine derived from theobromine. It is a broad-spectrum phosphodiesterase inhibitor with a variety of immunomodulatory properties. In rodents and humans it inhibits TNF-α, Il-1, Il-6, and Il-12 production, as well as the activation of T and B cells, and increases neutrophil mobility and chemotaxis. It increases erythrocyte cAMP levels, which results in increased erythrocyte deformability, lowered blood viscosity, and improved microcirculation and tissue perfusion. Pentoxifylline also decreases platelet aggregation, and increases tissue plasminogen activator in patients with hyperaggregable platelets, so may be useful for treatment of disorders that result in hypercoagulable states. The value of pentoxifylline for treatment of endotoxemia has been primarily studied in horses. Despite significant decreases in TNF and IL-6 activity after incubation of equine monocytes with pentoxifylline in vitro, these effects did not occur in horses in vivo.[87] Beneficial effects of pentoxifylline are limited in horses when administered IV after challenge with endotoxin.[88]

In dogs, pentoxifylline has been used to treat a variety of skin diseases, including canine atopic dermatitis, dermatomyositis, and cutaneous vasculopathies.[89,90] In cats it has been used to treat FIP, but a masked, placebo-controlled study of the related drug propentofylline showed no benefit of treatment.[91]

In dogs, pentoxifylline has a low and unpredictable oral bioavailability and a short half-life, and so three-times-daily administration has been recommended. Adverse effects include vomiting and decreased appetite, which are more likely to occur when the tablets are crushed. Crushed tablets are also unpalatable to cats.

Antimicrobial Drugs with Immunomodulatory Properties

Antimicrobial drugs with immunomodulatory properties include the macrolides, doxycycline, and metronidazole. The mechanisms of these activities are discussed in Chapter 8.

CHAPTER 8

Antibacterial Drugs

Jane E. Sykes and Mark G. Papich

VetBooks.ir

KEY POINTS

- An understanding of the mechanisms of action, spectrum of activity, pharmacokinetics, pharmacodynamics, and adverse effects of antibacterial drugs facilitates optimal treatment of bacterial infections while minimizing the chance for (1) selection of resistant bacteria, (2) adverse reactions, and (3) drug interactions.
- The importance of appropriate administration of antibiotics, compliance issues, and potential adverse effects of the drug chosen should be discussed with the pet owner when antibiotics are prescribed.

INTRODUCTION

This chapter reviews the classification, mechanisms of action, spectrum of activity, resistance mechanisms, tissue penetration, clinical use, and adverse effects of the major classes of antibiotics used to treat dogs and cats. Antimicrobials have been grouped together alphabetically according to their mechanism of action (cell wall synthesis, nucleic acid, and then protein synthesis inhibitors). Tables are dispersed throughout the text with drug dosages for each group of antibiotics. The reader is encouraged to review the accompanying text when using the tables. Not all antibiotics are reviewed here. Antibiotics that have specific uses, such as certain antimycobacterial drugs and nitrofurantoin, are reviewed in the relevant chapters of this book. Chapter 6 provides an overview of the basic principles of antimicrobial treatment.

Inhibitors of Cell Wall Synthesis

Beta-Lactam Antibiotics

β-Lactam antibiotics have a β-lactam ring in their molecular structure (Figure 8-1). They include penicillins, cephalosporins, monobactams, and carbapenems. They are bactericidal antibiotics (see Chapter 6) that bind covalently to and inhibit penicillin binding proteins (PBPs). These PBPs are needed to catalyze the cross-linking (or *transpeptidation*) of the peptidoglycan layer of bacterial cell walls, which is continuously remodeled by bacteria (Figure 8-2). When PBPs are inactivated by β-lactam antibiotics, bacterial enzymes that hydrolyze the peptidoglycan cross-links during cell wall remodeling continue to function, which breaks down the cell wall further. The accumulation of peptidoglycan precursors also triggers activation of cell wall hydrolases, with further digestion of intact peptidoglycan. The end result is bacterial rupture.

The peptidoglycan layer of gram-positive bacteria is 50 to 100 times thicker than that of gram-negative bacteria and is highly cross-linked, which maintains the structural integrity of gram-positive bacteria.[1] Therefore, compared to gram-negative bacteria, gram-positive bacteria are more easily inactivated by β-lactam antibiotics. Bacteria possess multiple PBPs, which are assigned numbers based on their molecular weight. PBPs vary in their affinities for different β-lactam antibiotics, which in part explains the difference in spectrum of activity and bactericidal action of β-lactam antibiotics. For example, inhibition of PBP1a and PBP1b leads to cell lysis, whereas inhibition of PBP2 results in rounded cells called spheroblasts. Drugs that produce rapid lysis (e.g., carbapenems) are the most bactericidal and have highest affinity for PBP1.

Resistance to β-lactam antibiotics is now widespread and results primarily from β-lactamase production.[2] It can also result from production of altered PBPs (such as PBP2a) and, among gram-negative bacteria, exclusion of drugs that normally diffuse through porins to their site of action. Gram-negative β-lactamases are strategically located just beneath the outer lipopolysaccharide layer, which acts as the barrier to drug penetration. Gram-positive bacteria secrete β-lactamases into their immediate surroundings. There are many different β-lactamase enzymes that vary in their specificity for β-lactam drugs.[3]

β-Lactam antibiotics have a short half-life and exhibit time-dependent pharmacodynamics (see Chapter 6). Drug concentrations should be maintained above the minimum inhibitory concentration (T > MIC) for at least 50% of the dosing interval. For penicillins and carbapenems, T > MIC can be less than 50%, but aiming for a target of 50% ensures that most patients will have adequate exposure. To maintain this target, some β-lactam antibiotics with short half-lives require frequent administration or slow infusion. For other drugs, a long half-life prolongs the

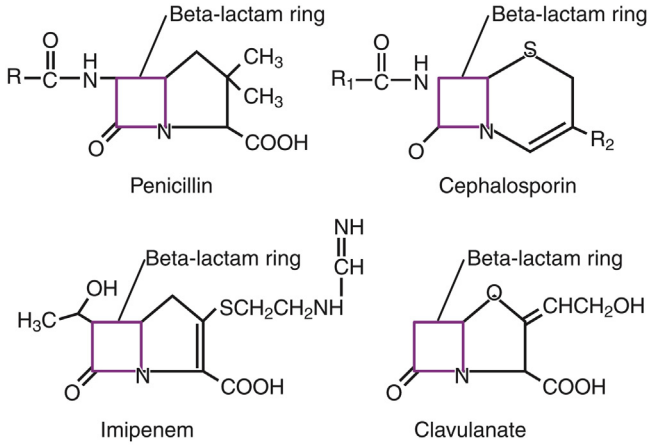

FIGURE 8-1 Structure of β-lactam antibiotics.

T > MIC to allow for infrequent administration. For example, cefpodoxime proxetil has a half-life longer than those of other oral cephalosporins, so it can be administered only once per day. Cefovecin has an extremely long half-life in dogs and cats and can be effective for some infections when administered at 14-day intervals. For other cephalosporins (e.g., injectable drugs with short half-lives such as cefotaxime), three- to four-times-daily dosing may be required for treatment of gram-negative bacterial infections.

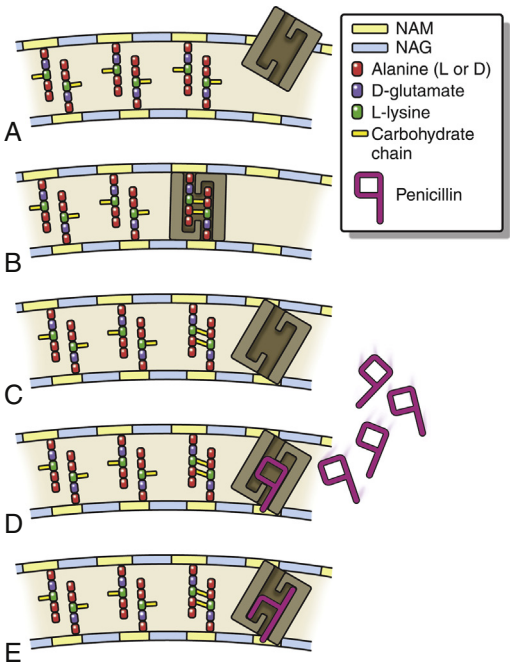

FIGURE 8-2 Interference of peptidoglycan production by β-lactam antibiotics. The bacterial cell wall consists of *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM) subunits. **A,** The penicillin binding protein (PBP, *brown squares*) binds peptide side chains and forms a cross-link **(B)**. **C,** The PBP dissociates from the wall once the cross-link has been formed. **D,** Penicillins enter the active site of the PBP. **E,** The β-lactam ring of the penicillin is irreversibly opened when it reacts with the PBP, which permanently blocks the active site.

Penicillins

Classification, Spectrum of Activity, and Resistance Mechanisms

Penicillins are derived from *Penicillium* molds. They are classified as naturally occurring penicillins such as penicillin G (benzyl penicillin), the semisynthetic aminopenicillins such as ampicillin and amoxicillin, penicillinase-resistant penicillins, and extended-spectrum penicillins. Table 8-1 shows the classification of the penicillins and their respective spectra of activity.

Penicillin G must be given parenterally because of poor oral bioavailability. Gram-positive bacteria that are susceptible to penicillin G are more susceptible to penicillin G than aminopenicillins such as ampicillin. The aminopenicillins have some activity against gram-negative bacteria, although many gram-negative bacteria are resistant because they produce β-lactamases. Ampicillin has limited absorption from the gastrointestinal tract, so it should be given parenterally for treatment of systemic infections. Amoxicillin has approximately twice the oral absorption of ampicillin and can be given orally.

Penicillinase-resistant penicillins (antistaphylococcal penicillins) such as methicillin have a structure that resists inactivation by β-lactamase enzymes. Methicillin is no longer used clinically. Drugs such as flucloxacillin and dicloxacillin have replaced the use of methicillin, because they can be administered orally and have fewer adverse effects. These drugs are highly protein-bound, which delays their elimination and maintains plasma drug concentrations, but tissue penetration is sufficient for treatment of skin and soft-tissue infections. Although dosages of penicillinase-resistant penicillins have been published for dogs and cats,[4] they are rarely used because other alternatives exist such as the combination of amoxicillin and the β-lactamase inhibitor clavulanic

TABLE 8-1

Classification and Spectrum of Activity of Penicillin Antibiotics

Penicillin Group	Examples	Antibacterial Spectrum
Natural penicillins	Penicillin G	Gram-positive aerobic bacteria (especially streptococci) and anaerobes. *Pasteurella multocida* may also be susceptible.
Aminopenicillins	Ampicillin Amoxicillin	Gram-positive aerobic bacteria (cocci and bacilli) and anaerobes; some susceptible gram-negative bacteria.
Penicillinase-resistant penicillins	Methicillin Oxacillin Cloxacillin Dicloxacillin	Susceptible β-lactamase producing gram-positive aerobic bacteria. Less active against penicillinase-susceptible organisms than penicillin G.
Extended spectrum carboxypenicillins	Ticarcillin Carbenicillin	Increased activity against susceptible gram-negative aerobes, which includes *Pseudomonas aeruginosa*, *Proteus* spp., *Klebsiella*, and anaerobes. Some reduction in gram-positive spectrum. Destroyed by β-lactamases.
Ureidopenicillins	Mezlocillin Piperacillin	Susceptible gram-positive and gram-negative aerobes, which includes *Pseudomonas aeruginosa*. Some loss of anaerobic spectrum. Destroyed by β-lactamases.
Penicillin–β-lactamase inhibitor combinations	β-Lactamase inhibitors: clavulanic acid, sulbactam, tazobactam	Susceptible β-lactamase producing gram-positive and gram negative aerobic bacteria and anaerobes.

VetBooks.ir

acid. Methicillin and oxacillin are used in the laboratory for susceptibility testing. Resistance to methicillin results from bacterial production of an altered penicillin-binding protein (PBP2a), which leads to resistance to all β-lactam antibiotics.[5]

Extended-spectrum penicillins (antipseudomonal penicillins) have enhanced activity against gram-negative bacteria, but must be given parenterally. They include the carboxypenicillins, such as ticarcillin and carbenicillin, and piperacillin, an ureidopenicillin.

Clavulanic acid, sulbactam, and tazobactam are β-lactamase inhibitors that are administered in conjunction with penicillins, which increases the spectrum of activity. β-Lactamase inhibitors possess weak intrinsic antibacterial activity. Clavulanate has been combined not only with amoxicillin (oral), but also ticarcillin (parenteral). Sulbactam has been combined with ampicillin for intravenous (IV) injection. Sulbactam is not as active as clavulanic acid against some gram-negative β-lactamases. Tazobactam is combined with piperacillin.

Clinical Use

Penicillin dosages for dogs and cats are listed in Table 8-2. Penicillins are distributed to the extracellular fluid of most tissues. Because of low penetration across the blood-brain barrier and blood-ocular barrier, high doses are needed in order to attain effective levels in these tissues. Penicillins undergo rapid renal elimination, and active drug is concentrated in the urine, so they are useful for treatment of bacterial urinary tract infections (UTIs). Liver impairment has little effect on the pharmacokinetics of penicillins. Increasing the length of the dose interval is important in order to minimize toxicity in animals with renal failure.

Because of a short half-life, frequent dosing is necessary, especially when treating gram-negative bacterial infections with aminopenicillins. Penicillin MICs are generally higher for gram-negative bacteria than gram-positive bacteria; therefore, higher penicillin dosages may also be needed for gram-negative bacterial infections.

Adverse Effects

Penicillins are generally well tolerated by dogs and cats. The most common adverse effects in dogs and cats are vomiting, diarrhea, and inappetence. These are more likely to occur with amoxicillin when clavulanic acid is administered concurrently. Hypersensitivity reactions that include fever, cutaneous

TABLE 8-2

Suggested Penicillin Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Penicillin G potassium or sodium	20,000-40,000 U/kg	6-8	D, C	IV, IM		≤8 enterococci; ≤0.12 staphylococci and streptococci
Ampicillin sodium	10-20	6-8	D, C	IV, IM, SC	Administer IV over 3 minutes. When reconstituted with sterile water to 250 mg/mL, vials should be used within 1 hour. When reconstituted with 0.9% NaCl to 45 mg/mL, stability is maintained for 48 hours if refrigerated.	≤0.25 staphylococci, streptococci, and gram-negative bacilli; ≤8 canine urinary tract pathogens
Ampicillin-sulbactam	10-20	8	D, C	IV, IM	See ampicillin. Dose according to ampicillin component.	≤8/4* staphylococci and gram-negative bacteria
Amoxicillin	10-20	8-12	D, C	PO		See ampicillin.
Amoxicillin-clavulanate potassium	12.5-25	12	D, C	PO	More frequent or higher doses recommended for gram-negative infections.	≤0.25/0.12* staphylococci, streptococci, *Escherichia coli* and *Pasteurella multocida*
Ticarcillin disodium, ticarcillin-clavulanate†	33-50	4-6	D, C	IV	When reconstituted with 0.9% NaCl, stable for up to 14 days when refrigerated.	≤64/2* *Pseudomonas aeruginosa* ≤16/2 gram-negative enteric bacteria
Piperacillin sodium/piperacillin-tazobactam†	40	6	D, C	IV	Reconstituted solution should be used within 7 days if refrigerated.	See ticarcillin.

C, Cats; CLSI, Clinical and Laboratory Standards Institute; D, dogs.
*The "/" distinguishes the ticarcillin from clavulanic acid concentrations.
†It is recommended that the use of these drugs be reserved for life-threatening infections that are susceptible to these drugs but resistant to other drugs, on the basis of culture and susceptibility testing.

reactions, immune-mediated cytopenias, and anaphylaxis are possible, especially in dogs, but are less common than in human patients. The use of penicillins should be avoided in animals with a history of such reactions. Rapid intravenous infusion or administration of high doses of penicillins to animals with coexisting renal failure is rarely followed by development of neurologic signs, such as seizures. Pain or tissue reactions can occur when penicillins are administered intramuscularly or subcutaneously. High doses of extended-spectrum penicillins such as ticarcillin have been associated with platelet function abnormalities and significant bleeding in human patients.[6]

Cephalosporins

Classification and Spectrum of Activity

The cephalosporins were originally derived from *Acremonium* spp. (previously known as *Cephalosporium* spp.). They have been broadly grouped into first-, second-, third-, and fourth-generation cephalosporins based on their spectrum of activity. As the generation increases, there is an increase in gram-negative spectrum, and fourth-generation drugs have truly broad-spectrum activity (Table 8-3). An exception to this pattern is the newest addition to the group, ceftaroline. It has activity against methicillin-resistant staphylococci as a result of an affinity for PBP2a and has been considered a "fifth-generation" cephalosporin. Cephalosporins are resistant to staphylococcal β-lactamase, and the extended-spectrum cephalosporins (primarily the third-generation drugs) are resistant to many gram-negative β-lactamases. However, extended-spectrum β-lactamase (ESBL) enzymes can hydrolyze even third-generation cephalosporins and present an important therapeutic challenge.

Clinical Use

Cephalosporin dosages for cats and dogs are listed in Table 8-4. First-generation cephalosporins such as cephalexin are moderately absorbed orally and distributed into extracellular fluids. In general, they have poor penetration of blood-brain barrier, even in the face of inflammation. Most are excreted unchanged in the urine, and so are useful for treatment of UTIs. Cefazolin has greater activity against a wider range of bacterial isolates than the oral first-generation cephalosporins (e.g., cephalexin and cefadroxil).[7] Cefazolin has been a popular injectable antibiotic for perioperative use in small animals. This perioperative use of cefazolin is with the intention to prevent postsurgical infections, particularly in orthopedic surgery (see Chapter 85).

Use of second-, third-, and fourth-generation cephalosporins may be indicated when there is resistance to first-generation cephalosporins and there are no other reasonable alternatives available. Three third-generation cephalosporins are approved by the U.S. Food and Drug Administration (FDA) for use in small animals: ceftiofur, cefpodoxime proxetil, and cefovecin. These agents are approved for treatment of skin and soft-tissue infections (cefpodoxime proxetil and cefovecin) and UTIs in dogs (ceftiofur). Although their use in small animal medicine has been controversial because of concerns that relate to selection for resistant bacteria, there is no evidence at this time that the use of these agents has been associated with increased resistance among isolates from dogs and cats. The injectable third-generation cephalosporins approved for people have greater in vitro activity than cefpodoxime or cefovecin and occasionally have been used in dogs and cats (e.g., cefotaxime, ceftazidime, cefoperazone). These drugs have a high degree of activity, but are expensive and must be administered frequently by injection. Distribution and excretion into urine and bile is variable. Some third-generation cephalosporins have a longer duration of activity than first- and second-generation drugs by virtue of long half-lives. Cefpodoxime proxetil is the most commonly used oral third-generation drug in small animals, approximately 50% of which is excreted in the urine in active form. Cefovecin is approved for use in dogs and cats in Europe and North America as a subcutaneous injection. The high protein binding and slow clearance result in a very long half-life in these species (approximately 7 days in cats and 5 days in dogs). Administration of cefovecin to cats results in a duration of activity of at least 14 days, and for at least 7 to 14 days in dogs

TABLE 8-3

Classification and Spectrum of Activity of Cephalosporin Antibiotics

Cephalosporin Generation	Examples	Antibacterial Spectrum
First	Cephalexin Cefazolin Cefadroxil	Methicillin-susceptible staphylococci and streptococci and aerobes; some activity against gram-negative aerobes (especially cefazolin). Unpredictable activity against anaerobes.
Second	Cefaclor Cefotetan Cefoxitin	Improved activity against gram-negative aerobes and anaerobes compared with first-generation drugs. Cefoxitin has greater stability against anaerobic β-lactamases (such as those produced by *Bacteroides*) than other second-generation drugs.
Third	Cefixime Cefpodoxime Ceftiofur Cefotaxime Ceftriaxone Cefovecin Ceftazidime	Activity primarily against gram-negative bacteria. Some drugs in this group have less activity against gram-positive bacteria and anaerobes.
Fourth	Cefepime	Gram-positive cocci, gram-negative bacilli, many β-lactamase-producing gram-negative bacteria. Reserve for life-threatening infections where no other alternative is available.

TABLE 8-4

Suggested Cephalosporin Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Route	Species	Comments	CLSI Breakpoints (μg/mL)
Cephalexin	10-30 15-20	6-12 12	PO	D C	Use 30 mg/kg q12h for pyoderma. More frequent dosing (q6-8h) is required for gram-negative bacterial infections.	≤2 susceptible organisms. Cephalothin can be used to test susceptibility for all other 1st generation drugs.
Cefadroxil	22	12 24	PO	D C		See cephalexin.
Cefazolin sodium	20-35	8	IV, IM	D, C	22 mg/kg q2h during surgery if indicated.	See cephalexin.
Cefaclor†	15-20	8	PO	D, C		≤8 all susceptible organisms
Cefoxitin sodium†	30	6-8	IM, IV	D, C	Pain on injection IM.	See cefaclor.
Cefixime†	10	12	PO	D, C	Use 5 mg/kg q12-24h for urinary tract infections.	≤1 all susceptible organisms
Cefpodoxime proxetil†	5-10	24	PO	D*	Of all third-generation cephalosporins, most active against staphylococci. Less active against gram-negative and anaerobic infections.	≤2 all susceptible organisms
Ceftiofur sodium†	2.2-4.4	24	SC	D*	For treatment of otherwise resistant urinary tract infections.	Not established for dogs and cats
Cefotaxime sodium†	50 20-80	12 6	IV, IM	D C	Partially metabolized by the liver to desacetyl cefotaxime which contributes to antibacterial activity. Good CNS penetration. Stable for 5 days in the refrigerator after reconstitution.	See cefpodoxime.
Ceftazidime†	30	6	IV	D, C	Potent antipseudomonal activity.	≤4 *Enterobacteriaceae*, ≤8 *Pseudomonas aeruginosa* and staphylococci
Cefovecin†	8	14 days	SC	D, C	Approved for use for skin and soft tissue infections and in some countries, urinary tract infections. Efficacy for treatment of infections in other sites not established.	No approved breakpoint. ≤2 all susceptible organisms is suggested
Cefepime†	40	6	IV, IM	D*	Reduce frequency in dogs with renal failure (q12-24h).	≤ 8 all susceptible organisms

C, Cats; CLSI, Clinical and Laboratory Standards Institute; CNS, central nervous system; D, dogs.
*Dose not established for cats.
†It is recommended that the use of most second-, third-, and fourth-generation cephalosporins be reserved for serious infections that are susceptible to those drugs but resistant to other reasonable alternatives on the basis of culture and susceptibility testing.

(depending on the pathogen). Injections can be repeated in dogs at 14-day intervals if necessary.

Adverse Effects

Adverse effects of cephalosporins in dogs and cats are similar to those of penicillins, with gastrointestinal signs and hypersensitivity reactions being most frequent. Although the incidence is low, cross-sensitivity can occur between penicillins and cephalosporins, so cephalosporins should be avoided or used with caution in animals that have a history of reactions to penicillin. Injectable cephalosporins can cause phlebitis and pain on injection. Cephalosporins have the potential to cause false-positive results on test strips that use copper reduction for urine glucose detection. Certain cephalosporins, such as cefotetan and ceftriaxone, may exacerbate bleeding tendencies due to vitamin K antagonism.[8] Reversible bone marrow suppression has been reported in dogs given high doses of ceftiofur, cefonicid, and cefazedone long-term.[9]

Monobactams (Aztreonam)

Aztreonam is a synthetic β-lactam antibiotic that is resistant to some β-lactamases. It is effective against a wide range of

VetBooks.ir

TABLE 8-5

Suggested Carbapenem Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Imipenem-cilastatin	5	6-8	D, C	IV, IM, SC	250 to 500 mg of reconstituted drug should be added to no less than 100 mL of fluids and administered IV over 30-60 minutes. Stable for 24 hours after reconstitution when refrigerated. For IM injections, reconstitute with 1% lidocaine.	≤1 Enterobacteriaceae, ≤2 *Pseudomonas aeruginosa*
Meropenem	8.5 24	12 12	D, C D, C	SC IV	SC injections may cause alopecia at the injection site. For *Pseudomonas aeruginosa* or infections with MIC values approaching the breakpoint, use 12 mg/kg q8h SC or 24 mg/kg q8h IV.	See imipenem.

Carbapenems should be used for serious infections resistant to other reasonable alternatives, on the basis of culture and susceptibility testing.
C, Cats; CLSI, Clinical and Laboratory Standards Institute; D, dogs; MIC, minimum inhibitory concentration.

gram-negative bacteria, including *Pseudomonas aeruginosa,* but not gram-positive or anaerobic bacteria. In human medicine, aztreonam is used to treat patients with serious gram-negative infections who are allergic to penicillins and cannot tolerate aminoglycosides.[10] Dosages have not been established for dogs.

Carbapenems

Spectrum of Activity and Clinical Use

Carbapenems are highly resistant to almost all bacterial β-lactamases and include imipenem, meropenem, ertapenem, and doripenem. They penetrate the outer membrane of gram-negative bacteria more effectively than many other β-lactam antibiotics and bind to a variety of PBPs, which leads to rapid lysis of a broad spectrum of bacteria.[11] In contrast to other β-lactam antibiotics, carbapenems have a postantibiotic effect (see Chapter 6) similar to that of aminoglycosides and fluoroquinolones. Although effective against many gram-positive, gram-negative, and anaerobic bacterial infections, the use of carbapenems is reserved for treatment of serious, multiple drug-resistant (MDR) gram-negative infections, especially *Escherichia coli, Klebsiella pneumoniae,* and *P. aeruginosa,* that are resistant to other antibiotics. Methicillin-resistant staphylococci are resistant to carbapenems. Dosages for dogs and cats are listed in Table 8-5.

The identification of carbapenemase production by some strains of gram-negative bacteria has raised great concern, because this confers resistance to a broad range of β-lactam antibiotics. Carbapenemase-producing *K. pneumoniae* (KPC) are resistant not only to all β-lactam antibiotics, but also to fluoroquinolones and aminoglycosides.[12] *K. pneumoniae* that produce a plasmid-encoded metallo-β-lactamase enzyme (NDM-1) appeared in India in 2008 and have subsequently spread worldwide.[13] The only options left for treatment of these infections are tigecycline and polymyxins, both of which have been associated with emergence of resistance during treatment.[14] The potential for spread of *K. pneumoniae* isolates that are resistant to all commercially available antibiotics now exists. Carapenemase (NDM-1) production was recently detected in an *E. coli* isolate from a cat in the United States.

Adverse Effects

Imipenem is degraded by dehydropeptidase-1, a brush border enzyme in the proximal renal tubules, which results in production of an inactive metabolite that is nephrotoxic. In order to prevent nephrotoxicity and maximize imipenem's antibacterial activity, imipenem is administered with cilastatin, which inhibits the dehydropeptidase-1 enzyme. Newer carbapenems such as meropenem are resistant to dehydropeptidase-1.

Adverse effects of carbapenems are otherwise rare and include vomiting, nausea, and pain on injection. Neurologic signs, including tremors, nystagmus, and seizures, can occur following rapid infusion of imipenem-cilastatin or in animals with renal insufficiency. Imipenem must be administered slowly in intravenous fluids (see Table 8-5). Slow administration is not required for meropenem, which is more soluble. Subcutaneous injections of meropenem have produced alopecia at the injection site,[4] but otherwise these injections have been very well tolerated and have eradicated infections associated with MDR gram-negative bacteria.

Glycopeptides

Mechanism of Action and Clinical Use

Glycopeptides are cyclic glycosylated peptide antimicrobials that inhibit the synthesis of peptidoglycan by binding to amino acids (D-alanyl-D-alanine) in the cell wall, preventing the addition of new units. Vancomycin, teicoplanin, and decaplanin are all glycopeptides, but only vancomycin has been used in small animals.

Vancomycin was discovered in the 1950s, but has not been frequently used in small animals because it is not absorbed orally, so IV infusion is required for treatment of systemic infections. When administered IV, it can be valuable for treatment of MDR gram-positive bacterial infections, such as methicillin-resistant staphylococcal infections, resistant enterococcal infections, and encrusting cystitis caused by *Corynebacterium urealyticum*. The last is an emerging infection of dogs, cats, and immunocompromised human patients, treatment of which requires surgical debridement of the bladder in conjunction with glycopeptide administration.[15,16] Vancomycin is a

valuable agent for treatment of methicillin-resistant staphylococci, because resistance among these organisms is extremely rare, and the bactericidal activity can be an advantage when treating immunocompromised patients. In human patients, oral vancomycin has been used to treat gastrointestinal infections caused by resistant *Clostridium difficile*.

Vancomycin-resistant methicillin-resistant *Staphylococcus aureus* (MRSA) isolates are extremely rare in people and have only been described in specific geographic locations. Vancomycin-resistant *Staphylococcus pseudintermedius* isolates have not yet been described. Vancomycin-resistant enterococci (VRE) are well documented in human patients and can present a therapeutic challenge. Although currently rare, the existence of VRE has been reported in companion animals.[17] Resistance to vancomycin results from bacterial alteration of the terminal amino acid to which vancomycin binds. In order to reduce inappropriate use of vancomycin, some laboratories do not report results for vancomycin susceptibility unless reporting is indicated on the basis of resistance in the remainder of the susceptibility panel.

Teicoplanin has a longer half-life and is up to 100 times more lipophilic than vancomycin. It is not commercially available in the United States but is used in Europe. Vancomycin and teicoplanin appear to be equally efficacious in human patients.[18]

Adverse Effects

Vancomycin is not commonly used to treat small animals, and so adverse reactions have not been well documented. The most common reaction in human patients is the "red man syndrome" caused by histamine release after rapid infusion. This can be prevented through the use of antihistamines and slower infusion rates. Other adverse reactions are rare. Previously cited nephrotoxicity from vancomycin may be exaggerated because of its frequent co-administration with aminoglycosides. Current formulations are of better quality and purity and less likely to produce kidney injury. Vancomycin is given by IV infusion over 30 to 60 minutes through a central or peripheral catheter (Table 8-6). Trough plasma concentrations can be monitored and should be greater than 10 µg/mL for skin and soft tissue infections, and 10 to 20 µg/mL for more complicated infections. Intramuscular administration is painful and irritates tissues.

Nucleic Acid Inhibitors

Fluoroquinolones

Classification and Mechanism of Action

The fluoroquinolones bind to DNA gyrase (also known as topoisomerase II) and topoisomerase IV, enzymes that cleave DNA during DNA replication. The result is disruption of bacterial DNA and protein synthesis. For the veterinary fluoroquinolones enrofloxacin, orbifloxacin, and marbofloxacin, DNA gyrase is the primary target for gram-negative bacteria and topoisomerase IV is the primary target for gram-positive bacteria. Because topoisomerase IV has a lower affinity than DNA gyrase for this group of drugs, higher MICs are observed for gram-positive bacteria compared to the Enterobacteriaceae.

Fluoroquinolones were created by addition of a fluorine group to nalidixic acid, which improves its spectrum of activity. Examples are enrofloxacin, ciprofloxacin, difloxacin, orbifloxacin, and marbofloxacin. Newer-generation fluoroquinolones inhibit *both* DNA gyrase and topoisomerase IV in gram-positive bacteria, leading to enhanced activity for treatment of gram-positive and anaerobic bacterial infections and reduced likelihood of selection for resistant mutants. Pradofloxacin, levofloxacin, moxifloxacin, and gatifloxacin are third-generation fluoroquinolones. The only antibiotic in this group approved for use in companion animals is pradofloxacin, which is approved for use in cats in the United States, and approved for both dogs and cats in European countries.

Resistance to fluoroquinolones results from DNA gyrase mutations, decreased bacterial permeability, and increased drug efflux.[19] Susceptibility to one fluoroquinolone generally predicts susceptibility to others, with the exceptions of third-generation fluoroquinolones (such as pradofloxacin) and ciprofloxacin, which has higher in vitro activity against *P. aeruginosa* than other fluoroquinolones.[20,21] Limited use of fluoroquinolones has been recommended by some human and veterinary medical authorities in order to minimize further development of resistance, but a clear association between prescription of fluoroquinolones and increased resistance has not been established in companion animals. Nevertheless, other "first line" drugs are often available for most infections, and the valuable fluoroquinolones can be reserved for cases that cannot tolerate other drugs, or when resistance to other drugs is more likely.

TABLE 8-6

Suggested Vancomycin Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (µg/mL)
Vancomycin*	15 12-15	6-8 8	D C	IV	Reconstituted drug is added to 0.9% NaCl or 5% dextrose and administered over 30 to 60 minutes. It can also be administered in 5% dextrose as a CRI, with a loading dose of 3.5 mg/kg, and then 1.5 mg/kg/hr IV. Therapeutic drug monitoring recommended.	≤4 *Enterococcus* and *Staphylococcus*

C, Cats; CLSI, Clinical and Laboratory Standards Institute; CRI, continuous-rate infusion; D, dogs.
*The use of vancomycin should be reserved for gram-positive infections that are susceptible to vancomycin but resistant to all other reasonable alternatives, on the basis of culture and susceptibility testing.

A sufficiently high dose should be used to minimize selection of resistant isolates.

Clinical Use

Fluoroquinolones are most valuable to treat gram-negative infections, because there are often few oral medication alternatives for these infections. The fluoroquinolones are also effective for infections caused by staphylococci, but staphylococci tend to have higher MICs for fluoroquinolones than gram-negative bacteria. The activity of fluoroquinolones against anaerobes is variable. Pradofloxacin has the greatest activity, followed by marbofloxacin and enrofloxacin.[22] Fluoroquinolones are concentration-dependent antibiotics, so they are best administered as a single high daily dose. Doses for fluoroquinolones are listed in Table 8-7.

Fluoroquinolones are usually well absorbed after oral administration. Poor absorption occurs when they are complexed by divalent and trivalent cation-containing medications (e.g., antacids) and supplements (aluminum, calcium, iron, zinc). Use of these should be avoided if animals are receiving fluoroquinolones by the oral route. Oral absorption of the human drug ciprofloxacin is lower and more variable in dogs than in people, which necessitates administration of a higher dose. In one study, oral absorption of generic ciprofloxacin tablets in dogs was 58%, but the coefficient of variation was 45%.[23] In cats, only 22% to 33% of orally administered ciprofloxacin is absorbed. Most fluoroquinolones are highly concentrated in the urine, so they are useful for treatment of UTIs. Enrofloxacin is metabolized to ciprofloxacin, which is subsequently excreted in the urine. Approximately half of the administered dose of marbofloxacin and orbifloxacin is excreted as unchanged drug in the urine. In contrast, difloxacin is excreted primarily in bile, and little drug enters the urine.[24]

TABLE 8-7

Suggested Fluoroquinolone Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (µg/mL)
Enrofloxacin	5-20 5	24 24	D C*	IV, IM, PO IM, PO	Interactions can occur with certain oral medications (see text). Reduce dose or increase dosage interval with renal failure. Dilute in fluids (e.g., 1:10 dilution) and infuse IV over 30 minutes.	≤0.5 susceptible infections. Use higher dosages (10-20 mg/kg) for organisms with MICs of 1 or 2 (except in cats). A dose of 5 mg/kg may be sufficient for UTIs.
Ciprofloxacin hydrochloride	20-30 10	24 24	D, C D, C	PO IV	See enrofloxacin. Oral absorption may be limited (see text).	In humans, ≤1 susceptible infections. More active against *Pseudomonas aeruginosa* than other fluoroquinolones
Marbofloxacin	2.75-5.5	24	D, C	PO	See enrofloxacin.	≤1 susceptible infections. Use higher doses for bacteria with higher MICs.
Orbifloxacin	2.5-7.5	24	D, C	PO	See enrofloxacin. Orbifloxacin suspension provides lower and more variable plasma levels than the tablets. A dose of 7.5 mg/kg should be used.	See marbofloxacin.
Difloxacin hydrochloride	5-10	24	D	PO	Urine concentrations may not be sufficient for treating UTIs.	≤0.5 susceptible infections
Moxifloxacin	10	24	D, C	PO	Moxifloxacin has enhanced activity against gram-positive bacteria and anaerobes. In humans, urine concentrations are not sufficient for treatment of UTIs.	See marbofloxacin.
Pradofloxacin	3† 5-7.5‡	24	D, C C	PO	See moxifloxacin for spectrum of activity. Food reduces bioavailability. Appears effective for treatment of UTIs.	Not established

C, Cats; CLSI, Clinical and Laboratory Standards Institute; D, dogs; MIC, minimum inhibitory concentration; UTI, urinary tract infection.
*The use of enrofloxacin to treat cats is controversial because of the potential for irreversible retinal toxicity and blindness. Do not exceed a dose of 5 mg/kg in cats. The use of alternative fluoroquinolones such as marbofloxacin, orbifloxacin, or pradofloxacin should be considered for cats.
†Tablet formulation. The use of pradofloxacin at high doses in dogs has been associated with myelosuppression and is off-label in the United States, but it is approved for both dogs and cats outside the United States at a dose of 3 mg/kg (tablets).
‡Oral suspension for cats. The dose of the oral suspension for cats is higher (5-7.5 mg/kg) owing to reduced bioavailability.

Fluoroquinolones have variable protein binding, but this does not inhibit distribution to tissue fluids. Because of good lipophilicity, these drugs penetrate the prostate and respiratory secretions. They also penetrate the ear canal, but high doses may be required for treatment of bacteria with relatively high MIC values.[25] Fluoroquinolones can attain high intracellular concentrations and can be used to treat infections caused by intracellular pathogens such as *Mycoplasma* spp. and some *Mycobacterium* spp.

Adverse Effects

Fluoroquinolones can occasionally produce gastrointestinal signs in dogs and cats, such as decreased appetite and vomiting. Rapid IV administration can cause systemic hypotension, tachycardia, and cutaneous erythema, possibly as a result of histamine release.[26] Neurologic signs, including tremors, ataxia, and seizures, can occur in dogs and cats treated with high doses of parenteral fluoroquinolones. Although not well understood, this is thought to result from fluoroquinolone interference with the binding of γ-aminobutyric acid to its receptors in the central nervous system (CNS).[27] In general, fluoroquinolones should be used cautiously in animals prone to seizures. Enrofloxacin causes hallucinations in humans and so is not marketed or approved for treatment of humans.

Cats treated with high doses of enrofloxacin (generally >5 mg/kg/day), especially parenteral enrofloxacin, have developed blindness resulting from acute retinal degeneration, manifested as bilateral mydriasis with tapetal hyperreflectivity.[28,29] This results from a functional defect in a fluoroquinolone transport protein in the cat, with subsequent accumulation of photoreactive drug in the retina.[30] In general, the blindness is irreversible, but if it is detected early and medication is discontinued, some resolution may occur. Orbifloxacin also can produce retinal injury in cats, but the dose needed for this reaction is much higher than doses used therapeutically. Studies of marbofloxacin (reported by the manufacturer) and pradofloxacin[31] showed no evidence of retinal toxicity in cats, even with high doses, although there are reports to the FDA of blindness in cats associated with the use of marbofloxacin. Cats with renal insufficiency or those treated with medications that increase plasma fluoroquinolone concentrations may be more likely to develop this adverse effect.

Because they inhibit proteoglycan synthesis and chelate magnesium, fluoroquinolones can cause cartilage and joint toxicity in young animals, although the clinical importance of this has been questioned.[32,33] In general, prolonged (>7 days) use of fluoroquinolones during the period of rapid growth in dogs (from about 1 to 2 months of age to 28 weeks) should be avoided if possible. Cats are thought to be more resistant to development of cartilage toxicity. Pradofloxacin has been associated with myelosuppression in dogs at doses greater than 10 mg/kg.

Fluoroquinolones inhibit some cytochrome P450 enzymes, which decreases metabolism of other drugs. This occurs with theophylline in dogs; therefore, the dose of theophylline should be adjusted if administered concurrently. Like cephalosporins, fluoroquinolones can cause false-positive results on test strips for urine glucose detection. Cutaneous photosensitization occurs in human patients but is rare in animals. Other adverse effects reported in humans, but not in dogs and cats, include cardiac arrhythmias, tendinitis and tendon rupture, altered glucose metabolism, and hepatic dysfunction.[34]

Metronidazole

Mechanism of Action and Spectrum of Activity

Metronidazole is a bactericidal nitroimidazole drug that is used primarily to treat anaerobic bacterial infections (both gram-negative and gram-positive), which includes those caused by *Bacteroides fragilis* and *Clostridium* spp., and infections with certain protozoa, such as *Giardia* spp. Metronidazole diffuses into bacterial cells as a prodrug and is activated in the cytoplasm. Once within the cell, the nitro group of metronidazole preferentially accepts electrons from electron transport proteins such as ferredoxin. A short-lived nitroso free radical is thus generated that damages DNA. The intermediate compounds then decompose into non-toxic, inactive end products.

Metronidazole has antioxidant properties that are believed to result from its ability to scavenge reactive oxygen species and modulation of neutrophil activity.[35] It is often used at low doses to treat inflammatory bowel disease in dogs and cats,[36] but it is not known if the benefit is from the antibacterial activity or direct effects on inflammatory cells.

Resistance to metronidazole is rare among anaerobes.[37] Mechanisms of resistance include reduced drug uptake and decreased reduction activity. Other proposed mechanisms include increased efflux, drug inactivation, and accelerated DNA repair.

Clinical Use

In dogs and cats, metronidazole is used to treat anaerobic bacterial and protozoal infections in a variety of tissues. Suggested

TABLE 8-8

Suggested Metronidazole Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments
Metronidazole	15 10-15	12 24	D C	PO	Reduce dose by 50% in animals with hepatic dysfunction. An intravenous solution, metronidazole hydrochloride, is available but is highly acidic. It should be diluted in 100 mL of IV crystalloids and neutralized with 5 mEq sodium bicarbonate per 500 mg for a pH of 6-7. Diluted solutions are stable for 24 hours.
Metronidazole benzoate	25	12	C	PO	More palatable formulation for cats may be available from some compounding pharmacies.

C, Cats; D, dogs.

doses are listed in Table 8-8. Metronidazole is rapidly and almost completely absorbed from the gastrointestinal tract, diffuses across lipid membranes, and achieves therapeutic concentrations in tissue fluids. Metronidazole is metabolized by the liver. The metabolites, along with intact drug, are excreted in the urine.

Adverse Effects

The main adverse effect of metronidazole is neurotoxicity, which tends to occur with high doses (>30 mg/kg/day) or in animals with hepatic dysfunction. Clinical signs of neurotoxicity are reversible on discontinuation of the drug and include lethargy, truncal ataxia, hypermetria, intention tremors, head tilt, falling, vertical nystagmus, extensor rigidity, opisthotonos and seizures, and reflect damage to the vestibular system.[38,39] Although not fully understood, neurotoxicity is believed to result from antagonism of γ-aminobutyric acid in the cerebellar and vestibular systems. Neurologic signs resolve more quickly when treated with a low dose of diazepam (0.4 mg/kg PO q8h for 3 days).[38] Bilateral symmetrical cerebellar lesions, most commonly in the dentate nucleus have been reported on magnetic resonance imaging in human patients with metronidazole toxicity,[40] and multifocal necrotic foci were detected at necropsy in the brainstem of a cat.[39] Administration of metronidazole to animals with a history of metronidazole toxicosis is not recommended.[38]

Less commonly, metronidazole causes decreased appetite, vomiting, and diarrhea. Metronidazole suspension has a bitter taste that may be unpalatable to cats, which can be overcome by administration of the drug in gel capsules. Although not approved by the FDA, metronidazole benzoate is a more palatable formulation for cats and pharmacokinetic studies have demonstrated good absorption.[41] There have been concerns that relate to toxicity from the benzoic acid component of the formulation, which can cause CNS signs, blindness, and respiratory problems at high doses. However, this possibility is considered to be unlikely.[41] Because metronidazole benzoate is only 62% metronidazole, dosage adjustment is required when this formulation is used. Metronidazole inhibits hepatic microsomal enzymes and so may increase the concentration of drugs such as warfarin and cyclosporine. It also lowers serum lipid concentrations (including cholesterol concentrations) in human patients.[42]

Rifamycins

Mechanism of Action and Spectrum of Activity

Named after the French crime movie *Rififi*, rifamycins are bactericidal antimicrobials that inhibit the β-subunit of DNA-dependent RNA polymerase in bacteria. This leads to impaired RNA synthesis. Only the semisynthetic drug rifampin (also known as rifampicin) has been used to any great extent in small animal medicine. Rifampin is active against staphylococci, streptococci, and only a few gram-negative organisms. When used as a component of antimycobacterial treatment regimes, it increases the chance of treatment success. Rifabutin is effective for treatment of some mycobacterial infections that are resistant to rifampicin.[43]

It has been recommended that rifampin be used in combination with other antimicrobials to reduce the risk of emergence of rifampin resistance, which occurs quickly when rifampin is used alone. However, this applies primarily when it is used for long-term treatment, such as for mycobacterial infections. Monotherapy has been successful when rifampin has been used to treat methicillin-resistant *Staphylococcus* infections, which accounts for most of the current small animal use. If combination treatment is pursued for treatment of methicillin-resistant staphylococci, there are often few effective alternatives with which to combine rifampin, because these infections are typically multidrug resistant. Resistance to rifampin results from a single mutation that leads to an altered RNA polymerase that does not effectively bind rifampin.

Clinical Use

One of the major advantages of rifampin is its high degree of lipid solubility, which provides the degree of intracellular penetration required for treatment of infections caused by intracellular bacteria such as *Mycobacterium* spp. and *Brucella canis* infections. Rifampin has been used to treat bartonellosis in combination with doxycycline.[44,45] Because of its activity against staphylococci and the fact that it can be administered orally, it has been used for treatment of methicillin-resistant staphylococcal infections in small animals. For other infections, rifampin is less attractive because of its adverse effect profile.

Rifampin dosing is shown in Table 8-9. Rifampin is rapidly absorbed from the gastrointestinal tract and metabolized by the liver. Active metabolites are excreted in bile and to a lesser extent the urine.

Adverse Effects

Vomiting and anorexia are common in dogs treated with rifampin. The drug can impart a red-orange color to the urine and, to a lesser extent, tears, saliva, the sclera, and mucous membranes. Rifampin can also be associated with increased

TABLE 8-9

Suggested Rifampin Dose for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Rifampin	5	12	D, C	PO	Preferably use in combination with other drugs. Avoid in animals with hepatic dysfunction. Do not administer with fatty meals. Drug interactions may occur (see text). Monitor liver enzymes with prolonged treatment. May impart a red-orange color to the urine and tears.	≤1 for susceptible organisms (usually MICs of gram-positive bacteria fall below this breakpoint)

C, Cats; CLSI, Clinical and Laboratory Standards Institute; D, dogs; MIC, minimum inhibitory concentration.

VetBooks.ir

serum liver enzyme activities and hepatopathy. Doses that exceed 10 mg/kg per day in dogs increase the risk of liver injury. In humans, fever, cutaneous reactions, thrombocytopenia, acute intravascular hemolytic anemia, and acute tubulointerstitial nephritis have been reported, which appear to have an immune-mediated pathogenesis.[46] Rarely, pancreatitis has been reported in human patients receiving rifampin. Adverse effects have not been reported in cats, but some of these risks may apply to cats as well as dogs. Because of poor palatability, it is a challenge to administer to cats.

Rifampin is one of *the* most potent inducers of hepatic microsomal enzymes and efflux proteins, such as P-glycoprotein. Subsequently, it can increase the clearance of several co-administered drugs (thereby decreasing their efficacy), such as glucocorticoids, cyclosporin, itraconazole, and digoxin. In human patients, recovery from the effect of rifampin on hepatic microsomal enzymes can take 4 weeks.[47]

Trimethoprim-Sulfonamides

Mechanism of Action

Trimethoprim and sulfonamides act synergistically to inhibit folic acid metabolism by bacteria. The combination interferes with purine and therefore DNA synthesis. Trimethoprim inhibits bacterial dihydrofolate reductase. Sulfonamides are chemical analogs of para-aminobenzoic acid (PABA), and competitively inhibit the incorporation of PABA into dihydropteroic acid by the enzyme dihydropteroate synthetase, which also leads to decreased folic acid synthesis. When administered separately, each drug is bacteriostatic, but the combination is bactericidal. Preparations used to treat dogs and cats include a 1:5 ratio of trimethoprim to sulfonamide. Because folic acid is of dietary origin in animals, only bacterial purine synthesis is affected.

Resistance to trimethoprim-sulfonamide (TMS) antibiotics most commonly results from plasmid-mediated production of altered dihydrofolate reductase or dihydropteroate synthetase, with reduced binding affinities. Other mechanisms include overproduction of dihydrofolate reductase or PABA by bacteria, and reduced bacterial permeability to trimethoprim and sulfonamides. Multiple mechanisms may operate simultaneously.[48]

Clinical Use

TMS antibiotics have a broad spectrum of activity and can be used to treat gram-positive and many gram-negative bacterial infections, as well as some protozoal infections. Enterococci are intrinsically resistant to TMS antibiotics. Many anaerobic bacteria are not treated successfully because despite in vitro susceptibility, the drugs are less active in tissues where anaerobes proliferate. TMS antibiotics are the treatment of choice for nocardiosis. They have also been used successfully for prevention of bacterial infections in dogs being treated with myelosuppressive chemotherapeutics such as doxorubicin.[49] Prophylactic protocols have selected for resistant bacteria in humans,[50] but this has not been reported in animals. TMS combinations are available as either trimethoprim-sulfadiazine or trimethoprim-sulfamethoxazole (the latter is a human medical preparation), which are used interchangeably. However, the veterinary formulation of trimethoprim-sulfadiazine is rarely available commercially, and most veterinarians rely on trimethoprim-sulfamethoxazole. No difference in activity between the two formulations has been documented, but this has never been evaluated. The primary difference between the formulations is that sulfadiazine is more water soluble and is excreted in the urine in an unchanged form. A similar formulation to the trimethoprim-sulfonamides for use in veterinary medicine is ormetoprim sulfadimethoxine, which has been used for the same indications as trimethoprim-sulfonamides. Doses for TMS combinations are listed in Table 8-10.

TMS is well absorbed after oral administration. As a weak base, trimethoprim is able to penetrate the blood-prostate barrier and can be used to treat prostatic infections. Both trimethoprim and sulfonamides are metabolized to some extent by the liver. Both active drug and inactive metabolites appear in the urine. Active TMS is highly concentrated in urine and is an appropriate first choice for treatment of UTIs in dogs and cats.[51]

Adverse Effects

TMS antimicrobials cause a wide range of adverse effects, which have somewhat limited their use. These reactions are primarily caused by the sulfonamide component. Some of the adverse

TABLE 8-10

Suggested Trimethoprim-Sulfonamide Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Trimethoprim-sulfamethoxazole, trimethoprim-sulfadiazine	30*	12	D, C	PO, IV	Avoid in animals with hepatic failure. Reduce dose in animals with renal insufficiency. Obtain baseline Schirmer tear test and monitor this and the CBC with prolonged treatment. Each 5-mL vial of the injectable preparation should be diluted in 75-125 mL of 5% dextrose and administered IV over 1 hour.	≤2/38 for susceptible infections
Ormetoprim-sulfadimethoxine	55 on first day, and then 27.5*	24	D	PO	See trimethoprim-sulfamethoxazole.	Use information for TMS.

C, Cats; CLSI, Clinical and Laboratory Standards Institute; D, dogs; TMS, trimethoprim-sulfonamide.
*Dose listed is for combined components, (e.g., 5 mg of trimethoprim and 25 mg of sulfonamide).

effects may be attributed to the inability of dogs to acetylate sulfonamide compounds. People who are "slow acetylators" are also more prone to adverse effects from sulfonamides.

Gastrointestinal signs such as vomiting can occur. Other common adverse effects in dogs are hypersensitivity reactions and include keratoconjunctivitis sicca, fever, polyarthritis, cutaneous drug eruptions,[52,53] immune-mediated thrombocytopenia, hemolytic anemia, hepatitis, pancreatitis, meningitis, interstitial nephritis, glomerulonephritis, and aplastic anemia (Figure 8-3).[54-57] These events are relatively uncommon, but have been documented well enough in dogs that it has discouraged their routine use among some veterinary clinicians. Reversible hypothyroidism can occur after periods of treatment as short as 10 days.[58] Hepatic necrosis can occur as an idiosyncratic reaction.[59] Ormetoprim has been associated with neurologic signs in dogs, including tremors, anxiety, and seizures. Schirmer tear tests should be performed before sulfonamides are administered to dogs, tear tests should be monitored when prolonged treatment is required (e.g., greater than 1 week), and the drug should be avoided in dogs with keratoconjunctivitis sicca. Sulfonamide cystolithiasis can occur in dogs treated with high doses of sulfonamides.[60] Doberman pinschers may be more susceptible than other breeds to adverse effects of TMS because of their inability to detoxify certain sulfonamide metabolites; in another study, Samoyeds and miniature schnauzers also appeared to be more susceptible.[55,61]

Protein Synthesis Inhibitors

Aminoglycosides

Mechanism of Action

All aminoglycosides contain an essential six-membered ring with amino-group substituents and are highly positively charged. Aminoglycosides with names that end in *-mycin* derive directly or indirectly from *Streptomyces* spp. (e.g., neomycin). Those with names ending in *-micin* are derived from *Micromonospora* (e.g., gentamicin).

Aminoglycosides have multiple mechanisms of action. They bind electrostatically to the bacterial outer membrane and displace cell wall Mg^{2+} and Ca^{2+}, which normally link adjacent lipopolysaccharide molecules. This initial binding is greater in gram-negative bacteria than gram-positive bacteria because of a greater presence of an outer membrane in gram-negative organisms. The end result is disrupted cell permeability. Subsequently, the bacterial cell takes up the aminoglycoside molecules, and they become trapped irreversibly within the cytoplasm. Because this is an oxygen-dependent process, anaerobes are intrinsically resistant to aminoglycosides. Once within the cell, aminoglycosides bind to the 30S subunit of the bacterial ribosome, which results in decreased protein synthesis.

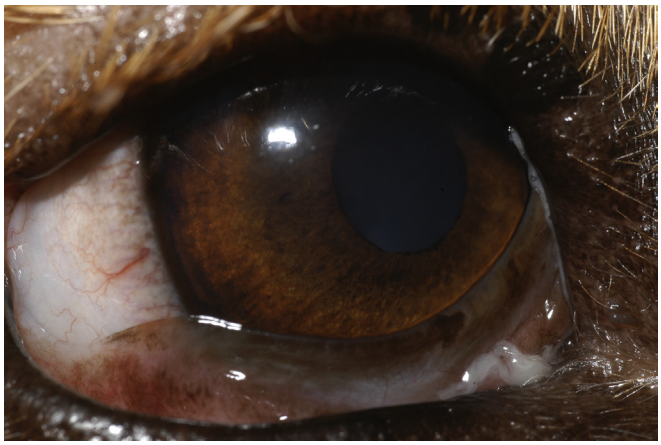

FIGURE 8-3 Right eye of a 7-year-old intact male golden retriever that developed keratoconjunctivitis sicca after administration of trimethoprim-sulfamethoxazole for 3 weeks for septic peritonitis. The owner noticed the dog pawing at his eyes. Mucoid ocular discharge is present at the medial canthus. Schirmer tear test strip results were 0 mm for both eyes. (Image courtesy University of California, Davis Veterinary Ophthalmology service.)

Aminoglycosides, particularly gentamicin, amikacin, and tobramycin, are highly active compounds for which resistance is uncommon. The most common mechanism of aminoglycoside resistance is enzymatic modification of the drug by bacteria. More than 50 modifying enzymes have been identified.[62] Reduced drug uptake by bacteria may also occur. Enterococci are intrinsically resistant to low levels (4 to 250 µg/mL) of aminoglycosides because of their anaerobic metabolism, and thus they require testing for high-level resistance using higher concentrations of aminoglycosides. Resistance to one aminoglycoside does not imply resistance to others. For example, tobramycin and amikacin are consistently more active than gentamicin, and kanamycin is one of the least active aminoglycosides. Because of these differences, a susceptibility panel should include gentamicin and either amikacin or tobramycin.

Clinical Use

Aminoglycosides are primarily used to treat gram-negative bacterial infections and MDR staphylococcal infections. They should not be used to treat anaerobes, and *Streptococcus* species are better treated with β-lactams. Aminoglycosides have usually been administered together with cell wall–active antimicrobial drugs (β-lactams and glycopeptides), but this is no longer believed to be a therapeutic advantage. They are very water soluble and poorly lipid soluble, so they penetrate tissue fluids well, but do not readily penetrate tissues that are dependent on lipid diffusion (prostate, brain, eye, or cerebrospinal fluid). Penetration of bile is also poor. Oral absorption is negligible, and they should not be administered orally unless specifically intended to treat intestinal bacteria (e.g., oral neomycin for treatment of hepatic encephalopathy). Doses are shown in Table 8-11. Aminoglycosides also may be administered topically. Because they penetrate bronchial secretions poorly, nebulization has been used in order to overcome this problem in human patients as well as dogs with resistant gram-negative bacterial bronchopneumonia (see Table 8-11).[63] Aminoglycosides are excreted unchanged by the kidney and concentrate 25- to 100-fold in urine within an hour of drug administration, so they can be used to treat resistant gram-negative bacterial UTIs. They also accumulate in renal tissue and remain active for several days after dosing is discontinued. Because they are not well distributed into fat, dose reduction may be indicated for obese animals.

Despite their primary mechanism of action being protein synthesis inhibition, aminoglycosides are rapidly bactericidal with a prolonged, concentration-dependent postantibiotic effect. Transient high peak drug concentrations result in faster killing and greater bactericidal activity than lower concentrations over a prolonged period of time (i.e., they are concentration-dependent antimicrobial drugs). Once-daily dosing of a high dose of an aminoglycoside is therefore preferred because it achieves optimal bacterial killing but minimizes toxicity. In order to further minimize toxicity, aminoglycosides are generally infused slowly. In human patients, it is recommended they

TABLE 8-11
Suggested Aminoglycoside Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)*	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Gentamicin sulfate	9-14 5-8	24 24	D C	IV, IM, SC	Ensure adequate fluid and electrolyte balance during treatment. Avoid in animals with renal impairment. Monitor BUN and creatinine. Amikacin and tobramycin are more active against some gram-negative bacteria than gentamicin, but gentamicin is preferred for *Serratia* infections. Do not mix in vials with other drugs.	≤2 susceptible infections
Amikacin	15-30 10-14	24 24	D C	IV, IM, SC	See gentamicin.	≤16 susceptible infections
Tobramycin sulfate	9-14 5-8	24 24	D C	IV, IM	See gentamicin. For nebulization, 160 mg of nebulization solution† q12h for 28 days. Preferred aminoglycoside for *Pseudomonas* infections.	≤4 susceptible infections
Kanamycin sulfate	20	24	D, C	IV or IM	See gentamicin. Less active than gentamicin and amikacin.	≤16 susceptible infections
Neomycin	10-20	6-12	D, C	PO	Not absorbed systemically; used to treat hepatic encephalopathy. Use cautiously in animals with renal disease and avoid use for >14 days.	Not applicable

C, Cats; CLSI, Clinical and Laboratory Standards Institute; D, dogs; MIC, minimum inhibitory concentration.
*Once-daily administration is preferred except for enterococcal endocarditis, where the continuous presence of both an aminoglycoside and a penicillin is recommended (see Chapter 86).
†TOBI nebulization solution. Injectable tobramycin or gentamicin can be used but may be associated with bronchospasm. They should be diluted in 3 mL of sterile saline, and albuterol should be administered just before nebulization.

be administered over a 15- to 30-minute period. Subcutaneous and intramuscular injections of water-soluble formulations of aminoglycosides are also acceptable routes of administration, although they may cause pain in some animals.

Adverse Effects

Aminoglycosides have the potential to cause nephrotoxicity, ototoxicity, and neuromuscular blockade. Their cationic structure and the high anionic phospholipid concentrations in the kidney and inner ear play an important role in toxicity. In the presence of gastrointestinal ulceration, systemic absorption of orally administered aminoglycosides can occur, with associated nephrotoxicity or ototoxicity.[64]

Nephrotoxicity results from apoptosis and necrosis of renal tubular epithelial cells, and direct damage to the glomerulus as well. The mechanisms involved are complex.[65] Recovery can occur when the aminoglycoside is removed, but because aminoglycosides accumulate in renal tissue, the insult can persist for some time even after treatment is discontinued. Efforts to understand the mechanism of nephrotoxicity should lead to improved preventative measures and increased applications for aminoglycoside antibiotics. Aminoglycosides bind to megalin-cubulin complexes on the surface of the cell and are endocytosed into the cytoplasm, where they accumulate in lysosomes. The lysosomes break down, with resultant drug leakage into the cytoplasm, where interference with mitochondrial function occurs. Aminoglycosides also bind membrane phospholipids and alter their turnover. Damaged renal tubular epithelial cells are shed into and obstruct the tubular lumen, which leads to a build-up of pressure within the glomerulus, leading to decreased glomerular filtration rate. Disrupted proximal tubular cell function leads to delivery of excessive water and electrolytes to the distal nephron, which in turn triggers tubuloglomerular feedback, with constriction of afferent arterioles and further decreases in the glomerular filtration rate.[65] Tubuloglomerular feedback is designed to protect the body from massive loss of water and electrolytes.

Risk factors for nephrotoxicity include older age, reduced renal function, concomitant liver disease, dehydration, sodium depletion, hypokalemia, and concurrently administered nephrotoxic drugs, most commonly nonsteroidal antiinflammatory drugs but also furosemide and cyclosporin. Although gentamicin nephrotoxicity can occur in young animals,[66] young age is not a contraindication to use of aminoglycosides, which are used widely to treat human neonatal sepsis.[67] The chance of toxicity increases with more prolonged treatment periods (≥3 days). Gentamicin and amikacin are more toxic than tobramycin. Volume and salt loading do not decrease toxicity, but high levels of dietary calcium and protein have protective effects.[68] The best preventative measure is to avoid these drugs in any

TABLE 8-12

Suggested Chloramphenicol Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Chloramphenicol, chloramphenicol sodium succinate	40-50 12.5-20	6-8 12	D C	PO, IV, IM	Avoid long-term use in cats. Monitor CBC with long-term use. Warn owners that human exposure to chloramphenicol may cause bone marrow disease. Drug interactions may occur (see text). Avoid in animals with hepatic failure.	≤4 for streptococci, ≤8 for other susceptible bacteria
Florfenicol	20 22	6 8	D, C	PO, IM	Not approved for use in dogs and cats. Doses and adverse effects have not been well studied.	See chloramphenicol.

C, Cats; CLSI, Clinical and Laboratory Standards Institute; D, dogs.

patients with preexisting renal disease. If renal disease develops after initiating treatment, the drug should be substituted with a safer drug.

Ototoxicity results from damage to the cochlear or the vestibular apparatus and is more likely to occur in animals with renal impairment or that are dehydrated. Cochlear toxicity results from damage to the hair cells of the organ of Corti, whereas vestibular toxicity results from damage to hair cells at the tip of the ampullae cristae. Auditory toxicity may be more common in dogs, whereas cats tend to develop vestibular toxicity.[69] Cochlear toxicity in dogs and cats may be underrecognized, because it may be overlooked by pet owners. In human patients, signs of vestibular toxicity can disappear with time because of compensatory mechanisms. Ototoxicity is generally irreversible, but in some human patients, gradual improvement in hearing can occur.[70]

Neuromuscular blockade is a rare but potentially life-threatening complication of aminoglycoside treatment. Severe neuromuscular blockade has not been reported in cats and dogs, but experimental studies show it does occur when aminoglycosides are used in conjunction with some anesthetic agents.[71-73] Neuromuscular blockade results from decreased release of acetylcholine at neuromuscular junctions, and decreased sensitivity of the postsynaptic neuron to acetylcholine. Autonomic blockade can also occur. The use of aminoglycosides should be avoided in animals with neuromuscular disease such as myasthenia gravis, because aminoglycosides have the potential to exacerbate the clinical signs.[74]

Measurement of serum aminoglycoside concentrations can be used to ensure adequate plasma concentrations or to minimize toxicity.[75] Assays are offered by specialized veterinary pharmacology laboratories or through human hospitals. Aminoglycoside doses that result in peak plasma concentrations approximately 8 to 10 times the MIC produce the optimal bactericidal effect. The effective volume of distribution for aminoglycosides is often higher in septic patients or animals that have a "third space" problem (such as pleural effusion), which may necessitate a higher dose. To perform therapeutic drug monitoring, the optimum time points are 1 hour after injection (C_{max}), followed by two additional time points in order to estimate the slope of the elimination curve. Trough levels could also be performed to minimize the chance of toxicity, with the recommendation that if high trough levels are detected, the drug should be discontinued. In patients with normal renal function, trough levels with once-daily dosing should be in the "undetectable" range.

Chloramphenicol

Mechanism of Action and Spectrum of Activity

Chloramphenicol binds to the 50S subunit of the bacterial ribosome and inhibits bacterial protein synthesis. It is usually described as bacteriostatic, but there is some evidence that chloramphenicol may be more bactericidal than previously thought. Like other ribosomal inhibitors, chloramphenicol has a broad spectrum of activity, which includes gram-positive and gram-negative bacteria, anaerobes, and some rickettsial pathogens. Because chloramphenicol can cause aplastic anemia in humans, its use in humans has greatly diminished, and it is only used for the treatment of MDR bacterial infections where few or no other antimicrobial drugs are useful. Thiamphenicol and florfenicol are related compounds, the availability of which varies from country to country. Although thiamphenicol was initially promoted as not inducing aplastic anemia in humans, cases of aplastic anemia have now been identified.[76] Florfenicol is more active than chloramphenicol and thiamphenicol, but has a shorter half-life in dogs and thus requires more frequent dosing (e.g., more often than every 8 hours) in this species. It was developed for food animal species where use of chloramphenicol is illegal.

Resistance to chloramphenicols results from porin mutations, drug efflux, or production of chloramphenicol acetyltransferase enzymes, which inactivate the antibiotic.[77] Resistance to one chloramphenicol derivative predicts resistance to the others.

Clinical Use

Doses are shown in Table 8-12. Chloramphenicol is absorbed orally with or without food. Tablets and capsules have similar oral absorption, but the extent of oral absorption varies

VetBooks.ir

considerably among dogs. Chloramphenicol distributes well to extracellular fluids of most tissues. Because of its high degree of lipid solubility, it also diffuses to tissues with barriers, such as the CNS and the eye. Topical ophthalmic preparations achieve high concentration in the aqueous humor. In dogs, most absorbed chloramphenicol is metabolized by glucuronidation in the liver, with inactive metabolites excreted by the kidney. The use of chloramphenicol should therefore be avoided in animals with hepatic failure. Provided renal failure is not present, sufficient active drug is excreted in the urine to enable treatment of UTIs that are resistant to other drugs, such as methicillin-resistant staphylococci and resistant enterococci.

Adverse Effects

Exposure of humans to even small amounts of chloramphenicol has the potential to lead to irreversible aplastic anemia, an idiosyncratic reaction, weeks to months after discontinuing treatment. The reaction is rare (1 in 24,000 to 1 in 40,000 exposed humans) and most commonly occurs when human patients are treated with oral formulations.[78] Whether use of ophthalmic preparations in human patients poses a risk has been controversial.[79] Nevertheless, it is recommended that owners of pets that are being treated with chloramphenicol wear gloves when handling the drug and to avoid splitting tablets at home. Chloramphenicol commonly causes gastrointestinal adverse effects in dogs and cats, including anorexia, hypersalivation, and vomiting. High doses or prolonged treatment can result in *reversible* bone marrow suppression, which usually resolves within days after discontinuation of treatment. High doses and prolonged treatment are needed to produce this effect in dogs, but cats are more susceptible and can be at risk within 2 weeks of administration. Chloramphenicol is a potent inhibitor of P450 enzymes, and so the potential for significant drug interactions exists. Florfenicol has not been widely used in dogs and cats, and adverse effects have not yet been reported.

Macrolides and Lincosamides

Classification and Mechanism of Action

The macrolides and lincosamides (clindamycin and lincomycin) are not chemically related but possess similar mechanisms of action, resistance, and antimicrobial activity. Macrolides and lincosamides inhibit protein synthesis by binding to the 50S subunit of bacterial ribosomes. Because they are weak bases, they concentrate in the relatively acidic interior of leukocytes. The high concentrations in leukocytes may also produce immunomodulatory effects. Macrolides, particularly the newer agents such as azithromycin, can impair leukocyte function, interfere with superoxide production by mast cells, suppress proinflammatory cytokine release, and produce apoptosis.[80,81] These effects may suppress inflammatory reactions in some tissues, but the significance of these effects has not been explored in small animal infections.

The first macrolide antibiotic to be discovered was erythromycin, a derivative of *Streptomyces erythreus*. Despite the common occurrence of gastrointestinal adverse effects, poor gastrointestinal absorption, and an extremely short half-life, erythromycin continues to have application in human medicine because of its safety in pregnancy and utility in human patients who are allergic to penicillin. Because these concerns are less important in dogs and cats, erythromycin is less commonly used in small animal patients.

Since the discovery of erythromycin, several semisynthetic macrolides have become available. Azithromycin and other new macrolide antibiotics, such as clarithromycin and roxithromycin, have been referred to as "advanced-generation" macrolides. These have an extended spectrum of activity, with greater efficacy against atypical and some gram-negative bacteria, a longer duration of antimicrobial activity, … improved gastrointestinal absorption, greater intracellular concentrations, and a marked reduction in gastrointestinal adverse effects. Clarithromycin has improved activity against streptococci and staphylococci compared with erythromycin.

Azithromycin is an *azalide*, because unlike other macrolides, it contains nitrogen. Azithromycin is extensively concentrated within cells and is retained in tissues for prolonged periods, with a half-life of 30 hours in the dog and 35 hours in the cat. In human patients, a 5-day course provides therapeutic tissue concentrations for at least 10 days. Although azithromycin has an improved spectrum against gram-negative bacteria, it has less activity against gram-positive bacteria than erythromycin.[82,83]

Susceptibility to erythromycin often predicts susceptibility to other macrolide antimicrobial drugs. Resistance to macrolides and lincosamides results from decreased bacterial permeability (for gram-negative bacteria), alteration in the target site, increased drug efflux, and enzymatic inactivation of certain macrolides by bacterial esterases. Alteration in the target site involves production of a ribosomal methylase that adds a methyl group to the 50S subunit RNA, preventing the macrolide from binding to the ribosome. Expression of the methylase enzyme confers high-level resistance to azithromycin, clarithromycin, and also clindamycin.

Clinical Use

Macrolides and lincosamides are primarily used to treat gram-positive bacterial infections. They are generally considered to be bacteriostatic. Doses are shown in Table 8-13. Erythromycin tablets have a protective coating to prevent degradation by gastric acid. After absorption, erythromycin is distributed well to most tissues and body fluids, with the exception of the CNS and urine. It is excreted in high concentrations in bile, followed by enterohepatic circulation, and ultimately eliminated in the feces. Non-absorbed drug is also present in the feces. It has activity against some anaerobes, spiral bacteria (particularly *Campylobacter*), and many intracellular bacteria. Tylosin has been used to treat chronic colitis in dogs[84] and is also active against *Campylobacter* and enteric *Clostridium* spp.

Clarithromycin and azithromycin have considerably longer half-lives than erythromycin. The intracellular concentration of clarithromycin is about two- to sixfold that in plasma. Clarithromycin is preferred over erythromycin or azithromycin for treatment of rapidly growing mycobacterial infections in dogs and cats (usually in combination with rifampin) (see Chapter 44). In humans, clarithromycin is extensively metabolized by the liver to a variety of specific active and inactive metabolites, with some excretion of active drug and its metabolites into urine. Formation and excretion of these metabolites have not been well studied in dogs and cats. Azithromycin is largely excreted unchanged in bile.

Because of its prolonged tissue retention, serum concentrations of azithromycin do not reflect tissue concentrations, and so the antibiotic can still be effective even if the serum concentration is less than the MIC. Intracellular concentrations of azithromycin are 10- to 100-fold those in serum, concentrations that are considered bactericidal. Concentrations can remain high within tissues several days after the drug has been

VetBooks.ir

TABLE 8-13

Suggested Macrolide and Lincosamide Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Erythromycin	10-20	8	D, C	PO	Do not administer to rabbits or rodents, as this may cause fatal diarrhea. Drug interactions may occur (see text).	≤0.25 for streptococci and ≤0.5 for other susceptible organisms
Tylosin	7-15 8-11	12-24 12	D, C	PO IM	See erythromycin. For colitis in dogs, use 20 mg/kg q8h with food, and taper to q24h if a response occurs.*	
Clarithromycin	7.5	12	D, C	PO	Drug interactions may occur (see text). Consider dosage reduction in severe renal failure.	≤2 for staphylococci. Respiratory cures may be possible for organisms with MICs up to 8, because drug concentrates within the lung.
Azithromycin	5-10	24	D, C	PO		≤ 2 for susceptible bacteria. Serum MIC values may not predict tissue concentrations.
Lincomycin hydrochloride	15-25	12	D, C	PO	See erythromycin. A dose of 10 mg/kg PO q12h has been suggested for pyoderma.	0.25 for streptococci and ≤ 0.5 for other susceptible organisms
Clindamycin hydrochloride, clindamycin phosphate	11-33 11 10	12 24 12	D C D, C	PO PO IV, IM	See erythromycin. For IV administration, dilute 1:10 in 0.9% saline and administer over 30-60 minutes. The oral suspension may be unpalatable to cats. For toxoplasmosis, use 25 mg/kg q12h PO.	See lincomycin.

C, Cats; CLSI, Clinical and Laboratory Standards Institute; D, dogs; MIC, minimum inhibitory concentration.
*20 mg/kg is equal to 1/8th teaspoon of tylosin phosphate (Tylan) for a 20-kg dog.

discontinued. Despite the improved spectrum of activity of clarithromycin and azithromycin, with activity against some gram-negative bacteria and intracellular pathogens, many of these organisms are resistant. The primary indication for these antibiotics in small animals is in combination with other drugs such as rifampin for treatment of mycobacteriosis or bartonellosis, or atovaquone for treatment of certain systemic protozoal infections such as babesiosis and cytauxzoonosis. Azithromycin has been used to treat secondary bacterial infections in cats with upper respiratory tract disease because its long half-life permits convenient dosing on an every-48- or every-72-hour basis. Despite its popularity for treating upper respiratory infections in cats, one study showed no benefit to this protocol over use of amoxicillin,[85] and the potential for overuse of azithromycin in this setting raises concerns in regard to selection for resistance to azithromycin.

Lincomycin is active against gram-positive bacteria and has been used to treat staphylococcal pyoderma. However, the use of lincomycin has largely been replaced by clindamycin, which has similar activity, favorable pharmacokinetics, and widely available formulations (tablets, capsules, oral liquid, and injection). Clindamycin is also used to treat anaerobic bacterial infections, as well as toxoplasmosis and neosporosis (see Chapters 72 and 73).

Adverse Effects

Although otherwise very safe, erythromycin frequently causes vomiting, decreased appetite and nausea because of stimulation of receptors of the gastrointestinal hormone motilin, which increases gastrointestinal smooth muscle activity.[86] Like other poorly absorbed oral antimicrobials, it can produce diarrhea due to changes in the gastrointestinal flora. Although diarrhea and pseudomembranous colitis are serious complications of clindamycin treatment in people, these problems are uncommon in small animals. Adverse effects are rarely reported for clarithromycin and azithromycin. Erythromycin and azithromycin inhibit P450 enzymes and so can increase the concentration of other drugs that are administered concurrently.

Clindamycin and lincomycin can cause vomiting and diarrhea, especially when clindamycin is used at high doses. Oral clindamycin hydrochloride can cause esophagitis in cats.[87,88]

TABLE 8-14

Suggested Linezolid Dose for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (µg/mL)
Linezolid*	10	8	D	PO, IV	If administered with other drugs IV, the administration line should be flushed first.	≤4 for staphylococci, ≤2 for *Enterococcus* spp.

CLSI, Clinical and Laboratory Standards Institute; D, dogs.
*The use of linezolid should be reserved for gram-positive infections that are susceptible to linezolid but resistant to all other reasonable alternatives, on the basis of culture and susceptibility testing.

Oxazolidinones (Linezolid)

Mechanism of Action and Spectrum of Activity

Linezolid is a synthetic antibiotic used to treat life-threatening infections caused by gram-positive bacteria that are resistant to other antimicrobial drugs, especially methicillin-resistant and vancomycin-resistant staphylococci. Linezolid binds to the 50S ribosome and prevents formation of the initiation complex for protein synthesis.[89] This is a unique mechanism, because other protein synthesis inhibitors interfere with polypeptide extension. Resistance to other protein synthesis inhibitors does not correlate with resistance to linezolid. Rarely, resistance to linezolid is due to modification of the drug's target site, but this is extremely rare because several step mutations are necessary before resistance can occur. The high cost of oral linezolid currently limits its application in small animals. Currently, its use has been limited to dogs and cats with resistant staphylococcal or enterococcal infections for which other antibiotics are not effective or have produced adverse effects. Linezolid has favorable pharmacokinetics in dogs,[90] with nearly 100% oral absorption, which is not influenced by food (Table 8-14). The pharmacokinetics in cats has not been published. Because linezolid is bacteriostatic, plasma concentrations should be maintained above the MIC throughout the dosing interval.

In human patients, adverse effects include vomiting, diarrhea, and, rarely, thrombocytopenia or reversible pure red cell aplasia (PRCA). Linezolid is a type A monoamine oxidase inhibitor and so can interact with serotonin reuptake inhibitors.[92] Linezolid appears to be well tolerated by dogs and cats. Despite the concern about monoamine oxidase inhibition and bone marrow suppression in human patients, these effects have not yet been documented in dogs or cats, although one of the authors is aware of a cat that developed reversible PRCA after treatment with linezolid.

Tetracyclines

Mechanism of Action

Tetracyclines are bacteriostatic, time-dependent antibiotics that have a broad spectrum of activity that includes gram-positive and gram-negative bacteria, some anaerobes, and atypical and intracellular pathogens such as spirochetes, *Mycoplasma* spp., and rickettsiae. In contrast to the macrolides and clindamycin, which bind to the 50S ribosomal subunit, tetracyclines inhibit bacterial protein synthesis by binding to the 30S subunit. Thus, resistance to macrolides does not imply resistance to tetracyclines. Examples of tetracyclines used to treat dogs and cats are tetracycline, oxytetracycline, and the semisynthetic tetracycline doxycycline. Doxycycline and minocycline are longer-acting tetracyclines that are more lipophilic than the older tetracyclines. Doxycycline and minocycline also have antiinflammatory and immunomodulatory properties that result from inhibition of inducible nitric oxide synthase and proinflammatory cytokines such as TNF-α.[91] These properties have led to the use of tetracyclines for treatment of immune-mediated dermatopathies in dogs[92] and plasmacytic pododermatitis in cats.[93] Delayed-release formulations that produce subantimicrobial doses have been developed for use in human patients with the inflammatory skin disease rosacea. Although development of tetracycline resistance in bacterial flora has not been documented in association with the use of these preparations, the possibility has not been ruled out.[94]

Resistance to tetracyclines primarily results from porin mutations that exclude tetracyclines from the bacterial cell, and increased drug efflux, mediated by the *tetK* gene. Some bacteria with tetK may still be susceptible to minocycline. Resistance mediated by *tetM* confers resistance to all tetracyclines.[95] In diagnostic laboratories, tetracycline is used to assess the susceptibility of bacteria to all other tetracyclines except the glycylcycline antibiotic tigecycline, a new antibiotic derived from minocycline that is reserved for treatment of multidrug-resistant bacterial infections.[96] In addition, resistance to doxycycline does not always imply resistance to minocycline.[97]

Clinical Use

Doses are shown in Table 8-15. Doxycycline is the most commonly used tetracycline in dogs and cats and has fewer adverse effects when compared with other tetracyclines. It is the drug of choice for treatment of a variety of tick-borne infectious diseases, feline chlamydiosis, salmon poisoning disease, and leptospirosis. The long half-life of doxycycline permits once-daily dosing, although twice-daily dosing is frequently recommended. Doxycycline is well absorbed from the gastrointestinal tract and distributed to a variety of tissues, including the lung, bronchial secretions, liver, kidney, and, to some extent, the CNS. If doxycycline is not available, minocycline can be used as a substitute. Minocycline is more lipophilic than doxycycline, it is better absorbed orally, and can be administered at similar doses as doxycycline. Absorption of other tetracyclines from the gastrointestinal tract is not as efficient. All tetracyclines are concentrated in bile. Sufficient drug is excreted in the urine to permit treatment of UTIs caused by bacteria that are resistant to other drugs.

VetBooks.ir

TABLE 8-15

Suggested Tetracycline Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Tetracycline	15-20 4.4-11	8	D, C	PO IV, IM	Do not mix with food containing cations such as calcium, zinc, magnesium, iron, aluminum.	≤2 for streptococci, ≤4 for other susceptible bacteria. Consider use of ≤1 for susceptible bacteria.
Oxytetracycline	20 7.5-10	12	D, C	PO IV	See tetracycline.	See doxycycline.
Doxycycline	5 10	12 24	D, C	PO, IV	For IV administration, dilute in 100 to 1000 mL of LRS or 5% dextrose and administer over 1 to 2 hours.	≤2 for streptococci, ≤0.25 for *Staphylococcus pseudintermedius*, ≤4 for other susceptible bacteria
Minocycline	5-12.5	12	D, C	PO		See doxycycline, but the pharmacokinetics of minocycline in dogs and cats require further study.

C, Cats; CLSI, Clinical and Laboratory Standards Institute; D, dogs; LRS, lactated Ringer solution.

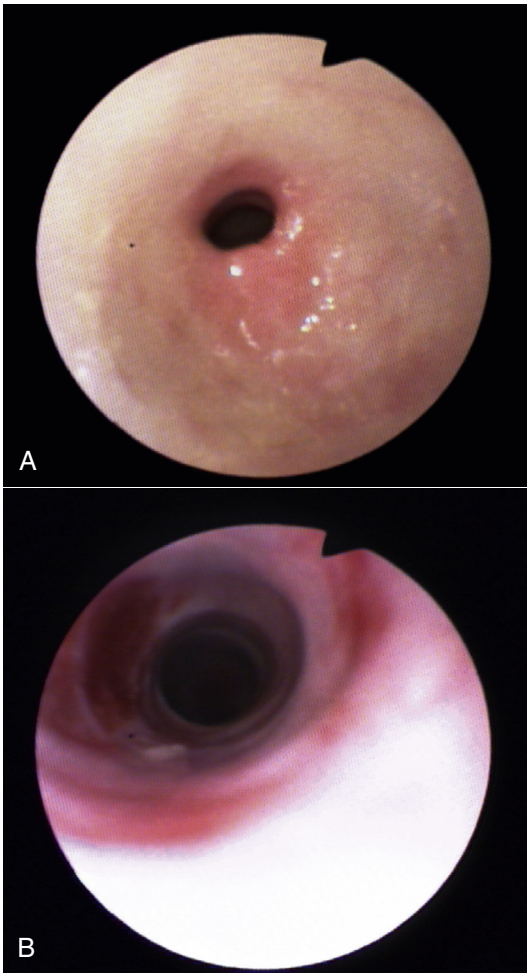

FIGURE 8-4 **A,** Esophageal stricture in a 9-year-old female spayed domestic shorthair that had been treated with doxycycline for possible hemoplasmosis. Regurgitation after eating commenced shortly after treatment was initiated. **B,** The stricture was treated via repeated balloon dilatation; the image is immediately after the ballooning procedure was performed.

Adverse Effects

The most common adverse effects of tetracyclines in dogs and cats are vomiting, decreased appetite, nausea, and diarrhea. These may be reduced when doxycycline hyclate tablets are administered intact (rather than being split or crushed) and by administering doxycycline with food. Administration of other tetracyclines with food can lead to significantly reduced drug absorption, because of extensive binding with divalent and trivalent cations in the gastrointestinal tract. The hyclate salt of doxycycline (doxycycline hydrochloride) has been associated with esophagitis and esophageal strictures in cats (Figure 8-4),[98] and life-threatening esophageal ulceration in a dog.[99] This is also a complication in people.[100] A bolus of water or food should be administered immediately after dosing in order to prevent this complication, or a suspension rather than tablets should be used. Compounded, high-concentration (e.g., 33.3 mg/mL or 167 mg/mL) suspensions in aqueous vehicles have limited stability; suspensions in some vehicles do not retain their potency beyond 7 days.[101]

In dogs and cats with renal failure, tetracyclines other than doxycycline should be avoided. Doxycycline is excreted in the intestinal tract in this situation. Tetracyclines other than doxycycline can interfere with bone growth and cause significant and permanent gray-brown or yellow discoloration of the teeth (Figure 8-5), and so their use is not recommended in puppies and kittens. Doxycycline is not likely to produce this effect because it binds calcium less avidly. As a result, the use of doxycycline in human pediatric medicine is now accepted.[102] All tetracyclines, including doxycycline, have the potential to cause hepatic failure and renal tubular necrosis. Cutaneous reactions occur rarely in animals treated with tetracycline, but have been reported in humans.

Intravenous preparations of doxycycline are available but can be considerably more expensive than the oral formulations. They must be given over 1 to 2 hours. Thrombophlebitis can occur at the site of injection, and anaphylactic shock has been reported following parenteral administration of tetracycline to a dog.[103]

FIGURE 8-5 Yellow discoloration of the teeth in a "puppy mill" puppy that was presumably treated with tetracycline antibiotics.

CHAPTER 9

Antifungal Drugs

Jane E. Sykes and Mark G. Papich

VetBooks.ir

KEY POINTS

- Compared to antibacterial drugs, the range of antifungal drug classes available is very limited, with most systemic treatment accomplished with the azole group of medications. The azoles have a similar mechanism of action and share other properties such as spectrum of activity, pharmacokinetics, tissue penetration, and adverse effect profiles. Proper understanding of these factors is most likely to result in successful treatment with minimal adverse effects.
- Drug interactions occur with many antifungal drugs.
- Although therapeutic drug monitoring would improve treatment with the azole antifungals and 5-flucytosine, this is rarely done because of variable availability of clinical assays and uncertainty in interpretation of the measured concentrations.
- Fungal infections often require prolonged treatment durations. This may be costly for some pet owners and can increase the risk of adverse effects to pets.
- Fungal organisms that are resistant to certain antifungal drugs are increasingly recognized. Although antifungal susceptibility testing can identify resistant organisms, this is often not performed because there are no standards for veterinary pathogens and drugs used in veterinary medicine, and few laboratories perform these tests.

INTRODUCTION

The use of antifungal drugs in human and veterinary medicine has increased in recent years. In humans, increased susceptibility to fungal infections has arisen because of immunosuppression secondary to HIV infection or treatment with potent immunosuppressive drugs. In animals, opportunistic fungal infections also result from immunosuppression, and the importance of fungal infections in dogs and cats is increasingly recognized. Antifungal drugs used in dogs and cats are generally not approved for use in these species. Therefore, veterinarians use human antifungal drugs off-label, with indications and dosing protocols often extrapolated from the human use. Because of differences in pharmacokinetics among species for these drugs, and differences in susceptibility to adverse effects in dogs and cats compared to people, this approach is not optimal. Fortunately, the clinical experience and pharmacokinetic data have expanded for these human drugs, which will improve antifungal treatment in animals. Efforts also have focused on the development of new, less toxic, and more efficacious antifungal drugs. This chapter reviews the classification, mechanisms of action, spectrum of activity, resistance mechanisms, tissue penetration, clinical use, and adverse effects of the major systemic antifungal drugs used to treat dogs and cats. Topical antifungal treatments are reviewed in the relevant chapters of this book. Basic principles of antimicrobial drug treatment are discussed in Chapter 6.

Antifungal drug treatment is often more prolonged than antibacterial drug treatment. One reason for this difference is that fungal organisms grow more slowly, and the drugs used (primarily azoles) are fungistatic, not fungicidal. Therefore, long-term treatment is needed to inhibit fungal growth and allow for the animal's immune system, which is often compromised, to eradicate the infection. Treatment of animals with deep mycoses with antifungal drugs must often be continued for months, and in some animals it may be weeks before clinical improvement is evident. Sometimes, disease worsens in the first week of treatment, because of the host's inflammatory response to killed organisms. This may have severe consequences for the host when there is extensive involvement of the pulmonary parenchyma or the central nervous system (CNS). Concurrent treatment with a nonsteroidal antiinflammatory drug (NSAIDs) or, when CNS involvement is present, judicious use of a short course of antiinflammatory glucocorticoids may improve outcome in these situations.[1]

The prognosis for animals with disseminated mold infections that have reversible underlying immunosuppression (such as drug-induced immunosuppression) may be better than the prognosis for animals with no apparent underlying immunosuppressive disease. This is because the latter group of animals are likely to have underlying (irreversible) genetic defects in immunity.

Azole Antifungals

Mechanism of Action, Classification, and Spectrum of Activity

Azole antifungal drugs inhibit sterol 14α-demethylase, a cytochrome P450–dependent fungal enzyme involved in synthesis of ergosterol, a key component of the fungal cell wall, from lanosterol. The result is the accumulation of 14α-methylsterols, which disrupt the fungal cell membrane (Figure 9-1). The majority of the adverse effects and drug interactions observed with these drugs relate to the cross-inhibition of mammalian P450 enzymes. All of the azole antifungals have the potential to be teratogenic, and their use should be avoided in pregnancy.

Azole antifungals are classified as imidazoles or triazoles based on whether they possess two or three nitrogen molecules

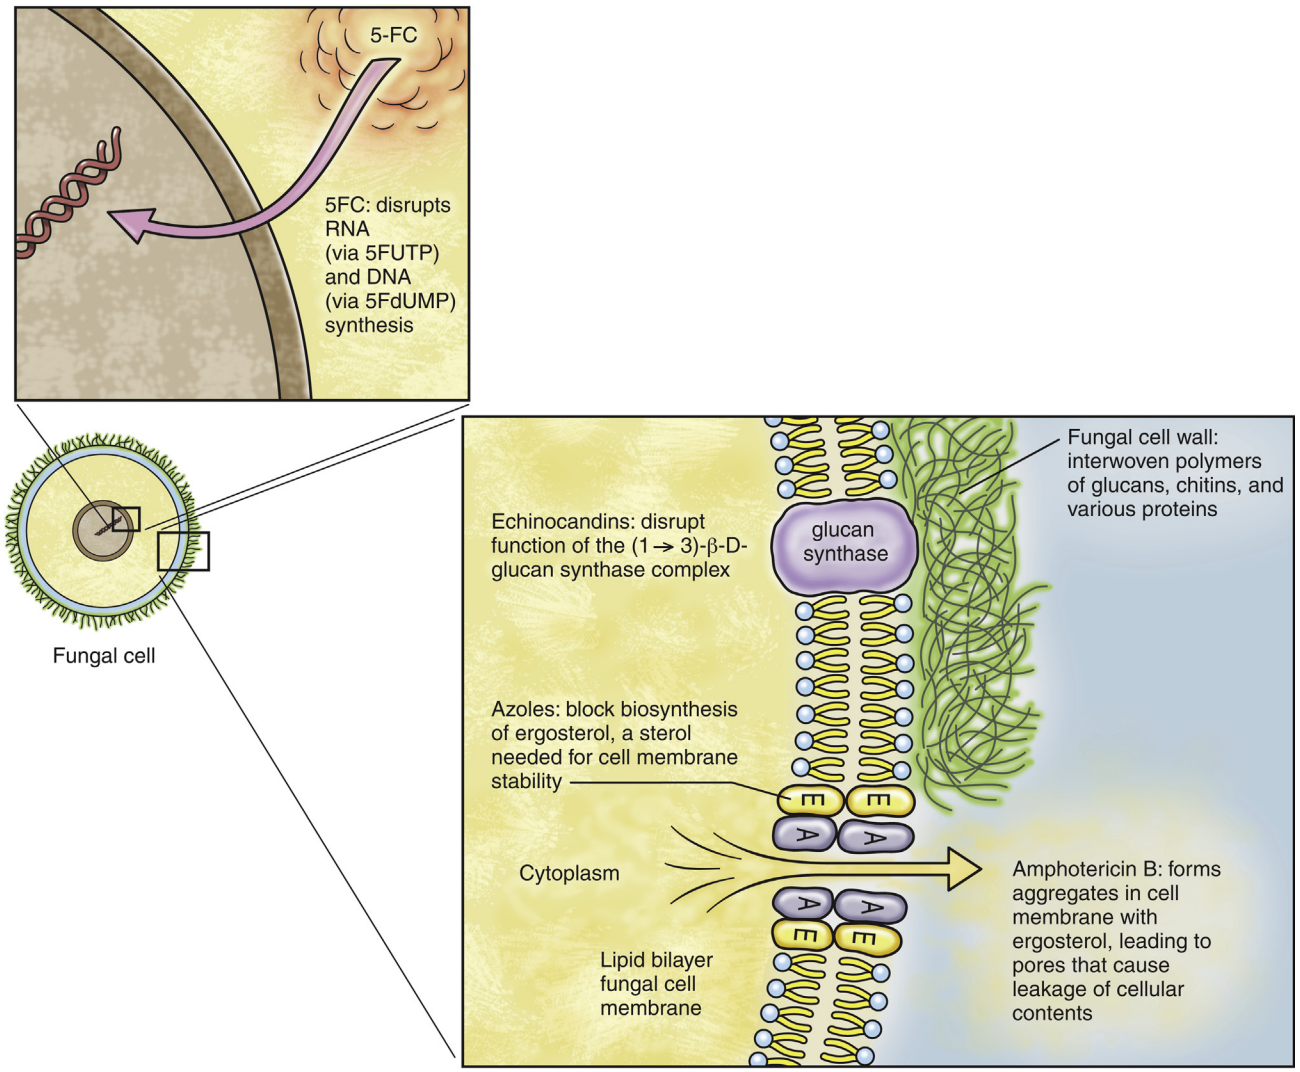

FIGURE 9-1 Mechanism of action of antifungal drugs. 5FC, 5-flucytosine; 5FUTP, 5-fluorouridine triphosphate; 5FdUMP, 5-fluorodeoxyuridine monophosphate; A, amphotericin B; E, ergosterol. Modified from Rex JH, Stevens DA. Systemic antifungal agents. In: Mandell GL, Bennett JE, Dolin R, eds. Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases, 7 ed. Philadelphia, PA: Churchill Livingstone Elsevier; 2011:549-563.

in their azole ring. Ketoconazole, enilconazole, and clotrimazole are imidazoles. The latter two drugs have poor oral bioavailability and are used topically in veterinary medicine for the treatment of superficial mycoses (see Chapters 65 and 67). Triazole antifungal drugs, such as itraconazole and fluconazole, are more slowly metabolized and have less impact on mammalian sterol synthesis than do imidazoles. Imidazoles and triazoles have been widely used to treat a variety of mycoses, which include candidiasis, cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis, dermatophytosis, sporotrichosis, and aspergillosis (Tables 9-1 and 9-2).

Unfortunately, resistance to azole antifungal drugs has emerged among some fungi. Resistance results from mutations in the gene encoding the demethylase enzyme, increased production of C-14α demethylase, and increased azole efflux by fungal cell membrane transporters. Methods for in vitro susceptibility testing have become more standardized,[2,3] with improved correlation between the results of in vitro susceptibility testing and clinical response, but breakpoints (criteria that define susceptible versus resistant minimum inhibitory concentration values) are still needed for many drug-fungus combinations. Increasingly, it is apparent that resistance to one azole does not always imply resistance to other azole antifungal drugs.

Ketoconazole

Spectrum of Activity and Clinical Use

The use of ketoconazole has largely been replaced by itraconazole for treatment of many mycoses, because of the greater toxicity and reduced efficacy of ketoconazole when compared with triazole antifungal drugs. Because of its low cost, ketoconazole continues to be used in veterinary medicine when the cost of other antifungal drugs is prohibitive to the client, and it remains efficacious for treatment of *Malassezia* dermatitis[4] and feline nasal and cutaneous cryptococcosis. The absorption of ketoconazole is improved when it is administered with food, but it is inhibited by concurrent use of antacids. Ketoconazole is highly protein bound and is metabolized extensively by the liver. Nevertheless, moderate hepatic dysfunction does not alter blood levels of ketoconazole. Inactive products are excreted in bile and, to a lesser extent, the urine. Because of poor CNS penetration, it is ineffective for treatment of meningeal cryptococcosis and aspergillosis.[5]

VetBooks.ir

TABLE 9-1

Spectrum of Activity and Tissue Distribution of Different Antifungal Drugs

Drug	Spectrum of Activity	Tissue Distribution
Ketoconazole	Dimorphic fungi, *Malassezia*. Ineffective for aspergillosis	Skin, bone, joint, lung. Poor CNS penetration
Itraconazole	Dimorphic fungi and molds, *Malassezia* spp.	Skin, bone, lung. May enter the CNS and eye with inflammation
Fluconazole	Some *Candida* spp., *Malassezia* spp., some dimorphic fungi. Poor activity against molds. *Aspergillus* spp. are intrinsically resistant	Widely distributed, including to the skin, lung, CNS, urine, and eye
Voriconazole	Dimorphic fungi, yeasts, and molds with the exception of *Sporothrix schenckii* and zygomycetes	CNS, eye, lung, bone
Posaconazole	Dimorphic fungi, yeasts, and molds including zygomycetes	Widely distributed
Amphotericin B	Broad spectrum. Also active against *Leishmania*	Limited penetration of the CNS and eye
5-Flucytosine	*Cryptococcus* and *Candida* spp.	Widely distributed, which includes the CNS, eye, and urine
Griseofulvin	Dermatophytes	Concentrates in skin
Terbinafine	Activity highest for dermatophytes. To a lesser extent may have activity against other dimorphic and filamentous fungi	Concentrates in skin and hair
Caspofungin	*Candida* and *Aspergillus* spp. Not active against *Cryptococcus* spp. or when given alone to treat *Coccidioides*	Widely distributed. Poor penetration of the CNS and eye

CNS, Central nervous system.

TABLE 9-2

Suggested Azole Antifungal Drug Doses for Dogs and Cats

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments
Ketoconazole	10 to 15 5 to 10	12	D C	PO	Do not administer to pregnant animals. Monitor liver enzymes monthly during treatment. Drug interactions may occur (see text). Inhibits adrenal function. Antacids impair absorption.
Itraconazole	5	12 to 24	D, C	PO	Do not administer to pregnant animals. Monitor liver enzymes monthly during treatment. Drug interactions may occur. Use of the oral suspension warrants dose reduction to 3 mg/kg. Monitor serum drug concentrations after 2 weeks if there is inadequate response to treatment (see text). Compounded formulations are unstable.
Fluconazole	5 to 10 50 mg/cat	12 12 to 24	D C	PO	Do not administer to pregnant animals. Monitor liver enzymes monthly during treatment. Drug interactions may occur.
Voriconazole	4 to 5	12	D	PO	Do not use in cats. Use cautiously in animals with liver disease. Also see fluconazole. Consider therapeutic drug monitoring (see text).
Posaconazole	5 to 10 5	12 to 24 24	D C	PO	Absorption may be improved when daily dose is split into 2 to 4 doses. Consider therapeutic drug monitoring. Also see fluconazole. Antacids impair absorption.

C, Cats; D, dogs.

Adverse Effects

The most common adverse effects of ketoconazole in dogs and cats are vomiting, anorexia, lethargy, and diarrhea.[6,7] Administration of ketoconazole with food may reduce gastrointestinal adverse effects. Mild increases in the activity of serum transaminases occur commonly during treatment, but do not warrant discontinuation of the drug. Less commonly, ketoconazole causes hepatitis, which may be accompanied by anorexia, vomiting, lethargy, increasing activities of serum ALT and ALP, and hyperbilirubinemia. The drug should be discontinued if this occurs and serum chemistry values checked 1 to 2 days later. Hepatitis can occur at any time, and the onset may be extremely rapid. Pruritis and cutaneous erythema have been reported in fewer than 1% of dogs treated with ketoconazole.[6] Lightening of the hair coat color and cataract formation occur rarely.

VetBooks.ir

Ketoconazole is a potent inhibitor of mammalian cytochrome P450 enzymes and efflux transporter proteins such as P-glycoprotein. It also inhibits testosterone and cortisol synthesis. As a result, it has been used to treat pituitary-dependent hyperadrenocorticism in dogs[8] and also to deliberately inhibit the metabolism of cyclosporin, allowing a reduction in dose and, therefore, cost,[9] although there are concerns about whether use of ketoconazole in this way could contribute antifungal drug resistance and it increases the risk of adverse drug reactions. Transient infertility can occur during treatment of intact male animals. Ketoconazole can interfere with P-glycoprotein transport of ivermectin, which predisposes dogs to ivermectin toxicity.[6,10]

Itraconazole

Spectrum of Activity and Clinical Use

Itraconazole is one of the most widely used azoles in veterinary medicine. It has been used to treat blastomycosis, sporotrichosis, aspergillosis, coccidioidomycosis, dermatophytosis, histoplasmosis, phaeohyphomycosis, paecilomycosis, cryptococcosis, and *Malassezia* infections. It is available in capsules (which contain itraconazole granules) and an oral solution. The IV solution has been withdrawn.[11] Itraconazole in capsules is best absorbed when given with food because the acid secretion stimulated with feeding increases the drug solubility, which is necessary for dissolution and absorption. However, the oral solution is complexed with cyclodextrin to improve solubility, and administration of food does not influence absorption of this formulation. Absorption of the oral solution is consistently better than absorption of the capsule formulation, regardless of feeding.[12] As with ketoconazole, concurrent administration of gastric acid suppressants (H_2-blockers, proton pump inhibitors) may reduce absorption of the oral capsule. In cats, the oral solution is very well absorbed, and dose reduction is indicated to reduce the chance of toxicity (see Table 9-2). In addition to hydroxypropyl-β-cyclodextrin, this formulation contains sorbitol, propylene glycol, hydrochloric acid, cherry flavor, and saccharin, which may be unpalatable for cats. In Europe and Canada an oral solution for cats is available (Itrafungol, 10 mg/mL). Compounded formulations prepared by pharmacists have highly variable, poor, and even negligible oral absorption in animals, in addition to being unstable formulations. As a result, compounded formulations should never be used.

Like ketoconazole, itraconazole undergoes hepatic metabolism and inhibits metabolism of other P450-dependent drugs (e.g., cisapride, diazepam, cyclosporin). It is the only triazole antifungal drug that is converted to an active metabolite, hydroxylitraconazole.[11] Itraconazole is highly (99%) plasma protein bound and does not appear in urine, cerebrospinal fluid (CSF), or ocular tissues, although penetration of the CSF and eye can occur in the presence of inflammation. Itraconazole accumulates in the skin and claws and is the drug of choice for treatment of dermatophytosis in cats. Itraconazole is also a good choice for treatment of fungal osteomyelitis. Although loading doses have been recommended, these initial high doses can increase the risk of toxicity and do not appear to improve outcome.[13] Advanced liver disease increases itraconazole concentrations. Because of the variable absorption of oral itraconazole, monitoring of steady-state plasma concentrations (e.g., 3 weeks after initiating treatment) may be helpful if clinical responses are suboptimal.[14] Trough plasma itraconazole concentrations should be 0.5 to 1 μg/mL as determined using high-performance liquid chromatography.[15,16]

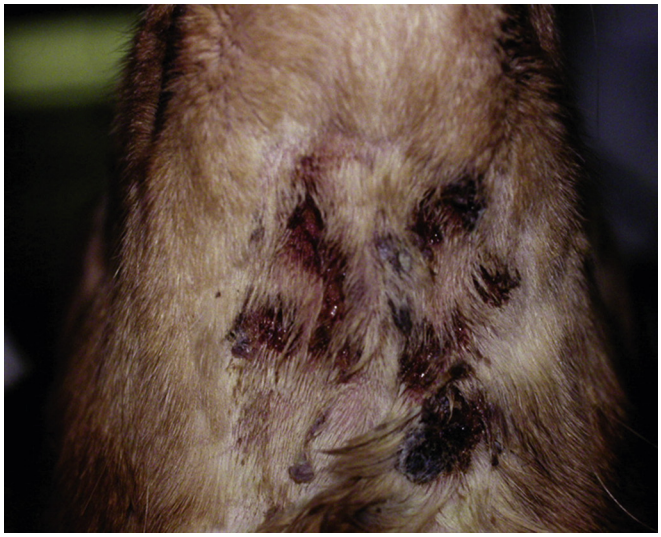

FIGURE 9-2 Submandibular ulcerative skin lesions in a golden retriever that had been treated with itraconazole for systemic blastomycosis.

Adverse Effects

The most common adverse effects of itraconazole in dogs and cats are vomiting and anorexia. Division of the total dose for twice-daily administration has been associated with decreased gastrointestinal signs and improved absorption in human patients.[5] Gastrointestinal adverse effects may be more common with the oral solution. Mild to moderate increases in serum ALT activity commonly occur during treatment. Provided these are not accompanied by inappetence, treatment need not be discontinued. Significant hepatotoxicity, accompanied by anorexia, vomiting, and hyperbilirubinemia, is less likely to occur than with ketoconazole but has been reported in humans as well as cats and dogs.[13,17-19] Hepatotoxicity more commonly occurs in dogs treated with 10 mg/kg/day.[13] Ulcerative skin lesions can occur in dogs, especially when doses of 10 mg/kg/day or higher are used (Figure 9-2). Development of hepatitis or severe cutaneous ulceration should prompt discontinuation of the drug. It may be possible to reinstitute treatment at a lower dose once the adverse effects have resolved. Occasionally mild, focal cutaneous ulcerative lesions can resolve spontaneously, without discontinuation of treatment.

Itraconazole does not suppress adrenal and testicular function like ketoconazole, but can inhibit the metabolism of other P450 enzyme-dependent drugs, including cyclosporine, digoxin, cisapride, and vinca alkaloids. It can also interfere with P-glycoprotein transport of ivermectin, which results in increased plasma ivermectin concentrations.[20]

Fluconazole

Spectrum of Activity and Clinical Use

Fluconazole is the least active azole antifungal drug and has the narrowest spectrum. The activity of fluconazole is limited to some *Candida* spp., *Cryptococcus* spp., *Malassezia* spp., and some dimorphic fungi. Fluconazole has poor activity against molds, and *Aspergillus* species are intrinsically resistant to fluconazole. Some *Cryptococcus* isolates are resistant to fluconazole, and resistance can develop during treatment. Itraconazole is preferable to fluconazole for treatment of histoplasmosis, blastomycosis, sporotrichosis, and dermatophytosis, although

VetBooks.ir

fluconazole has been successfully used to treat coccidioidomycosis, blastomycosis, and *Malassezia* infections in dogs.[19]

Fluconazole is available as tablets, an oral suspension, and as an IV solution. The availability of generic fluconazole has greatly reduced its cost and increased its use in veterinary medicine. Approved generic fluconazole tablets are bioequivalent to the brand name formulation in people. Similar bioequivalence is likely in animals. Fluconazole is more water-soluble and stable than itraconazole, and the compounded oral suspensions can be used in animals with a 14-day beyond-use-day (BUD). Some compounded preparations may have reduced activity. Fluconazole is almost completely absorbed after oral administration, and bioavailability is not altered by food or gastric acidity. In contrast to itraconazole and ketoconazole, fluconazole is only weakly protein bound. Because it is more water soluble than other azoles, fluconazole diffuses into body fluids such as saliva, urine, synovial fluid, and CSF. Therefore, it is the drug of choice for treatment of susceptible meningeal and urinary tract fungal infections. Renal excretion accounts for more than 90% of the elimination of fluconazole. The dosage should be decreased in animals with renal failure; this is especially important in patients receiving other P450-dependent drugs.

Adverse Effects

Adverse effects of fluconazole are uncommon to rare. When they occur, they are similar to those of itraconazole and include vomiting, anorexia, diarrhea, and increased liver enzymes. Dogs that fail to tolerate itraconazole may tolerate fluconazole without increases in liver enzymes.[19] Cutaneous rash, cytopenias, and retinal edema with impaired vision have been reported in human patients.[21,22] In contrast to itraconazole, cutaneous ulceration has not been reported in dogs.

Voriconazole

Spectrum of Activity and Clinical Use

Voriconazole is a second-generation triazole that is derived from fluconazole. In humans, it is the drug of choice for treatment of invasive aspergillosis.[23] It is also used to treat serious and refractory mold infections caused by *Scedosporium* spp., *Paecilomyces* spp., and *Fusarium* spp. Voriconazole is at least as active as itraconazole against veterinary isolates of *Cryptococcus* spp., *Candida* spp., and *Aspergillus fumigatus*.[24] It is not active against *Sporothrix* spp. or the zygomycetes.

Voriconazole is available as a tablet, an oral suspension, and an IV solution in a sulfobutylether–β-cyclodextrin base. Like fluconazole, it has excellent oral bioavailability, but its absorption is significantly reduced in the presence of food. Voriconazole is poorly water soluble and moderately protein bound. It is extensively metabolized by hepatic cytochrome P450 enzymes and eliminated into bile. The degree to which active drug enters the urinary tract in dogs is not clear. It has good CNS penetration. Voriconazole has been used with some success to treat systemic mold infections in dogs.[25] If therapeutic drug monitoring can be performed, the recommended trough concentration target is between 1 and 5 mg/L, and peak concentrations below 6 mg/L.[15,16,23]

Adverse Effects

In humans, adverse effects of voriconazole include reversible visual effects such as photophobia and blurred vision, hallucinations, peripheral neuropathies, and photosensitization, as well as the same toxicities as other triazoles. Of all the triazoles, it is the most potent inhibitor of P450 enzymes. Voriconazole can induce its own metabolism over time.[26] Because of its high cost, adverse effects have not been well documented in dogs. The author has observed inappetence, increased serum liver enzyme activities, and, uncommonly, CNS signs, including ataxia and staring. Tachypnea and marked pyrexia after IV infusion was observed in one dog. Cats are extremely sensitive to adverse effects of voriconazole and predictably develop inappetence, as well as ocular and CNS signs that have included ataxia, pelvic limb paresis, mydriasis, apparent blindness, decreased pupillary light responses, and a decreased menace response.[27] Cardiac arrhythmias and hypokalemia also occur in cats. A safe dose has not been established for cats.

Posaconazole

Posaconazole is an itraconazole analogue that has demonstrated good efficacy for treatment of several refractory deep mycoses in animals, which includes aspergillosis and mucormycosis in cats and invasive aspergillosis in dogs.[25,28-30] It has the broadest spectrum of activity of all the azoles. Its spectrum of activity is similar to that of voriconazole, but also includes the zygomycetes.[11] Posaconazole is available as an oral suspension. As with itraconazole, its absorption is *promoted* by the concurrent presence of fatty food. Gastric acid suppression can reduce the bioavailability of posaconazole.[31] Absorption is improved when the total daily dose is divided into two to four doses.[32] Therapeutic drug monitoring is recommended in human patients; target peak concentrations are greater than 1.48 mg/L.[15,16] Posaconazole is highly protein bound (>95%) and undergoes hepatic metabolism, with some inhibition of P450 enzymes. Most administered posaconazole is eliminated in the feces. Data on CSF concentrations of posaconazole are not yet available but it appears to be effective for treatment of CSF cryptococcosis. Adverse effects are less common in cats when compared with voriconazole, but information is limited at the time of writing.[28-30,33]

Other Azole Antifungals

Other azole drugs that are undergoing clinical trials in humans are ravuconazole and isavuconazole. Ravuconazole is a fluconazole derivative with good oral bioavailability. Isavuconazole is a water-soluble triazole with a spectrum similar to that of posaconazole but is available in oral and IV formulations. It is metabolized by P450 enzymes and does not achieve therapeutic concentrations in the urine. The CNS penetration of isavuconazole has not yet been evaluated.[34]

Amphotericin B

Mechanism of Action and Spectrum of Activity

Amphotericin B (AMB) is a polyene macrolide antibiotic produced by *Streptomyces nodosus*. It is closely related to nystatin. AMB irreversibly binds sterols in fungal cell membranes, forming pores or channels with subsequent leakage of ions. Although generally considered to be fungistatic, at high doses it may be fungicidal. AMB also possesses immunomodulatory effects; it activates macrophages and enhances macrophage-killing capacity. This may help explain its efficacy against pathogens such as *Pythium insidiosum*, which lack cell wall ergosterol.

Amphotericin B has antifungal activity against all of the important small animal fungal pathogens. It is also active against *Leishmania* spp.[35,36] In human medicine, AMB is the preferred drug for treatment of rapidly progressive mycoses,

VetBooks.ir

BOX 9-1

Suggested Amphotericin B Infusion Protocols for Dogs and Cats

Formulation	Protocol
All formulations	Obtain baseline CBC, kidney panel, and UA and ensure adequate hydration before starting treatment. Recheck a kidney panel before each infusion. Administer three times weekly for 4 weeks or until azotemia is detected. For some patients, monthly administration of a single dose may be required to maintain remission.
Amphotericin B deoxycholate (IV route)	Reconstitute vial contents in sterile water to 5 mg/mL. Administer 0.9% NaCl IV at 1.5-2 times the calculated maintenance rate for 1 hour before and after AMB treatment. Ensure lines are flushed with D5W before infusing AMB. Dogs: Transfer 0.5 mg/kg to a 250-mL to 1000-mL bag of D5W (total fluid volume administered should be based on body weight and ability to tolerate a fluid load). Administer IV over 4-6 hours. Cats: Dilute 0.25 mg/kg in 30 mL of D5W and administer IV over 30 minutes to 1 hour.
Amphotericin B deoxycholate (SC route)	Transfer 0.5 mg/kg (cats) or 0.8 mg/kg (dogs) to bag containing 400 mL (cats) or 500 mL (dogs) of 0.45% sodium chloride in 2.5% dextrose. Administer subcutaneously. Fractious cats may need to be sedated or placed in a restraint bag. Sterile injection site abscess formation may occur with this protocol, especially with concentrations of amphotericin B > 20 mg/L.
Amphotericin B lipid complex (Abelcet)	Dilute to 1 mg/mL in D5W. Administer calculated dose IV over 1 to 2 hours. Dogs: 3 mg/kg Cats: 1 mg/kg

AMB, Amphotericin B; D5W, 5% dextrose in water; UA, urinalysis.

immunosuppressed hosts, or fungal meningitis. Resistance to AMB is rare, although high minimum inhibitory concentrations have been observed for some molds, including some isolates of *Aspergillus terreus*, *Paecilomyces* spp., and *Scedosporium* spp., as well as *Sporothrix schenckii*. The mechanism of resistance is not well understood, but it may relate to decreased cell wall ergosterol content.[37]

Clinical Use

Amphotericin B has poor aqueous solubility and is not absorbed from the gastrointestinal tract, so it is formulated for IV infusion in lyophilized form as a complex with the bile salt deoxycholate (Fungizone, AMB-D) (Box 9-1). The complex forms a colloid in water. Addition of electrolytes to the solution causes it to aggregate, so it is administered in 5% dextrose (D5W). It is not necessary to protect the infusion from light, as recommended in the past. In the bloodstream, AMB dissociates from deoxycholate and binds extensively to plasma proteins and cholesterol in membranes throughout tissues. Penetration of the vitreous humor and CSF is poor, but some animals with CNS infections still respond to treatment. In human patients, AMB-D has been given intrathecally to treat fungal meningitis and intraocularly following vitrectomy.[38]

A protocol for subcutaneous administration of AMB-D has been reported for treatment of cryptococcosis,[39] which may be less costly than IV administration. Sterile injection site abscesses occur in some animals treated using this protocol, so IV administration is preferred if possible.

Adverse Effects

The major adverse effect of AMB-D is nephrotoxicity, which is dose dependent and transient if it is detected early and the drug is discontinued. Both an acute effect caused by renal vasoconstriction and a chronic cumulative effect from repeated administration occurs. Renal tubular acidosis, nephrogenic diabetes insipidus, hypokalemia, and hypomagnesemia uncommonly occur with treatment. Rarely, aggressive IV fluid therapy and potassium supplementation to counteract these may be required. Loading with sodium before the infusion may decrease nephrotoxicity.[40] Slow administration in a large volume of fluid also decreases nephrotoxicity. Concurrent use of other nephrotoxic drugs, such as aminoglycosides, should be avoided. In humans, AMB-D can also cause fever, chills, headache, nausea, vomiting, and, rarely, cytopenias and anaphylaxis.[40] Fever, inappetence, and vomiting also appear to occur in some dogs treated with AMB-D. Phlebitis can occur at the IV infusion site. Other adverse effects noted in humans include infusion-related hypotension and hypochromic, normocytic anemia. NSAIDs can be administered to decrease pyrexia during treatment.

Lipid Formulations of Amphotericin B

Three lipid formulations of AMB are marketed in the United States. These are less nephrotoxic than AMB-D but are considerably more expensive. Decreased nephrotoxicity results from a reduced rate of transfer of AMB to mammalian cell membranes and increased drug clearance from the blood by the mononuclear phagocyte system. This allows administration of a higher dose of the drug, sometimes with improved treatment efficacy. Nevertheless, renal function should still be monitored.

Amphotericin B colloidal dispersion (ABCD, Amphotec) contains AMB and cholesterol sulfate, which form disc-shaped particles. It is more likely to cause chills, fever, and hypotension in humans than AMB-D (80% compared with 12% for AMB-D), so it is given over 3 to 4 hours and with premedication.

Liposomal amphotericin B (Ambisome) is a widely used formulation for treatment of human patients. It consists of AMB and a lipid mixture (phosphatidylcholine, cholesterol, and distearoyl phosphatidylglycerol). After reconstitution in D5W, it forms 80-nm vesicles. Nephrotoxicity and infusion-related reactions are much less common with liposomal amphotericin B than with ABCD or AMB-D, and the drug appears to reach higher concentrations in the eye.[41] In human patients, it is used as salvage therapy for aspergillosis, cryptococcosis, and candidiasis.

VetBooks.ir

TABLE 9-3

Suggested 5-Flucytosine Drug Doses for Cats

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments
5-Flucytosine	25 to 50	6 to 8	C	PO	Monitor CBC. Use cautiously in animals with impaired renal function. Avoid use in dogs. Serum concentration monitoring is recommended in humans.

C, Cats.

Amphotericin B lipid complex (ABLC, Abelcet) is a mixture of AMB, dimyristoyl phosphatidylcholine, and dimyristoyl phosphatidylglycerol that forms ribbon-like sheets. ABLC is the most common formulation used in veterinary medicine. In humans, nephrotoxicity and infusion-related reactions are intermediate between AMB-D and liposomal amphotericin B. ABLC has been used in small animals to treat refractory cryptococcosis and cryptococcal meningitis and disseminated coccidioidomycosis, aspergillosis, blastomycosis, histoplasmosis, and pythiosis.

AMB cochleates are phosphatidylserine-calcium precipitates in the form of a continuous lipid bilayer sheet rolled up in a spiral. This formulation permits oral administration of AMB. Cochleates have been effective when used to treat mouse models of candidiasis and aspergillosis without significant toxicity. They remain under investigation on a research basis.

5-Flucytosine

Mechanism of Action and Spectrum of Activity

Flucytosine is a fluorinated pyrimidine related to fluorouracil. It has activity only against *Cryptococcus* spp. and *Candida* spp. These fungi deaminate flucytosine to 5-fluorouracil, which interferes with DNA replication and protein synthesis. Mammalian cells cannot convert flucytosine into 5-fluorouracil, so toxicity to mammalian cells is limited. Marked drug resistance arises during treatment (secondary drug resistance), and so flucytosine must always be used in combination with other drugs, most commonly AMB. Flucytosine may be synergistic with AMB. Resistance results from modifications in fungal enzymes that are required for flucytosine uptake and metabolism.[37]

Clinical Use

Flucytosine is absorbed rapidly and well from the gastrointestinal tract and is minimally bound to plasma proteins. Penetration of the CSF and aqueous humor is excellent. In cats, flucytosine may be considered to treat severe or refractory cryptococcosis in combination with other agents. Because about 80% of the dose is excreted unchanged in the urine, high urinary concentrations can be achieved. For the same reason, flucytosine toxicity is greatly increased in animals with renal failure, so the drug should be avoided in these animals or the dose lowered and plasma drug concentrations monitored carefully (Table 9-3). In human patients, toxicity is correlated with 2-hour postpill concentrations greater than 100 mg/L, and concentrations of 30 to 80 mg/L are suggested for treatment of cryptococcosis.[15] Because AMB can cause impaired renal function, careful monitoring for toxicity is indicated when flucytosine is used in conjunction with AMB. The use of flucytosine in animals has mostly been limited by its high cost.

Adverse Effects

Administration of flucytosine should be avoided in dogs, which often develop a severe (but reversible) drug eruption within 2 to 3 weeks of starting treatment. The most common adverse effects of flucytosine in cats are myelosuppression and gastrointestinal signs. The CBC should be monitored during treatment, and therapeutic drug monitoring should be considered. Myelosuppression is more likely to occur in human patients receiving other myelosuppressive drugs. Other adverse effects in humans include rash and reversible increases in liver enzyme activities. Flucytosine toxicity may result from conversion of flucytosine to 5-fluorouracil by the intestinal microflora.

Griseofulvin

Mechanism of Action and Spectrum of Activity

Griseofulvin is an oral antifungal drug derived from *Penicillium griseofulvum* that binds to fungal tubulin, leading to impaired microtubule function and mitotic arrest. It also has antiinflammatory properties.[42] After administration, griseofulvin is rapidly deposited in keratin precursor cells in the skin and hair, but disappears from the stratum corneum within 48 to 72 hours of discontinuation of treatment. Griseofulvin is fungistatic and has a limited spectrum of activity. It is used primarily to treat dermatophytosis and is not effective against yeasts such as *Candida* spp. and *Malassezia* spp. Resistance has been documented in some dermatophytes and may be due to altered tubulin.

Clinical Use

The absorption of griseofulvin is increased when it is administered with a fatty meal or whole milk. The drug is available in microsized and ultramicrosized formulations, which improve absorption from the stomach and small intestine. Most veterinary preparations are microsized. The dose of the ultramicrosized formulation can be reduced by 50%, because of improved absorption, but efficacy remains unchanged (Table 9-4). Prolonged treatment periods (months) are required for dermatophytosis (see Chapter 58).[43]

Adverse Effects

Griseofulvin is a potent inducer of cytochrome P450 enzymes and so decreases the efficacy of other drugs that are metabolized to inactive metabolites by P450 enzymes. It is teratogenic, so it should not be used to treat pregnant animals. Other adverse effects of griseofulvin include inappetence, vomiting, and diarrhea. In cats, it can cause myelosuppression, which is generally reversible on discontinuation of treatment, but irreversible pancytopenia has been reported.[44] Myelosuppression may be more likely to occur in cats with FIV infection.[45] The CBC should be monitored every 2 weeks during treatment.

VetBooks.ir

TABLE 9-4

Suggested Griseofulvin and Terbinafine Doses for Dogs and Cats

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments
Griseofulvin (microsized)	25	12	D, C	PO	Administration with fatty food improves absorption. Dose may be increased to 50 mg/kg q12h for refractory infections. Avoid in cats with FIV infections. Do not use in pregnancy. Drug interactions possible. Monitor CBC.
Griseofulvin (ultramicrosized)	15	12	D, C	PO	Avoid in cats with FIV infections. Do not use in pregnancy. Drug interactions possible. Monitor CBC.
Terbinafine hydrochloride	30 to 40	24	D, C	PO	Administer with food.

C, Cats; D, dogs.

Terbinafine

Mechanism of Action and Spectrum of Activity

Terbinafine is a synthetic allylamine that inhibits fungal squalene epoxidase, which blocks fungal lanosterol and ergosterol synthesis and leads to accumulation of toxic squalene, with resultant fungal cell lysis. It is most effective for treatment of dermatophytosis. It has also been used to treat *Malassezia* spp. dermatitis in dogs.[46] The efficacy of terbinafine for treatment of invasive fungal infections has not been well investigated. It has been used both successfully[47] and unsuccessfully[48] in combination with other drugs to treat pythiosis in dogs, and as an alternative to itraconazole to treat human sporotrichosis.[49] It also has in vitro activity against other dimorphic fungi and molds, although its activity is highest for dermatophytes.[50,51] Terbinafine may be synergistic when administered with other antifungal drugs, which may provide enhanced efficacy for treatment of refractory mycoses.[52] However, nondermatophyte molds including *Aspergillus* spp. and *Fusarium* spp. have been detected in people with onychomycosis that failed to respond to terbinafine treatment.[53] Resistance has been reported in dermatophytes as a result of altered squalene epoxidase.[54]

Clinical Use

Terbinafine is available in tablet form (Lamasil). It is well absorbed in dogs when given with food (see Table 9-4).[55] The drug is highly lipophilic and accumulates in skin, claws, hair, and fat, where it persists for weeks after treatment is discontinued. Hepatic and renal failure increase plasma levels unpredictably, and dosage reduction may be required.

Adverse Effects

Terbinafine is generally well tolerated. Gastrointestinal signs, especially vomiting and increased liver enzyme activities, are uncommon. Facial pruritis has been reported in cats.[56]

Echinocandins

The echinocandins are lipopeptide antifungals that inhibit the formation of β-1,3-D-glucans in the fungal cell wall, a mechanism of action that is completely different from that for AMB and the azoles. The prototype drug is caspofungin acetate (Cancidas). Other drugs in this class are micafungin and anidulafungin. Caspofungin is fungicidal against *Candida* spp. and fungistatic against *Aspergillus* species. Treatment with caspofungin induced remission in a dog with disseminated aspergillosis (1 mg/kg IV in 250 mL 0.9% NaCl over 1 hour, q24h).[25] Synergism has been reported when echinocandins are used in combination with other antifungal drugs.[57] The echinocandins are ineffective against *Cryptococcus* spp., which possess little glucan synthase, and were only effective for treatment of *Coccidioides* spp. in a mouse model when used in conjunction with AMB.[58] In human patients, caspofungin is approved for treatment of refractory invasive aspergillosis, but it is also effective for mucosal candidiasis.

Caspofungin is given once daily as a slow IV infusion. In human patients, it is extensively protein bound and metabolized slowly by the liver, with some renal excretion. It has limited ability to penetrate the CNS and eye.[59,60] The cost is similar to that of lipid formulations of amphotericin B. Adverse effects noted in humans include fever, phlebitis, and increased activity of serum ALT (<20% of patients). The proper dose and extent to which adverse effects occur in dogs and cats is unknown, but administration of anidulafungin to the dog treated with caspofungin was associated with the development of a severe diffuse urticarial reaction.[25]

Other Antifungal Treatments

In human patients, hyperbaric oxygen therapy has been used to treat some fungal infections in combination with antifungal drugs. Whether this is beneficial or harmful is controversial and requires further study.[61]

CHAPTER 10

Antiprotozoal Drugs

Jane E. Sykes and Mark G. Papich

VetBooks.ir

KEY POINTS

- Antiprotozoal drugs often have a restricted spectrum of activity, although some are also active against bacteria and fungi. Many interfere with enzyme pathways specific to certain protozoal species.
- Treatment with antiprotozoal drugs may not consistently clear an infection.
- Resistance to antiprotozoal drugs is a growing problem among protozoal pathogens.
- Some antiprotozoal drugs have minimal to no adverse effects, whereas for others, adverse effects severely limit use.
- The availability of antiprotozoal drugs is restricted in some countries.

INTRODUCTION

The use of antiprotozoal drugs in dogs and cats is frequently extrapolated from their use in human patients or food animal species. Almost all antiprotozoal drugs are not specifically approved for treatment of protozoal infections in dogs and cats. Some antibacterial and antifungal drugs also have antiprotozoal activity (see Chapters 8 and 9 for the use and adverse effects of these drugs). In vitro activity of antiprotozoal drugs, and monitoring of resistance, is more difficult for antiprotozoal drugs because standardized susceptibility testing is not routinely performed for these pathogens. In addition, many antiprotozoal drugs are designed to be active in the lumen of the intestine for treatment of intestinal protozoal infections and the concentration of active drug in the intestinal lumen after oral administration is difficult to measure. Therefore, the concentration of drug to which these pathogens are exposed is often not known. The activity and dosage regimens of antiprotozoal drugs are often based on the results of clinical trials, rather than concentration-exposure relationships between antiprotozoal drugs and the organism of interest.

Many antiprotozoal drugs are active only against a restricted range of protozoal species. To reflect this, drugs in this chapter are organized into antiprotozoal drugs primarily used for gastrointestinal infections; those with a broad spectrum of activity; those used to treat systemic protozoal infections (such as hepatozoonosis, toxoplasmosis, neosporosis, and sarcocystosis); antiprotozoal drugs used to treat leishmaniosis; and those used to treat Chagas' disease. For many infections, treatment does not consistently result in parasitologic cure.

Antiprotozoal Drugs Used Primarily for Gastrointestinal Infections

Amprolium

Amprolium is a thiamine analogue that is used to prevent and treat intestinal coccidiosis (Table 10-1). It is available as a feed additive for livestock and is sometimes administered in food or drinking water to puppies and kittens. Adverse effects of anorexia or diarrhea are rare and primarily occur at high doses and with prolonged use. Central nervous system (CNS) signs can result from thiamine deficiency, which is reversible on addition of thiamine to the diet. However, thiamine supplementation may interfere with the drug's efficacy.

Benzimidazoles

Fenbendazole and Albendazole

Benzimidazoles bind to β-tubulin within a variety of helminths and protozoa. This leads to inhibition of tubulin polymerization and the formation of microtubules, with impaired cell division. Glucose uptake by parasites is also impaired. Resistance can result from production of altered β-tubulin by parasites, which reduces binding of benzimidazole drugs.

Fenbendazole is widely used to treat giardiasis in dogs and cats. It is safer than metronidazole, can be administered to young animals, and has higher efficacy, although treatment failure can still occur. A second course of treatment or administration of fenbendazole in combination with metronidazole can be effective in refractory cases. Administration with food may improve absorption, but the fat content of the food does not influence absorption.[1] Adverse effects of fenbendazole are very rare but can include decreased appetite, vomiting, diarrhea, and rarely reversible pancytopenia.[2] At high doses used to treat *Mesocestoides* spp. peritonitis (100 mg/kg q12h), neurologic signs have been observed.[3] Febantel is metabolized to a benzimidazole compound and has been used in combination with praziquantel and pyrantel (Drontal Plus) to treat *Giardia* spp. infection in dogs, although efficacy at label dosages has been variable and some dogs can re-shed low numbers of cysts when treatment is discontinued.[4] Albendazole has an affinity for rapidly dividing cells, and although it is used extensively for treatment of parasitic infections in human patients, it been associated with anorexia and reversible bone marrow suppression in dogs and cats especially when high doses are administered for more than 5 days.[5] As a result, fenbendazole is used more commonly in small animals.

Nitroimidazoles

Protozoa reduce nitroimidazoles to nitro anion free radicals, which cause damage to parasite DNA. Some nitroimidazoles are mutagens and carcinogens, but carcinogenesis has not been demonstrated in dogs and cats with long-term use. Metronidazole,

VetBooks.ir

TABLE 10-1

Suggested Doses of Drugs That Are Primarily Used to Treat Protozoal Infections of the Gastrointestinal Tract in Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Duration (days)	Comments
Fenbendazole	50	24	C, D	PO	5	Giardiasis. May be administered with food. Safe in pregnancy.
Albendazole	25	12	C, D	PO	3	Giardiasis. May cause bone marrow suppression. Do not use in pregnancy.
Metronidazole	15	12	C, D	PO	8	Giardiasis. Use caution with hepatic insufficiency. Dose for metronidazole benzoate is 25 mg/kg.
Tinidazole	15	12 24	D C	PO	5	Giardiasis. Administer with food or in capsules to reduce bitterness.
Ronidazole	30	24	C	PO	14	Tritrichomoniasis. Avoid doses ≥60 mg/kg/day. Compounded from powder.
Paromomycin	10	8	D	PO	5-10	Cryptosporidiosis. Caution in animals with diarrhea due to possible systemic absorption. Avoid in cats.
Nitazoxanide	100 mg/animal	12	D, C	PO	3	Cryptosporidiosis. Efficacy and safety unclear. Vomiting common in cats.
Amprolium	1.25 g of 20% powder or 30 mL of 9.6% solution to 3.8 L of water	24	D, C	PO	7	Isosporiasis. Add to food. Do not administer for prolonged periods.
Sulfadimethoxine	55 on day 1, 27 thereafter	24	D, C	PO	3-23 or for 48 hr after signs resolve	Isosporiasis with or without a dihydrofolate reductase inhibitor.

C, Cats; D, dogs.

ronidazole, and tinidazole have primarily been used to treat enteric protozoal infections. Benznidazole is specifically used to treat infections with *Trypanosoma cruzi*.

Metronidazole

Metronidazole is used to treat giardiasis in dogs and cats, although efficacy may be as low as 50%. It also has activity against amoebic infections. The clinical use and adverse effects of metronidazole are described in Chapter 8. Doses of metronidazole used for treatment of giardiasis have the potential to be associated with neurotoxicity, so fenbendazole is preferred because of greater safety and efficacy. Metronidazole can be combined with fenbendazole for refractory giardiasis.

Tinidazole

Tinidazole is a 5-nitroimidazole that has amoebicidal, giardicidal, trichomonicidal, and anaerobic bactericidal activity. It is sometimes used as a single-dose treatment for giardiasis in human patients. The efficacy of tinidazole for treatment for giardiasis in dogs and cats has not been evaluated, and the half-life in dogs (4.4 hours) and cats (8.4 hours) is shorter than that in human patients (>12 hours).[6,7] Tinidazole is very well absorbed in dogs and cats, with a bioavailability of 100%. Adverse effects are similar to those of metronidazole. Like metronidazole, tinidazole has a bitter taste.

Ronidazole

Ronidazole is the drug of choice for treatment of *Tritrichomonas foetus* infections, which are less responsive to metronidazole and tinidazole.[8-10] Resistance to ronidazole has been identified in some isolates of *T. foetus* and is associated with treatment failure in infected cats.[11] Resistance is thought to result from increased oxygen-scavenging capacity by the parasite, whereby oxygen competes effectively with ronidazole and other nitroimidazoles for ferredoxin-bound electrons.

Ronidazole is absorbed rapidly and completely after oral administration to cats. Some compounded formulations may have decreased efficacy as a result of low ronidazole content or differences in drug release at the site of action (the large bowel). A modified-release formulation that is delivered to the colon may have improved efficacy.[12] Decreased appetite, vomiting, and neurologic signs can occur in dogs and cats, especially at doses above 30 mg/kg q12h in cats and at doses as low as 10 mg/kg/d in dogs.[13] Once daily dosing is probably sufficient because of the long half-life of the drug in cats.[12] Doses of 20 mg/kg or less may not effectively clear infection with *T. foetus*. Neurologic signs result from γ-aminobutyric acid (GABA) antagonism in the CNS and include ataxia, decreased mentation, agitation, tremors, and hyperesthesia, which occur up to 9 days after the start of treatment and resolve when the drug is discontinued.[13]

Nitozoxanide

Nitazoxanide is a nitrothiazolyl-salicylamide derivative that has activity against *Giardia* spp., *Cryptosporidium* spp., *Sarcocystis neurona,* some anaerobic bacteria, *Helicobacter* spp., and *Campylobacter jejuni*. It inhibits the pyruvate-ferredoxin/flavodoxin oxidoreductase enzyme-dependent electron transfer reaction

VetBooks.ir

that is essential for anaerobic metabolism in these organisms. Resistance has been documented in *Giardia* spp.[14]

Reports of nitazoxanide use in dogs and cats have been rare, and its efficacy in dogs and cats is largely unknown. An equine formulation (Navigator) that was used to treat equine protozoal meningoencephalitis caused by *Sarcocystis neurona* has been removed from the market. Doses have been extrapolated from those used for human patients. Nitazoxanide treatment of cats co-infected with *Cryptosporidium* spp. and *T. foetus* led to cessation of shedding during treatment, but infection was not eliminated.[15] Vomiting occurred frequently, especially at higher doses (75 mg/kg PO q12h). In humans, nitazoxanide is rapidly absorbed from the gastrointestinal tract and metabolized to the active metabolite tizoxanide, which is highly protein bound. After hepatic glucuronidation, it is excreted in urine and bile.

Antibacterial Drugs with Broad-Spectrum Antiprotozoal Activity

Folic Acid Antagonists

Trimethoprim, pyrimethamine, ormetoprim, and sulfadiazine inhibit parasite replication through folate antagonism. Synergistic combinations of sulfadiazine with trimethoprim or pyrimethamine are primarily used to treat toxoplasmosis, neosporosis, and intestinal coccidiosis (*Isospora* spp. infections) in dogs and cats. A combination of pyrimethamine, trimethoprim-sulfadiazine, and clindamycin has also been used to treat *Hepatozoon americanum* infections.[16] The mechanisms of action, use, and adverse effects of trimethoprim and sulfonamides are discussed in Chapter 8.

Pyrimethamine

Like trimethoprim, pyrimethamine inhibits dihydrofolate reductase, which is necessary for synthesis of thymidine. However, in contrast to trimethoprim, it has a greater affinity for the protozoal enzyme than the bacterial enzyme. Resistance to pyrimethamine can occur when parasites synthesize dihydrofolate reductase enzymes with an altered drug target site. Pyrimethamine is well absorbed after oral administration and penetrates a variety of tissues including the CNS. Hepatic metabolism and some renal excretion occur. Although clearance of pyrimethamine is not affected by renal disease, the use of caution with hepatic or renal insufficiency has been recommended in human patients.

Pyrimethamine is well tolerated. Gastrointestinal signs such as vomiting, diarrhea, and decreased appetite occur in some treated animals. Bone marrow suppression can occur with prolonged treatment at higher doses as a result of folic acid deficiency. In human patients, concurrent administration of folinic acid is recommended when high doses are used for treatment of toxoplasmosis. Folinic acid, but not folic acid supplementation also reverses marrow suppression in dogs treated with pyrimethamine.[17] The CBC should be monitored weekly during treatment, and supplementation should be provided if leukopenia develops and continued treatment is necessary. Stomatitis, ulcerative glossitis, and exfoliative dermatitis have also been described in human patients as a result of folic acid deficiency.[18] Other adverse effects of pyrimethamine-sulfadiazine combinations result from the sulfadiazine component (see Chapter 8).

Unlike trimethoprim-sulfadiazine, there are no approved formulations of pyrimethamine-sulfonamides for dogs and cats. Pyrimethamine is available as a single agent in tablets but should be administered with a sulfonamide for the best efficacy. Another alternative is the combination of pyrimethamine-sulfadiazine, which is available in an oral liquid suspension for horses (ReBalance). Although off-label, it is a convenient formulation for small animal veterinarians. This formulation can be administered at a dose of 1 mg/kg pyrimethamine + 20 mg/kg sulfadiazine PO q24h. This is equivalent to 0.33 mL of the equine formulation per 4 kg of body weight for dogs and cats.

Macrolides and Lincosamides

Clindamycin, azithromycin, and clarithromycin have antiprotozoal activity. The use of these macrolides and lincosamides in dogs and cats and their adverse effects are discussed in Chapter 8. Clindamycin is the most widely used antiprotozoal for treatment of toxoplasmosis and neosporosis in dogs and cats. Although clindamycin inhibits shedding of *Toxoplasma gondii* oocysts by cats,[19] clinical efficacy of clindamycin for treating toxoplasmosis in dogs and cats has been questioned by experts and in published studies. Trimethoprim-sulfonamides are a suitable alternative, or if clindamycin is used, pyrimethamine may be used in combination. In human patients, pyrimethamine and clindamycin are used as a substitute for pyrimethamine and sulfadiazine for treatment of toxoplasmosis in sulfadiazine-sensitive individuals. Azithromycin is used in combination with atovaquone for treatment of babesiosis and cytauxzoonosis.

Paromomycin

Paromomycin is the only aminoglycoside antibiotic that has efficacy against protozoa. It is poorly absorbed from the gastrointestinal tract and so has been used to treat enteric protozoal infections, particularly cryptosporidiosis. It is ineffective for treatment of tritrichomoniasis in cats.[10] Furthermore, when used to treat intestinal protozoal infections in cats, paromomycin has been absorbed systemically because of intestinal mucosal compromise, with resultant acute renal failure, deafness, and cataract formation.[20] As a result, its use has been limited. In human patients, paromomycin has been used topically to treat cutaneous leishmaniasis and parenterally to treat visceral leishmaniasis.[21]

Tetracyclines and Ciprofloxacin

Doxycycline has primarily been used for malaria prophylaxis in humans. Ciprofloxacin is thought to inhibit DNA gyrase within a chloroplast organelle (the apicoplast) of apicomplexan parasites (see the triazines, later). It is an alternative to sulfadiazine for treatment of isosporiasis in human patients.[18] Tetracyclines and ciprofloxacin have not been widely used for prevention or treatment of protozoal infections in dogs and cats with the possible exception of doxycycline as part of combination treatment for babesiosis (see Chapter 75).

Antiprotozoal Drugs Used for Systemic Protozoal Infections

Quinolone Derivatives

Atovaquone

Atovaquone is a hydroxynaphthoquinone that inhibits electron transport in protozoa by targeting the cytochrome bc_1 complex (Table 10-2). It has been used in combination with other antiprotozoal drugs as an alternative treatment for malaria,

VetBooks.ir

TABLE 10-2

Suggested Doses of Drugs Primarily Used to Treat Systemic Protozoal Diseases Excluding Leishmaniosis and Trypanosomiasis in Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Duration (days)	Comments
Pyrimethamine	1 0.5-1	24	D C	PO	14-28	Primarily neosporosis, toxoplasmosis, and American hepatozoonosis. Use with a sulfonamide. Use caution with hepatic and renal insufficiency. Monitor CBC. Folinic acid supplementation (5 mg/day) may be required.
Clindamycin	22	12	D, C	PO		Toxoplasmosis, neosporosis, sarcocystosis, and American hepatozoonosis.
Azithromycin	10	24	D, C	PO	10	Babesiosis and cytauxzoonosis. Used with atovaquone.
Atovaquone	13.3 15	8	D C	PO	10	Babesiosis and cytauxzoonosis with azithromycin. Administer with food.
Decoquinate	10-20	12	D	PO	≥365	American hepatozoonosis and sarcocystosis. Powder (6% decoquinate; 60 mg active ingredient per gram) is mixed with food. This equates to 0.5 to 1 tablespoon/10 kg body weight q12h.
Imidocarb dipropionate	6.6 5	Once, repeat in 14 days	D C	Deep IM	N/A	Large *Babesia* spp. infections. Caution with hepatic or renal insufficiency. Avoid use with other cholinesterase inhibitors.
Diminazene aceturate	3-5	Once	D	Deep IM	N/A	Babesiosis and African trypanosomiasis. Narrow therapeutic range.
Ponazuril	20-50	12-24	D	PO	3-28	Toxoplasmosis, neosporosis, isosporiasis. Optimal dose, duration, efficacy, and adverse effects unknown.
Toltrazuril	5-10 18	12-24	D C	PO	1-14	Hepatozoonosis, isosporiasis. One dose may be effective for isosporiasis. Optimal dose and duration for hepatozoonosis unknown.

C, Cats; D, dogs; N/A, not applicable.

toxoplasmosis, and pneumocystosis in human patients.[18] In veterinary medicine, atovaquone is used in combination with azithromycin for treatment of *Babesia gibsoni* and *Babesia conradae* infections and cytauxzoonosis (see Chapters 75 and 76), but is expensive. Resistance has been reported in *Plasmodium* spp., *T. gondii, Pneumocystis jirovecii,* and canine *B. gibsoni* strains as a result of mutations in the cytochrome bc_1 complex.

Atovaquone is highly lipophilic and extensively protein bound. Little is known about atovaquone metabolism in dogs and cats. Its oral bioavailability increases significantly when food is administered concurrently. Atovaquone is available alone or in a formulation with proguanil for treatment and prevention of malaria in human patients. The combination formulation may cause vomiting and diarrhea in dogs, but otherwise atovaquone appears well tolerated by both dogs and cats.[22-24] In human patients, adverse effects have included gastrointestinal signs, headache, fever, and increased liver enzyme activities. Coadministration with metoclopramide, tetracycline, or rifampin significantly decreases plasma drug concentrations in humans.

Decoquinate

Decoquinate is a 4-hydroxyquinolone coccidiostat that inhibits electron transport in protozoal mitochondria and interferes with sporozoite development. It likely has a similar mechanism of action to atovaquone, because resistance to atovaquone can result in cross-resistance to decoquinate.[25] Although developed as a food additive for use in production animals, decoquinate can be used successfully and without adverse effects to prevent relapses in dogs that are chronically infected with *Hepatozoon americanum*.[16] Decoquinate also appeared to be effective for treatment of *Sarcocystis* spp. myositis in a dog.[26] Its distribution and metabolism in dogs and cats have not been described.

Aromatic Diamines

The aromatic diamines include imidocarb dipropionate, diminazene aceturate, pentamidine isethionate, and phenamidine isethionate. These drugs inhibit DNA synthesis in protozoa. In dogs, imidocarb and diminazene have been used most widely, primarily for treatment of *Babesia* spp. and *Hepatozoon canis* infections. In general, the use of imidocarb has been preferred over diminazene because of diminazene's narrow therapeutic index. Pentamidine and phenamidine have also been used in dogs. Pentamidine isethionate is a second-line treatment for leishmaniasis in human patients and is used as an alternative to diminazene for treatment of African trypanosomiasis (see Chapter 78). Treatment of protozoal infections using the aromatic diamines may not result in complete parasite elimination.

Imidocarb Dipropionate

Imidocarb dipropionate is primarily used to treat large *Babesia* spp. and *Hepatozoon canis* infections in dogs. More effective

agents have replaced imidocarb for treatment of canine monocytic ehrlichiosis and feline cytauxzoonosis.

Imidocarb is given by intramuscular injection, twice, 2 weeks apart. It is generally well tolerated, although it can cause transient pain at the site of injection. It appears to be eliminated in urine and feces.[27] Acute adverse effects result from its anticholinergic activity and include vomiting, shivering, hypersalivation, lacrimation, diarrhea, agitation, lethargy, pyrexia, and periorbital swelling. These generally resolve within a few hours. A possible association between imidocarb treatment and acute renal tubular necrosis has been reported in dogs.[28] Massive hepatic necrosis was described after overdosage of dogs with 10 times the recommended dose.[29]

Diminazene Aceturate

Diminazene aceturate is administered parenterally, primarily to dogs, for treatment of babesiosis, African trypanosomiasis, and, most recently, infections with *Rangelia vitalii*, a novel protozoal pathogen of dogs from Brazil.[30] Diminazene aceturate is not readily available in the United States. Resistance to diminazene has been described in *Babesia gibsoni*.[31]

Although formulations for small animals are not available, a powdered commercial drug formulation (Veriben) has been reconstituted with sterile water to a concentration of 7 mg/mL and administered intramuscularly at a dose of 3 mg/kg diminazene diaceturate for a pharmacokinetic study in cats.[32] The dose was well tolerated, and diminazene was eliminated with a half-life of only 1.7 hours and a peak concentration of only 0.5 µg/mL. Development of clinically effective doses from these data requires further studies. Diminazene was administered to seven cats experimentally infected with *Trypanosoma evansi* at a dose of 3.5 mg/kg intramuscularly on five consecutive days.[33] The treatment was 85.7% efficacious for elimination of the parasite, and no adverse effects were observed.

Effective doses of diminazene approach doses that are toxic, so it should be used with caution.[34] Adverse effects include tachycardia and CNS signs such as ataxia, nystagmus, and opisthotonos. A single treatment can be given, or the dose can be repeated 72 to 96 hours after drug administration. In some protocols for *B. gibsoni* infections, diminazene administration has been followed a day later by treatment with imidocarb.

Triazine Antiprotozoals (Toltrazuril and Ponazuril)

Toltrazuril and its major metabolite ponazuril (toltrazuril sulfone, Marquis) are triazine-based antiprotozoal drugs that have specific activity against apicomplexan coccidial infections. Toltrazuril is not available within the United States. Ponazuril and toltrazuril appear to act on a plastid-like chloroplast organelle (the *apicoplast*) in apicomplexan protozoa, which may have originally been acquired from a green alga.[35] This organelle contains a small circular genome and operates key biochemical pathways. Although their mechanism of action is unclear, triazines may inhibit metabolic enzymes or decrease pyrimidine synthesis within the apicoplast. Ponazuril and toltrazuril have been used in animals to treat isosporiasis, toxoplasmosis, neosporosis, and equine protozoal meningoencephalitis. Triazine resistance has been described in coccidia from production animals.[36]

In dogs and cats, toltrazuril has been used to treat isosporiasis and hepatozoonosis, although infection may persist in some animals.[16,37-42] In Europe it is available in combination with the anthelmintic emodepside (Procox Oral Suspension for Dogs, Bayer Animal Health) for treatment of isosporiasis and roundworm infections in puppies over 2 weeks of age. The suspension contains 18 mg/mL of toltrazuril, and a single 9-mg/kg dose is recommended. Toltrazuril appeared to be as effective as trimethoprim-sulfadiazine-clindamycin-pyrimethamine for treatment of canine American hepatozoonosis.[16] One dog with *Hepatozoon canis* infection recovered after treatment with toltrazuril and trimethoprim-sulfamethoxazole,[42] but a toltrazuril and imidocarb combination did not offer benefit over treatment of *H. canis* infection with imidocarb alone.[43] Dogs with *H. canis* infection respond clinically within 72 hours of starting treatment with toltrazuril. Anecdotal reports exist of the use of ponazuril to treat *Isospora* spp. infections in dogs and cats, but its efficacy is unclear. Doses of ponazuril used have ranged from 20 to 50 mg/kg for 2 to 5 days. In one dog, ocular toxoplasmosis that was refractory to clindamycin resolved after treatment with ponazuril for 28 days.[44]

The pharmacokinetics of the triazines in dogs has not been reported. In horses, ponazuril crosses the blood-brain barrier to some extent and achieves concentrations in the cerebrospinal fluid sufficient to inhibit protozoa. It has long half-life in horses (>4 days) and in cattle (2 to 3 days). Because of its specific activity against apicomplexan parasites, significant toxicity in mammalian species has not been reported.

Antileishmanial Antiprotozoal Drugs

Antifungal Agents

Amphotericin B

Amphotericin B is a treatment of choice for human visceral leishmaniasis.[18] It is thought to bind to ergosterol in the protozoal membrane, and blocks the ability of *Leishmania* spp. to bind to and enter macrophages.[45] Lipid amphotericin B formulations have been used to treat visceral leishmaniosis in dogs, although organism persistence and relapse have been reported in some dogs after twice-weekly treatment for up to 10 administrations (0.8 to 3.3 mg/kg intravenously).[46,47] In an effort to reduce selection for resistant parasites, the World Health Organization recommends against the use of amphotericin B for treatment of canine leishmaniosis.[48] A full discussion of amphotericin B is provided in Chapter 9.

Azole Antifungals

Azole antifungals such as fluconazole have been used to treat cutaneous leishmaniasis in human patients. More effective antiprotozoal drugs are substituted for visceral leishmaniasis. Posaconazole and ravuconazole also have activity against *Trypanosoma cruzi* (see Chapter 78), and fluconazole may have activity against *Toxoplasma* (see Chapter 72).

Antimony Compounds

Sodium stibogluconate (Pentostam) and *N*-methylglucamine antimoniate (meglumine antimoniate, Glucantime) are derived from the heavy metal antimony (Sb). They are called pentavalent antimony compounds (symbol Sb^{v}) because they contain Sb atoms that have five electrons in their outer shell. Pentavalent antimonials have been recommended as the first choice for treatment of *Leishmania* infections in humans and in dogs.[49] Their mechanism of action is still not completely clear, but it is thought that pentavalent antimony undergoes reduction to the more toxic trivalent version, possibly within macrophage phagolysosomes or within the parasite itself.[50] The trivalent compound inhibits protozoal enzymes and damages protozoal

TABLE 10-3

Suggested Doses of Drugs Primarily Used to Treat Leishmaniosis or Chagas' Disease in Dogs

Drug	Dose (mg/kg)	Interval (hours)	Route	Duration (days)	Comments
Meglumine antimoniate	75-100	24	SC	30-60	Leishmaniosis. Use with allopurinol. Available in ampules. Dose based on concentration of meglumine antimoniate. Caution in dogs with renal insufficiency.
Allopurinol	10	12	PO	At least 6-12 months	Leishmaniosis. Use with meglumine or miltefosine. Monitor CBC and serum chemistry in dogs with hepatic and renal insufficiency.
Miltefosine	2	24	PO	28	Leishmaniosis. Use with allopurinol.
Benznidazole	5-10	24	PO	60	Chagas' disease

DNA.[51] Resistance to antimonials is an emerging problem in human *Leishmania* spp. isolates. This has led to the use of higher drug dosages, with an associated rise in the rate of drug toxicity. The availability of antimonial drugs is limited in the United States.

Both sodium stibogluconate and meglumine antimoniate are administered subcutaneously (Table 10-3). The treatment of choice for canine leishmaniosis is a combination of meglumine antimoniate and allopurinol.[48,49] Complete clearance of the infection may not always occur.[52] After subcutaneous administration, more than 80% of meglumine antimoniate is eliminated by the kidneys. Pain at the site of injection is the most common adverse effect, and cutaneous abscesses or cellulitis may also occur.[53] Systemic adverse effects such as lethargy, vomiting, diarrhea, inappetence, and increased serum liver enzyme activities may be more likely to occur in the presence of renal failure, which can be a complication of leishmaniosis. Of concern, the administration of meglumine antimoniate to healthy dogs has led to renal tubular necrosis, in the absence of azotemia.[54] In human patients, other adverse effects include generalized arthralgias, abdominal pain, mild cytopenias, cardiotoxicity, and chemical pancreatitis.[21] Novel formulations of antimony compounds are being developed for treatment of leishmaniasis, including lipid formulations and preparations that could be administered orally.[50]

Allopurinol

Allopurinol is a purine analogue. In parasites, allopurinol is metabolized to derivatives that are incorporated into RNA, which leads to impaired protein synthesis. Resistance can occur and appears to result from reduced activity of purine transporters and a reduced ability to accumulate purine.[55] Although it has been used alone for treatment of canine leishmaniosis, allopurinol is most commonly used in combination with meglumine or miltefosine.

Allopurinol is rapidly absorbed from the gastrointestinal tracts of dogs. Peak drug concentrations occur 1 to 3 hours after administration.[56] Allopurinol is not bound to plasma proteins. Allopurinol rarely causes adverse effects in dogs. It inhibits mammalian xanthine oxidase, which results in decreased uric acid production from xanthine. As a result, long-term use can result in xanthine urolithiasis.[57] In human patients, allopurinol most commonly causes skin rashes. Gastrointestinal signs can also occur. Rarely administration of allopurinol to humans results in aplastic anemia or a hypersensitivity syndrome characterized by toxic epidermal necrolysis with hepatic and renal failure.[58,59] Serious adverse reactions are more likely to occur in human patients with renal insufficiency. At usual doses, allopurinol treatment leads to improvement in kidney lesions in dogs with leishmaniosis that have renal insufficiency.[60] Nevertheless, careful monitoring for adverse effects is indicated in these dogs (see Table 10-3). Serious drug interactions can occur when allopurinol is administered with azathioprine.

Miltefosine

Miltefosine is an effective alternative to pentavalent antimonials for treatment of leishmaniosis.[61] It is a phospholipid analogue that activates cellular proteases in *Leishmania* spp., which results in apoptosis. Miltefosine is the first highly active oral drug for treatment of leishmaniosis. Nevertheless, despite clinical improvement in treated dogs, elimination of the parasite may not always occur.[62,63] Resistance to miltefosine can result from increased P-glycoprotein–mediated drug efflux and decreased drug uptake. Because miltefosine has a long half-life and must be administered for 28 days, selection for resistant isolates has been a concern. The World Health Organization has recommended that veterinary use of miltefosine in dogs with leishmaniosis be avoided in order to minimize the rate of selection for resistant strains.[64]

Over 90% of miltefosine is absorbed from the gastrointestinal tract of dogs after oral administration.[54] The half-life of miltefosine in the dog is approximately 6 days, so it accumulates until a steady-state plasma concentration is reached after 3 to 4 weeks of treatment. Clearance is believed to result from slow hepatic metabolism and excretion in bile. In dogs, adverse effects of treatment are mild and transient and consist of occasional vomiting and diarrhea.[65] In contrast to meglumine antimoniate, miltefosine does not appear to contribute to renal pathology in dogs.[54,66]

Antiprotozoal Drugs for Treatment of Chagas' Disease

Benznidazole

Benznidazole is a nitroimidazole that is used to treat acute Chagas' disease (see Chapter 78). Benznidazole is activated by a parasite-specific nitroreductase to produce toxic metabolites.[67] Resistance can result from reduction in the level of activity of the nitroreductase and confers cross-resistance to nifurtimox.

Benznidazole is lipophilic, is readily absorbed from the gastrointestinal tract, and undergoes hepatic metabolism. In the United States, it is available from the Centers for Disease Control and Prevention (CDC). The main adverse effect of treatment in dogs is vomiting. In human patients, it can cause skin

VetBooks.ir

rashes, peripheral neuropathy, and less commonly bone marrow suppression. It also has the potential to be carcinogenic.

Nifurtimox

Nifurtimox is a nitrofuran derivative used to treat Chagas' disease in humans. It has limited efficacy, with 70% parasitologic cure for acute disease and at best 20% for chronic disease.[18] As with benznidazole, metabolic reduction of the nitro group by a trypanosome-specific nitroreductase leads to the formation of toxic metabolites. In human patients, it is well absorbed orally and undergoes hepatic metabolism. Gastrointestinal and neurologic signs are the primary adverse effects of nifurtimox, and like benznidazole, it has carcinogenic properties.[68] Severe adverse effects have precluded the use of nifurtimox in dogs.[69]

SECTION 3

Basic Principles for Infection Control

Jane E. Sykes and J. Scott Weese

CHAPTER 11

Infection Control Programs for Dogs and Cats

Jane E. Sykes and J. Scott Weese

KEY POINTS

- A hospital infection control program consists of infectious disease control personnel, a written protocol, training, and documentation. The aim of such a program is to reduce the incidence of hospital-acquired infections among patients, staff, and visitors to a small animal hospital.
- The infection control program describes the requirement for practices that optimize hygiene such as hand washing, the use of protective clothing, cleaning and disinfection, and appropriate disposal of infectious agents. The protocol can also be used to educate staff about specific transmission precautions for infectious diseases seen within a practice.
- This chapter describes the infection control program and important components of an infection control protocol, including the advantages and disadvantages of various methods of sterilization, disinfection, and antisepsis used in small animal hospitals.
- Information in this chapter also has relevance to infection control in shelters and in breeding and boarding facilities.

INTRODUCTION

The primary role of an infection control program is to reduce the incidence of hospital-acquired infections (HAIs) by patients, staff, and visitors to a small animal hospital. Infection control programs in veterinary hospitals have largely evolved from evidence and protocols from the human health care setting, together with our understanding of transmission pathways for veterinary pathogens. In recent years, several factors have led to an increased rate of adoption of infection control programs by veterinary hospitals, such as an increased prevalence of multidrug-resistant bacterial infections among small animal patients, the appearance of more studies that support the common occurrence of transmission of hospital-associated and zoonotic pathogens in the veterinary setting, the requirement for an infection control program in veterinary teaching hospitals for accreditation purposes, and increased scrutiny of hospital-associated and zoonotic infections to protect hospitals against litigation.

Infection Control Programs

Every small animal hospital should have an infection control program. At a minimum, this should consist of an infectious disease control officer, a written infection control protocol, regular training of staff, and documents that record all training and surveillance efforts. In large hospitals, formation of an infectious disease control committee may be required. In this situation, the infectious disease control committee could consist of an internist or criticalist with an interest or training in infectious diseases, a veterinary clinical microbiologist, a nursing supervisor, a safety officer, the hospital administrator, and the hospital director. There should be adequate personnel and communication so that proper coverage is maintained when one individual is absent or unavailable. All personnel who work in a veterinary hospital, as well as visitors, should be familiar with the infectious disease control personnel as well as procedures and policies listed in the infection control protocol. Documentation of training should be maintained for all hospital personnel.

The Hospital Infection Control Protocol

The objective of a hospital infection control protocol is to provide a standard procedure for the control of infectious diseases in the hospital, in order to minimize animal-to-animal, animal-to-human, and human-to-animal transmission of pathogens. Adherence to the infection control protocol can also reduce transmission of infectious agents between personnel through increased hand washing and reduction of fomite contamination. The infection control protocol is a legal document and should

VetBooks.ir

be regularly updated by a designated hospital infection control officer or committee. Each hospital should develop a protocol that is tailored to address specific practice requirements and the hospital design, purpose, and equipment used. Additional special precautions may need to be described for hospitals that see avian and exotic pet animal species, and in geographic locations where serious zoonotic diseases such as rabies and plague are endemic (see Chapters 13 and 55).

The infection control protocol details practices that optimize hygiene such as hand washing, the use of protective clothing, cleaning and disinfection, and appropriate disposal of infectious agents. Specific infectious disease control procedures to be followed in different areas of the hospital (radiology, surgery, the intensive care unit, isolation, wards) can be included, as well as policies on antimicrobial use. The protocol can also be used to educate staff about routes of transmission, the potential for zoonotic transmission, specific transmission precautions for infectious diseases that are seen within the practice, and immunization requirements, such as those for rabies (see Chapter 13).

Standard Precautions

All animals that enter a veterinary hospital are potential carriers of pathogens that may be spread to other animals or people. Animals may be colonized with multidrug-resistant bacteria, often without showing evidence of disease due to these organisms. Pet owners may carry these organisms on their hands and clothing. Standard precautions such as hand hygiene and the wearing of routine protective clothing can minimize the spread of these bacteria around the hospital and to immunocompromised animals.

Hand Hygiene

Frequent and proper hand and wrist washing to remove transient flora on the hands has been proven as the most important component for prevention of the spread of infectious diseases in human hospitals.[1] Signs that outline proper hand-washing technique, including the use of paper towels to turn off the faucet, posted adjacent to basins around the hospital can improve compliance among staff. Online videos that demonstrate proper hand-washing technique are available for educational purposes.[2] Guidelines for hand washing are shown in Box 11-1. Antibacterial soap should be used, and all surfaces of the hands should be rubbed together, which should include the backs of the hands, between the fingers, and under the fingernails, for a total hand-washing time of at least 20 seconds. In order to prevent chapped skin, which can harbor bacteria, water used for hand washing should not be too hot, and hand lotion should be applied regularly. Behaviors such as keeping fingernails short, avoidance of artificial and/or polished fingernails or hand jewelry, or wearing jewelry on a chain around the neck instead of on the hand can be encouraged. Meticulous hand hygiene is particularly important for personnel who work frequently with immunocompromised animals, such as emergency and critical care personnel. The use of touch-free taps and paper towel dispensers can also reduce transmission of bacteria during hand washing.

Alcohol-based hand sanitizers are a more convenient form of sanitization. These can be provided in multiple locations around a hospital, or travel-sized bottles can be carried in a coat pocket. At least one to two full pumps or a 3-cm diameter pool of the product should be dispensed onto one palm. All surfaces of the hands and wrists should be rubbed with the product until it has dried. Use of soap and water, rather than hand sanitizer, is recommended when there is gross contamination with organic matter, or when exposure to alcohol-resistant pathogens such as *Clostridium* spp. spores or parvovirus might have occurred. However, the availability of hand sanitizers improves compliance in busy hospital situations, is associated with lower rates of dermatitis than medicated soaps, and is recommended for routine hand sanitation in human health care settings by the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO).[3,4]

The use of gloves prevents contamination of the hands with microorganisms, prevents exposure to bloodborne pathogens, and reduces the risk of transmission of microorganisms from personnel to animals. However, gloves are not a substitute for proper hand hygiene. Guidelines for wearing disposable gloves are shown in Box 11-1. Gloves should be promptly removed after use, before other surfaces are touched, and hands should then be washed. If a glove is torn or punctured, it should be removed and replaced as soon as possible.

BOX 11-1

Guidelines for Hand Washing and the Wearing of Disposable Gloves

Situations That Require Hand Washing

Immediately before handling a patient
Immediately after handling a patient
Immediately before and after procedures that involve nonintact skin
Before and after gloves are worn for procedures
After blood, body fluids, secretions, excretions, or contaminated items are touched
After cages are cleaned
Before and after eating, smoking, or leaving the hospital
After going to the restroom

Situations When Disposable Gloves Should Be Worn

Contact with broken skin and bodily fluids (blood, urine, and feces)
Handling of disinfectants
Handling of animals with suspected or known infectious diseases
Handling of all animals for immunocompromised people

Hospital Attire

Nonsurgical Areas

Staff should be encouraged to wear dedicated hospital attire that is not worn elsewhere, so that hospital pathogens are not transported to and from locations outside the hospital. At the minimum, protective clothing such as clean laboratory coats or hospital scrubs and closed-toe shoes must be worn in nonsurgical areas. Sleeves must be short enough or rolled up to expose the wrists, and laboratory coats changed whenever gross soiling occurs. In the absence of gross soiling, coats should be changed daily. If neckties are worn, they must be secured in place by an outer layer of clothing or a tie pin so that they cannot be contaminated as a result of contact with patients or environmental

VetBooks.ir

TABLE 11-1

Transmission Precautions for Selected Infectious Diseases of Dogs and Cats

	Infectious agent	Specific precautions
Airborne	*Mycobacterium tuberculosis* *Yersinia pestis* *Francisella tularensis*	Isolation, preferably in negative pressure facility Properly fitted N95 respirator masks Contact precautions
Droplet	Canine and feline transmissible respiratory disease pathogens (e.g., canine distemper virus, canine respiratory coronavirus, feline herpesvirus-1, feline calicivirus)	Isolation Space animals at least 4 feet apart Contact precautions
Contact	Multidrug-resistant bacteria Dermatophytes *Leptospira* spp. *Salmonella* spp. Parvoviruses	Warning signage Gown, gloves, dedicated equipment Isolation for select pathogens (see Box 11-2) Limitation of movement Standard hand hygiene precautions Proper cleaning, disinfection, and disposal of medical waste

surfaces and act as fomites, as has been shown to occur in human hospital environments.[5] Long hair must be tied back so that it does not drape on animals and hospital surfaces. Face shields and a clean gown should be worn during procedures that are likely to generate splashes or sprays of blood and body fluids. Gowns must be made of impervious material and tied on securely and correctly. Soiled gowns must be removed as soon as they are no longer required and face shields cleaned.

Surgical Areas

Dedicated operating room attire should be worn in surgical areas and should be changed after gross soilage and when leaving the operating room for the day. Caps and masks should be worn and hands thoroughly washed on entry to the operating room. There is no evidence that dedicated footwear or foot protection should be worn for prevention of surgical site infections in human patients, and major human guidelines do not advocate that footwear be addressed.[6] Protective wear should be removed whenever staff members leave the operating room. Traffic in and out of the operating room should be limited to the minimum required for patient care.

General Animal Handling Precautions

All animals seen at a veterinary hospital should undergo a history and physical examination by a veterinarian to determine the likelihood and nature of any transmissible infections that might be present. Ideally, client beds, blankets, collars, and leashes should not be brought into the hospital, where they could become contaminated. Animals should always be placed in cages that have been cleaned and disinfected appropriately. Disposable thermometer sleeves should always be used on thermometers. Equipment should not be shared between animals unless it has been cleaned and disinfected. Diets that contain raw meat and bones should not be fed or stored in the hospital, because they commonly contain and can potentially transmit foodborne gastrointestinal pathogens.[7] The handling of sick animals should be minimized, unless required for patient care.

Because some infections can be transmitted through bites and scratches, staff should be educated on bite and scratch avoidance, such as the use of restraint devices, protective gloves, and warning signage on cages and medical records. Should bites or scratches occur, they should be vigorously flushed and immediately washed with water and chlorhexidine or a dilute iodophor solution, and the bite reported to appropriate officials as necessary. Deep wounds could be irrigated with pressure using a syringe without an attached needle. If a bite occurs, medical attention should be sought as soon as possible. All bites or scratches must be documented and consideration be given as to why the injury occurred, so that procedures or training to prevent future injuries can be implemented if necessary.

Consumption of food and drink should be limited to parts of a hospital where patient care and the handling of biologic specimens and medications do not occur. Food and beverages should not be left out open on benches for long periods. Microwaves used for animal care purposes should not be used to heat food intended for people.

Transmission-Based Precautions

Transmission-based precautions are instituted for selected patients that are confirmed to be or suspected to be infected or colonized with important transmissible pathogens. Transmission-based precautions are used in combination with standard precautions. In the human hospital setting, three types of transmission-based precautions have been developed—airborne, droplet, and contact precautions (Table 11-1).[8] *Airborne precautions* are used to prevent the transmission of diseases by droplet nuclei (particles <5 μm). Transmission by droplet nuclei occurs with diseases such as measles, varicella, and pulmonary tuberculosis. The precautions for human patients involve isolation in a single-bed, negative-pressure room and the wearing of high-density respirator (N95) masks. These resemble surgical masks but filter 1-μm particles with an efficiency of at least 95% and must be properly fitted. Airborne contact precautions are rarely necessary in hospitals that treat only dogs and cats, but could be considered when animals suspected to have pneumonic plague, tularemia, or *Mycobacterium tuberculosis* infection. *Droplet precautions* are used to prevent transmission by large-particle aerosols and do not require a negative-pressure room. Droplet precautions apply to dogs and cats with transmissible respiratory disease. *Contact precautions* are indicated

VetBooks.ir

for animals with infections that can be transmitted by direct contact with the patient or through fomite contact.

If it is known in advance that an animal with a suspected or known transmissible disease is to be seen at the hospital, arrangements should be made to have the pet owner take the animal from the parking area directly to an examination room, so that the animal does not contaminate the waiting area. After the animal has been examined, appropriate signage should be placed on the door of the examination room to prevent use until it has been properly cleaned and disinfected.

If hospitalization is required, animals with known or suspected transmissible disease must be admitted either to an isolation ward or to regular hospital cages with handling precautions, based on the pathogen suspected. Immediately after hospitalization, the name of the suspected or known pathogen should be posted on the cage or run, together with a handling precautions notice. Animals that require contact precautions should be placed in cages away from other animals in the ward and should not be moved from one cage to another, unless there is a medical need. Animals with transmissible respiratory disease should be placed in isolation and separated both horizontally and vertically from other patients by at least 4 feet. Gloves and a gown should be put on before the patient is handled, and then removed and disposed of immediately afterward. Hands should be washed after the gloves are removed. Additional items of personal protective equipment (masks, gowns, gloves, booties) may be required in some circumstances. Soiled linen and equipment should be handled, transported, and processed in a manner that prevents skin and mucous membrane exposures and contamination of clothing and that avoids transfer of microorganisms to other patients and environments. All equipment that contacts the patient (scales, examination tables, stethoscope heads, floor) should be cleaned and disinfected immediately after use. Medications and fluids from these patients should not be returned to the hospital pharmacy. When possible, personnel who handle these animals should not work with other immunosuppressed animals in the hospital, or they should work with the infectious disease cases last. If animals with contact precautions must be moved within the hospital, personnel should ensure that precautions are maintained throughout and that equipment and environmental surfaces that come into contact with the patient are properly disinfected and/or disposed of. The cleaning and bandaging of wounds infected with multidrug-resistant bacteria should be conducted in low-traffic areas that can be properly cleaned and disinfected.

The owners of dogs and cats that have transmissible diseases should be provided with general information regarding the risk of disease transmission to in-contact animals and people that includes the mode of transmission, duration of organism shedding, and if there are special implications for young children or other immunosuppressed individuals. If dogs and cats are diagnosed with a zoonotic disease, the owners should be notified without delay. The owners should be told to see their physicians if they become unwell or, in some circumstances, immediately, and to advise a physician of the potential exposure.

Isolation

In contrast to human hospitals where patients can be more readily isolated in single-bed rooms or cubicles, isolation of veterinary patients can be more difficult because of the close proximity of one animal to another. Floor contamination with secretions and excretions can also occur more readily. Isolation rooms are available in many veterinary hospitals, but they may be poorly visible and/or accessible and may not provide access to an oxygen source or be amenable to intensive monitoring and care. For some animals (especially puppies and kittens) suspected to have a transmissible disease, housing in a general ward or ICU area with as much physical and procedural separation as possible, and with strict infection control practices, may be acceptable (if perhaps not optimal). Once a diagnosis is confirmed, the animal should be moved immediately to isolation whenever possible. Patients chosen for strict isolation vary based on the specific situation and facilities available, but suggestions are provided in Box 11-2.

Only the individuals directly involved in the care of the patient should enter isolation. Pet owners should not be allowed into the isolation ward. No equipment used outside isolation (pens, thermometers, stethoscopes, cell phones) should be brought into isolation. Laboratory coats should be removed, and personnel must put on protective wear such as a disposable gown, gloves, and booties when entering the isolation ward. Face protection may also be required, depending on the situation. A notice that outlines the required precautions should be posted on the door of isolation. Protective clothing should be removed before leaving isolation, and hands should be washed. Once a patient has been discharged, the room should be properly disinfected.

Handling of Potentially Infectious Materials and Waste

The risk of human infection from patient blood and body fluids in small animal hospitals is clearly lower than that in human hospitals. However, a number of zoonotic pathogens have the potential to be spread from dogs or cats to humans through contact with medical waste, and a number of emerging zoonotic infectious agents are bloodborne. Examples include *Bartonella* spp., *Anaplasma phagocytophilum, Brucella* spp., and hemoplasmas. Proper handling of blood and body fluids also has the potential to protect staff against as-yet-unrecognized zoonotic pathogens. Improper disposal of medical waste in veterinary hospitals risks injuring others who handle the waste and has the potential to result in serious penalties or fines.

Potentially contaminated waste should be disposed of in an approved plastic bag in a container labeled on all exposed sides

BOX 11-2

Examples of Infectious Agents of Dogs and Cats for Which Strict Isolation Is Indicated

Salmonella spp.
Francisella tularensis
Yersinia pestis
Mycobacterium tuberculosis or *Mycobacterium bovis*
Microsporum canis
Rabies virus
Enteric viruses, such as parvoviruses
Canine transmissible respiratory disease pathogens (*Bordetella*, canine distemper virus, influenza viruses, canine respiratory coronavirus, canine adenovirus, canine parainfluenza virus)
Feline upper respiratory tract disease pathogens (feline herpesvirus-1, feline calicivirus, influenza virus, *Chlamydia*)

VetBooks.ir

with "biohazardous waste." Blood-soaked materials, infected materials, and empty fluid bags should all be placed in biohazardous waste containers. Care should be taken not to contaminate the outside of the container during disposal. The lid of the biohazardous waste container must close properly. Blood and body fluids should be inactivated with an appropriate disinfectant (e.g., bleach or accelerated hydrogen peroxide) and allowed to stand for 10 minutes before disposal. Disposal regulations may vary depending on local laws, but liquid waste should not be disposed of into storm drains.

Specimens for laboratory testing that are collected from a patient with suspected zoonotic infectious diseases should be placed in an outer plastic bag, taking care not to contaminate the outside of the plastic bag, and labeled with an appropriate warning label. Fecal material should be picked up using a tongue depressor while wearing gloves, and placed in a sealed plastic cup and clearly labeled. Urine specimens should be submitted in a sealed container.

Sharps Handling

Sharps handling practices receive considerable attention in human medicine because of the risk of transmission of various bloodborne pathogens. Although the risks are less in veterinary medicine, significant injury or illness can follow sharps injuries, such as transmission of infectious agents from the patient, allergic or inflammatory reactions from exposure to medication, and inoculation of opportunistic pathogens from the injured person's own skin microflora. Care should be taken to prevent injuries when needles, scalpels, and other sharp instruments are used, cleaned, or disposed of. Used needles should never be recapped, and they should not be removed from the barrel of a disposable syringe. Personnel should be instructed not to walk with uncapped needles and not to hold syringe or needle caps in the mouth. Used needles should not be carried in a pocket. Animals suspected of having an infectious disease that could be transmitted to humans through a needle-stick injury should be sedated before skin masses or peripheral lymph nodes are aspirated or venipuncture is performed. Contaminated sharps (slides, scalpel blades, broken glass, needles with attached syringes) must immediately be placed into an approved puncture-resistant sharps disposal biohazard container. Personnel who perform necropsy examinations should take care to use sharp knives in the proper manner and to avoid rushed situations. If a contaminated sharps injury occurs, medical attention should be sought immediately if necessary.

Hospital Cleaning, Disinfection, and Sterilization

Definitions

Sterilization refers to complete elimination of all microbes, including bacterial spores, and is accomplished in hospital settings using processes such as pressurized steam, dry heat, ethylene oxide gas, or liquid chemicals.

Disinfection is the process that eliminates many or all microbes from inanimate objects, but not bacterial spores. Factors that influence the efficacy of disinfection include the type of microorganism present, their number, the amount and type of organic matter present, the presence of biofilms, and the porosity of the surface to be disinfected. Some disinfectants kill spores at high concentrations and with prolonged exposure times. These are known as *chemical sterilants*. At low concentrations and short contact times, chemical sterilants inactivate all microbes except large numbers of bacterial spores and are known as *high-level disinfectants*. *Low-level disinfectants* inactivate most vegetative bacteria, some fungi, and enveloped viruses, but not bacterial spores. *Intermediate-level disinfectants* inactivate mycobacteria, vegetative bacteria, most viruses, and most fungi (Tables 11-2 and 11-3).

Antisepsis is the process that reduces the number of microbes from *living tissue and skin*. Disinfectants are rarely used for skin antisepsis because they can injure tissues and skin. *Sanitation* is the reduction in the number of microorganisms *on a surface* to a safe level. *Germicides* are agents that inactivate microorganisms and include disinfectants, antiseptics, and sanitizers.

TABLE 11-2

Characteristics of Selected Disinfectants

Disinfectant Category	Activity in the Presence of Organic Matter	Advantages	Disadvantages	Precautions	Comments
Alcohols: Ethyl alcohol, isopropyl alcohol	Rapidly inactivated	Fast-acting No residue Relatively nontoxic	Rapid evaporation	Flammable	Not appropriate for routine environmental disinfection Primarily used as antiseptics
Aldehydes: Formaldehyde, glutaraldehyde	Good	Broad spectrum Relatively noncorrosive	Highly toxic	Irritant Carcinogenic Requires ventilation	Used as an aqueous solution or as a gas (fumigation)
Alkalis: Ammonia			Unpleasant odor Irritating	Do not mix with bleach.	Not recommended for general use
Biguanides: Chlorhexidine	Rapidly inactivated	Nontoxic	Incompatible with anionic detergents		Not appropriate for environmental disinfection Primarily used as antiseptics

Continued

VetBooks.ir

TABLE 11-2

Characteristics of Selected Disinfectants—cont'd

Disinfectant Category	Activity in the Presence of Organic Matter	Advantages	Disadvantages	Precautions	Comments
Halogens: Hypochlorites (bleach)	Rapidly inactivated	Broad spectrum, sporicidal Inexpensive Can be used on food preparation surfaces	Inactivated by cationic soaps/detergents and sunlight. Frequent application required.	Corrosive Irritant May produce toxic gas when mixed with other chemicals	Used to disinfect clean environmental surfaces Only commonly available sporicidal disinfectant
Oxidizing agents	Good	Broad spectrum Environmentally friendly	Breakdown with time	Corrosive	Excellent choice for environmental disinfection
Phenolics	Good	Broad spectrum Noncorrosive Stable in storage	Toxic to cats Unpleasant odor Incompatible with cationic or nonionic detergents	Irritant	Some residual activity after drying
Quaternary ammonium compounds (QUATs)	Moderate	Stable in storage Nonirritating to skin Low toxicity Can be used on food preparation surfaces Effective at high temperatures and pH	Incompatible with anionic detergents		Commonly used primary environmental disinfectant Some residual activity after drying

TABLE 11-4

Recommended Conditions for Heat Sterilization

	Conditions	Time
Gravity displacement steam sterilization	121°C (250°F), 106 kPa (15 lb/in^2)* 132°C (270°F), 30 lb/in^2	30 min wrapped items, 20 min unwrapped 15 min wrapped items
High-speed prevacuum steam sterilization	132°C (270°F), 30 lb/in^2	4 min
Dry heat sterilization	160°C (320°F) 170°C (340°F)	2 hours at temperature, 3 to 3.5 hours with cooling 1 hour at temperature, 2 to 2.5 hours with cooling

*Pressure settings may vary between incubators. When possible, follow manufacturer's recommendations.

Cleaning involves the removal of all visible organic and inorganic material from objects and surfaces through the use of manual or mechanical processes and detergent or enzymatic solutions.

According to the Spaulding method of classification, items to be sterilized or disinfected can be grouped into *critical, semicritical,* and *noncritical* items.[9] Critical items enter tissue or the vascular system, or devices through which blood flows. Critical items require sterilization before they can be used. Semicritical items are items that contact mucous membranes or nonintact skin and include endoscopes and balloon dilation catheters. These generally require high-level disinfection. Noncritical items are items that contact intact skin. Noncritical items generally require low-level or intermediate-level disinfection and contact times of 1 to 10 minutes.[9]

All personnel should be educated regarding the standard hospital germicides used for disinfection and antisepsis, how they should be diluted and applied, and the hazards associated with their use. Gloves and eye protection should be worn when disinfectant solutions are handled or mixed. In large hospitals, posters on hospital walls can be used to guide selection of appropriate germicides for different situations. Disinfectant solution should be readily accessible throughout the hospital. Because mops can spread infection, cotton mops should be laundered daily, or mops with detachable microfiber heads should be used. Microfiber heads absorb a large amount of water and are not returned to the mop bucket after use. They can be laundered and reused the following day.

Methods of Sterilization

Steam sterilization. Steam sterilization involves the use of saturated steam under pressure in an autoclave to achieve sterilization. This is the most effective form of sterilization, is nontoxic and inexpensive, and as a result is the most widely used as well. The use of steam under pressure allows lower temperatures to be used for shorter periods of time when compared with dry heat sterilization (Table 11-4). The most common temperatures used for steam sterilization are 121°C (250°F) and 132°C (270°F). Cycle times vary depending on the autoclave used and whether items are wrapped or unwrapped, but are generally less than 30 minutes (see Table 11-4). There are two basic types of autoclaves: gravity displacement autoclaves, and high-speed prevacuum sterilizers. Gravity displacement autoclaves admit steam at the top or sides of the autoclave, which displaces air through a drain vent at the bottom of the chamber (Figure 11-1). High-speed prevacuum sterilizers rapidly pump air out of the sterilizer before steam is admitted. This leads to rapid penetration of steam into all surfaces. As a result, cycle times can be reduced to less than 15 minutes. Drying times are also reduced with prevacuum sterilizers.

Sterilizers should be located away from potential sources of contamination, such as sinks, trash disposal, or high-traffic areas. Before steam sterilization is performed, instruments should be cleaned thoroughly to remove organic and inorganic material, and then dried. All jointed items should be opened or unlocked, and items should not be crowded in the autoclave, so that steam can circulate freely. At least 3 inches should be left between the autoclave wall and items to be sterilized. The manufacturer's instructions for autoclave operation should be followed.

The efficacy of autoclaving must be tested for every autoclaved item, with additional quality control performed on a periodic basis. Autoclave indicator tape is routinely used; although this only indicates conditions on the outside of the package. Steam indicator strips should be included in each surgical pack and evaluated by the person opening the pack. Biological indicators provide a more definitive assessment of autoclave efficacy and should be used periodically (e.g., weekly) and the results documented. These consist of a standardized population of bacterial spores, usually on a filter paper strip or contained within a vial. The strip is then sent to the microbiology laboratory for culture, or cultured in-house, to ensure that the spores have been completely inactivated by the sterilization process. Any indicator failure should result in immediate inspection of the autoclave. Sterilization indicators should never be used as a substitute for proper autoclave operation and careful preparation, packing, and loading of equipment to be sterilized.

After steam sterilization, instruments should be allowed to dry before they are removed, which typically takes an additional 30 minutes. Items should then be stored in a location and manner that prevents further contamination.

Flash sterilization. Flash sterilization refers to the rapid sterilization of unwrapped instruments and is usually performed as an emergency procedure in an operating room setting when time is insufficient to perform the preferred sterilization of wrapped items. In general it is performed for 3 minutes at 270°F and 27 to 28 lb/in^2. Each instrument must be carefully protected to ensure it does not become recontaminated during transport back to the operating room, usually in a "flash pan." Flash sterilization has occasionally been associated with intraoperative infections and should not be used for routine disinfection purposes.

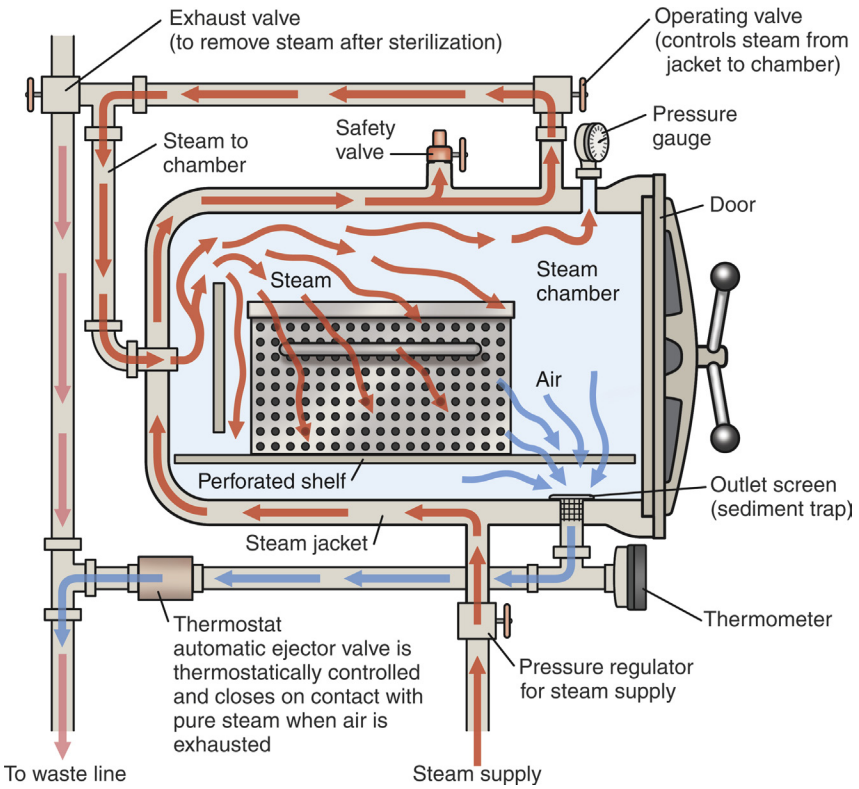

FIGURE 11-1 Gravity displacement sterilization. Steam is admitted at the top or sides of the autoclave, which displaces air through a drain vent at the bottom of the chamber.

Gas sterilization. Gas sterilization is used for sterilization of heat- and moisture-sensitive instruments but can have significant toxicity. Gases that can be used for sterilization include formaldehyde, ethylene oxide (ETO), hydrogen peroxide vapor, and ozone gases. The most commonly used gas in veterinary medicine, ETO, has strong alkylating properties and causes protein coagulation, enzyme inactivation, and damage to nucleic acid. When compared with heat sterilization, ETO sterilization takes longer (24 hours or more including the time required to allow ETO to diffuse out of packages at the end of sterilization) and is more expensive. In addition, it only achieves surface sterilization and requires sophisticated equipment and trained staff. The gas is extremely flammable, irritates the eyes and mucous membranes, is mutagenic and carcinogenic, and has a misleadingly pleasant smell.

Irradiation. Gamma irradiation uses a cobalt-60 radiation source to destroy microorganisms through generation of high-energy photons. Health care product manufacturers use gamma irradiation to sterilize disposable medical supplies, such as catheters, gloves, syringes, and pharmaceuticals.

Chemical sterilants. Chemical sterilants are used when heat or ETO gas sterilization is not available or would otherwise damage instruments, such as endoscopes or laparoscopes. Disinfectants that act as sterilants when they are used at high concentrations and for adequate contact periods include certain solutions that contain glutaraldehyde (e.g., >2.4% glutaraldehyde solutions, 0.95% glutaraldehyde with 1.64% phenol/phenate), 0.55% *ortho*-phthalaldehyde (OPA), 7.5% hydrogen peroxide, or greater than or equal to 0.2% peracetic acid (see section on Disinfectants following). Chemical sterilants must be rinsed repeatedly with sterile water and dried once sterilization is complete. Chemical sterilants must be used with the proper contact times and at the right concentration. Solutions may lose efficacy, become diluted, or become contaminated with bacteria over time. They should be replaced frequently according to the manufacturer's recommendations, and they should never be used in procedures that involve sterile body sites unless there is no other sterilizing option.

Disinfectants

Glutaraldehyde. Glutaraldehyde is a saturated dialdehyde. Glutaraldehyde solutions are relatively inexpensive, are noncorrosive, and can be used to disinfect rubber, plastics, and endoscopic equipment. Aqueous solutions require activation by alkalinization to a pH of 7.5 to 8.5 for sporicidal activity to occur. When alkalinized glutaraldehyde is used at a concentration of 2.4% for adequate periods of time, either chemical sterilization or high-level disinfection occurs, depending on the contact time (e.g., Cidex). Contact times of at least 20 minutes (at or above 20°C) are effective for high-level disinfection. Sterilization requires a 10-hour contact time and higher concentrations of glutaraldehyde (e.g., Cidex Plus, which contains 3.4% glutaraldehyde), or formulations that combine glutaraldehyde with another disinfectant.

Once activated, 2.4% glutaraldehyde solution retains activity for 14 days, provided inadvertent dilution does not occur. The solution is active in the presence of 2% organic matter. Inadvertent dilution can occur when endoscopes that contain fluid within their channels are immersed in the solution. Test strips are available from the manufacturer to monitor the activity of the solution, but should not be used to extend the solution's expiration date. They indicate inactivity when the concentration drops below 1.5%, the minimum concentration required for activity.

VetBooks.ir

Glutaraldehyde irritates mucous membranes of the respiratory and gastrointestinal tracts, and so endoscopes must be rinsed properly after disinfection. It can also cause allergic contact dermatitis, but it is not mutagenic or carcinogenic. The wearing of nitrile rubber or butyl rubber gloves is recommended. Because of its relative expense and toxicity, it is not used to disinfect noncritical surfaces.

***ortho*-Phthalaldehyde.** OPA (e.g., Cidex OPA) is favored over glutaraldehyde for high-level disinfection in the United States, because it does not require activation, is stable over a wide pH range, does not cause irritation of mucous membranes, and it has a barely perceptible odor. Its activity is greater than that of glutaraldehyde, and high-level disinfection is achieved with a contact time of 12 minutes at or above 20°C.[10,11] The primary disadvantage of OPA is that it stains tissues and mucous membranes gray. Protective equipment must be worn when handling the solution, and it must be rinsed thoroughly from items after treatment. Irritation can occur with eye contact. OPA is also more expensive than glutaraldehyde.[12] Solutions can be reused for a maximum of 14 days.

Hydrogen peroxide. Hydrogen peroxide (H_2O_2) is a potent oxidizer. Hydrogen peroxide solutions are widely available, are inexpensive, and can enhance removal of organic matter. When used at concentrations of 7.5% for contact periods of at least 6 hours, hydrogen peroxide is a chemical sterilant (e.g., Sporox). High-level disinfection can be achieved with contact times of 12 to 30 minutes. Unfortunately 7.5% hydrogen peroxide causes discoloration and functional changes within endoscopes and so is not suitable for endoscope reprocessing. Although nonirritating to mucous membranes, serious ocular damage can occur with eye contact.

Accelerated hydrogen peroxide (AHP) is a patented hydrogen peroxide solution that contains surfactants, an acid, and hydrogen peroxide. Use of a 4.5% AHP gel with contact times of 10 minutes can inactivate bacterial spores.[13] Even 0.5% solutions have some sporicidal activity and can inactivate non-enveloped viruses such as canine parvovirus.[14,15] AHP has gained popularity as a disinfectant among health care institutions because it is odorless, does not generate volatile gas, is nonirritating, and is noncorrosive at dilutions used in health care settings.

Peracetic acid. Peracetic acid belongs to the peroxygen family of compounds. When used at 50°C to 56°C in a specific peracetic acid reprocessing system (Steris System 1, Steris), 0.2% solutions achieve sterilization in very short time periods (30 to 45 minutes). Peracetic acid is active in the presence of organic matter and may actually enhance its removal. Nevertheless endoscopes must still be thoroughly cleaned before sterilization to avoid fixation of blood onto the instrument. After sterilization, the processor rinses the instrument thoroughly. Peracetic acid is stable but can be corrosive and causes discoloration of endoscopes over time. It is more expensive than other chemical sterilants. Peracetic acid concentrates can cause irritation to mucous membranes and are corrosive to the eye and skin, but 0.2% solutions are generally nonirritating.

Potassium peroxymonosulfate (Trifectant, Virkon S). Like peracetic acid, potassium peroxymonosulfate is an oxidizing agent, and 1% solutions are high-level disinfectants that are capable of inactivation of non-enveloped viruses when contact times of 10 minutes are used.[16] Thus it is suitable for inactivation of canine parvovirus and feline calicivirus. Potassium peroxymonosulfate retains some activity in the presence of organic matter. Solutions are prepared from powder and remain active for 7 days. The powder is corrosive and can cause serious skin and ocular burns, but the solution is nonirritating and less corrosive than bleach. The solution stains fabric and may damage surfaces, particularly metal, over time if rinsing is not performed.

Sodium Hypochlorite (Bleach). Household bleach, which contains 5.25% to 6.15% sodium hypochlorite, is widely available, inexpensive, and active in the presence of hard water. When used at a 1:10 dilution for a 10-minute contact time, household bleach is sporicidal but is irritating and can be highly corrosive to metal surfaces. This 1:10 dilution is used to control outbreaks of clostridial diarrhea. For most hospital situations, 1:30 to 1:50 dilutions of household bleach provide more than 1000 ppm available chlorine and are effective for intermediate-level disinfection. Noncritical surfaces can be disinfected with 1:500 dilutions of household bleach (>100 ppm available chlorine), with contact times of at least 1 minute. Sodium hypochlorite is inactivated by organic matter, so cleaning is required before disinfection is performed. Solutions lose 50% of their activity over a 1-month period unless they are stored in closed brown bottles. Other disadvantages of bleach solutions are bleaching of colored fabric and the release of toxic chlorine gas when they are combined with other disinfectants such as quaternary ammonium compounds (QUATs).

Quaternary Ammonium Compounds. QUATs are often used as low-level disinfectants for noncritical surfaces in health care facilities. Although they are generally fungicidal, bactericidal, and virucidal for enveloped viruses, some bacteria resist and even grow within QUATs, and such contamination has resulted in HAIs.[17] Contact times vary by product so manufacturer recommendations should be followed; however, 10-minute contact times are often used. Advantages of QUATs include their low cost, high stability, and low toxicity. QUATs are inactivated by hard water, organic materials, soaps, and detergents.

Phenolics. Phenolics are one of the oldest known disinfectant classes. Phenol derivatives that are available for hospital disinfection include *ortho*-phenylphenol and *ortho*-benzyl-*para*-chlorophenol (e.g., Qualitrol, Vetnex). Effective contact times vary with the product. They are active against enveloped viruses and bacteria, but they are not sporicidal and have limited activity against fungi and non-enveloped viruses. Phenol derivatives are active in the presence of organic matter and hard water, are stable, and are noncorrosive. They irritate skin and mucous membranes, and have the potential to be highly toxic if ingested by cats. Because of these limitations and the availability of other effective disinfectants, phenolics are rarely used in veterinary hospitals.

Antiseptics

Alcohol. Ethyl alcohol and isopropyl alcohol are bactericidal, virucidal (for enveloped viruses), and variably fungicidal. The optimum bactericidal concentration is 60% to 90% in water (volume/volume). They do not destroy bacterial spores or penetrate proteinaceous material and so are not recommended for high-level disinfection. They can be used to disinfect noncritical items such as hospital fomites and have very low toxicity, so they are often included in waterless hand sanitizer products together with emollients to prevent drying of the skin. They are flammable and dry quickly, so it can be difficult to achieve adequate contact times (≥1 minute). As a result, alcohol should not be used for routine environmental disinfection.

Iodophors. Iodine solutions are primarily used as skin antiseptics. Formulations for disinfection are also available, which contain higher concentrations of free iodine than antiseptic

VetBooks.ir

preparations. An iodophor is a combination of iodine and a solubilizing agent (e.g., polyvinylpyrrolidone in povidone-iodine), which serves to provide a sustained-release form of iodine. Dilutions of iodophors are more active against microbes than concentrated povidone-iodine, so iodophores must be diluted correctly. Iodophors are bactericidal and virucidal. Their antibacterial activity does not persist for long periods on skin or in tissues, so frequent reapplication is required. Iodophors are relatively nontoxic and nonirritating. They are stable in solution but are inactivated by organic material and they can stain plastics and, to some extent, tissues.

Chlorhexidine. Chlorhexidine is a cationic bisbiguanide that disrupts microbial cell membranes and precipitates cell contents. It is used widely for skin antisepsis in veterinary medicine. Chlorhexidine has persistent activity on the skin, is nonirritating, is active in the presence of body fluids, and has rapid bactericidal activity. Like iodophors, chlorhexidine has limited activity against fungi and mycobacteria. A 2% chlorhexidine solution is preferred over 70% alcohol or povidone-iodine for skin preparation of central venous catheter sites in human patients[18] and is the skin antiseptic of choice for collection of blood for blood cultures. Chlorhexidine may have slightly lower activity against gram-negative bacteria and fungi than povidone-iodine, and both chlorhexidine and iodophors have a slower antimicrobial activity than 60% to 90% alcohol solutions.

Principles of Cleaning and Disinfection

Standard operating procedures that describe preparation and application of disinfectants for all surfaces and objects used in a veterinary hospital, as well as waste management, should be developed, and staff and visitors should receive education about the location of protocols and their use. Wards and procedure and examination rooms should remain uncluttered in order to facilitate effective cleaning. Because organic matter can inactivate disinfectants, all visible debris should be removed before disinfection. Disinfectants are only active when applied to clean, nonporous surfaces. Porous surfaces such as dirt and wood cannot be effectively disinfected using routine procedures. Hard porous surfaces should be scrubbed with disinfectant using brushes, and then rinsed with water after the contact time has elapsed.

When hospital surfaces are cleaned, attention should be paid to corners, under cabinets, chairs, the bases of examination tables, door handles, elevator buttons, shelves, sinks, faucets, and other surfaces that might otherwise be ignored. Personal items such as cell phones and stethoscope heads should be regularly disinfected with disinfectant wipes. Cell phones should be disinfected at least daily, and stethoscope heads wiped between patients. Stethoscope tubing should be cleaned regularly with soap and water. Disinfection of other fomites should be performed on a regular (at least daily) basis. These include digital thermometers, computer keyboards and mice, land-line telephones, calculators, microscopes, otoscopes, and blood pressure cuffs.

Cleaning staff should wear gloves when general hospital disinfection is performed. This may not be necessary for spot cleaning of areas such as examination room tables or fomites. Depending on the disinfectant, additional protective attire, such as a gown, boots, or face mask, may be required if there is a probability of significant splashing during the disinfection process. After disinfection is complete, protective clothing should be removed and handwashing performed. The individuals responsible for cleaning and disinfection at each time point, situation, and location in the hospital should be clearly identified. A plan for the cleaning of outdoor areas that become contaminated with excretions or other biohazardous material should be outlined.

When disinfection of cages or runs is performed, animals should be removed and placed in a clean holding cage or run, away from other patients. Solid waste and soiled laundry or paper should be removed and placed directly in waste or laundry containers, taking care to avoid dripping onto the floor. If laundry is contaminated with potentially infectious material, it must be bagged and labeled with the contents and suspected infectious agent. Proper contact times should be used after application of disinfectant solution. Runs and cages should be allowed to dry completely before a new patient is introduced.

Immunocompromised People and Children

People are considered immunocompromised if they (1) have various comorbidities such as diabetes mellitus, chronic kidney failure, leukopenia, immune-mediated disease, HIV/AIDS, congenital immunodeficiencies, hepatic cirrhosis, cancer, or splenectomy; (2) are being treated with immunosuppressive drugs or chemotherapeutics; (3) are very young (5 and under) or very old; or (4) are pregnant, although the immunosuppressive effects of pregnancy are considerably lower than those of the preceding disorders.

Immunocompromised staff members who work in small animal hospitals should discuss any necessary work restrictions and precautions in light of their specific condition with their physician or an infectious disease doctor. The risks for a diabetic, for example, may be significantly different from those for a transplant recipient. In general, immunosuppressed individuals who work in small animal hospitals should avoid handling patients with suspected or known infectious diseases. Gloves should always be worn when handling animals and animal fluids or excreta, and strict attention to general hand hygiene and any bites, scratches, or sharps injuries is critical. Children 5 years of age or younger should be kept out of patient care areas. Strict attention to hygiene and protective apparel is necessary when handling soiled cat litter or animal feces, because of the risk for transmission of enteropathogens. The reader is referred to other chapters in this book for public health implications of specific infectious diseases that may be encountered in small animal hospitals. If possible, small animal clinics should establish a relationship with a doctor who is prepared to consult on zoonotic exposures with staff members.

Transmissible Disease Surveillance and Reporting

A transmissible disease surveillance program allows collection of baseline data that establishes the prevalence of certain infectious diseases, so that possible outbreak situations can be readily identified. It can also provide background prevalence information on antimicrobial drug susceptibility patterns, which can assist in the initial selection of antibacterial drugs for individual animal patients while culture and susceptibility test results are in progress. Information is generally collected for multidrug-resistant bacterial infections, zoonotic diseases, highly contagious diseases, pathogens that are difficult to inactivate with

VetBooks.ir

disinfectants, or agents of regulatory concern. Although surveillance may seem like a difficult, time-consuming, and expensive measure, in reality, it can be easy and cost-effective and can provide important information.

There are two main forms of infection control surveillance applicable to veterinary hospitals: active and passive. *Active surveillance* involves collection of data specifically for infection control purposes. This can provide the highest quality and most relevant information, but it can be expensive and time consuming. Examples of this would be collection of swab specimens to screen for infection with methicillin-resistant *Staphylococcus pseudintermedius* (MRSP) from dogs before surgery as part of MRSP outbreak investigation. Active surveillance is a core component of infection control in most human hospitals, but it is only sporadically used in veterinary medicine and is rarely needed in most veterinary clinics. It is typically reserved for large facilities with increased infection control risks and personnel available to direct such testing, or as a part of outbreak control.

In contrast, *passive surveillance* is a practical, easy, and cost-effective surveillance approach that can and should be performed in every veterinary clinic. It involves the use of data that are already available, such as information about surgical site infections collected during routine follow-up or culture results from clinical testing. The quality of passive surveillance data can be limited by poor or incomplete record keeping or sporadic use of appropriate diagnostic tests, but if properly collected and if potential biases are understood, passive surveillance data can provide important insight into aspects such as endemic disease rates, common pathogens, and antimicrobial susceptibility trends. To facilitate passive surveillance, clinicians should be encouraged to use appropriate diagnostic testing to determine the etiology of nosocomial infections, even if the clinical consequences are not severe. They also should be encouraged to confirm a diagnosis in animals with suspected transmissible disease. This allows clients to protect their other animals and their families and friends who might be in contact with the pet, and it benefits the hospital.

Another form of surveillance that is easy to perform and potentially very useful is *syndromic surveillance*. This involves surveillance for readily identifiable syndromes (i.e., diarrhea, cough) instead of specific diagnoses. Although syndromes do not indicate a specific disease, they can indicate an increased risk of infectious disease. Syndromic surveillance is an initial screening tool that can be used by all personnel, including lay personnel, to flag potentially high-risk cases and allow for early implementation of enhanced infection control practices. All clinic personnel should be made aware of certain syndromes that indicate the need either for isolation or for further investigation, such as diarrhea, fever of unknown origin, acute neurologic disease, wound infections, and acute respiratory tract disease. Protocols to deal with these animals on arrival should be developed. As an example, a dog with an acute onset of cough should be considered potentially infectious, and if front office personnel note this syndrome at the time the appointment is made, the dog can be handled appropriately on arrival (e.g., admitted directly to isolation or an examination room, with personnel wearing enhanced barrier precautions from the onset). The role of lay staff (i.e., front office stall) is critical, as these people are the ones who are most able to identify such cases before they enter the clinic and ensure that they are properly handled to prevent nosocomial or zoonotic transmission.

BOX 11-3

Infectious Diseases of Dogs and Cats That Are Reportable or Potentially Reportable to Public Health Agencies

- Amebiasis
- Granulocytic anaplasmosis
- Brucellosis
- Campylobacteriosis
- Coccidioidomycosis
- *Cryptococcus gattii* infection
- Cryptosporidiosis
- Giardiasis
- Leishmaniosis
- Leptospirosis
- Lyme disease
- Q fever
- Rabies
- Salmonellosis
- Tularemia
- Tuberculosis
- MRSA (not MRSP)
- Novel H1N1 influenza virus infections
- West Nile Virus infection
- *Yersinia* infections

Environmental cultures are rarely informative and so are not considered a useful routine infection control tool. They may be used to detect a specific pathogen if an outbreak of an HAI is suspected when there is suspicion that the environment is a source of exposure. However, it is often difficult to distinguish cause from effect (i.e., environmental contamination that leads to transmission vs. environmental contamination that occurs as a result of contamination from a patient in the absence of a risk of transmission).

Although surveillance programs require time, effort, and expense, in the long term they may save morbidity and mortality and reduce costs that relate to control of large outbreak situations or the legal ramifications of HAIs.

When zoonotic diseases are identified, all in-contact individuals and, if necessary, public health authorities should be notified in the appropriate manner. The specific diseases that must be reported to authorities vary among geographic locations. Examples of diseases that may be of interest to public health authorities are listed in Box 11-3.

Surgical Preparation

Surgical site infections (SSIs) are an uncommon but important and sometimes devastating complication of surgery. Every patient undergoing a surgical procedure is at some risk of SSI. Standard practices have been developed to reduce the risk of SSIs. Although a wide range of practices are relevant, preparation of the patient and preparation of the surgeon are critical.

Patient Preparation

The patient's endogenous microflora is an important source of pathogens that cause SSIs. Careful preparation of the patient, therefore, can help reduce contamination of the surgical site during surgery. The goal of preoperative surgical site management is to eliminate potential pathogens while not creating a physical environment that is more conducive to bacterial colonization or infection postoperatively. Bathing of the patient preoperatively is reasonable if there is significant contamination of the haircoat[19] and if the patient's coat can be dried by the time of surgery. In most situations, bathing is not required. Rather, careful hair removal and skin antisepsis are the main measures.

VetBooks.ir

The goals of surgical scrubbing of patients are to reduce bacterial counts, reduce debris, and facilitate later antisepsis. Scrubbing should be done as atraumatically as possible. Minimizing skin damage during clipping and scrubbing is essential, because skin damage from excessive attempts to clip all remaining pieces of hair or from forceful scrubbing of the surgical site can create an environment that is more amenable to bacterial growth. This predisposes to infection rather than reducing the risk. Clipping should be performed after anesthesia, to reduce the risk of trauma associated with a struggling patient and to minimize the time between clipping and surgery. Clipping should be done outside the operating environment. There is currently no information that relates to optimal methods of cleaning and disinfecting clippers. Repeated use of clipper blades without sterilization not surprisingly results in higher levels of bacterial contamination of blades[20]; however, the clinical relevance of this is unclear, because the surgical site is cleaned and disinfected after clipping. Regular cleaning and disinfection of clippers are probably useful, and they should be thoroughly cleaned and disinfected after use on an animal with a potentially transmissible infection (e.g., an animal with diarrhea), on an area where the skin is broken, or on any area where the skin or hair is significantly contaminated with feces, urine, blood, or other body fluids.

After hair removal, various approaches for skin antisepsis can be used. There is little outcome-based evidence of the relative efficacy of different approaches in the human literature. Typically, a three-step process is used, with initial scrubbing of the site with biocidal (i.e., chlorhexidine, povidone-iodine) soap, followed by application of alcohol for biocidal effects and to remove oils, and a final application of a biocidal solution with residual activity (e.g., chlorhexidine).

Surgeon Preparation

The surgeon's body and clothing are potential sources of SSI pathogens, and standard practices have been developed to reduce the risk of contamination of the surgical site. One aspect is the use of proper protective clothing. Every person in the operating environment should wear clean surgical scrubs. These scrubs should be dedicated for use only in the operating room or should be covered with a clean laboratory coat whenever the individual is outside of the operating room.

Surgical hand antisepsis is critical because of the close contact of the hands with the surgical site and the relatively high incidence of grossly evident breaks or micro-breaks in gloves. Surgical hand antisepsis is designed to greatly reduce bacterial burdens on the hands, particularly the abundant transient microflora that contains most of the relevant pathogens that cause SSIs. Surgical antisepsis must find a balance between effective elimination of pathogens, minimization of trauma to the skin (because skin irritation facilitates bacterial growth), and time constraints. The traditional approach to surgical hand antisepsis has involved structured scrubbing of the hands for a predetermined time. Recommended scrub times vary between products but are typically 2 to 4 minutes.

Application of alcohol-chlorhexidine combinations has been evaluated as a replacement for surgical scrubbing and has been shown to be more effective than standard surgical scrub methods.[21,22] Specific manufacturer instructions should be followed, and hands and arms must be dry before application of gloves. The use of alcohol-based surgical hand antisepsis products is encouraged as a replacement for traditional scrubbing.

BOX 11-4

Example of Criteria Specified within a Hospital for Use of Restricted Antimicrobial Drugs

- Infection must be documented based on clinical abnormalities *and* culture.
- Subclinical infections should not be treated with these antibiotics. These antibiotics should be reserved for infections that are life threatening.
- Resistance to all other reasonable options and susceptibility to the chosen antimicrobial must be documented.
- The infection must be potentially treatable.
- The clinician should contact the infectious disease control officer or a clinical microbiology faculty member by email or telephone to discuss antimicrobial susceptibility test results, determine whether there are any other viable options, and confirm that a restricted antimicrobial is necessary.

Regardless of the method used, a thorough handwash with careful cleaning under the fingernails must be performed at the beginning of each day.[23] Long (>¼-inch) and artificial nails are prohibited in many human health care facilities and some veterinary hospitals because they harbor pathogenic bacteria[24] and are associated with surgical glove tears.

A cap and mask must be worn during hand antisepsis, and sterile gown and gloves must then be donned using appropriate technique.

Antimicrobial Drug Use

The use of antimicrobial drugs contributes to the selection for antimicrobial-resistant bacteria. Inclusion of a policy on antimicrobial drug use in the infection control protocol may help to reduce the prevalence of multidrug-resistant HAIs. On their own, fever and leukocytosis are not justification for antimicrobial drug treatment. Whenever possible, when infection is suspected, attempts to obtain material for culture and susceptibility testing should be made before antimicrobial drug treatment is initiated. When secondary bacterial infection is likely, attempts to identify and treat the underlying cause should be made. In an effort to minimize the emergence of resistance in bacterial flora of animals in the hospital and decrease the risk of resistant HAIs, the use of several antimicrobials (e.g., certain parenteral third-generation cephalosporins, vancomycin, linezolid, and carbapenems such as imipenem and meropenem) may be restricted unless criteria must be met (Box 11-4).

Prevention of Infectious Disease in Shelters and Breeding and Boarding Facilities

Attention to hand hygiene and proper disinfection of fomites and the environment as outlined for hospitals can also be used to reduce transmission of infectious pathogens in shelters and in breeding and boarding facilities (Box 11-5). Disinfectants with activity against parvoviruses and feline calicivirus should be used routinely, such as a 1:30 dilution of household bleach,

VetBooks.ir

BOX 11-5

Factors That Should Be Considered for the Reduction of Infectious Disease Transmission in Animal Housing Facilities

- Adequate ventilation and air quality
- Adequate temperature
- Adequate lighting conditions (including provision of darkness at night)
- Population density/space per animal
- Daily removal of fecal and urine contamination and disinfection
- Adequate drainage
- Separate housing areas for dogs and cats
- Isolation for sick animals
- Separate housing areas for young and adult animals
- Individual housing or small groups of two to four compatible animals
- Separation of elimination, feeding, and resting areas
- Elevated resting areas
- Elevated cages for cats
- Provision of hiding areas
- Sound control
- Use of surfaces that can be readily disinfected
- Proper use of appropriate disinfectants
- Hand hygiene and protective clothing
- Fomite control
- Use of appropriate vaccination protocols
- Order of care (young animals, healthy adults, and then sick animals)
- Proper nutrition
- Pain management
- Free access to clean water
- Rodent and pest control
- Parasite control
- Daily monitoring by properly trained individuals
- Proper diagnosis of disease outbreaks

potassium peroxymonosulfate, or accelerated hydrogen peroxide solutions. Removal of organic matter, the use of surfaces that can be adequately disinfected, and proper contact times are essential.

Factors that increase stress should also be minimized, such as high population densities, the grouping of animals, and poor nutrition. Cats and dogs should be separated from one another. In cats, the use of methods that reduce stress, such as provision of a low-stress cage environment, can dramatically reduce the frequency of upper respiratory tract disease. Compartmentalized housing allows animals to urinate and defecate away from areas where they rest and eat, and provision of a hiding area so that animals can retreat from visual stimulation can also reduce stress. A total of 10 to 20 air changes per hour is often recommended for animal housing, but higher levels of ventilation may be needed with increased population density and concentration of airborne contaminants. Cages should be cleaned and disinfected at least daily. The use of compartmentalized housing areas also facilitates cleaning and disinfection without requiring an animal to be removed from the housing area. Isolation areas for sick animals should be present and these should have separate airflow from areas that house healthy animals. Mass treatment of dogs and cats with upper respiratory tract disease with antimicrobials without attention to the underlying causes only results in selection for antimicrobial drug resistant organisms and is not recommended. Detailed information on the control of infectious diseases in shelter environments is beyond the scope of this book but can be found elsewhere.[25] The American Association of Shelter Veterinarians and the Humane Society of the United States have published guidelines for operation of animal shelters.[26,27]

Immunization

Jane E. Sykes

VetBooks.ir

KEY POINTS

- Active immunization can partially or completely protect dogs and cats from severe consequences of infection with a variety of different pathogens, and in some cases it reduces shedding of these pathogens.
- Vaccines contain attenuated live microorganisms, inactivated microorganisms, or portions of these organisms. They also contain preservatives and adjuvants.
- Failure of immunization can occur with improper storage or administration of vaccines, a large challenge dose, host factors such as concurrent infections or disease, and interference by maternal antibody.
- Other adverse effects of vaccine administration are uncommon to rare but include hypersensitivity reactions, disease induced by live attenuated vaccine organisms, and injection-site sarcomas in cats.
- The decision to administer a vaccine should be based on discussion of risks and benefits between the veterinarian and pet owner. This should be documented in the medical record.
- Guidelines for vaccine selection and administration have been published by a number of veterinary bodies, such as the AAFP, AAHA, AVMA, and WSAVA; suggestions can also be found in Appendix I.

INTRODUCTION

Immunization refers to artificial induction of immunity or protection from infectious disease and may be *active* or *passive*. *Active immunization* involves administration of vaccines that stimulate cell-mediated or humoral immunity, or both, to a specific pathogen. *Passive immunization* refers to the administration of antibodies in order to provide temporary protection from disease and can occur through acquisition of maternally derived antibody (MDA) transplacentally, in colostrum, or milk; or treatment with preparations that contain specific or nonspecific immunoglobulins (see Immunomodulators, Chapter 7, and post-exposure prophylaxis for rabies, Chapter 13). Readers are referred to advanced immunology texts for detailed descriptions of the physiology of active and passive immunity.[1]

The goal of immunization is to generate a protective immune response of prolonged duration against a specific infectious disease, with minimal adverse effects. Because of the potential for adverse effects, vaccination should be performed only if there is a risk for significant morbidity or mortality from an infectious disease. Since the 1950s, a huge number of vaccines for dogs and cats have been developed and marketed worldwide, and more are in development. Nevertheless, it is estimated that even in developed countries such as the United States, only 30% to 50% of dogs are properly immunized, and possibly an even smaller proportion of cats.[2,3] Appropriate vaccination of a larger proportion of the pet population may assist in reduction of the prevalence of infectious diseases through the induction of herd immunity.

With the appearance of injection-site sarcomas in cats, increased emphasis has been placed on vaccine safety, and a change from annual to 3-yearly immunization protocols for some vaccines has been recommended, with administration of other vaccines based on exposure risk. Vaccines have had a profound influence in the control of infectious disease, and for many vaccines the benefits of vaccination outweigh the risks.

Vaccine Composition and Types of Vaccines

A vaccine is a suspension of attenuated live or inactivated microorganisms, or parts thereof, that is administered to induce immunity. In addition to protective antigens, vaccines may contain preservatives and stabilizers as well as specific antibiotics to preserve the antigen and inhibit bacterial and fungal growth within the vaccine. Some vaccines also contain an *adjuvant* to enhance the immune response to the antigen. Although the mechanisms are not completely clear, adjuvants can delay the release of antigen from the site of injection and induce the secretion of chemokines by leukocytes.[4] The most widely used adjuvants are particulate adjuvants, such as those that contain aluminum salt precipitates such as aluminum hydroxide.[5] Other particulate adjuvants include immunostimulators such as saponin, which is present in a canine *Leishmania* vaccine.

Attenuated live vaccines (or modified live vaccines) contain microorganisms that are artificially manipulated so as to negate or greatly reduce their virulence, or are field strains of low virulence. Repeated passage through cell culture is the most common means of attenuation. Because they replicate in the host, organisms in attenuated live vaccines usually stimulate an immune response that most closely mimics the protection that results from natural infection. Vaccination with attenuated live canine parvovirus (CPV) and canine distemper virus (CDV) vaccines in the absence of MDA can result in protective immune responses within 3 days of a single injection, which may be followed by immunity that lasts many years, if not for life.[6-8] Partial immunity after vaccination with attenuated live CDV and feline panleukopenia virus (FPV) vaccines can occur within hours.[3,9,10] In addition, vaccine organisms that are shed can serve to immunize other animals in a population. However, the potential for reversion to virulence or vaccine-induced disease exists. Vaccine-induced disease is most likely to occur in highly immunosuppressed animals. Attenuated live vaccines also have the potential to cause some immunosuppression in their

VetBooks.ir

TABLE 12-1

Advantages and Disadvantages of Attenuated Live and Inactivated Vaccines

	Attenuated Live	Inactivated
Advantages	Rapid onset of immunity Sustained immunity after single dose May immunize others in populations Improved breakthrough of maternal antibody interference	Safe, even in immunocompromised and pregnant animals Do not interfere with development of immunity from other vaccines Stable in storage
Disadvantages	Potential for reversion to virulence Virulence in the immunocompromised Contraindicated in pregnancy May cause immune suppression Can interfere with development of immunity if administered within days to 2 weeks of another vaccine Less stable in storage Potential for vaccine contamination	Slow onset of immunity Multiple boosters required Often highly adjuvanted, with greater potential for adverse effects Reduced degree of protection compared with attenuated live vaccines Poor breakthrough of maternal antibody interference

own right,[11,12] or they may shift the balance from Th1 to Th2 immune responses.[13] Rarely, this can lead to clinical disease. For example, an outbreak of salmonellosis was reported in cats after use of a high-titered attenuated live FPV vaccine.[14] Very rarely, contamination of attenuated live vaccines has occurred with other pathogenic microorganisms present within cell cultures used to propagate the vaccine.

Generally speaking, *inactivated vaccines* are less effective than attenuated vaccines, because replication in the host does not occur. They produce weaker immune responses of shorter duration, and more frequent booster immunizations may be required. Two initial doses of vaccine 3 to 4 weeks apart are essential to produce an effective immune response, and if more than 6 weeks elapses between these doses, it has been recommended that the series should be repeated.[15] Beyond the initial vaccination series, it is not clear whether lapsed annual boosters require the series to be restarted. This is not considered necessary for human immunization[16] but has been suggested for dogs when more than 2 or 3 years elapses between boosters.[15] Inactivated vaccines usually contain adjuvant as well as a large infectious dose to improve immunogenicity. They are safer than live attenuated vaccines for use during pregnancy and in very young or debilitated animals. Although bacterins have traditionally been associated with a greater likelihood of allergic reactions than live attenuated vaccines, newer inactivated vaccines are safer and have reaction rates that more closely approach those of live attenuated vaccines. The maximum duration of immunity that is induced by commercially available bacterins for dogs and cats remains largely unknown, partly because challenge studies that evaluate long-term duration of immunity are prohibitively expensive. However, some inactivated viral vaccines have been shown to have durations of immunity in excess of 7 years in cats.[17] Caution is required when extrapolation is made from the duration of immunity for one product to that for a similar product from a different manufacturer, because it may not be equivalent. Although bacterins usually do not protect all animals from infection, they may prevent clinical illness. In some cases, natural infection of vaccinated animals serves to further boost the immune response, and this can influence duration of immunity in the field. The advantages and disadvantages of attenuated live and inactivated vaccines are shown in Table 12-1.

Subunit vaccines contain specific structural components of a microbe that stimulate a protective immune response, together with adjuvant. They contain reduced amounts of foreign protein, which minimizes the potential for hypersensitivity reactions.

Recombinant DNA vaccines are created through manipulation of the DNA of a pathogen in the laboratory, with the negation of pathogen virulence. Sometimes this also can allow diagnostic tests to differentiate naturally infected from vaccinated animals (DIVA), because of differences in the antibody response evoked by the vaccine. There are several different types of recombinant DNA vaccines:

1. Recombinant subunit vaccines. These are produced by cloning one or more genes for a protective antigen into an expression vector, such as in *Escherichia coli*. The protein expressed by the bacteria is then purified and used in the vaccine (Figure 12-1, *A*). An example of a recombinant subunit vaccine is the Lyme recombinant OspA vaccine.
2. Deletion mutant vaccines. These are produced by deleting virulence genes from a pathogen while protective antigens are left in place. There are currently no such vaccines for dogs and cats.
3. Vectored vaccines. These are produced by inserting genes for one or more protective antigens into the genome of a virus. The virus replicates in the host and expresses the antigens but is nonpathogenic (see Figure 12-1, *B*). Currently available vectored vaccines for dogs and cats use canarypox virus as a vector.
4. DNA vaccines. These consist of naked DNA that encodes the antigens required for protective immunity. The DNA is injected directly to the animal using an inoculation system. The DNA is then taken up by host cells and translated into antigen. Both humoral and cell-mediated immune responses are produced. DNA vaccines are not currently available commercially for use in dogs and cats.

Vaccine Storage, Handling, and Administration

Vaccines should be stored and administered according to label recommendations. Inactivation of vaccines can occur if they

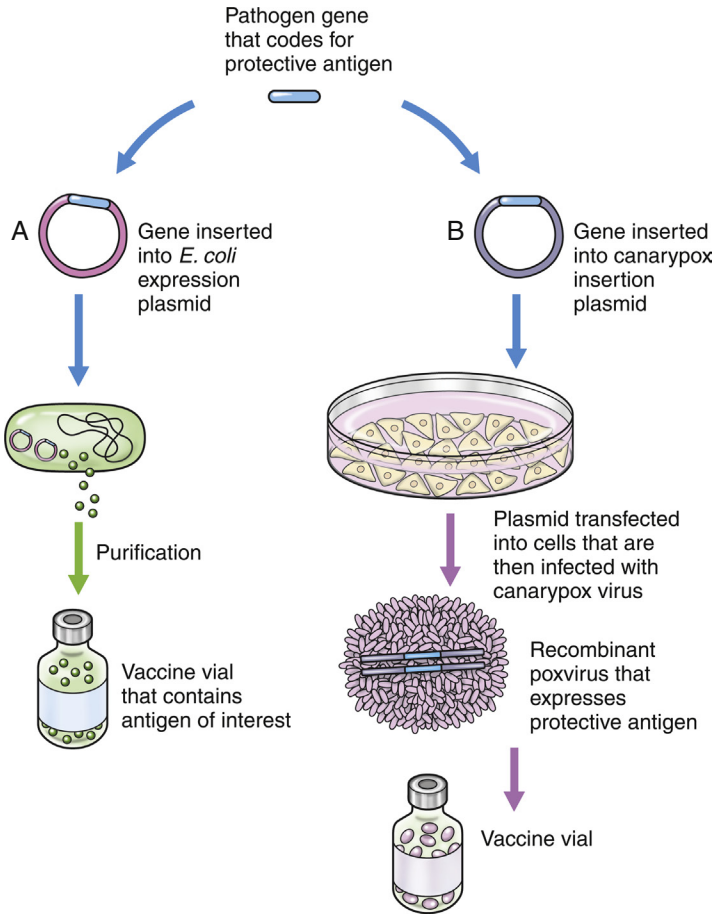

FIGURE 12-1 Examples of recombinant DNA vaccines. **A,** Recombinant subunit vaccine. The gene of interest is inserted into an expression vector such as a plasmid taken up by *Escherichia coli,* which subsequently produces large amounts of an immunogenic protein. This is purified and used in the vaccine. **B,** Vectored vaccine. The gene or genes of interest are inserted into a canarypox or vaccinia vector, which is then inoculated into an animal. Replication of the vector within the host is followed by expression of the immunogenic protein.

are inadvertently frozen or heated to excessive temperatures, exposed to excessive amounts of light, or used beyond their expiration date. Hands should be washed before preparation and administration of the vaccine. Lyophilized products should be reconstituted with the proper diluent, and different vaccines should not be mixed in the same syringe or vial. Reconstituted products should be used immediately. It has been recommended that attenuated live vaccines be discarded if more than 1 hour has lapsed since reconstitution,[15] although no published reports exist of the viability of vaccine organisms over time after reconstitution or of the ability of stored, reconstituted vaccine to elicit an immune response. Vaccines should only be used in the animal species for which they are labeled, or serious adverse effects or failure of immunization can occur.

If vaccines for multiple different pathogens are to be administered simultaneously, they should be injected at distant sites or, if possible, a combination vaccine should be used. Simultaneous vaccination for more than one pathogen does not appear to interfere with immune responses to each component of the vaccine,[18-20] and vaccine manufacturers must demonstrate that the protection that occurs for a specific pathogen after vaccination with a combination product equals the protection that occurs when a vaccine for only that pathogen is given. In contrast, successive parenteral administration of different attenuated live vaccines at 3 to 14 day intervals has the potential to interfere with immune responses. An interval of 4 weeks is preferred for human patients.[16,21] Inactivated vaccines do not produce interference in this way.[16] If possible, administration of vaccines to animals that are under anesthesia should be avoided because adverse reactions may be difficult or impossible to recognize in this situation. It is not necessary to re-administer an intranasal vaccine if the animal coughs or sneezes after administration.

The site and route of administration, product, serial number, expiry date, and individual who administered the vaccine should be recorded for each vaccine administered.[2] Vaccine vials often possess adhesive labels that can be easily removed and applied to a paper medical record.

Components of the Immune Response

The immune response is divided into innate and adaptive immune responses. The innate immune response is nonspecific and acts as an immediate line of defense against an infection. Components of the innate immune response consist of natural killer cells, which recognize host cells that are infected by viruses; complement, which is activated by bacterial cell wall components; and phagocytes, such as macrophages and dendritic cells. The adaptive immune response develops over several days and involves presentation of antigen by dendritic cells in association with the major histocompatibility complex and stimulation of B and T cell responses, together with the

VetBooks.ir

BOX 12-1

Factors That Can Affect Immune Responses to Vaccines

Target pathogen (e.g., respiratory versus systemic pathogen)
Vaccine composition (e.g., inadequate adjuvant)
Route of administration
Young age
Breed/genetic factors
Nutrition
Pregnancy status
Concurrent moderate to severe illness
Fever
Immunosuppressive drugs
Presence of maternal antibody
Improper vaccine storage and administration
Vaccination with an attenuated live viral vaccine within last 3 days to 2 weeks
Inadequate time allowed for immunization before exposure to field organisms

formation of memory B cells. The nature of the innate response influences the subsequent adaptive response. Cells of the innate immune system possess pattern recognition receptors that can recognize patterns that are characteristic for various pathogens (pathogen-associated molecular patterns, or PAMPs), including Toll-like receptors and NOD-like receptors. PAMPs are under investigation for use as adjuvants in human and animal vaccines in order to create improved T cell immune responses.[4,22]

Determinants of Immunogenicity

All vaccines that are available for dogs and cats induce cell-mediated immunity (CMI) with induction of immunologic memory and a booster effect on repeat administration. Although the presence of antibody correlates with protection for some pathogens, such as CDV and CPV, a lack of antibody does not infer a lack of protection, because of the presence of CMI, which is more difficult to measure.

Vaccines rarely protect all vaccinated individuals from infection and disease. In particular, vaccines for canine and feline respiratory pathogens do not prevent disease but can reduce the prevalence and severity of disease as well as reduce the number of organisms shed. Limited immunity following vaccination is especially likely for infections for which immunity after natural infection is partial or short-lived.

The ability of a vaccine to induce an immune response depends not only on the target pathogen, vaccine composition, and route of administration, but also on host factors such as age, nutrition, pregnancy status, stress, concurrent infections, and immune status, including the presence or absence of passively acquired antibody (Box 12-1). Some of these factors may also influence vaccine safety. Some animals, particularly dogs of the Rottweiler breed, may have an impaired ability to respond to vaccination. These dogs have been termed *nonresponders*.[2,23] This situation is probably rare if efficacious vaccines are used and booster vaccines are administered. Young dogs, less than 1 year of age, have a significantly reduced response to vaccination with rabies virus vaccines when compared with adult dogs.[24] Small-breed dogs have a greater serologic response to rabies vaccines than large-breed dogs.[25] Administration of vaccines to febrile animals or animals with moderate to severe illness should be avoided if possible until recovery has occurred, because the immune response to the vaccine may be suboptimal.

Failure of immunization can result from an inadequate dose of antigen. Thus, division of a single vaccine dose for administration to a larger number of dogs and cats, or small-breed dogs as opposed to large-breed dogs, may lead to failure of immunization. Veterinarians should not split vaccine doses because this shifts the liability from the vaccine manufacturer to the veterinarian if vaccine failure occurs. Immunization can also fail in the face of an overwhelming challenge dose.

The route of administration can influence the type of immune response generated. Subcutaneous administration is associated primarily with an IgG response, and rarely induces high levels of secretory IgA antibodies. In contrast, intranasal administration results in an IgA and, to a lesser extent, an IgG response. Immunogenicity and safety may be compromised when a vaccine is administered using the incorrect route.

In young animals, MDA can neutralize vaccine antigens and interfere with effective immunization. This is one of the most common reasons for vaccine failure in dogs and cats. Any MDA titer against CPV has the potential to interfere with immunization. The amount of MDA in a puppy or kitten at any one point in time cannot be predicted because it varies depending on the titer of the dam and the amount of colostrum ingested after birth. As a result, a series of vaccinations are administered in order to increase the chance that successful immunization will occur soon after the decline of MDA titers to sufficiently low concentrations (Figure 12-2). Nevertheless, a window always exists when MDA concentrations are high enough to interfere with immunization, but not sufficient to prevent natural infection. This window is known as the *window of susceptibility* or the *window of vulnerability*. The use of recombinant vectored vaccines can overcome the interference by MDA, although the extent to which this applies in animals that have passive immunity to the vector virus (i.e., immunity transferred from a dam that was immunized with a recombinant vector vaccine) requires clarification. Because replication of the vector is aborted, the immune response to the vector itself may be reduced. As a result, passive transfer of neutralizing antibody titers to the vector may not occur. Mucosal vaccines can also provide greater protection in the face of MDA; the mucosal immune system matures shortly after birth.[26,27]

Whenever possible, animals should be isolated until sufficient time has elapsed for proper immunization. For most parenteral and mucosal vaccines, this is 1 week (and at the absolute minimum, 3 days) after inoculation. Vaccine failure can also occur in animals that are incubating the disease for which vaccination is performed at the time of vaccination.

Measurement of the Immune Response

For some vaccines, such as rabies, CDV, CPV, and FPV, the presence of circulating antibodies correlates with protection (Table 12-2). Thus, serologic assays have been used in dogs and cats to decide whether vaccination is necessary or likely to be effective. These serologic assays have also been used to clear pets for travel.

Although tests that measure antibody responses in dogs and cats have improved in recent years, different laboratories can report significantly different values for the same serum

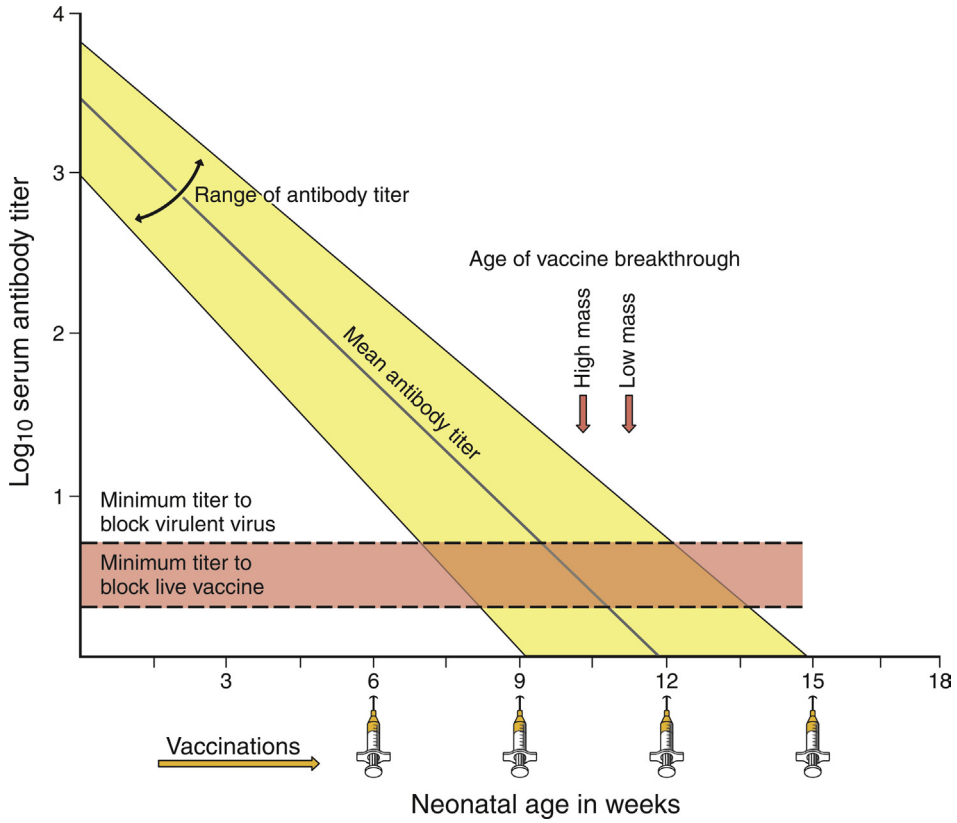

FIGURE 12-2 Influence of maternal antibody (MDA) on immunization. Puppies and kittens acquire variable amounts of MDA transplacentally and through colostrum after birth. This binds to vaccine antigens and inhibits the immune response. A series of vaccines are administered to maximize the chance of inducing an immune response as MDA concentrations decline. The *window of susceptibility* is the period of time when MDA concentrations are high enough to interfere with immunization, but not sufficient to prevent natural infection. High antigen mass vaccines provide protection earlier than low mass vaccines. (From Greene CE, Schultz RD. Immunoprophylaxis. In: Greene CE, ed. Infectious Diseases of the Dog and Cat, 3 ed. St Louis, MO: Saunders; 2006.)

TABLE 12-2

Antibody Titers That Correlate with Protection against Distemper, Parvovirus, and Rabies

Pathogen	Minimum Protective Titer	Methodology Used
Canine distemper virus	≥1:16 to 1:20	Serum neutralization (SN)
Canine parvovirus	≥1:80 to 1:100	Hemagglutination inhibition (HI)
Rabies	≥0.5 IU/mL	Fluorescent antibody virus neutralization (FAN)

specimen, and there is a lack of validated sensitivity and specificity for these assays. Sometimes use of these assays increases costs significantly and delays immunization. In-practice assays also are available for detection of antibody responses, and these have the potential to overcome problems associated with laboratory quality control and delays in immunization. In-practice assays are generally not quantitative. Although high antibody titers are generally associated with greater protection, an animal with no titer may still be resistant to challenge because of CMI, which is not measured. Conversely, an animal with a titer that is generally regarded as protective has the potential to develop disease after challenge, possibly because of overwhelming exposure or immune suppression. Measurement of antibody titers may be considered for animals that have had previous adverse responses to vaccination, particularly susceptible breeds (e.g., Rottweilers and CPV infection). The World Small Animal Veterinary Association (WSAVA) has suggested that puppies could be tested at least 2 weeks after the final puppy vaccine to decide whether further vaccination for CDV or CPV is necessary.[2] Negative titers should prompt additional vaccination for these puppies.

Rapid in-house serologic assays have also been used to make decisions regarding isolation or euthanasia in shelter situations, through identification of immune animals.[28] Unfortunately, it is not always be possible to know if positive titers represent recent infection, and animals that test positive may still shed virus and pose a risk to other animals. In young puppies and kittens, positive results may represent persistent MDA or the presence of active immunity, and MDA does not have the same ability to protect against infection. In-house serologic assays can also be used to decide whether pregnant animals are susceptible in a shelter environment and thus minimize adverse reactions to attenuated live vaccines in this group of animals (see Appendix I). A study that evaluated the performance of one ELISA assay (Synbiotics TiterCHEK CPV/CPV) found that for CPV antibodies, the sensitivity and specificity of the assay was 92% and 94%, respectively, when compared with hemagglutination inhibition; and for CDV was 76% and 92%, respectively, when compared with serum neutralization.[29]

FIGURE 12-3 Facial edema and hyperemia in a 4-month old intact male Chihuahua mix after vaccination with a bacterin vaccine. (Courtesy Dr. Stephen D. White, University of California, Davis Veterinary Dermatology Service.)

Adverse Reactions to Vaccines

A vaccine is needed if an infectious disease causes significant morbidity and mortality. Vaccines should prevent more disease than they cause. In order to produce protective immunity, a vaccine *must* stimulate a reaction in an animal, both at the site of injection and systemically. This may cause clinical signs. Ideally, the signs are mild and either unnoticeable or acceptable to the pet owner. In rare situations, adverse reactions are severe enough to threaten a pet's life. Sometimes, enhanced efficacy leads to a reduction in vaccine safety. Veterinarians are encouraged to report adverse reactions to vaccines to a technical service veterinarian employed for this purpose by the vaccine manufacturer. In some countries, the drug company then reports details of the adverse reaction to drug regulatory authorities. An understanding of the true nature and incidence of adverse effects associated with vaccination has been hampered by underreporting and variable delays between vaccination and the inconsistent appearance of potential, more chronic systemic adverse effects.[30] In addition, correlation of adverse reactions to vaccine administration in young animals may be difficult because of the uniform and frequent administration of vaccines to this group. For example, it has been difficult to prove a connection between vaccination for distemper and development of hypertrophic osteopathy in Weimaraner dogs.

Immune-Mediated Vaccine Reactions

Type I Hypersensitivity Reactions

Type I hypersensitivity reactions occur when allergens cross-link IgE molecules that are bound to receptors on mast cells and basophils and trigger degranulation. Clinical signs of type I hypersensitivity responses that occur after vaccine administration include facial or periorbital edema, urticaria, cutaneous hyperemia, generalized pruritus, salivation, hypotensive shock, tachypnea, vomiting, diarrhea, collapse, and even death (Figure 12-3). Vomiting and respiratory distress are common in cats. These signs generally occur within 24 hours of vaccine administration; anaphylaxis usually begins within minutes. The estimated incidence of anaphylaxis after vaccination of dogs and cats is 1 in 5000 to 1 in 50,000 and depends on the vaccines used. One retrospective study evaluated 1.23 million dogs and nearly 0.5 million cats from more than 300 Banfield hospitals in the United States in 2002 through 2005. In this study, vaccine-associated adverse effects that were listed as vaccine reactions, allergic reactions, anaphylaxis, urticaria, and/or cardiac arrest were documented within 3 days of vaccine administration in 38.2 per 10,000 dogs and 47.4 per 10,000 cats.[20,31] Reactions coded as "allergic" or "anaphylaxis" were reported in approximately 1 in 785 dogs and 1 in 1200 cats. Reactions coded as anaphylaxis constituted only 5% of these reactions. Death occurred in 1 in 400,000 dogs and 1 in 125,000 cats that received vaccines, and all 3 dogs and 1 of the 4 cats that died received four or more doses of a vaccine (i.e., more than one vaccine product administrated simultaneously). Most reactions in dogs (73%) occurred on the day the vaccine was administered (day 0), 19% occurred on day 1, 6% on day 2, and 3% on day 3. Data from the UK Veterinary Products Committee report indicated anaphylaxis in 1 in 385,000 vaccinated dogs and 1 in 555,000 cats.[23]

Vaccines that contain large amounts of adjuvant, certain preservatives, or inactivated bacteria with proinflammatory outer surface components are more likely to cause reactions. Proteins present in fetal calf serum and stabilizers such as gelatin within the vaccine may also be responsible for allergic reactions.[32] In the Banfield study, the risk of reactions increased with the number of vaccine doses (i.e., volume of vaccine in milliliters) administered per office visit.[20] Small-breed dogs, such as miniature dachshunds, pugs, Boston terriers, miniature pinschers, and Chihuahuas, were more susceptible to development of acute vaccine reactions, and the risk of a vaccine-related adverse increased as body weight decreased. The risk of vaccine-related adverse events was 4 times greater in dogs that weighed 5 kg or less than in those that weighed more than 45 kg (Figure 12-4). Adverse events increased in frequency with age up until 2 years of age in dogs and 1 year of age in cats, after which the frequency progressively declined to rates lower than that observed in animals less than 1 year of age (see Figure 12-4). The decrease in frequency with older age may have occurred because of owners' unwillingness to have their pets vaccinated if a previous reaction occurred. Sexually intact dogs were less likely to develop adverse reactions than neutered dogs, but the opposite was true for cats.[20,31] Female cats were more likely to exhibit reactions than male cats.

The treatment of choice for anaphylaxis is epinephrine, together with other supportive treatments such as intravenous fluids and supplemental oxygen if necessary. Antihistamines and corticosteroids can be administered to dogs with less severe reactions. Vaccination should be avoided in animals with a history of severe reactions. Pretreatment with an antihistamine could be considered in animals with a history of mild reactions. These animals should also be monitored closely in the hospital for several hours after vaccine administration. It has been suggested that in the future, commercial production of low-dose vaccines for small-breed dogs might be more appropriate, given their increased risk of reactions and more marked serologic responses to vaccination.[33]

Other Hypersensitivity Reactions, including Autoimmune Disease

Type II hypersensitivity reactions occur when IgG and IgM bind to cell surface antigens and fix complement, with target cell lysis or removal of target cells by macrophages within reticuloendothelial tissues. Concerns have been raised that vaccination may predispose certain genetically susceptible individuals to immune-mediated cytopenias, although as in human medicine, studies of dogs and cats to date have failed to conclusively document vaccines as causes of these and other chronic diseases.[21,34]

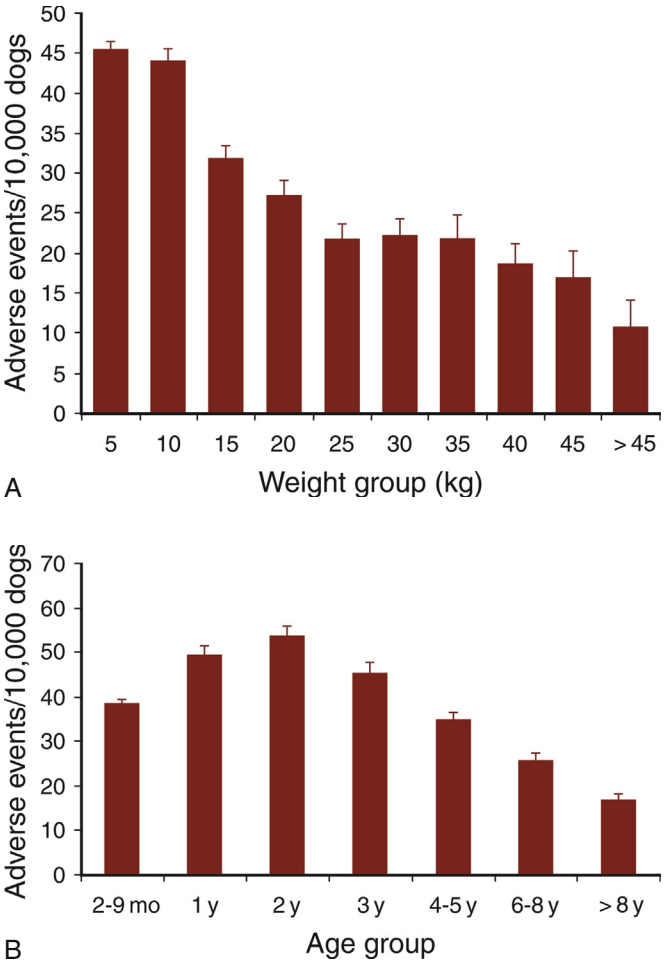

FIGURE 12-4 Correlation between **(A)** body weight and **(B)** age and the occurrence of vaccine-associated adverse effects within 3 days of vaccination in dogs. (From Moore GE, Guptill LF, Ward MP, et al. Adverse events diagnosed within three days of vaccine administration in dogs. J Am Vet Med Assoc 2005;227(7):1102-1108.)

Immune-mediated hemolytic anemia was suspected to occur following parvovirus vaccination, possibly due to the hemagglutinating properties of the virus and the high antigen mass in some of these vaccines,[35] but a later retrospective case-control study found no association.[36] Transient thrombocytopenia can occur after vaccination in some dogs.[37] In one study, dogs developed antithyroglobulin antibodies after vaccination, although this was not associated with development of hypothyroidism.[38] Cats that are vaccinated with Crandell-Rees feline kidney (CRFK) cell-derived vaccines develop antibodies against the CRFK proteins alpha-enolase and annexin A2.[39] Whether production of these antibodies has clinical significance remains to be determined.

Type III hypersensitivity reactions are characterized by immune-complex deposition in tissues and may be a consequence of immunization with certain vaccines. For example, anterior uveitis and subclinical nephritis developed in 0.4% of dogs receiving the canine adenovirus-1 (CAV-1) vaccine. This vaccine has now been replaced by CAV-2 vaccines, which rarely produce these lesions. A cutaneous vasculitis has been described after vaccination of dogs and cats with rabies virus vaccines ("rabies vaccine-induced vasculitis")[40-42] (Figure 12-5). This can occur at the site of vaccine administration, and in some animals, a multifocal ischemic dermatopathy and myopathy that affects sites such as the pinnal margins, periocular areas, tail tip, and paw pads has been reported to occur 1 to 5 months after the appearance of the initial skin lesion.[40] The multifocal dermatopathy and myopathy has been reported to resolve after treatment with pentoxifylline and vitamin E. Additional evidence is required to strengthen the association between the multifocal condition and rabies vaccination. Similarly, concerns have been raised about a possible temporal association between vaccination and immune-mediated polyarthritis in some dogs,[43] but this association remains unproven. Immune-mediated polyradiculoneuritis, a type IV hypersensitivity reaction (delayed-type hypersensitivity), occurred after vaccination of dogs with suckling-mouse brain-derived inactivated rabies vaccines, which are no longer

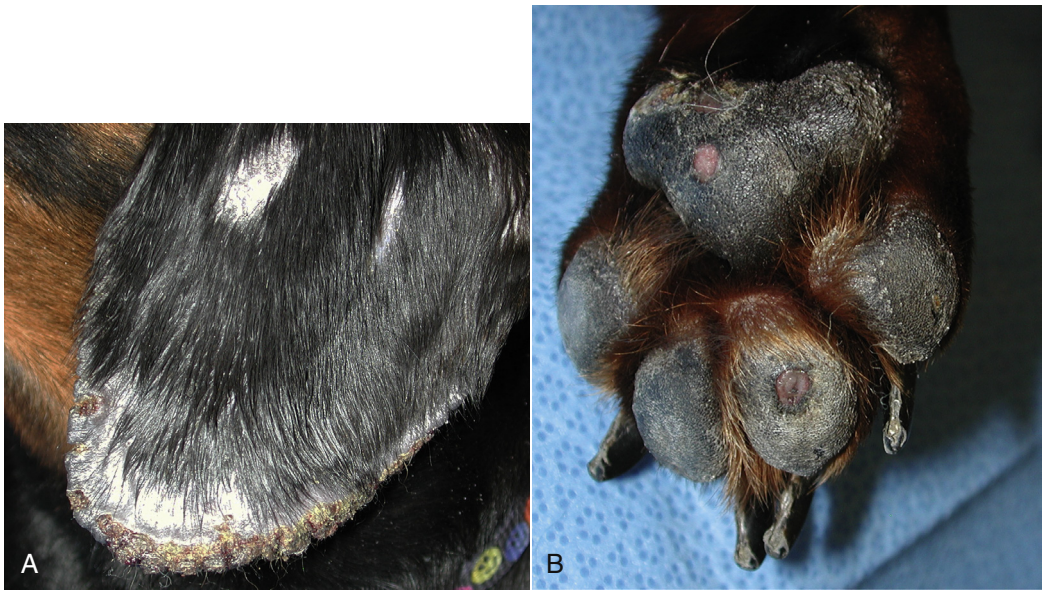

FIGURE 12-5 Ischemic dermatopathy suspected to be associated with rabies virus vaccination that involved the pinnae **(A)** and footpads **(B)** of a 1-year-old male dachshund. VetBooks.ir

available.[44] Subsequent reexposure resulted in more severe and prolonged paralysis. Granuloma formation at the site of vaccine administration also represents a type IV hypersensitivity reaction.

Despite the lack of conclusive evidence for an association between vaccination with currently available vaccines and autoimmune disease, it is possible that vaccination may be associated with dysregulation of the immune response in predisposed individuals. Therefore, vaccination is often withheld if not absolutely necessary in dogs and cats with a history of autoimmune disease. Serum titers could also be assessed to gauge the need for specific immunization in these animals.

Vaccine Organism-Induced Disease

Disease occasionally results from replication of microorganisms present in a vaccine, although severe disease is uncommon with currently available vaccines. Fever and lethargy are the most common adverse effects of vaccination and result from cytokine production in response to the vaccine. These are transient and usually resolve within 1 to 2 days.

In the past, the use of attenuated rabies virus vaccines resulted in ascending paralytic disease in a proportion of cats and dogs. This led to a change to inactivated, adjuvanted rabies vaccines. Administration of attenuated parvovirus vaccines to pregnant cats and dogs can lead to cerebellar disease in the fetus, and these vaccines have the potential to cause severe disease if shed vaccine virus infects colostrum-deprived neonates that are less than 2 weeks of age.[2] Some CDV vaccines have been associated with postvaccinal distemper in young puppies.[45] As a result, vaccination with live attenuated CDV and CPV (dogs) and feline panleukopenia virus (cats) vaccines should be avoided in pregnant animals, puppies and kittens less than 6 weeks of age, and animals receiving potent anticancer chemotherapy drugs. Some CDV vaccine strains, such as Rockborn-like strains, are more virulent than others, and these may continue to circulate and contribute to distemper in the dog population.[46] The safest attenuated live CDV vaccines contain the Onderstepoort strain. Vaccination of certain exotic pet, zoo, and wild animal species, such as ferrets, with any attenuated live CDV vaccine for dogs can also lead to postvaccinal distemper.[47,48] For animals with chronic immunocompromise, the use of inactivated vaccines has been recommended if immunization is deemed necessary. However, inactivated vaccines may have reduced efficacy in immunocompromised animals compared with healthy animals.

The use of mucosal (e.g., intranasal) vaccines for respiratory pathogens in dogs and cats can be followed by development of mild to moderate, transient upper respiratory tract signs. There have been concerns that mucosal *Bordetella bronchiseptica* vaccines may cause respiratory disease in immunosuppressed humans who inhale the vaccine directly during administration or who contact vaccine organisms that are subsequently shed by the vaccinated dog,[49,50] but definitive proof of this is still required. Inadvertent parenteral administration of the avirulent live intranasal *B. bronchiseptica* vaccine to dogs can lead to local injection-site reactions and, occasionally, fatal hepatic necrosis.[51] Inadvertent parenteral administration of mucosal *B. bronchiseptica* vaccines should be treated with subcutaneous fluids at the site of administration and treatment with an oral antibiotic likely to be effective against *B. bronchiseptica*, such as doxycycline. The ASPCA Poison Control Center also recommends injection of a gentamicin sulfate solution into the affected area (2 to 4 mg/kg gentamicin sulfate in 10 to 30 mL of saline).[4] Doxycycline treatment could be continued for 5 to 7 days. Dogs that develop hepatic necrosis may need more aggressive supportive care.

FIGURE 12-6 Two-year-old female toy poodle/maltese terrier mix that developed focal alopecia at the site of vaccination followed by regrowth of hair with an altered color and texture. (Courtesy Nicole Pierce, University of California, Davis, Class of 2013.)

Local Cutaneous Reactions and Injection-Site Sarcomas

Local cutaneous reactions are common adverse effects of vaccination, especially in cats, and include pain, swelling, irritation, and abscess formation. In dogs, focal alopecia or discoloration of the haircoat at the vaccination site can also occur (Figure 12-6). Inactivated, adjuvanted vaccines have been most commonly incriminated. Focal cutaneous granulomas and sometimes permanent focal alopecia have been most commonly reported after inactivated rabies vaccine administration to breeds such as Maltese terriers and bichon frisé.

In the late 1980s, an increase in inflammatory injection-site reactions at the site of rabies vaccine administration were noted in canine and feline biopsy specimens sent to the University of Pennsylvania. Shortly thereafter, sarcomas were observed at these sites in cats in the United States, with a 25% increase each year from 1987 to 1991 (Figure 12-7).[52] This followed (1) the change from attenuated live to inactivated rabies vaccines, (2) increased use of rabies vaccines in cats, and (3) the introduction of FeLV vaccines. The national incidence of sarcoma formation is estimated to be 0.6 to 2 sarcomas per 10,000 cats that are vaccinated.[53,54] In contrast, in the United Kingdom, it was 0.21 per 10,000 vaccine doses sold between 1995 and 1999.[22] The interval between tumor development and the last rabies vaccine typically ranges from 3 months to 3.5 years. Most tumors are fibrosarcomas, but other types of sarcomas can also occur. Although development of injection-site sarcomas is clearly linked to administration of FeLV, rabies, and other vaccines, development of sarcomas is not related to the use of specific brands or types of vaccine within an antigen class (with the possible exception of recombinant vaccines[56]), reuse of syringes, needle gauge, use and shaking of multidose vials, or concomitant viral infection.[55] There is also no evidence that aluminum-containing vaccines are associated with a higher risk of sarcoma development than aluminum-free vaccines, but there has been concern that adjuvant stimulates an inflammatory response that predisposes to sarcoma formation. A recent study showed that

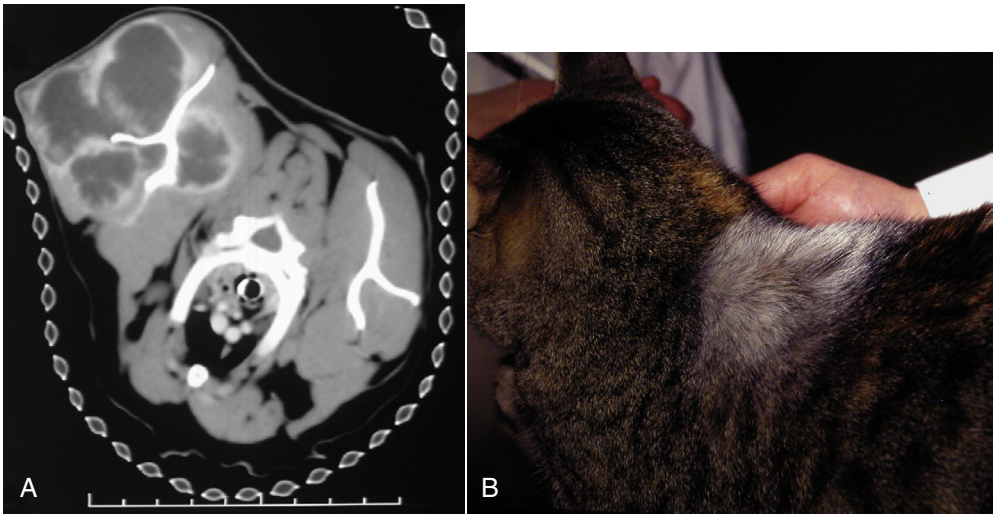

FIGURE 12-7 **A,** Computed tomographic image of an injection-site sarcoma over the scapula of a 12-year old male neutered domestic shorthair cat. **B,** Discoloration of the haircoat after radiation therapy.

inactivated vaccines were approximately 10 times more likely to be associated with injection-site sarcomas when administered at the pelvic limb site than nonadjuvanted recombinant vaccines.[56] However, neither attenuated live, recombinant, nor inactivated vaccines are risk-free, and injection of certain long-acting injectable medications (especially glucocorticoids) can also be associated with sarcoma formation in cats years later.[56,57] There is some evidence that administration of cold vaccine may also be more likely to be associated with sarcoma formation, but this requires verification.[55] It is currently hypothesized that an individual cat's genetically programmed wound healing response is responsible for the development of injection-site sarcomas.

Treatment of injection-site sarcomas involves aggressive surgical resection followed by full-course post-operative radiation therapy, because of the high incidence of recurrence. Possible adverse effects of radiation include mild to moderate cutaneous burns, hypopigmentation of the hair in the field (see Figure 12-7, *B*), and damage to the spinal cord, lungs, and kidneys within the field, although the last is rare. In one study, the median survival time for cats treated with postsurgical curative radiation therapy was 43 months.[57] Most of these cats had clean margins after surgical resection of the tumor. In contrast, the median survival times for cats treated with coarse fractionated radiation therapy was 24 months. These cats generally had macroscopic disease or dirty margins. Adjuvant chemotherapy with carboplatin or single-agent doxorubicin also has been associated with improved outcome.[57]

In order to prevent death from sarcoma formation in cats, the Vaccine-Associated Feline Sarcoma Task Force (VAFSTF) in North America recommended that rabies vaccines be administered as distally as possible on the right pelvic limb, and leukemia vaccines be administered as distally as possible on the left pelvic limb (rabies right, leukemia left). Care should be taken not to administer the vaccine too proximally or in the flank region, because tumors in these locations cannot be resected as effectively.[58] Other core vaccines should be administered over the right shoulder. These recommendations were not adopted by the WSAVA, which suggested that the skin of the lateral thorax and abdomen be used for vaccination, and vaccination sites be rotated from year to year.[2] Both groups recommended that the interscapular region be avoided, because vaccine constituents can pool in this region and contribute to a chronic inflammatory response. In addition, both groups recommended that the sites of administration and the product and batch number be documented to facilitate the reporting of adverse events. Excessive administration of vaccines to cats should be minimized, and alternative routes, such as intranasal immunization, should be considered. Owners should be advised to monitor injection sites for 3 months after vaccines are administered. If a lump forms and increases in size 1 month after vaccination, or persists beyond 3 months, the owner should have the mass evaluated by the veterinarian.

In accordance with the VAFSTF recommendations, the anatomic location, shape, and size of masses that develop at injection sites should be documented, and an incisional or tru-cut biopsy performed. Fine-needle aspiration is not recommended. If the mass is malignant, routine laboratory tests and thoracic radiography should be performed, together with computed tomography or magnetic resonance imaging of the mass if client finances allow. A veterinary oncologist should be consulted, and if possible, referral to a specialist surgeon or oncologist is recommended. Wide excision that includes at least a 2-cm margin is necessary, and the entire piece of tissue excised should be submitted for histopathology and evaluation of surgical margins. Additional treatment, such as chemotherapy and radiation therapy, is often necessary. Cats should be reevaluated at 3-month intervals for a year after surgery.

Interference with Diagnostic Test Results

Vaccination has the potential to interfere with the results of assays that detect the antibody response to infection or assays that detect components of a pathogen itself.

Interference with antibody test results can be specific or nonspecific. Nonspecific interference is rarely identified, but results from cross-reactivity between antibodies to vaccine components (such as albumin) and the reagents used in serodiagnostic tests. More commonly, specific interference with serodiagnostic tests for the infection that is targeted by the vaccine occurs. This especially problematic if (1) vaccination does not completely protect against infection, (2) the results of serologic tests are required for diagnosis, and (3) infection is chronic and persistent, and so identification of recent natural infection through seroconversion

VetBooks.ir

is usually not possible. For example, the inactivated FIV vaccine does not provide 100% protection, but vaccinated cats develop antibodies to the vaccine virus. These antibodies are detected by ELISA and Western blot immunoassays used for diagnosis of FIV infection. In the absence of a history of vaccination, positive antibody test results indicate active infection.[59] PCR can be used to detect FIV infection in infected cats that have a history of vaccination with FIV vaccines, but PCR can occasionally be negative in cats with active infection, so a negative PCR result does not rule out natural infection with FIV. Vaccine interference with serodiagnosis can occur after vaccination of dogs for influenza or leptospirosis, but because both of these diseases are acute, seroconversion can be used for diagnosis of recent infection in vaccinated dogs. Some serologic assays differentiate between vaccinated and naturally infected animals (DIVA). For example, serologic assays that detect the C6 antigen of *Borrelia burgdorferi* do not detect antibodies that result from immunization with Lyme vaccines. The development of recombinant vaccines that stimulate a pattern of antibody responses that differ from those that result from natural infection can help to overcome issues related to differentiation of naturally infected and vaccinated animals.

Interference with the results of assays *that detect the pathogen itself (as opposed to the antibody response)* occurs after vaccination with attenuated live vaccines that are shed by animals after vaccination. For example, cats may test positive using ELISA assays for FPV antigen after vaccination with attenuated live FPV vaccines, although for some assays, the rate at which this occurs is very low.[60] PCR tests can be positive for extended periods after vaccination with attenuated live vaccines. In some cases, sequence analysis of the PCR product can sometimes allow differentiation between vaccine and field strains, but this is currently performed only on a research basis.[61] Rapid PCR assays have also been designed that differentiate between vaccine and field strains of some pathogens, such as CDV or *B. bronchiseptica*.[62,63] Quantification of organism numbers present in a specimen through the use of real-time PCR assays (e.g., for CDV) may shed light on whether natural infection (high organism load) or vaccination (low organism load) has occurred.

Vaccine Selection

The advantages and disadvantages of vaccines and vaccine combinations that are currently available on the market are provided in the relevant sections of this book for each infection entitled "Immunity and Vaccination." Suggested vaccination schedules for individual pets and shelter animals that are based on recommendations provided by the American Animal Hospital Association (AAHA), the American Association for Feline Practitioners (AAFP), the European Society for Feline Medicine (ESFM), and WSAVA are summarized in tables in Appendix.[2,15,64-73]

To facilitate vaccine selection, vaccines for dogs and cats have been divided by various task forces into core vaccines, noncore vaccines, and those that are generally not recommended.

Core vaccines are recommended for all animals with an unknown vaccination history. The diseases involved have significant morbidity and mortality and are widely distributed, and in general, vaccination results in good protection from disease. All shelter animals should be vaccinated with core vaccines before entry to a shelter or at the time of entry if immunization ahead of time is not possible. Canine core vaccines include vaccines for CPV, CDV, CAV, and rabies for countries where rabies is endemic. The core feline vaccines are those for feline herpesvirus-1 (FHV-1), feline calicivirus (FCV), FPV, and rabies.

Noncore vaccines are optional vaccines that should be considered in light of exposure risk, that is, based on geographic distribution and the lifestyle of the pet. Vaccines considered as noncore vaccines for dogs are canine parainfluenza virus, canine influenza virus, *B. bronchiseptica, Leptospira* spp., and *Borrelia burgdorferi*. Optional or noncore vaccines for cats include FeLV, FIV, virulent FCV, *Chlamydia felis,* and *B. bronchiseptica* vaccines.

Several other vaccines are currently available on the market. For dogs, these are vaccines for canine coronavirus, CAV-1, and rattlesnake envenomation. The reports of the American Veterinary Medical Association (AVMA) and the AAHA canine vaccine task force have listed the first two vaccines as not generally recommended, because "the diseases are either of little clinical significance or respond readily to treatment," evidence for efficacy of these vaccines is minimal, and they may "produce adverse events with limited benefit." Currently, information regarding the efficacy of the canine rattlesnake vaccine is insufficient. For cats, the feline infectious peritonitis (FIP) vaccine is not generally recommended by the AAFP.

Viral Diseases

CHAPTER 13

Rabies

Jane E. Sykes and Bruno B. Chomel

Overview of Rabies

First Described: Circa the second millennium BC, Mesopotamia[1]

Cause: Rabies virus (Family Rhabdoviridae, Genus *Lyssavirus*)

Primary Mode of Transmission: biting, with inoculation of saliva containing the virus

Affected Hosts: All warm-blooded animals. Highly susceptible hosts include wolves, foxes, coyotes, jackals, dogs, cattle, raccoons, skunks, bats, and mongooses. Moderately susceptible hosts include cats, ferrets, primates, sheep, goats, and horses.

Geographic Distribution: Classic (genotype 1) rabies is found worldwide except for Taiwan, Australia, New Zealand, Iceland, the United Kingdom, Japan, most of western Europe, Fiji, Hawaii, and Guam.

Major Clinical Signs: Fever, lethargy, behavioral changes, pupillary dilation, ataxia, lower motor neuron paresis or paralysis (including of the muscles of mastication), vestibular signs (including a head tilt), dysphagia, dysphonia, tremors, seizures, ptyalism.

Differential Diagnoses: Distemper virus infection; West Nile virus infection; equine encephalitis virus infection; bacterial, protozoal, or fungal meningoencephalitis; toxins such as strychnine; central nervous system trauma; spinal neoplasia; granulomatous meningoencephalitis.

Public Health Significance: Rabies is a deadly zoonosis and dogs are a major natural reservoir of the virus. In the United States, most human rabies is associated with bat contact.

Etiologic Agent and Epidemiology

Rabies is a deadly, zoonotic, neurologic disease caused by a bullet-shaped, enveloped RNA virus that belongs to the genus *Lyssavirus* (from Lyssa, the Greek goddess of madness, rage, and frenzy) (Figure 13-1). The virus is fragile in the environment, and readily inactivated by a variety of disinfectants, soaps, ultraviolet light, and heat. It can survive up to 3 to 4 days in carcasses at 20°C, and longer with refrigeration.[2,3] Freezing tissues at temperatures less than –20°C may prolong survival of the virus for years.

There are seven lyssavirus genotypes (Table 13-1). Classical rabies virus belongs to genotype 1. The remaining six lyssavirus genotypes primarily infect bats and less frequently cause fatal human encephalitis, which is clinically indistinguishable from classical rabies.[4] Thus, although Taiwan, Australia, New Zealand, Iceland, the United Kingdom, Japan, most of western Europe, Fiji, Hawaii, and Guam are designated terrestrial rabies-free, lyssaviruses capable of causing fatal encephalitis in humans exist in some of these regions, including Australia, Western Europe, and the United Kingdom (Figure 13-2). The remaining information in this chapter pertains only to genotype 1 rabies virus infections.

Infection with rabies virus most commonly occurs as a result of inoculation of virus-containing saliva into a bite wound, in the large majority of the cases after a dog bite. Other routes of transmission reported in species other than dogs and cats

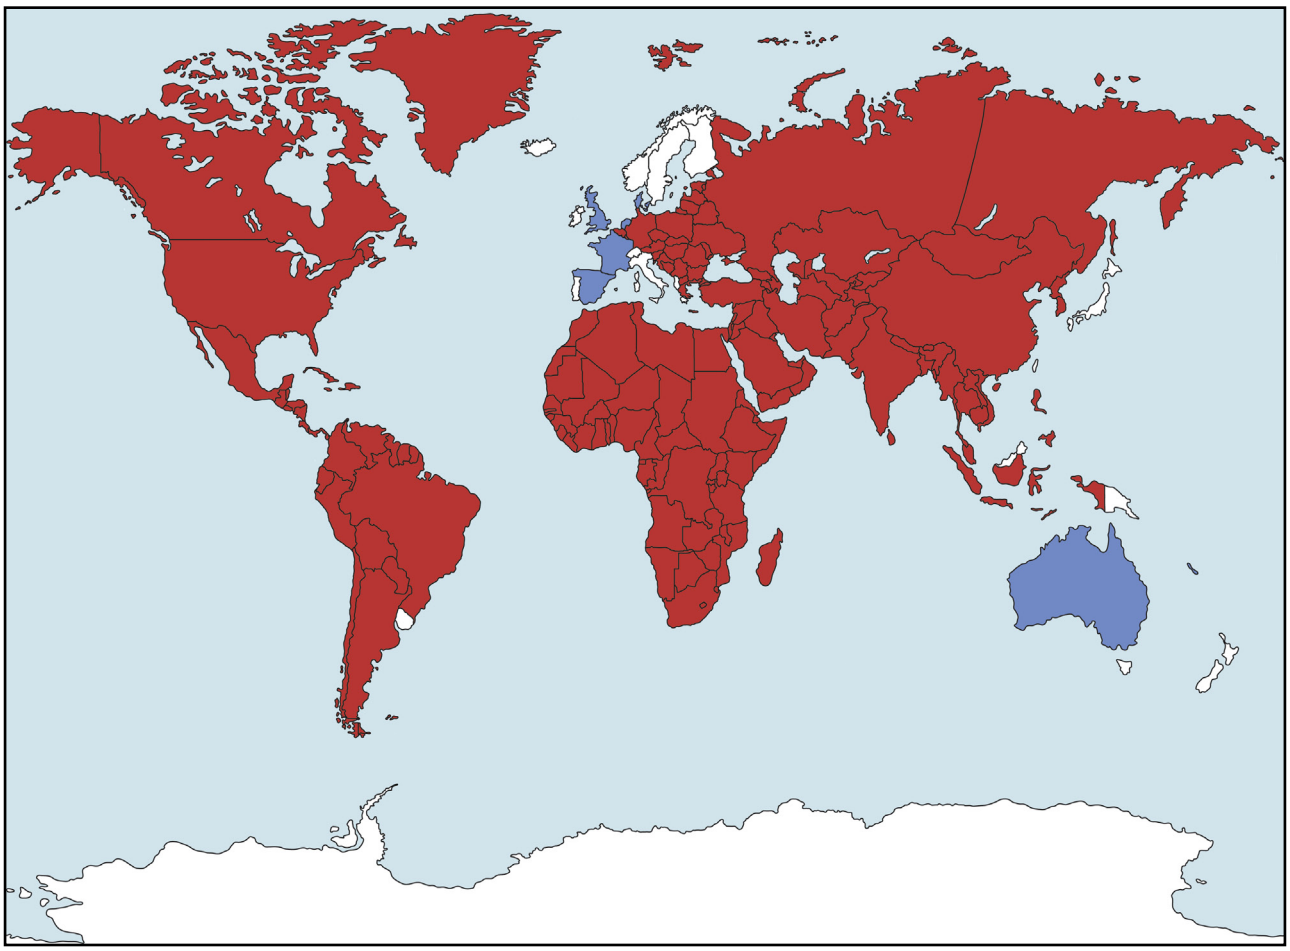

FIGURE 13-2 Global distribution of lyssaviruses. Distribution of rabies virus *(red)*. Areas where rabies-related viruses only, and not classic rabies genotype 1, are documented are classified by the WHO as "rabies free" *(dark blue)*. White areas are free of rabies and rabies-related viruses. (Redrawn from Warrell MJ, Warrell DA. Rabies and other lyssavirus diseases. Lancet 2004;363:959-969.)

are rare and include corneal or solid-organ transplantation in human patients[5]; aerosol transmission, such as that occurring within caves containing large numbers of bats[6,7]; and transmission after ingestion of infected tissues or milk.[6,8]

All warm-blooded animals are susceptible to rabies, although dogs, wild carnivores, and bats are considered the main natural reservoirs of rabies virus. In general, wolves, foxes, coyotes, jackals, dogs, cattle, raccoons, skunks, bats, and mongooses are highly susceptible to infection. Moderately susceptible hosts include cats, ferrets, primates, sheep, goats, and horses. Marsupials, including opossums, have a low degree of susceptibility. Some bird species can be experimentally infected but do not develop clinical signs and are unlikely hosts.[9]

Not every bite from a rabid animal leads to rabies virus infection, and infection may not always culminate in death, unless clinical signs develop. Factors influencing the outcome after a

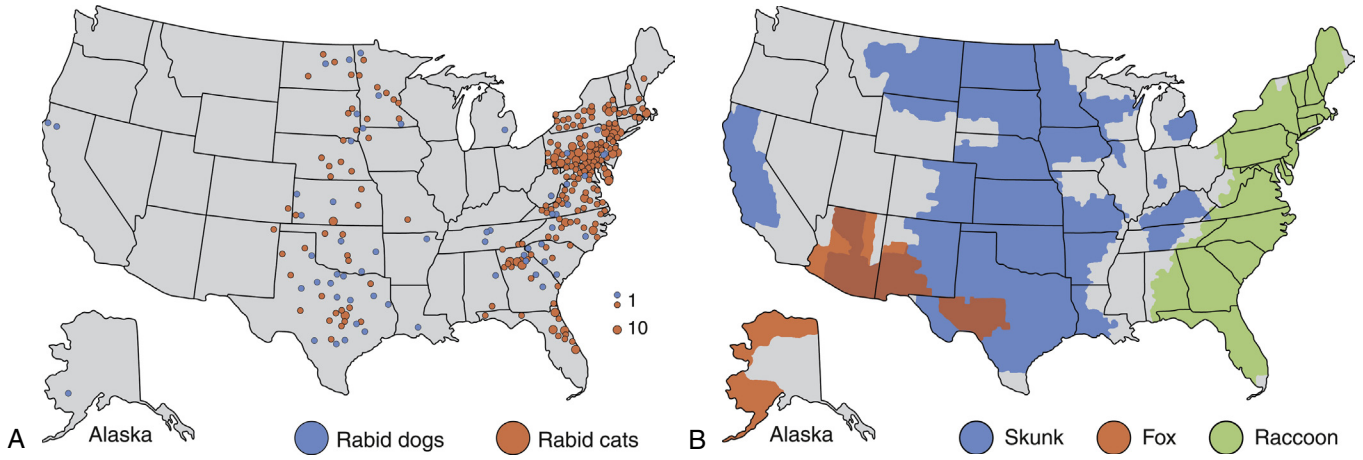

FIGURE 13-3 **A,** Reported cases of rabies that involve cats and dogs, by county, 2010. Histogram represents numbers of counties in each category for total number of cats and dogs submitted for testing. Note the overlap with the distribution of wildlife reservoir hosts in **B**. **B,** Distribution of major rabies virus variants among mesocarnivore reservoirs in the United States. bite from a rabid animal include the proximity of the bite site to the central nervous system (CNS), the degree of innervation of the bite site, the age of the host (young animals are more susceptible), the amount of virus inoculated, and the neuroinvasiveness of the rabies virus variant involved. If left untreated, up to 60% of humans bitten by a rabid dog on the head or neck develop rabies, compared with up to 40% of those bitten on the hand, and 10% of those bitten on the trunk or leg.[10]

Rabies viruses that circulate within a certain geographic region are adapted to specific dominant reservoir hosts (e.g., bat rabies virus variants or raccoon rabies virus variants). All rabies virus variants can infect and cause disease in animals other than their reservoir hosts (spillover hosts). In all host species, rabies is usually an acute fatal illness, although some animals, such as bats and skunks, have a more prolonged course of illness than others, such as foxes, coyotes, or raccoons. The possibility of a subclinical carrier state, especially in bats, has been suggested based on the detection of rabies virus antibody and, rarely, the virus itself in some reservoir host species that are not showing signs of illness.[4]

Over the past 50 years, owing to mandatory vaccination and control programs, domestic animal rabies in the United States has decreased in prevalence, whereas wildlife rabies has increased. The dog rabies virus variant was considered eradicated from the United States at the beginning of the 21st century. Currently, cats are more commonly reported with rabies in the United States (about 300 cases/year) than dogs (fewer than 100 cases/year), most likely reflecting rabies vaccination practices (Figure 13-3, *A*). No feline rabies virus variant has been described. The geographic distribution of feline and canine rabies follows that of regions where wildlife rabies is endemic. Most cats and dogs are infected with the rabies virus variant that is associated with the major wildlife reservoir host in their respective geographic location (see Figure 13-3, *B*). Rabid cats are most often reported from the northeastern United States, mid-Atlantic, and south-Atlantic states, with lesser numbers from the north and south central states. The eastern distribution of feline rabies follows the distribution of raccoon rabies.[11,12] Rarely, cats are infected from bats. Rabies in dogs and cats is most commonly reported from the north central, south central, and Atlantic states (see Figure 13-3, *A*). Dogs may be infected with rabies virus variants from skunks or raccoons. Infected dogs have also been imported into the United States from other countries where canine rabies variants are endemic.[13,14] In Europe, the major wildlife reservoir species have been foxes and raccoon dogs, and in South Africa, jackals and mongooses predominate. In western Europe, fox rabies has largely been eliminated as a result of mass vaccination campaigns. Spillover occurs from wildlife reservoir hosts to domestic animal species, which subsequently contact humans. Nevertheless, the vast majority of human cases in North America result from contact with infected bats, which are present in all states except Hawaii (see Public Health Aspects). Rabies in rodents and lagomorphs is rare, possibly because they are always killed by the bite of a rabid animal. In the United States, most reports have been from woodchucks in raccoon endemic areas.[15] A few cases of rabies in pet ferrets, rabbits, and a pet guinea pig have been described.[16]

Although rabies occurs in cats and dogs of any age, it is most frequently reported in young dogs and cats, with a median age of 1 year for both cats and dogs in one study; 75% of animals were 3 years of age or younger.[17] Rabies can occur in puppies and kittens that have not yet reached the age at which routine rabies vaccination is approved, which is an emerging issue as a result of illegal importation of pet dogs from Mexico through California and Texas. Male dogs may be slightly more predisposed, and most dogs and cats with rabies have not been neutered and live in rural environments, frequently being unrestrained at night.[11,17] In the United States, some degree of seasonality occurs for rabies in dogs and cats, which correlates with seasonal increases in rabid raccoons and skunks.[11,17] For the majority of cats and dogs with rabies, a history of known contact with wild animals or a wound is lacking.

Clinical Features

Signs and Their Pathogenesis

After inoculation into the subcutaneous tissues and muscle, rabies virus replicates locally within muscle cells and then attaches to peripheral nerve endings. Local replication around the bite site can continue for months before the virus enters peripheral sensory and motor nerve endings, with the nicotinic acetylcholine receptor being the main receptor for the virus. The virus then travels in a retrograde fashion up nerve axons at a

From Eng TR, Fishbein DB. Epidemiologic factors, clinical findings, and vaccination status of rabies in cats and dogs in the United States in 1988. National Study Group on Rabies. J Am Vet Med Assoc 1990;197:201-209.

rate of 3 mm/hr.[6] Once the virus is within the CNS, there is massive viral replication, with cell-to-cell transmission of the virus across synaptic junctions. The spinal cord, medulla oblongata, periaqueductal gray matter, limbic system, and cerebellum are particularly affected. The virus also moves outwards from the CNS in somatic and autonomic nerves and is deposited in a variety of tissues, including cardiac and skeletal muscle, the eye, the kidney, pancreas, nerves around hair follicles, and the salivary glands. Production of new virions through budding from the plasma membranes occurs primarily within the salivary glands, which results in the shedding of virus that can be transmitted to other hosts. Thus, the presence of virus in the saliva indicates that the CNS has been infected. In some animals, death occurs before the saliva becomes infected. Virus is shed by some dogs for up to 13 days before the onset of clinical signs.[18]

Clinical signs probably result from impaired neuronal function[6] and occur after an incubation period that ranges from just over a week to 6 months. Most dogs and cats develop disease 1 to 2 months after exposure. In general, the closer the bite site is to the CNS, the shorter the incubation period. The incubation period is also influenced by the host species, age, degree of innervation of the bite site, neuroinvasiveness of the rabies virus variant, and the amount of virus inoculated. Although 90% of humans develop disease within 6 months of exposure, incubation periods of 6 years or more have been reported.[19-21]

The clinical presentations of rabies virus infection have been divided into excitatory ("furious") and paralytic ("dumb") forms. Three phases have been described in the progression of the disease, the prodromal, furious, and paralytic phases, but the stages are variable and may overlap, and signs may be atypical (Table 13-2). Infrequently, there is a history of a wound, or wounds are still present at the time neurologic signs occur. Unfortunately, rabies is infrequently suspected as the possible diagnosis at the time rabid animals are examined by veterinarians.[11,17]

When it occurs, the *prodromal phase* lasts 2 to 3 days in dogs and 1 to 2 days in cats, and is characterized by a variable fever, licking or chewing at the bite site, and behavioral changes. Dogs and cats may become lethargic, anorexic, apprehensive, restless, or reclusive, and vomiting may occur.[11] Some animals become more docile or affectionate. Pupillary dilation, sometimes with decreased pupillary light reflexes, may occur. The *furious phase* occurs in approximately two thirds of affected cats and dogs[22] and lasts 0 to 7 days. Clinical signs result from forebrain involvement and include irritability, anxiousness or excitability, hyperesthesia, hypersalivation, vocalization, roaming, and aggression. Affected animals may try to eat foreign objects, which may become lodged within the gastrointestinal tract, or they may attack their surroundings or moving objects. Some animals develop ataxia, vestibular signs, and grand mal seizures. Tremors; staring, or a wild, spooky, or blank look in the eyes; increased vocalization; and compulsive running can occur cats, which also often develop aggressive behavior.[11,17,23] The *paralytic phase* develops 1 to 10 days after the onset of clinical signs and is characterized by flaccid paralysis, which is ascending and often initially involves the bitten extremity. Neurologic examination reveals flaccid paralysis with absent segmental reflexes. Laryngeal paralysis may lead to a change in the sound or pitch of a dog's bark or cat's meow. Hypersalivation results from paralysis of the pharyngeal muscles, and a "dropped jaw" can occur as a result of masticatory muscle paralysis, especially in dogs, which may appear to owners as if they are choking.

If euthanasia is not performed, coma and death usually occurs within a week of the onset of signs, with a few animals dying as long as 10 days after the onset of illness. Death is associated with multiorgan failure, especially cardiac and respiratory failure. Recovery from rabies is extremely rare. Experimentally, some dogs have recovered from clinical rabies days to months after being infected with certain rabies virus strains.[24,25]

Diagnosis

Rabies should be suspected in dogs and cats evaluated for sudden onset of behavioral changes and flaccid paralysis, especially in rabies-endemic regions, or in animals imported from rabies-endemic countries. Although a particularly high degree of suspicion is warranted for animals that lack a vaccination history for rabies, the disease has been reported in partially and completely vaccinated dogs and cats,[11,17,23] so a history of rabies vaccination should not be used to dismiss suspicion for rabies.

Laboratory Abnormalities

No specific or characteristic hematological or biochemical changes have been reported in dogs and cats with rabies. Mild anemia was reported in one dog.[26] Analysis of the cerebrospinal fluid (CSF) may be unremarkable or show an increase in CSF protein concentration and mild to marked CSF pleocytosis. Small lymphocytes account for most of the differential cell count.[26]

Electromyography in one dog revealed abnormalities consistent with impaired neuromuscular transmission, including moderate fibrillations, positive sharp waves, and an absent M wave.[26] Changes suggestive of denervation have also been described in humans with rabies.[27]

VetBooks.ir

TABLE 13-3

Diagnostic Assays Available for Rabies in Dogs and Cats

Assay	Specimen type	Target	Performance
Direct fluorescent antibody staining or immunohistochemistry	Brain, spinal cord, skin biopsies (latter not recommended in animals), other extracranial tissues	Rabies virus N (nucleocapsid) protein	High sensitivity and specificity on brain tissue; because a single negative result does not rule out rabies, confirmatory tests such as mouse inoculation or reverse-transcription polymerase chain reaction (RT-PCR) are required for specimens testing negative. Sensitivity when used on extracranial tissues is relatively low.
Serology	Serum or cerebrospinal fluid (CSF)	Antirabies virus antibodies	Virus neutralization assays are the gold standard for serology, although ELISA assays are also available. Rarely useful for diagnosis of rabies, as the antibody response is delayed and so titers are often negative. Titers often determined before importation of animals into rabies-free countries.
Histopathology	Brain, spinal cord	Intracytoplasmic eosinophilic inclusions (Negri bodies)	Detection of Negri bodies has low sensitivity.
RT-PCR	Brain, spinal cord, saliva, CSF, extracranial tissues	Rabies virus RNA	Rapid (within hours), has the potential to be very sensitive and specific; can be used to identify rabies genotypes and strains.

Diagnostic Imaging

Magnetic Resonance Imaging Findings

Findings on MRI in dogs with rabies have included hyperintense lesions on T2-weighted images, especially in the midbrain, thalamus, and basal ganglia, that do not enhance with contrast.[28] In human patients with rabies, no significant abnormalities may be present on MRI, or it may show hyperintensities on T2-weighted images, especially in association with the gray matter. Lesions are frequently described in the medulla, pons, basal ganglia, and thalamus and reflect concentrations of rabies virus antigen.[29] Contrast enhancement can be present in comatose human patients but is usually not detected early in the course of illness. Computed tomography commonly does not reveal lesions in humans with rabies.

Microbiologic Testing

Diagnostic assays for rabies in dogs and cats are listed in Table 13-3.

Direct Fluorescent Antibody Testing and Immunohistochemistry

Rabies virus diagnosis is generally based on direct fluorescent antibody (DFA) staining for virus on impression smears of brain tissue obtained at necropsy. This is rapid, sensitive, and economical and is performed only in qualified laboratories that have been approved by local or state public health departments. In the United States, a national standardized protocol for rabies testing is published by the Centers for Disease Control and Prevention.[30] False-negative results with DFA staining are rare when compared with mouse inoculation testing,[31] and all animals with virus in their saliva test positive. A direct rapid immunohistochemistry test is also available, which has a similar sensitivity and specificity and does not require a fluorescence microscope.[32]

If rabies is suspected, the animal should be handled with extreme caution (see Prevention). Humane euthanasia should be performed, and the entire head should be submitted as soon as possible to public health authorities, so as not to delay post-exposure prophylaxis measures for exposed individuals (see Public Health Aspects). Opening the skull using a saw generates aerosols and is not recommended. Although not optimal, if the head is not available, the spinal cord can be submitted. Tissues should be refrigerated and not frozen for optimal test sensitivity. Approved shipping containers should be used, which must be labeled with appropriate warnings.

Antemortem, DFA testing has been used to detect rabies virus in corneal touch impressions and frozen skin biopsy sections from the nuchal area in humans[33,34] or the region of the whiskers in dogs and cats. The sensitivity of this method is as low as 25%, and it should not be used for clinical diagnosis in dogs and cats suspected to have rabies. DFA staining has also been used for detection of rabies virus antigen in extracranial tissues at necropsy, including the tongue, salivary glands, adrenal glands, pancreas, gastrointestinal tract, and myocardium.[35,36]

Serologic Diagnosis

Serologic tests for rabies virus antibodies are often negative in affected animals, as a result of immune evasion by the virus during the incubation period and possibly also virus-induced immunosuppression after the onset of clinical signs. If seroconversion occurs, it is typically late in the course of illness. Prior vaccination for rabies may result in confusing results. Determination of acute and convalescent titers on serum and determination of CSF antibody titers can aid diagnosis of human rabies.[34] In dogs and cats, serologic testing is most commonly used to document proof of prior vaccination, which is required for importation into rabies-free countries. It is not suitable for determining the need for booster vaccinations.[37]

Serologic methods include virus neutralization assays and ELISA assays.[38] The gold standard of rabies serology is the

rapid fluorescent focus inhibition test (RFFIT), a virus neutralization assay, which assesses the ability of antibodies to prevent viral replication in cell culture. The fluorescent antibody virus neutralization (FAVN) test has been accepted as an alternative for determining titers in animals before importation. A minimum titer of 0.5 U/mL is required before importation to rabies-free countries is permitted.

Virus Isolation and Mouse Inoculation

Rabies virus can be isolated in a variety of cell culture lines, although isolation may be less sensitive than nucleic acid-based detection methods.[39] Virus isolation and inoculation of mice with tissue from affected patients can be used to confirm rabies virus infection by public health authorities when direct fluorescent antibody testing of brain tissue is negative.

Molecular Diagnosis Using the Polymerase Chain Reaction

Nucleic acid detection techniques are increasingly employed to detect rabies virus in tissues and may ultimately replace techniques such as isolation and histopathology.[40] Reverse-transcriptase polymerase chain reaction (RT-PCR) assays have been used to rapidly detect rabies virus RNA in dogs and humans and, when used on brain tissue, are sensitive and specific, the results correlating with those of DFA testing.[41,42] RT-PCR can be used to detect virus in decomposing tissue, when the results of other assays might be negative.[43,44] Genetic analysis of resultant PCR products can also be used to identify lyssavirus genotypes and rabies virus variants (see Table 13-1).[45] For antemortem diagnosis in human patients, saliva is more likely to test positive than CSF. A nuchal biopsy specimen can also be tested.[46] The same appears to be true in dogs, although again, attempts to make an antemortem diagnosis of rabies are not recommended in animals.[47] The sensitivity of RT-PCR for detection of rabies virus in the saliva of rabid dogs was 87%, so a negative result does not rule out a diagnosis of rabies.

Pathologic Findings

Gross Pathologic Findings

Gross lesions are generally absent in the CNS of dogs and cats with rabies. Lesions consistent with a previous wound or traumatic event may be present elsewhere on the body.

Histopathologic Findings

Rabies virus infection results in a remarkably mild, nonsuppurative polioencephalomyelitis. Changes include mild neuronal degeneration and neuronophagia, which may be followed by neuronal necrosis.[26] Lymphoplasmacytic perivascular cuffing and focal microglial hyperplasia are frequently described. The longer the duration of illness, the more pronounced the nonsuppurative inflammatory response. Sometimes, a spongiform encephalopathy with vacuolization in the gray matter is present.[16] In some animals, eosinophilic intracytoplasmic viral inclusion bodies (Negri bodies) are identified. Negri bodies are considered a hallmark of rabies virus infection and are most commonly seen in tissues such as the pons, thalamus, hypothalamus, and hippocampus. They are generally only seen once neurologic signs have developed, and only in about 50% of animals that test positive using direct fluorescent antibody testing. Inclusions that resemble Negri bodies have been described in the brain of nonrabid cats, and so the potential for confusion and a false positive diagnosis of rabies exists.[48]

Treatment and Prognosis

Immediate euthanasia and testing of dogs and cats suspected to have rabies is recommended. Once clinical signs have developed, rabies is almost always fatal and very few humans have survived. Most have been children, and several of those individuals had been vaccinated for rabies before the onset of illness. In all individuals, moderate to severe neurologic sequelae persisted. A person in Texas appeared to survive rabies without the need for intensive care.[49] After treatment with induced coma (the "Milwaukee protocol"), an 8-year old girl survived rabies that may have been acquired after a scratch from a stray cat.[50] Rarely, dogs inoculated experimentally with certain canine rabies virus variants have recovered from rabies encephalitis, sometimes with intermittent shedding of rabies virus in saliva after recovery.[25]

Immunity and Vaccination

In most cases of human rabies, no immune response is detectable at 7 to 10 days after the onset of clinical signs. Rabies virus may evade immune recognition through inhibition of apoptosis and destruction of invading T cells, which may explain the relative lack of an inflammatory response within the CNS.[51]

Currently available vaccines contain inactivated virus or are canarypox-vectored recombinant rabies (cats) vaccines. Modified live rabies vaccines are no longer available in the United States because of their association with occasional postvaccinal rabies encephalitis in dogs and cats.[52] Vaccinia poxvirus-vectored glycoprotein recombinant vaccines are used for wildlife vaccination.

All dogs and cats should be vaccinated for rabies at 3 or 4 months of age (depending on state legislation), with a booster dose 1 year later, then every 3 years with approved inactivated vaccines, or annually with recombinant vaccines (see Chapter 12). It has been recommended that rabies vaccines be administered as distally as possible in the right pelvic limb, to allow better understanding of which vaccines are associated with sarcoma formation and to permit complete removal of sarcomas by amputation should they develop.[53,54] Canine rabies vaccination is required by law within most of the United States, and vaccines must be administered only by (or under the direct supervision of) a veterinarian.[37] Effective vaccination of at least 70% of the dog population is required to prevent rabies epizootics.[55] Owners who fail to comply with state or local requirements should be reported to the public health authorities.

Although rare, rabies has been reported in vaccinated animals, especially when vaccinations are not up to date.[23] Dogs and cats less than 1 year of age are not considered immunized until 28 days after the initial vaccination.[37] Because of a rapid anamnestic response, an animal is considered fully vaccinated immediately after booster vaccination.

The use of inactivated rabies virus vaccines in cats has been associated with formation of injection-site sarcomas.[56,57] More commonly, rabies virus vaccination is associated with pain at the injection site, lameness, transient fever, and local cutaneous reactions, such as alopecia, focal cutaneous vasculitis, and focal granulomas.[58] A more generalized ischemic skin disease characterized by variable alopecia, crusting, erosions, and ulcers on the pinnal margins, periocular areas, tail tip, and paw pads has been described that occurs several months after rabies virus vaccination of dogs and begins with a lesion at the site of vaccination (see Chapter 12).[59]

VetBooks.ir

TABLE 13-4

Procedures Required by Public Health Officials for Prevention of Rabies According to the 2011 Compendium of Animal Rabies Prevention and Control[37]

Situation	Rabies Vaccination History	Procedure	Rationale
Dog or cat exposed* to a rabid wild animal or wild animal that is unavailable for testing	Unvaccinated, dog or cat	Euthanize immediately or place in strict isolation for 6 months. Administer rabies vaccine on isolation or up to 28 days before release.	The quarantine period is based on the known incubation period for rabies. Animals that develop signs consistent with rabies during quarantine should be euthanized and tested for rabies.
	Not up to date with booster vaccinations	Contact public health authorities, who decide procedures (revaccination or euthanasia) based on biting species, local prevalence of rabies, timing of previous vaccinations.	
	Vaccinated, dog or cat	Revaccinate, and keep under owner's control and observation for 45 days.	
Person bitten by a healthy dog or cat	Any	Confine animal and observe daily for 10 days; report illness that develops immediately to public health authorities. If signs of rabies develop, euthanize and test for rabies. Vaccination should not be performed until after the isolation period is complete.	Dogs and cats shedding rabies virus within the saliva will develop illness and die within the 10-day quarantine period.
Human bitten by a stray or unwanted dog or cat		Euthanize biting animal immediately and submit for rabies testing.	
Human bitten by a known rabid animal	Vaccinated, human	Vaccinate on day 0 and day 3 intramuscularly, in the upper deltoid muscle.	
	Unvaccinated, human	Postexposure prophylaxis (injection of human rabies immune globulin infiltrated at the bite site, followed by vaccination on days 0, 3, 7, 14, and 28)	

Modified from Brown CM, Conti L, Ettestad P, et al. Compendium of animal rabies prevention and control, 2011. J Am Vet Med Assoc 2011;239:609-617. Compendium updates are available online at http://www.nasphv.org/documentsCompendia.html.
*Exposure for rabies constitutes introduction of the virus into bite wounds, open cuts in skin, or onto mucous membranes from saliva or other potentially infectious material such as neural tissue.

Oral vaccinia-vectored recombinant rabies vaccines, which express the rabies virus glycoprotein, have been used in North America and Europe to control the spread of rabies in wild animals such as raccoons, coyotes, and gray foxes.[60] Canine and feline rabies vaccines are not approved for use in wild animals, which include wild animal hybrids such as wolf hybrids and Savannah cats. Wolf hybrids and Savannah cats are considered unvaccinated when decisions must be made regarding quarantine and euthanasia (Table 13-4).

Prevention

Prevention of rabies is dependent on widespread education of the public regarding the need to vaccinate dogs and cats for rabies, and the risks of wildlife contact. Control of stray dogs and cats and wild animal vaccination programs also help to prevent the disease. Ownership and importation of wild animals and hybrids is discouraged. Puppies and kittens that have not yet reached the age for rabies vaccination should be kept away from wildlife.

According to U.S. regulations, unvaccinated dogs and cats that have been exposed to a rabid animal should be euthanized immediately or vaccinated and placed in strict isolation, without direct contact with people or other animals, for 6 months.[37] If the biting animal is a wild animal that is unavailable for testing, the biting animal is presumed to be rabid. Animals that are overdue for a booster vaccination are evaluated on a case-by-case basis by public health authorities. Dogs and cats that are currently vaccinated should be revaccinated immediately (within 48 hours), kept under the owner's control, and observed for 45 days. Any illness in isolated or confined animals should be reported to local public health officials. If clinical signs suggestive of rabies develop, euthanasia and rabies testing should be performed.

Animals suspected to have rabies should be isolated from other animals and humans and handled with extreme caution, using heavy gloves, catch poles, and cages for restraint. Care should be taken not to allow people's skin to come into contact with salivary secretions. Signs that warn of the possibility of rabies should be placed on the cages of animals that are hospitalized for any period of time. If the risk of rabies is low, the animal should be confined and observed for 10 days. The clinician in charge should keep a list of all in-contact personnel during that period, and procedures should be minimized. High-risk rabies suspects should be confined in isolation using an established hospital protocol (see Chapter 11). Marked improvement in an animal's condition that occurs during a 10-day period is not consistent with a diagnosis of rabies. All

specimens submitted to the laboratory should be labeled with warning labels.

Public Health Aspects

Each year, 50,000 to 55,000 people die from rabies worldwide. Approximately half those numbers occur in India alone, and it has been estimated that 3 billion people continue to be at risk of rabies virus infection in more than 100 countries.[61] A large proportion of these people are children who have been attacked by rabid dogs. In the United States, human deaths due to rabies have decreased from more than 100 per year in the early 20th century to 2 to 3 per year.[62] Most humans in the United States are infected as a result of contact with insectivorous bats, which often appear injured or are behaving abnormally (including flying during the day), and, depending on the bat species, around 5% to 40% of dead or ill bats submitted for testing have rabies.[63,64] Seemingly insignificant contact with tiny bats, particularly the eastern pipistrelle and silver-haired bats, is reported in many human rabies cases (cryptic bat rabies). Despite the high prevalence of raccoon rabies in the eastern United States, the only human death associated with a raccoon rabies variant was reported in 2003.[65]

Prodromal signs of rabies in humans include malaise, fever, and pain, itching, or paresthesia at the site of the bite. People with furious rabies become nervous and hyperexcitable, after which signs of hydrophobia, aerophobia, confusion, and aggression develop. Autonomic signs such as hypersalivation, vomiting, miosis or mydriasis, excessive sweating, and priapism may occur. Paralytic rabies can be confused with Guillain-Barré syndrome.[34]

Sick domestic and wild animals that bite humans in regions where rabies is endemic and that subsequently die should be tested for rabies without delay. Prompt and aggressive treatment of wounds including irrigation under pressure with 20% aqueous soap solution, and application of a greater than 50% ethanol solution or povidone-iodine, can dramatically reduce the risk of contracting rabies after a bite.

The chain of events that must occur after a dog or cat bites a human are listed in Table 13-4 and depend on whether the animal is owned or stray and the animal's vaccination status.[37] Public health authorities must be notified when potential exposure occurs and make the final decision as to how these animals are handled.

Postexposure prophylaxis (PEP) is administered to humans after a bite from a known or suspected rabid animal. In the United States it consists of an injection of human rabies immune globulin (H-RIG), ideally with at least half of the whole dose in the region of a bite site as soon as possible within the first 7 days of the bite, followed by vaccination by the intramuscular route on days 0, 3, 7, 14, and 28 in the upper deltoid muscle. Fewer than 5 humans develop rabies each year in the United States, but PEP is given to 20,000 to 40,000 people each year, with on average 50 humans receiving PEP for each rabies case investigated.

Depending on risk, certain individuals may receive prophylactic vaccines against rabies. These individuals include veterinarians, veterinary students and staff, dog catchers, rabies researchers, rabies diagnosticians, wildlife workers, and travelers visiting rabies-enzootic regions. After exposure to a rabid animal, administration of immunoglobulin to these individuals is not necessary. Instead, rabies vaccine boosters are given immediately and 3 days later. The major vaccine in use in the United States is the human diploid cell vaccine (HDCV), although in developing countries, access to this vaccine is limited. Among animal workers, antibody titers are generally checked every 2 years, with administration of a booster dose if necessary.

CHAPTER 14

Canine Parvovirus Infections and Other Viral Enteritides

Jane E. Sykes

VetBooks.ir

Overview of Canine Parvoviral Enteritis

First Described: 1978, worldwide, Appel and others[1]

Cause: Canine parvovirus-2 variants (Family Parvoviridae, subfamily Parvovirinae, Genus *Parvovirus*)

Affected Hosts: Dogs and other Canidae such as coyotes, foxes, and wolves; cats

Geographic Distribution: Worldwide

Route of Transmission: Direct contact with virus in feces and vomitus as well as contact with contaminated fomites

Major Clinical Signs: Fever, lethargy, inappetence, vomiting, diarrhea, dehydration. Sudden death or tachypnea due to myocarditis occurs rarely.

Differential Diagnoses: Canine distemper virus infection, other canine viral enteritides, dietary indiscretion, toxins, gastrointestinal foreign body, enteric parasitic infections such as giardiasis and helminth infections, enteric bacterial infections such as salmonellosis, salmon poisoning disease, pancreatitis, hypoadrenocorticism, inflammatory bowel disease

Human Health Significance: CPV-2 variants do not infect humans

Etiology and Epidemiology

Canine parvovirus is the most widely recognized cause of transmissible viral diarrhea in dogs and one of the most common infectious diseases of dogs worldwide. It is caused by variants of canine parvovirus-2 (CPV-2), which are members of the genus *Parvovirus*. CPV-2 emerged in the early to mid-1970s and caused a worldwide pandemic of illness in dogs.[2] The spread of the virus worldwide occurred over a remarkable period of about 6 months. CPV-2 may have been derived from feline panleukopenia virus (FPV) or a closely related virus of wild carnivores. It has since mutated to CPV-2a in 1979, CPV-2b in 1984, and, most recently, CPV-2c, which was first detected in Italy in 2000 and has subsequently been found worldwide, with the exception of Australia. Separate lineages have been identified in different geographic locations worldwide.[3] The virus uses the transferrin receptor to enter host cells. With the mutation from CPV-2 to CPV-2a, the virus developed the ability to replicate readily in feline cells, and CPV-2a, CPV-2b, and CPV-2c are now responsible for some cases of feline viral enteritis.[4,5] Feline parvoviral enteritis is further discussed in Chapter 19. CPV-2 variants must be differentiated from CPV-1, also known as canine minute virus, which belongs to the genus *Bocavirus*. In general, CPV-1 is thought to have minimal pathogenic potential, but it has been associated with abortion in pregnant dogs; respiratory, cardiac, and gastrointestinal signs in neonatal dogs; severe gastroenteritis in adult dogs; and possibly neurologic signs in dogs.[6-8]

Parvoviruses are small, non-enveloped single-stranded DNA viruses (Figure 14-1, *A*) that can survive for long periods (over 1 year) in the environment. As a result, contact with virus that persists in the environment is an important means of transmission. Insects and rodents may also serve as mechanical vectors for the virus. Canine parvovirus requires the presence of mitotically active cells in order to replicate. Young animals (6 weeks to 6 months, and especially those less than 12 weeks of age) are more likely to develop severe illness; however, disease can also occur in unvaccinated or improperly vaccinated adult dogs. In North America, Rottweilers, American pit bull terriers, Doberman pinschers, English springer spaniels, and German shepherd dogs appear to be at increased risk for development of parvoviral enteritis,[9,10] but this has not been the case in other geographic locations. A seasonal distribution of disease has been reported in some geographic locations, which may reflect times when dogs access the outdoors and contact virus in the environment. For example, in Saskatoon, Canada, dogs were three times more likely to be admitted with parvoviral enteritis in July, August, and September, compared with the rest of the year.[9] In other locations, the seasonal pattern of disease has differed or been nonexistent.[11,12] For dogs older than 6 months of age, intact males were twice as likely as females to develop parvoviral enteritis.[9] A surveillance study from Australia found a correlation between clusters of parvoviral enteritis and regions of relative socioeconomic disadvantage.[12]

Other viral pathogens that have been associated with enteritis and diarrhea in dogs are canine distemper virus (CDV) (see Chapter 15), canine enteric coronavirus (Figure 14-1, *B*), rotaviruses, astroviruses, adenoviruses, caliciviruses, and novel viruses that include a norovirus, kobuvirus, sapovirus, and possibly also a circovirus.[13-17] Canine enteric coronavirus primarily causes mild diarrhea in puppies that are less than 6 weeks of age and may be found in co-infections with other viral causes of gastroenteritis, including CPV-2 variants. Rarely, it has been identified as a more significant cause of diarrhea in young dogs.[18] This chapter focuses on canine parvoviral enteritis, which is the most widely recognized and pathogenic viral enteritis of dogs.

Clinical Features

Signs and Their Pathogenesis

Transmission of parvovirus and other viral causes of gastroenteritis occurs by the fecal-oral route, after exposure to virus in feces or vomit, or importantly, virus that persists on fomites.

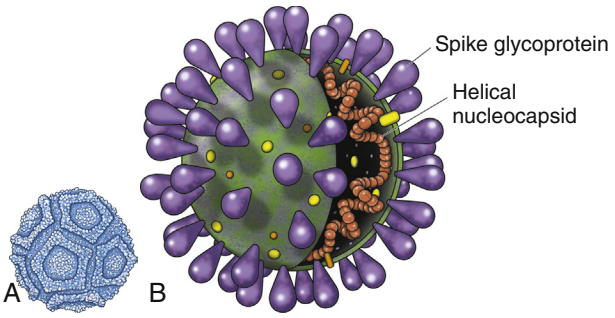

FIGURE 14-1 **A,** General structure of canine parvovirus. The virus is non-enveloped, is 25 nm in diameter, and has icosahedral symmetry. **B,** Structure of a coronavirus, which is an enveloped virus. Canine parvovirus is about one-quarter the size of a coronavirus.

Virus is shed for a few days before the onset of clinical signs, and shedding declines considerably after 7 days.[19] The severity of clinical signs depends on factors such as virus strain and host immunity, which is affected by stressors such as weaning and overcrowding, maternal antibody, and the presence of concurrent infections such as other enteric viral and parasitic infections. Subclinical infections are probably widespread.

The incubation period for canine parvoviral enteritis is 7 to 14 days in the field, but shorter incubation periods (as short as 4 days) have been observed with experimental infections. The virus replicates in oropharyngeal lymphoid tissues, after which viremia occurs. Damage occurs to rapidly dividing cells in the gastrointestinal tract, thymus, lymph nodes, and bone marrow. Affected gastrointestinal tissues include the epithelium of the tongue, oral cavity, esophagus, and intestinal tract, and especially the germinal epithelial cells of the intestinal crypts. Neutropenia results not only from infection of the marrow but also sequestration of neutrophils in damaged gastrointestinal tissue. Malabsorption and increased intestinal permeability result. Secondary bacterial infections of the gastrointestinal tract, which may be followed by bacterial translocation, bacteremia, and endotoxemia, play a key role in the pathogenesis of the disease. Mucosal candidiasis has also been described in puppies with parvoviral enteritis (see Chapter 67). The outcome is clinical signs of fever, lethargy, inappetence, vomiting, diarrhea, rapid dehydration, and abdominal pain. Diarrhea is often liquid, foul-smelling, and may contain streaks of blood or frank blood. Ascarid nematodes may be identified in the vomitus of some dogs. Dogs with canine parvoviral enteritis have evidence of disordered coagulation, with decreased antithrombin activities, prolonged activated partial thromboplastin time, increased thromboelastography maximum amplitude, and increased fibrinogen concentrations. Catheter and organ thrombosis may occur.[20] Secondary bacteremia may be associated with multiple organ failure and death.

Infection of the dam by CPV-2 variants early in gestation can lead to infertility, resorption, or abortion. Puppies that are infected in utero or up to 2 weeks of age may develop viral myocarditis, which results in signs of sudden death or congestive heart failure.[21-23] Damage to the developing myocardium usually occurs up to the first 2 weeks of life, but clinical signs of myocardial damage may be delayed until up to 2 months of age. Cerebellar hypoplasia has been rarely reported in dogs after in utero infection[24] but is more common in kittens infected with FPV (see Chapter 19). Generalized infection has been reported in neonatal puppies, with hemorrhage and necrosis within the brain, liver, lungs, kidneys, lymphoid tissues, and gastrointestinal tract.[25] Because maternal antibody protects puppies during this period, the incidence of neonatal complications of parvovirus infection and myocarditis has declined dramatically since the virus first emerged, because of widespread vaccination and exposure of adult animals.

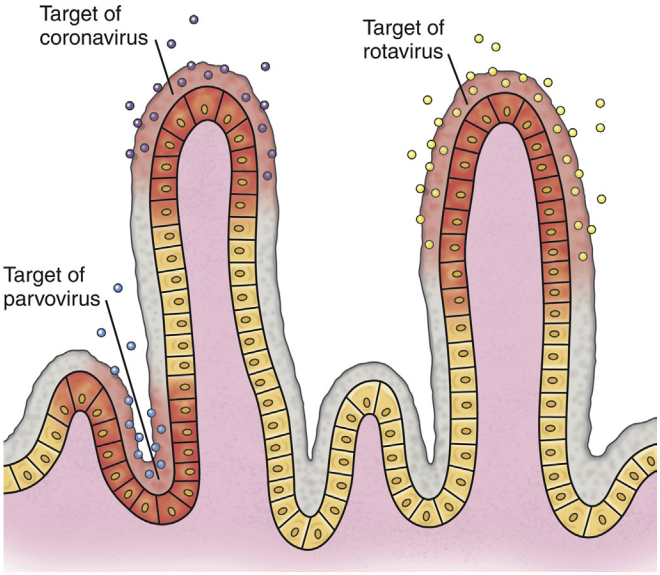

FIGURE 14-2 Target sites of replication of selected enteric viral pathogens. The most pathogenic enteric viruses, such as canine parvovirus, replicate and destroy crypt epithelial cells.

Neurologic signs in puppies with parvoviral enteritis may result from hypoxia secondary to myocarditis, hypoglycemia, or intracranial thrombosis or hemorrhage. The possibility of co-infection with CDV should also be considered. The DNA of CPV-2 variants has also been detected in the central nervous system,[26] and there have been rare reports of leukoencephalomalacia in association with infection.[27,28]

In contrast to canine CPV-2 variants, the replication of less pathogenic enteric viruses is restricted to the intestinal tract, and the crypt epithelial cells are generally spared (Figure 14-2). Canine enteric coronavirus, for example, infects the mature enterocytes at the tips of the villi. Crypt cell hyperplasia occurs to replace the damaged cells. The villi become shortened or distorted, which leads to malabsorption and diarrhea.

Physical Examination Findings

Physical examination of puppies with parvoviral enteritis often reveals fever (up to 41°C or 105°F), lethargy, weakness, dehydration, and abdominal tenderness and a fluid-filled intestinal tract on palpation (Figure 14-3). Vomiting or diarrhea may occur during the examination, or there may be evidence of diarrhea or frank blood on the perineum or the rectal thermometer. Occasionally abdominal palpation reveals a tubular mass as a result of intestinal intussusception. Ulcerative glossitis can occur in some puppies. Mucosal pallor, prolonged capillary refill time, or rarely hypothermia may be observed in some dogs.[29] Septic shock may be associated with tachycardia or bradycardia, mental obtundation, and poor pulse quality. Uncommonly, neurologic signs such as tremors and seizures are observed. Puppies with myocarditis may be tachypneic and have increased lung sounds as a result of congestive heart failure. Erythema multiforme has been reported in dogs with canine parvoviral enteritis; these dogs had generalized cutaneous and mucosal ulceration as well as swelling of the pinnae and paws.[30,31]

FIGURE 14-3 Obtundation in a 3-month-old intact male standard poodle puppy with canine parvovirus enteritis. The dog had been vaccinated for canine parvovirus at 8 and 10 weeks of age.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

The most common abnormalities found on the CBC are leukopenia, neutropenia, and lymphopenia (Table 14-1). Toxic neutrophils and monocytopenia may also be present. Only around one third of dogs had leukopenia in one study.[29] Leukopenia can develop after the onset of gastrointestinal signs, when puppies are first brought for examination. Some dogs have leukocytosis due to a neutrophilia and monocytosis. Although the presence of leukopenia supports a diagnosis of parvoviral enteritis, other severe gastrointestinal infections such as salmonellosis can also cause leukopenia and diarrhea, so it is not specific for diagnosis of the disease. Thrombocytosis or, less commonly, thrombocytopenia may also occur.[29] Some puppies develop anemia as a result of gastrointestinal blood loss, which may be non regenerative or become regenerative.

Serum Biochemical Tests

The serum biochemistry panel in dogs with parvoviral enteritis often shows hypoproteinemia, hypoalbuminemia, and hypoglycemia. Mild hyperglycemia has also been reported. Electrolyte abnormalities such as hyponatremia, hypochloremia, and hypokalemia may occur (Table 14-2). Occasionally severe dehydration results in prerenal azotemia. Puppies with bacterial sepsis may develop increased liver enzyme activities and hyperbilirubinemia.

Coagulation Profile

Coagulation abnormalities have been reported in a small number of dogs with parvoviral enteritis. When abnormalities occur, findings include prolonged activated partial thromboplastin time, decreased antithrombin activity, increased fibrinogen

TABLE 14-1

Complete Blood Count Findings at Admission in 45 Dogs Diagnosed with Canine Parvoviral Enteritis at the UC Davis VMTH

Test	Reference Range	Percent below the Reference Range	Percent within the Reference Range	Percent above the Reference Range	Range for Dogs with CPV Enteritis	Number Tested

concentrations, and increased thromboelastography maximum amplitude.[20] An increase in D-dimers or fibrin degradation products has not been reported. More research is warranted to understand the range of coagulation abnormalities that can occur in parvoviral enteritis.

Diagnostic Imaging

Plain Radiography

Plain abdominal radiography in dogs with parvoviral enteritis may show poor serosal detail (often due to lack of intra-abdominal fat in puppies) and a fluid- and gas-filled gastrointestinal tract. Abdominal radiography is usually performed to assess for the presence of a gastrointestinal foreign body.

Sonographic Findings

Findings on abdominal ultrasonography in canine parvoviral enteritis are nonspecific but can include a thickened gastrointestinal mucosa, mild peritoneal effusion, fluid distention of the gastrointestinal tract, and decreased gastrointestinal motility. Mild mesenteric lymphadenopathy may be present. Abdominal ultrasound is useful to confirm a diagnosis of secondary intestinal intussusception.

Microbiologic Tests

Diagnostic assays for canine parvoviral enteritis in dogs are listed in Table 14-3.

Fecal Parvovirus Antigen ELISA

The most widely used assay for diagnosis of canine parvoviral enteritis is an in-house fecal antigen ELISA, which is performed on a rectal swab specimen. Several assays are available, and although they detect all variants of CPV-2 including CPV-2c, their sensitivities and specificities vary.[32,33] Sensitivity is particularly problematic, because viral shedding is transient, and antibody present may bind viral antigen so that it is unavailable for reaction with the assay. The sensitivities of three commercially available fecal antigen assays (SNAP Parvo antigen, IDEXX Laboratories GmbH; FASTest Parvo Strip, Scil Animal Care Company GmbH; Witness Parvo Card, Selectavet GmbH) were 50%, 40%, and 60%, respectively, when compared to immunoelectron microscopy, and 18%, 16%, and 26%, respectively, when compared with results of a fecal PCR assay.[33] Because some dogs that lack evidence of gastrointestinal signs can be positive using PCR assay, immunoelectron microscopy may be a more appropriate gold standard for disease (although it is not widely available for routine diagnosis). In another study, the sensitivity of a fecal antigen test for detection of CPV-2a, CPV-2b, and CPV-2c, on specimens that contained high CPV DNA loads (>10^5 copies/mg of feces as determined with real-time PCR) was 80%, 78%, and 77%, respectively.[32]

When compared with PCR and immunoelectron microscopy of stool, the specificities of the three commercially available antigen assays above were 98%, 98%, and 92%, respectively,[33] so false positives were uncommon. It has been suggested that false-positive antigen tests can occur 4 to 8 days after vaccination with attenuated live CPV-2 vaccines.[34] In kittens, false-positive test results did occur after vaccination for FPV, but they were more likely to occur with some assays as opposed to others, were generally weak positives, and occurred even after vaccination with inactivated vaccines.[35] Similar studies have not been reported for CPV.

TABLE 14-3

Diagnostic Assays Available for Canine Parvoviral Enteritis in Dogs

Assay	Specimen type	Target	Performance
Fecal antigen ELISA	Feces	CPV antigen	Specificity for detection of virus nears 100%, but weak false positives have the potential to occur after immunization with attenuated live vaccines. False negatives are common (low sensitivity).
Hemagglutination assay	Feces	CPV antigen	Inexpensive and rapid. Sensitivity and specificity in naturally infected dogs has not been well established.
Histopathology	Usually necropsy specimens, especially gastrointestinal tissues	Crypt necrosis with intranuclear inclusions; parvovirus antigen with IHC or parvovirus DNA with in situ hybridization	Can be used for diagnosis at necropsy. In situ hybridization may be most sensitive for detection of virus in tissues.
Polymerase chain reaction (PCR)	Feces, tissue species	CPV DNA	Sensitivity and specificity may vary depending on assay design. Attenuated live vaccine virus may be detected in feces for days to weeks after vaccination, but some assays differentiate between vaccine and field virus. Because of the high sensitivity of some assays, the significance of a positive result may be difficult to interpret. False negative results may occur as a result of inhibition of PCR by components of feces. Degradation of nucleic acid during specimen transport is more problematic for RNA viruses such as canine coronavirus.
Fecal electron microscopy	Feces	Virus particles	Not widely available, turnaround time can be slow, and may be expensive. Requires the presence of large amounts of virus.
Virus isolation	Feces, tissues	CPV	Difficult, not widely available. Used as a research tool.

CPV, Canine parvovirus (refers to CPV-2 variants); IHC, immunohistochemistry.

Hemagglutination Testing

Canine parvovirus agglutinates erythrocytes, and so the presence of the virus in stool can be detected with a simple hemagglutination test that involves mixing a suspension of feces with porcine erythrocytes. Agglutination of erythrocytes in a microwell plate or on a slide indicates the presence of parvovirus in the feces.[36] The sensitivity and specificity of these assays in dogs with and without natural parvoviral infections in the field require further investigation.

Molecular Diagnosis Using the Polymerase Chain Reaction

Several commercial veterinary diagnostic laboratories now offer real-time PCR assays for detection of CPV-2 variants and other enteric viral pathogens (such as canine coronavirus). Assays may detect as few as 1000 copies of viral DNA per milligram of stool. Turnaround times are less than 24 hours in some laboratories. PCR assays are useful when fecal antigen tests are negative but parvoviral enteritis is still suspected as a diagnosis, or when canine enteric coronavirus infection is a potential cause of illness (because PCR panels that assay for parvovirus DNA also often include an assay for canine enteric coronavirus RNA). Unfortunately, although infrequent, positive PCR assay results for CPV can occur in dogs without signs of gastroenteritis or in dogs with chronic diarrhea, and so it may be difficult to ascertain whether a positive parvovirus PCR result indicates that CPV is the cause of a dog's illness. Attenuated live vaccine virus can also be detected in the feces with PCR assays after vaccination, although assays have been designed that can differentiate between vaccine and wild-type virus.[37] It is not yet clear for how long after vaccination false-positive PCR results might occur, and this could vary based on the design of the PCR assay used. Both vaccine and field virus have been detected simultaneously in some dogs using these assays. In the future, quantitation of virus loads in feces using real-time PCR may be helpful for interpretation of the significance of a positive PCR assay result.

Fecal Electron Microscopy

Fecal electron microscopy is still offered by some institutions for diagnosis of viral enteritis. It is generally used on a research basis when viral enteritis is suspected but a diagnosis cannot be made with antigen tests or PCR assays. Fecal electron microscopy may facilitate diagnosis of other viral infections such as rotavirus, norovirus, and coronavirus infections. Turnaround time may be slow. Generally speaking, large amounts of virus must be present for results to be positive, and technical expertise is required to accurately identify virus in the stool.

Virus Isolation

Canine parvovirus variants can be isolated in canine and feline cells, but isolation is difficult, and the virus shows minimal cytopathic effects. As a result, virus isolation is rarely used for diagnosis and is not widely available. It remains important as a research tool.[38]

Serology

Antibodies to CPV-2 can be measured in the laboratory using hemagglutination inhibition (see Chapter 2). In addition, an in-clinic ELISA assay is available for semiquantitative measurement of antibodies to CPV-2. These assays are generally used to assess the need for vaccination, rather than for diagnosis of CPV-2 enteritis, because affected dogs are either seronegative or previous vaccination or material antibodies confound early serodiagnosis.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with CPV enteritis include thickening and discoloration of the intestinal wall with serosal hemorrhage (Figure 14-4) and enlarged, edematous abdominal lymph nodes. The intestine may contain bloody liquid contents, and mucosal hemorrhage may be identified. Pale areas may be seen within the myocardium of dogs with parvoviral myocarditis.

Histopathologic Findings

The major histopathologic finding is necrosis of the crypt epithelium in the small intestine, with widespread systemic lymphoid depletion and necrosis. The crypts can be dilated and distended with cellular debris and mucus (Figure 14-5). Proliferation of crypt enterocytes may be observed as part of the recovery response. Intestinal villi are collapsed, shortened, and fused, with attenuation of the epithelial lining, and there may be mild to severe fibrinous inflammation and hemorrhage. Myeloid depletion may be found in the bone marrow. Parvoviral myocarditis is characterized by myocardial degeneration and necrosis, with a lymphocytic inflammatory infiltrate. Myocardial fibrosis can also be present. Rarely, central nervous system lesions consisting of leukoencephalomalacia have been described.[27] Viral intranuclear inclusions may be visible in some cells, especially the intestinal crypt epithelium. Immunohistochemistry can be used to detect viral antigen in the gastrointestinal tract, marrow, lymphoid tissues, and rarely in the myocardium. In situ hybridization (see Chapter 5) can also be used to detect virus in histopathology specimens and may have greater sensitivity than immunohistochemistry.[39,40]

Treatment and Prognosis

Antimicrobial Treatment and Supportive Care

Treatment of CPV enteritis involves supportive care and treatment of secondary bacterial infections with antimicrobial drugs (Table 14-4). Whenever possible, the patient should be hospitalized in isolation. Appropriate fluid therapy and maintenance of adequate blood glucose concentrations are the most critical aspect of treatment. Whenever possible, fluids should be given intravenously and supplemented as needed with potassium chloride and dextrose. Blood glucose concentrations should be monitored at least twice daily, and more frequent monitoring may be indicated if hypoglycemia is present. Although not generally recommended for puppies that are vomiting or dehydrated, administration of subcutaneous fluids and antimicrobial drugs in the home can sometimes result in recovery when client finances do not permit treatment in hospital. Fluids administered subcutaneously should never be supplemented with dextrose, because dextrose is hyperosmotic and can cause further dehydration, as well as injection-site reactions. Unfortunately, the owners of many dogs with parvoviral enteritis lack financial resources for treatment. In these situations, the inability to afford vaccination may have been a reason the puppy develops parvoviral enteritis in the first place.

An antimicrobial drug or drug combination with activity against gram-negative and anaerobic bacteria should be administered parenterally. Injectable ampicillin or cefazolin alone may be sufficient for many dogs, but puppies that have hemorrhagic diarrhea or evidence of the systemic inflammatory response syndrome (SIRS) should probably be treated with a combination of a penicillin and a fluoroquinolone, or a combination of a penicillin and an aminoglycoside. Use of fluoroquinolones in young, rapidly growing animals has been associated with cartilage damage (see Chapter 8), but when used for the short periods of time required to treat parvoviral enteritis, this may not be of significant concern. Proper hydration is critical before aminoglycosides are used because of their potential for nephrotoxicity.

Treatment with antiemetics (such as a constant rate infusion of metoclopramide or parenteral ondansetron), H2 blockers such as famotidine, whole blood or plasma transfusions, colloids such as hetastarch, or partial or total parenteral nutrition may be indicated in some dogs. Placement of a central line or multilumen catheter may be necessary in severely ill puppies, but strict sterile technique must be adhered to because of the potential for hospital-associated infection. In general, unless absolutely necessary, invasive surgical procedures and the use of parenteral nutrition solutions should be avoided in puppies with severe neutropenia. Whether plasma or hetastarch is the treatment of choice for dogs with low colloid oncotic pressure requires further study. Plasma may offer benefit over hetastarch in that it contains antibodies from immune dogs, but titers may not be sufficient to be beneficial, and most puppies

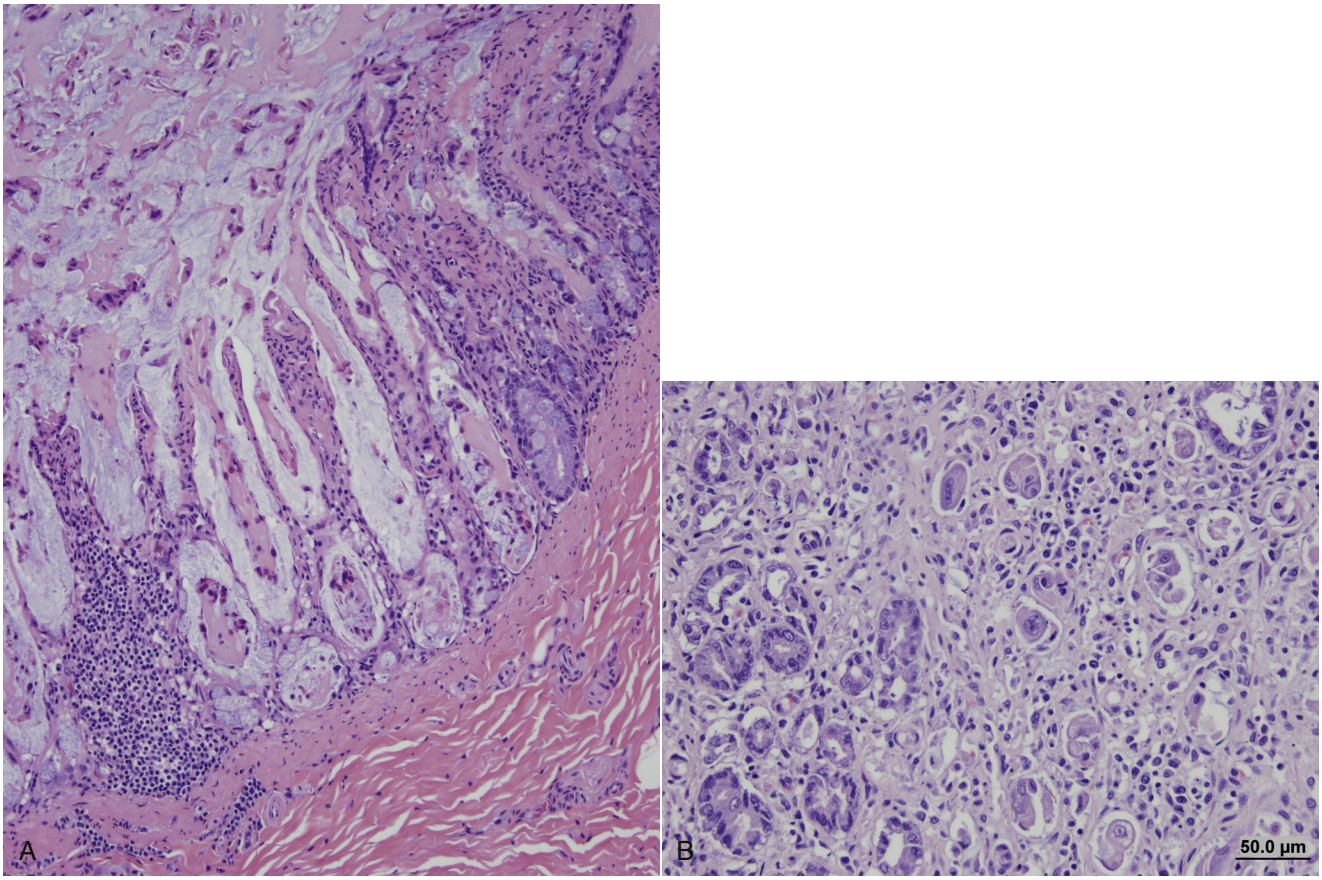

FIGURE 14-5 **A,** Segmental crypt necrosis in the ileum of a dog infected with a CPV-2 variant. There is severe loss of crypt epithelial cells. Hematoxylin and eosin (H&E) stain. **B,** Jejunum of a dog after infection by a CPV-2 variant. Regenerating epithelial cells, which here are nested in an inflamed jejunal lamina, have a large and bizarre appearance and resemble adenoma cells. As a result, the disease has been termed *adenomatosis*. Parvovirus antigen was no longer detectable by immunohistochemistry at this stage. The crypts in the bottom left corner have a more normal appearance. H&E stain. (Courtesy Dr. Patricia Pesavento, University of California, Davis Veterinary Anatomic Pathology Service.)

TABLE 14-4

Medications That May Be Used in Conjunction with Fluid Therapy to Treat Canine Parvoviral Enteritis

Drug	Dose (mg/kg)	Route	Interval (hours)
Ampicillin sodium	20	IV	6
Cefazolin sodium	20	IV	8
Enrofloxacin*	5	IV	24
Ondansetron	0.5 to 1	IV	12
Maropitant citrate	1	SC	24
Metoclopramide	1-2 mg/kg/d	IV	CRI
Famotidine	0.5	IV	12 to 24

CRI, Constant-rate infusion.
*Has been associated with cartilage injury in growing animals. Prolonged use (>7 days) is not recommended. See Chapter 8.

show evidence of an antibody response within 3 days after onset of clinical signs. Hetastarch has anticoagulant properties that could be beneficial in light of the hypercoagulable state that has been documented in canine parvoviral enteritis, but these effects also have the potential to increase mortality, and hetastarch has been associated with acute kidney injury in critically ill human patients.[41] Early enteral nutrition with a nasogastric feeding tube was associated with reduced hospitalization times in one study, as compared to withholding food until vomiting had ceased (Figure 14-6).[42] Gastric suction should be performed through the tube before food is administered.

Other treatments that have been investigated include anti-endotoxin sera, recombinant bactericidal permeability-increasing (BPI) protein, recombinant granulocyte colony-stimulating factor (G-CSF), recombinant feline interferon-omega (rfIFN-ω, Virbagen omega), and oseltamivir. Anti-endotoxin sera, recombinant BPI protein, and human recombinant G-CSF were not found to be beneficial. Although neutrophil counts were higher and hospital times were shorter in dogs treated with recombinant canine G-CSF, survival times in these dogs were decreased.[43] Treatment of parvovirus infections with G-CSF might cause harm, because the increased cell turnover induced by the drug might promote parvovirus replication. Treatment of puppies with parvoviral enteritis with rfIFN-ω in a number of placebo-controlled trials has been associated with reduced disease severity and, in some studies, significantly reduced mortality, but it has not been beneficial for treatment of FPV infections (see Chapter 19).

Oseltamivir inhibits the neuraminidase of influenza viruses and does not have specific anti-parvoviral activity, but it has been widely used for treatment of canine parvoviral enteritis. As canine parvovirus does not possess a neuraminidase, it has been

FIGURE 14-6 Puppy in Figure 14-2 after placement of a nasogastric feeding tube.

hypothesized that oseltamivir instead may act on the neuraminidases of bacteria that are normally responsible for secondary bacterial infections in parvovirus enteritis, primarily those of the gastrointestinal tract. A single prospective, randomized, masked, placebo-controlled trial of 35 dogs with parvovirus enteritis showed that dogs treated with oseltamivir (2 mg/kg PO q12h) had no significant drop in their leukocyte count, whereas untreated dogs had a significant drop in their leukocyte count in the first 5 days of hospitalization.[44] Treated dogs also gained weight during hospitalization, whereas untreated dogs lost weight. However, there was no difference in hospitalization time, clinical scores, morbidity, or mortality between the two groups, and the number of dogs in each group was small. The authors acknowledged the potential concerns that relate to administration of an oral medication to dogs with enteritis, with possible variability in drug absorption. A major concern that relates to treatment of canine parvoviral enteritis with oseltamivir is the possibility of selection for resistant mutants among influenza viruses if widespread use of the drug occurs in veterinary clinics. Given the restrictions on the use of this drug for treatment of human influenza virus infections, further investigation is required before the widespread use of oseltamivir can be recommended for treatment of CPV enteritis. More information on canine G-CSF, rfIFN-ω, and oseltamivir can be found in Chapter 7 of this book.

After recovery from viral enteritis, intestinal parasites should be treated with a broad-spectrum anthelmintic such as fenbendazole.

Prognosis

The prognosis for viral enteritis in puppies varies with the severity of illness and the owners' ability to afford appropriate treatment. Survival rates for puppies with CPV-2 enteritis have ranged from 9% in untreated puppies to greater than 90% with aggressive treatment in tertiary referral hospitals.[10,45-47] Factors that have been related to mortality include the presence of initial leukopenia or lymphopenia, monocytopenia, neutropenia, and evidence of SIRS.[29,48,49] SIRS was defined as the presence of at least three of the following four criteria: heart rate greater than 140 beats/min, temperature above 102.5°F or below 100°F, and white blood cell counts greater than 17,000 or less than 6000 cells/μL (see Chapter 86). Survival may also be lower in Rottweilers when compared to other breeds and in young puppies (less than 7 to 12 weeks of age).[50] In Australia, euthanasia was more likely to occur in summer; among pedigree dogs, in hounds, gundogs, and non-sporting breed dogs; and in puppies less than 6 months of age.[47] Vomiting and lethargy at admission as well as lymphopenia and hypoalbuminemia have been associated with prolongation of hospitalization times by approximately 2 days.[29] Positive changes in leukocyte counts (and especially lymphocyte counts) as early as 24 hours after admission have also been associated with survival.[48] In general, puppies that survive the first 3 to 4 days of treatment make complete recoveries. Complications of infection include bacteremia and septic shock, intestinal intussusception, aspiration pneumonia, and esophageal strictures.

Immunity and Vaccination

Immunity that follows natural infection by CPV-2 variants is probably lifelong. Immunization with attenuated live viral vaccines also provides sterile immunity that may even be lifelong. Both attenuated live and inactivated CPV vaccines are available. With the possible exception of shelter environments, attenuated live vaccines should never be administered to pregnant bitches because they may cause disease in the developing fetus. If possible, pregnant bitches introduced into shelter environments should be tested for antibody to CPV before vaccination with attenuated live vaccines, and these dogs should only be vaccinated if they test negative. The use of inactivated vaccines is not recommended in contaminated environments, because the window of vulnerability and the time to onset of protection is too long. The *window of vulnerability* is the period when maternal antibody interferes with the vaccine's ability to stimulate an effective immune response, but does not prevent infection with virulent field virus (see Chapter 12 for a discussion of this concept). Small quantities of attenuated live vaccine virus are shed from the intestinal tract after immunization, but this should not be relied on to immunize other in-contact animals. Protection against challenge with field virus occurs for at least 3 years and possibly for life after the initial puppy series is administered (see Chapter 12). Exposure of dogs to virus in the environment may also serve to booster immunity after vaccination.

The initial immunization series should be given every 3 to 4 weeks from 6 to 8 weeks of age, until no sooner than 14 to 16 weeks (16 to 20 weeks in breeding kennels), because of persistence of sufficient titers of maternal antibody in some puppies until this age. After that, a booster should be given at 1 year of age, and every 3 years thereafter (see Appendix). Puppies should be isolated in the home environment until 7 to 10 days after the last booster. Attendance at organized puppy classes has been advocated as a way to promote socialization in this period,

VetBooks.ir

and currently there is no evidence that such activities increase risk for parvoviral enteritis. Serum antibody titers of at least 1:80 as determined with hemagglutination-inhibition correlate well with protection.

Concern has been raised that currently available CPV vaccines may not provide adequate protection against CPV-2c infection, because of reports of CPV-2c enteritis in vaccinated dogs.[51] Furthermore, the serum of animals immunized against CPV-2, CPV-2a, and CPV-2b poorly recognized CPV-2c.[52] However, experimental challenge studies have demonstrated strong protection against CPV-2c challenge when dogs are immunized with vaccines that contain CPV-2.[53,54] The extent to which maternal antibody against non-CPV-2c strains protects against infection with CPV-2c requires investigation.

Both inactivated and attenuated live vaccines are available for prevention or reduction of canine enteric coronavirus infection, but because the disease is generally mild or inapparent and primarily occurs in puppies younger than 6 weeks of age, their use has not been generally recommended.[55]

Prevention

Prevention of CPV-2 enteritis requires immunization and appropriate quarantine, isolation, cleaning, and disinfection procedures. Proper immunization is the most effective method. Puppies that are incompletely vaccinated should not be introduced into environments where there has been a history of parvoviral enteritis and adequate environmental disinfection cannot be guaranteed. Although extremely resistant to disinfectants, parvoviruses can be inactivated with a 1 in 30 dilution of household bleach; potassium peroxymonosulfate (Trifectant, Virkon S); accelerated hydrogen peroxide; or high-level chemical disinfectants such as glutaraldehyde and *ortho*-phthalaldehyde, when contact times of at least 10 minutes are used (see Chapter 11 for more information on disinfection). These disinfectants will also inactivate other enteric viruses. Steam cleaning should be used on surfaces that cannot be otherwise disinfected, and dishwashers that attain temperatures of at least 75°C should be used to wash dishes. For shelters, quarantine periods of 2 weeks have been recommended before introduction of puppies that might be shedding virus, because shedding rarely continues for longer than 10 days.[56] The bathing of recovered puppies can help to remove virus that persists on the haircoat. Rodent and insect vector control can also be used to prevent spread of the virus in the environment. Outdoor grassy areas and dirt are difficult or impossible to adequately disinfect, and so only immunized animals should be allowed on these areas. The use of bleach on these areas is not recommended because of adverse environmental effects from runoff.

The prevalence and impact of enteric viral infections can also be reduced through regular removal of fecal contamination, prolonged exposure of contaminated surfaces to sunlight and drying, and elimination of stressors such as overcrowding, transport, poor nutrition, and concurrent infections such as intestinal parasites.

Public Health Aspects

Enteric viral pathogens of dogs, including CPV-2 variants, do not infect humans. However, other infectious causes of gastroenteritis in puppies have the potential to be zoonotic, and coinfections with these pathogens can occur, so caution should be maintained when handling puppies with diarrhea. Precautions used in isolation should be sufficient to prevent enteric zoonoses (see Chapter 11).

CASE EXAMPLE

Signalment: "Sam", an 8-week old intact male Hungarian vizsla puppy from northern California.

History: Sam was acquired 6 days ago from a breeder, and at that time was eating and active. The next day Sam was examined at a local veterinary clinic, and a routine fecal examination revealed infection with *Giardia* and *Isospora* spp. Treatment with sulfamethoxazole was initiated, but 1 day later the puppy developed diarrhea. The next day, lethargy and vomiting were noted. Vomiting and diarrhea occurred every few hours. The diarrhea contained fresh blood and the vomitus consisted of clear, frothy fluid. Inappetence and intermittent vomiting continued for the next 2 days.

Current Medications: None

Other Medical History: Vaccination with an attenuated live CDV, CPV-2, and canine parainfluenza vaccine was performed when Sam was 6 weeks of age. There were no other dogs in the household, only one adult cat.

Physical Examination:

Body weight: 4.2 kg

General: Quiet, alert, responsive. Estimated to be 7% to 8% dehydrated, T = 103.4°F (39.7°C), HR = 240 beats/min, RR = 36 breaths/min, mucous membranes pale pink and tacky, CRT = 2 seconds.

Integument: Full, shiny haircoat. No ectoparasites were seen.

Eyes, ears, nose, and throat: Enophthalmos and a dry nasal planum were present.

Musculoskeletal: Body condition score 2/9. The dog was ambulatory, but emaciated and weak.

Cardiovascular: Weak but synchronous femoral pulses. No murmurs or arrhythmias ausculted.

Respiratory: No clinically significant findings.

Gastrointestinal: No evidence of abdominal pain on palpation. Fluid-filled intestinal tract. Full urinary bladder noted.

Rectal examination: Bloody diarrhea was present on the thermometer. Rectal examination was not performed.

Lymph nodes: All lymph nodes were within normal limits.

Laboratory Findings:

CBC:

HCT 31.5% (40-55%)
MCV 62.6 fL (65-75 fL)
MCHC 35.6 g/dL (33-36 g/dL)
WBC 530 cells/µL (6000-13,000 cells/µL)
Neutrophils 16 cells/µL (3000-10,500 cells/µL)
Lymphocytes 504 cells/µL (1000-4000 cells/µL)
Monocytes 11 cells/µL (150-1,200 cells/µL)
Platelets clumped but appeared adequate.

Serum Chemistry Profile:

Sodium 143 mmol/L (145-154 mmol/L)
Potassium 3.8 mmol/L (3.6-5.3 mmol/L)

Continued

VetBooks.ir

Chloride 106 mmol/L (108-118 mmol/L)
Bicarbonate 23 mmol/L (16-26 mmol/L)
Phosphorus 4.8 mg/dL (3.0-6.2 mg/dL)
Calcium 10.3 mg/dL (9.7-11.5 mg/dl)
BUN 6 mg/dL (5-21 mg/dL)
Creatinine <0.2 mg/dL (0.3-1.2 mg/dL), glucose 133 mg/dL (64-123 mg/dL)
Total protein 4.3 g/dL (5.4-7.6 g/dL)
Albumin 2.4 g/dL (3.0-4.4 g/dL)
Globulin 1.9 g/dL (1.8-3.9 g/dL)
ALT 22 U/L (19-67 U/L), AST 15 U/L (19-42 U/L)
ALP 179 U/L (21-170 U/L)
Creatine kinase 274 U/L (51-399 U/L)
Gamma GT <3 U/L (0-6 U/L)
Cholesterol 278 mg/dL (135-361 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL)
Magnesium 2.0 mg/dL (1.5-2.6 mg/dL).

Imaging Findings:

Abdominal radiographs: The stomach wall appeared thickened. Numerous round gas opacities were present in a loop of intestine in the right cranial abdomen, which were believed to represent gas in the ascending colon or duodenum. Multiple additional gas opacities were present in a loop of intestine in the mid right abdomen at the level of the fourth lumbar vertebra. There was reduced serosal detail compatible with the age of the animal. Changes were considered consistent with the presence of gastroenterocolitis.

Microbiologic Testing:

Fecal Parvovirus Antigen ELISA: Negative

Fecal Enteric Real-time PCR Panel: PCR positive for CPV in fecal specimen. PCR negative for *Clostridium difficile* toxin A and toxin B genes, *Cryptosporidium* spp., *Salmonella* spp., and *Giardia* spp. DNA.

Fecal Zinc Sulfate Centrifugal Flotation: Negative for parasite ova.

Diagnosis: Enteritis and leukopenia secondary to canine parvoviral infection.

Treatment: Sam was admitted to isolation and treated aggressively with intravenous lactated Ringer's solution that was supplemented with 20 mEq KCl/L, famotidine (0.5 mg/kg IV q12h), ondansetron (0.5 mg/kg IV q12h), ampicillin (22 mg/kg IV q6h), and enrofloxacin (5 mg/kg IV q24h). Because of persistent vomiting, maropitant citrate (1 mg/kg IV q24h) was added as a second antiemetic. Blood glucose concentration was monitored three times daily, but supplementation with dextrose was not required. Bloody diarrhea that contained sloughed intestinal mucosa occurred every few hours for the first 24 hours. The neutrophil count was 9 cells/µL the following day, but by day 4 of hospitalization was 261 cells/µL, with 241 moderately toxic bands/µL and a lymphocyte count of 1226 cells/µL. There was gradual clinical improvement during this time, and Sam began to ingest small quantities of cottage cheese and rice on day 4. He was discharged from the hospital on day 5.

Comments: Despite the negative fecal antigen ELISA assay, CPV enteritis was suspected in this dog based on the history, clinical signs, and severe leukopenia. The finding of leukopenia and diarrhea is not diagnostic for parvoviral enteritis, because it can also be caused by other severe enteritides such as salmonellosis. The positive fecal real-time PCR assay for CPV supported the diagnosis, but because positive fecal PCR results can occur in healthy dogs with some assays, and also after vaccination, the fecal PCR result alone did not confirm the diagnosis of CPV enteritis. The diagnosis was therefore made on the basis of the combination of findings. The neutropenia in this dog was profound. Infection likely occurred before the owner acquired the puppy because the diarrhea began only 2 days after the puppy was purchased.

CHAPTER 15

Canine Distemper Virus Infection

Jane E. Sykes

VetBooks.ir

Overview of Canine Distemper

First Described: 1905, Henri Carré, France[1]

Cause: Canine distemper virus (family Paramyxoviridae, subfamily Paramyxovirinae, genus *Morbillivirus*)

Affected Hosts: Dogs and other Canidae such as coyotes, foxes, and wolves; Procyonidae (raccoons, pandas); Mustelidae (ferrets, mink, skunks, otters). Large wild Felidae can also be affected.

Geographic Distribution: Worldwide

Mode of Transmission: Oronasal contact with virus in secretions or excretions, droplet nuclei, and large particle aerosol transmission

Major Clinical Signs: Fever, lethargy, inappetence, vomiting, diarrhea, dehydration, tachypnea, cough, conjunctivitis, neurologic signs, footpad, and nasal planum hyperkeratosis

Differential Diagnoses: Canine parvovirus infection, other infectious causes of gastroenteritis, other causes of canine infectious respiratory disease, rabies, parasitic gastrointestinal and respiratory disease, toxins such as lead and ethylene glycol, gastrointestinal foreign body, dietary indiscretion, protozoal meningoencephalitis, systemic fungal infections such as cryptococcosis, portosystemic shunting with hepatic encephalopathy

Human Health Significance: CDV has been used as a model to study measles virus infection. There is some evidence that it may be involved in the pathogenesis of Paget's disease, a chronic, focal skeletal disorder of the elderly.

Etiology and Epidemiology

Canine distemper is an important disease of domestic dogs and wild animals worldwide. It is caused by canine distemper virus (CDV), an enveloped, pleomorphic RNA virus that belongs to the genus *Morbillivirus* (family Paramyxoviridae). CDV is closely related to human measles virus and rinderpest virus and has been used as a model to study the pathogenesis of measles virus infections. The outer envelope of CDV contains hemagglutinin (H) and fusion (F) proteins, which are important in cellular attachment and entry (Figure 15-1). Infection of dogs can lead to a severe, multisystemic disease that primarily affects the gastrointestinal, respiratory, and neurologic systems (Figure 15-2).

Ferrets also are highly susceptible to distemper, but domestic cats are not affected. In addition, distemper occurs in a variety of wildlife species that belong to the families Canidae, Mustelidae, Procyonidae, and Felidae (see Overview). Virus shed by wildlife species such as raccoons can infect domestic dogs, but virus that is shed by dogs may also be a significant threat to wildlife populations, with catastrophic outbreaks of disease and high mortality rates. In domestic dogs with signs of infectious upper respiratory disease ("kennel cough"), distemper is an important differential diagnosis, and distemper can also mimic canine parvovirus (CPV) enteritis. In fact, dual infections with CDV and CPV are probably underrecognized.

Worldwide, at least eight different geographic lineages (also referred to as genotypes or clades) of CDV exist based on sequence analysis of the H gene: Asia-1, Asia-2, America-1, America-2, Europe-1/South America-1, Europe-2 (European wildlife), Europe-3 (Arctic-like), and South Africa. In addition, strains recognized in Argentina, Africa, Asia, and Mexico may represent separate geographic lineages.[1,2] In the United States, vaccine strains belong to the America-1 lineage, whereas most field strains belong to the America-2 lineage. Strains that belong to the Europe-2 and Europe-3 lineages have also been detected in North American dogs.[3]

Although vaccination has reduced the incidence of the disease, distemper still remains important where large numbers of

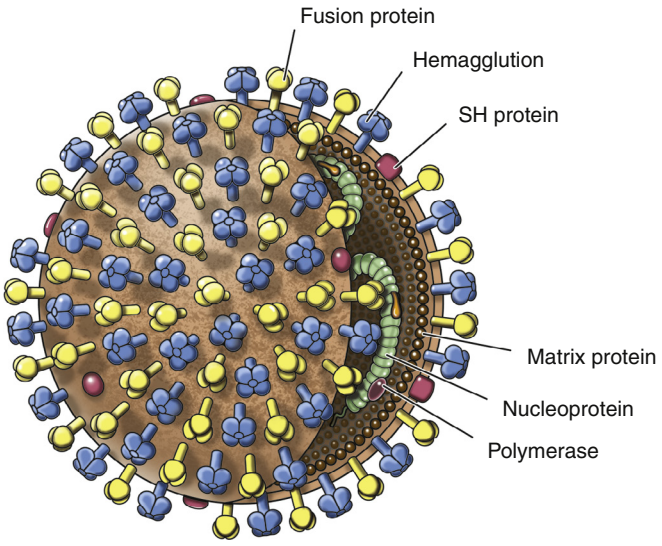

FIGURE 15-1 Structure of CDV. The outer envelope contains hemagglutinin (H) and fusion (F) proteins, which are connected to the nucleocapsid by a matrix (M) protein, which is the most abundant protein in the virion.

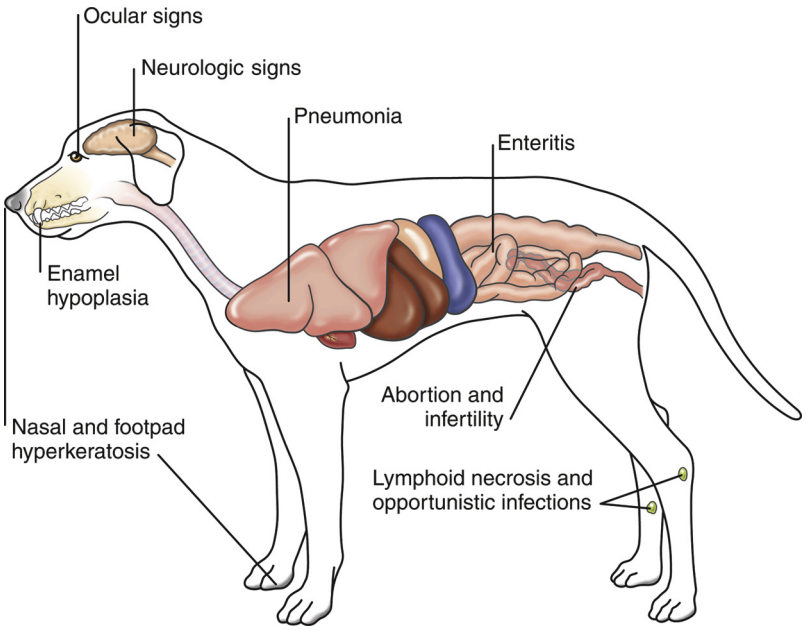

FIGURE 15-2 Anatomic sites targeted by CDV infection.

young dogs with inadequate immunity are housed together, such as in kennels, large breeding facilities, and shelter environments. Puppies that have lost their maternal antibody are predisposed in regions where vaccination is performed, but occasionally disease occurs in older, vaccinated dogs.[4-6] Distemper also occurs in regions where vaccination of dogs is not performed or is poorly timed. As an enveloped virus, CDV is susceptible in the environment (surviving less than 1 day at room temperature) and is readily inactivated by heat, drying, and disinfectants; thus, contact between infected dogs is important to maintain transmission of the virus.

Clinical Features

Signs and Their Pathogenesis

CDV is highly contagious and is spread through droplet nuclei and large-particle aerosol transmission. Dogs are generally exposed to CDV through contact with infected oronasal secretions, which may be shed by subclinically or clinically affected dogs. The virus initially infects monocytes within lymphoid tissue in the upper respiratory tract and tonsils and is subsequently disseminated via the lymphatics and blood to the entire reticuloendothelial system. The viral hemagglutinin binds to a molecule on the surface of host cells known as the signaling lymphocytic activation molecule (SLAM, also known in humans as CD150). SLAM is a membrane glycoprotein of the immunoglobulin superfamily. It is important for cell entry by CDV as well as other morbilliviruses and is a key molecule in the pathogenesis of disease.[7] SLAM is expressed by immature thymocytes, activated lymphocytes, macrophages, and dendritic cells. Direct viral destruction of a significant proportion of the lymphocyte population, and especially CD4+ T cells, occurs within the blood, tonsils, thymus, spleen, lymph nodes, bone marrow, mucosa-associated lymphoid tissue, and hepatic Kupffer cells (Figure 15-3).[8-10] Massive destruction of lymphocytes results in an initial lymphopenia and transient fever, which occurs a few days after infection. Subsequently, there is a second stage of cell-associated viremia and fever

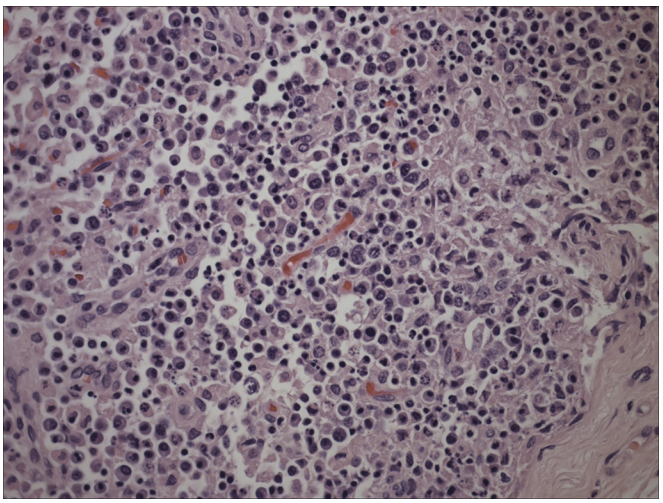

FIGURE 15-3 Lymph node histopathology of a 5-month-old German shepherd mix with distemper. The dog had been adopted from a shelter and subsequently developed neurologic signs, diarrhea, and pneumonia. There is marked lymphoid necrosis. H&E stain.

(8 to 9 days after infection), after which CDV infects cells of the respiratory, gastrointestinal tract, central nervous system (CNS), urinary tract, and skin, as well as red and white blood cells, including additional lymphoid cells. In this stage of infection, CDV infects a variety of cell lineages, including epithelial, mesenchymal, neuroendocrine, and hematopoietic cells, and forms intracytoplasmic but also intranuclear inclusions (Figure 15-4). Infection of epithelial cells by the virus is inefficient and occurs relatively late in the course of infection, through a SLAM-independent mechanism that appears to involve the nectin 4 receptor, as is true for measles virus.[11] CDV is shed in all secretions and excretions from as early as day 5 after infection, before the onset of clinical signs. Shedding of virus can continue for as long as 3 to 4 months, but usually resolves after 1 to 2 weeks.

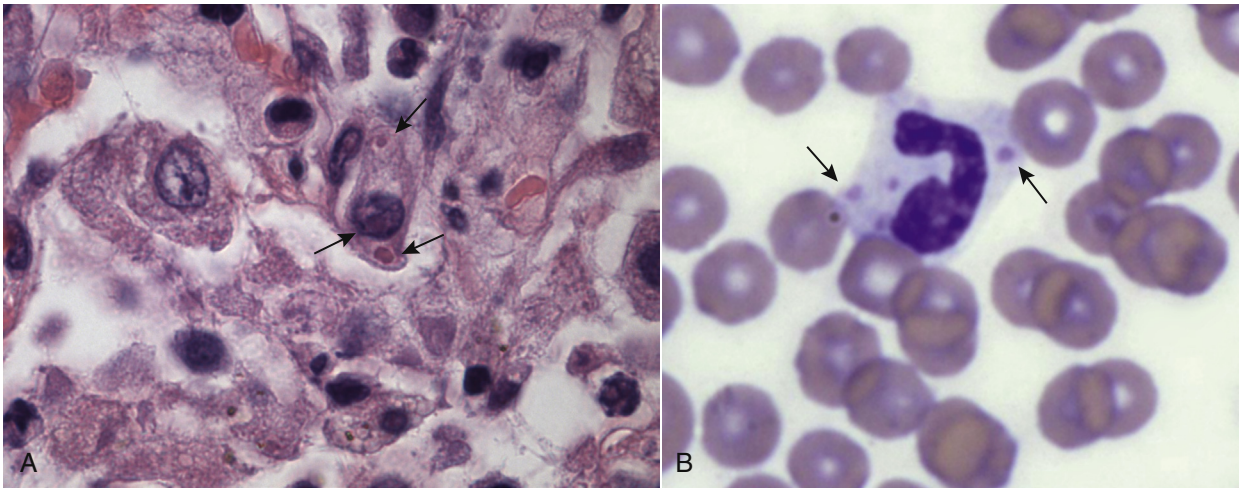

FIGURE 15-4 **A,** Eosinophilic intracytoplasmic and intranuclear viral inclusions *(arrows)* in the lung of the dog from Figure 15-3. Hematoxylin and eosin stain, 1000× oil magnification. **B,** Intracytoplasmic inclusions *(arrows)* in a circulating leukocyte of a 4-month-old Border collie mix with distemper.

The clinical signs of distemper in dogs vary dramatically and are highly dependent on virus strain and the age and immune status of the host, as well as concurrent infections with other viruses and bacteria. Many dogs experience subclinical infection, whereas others experience rapidly progressive infection followed by death. The incubation period ranges from 3 to 6 days. Respiratory or gastrointestinal tract signs may be indistinguishable from those caused by other respiratory or enteric viruses and bacteria, or signs may be so mild that they go unnoticed by the owner. Dogs with respiratory involvement may exhibit fever, bilateral serous and nasal ocular discharges, conjunctivitis, and a nonproductive cough. Secondary bacterial infection, which occurs unhindered as a result of virus-induced immunosuppression, can lead to the development of mucopurulent nasal and ocular discharges and bacterial bronchopneumonia, with tachypnea, productive cough, lethargy, and decreased appetite. Viral destruction of the gastrointestinal tract epithelium can result in inappetence, vomiting, diarrhea, electrolyte abnormalities, and dehydration. Dogs that mount an intermediate or delayed immune response may recover from acute illness but fail to eliminate the virus completely, which leads to a spectrum of more chronic disease manifestations, which often involve the uvea, lymphoid organs, footpads, and especially the CNS. Opportunistic infections can also develop in these dogs.

Up to 30% of infected dogs develop CNS signs. These usually occur 1 to 6 weeks after the onset of acute illness but can occur even when initial infection is subclinical. Neurologic signs are more likely to develop following infection with certain CDV strains, such as the Snyder Hill strain.[12] The types of brain cells that are infected differ with the strain of CDV involved,[13] but neuronal necrosis and atrophy can occur.[14] Neurologic signs are often progressive and generally do not resolve, so dogs that recover often have residual neurologic deficits. "Old dog encephalitis" is a poorly characterized, progressive immune-mediated demyelinating leukoencephalomyelitis induced by CDV that occurs weeks to years after recovery from the acute infection and is difficult to diagnose. The term "old dog encephalitis" is a misnomer, because affected dogs are not necessarily old. Both CDV and measles virus have been incriminated as possible agents of multiple sclerosis because of the resemblance of demyelinating CDV encephalitis to the pathology of this disease.[15] Virus has been detected within the brains of these dogs with immunohistochemistry and reverse-transcriptase PCR assays.[16] Persistent infection of astrocytes in the CNS by some CDV strains has been postulated as a mechanism for this chronic manifestation of infection, with transmission from cell to cell through induction of cell-cell fusion and resultant evasion of the host immune response.[17]

FIGURE 15-5 Enamel hypoplasia induced by CDV infection.

Ocular signs of persistent CDV infection include uveitis, chorioretinitis, keratoconjunctivitis sicca (KCS), keratitis, and optic neuritis, which may be associated with blindness. KCS is thought to result from damage to the lacrimal gland by CDV.[18] It may be transient or permanent, and can lead to keratitis and corneal ulceration. The virus itself can also infect the corneal epithelial and stromal cells. Enamel and dentin hypoplasia, manifested as irregularities of the teeth, is an incidental finding in recovered dogs due to infection of the stratum intermedium of developing teeth (Figure 15-5). Retention and partial eruption of teeth has also been reported as a sequela of CDV infection.[19,20] Infection of the skin can lead to a cutaneous measles-like rash, although this is uncommonly recognized. Persistent infection of the footpad and nasal planum epithelium leads to hyperkeratosis in these regions (Figure 15-6).

FIGURE 15-6 Nasal planum **(A)** and footpad **(B)** hyperkeratosis induced by CDV infection in a 4-month-old Border collie mix with conjunctivitis, mucopurulent nasal and ocular discharge, and myoclonus. Blepharospasm is also present. **C,** Histopathology of the footpad of a 1-year old German shepherd mix with distemper. Marked hyperkeratosis is evident. H&E stain, 40× magnification.

Immunosuppression results from lymphopenia, necrosis of hematopoietic cells in the bone marrow, and dendritic cell malfunction. Lymphocyte apoptosis also occurs independent of viral infection of lymphocytes.[21] The viral V protein allows CDV to replicate rapidly in T cells and is critical in CDV-mediated immunosuppression. This protein almost completely antagonizes IFN-α, TNF-α, Il-6, IFN-γ, and Il-2 in the acute phase of infection.[10] Finally, the nucleocapsid (N) protein of morbilliviruses binds to the CD32 (Fc-γ) receptor on B cells, which results in impaired differentiation of B cells into plasma cells.[22] When the virus binds this receptor on dendritic cells, impaired antigen presentation by dendritic cells results, which disrupts T-cell function. The most common secondary infections in distemper are secondary bacterial infections that contribute to bronchopneumonia. *Bordetella bronchiseptica* is a common copathogen. Dogs may be diagnosed with bordetellosis in the early stages of distemper, and the underlying CDV infection may be overlooked. Other opportunistic infections that have been identified in dogs with distemper include toxoplasmosis,[23] salmonellosis,[24] nocardiosis,[25,26] and generalized demodecosis. Infection with *Pneumocystis carinii* was associated with CDV infection in a mink,[27] and concurrent neosporosis and canine distemper was reported in a raccoon.[28]

Uncommonly, CDV infection has been associated with metaphyseal bone lesions in young dogs as a result of infection of osteoclasts, osteoblasts, and osteocytes.[29] Infected cells undergo degeneration and necrosis, and metaphyseal osteosclerosis occurs (Figure 15-7). This may lead to pain and lameness. CDV RNA has also been detected in bone cells of dogs with hypertrophic osteodystrophy, and CDV may play a role in this disease.[30]

Finally, transplacental infections with CDV may be associated with infertility, stillbirth, or abortion and with neurologic signs in puppies that are less than 4 to 6 weeks of age.

Physical Examination Findings

Physical examination findings in dogs with distemper depend on the severity and chronicity of the disease, but include fever (occasionally up to 106°F or 41.1°C), conjunctivitis, serous to mucopurulent ocular and nasal discharges, blepharospasm and photophobia, tonsillar enlargement and hyperemia, tachypnea, and increased lung sounds (see Figure 15-6). Cough may occur during the examination. Dehydration may also be present, especially in dogs with gastrointestinal and severe neurologic signs. Rarely, a measles-like cutaneous rash or pustular dermatitis is evident.

Dogs with chronic disease can be thin or emaciated and show hyperkeratosis of the nasal planum and footpads. Puppies with hyperkeratosis, also known as "hardpad," have thickened, crusty footpads that resemble those of adult dogs (see Figure 15-6). Myoclonus (involuntary twitching of isolated muscle groups) is common and, when mild, is most readily detected

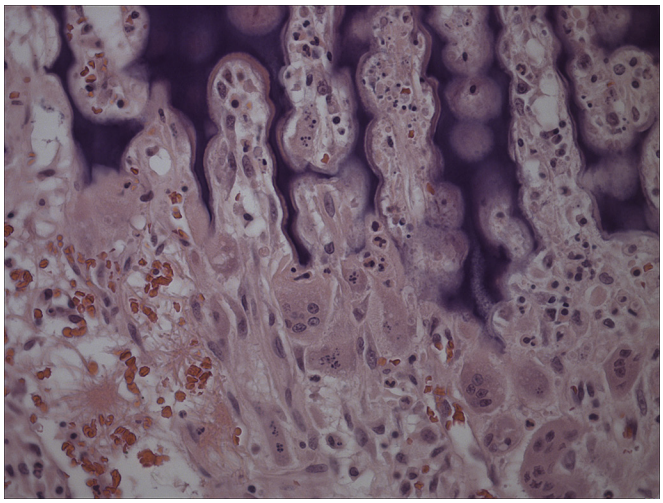

FIGURE 15-7 Severe, neutrophilic osteomyelitis with submetaphyseal osteonecrosis and extensive bony resorption in a 4-month-old intact male Labrador retriever mix with distemper. The dog was seen for lethargy, mild diarrhea, fever, and reluctance to stand; joint pain was detected on physical examination. Direct IFA on urine sediment was positive for CDV, but a conjunctival scrape tested negative with direct IFA. Necropsy also revealed pneumonia with intracytoplasmic and intranuclear viral inclusions. H&E stain.

when affected puppies are at rest. Other neurologic signs include obtundation, seizures, tremors, opisthotonos, tetraparesis, paraparesis, delayed placing reactions, ataxia, and, less commonly, behavioral abnormalities, compulsive pacing, and vestibular signs such as a head tilt, nystagmus, strabismus, and circling.[4] Focal seizures may be localized to the head and jaw, with accompanying foamy hypersalivation ("chewing gum" seizures). Vocalization and apparent blindness can also occur. In addition to conjunctivitis and ocular discharge, an ophthalmologic examination may reveal corneal edema, corneal ulceration, aqueous flare, chorioretinitis, and uveitis, or optic neuritis. Markedly decreased Schirmer tear test results and positive fluorescein tests may be present.[18] Optic neuritis appears as a large, pale, fluffy, optic disc with no physiologic depression. Rarely, lameness may be observed.

Dogs that have recovered from CDV infection may have evidence of dental abnormalities and enamel hypoplasia (see Figure 15-5); healed chorioretinitis lesions, which appear as hyperreflective circular lesions ("gold medallion lesions"); keratoconjunctivitis sicca; or residual neurologic signs, especially myoclonus.

Diagnosis

Establishment of a diagnosis of distemper is most easily accomplished in dogs that have the full spectrum of clinical abnormalities, and especially when myoclonus is present, because there are few other diseases that cause this array of clinical signs. In dogs with isolated respiratory, gastrointestinal, or neurologic signs, antemortem diagnosis is more challenging because these signs are less specific, laboratory diagnostic assays can be insensitive, and the presence of attenuated live vaccine virus can lead to false-positive results. A combination of laboratory tests may be required to establish the diagnosis, and the finding of a negative result for any assay does not rule out distemper. Sensitivity for detection of CDV using assays that detect virus may also be increased by testing of multiple specimens from different anatomic locations, such as various combinations of blood, urine, conjunctival smears, and CSF. In dogs with respiratory signs, the presence of conjunctivitis, blepharospasm, and ocular discharge should raise suspicion for distemper. Distemper should always be considered as a diagnosis in young dogs with neurologic signs, whether or not respiratory or gastrointestinal signs are present. Finally, clinicians should maintain a high suspicion for the presence of concurrent infections such as parvoviral enteritis, concurrent respiratory viral infection, or bordetellosis.

Laboratory Abnormalities

Complete Blood Count

The CBC in dogs with acute distemper most commonly reveals mild anemia and lymphopenia (Table 15-1). However, the lymphocyte count may also be normal, especially with more chronic distemper. Neutropenia, monocytopenia, and thrombocytopenia can occur, and occasionally these are severe. Neutrophilia with a left shift and toxic neutrophils may be present. Rarely, examination of Romanowsky-stained blood smears using light microscopy reveals CDV inclusions in the cytoplasm of circulating erythrocytes and leukocytes (see Figure 15-4, *B*).

Serum Biochemical Tests

Abnormalities on the serum biochemistry panel in dogs with distemper are nonspecific and include electrolyte changes that occur with vomiting and diarrhea such as hyponatremia, hypokalemia, and hypochloridemia (Table 15-2). Hypoalbuminemia and associated hypocalcemia are also common. Mild increases in liver enzyme activities occur in some dogs, which may reflect hypoxia or secondary infections that occur as a result of translocation of intestinal bacteria.

Urinalysis

No specific urinalysis findings are reported in dogs with distemper.

CSF Analysis

CSF analysis may show no clinically significant findings in dogs with distemper, especially when chronic demyelinating encephalitis is present. In some dogs with CNS involvement, a mild to moderate increase in CSF protein concentration is present (usually <100 mg/dL), and there is lymphocytic or monocytic pleocytosis, sometimes with reactivity. Nucleated cell counts are usually less than 50 cells/μL and rarely less than 100 cells/μL.[4]

Diagnostic Imaging

Plain Radiography

When present, abnormalities on thoracic radiography in dogs with distemper include pulmonary interstitial to alveolar infiltrates and consolidation compatible with bronchopneumonia, especially in the cranial and ventral lung lobes.

Magnetic Resonance Imaging

Dogs with distemper encephalomyelitis can have normal magnetic resonance imaging findings. Hyperintense lesions and loss of contrast between gray and white matter in the cerebellum and/or the brainstem have been described in T2-weighted images, which correspond to demyelination on histopathology.[31] Multifocal T2 and fluid-attenuated inversion recovery (FLAIR) hyperintensities can occur in other locations in the brain, and there may be mild meningeal contrast enhancement.

Note: Adult reference ranges were used by the laboratory.

Microbiologic Tests

Microbiological tests for CDV infection are shown in Table 15-3.

Virus Isolation

CDV can be readily isolated in SLAM transfected Vero cell lines, which show cytopathic effects within 24 hours of inoculation. Isolation is generally used as a research tool rather than for commercial diagnostic purposes. Wild-type virus must be distinguished from vaccine virus in dogs that have been recently vaccinated with attenuated live vaccines.

Cytologic Demonstration of CDV Inclusions

Intracytoplasmic viral inclusions can occasionally be seen in circulating blood cells of affected dogs, especially early in infection (see Figure 15-4, *B*). Inclusions may also be visible in the cytoplasm of conjunctival epithelial cells. Epithelial

cells can be scraped from the conjunctiva using a curette after application of a topical ophthalmic local anesthetic preparation. The cells are smeared onto a glass slide, stained with a Romanowsky stain and examined with light microscopy. Unfortunately, this has low sensitivity for diagnosis of distemper.

Immunostaining for CDV Antigen

Direct immunofluorescent antibody (IFA) techniques are often used in practice to detect CDV antigen in a variety of cell types, including conjunctival epithelial cells, leukocytes in a buffy coat smear, urine sediment, or tissues obtained at necropsy. Immunoperoxidase antibody can also be used. Immunostaining is more sensitive than identification of CDV inclusions with routine stains, but false negatives still occur when low quantities of virus are present in the specimen.

Transient false positive results might occur after vaccination with attenuated live vaccines, so the results must be interpreted with caution in recently vaccinated dogs. False positives also have the potential to occur if nonspecific fluorescence is interpreted as a positive result by inexperienced laboratory technicians. Further research is required to understand the prevalence of, and influence of vaccination on false positive direct IFA results for diagnosis of distemper.

Antigen Detection ELISA Assays

ELISA assays that detect CDV antigen in serum (Table 15-3) are available commercially as in-practice kits in some countries. The sensitivity and specificity of these assays has not been well studied, and there are no published reports in the scientific literature of the performance of commercially available assays, only those in the research and development phase. One assay had a low sensitivity in dogs that were naturally infected with distemper, with positive results in only 27% of 26 dogs at initial examination and 12% when the dogs were examined 2 to 3 weeks later.[32] False-positive results occurred for up to 4 weeks after vaccination in 20% of 40 dogs immunized with attenuated live viral vaccines. Another lateral flow (immunochromatography) assay had sensitivity equivalent to that of an RT-PCR assay when applied to conjunctival swab specimens, but sensitivity was 90% and 86% when the assay was applied to blood lymphocytes and nasal swab specimens from dogs with distemper.[33]

Molecular Diagnosis Using the Polymerase Chain Reaction

Reverse transcriptase-PCR (RT-PCR) assays are offered by a number of commercial veterinary diagnostic laboratories for diagnosis of distemper, sometimes as part of a panel that includes assays for other canine respiratory pathogens (see Chapter 17). Most assays detect a portion of the N protein gene. RT-PCR can be performed on whole blood, buffy coat, skin biopsies, conjunctival scrapings, urine, CSF, transtracheal washes, nasal and oropharyngeal swabs, and a variety of other tissues collected at necropsy (e.g., lung, small intestine, stomach, kidney, brain, bladder, lymphoid tissues). In one study of a limited number of experimentally infected dogs, conjunctival swabs were superior to whole blood, nasal flushes, and urine for PCR diagnosis of CDV infection,[34] whereas another study of naturally infected dogs showed highest viral loads in blood, followed by conjunctival swabs, and then urine.[35] RT-PCR is more sensitive than direct IFA, but false positives may be more likely to occur after vaccination with attenuated live virus vaccines, because RT-PCR assays that are currently available for routine diagnostic purposes do not distinguish between vaccine and wild-type strains. Assays have been developed that differentiate between field and vaccine strains of CDV.[36] False-positive test results should not occur after use of *recombinant* CDV vaccines. More research is needed to clarify the influence of vaccination on the results of RT-PCR for distemper. Quantitation of RT-PCR results may ultimately be helpful in differentiating vaccination with attenuated virus vaccines (low viral load) and natural infection (high viral load).

False-negative RT-PCR results can occur if the virus is present in low levels at the site from which specimens are collected. Because RNA is labile, degradation of viral RNA during specimen collection and transport to the laboratory can also lead to false-negative PCR results. In outbreak situations, collection of specimens from multiple dogs (at least 5 to 10) may increase the chance of positive test results.[37] The diagnosis is strengthened when positive PCR assay results are combined with positive results of other assays such as direct IFA.

Serology

Antibodies to CDV can be measured in the laboratory using serum neutralization (SN) assays (see Chapter 2). ELISA assays that detect IgG and IgM are also available for routine diagnosis of distemper in dogs, which have improved sensitivity and specificity over SN.[38] In one study, IgM antibodies appeared 1 week before SN titers.[39] Use of serology for diagnosis of distemper is complicated by the confounding effect of vaccination. This is especially true in shelter environments where all dogs are vaccinated on intake. Nevertheless, a fourfold rise in titer over a 2- to 4-week period supports recent infection. Acute and convalescent sera should be submitted to the same laboratory, because interlaboratory variation in assay results occurs. Ideally, an aliquot of the acute serum specimen should be retested at the same time the convalescent titer is determined. Antibodies within the CSF can be quantified and compared to those in serum to determine whether local production of antibody in the CSF is likely. Dogs with delayed-onset CDV encephalomyelitis have high levels of antibody in the CSF when compared with serum.[40]

The results of serologic tests can be used to assess the need for vaccination, and also to determine which dogs are protected and therefore of low risk for development of disease and to some extent, virus shedding in outbreak situations. Serum neutralization titers of at least 1:16 to 1:20 correlate with protection after vaccination. Titers of 1:100 or more correlate with protection in puppies that have received maternal antibodies.[41] Because of the presence of cell-mediated immunity, negative serologic results do not imply lack of protection. Point-of-care ELISA assays are also available for semiquantitative measurement of antibodies to CDV. One assay (Synbiotics TiterCHEK CDV/CPV) had a sensitivity of 76% and a specificity of 92% compared with SN when performed as a point-of-care assay.[42] The low sensitivity would tend to overestimate the need for vaccination, which is preferable to an assay with low specificity, which might result in unnecessary exposure of a susceptible dog to infected dogs.

Pathologic Findings

Gross Pathologic Findings

In addition to physical examination abnormalities described earlier, gross pathologic findings in canine distemper include thymic atrophy, pulmonary congestion and consolidation, liquid intestinal contents, and lymph node congestion and enlargement. Less common findings are mild pleural, pericardial, and/or peritoneal effusion and, uncommonly, visceral congestion and ecchymotic

VetBooks.ir

TABLE 15-3

Diagnostic Assays Available for Distemper in Dogs

Assay	Specimen Type	Target	Performance
Virus isolation	Conjunctival and nasal swabs, blood, urine, transtracheal wash specimens, necropsy specimens	CDV	False negatives can occur in specimens that contain low numbers of virus particles. Attenuated live vaccine virus may also be isolated. Not widely offered for routine diagnostic purposes.
Direct immunostaining (such as direct fluorescent antibody)	Smears made from conjunctival scrapings, urine sediment, respiratory lavage specimens, impression smears of tissue specimens	CDV antigen	False negatives can occur in specimens that contain low numbers of virus particles. False positives can occur if nonspecific fluorescence is incorrectly interpreted as a positive result. Possibility of false positives after recent vaccination with attenuated live CDV vaccines.
Distemper ELISA antigen assay	See Virus isolation	CDV antigen	Inexpensive and rapid. Sensitivity and specificity in naturally infected dogs have not been well established. False positives can occur for weeks after vaccination with attenuated live CDV vaccines.
RT-PCR	See Virus isolation	CDV RNA	Sensitivity and specificity can vary depending on assay design. Testing specimens from multiple anatomic sites or combining PCR assays with other diagnostic tests for CDV improves sensitivity. Attenuated live vaccine virus may be detected for days to weeks after vaccination. Because of the high sensitivity of some assays, the significance of a positive result in relation to disease may be difficult to interpret. False-negative results can occur when virus levels are low or as a result of degradation of viral nucleic acid during specimen transport.
Serology (IgG and IgM ELISA; SN)	Serum and/or CSF	Antibodies against CDV antigens	Acute and convalescent sera are required for diagnosis of acute distemper, so diagnosis is retrospective. False positives can occur with recent CDV vaccination.
Histopathology	Usually necropsy specimens, but also skin biopsies (such as footpad biopsies)	Eosinophilic intracytoplasmic and intranuclear inclusions; CDV antigen with immunostaining or CDV RNA with in situ hybridization	If available, in situ hybridization may be most sensitive for detection of virus in tissues.

CDV, Canine distemper virus; RT, reverse transcriptase; SN, serum neutralization.

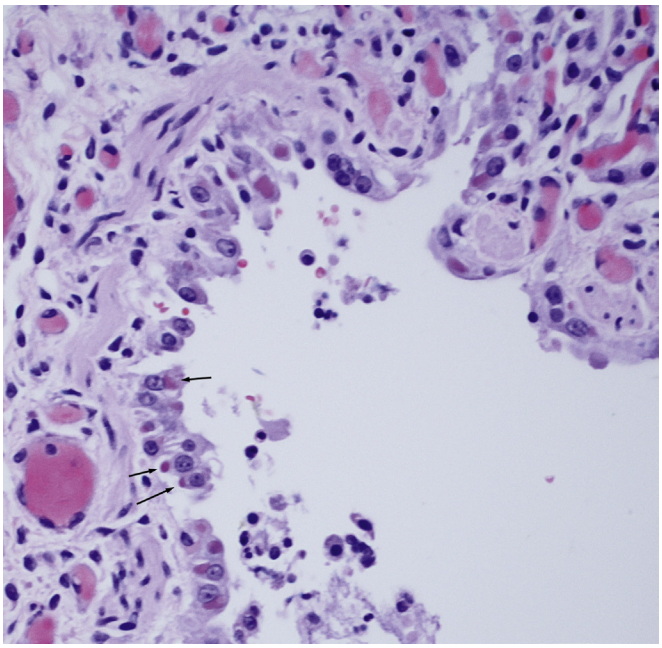

FIGURE 15-8 Bronchial epithelium from a dog infected with CDV. Intracytoplasmic inclusions are abundant *(arrows)*. H&E stain. (Image courtesy Dr. Patricia Pesavento, University of California, Davis Veterinary Anatomic Pathology service.)

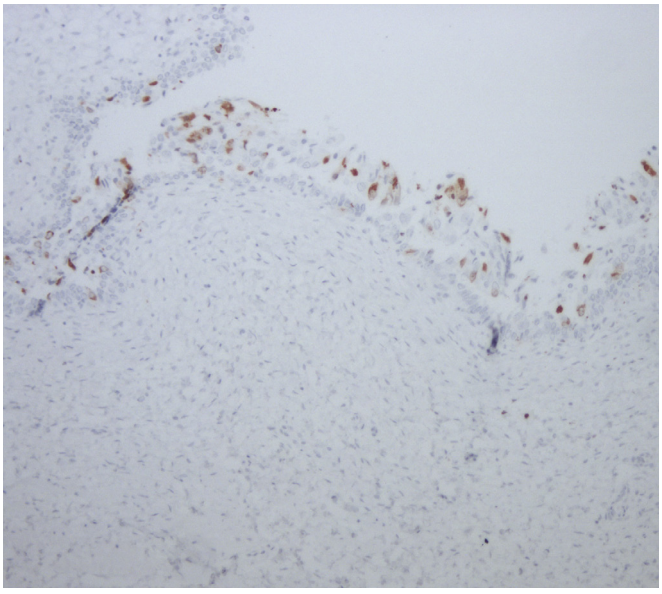

FIGURE 15-9 Immunohistochemistry that shows CDV antigen (brown staining) in bladder transitional epithelial cells from a 2-year-old male neutered Australian cattle dog infected with CDV that had been recently adopted from a shelter and developed cough, ataxia, blindness, and seizures.

hemorrhages and meningeal congestion. In some dogs, gross necropsy abnormalities are minimal. Concurrent external and intestinal parasitic infections may also be identified.

Histopathologic Findings

Histopathologic findings in the brain and spinal cord are variable and depend on the CDV strain, the immune status of the host, the presence of secondary infections, and disease chronicity. Findings in the brain and spinal cord include neuronal necrosis and degeneration, and demyelination with subacute to chronic infection. Multifocal gliosis, astrocytosis, vacuolization, and lymphoplasmacytic perivascular cuffing may be present. The virus has a predilection for white matter of the lateral cerebellar peduncles, the cerebellum, and the dorsolateral medulla adjacent to the fourth ventricle, but lesions can also occur elsewhere, such as the thalamus, midbrain, and pyriform lobes of the cerebral cortex. Less commonly, nonsuppurative meningitis is observed. Infection of the lungs leads to a lymphocytic and histiocytic interstitial pneumonia with proliferation of the alveolar epithelium; neutrophilic bronchopneumonia occurs as a result of secondary bacterial infection. There is often widespread lymphoid depletion and necrosis in all reticuloendothelial tissues (see Figure 15-3), although lymphoid hyperplasia may be observed in dogs with chronic distemper. Epithelial cell necrosis may be noted in the dental ameloblast layer, trachea, and bladder mucosa.

The diagnosis of CDV infection is supported by the identification of eosinophilic intracytoplasmic or intranuclear inclusion bodies, which are 1 to 5 μm in diameter and occur in a variety of cell types, but especially in neurons, astrocytes, microglial cells, conjunctival epithelial cells, bladder epithelium, footpad epithelium, and sometimes lymphocytes (Figure 15-8). Less commonly, syncytia may be identified, such as within the meninges, and lymph nodes. Confirmation of the presence of CDV in tissues can be established with the use of immunostaining, in situ hybridization, or RT-PCR (Figure 15-9).

Treatment and Prognosis

When required, the mainstay of treatment for CDV infection is supportive care. No specific antiviral drug is available for treatment of CDV infection, although ribavirin and 5-ethynyl-1-β-D-ribofuranosylimidazole-4-carboxamide (EICAR) have shown efficacy in vitro[43] and for treatment of measles in a rodent model.[44] The pharmacokinetics and toxicity of these drugs in dogs require further study.

Dogs with mild respiratory or gastrointestinal distemper may recover spontaneously without treatment. Dogs with severe respiratory and gastrointestinal disease may require hospitalization and treatment with IV fluids, antimicrobial drugs for secondary bacterial pneumonia, oxygen supplementation, nebulization, and coupage. Ideally, these dogs should be housed in isolation, although in many veterinary hospitals, isolation may not permit treatment with oxygen and adequate monitoring. Under these circumstances, dogs could be housed under strict barrier precautions where oxygen and critical care can be provided (see Chapter 11). When possible, collection of a transtracheal lavage specimen for culture and susceptibility is recommended for dogs with secondary bacterial pneumonia. When this is not possible, the use of antimicrobial drugs likely to be effective against *Bordetella bronchiseptica* (such as doxycycline) is recommended (see Chapter 38). Dogs with severe bronchopneumonia may require treatment with parenteral broad-spectrum antimicrobial drug combinations, such as ampicillin and a fluoroquinolone. Other supportive treatments include enteral nutrition, artificial tears for dogs with KCS, and antiemetics. Parenteral nutrition should be used only if absolutely necessary, because of the immunosuppression that occurs with CDV infection and possibility of nosocomial infections. Vitamin A supplementation before experimental infection reduced morbidity and mortality associated with CDV infection in ferrets,[45] but its usefulness as a treatment for canine distemper requires further investigation. Administration of daily oral vitamin A for 2 days to children younger than 2 years of age with measles reduces the

VetBooks.ir

risk of mortality and pneumonia-specific mortality.[46] Ascorbic acid has also been advocated as a treatment for distemper in dogs, but its efficacy remains unproven.[41]

Owners of dogs with respiratory and gastrointestinal illness should be warned that CNS signs have the potential to develop weeks to even months after apparent recovery. Unfortunately, the development of CNS signs is unpredictable. When neurologic signs occur, they rarely resolve and may be progressive. The prognosis for dogs with severe neurologic signs is poor, but some neurologic signs, such as mild myoclonus, may still be compatible with normal daily activities and do not interfere with quality of life. Euthanasia is recommended for dogs with neurologic signs that are progressive and not compatible with a good quality of life.

A single IV dose of dexamethasone or tapering antiinflammatory doses of glucocorticoids has been advocated to halt or reduce the severity of progressive CNS signs,[41] although controlled prospective studies are required to fully evaluate the usefulness of this treatment in dogs with distemper. Anticonvulsants such as diazepam and, for chronic management, potassium bromide or phenobarbital can be used to treat seizures and prevent the spread of a seizure focus. However, they do not prevent progressive CDV infection of the CNS and are sometimes poorly effective. Mexiletine and procainamide have also been suggested as treatments for distemper myoclonus, but their true efficacy is unreported. To date, the author has had disappointing results using these treatments in a limited number of dogs with persistent distemper myoclonus.

Immunity and Vaccination

Immunity to CDV requires antibodies as well as cell-mediated immunity. Recovery from natural infection provides lifelong immunity. Distemper can be effectively prevented through immunization with attenuated live or recombinant vaccines. Inactivated vaccines do not provide sufficient protection and are not available in the United States. In contrast, proper vaccination with attenuated live vaccines can provide long-lasting (at least 3 to 5 years), sterile immunity.[47] Attenuated live vaccines should be given every 3 to 4 weeks, commencing no earlier than 6 weeks of age. Maternal antibodies are usually absent by 12 to 14 weeks of age, and so the last vaccine should be given no sooner than 14 to 16 weeks of age (consider extension to 16 to 20 weeks in breeding kennels and shelters).[47] Ideally pups should be isolated for at least 7 to 10 days after the last vaccine is administered (see Appendix). For dogs older than 16 weeks of age that are brought to the veterinarian for their first vaccination, two doses of vaccine should be given 3 to 4 weeks apart, although a single dose may provide protection. A booster is recommended at 1 year and then no earlier than every 3 years thereafter.[47] For shelter dogs, vaccination should be performed as soon as possible before entry into the shelter. A single vaccine given even hours before entry can provide protection from severe disease.[48] Infection can still occur, but disease severity is lessened.

Although generally safe and effective when used according to label recommendations, attenuated live CDV vaccine virus can cause encephalitis when administered to immunocompromised dogs and puppies less than 6 weeks of age, and severe disease can occur in susceptible species such as ferrets and certain wildlife species. Administration of attenuated live CDV vaccines to dams immediately after whelping has been associated with the development of encephalitis in the puppies, and it was suggested that vaccine virus shed by the dam may cause disease in the pups.[49] Postvaccinal encephalitis usually occurs 3 to 20 days after vaccination and has been associated with certain batches of vaccines that contain the Rockborn strain.[50] Neurologic signs such as ataxia may be reversible in some dogs. Seizures may be progressive and irreversible. Some distemper vaccines available on the market still contain the Rockborn strain, and Rockborn-like viruses have been isolated from dogs with distemper, which may represent residual virulence of vaccine virus or circulation of vaccine-derived Rockborn-like viruses in the dog population.[51] Attenuated live CDV vaccines have been incriminated as a cause of hypertrophic osteodystrophy, especially in young Weimaraner dogs,[41,52] but there is a paucity of published evidence that supports the association (see Chapter 12).

A canarypox-vectored recombinant vaccine that expresses the H and F glycoproteins of CDV is also available for prevention of canine distemper (Merial Limited). This vaccine induces a 3-year duration of immunity, protects dogs from severe disease when administered hours before shelter admission, can protect puppies from virulent CDV infection in the face of maternal antibody, and can be used in pregnant bitches and puppies as young as 4 weeks of age in the face of an outbreak or in heavily contaminated environments.[48,53] The recombinant vaccine has replaced the use of canine measles vaccines, which were previously used to overcome maternal antibody in the face of distemper outbreaks. Whether the recombinant vaccine overcomes maternal antibody that is directed against the canarypox vector vaccine virus as effectively as it overcomes maternal antibody against the attenuated CDV vaccine virus requires further evaluation. Further study of the relative efficacy of the recombinant and attenuated live vaccines in heavily contaminated environments such as shelters is also required. The canarypox vectored recombinant vaccine is also the vaccine of choice for ferrets, and a specific ferret vaccine is available at the time of writing (Purevax Ferret Distemper, Merial Limited).

Vaccine strains of CDV, such as Onderstepoort, Snyder Hill, and Lederle, belong to the America-1 lineage, but field strains that circulate in North America belong primarily to the America-2 lineage. Concern has been raised that these vaccines may not adequately protect against infection with field strains, but cross-neutralization studies suggest that antigenic differences are not sufficient to warrant changes in the current vaccines. The development of distemper in vaccinated dogs may reflect failure of vaccine efficacy as a result of the improper administration of vaccines, improperly timed vaccination series, or the use of vaccines that have been stored and handled inappropriately. The last is especially important for CDV vaccines because attenuated live vaccine virus is so labile. Vaccines should be stored in a refrigerator that maintains an internal temperature of 0°C to 4°C and reconstituted with the proper diluent immediately (within 1 hour) before administration. It has been recommended that vaccine held for longer than 1 hour after reconstitution be discarded.[47] A second dose should be given if some of the vaccine is found on the haircoat after administration.

Prevention

Properly timed vaccination is the key to prevention of CDV infection. Puppies with declining maternal antibody titers should be kept away from other dogs until the vaccination series is complete. In shelter situations, dogs with signs of respiratory or

gastrointestinal disease should be held well away from other dogs (at least 25 feet has been suggested[37]) and handled only after apparently healthy dogs have been cared for. Puppies should always be separated from adult dogs using equipment designated only for that area, and overcrowding should be prevented. Quarantine for CDV is difficult because the incubation period for development of neurologic signs may be as long as 6 weeks. Wildlife species such as raccoons can also shed CDV and were suspected as a source of infection in an outbreak that occurred in a Chicago shelter, when raccoons and dogs were co-transported in the back of a vehicle.[37] Routine cleaning and disinfection of contaminated surfaces readily eliminates virus in the environment. Proper nutrition may also help to prevent disease due to CDV. Isolated vitamin A deficiency is a major risk factor for severe measles and death in humans and distemper in ferrets. Retinoids interfere with replication of measles virus in vitro through a type I IFN-dependent mechanism.[54] The impact of nutritional status on disease due to CDV requires further investigation.

Public Health Aspects

In general, CDV is not believed to infect human cells or cause disease in people. However, both CDV and measles virus have played a controversial role in Paget's disease of bone, a common skeletal disorder characterized by focal abnormalities of increased bone turnover, which is associated with bone pain, deformity, and pathologic fractures.[55] Paget's disease most often occurs in the elderly, men are more likely to be affected than women, and the overall prevalence of the disease has decreased in many geographic locations.[56] Genetic factors clearly play a role in the disease, but in some studies, the RNA of paramyxoviruses that include CDV has been detected within lesions.[57] Other studies have failed to detect the nucleic acid of CDV in lesions, and contamination has been suggested as a reason for positive test results.[55] However, CDV has been shown to infect and replicate in human osteoclast precursors, further raising concern about the possibility of zoonotic transmission of CDV.[58]

CASE EXAMPLE

Signalment: "Molly", a 1.5-year-old female spayed golden retriever from Sacramento, CA

History: Molly was evaluated for a 1-month-long history of abnormal behavior that included stumbling, failure to catch balls, and loss of interest in activity. She also had a 1-year history of seizures, which were thought to be due to idiopathic epilepsy and which were treated with phenobarbital (4 mg/kg PO q12h) and potassium bromide (17 mg/kg PO q12h). This was associated with a decrease in seizure frequency. Two weeks after the onset of abnormal behavior, Molly was taken to a local veterinary clinic. A serum phenobarbital level at that time was 50 µg/mL (therapeutic range, 10 to 40 µg/mL). The phenobarbital dose was decreased (1.4 mg/kg PO q24h), but Molly began circling to the left, head pressing, pacing, and vocalizing. She also stopped responding to the owners when they called her name, and two episodes of vomiting were noted. In the week before evaluation, Molly refused to eat dry food, but ate canned dog food. Her thirst had decreased and she was voluntarily urinating in the house. A serum phenobarbital level was repeated 2 days before she was evaluated and was 13 µg/mL. Molly had been immunized regularly (CDV, CPV, CAV-2, and parainfluenza) and received monthly flea, tick, and heartworm prophylaxis.

Current medications: Phenobarbital (1.4 mg/kg PO q24h); potassium bromide (17 mg/kg PO q12h).

Physical Examination:

Body weight: 23.2 kg

General: Obtunded but hydrated. T = 101.7°F (38.7°C), HR = 60 beats/min, RR = 36 breaths/min, mucous membranes pink, CRT = 1 sec.

Integument, eyes, ears, nose and throat: No clinically significant abnormalities were identified. A full ophthalmologic examination was also unremarkable.

Musculoskeletal: Body condition score was 5/9. Molly was ambulatory on all four limbs.

Cardiovascular, respiratory, gastrointestinal, and urogenital systems: No clinically significant findings were identified. All peripheral lymph nodes were normal sized. Average systolic blood pressure (10 measurements) was 120 mm Hg.

Neurologic Examination:

Mentation: Obtunded and not responsive to verbal and most tactile stimuli; head pressing.

Gait/Posture: Compulsive circling and leaning to the left was present.

Cranial nerves: No clinically significant abnormalities were identified.

Postural reactions: Placing reactions were absent in the left thoracic and left and right pelvic limbs.

Segmental reflexes: Diminished biceps and withdrawal reflexes were present, left thoracic limb only.

Panniculus: No abnormalities detected.

Spinal palpation: Pain was elicited in several regions along the spine. Resisted cervical ventroflexion.

Neuroanatomic localization: Diffuse cerebral or thalamic disease; C6 to T2 myelopathy.

Laboratory Findings:

CBC:

HCT 37.9% (40-55%)
MCV 68 fL (65-75 fL)
MCHC 35.4 g/dL (33-36 g/dL)
WBC 7510 cells/µL (6000-13,000 cells/µL)
Neutrophils 4859 cells/µL (3000-10,500 cells/µL)
Lymphocytes 2155 cells/µL (1000-4000 cells/µL)
Monocytes 338 cells/µL (150-1200 cells/µL)
427,000 platelets/µL (150,000-400,000 platelets/µL).

Serum Chemistry Profile:

Sodium 141 mmol/L (145-154 mmol/L)
Potassium 4.4 mmol/L (4.1-5.3 mmol/L)
Chloride 109 mmol/L (105-116 mmol/L)
Bicarbonate 21 mmol/L (16-26 mmol/L)
Phosphorus 3.9 mg/dL (3.0-6.2 mg/dL)
Calcium 12.2 mg/dL (9.9-11.4 mg/dl)
BUN 6 mg/dL (8-31 mg/dL)

VetBooks.ir

Creatinine 0.6 mg/dL (0.5-1.6 mg/dL)
Glucose 109 mg/dL (70-118 mg/dL)
Total protein 6.1 g/dL (5.4-7.4 g/dL)
Albumin 2.7 g/dL (2.9-4.2 g/dL)
Globulin 3.4 g/dL (2.3-4.4 g/dL)
ALT 132 U/L (19-67 U/L)
AST 62 U/L (21-54 U/L)
ALP 155 U/L (15-127 U/L)
Creatine kinase 399 U/L (46-320 U/L)
Gamma GT 10 U/L (0-6 U/L)
Cholesterol 291 mg/dL (135-345 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.4 mg/dL).

Serum ionized calcium: 1.39 mmol/L

Urinalysis: SGr 1.014; pH 7.0, few amorphous crystals. No other abnormalities detected.

Serum bromide concentration: 1.1 mg/mL (therapeutic range, 1.0 to 2.0 mg/mL)

Serum phenobarbital concentration: 1.4 µg/mL (therapeutic range, 15 to 40 µg/mL)

Serum bile acids: Pre-meal, 14 µmol/L (reference range, 0-12 µmol/L); post-meal, 16 µmol/L (reference range, 0-16 µmol/L)

Imaging Findings:

Thoracic radiographs: No clinically significant abnormalities were present.

Spinal radiographs: Disc space narrowing was present between the sixth and seventh cervical vertebrae and to a greater extent between the seventh cervical and first thoracic vertebrae.

Abdominal ultrasound: No significant lesions were identified.

Magnetic resonance imaging: Precontrast: Multiple small regions of hyperintensity were noted on dual echo and FLAIR sequences, one of which was in the left thalamus along the third ventricle and another diffusely along the lateral aspect of the right thalamus. There was a linear region of hyperintensity along the right parietal and temporal lobes. On T1-weighted postcontrast images, a small focus of contrast enhancement was noted in the ventral aspect of the right thalamus in the region of hyperintensity on the precontrast fluid-weighted sequences. Impressions: Multifocal, relatively non–contrast-enhancing lesions in the cerebrum and thalamus suggestive of cerebral edema, encephalitis, or small infarcts.

Electroencephalography: No abnormalities were detected.

CSF Analysis:

	Lumbar	Cisternal
Protein (mg/dL)	31	21
Total RBC (cells/µL)	111	2
Total nucleated cells (cells/µL)	1	3
Neutrophils (%)	0	0
Small mononuclear cells (%)	92	80
Large mononuclear cells (%)	8	20
Microscopic evaluation	Mild to moderate lymphocytic reactivity	Marginal mononuclear (lymphocytic) pleocytosis

Treatment and Outcome: Molly was hospitalized for a week during the diagnostic work-up and treated with intravenous fluids and potassium bromide (35 mg/kg PO q12h). She became progressively more obtunded and showed additional neurologic signs of circling to the right and positional horizontal nystagmus with a fast phase to the right. The narrowed disc spaces were thought to represent intervertebral disc disease, and granulomatous meningoencephalitis was suspected. Potassium bromide was discontinued, and treatment with phenobarbital (5 mg/kg PO q12h) reinstituted. Dexamethasone was administered (0.2 mg/kg, IV q24h), but there was minimal improvement, and euthanasia was elected.

Necropsy Findings:

- Brain, cerebrum: severe, generalized, chronic neuronal loss, axonal necrosis, and myelin degeneration with abundant eosinophilic inclusion bodies and canine distemper antigen (immunohistochemistry)
- Brain and spinal cord (C1 to T7), corticospinal tracts: severe, diffuse axonal necrosis and myelin degeneration
- Brain, cerebrum, and meninges: generalized, lymphoplasmacytic, perivascular cuffing
- Tonsil, lymph nodes (mandibular, mesenteric, thoracic): mild, multifocal lympholysis with intranuclear and intracytoplasmic eosinophilic inclusion bodies and canine distemper antigen

Diagnosis: Chronic distemper encephalitis with demyelination ("old dog encephalitis")

Comments: Distemper was not suspected in this dog because of the dog's older age and history of vaccination. Initial infection may have occurred before vaccination was complete, vaccination may have been improperly performed, or the dog may have been a vaccine nonresponder, which is believed to occur rarely. The previous diagnosis of epilepsy further complicated the identification of distemper as an underlying cause. This case example highlights the importance of including distemper on the differential diagnosis list for young adult dogs with neurologic signs, because of the chronic course of disease that can occasionally occur. Additional laboratory tests that might or might not have been helpful for diagnosis of distemper in this dog include comparison of serum antibody titers to CDV in the CSF and serum, and RT-PCR for CDV on CSF. Neurologic signs were progressive in this dog and largely unresponsive to anticonvulsant drugs, and so the prognosis was extremely poor.

CHAPTER 16

Canine Herpesvirus Infection

Autumn P. Davidson

VetBooks.ir

Overview of Canine Herpesvirus Infection

First Described: New York State, United States, 1965[1]

Cause: Canine herpesvirus-1 (Family Herpesviridae)

Affected Hosts: Domestic and wild Canidae

Geographic Distribution: Worldwide

Mode of Transmission: Direct oronasal contact with infected secretions, transplacental transmission

Major Clinical Signs: Abortion in bitches; upper respiratory disease and keratitis in adult dogs; in neonates, inappetence, failure to thrive, vocalization, tachypnea, diarrhea, neurologic signs, abdominal pain, nasal discharge, weight loss, mucosal petechiation, death

Differential Diagnoses: Bacterial sepsis, infections with other viruses such as canine distemper virus and canine parvovirus

Human Health Significance: Canine herpesvirus-1 does not infect humans.

Etiology and Epidemiology

Canine herpesvirus (CHV-1) is an enveloped virus that belongs to the family Herpesviridae (Figure 16-1). It has been reported from the United States, Canada, Australia, Japan, England, and Germany. CHV-1 was first recognized in the mid-1960s in association with a fatal disease in puppies.[2] The virus is commonly blamed for acute neonatal puppy death or failure to thrive, sometimes termed the "fading puppy syndrome." When confirmed as a cause of disease, untreated CHV-1 infection in neonates can cause high (up to 100%) mortality among littermates. The virus is temperature sensitive and prefers to replicate at temperatures less than 37°C. It is not stable in the environment and is readily inactivated by disinfectants. As with other herpesviral infections, recovery from disease is associated with lifelong latent infection of the neural ganglia, with periodic reactivation of shedding in association with stress or immunosuppression, such as that which results from overcrowding and pregnancy. CHV-1 infection has not been reported in cats.

Clinical Features

Signs and Their Pathogenesis

Transmission of CHV-1 can occur subsequent to close contact with infectious vaginal fluids during whelping or with vulvar or oronasal secretions in the postpartum period. Exposure of a naïve bitch to CHV-1 during the last 3 weeks of gestation results either in late-term abortion of a litter or neonatal death within the first few weeks of life, because inadequate peripartu-rient maternal antibodies exist to allow passive immunity to be acquired by the neonates. Puppies born to a naïve bitch may also become infected as a result of contact with other dogs that shed the organism. The incubation period of CHV-1 disease is 6 to 10 days. The virus replicates in the epithelial cells of the oronasal and pharyngeal mucosa, the genital tract, and the regional lymphatics. Replication and spread of the virus is facilitated by the presence of a low body temperature (<38°C or 100°F), which is normal for canine neonates.

Older (>3 to 5 weeks of age) puppies that are exposed to CHV-1 may develop subclinical infection, or the course of disease is less severe, as a result of their ability to mount a febrile response. Latent infection also may develop. Concerns have been raised about latency and the possibility of late development of neurologic signs.[3]

Clinical signs are more likely to occur in animals that are hypothermic or immunosuppressed. Signs in the neonate are not specific and include incessant vocalization, anorexia (with poor weight gain), dyspnea, abdominal pain, incoordination, diarrhea, serous to hemorrhagic nasal discharge, and petechiation of the mucous membranes. The mortality rate in litters infected in utero or during birth can approach 100%, with deaths occurring during the first few days to a week of life. Exposed, surviving older neonates may develop a late onset of central nervous signs including blindness, ataxia, and deafness; apparent complete recovery has also been reported.

The recently infected brood bitch generally shows no clinical signs. Healthy adult dogs of either gender can develop mild upper respiratory signs (sneezing, serous oculonasal discharge, keratitis) for a few days but are otherwise usually clinically unaffected.[4-6] Additional information on respiratory and ocular disease caused by CHV-1 can be found in Chapter 17.

Diagnosis

Antemortem diagnosis of CHV-1 infection in neonates can be challenging. Necropsy of a deceased littermate is usually required.

Virus Isolation and Molecular Diagnosis Using the Polymerase Chain Reaction

Tissues obtained at necropsy can be submitted for virus isolation or molecular diagnosis using the PCR. Diagnosis by virus isolation takes days. CHV-1–specific PCR assays can also confirm infection, in a more timely fashion. Clinicians should confirm the availability and turnaround time of commercially available diagnostic tests when attempting to investigate a possible outbreak of CHV-1 infection in puppies.[7-9]

Pathologic Findings

Gross Pathologic Findings

Gross changes in the kidneys at necropsy of pups infected with CHV-1 include multifocal petechial to ecchymotic subcapsular hemorrhages (Figure 16-2). The pleural surfaces may be mottled pink and red due to coagulation necrosis (Figure 16-2, *B*). Multifocal random acute necrosis of other organs, including the liver, pancreas, intestine and adrenal glands, may also be apparent. Lesions may resemble those of bacterial sepsis.

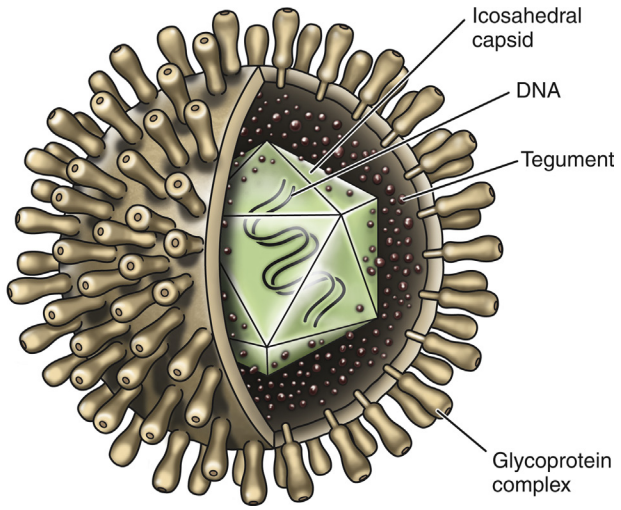

FIGURE 16-1 Structure of a herpesvirus. Herpesviruses are large, enveloped DNA viruses. The DNA is contained within an icosahedral capsid.

Histopathologic Findings

Histopathology can be used to confirm CHV-1 infection but may be unrewarding in the clinical scenario unless very timely. Characteristic viral intranuclear inclusion bodies can be difficult to find. Histopathologic evaluation commonly reveals severe nephrosis (proximal renal tubular epithelial necrosis and renal pelvic epithelial apoptosis with swollen vesicular nuclei); diffuse severe hepatic congestion and inflammation with vacuolar hepatopathy (neutrophilic, histiocytic, and lymphocytic infiltration with apoptosis); acute severe necrotizing bronchointerstitial pneumonia with pulmonary edema and hemorrhage (terminal bronchiolar hemorrhage and edema with fibrin accumulation, macrophage infiltration, necrosis, and alveolar disruption); and thymic, lymph node, and splenic lympholysis (severe diffuse cortical lympholysis with sinus congestion).

Treatment

Treatment of puppies with CHV-1 infection is unrewarding and rarely effective, and residual cardiac and neurologic damage can occur in recovered animals. Treatment with immune serum from seroconverted dams is typically ineffective in sick puppies, and warming also has little effect.

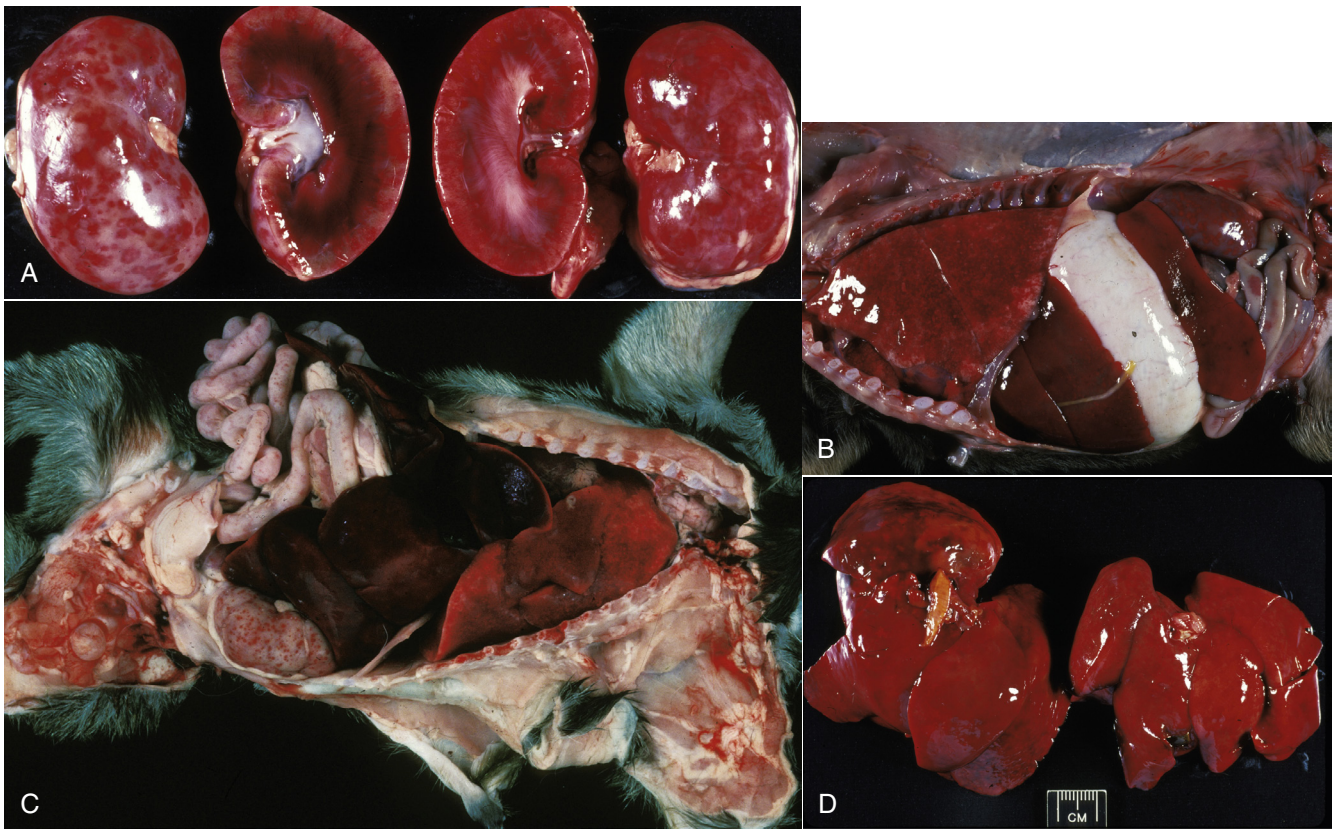

FIGURE 16-2 **A,** Kidneys from 12-day-old mastiff puppy from a litter of 17 puppies, 14 of which died. CHV-1 was isolated from the puppy. Gross changes include subcapsular hemorrhagic foci typical of (but not pathognomonic for) herpetic nephritis. On cut section, white and red cortical streaks are evident; a hemorrhagic medulla is evident. **B,** Multifocal pink and red pleural mottling in the puppy described in **A**. Serosanguineous pleural fluid was present. Histopathology identified multiple areas of pulmonary necrosis and bronchopneumonia. **C,** Small-intestinal serosal petechiation in the same puppy. Histopathology identified enterocyte necrosis consistent with CHV-1 infection. **D,** Liver of the same puppy showing uniform firmness and diffuse mottle with rounded edges. Histopathology identified scattered multiple foci of acute hepatic coagulation necrosis; eosinophilic intranuclear inclusions typical of herpes viral inclusions were seen within viable hepatocytes. (Images courtesy JR Peauroi.)

VetBooks.ir

An incompletely developed immune system and inadequate thermoregulation during the first days of life means neonates are vulnerable to systemic infection (by both bacterial and viral pathogens). The umbilicus of neonates should be treated with tincture of iodine immediately after birth to reduce contamination and prevent bacterial ascent into the peritoneal cavity (omphalitis-peritonitis). Neonatal bacterial peritonitis with bacteremia can cause rapid neonatal death if not recognized and treated promptly (see Figure 34-1). Factors that predispose puppies to bacteremia and sepsis include endometritis in the bitch, a prolonged delivery/dystocia, feeding of replacement formulas, the use of ampicillin, stress, low birth weight (<350 g), and chilling with body temperatures less than 35.5°C or 95°F. Bacterial organisms most frequently associated with bacteremia are *Escherichia coli*, streptococci, staphylococci, and *Klebsiella* spp. Commonly, a decrease in weight gain, failure to suckle, hematuria, persistent diarrhea, unusual vocalization, abdominal distention and pain, and sloughing of the extremities indicate sepsis may be present. These signs are similar to those encountered with CHV-1 infection. Prompt therapy with broad-spectrum, bactericidal antibiotics; optimal nutrition via supported nursing, tube feeding, or bottle feeding; maintenance of body temperature; and appropriate fluid replacement are indicated. The third-generation cephalosporin ceftiofur sodium is an appropriate choice for treatment of neonatal sepsis, because it alters normal intestinal flora minimally and is usually active against the causative organisms.

Failure of neonatal sepsis to respond to antibacterial drug treatment should prompt consideration of CHV-1 infection. Specific antiviral therapy, if instituted in a timely manner, may reduce mortality from CHV-1. Acyclovir has activity against herpes simplex virus (see Chapter 7). Its use in veterinary medicine is not well established, and it should be used with caution and only in situations where indicated. The safety and effectiveness in humans less than 2 weeks of age is not established. The dose (20 mg/kg PO q6h for 5 days) is extrapolated from that for humans.[10] The efficacy of famciclovir for treatment of CHV-1 infection requires study, but the pharmacokinetics of famciclovir in dogs resembles that in humans,[11] so much lower doses may be required when compared with cats.

Immunity, Vaccination, and Prevention

Minimal transplacental transfer of immunity occurs in the dog. Adequate ingestion of colostrum must occur promptly postpartum for puppies to acquire passive immunity. The transmission of protective passive immunity (placental or colostral antibodies) between a bitch and her puppies depends on the prior existence of adequate serum maternal antibodies. Therefore, breeding bitches with exposure to CHV-1 earlier in life have the best opportunity to seroconvert and develop protective antibodies. This commonly occurs in kennels or at crowded canine events such as dog shows and trials. Documentation of positive CHV-1 serology generally indicates the presence of adequate maternal antibodies.

Bitches who are naïve to CHV-1 during pregnancy must be strictly isolated from potential exposure during gestation and for at least 6 weeks postpartum to prevent transmission of the virus to her fetuses or neonates. Subsequent litters of the infected pregnant or postpartum bitch are usually normal because of acquisition of maternal antibodies.

Vaccine development has been hampered by the poor immunogenicity characteristic of the herpesviral vaccines developed for other species, such as feline herpesvirus-1 vaccines. In Europe, a vaccine (Eurican Herpes 205) has been available since 2003. Administration of two doses of the vaccine is recommended, first during estrus or early pregnancy and again 1 to 2 weeks before whelping. No suggestion for an evaluation of the bitch's serologic status prior to vaccination is made by the manufacturer. Revaccination with two doses of the vaccine is recommended at each pregnancy. No independent, nonproprietary studies exist corroborating this vaccine's efficacy or benefit. The vaccine is not currently available in the United States.[12,13]

Public Health Aspects

In general, herpesviruses are very host specific, and CHV-1 is not known to infect humans.

CASE EXAMPLE

Two, 25-day-old, female Labrador retriever puppies were examined because of acute tachypnea and vocalization. The puppies belonged to a litter of eight. Whelping occurred without incident, and the pups showed normal weight gain and behavior until the last 24 hours. Four days previously, the litter was vaccinated with an intranasal *Bordetella bronchiseptica* vaccine and dewormed with pyrantel pamoate according to routine preventative health care practice. The litter nursed from birth, and the dam was normal.

Physical examination of both puppies revealed hypothermia (rectal temperature 36.3°C [97°F] and 36.0°C [97°F], respectively), tachypnea, a markedly tense abdomen, and continuous vocalization. Despite supportive care (exogenous warming, supplemental feeding with artificial bitch's milk [Esbilack Pet Ag, Inc.], subcutaneous lactated Ringer's solution, and ceftiofur sodium [2.5 mg/kg SC q12h]), the puppies died within 12 hours and then underwent necropsy examination. Tissues collected for histopathologic evaluation included kidney, liver, lung, thymus, mesenteric lymph node, and spleen.

Because of gross findings of hemorrhagic foci in the lungs and kidneys, renal tissue was submitted for a CHV-1–specific PCR assay. The PCR assay later confirmed the presence of CHV-1 DNA in the renal tissue. Gross (foci of hemorrhage in the lungs and kidneys) and histopathologic evaluations of the deceased puppies were typical of CHV-1 but were not confirmatory because of the similarity of findings to those of neonatal bacterial sepsis. Intranuclear inclusion bodies were suspected in macrophages from the lung of one puppy. Aerobic bacterial culture of the peritoneal cavity was negative for bacterial growth.

Poor weight gain and vocalization were reported in two additional puppies. The primary differentials included neonatal bacterial sepsis and CHV-1 infection. Because of the lack of

VetBooks.ir

response to therapy for bacterial infection in the two deceased puppies, the remaining six puppies were treated with acyclovir suspension (20 mg/kg PO q6h) for 7 days, and exogenous warming adequate to raise the rectal temperature to just above 37.7°C (100°F). Therapy was initiated the day before the PCR assay confirmed infection with CHV-1.

All six treated puppies survived and were successfully weaned between 5 and 6 weeks of age. All were placed in private homes and had uneventful subsequent health histories and normal behavior. Physical examinations including complete fundic evaluations were performed at 12 to 14 months of age and were normal in all. Two of the dogs have become active guide dogs for the blind, and one is an assistance dog for the hearing impaired. All remain physically normal at more than 26 months of age.

Comments: The epizootiology of this outbreak suggests that the puppies were born from a naïve bitch and exposed to CHV-1 from another carrier dog at days 14 to 17 after birth. Two of 8 (25%) succumbed to the disease; 2 of the remaining 6 showed early clinical signs, after which antiviral therapy was initiated for all dogs.

CHAPTER 17

Canine Viral Respiratory Infections

Jane E. Sykes

VetBooks.ir

Overview of the Canine Viral Respiratory Infections

First Described: Respiratory disease in dogs (due to canine adenovirus-2) was first described in 1961 in Canada.[1] The most newly recognized virus, canine pneumovirus, was described in the United States in 2010.[2]

Proposed Causes: Canine adenovirus, canine influenza virus, parainfluenza virus, canine respiratory coronavirus, canine herpesvirus, possibly reoviruses and canine pneumovirus

Geographic Distribution: Worldwide

Mode of Transmission: Aerosol transmission or close contact, sometimes fomites

Major Clinical Signs: Harsh or honking cough, serous nasal discharge, conjunctivitis, fever (uncomplicated disease). Fever, lethargy, inappetence, tachypnea, productive cough, mucopurulent nasal and ocular discharge, rarely death (complicated disease).

Differential Diagnoses: Upper and lower respiratory diseases such as airway collapse, bordetellosis, *Streptococcus equi* subsp. *zooepidemicus* infection, fungal or protozoal pneumonia, respiratory tract neoplasia, airway foreign bodies, chronic bronchitis, eosinophilic bronchopneumopathy or granulomatosis, parasitic infections (such as *Filaroides, Oslerus, Capillaria, Paragonimus, Dirofilaria*), aspiration bronchopneumonia, left-sided congestive heart failure

Human Health Significance: Viruses that cause canine infectious respiratory disease generally are not considered zoonotic. Canine parainfluenza and reoviruses represent potential zoonoses, but the significance of this is unknown.

Etiology and Epidemiology

Canine viral respiratory disease is a widespread problem where large numbers of dogs are housed indoors together, such as in shelters, commercial dog colonies, and breeding facilities. The longer dogs are housed in a shelter situation, the greater the risk that respiratory illness will occur.[3] In shelter environments, transmissible respiratory disease (or canine infectious respiratory disease complex [CIRDC], previously referred to as "kennel cough" or canine infectious tracheobronchitis) delays the placement of dogs in homes and can result in unmanageable costs related to treatment, quarantine, and isolation. Transmissible respiratory disease occasionally occurs in owned dogs after a period of contact with large numbers of other dogs at dog parks, dog sporting events such as fly ball, or dog behavior classes. It can also occur after dogs (or dog owners) visit veterinary hospitals, boarding facilities, or pet daycare centers.

With the widespread clinical application of molecular diagnostic assays, it is increasingly apparent that the number of viruses that can infect the canine respiratory tract is much larger than previously thought. This has led to exciting new discoveries in the field of canine infectious respiratory disease, and our knowledge of the pathogens involved continues to expand. Co-infections with multiple viruses and bacteria such as *Mycoplasma* spp., *Bordetella bronchiseptica*, and *Streptococcus equi* subspecies *zooepidemicus* are common and contribute to an increased severity of disease.[4-6] Viruses believed to play a role in canine respiratory disease include canine herpesvirus-1 (CHV-1), canine adenovirus-2 (CAV-2), canine distemper virus (CDV), canine parainfluenza virus (CPiV), canine pneumovirus, canine respiratory coronavirus (CRCoV), and canine influenza virus (CIV) (Table 17-1). CAV-1 may also play a role when vaccination is not performed or when it is performed improperly.[7] Reoviruses may also play a role.[8] CDV, CHV-1, and CAV are discussed in more detail in Chapters 15, 16, and 18, respectively. The major bacterial causes of canine transmissible respiratory disease are covered in Part II, Section 2 of this book (Chapters 34, 38, and 40). Although most of the canine respiratory viruses have a worldwide distribution, their relative prevalence varies from year to year and between geographic locations. Even within a state or city, predominant pathogens may differ from one shelter and boarding kennel to another.

CDV, CHV-1, CPiV, CRCoV, and CIV are enveloped viruses, so they survive poorly in the environment and are susceptible to a variety of disinfectants. Despite this, contact with virus that persists in the environment may be important for transmission in densely housed populations of dogs. CAV-2 is a non-enveloped virus and has the potential to survive several weeks on fomites.

Canine Adenovirus-2

Adenoviruses are icosahedral DNA viruses that infect a variety of animal species. CAV-2 is found worldwide and primarily infects the respiratory tract of dogs. Rarely, it has been implicated as a cause of enteritis in dogs, and it was found in the brains of puppies with neurologic signs.[9] The virus replicates in nonciliated bronchiolar epithelial cells; epithelial cells of the nasal mucosa, pharynx, and tonsillar crypts; mucous cells in the trachea and bronchi; and type 2 alveolar epithelial cells. CAV-2 can also be isolated from retropharyngeal and bronchial lymph nodes as well as epithelial cells of the intestinal tract. Shedding typically ceases 1 to 2 weeks after initial infection.

VetBooks.ir

TABLE 17-1

Potential Causes of Transmissible Respiratory Disease in Dogs

Organism	Incubation Period (days)*	Shedding Period*	Environmental Survival
Canine adenovirus-1	4 to 9	6 to 9 months	Weeks to months
Canine adenovirus-2	3 to 6	1 to 2 weeks	Weeks to months
Canine distemper virus	3 to 6, longer for neurological signs	Weeks to months	Hours
Canine herpesvirus-1	6 to 10; may be longer with stress-induced reactivation	Unknown	Hours
Canine influenza virus	2 to 4	7 to 10 days	Hours
Canine parainfluenza virus	3 to 10	8 to 10 days	Hours
Canine respiratory coronavirus	Probably days	6 to 8 days	Hours
Bordetella bronchiseptica	2 to 6	Months	Has the potential survive and grow in environmental water for several weeks
Mycoplasma cynos	3 to 10	Months	Hours
Streptococcus equi subspecies *zooepidemicus*	Probably days	At least 2 weeks	Unknown; other streptococci can survive weeks

*Incubation and shedding periods are approximate and may differ when co-infections or immunosuppression operate.

Canine Herpesvirus-1

The extent to which CHV-1 plays a role in respiratory disease in dogs has been debated.[10] Experimental infections of dogs can result in rhinitis or signs of tracheobronchitis, and intraocular infection results in conjunctivitis and keratitis.[11-14] There is evidence of widespread exposure to CHV-1 in dogs worldwide,[10] and a substantial proportion of the dog population may be latently infected. Like other herpesviruses, CHV-1 becomes latent in neurologic tissues, with precipitation of virus shedding by stress. Consistent with the time delay required for reactivation after stress, CHV-1 was most frequently detected 3 to 4 weeks after dogs were introduced to a rehoming center, whereas CRCoV and CPiV were most frequently detected in the first and second week. Dogs infected with CHV-1 were more likely to have severe respiratory disease, although severe respiratory disease itself might predispose dogs to the shedding of CHV-1.[10] Infection with CHV-1 was reported in association with fatal hepatic necrosis in an adult dog that lacked any evidence of immunosuppression.[15] Refer to Chapter 16 for information on CHV-1 infections in neonates.

Canine Influenza Virus

Influenza viruses are enveloped viruses with segmented single-stranded RNA genomes that belong to the family Orthomyxoviridae. Influenza viruses that cause disease in domestic animals belong to the genus Influenzavirus A, whereas influenza B and influenza C viruses primarily circulate among humans. Influenza A viruses are classified based on the genetic composition of their hemagglutinin (H) and neuraminidase (N) genes. To date, 16 H types and 9 N types have been identified, each of which are antigenically distinct.[16] The names of influenza viruses are specified as follows: influenza genus (A, B, or C)/host/geographic origin/strain number/year of isolation and, in parentheses, H and N type—for example, A/canine/Florida/43/2004 (H3N8).[17] Extensive genomic rearrangements that occur within influenza A viruses allow for occasional cross-species transmission among birds and mammals. These rearrangements occur when two different viruses simultaneously infect a host, with subsequent genetic reassortment. Occasionally, cross-species transmission occurs without alteration of the viral genome.

In the United States, CIV emerged in racing greyhounds in Florida in 2003 and 2004,[17] where it caused hemorrhagic pneumonia and a high mortality. However, serologic evidence of infection in the greyhound dog population dates back to 1999.[18] Infections spread slowly and were subsequently reported in racing greyhounds and non-greyhounds in at least 38 U.S. states. Outbreaks have continued to occur in shelter situations for nearly a decade after the virus was discovered. The virus that currently circulates in the United States is an H3N8 virus that closely resembles an equine influenza virus, which suggested that an interspecies jump occurred without genetic reassortment.[17] Instead, accumulation of point mutations with minor amino acid changes occurred, with sustained transmission among dogs. The most significant outbreaks of disease due to CIV have occurred in Florida, New England, Colorado, Wyoming, and Texas. In many other states, sustained transmission of the virus from one dog to another has not occurred. The most significant risk factor for infection has been indoor housing.[19] Virtually all cases to date have involved dogs in kennels, animal shelters, or dog daycare facilities. Dogs of all ages and breeds are susceptible, but to date severe hemorrhagic pneumonia has occurred only in greyhounds.[20] The virus is shed for up to 7 to 10 days. CIV has retained the ability to infect horses, but horses develop only mild disease or no clinical signs.[20]

Avian-lineage H3N2 CIV emerged in South Korean dogs in 2007, and a similar virus was subsequently isolated from dogs in China.[21,22] Experimentally, cats are also susceptible to infection by this virus.[23] Korean isolates were associated with epidemics of respiratory disease in kennels within veterinary clinics.[22] A novel H3N1 virus was also detected in South Korean dogs that lacked signs of respiratory disease.[24] A novel H5N2 influenza virus was recently detected in a dog with

respiratory disease in China.[25] Dogs are susceptible to infection with human influenza virus H1N1[26,27] and avian H5N1,[28] but sustained transmission of these viruses in the dog population has not been reported. Limited infection of dogs with equine H3N8 viruses was detected in hounds in England[29] and during an equine influenza outbreak in Australia.[30] In England, disease was so severe that several hounds had to be euthanized, and subacute bronchointerstitial pneumonia was detected at necropsy.[29] The Australian dogs developed inappetence, lethargy, nasal discharge, and a cough that persisted for several weeks, but dog-to-dog transmission was not identified. Experimental transmission of H3N8 influenza virus from horses to dogs was documented in Japan, but infected dogs did not show signs of illness.[31]

Canine Parainfluenza Viruses

CDV, CPiV, and canine pneumovirus belong to the family Paramyxoviridae, which are enveloped RNA viruses. CPiV belongs to the genus *Rubulavirus*. Although previously referred to as canine parainfluenza virus-2, it is probably the same virus as simian virus 5, which was originally isolated from monkey cell cultures. It has been proposed that it be renamed parainfluenza virus 5.[32] Unlike CDV, the outer envelope possesses not only hemagglutinin but also neuraminidase activity (HN attachment glycoprotein). The virus infects dogs worldwide, replicates in epithelial cells of the upper respiratory tract, and often causes no signs or mild respiratory illness. Respiratory disease may be more severe when co-infections with other pathogens such as *B. bronchiseptica* are present.[33] Viremia seems to be uncommon, but occasionally CPiV has been isolated from the liver, spleen, and kidneys. A strain of CPiV was also isolated from a dog with neurologic signs.[34] There is some evidence that cats may be infected with CPiV or a closely related virus.[35] Virus is shed for up to 10 days after infection.

Canine pneumovirus belongs to the genus *Pneumovirus*. It was first isolated from dogs with acute respiratory disease in shelters in the United States in 2010.[2] The virus is most closely related to a murine pneumovirus and in fact can replicate in mice and cause severe inflammatory pathology.[36]

Canine Reoviruses

Reoviruses (family Reoviridae, genus *Orthoreovirus*) are nonenveloped viruses with a segmented, double-stranded RNA genome. Mammalian reoviruses infect a variety of host species and have a worldwide distribution. The prefix *reo-* stands for *r*espiratory *e*nteric *o*rphan virus, which highlights the tropism of reoviruses for cells of the respiratory and gastrointestinal tract, and their uncommon association with disease. Despite serologic evidence of widespread exposure to reoviruses in dogs, they have been found only rarely in dogs with respiratory disease[8,37] and dogs with enteritis.[38] There are three mammalian reovirus (MRV) serotypes, and all three have been detected in dogs. The role of reoviruses in disease causation in dogs is unclear, because disease has not been reproducible experimentally. It has been speculated that reoviruses might act synergistically with other respiratory pathogens to cause disease.[10]

Canine Respiratory Coronavirus

Coronaviruses are enveloped RNA viruses that possess large, club-shaped spikes on their outer surface, also known as peplomers (see Figure 14-1, *B*). CRCoV is a relatively newly identified cause of contagious respiratory disease in dogs. The virus is a group 2a coronavirus (family Coronaviridae, genus *Coronavirus*) and is distinct from canine enteric coronavirus, a group 1a coronavirus (Box 17-1).[39] Minimal serologic cross-reactivity exists between these two viruses. Group 2a coronaviruses possess a gene that encodes hemagglutinin esterase, an outer membrane protein glycoprotein. This gene is absent in group 1 and 3 coronaviruses. CRCoV is most closely related to a bovine coronavirus but also resembles human coronavirus OC43.[40]

CRCoV was first reported in 2003, in a group of dogs with respiratory disease in a rehoming facility in England that had been vaccinated against CAV-2, CDV, and CPiV.[6,40] Some of the dogs were co-infected with CPiV and CHV-1.[6] CRCoV spread rapidly and primarily was detected in the first week that dogs were introduced to the kennel, after which time CPiV and CHV-1 were detected. Alone, CRCoV causes subclinical infections or mild respiratory disease, but like human respiratory coronaviruses, it can cause reversible damage to, or loss of, the cilia on respiratory epithelial cells (Figure 17-1). As a result, infected dogs are predisposed to secondary infections. Serologic evidence of exposure to CRCoV is widespread in dogs from North America, Great Britain and continental Europe, Japan, Korea, and New Zealand,[10,41-43] and the virus has been detected widely using PCR-based methods in dogs with respiratory disease from many of these countries. To date, there is no evidence that cats can be infected with CRCoV.

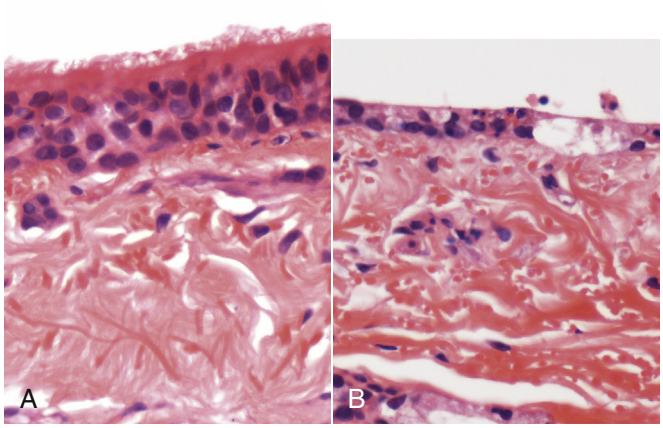

FIGURE 17-1 Effect of canine respiratory coronavirus infection on ciliated respiratory epithelial cells. **A,** Respiratory epithelium immediately before inoculation with CRCoV. **B,** The same cells 48 hours after inoculation with CRCoV. There is marked loss of cilia, thinning of the epithelium with individual cell necrosis, and sloughed necrotic cells on the surface. There are also occasional large vacuoles within the epithelium, which likely represent foci of cell loss secondary to viral replication. (Courtesy Dr. Simon Priestnall and Professor Joe Brownlie, Royal Veterinary College, UK.)

Infection with pancytotropic strains of canine enteric coronavirus has recently been associated with severe systemic disease in puppies from Europe. Affected pups have fever, mucoid to hemorrhagic enteritis, lymphopenia, neurologic signs such as seizures, and bronchopneumonia.[44,45] Co-infections with CPV-2 were present in some puppies, but the disease has been reproduced by experimental infection by canine enteric coronavirus alone. Death occurred in some puppies, but others developed transient gastrointestinal signs and recovered.[46]

Clinical Features

Signs and Their Pathogenesis

The incubation period for viral respiratory disease is generally less than 2 weeks and can be as short as 2 to 3 days. Influenza virus infections, in particular, have been associated with very short incubation periods.[20] Transmission occurs by aerosol, but direct contact between dogs and fomite transmission (hands, clothing, contaminated food and water bowls, common hallways and exercise areas) are important routes in population-dense environments. Cells of the larynx, trachea, bronchi, and sometimes the nasal mucosa, bronchioles, and alveoli are infected, and although viral shedding patterns differ between pathogens, shedding may occur before the onset of clinical signs. The duration of shedding for CIV and CPiV is very short, typically a few days, and in some dogs, shedding has ceased by the time clinical signs are most apparent. In contrast, CDV can be shed for weeks (see Chapter 15).

Infection with respiratory viruses may be associated with no signs, or complicated pneumonia and death can occur. In general, morbidity is high, but mortality is low. Moderate to severe signs may be more likely to occur in very young puppies, genetically susceptible animals, and when stress and co-infections with multiple viral and bacterial pathogens are present. Infection with CDV is especially effective at predisposing dogs to other respiratory viral infections, because of its immunosuppressive properties, but other viruses that damage ciliated epithelial cells, such as CRCoV and CPiV, also predispose to co-infections. Clinical signs of acute respiratory disease include

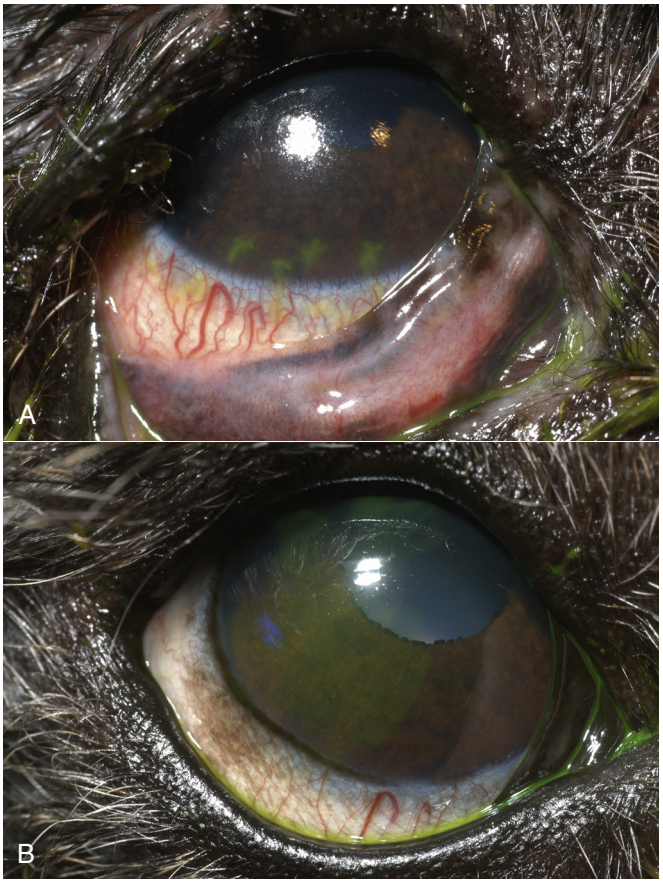

FIGURE 17-2 **A,** Right eye of a 10-year-old male neutered miniature schnauzer infected with bilateral conjunctivitis and dendritic ulceration associated with canine herpesvirus infection. Fluorescein uptake can be seen in a branching pattern at the limbus of the right eye. **B,** The same dog 1 month later. Note diffuse stain uptake over at least 25% of the corneal surface. (Courtesy University of California, Davis Veterinary Ophthalmology Service.)

mild fever, a paroxysmal harsh or "honking" cough, serous nasal discharge, and sometimes sneezing, but usually otherwise affected dogs are often alert, active, and appetent. The cough may be followed by gagging or retching, which may be followed by the production of frothy mucus. An altered bark or stridor may occur in dogs that develop laryngitis, tonsillitis, and/or pharyngitis. CAV-2 and CHV-1 may cause conjunctivitis.[47] In addition, CHV-1 has been associated with ulcerative and nonulcerative keratitis, which may be precipitated by immunosuppression (Figure 17-2).[48-50] Infections with CIV or CDV, or infections with multiple respiratory pathogens, may be more likely to produce systemic signs of fever and lethargy. Dogs that develop secondary bacterial infections may show fever, inappetence, lethargy, a mucopurulent nasal discharge, tachypnea, and a moist, productive cough.

Physical Examination Findings

On physical examination, dogs with uncomplicated transmissible respiratory disease are typically bright, alert, and active with a paroxysmal cough. The cough is often easily elicited on tracheal palpation. Conjunctivitis and serous ocular and/or nasal discharge may be present, and the tonsils may be enlarged and hyperemic. Dogs with secondary bacterial infections may be pyrexic, lethargic, and tachypneic with increased respiratory effort and

TABLE 17-2

Diagnostic Assays Available for Respiratory Viruses in Dogs

Assay	Specimen Type	Target	Performance
Virus isolation	Conjunctival, nasal, and caudal pharyngeal swabs; transtracheal and bronchoalveolar wash specimens; airway and lung specimens collected at necropsy	Virus	False negatives can occur in specimens that contain no or low numbers of virus particles. Attenuated live vaccine virus may also be isolated. May take several days and requires specialized techniques and expertise.
Influenza ELISA antigen assay	Same as virus isolation	CIV antigen	Inexpensive and rapid. Sensitivity and specificity in naturally infected dogs have not been well established, so results should be interpreted with caution.
PCR or RT-PCR	Same as virus isolation	Viral nucleic acid	Sensitivity and specificity may vary with assay design. Sensitivity may be low because of brief shedding for some viruses. Assays may not be available for all viruses or may not detect all virus strains. Testing specimens from multiple different anatomic sites or combining PCR with other diagnostic tests can increase sensitivity. Attenuated live vaccine virus may be detected after vaccination. Because of subclinical shedding, the significance of a positive result may be difficult to interpret. False-negatives may occur as a result from degradation of viral nucleic acid during specimen transport.
Serology	Serum	Antibodies against respiratory viral antigens	Interpretation complicated by previous vaccination and exposure. May be useful when the exposed population is naïve and unvaccinated for the virus of interest. Acute and convalescent sera required for diagnosis.
Histopathology	Necropsy specimens	Viral inclusions; immunostaining	Can be used for diagnosis at necropsy. Detection of inclusions has low sensitivity, and immunostaining and/or PCR is required to definitively identify the infecting virus.

CIV, Canine influenza virus; RT, reverse transcriptase.

increased lung sounds on thoracic auscultation. A mucopurulent nasal discharge may also be present. Ulcerative or nonulcerative keratitis may be present in dogs infected with CHV-1.

Diagnosis

It is not possible to identify the cause of transmissible respiratory disease in dogs based on clinical signs alone, because each pathogen produces a similar spectrum of signs. The high prevalence of co-infections further complicates diagnosis. In addition, other, noncontagious causes of respiratory disease in dogs can lead to signs that closely resemble transmissible respiratory disease. A history of exposure to other dogs can support the diagnosis.

Most dogs experience self-limiting disease. Attempts to obtain an etiologic diagnosis should be made when disease persists for longer than 7 to 10 days or is complicated by bacterial pneumonia, with lethargy and inappetence. When outbreaks occur in shelters or the pattern of endemic respiratory disease changes, attempts to make an etiologic diagnosis are also indicated and encouraged (Table 17-2). Collection of multiple specimen types from several dogs with and without clinical signs in an outbreak situation can facilitate diagnosis and allow interpretation of the significance of positive test results. Organism detection methods, such as PCR assays, are likely to be of highest yield early in the course of illness (e.g., the first 1 to 3 days) or in exposed dogs that have not yet developed clinical signs. Use of a combination of serology and organism detection methods also facilitates diagnosis. In shelter situations or outbreaks where severe disease occurs, necropsies can provide valuable information and should be performed by a veterinary pathologist as soon as possible after death or euthanasia. Tissues should be submitted for histopathology (in formalin), bacterial and virus cultures (fresh tissue), and PCR assay for respiratory viruses and bacteria (fresh or frozen tissue; see Chapter 5).

Laboratory Abnormalities

There are no specific abnormalities in the CBC, serum biochemistry profile, or urinalysis that aid in a diagnosis of canine viral respiratory disease. The CBC may be normal or show a mild to moderate neutrophilia. Band neutrophils and neutrophil toxicity may be apparent in dogs with secondary bacterial pneumonia. Severe infections may be associated with leukopenia, which may be followed by leukocytosis in dogs that recover.

VetBooks.ir

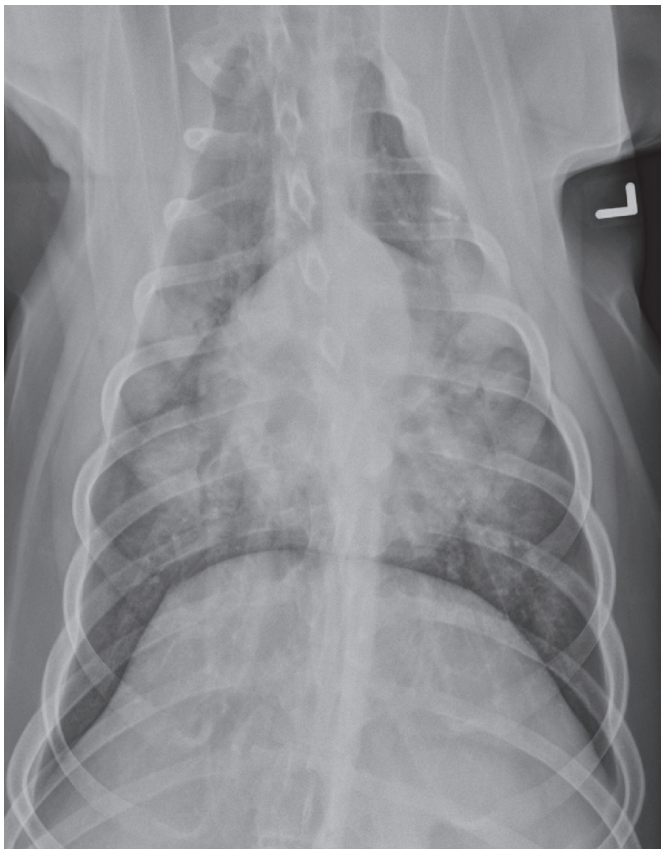

FIGURE 17-3 Dorsoventral thoracic radiograph from a 2-year-old male neutered coonhound that had left a boarding facility 6 days previously with a moist, productive cough that subsequently progressed and was complicated by the development of fever and a mucopurulent nasal discharge. A CBC showed neutrophilia (17,840 cells/μL), increased numbers of band neutrophils (223 cells/μL), and monocytosis (3,345 cells/μL). Bronchopneumonia is present that involves the right cranial, right middle, and left cranial lung lobes. Interestingly, canine herpesvirus DNA was detected in a pooled extract from nasal, conjunctival, and oral swab specimens, as well as a whole blood sample using a PCR assay.

Transtracheal wash and bronchoalveolar lavage specimens from dogs with viral pneumonia typically show a suppurative or mixed exudate, sometimes with evidence of intracellular bacteria. Culture for aerobic bacterial culture and *Mycoplasma* spp. are indicated on wash specimens, and antimicrobial susceptibilities should be obtained for any aerobic bacteria isolated. Organisms such as *Pasteurella* spp., *Staphylococcus pseudintermedius, Streptococcus canis, Escherichia coli, Klebsiella pneumoniae,* and some *Mycoplasma* spp. infect the airways as opportunists and are not considered to be primary pathogens. Bacterial culture of nasal swabs is generally not recommended because it often leads to growth of normal flora, which has no clinical relevance.

Diagnostic Imaging

Plain Radiography

In uncomplicated viral infections, plain thoracic radiography in dogs often shows no significant abnormalities, or there may be a mild diffuse interstitial or bronchointerstitial pattern. Secondary bacterial bronchopneumonia may be characterized by development of peribronchial and alveolar infiltrates or lobar consolidation (Figure 17-3).

Microbiologic Tests

Virus Isolation

Efforts to isolate viruses from dogs with acute respiratory disease have been most useful for identification of novel or reemerging pathogens.[2,38,40] Despite the increased availability of molecular diagnostic assays, virus isolation is still offered to veterinarians for routine diagnostic purposes by laboratories that specialize in virology (e.g., the Animal Health Diagnostic Laboratory at Cornell University in Ithaca, NY). Suitable specimens for respiratory virus isolation are nasal and pharyngeal swab specimens, transtracheal or bronchoalveolar lavage specimens, or upper airway or lung tissue obtained at necropsy. If swabs are used to collect specimens, polyester-tipped swabs and specific virus transport media should be used. Cotton swabs should be avoided, because influenza viruses adhere to the cotton, which can lead to reduced sensitivity.[20] Virus isolation is a specialized process that may take several days. As with PCR assays, sensitivity may be low because shedding of respiratory viruses occurs early in the course of illness and may be transient. CRCoV fails to replicate in many cell lines, but was successfully isolated in HRT-18 cells.[51] This may explain its relatively recent discovery relative to other respiratory viral pathogens.

Fluorescent Antibody Testing

Fluorescent antibody can be applied to smears made from swabs from the upper respiratory tract, or tissues collected at necropsy, such as fresh lung tissue. Assays are available for detection of CPiV, CAV, CDV (see Chapter 15), and CHV-1. Attenuated live vaccination with intranasal vaccines for CPiV and CAV has the potential to interfere with fluorescent antibody results, but this requires further study. The sensitivity of fluorescent antibody testing is likely to be lower than that of PCR assays, and inexperienced personnel may misinterpret nonspecific fluorescence as a positive result.

Enzyme-Linked Immunosorbent Assays for Influenza Virus Antigen

Point-of-care ELISAs are available for detection of nucleoprotein antigen of human influenza A viruses. The assays are easily performed and provide rapid results. Unfortunately, such assays have had limited sensitivity and specificity for diagnosis of CIV infections, and so their use is not recommended. False positives may especially be a problem in shelters where canine influenza is not endemic.

Molecular Diagnosis Using the Polymerase Chain Reaction

Panels of real-time PCR assays that detect respiratory pathogens are offered by some commercial veterinary diagnostic laboratories. These may include assays for CRCoV, parainfluenza virus, and CIV, as well as bacterial pathogens such as *B. bronchiseptica* and *Mycoplasma* spp. Swabs of the nasal cavity and/or caudal pharynx, or respiratory lavage specimens could be submitted for testing. At necropsy, CRCoV is most readily detected in upper respiratory tract specimens, such as the nasal mucosa, nasal tonsil, and trachea.[52] Lung specimens may also yield positive results. Unfortunately, false-negative PCR results are common, especially in antemortem specimens, because of transient or low-level shedding of many respiratory viruses. In addition, because many respiratory viruses are RNA viruses and RNA is very labile when compared with DNA, false negatives can occur when viral RNA degrades during specimen transport.

VetBooks.ir

In outbreak situations, false-positive PCR results may occur if swab specimens become contaminated with virus from the environment or the hands of personnel. Clean examination gloves should be worn for each dog, and the swab should only touch the anatomic site to be tested. Vaccination with live attenuated vaccines (especially intranasal vaccines) may cause positive test results with real-time PCR assays, but the extent to which this occurs in dogs with respiratory viral illness requires further study. Because CIV vaccines are parenteral inactivated vaccines, they would not be expected to lead to false-positive PCR assay results. The detection of nucleic acid from a respiratory virus in a specimen may not imply disease causation.

Serologic Diagnosis

Diagnostic laboratories that specialize in veterinary virology may offer serologic assays for antibodies to canine respiratory viral pathogens on a commercial basis to practitioners. Serology has limited use for diagnosis because of vaccine titer interference for some organisms, and the high prevalence of subclinical exposure to organisms endemic in the dog population. Titers may be negative in the first 10 days of illness, and some dogs may not show a significant increase in antibody titer after infection. Despite these limitations, serologic assays have been key to identification of infection and disease caused by emerging pathogens such as CIV, when the disease is not endemic.[20] In this situation, analysis of paired serum specimens collected 2 weeks apart can be used to document recent infection. In some dogs, no other diagnostic test may be useful for antemortem diagnosis because virus shedding is so transient and difficult to detect.

Serologic assays for CIV exposure are based on serum neutralization or hemagglutination-inhibition (see Chapter 2). Assays for CIV that use equine influenza virus antigen for antibody detection have suboptimal sensitivity, whereas an assay based on H3N8 CIV antigen was sensitive and specific when compared with serum neutralization.[53] Seroconversion to CRCoV in a bovine coronavirus antigen ELISA assay helped identify the association between infection with this virus and respiratory disease in dogs in the rehoming kennel in the United Kingdom.[6] Serum neutralization assays can be performed for detection of antibodies to CAV-2, CPiV, and CHV-1. Antibodies to CAV-2 and CPiV can also be detected by hemagglutination-inhibition.

Pathologic Findings

Gross Pathologic Findings

Necropsy of dogs with viral respiratory infections may show no gross lesions, or pulmonary consolidation and hyperemia of the tracheal mucosa may be present. Purulent exudate may be present in the bronchi. Greyhounds that died of CIV infection had extensive hemorrhage within the lungs, mediastinum, and pleural space, together with mild, fibrinous pleuritis.[17]

Histopathologic Findings

Histopathology of the airways of dogs with viral respiratory infections may show loss or irregularity of normal respiratory cilia and epithelial necrosis and ulceration within the trachea, bronchi, and bronchioles. With secondary bacterial infection, a neutrophilic or mixed inflammatory infiltrate may be seen in the airway mucosa, submucosa, and alveoli.[54] Bronchial and bronchiolar lumina may contain neutrophils, macrophages, and cellular debris. Thickening of the alveolar walls with type 2 pneumocyte hyperplasia and interstitial edema has also been described. Hemorrhagic interstitial and bronchointerstitial pneumonia, vasculitis, and thrombus formation have been observed in greyhounds with CIV infection.[20] CAV-2 can produce large, basophilic intranuclear inclusion bodies within bronchial, bronchiolar, and alveolar cells. These must be differentiated from the eosinophilic inclusions of CDV (see Chapter 15).[55] Reoviruses can also produce intracytoplasmic inclusions within bronchial epithelial cells.[8] Use of immunohistochemistry can facilitate definitive identification of viral antigen within cells of the respiratory tract.[5,55]

Treatment and Prognosis

Like the common cold in humans, contagious respiratory disease in dogs resolves without treatment in the vast majority of dogs, regardless of the underlying cause. For dogs with signs of respiratory disease that have been present for less than 7 to 10 days and that remain bright and appetent, no treatment is indicated. In some dogs, cough persists for as long as 10 to 30 days. Cough suppressants such as hydrocodone could be used for dogs with a nonproductive, honking cough that occurs throughout the day and night. Cough suppressants should not be used in dogs that have productive cough, because they suppress normal clearing mechanisms. Use of a harness or gentle leader for leash walking rather than a neck collar may also reduce cough. The efficacy and optimal dosage of neuraminidase inhibitors such as oseltamivir (see Chapter 7) is unknown, and because of this and the fact that oseltamivir is a first-line treatment for pandemic influenza in humans, it should not be used to treat dogs with respiratory disease, even when CIV infection is present. For dogs with confirmed ocular CHV-1 infections that are associated with corneal ulceration, topical antiviral ophthalmic preparations such as idoxuridine or cidofovir could be considered (see Chapter 7).[50]

Antimicrobial drug treatment could be considered for dogs with signs that persist beyond 7 to 10 days, but is primarily indicated when there is evidence of secondary bacterial bronchopneumonia, such as pulmonary alveolar infiltrates and consolidation on thoracic radiography, lethargy, mucopurulent oculonasal discharges, and/or decreased appetite. Because antimicrobial drug resistance is increasingly reported among secondary bacterial pathogens and *B. bronchiseptica*, treatment of dogs with secondary bacterial bronchopneumonia is optimally based on the results of culture of a transtracheal wash specimen from each affected dog and antimicrobial susceptibility testing. For dogs with severe pneumonia, initial treatment should involve the use of broad-spectrum parenteral antimicrobial drugs such as a combination of a fluoroquinolone and a penicillin or clindamycin. When infection with *B. bronchiseptica* or *Mycoplasma* spp. is suspected, doxycycline may be the best first choice. Indiscriminate use of antimicrobial drugs leads only to widespread bacterial resistance and failure of antimicrobial drug treatment in dogs that develop severe disease.

Dogs with pneumonia may also require treatment with intravenous fluids, supplemental oxygen, nebulization, and coupage. Nutritional support in the form of feeding tubes may be required for dogs that are inappetent.

Prognosis depends on the virulence of the causative agent(s), the presence of co-infections, and other factors that contribute to host immunosuppression. Prognosis is generally excellent for dogs with uncomplicated infections with a single pathogen. For CIV infection, mortality rates have been less than 8% and could be lower with rapid diagnosis and appropriate treatment.[20]

Immunity and Vaccination

Vaccines are available for reduction of disease due to CPiV, CAV-2, CDV, and CIV. With the exception of CDV vaccines, none of the available vaccines completely prevent infection and shedding, but they can lessen the severity of disease, provided other factors such as overcrowding and appropriate disinfection and reduction of other stressors are also addressed. Parenteral and mucosal (intranasal and oral) attenuated live vaccines are available for CPiV and CAV-2. The vaccine for CIV is an inactivated vaccine. Vaccines for canine transmissible respiratory disease are considered noncore vaccines, so they should be administered to dogs at risk of exposure, such as those that enter shelters, boarding kennels, shows, sporting competitions, popular dog parks, or pet daycare facilities.

Canine Adenovirus-2

Mucosal and parenteral vaccines are available for prevention of disease due to CAV-2. Parenteral CAV-2 vaccines also protect against CAV-1 infection. Maternal antibodies persist for up to 12 to 14 weeks after birth. Mucosal vaccines may be useful to overcome maternal antibodies in young dogs that are introduced to shelter environments. However, parenteral vaccines are still required for adequate protection against CAV-1.

Canine Herpesvirus

An inactivated vaccine for CHV-1 is available in Europe for pregnant bitches to protect puppies against neonatal infections (see Chapter 16). It is not intended to reduce respiratory disease due to CHV-1 infection.

Canine Influenza Virus

Inactivated, parenteral vaccines are available for reduction of disease and shedding caused by H3N8 CIV.[56] One vaccine also reduced the severity of illness caused by co-challenge with CIV and *Streptococcus equi* subspecies *zooepidemicus*.[4] The use of these vaccines could be considered for dogs that are likely to contact other dogs in regions where CIV is endemic, especially those that enter boarding or pet daycare facilities. Vaccination against CIV is required for importation of North American dogs to Australia.[57] The initial vaccine can be given as early as 6 weeks of age. Because CIV vaccines are inactivated, two initial doses are required 3 to 4 weeks apart, and maximum immunity does not occur until 1 week after the second dose. As a result, CIV vaccines may not protect dogs that enter shelters where canine influenza is endemic, unless newly introduced dogs are separated from dogs that might be shedding CIV until immunization is complete. Annual boosters are recommended for dogs that remain at risk of infection, but the maximum duration of immunity is unknown.

Canine Parainfluenza Virus

Intranasal vaccination with CPiV significantly reduces clinical signs and virus shedding after challenge.[58-60] One study showed that intranasal CPiV vaccination reduced clinical signs even when dogs were challenged as long as 1 year after immunization.[58] Few studies have compared the efficacy of parenteral and intranasal vaccines. In a study reported in the early 1980s, the parenteral vaccine was less effective at reducing shedding than the intranasal vaccine,[59] but a study reported in the 1970s showed reduction of clinical signs and shedding after parenteral vaccination.[61] The use of one parenteral CPiV vaccine resulted in antibody titers that persisted for at least 2 years.[62] Use of intranasal CPiV vaccines, as opposed to parenteral vaccines, has been advocated, because they produce local immunity, reduce shedding, and can be used in puppies as young as 3 to 4 weeks of age.[63] However, proper administration of mucosal vaccines may be difficult in aggressive dogs or dogs that refuse to be restrained. Mucosal vaccines may also be associated with transient respiratory illness for 3 to 10 days after immunization in a small percentage of dogs. This may be problematic in shelter and boarding environments, because these signs cannot be distinguished from those that result from natural infection with wild-type viruses. More studies that evaluate the relative efficacy of mucosal and parenteral CPiV vaccines are required.

Prevention

Although vaccination can reduce the prevalence of respiratory disease in dogs,[3] current vaccines do not provide protection against all the organisms that cause respiratory disease in dogs, and immunity is not sterile, so infection and mild clinical signs can still occur. When factors such as stress, immunosuppression, co-infections, and overwhelming challenge doses are present, vaccine-induced protection may be overwhelmed. Prevention of transmissible respiratory tract disease in dogs therefore involves not only vaccination, but also control methods that include quarantine of dogs introduced into densely populated environments, early identification and isolation of dogs with signs of respiratory disease through proper training of shelter personnel, avoidance of overcrowding and mixing of dogs, use of solid walls between runs, reduction of time dogs spend in a shelter environment, optimum nutrition, fomite control, control of noise such as barking, and proper ventilation and disinfection (see Box 11-5). Distances traveled by aerosols generated by dogs are unknown. Dogs with respiratory disease should be separated from other dogs in shelter environments by at least 25 feet (or as far as possible) and ideally placed in an enclosed room with a separate ventilation system. Isolated dogs should not be moved back into the general shelter population, but adopted out of isolation or a separate recovery room. Provided proper cleaning and contact times are used, use of disinfectants with activity against parvovirus should also kill respiratory viruses, with CAV-2 being the respiratory virus that is most resistant to disinfection. The order of inspection of dogs in shelters should be healthy dogs, then quarantined dogs, and finally dogs in isolation.

When outbreaks occur, attempts should be made to identify the pathogen(s) involved. This allows potential routes of transmission of infection and shedding patterns to be identified, proper vaccination and control strategies to be implemented, and adequate disinfectants to be selected. For example, quarantine for 2 weeks and isolation or removal of any dogs that develop illness may be effective for diseases such as canine influenza, because of the short incubation and shedding periods. However, it is less likely to be successful for distemper and bordetellosis, which can have prolonged incubation and shedding periods. For some viral respiratory diseases such as canine influenza, discontinuation of intake and adoptions for 2 to 3 weeks may be necessary while the disease runs its course. Exposed dogs could also be transferred to foster care in a household with no other dogs. Because of a lack of adequate resources for treatment, diagnostic evaluation, and management, some shelters have elected to euthanize large numbers of affected dogs.

Shelters should provide written information on transmissible respiratory disease to clients who adopt shelter animals, regardless of the presence or absence of clinical signs at the time of adoption, and communicate fully about diseases that are endemic in the shelter. Whenever possible, dogs that leave shelters should be kept away from other dogs for at least 2 weeks (consider 4 weeks if bordetellosis is endemic), and informed about follow-up medical care. Other dogs in the household should be vaccinated before they are placed in contact with the shelter animal. Clients should also be instructed to ensure their local veterinary clinic is aware that their dog is newly adopted from a shelter, so that precautions can be taken to prevent contamination of the hospital environment when the dog is examined a few days after leaving the shelter.

Public Health Aspects

Viruses related to simian virus 5 (parainfluenza virus 5) have been detected in humans, but the role of CPiV as a human pathogen is controversial. Reoviruses have a broad host range, and human infection has been associated with enteritis and respiratory disease; MRV-3 infection was associated with meningitis in a child.[64] Thus they represent a potential zoonosis. Although adenoviruses, influenza viruses, coronaviruses, and paramyxoviruses cause respiratory disease in humans, there is no evidence that CAV-2, CIV, CDV, CHV-1, or CRCoV can be transmitted to humans. Human influenza viruses such as H1N1 can cause disease in dogs and may have the potential to spread from infected dogs back to humans.

CASE EXAMPLE

Signalment: "Winnie", a 10-year old male neutered miniature Schnauzer from Sacramento, CA

History: Winnie was brought to his local veterinarian because of a 1-day history of serous ocular and nasal discharge, and sneezing. Fever (103.5°F or 39.7°C) was documented on physical examination, and enrofloxacin (2 mg/kg PO q24h), bacitracin-neomycin-polymyxin ophthalmic ointment (both eyes q8h), and diphenhydramine (2.2 mg/kg PO q12h) were prescribed, without clinical improvement. A day later, he became lethargic, inappetent, and polydipsic, and the owners described continuous nasal discharge, and a moist cough. Winnie was brought to the UC Davis VMTH for a second opinion. He had been vaccinated regularly for CDV, CAV-2, CPV, rabies, *Bordetella bronchiseptica,* and CPiV. He was recently cared for in a boarding facility for a week and had been home for the past 11 days. He also regularly visited dog parks. There were two other miniature Schnauzers at home, and both were currently well.

Current Medications: Enrofloxacin, 2 mg/kg PO q24h

Other Medical History: Increased activity of serum ALP was noted at a senior care visit 2 months before the onset of respiratory signs.

Physical Examination:

Body Weight: 9.4 kg

General: Lethargic but hydrated. T = 100.8°F (38.2°C), HR = 104 beats/min, respiratory rate = 12 breaths/min, mucous membranes pink, CRT = 1 to 2 s.

Eyes, Ears, Nose, and Throat: Severe chemosis, hyperemia, and mucoid ocular discharge were present bilaterally. There was also profuse bilateral serous nasal discharge and decreased nasal airflow, hypersalivation, and right tonsillar enlargement.

Musculoskeletal: Body condition score 5/9.

Respiratory: Stertorous respiratory noises were noted. Increased respiratory effort with a normal respiratory rate was also present. Auscultation revealed referred wheezing noises in all lung fields.

Gastrointestinal: Tense abdomen, hepatomegaly was detected on abdominal palpation.

All Other Systems: No abnormalities were detected.

Ophthalmologic Examination: Pupillary light reflexes (PLRs) (direct and consensual) were brisk and complete. There was no evidence of anisocoria. Menace response, dazzle, and palpebral reflexes were all complete. Globe position and movements were normal bilaterally (OU). Periorbital palpation and globe retropulsion were also normal. The dog behaved as if sighted. The eyelids were normal. Both nictitans were hyperemic and edematous, and there was moderate conjunctival hyperemia, chemosis, and mucoid ocular discharge OU. Bilateral iris atrophy and lens nuclear sclerosis were also present. The cornea, anterior chamber, vitreous, and dilated fundic examination were normal OU. In the left eye (OS), a pinpoint incipient anterior cortical cataract was identified just ventral to the center of the lens. In the right eye (OD), a linear pigment deposition on the anterior lens capsule was present at the 5 o'clock position.

Schirmer Tear Test: 8 mm/min OU

Intraocular Pressure: 16 mm Hg OS, 17 mm Hg OD

Fluorescein Stain: Multiple dendritic ulcers were identified at the ventral peripheral cornea OD (see Figure 17-2).

Laboratory Findings:

CBC:

HCT 53.5% (40-55%)
MCV 67.7 fL (65-75 fL)
MCHC 35.3 g/dL (33-36 g/dL)
1 nucleated red cell/100 WBCs
WBC 14,600 cells/μL (6000-13,000 cells/μL)
Neutrophils 10,804 cells/μL (3000-10,500 cells/μL)
Band neutrophils 438 cells/μL
Lymphocytes 1752 cells/μL (1000-4000 cells/μL)
Monocytes 1460 cells/μL (150-1200 cells/μL)
Eosinophils 0 cells/μL (0-1500 cells/μL)
Platelets 216,000 platelets/μL (150,000-400,000 platelets/μL)
A few highly reactive lymphocytes were noted.

Serum Chemistry Profile:

Sodium 142 mmol/L (145-154 mmol/L)
Potassium 6.1 mmol/L (3.6-5.3 mmol/L)
Chloride 102 mmol/L (105-116 mmol/L)
Bicarbonate 25 mmol/L (16-26 mmol/L)
Phosphorus 6.7 mg/dL (3.0-6.2 mg/dL)
Calcium 9.5 mg/dL (9.9-11.4 mg/dl)
BUN 20 mg/dL (8-31 mg/dL)
Creatinine 0.7 mg/dL (0.5-1.6 mg/dL)

VetBooks.ir

Glucose 80 mg/dL (60-104 mg/dL)
Total protein 5.7 g/dL (5.4-7.4 g/dL)
Albumin 2.2 g/dL (2.9-4.2 g/dL)
Globulin 3.5 g/dL (2.3-4.4 g/dL)
ALT 564 U/L (19-67 U/L)
AST 116 U/L (21-54 U/L)
ALP 1024 U/L (15-127 U/L)
Gamma GT 10 U/L (0-6 U/L)
Cholesterol 195 mg/dL (135-345 mg/dL)
Total bilirubin 0.4 mg/dL (0-0.4 mg/dL).

Urinalysis: SGr 1.009; pH 8.5, negative for protein, bilirubin, hemoprotein, glucose; rare WBC/HPF, 0 RBC/HPF, 0-3 hyaline casts/HPF, few amorphous crystals, moderate degenerated cells and amorphous debris in the sediment.

Imaging Findings:

Thoracic and Cervical Radiographs: A mild to moderate bronchial and interstitial pattern was identified and was most prominent in the caudal lung fields. Cervical radiographs were unremarkable. The pulmonary changes were considered nonspecific, but more significant than those expected due to age.

Abdominal Ultrasound: The cranial pole of the right adrenal was mildly to moderately enlarged. The liver appeared sonographically normal. A 3 mm stone was identified in the urinary bladder.

Microbiologic Testing: A nasal swab specimen was submitted for real-time PCR panel for canine respiratory pathogens, which included CHV-1, CIV, CDV, CPiV, CAV-2, and *B. bronchiseptica*. The results were available 3 days later, and the specimen was positive for CHV-1 DNA.

Diagnosis: Upper respiratory disease and keratitis associated with CHV-1 infection.

Treatment: Winnie was hospitalized in isolation and treated with 0.9% NaCl (30 mL/hr IV), nebulization for 15 min q8h, clavulanic acid-amoxicillin (13.5 mg/kg PO q12h), and lubricating eye ointment (1 inch OU q4h). Clinical improvement occurred a day later, electrolyte abnormalities normalized, and the dog was discharged with instructions to administer topical idoxuridine (0.1% ophthalmic solution, 2 drops OU q4-6h). Unfortunately a caretaker of the dog did not regularly administer the idoxuridine. At a recheck 5 weeks after the dog was first seen, the owner reported 80% improvement in Winnie's respiratory signs, but he continued to sneeze approximately six times a day and was pawing at his eyes. Examination revealed persistent conjunctivitis, and a fluorescein stain showed large, superficial areas of uptake over the central cornea OU (see Figure 17-2). A Schirmer tear test (STT) was 13 mm/min OS and 8 mm/min OD. A CBC was normal, and the serum biochemistry profile showed persistently increased ALP (835 U/L) and GGT activities (12 U/L) and improvement in the serum ALT activity (124 U/L). The owner was instructed to administer idoxuridine for an additional 2 weeks, as well as lubricating ointment, bacitracin-neomycin ophthalmic ointment (q8h OU), and L-lysine gel (2 mL [400 mg] q12h PO), separating the ophthalmic medications with administration of the idoxuridine first. At a recheck 2 weeks later, all signs had resolved and there was no fluorescein uptake. STT results were 14 mm/min OS and 10 mm/min OD. The idoxuridine was discontinued. Winnie had another episode of respiratory signs 4 months later, at which time the STT results were 15 mm/min OU. Treatment with lubricating eye ointment and L-lysine was continued.

Comments: This was an unusual case of ocular and respiratory herpesviral infection. The early detection of dendritic ulcers allowed a connection to be made between the clinical signs and positive PCR assay result. The negative PCR assay results for other respiratory pathogens did not rule out the possibility of co-infections, because shedding of these organisms may have ceased or been at undetectable levels. Although idoxuridine was used to treat this dog, topical cidofovir may also have been effective.[50] Approximately 2 years later, mild serous nasal discharge and depigmentation of the planum nasale developed. A biopsy of the nasal planum showed epitheliotropic lymphoma. The dog was treated with multiagent chemotherapy for over a year without relapse of herpetic keratitis.

CHAPTER 18

Infectious Canine Hepatitis

Jane E. Sykes

VetBooks.ir

Overview of Infectious Canine Hepatitis

First Described: First described as infectious canine hepatitis (ICH) in 1947 in Sweden by Rubarth[1]; CAV-1 was first isolated in chick embryos in 1951[2]

Cause: Canine adenovirus-1 (family Adenoviridae, genus *Mastadenovirus*)

Affected Hosts: Dogs, coyotes, foxes, wolves, bears, skunks

Geographic Distribution: Worldwide

Mode of Transmission: Direct contact with infected saliva, feces and urine, and contaminated fomites

Major Clinical Signs in Dogs: Fever, lethargy, inappetence, vomiting, hemorrhagic diarrhea, abdominal pain, dehydration, conjunctivitis, petechial hemorrhages, tachypnea, cough, corneal edema ("blue eye"), rarely icterus or neurologic signs.

Differential Diagnoses: Other systemic viral diseases such as parvoviral enteritis and canine distemper, enteric viral and bacterial infections, hepatotoxicosis (e.g., mushrooms), Rocky Mountain spotted fever, gastrointestinal foreign body, dietary indiscretion, leptospirosis, portosystemic shunting with hepatic encephalopathy, disseminated fungal infections (especially systemic candidiasis), systemic protozoal infections (especially sarcocystosis, toxoplasmosis or African trypanosomiasis), hemic neoplasia (especially lymphoma).

Human Health Significance: CAV-1 does not infect humans.

Etiology and Epidemiology

Infectious canine hepatitis (ICH) is an uncommonly recognized disease of dogs that is caused by canine adenovirus type 1 (CAV-1), a non-enveloped, icosahedral double-stranded DNA virus that is antigenically related to CAV-2 (see Chapter 17) (Figure 18-1). CAV-1 also causes disease in wolves, coyotes, skunks, and bears, as well as encephalitis in foxes, but the diversity of wildlife hosts is not as great as that for CDV. Ferrets are not susceptible.[3] ICH has also been referred to as Rubarth's disease, after Carl Sven Rubarth, a veterinarian who first described the disease in the late 1940s.[1] Over the subsequent 10 years, ICH was described worldwide, including the United States, Canada, United Kingdom, Australia, Japan, Brazil, and throughout Europe. The virus can survive for months at room temperature, but should be readily inactivated by disinfectants with activity against canine parvovirus (CPV).[4] Disease most commonly occurs in dogs that are less than 1 year of age, but was reported in adult dogs before widespread vaccination for ICH was introduced.

The strong antigenic relationship between CAV-1 and CAV-2 is clinically important, because vaccines that contain CAV-2 protect against infection with CAV-1 and vice versa. After the introduction of CAV-1 vaccines, ICH largely disappeared, but over the past decade it has reemerged, with published reports of disease from Italy, Switzerland, and the United States.[5-8] Disease in Europe has been associated with puppy trading from kennels in eastern European countries and possibly spillover of virus circulating in wildlife.[9] In Italy, three outbreaks occurred in shelters in southern Italy, and the others involved purebred puppies imported from Hungary a few days before the onset of clinical signs. Several of the dogs were co-infected with other viruses, such as canine distemper virus (CDV), CPV, or canine enteric coronavirus. Encephalopathy due to CAV-1 infection was described in nine 5-week-old Labrador retriever puppies from Arkansas in the United States, all of which belonged to the same litter.[8] The litter was from an unvaccinated bitch. These case descriptions confirm that CAV-1 continues to circulate in the dog population and can result in severe disease in young dogs when vaccination does not occur, is improperly timed, and stress, co-infections, and overcrowded conditions prevail.

Clinical Features

Signs and Their Pathogenesis

CAV-1 is shed in saliva, feces, and urine, and transmission occurs through direct dog-to-dog contact or contact with contaminated fomites such as hands, utensils, and clothing. Ectoparasites such as fleas and ticks are also potential mechanical vectors.[4] Airborne transmission does not appear to be important. Initial infection occurs through the nasopharyngeal, conjunctival, or oropharyngeal route, and the virus replicates within the tonsils, after which it spreads to regional lymph nodes and the bloodstream via lymphatics. Subsequently, infection of hepatocytes and endothelial cells within a variety of tissues occurs, such as the lungs, liver, kidneys, spleen, and eye with resultant hemorrhage, necrosis, and inflammation. The virus replicates in the nucleus of host cells, where crystalline arrays of virions form. There is severe condensation and margination of nuclear chromatin, with inclusion body formation (Figure 18-2). The virions are released by cell lysis, which leads to tissue injury and disseminated intravascular coagulation (DIC). Within the liver, the virus initially infects Kupffer's cells and subsequently spreads to hepatocytes.

Clinical signs generally occur after an incubation period of 4 to 9 days, although many dogs probably show no signs of illness.[4] Three overlapping disease syndromes have been described. The first is peracute disease with circulatory collapse, coma, and death after a brief illness that lasts less than 24 to 48 hours. The second, most commonly described syndrome is acute disease, which is associated with high morbidity and reported mortality rates of around 10% to 30%.[4] Dogs with acute disease

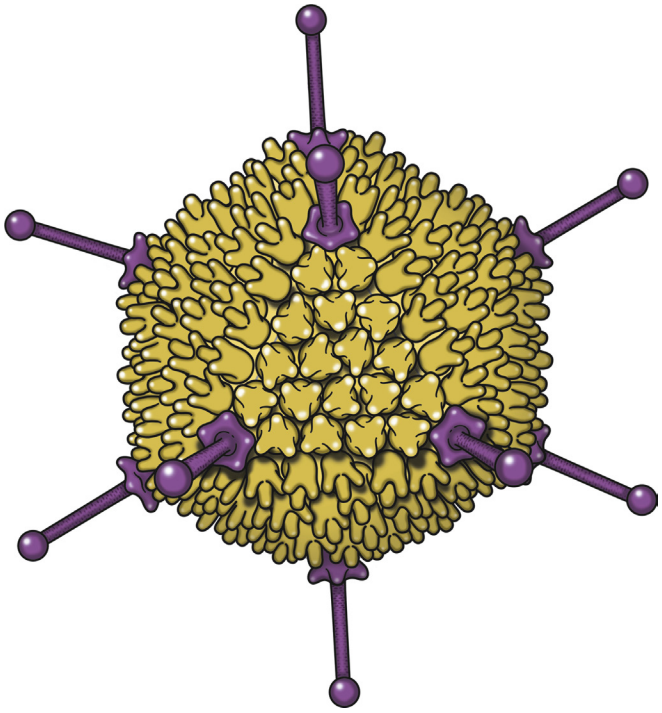

FIGURE 18-1 Structure of canine adenovirus. The virus is a non-enveloped, Icosahedral virus with fibers (purple) that radiate outwards from the virion.

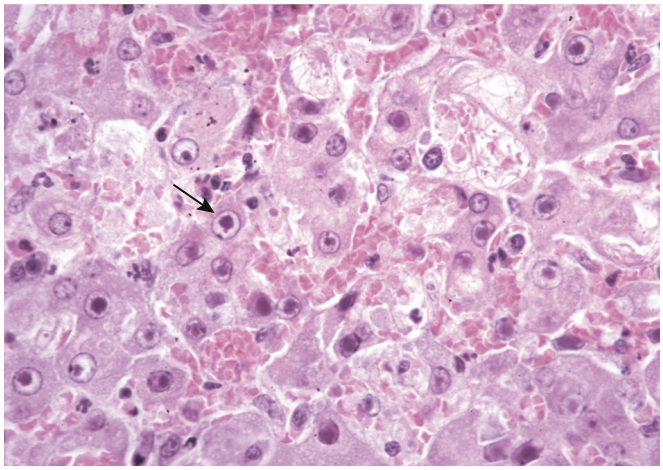

FIGURE 18-2 Infection of hepatocytes and endothelial cells with CAV-1 produces characteristic basophilic intranuclear inclusions surrounded by a clear zone that separates them from the marginated chromatin *(arrow)*. H&E stain. (Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia and Noah's Archive, College of Veterinary Medicine, The University of Georgia. In Zachary JF, McGavin M. Pathologic Basis of Veterinary Disease, 5 ed. St. Louis, MO: Mosby; 2012.)

either recover or die within a 2-week period. The third is a more chronic form that occurs in dogs with partial immunity, with death due to hepatic failure weeks (subacute disease) or months (chronic infection) after initial infection.[10]

Acute disease is variably characterized by the presence of fever, tonsillitis, conjunctivitis, inappetence, lethargy, weakness, polydipsia, vomiting, hematemesis, diarrhea, cough, tachypnea, and icterus. Diarrhea may contain frank blood or melena. Widespread petechial and ecchymotic hemorrhages and hematuria can be seen. Corneal edema ("blue eye") occurs in the first week of illness and results from replication of virus within corneal endothelial cells (Figure 18-3). Rarely, neurologic signs such

FIGURE 18-3 Young adult dog with corneal edema from an Italian shelter outbreak of CAV-1 infection. (Courtesy Dr. Nicola Decaro, Department of Veterinary Public Health, Faculty of Veterinary Medicine of Bari, Italy.)

as seizures, ataxia, circling, apparent blindness, head pressing, and nystagmus have been reported in association with CAV-1 encephalitis.[7,8] The development of neurologic signs may also represent hepatic encephalopathy, intracranial thrombosis or hemorrhage, or, as occurred in one outbreak, concurrent infection with CDV.[7]

The antibody response appears 7 days after infection and limits tissue damage. Viral persistence within the renal glomeruli, uveal structures of the eye (the iris and ciliary body), and the cornea can trigger immune complex formation in dogs that recover from acute illness. This leads to glomerulonephritis with proteinuria, severe uveitis, and persistent corneal edema in some surviving dogs. Glomerulonephritis usually occurs about 1 to 2 weeks after the acute signs resolve. Glomerular lesions contain deposits of viral antigen, IgG, IgM, and C3.[11,12] Infection of the glomerular endothelium is followed by a persistent tubular infection, development of interstitial nephritis, and viruria, but chronic renal failure has not been described. Viral shedding in the urine can occur for up to 6 to 9 months after infection. Anterior uveitis is associated with massive influx of inflammatory cells into the anterior chamber. Occasionally persistent corneal edema fails to resolve for months and may be associated with complications such as glaucoma.[13] The Afghan hound is reportedly susceptible to this complication.[14]

In experimental infections with CAV-1, chronic hepatitis with extensive fibrosis was observed in some dogs that recovered from acute illness, with survival for up to 8 months.[10] The virus could not be found in hepatic lesions from these dogs. Attempts to detect CAV-1 in the liver of other dogs with chronic active hepatitis using PCR assays have to date been unrewarding.[15-17]

Physical Examination Findings

Physical examination findings in dogs with acute ICH vary, but might include lethargy, dehydration, fever (up to 106°F or 41°C),

VetBooks.ir

TABLE 18-1

Diagnostic Assays Available for Infectious Canine Hepatitis

Assay	Specimen Type	Target	Performance
Histopathology	Usually necropsy specimens, but also liver biopsy	Hepatic necrosis with intranuclear inclusions; CAV-1 antigen with immunohistochemistry	True sensitivity and specificity of inclusion visualization unknown. Liver biopsy may not be feasible because of coagulopathies.
Polymerase chain reaction (PCR)	Blood; rectal, conjunctival and nasal swabs; urine; tissues collected at necropsy	CAV-1 DNA	Sensitivity and specificity may vary depending on assay design. Specific CAV-1 assays are not widely offered by commercial veterinary diagnostic laboratories. Some assays differentiate between vaccine (CAV-2) and field virus (CAV-1). The significance of a positive result from urine may be difficult to interpret due to subclinical shedding. False-negative results may occur as a result of PCR assay inhibition by components of feces or in dogs with subacute or chronic presentations.
Virus isolation	All body secretions, tissues	CAV-1	Sensitive and specific, but generally only available as a research tool.

CAV, Canine adenovirus.

congestion and enlargement of the tonsils (which may be severe), pallor, conjunctivitis, peripheral lymphadenopathy, tachypnea, increased lung sounds, and tachycardia. In some reports, serous to mucopurulent ocular and nasal discharge have been observed, but these may have resulted from co-infections with other respiratory viruses.[4] Abdominal palpation may reveal hepatomegaly, splenomegaly, or abdominal pain. Icterus is uncommon but can occur in dogs with a more prolonged course of disease. Peripheral edema that involves the head, neck, and ventral abdomen has been described.[18] Puppies with CAV-1 encephalitis may show signs of circling, vocalization, head pressing, ataxia, and blindness.[8] Coagulopathies may be manifested as cutaneous or mucosal petechial hemorrhages; gingival hemorrhages; epistaxis; or prolonged bleeding from venipuncture sites.

Ocular complications occur in at least 20% of affected dogs. Unilateral or, less commonly, bilateral corneal edema may be observed, which initially develops at the limbus and is occasionally associated with blepharospasm, photophobia, and a serous ocular discharge.[13] Unilateral involvement may progress to bilateral involvement over several days. Using a slit lamp, the cornea is markedly thickened, and there is episcleral and ciliary injection. Uveitis may also be apparent. Corneal ulceration and increased intraocular pressure has also been described in dogs with corneal edema, the latter of which may result in blindness.[13]

Diagnosis

ICH should be suspected in any dog less than 1 year of age that has a questionable vaccination history and signs of fever, respiratory, gastrointestinal, and hepatic disease, and certainly in any young dog that develops corneal edema. Diagnosis is easily achieved at necropsy when characteristic intranuclear inclusion bodies are seen in tissues, but the sensitivity and specificity of this finding is unknown. Inclusion bodies may be seen on impression smears of liver biopsies or tissue obtained at necropsy. At the time of writing, antemortem diagnosis is challenging owing to the lack of commercially available assays that specifically detect the virus or viral DNA, and the disease may be underdiagnosed (Table 18-1). Serologic assays are available, but they provide only retrospective diagnosis, and interpretation of these assays may be a challenge when there is a history of vaccination.

Laboratory Abnormalities

Complete Blood Count

Findings reported on the CBC are variable and include leukopenia, anemia, increased nucleated red blood cells, and moderate to severe thrombocytopenia. Leukopenia occurs early in the course of infection and may be profound. Initially there is a lymphopenia, after which neutropenia occurs and worsens progressively until death.[18] Increased band neutrophils and toxic changes may also be present. Occasionally leukocytosis is observed.[19] Leukocytosis and lymphocytosis may occur as part of the recovery process.

Serum Biochemical Tests

Changes on the serum biochemistry profile include increased activity of serum ALT (sometimes >1000 U/L) and ALP, hyperbilirubinemia, hypoglycemia, and hypoalbuminemia.[20] Determination of serum ammonia concentration may facilitate diagnosis of hepatic encephalopathy in dogs with neurologic signs.

Urinalysis

The urinalysis of dogs with ICH may reveal proteinuria, hyaline and granular cylindruria, hematuria, and bilirubinuria.

Coagulation Profile

In addition to thrombocytopenia, coagulation abnormalities reported in ICH reflect the presence of DIC and hepatic failure and include prolonged prothrombin time, markedly prolonged activated partial thromboplastin time (to 6 to 7 times control values), decreased factor VIII activity, hypofibrinogenemia, and increased fibrinogen degradation products. Platelet function assays have shown reduced platelet adhesion.[18]

Diagnostic Imaging

Findings on plain radiography and abdominal sonography in dogs with ICH have not been reported. Plain radiography might reveal a normal to slightly enlarged liver, and poor detail as a

result of abdominal effusion or the young age (and therefore low intra-abdominal fat content) of affected dogs.

Microbiologic Tests

Virus Isolation

CAV-1 can be readily isolated in a variety of cell types, such as Madin-Darby canine kidney cells.[7,8] In dogs with acute illness, any body fluid or tissue is likely to contain sufficient virus for isolation. Cultures are evaluated for a cytopathic effect with intranuclear inclusions, and the presence of CAV-1 is confirmed using immunostaining. Isolation is not widely offered by commercial veterinary diagnostic laboratories.

Serologic Diagnosis

Serologic tests are available commercially for detection of IgG and IgM against CAV-1, which include ELISA assays, hemagglutination-inhibition, and serum neutralization. Unfortunately, dogs with acute disease may die before they develop antibodies to the virus.[10] For dogs that recover from illness, a recent history of vaccination may complicate interpretation of acute and convalescent phase serology. In the absence of a vaccination history, a fourfold rise in titer over a 2- to 3-week period together with compatible clinical signs is supportive of the diagnosis of ICH. Titers that follow natural infection may be higher than those that follow vaccination.

Molecular Diagnosis Using the Polymerase Chain Reaction

Conventional PCR assays for detection of CAV-1 in clinical specimens such as nasal, rectal, and ocular swabs and blood, as well as tissue obtained at necropsy, have been described. These include assays that differentiate between CAV-1 and CAV-2[21] and represent one of the most rapid means of antemortem diagnosis. Because of the rarity of the disease, the clinical sensitivity and specificity of these assays are not well understood. Real-time PCR assays that specifically detect CAV-1 infection were not available at the time of writing (see Chapter 5 for a discussion of the differences between conventional and real-time PCR assays). The results of PCR assays on urine may be more difficult to interpret than those for other specimens, because of the potential for chronic shedding from this site in the absence of clinical signs. Assays that specifically detect CAV-1 differentiate between virulent CAV-1 virus and vaccine virus, because vaccines for ICH all contain only CAV-2.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with ICH include blood-tinged ascites or hemoabdomen; a slightly enlarged, congested or mottled liver; mild splenomegaly; enlarged, congested, and edematous lymph nodes; and fibrin deposition on the surface of abdominal viscera (Figure 18-4). The gallbladder wall is typically markedly thickened and edematous. Petechial and ecchymotic subserosal hemorrhages may be apparent in multiple viscera, and the intestinal tract may contain bloody fluid. The brain may also contain petechial hemorrhages or areas of gray discoloration.[8] Parenchymal organs may contain fibrin thrombi. Occasionally, multifocal pulmonary consolidation and/or serosanguineous pleural fluid is noted.

Histopathologic Findings

Histopathologic findings are variable and depend on the course of infection and possibly the virus strain. The most characteristic finding is hepatocellular necrosis and intranuclear viral inclusion bodies within Kupffer's cells and hepatocytes, and a mixed

FIGURE 18-4 Infectious canine hepatitis, hepatic necrosis, liver, dog. The liver from dogs with ICH can be slightly enlarged and friable with a blotchy yellow discoloration. Sometimes fibrin is evident on the capsular surface. Note the petechiae on the serosal surface of the intestines caused by vascular damage. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. In Zachary JF, McGavin MD. Pathologic Basis of Veterinary Disease, 5 ed. St. Louis, MO: Mosby; 2012.)

inflammatory cell infiltrate (see Figure 18-2). Fibrosis may be observed in dogs with chronic liver injury. Interstitial nephritis, with focal accumulations of neutrophils, mononuclear cells, and fibrosis, may also be present,[22] as well as evidence of widespread hemorrhage, thrombosis, and necrosis as a result of DIC. Findings in dogs with CAV-1 encephalitis have included mild spongiosis, neuronal necrosis, hemorrhage, and perivascular cuffing with mononuclear cells.[8] Viral inclusion bodies may be found in endothelial cells of meningeal vessels, the cornea, renal glomeruli, and the tonsils. Immunohistochemistry can be used to confirm the presence of the virus within tissues.

Treatment and Prognosis

Supportive Care

Treatment of dogs with acute ICH is purely supportive and consists primarily of fluid therapy, including crystalloid fluids and blood products. Fluid therapy should be aggressive with careful monitoring and avoidance of overhydration, because of increased vascular permeability and hypoalbuminemia. Fluids should be supplemented with electrolytes and dextrose as required. Other medications that may be indicated include antiemetics, antacids, sucralfate, whole blood or plasma transfusions, and colloids such as hetastarch. Partial or total parenteral nutrition may be indicated for severely affected dogs that do not tolerate enteral feeding. Dogs with DIC may require treatment with heparin in addition to plasma. Management of hepatic encephalopathy with lactulose enemas, oral lactulose (in the absence of vomiting), and poorly absorbed oral antimicrobial drugs such as ampicillin may also be indicated. The use of parenteral broad-spectrum antimicrobial drugs should be considered for dogs with hemorrhagic gastroenteritis that may develop bacteremia as a result of bacterial translocation. After fluorescein staining has shown no evidence of corneal ulceration, dogs with severe corneal edema and uveitis should be treated with topical ophthalmic preparations that contain glucocorticoids and atropine to prevent development of glaucoma.

VetBooks.ir

Prognosis depends on the severity of disease, which reflects the immune status of the affected dog and possibly the virus strain. There is a possibility that recovered dogs may develop chronic hepatitis or chronic glomerulonephritis, but the extent to which this truly occurs is unknown.

Immunity and Vaccination

Immunity to natural infection with CAV-1 is probably lifelong. Effective vaccines have been available and widely used as part of core vaccine programs for dogs for many years. Immunity after immunization with attenuated live vaccines lasts at least 3 years and probably longer. Early vaccines, which contained CAV-1, were associated with the development of corneal edema and glomerulonephritis in a small percentage (<1%) of immunized dogs. Replacement of attenuated live CAV-1 with CAV-2 occurred after 1980 and eliminated this complication.[23] These vaccines have the potential to cause transient respiratory signs and tonsillitis in dogs if accidental inhalation occurs, so care should be taken not to aerosolize the vaccine during administration. Maternal antibody persists until puppies are 12 weeks of age and interferes with immunization when virus neutralization titers exceed 1:100. Vaccines should be administered every 3 to 4 weeks from 6 weeks of age, with the last vaccine given no earlier than 16 weeks of age (see Appendix). Vaccine virus may be shed from the respiratory tract by dogs after vaccination, which has the potential to immunize other dogs as well. It has been suggested that this phenomenon may have been responsible for the virtual disappearance of the disease in the dog population in regions where vaccination is widely performed.[24]

Prevention

The best means of prevention of ICH is proper vaccination. Additional control measures that could be considered in locations where outbreaks occur, such as in shelters, include proper disinfection, isolation, and prevention of overcrowding and other co-infections, which may worsen disease. Because contact with wild animal species such as coyotes, wolves, and foxes that might be shedding the virus may also be a source of infection for dogs, exclusion of these species from interactions with domestic dogs may also serve to prevent the disease.

Public Health Aspects

There is no evidence that CAV-1 infects humans.

CHAPTER 19

Feline Panleukopenia Virus Infection and Other Viral Enteritides

Jane E. Sykes

VetBooks.ir

Overview of Feline Parvoviral Enteritis

First Described: 1928, Verge and Christoforoni, France[1]

Cause: Feline panleukopenia virus (FPV); also canine parvovirus (CPV)-2a, CPV-2b, and CPV-2c (Family Parvoviridae, subfamily Parvovirinae, genus *Parvovirus*)

Affected Hosts: Domestic and wild cats; foxes, mink, and raccoons

Geographic Distribution: Worldwide

Mode of Transmission: Direct contact with virus in feces and vomitus and contaminated fomites.

Major Clinical Signs: Fever, lethargy, inappetence, vomiting, diarrhea, dehydration, sudden death. Neurologic signs (primarily cerebellar signs) may also occur.

Differential Diagnoses: Other feline viral enteritides, toxins, gastrointestinal foreign body, enteric parasitic infections such as giardiasis and nematode infections, enteric bacterial infections such as salmonellosis, pancreatitis, or inflammatory bowel disease. Congenital central nervous system defects should be considered in cats with neurologic signs.

Human Health Significance: FPV is not known to infect humans, but was isolated from a monkey.

Etiology and Epidemiology

Feline panleukopenia virus (FPV) is a parvovirus that causes enteritis and panleukopenia in domestic and wild cat species worldwide.[2] It has also been associated with disease in raccoons, mink, foxes, and a monkey, and can replicate in ferrets without causing disease. Feline panleukopenia is sometimes confusingly referred to as "cat plague" and "feline distemper." FPV is a small, single-stranded non-enveloped DNA virus that is closely related to CPV-2, but in contrast to CPV-2, which emerged in the late 1970s, the existence of FPV has been known since the 1920s.[1] FPV has the same ability as CPV-2 to survive long periods in the environment and resist disinfection, and has the same preference for replication in rapidly dividing cells (see Chapter 14).

Feline panleukopenia is most likely to occur in cats younger than 1 year of age, but it can occur in unvaccinated or improperly vaccinated cats of all ages. The median age of affected cats in one study was 4 months, and when disease occurred in vaccinated cats, it occurred only in cats that had not received a booster vaccine after 12 weeks of age.[3] However, kitten deaths have been reported in households of fully vaccinated kittens, possibly because of exposure to large amounts of virus in the environment.[4] Outbreaks of panleukopenia in cats correlate seasonally with increases in susceptible newborn kitten numbers. Panleukopenia occurs most commonly in multicat households, and especially in enclosed, shelter environments. It can also occur in cats with outdoor exposure, such as barn, feral, and stray cats. In one study, the prevalence of protective antibody titers to FPV in feral cats in Florida was only 33%, which suggested a low rate of exposure to the virus.[5] In some North American shelters, devastating outbreaks of panleukopenia have led to euthanasia of large numbers of cats. Contact with other cats may not be present in the history, because fomite transmission is so effective.[3] FPV replicates to a limited extent in dogs, without disease or virus shedding. Some feline panleukopenia results from infection of cats by the related mink enteritis virus, CPV-2a, CPV-2b, or CPV-2c.[6-8] Mixed infections with FPV and CPV-2 variants have been detected in cats, and there is evidence for recombination between FPV and CPV-2 variants.[7,9] Infection of cats with CPV-2 variants is uncommon in Europe but predominated among cats with panleukopenia in Asia.[10]

Other viral pathogens that have been associated with gastroenteritis in cats include feline enteric coronavirus (see Chapter 20), FeLV, rotaviruses, caliciviruses, reoviruses, and astroviruses. A torovirus-like agent has been associated with a syndrome of diarrhea and protrusion of the nictating membranes in cats.[11] Togavirus-like and picornavirus-like particles have been identified in the feces of Australian cats, but their significance is uncertain.[12]

Clinical Features

Signs and Their Pathogenesis

The pathogenesis of FPV infection is similar to that of CPV infection (see Chapter 14). Transmission is by the fecal-oral route, and indirect transmission through contaminated fomites represents the most important means of infection. Like CPV, FPV enters cells using transferrin receptors[13] and replicates in cells that are in the S-phase of the mitotic cycle. Initially, the virus replicates in oropharyngeal lymphoid tissue, after which it disseminates in blood to all tissues. Infection of lymphoid tissues leads to lymphoid tissue necrosis. Infection of the marrow is associated with leukopenia, which is compounded by neutrophil sequestration in damaged gastrointestinal tissue. The virus replicates in the intestinal crypt epithelial cells, with shortening of villi, increased intestinal permeability, and malabsorption.

Subclinical infection is probably widespread, especially in young adult or adult, immune-competent cats. Disease severity depends on factors such as age, immune status, and concurrent

VetBooks.ir

infections with other bacterial or viral pathogens, which increase the turnover rate of intestinal epithelial cells and enhance viral replication and cellular destruction. Co-infections can occur with feline enteric coronavirus, *Clostridium piliforme, Salmonella* spp., FeLV, or astroviruses.[14-17] Disease generally occurs after an incubation period of 2 to 10 days. The peracute form of disease involves death without apparent premonitory signs. Infection of kittens or adult cats results in clinical signs of fever, lethargy, vocalization, weakness, and inappetence, which may progress to profound dehydration, vomiting, sometimes watery to hemorrhagic diarrhea, and rapid loss of weight. Some cats develop only anorexia and lethargy, in the absence of vomiting, diarrhea, or leukopenia.[3] Secondary bacterial infections appear to be essential for signs of disease to occur. Death usually results from complications relating to dehydration, electrolyte imbalances, hypoglycemia, hemorrhage, or bacteremia and endotoxemia.

In the developing fetus or neonate, FPV replicates in a variety of tissues. Abortion, congenital abnormalities, or infertility can result from infection early in pregnancy, although the queen is generally otherwise unaffected. Later in pregnancy or in neonates up to approximately 1 week of age, viral destruction of Purkinje cells and granule precursor cells located in the cerebellar external granular layer leads to cerebellar hypoplasia (Figure 19-1). The severity of infection can vary between kittens in a litter. Sometimes a portion of the litter fails to survive and the remainder develop neurologic signs.[18] Signs of cerebellar ataxia are nonprogressive and are most apparent when kittens begin to walk at about 2 to 3 weeks of age, although mentation and appetite are otherwise normal, and these kittens can sometimes make acceptable pets. Other developmental central nervous system (CNS) abnormalities have been reported less commonly, and include hydrocephalus, porencephaly (cystic lesions within the cerebral hemispheres), or hydranencephaly (complete replacement of the cerebral hemispheres with cystic lesions). These abnormalities may be accompanied by signs of forebrain damage, such as seizures and behavioral changes. Unlike canine parvoviruses, FPV appears to be able to infect neurons other than the cerebellar Purkinje cells, which are terminally differentiated cells.[19] Ocular lesions can also develop and include retinal folding, dysplasia and degeneration, and optic nerve hypoplasia.

The DNA of FPV has been detected in the myocardium of cats with hypertrophic, dilated, and restrictive cardiomyopathy, but was not detected in a subset of healthy control cats.[20] Additional studies to assess the role of FPV in feline myocarditis and cardiomyopathy are needed.

Fecal shedding of virus usually lasts for several days, and in some cats, it may persist for up to 6 weeks. Kittens infected in utero have been reported to develop immune tolerance to the virus, with viral persistence in the kidneys and lungs for up to 1 year in the absence of shedding.

Physical Examination Findings

The most common physical examination findings are weakness, lethargy, and dehydration. Fever (103°F to 107°F or 39.5°C to 42.5°C) may be present early in the course of illness. Pain may be noted on palpation of the abdomen, or a hunched posture may be present. The perianal region may be contaminated with feces. Oral ulceration and mucosal pallor may be present in severely affected cats, and rarely, bacteremia may be accompanied by icterus. Terminally, affected cats may be hypothermic, bradycardic, and comatose.

Kittens with cerebellar signs are generally bright and alert but exhibit intention tremors, incoordination, ataxia, hypermetria, a broad-based stance, decreased postural reactions, a truncal sway, and absence of a menace response. Cats with forebrain disease may show abnormal behavior, such as aggression or decreased mentation. Examination of the ocular fundus may reveal folding of the retina, evidence of retinal degeneration with discrete gray spots, and optic nerve hypoplasia. Retinal lesions may be an incidental finding in older, recovered cats, which includes surviving cats with cerebellar hypoplasia.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

The most common abnormality on the CBC in feline panleukopenia is leukopenia, which is due to a neutropenia and lymphopenia (Box 19-1).[3] Total leukocyte counts may be as low as 50 cells/μL, and toxic band neutrophils may be present. In one study, only 65% of 187 cats with panleukopenia were leukopenic, so an absence of leukopenia does not rule out FPV infection. Recovery may be associated with lymphocytosis and

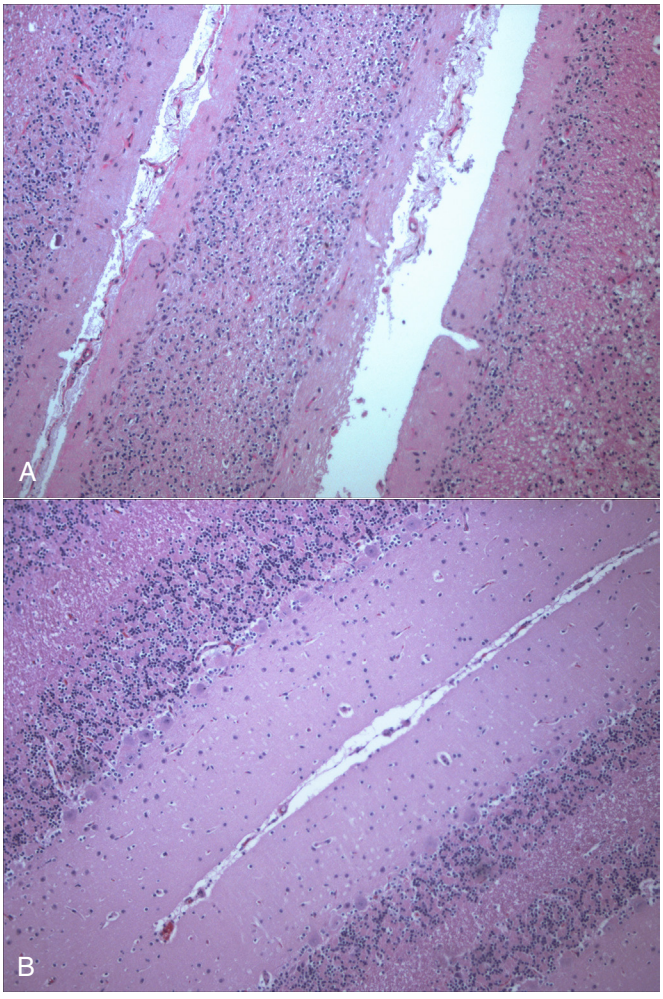

FIGURE 19-1 **A,** Severe cerebellar hypoplasia in a 1-year-old male neutered domestic shorthair that was euthanized for cerebellar signs and seizures. The neurologic signs had been present since the cat was found at approximately 4 months of age. There is a paucity of neurons and glial cells in all layers. **B,** Normal feline cerebellum. Note the dramatically increased width of the molecular layer when compared to (A).

leukocytosis. Thrombocytopenia and mild anemia are also common. Thrombocytopenia may result from damage to the marrow or, possibly, disseminated intravascular coagulation (DIC).

BOX 19-1

Prevalence of Laboratory Abnormalities in Cats with Panleukopenia

Leukopenia: 122/187 (65%)
Thrombocytopenia: 83/153 (54%)
Anemia: 91/187 (48%)
Neutropenia: 64/137 (47%)
Lymphopenia: 53/137 (39%)
Hypoalbuminemia: 45/101 (45%)
Hypochloremia: 40/112 (36%)
Hyponatremia: 41/127 (32%)
Hypoproteinemia: 46/153 (30%)
Hyperglycemia: 48/168 (29%)
Increased AST activity: 26/98 (27%)
Hyperkalemia: 30/132 (23%)
Increased BUN: 36/168 (21%)
Hyperbilirubinemia: 19/134 (14%)
Increased ALT activity: 18/135 (13%)
Increased creatinine: 12/155 (8%)
Hypokalemia: 9/132 (7%)
Hypernatremia: 8/127 (6%)
Hypoglycemia: 10/168 (6%)

Modified from Kruse BD, Unterer S, Horlacher K, et al. Prognostic factors in cats with feline panleukopenia. J Vet Intern Med 2010;24:1271-1276.

Serum Biochemical Tests

Serum biochemistry analysis may show hypoalbuminemia, hypoglobulinemia, and/or hypocholesterolemia; electrolyte abnormalities such as hyponatremia or hypernatremia, hypochloremia, hyperkalemia, or, less commonly hypokalemia; and acid-base abnormalities (see Box 19-1). In severely affected cats, azotemia, increased serum activities of AST or ALT, or hyperbilirubinemia may be present. Hyperglycemia or hypoglycemia may also be identified.

Diagnostic Imaging

Plain Radiography

As in dogs with parvoviral enteritis, abdominal radiography in cats with panleukopenia may show evidence of poor serosal detail and a fluid- and gas-filled gastrointestinal tract.

MRI Findings

MRI of cats with neurologic signs due to FPV may reveal evidence of cerebellar agenesis or hypoplasia. Rarely, hydrocephalus, porencephaly, or hydranencephaly can be detected.[18]

Microbiologic Tests

Diagnostic assays available for feline panleukopenia are listed in Table 19-1.

Serologic Diagnosis

Use of serology for diagnosis of feline panleukopenia is complicated by widespread exposure or immunization, so serologic assays that detect antibody against FPV are generally used to assess the need for vaccination rather than for diagnosis. They can also be used in outbreak situations in order to determine which cats are at risk for development of disease and virus shedding, and which cats are protected and therefore at low risk. The gold standard method for FPV serology is hemagglutination

TABLE 19-1

Diagnostic Assays Available for Feline Panleukopenia

Assay	Specimen Type	Target	Performance
Canine parvovirus fecal antigen ELISA	Feces	Parvoviral antigen	Sensitivity varies with the assay used and the timing of specimen collection. False negatives are common, but a positive result generally indicates infection.
Histopathology	Usually necropsy specimens, especially gastrointestinal tissues	Crypt necrosis with intranuclear inclusions; FPV antigen with IHC or IFA	Can be used for necropsy diagnosis.
Polymerase chain reaction (PCR)	Feces, tissue samples	FPV DNA	Sensitivity and specificity varies depending on assay design. The extent to which attenuated live vaccine virus can be detected after vaccination is not well understood. Because of the high sensitivity of some assays, the significance of a positive result may be difficult to interpret. False-negative results may occur as a result of inhibition of PCR by components of feces.
Fecal electron microscopy	Feces	Virus particles	Not widely available, turnaround time can be slow, and may be expensive. Requires the presence of large amounts of virus.
Virus isolation	Feces, tissues	FPV	Difficult, not widely available. Used primarily as a research tool.

FPV, feline panleukopenia virus; IFA, immunofluorescent antibody; IHC, immunohistochemistry.

VetBooks.ir

inhibition, which measures the ability of serum to prevent agglutination of erythrocytes by the virus (see Chapter 2). Serum neutralization assays may also be used. Point-of-care assays designed to detect antibody titers to CPV have a low sensitivity (28%) for detection of antibodies to FPV in cats.[21] A point-of-care assay designed to detect feline antibodies (ImmunoComb Feline VacciCheck Test Kit, Biogal, Galed Labs, Israel) also had a low sensitivity (49%), although specificity was high.[21] The use of this test for risk analysis in shelter situations may lead to inappropriate removal or isolation of cats with false-negative results for protective antibody titers, which might waste time, space, and financial resources.[21] However, positive results should reliably indicate protection. The test can be performed quickly (30 minutes) and requires as little as 5 µL of serum or plasma, so provided it is understood that a negative result means either a protected or susceptible status, and a positive result equates to protection, the test still has the potential to provide useful information.

Antigen Detection Enzyme Linked Immunosorbent Assay

FPV can be detected in feces or rectal swabs using antigen assays designed to detect CPV.[22,23] The sensitivity and specificity of these assays varies from one assay to another and with the stage of infection, because virus shedding may be transient. In general, false-negative results are common with these assays, but false positives are uncommon, so a positive test result in a cat with consistent clinical signs suggests a diagnosis of feline panleukopenia. The specificity of one point-of-care device (SNAP Parvo, IDEXX Laboratories, Westbrook, ME) was high; 54 of 55 positive assay results were confirmed with a PCR assay. Another study of 52 cats with diarrhea and 148 healthy cats showed variability in the sensitivity and specificity of five different test kits when compared with fecal electron microscopy.[23] Sensitivity ranged from 50% to 80%, and specificity ranged from 94% to 100%. This study included only 10 cats with FPV as determined with electron microscopy. Additional studies are warranted that evaluate the sensitivity and specificity of these assays in larger numbers of cats with FPV infection when both real-time PCR and electron microscopy are used as the gold standard. False-positive fecal antigen assay results after vaccination with attenuated live viral vaccines appear to be uncommon, but again vary with the test used.[24] Of the SNAP Parvo (IDEXX Laboratories), AGEN CPV (AGEN Biomedical Ltd., Brisbane, Australia), and the Witness CPV (Synbiotics Corp, San Diego, CA), the SNAP Parvo was least likely to yield positive results after vaccination.

Fecal Electron Microscopy

Fecal electron microscopy is still offered by some institutions for diagnosis of viral enteritis. It may also facilitate diagnosis of other infections such as rotavirus, astrovirus, torovirus, and coronavirus infections. Turnaround time may be slow. Generally speaking, large amounts of virus must be present for results to be positive, and technical expertise is required to accurately identify virus in the stool.

Virus Isolation

FPV can be isolated in feline cells, but as with CPV, isolation can difficult, and the virus shows minimal cytopathic effects. As a result, isolation of FPV is a specialized procedure that is uncommonly used for diagnosis.

Molecular Diagnosis Using the Polymerase Chain Reaction

Specific real-time PCR assays have been developed for detection of FPV and differentiation of FPV from CPV-2 variants and are offered by veterinary diagnostic laboratories. Clinicians should contact their laboratory to determine the specificity of the assay offered.[25] These assays can be used on whole blood or feces. The extent to which these assays detect attenuated live vaccine virus after vaccination requires further study. Assays have also been developed that differentiate between field and vaccine strains of FPV.[26]

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in feline panleukopenia include thymic involution; thickening, distention, and discoloration of the intestinal wall with serosal hemorrhage (Figure 19-2); and enlarged, edematous mesenteric lymph nodes. The intestine may contain bloody liquid contents, and mucosal hemorrhage may be identified. Hemorrhages may be visible on the surface of other organs as well. In some cats, mild pleural or peritoneal effusion is present. Cats infected prenatally may have cerebellar aplasia, or more commonly a small cerebellum (often half to three-quarters normal size).[27] Rarely other developmental CNS abnormalities such as hydrocephalus, hydranencephaly, or porencephaly are observed.[18]

Histopathologic Findings

Histopathologic findings in the intestinal tract are similar to those described for CPV-2 infection, with crypt dilation and necrosis of crypt epithelial cells, accumulation of cellular debris, neutrophil infiltration, loss of villi, and submucosal edema throughout the small and large intestines; the jejunum and ileum are usually most severely affected (Figure 19-3, *A*). Acutely affected cats show widespread lymphoid depletion and there may be hyperplasia of mononuclear phagocytes. Intranuclear inclusions are found in some cats (Figure 19-3, *B*). Examination of the bone marrow may reveal bone marrow hypoplasia. Examination of the cerebellum shows cellular depletion; reactive astrocytosis may be present. Immunohistochemistry or immunofluorescent

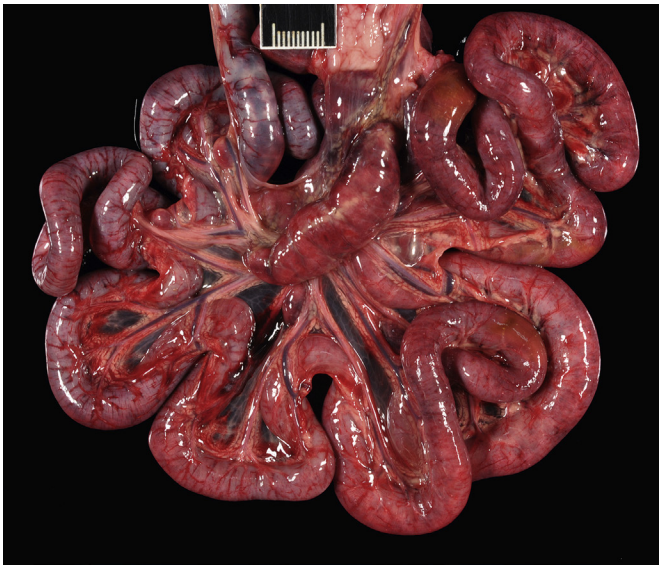

FIGURE 19-2 Intestinal tract of a 2-year-old intact female domestic longhair cat with severe feline panleukopenia. The intestinal loops are dilated and flaccid and discolored red to purple. Ruler = 1 cm.

antibody may be used to document the presence of the virus within tissues (see Figure 19-3, *C*).

Treatment and Prognosis

Antimicrobial Treatment and Supportive Care

Treatment of cats with feline panleukopenia is with supportive care, especially intravenous crystalloids and parenteral antimicrobial drug treatment as for CPV-2 infections (see Chapter 14). Dextrose supplementation of the fluids may be required, and blood glucose concentration should be monitored. Oral intake of food and water should be withheld until vomiting has ceased. Experience with early enteral nutrition has not been reported in cats, and extreme care is warranted to prevent aspiration pneumonia. Antiemetics such as metoclopramide or ondansetron may be effective. In contrast to canine parvoviral enteritis, treatment with rfIFN-ω has not been beneficial for treatment of feline panleukopenia, although increased antibody production and a reduced acute inflammatory response was observed.[28]

Prognosis

Cats with panleukopenia that survive the first 5 days of treatment usually recover, although recovery is often more prolonged than it is for dogs with parvoviral enteritis. In 244 cats with feline panleukopenia from Europe, the survival rate was 51.1%.[3] Nonsurvivors had lower leukocyte and platelet counts than survivors, and cats with white cell counts below 1000/μL were almost twice as likely to die than those with white cell counts above 2500/μL. Only total leukopenia, and not lymphopenia, was correlated with mortality. Hypoalbuminemia and hypokalemia were also associated with an increased risk of mortality. In contrast to dogs with parvoviral enteritis, mortality in cats does not appear to be correlated with age.

Cerebellar signs in kittens with cerebellar hypoplasia typically do not progress and may improve slightly as a result of compensatory responses from other senses such as vision.[29]

Immunity and Vaccination

Recovery from feline panleukopenia is thought to confer lifelong immunity. Effective vaccines are widely available, and include both parenteral inactivated and attenuated live viral vaccines. An intranasal FPV, FHV-1 and feline calicivirus vaccine is available; its use has been controversial, because panleukopenia is a systemic disease. An outbreak of salmonellosis and panleukopenia occurred in one cattery that used an intranasal FPV vaccine.[4] No difference was noted in seroconversion rates between five cats vaccinated with the intranasal vaccine and five cats vaccinated with a parenteral attenuated live vaccine, but the number of cats in this study was small, and a larger number of cats that were vaccinated with the parenteral vaccine had protective antibody titers on day 7.[30]

Both inactivated and attenuated live vaccine types induce protective antibody titers after vaccination in a high proportion of cats,[5] although the attenuated live vaccine may be more likely to induce protective titers than the inactivated vaccine.[24] Provided maternally-derived antibody (MDA) is absent, immunity occurs within 1 week after a single vaccination with an attenuated live viral vaccine[31] and lasts for at least 3 years, and possibly for life.[32] Nevertheless, two doses, 3 to 4 weeks apart, have been recommended for initial vaccination with attenuated live vaccines in the absence of MDA. Two injections are always required for inactivated vaccines, and maximal immunity does not occur until 1 week after the second dose. However, even with an inactivated vaccine, challenge 7.5 years after vaccination was associated with protection.[33] The use of inactivated vaccines should be reserved for immunosuppressed cats or colostrum-deprived neonates that are less than 4 weeks of age, or when there is a need to vaccinate pregnant cats. In shelter situations, the use of attenuated live vaccines is always recommended because of the slow onset of immunity with inactivated vaccines.[34] FPV vaccines protect cats against challenge with CPV-2b strains.[35,36] However, cross-reactivity of antibodies induced by FPV vaccination to CPV-2 strains was lower than that to FPV as determined using hemagglutination inhibition.[37] The extent to which FPV vaccines protect against infection with other CPV-2 variants requires further investigation.[38]

The most common reason for vaccine failure is interference by MDA. Maternal antibody persists until at least 12 weeks, and possibly longer in some cats. Virus neutralization titers above 1:10 are likely to interfere with vaccination, and kittens with titers below 1:40 are generally considered to be susceptible to infection by FPV. Kittens should be vaccinated every 3 to 4 weeks from 6 to 8 weeks of age, and it is recommended

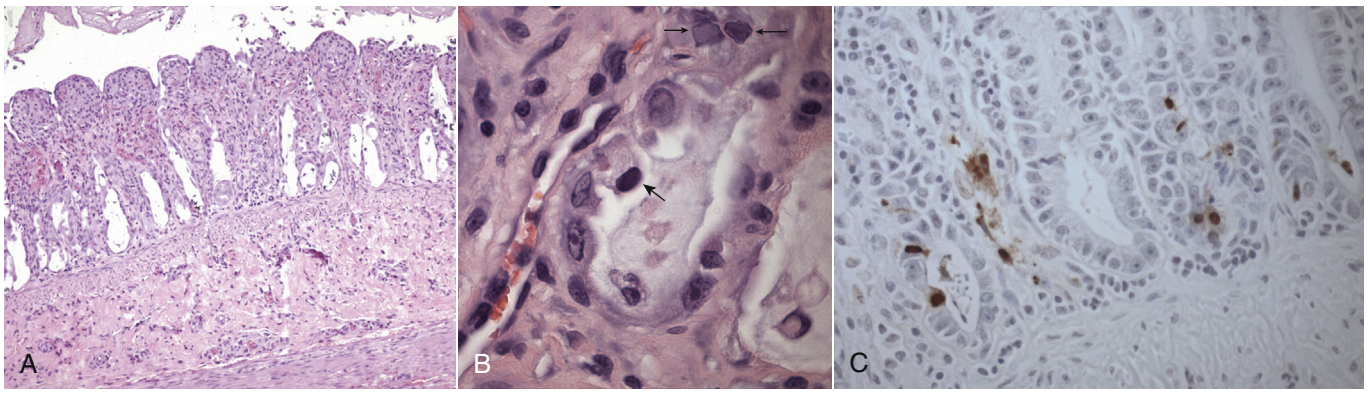

FIGURE 19-3 **A,** Histopathology of the jejunum from a kitten with panleukopenia. Villi are rounded and blunted with nearly complete epithelial loss and crypt dilation. H&E stain. **B,** Histopathology of the jejunum from a young barn cat that died after several days of profound weakness and neurologic signs. Six other cats in the barn died with the same signs. Mucosal crypts are dilated and contain debris, and intranuclear inclusions are present *(small arrows)*. Another cell *(large arrow)* is foamy and degenerate and has a hyperchromatic nucleus. H&E stain. **C,** Same cat as in **B.** The presence of FPV in the intestinal tract is confirmed with immunohistochemistry (brown stain). VetBooks.ir

that the last vaccine in the kitten series be given no earlier than 14 to 16 weeks of age. When there is a history of an outbreak situation, the final booster could be given no earlier than 18 to 20 weeks of age.[39] In all situations, a booster should be administered at 1 year, and every 3 years thereafter.

Vaccination of pregnant queens with attenuated live viral vaccines can cause cerebellar hypoplasia or fetal losses. The frequency with which this occurs is unknown. As a result, it has been suggested that pregnant queens only be vaccinated with attenuated live FPV vaccines if they are being introduced into a shelter and quarantine while immunization with inactivated vaccines is performed is not possible. Alternatively, assessment for protective antibody titers with an in-house test kit (where available) could be performed.

Prevention

New kittens should not be introduced into households that previously contained cats infected with FPV unless they are fully vaccinated. In the face of an outbreak, exposed and susceptible kittens may be effectively protected for 2 to 4 weeks through subcutaneous or intraperitoneal administration of 2 mL of type-matched serum from cats with a high antibody titer.[39,40] However, this is only effective when administered before the onset of clinical signs, and it can interfere with subsequent vaccination. For these kittens, it has been recommended that vaccination be withheld for 3 weeks after the serum has been administered.[39] Passive immunization may be useful when cats are introduced into a shelter situation where a known problem exists. Repeated treatment with serum should be avoided because hypersensitivity reactions may occur. Prevention of feline panleukopenia should also include proper disinfection with disinfectants that are effective against parvoviruses, such as bleach, accelerated hydrogen peroxide, or potassium peroxymonosulfate (see Chapter 11) and, in shelter situations, isolation or removal of cats that develop gastrointestinal illness, and separate housing for healthy kittens.

Public Health Aspects

Although FPV is not known to infect humans, a unique strain of FPV was recently isolated from a diarrheic monkey in China.[41] This strain was shown to cause panleukopenia in inoculated cats.

CASE EXAMPLE

Signalment: "Callie", a 2 year-old, female intact domestic longhair from Woodland, CA

History: Callie was brought to an emergency clinic for acute onset of collapse and severe illness. The current owner had fostered the cat for 1 week after she was found as a stray. The cat had been nursing a litter of kittens. The kittens were 4 weeks old, being weaned and apparently healthy. Since being fostered, the cat had exhibited a progressive decrease in appetite and thirst, and her feces had become soft and pasty. The night before she was brought to the emergency clinic, she had been bathed, and afterwards she vomited bile-stained fluid twice and was placed on a heating pad. The following morning she was found laterally recumbent and minimally responsive.

Physical Examination:

Body Weight: 2.3 kg

General: Stuporous mentation, estimated to be 8% to 10% dehydrated, T < 92°F (<33°C), HR = 132 beats/min, RR = 32 breaths/min, mucous membranes pale and tacky, unable to assess CRT. Fecal and urinary stains were present around the perineum and on the caudal aspect of the pelvic limbs.

Musculoskeletal: Body condition score 2/9. Diffuse muscle wasting was present. The cat was laterally recumbent and nonambulatory.

Cardiovascular: Weak femoral pulses. No murmurs or arrhythmias were detected.

Gastrointestinal and Urogenital: The abdomen was soft and nonpainful on palpation. Fluid-filled intestinal loops were palpated, and the urinary bladder was small (<5 cm) and soft.

All Other Systems: No abnormalities were detected.

Laboratory Findings:

CBC:

HCT 46% (30-50%)
MCV 49.8 fL (42-53 fL)
MCHC 30.4 g/dL (30-33.5 g/dL)
WBC 150 cells/µL (4500-14,000 cells/µL)
Neutrophils 0 cells/µL (2000-9000 cells/µL)
Lymphocytes 141 cells/µL (1000-7000 cells/µL)
Highly reactive lymphocytes 6 cells/µL
Monocytes 3 cells/µL (50-600 cells/µL)
Platelets 32,000 platelets/µL (180,000-500,000 platelets/µL).

Serum Chemistry Profile:

Sodium 141 mmol/L (151-158 mmol/L)
Potassium 4.0 mmol/L (3.6-4.9 mmol/L)
Chloride 111 mmol/L (117-126 mmol/L)
Bicarbonate 23 mmol/L (15-21 mmol/L)
Phosphorus 6.0 mg/dL (3.2-6.3 mg/dL)
Calcium 7.4 mg/dL (9.0-10.9 mg/dl)
BUN 24 mg/dL (18-33 mg/dL)
Creatinine 0.5 mg/dL (1.1-2.2 mg/dL)
Glucose 68 mg/dL (63-118 mg/dL)
Total protein 3.2 g/dL (6.6-8.4 g/dL)
Albumin 1.6 g/dL (2.2-4.6 g/dL)
Globulin 1.6 g/dL (2.8-5.4 g/dL)
ALT 125 U/L (27-101 U/L)
AST 143 U/L (17-58 U/L)
ALP 4 U/L (14-71 U/L)
Creatine kinase 2409 U/L (73-260 U/L)
Gamma GT <3 U/L (0-4 U/L)
Cholesterol 68 mg/dL (89-258 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.2 mg/dL)
Magnesium 2.5 mg/dL (1.5-2.5 mg/dL).

Imaging: An abdominal ultrasound showed marked fluid distention of the small intestines.

Microbiologic Testing: In-clinic ELISA serology for FeLV antigen and FIV antibody: negative.

VetBooks.ir

Treatment and Outcome: Callie was treated with active warming, and a central venous access line was placed. Intravenous crystalloids (four warmed 60-mL boluses of lactated Ringer's solution [LRS], each given over 20 minutes) were administered, after which an venous acid-base panel showed a pH of 7.267 (7.31-7.46), bicarbonate of 17.5 mmol/L (14-22 mmol/L), base excess of −8.1 mmol/L (−4 to +2 mmol/L), pCO_2 of 39.7 mm Hg (25-37 mmHg), lactate of 4.5 mEq/L (<2 mEq/L), glucose of 52 mg/dL, potassium of 3.1 mEq/L, sodium of 141 mEq/L, and ionized calcium of 1.17 (1.1-1.4 mmol/L). A dextrose bolus and ticarcillin-clavulanic acid (22 mg/kg, q6h, IV) were administered. The cat repeatedly vomited blood-tinged fluid, and so treatment with metoclopramide (0.02 mg/kg/hr) and famotidine (0.5 mg/kg IV q12h) was initiated. Aggressive crystalloid fluid therapy was continued (LRS supplemented with 30 mEq/L KCl and 2.5% dextrose), and treatment with hetastarch was also initiated. Systolic blood pressure (Doppler) was 60 to 90 mm Hg, heart rate increased to 170 beats/min, and rectal temperature increased to 100°F. When the CBC results were available, the cat was placed in the isolation ward.

Pasty diarrhea that contained sloughed mucosa occurred every 1 to 2 hours, which transitioned to liquid red feces over 24 hours. A CBC again showed absolute neutropenia and 15,000 platelets/μL. After another 24 hours, the cat's condition deteriorated despite aggressive treatment and monitoring. Partial parenteral nutrition was initiated. That evening, pyrexia developed (104.6°F) as well as tachypnea and increased respiratory effort. The owner elected euthanasia. The cat regurgitated approximately 200 mL of dark brown fluid at the time of euthanasia.

Gross Necropsy Findings: Ten mL of semiopaque red fluid was present in the peritoneal cavity. Streaks of hemorrhage were noted throughout the skeletal muscle. Between the pylorus and the ileocecocolic junction, the serosa of the small intestinal tract was dark red to purple to black (see Figure 19-2). The entire small and large intestinal tract was dilated and flaccid. The small intestinal mucosa was dark red to purple and contained a small amount of dark red mucoid material. The mesenteric lymph nodes were prominent, and their cut surface was discolored red to dark pink. The liver was pale yellow and extended beyond the costal arches. Numerous petechial hemorrhages were present on the serosal surface of the urinary bladder.

Histopathologic Findings: Within the duodenum, jejunum, and ileum there was severe, subacute, diffuse necrotizing and fibrinohemorrhagic enteritis. The villi were necrotic, fused, and markedly blunted with a minimal inflammatory response. Necrosis extended into the crypts, and there was some evidence of a regenerative response that included enterocyte hypertrophy, karyomegaly, and rare mitotic figures. Mixed bacteria, which included small gram-negative rods and large numbers of gram-positive cocci, lined and effaced the denuded villi. There was diffuse lymphoid depletion in lymph nodes, as well as the mucosa-associated lymphoid tissue in the cecum and colon. Marked depletion of erythroid and myeloid precursors was present in the bone marrow. There were multifocal areas of hemorrhage in the skeletal and cardiac muscle, intestinal tract, and lungs, as well as fibrin thrombi in the lungs. FPV antigen was identified in intestinal epithelial cells using immunohistochemistry. Culture of the jejunum for *Salmonella* spp. was negative.

Diagnosis: Feline panleukopenia

Comments: The cat in this report was a stray with an unknown vaccination history, which demonstrates that severe disease can occur even in adult cats. Antemortem diagnostic testing for FPV with a fecal antigen ELISA assay or PCR assay was discussed with the owner, but was declined because of the high degree of suspicion for the disease and the lack of impact that a positive or negative result would have had on the treatment plan. Secondary bacterial sepsis was suspected. Additional co-infections with other viruses, such as feline coronavirus, or enteropathogenic bacteria could not be ruled out. During the cat's treatment, one of the kittens in the litter died suddenly and the other developed signs of illness.

CHAPTER 20

Feline Coronavirus Infection

Jane E. Sykes

VetBooks.ir

Overview of Feline Coronavirus Infections

First Described: 1963[1]; a viral etiology was not identified until the 1970s.

Cause: Feline coronavirus (Family Coronaviridae, genus *Coronavirus*)

Affected Hosts: Cats and wild felids, especially cheetahs

Mode of Transmission: Fecal-oral

Geographic Distribution: Worldwide

Major Clinical Signs: Fever, lethargy, inappetence, vomiting, diarrhea, dehydration, icterus, tachypnea, uveitis, neurologic signs, abdominal distention due to ascites.

Differential Diagnoses: Toxoplasmosis, congestive heart failure, carcinomatosis, lymphoma, pancreatitis, rabies, cryptococcosis, bacterial peritonitis, pyothorax, bacterial meningitis, chronic stomatitis, multiple myeloma, infection with FeLV or FIV.

Human Health Significance: Feline coronaviruses do not infect humans.

Etiology and Epidemiology

Coronaviruses are large, enveloped, single-stranded RNA viruses with club-shaped spikes on their outer surface (see Figure 14-1, *B*). They have the largest RNA genomes of all known viruses. Feline coronaviruses (FCoV), like canine enteric coronavirus, belong to the Group 1a coronaviruses (see Box 17-1). In fact, even canine enteric coronavirus has the potential to infect cats and cause diseases similar to those caused by FCoV.[2] Among FCoVs, there are two different serotypes, type I and type II, which use different receptors for cellular entry in vitro[3,4] but cause the same clinical manifestations. Type I strains predominate worldwide.[5-7] Type II strains, which are thought to have evolved from genetic recombination between canine enteric coronavirus and FCoV, are more readily grown in culture and so have been more extensively studied; they possess a spike protein that resembles that of canine enteric coronavirus.

FCoVs cause enteric disease in cats as well as feline infectious peritonitis (FIP), a serious systemic pyogranulomatous to granulomatous disease that progresses over a period of weeks to months and, once it occurs, is ultimately always fatal. FIP is a major cause of death in young and young adult cats, especially cats from multicat environments such as purebred catteries and shelters. Wild cats, especially cheetahs, are also susceptible.[8] The vast majority of domestic cats that develop FIP are 3 months to 3 years of age, with at least 50% of affected cats aged 12 months or younger (Figure 20-1). However, FIP can occur at any age, and there is a secondary peak of incidence in geriatric cats (>10 years of age), possibly as a result of suboptimal immune function. Males and sexually intact cats have been predisposed in some studies,[9-11] and a disease peak may exist in the fall and winter.[12] Although the disease occurs in all breeds, purebred cats are more susceptible; Abyssinians, Australian mist, Bengals, birmans, Burmese, British shorthairs, Himalayans, ragdolls, rexes, and possibly Scottish folds may be predisposed.[9-14] Breed predispositions may vary geographically and temporally depending on the preferences of breeders in a region, and specific lines may be more predisposed than the breeds themselves.[6] The molecular basis of genetic susceptibility to FIP is currently unclear. Siblings of cats that die of FIP may be at increased risk for FIP.[15]

In multiple-cat household situations, cats are repeatedly infected, shed virus, and recover, but some cats remain persistently infected and chronically shed FCoV in the absence of clinical signs (Figure 20-2). More than half, and as many as 100% of cats in environments with more than six cats, become infected with FCoVs.[6] The seroprevalence is lower in cats from single-cat households and among feral cats.[16] However, even though the prevalence of infection in multicat households is high, fewer than 10% of cats from large, multicat households ultimately develop FIP. Thus, although the incidence of *infection* is high, the incidence of *disease* in single- or two-cat households is only around 1 in 5000; in catteries it is around 5% to 10%.[17,18] Provided they are unrelated by birth, cats in households with a history of FIP are not more likely to develop FIP than cats in households without FIP.[19] Thus, FIP is usually a sporadic disease that does not spread from one cat to another. However, every few years, epidemics of disease can occur in catteries or shelters, with mortality rates that exceed 10%.[12] Because it is an enveloped virus, FCoV is readily inactivated by disinfectants and generally survives less than a day or two at room temperature. However, the possibility of prolonged survival (up to 7 weeks) in the environment under certain conditions has been suggested.[15,20] In this situation, fomites might play an important role in transmission.

The epidemiology and pathogenesis of FIP has both fascinated and confused veterinary virologists worldwide for decades. The most widely accepted theory (the "internal mutation hypothesis") is that cats are initially infected with a low-pathogenicity coronavirus after oronasal exposure, which results either in no signs, or mild enteric disease. This low-pathogenicity virus has been referred to as *feline enteric coronavirus* in some publications in order to distinguish it from virulent FIP virus. The use of this name has been controversial, because although the virus is primarily confined to the gastrointestinal tract (and especially colonic epithelial cells), FCoV RNA can also be found in blood

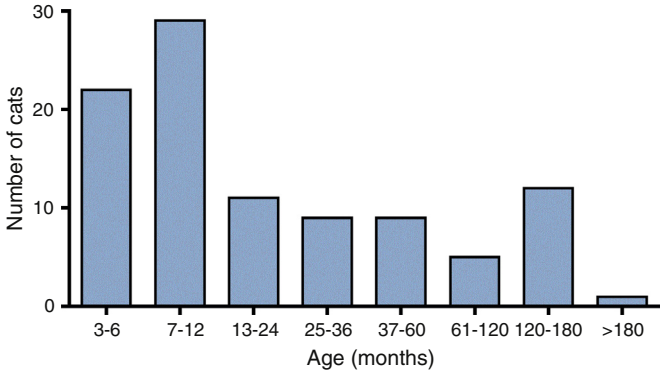

FIGURE 20-1 Age distribution of 99 cats with necropsy-confirmed FIP at the UC Davis VMTH. An additional six cats were reported to be "juvenile" or kittens. There were 38 females (17 intact) and 66 males (22 intact).

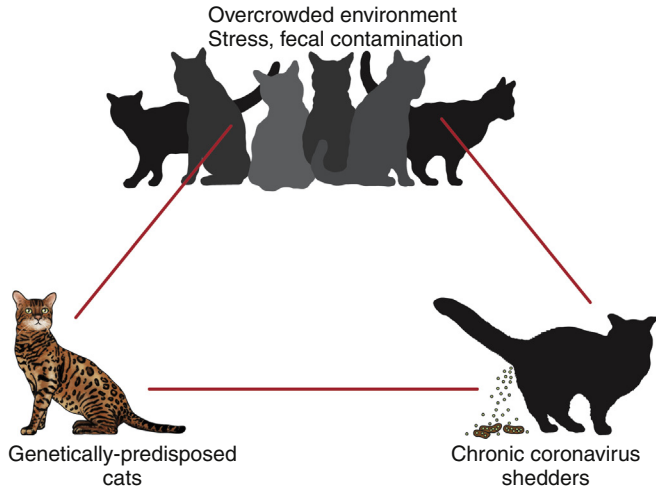

FIGURE 20-2 Interplay between genetics, virus shedding, and environment in feline coronavirus infections and FIP.

and tissue macrophages of cats that do not have FIP.[21,22] In some infected cats, the low-pathogenicity virus is believed to mutate to a virulent strain that can multiply within macrophages without hindrance by the immune system and incite a systemic pyogranulomatous vasculitis. The mutation may occur shortly after initial infection, or years later, which may explain why some indoor cats from single-cat households develop FIP several years after they are acquired. Virulent strains may not be able to replicate effectively within the gut,[23] which may be the reason why cat-to-cat transmission of FIP does not occur, yet the disease can be transmitted effectively by inoculating naïve cats with effusion from a cat with FIP. Factors that contribute to immunosuppression, such as concurrent viral infection, stress due to overcrowding, surgery, or transport, and especially genetic factors may allow viral replication and mutation to proceed unchecked. Simultaneous immune compromise of a large number of cats, such as in a shelter situation, may explain epidemics of FIP. Other risk factors for FIP include regular introduction of new cats to a cattery and the proportion of cats in a cattery that shed coronavirus chronically.[12] There is no distinct mutation that allows avirulent FCoV strains to be differentiated from virulent strains, and therefore no diagnostic test exists that distinguishes FIP from benign FCoV strains. However, mutations in the spike protein gene,[24,25] membrane protein gene,[26] and the nonstructural *3c* and *7b* genes[23,27-29] may play a role. In particular, the *3c* gene appears to be disrupted in many (but not all) virulent FCoV strains.

The other hypothesis proposed to explain the pathogenesis of FIP is that distinct circulating virulent and avirulent FCoV strains exist, and the combination of infection with a virulent FCoV and an individual cat's genetic and environmental predispositions leads to FIP.[25] It has also been suggested that both hypotheses may play a role.[30]

Clinical Features

Signs and Their Pathogenesis

Cats are usually infected with FCoV by oronasal exposure to virus in feces or fomites contaminated with fecal material. Shared litter boxes are thought to play a major role in transmission.[15] Replication of low-pathogenicity strains of FCoV in epithelial cells at the tips of intestinal villi may be associated with no signs, or acute or chronic, persistent or intermittent small-bowel diarrhea, and less commonly, vomiting and/or inappetence. Transient upper respiratory signs have been reported in some cats on initial infection with FCoV.[15] Virus is shed in the feces from 1 week after infection. Some cats then shed large quantities of virus continuously for life.[12,22,31-33]

Both serotype I and serotype II strains appear to enter macrophages via a lectin receptor known as fDC-SIGN (feline dendritic cell-specific intercellular adhesion molecule grabbing non-integrin receptor).[3,34] Replication of virulent FCoV strains within macrophages results in two forms of disease, which reflect the immune response mounted by the host. FIP is an immune complex disease. *Noneffusive* ("dry") FIP occurs in cats that mount a partial CMI response and is characterized by pyogranulomatous to granulomatous inflammation within a variety of organs, but especially the mesenteric lymph nodes, kidneys, liver, lungs, brain, and eye. Solitary or multifocal granulomas of the intestinal wall also occasionally develop, especially in the region of the ileocecal junction (Figure 20-3).[15] *Effusive* ("wet") FIP occurs in cats that are unable to mount an immune response and is characterized by accumulation of high protein exudates in the thorax and/or abdomen, which typically contain low numbers of cells. Production of vascular endothelial growth factor by infected monocytes may be lead to increased vascular permeability and contribute to cavitary effusion.[35] Many cats have a mixture of both forms of the disease, and noneffusive disease may progress to effusive disease. Infection itself results in immune dysregulation, with a profound, virus-induced depletion of CD4+ and CD8+ cells; production of TNF-α, granulocyte-macrophage colony stimulating factor (GM-CSF), and granulocyte colony-stimulating factor (G-CSF) by infected macrophages; impaired IFN-γ production; and hypergammaglobulinemia.[36-38] The mechanism of T-cell depletion is not clear, as the virus does not infect lymphocytes, only monocytes and macrophages. Infection of antigen-presenting cells, specifically dendritic cells, has been hypothesized to lead to T-cell apoptosis. Progressive immune system failure may be associated with a conversion to predominantly effusive disease manifestations. Despite the profound T-cell deficiency that accompanies FIP, opportunistic infections are rarely reported. Nevertheless, concurrent infections with retroviruses and *Toxoplasma gondii* and opportunistic bacterial infections can occur;[6] the author is aware of one cat that was co-infected with *Sporothrix schenckii*.

FIGURE 20-3 Colonic mass removed at surgery from a 7-month-old female spayed domestic shorthair with anorexia and hematochezia. Histopathology showed severe, multifocal coalescing pyogranulomatous colitis and lymphadenitis. (Courtesy of the University of California, Davis Veterinary Anatomic Pathology service.)

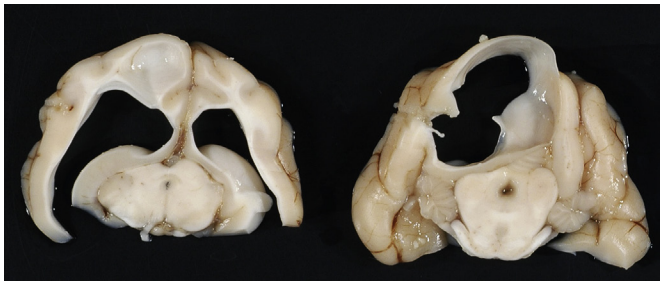

FIGURE 20-4 Obstructive hydrocephalus in an 8-month-old male neutered exotic shorthair cat that developed ataxia and head tremors. Hydrocephalus and secondary cerebellar herniation were found at necropsy. Histopathology revealed severe, multifocal pyogranulomatous meningoencephalitis, choroiditis, and ventriculitis, and pyogranulomatous inflammatory lesions were also found throughout the thoracic and abdominal viscera. (Courtesy of the University of California, Davis Veterinary Anatomic Pathology service.)

The incubation period for FIP is highly variable. Kittens usually become infected at 4 to 8 weeks of age, when maternal antibody begins to wane, but infections have been reported in kittens as young as 2 weeks of age.[20] Disease may occur a few weeks after infection or years later, but most often it occurs 6 to 18 months after initial infection.[19] Even after the onset of systemic pyogranulomatous inflammatory disease, clinical signs may not be apparent for months. In support of this, lesions consistent with FIP have been found incidentally in cats during abdominal surgery such as ovariohysterectomy.[20]

The clinical signs of FIP often change over time and depend on the organs affected and the relative predominance of inflammatory versus effusive disease manifestations. The most common signs are lethargy and inappetence, as well as a fluctuating fever that does not respond to antibacterial drug treatment. Nevertheless, many cats are bright, appetent, and in good body condition early in the course of illness. Some cats have increased thirst and urination, possibly secondary to pyrexia. Ultimately, weight loss develops, but owners of cats that develop abdominal distention may mistake the distention for weight gain or pregnancy. Stunted growth may occur in affected kittens. Pleural effusion may be associated with tachypnea and respiratory distress. Testicular enlargement may occur in cats with serositis that involves the tunica vaginalis. FIP is responsible for approximately 10% of pericardial effusions in cats, the third most common cause of pericardial effusion after cardiomyopathy and neoplasia.[39] Rarely, pericardial effusion results in cardiac tamponade. Pyogranulomatous or granulomatous inflammation may lead to mesenteric lymphadenomegaly, irregular renomegaly, intestinal masses, hepatomegaly, icterus, pneumonia, uveitis, chorioretinitis, and, rarely, nodular skin lesions. Neurologic signs, which can include focal or generalized seizures, occur in at least 10% of cats with FIP and result primarily from meningoencephalitis, meningomyelitis, ependymitis, choroiditis, and obstructive hydrocephalus. Obstructive hydrocephalus occurs secondary to choroiditis and ependymitis (Figure 20-4). In one study, FIP was responsible for almost half of all neurologic disease in 97 cats due to infectious or inflammatory causes.[40] Occasionally profound anemia occurs secondary to immune-mediated hemolysis[13,14] or possibly microangiopathic damage, whereby erythrocytes are lysed as they travel through inflamed blood vessels. Immune-mediated glomerulonephritis has also been reported, and FIP should always be considered in cats with protein-losing nephropathy, which is otherwise rare in cats.[41] Uncommonly, lameness occurs as a result of synovitis.[6]

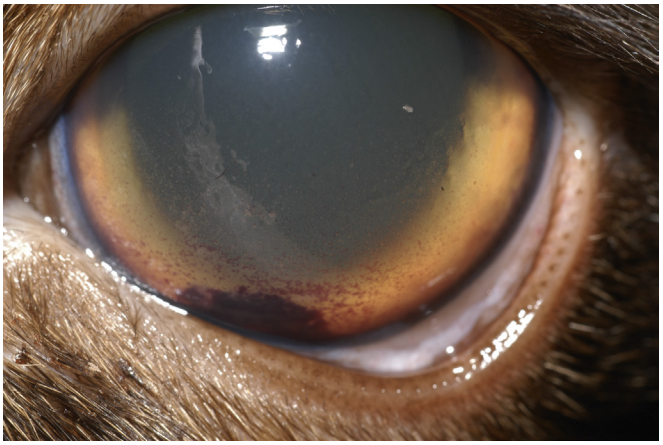

FIGURE 20-5 Keratic precipitates in a 5-year-old intact male Burmese cat with FIP. (Courtesy of the University of California, Davis Veterinary Ophthalmology service.)

Physical Examination Findings

Physical examination findings in cats with FIP reflect the type of disease present (effusive versus noneffusive) and the location where lesions occur. Cats with respiratory tract involvement may show tachypnea, and if there is pleural effusion, a rapid, shallow breathing pattern and muffled heart and lung sounds may be present. Other signs include pyrexia, dehydration, mucosal pallor or icterus, a thin body condition, and evidence of ascites. Abdominal palpation may reveal hepatomegaly, irregular renomegaly, and/or abdominal mass lesions that result from mesenteric lymphadenomegaly or intestinal pyogranulomas. Sometimes pain is appreciated on abdominal palpation, which may reflect pancreatic involvement in some cats. Testicular enlargement may be detected in intact male cats. A wide range of neurologic signs may be present, such as obtundation, twitching, tremors, behavioral changes, nystagmus, hyperesthesia, exaggerated segmental reflexes, ataxia, urinary incontinence, or cranial nerve defects. Ocular signs include conjunctivitis, mucopurulent ocular discharge, thickening and hyperemia of the nictitans, uveitis with dyscoria or anisocoria, aqueous flare, keratic precipitates, hypopyon, hyphema, chorioretinitis, perivascular infiltrates, retinal detachment, or blindness (Figure 20-5).

FIP, Feline infectious peritonitis; RDW, red cell distribution width.
*22 (58%) had evidence of toxic neutrophils.
†A smear was evaluated manually for 37 of the 38 cats. The presence of macroplatelets were reported for 18 (49%) of cats.

Diagnosis

Currently, definitive diagnosis of FIP is made only by immunohistochemical staining for coronavirus antigen within lesions characterized by pyogranulomatous or granulomatous vasculitis. Because it can be difficult or impossible to safely obtain biopsy specimens from cats with FIP, antemortem diagnosis is often only suspected on the basis of history, signalment, and clinical and laboratory findings, and by ruling out other causes of disease. Provided it is correctly performed and interpreted, immunocytochemistry may be helpful. Because the presence of the characteristic effusion is most helpful for antemortem diagnosis, efforts should be always made to identify and analyze any fluid that is present in body cavities. When owner funds are limited, laboratory analysis of effusion, rather than blood, may be the most economic diagnostic approach. Unfortunately, the lack of a definitive noninvasive diagnostic assay for FIP and the extremely poor prognosis sometimes leads clinicians to perform large numbers of diagnostic tests in the hope that an answer will appear. In other situations, the diagnosis of FIP is made too hastily, and euthanasia is performed without sufficient clinical and laboratory justification.

Laboratory Abnormalities

Complete Blood Count

A mild, nonregenerative anemia is often present in cats with FIP, and sometimes severe anemia occurs, which is usually poorly regenerative or nonregenerative (Table 20-1). Microcytosis may be present. Examination of erythrocyte morphology occasionally reveals schistocytosis, mild normoblastosis, or agglutination. There may be a leukocytosis due to a neutrophilia and monocytosis, or leukopenia. Lymphopenia occurs in more than 50% of affected cats, and eosinopenia is also common. In some cats, a left shift and evidence of toxic neutrophils are seen. Mild to moderate thrombocytopenia is common in cats with noneffusive disease and may reflect the presence of disseminated intravascular coagulation or immune-mediated platelet destruction. However, thrombocytosis can also occur.

Serum Biochemical Tests

Many cats with FIP have hyperproteinemia due to hyperglobulinemia, which results from a polyclonal gammopathy (Figure 20-6). Rarely, a monoclonal gammopathy can occur.[42] Total protein concentrations may be as high as 12 g/dL (Table 20-2).[20] In one study, hyperglobulinemia was present in 50% of cats with effusion and 70% of cats without effusion.[43] Globulin concentration may decrease terminally, so cats with advanced disease may have protein concentrations that are within the reference range.[14] Hypoalbuminemia is often present because of liver involvement, leakage from damaged vessels, urinary loss in cats with glomerulonephritis, or inflammation (albumin is a negative acute-phase reactant protein). Thus, the serum albumin:globulin ratio

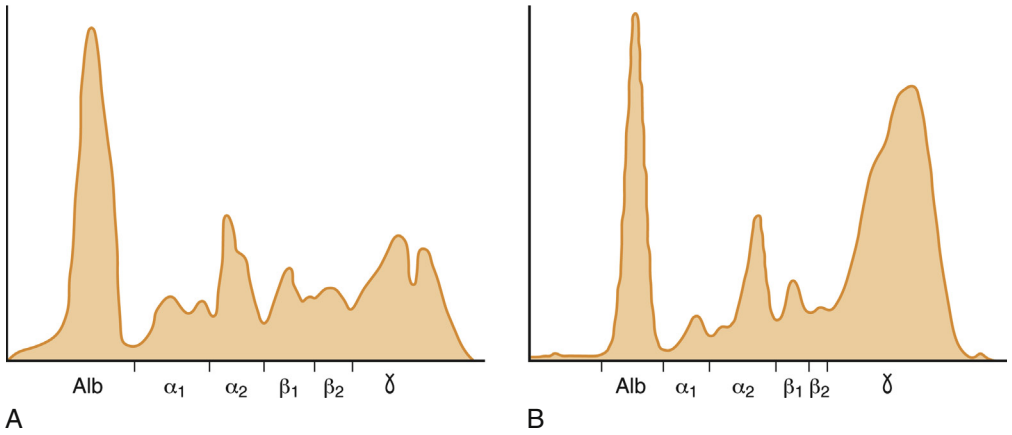

FIGURE 20-6 **A,** Densitometric scan of serum protein electrophoresis of normal feline serum. **B,** Scan from a 9-month-old male neutered domestic shorthair cat with FIP. There is a polyclonal gammopathy, represented by a broad peak in the γ-globulin region, with a mild decrease in the albumin and mild increases in the α_2 and β_1 fractions. (A redrawn from Baker RJ, Valli VE. Electrophoretic and immunoelectrophoretic analysis of feline serum proteins. Am J Vet Res 1988;52[3]:308-304.)

Albumin (g/dL)	2.2-4.6	50	50	0	0.9-3.6	36
Globulin (g/dL)	2.8-5.4	3	42	56	2.5-9.4	36
Cholesterol (mg/dL)	89-258	17	83	0	56-247	36
Total bilirubin (mg/dL)	0-0.2	0	40	60	0-5.3	36
ALT (U/L)	27-101	50	25	25	18-648	36
AST (U/L)	17-58	6	43	51	0-1554	36
ALP (U/L)	14-71	28	61	11	0-161	36
GGT (U/L)	0-4	0	96	4	0-5	23

FIP, feline infectious peritonitis.

may be more useful than the globulin alone for diagnosis; ratios less than 0.8 are uncommon (but not impossible) in cats with FIP, so they help to rule out (but not to rule in) a diagnosis of FIP.[44,45] Other variable findings include hyponatremia, hypokalemia, hypochloremia, hyperglycemia, azotemia, increased liver enzyme activities, hypocholesterolemia, and hyperbilirubinemia. The cause of hyperbilirubinemia is not clear, but it may result from hemolysis, hepatic necrosis, and/or cholestasis.

Measurement of α_1-acid glycoprotein (an acute phase protein) has been suggested for diagnosis, because serum concentrations often exceed 1500 µg/mL in cats with FIP.[20,46,47] However, α_1-acid glycoprotein concentrations also increase with other inflammatory diseases.[20]

Lymphocytes (%)	5-89	19		10
Monocytes (%)	0-20	7		10

TNC, total neutrophil count.
*Insufficient quantity available from some cats for determination of protein concentration.

Urinalysis

The urinalysis in cats with FIP may be unremarkable or contain protein due to glomerular or tubular damage. Hematuria and, less commonly, pyuria and cylindruria may be present. Bilirubinuria may be detected in cats with liver injury.

Coagulation Profile

In addition to thrombocytopenia, abnormalities of coagulation in cats with FIP include prolonged prothrombin time and partial thromboplastin time as a result of severe liver injury, and increased fibrin degradation product or D-dimer concentrations.[15]

Analysis of Effusion Fluid

The "classic" FIP effusion fluid is a high-protein (greater than 3.5 g/dL) exudate that contains a low number of nucleated cells (<5000 cells/μL), usually nondegenerate to mildly degenerate neutrophils and macrophages (Table 20-3). Erythrophagocytosis, leukophagia, and reactive mesothelial cells can be observed in the fluid from some cats. Grossly, the fluid has a yellow appearance and may contain fibrin clots. However, the total protein content and cell counts of abdominal and pleural effusions vary considerably, which complicates the diagnosis for some cats with effusive disease. Very rarely, chylous effusions occur.[48] An effusion albumin/globulin ratio below 0.4 is suggestive of FIP.[49]

The *Rivalta test* is a simple test that can differentiate between transudates and exudates. In this test, a drop of 98% glacial acetic acid is mixed with 7 to 8 mL of distilled water in a transparent 10-mL tube. A drop of effusion is then added to the tube, and if it dissipates in the solution, the test is negative. If it retains its shape, stays attached to the surface, or moves slowly down in the solution, then the test is positive.[20] In a study of cats with effusion, 35% of which had FIP and a conclusive Rivalta test, the positive predictive value of this test for the diagnosis of FIP was 58% (58% chance that a cat that tests positive truly has FIP), and the negative predictive value was 93% (93% chance that a cat that tests negative does not have FIP).[50] In younger cats, the positive predictive value of the test is higher, because diseases such as lymphoma and bacterial peritonitis are less common. Positive test results indicate only the presence of an exudate, so cytologic examination of the fluid must still be performed.

Cerebrospinal Fluid Analysis

The cerebrospinal fluid (CSF) of cats with neurologic FIP often has increased protein content (30 to more than 1000 mg/dL, reference range less than 25 mg/dL) and increased total nucleated cell count (20 to 10,000 cells/μL), usually consisting of a mixed but predominantly neutrophilic cellular pleocytosis (Table 20-4). In some cats, protein content and leukocyte counts are normal.[51,52]

Diagnostic Imaging

Plain Radiography

Plain thoracic radiography may reveal pleural effusion, enlargement of the cardiac silhouette in cats with pericardial effusion, and pulmonary nodular or peribronchial infiltrates in cats with pyogranulomatous pneumonia (Figure 20-7). Abdominal radiographs may show loss of peritoneal or retroperitoneal detail due to peritoneal effusion, hepatomegaly, splenomegaly, renomegaly, or mass lesions associated with the gastrointestinal tract or abdominal lymph nodes.

Sonographic Findings

Abdominal ultrasound findings in FIP include the presence of anechoic or mildly echogenic peritoneal fluid; hyperechogenicity and "clumping" of the mesentery; enlarged and hypoechoic abdominal lymph nodes (Figure 20-8, *A*); enlargement and diffuse or focal hypoechogenicity of the liver and spleen;[53] renal asymmetry with increased cortical echogenicity, hypoechoic nodules, subcapsular fluid accumulation, or loss of corticomedullary distinction (see Figure 20-8, *B*); and/or thickening of all intestinal wall layers or intestinal mass lesions. Pleural effusion or comet-tail artifacts (due to pulmonary infiltrates) may be seen through the diaphragm.

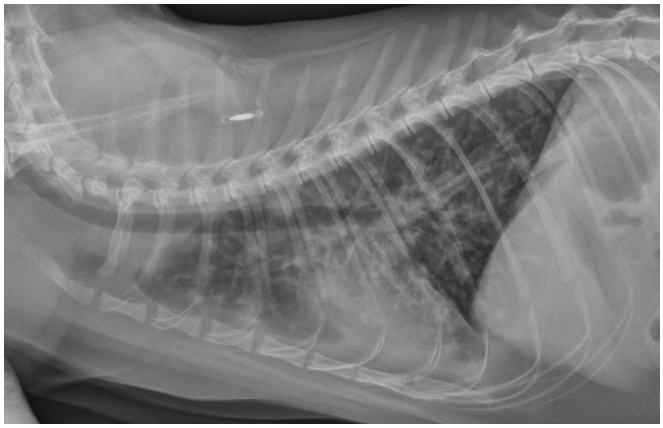

FIGURE 20-7 Lateral thoracic radiograph from a 9-month-old male neutered domestic shorthair cat with FIP and pyogranulomatous pneumonia. There is a severe, diffuse, patchy alveolar and nodular interstitial pattern with thickening of the bronchial walls and mild pleural effusion.

Magnetic Resonance Imaging of the Central Nervous System

Findings on MRI that suggest FIP consist of ventricular dilatation and variable contrast enhancement of the periventricular regions, choroid, and meninges. In some cats, MRI findings are unremarkable.

Microbiologic Tests

Serologic Diagnosis

Detection of antibodies to FCoV can be performed using immunofluorescent antibody testing, ELISA, or virus neutralization.[54] The methods used, as well as the titers themselves, vary considerably between laboratories. For example, some laboratories use related coronaviruses as a source of antigen for the test, rather than FCoV.[15] Use of a reliable laboratory that reports quantitative titers (to the endpoint dilution, as well as down to 1:100) is critical. Even when performed correctly, a positive FCoV antibody titer is not diagnostic for FIP, because cats that have been exposed to avirulent FCoV strains or even other related coronaviruses are also seropositive. Therefore, serology is a "coronavirus antibody test" and not an "FIP test." It has been suggested that more cats have been killed as a result of misinterpretation of FCoV antibody tests than by the disease itself.[20] Certainly a diagnosis of FIP should *never* be made based on the presence of nonspecific clinical or laboratory abnormalities such as fever or leukocytosis and a positive coronavirus antibody test. Occasionally (up to 10% of the time), cats with advanced disease are seronegative, because of failure of antibody production with severe immunosuppression, or the complexing of antibody by the large quantities of virus present. In one study, titers of 1:1600 or higher were highly suggestive (94% chance) of FIP in the presence of compatible clinical signs.[44] In addition, strong positive titers (e.g., ≥ 1:6400) in cats with consistent signs and laboratory abnormalities support a diagnosis of FIP if a cat resides in a household that contains only one or two cats, because cats often become seronegative within a few months once they are removed from households that contain large numbers of cats.

Other body fluids can also be analyzed for antibodies to FCoV. In one study, positive antibody titers in effusion had a positive predictive value of 90% and a negative predictive value of 79%, but the magnitude of the titer did not correlate with the diagnosis of FIP.[44] The presence of anti-FCoV antibody in the CSF correlated well with a diagnosis of FIP in one study,[52] but not in another study.[51] In addition, the presence of sufficient quantities of CSF for serology are frequently not available.

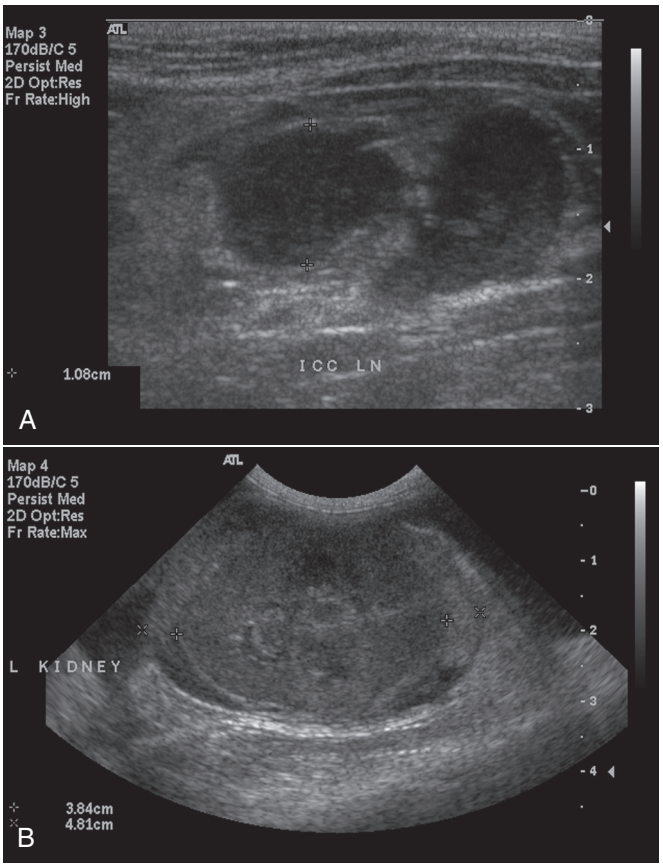

FIGURE 20-8 **A,** Abdominal ultrasound image from a 9-month-old male neutered domestic shorthair cat with FIP and ileocecocolic lymphadenopathy. The lymph nodes are enlarged and hypoechoic. **B,** Abdominal ultrasound image from a 1-year-old male intact Scottish fold with FIP. There is renal irregularity and subcapsular fluid, as well as moderate peritoneal effusion.

Molecular Diagnosis Using the Polymerase Chain Reaction

Real-time reverse transcriptase–PCR (RT-PCR) assays have been developed for detection of FCoV, but these do not differentiate between virulent and avirulent strains. In addition, avirulent strains can be found in the blood and tissues of cats that do not have FIP,[21,22] so the finding of virus in locations other than the gastrointestinal tract is not helpful for diagnosis. False-negative test results can occur when there are low quantities of virus present or if degradation of RNA occurs during specimen transport. Some RT-PCR assays do not detect all strains of FCoV. Positive RT-PCR results in blood or effusion fluid from cats with other clinical abnormalities that suggest FIP do indicate the presence of a coronavirus and, in that respect, may help to support the diagnosis made, provided the limitations of the test are recognized.

Immunostaining of FCoV Antigen

FCoV antigen can be detected in macrophages with immunocytochemistry or immunohistochemistry (Figure 20-9). Either fluorescent antibody or immunoperoxidase methods

VetBooks.ir

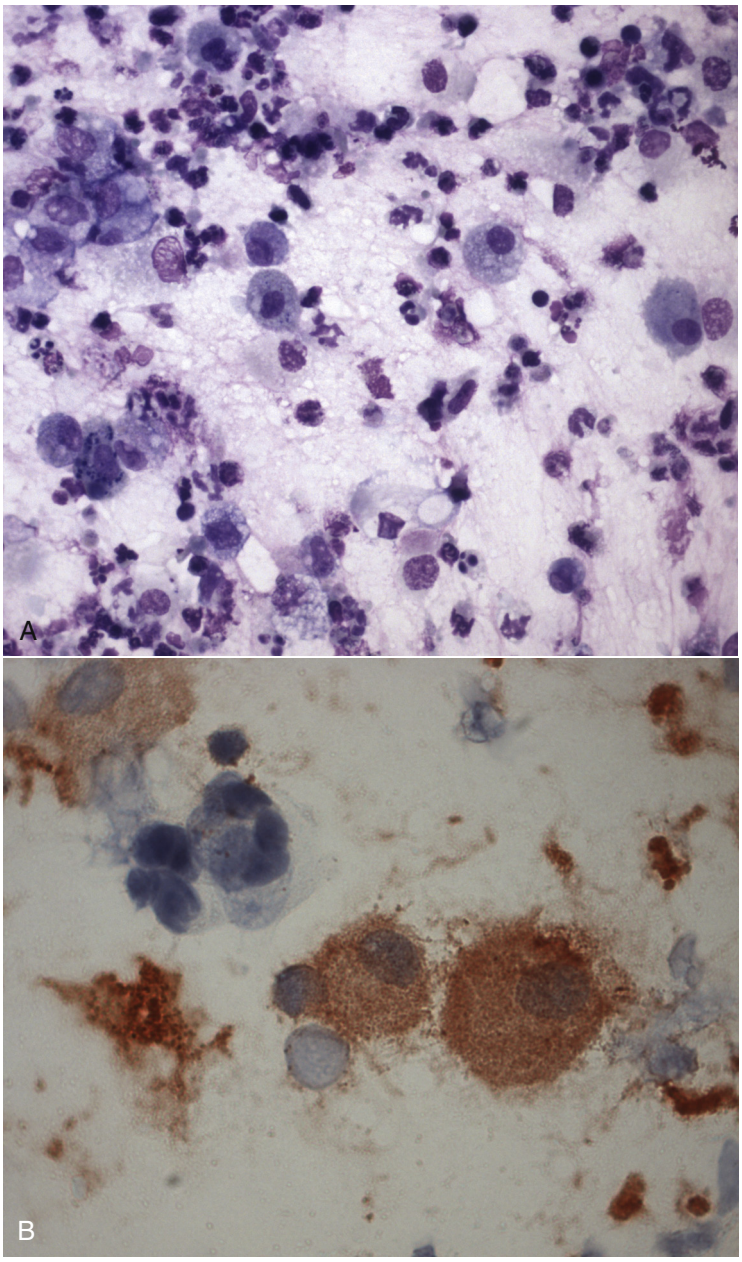

FIGURE 20-9 **A,** Cytospin preparation of a tracheobronchial lavage from the cat in Figure 20-7. The specimen was highly cellular (4400 cells/μL) and the cells consisted of 42% degenerate and nondegenerate neutrophils, 5% lymphocytes, and 53% macrophages. **B,** Immunocytochemistry stain on the same specimen for coronavirus antigen showing positive staining in association with macrophages.

may be used (Table 20-5). When antigen tests are positive, provided the test is performed and interpreted properly (with use of positive and negative control slides), studies suggest that only cats with FIP have positive test results.[44,55] False-negative results occur when there are insufficient numbers of infected cells, when low quantities of virus are present, or when antigen is unavailable for detection because of complexing by antibody.

Pathologic Findings

Gross Pathologic Findings

At necropsy, gross findings in cats with FIP include variable quantities of pleural, pericardial, and peritoneal effusion (Figure 20-10, *A*). Fibrin adhesions may be present and the mesentery may be clumped. Abdominal organs may be enlarged or irregular. Granulomas appear as variably sized multifocal white, cream, tan, or yellow nodular lesions on serosal surfaces and within the parenchyma of organs such as the lungs, spleen, kidneys, pancreas, and liver (see Figure 20-10, *B*). Lesions have also been described within the nasal cavity and sinuses. Pyogranulomas may be visible grossly as miliary lesions, or they may be several centimeters in diameter. Thoracic and/or abdominal lymphadenomegaly is a common finding. Diffuse or focal thickening of the intestinal wall or intestinal mass lesions may be present. Examination of the brain can reveal fibrinous exudate in association with the meninges, with or without ventricular dilation and hydrocephalus (see Figure 20-4). Thymic involution may also be present.

VetBooks.ir

TABLE 20-5

Assays Available for Diagnosis of Feline Infectious Peritonitis

Assay	Specimen Type	Target	Performance
Fluorescent or immunoperoxidase antibody staining	Wash or effusion specimens, tissue aspirates, tissues obtained at biopsy or necropsy	FCoV	Gold standard for diagnosis. False negatives can occur in specimens that contain low numbers of macrophages or virus particles, or when virus is complexed by antibody. Immunofluorescence is more sensitive than immunoperoxidase methods. Non-specific staining may be interpreted as positive results by untrained personnel.
Serology	Blood, CSF, aqueous humor, effusion fluid	FCoV antibody	Positive antibody titers reflect only antibodies to a coronavirus and are not specific for a diagnosis of FIP. Most cats in multicat households test positive. Negative titers can occur in cats with advanced FIP. High titers in cats that do not reside in multicat households and that have signs suggestive of FIP may support the diagnosis. Interlaboratory variation in methodology and titer reporting occurs.
RT-PCR	Blood, wash or effusion specimens, tissue aspirates, tissues obtained at biopsy or necropsy	FCoV RNA	Does not differentiate between virulent and avirulent FCoV strains, and avirulent strains may be found in tissues and blood. Sensitivity and specificity can vary depending on assay design. False negative results occur when virus levels are low, when variant virus strains are present, or as a result of degradation of viral nucleic acid during specimen transport.
Histopathology	Usually necropsy specimens, but also biopsies	Inflammatory lesions induced by FCoV (pyogranulomatous vasculitis)	Biopsy is often not feasible antemortem as a result of critical illness and coagulopathies.

FCoV, feline coronavirus; FIP, feline infectious peritonitis; RT-PCR, reverse transcriptase–polymerase chain reaction.

Histopathologic Findings

The characteristic histopathologic findings of FIP are systemic perivascular, multifocal to coalescing pyogranulomatous or granulomatous inflammatory lesions (Figure 20-11). Lesions predominantly contain macrophages and neutrophils, with lesser numbers of lymphocytes and plasma cells, although occasionally the histiocytic or the lymphoplasmacytic component of the inflammatory response is more florid. Necrosis may be present within the lesions. Lesions in the central nervous system consist of pyogranulomatous meningoencephalomyelitis and choroiditis. Other findings that may be identified include lymphoid depletion, which results from apoptosis, and membranous glomerulonephritis.

Treatment and Prognosis

Currently, no cure for FIP exists; it is a progressive, invariably fatal disease. The goal of treatment is to prolong life span and improve quality of life through reduction of inflammation and supportive care. The most effective treatment known is prednisolone, administration of which results in temporary remissions in some cats (Table 20-6). Other immunosuppressive drugs, such as chlorambucil and cyclophosphamide, have been used in addition to prednisolone, but whether these drugs improve outcome is unknown, and they have the potential to be toxic. A variety of immunomodulators and antiviral drugs have been tried, such as ribavirin and oral and parenteral human recombinant IFN-α, but none have convincingly shown benefit in vivo. Prolonged remissions were reported in several cats treated with a combination of glucocorticoids and feline IFN-ω,[56] but a randomized, placebo-controlled clinical trial reported no effect of feline IFN-ω.[57] Other drugs used to treat cats with FIP include the immunomodulatory drugs pentoxifylline and Polyprenyl Immunostimulant (see Chapter 7)[58]; ozagrel hydrochloride, a thromboxane synthetase inhibitor[59]; and the antiviral drug nelfinavir.[14,60] Controlled clinical trials are required to assess the efficacy and safety of these treatments. Because FIP is an immune-mediated disease, nonspecific immune stimulation has the potential to cause harm. The use of small interfering RNA molecules, which bind viral RNA and prevent viral replication, has recently shown promising results in vitro.[61] Cyclosporin inhibits FIPV replication in vitro;[62] studies are required to determine if cyclosporin treatment benefits infected cats or whether harm results from immunosuppression.

Supportive treatments that may be required include subcutaneous fluid therapy and nutritional support. Inappetent cats can benefit from enteral nutrition through a feeding tube. The use of broad-spectrum antimicrobial drugs to treat cats with FIP is controversial; it may only promote opportunistic infections with resistant bacteria.

The prognosis for cats with FIP is generally grave. Almost all cats with effusion at the time of diagnosis die within weeks. Very rarely, more prolonged survival times (1 to 2 years) have been documented after glucocorticoid treatment (see Case Example).

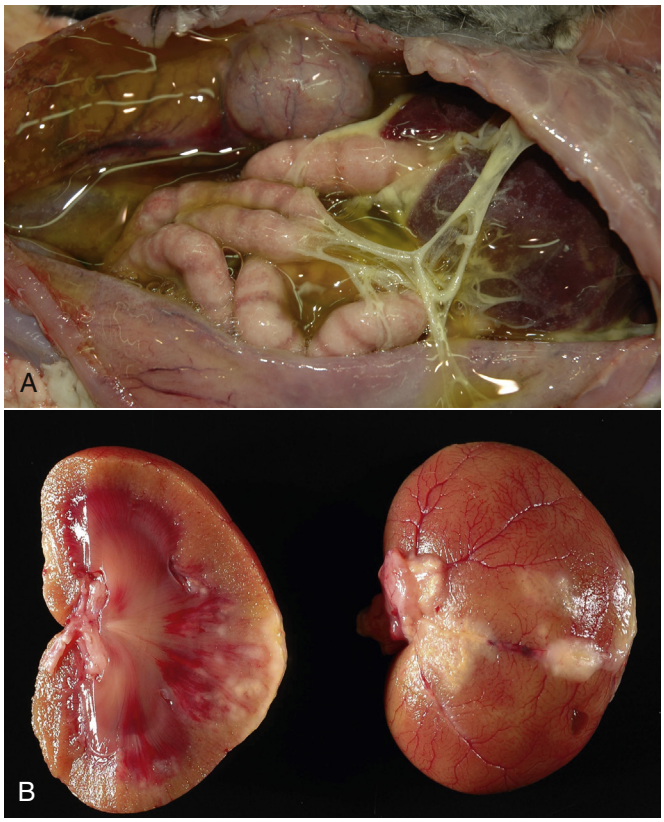

FIGURE 20-10 **A,** Gross necropsy findings in a 10-month-old male intact domestic shorthair cat with effusive FIP. Approximately 1.2 liters of yellow fluid was present in the abdomen, and there are abundant fibrin strains adherent to the visceral and parietal peritoneal surfaces. **B,** Kidneys of the cat in Figure 20-8. Multiple, pale tan firm nodules expand the renal cortices and protrude from the cortical surfaces. (Courtesy of the University of California, Davis Veterinary Anatomic Pathology service, D. Gasper and M. Jones.)

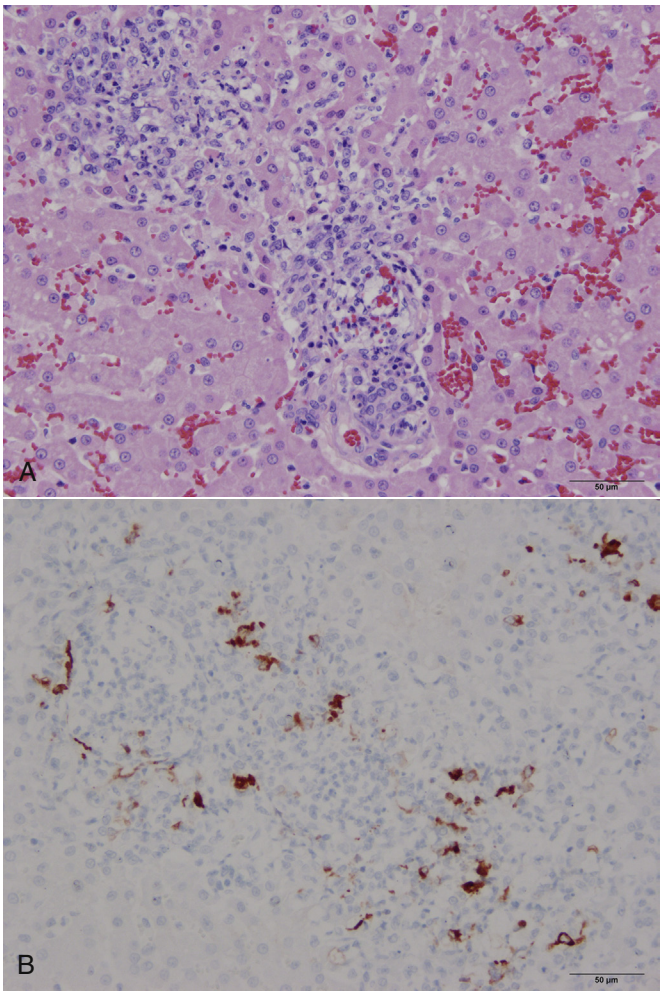

FIGURE 20-11 **A,** Histopathology of the liver of a cat with FIP. There is pyogranulomatous hepatitis. Hematoxylin and eosin stain. **B,** Macrophages stain strongly positive for feline coronavirus antigen with immunohistochemistry. (Courtesy Dr. Patricia Pesavento, University of California, Davis Veterinary Anatomic Pathology service.)

The median survival time in one study of 37 cats was 9 days (range, 3 to 200 days).[57] In another it was 21 days (range, 1 to 99 days) for 30 cats with effusive disease, 38 days (range, 1 to 171 days) for 12 cats with noneffusive disease, and 111 days (range, 7 to 477 days) for 9 cats with mixed effusive and noneffusive disease.[14] Hyperbilirubinemia, the presence of effusion, and lymphopenia are negative prognostic factors[20]; in one study, the hematocrit, lymphocyte count, and serum albumin, potassium, sodium, and globulin concentrations decreased as disease progressed, and total bilirubin concentration and serum liver enzyme activities increased.[14] Euthanasia should be considered for cats with severe illness that fail to respond to treatment within a 3-day period.[20]

Immunity and Vaccination

Although antibodies to the spike protein can neutralize virus, antibodies are required for FIP to occur, because FIP is an immune complex disease. Cell-mediated immunity is important for protection,[6] but if immunity is incomplete, granulomatous or pyogranulomatous disease results.

The development of vaccines for FIP has been complicated by the fact that stimulation of antibody production against FCoV can accelerate the disease, should FIP develop after vaccination has been performed. Antibodies may bind to Fc receptors on macrophages and accelerate virus uptake in a phenomenon known as *antibody-dependent disease enhancement* (ADDE). Currently, an intranasal, temperature-sensitive mutant serotype II FIP virus vaccine is available on the market, but its use has been controversial. The vaccine virus replicates in the lower temperatures found in the respiratory tract. It is licensed for administration from 16 weeks of age, by which time most kittens have already been exposed to FCoV. The vaccine does not appear to cause ADDE,[63-65] but its efficacy and ability to induce

TABLE 20-6

Suggested Drug Dosages for Treatment of Feline Infectious Peritonitis

Drug	Dose (mg/kg)	Route	Interval (hours)
Prednisolone	1-2	PO	12-24
Chlorambucil*	2 mg/cat	PO	48-72

*Monitor the CBC during treatment.

VetBooks.ir

immunity against heterologous strains is controversial. In a study of 138 cats that belonged to 15 different cat breeders, virtually all of which were seropositive, there was no difference in prevalence of FIP in vaccinated versus placebo-treated cats.[63] A slight reduction in the prevalence of FIP occurred when the vaccine was used in cats that had not been exposed to FCoV before vaccination, but protection was not convincing based on the small numbers of cats that developed the disease in each group.[6,65]

Prevention

In households that contain only one or a few cats, young cats that develop FIP likely become infected with FCoV before they are acquired. They may or may not have FIP at the time of acquisition. When a cat from a single-cat household dies with FIP, it is suggested that the owner wait at least 2 months before a new cat is obtained, so that any virus in the environment becomes inactivated.[20] Selection of a new cat from a different genetic background than the previous cat should be considered, and if possible, the breeder should be informed if a purebred cat develops FIP. If a low number of other cats remain in the household, they may or may not continue to shed virus. These cats often have a positive antibody titer, but this in no way predicts that they will develop FIP. Before a new cat is introduced to a household that has a history of FIP, factors that could reduce stress and overcrowding should be identified and addressed.

The risk of transmission and disease can be reduced through attention to hygiene, prevention of overcrowding, maintenance of a larger ratio of adult to juvenile cats, and ensuring that cats are in stable groups of three or fewer per room. Cats should have sufficient numbers of regularly cleaned litter trays located in a different area from where they are fed. Methods to control FIP in cattery situations, such as identification and removal of chronic shedders with serial fecal RT-PCR assays and removal of kittens from the queen followed by isolation at 5 to 6 weeks of age (before maternal antibody has declined), have limitations and are difficult to achieve properly in large catteries.[20] For example, cats that do not shed FCoV may still be infected with avirulent FCoV strains, and shedding may recommence at a later date.[22] Isolation of kittens may be useful if reexposure is prevented until after they are 16 weeks of age, when their immune system is more mature.[6] In shelter situations, FIP may be reduced when overcrowding and prolonged stays are minimized, especially during kitten season.[6] If possible, owners that adopt cats from shelter environments should be provided with a handout that provides basic information on the disease (and other major infectious diseases of shelter cats such as retrovirus infections, bartonellosis, and feline upper respiratory tract disease) and the ubiquitous nature of infection.

Further understanding of genetic factors that contribute to FIP is required, because selective breeding may reduce the risk of the disease. In the meantime, the breeding of cats that produce litters that succumb to FIP should be avoided. This is especially true for male cats, because a single male cat can have an effect on far more kittens and litters than a single queen. It is recommended that no more than six breeding animals be maintained if possible.[6]

Public Health Aspects

There is no evidence that humans can become infected with FCoV. The closest human coronavirus relative is the severe acute respiratory syndrome (SARS) coronavirus. Other coronaviruses cause FIP-like disease in nonfelids such as ferrets and mice. If a coronavirus emerged that could cause similar clinical manifestations and outcomes in humans as FIPV can in cats, it would represent a major threat to humans and would be the subject of intense research.

CASE EXAMPLE

Signalment: "Ricky", a 9-month-old male castrated domestic shorthair from Sacramento, CA

History: Ricky was brought to a local veterinary clinic because of increased thirst and urination. A serum chemistry panel showed hyperglobulinemia (7.7 mg/dL), and urinalysis showed a specific gravity (SGr) of 1.025 with an inactive sediment; aerobic bacterial urine culture was negative. Three days later, Ricky became inappetent and was returned to the local veterinary clinic. Laboratory abnormalities included mature neutrophilia (11,904 cells/μL), lymphocytosis (5104 cells/μL), eosinophilia (1536 cells/μL), hyperglobulinemia (6.9 mg/dL), and hypoalbuminemia (2.4 mg/dL). A feline coronavirus antibody titer was 1:400. Serology for *Toxoplasma gondii* was negative. Plain thoracic radiographs showed a mild interstitial pattern. Abdominal ultrasound showed mesenteric lymphadenomegaly, and an aspirate of the lymph nodes showed lymphoid reactivity. Treatment with cyproheptadine was initiated, and Ricky's appetite recovered, after which treatment was discontinued. For the 3 weeks that followed, the cat had been appetent and energetic, but occasional soft feces had been noticed in the litter box. The owners were concerned about the possibility of FIP.

Ricky was obtained at 3 months of age from a rescue group, who rescued him as an 8-week-old stray kitten. As a kitten he had multiple upper respiratory tract infections, but since adoption he had been healthy and shared a household with one other cat. He was an indoor cat that was sometimes walked briefly outdoors. He was fed commercial dry and wet cat food.

Physical Examination:

Body Weight: 4.2 kg

General: Bright, alert and responsive, hydrated. T = 103°F (39.4°C), HR = 200 beats/min, eupneic.

All Systems: No clinically significant abnormalities of any body system were detected. Body condition score was 5/9.

Laboratory Findings:

CBC:

HCT 27.3% (30%-50%)
MCV 42.1 fL (42-53 fL)

VetBooks.ir

MCHC 34.1 g/dL (30-33.5 g/dL)
WBC 24,950 cells/μL (4500-14,000 cells/μL)
Neutrophils 17,141 cells/μL (2000-9000 cells/μL)
Lymphocytes 6886 cells/μL (1000-7000 cells/μL)
Monocytes 724 cells/μL (50-600 cells/μL)
Eosinophils 200 cells/μL (150-1100 cells/μL)
Basophils 25 cells/μL (0-50 cells/μL)
Platelets 518,000/μL (180,000-500,000 platelets/μL).

Serum Chemistry Profile:
Sodium 147 mmol/L (151-158 mmol/L)
Potassium 4.5 mmol/L (3.6-4.9 mmol/L)
Chloride 116 mmol/L (117-126 mmol/L)
Bicarbonate 18 mmol/L (15-21 mmol/L)
Phosphorus 6.4 mg/dL (3.2-6.3 mg/dL)
Calcium 9.5 mg/dL (9.0-10.9 mg/dl)
BUN 22 mg/dL (18-33 mg/dL)
Creatinine 1.1 mg/dL (1.1-2.2 mg/dL)
Glucose 83 mg/dL (63-118 mg/dL)
Total protein 10.7 g/dL (6.6-8.4 g/dL)
Albumin 2.6 g/dL (2.2-4.6 g/dL)
Globulin 8.1 g/dL (2.8-5.4 g/dL)
ALT 31 U/L (27-101 U/L)
AST 17 U/L (17-58 U/L)
ALP 35 U/L (14-71 U/L)
Gamma GT <3 U/L (0-4 U/L)
Cholesterol 143 mg/dL (89-258 mg/dL)
Total bilirubin < 0.1 mg/dL (0-0.2 mg/dL).

Serum Protein Electrophoresis: A polyclonal gammopathy with a mild decrease in albumin concentration and mild increases in the α_2 and β_1 fractions was present (see Figure 20-4). These changes were consistent with the acute-phase inflammatory response.

Imaging Findings: Abdominal ultrasound: The spleen was moderately enlarged. There was diffuse mesenteric lymphadenopathy (see Figure 20-8, *B*).

Mesenteric Lymph Node Aspirate Cytology: Intact nucleated cells were composed of a heterogenous population of lymphocytes, predominated by small, mature lymphocytes. Lower numbers of intermediate and large reactive lymphocytes, moderate numbers of mildly degenerate neutrophils, and scattered plasma cells and histiocytes were noted. Immunocytochemistry using two different monoclonal antibodies against FCoV was negative, but macrophages were low in number.

Microbiologic Testing: FeLV antigen and FIV antibody serology: negative
Serology (IFA) and blood culture for *Bartonella clarridgeiae* and *Bartonella henselae*: negative
Serology (IFA) for vector-borne diseases: negative for antibodies to *Ehrlichia canis*, *Neorickettsia risticii*, *Anaplasma* spp., and *Rickettsia* spp.
PCR for FCoV (whole blood): negative
PCR panel for other bloodborne pathogens *(Anaplasma phagocytophilum, Anaplasma platys, Bartonella* spp., *E. canis, N. risticii, Mycoplasma haemofelis):* negative
Aerobic and anaerobic bacterial culture of mesenteric lymph node aspirate: negative
Serology for FCoV: positive at 1:102,400

Diagnosis: A tentative diagnosis of FIP was made on the basis of Ricky's background, the marked polyclonal gammopathy, and the strongly positive coronavirus titer.

Treatment and Outcome: Biopsy of the enlarged mesenteric node was offered, but the owners declined. Ricky was treated with prednisolone (5 mg PO q12h for 7 days, followed by 5 mg PO q24h thereafter), chlorambucil (2 mg PO every 3 days), and pentoxifylline (50 mg PO q8h). Six weeks later, the cat was well and CBC variables within reference ranges. Serum total protein concentration was 8.5 g/dL, with a globulin concentration of 4.5 g/dL. Abdominal ultrasound examination showed persistent but mild mesenteric lymphadenomegaly (0.5 to 0.75 cm in diameter). A feline coronavirus titer was 1:25,600. Treatment with feline interferon-ω was commenced (4.5 million units SC once weekly). Ricky was seen again 3 months later, at which time he continued to be playful and appetent, with a stable body weight of 4.5 kg. A CBC showed mild anemia (HCT 29%), a neutrophil count of 4439 cells/μL, and lymphopenia (468 cells/μL). A chemistry panel and abdominal ultrasound showed no abnormalities. Chlorambucil and interferon-ω were discontinued. The next time the cat was reexamined was 12 months after the onset of illness, at which time he continued to be apparently healthy. CBC findings were unchanged, and the serum globulin concentration was 4.7 g/dL. The prednisolone dose was decreased to 5 mg q48h and pentoxifylline treatment was discontinued. One month later, albumin and globulin concentrations were 3.3 and 5.1 g/dL, respectively, and the prednisolone dose was reduced to 2.5 mg q48h. At the next 1-month recheck, a CBC was unremarkable but globulin was 5.7 g/dL. Abdominal ultrasound showed mildly enlarged mesenteric lymph nodes, and the serum coronavirus antibody titer was 1:409,600. The prednisolone dose was increased to 5 mg PO q24h; 1 month later, the serum globulin concentration was 4.9 g/dL. One and a half years after the onset of illness, Ricky was still apparently healthy according to the owner, but a midabdominal mass was palpated on physical examination, and the serum globulin concentration had increased again (5.6 g/dL). Abdominal ultrasound showed several moderately enlarged and hypoechoic lymph nodes in the ileocolic region, the largest of which was 0.9 cm in diameter. The surrounding mesentery was focally hyperechoic. There was also focal hyperechoic retroperitoneal tissue surrounding the right kidney with scant retroperitoneal fluid. Attempts to obtain aspirates from the lymph nodes were unsuccessful. The prednisolone dose was increased to 5mg PO q12h, and treatment with chlorambucil and pentoxifylline was reinstituted.

One week later, Ricky developed lethargy and inappetence. A CBC showed macrocytic anemia (HCT 24.3%, MCV 57.2 fL) and lymphopenia (782 cells/μL). A serum chemistry panel showed only hyperglobulinemia (5.8 g/dL). FeLV and FIV serology was repeated and was again negative, and the coronavirus antibody titer was 1:25,600. Treatment with cyproheptadine was initiated and the chlorambucil and pentoxifylline discontinued. However, inappetence continued, and persistent pyrexia (103.4° to 104°F), hematochezia, and tachypnea developed over the next few days. The hematocrit dropped to 16.5%, and hypokalemia, hyponatremia, and hypochloremia were identified. Ricky was hospitalized and treated with 1 unit of packed RBC, IV crystalloids, and parenteral antimicrobial drugs. Thoracic radiographs showed a severe, diffuse, patchy alveolar and nodular interstitial pattern with thickening of the bronchial walls and mild pleural effusion (see Figure 20-7). A tracheobronchial

VetBooks.ir

lavage showed marked mixed, predominantly pyogranulomatous inflammation with moderate epithelial hyperplasia and some degenerate neutrophils (see Figure 20-9). Immunocytochemistry with an anti-FCoV antibody was strongly positive in macrophages. Aerobic and anaerobic bacterial cultures of the wash specimen were negative. The cat subsequently seizured and was euthanized.

Necropsy Findings: Necropsy showed moderate to severe, multifocal to coalescing pyogranulomatous capsulitis and serositis that involved the spleen, liver, kidney, intestines, diaphragm, thoracic and abdominal walls, and pericardium. There was also multifocal pyogranulomatous splenitis, hepatitis, nephritis, meningoencephalitis, and pneumonia with necrosis. Straw-colored effusion was present in the abdominal cavity, thoracic cavity, and pleural space. Immunohistochemistry was strongly positive for FCoV antigen (see Figure 20-11).

Comments: The course of disease and survival time (587 days) in this cat was unusually prolonged for FIP, and on many occasions the diagnosis was questioned. However, the persistently increased FCoV antibody titer in a cat that lived with only one other cat raised suspicion for the disease. Chronic, smoldering FIP may be more common than recognized.[6] The initial clinical signs in this cat were mild and may have been overlooked by some owners. Although the cat appeared to respond to prednisolone treatment, it was not known whether the other medications used had any effect. Ultimately, disease progressed, and a diagnosis of FIP was confirmed with immunocytochemistry on the tracheobronchial lavage specimen. Although effusion developed, the amount was too low to permit collection of the fluid for analysis. The initial negative PCR and immunocytochemistry results may have reflected the presence of low quantities of virus.

CHAPTER 21

Feline Immunodeficiency Virus Infection

Jane E. Sykes

VetBooks.ir

Overview of Feline Immunodeficiency Virus Infection

First Described: California, 1986 (Pedersen)[1]; serologic evidence of infection dates back to the 1960s[2,3]

Cause: Feline immunodeficiency virus (FIV) (family Retroviridae, subfamily Orthoretrovirinae, genus *Lentivirus*)

Affected Hosts: Domestic and wild cats; hyenas

Geographic Distribution: Worldwide

Mode of Transmission: Biting, and to a lesser extent transplacental, through milk, possibly venereal, blood transfusion

Major Clinical Signs: Lethargy, fever, pallor, stomatitis, diarrhea, muscle atrophy, neurologic signs, signs of underlying neoplastic or immune-mediated disorders or opportunistic infections

Differential Diagnoses: FeLV infection, bartonellosis, other causes of stomatitis such as feline calicivirus infection, immune-mediated disease, other chronic inflammatory and neoplastic diseases of cats that occur in the absence of detectable infection with FIV.

Human Health Significance: FIV does not infect humans.

Etiology and Epidemiology

Feline immunodeficiency virus (FIV) is an enveloped, RNA virus that belongs to the *Lentivirus* genus of the Retroviridae. It infects domestic and wild cats worldwide, as well as hyenas.[4] Like HIV, FIV establishes a chronic, persistent infection that, in some cats, ultimately culminates in immunodeficiency. Because of its similarities to HIV, FIV infection in cats has been used as a research model for HIV infection and acquired immunodeficiency syndrome (AIDS),[5] and relative to other viral infections of companion animals, much is known about its pathogenesis.

Knowledge of retroviral structure and replication is required in order to understand diagnostic, treatment, and prevention strategies that target these viruses. Like other retroviruses, FIV has a three-layered structure that is composed of an innermost genome-nucleocapsid complex with helical symmetry, an icosahedral capsid, and an envelope with glycoprotein spikes (Figure 21-1). The FIV genome contains three major genes: *gag*, which encodes the virion core proteins (capsid [p24], nucleocapsid, and matrix); *pol,* which encodes the reverse transcriptase, protease and integrase enzymes; and *env*, which encodes surface (gp120) and transmembrane virion (gp41) envelope glycoproteins. Several other accessory and regulatory genes are also present. FIV invades cells via the primary receptor CD134, which is expressed on feline CD4+ T cells, B cells, and activated macrophages,[6,7] and the secondary receptor CXCR4, which is normally a chemokine receptor. The viral envelope fuses with the cell membrane, and the capsid enters the cytoplasm, where reverse transcription occurs and a double-stranded DNA (dsDNA) copy of the retroviral genome is made. Additional sequences, known as *long terminal repeats* (LTRs), are added to either end of the viral genome. The virus then passes into the nucleus where the dsDNA copy integrates into the host genome; at this point the integrated dsDNA becomes a *provirus*. Transcription of this DNA, which is controlled by the LTRs, leads to synthesis of new virion components, and virus assembly and budding occur at the cell surface (Figure 21-2). Depending on the cellular environment, proviral DNA may either be *latent*, whereby transcription does not occur, or be transcriptionally active. Latency is one mechanism by which retroviruses can evade the host immune system. Because the reverse transcriptase enzyme is prone to error, the mutation rate of retroviruses is high, and a diversity of viral variants continuously emerges from infected hosts. Integration of retroviral DNA into host cell DNA can disrupt genes that are responsible for cell growth and differentiation (proto-oncogenes). Alternatively, cellular oncogenes captured and carried by retroviruses develop mutations during retroviral replication, and are then re-inserted into host cell DNA. The end result is abnormal cell growth and differentiation, which results in tumor formation by some retroviruses.

Based on sequence diversity of the *env* gene, there are six different subtypes of FIV, A through F. Subtypes A and B are distributed most widely, followed by subtype C[8-10]—although a recent study from the United States showed an equal distribution of subtypes A, B, and C (Table 21-1).[11-31] In addition, a number of recombinant subtypes have been recognized, such as A/B, A/C, B/D, B/E, and A/B/C recombinants, and additional subtypes also likely exist.[9,11] The heterogeneity of the virus complicates the design of molecular diagnostic tests and vaccines for FIV. Whether differences in the clinical manifestations of disease relate to infection by different subtypes requires further study.[9,10,31]

Retroviruses survive only minutes outside the host and are very susceptible to disinfection. FIV is shed in high concentrations in saliva, and the major mode of transmission is through bites. Transplacental transmission, transmission during parturition, and through milk have been documented experimentally, but these modes appear to be uncommon in naturally infected cats, and kittens infected by this route may not sustain productive infection.[32,33] Venereal transmission has not been demonstrated, but FIV can be recovered from semen, and experimental inoculation of FIV into the vaginas of queens results in transmission.[34,35] Transmission also has the potential to occur through blood donation.

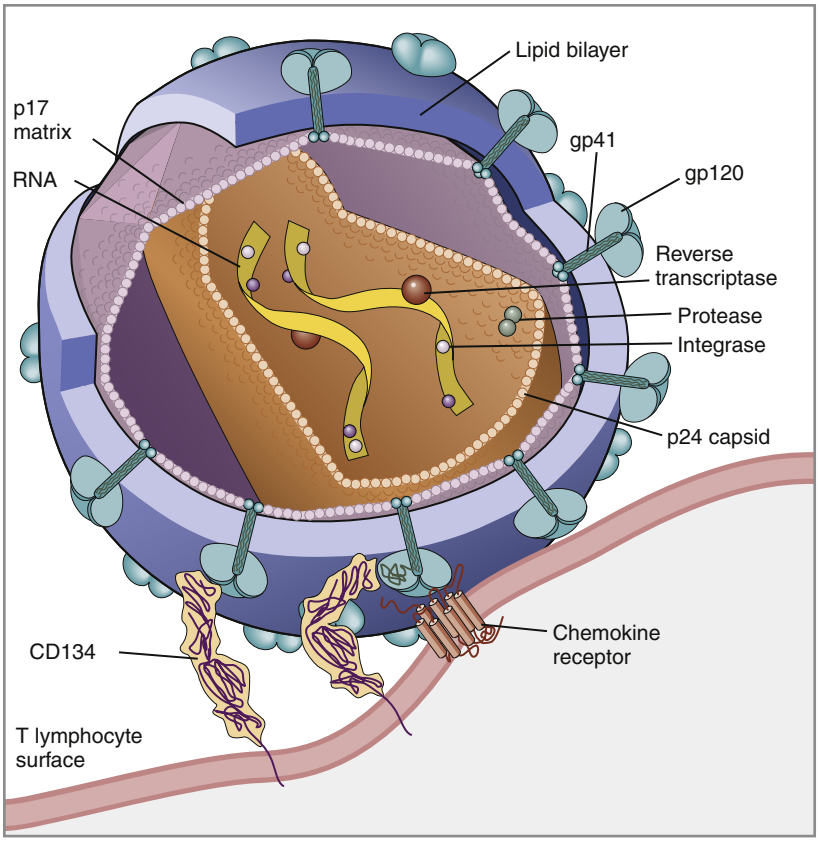

FIGURE 21-1 Structure of FIV. An FIV virion is shown adjacent to the surface of a CD4+ T cell. Lentiviruses contain two identical strands of RNA (the viral genome) and associated enzymes, which include reverse transcriptase, integrase, and protease, packaged into a core composed of the p24 capsid protein with a surrounding p17 protein matrix, all enclosed by a phospholipid membrane envelope that is derived from the host cell. Viral encoded membrane proteins (gp41 and gp120) are bound to the envelope. CD134 and CXCR4 (chemokine) receptors on the host cell surface function as the receptors for FIV.

Seropositivity to FIV (which is equivalent to infection because of viral persistence) is consistently associated with a history of bite wounds, older age, male sex, illness, and outdoor access (Table 21-2).[12,36-41] Being of mixed breed has also been a risk factor in some studies. The mean age at diagnosis is around 6 to 8 years, and 80% to 90% of cats are more than 2 years of age. Male cats are up to 4.7 times more likely to be seropositive than female cats.[40] Indoor housing decreases transmission but does not eliminate it.[42] Worldwide, the seroprevalence of FIV in domestic pet cats ranges from around 1% to 12%.[9,40,41] A study that included more than 18,000 North American cats estimated the overall prevalence of FeLV and FIV infections as around 2.3% and 2.5%, respectively.[5] Higher prevalences are found in feral and free-ranging cats and sick cats. In the North American study, the prevalence of FIV infection in sick, feral cats was 18.2%, whereas that in healthy indoor cats was only 0.7%. A study from France showed a seroprevalence of 21% in unowned cats, compared with 10% in owned cats.[43] In Japan, the overall seroprevalence is very high (23% in one study), and as many as one-third of male cats test positive.[12] Occasionally, co-infections with FeLV occur, and infection with one retrovirus is a risk factor for infection with the other.[36,37]

Clinical Features

Signs and Their Pathogenesis

The main cellular target for FIV is the CD4+ T cell. However, FIV also infects CD8+ T cells, B cells, macrophages, and dendritic cells, microglia, and astrocytes. The subsequent effects of the virus on the immune system are complex, incompletely understood, and seem to result in both immune suppression and immune activation.

Three phases of disease have been delineated, *acute (primary)*, *subclinical*, and *terminal*, although not all phases are recognized in many naturally infected cats. After inoculation, the virus replicates in lymphoid tissues, and high concentrations of virus are present in blood 2 weeks after infection. A peak of viremia occurs 8 to 12 weeks after infection (Figure 21-3). There is a decline in CD4+ and CD8+ T cells in peripheral blood. This may be associated with transient illness, which lasts 3 to 6 months and is often unrecognized by cat owners. Some cats show lethargy, fever, anorexia, diarrhea, stomatitis, weight loss, and/or lymphadenopathy during the acute phase. Lymphadenopathy results from lymphoid hyperplasia, and can persist for weeks to months. Neutropenia can also occur,[44] possibly as a result of neutrophil apoptosis. CD4+/CD25+ T regulator (Treg) cells are infected and activated during the acute phase. These cells then inhibit the proliferation of activated CD4+ and CD8+ T cells, and cause them to undergo apoptosis. This may contribute to persistence of FIV and further immunosuppression.[45-47] Altered dendritic cell function may also occur.[48,49] In general, impaired T cell function in acute infection is thought to result from cytokine dysregulation, immunologic anergy (failure to respond to specific antigens), and increased apoptosis.[45] Nevertheless, most cats survive this phase because of a rebound in CD8+ T cell numbers and a strong humoral immune response.

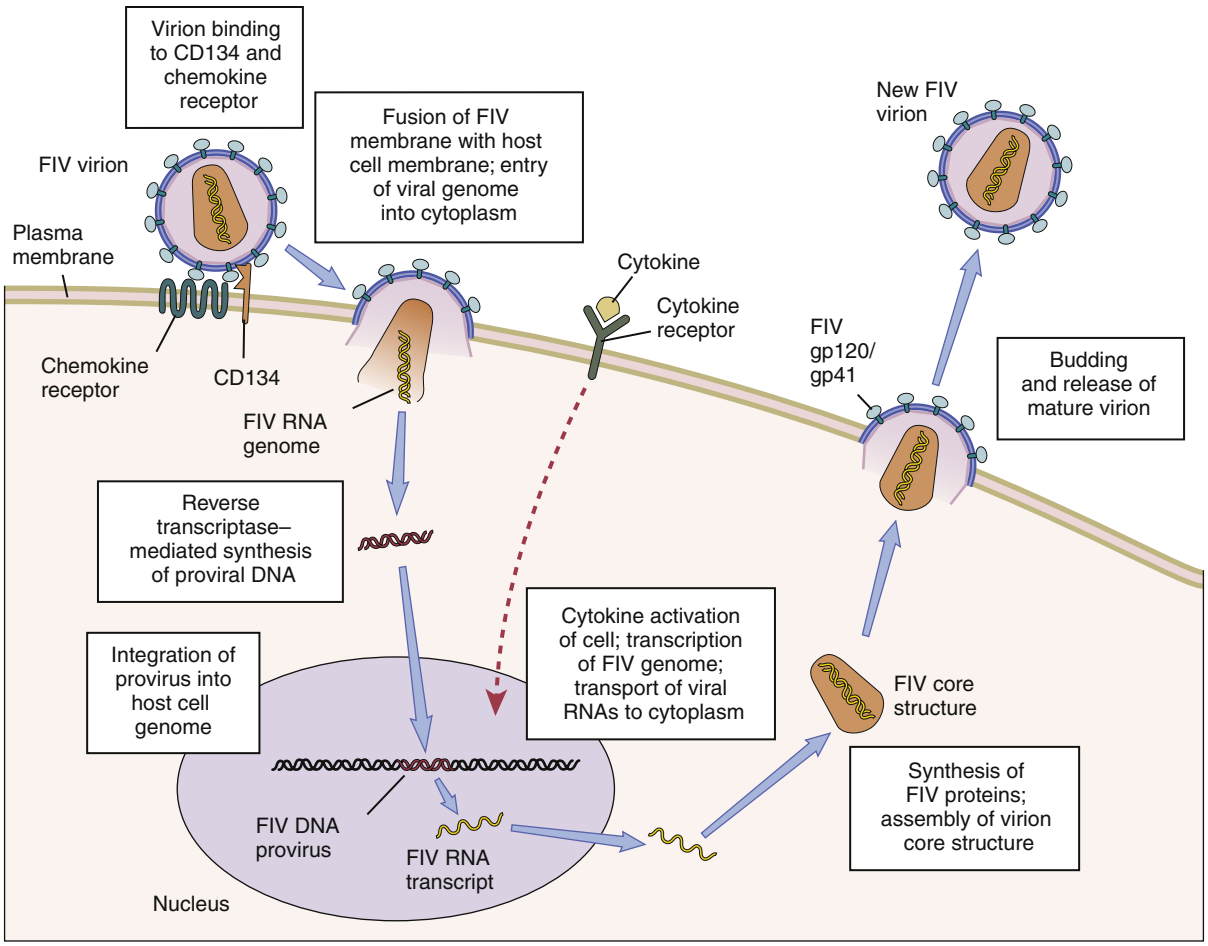

FIGURE 21-2 The life cycle of FIV. The sequential steps in FIV reproduction are shown, from initial infection of a host cell to release of a new virus particle. An infected cell produces many virions, each capable of infecting nearby cells, with subsequent spread of the infection.

TABLE 21-1

Distribution of FIV Subtypes Worldwide

A	Australia, New Zealand, United States (especially western United States), South Africa, northwestern Europe, Japan, United Kingdom[11-19]
B	Central and eastern United States, Caribbean, central and western Europe, Brazil, eastern Japan[11,14,20-25]
C	United States, Canada, New Zealand, southeast Asia[11,12,26-29]
D	Japan, Vietnam, rarely United States[21,27,31]
E	Argentina[10,30]
F	United States[10,31]

In the subclinical (or asymptomatic) phase, CD4+ T cell numbers rebound, and the plasma virus load declines to very low levels. Cats remain subclinically infected, often for years or even for life. This is not latent infection, because virus production continues at low levels; a slow, progressive decline in CD4+ T cell numbers; reduction in the CD4+:CD8+ T cell ratio; and in some cats, hyperglobulinemia, which results from B cell hyperactivation. Some studies also describe a sustained increase in CD8+ T cell numbers. Although activated, paradoxically, T cells have a reduced ability to respond to antigenic stimulation. Altered lymphocyte expression of cell surface molecules (including CD4 and cytokine receptors, and MHC II antigens), and continued alteration of dendritic cell and neutrophil function also contribute to immunosuppression. Dysregulation of cytokine production occurs. For example, cats that are chronically infected with FIV fail to produce Il-2, Il-6, and Il-12 in response to *Toxoplasma gondii* infection and instead produce elevated levels of the antiinflammatory cytokine Il-10.[45,50] There is a slow influx of immune cells into the brain, with gradual progression of central nervous system (CNS) disease.[51] The rate of progression of the subclinical phase depends on factors such as the virus strain, co-infections with other agents that activate virus transcription, and host immunity.

In some cats, these changes ultimately lead to the terminal phase, which is characterized by clinical signs of opportunistic infections, neoplastic disease, myelosuppression, and neurologic disease. This is the phase most commonly recognized in naturally infected cats (Table 21-3). However, many infected cats never develop FIV-related clinical signs, even when CD4+ T cell counts are low, and instead die from other causes. The terminal phase of FIV infection is commonly associated with moderate to severe periodontal disease, lymphoplasmacytic stomatitis (Figure 21-4), gingivitis, and feline odontoclastic resorptive

ÅòIn other words, female cats were four times less likely to be FIV+ than male neutered cats.

lesions,[52] which may result from opportunistic bacterial and viral infections. Other opportunistic infections include chronic bacterial skin and ear infections, persistent viral upper respiratory tract infections, dermatophytosis, mycobacterial infections, fungal infections such as cryptococcosis and sporotrichosis, hemoplasmosis, toxoplasmosis, and/or parasitic infections such as demodecosis and severe flea burdens. With the exception of stomatitis, the relationship between many of these opportunistic infections and FIV infection is somewhat unclear, because the prevalence of many of these infections in cats with FIV infection is similar to that in cats without FIV infection. However, infections are often more severe and less responsive to treatment than the same infections in immunocompetent cats.

The development of neoplasia in FIV-infected cats is thought to result primarily from immune suppression, although there is serologic evidence that cats may be infected with a gammaherpesvirus similar to Epstein-Barr virus that might be reactivated in cats infected with FIV.[53] Lymphomas are the most commonly reported FIV-associated tumor, especially B cell lymphomas, but also T cell and non-B, non-T cell lymphomas.[54] FIV-infected cats are 5 times more likely to develop lymphoma than cats not infected with FIV and are more likely to develop it an earlier age. Leukemia and squamous cell carcinomas (SCCs) are also common tumors in cats with FIV, although the association with SCC may be confounded by outdoor exposure. Other tumors include mast cell tumors, fibrosarcomas, meningiomas, and metastatic carcinomas; some infected cats develop more than one type of neoplasia. Rarely, lymphoma may develop as a result of viral integration into the genome and disruption of proto-oncogenes.[54,55]

Immune dysregulation and increased circulating immune complexes in the terminal phase can lead to immune-mediated disorders, such as immune-mediated glomerulonephritis and uveitis.[56] Myelodysplasia develops in some cats,[57,58] which may be manifested by clinical signs of lethargy, inappetence, pallor, or evidence of bleeding tendencies such as petechial hemorrhages.

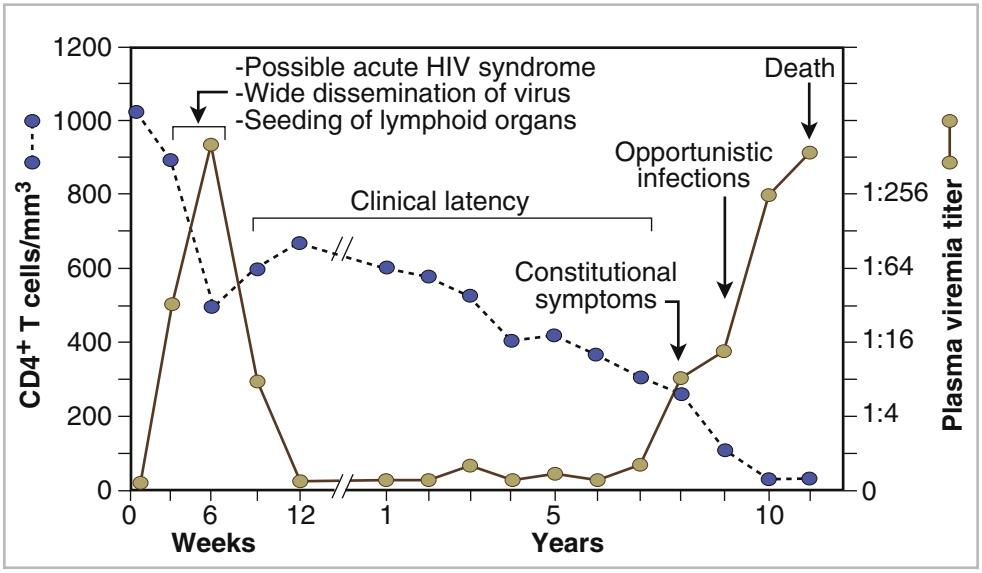

FIGURE 21-3 Changes in virus load and CD4+ T Cell numbers over the course of infection with HIV. A similar clinical course of infection occurs for FIV infection. Viremia is detected early after infection and may be accompanied by systemic signs (acute phase). Plasma viremia then falls to very low levels and remains this way for many years (subclinical phase). Although this period is referred to here as "clinical latency," the virus itself is not latent during this time, because there is ongoing production of virus and a steady decline in CD4+ T cell counts. In the terminal phase of infection, signs of immunodeficiency develop and plasma viremia increases. Some infected cats never reach this phase. Antibody production declines, and antibody tests may be negative in cats with advanced terminal-phase disease, but PCR assays are more likely to be positive.

*Results should be interpreted with caution because the data were retrospectively collected. Some cats may have had undiagnosed disease, such as subclinical chronic kidney or cardiac disease. The pathogenesis of a disease process in FIV-positive cats might also differ from that found in FIV-negative cats.

†All cats were >6 months of age and none had a history of FIV vaccination.

‡All control cats were negative for FIV antibody at their visit to the University of California, Davis.

§As determined by chi-square (univariate) analysis. P-values <0.05 were significant.

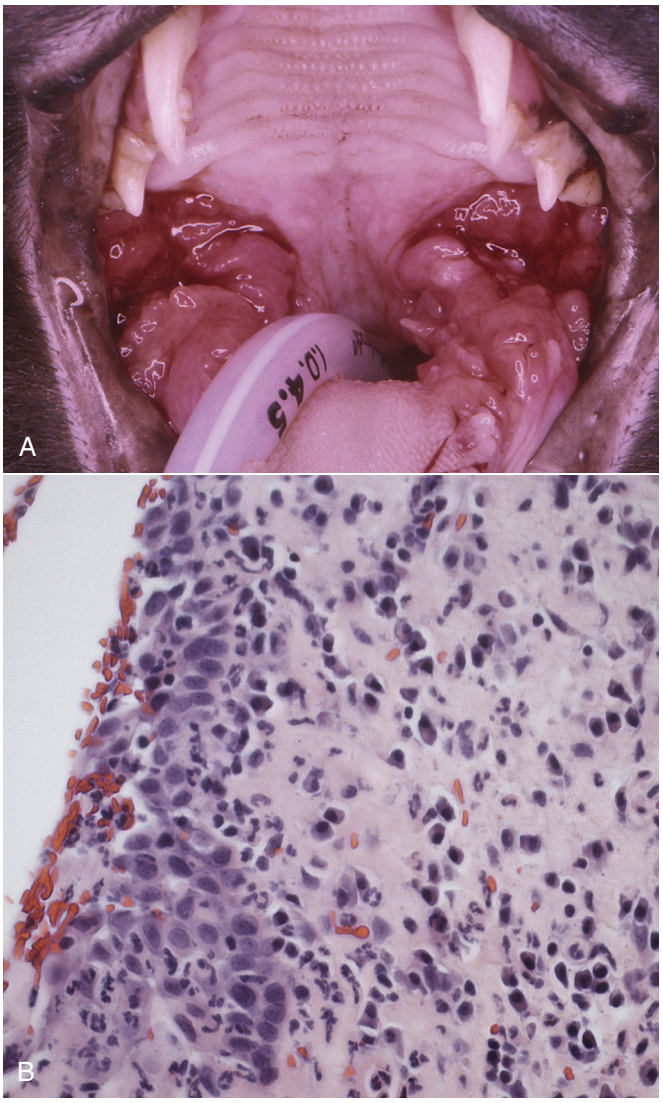

FIGURE 21-4 severe lymphoplasmacytic stomatitis in a cat infected with feline immunodeficiency virus. **A,** There is marked hyperemia, ulceration, and proliferative lesions in the palatoglossal folds. (From Bonello D, Roy CG, Verstraete FJM. Non-neoplastic proliferative oral lesions. In: Verstraete FJM, Lommer MJ, eds. Oral and Maxillofacial Surgery in Dogs and Cats. Philadelphia, PA: Saunders; 2011.) **B,** Histopathology of a biopsy from a cat with severe stomatitis associated with FIV infection.

The end result of infection by neurovirulent strains of FIV can be progressive behavioral changes such as increased aggression and cognitive disturbances, tremors, sleep disturbances, anisocoria, delayed reflexes, abnormal cranial nerve function, urinary and fecal incontinence, and seizures. Decreased nerve conduction velocities and abnormal electroencephalograms and brainstem evoked potentials have been documented.[59] The virus does not infect neurons, but neuronal cell death occurs through multiple incompletely defined mechanisms.[51]

Inflammatory lesions can develop in a variety of organs in cats infected with FIV. An inflammatory myopathy has been described,[60] and terminally, severe muscle atrophy can occur. Infection is associated with gut inflammation and intestinal epithelial cell damage (also known as AIDS enteropathy), which may result in chronic diarrhea and failure to gain weight.[61] The extent to which chronic FIV infection contributes to inflammatory or degenerative changes in other organs, such as the myocardium and the kidneys, is not well understood, because the prevalence of cardiomyopathy and interstitial nephritis in geriatric cats not infected with FIV is high (see Table 21-3).

When transplacental transmission occurs in FIV-infected queens, only some kittens in a litter may be infected. In the first year of infection, the overall rate of such transmission is around 70%.[62] Rates of mother-to-kitten transmission are highest in queens that have a CD4+ count less than 200 cells/μL, those with signs of immunodeficiency, and those infected within the past 15 months.[63] In utero transmission can lead to arrested fetal development, abortion, stillbirth, low birth weights, and the birth of T cell deficient kittens.[62,64]

Physical Examination Findings

Many cats infected with FIV have no signs of illness, or clinical signs that are unrelated to FIV infection. Cats in the acute

VetBooks.ir

TABLE 21-4

Diagnostic Assays Available for Feline Immunodeficiency Virus Infection

Assay	Specimen Type	Target	Performance
Serology (ELISA, Western blotting, IFA)	Blood, serum	Antibody to FIV	Positive test results in cats >6 months of age that have not been vaccinated for FIV equal infection, but confirmation is recommended in healthy cats using a second test from a different manufacturer or Western blot. False positives occur in cats <6 months of age (maternal antibody) and cats vaccinated with the FIV vaccine. False negatives can occur in the first 2 months of infection or with advanced disease and severe immunosuppression.
PCR	Blood	FIV proviral DNA or viral RNA	Sensitivity and specificity vary between laboratories. Even well-designed assays may be insensitive because of viral variability and low-level viremia. PCR assays are the only assay that can definitively diagnose infection in cats vaccinated for FIV. Never use without performing serology.
Virus isolation	Blood	FIV	Difficult, not widely available. Used primarily as a research tool.

IFA, immunofluorescent antibody.

phase of FIV infection may be febrile or show generalized peripheral lymphadenopathy. Behavioral abnormalities such as obtundation, aggression, and cognitive impairment may be evident in cats with terminal neurologic disease; other neurologic abnormalities include ataxia, anisocoria, and abnormal segmental reflexes. Ocular abnormalities may be present as a result of the FIV infection itself, opportunistic infections, or lymphoma, and include anterior uveitis, hyphema, pars planitis, chorioretinitis, and/or glaucoma.[65] Other common physical examination findings in cats with terminal disease are periodontal disease and chronic stomatitis, signs of chronic upper respiratory tract infection, otitis externa, pyoderma, cutaneous abscesses, and a diverse and variable spectrum of disease manifestations that relate to other underlying opportunistic infections or neoplasia.

Diagnosis

For many cats, infection with FIV is diagnosed during screening efforts. Screening for infection should be performed with tests that detect antibody against FIV, because these assays have the highest overall sensitivity and are rapid and widely available (Table 21-4). It has been recommended that the retrovirus status of all cats be known regardless of the presence of absence of illness.[66] Indications for testing as recommended by the American Association of Feline Practitioners (AAFP) are shown in Box 21-1. In practice, compliance with retrovirus testing is low. In a study that evaluated 967 cats with bite wounds or cutaneous abscesses that presented to veterinary practitioners from 134 practices in 30 states, the combined FeLV-FIV status of only 96 (9.9%) of the cats was known.[38] In addition, despite the availability of a financial incentive for retesting, only 64 of 478 cat owners returned their cats for retesting after treatment.

When positive test results occur in sick cats, the role that FIV plays as a cause of the signs may be unclear, although it is reasonable to assume that FIV may be playing a role in cats with severe stomatitis, unusual infections with intracellular pathogens such as mycobacteria, and lymphoma. With refinement and improved availability of test methodologies in the future, clinical assessment of CD4+ T cell counts, the CD4+/CD8+ ratio, and plasma viral loads may facilitate interpretation of the relationship between disease manifestations and infection and provide prognostic information, as in human patients infected with HIV.[67]

BOX 21-1

Indications for Serologic Testing for FIV and FeLV

- Sick cats, even if tested negative in the past
- All newly acquired cats or kittens (2 tests, at least 60 days apart)
- After exposure to a retrovirus-infected cat or a cat with unknown status, and especially after a bite wound (2 tests, at least 60 days apart)
- Cats that live in a household with other retrovirus-infected cats (annual retesting unless isolated)
- Before initial vaccination with FeLV or FIV vaccines
- Before use as a blood donor (in conjunction with real-time PCR)
- On entry to a shelter or before adoption (2 tests, at least 60 days apart); if financial resources are not available for this, cats should be held singly and postadoption testing (2 tests, at least 60 days apart) recommended before mingling with other cats occurs. The status of the other cats in the household should be known before new cats are introduced.
- For group-housed cats, before introduction (2 tests, at least 60 days apart if possible) and on an annual basis
- Testing is considered optional for feral cat trap-neuter-return programs

Laboratory Abnormalities

Complete Blood Count

Common abnormalities on the CBC in cats infected with FIV include mild anemia, lymphopenia, and neutropenia. Occasionally severe anemia, thrombocytopenia, thrombocytosis, monocytopenia, or leukocytosis occur. In one large European study, neutrophil counts of FIV-infected cats were lower than those of control cats, and lymphocyte counts were higher than those of control cats.[68] Leukopenia and neutropenia were more likely to be present in FIV-infected cats.

Serum Biochemical Tests

The most common and significant abnormality on the chemistry panel in cats infected with FIV is hyperproteinemia, which results from increased γ-globulin concentrations and is a direct result of FIV infection (rather than the result of opportunistic infection). Total protein concentrations that ranged from 4.5 to 11 g/dL were reported in one study.[68] Other findings are variable and relate to the presence of concurrent disease, neoplasia, or opportunistic infections.

Urinalysis

Urinalysis may reveal proteinuria in cats with glomerulonephritis.

Coagulation Testing

Cats infected with FIV can have mild prolongations in their APTT, thrombin time, and fibrinogen concentrations, although the PT and platelet function are generally normal.[69]

Cytologic Evaluation of Bone Marrow

Bone marrow cytologic evaluation in FIV-infected cats with cytopenias and nonregenerative anemias may show mild dysplasia (usually not as severe as in FeLV infections); erythroid hypoplasia; and/or myeloid hyperplasia despite peripheral leukopenia, sometimes with a left shift. The latter suggests ineffective hematopoiesis or maturation arrest.

Microbiologic Tests

Serologic Diagnosis

The initial assay of choice for diagnosis of, and screening for, FIV infection is an ELISA assay that detects antibody to FIV. Provided there has not been a history of vaccination for FIV and the tested cat is less than 6 months of age, positive antibody test results equate with infection, because the virus establishes a lifelong, persistent infection. Point-of-care, lateral-flow ELISA assays and diagnostic laboratory-based ELISA assays are in widespread use and have rapid turnaround times and high sensitivities and specificities.[70] These assays usually detect antibodies to the FIV p24 core protein, and sometimes to the gp40 transmembrane protein. False positive test results occur rarely as a result of operator error or nonspecific reactivity against tissue culture components after vaccination.[71] When Western immunoblotting was used as the gold standard, the sensitivities, specificities, and positive and negative predictive values of six different ELISA assays (Synbiotics Witness, Viracheck FIV, IDEXX SNAP Combo Plus, PetChek Plus Anti-FIV, MegaCor Fastest, and Bio Veto Duo Speed) in one U.S. study of 535 cats with an overall FIV seroprevalence of 10.3% ranged from 94.5% to 100%, 98.5% to 100%, 91.2% to 100%, and 99.2% to 100%, respectively.[70] The Mapic FIV test had a high (23.1%) rate of invalid test results and was not recommended for clinical practice. When these assays are used to screen healthy cats for infection, confirmation of positive results is recommended because of the low prevalence of infection in this population of cats and the higher possibility that false-positive test results may occur. Confirmation can be done using an assay from a different manufacturer or Western blotting. However, Western blotting is technically demanding, subject to interoperator variability in interpretation, and it may be less sensitive than ELISA assays when performed by some laboratories.[72]

Positive ELISA assay results in the absence of FIV infection can occur in cats that have been vaccinated for FIV, or kittens less than 6 months of age that possess maternal antibody (because of infection or vaccination of the queen). No currently available serologic test, including Western immunoblotting, distinguishes between natural infection and vaccination or the presence of maternal antibody. Kittens that test positive should be retested after 6 months of age (the Advisory Bureau on Cat Diseases recommends retesting after 4 months of age).[66,73] Nevertheless, kittens less than 6 months of age should still be tested, because the vast majority of negative kittens will be declared free of infection. Molecular testing could be considered to confirm infection in kittens that test positive at less than 6 months of age (see later discussion). Cats with a history of FIV vaccination may remain antibody-positive for more than 4 years.[66] Because infection can occur in the face of vaccination, positive test results in a vaccinated cat may represent infection and/or historical vaccination. Currently, molecular testing with PCR assays is required to identify infection in these cats, but some infected cats test PCR-negative. An ELISA assay has been developed that can distinguish naturally infected from vaccinated cats, but this assay is not commercially available. The assay was used to test blood samples from 73 uninfected, unvaccinated cats; 89 uninfected, FIV-vaccinated cats; and 102 FIV-infected cats, including 3 cats that had been vaccinated.[9] The assay had a sensitivity of 97% and a specificity of 100% for detection of FIV infection in these cats.

False-negative ELISA assay results occur early in the course of illness, because cats may take up to 60 days to develop an antibody response.[66] Rarely, antibody production is delayed for 6 months or longer. Thus when recent exposure is possible, testing should be repeated a minimum of 2 months later. False-negative test results also occur in cats in the terminal phase of disease, as a result of impaired antibody production, or in kittens with rapidly progressive infections. These cats often have high plasma viral loads. Thus, if advanced FIV infection is suspected, negative test results should be followed by virus detection using PCR. When serology is used as a *screening test*, negative results are considered to be highly reliable because of the high sensitivity of the test and the low prevalence of infection in most populations of healthy cats.[66]

Immunofluorescent antibody (IFA) assays that detect antibodies to FIV have also been described. When performed by experience laboratory personnel, these have sensitivities and specificities that range from 95% to 100% when compared with Western immunoblotting.[71]

Molecular Diagnosis Using the Polymerase Chain Reaction

A variety of PCR assays have been developed for diagnosis of FIV infection. Assays may detect viral RNA (reverse transcriptase [RT]-PCR), proviral DNA, or both RNA and proviral DNA in peripheral blood. Because the FIV vaccine is inactivated and

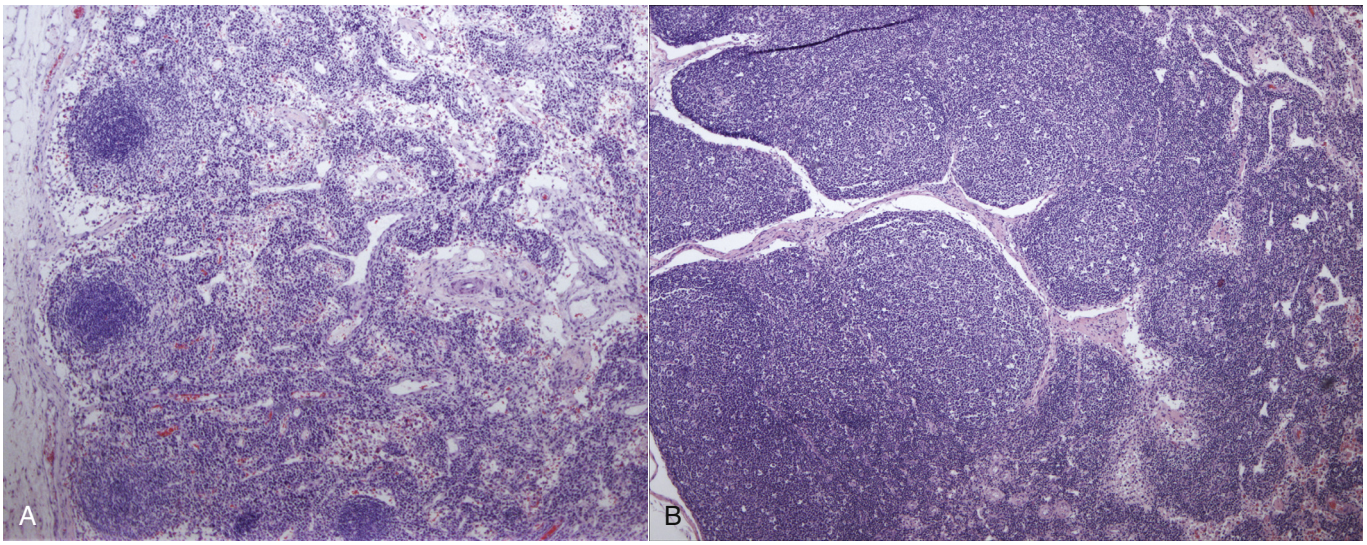

FIGURE 21-5 **A,** Depletion of paracortical areas in the mesenteric lymph node of an 8-year-old female spayed domestic shorthair with FIV infection that was euthanized as a result of the development of progressive neurologic signs. **B,** Normal feline lymph node for comparison purposes.

does not replicate or integrate into the host genome, PCR assays should not detect vaccine virus in cats that have been vaccinated for FIV. Compared with serology, PCR can be insensitive (sensitivity <80%), because viral loads in healthy cats are often extremely low, and some strains may not be detected because of variability in the sequence of the viral genome among FIV isolates. Sensitivity is likely to be higher in cats in the acute and terminal phases of disease when viral loads are higher, but this requires further study. False-positive test results have the potential to occur as a result of laboratory contamination; in some commercial laboratories, unacceptable sensitivities and specificities have been reported (as low as 41% and 44%, respectively).[74,75] In advertising materials, IDEXX Laboratories report an assay sensitivity and specificity of 80.5% and 99.9%, respectively, among 36 FIV-infected cats, 96 uninfected vaccinated cats and 92 uninfected unvaccinated cats, with no difference in specificity in the latter two groups.[76] A FRET real-time PCR assay directed at the *gag* gene has been described that differentiates between FIV subtypes (see Chapter 5 for an explanation of FRET PCR assays).[11] The assay was positive in 60% of 101 cats with positive antibody tests for FIV. A history of vaccination with the FIV vaccine was present in 13 of the cats, and all these cats tested negative. The vaccination history of the remaining cats was unknown. Given their limitations, PCR assays should not be used for diagnosis of FIV infection in the absence of concurrent serologic testing, and the results of PCR assays should not be used to decide whether vaccination should be performed. Cats that are seronegative that test positive with PCR may be in the terminal phase of disease and unable to produce antibody, or the PCR assay result may be a false positive. Latently infected cats have rarely been described that test positive for proviral DNA but negative for antibody.[76] These cats lack any immunologic or clinical abnormalities that occur with active infection.[76] Whether these cats are likely to develop productive infection (as reported in humans with latent HIV infection) is unknown.[77]

Virus Isolation

FIV can be isolated from peripheral blood lymphocytes in primary feline T cell cultures, but this is technically demanding and expensive and can take 2 to 3 weeks, so it is not used for routine diagnostic purposes.

Pathologic Findings

Gross pathologic findings in cats with FIV infection include emaciation, stomatitis, lymphadenopathy, and evidence of secondary neoplasia or opportunistic infections. Evidence of disorders of aged cats, such as hyperthyroidism, cardiomyopathy, and interstitial nephritis, may also be present. Histopathologic changes in cats with FIV infection include follicular hyperplasia or, in the chronic phase, lymphoid depletion in the paracortical regions and plasma cell infiltration of lymph nodes (Figure 21-5); lymphoplasmacytic ulcerative stomatitis (see Figure 21-4, *B*); and bone marrow pathology as described previously in this chapter. Evidence of chronic interstitial nephritis, sometimes with membranous glomerulonephritis and glomerulosclerosis, may be present. Inflammatory changes may be seen within skeletal muscle and/or the gastrointestinal tract. Histopathology of the CNS in cats infected with neurovirulent FIV strains may show mild lymphoplasmacytic meningitis, perivascular lymphocytic infiltrates, diffuse gliosis, microglial nodules, and mild neuronal degeneration and apoptosis.[59,78] Neuronal dysfunction may be more important than neuronal loss.[59]

Treatment and Prognosis

Supportive Care

Cats in the terminal phase of FIV infection may require fluid therapy, nutritional support, regular dental prophylaxis, dilute chlorhexidine-based mouth washes or oral gels, and dental extractions and antimicrobial drugs with activity against anaerobes for severe stomatitis (Table 21-5). Whole mouth extractions have been beneficial for some cats with severe stomatitis, but it is critical that all tooth roots be removed. Referral to a board-certified veterinary dentist should be considered. Topical glucocorticoids (e.g., 1% prednisolone acetate, every 4 to 12 hours depending on severity) and topical atropine are indicated for cats with anterior uveitis. Systemic glucocorticoids should only be used if absolutely necessary, because their use

VetBooks.ir

TABLE 21-5

Suggested Medications for Treatment of Cats in the Terminal Phase of Feline Immunodeficiency Virus Infection

Drug	Dose	Route	Interval (hours)	Comments
Zidovudine (AZT)	5 to 15 mg/kg	PO	12	May have benefit for cats with neurologic signs or stomatitis. Monitor CBC (see text). Toxicity may be more likely at doses above 5 mg/kg.
Human recombinant interferon alpha	1 to 50 U/cat	PO	24	For stomatitis
0.12% Chlorhexidine plus zinc gluconate oral gel	1 mL	Topical	12 to 48	For stomatitis
Clavulanic acid–amoxicillin	12.5 to 25 mg/kg	PO	12	For stomatitis
Lactoferrin	200 mg powder or 40 mg/kg solution	Topical	24	For refractory gingivitis and stomatitis. Must be purchased from chemical suppliers.
Prednisolone	5 mg	PO	24	For refractory stomatitis or advanced neurologic disease. May also be required for lymphoma or other CNS neoplasms. Use only if absolutely necessary.

is associated with increased plasma viremia. Some cats with advanced neurologic signs show clinical improvement after treatment with glucocorticoids. Opportunistic infections may respond to appropriate antimicrobial treatment, but prolonged or lifelong treatment may be required. Griseofulvin should not be used to treat dermatophytosis, because it has been associated with bone marrow suppression in FIV-positive cats.[79] Recombinant human erythropoietin or darbepoetin may be useful for some cats with nonregenerative anemia and does not appear to increase viral load through activation of transcription of latent virus.[80] Although recombinant human granulocyte colony stimulating factor (G-CSF) can increase neutrophil counts in cats infected with FIV, antibodies can develop within a few weeks that cross-react with endogenous G-CSF. When recombinant human granulocyte-macrophage colony stimulating factor (GM-CSF) was used, an increase in virus load occurred, so the use of these drugs is not recommended.

Antiviral and Immunomodulator Drugs

Topical lactoferrin administration has been associated with clinical improvement in some FIV-infected cats with stomatitis (see Chapter 7). Cats with stomatitis or neurologic disease may benefit from oral or subcutaneous treatment with zidovudine (AZT), but AZT can cause bone marrow suppression, so the CBC must be monitored weekly for the first month and monthly thereafter. Treatment is not recommended for cats with myelosuppressive disease.[73] AZT should be discontinued if the hematocrit drops below 20%, after which anemia usually resolves in a few days.[73] AZT-resistant FIV mutants can develop as early as 6 months after the start of treatment. Fozivudine (45 mg/kg PO q12h) reduces viremia in cats with acute FIV infection and may be less likely to produce hematologic adverse effects.[81] Plerixafor (AMD3100), a selective antagonist of the CXCR4 receptor, is active against FIV in vitro.[82] When used in 40 naturally infected cats for 6 weeks in a placebo-controlled double-blind study, a decreased proviral load was reported without evidence of adverse effects, but there was no improvement in clinical or immunologic variables.[73,83]

Results of treatment with human recombinant IFN-α have been mixed, but prolonged survival was reported in 24 FIV-infected cats after oral administration of a low dose of the drug when compared with 6 untreated control cats.[83] Clinical scores and laboratory parameters improved in some sick, naturally infected cats that were treated with recombinant feline IFN-ω, despite no significant changes in viral load.[84]

Management of FIV-Infected Cats

Cats that test positive for FIV should be housed indoors to prevent transmission to other cats, as well as to protect them from other infections. The latter is important even in subclinically infected cats, as other infections have the potential to activate viral transcription and accelerate disease progression. The feeding of raw foods and hunting behavior should be avoided. Cats should be neutered to reduce the chance of roaming and aggressive interactions with other cats. Minimally, FIV-positive cats should be rechecked every 6 months in order to monitor body weight, assess for periodontal disease, and discuss the need for routine laboratory testing and vaccination with core vaccines. A complete physical examination, CBC, serum biochemistry panel, and urinalysis are recommended on an annual basis.[66] At least during acute FIV infection, cats can mount an immune response to vaccines,[85,86] but because vaccination with core vaccines may activate viral transcription, vaccination should be performed only for FIV-positive cats that are likely to be exposed to other cats. The use of inactivated vaccines is recommended, because of the potential for vaccine-induced disease in immunosuppressed cats.[73] When hospitalized, FIV-infected cats should be kept in separate cages *away from* isolation, where there may be other cats with transmissible infectious diseases. Perioperative antimicrobial drug treatment

VetBooks.ir

could be considered for cats that undergo invasive surgery or dental treatments.[66,73]

Prognosis

A limited number of studies have shown no significant difference in life span between FIV-infected cats and uninfected cats.[42,87] In one study, the median survival times of these two groups after testing for FIV infection were 3.9 (39 cats) and 5.9 (22 cats) years, respectively.[87] In a larger study of more than 1000 FIV-infected cats and more than 8000 age- and sex-matched control cats, the median survival times of the two groups were 4.9 years and 6.0 years, respectively.[66] The progression and severity of disease is related to virus strain and host immunity. Infection of geriatric and neonatal cats is associated with more rapid progression and severity of disease than infection of young adult cats.[84,88] For example, progression to terminal immunodeficiency can occur within 2 months in kittens.[89] Because the life span of FIV-infected cats may not differ greatly from that of uninfected cats, no cat should be euthanized on the basis of a positive FIV test alone.[66,73] However, other factors, such as control of the infection in group-housed or breeding cats, may necessitate euthanasia or rehoming of some cats that test positive. Once terminal FIV-related disease occurs, life spans are typically less than 1 year.

Immunity and Vaccination

The FIV vaccine first became available in the United States in July 2002 (Fel-O-Vax FIV, Fort Dodge Animal Health) and is an inactivated, adjuvanted, whole-virus vaccine that contains FIV Petaluma (subtype A) and FIV Shizuoka (subtype D). The vaccine has been available in New Zealand and Australia since 2004. It is licensed for the vaccination of healthy cats that are 8 weeks of age or older as an aid in the prevention of FIV, and in experimental challenge studies, protected 60% to 80% of cats from infection. The introduction of the vaccine generated controversy, because (1) existing serologic assays cannot differentiate between natural infection and vaccination, (2) vaccination provides only partial protection from infection, and (3) PCR assay results cannot be relied upon in vaccinated cats. Although concerns exist that the vaccine may only protect against infection with strains from homologous subtypes, studies have shown moderate protection against infection with subtype B strains.[90,91] In one study, 10 of 14 cats were protected from subtype B infection when challenged 1 year after vaccination compared with none of 5 control cats.[90] However, 13-week-old vaccinated cats were not protected from challenge with FIV subtype A strain Glasgow-8; all vaccinated and control cats were infected.[92]

Because of diagnostic test interference, uncertain efficacy in the field, and the increased risk of sarcoma formation associated with adjuvanted vaccines, the FIV vaccine is considered a noncore vaccine that should only be used for cats at high risk of infection, such as outdoor cats that fight with other cats. The initial vaccine should only be given to cats that test negative with FIV ELISA assays. Cat owners should be informed that protection is incomplete and that identification of subsequent infection may be impossible in some cats with the available diagnostic tests. The initial vaccine dose is followed by two booster doses at 3- to 4-week intervals, followed by annual boosters so long as risk persists. An identification microchip should be placed that links FIV vaccination to the microchip number, so should the cat escape or be relinquished to a shelter, a positive antibody test result is not interpreted as FIV infection.

Prevention

Transmission of FIV is reduced when cats are housed indoors. When one positive cat is identified in a household, all other cats should be tested and no new cats should be introduced, as this may lead to conflict and increased fighting behavior. Isolation of positive cats in a household should be considered. In breeding catteries, infection can be prevented by screening all new introductions, preferably with a 2-month quarantine period for introductions followed by retesting, and removal of all infected queens and toms from the cattery. Transmission in shelters can be reduced by testing on intake or housing cats singly in cages, and testing at or shortly after adoption, together with education of adopters in regard to the need to retest for infection.

Surgical needles, endotracheal tubes, breathing circuits, and instruments should never be shared between cats without proper cleaning and disinfection, and all cats used as blood donors should test negative for FIV antibodies with ELISA and, if possible, PCR assays offered by a diagnostic laboratory that has a high level of quality control. Fluid lines and multidose vials should not be shared between cats, because they can become contaminated with body fluids.

Public Health Aspects

Despite its similarities to HIV, no evidence of natural infection of humans with FIV exists.

VetBooks.ir

CASE EXAMPLE

Signalment: "Arthur" an 11-year-old male neutered domestic shorthair from northern California

History: Arthur was initially brought to his veterinarian for a 2-day history of lethargy and decreased appetite. Physical examination was unremarkable. Blood work showed a hematocrit of 28% (reference range, 29% to 38%), a white cell count of 6400 cells/μL with a normal differential, clumped platelets, mild hyperbilirubinemia (0.5 mg/dL), mild hypoalbuminemia (2.4 g/dL), and hyperglobulinemia (5.5 g/dL). He was treated with amoxicillin and mirtazapine, but lethargy and inappetence persisted. Serial hemograms performed over the subsequent 3 months showed progressive leukopenia due to a neutropenia and lymphopenia (Table 21-6), during which time Arthur was treated with orbifloxacin, with some improvement in his appetite and attitude. A bone marrow aspirate performed 5 weeks after the onset of illness showed myeloid hyperplasia with a left shift. Serology for FIV and FeLV was performed 11 weeks after onset of illness, and the cat was negative for FeLV antigen and had an equivocal test result for FIV antibody. Serum thyroxine concentration was low (0.7 mcg/dL, reference range 1.1 to 3.3 mcg/dL). The cat was referred for further evaluation.

Arthur was an indoor and outdoor cat and had a history of predation (mice and birds) and fighting with other cats in the neighborhood. His diet otherwise consisted of a commercial wet cat food. He was vaccinated regularly for rabies, FeLV, feline herpesvirus-1, feline calicivirus, and feline panleukopenia virus infections.

Current Medications: Orbifloxacin, 7 mg/kg PO q12h

Other Medical History: Routine blood work had been performed 3 years previously, which showed a normal CBC, a globulin of 5 g/dL, a urine specific gravity of 1.069, and a T4 of 1.3. At that time, Arthur tested negative for FeLV antigen and positive for FIV antibody.

Physical Examination:

Body Weight: 3.1 kg

General: Quiet, alert, responsive, estimated to be 5% to 7% dehydrated, T = 103.9°F (39.9°C), HR = 144 beats/min, RR = 50 breaths/min, mucous membranes pale pink, CRT < 2 s. A dry haircoat with moderate amounts of scale was present. There was no evidence of ectoparasites.

Eyes, Ears, Nose, and Throat (with Dilated Fundoscopic Examination): Moderate gingivitis and absent mandibular canine teeth. No other clinically significant abnormalities were detected.

Musculoskeletal: Body condition score 2/9. Generalized muscle atrophy was noted. Ambulatory in all four limbs.

Cardiovascular: Aside from an intermittent gallop rhythm, no abnormalities were noted.

Respiratory: No abnormalities were detected.

Gastrointestinal and Urogenital: Abdomen soft and nonpainful on palpation, mild hepatomegaly. Urinary bladder was small and soft.

Lymph Nodes: All lymph nodes less than 1 cm in diameter.

Laboratory Findings:

CBC:

HCT 22.5% (30%-50%)
MCV 47.5 fL (42-53 fL)
MCHC 32.9 g/dL (30-33.5 g/dL)
Reticulocytes 7400 cells/μL
WBC 1100 cells/μL (4500-14,000 cells/μL)
Neutrophils 704 cells/μL (2000-9000 cells/μL)
Band neutrophils 99 cells/μL
Lymphocytes 220 cells/μL (1000-7000 cells/μL)
Monocytes 77 cells/μL (50-600 cells/μL)
32,000 platelets/μL (180,000-500,000 platelets/μL).
Neutrophils showed moderate toxicity with many Döhle bodies, and there were many macroplatelets.

Serum Chemistry Profile:

Sodium 149 mmol/L (151-158 mmol/L)
Potassium 3.1 mmol/L (3.6-4.9 mmol/L)
Chloride 115 mmol/L (117-126 mmol/L)
Bicarbonate 17 mmol/L (15-21 mmol/L)
Phosphorus 4.3 mg/dL (3.2-6.3 mg/dL)
Calcium 8.8 mg/dL (9.0-10.9 mg/dl)
BUN 17 mg/dL (18-33 mg/dL)
Creatinine 1.1 mg/dL (1.1-2.2 mg/dL)
Glucose 158 mg/dL (63-118 mg/dL)
Total protein 8.1 g/dL (6.6-8.4 g/dL)
Albumin 3.0 g/dL (2.2-4.6 g/dL)
Globulin 5.1 g/dL (2.8-5.4 g/dL)
ALT 121 U/L (27-101 U/L)
AST 113 U/L (17-58 U/L)
ALP 10 U/L (14-71 U/L)
Creatine kinase 278 U/L (73-260 U/L)
Gamma GT <3 U/L (0-4 U/L)
Cholesterol 204 mg/dL (89-258 mg/dL)
Total bilirubin 0.8 mg/dL (0-0.2 mg/dL)
Magnesium 2.4 mg/dL (1.5-2.5 mg/dL).

Anti-nuclear Antibody Serology: Positive at 1:32

Microbiologic and Virologic Testing: Point-of-care ELISA serology for FeLV antigen and FIV antibody: negative

Feline coronavirus antibody serology: negative at 1:25

Aerobic and anaerobic blood cultures (three specimens): negative

PCR for FIV proviral DNA: positive (cycle threshold value = 30, values <40 are positive)

Imaging Findings:

Abdominal Ultrasound: Hepatomegaly was identified and the spleen had a mottled echotexture. There was mild enlargement of the ileocecal lymph nodes and mild diffuse thickening of the small intestinal submucosal layer.

Thoracic Radiographs: Cardiopulmonary structures were within normal limits.

Cytologic Findings:

Liver Aspiration Cytology: A moderately bloody background contained scattered, variably sized clusters of uniform hepatocytes and low numbers of nucleated cells. The nucleated cells consisted of a mixture of nondegenerate neutrophils, lymphocytes, macrophages, and rare myeloid precursors. Several macrophages were erythrophagic. Interpretation: Possible mild myeloid extramedullary hematopoiesis.

Spleen Aspiration Cytology: The specimen was highly cellular with a pink background that contained a moderate amount

VetBooks.ir

of blood and scattered clumps of hemosiderin. A mixed population of lymphocytes was admixed with variable numbers of hematopoietic precursor cells. Hematopoietic precursors were primarily granulocytic precursors, with many progranulocytes. A few erythroid precursors, including erythroblasts, were noted. Plasma cells were moderately increased in number, and both immature and mature forms were seen. Several binucleated and rare trinucleated plasma cells and scattered immature lymphocytes were noted. Vacuolated macrophages were increased in number and often contained phagocytized erythrocytes or blue-green pigment consistent with hemosiderin. Scattered mitotic figures were noted. Interpretation: Moderate plasmacytosis, extramedullary hematopoiesis, and histiocytic hyperplasia with erythrophagocytosis and increased iron. The large number of immature plasma cells raised the possibility of plasma cell neoplasia; however, reactive plasmacytosis could not be ruled out.

Bone Marrow Aspiration Cytology: Numerous hypercellular unit particles were present. A few mature megakaryocytes were noted. Hematopoietic cells consisted largely of myeloid precursors, with an estimated myeloid to erythroid ratio greater than 10. Myeloid cells showed orderly maturation to the band neutrophil stage, with few segmented neutrophils. Few erythroid precursors were noted, which included rare prorubricytes, rubricytes, and metarubricytes. Scattered well-differentiated plasma cells and a small amount of hemosiderin were noted. Interpretation: Marked myeloid hyperplasia, marked erythroid hypoplasia, and moderate megakaryocytic hypoplasia. The myeloid hyperplasia together with persistent neutropenia suggested myelodysplasia.

Serum Protein Electrophoresis: A mild increase in α_2 globulins was present (1.34 g/dL, reference range, 0.4-0.9 g/dL) together with a broad-based gamma region. This was consistent with an acute-phase inflammatory response.

Diagnosis: Terminal phase of FIV infection, characterized by pancytopenia secondary to myelodysplasia; hepatopathy (open diagnosis).

Comments: The progression of FIV infection was apparent in this cat, which transitioned from a seropositive to a seronegative, PCR-positive state as a result of progressive decline in immune function and, ultimately, failure to produce antibodies. The cause of the hepatopathy was not identified. Blood cultures were negative, and spleen and liver aspiration cytology failed to reveal evidence of underlying neoplasia. Because of the plasmacytosis in the spleen, serum protein electrophoresis was performed to assist diagnosis of a plasma cell tumor (as supported by a monoclonal gammopathy), but this was not apparent. The cat was treated with clavulanic acid–amoxicillin without clinical improvement. Treatment with glucocorticoids was also offered because of the possibility of undiagnosed round cell neoplasia or immune-mediated neutropenia (in light of the myeloid hyperplasia combined with a positive antinuclear antibody test). The cat died at home 1 month later, and necropsy was not performed.

TABLE 21-6

Progression of Laboratory Abnormalities in an 11-Year-old Male Neutered Domestic Shorthair That Tested Positive for Antibodies to FIV 3 Years Earlier, at Which Time a CBC was Normal

	Days after Onset of Illness					
	39	**47**	**56**	**74**	**83**	**Reference Range**
Hematocrit (%)	29	29	33	27	22	30-50

CHAPTER 22

Feline Leukemia Virus Infection

Jane E. Sykes and Katrin Hartmann

VetBooks.ir

Overview of Feline Leukemia Virus Infection

First Described: Scotland, 1964 (Jarrett et al.)[1]

Cause: Feline leukemia virus (family Retroviridae, subfamily Orthoretrovirinae, genus *Gammaretrovirus*)

Affected Hosts: Domestic and some wild Felidae

Geographic Distribution: Worldwide

Mode of Transmission: Prolonged close contact with salivary secretions; to a lesser extent biting, transplacental transmission, transmission through milk, and through blood transfusion

Major Clinical Signs: Lethargy, fever, pallor, stomatitis, signs of underlying lymphoma or leukemia, signs of immune-mediated disorders or opportunistic infections

Differential Diagnoses: FIV infection is the primary differential diagnosis for cats with signs of immunosuppression; feline calicivirus infection, or FIV infection are differential diagnoses for cats with stomatitis; primary immune-mediated disease and other bone marrow diseases are differential diagnoses for cats with immune-mediated diseases and cytopenias

Human Health Significance: FeLV does not infect humans.

Etiology and Epidemiology

FeLV is an enveloped RNA virus that belongs to the genus *Gammaretrovirus* of the family Retroviridae. FeLV infection remains an important cause of mortality in domestic cats through its ability to cause immune suppression, bone marrow disorders, and hematopoietic neoplasia. FeLV also causes disease in wild felids such as the highly endangered Iberian lynx.[2]

FeLV infection progresses more rapidly than FIV infection and is more pathogenic, so most cats that develop progressive infections ultimately die of FeLV-related disease. However, in contrast to FIV infection, many cats in the early state of FeLV infection regress to a permanent state of viral latency ("regressive infection"). It is possible that some cats, after exposure to a low dose of FeLV, may eliminate the infection altogether ("abortive infection"), although this appears to be a rare outcome. Regardless, a positive test result for FeLV infection in an apparently healthy cat does not always imply that FeLV-related disease and mortality will occur.

The structure of FeLV is similar to that of FIV, except that the capsid is icosahedral rather than cone shaped (Figure 22-1). There are three main subtypes of FeLV: FeLV-A, FeLV-B, and FeLV-C. Each subtype uses a different receptor to enter cells (Table 22-1). All cats infected with FeLV-B and FeLV-C are co-infected with FeLV-A, and only FeLV-A is transmitted between animals. FeLV-B and FeLV-C are more pathogenic than FeLV-A. FeLV-B arises through recombination of FeLV-A proviral DNA with endogenous FeLV sequences present in host cellular DNA.[3] FeLV-C arises from accumulation of mutations or insertions in the *env* (SU) gene of FeLV-A.[4,5] The FeLV subtype influences the clinical expression of disease (see Table 22-1). For example, FeLV-C is associated with nonregenerative anemia. Even within an FeLV subtype, mutations in the SU and the LTR regions of the viral genome affect disease outcome.[6,7] An additional subtype, FeLV-T, has been associated with immunodeficiency.

Transmission of FeLV-A primarily results from close contact with salivary secretions, such as through licking, mutual grooming, and shared food and water dishes. Other routes of transmission, such as by biting, blood transfusion, in milk, and possibly by fleas, can also occur.[8-10] The virus survives poorly outside the cat and is readily inactivated by disinfectants, soap, and desiccation. The overall prevalence of FeLV infection has declined over the past two decades with more extensive testing and vaccination. Before the institution of widespread testing and vaccination, more than 30% of cats in some catteries were infected.[11] In the early 1990s, the overall prevalence of infection was 13% in nearly 28,000 sick cats from North

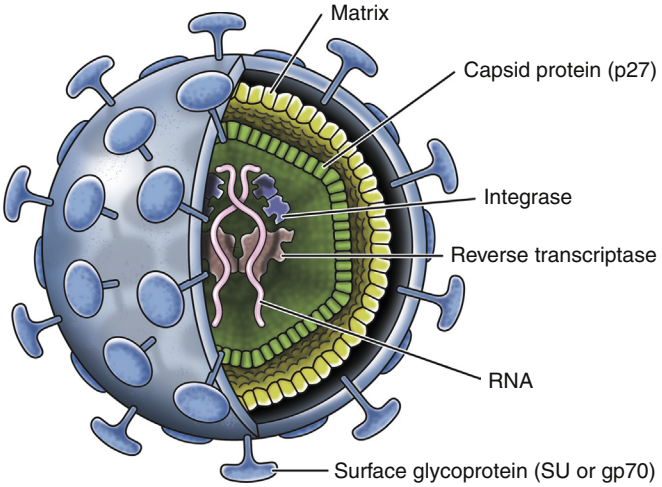

FIGURE 22-1 Structure of feline leukemia virus. Gammaretroviruses contain two identical strands of RNA and associated enzymes, which include reverse transcriptase, integrase, and protease, packaged into a core composed of the capsid protein (p27) with a surrounding matrix, all enclosed by a phospholipid membrane envelope derived from the host cell. The envelope contains a gp70 glycoprotein and the transmembrane protein p15E.

TABLE 22-1

Host Cellular Receptors Involved in FeLV Infection

FeLV Subtype	Receptor	Receptor Function	Comments
FeLV-A	FeTHTR1*	Thiamine transporter protein	Present in all cats with FeLV; transmitted exogenously
FeLV-B	FePit1 or FePit2†	Inorganic phosphate transporter protein	Results from recombination between FeLV-A and feline endogenous FeLV-related retrovirus sequences; may accelerate development of lymphoma or enhance neuropathogenicity
FeLV-C	FLVCR‡	Heme transporter protein	Arises from point mutations in FeLV-A *env* gene; associated with nonregenerative anemia

*Mendoza R, Anderson MM, Overbaugh J. A putative thiamine transport protein is a receptor for feline leukemia virus subgroup A. J Virol 2006;80(7):3378-3385.

†Anderson MM, Lauring AS, Robertson S, et al. Feline Pit2 functions as a receptor for subgroup B feline leukemia viruses. J Virol 2001;75(22):10563-10572.

America that were at risk for exposure.[12] The prevalence was just 7% in a similar population of approximately 1400 cats in 2006.[13] The prevalence of FeLV infection in European cats has also declined markedly.[14] Currently, the overall prevalence of infection in mixed populations of cats is 1% to 6%.[13,15-19] Cats with access to the outdoors; those that have contact with other cats; cats that are male, aggressive, or intact; and cats that are co-infected with FIV are at increased risk of FeLV infection.[12,13,15,17] Male cats are less strongly predisposed to FeLV infection than to FIV infection, and in some studies,[20] no male predisposition has been recognized. Adult cats are more likely to be infected with FeLV than cats aged less than 6 months,[13,17] but the median age of cats infected with FeLV is 3 years,[15] which is lower than that for FIV. This reflects a) the greater degree of pathogenicity of FeLV than FIV and its ability to significantly reduce lifespan; and b) the phenomenon of age-related resistance to FeLV, whereby exposure of cats that are less than 4 months of age to the virus is much more likely to lead to progressive infection than exposure of adults.[21] When 12- to 16-week old kittens are exposed to a multicat household with endemic FeLV infection, between 60% and 70% of kittens will become infected within a 5-month time period. In contrast, less than 5% of cats aged 6 months or older will become infected over the same time period; over a 2-year period, 40% to 50% of these adult cats will become infected. Infection of adult cats can also still occur with exposure to high doses of the virus or when there is underlying host immune compromise.

Clinical Features

Signs and Their Pathogenesis

The outcome of FeLV infection is extremely variable and depends strongly on the virus strain involved, the challenge dose, the route of inoculation, and factors that influence host immune function such as age, genetics, co-infections, stress, and treatment with immunosuppressive drugs. After oronasal exposure to the virus, the virus replicates in oral lymphoid tissue and then circulates in a few monocytes and lymphocytes within peripheral blood. Some cats develop systemic signs, such as fever, lethargy, and/or lymphadenopathy, during this period. A small number of infected lymphocytes then travel to the bone marrow, where the virus infects rapidly dividing precursor cells and subsequently lymphoid and epithelial cells throughout the body. This infection of the bone marrow is considered a critical step in the pathogenesis of FeLV infection. Once infection of epithelial cells in the salivary glands occurs, the virus is shed in massive quantities in saliva; low quantities of virus can also be shed in urine and feces.

Possible outcomes of infection with FeLV are shown in Figure 22-2. The immune system of some infected cats suppresses viral replication within a few weeks after infection, before significant infection of the marrow occurs. These cats develop a *regressive infection,* whereby proviral DNA is present in the host cell genome but production and shedding of virus no longer occurs (see Chapter 21). This may occur after the initial period of viremia, or viremia may never be detectable.[22] Regressive infection can persist for life and may be reactivated with immunosuppression, such as might occur during pregnancy or following treatment with immunosuppressive drugs.[23] Later in life, an unknown percentage of cats with regressive infections may develop FeLV-negative malignancies as a result of integration of viral DNA within host cellular oncogenes. Most cats with regressive infection, however, never develop clinical signs related to FeLV infection. Viral genome sequences may eventually be incompletely replicated, and as a consequence, reactivation of virus replication will become impossible in some cats over time. In *abortive infections*, no viremia occurs after infection, and virus cannot be detected using any method. Cats with abortive infections have been exposed to low doses of FeLV, and although they fail to develop viremia, they will develop antibodies to the virus.[24] Some cats that never test antigen-positive may have *focal infections*, that is, evidence of proviral DNA in some tissues but not in blood or bone marrow.[9] Cats develop *progressive infection* once involvement of the marrow is established and cellular destruction by the virus exceeds the ability of the host's immune system to suppress viral replication. Persistent viremia and progressive FeLV-related disease result (Box 22-1).

VetBooks.ir

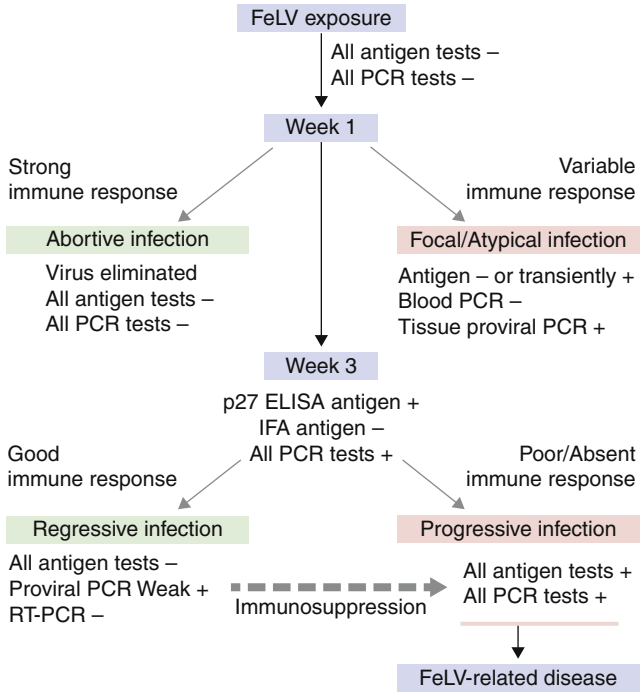

FIGURE 22-2 Outcomes of infection with FeLV. In the first week of infection, cats test negative with all antigen assays (i.e., p27 ELISA and IFA assays), RT-PCR for viral RNA, and PCR for proviral DNA. Rarely, cats exposed to low levels of virus eliminate the infection before or at this time point *(abortive infection)*. Soluble antigen assays and proviral PCR assays become positive from about the third week after infection, and virus is shed in saliva, tears, urine, and feces. After this time point, productive viral infection is suppressed by the host immune response *(regressive infection)* or the virus multiplies rapidly in the bone marrow and a progressive infection occurs, which is characterized by persistently positive antigen ELISA, IFA, viral RNA, and proviral DNA assay results. Cats with *focal or atypical infection* are never or transiently antigen positive and test negative using PCR assays on blood or bone marrow, but some tissues (such as the mammary gland or bladder) are positive with proviral PCR. The latter occurs in only a small percentage (e.g., < 5%) of infected cats.

Opportunistic Infections

Opportunistic infections may develop in FeLV infections as a result of myelo suppression or an acquired cell-mediated immunodeficiency. The immunosuppressive properties of FeLV are not fully understood but have been linked in part to the viral envelope peptide, p15E, which inhibits T and B cell function, inhibits cytotoxic lymphocyte responses, alters monocyte morphology and distribution, and has been associated with impaired cytokine production and responsiveness.[25-28] Kittens with progressive FeLV infection have impaired T cell and, to a lesser extent, B cell function.[29-32] Infected cats may develop lymphopenia, thymic atrophy, and depletion of lymphocytes within lymph node paracortical zones. CD4+ T cell malfunction may contribute to a decreased humoral and cell-mediated immune response in affected cats,[33,34] and the response to vaccination may also be impaired. Impaired neutrophil function compounds the effect of neutropenia in some infected cats.[35-37] Opportunistic infections that result include bacterial infections of the upper and lower urinary tract, hemoplasmosis, upper respiratory tract infections, feline infectious peritonitis, chronic stomatitis, toxoplasmosis, dermatophytosis, and cryptococcosis (Figure 22-3). The prevalence of some of these infections in cats with FeLV infection does not differ significantly from that in cats not infected with FeLV, but clinical signs are more severe and refractory to therapy. Infection with FeLV is an established risk factor for hemoplasma infection. In one study, it was also a risk factor for *Bartonella henselae* infection, but no evidence of clinical disease was identified in the cats infected with *B. henselae*.[38]

BOX 22-1

Clinical Outcomes of Progressive FeLV Infection

Neoplasia, especially lymphoma, leukemia and fibrosarcomas (with FeSV)
Opportunistic infections
Pure red cell aplasia
Aplastic anemia, myelodysplasia, or myelofibrosis
Immune-mediated disease (immune-mediated hemolytic anemia, thrombocytopenia, glomerulonephritis, polyarthritis, uveitis)
Peripheral lymphadenopathy
Neurologic disease (e.g., anisocoria, urinary incontinence)
Reproductive failure
Gastrointestinal disease (uncommon)
Other (e.g., osteochondromatosis, cutaneous horns)

FeSV, feline sarcoma virus.

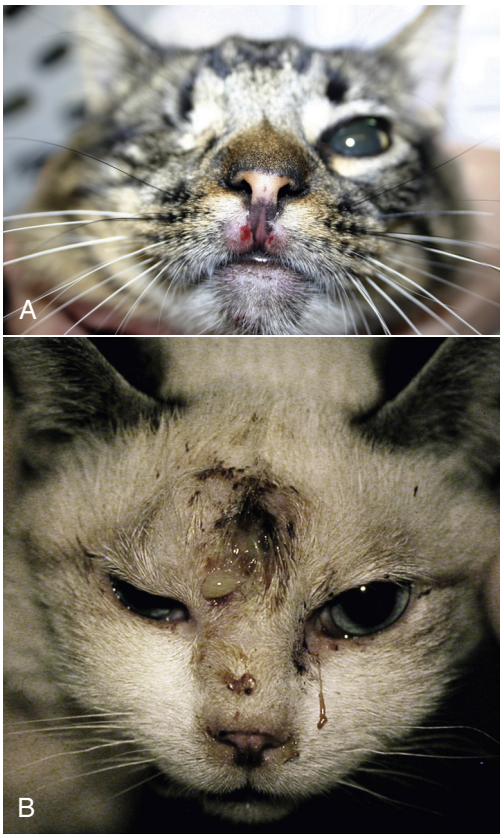

FIGURE 22-3 Opportunistic infections in cats with progressive FeLV infection. **A,** Ulceration of the nasal planum in a 6-month-old male neutered domestic medium hair cat with progressive FeLV infection as defined by positive ELISA antigen and IFA assays on peripheral blood. Stomatitis was also present, and feline calicivirus infection was suspected. **B,** Severe nasal cryptococcosis in a Siamese cat from a cattery with endemic FeLV infection.

VetBooks.ir

Neoplasia

FeLV causes neoplasia in cats primarily as a result of insertional mutagenesis, by which the virus activates proto-oncogenes (especially *c-myc*, but also others such as *flit-1*) or disrupts tumor suppressor genes.[39] The most common types of neoplasia in cats infected with FeLV are lymphoma and leukemia. Cats infected with FeLV are more than 60-fold more likely to develop lymphoma than cats not infected with FeLV; this compares with approximately 5-fold for FIV.[40] Lymphoma or leukemia can be detected in nearly one quarter of cats with progressive FeLV infection at necropsy.[41] In the 1980s, as many as 70% of cases of feline lymphoma were associated with FeLV infection, but with improved control measures and vaccination, the vast majority of cats (more than 80% to 90%) seen at veterinary clinics with lymphoma now test negative for FeLV antigen.[42-44] The most common types of lymphoma in cats infected with FeLV are thymic (mediastinal), multicentric, spinal, renal, or ocular lymphoma. FeLV-associated lymphomas are mostly of T-cell origin, but B cell lymphoma can also occur. In contrast, FIV-associated lymphomas tend to be of B-cell origin.[42] Approximately 80% of cats with thymic lymphoma test positive for FeLV antigen, whereas fewer than 10% of cats with gastrointestinal lymphoma are FeLV antigen-positive. Large granular lymphoma is rarely associated with FeLV infection.[45] Cats with thymic lymphoma typically develop clinical signs of lethargy, tachypnea, and sometimes regurgitation. Most FeLV-positive cats with lymphoma are less than 4 years of age.[14]

Cats with regressive infection appear to be at greater risk for development of lymphoma than cats that were never exposed to FeLV. FeLV-negative cats that live with cats that test positive for FeLV antigen have a more than 40-fold increased risk of lymphoma compared to that expected without exposure to FeLV.[46] Several studies have investigated the prevalence of FeLV proviral DNA in tumor cells from cats that test negative for FeLV antigen. Some studies (including more recent studies that used real-time PCR assays) found no evidence of FeLV proviral DNA in feline lymphomas.[14,47,48] In older studies that used conventional PCR, more than 20% of antigen-negative lymphomas tested positive.[49,50] Additional studies from a variety of geographic locations that use multiple real-time PCR assays are required to clarify the role that FeLV plays in lymphomas and leukemias that develop in cats that test negative for FeLV antigen.

FeLV is responsible for the majority of myelogenous leukemias, erythroleukemias, megakaryocytic, and lymphoid leukemias in cats, although not all cats with these tumors test positive for FeLV antigen. Most FeLV-associated leukemias are acute. FeLV infection can underlie chronic eosinophilic leukemia,[51] chronic myelomonocytic leukemia,[52] and chronic lymphocytic leukemia. However, most cats with chronic lymphocytic leukemia are seronegative for FeLV antigen.

FeLV infection can result in the development of multiple fibrosarcomas in young cats. These occur when FeLV-A recombines with cellular oncogenes (such as *c-fes*, *c-fms*, or *c-fgr*) to form feline sarcoma viruses (FeSV). These viruses then develop mutations in these oncogenes that, when reinserted into cellular DNA, cause malignant transformation.[53,54] To replicate, FeSV requires the presence of FeLV-A, which supplies proteins such as those encoded by the *env* gene. Thus, all cats infected with FeSV test positive for FeLV antigen. FeSV-associated fibrosarcomas are characterized by multifocal, locally invasive, often ulcerated cutaneous masses that metastasize readily to the lung and other sites with a poor prognosis. FeLV-FeSV DNA sequences have been detected in some uveal melanomas from cats,[55] but other studies have failed to identify an association between FeSV and ocular melanomas or sarcomas in cats.[56,57] FeLV infection does not appear to be important in the pathogenesis of solitary fibrosarcomas or injection-site sarcomas in cats.[58,59]

Other tumor types that are variably associated with FeLV infection are feline olfactory neuroblastomas, cutaneous horns, and osteochondromatosis (multiple cartilaginous exostoses).[60] Feline olfactory neuroblastomas are rare and aggressive tumors of the nasal cavity that can lead to signs of rhinosinusitis and neurologic signs. Osteochondromatosis is characterized by benign cartilage-capped exostotic growths that arise from the surface of a bone, which can cause pain, lameness, disfigurement, and paresis due to spinal cord compression. Cutaneous horns occur as a result of benign keratinocyte hyperplasia.

BOX 22-2

Mechanisms of Anemia in Cats Infected with FeLV

Decreased RBC Production
- Pure red cell aplasia (FeLV-C)
- Aplastic anemia
- Leukemia (myelophthisis)
- Myelofibrosis
- Anemia of inflammatory disease

RBC Loss
- Thrombocytopenia secondary to immune-mediated or bone marrow disease

Increased RBC Destruction
- FeLV-associated IMHA
- Co-infection with hemoplasmas

IMHA, immune-mediated hemolytic anemia.

Anemia and Bone Marrow Disorders

Multiple mechanisms can lead to anemia in cats infected with FeLV (Box 22-2). Approximately 90% of FeLV-associated anemias are nonregenerative.[61] A variety of bone marrow disorders lead to decreased red blood cell production. FeLV-C infection results in pure red cell aplasia, a severe nonregenerative anemia associated with erythrocyte macrocytosis and depletion of erythroid precursors in the bone marrow. This occurs because FeLV-C binds to and interferes with a heme exporter protein, which results in subsequent heme toxicosis to the developing erythrocyte.[62] The presence of macrocytosis in the absence of reticulocytosis should thus raise suspicion for FeLV infection. FeLV infection can also lead to aplastic anemia in some cats, which is a deficiency in all cell lineages (platelets, myeloid, and erythroid) in the bone marrow, and replacement of the bone marrow space by adipose tissue. Anemia and bone marrow dysfunction may also result from myelophthisis secondary to leukemia, myeloid and/or erythroid dysplasia, or myelofibrosis (progressive replacement of the marrow with collagenous connective tissue) (Figure 22-4). Myelodysplasia is characterized by disordered maturation of marrow precursors, which in some

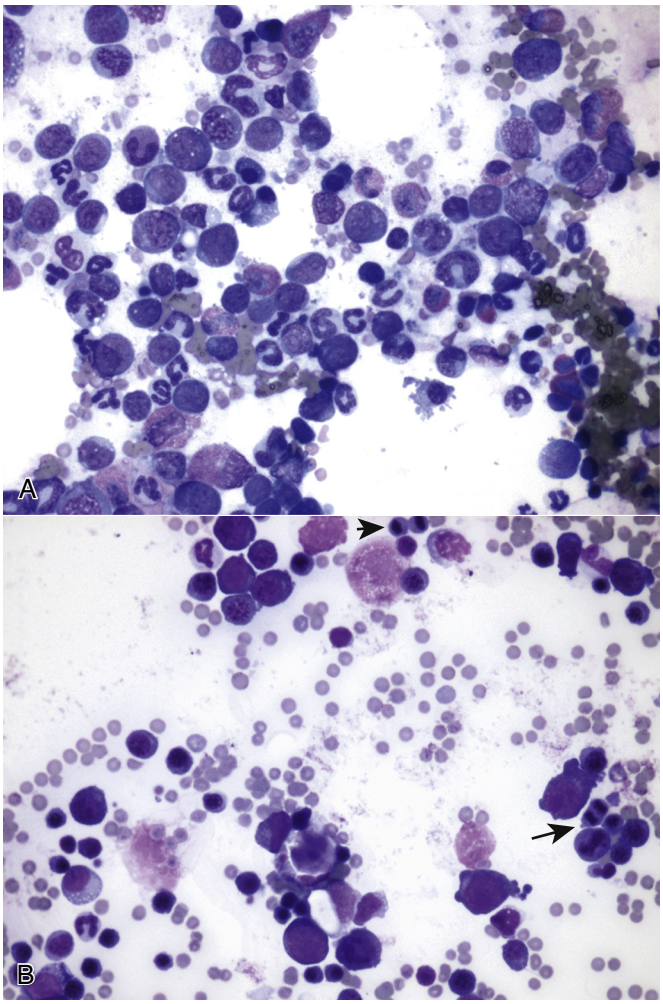

FIGURE 22-4 Bone marrow abnormalities in cats with FeLV infection. **A,** Bone marrow aspirate cytology from a 6-month old male neutered domestic shorthair cat that was evaluated for lethargy and fever. Acute leukemia, marked erythroid aplasia, marked granulocytic dysplasia, and increased eosinophilopoiesis is present. Megakaryocytic dysplasia was also identified. The G:E ratio was approximately 2950:1 with marked erythroid aplasia. Wright's stain. **B,** Bone marrow aspirate cytology from a 1-year-old male neutered domestic shorthair. Severe megaloblastic erythrodysplasia and mild megakaryocytic dysplasia were identified. The myeloid series is present but markedly decreased in all stages; the myeloid to erythroid ratio was estimated at 1:6.5 *(compare with A)*. Nuclear to cytoplasmic asynchrony (megaloblastic change) is present, with immature nuclei in cytoplasm with hemoglobinization. Mitotic figures are present in moderate numbers and are seen in the late stages of the erythroid series *(arrows)*.

cases precedes emergence of leukemia. FeLV infection underlies many myelodysplastic syndromes (MDS) and leukemia in cats.[63] However, over the past two decades, 50% of 28 cats with myelodysplasia and 44% of 41 cats with leukemia seen at the University of California, Davis, tested negative for FeLV antigen in peripheral blood, and only 36% of 34 cats with dysmyelopoiesis seen at the University of Minnesota were positive for FeLV antigen.[64] Several different classification systems have been used to describe feline MDS.[64] The French-American-British (FAB) classification scheme used for humans has been modified for dogs and cats. This divides MDS into 2 groups: 1) MDS with refractory cytopenia (less than 6% myeloblasts in the bone marrow, MDS-RC) and 2) MDS with excessive numbers of myeloblasts (6% to 30% myeloblasts, MDS-EB). The presence of more than 30% blasts indicates leukemia. The most common form of MDS in cats is MDS-EB.[64] Regressive FeLV infections have been detected by proviral DNA PCR in some cats with bone marrow disorders,[65] but the relationship between the presence of proviral DNA and the pathogenesis of disordered marrow function is unclear.

Anemia in cats with FeLV infection may also result from anemia of inflammatory disease, which can be triggered by opportunistic infections or neoplastic disease. Erythrocyte destruction occurs in some FeLV-infected cats as a result of secondary immune-mediated hemolytic anemia (IMHA) or co-infection with hemoplasmas (see Chapter 41). Hemorrhage as a result of thrombocytopenia or defective platelet function may also contribute to anemia. Mechanisms of thrombocytopenia include immune-mediated thrombocytopenia (ITP) and bone marrow dysfunction. Similarly, neutropenia can result from myeloid hypoplasia, myelofibrosis, myelodysplasia, myelophthisis, or maturation arrest at the myelocyte or metamyelocyte stages. In some cases, peripheral neutropenia accompanied by myeloid hyperplasia reflects underlying immune-mediated neutropenia.

Immune-Mediated Disorders

In addition to immune-mediated cytopenias, other immune-mediated disorders that can occur in association with progressive FeLV infection are glomerulonephritis,[66] uveitis,[67] and polyarthritis.[68] Circulating immune complexes have been detected in infected cats.[69-71] Because primary immune-mediated disorders are otherwise rare in cats, retrovirus testing is essential in cats that are diagnosed with these conditions before immunosuppressive drug treatment is initiated.

Neurologic Disorders

Neurologic disorders in cats with progressive FeLV infections may occur secondary to central nervous system (CNS) neoplasia, opportunistic infections, or FeLV infection itself. The envelope protein of FeLV may be neurotoxic.[72,73] Anisocoria, mydriasis, Horner's syndrome, and urinary incontinence can occur. FeLV infection may be one of the most frequent causes of urinary incontinence in cats, an otherwise uncommon condition. A myelopathy has been described in FeLV-infected cats that showed various neurologic signs such as disorientation, lethargy, increased vocalization, progressive ataxia, paresis, paralysis, hyperesthesia, urinary incontinence, recurrent constipation, and anisocoria with diminished pupillary light reflexes.[74] At necropsy, abundant FeLV antigen was detectable within neurons, endothelial cells, oligodendroglia, and astrocytes within the spinal cord.[74]

Gastrointestinal Disease

Uncommonly, FeLV causes enteritis that clinically and histologically resembles that caused by feline panleukopenia virus (FPV), except that lymphoid depletion is absent.[75] Clinical signs include vomiting, acute or chronic diarrhea that may be hemorrhagic, inappetence, weight loss, and dehydration. FeLV-infected cats with "panleukopenia-like syndrome" have intestinal crypt destruction and pancytopenia that results from myeloid destruction (Figure 22-5).[76] Although now very rare, co-infections with FeLV and FPV can also occur, and the 2 viruses may enhance each other's pathogenicity.[77] Co-infections with FeLV and other enteric viruses, such as feline coronavirus, also occur.[78] In most cases, diarrhea in cats infected by FeLV results from an etiology other than FeLV alone.

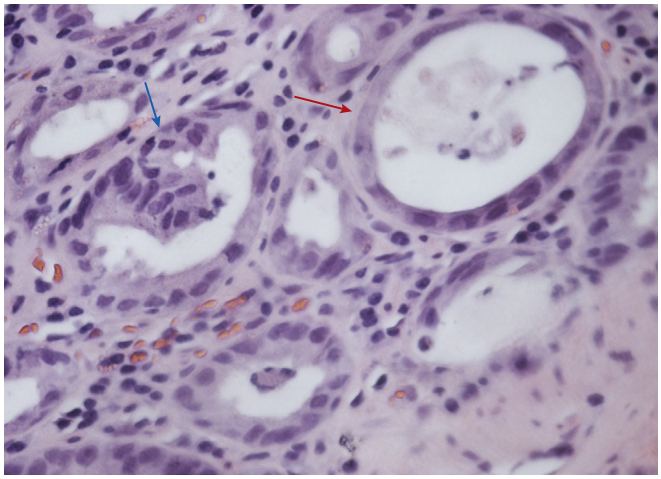

FIGURE 22-5 Histopathology of a colonic biopsy specimen from a 6-year-old intact male FeLV+ domestic shorthair with a 1-week history of anorexia, weight loss, lethargy, fever, and bloody mucoid diarrhea. Severe, diffuse, plasmacytic colitis was present with crypt epithelial necrosis and regeneration. One crypt is dilated, lined with attenuated epithelium, and contains necrotic debris *(red arrow)*. An adjacent crypt shows evidence of regeneration *(blue arrow)*. A tissue gram stain showed a mixed population of bacteria on the luminal surface, but not within crypts. A CBC showed thrombocytopenia (22,000 platelets/μL) and neutropenia (2700 neutrophils/μL) with neutrophil toxicity. A fecal parvovirus antigen test was negative, and bone marrow aspirate cytology showed evidence of myelodysplasia. Remarkably, this cat lived another 3 years with transfusion support, but ultimately was euthanized because of acute granulocytic leukemia with secondary sepsis.

Reproductive Disorders

Transplacental spread of FeLV can lead to fetal resorption, abortion, neonatal death, and fading kitten syndrome.[76] Fetal loss may also result from secondary endometritis. Kittens infected in late gestation or after birth develop thymic atrophy, failure to nurse, dehydration, lethargy, and death within the first 2 weeks of life.

Physical Examination Findings

Physical examination findings in cats with progressive FeLV infection vary dramatically depending on the stage of infection and the secondary disease process present. There may be no abnormalities, or cats may show signs of lethargy, pyrexia, mucosal pallor, petechial hemorrhages, dehydration, peripheral lymphadenomegaly, thin body condition, stomatitis, subcutaneous abscesses, or upper respiratory tract disease. Anemic cats may have a hemic murmur, tachypnea, or tachycardia, or they may be icteric. Cats with severe anemia can be laterally recumbent or comatose and hypothermic. Cats with thymic lymphoma may be tachypneic and have decreased lung and cardiac sounds on thoracic auscultation as a result of malignant pleural effusion, or heart sounds may be displaced caudally. Decreased compressibility of the cranial thorax may also be detected. Splenomegaly, hepatomegaly, renomegaly, intestinal masses, and/or abdominal lymph node enlargement may be detected on abdominal palpation of cats with multicentric lymphoma. Neurologic signs are detected infrequently when compared with signs of anemia or thoracic or abdominal lymphoma and include ataxia, anisocoria, and mydriasis. Although also relatively uncommon, uveitis may be identified, or there may be other ocular abnormalities as a result of intraocular lymphoma or co-infections with other pathogens.

Diagnosis

Infection with FeLV is often diagnosed when healthy cats are screened for infection. Screening should be performed with ELISA or related immunochromatographic in-house assays for free FeLV antigen in serum, because these assays are sensitive, specific, rapid, widely available, and most well understood. The retrovirus status of all cats should be known regardless of the presence of absence of illness.[79] The indications for retrovirus testing are described in Chapter 21 (see Box 21-1).

Even though many cats that test positive for FeLV antigen have no clinical signs or physical examination abnormalities, a CBC, chemistry panel, and urinalysis should be obtained from these cats (and at a minimum, a complete CBC with blood smear evaluation) to assess for underlying abnormalities that could signal the presence of FeLV-related disorders. Subtle hematologic abnormalities, such as erythroid macrocytosis or monocytopenia, may be present in the absence of overt clinical signs and can signify a poorer long-term outcome. Additional diagnostic tests indicated in infected cats that are anemic include a reticulocyte count, Coombs' test, and PCR assay for hemoplasmas. Bone marrow aspiration and core biopsy are indicated in cats with pancytopenia or persistent nonregenerative anemias.

Laboratory Abnormalities

Complete Blood Count

The CBC may be normal or show regenerative or nonregenerative anemia, neutropenia, lymphopenia, monocytopenia, and/or thrombocytopenia. Evidence of agglutination may be present in cats with IMHA. Moderate to marked leukocytosis and increased band neutrophils may also be present. Large numbers of circulating blasts, megakaryocytes or dysplastic cells (such as erythrocytes with giant Howell-Jolly bodies) can be found in cats with leukemia or MDS. When compared with uninfected cats, FeLV-infected cats were nearly 3.8-fold more likely to be anemic, 5-fold more likely to be thrombocytopenic, 3.6-fold more likely to be neutropenic, and 2.8-fold more likely to have lymphocytosis.[80]

Serum Biochemical Tests and Urinalysis

Findings on serum biochemistry analysis and urinalysis are nonspecific and reflect underlying disease processes. Hyperbilirubinemia and bilirubinuria may be present in cats with immune-mediated hemolytic anemia or hemoplasmosis. Cats with glomerulonephritis may be proteinuric. Some cats have evidence of bacterial urinary tract infections. Urine culture and susceptibility testing of a urine specimen obtained via cystocentesis are indicated in cats with suspected urinary tract infection.

Bone Marrow Cytology and Histopathology

Both bone marrow aspirate and core biopsy specimens should be obtained in cats with pancytopenia or nonregenerative anemia. If aspirate results are not diagnostic, the core biopsy should be submitted for interpretation. This is because bone marrow aspirates from cats with aplastic anemia or myelofibrosis are typically of low cellularity. Bone marrow findings in cats with FeLV infection include evidence of neoplastic lymphoid, erythroid, or myeloid cells (which circulate in the peripheral blood of cats with leukemia); myelodysplasia; hypoplasia or aplasia of erythroid, myeloid, or megakaryocyte cell lines; erythroid, myeloid, and megakaryocyte hyperplasia despite peripheral cytopenias; and megakaryocyte hypoplasia. Cytochemical stains

VetBooks.ir

that identify cells of the myeloid lineage (such as alkaline phosphatase, peroxidase, Sudan black B, and nonspecific esterase), immunocytochemistry, or flow cytometry using antibodies that target cell surface cluster of differentiation (CD) molecules may be needed to definitively identify the cell type involved in some acute undifferentiated leukemias.

Diagnostic Imaging

Imaging findings in cats with FeLV infection reflect the underlying disease process and are extremely variable. Cats with FeLV-associated thymic lymphosarcoma have a mediastinal mass on thoracic radiography that may be accompanied by mild to severe pleural effusion (Figure 22-6). Abdominal sonography in cats with multicentric lymphoma may reveal hypoechoic and enlarged abdominal lymph nodes and enlargement, hypoechogenicity, or mottling of the spleen, liver, or kidneys. Increased hepatic echogenicity can also occur with lymphoma. Intestinal masses with loss of normal bowel wall layering may also be detected. Splenomegaly may be detected in cats with immune-mediated cytopenias.

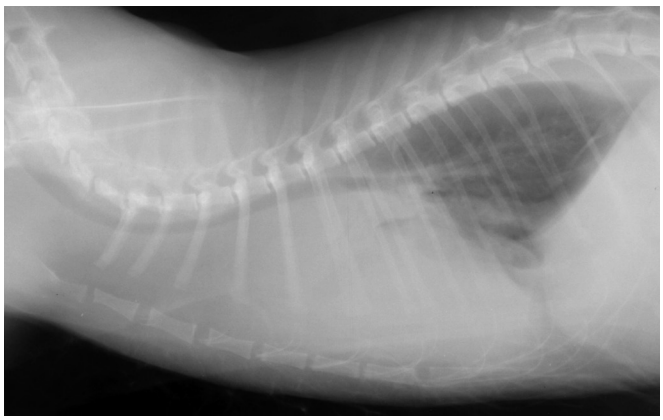

FIGURE 22-6 Lateral thoracic radiograph from a 5-year-old male neutered domestic shorthair cat with mediastinal lymphoma 11 months after it tested positive for circulating FeLV antigen. The cat was tachypneic and had muffled heart sounds that were displaced caudally. There is evidence of pleural effusion and dorsal displacement of the trachea. Cytologic examination of pleural fluid revealed large numbers of malignant lymphocytes.

Microbiologic Tests

Diagnostic assays available for FeLV infection are listed in Table 22-2.

Antigen Assays

The initial assay of choice for diagnosis of FeLV infection is an ELISA or a similar immunochromatographic test that detects soluble p27 capsid protein antigen in blood. The term *soluble* is used to distinguish these assays from assays such as IFA, which detect fixed antigen within cells. In most cats, the presence of circulating antigen correlates with viremia, although a few cats have viremia in the absence of detectable antigen or antigenemia in the absence of detectable viremia.[79] In-practice lateral flow assays are available that detect antigen in anticoagulated whole blood, plasma, or serum. In the past, the use of whole blood generated less reliable results than when plasma or serum was used, but with new-generation tests, whole blood is considered an acceptable alternative.[79] When a choice is available, serum is the preferred specimen. The use of tears or saliva is not recommended, because errors are more likely to occur. When virus isolation in culture was used as the gold standard, the sensitivity of seven different assays ranged from 92.1% to 96.8%, and the specificity ranged from 95.4% to 99.2%.[81]

TABLE 22-2

Diagnostic Assays Available for Feline Leukemia Virus Infection

Assay	Specimen Type	Target	Performance
ELISA or similar immunochromatographic tests for soluble FeLV antigen	Serum, plasma, whole blood	FeLV p27 antigen	Confirmation of positive results is recommended in healthy cats with a second test from a different manufacturer. Positive antigen test results do not signify progressive infection, and the assay must be repeated in 1 to 3 months or an IFA performed. False negatives can occur in the first month of infection.
IFA	Serum, bone marrow	FeLV antigen in blood cells	Less sensitive than ELISA. Positive results indicate infection of the bone marrow and therefore progressive infection. False positives may occur if nonspecific fluorescence is interpreted as a positive result.
PCR	Blood, bone marrow, saliva (RT-PCR); bone marrow, tissue, lymph node aspirates (PCR)	FeLV RNA (RT-PCR) or proviral DNA	Sensitivity and specificity may vary between laboratories. Never use in the absence of antigen testing. Assays that have demonstrated sensitivity and specificity may be useful to detect cats with regressive infection for elimination from blood donor programs, or to resolve the results of discordant ELISA and IFA assays. False-negative test results may occur when variant strains are present.
Virus isolation	Blood, bone marrow	Replication-competent FeLV virus	Difficult, not widely available. Requires a specialized laboratory. Used primarily as a research tool.

IFA, immunofluorescent antibody; RT, reverse transcriptase.

VetBooks.ir

When ELISAs are used as screening tests, confirmation of positive test results is recommended because of the low prevalence of infection in healthy cats and the higher possibility that false-positive test results may occur. Positive test results in the absence of FeLV antigen have the potential to occur rarely as a result of operator error or nonspecific reactivity.[82] As for FIV infection, it is especially important to immediately confirm positive test results if they are likely to result in euthanasia or rehoming for disease control purposes. There are several options to confirm a positive test result:

- Perform another ELISA antigen test using an assay from a different manufacturer. However, it should be remembered that in contrast to FIV infection, cats that test truly positive for FeLV antigen early in the course of infection (i.e., before involvement of the bone marrow) may ultimately control the infection. Thus a single positive test result does not imply progressive infection, even if it is immediately repeatable using a test from a different manufacturer. If the cat has signs consistent with FeLV-related disease, a single positive test result is more likely to mean that progressive infection is present.
- Perform an IFA assay on peripheral blood smears, because cats with positive IFA results have infection of the bone marrow and, with rare exceptions, are almost always progressively infected. Cats that test negative with IFA assays may be in a transient viremic phase that may result in either progressive or regressive infection, or they may have progressive infection but the sensitivity of IFA is too low to detect it. In this case, both ELISA and IFA assays, or the ELISA assay alone, could be repeated in 1 to 4 months.
- Retest with ELISA 6 months later. If the antigen test remains positive, progressive infection is likely. In some cats, antigenemia persists for 16 weeks before regression occurs, so the test could be repeated earlier than 6 months (e.g., 12 weeks later) or monthly if client finances permit so long as the cat remains healthy.
- Perform a full CBC. If hematologic abnormalities are present, progressive infection is likely.

Negative ELISA results can occur in the first month after exposure to FeLV, before sufficient antigen is detectable in the peripheral blood. Cats that test negative within 30 days of possible exposure to the virus should be retested 1 to 2 months later. Because development of antibodies to FIV can take up to 2 months, it is usually most practical to retest for both viral infections 2 months after possible exposure. Kittens can be tested at any time, because maternal antibody does not interfere with FeLV testing.

Immunofluorescent Antibody or Immunoperoxidase Staining

IFA assays are widely offered by veterinary diagnostic laboratories and can be performed on fresh peripheral blood or bone marrow. At least two fresh smears (without anticoagulant) should be air-dried and mailed to the laboratory. IFA is less sensitive than ELISA and, depending on the laboratory, is more prone to false-negative and false-positive results and so is not recommended for screening purposes. The presence of detectable virus using IFA in circulating blood cells indicates progressive infection more than 90% of the time. Cats with early viremia (before the bone marrow is infected) test IFA-negative but ELISA-positive. Cats with regressive infection test negative with both IFA and ELISA assays (see Figure 22-2). Negative IFA test results can occur in cats with progressive infection when there are inadequate blood cells in the periphery, such as in neutropenic cats. Performing IFA on bone marrow rather than peripheral blood may help to overcome this problem. False-positive results can occur when inexperienced laboratory personnel interpret nonspecific fluorescence as a positive test result. They also have the potential to occur when the antibody conjugates bind nonspecifically to eosinophil granules, so eosinophils must be excluded in interpretation of fluorescing cells.[83]

Some cats with clinical abnormalities that strongly suggest FeLV-related disease (such as leukemia or myelodysplasia) test negative for circulating antigen using ELISA but have bone marrow cells that test positive for FeLV antigen using IFA. For example, at the author's teaching hospital, 8 of 18 cats with leukemia or MDS that tested negative for soluble FeLV antigen had bone marrow smears that were positive using IFA; the remainder tested IFA negative. This phenomenon may reflect either false-positive IFA assay results, or true infection with undetectable levels of antigen in the peripheral blood. The use of PCR on bone marrow may help to resolve the FeLV status in at least some of these cats.

Immunohistochemistry can also be used to detect viral antigen in tissue specimens or bone marrow core biopsies, although it may be less sensitive than IFA.

Molecular Diagnosis Using the Polymerase Chain Reaction

Several different PCR assays have been developed for detection of FeLV nucleic acid. Currently the major clinical indications for PCR are (1) to screen potential blood donors in conjunction with antigen testing or (2) to test for regressive infection when FeLV is strongly suspected as the cause of neoplasia but antigen tests are negative.

PCR assays may detect FeLV RNA (reverse transcriptase–polymerase chain reaction [RT-PCR]) or proviral DNA and must be carefully designed so that they do not detect endogenous FeLV sequences. At the current time, PCR assays should *never* be used in the absence of antigen testing in order to screen for or diagnose FeLV infection. The clinician needs to understand if the assay used detects proviral DNA, viral RNA, or both (some laboratories run both assays), because the clinical significance of a positive viral RNA assay (i.e., productive viral infection) differs from that of a positive proviral DNA assay (which suggests nonproductive viral infection for cats with negative antigen tests). After infection, RT-PCR assays may be positive several weeks before antigen tests or virus isolation become positive,[84] and depending on the assay, PCR for viral RNA can be more sensitive than soluble antigen tests. High viral RNA loads in blood and saliva appear to be associated with progressive infection, whereas low loads may be associated with regressive infection (Figure 22-7).[84]

PCR assays for proviral DNA can be used on blood, buffy coats, bone marrow, or tissues of cats that test negative for FeLV antigen. Cats with a positive proviral PCR test result but negative soluble antigen test, which in one study represented about 10% of cats with negative antigen test results, have regressive infection.[85,86] These cats are probably not infectious to other cats but may reactivate virus shedding with severe stress or immunosuppression, or transmit the virus through blood transfusion or vertical transmission. Proviral DNA appears to be present at much lower levels in cats with regressive infection than in those with progressive infection.[86,87] The cell types that contain FeLV proviral DNA also may differ for antigen-negative and antigen-positive cats. The proviral DNA of one FeLV strain was

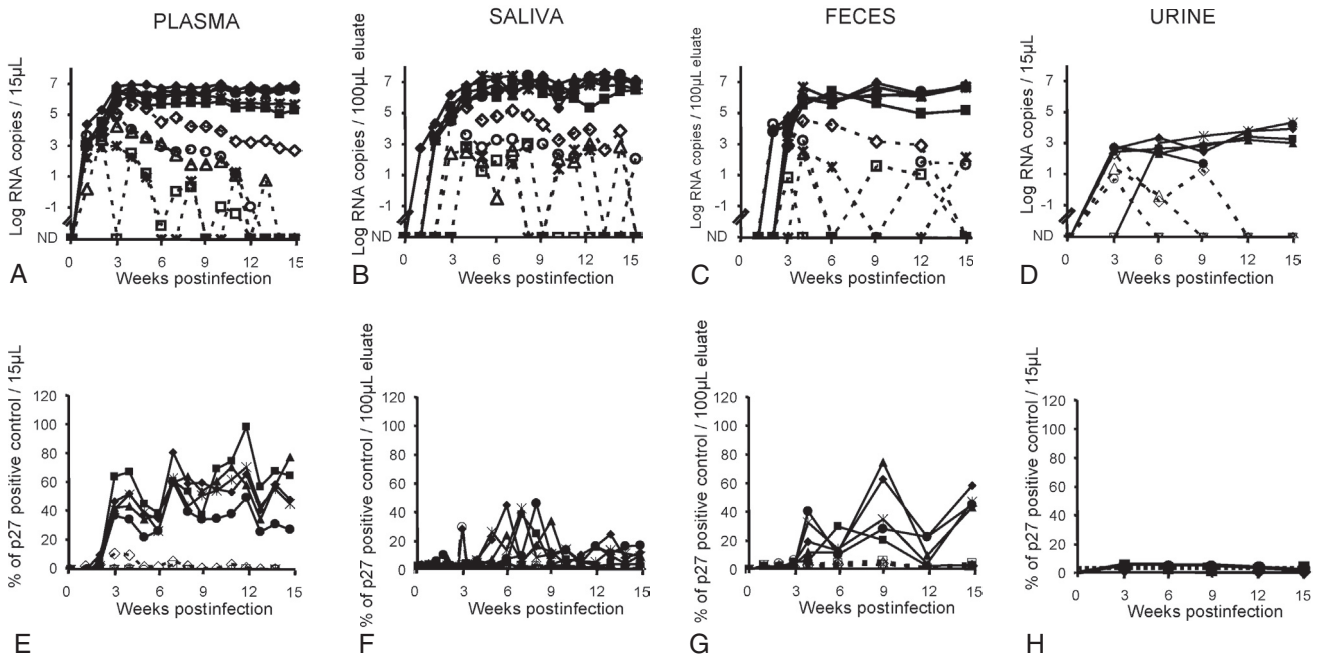

FIGURE 22-7 Viral RNA (**A-D**) and p27 antigen (**E-H**) loads in plasma (**A** and **E**), saliva (**B** and **F**), feces (**C** and **G**), and urine (**D** and **H**) in 10 cats experimentally infected with FeLV. Each line represents observations for a single cat. Continuous lines represent data from cats with progressive infection, and broken lines represent data from cats with regressive infection. (Modified from Cattori V, Randon R, Riond B, et al. The kinetics of feline leukemia virus shedding in experimentally infected cats are associated with outcome. Vet Microbiol 2009;133(3):292-296, Figure 1.)

found only in the lymphocytes of antigen-negative cats, whereas antigen-positive cats had high loads within all leukocyte types, including lymphocytes, monocytes, and granulocytes.[86,87] The use of bone marrow or tissue specimens, rather than whole blood, may increase sensitivity for detection of proviral DNA.

The sensitivity and specificity of commercially available PCR assays are likely to vary with assay design, and the usefulness of assays offered commercially has not been published, so until more information is available, great caution is warranted when interpreting the results of PCR assays for FeLV infection. Retroviruses have high rates of mutation, and the presence of sequence variations may lead to false-negative results. False-positive results occur in some PCR laboratories as a result of contamination or manual loading errors, or poor assay design. Because FeLV vaccine virus is inactivated or recombinant, it does not replicate or integrate into the host genome, so vaccination should not lead to false-positive PCR results.

Virus Isolation

FeLV can be readily isolated in cell culture. The cell culture supernatant can then be tested for production of FeLV using antigen assays or viral RNA PCR. Because growth requires several days and specialized techniques, cell culture is not routinely used for clinical diagnosis.

Antibody Assays

Although not useful for diagnosis of FeLV infection, detection of antibody responses to FeLV infection is performed on a clinical research basis with virus neutralization assays and IFA assays that detect antibodies against feline oncornavirus cell membrane–associated antigen (FOCMA).[24,48,84,88,89] Positive antibody test results in cats that test negative for FeLV antigen indicate previous exposure followed by abortive or regressive infection. Cats with progressive infections and high viral loads usually fail to develop antibody responses.[24,48,88] Antibody responses may occur after vaccination with FeLV vaccines.

Pathologic Findings

Gross and histopathologic findings in cats with FeLV infection usually reflect secondary disease processes. Lymphoma and evidence of myelodysplasia or leukemias are the most common findings, but opportunistic infections may also be detected. The intestinal tracts of cats with FeLV-associated enteritis reveal crypt cell necrosis and regeneration, lymphoplasmacytic infiltrates, and blunting and fusion of villi (See Figure 22-5).[90] Reactive lymphoid hyperplasia is also a common finding. CNS lesions include loss of axons and dilated myelin sheaths within the spinal cord.[74] Immunohistochemical stains may be applied to tissue sections to confirm the presence of FeLV antigen in association with lesions.

Treatment and Prognosis

Cats with opportunistic infections and lymphoma can be successfully treated using the same medications and supportive treatments used for FeLV negative cats with these problems. Opportunistic infections may require longer periods of treatment or, in some cases, lifelong treatment with antimicrobial drugs. Hemoplasma infections should be treated with doxycycline (see Chapter 41). Cats with nonregenerative anemias may require periodic blood transfusions. Serum erythropoietin concentrations are already high in these cats, and in many cases, treatment with darbepoetin or human recombinant erythropoietin is unsuccessful but could be attempted. The efficacy of treatments such as filgrastim is not known and may be complicated by the formation of antibodies (see Chapter 7). The management of cats with stomatitis is discussed in Chapter 21. In general, glucocorticoids and other immunosuppressive drugs

TABLE 22-3

Suggested Medications for Treatment of Cats with Feline Leukemia Virus Infection

Drug	Dose	Route	Interval (hours)	Comments
Zidovudine (AZT)	5 mg/kg	PO	12	Monitor CBC weekly during treatment for the first month, then monthly.
Feline recombinant interferon omega	1 million U/kg	SC	q24h for 5 consecutive days starting on days 0, 14, and 60	
Human recombinant interferon alpha	1 to 50 U/cat	PO	24	

should be avoided unless immune-mediated cytopenias are suspected. Some cats with FeLV-associated IMHA respond well to treatment with glucocorticoids, and glucocorticoid treatment may be unavoidable.

Antiviral agents and immunomodulators are of limited benefit for treatment of cats with FeLV infections (see Chapter 7 for more information) (Table 22-3). The use of feline recombinant IFN-ω improved clinical scores and survival times in cats with FeLV infection over a short time period (2 months) in one study.[91] Beneficial outcomes have also been described after treatment with low-dose oral human recombinant IFN-α. Zidovudine (AZT) has not performed as well for treatment of sick cats with FeLV infections as it has for those with FIV infections, and the results of some studies have shown minimal benefit. In other studies, AZT improved oral cavity inflammation, reduced antigenemia, and prolonged life span in naturally and experimentally infected cats with FeLV infection.[92,93] Controlled studies of the efficacy of other treatments, such as lymphocyte T-cell immunomodulator (T-cyte Therapeutics, Inc.) and acemannan, are required. Antivirals that show promise for treatment of FeLV infection include fozivudine (which is closely related to AZT) and the integrase inhibitor raltegravir, which has been used to treat gammaretrovirus infections in humans and inhibits FeLV replication in cell culture.[94] The safety of these drugs in cats remains to be determined.

Cats infected with FeLV should be housed indoors to prevent spread of infection to other cats. Indoor housing also minimizes exposure of infected cats to other opportunistic pathogens. Raw food diets should not be fed. Survival may be prolonged in low-stress environments, so provision of space, adequate litter boxes, management of co-infections, and a proper diet are important. Vaccines administered for prevention of respiratory viruses and FPV should be inactivated. Some FeLV-infected cats may not respond as well to vaccination as noninfected cats.

Prognosis

Survival times vary considerably depending on the stage of infection, host immunity, and the strain of FeLV involved. Nevertheless, virtually all cats that are progressively infected with FeLV go on to develop FeLV-related disease within 5 years of diagnosis.[95] A comparison of more than 800 FeLV-infected cats and 8000 controls revealed a median survival time of 2.4 years for FeLV-infected cats versus 6.3 years for controls.[79] Many progressively infected cats, especially adult cats, may live for several years with a good quality of life, and so euthanasia is not recommended on the basis of a positive FeLV test alone. Some cats with FeLV-associated lymphoma may have long-term remissions when treated with standard chemotherapy protocols. Some, but not all, studies suggest that FeLV infection is a negative prognostic indicator in cats with lymphoma.[96] One of the authors has treated a cat that initially tested positive for FeLV antigen using ELISA and had evidence of IFA-positive, severe megaloblastic erythroid dysplasia in the marrow and IMHA, yet subsequently became ELISA-negative and remained in clinical remission while being treated with glucocorticoids more than 4 years later.[97] The prognosis is least favorable for cats with leukemia, which generally survive less than a few weeks.

Immunity and Vaccination

Several parenteral vaccines are available for prevention of FeLV infection, which include adjuvanted inactivated whole virus vaccines; nonadjuvanted canarypox vectored virus vaccines that incorporate the *env* and *gag* genes of FeLV (Purevax and Eurifel, Merial); and a recombinant subunit vaccine that contains p45, the nonglycosylated form of gp70 (Leucogen, Virbac). The recombinant canarypox vaccine available in Europe is a different product than that licensed for use in the United States. Studies that have used highly sensitive PCR assays have shown that vaccination does not produce sterilizing immunity (that is, complete absence of viral RNA, DNA, antigenemia, and viremia after challenge).[98] In other words, cats develop regressive or even progressive infections, but not abortive infections after challenge.[98] Nevertheless, vaccination with recombinant subunit, canarypox vectored, and whole virus vaccine prevented progressive infection in 87%, 78%, and 44% of cats when compared with controls, respectively. One vaccine protected 83% of cats against antigenemia after challenge as long as 2 years after vaccination.[99]

In summary, no vaccine provides 100% protection against FeLV infection, and even when protection against progressive infection occurs, regressive infections still occur. However, because vaccination protects cats from progressive infection, it is indicated for all at-risk cats, such as those with outdoor exposure or those that reside in households with other FeLV antigen-positive cats. The American Association of Feline Practitioners (AAFP) highly recommends that all FeLV antigen-negative kittens be vaccinated for FeLV, because of the potential that some of these kittens may escape or become outdoor cats, even when the intention of the owner is to keep the kitten indoors.[100] Vaccination is also recommended for cats entering shelters that are likely to be housed with other cats.[79] Two doses are given in

VetBooks.ir

the left pelvic limb as distally as possible, 3 to 4 weeks apart from 8 to 9 weeks of age, followed by a booster at 1 year and then every 1 to 3 years thereafter, although more information is required on the duration of immunity for FeLV vaccines. The European Advisory Bureau on Cat Diseases (ABCD) suggests a booster every 2 to 3 years for cats older than 3 to 4 years of age, in light of the lower susceptibility of adult cats to infection.[101] Annual boosters are required for recombinant vaccines. Acutely ill cats should not be vaccinated, but it is acceptable to vaccinate cats with chronic diseases, such as chronic kidney disease. Testing for FeLV should be performed before each booster if exposure to FeLV was likely before the booster was required (which should apply for most cats vaccinated for FeLV). Vaccination with FeLV vaccines has been associated with injection-site sarcomas, so only cats that are likely to be exposed should be vaccinated.

Prevention

Prevention of FeLV infection involves indoor housing of cats away from other cats infected with FeLV, testing and removal (or separation) of cats that test antigen-positive from other cats, vaccination, and proper screening of blood donor cats with soluble antigen assays *and* PCR. Routine hand-washing precautions are indicated for hospitalized cats, and precautions should be taken (such as the wearing of gloves) to protect FeLV-infected cats from nosocomial pathogens. Fomites such as food and water bowls and litter boxes should not be shared between FeLV antigen-negative cats and cats with unknown or antigen-positive FeLV status. Neutering can prevent roaming and reduce the likelihood of FeLV infection. When a cat from a multicat household tests antigen-positive, all cats should be tested and retested and positive cats should be separated from other cats if possible. Euthanasia is recommended for sick, FeLV-positive cats that enter shelters.[101] People who adopt cats that have unknown retrovirus status from shelters should be educated about the disease and the need for quarantine and testing after adoption.

Public Health Aspects

Although FeLV can replicate in human cell culture lines, no conclusive evidence of natural infection with FeLV has ever been detected in humans.

CASE EXAMPLE

Signalment: "Hamster" a 6-year-old female spayed domestic shorthair from Fairfield, CA.

History: Hamster was brought to the University of California, Davis, Veterinary Medical Teaching Hospital for the problems of fever, lethargy, anorexia, diarrhea, and vomiting. The diarrhea had been present for 3 days and was greenish, mucoid, and occurred once to twice daily. The owner reported that Hamster had vomited yellow fluid at least three times during this period and was completely inappetent. Her urination habits had not changed. Hamster was taken to a local veterinary clinic on the first day of illness, where a physical examination revealed pyrexia (105.1°F or 40.6°C). She was treated with clavulanic acid–amoxicillin and a single intramuscular injection of enrofloxacin but there was no clinical improvement. Hamster had tested positive for FeLV antigen 1.5 years ago, after which time she had been housed exclusively indoors. She lived with some caged birds and three other FeLV-positive cats. None of the other cats were ill. Hamster played with elastic bands, but there was no known toxin exposure and no recent changes in her environment. Her diet usually consisted of a commercial dry cat food.

Physical Examination:

Body Weight: 6.9 kg

General: Quiet, alert, responsive, hydrated, T = 104.4°F (40.2°C), HR = 220 beats/min, RR = 36 breaths/min, mucous membranes pink, CRT = 1 s. Haircoat unkempt.

Eyes, Ears, Nose, and Throat (with Dilated Fundoscopic Examination): The only abnormality noted was mild gingivitis.

Musculoskeletal: Body condition score 7/9. Normal ambulation was present.

Cardiovascular and Respiratory: No clinically significant abnormalities were detected.

Gastrointestinal and Urogenital: The cat resented palpation of her cranial abdomen. The perianal region was stained with green fecal material.

Lymph Nodes: All lymph nodes were <1 cm in diameter.

Laboratory Findings:

CBC:

HCT 24.6% (30%-50%).
MCV 48.4 fL (42-53 fL), MCHC 32.1 g/dL (30-33.5 g/dL)
Reticulocytes 7800 cells/μL
WBC 11,470 cells/μL (4500-14,000 cells/μL)
Neutrophils 10,438 cells/μL (2000-9000 cells/μL)
Band neutrophils 459 cells/μL
Lymphocytes 344 cells/μL (1000-7000 cells/μL)
Monocytes 229 cells/μL (50-600 cells/μL)
Platelets 122,000 platelets/μL (180,000-500,000 platelets/μL). The neutrophils showed slight toxicity, and there were a few macroplatelets

Serum Chemistry Profile:

Sodium 148 mmol/L (151-158 mmol/L)
Potassium 3.8 mmol/L (3.6-4.9 mmol/L)
Chloride 110 mmol/L (117-126 mmol/L)
Bicarbonate 18 mmol/L (15-21 mmol/L)
Phosphorus 2.9 mg/dL (3.2-6.3 mg/dL)
Calcium 9.5 mg/dL (9.0-10.9 mg/dL)
BUN 15 mg/dL (18-33 mg/dL)
Creatinine 1.2 mg/dL (1.1-2.2 mg/dL)
Glucose 169 mg/dL (63-118 mg/dL)
Total protein 7.0 g/dL (6.6-8.4 g/dL)
Albumin 2.6 g/dL (2.2-4.6 g/dL)
Globulin 4.4 g/dL (2.8-5.4 g/dL)
ALT 72 U/L (27-101 U/L), AST 121 U/L (17-58 U/L)
ALP 12 U/L (14-71 U/L), γ- GGT 0 U/L (0-4 U/L)
Cholesterol 104 mg/dL (89-258 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.2 mg/dL).

VetBooks.ir

Urinalysis (Cystocentesis): SGr 1.020; pH 7.0, 1+ protein, 2+ hemoprotein, 0-1 WBC/HPF, 0-2 RBC/HPF, rare rods, few amorphous crystals.

Imaging Findings:

Plain Abdominal Radiographs: The small bowel was diffusely gas- and fluid-filled with normal intestinal diameter. The colon was relatively empty with a small amount of fluid. No masses were identified. There was renal asymmetry with poor visualization of the right kidney. Abdominal serosal detail appeared normal.

Abdominal Sonography: The right kidney could not be identified. The left kidney appeared normal and measured 4.2 cm in length. A small amount of fluid was present in the colon. The remainder of the abdomen was unremarkable.

Microbiologic and Virologic Testing: Aerobic bacterial urine culture: negative

Point-of-care ELISA serology for FeLV antigen and FIV antibody: positive for FeLV antigen

PCR for *Mycoplasma haemofelis* and *Candidatus* Mycoplasma haemominutum (whole blood): negative

Diagnosis: Progressive FeLV infection with suspected acute pyelonephritis (characterized by fever, gastrointestinal signs, bacteriuria, neutrophilia with a left shift, and mild thrombocytopenia). Right renal agenesis (likely congenital).

Treatment: Hamster was hospitalized and treated with intravenous fluids, enrofloxacin (5 mg/kg, slow IV, q24h) and ampicillin (20 mg/kg, IV, q8h) (note that the parenteral use of enrofloxacin in this cat was off-label and has the potential to cause irreversible blindness). Her temperature normalized within 24 hours, and there was no more vomiting or diarrhea. After 48 hours, the hematocrit was 27.6%, neutrophil count was 5759 cells/μL with no bands or toxicity, and lymphocyte count was 917 cells/μL. She was discharged from the hospital with instructions to continue antibiotic treatment for 1 month. Two weeks after the antibiotics had been discontinued, she was apparently healthy and a physical examination, CBC, kidney panel, urinalysis, and aerobic bacterial urine culture showed no abnormalities. Her hematocrit was 38.9%, white cell count was 4620 cells/μL, and platelet count was 220,000/μL. One year later, she remained clinically healthy and a CBC showed a hematocrit of 38.2%, white cell count of 4500 cells/μL, neutrophil count of 3362 cells/μL, lymphocyte count of 905 cells/μL, and a monocyte count of 45 cells/μL. Despite the mild cytopenias present, Hamster remained alive and well with a normal CBC 4 years after she was initially seen for gastrointestinal signs. She died 2 years after that, 7.5 years after she first tested positive for FeLV infection.

One of the other cats in the household, a 5-year-old, male neutered domestic medium hair cat, was euthanized 1.5 years after Hamster was initially evaluated. He developed severe normocytic, normochromic nonregenerative anemia (HCT 10.5%, with 5200 reticulocytes and 11 nucleated RBC/HPF) with neutropenia (1320 cells/μL) in association with circulating blast cells.

Comments: Even though this cat was initially seen for moderately severe illness in association with progressive FeLV infection, she made a full recovery with treatment and remained alive and well for 6 additional years. The nonregenerative anemia likely resulted from inflammatory disease. The negative urine culture may have resulted from recent treatment with antimicrobial drugs, and renal ultrasound is insensitive for diagnosis of pyelonephritis. The age of this cat, the strain of FeLV involved, and the challenge dose, as well as other environmental and genetic factors, probably all played a role in the course of disease. This case clearly demonstrates that other treatable diseases may be present in FeLV-infected cats and that search for the underlying cause of clinical signs and adequate treatment is always recommended. The second cat in the household likely also had progressive FeLV infection; the development of anemia suggested infection with FeLV-C.

CHAPTER 23

Feline Respiratory Viral Infections

Jane E. Sykes

Overview of Feline Viral Respiratory Disease

First Described in Cats: Feline herpesvirus-1 (FHV-1), 1958 (United States)[1]; feline calicivirus (FCV), 1957 (New Zealand)[2]; H5N1 influenza virus, 2006 (Thailand)[3]; pandemic H1N1 influenza virus, 2010 (United States).[4]

Causes: Feline herpesvirus-1, feline calicivirus, avian and human origin influenza A viruses

Geographic Distribution: Worldwide

Mode of Transmission: Close contact, fomite spread, to a lesser extent aerosols

Major Clinical Signs: Serous to mucopurulent nasal and ocular discharge, sneezing, stertor, conjunctivitis, lingual or facial ulceration, fever, inappetence, tachypnea, cough, rarely death. Keratitis occurs with FHV-1 infection.

Differential Diagnoses: Infections with bacteria such as *Bordetella bronchiseptica, Streptococcus* spp., or *Chlamydia felis*; other causes of rhinitis such as cryptococcosis, aspergillosis, neoplasia, foreign bodies, chronic idiopathic feline rhinosinusitis, nasopharyngeal stenosis, or nasopharyngeal polyps; feline chronic airway disease.

Human Health Significance: Influenza virus infections have been transmitted from humans to cats, and the potential for zoonotic transmission exists. FHV-1 and FCV do not infect humans.

Etiology and Epidemiology

Infectious feline upper respiratory tract disease (URTD) is a widespread and important cause of morbidity and mortality where large numbers of cats are housed together, especially in overcrowded or stressful conditions.[5] Multiple pathogens are involved and co-infections are common (Table 23-1). The most prevalent viral causes of URTD are feline herpesvirus-1 (FHV-1) and feline calicivirus (FCV). Influenza viruses also cause respiratory disease in cats but are relatively rarely identified. Bacterial causes of respiratory disease in cats include *Bordetella bronchiseptica*, *Chlamydia felis*, and *Mycoplasma* species. *Streptococcus canis* and *Streptococcus equi* subspecies *zooepidemicus* can also play a role in shelter situations and catteries. More information on the bacterial causes of feline URTD can be found in Chapters 33, 34, 38, and 40.

Feline Herpesvirus-1

FHV-1 is a large, enveloped DNA virus that has a worldwide distribution. Most cats are exposed to FHV-1 during their lifetime. FHV-1 is an alphaherpesvirus that is closely related to canine herpesvirus-1, and to a lesser extent, herpes simplex virus. There is only a single serotype of FHV-1. Isolates are also genetically similar, yet some variation in strain virulence exists.[6]

Using culture, FHV-1 has been detected in 0% to 39% of cats with URTD, although in some catteries and shelters with endemic FHV-1 infection, the prevalence may be much higher. When sensitive PCR assays are used to detect FHV-1, prevalences of infection that approach 100% have been detected in some groups of cats with acute URTD.[7] The prevalence of shedding by apparently healthy cats has ranged from 0% to 10% and most often has been lower than 2%.[5,8-14] Virtually all infected cats develop latent infection, which primarily occurs in the trigeminal ganglia. FHV-1 DNA can also be detected in other tissues of the head, such as the cornea and nasal cavity, but whether this is a true state of latency or just chronic persistent infection is not clear. Reactivation of shedding, with or without concurrent clinical signs of URTD, occurs in less than half of latently infected cats 4 to 12 days after stress.[15] Examples of stressors include transportation (such as to a veterinary clinic, boarding or breeding facility, shelter, or cat show), lactation, exposure to new cats, concurrent illness, or treatment with immunosuppressive drugs such as glucocorticoids. The duration of shedding after reactivation ranges from 1 to 13 days (mean, 7 days).[16,17] Shedding that coincides with lactation results in infection of susceptible kittens.

FHV-1 survives a maximum of 18 hours at room temperature and is readily inactivated by drying and most disinfectants. Because of this, transmission occurs primarily through close contact, although fomites remain a very important mode of transmission in crowded environments. Aerosol transmission is of lesser importance.[15,18] Aerosols generated by sneezing cats typically travel no further than a distance of 4 to 5 feet.

Feline Calicivirus

Feline calicivirus (FCV) is a non-enveloped, single-stranded RNA virus with a spherical capsid that is studded with cup-shaped depressions (*calici* = "cup") (Figure 23-1). Like FHV-1, FCV commonly causes feline URTD, accounting for 10% to over 50% of cases. The highest prevalences occur in large multicat environments. Natural infection of dogs by FCV-like strains has been reported.[19] Like other RNA viruses, the genome of FCV continually undergoes rapid mutation, which increases the diversity of strains over time. Although considerable antigenic diversity exists among FCV isolates, the degree of antigenic cross-reactivity between them is sufficient for them to be classified as a single serotype. Nucleotide sequence analysis also suggests that isolates worldwide are a single, but highly diverse, group. No correlations have been found between the genetic composition of FCV strains, different clinical manifestations of disease, or geographical location.

TABLE 23-1

Viral Causes of Transmissible Respiratory Disease in Cats

Organism	Incubation Period (days)*	Shedding Period*	Environmental Survival
Feline herpesvirus-1	2 to 6	1 to 2 weeks, with intermittent reactivation of shedding with stress	Less than a day
Feline calicivirus	2 to 6	Most <30 days, may be lifelong	Up to 1 month
Influenza viruses	Few days	<2 weeks	Hours

*Incubation and shedding periods are approximate and may differ when co-infections or immune suppression operate.

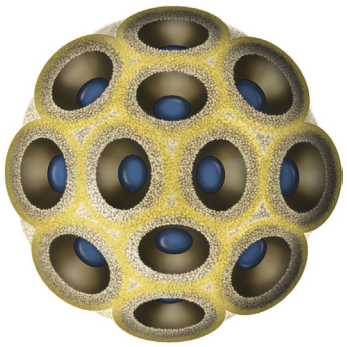

FIGURE 23-1 Schematic of the structure of the capsid of feline calicivirus.

Infected cats can develop a persistent oropharyngeal infection (>1 month in duration) in the absence of obvious clinical signs. This is termed the carrier state for FCV, and may result from immune evasion through antigenic variation of the capsid protein.[20] FCV is shed continuously from the oropharynx, and the magnitude of shedding varies with time and between individual cats.[21] Carrier cats serve as a source of infection for other cats. In many cats, shedding terminates weeks to months after infection, but in a few cats, shedding is lifelong. A single cat can be simultaneously infected with multiple variants of FCV, each derived from the original infecting strain as a result of genetic mutation, drift, and selection pressures.[20] Because of the chronic carrier state, the prevalence of FCV infection in healthy cats is high and ranged from 8% of household cats to 24% of show cats.[12]

Environmental persistence of FCV is considerably more prolonged than that of FHV-1, and FCV resists routine disinfection with quaternary ammonium compounds. Susceptibility to disinfectants may vary between FCV strains.[22] Survival in the environment has been demonstrated for as long as 28 days,[23] and related caliciviruses persist in a dried state for several months.[24] As a result, fomites are a very important means of transmission. FCV is also transmitted through direct contact with respiratory secretions and through aerosols. Fleas may spread FCV through their feces or when cats ingest fleas while grooming.[25]

Highly virulent FCV strains have been isolated from outbreaks of severe systemic febrile illness in cats in the United States and Europe known as *virulent systemic disease* (VSD),[26-31] which was first described in California in 1998. Shelter cats that were hospitalized in veterinary clinics have been a source of infection in many outbreaks, and for each outbreak, the FCV strain involved has differed. VSD has also been described in one cat from a multiple-cat household, that is, in the absence of an outbreak.[32] Otherwise healthy, adult, vaccinated cats are often affected, whereas kittens tend to show less severe signs. Although infections typically spread rapidly in outbreaks, including through fomites to pet cats of hospital staff, spread of disease has been limited to affected clinics or shelters, with no further spread within the community, and outbreaks resolve within approximately 2 months once appropriate control measures are instituted.

Influenza Viruses

Pandemic H1N1 influenza viruses originated from pigs and have caused widespread illness in humans. Natural infection with these strains has been reported in cats from the United States and Europe. Affected cats had signs of fever and respiratory and gastrointestinal tract disease and, in some cases, death.[4,33-35] Transmission from sick humans who were in contact with the cats was suspected. Cat-to-cat transmission may also have occurred.[34]

Highly pathogenic avian origin H5N1 influenza virus infection, which emerged as a cause of human illness in Hong Kong in 1997 and subsequently spread worldwide,[36] has been detected in sick and apparently healthy domestic cats and wild felids from southeast Asia[3,37,38] and central Europe.[39,40] Nevertheless, no evidence of infection was found in more than 170 cats where infected birds had been identified in Germany and Austria.[41] Infection of cats follows direct or indirect contact with infected birds, especially consumption of raw poultry; cat-to-cat transmission may also occur.[37]

Canine H3N2 virus infection was associated with bronchopneumonia in shelter-housed cats in China and Korea.[42] Experimentally, cats can also be infected with other influenza viruses, including human H2N2 and H3N2, and avian origin H7N7 and H7N3 viruses.[43,44] Widespread evidence of exposure to pandemic H1N1, seasonal H1N1, and seasonal H3N2 was found in 400 cats from Ohio in the United States.[45] Seropositive cats were 7.4 times more likely to have had respiratory illness than seronegative cats, and twice as likely to have had nonrespiratory illness than seronegative cats. More information on influenza viruses can be found in Chapter 17.

Clinical Features

Signs and Their Pathogenesis

After direct or indirect contact with virus in respiratory secretions from the conjunctiva, nasal cavity and oropharynx, FCV and FHV-1 replicate within lymphoid and epithelial cells in the upper respiratory tract and cause cytolysis. FHV-1 also replicates in corneal epithelial cells.[46] Although FHV-1 prefers to replicate in the cooler tissues of the upper respiratory tract,

systemic infection with viremia occurs in some cats infected with FHV-1 and may be more likely to occur in neonates and debilitated cats. FCV and influenza viruses also replicate systemically. FCV is shed in the urine and feces of infected cats, in addition to respiratory secretions. Influenza viruses are shed in both respiratory secretions and the feces. Avian origin H5N1 influenza viruses replicate initially in the lower respiratory tract (type II pneumocytes and alveolar macrophages) or gastrointestinal tract (for example, after ingestion of an infected bird), which is followed by severe systemic infection with necrosis and inflammation in multiple organs.[38] In contrast, severe systemic infection is not a feature of H1N1 influenza virus infections in cats.[47]

Clinical signs of viral URTD occur after an incubation period of 2 to 6 days, although longer incubation periods are also possible, and incubation periods as short as 1 to 2 days can occur in cats infected with influenza viruses.[47] Viral shedding occurs as early as 24 hours after infection, and often before the onset of clinical signs. Clinical signs range considerably in severity from no signs or mild serous ocular discharge to pneumonia and death. The most severe signs tend to occur in very young or elderly debilitated cats. Concurrent immunosuppressive illness or infection with other respiratory pathogens and opportunistic bacteria also profoundly influences disease severity. Clinical signs include conjunctivitis, serous or mucopurulent ocular and nasal discharge and sneezing, and, less commonly, cough or tachypnea (Figure 23-2, *A*). Mucopurulent discharges result from secondary bacterial infections with opportunistic pathogens such as *Streptococcus* spp., *Staphylococcus* spp., *Pasteurella multocida*, and *Escherichia coli*. Ocular and nasal discharges may become crusted, and kittens' eyes may not open as a result of the sticky exudates; when severe this can be followed by extensive corneal damage and rupture of the globe. Lethargy, inappetence, hypersalivation, and fever may be present in acute infections. FCV and FHV-1 infections may also lead to pharyngitis and laryngitis, which can be accompanied by clinical signs of gagging or obstructive respiratory patterns. Ulcerative glossitis and ulceration of the nasal planum, conjunctiva, and skin is more common and severe with FCV infection but can also be associated with FHV-1 infection (see Figure 23-2, *B*). Clinical features unique to each infection are outlined next.

FIGURE 23-2 Chemosis, mucopurulent ocular and nasal discharge **(A)** and lingual ulceration **(B)** in a 6-month-old intact male domestic medium-hair cat with chronic nasal discharge and conjunctivitis. A conjunctival swab specimen tested positive with a PCR assay for FCV RNA and negative for FHV-1, *Chlamydia felis*, and *Mycoplasma* spp. DNA. (Courtesy of the University of California, Davis Veterinary Ophthalmology Service.)

Feline Herpesvirus-1

In neonatal infections caused by FHV-1, damage to upper respiratory epithelium may lead to osteolysis of the nasal turbinates and persistent or recurrent sinusitis and rhinitis. Rarely, neurologic signs and reproductive complications such as abortion and fetal resorption have been observed in infected cats, although it is unclear what role FHV-1 itself plays in the pathogenesis of these clinical manifestations. FHV-1 is an important cause of corneal disease in cats, and has been implicated as a cause of acute and chronic ulcerative (epithelial) keratitis, stromal keratitis, eosinophilic keratitis, corneal sequestra, and uveitis. Stromal keratitis is thought to be an immunopathologic response to persistent viral antigens. The presence of dendritic corneal ulcers is thought to be pathognomonic for FHV-1 infection. However, the role that FHV-1 plays as a cause of eosinophilic keratitis, corneal sequestra, and uveitis requires further study, because a clear association between these abnormalities and the detection of FHV-1 within corneal tissues has not always been present.[48] Consequences of ocular disease due to FHV-1 include symblepharon (adhesion of an ulcerated conjunctiva to itself or the cornea) and keratoconjunctivitis sicca. FHV-1 can also cause a severe ulcerative and eosinophilic facial dermatitis (Figure 23-3). Lesions have also been described elsewhere on the body in the absence of facial lesions.[49]

Feline Calicivirus

FCV infection has been most strongly associated with erosive or ulcerative lesions, which can occur on the nasal planum, tongue, lips, and occasionally the conjunctiva and heal over a period of 2 to 3 weeks.[50] Persistent infection with FCV has also been linked to chronic ulceroproliferative and lymphoplasmacytic stomatitis, which involves the mucosa lateral to the palatoglossal arches (caudal stomatitis), the alveolar mucosa in the premolar and molar area, and sometimes the buccal mucosa (alveolar/buccal mucositis) (Figure 23-4).[51-53] Some persistently infected cats have isolated hyperemia of the buccal mucosa along the length of the dental arcade in the absence of significant periodontal disease. There is no age predisposition for this condition.[53] Pyrexia and transient lameness due to synovitis has been described days to weeks after clinical signs of acute FCV infection and after vaccination with certain FCV vaccines. FCV has been investigated as a possible cause of feline lower urinary tract disease (feline interstitial cystitis) and enteritis in cats. Because

FIGURE 23-3 Ulcerative and eosinophilic facial dermatitis secondary to FHV-1 infection. **A,** 3-year-old female spayed domestic shorthair with a 2-month history of a crusted lesion on the right dorsal muzzle. **B,** Fourteen-year-old female spayed domestic shorthair with blepharokeratoconjunctivitis and severe ulcerative facial dermatitis. **C,** Same cat as in **B** after 4 months of treatment with famciclovir. Fluorescein stain is present. Biopsy in both cats showed severe, diffuse, necrotizing, and eosinophilic dermatitis with a few intranuclear inclusions bodies. A PCR assay for FHV-1 DNA on a biopsy from the cat in **B** was positive. (Courtesy of the University of California, Davis Veterinary Dermatology and Ophthalmology Services.)

FCV can be shed in the urine and feces of apparently healthy cats, the significance of the virus in the pathogenesis of these conditions remains unclear.

Cats with VSD show severe signs of caliciviral URTD, including anorexia, fever (often >105°F [40.6°C]), weight loss,

FIGURE 23-4 Severe caudal stomatitis in a retrovirus-negative, 8-year-old female spayed domestic shorthair cat that was evaluated for ptyalism. The cat lived with 12 other cats. Histopathology revealed severe plasmacytic and neutrophilic inflammation with multifocal epithelial ulceration and hyperplasia.

oral and footpad ulceration, and nasal and/or ocular discharge. VSD strains infect not only epithelial cells of the upper respiratory tract and oral cavity, but a variety of other cell types, such as endothelial cells, hepatocytes, pneumocytes, and pancreatic acinar cells.[54] FCV uses feline junctional adhesion molecule A (JAM-A) as a receptor, a member of the immunoglobulin superfamily. The lesions that develop are thought to result from disruption of intercellular tight junctions and vasculitis. Distinctive clinical signs of VSD include cutaneous edema, alopecia, crusting, and ulceration. Edema occurs most commonly on the head and limbs but may become generalized. Crusting and ulceration are most prominent on the nose, lips, pinnae, periocular regions, and distal limbs. Severe respiratory distress due to pulmonary edema or pleural effusion, or icterus as a result of hepatic necrosis or pancreatitis, develop in some cats and have been associated with a poor prognosis. Involvement of the gastrointestinal tract, liver, and pancreas may also result in vomiting and/or diarrhea. Cats also develop a coagulopathy, which can be manifested by petechial and ecchymotic hemorrhages and, rarely, epistaxis and hematochezia. In peracute infections, cats die as a result of cardiovascular arrest with few preceding signs apart from fever.

Influenza Virus Infections

In addition to fever, anorexia, lethargy, conjunctivitis, nasal and ocular discharges, and tachypnea as a result of viral pneumonia, highly pathogenic H5N1 avian origin influenza virus infections have been associated with neurologic signs such as seizures and ataxia, which result from nonsuppurative meningoencephalitis and vasculitis.[36] Diarrhea and vomiting have not been observed in cats infected with H5N1 viruses. Vomiting has been reported in cats infected with pandemic H1N1 influenza viruses, which may have a predilection for the gastrointestinal tract.[33,34]

Physical Examination Findings

Physical examination findings in cats with acute viral URTD vary from mild serous ocular discharge and conjunctivitis

VetBooks.ir

through to fever, severe mucopurulent ocular and nasal discharges, chemosis, dehydration, thin body condition, stertorous or stridorous respiration, tachypnea, increased breath sounds on thoracic auscultation, hypersalivation, and ulceration of the nasal planum, tongue, and lips. Because ulcerative lesions can occur at the base of the tongue near the larynx, examination of the entire tongue should be performed in cats that are febrile and inappetent, which may require sedation. Cats with VSD can have edema of the face and lips, icterus, cutaneous ulceration, evidence of petechial hemorrhages, and abdominal pain. Ulcerative keratitis with dendritic or geographical corneal ulceration may be seen in cats with acute FHV-1 infection; chronic FHV-1 infection may be manifested as stromal keratitis with neovascularization, pigmentation and fibrosis of the cornea, symblepharon, and conjunctivalization of the cornea (Figure 23-5). Eosinophilic keratitis manifests as superficial, pink to white vascularized proliferative lesions on the cornea or conjunctiva; abundant eosinophils are present in smears of corneal scrapings. Herpetic facial dermatitis is manifested as cutaneous ulceration, erythema, exudation, and adherent crusts, most commonly around the nose and eyes but occasionally on the trunk and limbs.[55] Cats with persistent FCV infection may have ulceroproliferative caudal stomatitis or buccal/alveolar mucositis, and exhibit pain on examination of the oral cavity.

Diagnosis

It is not always possible to identify the cause of transmissible respiratory disease in cats based on clinical signs alone, because each pathogen produces a similar spectrum of signs. The presence of corneal ulceration raises suspicion for FHV-1 infection, and severe lingual ulceration or facial edema and crusting raises suspicion for FCV infection, but mixed infections occur and complicate diagnosis. A history of exposure to other cats provides support for a diagnosis of viral respiratory disease, but because FHV-1 infections can recrudesce with stress, potential or known exposure to other cats is not essential to implicate respiratory viruses as a cause of disease. Previous immunization for feline respiratory viruses does not rule out the possibility of viral URTD. All cats with signs of URTD should have known retrovirus infection status, because viral URTD is common in retrovirus-infected cats. When signs such as chronic nasal discharge are present, other etiologies should also be considered, such as fungal infections, neoplasia, and foreign bodies. Diagnosis of eosinophilic keratitis and ulcerative facial dermatitis may require corneal scrapings or skin biopsy, respectively.

Laboratory Abnormalities

There are no specific CBC, biochemistry profile, or urinalysis abnormalities that aid in a diagnosis of feline viral respiratory disease. The CBC can be normal or show a mild to moderate neutrophilia, sometimes with band neutrophils or neutrophil toxicity. Lymphopenia may be present in severely affected cats. Serum biochemistry findings in cats with viral respiratory disease are usually unremarkable unless disease is severe or chronic. In cats with VSD, hematologic abnormalities include mild to severe anemia, thrombocytopenia, neutrophilia, and lymphopenia. Cats with VSD may also have hypoalbuminemia, hyperbilirubinemia, mildly increased serum activities of ALT and AST, and increased serum CK activity. Serum CK activities up to 11,000 U/L can occur.[26] Cats with chronic stomatitis may have hyperglobulinemia due to a polyclonal gammopathy.

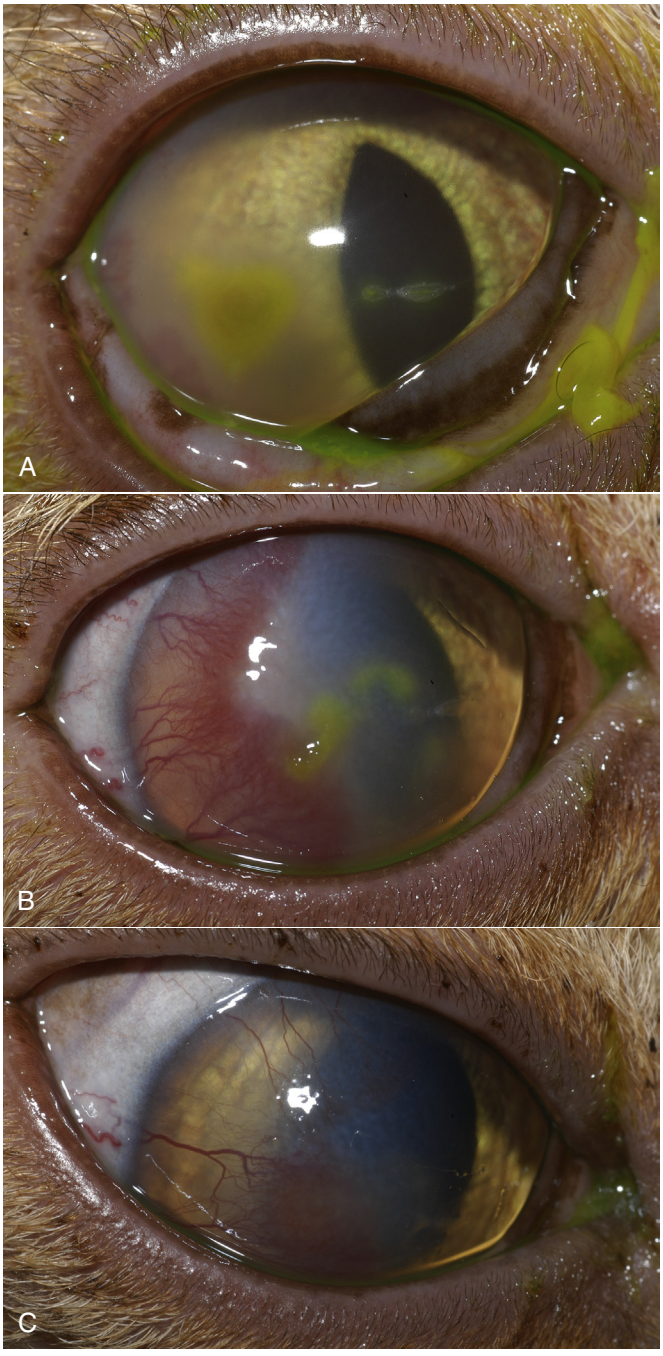

FIGURE 23-5 **A,** Ulcerative and stromal keratitis in a 2-year-old male neutered rex cat. FHV-1 infection was suspected. Treatment with famciclovir (375 mg PO q8h), L-lysine (500 mg PO q12h), and cidofovir (0.5%; one drop OD q12h) was associated with clinical improvement over a 1 month period (**B** and **C**). The cat had a history of a corneal sequestrum and subsequently developed eosinophilic keratitis. (Courtesy of the University of California, Davis Veterinary Ophthalmology Service.)

Tracheobronchial lavage specimens from cats with pneumonia may show a suppurative or mixed exudate, sometimes with evidence of secondary bacterial infection. Aerobic bacterial culture and susceptibility testing and culture for *Mycoplasma* spp. are indicated on wash specimens. Organisms such as *Pasteurella* spp., *Staphylococcus pseudintermedius*, *Streptococcus* spp., *Escherichia coli, Klebsiella pneumoniae*, and some *Mycoplasma* spp. infect the airways as opportunists. Bacterial culture of nasal swabs is generally not recommended because it often

VetBooks.ir

TABLE 23-2

Diagnostic Assays Available for Respiratory Virus Infections in Cats

Assay	Specimen Type	Target	Performance
Virus isolation	Conjunctival, nasal, and caudal pharyngeal swabs, transtracheal and bronchoalveolar wash specimens, airway and lung specimens collected at necropsy	Virus	Negative results can occur if specimens contain no or low numbers of virus particles. May take several days and requires specialized techniques and expertise. May be the most sensitive assay for detection of FCV infections.
PCR	See Virus isolation	Viral nucleic acid	Sensitivity and specificity may vary depending on assay design. Sensitivity may be low because of brief shedding for some viruses or low-level shedding in chronic infections. Assays may not detect all virus strains. Testing specimens from multiple different anatomic sites or combining PCR with other diagnostic tests can increase sensitivity. Attenuated live vaccine virus may be detected after vaccination. Because of subclinical shedding, the significance of a positive result may be difficult to interpret. False-negative results may occur as a result of degradation of viral nucleic acid during specimen transport.
Serology	Serum	Antibodies against respiratory viral antigens	Interpretation complicated by previous vaccination and exposure. Acute and convalescent serology may be useful in outbreak situations that involve a novel strain of FCV or influenza A virus.
Histopathology	Necropsy or biopsy specimens	FHV-1 inclusions; immunostaining	Detection of FHV-1 inclusions has low sensitivity, and immunostaining and/or PCR is required to definitively identify the infecting virus.

FCV, Feline calicivirus; FHV-1, feline herpesvirus-1.

leads to growth of normal flora, which has no clinical relevance. However, resistant *Pseudomonas aeruginosa* infections can develop in some cats with chronic URTD that have been treated repeatedly with antimicrobial drugs.

Diagnostic Imaging

In uncomplicated feline URTD viral infections, plain thoracic radiographs may be unremarkable or show a mild diffuse interstitial to bronchointerstitial pattern. Alveolar patterns or lung lobe consolidation can occur with secondary bacterial pneumonia.

Microbiologic Tests

Because many cats experience self-limiting disease, attempts to obtain an etiologic diagnosis should be made when disease persists for longer than 7 to 10 days or is complicated by pneumonia, with lethargy and inappetence. When outbreaks occur in shelters or the pattern of endemic respiratory disease changes, attempts to make an etiologic diagnosis are also indicated and strongly encouraged. Because FCV and FHV-1 can be detected in apparently healthy cats, it may be difficult to know the significance of a positive test result in a single cat with signs of respiratory disease. In an outbreak situation, collection of multiple specimen types from several cats with and without clinical signs can facilitate diagnosis and allow interpretation of the significance of test results. In shelter situations or outbreaks of severe disease, necropsies can provide valuable information and should be performed by a veterinary pathologist as soon as possible after death or euthanasia. Tissues should be submitted for histopathology (in formalin), bacterial and virus isolation (fresh tissue), and PCR for respiratory viruses and bacteria (fresh or frozen tissue; see Chapter 5). There is currently no way to distinguish FCV strains that cause VSD from other FCV strains.

Assays available to detect feline respiratory viruses include virus isolation, direct immunofluorescence, and PCR assays (Table 23-2). Point-of-care ELISA assays developed for use in humans have been evaluated for detection of H5N1 influenza virus antigen in cats[56] but have low sensitivity and will not be discussed further. Because influenza viruses and FCV are RNA viruses that exhibit considerable sequence diversity, virus isolation may offer the greatest sensitivity for detection of these viruses and enables typing for influenza viruses. In contrast, FHV-1 loses infectivity more rapidly than FCV and has little sequence diversity, so PCR is more useful. The use of both PCR and culture together offers the greatest sensitivity when it is important to obtain a diagnosis. Serology may be of use for investigation of outbreaks that involve novel FCV strains or influenza virus types.

Virus Isolation

FCV, FHV-1, and influenza viruses are readily isolated in cell culture. Virus isolation for diagnosis of feline respiratory viral

VetBooks.ir

infections is offered to veterinarians by some commercial veterinary diagnostic laboratories that specialize in virology. The laboratory should be notified if influenza virus infection is a possibility. Suitable specimens for isolation of respiratory viruses include conjunctival, nasal, and oropharyngeal swabs, transtracheal or bronchoalveolar lavage specimens, or upper airway tissue or lung obtained at necropsy. Influenza viruses may also be isolated from feces or rectal swabs. If swabs are used for specimen collection, polyester-tipped swabs and specific virus transport media should be used, which are available from commercial testing laboratories. Cotton swabs should be avoided, because influenza viruses adhere to the cotton, which may lead to reduced sensitivity.[57] When conjunctival swabs are collected, the use of topical anesthetics should also be avoided, because they have the potential to reduce the sensitivity of virus isolation.[58] Isolation may take several days. Sensitivity can be very low in cats with chronic manifestations of infection (for example, more than 1 week after the onset of clinical signs), because shedding of respiratory viruses can be transient. In cats with mixed FCV and FHV-1 infections, FCV may obscure the presence of FHV-1, because it produces cytopathic effects more rapidly.

Fluorescent Antibody Testing

Fluorescent antibody that specifically detects FHV-1 or FCV can be applied to conjunctival smears or impression smears from lung tissue collected at necropsy. The effect of vaccination with attenuated live vaccines on fluorescent antibody test results has not been reported. The sensitivity of fluorescent antibody testing is lower than that of PCR and virus isolation,[59] and inexperienced laboratory personnel may misinterpret nonspecific fluorescence as a positive result.

Molecular Diagnosis Using the Polymerase Chain Reaction

Panels of real-time PCR assays that detect feline respiratory pathogens are offered by some commercial veterinary diagnostic laboratories and are rapid and relatively inexpensive. These can include assays for FHV-1 and FCV, as well as bacteria such as *Mycoplasma* spp., *B. bronchiseptica*, and *C. felis*. RT-PCR assays for the detection of influenza viruses are also available. The sensitivity and specificity of PCR assays can vary considerably between laboratories. Swabs of the nasal cavity, conjunctival sac, or caudal pharynx; tracheobronchial lavage specimens; skin biopsies; or upper respiratory tract and lung tissue collected at necropsy are suitable specimens for testing. Topical anesthetics and fluorescein can reduce the sensitivity of PCR assays for human herpesviral infections,[60] and so they should be avoided, although one study showed no inhibitory effect of topical fluorescein or proxymetacaine in cats on FHV-1 or *C. felis* PCR results.[61] False-negative PCR results can occur in cats with chronic infections that shed at low levels. Because FCV and influenza viruses are RNA viruses, false negatives may also result from degradation of viral RNA during specimen transport or as a result of strain variation.

Positive PCR assay results for FCV and FHV-1 should be interpreted with caution, because apparently healthy cats can shed these viruses and, although controversial, FHV-1 DNA detected in corneal, conjunctival, or nasal biopsy tissue may represent latent virus. In one shelter, a correlation between the quantity of FHV-1 present in pooled oropharyngeal and conjunctival swabs as determined using quantitative real-time PCR and the severity of histologic lesions within the nasal cavity was detected, with cycle threshold values less than 29 correlating with the most severe histologic lesions.[62] In the future, quantitation of viral nucleic acid within swabs may assist interpretation of the clinical significance of positive PCR results. PCR can also detect attenuated live vaccine virus that is shed after routine vaccination. However, this appeared to be an uncommon phenomenon in one study that used PCR to detect FHV-1 and FCV in 12 cats over a 3-week period after vaccination with intranasal or parenteral attenuated live FHV-1 and FCV vaccines. [14] The cats in this study had been previously exposed to FHV-1, and two had been vaccinated with FHV-1 and FCV vaccines, which may have reduced shedding after vaccination. Additional studies are required to determine the prevalence of positive assay results after vaccination and their relationship to vaccine virus. In outbreak situations, false-positive PCR results have the potential to occur if swabs become contaminated with virus from the environment or the hands of personnel. Clean examination gloves should be worn for each cat, and the swab should touch only the anatomic site to be tested.

Serologic Diagnosis

Serologic assays (such as ELISA or serum neutralization assays) that detect antibodies to FHV-1 and/or FCV are offered on a commercial basis to veterinarians. Unfortunately, serology is not useful for diagnosis, because of vaccine titer interference and the high prevalence of subclinical exposure to these viruses in the cat population. Titers to FCV may vary depending on the degree of homology between the infecting virus and the FCV strain used in the assay. Nevertheless, serology has been useful to investigate some outbreaks of VSD. Serology has also been used to predict protection from infection, although cats with negative titers can still have some degree of immunity, and cats with positive titers may develop illness after challenge.

Serologic assays for influenza virus exposure are based on serum neutralization or hemagglutination-inhibition (see Chapter 2) and are specific for the influenza virus strain of interest (i.e., H5N1, H1N1).

Pathologic Findings

Gross lesions in cats with viral URTD include cutaneous and lingual ulcerations, evidence of keratitis in cats infected with FHV-1, submandibular or retropharyngeal lymph node enlargement, mucosal hyperemia, and mucopurulent exudate within the nasal cavity and trachea. In cats with pneumonia, the lungs may be edematous with diffuse or multifocal consolidated areas. Histopathology may show fibrinosuppurative and necrotizing stomatitis, rhinitis, tracheitis, and/or alveolitis. When FHV-1 is present, intranuclear viral inclusions may be found within epithelial cells of the upper respiratory tract (Figure 23-6). Osteolytic changes within the nasal turbinates may also be identified in cats infected with FHV-1. Virus can be detected in epithelial cells using immunohistochemistry or fluorescent antibody staining. Skin biopsies from cats with ulcerative herpesviral dermatitis show epidermal ulceration and necrosis that extends into the superficial dermis, and infiltration with degenerated neutrophils, eosinophils, and fewer numbers of histiocytes, plasma cells, and lymphocytes. In some skin biopsies, intranuclear viral inclusions are identified.[55]

Necropsy findings in cats with VSD are variable. Frequently reported findings include individual hepatocellular necrosis and dissociation with minimal inflammation, acute interstitial pneumonia, and free pleural and abdominal fluid.[26-28,31] Acute necrotizing vasculitis of subcutaneous and oral submucosal vessels has been described.[32] Intestinal crypt necrosis and pancreatitis have been reported in experimentally infected cats.

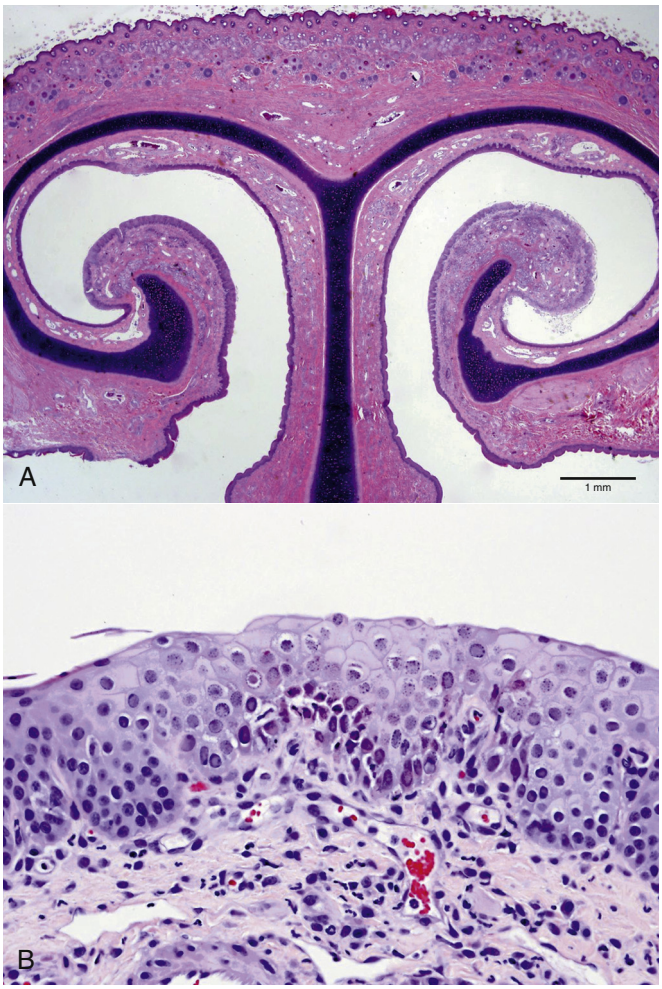

FIGURE 23-6 **A,** Cross-section of the nares of a shelter cat with rhinitis due to infection by FHV-1. Ulceration is most severe on the right side. Hematoxylin and eosin stain. **B,** Higher magnification of the nasal epithelium that shows rhinitis and the presence of intraepithelial, intranuclear inclusion bodies. (From Burns RE, Wagner DC, Leutenegger CM, et al. Histologic and molecular correlation in shelter cats with acute upper respiratory infection. J Clin Microbiol 2011;49(7):2454-2460. Images courtesy Dr. Patricia Pesavento, University of California, Davis Veterinary Anatomic Pathology Service.)

In addition to acute respiratory lesions, cats infected with H5N1 influenza viruses can have widespread necrosis and inflammation in many organs.

Treatment and Prognosis

Acute Upper Respiratory Disease

Supportive care is the mainstay of treatment for acute feline URTD and includes subcutaneous fluid therapy, antimicrobial drugs for secondary bacterial infections, and enteral nutrition. Appetite stimulants such as diazepam may be useful in some cats, but if inappetence persists for longer than 3 days, feeding tube placement is indicated. Severely affected cats may require hospitalization in isolation and treatment with parenteral fluids, nebulization, and supplemental oxygen. Acute signs generally resolve within 2 to 3 weeks with supportive care, but some cats experience frequent disease relapses and chronic complications such as keratitis and persistent stomatitis. Cats with VSD may require treatment with colloids. Mortality rates that exceed 50% can occur in outbreaks of VSD.[31]

Herpetic Keratoconjunctivitis and Facial Dermatitis

The use of antiviral drugs should be considered for cats with severe and recurrent or persistent manifestations of FHV-1 infection such as keratitis, severe conjunctivitis, and ulcerative facial dermatitis. Antiviral drugs are discussed in more depth in Chapter 7 (see Table 7-2 for dosages). Referral to a veterinary specialist for assessment of an underlying cause should be considered for cats with signs of chronic URTD. Acyclovir and its prodrug, valacyclovir, cause unacceptable toxicity when administered systemically to cats, and so their use is not recommended. In contrast, oral famciclovir is well tolerated by adult cats and kittens and results in significant clinical improvement and decreased viral shedding in cats with acute and chronic herpesviral disease (see Figure 23-3, *B* and *C*).[63,64] The prodrug of famciclovir, penciclovir, also has potential to be a useful drug for treatment of feline herpesviral infections. Because FHV-1 infection can deplete conjunctival goblet cells,[64a] frequent application of a topical mucinomimetic that contains hyaluronic acid is recommended in conjunction with famciclovir.

Topical ophthalmic preparations that contain idoxuridine, trifluridine, vidarabine, or acyclovir can be used to treat herpesviral keratitis, although the true efficacy of these drugs has not been well studied. Frequent topical application is required (5 to 6 times daily), and prolonged use can cause corneal irritation or ulceration. Idoxuridine and vidarabine are better tolerated by cats than trifluridine; vidarabine is effective against idoxuridine-resistant strains. Cidofovir and ganciclovir show greater promise as topical treatments and are highly active against FHV-1 in vitro. Topical cidofovir decreases disease severity and viral shedding in experimentally infected cats,[65] and has the advantage of requiring only twice daily administration.

Human recombinant IFN-α and recombinant feline IFN-ω inhibit FHV-1 replication in vitro and have been administered parenterally, topically (for keratitis), and orally to cats with FHV-1 infection. Obvious clinical responses to treatment have not been uniformly observed, but controlled clinical trials that involve large numbers of cats are lacking. Improvement was noted when IFN-α was given subcutaneously 2 days before inoculation of cats with FHV-1,[66] but the effect of parenteral IFN-α after the onset of clinical signs requires further investigation. Parenteral administration may be followed by the development of neutralizing antibodies beyond 3 weeks of treatment.

Lysine has shown efficacy for treatment of herpesviral conjunctivitis in cats when administered as tablets[67] and can reduce reactivated shedding by latently infected cats.[68] However, when administered to shelter cats, there was no reduction in URTD, possibly because of the stress of tablet administration.[69] Dietary formulation with lysine has also not been effective for management of URTD in shelters and in fact may contribute to a worsened outcome.[70] Administration of lysine tablets or paste could be considered for client-owned cats with chronic herpesviral disease but is not recommended in shelter situations.

The use of glucocorticoids to treat refractory keratitis is controversial, because it may reactivate virus and worsen disease. However, eosinophilic keratitis may require treatment with topical glucocorticoids. Because the role of FHV-1 in this condition is unclear, topical antiviral medications such as cidofovir are often given concurrently. Topical glucocorticoids are contraindicated when corneal ulceration is present, so the eyes should first be carefully examined after staining with fluorescein. Cats

VetBooks.ir

with ulcerative eosinophilic keratitis may require systemic glucocorticoid treatment until the ulcers heal. Referral to a veterinary ophthalmologist is recommended.

Chronic Gingivostomatitis

Caudal stomatitis in cats infected with FCV is often refractory to medical treatment. Clinical cure occurs in 50% to 60% of cats and there is significant improvement in 30% to 40% of cats after 1) extraction of teeth in the vicinity of lesions, 2) treatment with antimicrobial drugs with activity against anaerobic and gram-positive aerobic bacteria, and 3) the use of antiseptic mouthwashes (see Chapter 21). Cats that fail to respond to this treatment may require long-term treatment with antimicrobial and antiinflammatory drugs, although one study showed minimal improvement in cats with refractory stomatitis that were treated with prednisolone.[53] Recombinant feline IFN-ω has also been used subcutaneously and orally to treat caudal stomatitis. In a randomized, multicenter, controlled, double-blinded study of cats with refractory caudal stomatitis and alveolar/buccal mucositis, oromucosal treatment with rfIFN-ω (0.1 million units q24h) was associated with significant improvement in lesions and decreased pain scores from day 0 to day 90.[53]

Influenza Virus Infections

Oseltamivir has been used to treat captive wild and domestic cats with influenza virus infections,[33,71] but it was not effective. The optimal dose of this drug in cats is not known. Therefore, cats with suspected influenza virus infections should be treated supportively.

Immunity and Vaccination

Immunity to respiratory viruses depends on cell-mediated and systemic and local (mucosal IgA) humoral immune responses. Maternal antibody to respiratory viruses can persist until 14 weeks of age,[15] although other kittens may be susceptible to infection at 6 weeks of age.

Vaccines for FHV-1 and FCV have been available for decades, but these do not provide complete protection, and disease continues to be widespread in the cat population. Infection of kittens before completion of the primary vaccine series contributes to this problem. Both inactivated and attenuated live FHV-1 and FCV vaccines are available, and attenuated live vaccines are available for parenteral or intranasal administration. Inactivated vaccines contain adjuvant, and their use should be reserved for immunosuppressed cats (such as retrovirus-infected cats) or pregnant cats, if deemed necessary. When infections are a problem in kittens in breeding catteries, vaccination of the queen before mating is preferable to vaccination during pregnancy and may prolong the duration of maternal antibody persistence.[50] Vaccination as early as 4 weeks of age (but not before) could be considered in catteries with high rates of viral URTD. The primary series should consist of vaccines administered every 3 to 4 weeks of age until no earlier than 16 weeks of age.

No respiratory viral vaccine prevents infection, the carrier state, or reactivation of FHV-1 infection with stress, but they can reduce disease severity. Whether a cat contracts feline viral URTD after vaccination depends on factors such as virus strain virulence, the challenge dose, environmental temperature and humidity, and the presence of underlying immunosuppressive disease or other concurrent disease.

For FHV-1 infections, vaccination can reduce the duration of shedding, viral infectivity (presumably as a result of complexing of virus by antibody), and the load of latent virus in the trigeminal ganglia.[15,72,73] It is unclear if the frequency of reactivation is reduced, although this is the case for herpesviral vaccines in other species (such as the shingles vaccine for humans). The intranasal FHV-1 vaccine virus can itself become latent, but whether parenteral FHV-1 vaccine virus becomes latent is unknown. Most FCV vaccines do not prevent shedding, and virus shedding from the oropharynx can actually increase after FCV vaccination, because of shedding of attenuated live vaccine virus.

Because FHV-1 strains are antigenically similar, the immune response to one FHV-1 strain cross protects against other FHV-1 strains. Greater variability in cross protection occurs for FCV strains. Vaccines that contain F9, the most widely used FCV vaccine strain, provide partial protection against aerosol challenge with heterologous strains.[74] Cross-neutralization studies have shown that the antigenic composition of current field FCV strains may differ enough from the original F9 strain that the level of cross-protection induced by F9 vaccines may be suboptimal. As a result, it has been suggested that new FCV strains should be incorporated into FCV vaccines. However, vaccines that contain F9 still appear to generate cross-reactive antibody to a large number of currently circulating strains.[75] A nonadjuvanted, inactivated vaccine that contains two FCV strains (G1 and 431) is available in Europe, which provided greater reduction in clinical scores after challenge with a heterologous strain that the use of either strain alone and also reduced shedding.[76] Exposure of vaccinated cats to field strains of FCV may also serve to boost immune responses and ultimately broaden protection. Cats that are not exposed to field strains, such as isolated indoor cats, may be more susceptible to severe disease when hypervirulent strains appear. An adjuvanted, inactivated vaccine for VSD that contains a single hypervirulent strain was introduced in the United States in 2007. However, the degree to which this vaccine cross-protects against other hypervirulent strains is unknown, and outbreaks cease when infection control measures are implemented. Because of this and the increased risk of sarcoma formation with adjuvanted vaccines, the usefulness of the vaccine has been questioned.

Parenteral vaccines that contain FCV and FHV-1 are generally safe, although mild signs of URTD have the potential to occur if the cat licks the site of vaccination or aerosolization of vaccine occurs during administration. Intranasal vaccines are less well tolerated by cats and can be occasionally be followed by mild to moderate postvaccinal signs of URTD. This may be problematic in shelter environments where clinical signs of URTD warrant the need for separate housing. On the other hand, intranasal vaccines are advantageous in this situation because of rapid onset of immunity, with partial protection after 2 days and significant protection after 4 days.[15] They can also overcome maternal antibody at a young age, although some injectable vaccines may also still be effective at an early age. Because vaccine virus is propagated in feline kidney cells, there has been concern that parenteral administration of feline vaccines might lead to chronic renal inflammation when immune responses to vaccine components cross-react with endogenous renal antigens.[77] Further studies are required to determine whether this is clinically important.

Vaccine boosters are recommended 1 year after completion of the primary series, and at 3-yearly intervals thereafter in cats with low levels of exposure to respiratory viruses. For cats in contaminated environments such as catteries, boarding facilities, or large multicat households with frequent introductions, annual vaccination may be more appropriate. The duration of

immunity after vaccination remains incompletely understood. Although partial protection persists for several years after vaccination,[78] the degree of protection does wane with time, at least for cats that receive no natural boostering in the interim (i.e., from exposure to field virus). In one report, relative FHV-1 and FCV vaccine efficacies were 95% and 85%, respectively, when challenge occurred a few weeks after primary vaccination with an inactivated vaccine.[79] This compared with 52% and 63%, respectively, when challenge occurred after 7.5 years.[80] In another study, a 50% reduction in clinical scores occurred after challenge 1 year after administration of an attenuated live FHV-1 vaccine, compared with around 75% after challenge 4 weeks after vaccination.[81] Similar results were observed for an inactivated FCV vaccine. In the field, natural boostering as a result of contact with virus shed by other cats or subclinical reactivation may maintain immunity for longer periods of time.

Prevention

In addition to vaccination, reduction of stress and overcrowding is critical for prevention of URTD, especially that due to FHV-1. Proper hand washing and disinfection in shelters, boarding facilities, and veterinary hospitals to prevent fomite transmission is also very important, and dedicated food and water bowls should be used. Inactivation of FCV requires the use of disinfectants such as sodium hypochlorite (household bleach diluted 1:30), potassium peroxymonosulfate (Trifectant, Virkon S), or accelerated hydrogen peroxide. Veterinarians should remember that all cats, whether apparently healthy or sick, can be a source of FHV-1 or FCV infection, and cats examined for routine vaccination purposes may be susceptible to nosocomial infection with these viruses. Cats should be housed individually (unless they are from the same household and tolerate close proximity to one another). Barriers between cats should be impermeable, and cats with URTD should be separated by at least 4 to 5 feet to prevent aerosol transmission. If possible, cats that enter large multicat environments and shelters should be quarantined for 3 weeks to identify cats that are incubating disease. When all other control measures fail in breeding catteries, early weaning and isolation of kittens from 4 weeks could be considered.

In regions where highly pathogenic H5N1 avian influenza virus infections have been identified in birds, cats should be kept indoors. Restriction zones defined for this purpose consist of an area within a 10-km radius of an outbreak of influenza in birds for 30 days after the discovery of infected birds.[36] Cats should also not be fed raw poultry. Separation of cats from avian species in shelters and hospital situations should be maintained.

Public Health Aspects

FHV-1 and FCV do not infect humans. Although cats can acquire influenza virus infections from humans, the risk of transmission from cats back to humans is unknown. Nevertheless, cats suspected to have influenza virus infections (such as during a recognized outbreak) should be isolated, the handling of these cats should be minimized, and appropriate protective attire should be worn, which should ideally include properly fitted high-density surgical masks.

CASE EXAMPLE

Signalment: "Boris", a 7-year-old male neutered Burmese cat from northern California.

History: Boris was brought to the University of California, Davis, Veterinary Medical Teaching Hospital for a 3-day history of inappetence, head-shaking, gagging, hypersalivation, coughing, and sneezing. The gagging occurred throughout the day and occasionally was followed by vomiting. The vomit consisted of bile-stained fluid. Boris had not been drinking. He was taken to a local emergency clinic where bilateral serous nasal discharge was noted, and he was treated for 24 hours with intravenous crystalloid fluids and amoxicillin. Blood work showed hypokalemia (4.0 mEq/L, reference range 4.5 to 5.3 mEq/L), hyperglycemia (292 mg/dL, reference range 70 to 150 mg/dL), neutrophilia (12,920 cells/μL, reference range 2500 to 12,500) and lymphopenia (136, reference range 1500 to 7000). FeLV and FIV serology was negative. A urinalysis showed a specific gravity of 1.050, pH of 7, and 1+ proteinuria and glucosuria. Lateral and dorsoventral radiographs of the thorax and abdomen showed moderate to severe gas distention of the proximal esophagus and stomach. Profuse salivation and gagging continued, and he was referred to a specialty clinic because of concerns for a possible gastrointestinal foreign body. There had been no diarrhea, no history of travel or trauma, and no recent surgical procedures. A new indoor plant was brought into the house 2 days before the onset of clinical signs. He was last immunized for FHV-1, FCV, FPV, and rabies 1 year previously. Boris was housed completely indoors and was exposed to one other cat that only occasionally had access to the outdoors. His diet consisted of a commercial dry cat food.

Physical Examination:

Body Weight: 4.8 kg

General: Lethargic, but responsive, 5% to 7% dehydrated. Held head extended and gagged and hypersalivated throughout the examination; seemed unable to swallow. Vomited bile-stained fluid once during the examination. T = 100.8°F (38.2°C), HR >240 beats/min, respiratory rate = 24 breaths/min, mucous membranes pink, CRT = 1 s. The cat's haircoat was unkempt.

Eyes, Ears, Nose, and Throat: Bilateral serous nasal discharge was present. A linear ulcer was identified on the right lateral aspect of the tongue.

Musculoskeletal: Body condition score 4/9. Ambulatory.

Cardiovascular and Respiratory: Other than tachycardia, no other abnormalities were detected.

Gastrointestinal and Genitourinary: Mild abdominal distention was present.

Lymph Nodes: All lymph nodes were < 1 cm in diameter.

Laboratory Findings:

CBC:

HCT 34.2% (30%-50%)
MCV 51.0 fL (42-53 fL)
MCHC 32.5 g/dL (30-33.5 g/dL)
WBC 12,600 cells/μL (4500-14,000 cells/μL)
Neutrophils 11,844 cells/μL (2000-9000 cells/μL)

VetBooks.ir

Band neutrophils 126 cells/μL
Lymphocytes 126 cells/μL (1000-7000 cells/μL)
Monocytes 252 cells/μL (50-600 cells/μL)
Eosinophils 126 cells/μL (150-1100 cells/μL)
Platelets 989,000 platelets/μL (180,000-500,000 platelets/μL). The neutrophils showed slight toxicity, and there were a few Heinz bodies

Serum Chemistry Profile:

Sodium 141 mmol/L (151-158 mmol/L)
Potassium 4.0 mmol/L (3.6-4.9 mmol/L)
Chloride 108 mmol/L (117-126 mmol/L)
Bicarbonate 27 mmol/L (15-21 mmol/L)
Phosphorus 4.5 mg/dL (3.2-6.3 mg/dL)
Calcium 8.1 mg/dL (9.0-10.9 mg/dl)
BUN 21 mg/dL (18-33 mg/dL)
Creatinine 1.1 mg/dL (1.1-2.2 mg/dL)
Glucose 212 mg/dL (63-118 mg/dL)
Total protein 5.1 g/dL (6.6-8.4 g/dL)
Albumin 2.2 g/dL (2.2-4.6 g/dL)
Globulin 2.9 g/dL (2.8-5.4 g/dL)
ALT 83 U/L (27-101 U/L)
AST 50 U/L (17-58 U/L)
ALP 16 U/L (14-71 U/L)
Cholesterol 147 mg/dL (89-258 mg/dL)
Total bilirubin 0 mg/dL (0-0.2 mg/dL)

Endoscopy: Boris was anesthetized and an oral examination performed, which showed only mild dorsal pharyngeal lymphoid hyperplasia. Rhinoscopy showed a moderate amount of mucus and mild diffuse erythema of the nasal mucosa. Gastroduodenoscopy revealed focal areas of gastric erosion with hemorrhage.

Treatment: Boris was treated with IV crystalloid fluids (LRS with 20 mEq/L KCl at 20 mL/h), ampicillin (23 mg/kg IV q8h), enrofloxacin (2.6 mg/kg IV q24h), sucralfate (0.25 g PO q8h), and famotidine (0.25 mg/kg IV q12h). He continued to hypersalivate, and he vomited approximately 100 mL of fluid twice daily. After the first day of hospitalization, the owners reported that their other cat had developed signs of URTD, with sneezing and nasal discharge. Enteral or parenteral nutrition was discussed with the owner, but on the evening of the second day of hospitalization, Boris was found gagging and cyanotic. He was taken to the intensive care unit but developed cardiorespiratory arrest. CPR was instituted and tracheal suction revealed yellow fluid consistent with possible aspiration. Although CPR was initially successful, Boris arrested again and died shortly afterward.

Necropsy Examination: Gross necropsy examination showed numerous lingual ulcerations, mostly pinpoint but some coalescing into larger ulcers up to 1 cm long and 0.5 cm wide. Both lungs were diffusely dark red, poorly collapsed, and oozed large amounts of clear fluid on cut surface. There was a small amount of yellow ascites fluid. Histopathology revealed marked, multifocal, acute to subacute necrotizing stomatitis, rhinitis, tracheitis, bronchiolitis, and alveolitis with intranuclear herpesviral inclusions in the bronchiolar epithelium. Immunofluorescent antibody testing on lung tissue was positive for FHV-1. Virus isolation was negative. Histopathology of gastrointestinal biopsies collected at endoscopy and tissues collected at necropsy was unremarkable.

Comments: This cat died of a severe and overwhelming FHV-1 infection, despite the fact that he was an adult cat that had been vaccinated regularly. Clinical signs of anorexia, gagging and hypersalivation likely resulted from stomatitis, pharyngitis, and tracheitis. Histopathology with immunofluorescent antibody staining confirmed the involvement of FHV-1. The negative virus isolation result may have been because of an insufficient sample size, inactivation of virus by antibody, or lack of viable virus in the specimen. Because FHV-1 survives poorly in the environment, it may deteriorate in clinical specimens during transport to the laboratory.

CHAPTER 24

Feline Poxvirus Infections

Malcolm Bennett

VetBooks.ir

Overview of Feline Poxvirus Infections

First Described: Feline poxvirus infection was first described in 1978[1]

Causes: Poxviruses (family Poxviridae). Cowpox virus infection is by far the most frequently reported poxviral infection of both cats and dogs. Other poxvirus infections, including parapoxvirus (assumed to be orf virus) and raccoonpox virus infections, have also been described in pets. Other poxviruses are also likely to infect cats and dogs but go unreported.

Affected Hosts: Cats, less often dogs, and a variety of other mammalian host species

Geographic Distribution: Cowpox virus is limited to Europe and Asia. Infections with other poxviruses have been described in North America.

Mode of Transmission: Entry through a break in the skin

Major Clinical Signs: Single or multiple, papular, and crusted skin lesions. Fever, lethargy, inappetence, and signs of pneumonia can also occur in affected cats.

Differential Diagnoses: Allergic dermatitis, facial dermatitis caused by feline herpesvirus-1, nocardiosis, mycobacteriosis, cutaneous lymphoma, autoimmune dermatoses such as pemphigus foliaceus, cutaneous drug reactions

Human Health Significance: Many poxviruses, including cowpox and orf viruses, are zoonotic, and owners of affected animals need to be advised of the threat to their health.

Etiology and Epidemiology

Cowpox Virus

Cowpox virus is a member of the *Orthopoxvirus* genus within the family Poxviridae, which are large, enveloped, double-stranded DNA viruses.[2] Other orthopoxviruses include the viruses of smallpox (now eradicated), vaccinia (the smallpox vaccine), monkeypox (which is endemic to central Africa but was recently introduced to, and eradicated from, North America), and a range of other mammalian orthopoxviruses. All orthopoxviruses are closely related genetically and antigenically; therefore, vaccinia virus can be used to immunize against all orthopoxvirus infections. Cowpox virus has the largest genome of all the orthopoxviruses. Different strains of cowpox virus exist, as determined by both biologic characteristics and nucleotide sequence. Whether these merely reflect geographic variation of the virus (and therefore its main hosts and pathogenicity) or a range of independent virus species is still to be determined. For the purpose of this account, however, they are regarded as a single viral species.

Despite its name, cowpox is rarely described in cattle; cowpox virus circulates primarily in wild rodents. It has a wide host range that includes not only rodents, cats, dogs, cattle, and human beings, but a variety of captive wildlife mammals. The main route of transmission among rodents is not known, although, as for many orthopoxviruses, the respiratory route is probably important. In most accidental hosts, which include domestic animals and human beings, the most frequent source of infection is through a break in the skin. This gives rise to the "primary" lesion. The main reservoirs of cowpox virus are voles and, to a slightly lesser extent, *Apodemus* mice. As these rodent species undergo annual population cycles, breeding mainly in the summer and fall months, viral transmission and prevalence has strong seasonality. Transmission to accidental hosts such as cats, dogs, people, and zoo animals therefore also occurs mainly (but not exclusively) in the late summer, fall, and early winter. Cats probably become infected directly from rodent hunting, whereas infection in other species is often acquired from a "liaison" or "amplifying" host. These are accidental hosts in which the virus replicates to higher titers than in the reservoir rodent hosts; thus they bridge the epidemiologic gap between the reservoir and the host of interest. The main liaison hosts for human cowpox are the domestic cat (and, in the past, possibly cattle), followed by peridomestic rodent species such as rats. Rats can also be a source of infection for captive wildlife species. The virus is very hardy and survives in scabs for weeks or months, including in the environment, where it may be a source of human infection.

Raccoonpox Virus

Raccoonpox virus is also an orthopoxvirus. Remarkably little is known about its epidemiology, or indeed about the other known North American orthopoxviruses, skunkpox, and volepox viruses, which together form a distinct clade. Raccoonpox virus appears to be fairly host specific but was isolated from a cat with cowpox-like disease in Canada.[3]

Raccoonpox virus was originally isolated from the lungs of apparently healthy raccoons in the northeastern United States, and serologic surveys in the same area suggested that more than 20% of wild raccoons had antibody to the virus. Experimental infection of raccoons also caused no obvious disease.[4] The narrow host range, low zoonotic and pathogenic potential, and endemicity of raccoonpox virus to North America has led to its development as a vector for recombinant vaccines for use in American wildlife species.

VetBooks.ir

Parapoxviruses

The parapoxviruses comprise a different genus from the orthopoxviruses in the family Poxviridae. Parapoxviruses are genetically very similar to each other (but significantly different antigenically and genetically from the orthopoxviruses), and differentiation of individual species is difficult.[5] Parapoxvirus infections have been described in cats in several countries, and when characterized, the causative virus has been shown to be orf virus.[6] Orf occurs worldwide, mainly in sheep and goats, and is readily transmissible to human beings.

Parapoxviruses, like many other poxviruses, survive in the environment for long periods—possibly months or even years under the right conditions. So although cats can become infected through direct contact with sheep or goats, it is more likely that infection occurs through contact with a contaminated fomite—perhaps a piece of barbed wire or fencing that contacts a preexisting wound. The rarity of parapoxvirus infection in cats makes its study very difficult.

Clinical Features

Signs and Their Pathogenesis

Cowpox Virus

In many hosts, such as human beings, dogs, and cattle, the primary lesion of cowpox virus infection, plus perhaps some virus replication in draining lymph nodes, may be as far as disease progresses. In cats and many captive wild mammalian species, however, the virus replicates in monocytes and macrophages and spreads to multiple organs, particularly the lungs and the spleen. Here, the virus replicates further, giving rise to a secondary viremia, which is often associated with pyrexia and mild or occasionally severe systemic signs. Pneumonia can itself be fatal, but usually the secondary viremia leads to a "secondary rash" of lesions distributed across the skin and mucosae.

The signs of cowpox vary according to the host species. The classical presentation in cats is of a primary skin lesion, often with secondary bacterial infection, usually on a forelimb or the face, thought to arise from the inoculation of virus into a wound—perhaps a bite wound—while hunting infected wild rodents. In some cases, severe necrotizing facial dermatitis develops. The primary lesion may be followed by lethargy and possibly pyrexia for up to 10 days, after which multifocal skin lesions appear. These first develop as papules (Figure 24-1), which become ulcers up to 1-cm in diameter that crust over and heal over 4 to 6 weeks. This leaves small patches of alopecia until the hair regrows. In cats such as Siamese, the hair can grow back a darker color, and scars are often visible for years in cats if their hair is clipped. Infection of dogs is less common, and in dogs, lesions are usually more localized and the systemic disease much less severe.[6-8]

In many captive wild Felidae, pneumonia is more common than in domestic cats, and mortality is high. Similarly, elephants and rhinoceroses in central European zoos develop severe systemic disease and often die—indeed, this can be such a severe disease that many European zoological parks vaccinate their elephants. There are few reports of fatal cowpox in captive primates,[9] but there are anecdotal reports of high rates of subclinical seroconversion in other primate populations. Other affected zoo-kept species include giant anteater, beavers, okapi, banded mongoose, jaguarondi, and the cavy. In wild rodent reservoir hosts, clinical signs are absent or, at least, subtle. Population-level studies of naturally infected voles and mice show that infection may be associated with decreased fecundity and decreased survival.[10] When lesions are seen in rodents, they are often in "accidental" rodent hosts such as rats.

FIGURE 24-1 Secondary papules and crusted skin lesions in a cat with cowpox virus infection.

Other Poxviruses

Raccoonpox has only been reported once in a domestic cat,[3] in which it caused a disease that resembled the primary lesion of cowpox. The cat was initially evaluated for a swollen, crusty lesion on a thoracic limb digit, and 4 weeks later infection of the neighboring digit developed. Widespread secondary lesions did not develop, and the cat recovered completely. Human infection with a raccoonpox recombinant vaccine led to a single lesion on the inoculated finger, which became swollen and painful and was accompanied by axillary lymphadenopathy. Complete recovery occurred within 4 weeks.

Parapoxvirus infections have been described in cats in the United Kingdom and New Zealand.[5,10] The British cat developed multiple crusted lesions on its face and dorsum that healed within a few weeks. Two cats from farms in New Zealand had more severe clinical signs. One had a recurrent lesion on the paw of a pelvic limb. The other had a nonhealing lesion on the paw of a thoracic limb that progressed, despite surgery, over four months. Both cats were euthanized.

Diagnosis

Definitive diagnosis of poxvirus infections requires laboratory identification of the causative virus. In Europe, where cowpox virus is endemic, clinical signs combined with identification of an orthopoxvirus probably suffice to make a diagnosis. Elsewhere, however, more extensive laboratory tests are required to identify the causative virus more precisely.

Microbiologic Tests

Diagnostic assays available for poxvirus infections are shown in Table 24-1.

Cell Culture

The best specimens to collect for virus isolation are fresh skin lesions, although virus can be found in crusts from healing lesions for several weeks.[11] No special transport media are

VetBooks.ir

TABLE 24-1

Diagnostic Assays Available for Poxvirus Infections

Assay	Specimen Type	Target	Performance
Virus isolation	Skin biopsies, crusts	Poxviruses	May not be widely available in some regions. Sensitive for diagnosis of orthopoxviruses, but parapoxviruses are difficult to culture.
Polymerase chain reaction (PCR)	Skin biopsies, crusts	Poxvirus DNA	Sensitivity and specificity may vary depending on assay design; assays may not differentiate between orthopoxviruses. Availability on a commercial basis may be limited in some regions. Assays for parapoxviruses are not widely available.
Histopathology	Skin biopsies, necropsy specimens	Poxvirus inclusions	Histopathology is similar for cowpox virus and raccoonpox virus. Confirmation of poxvirus infection requires immunohistochemistry or PCR.
Electron microscopy	Skin crusts	Virus particles	May not be widely available, turnaround time can be slow, and may be expensive. Orthopoxviruses and parapoxviruses can be differentiated based on their morphology.

needed. Lesions can be placed into a dry container for shipping to the laboratory at room temperature. The virus replicates in a variety of cell lines, in which it causes an obvious cytopathic effect (CPE) that resembles that of feline herpesvirus-1. Unlike most feline viruses, however, cowpox virus grows easily in cell lines derived from other mammalian species, including primates. Lesion material is ground or finely chopped and freeze-thawed several times to release virus particles. CPE usually appears within 24 to 76 hours and comprises plaques of syncytia followed by rounding and loss of cells from the center of the plaque. Staining with hematoxylin and eosin reveals large, intracytoplasmic, eosinophilic inclusion bodies. Further confirmation can be by immunostaining (e.g., immunofluorescence) to identify the virus as an orthopoxvirus, or PCR assay and sequencing.

Although raccoonpox virus grows in a variety of cell lines, diagnosis is more likely to be made by histopathology and PCR assays. This is because the virus is unlikely to be suspected initially, and biopsy and histology would be the first response of most veterinarians. Parapoxviruses are notoriously difficult to grow in cell culture, requiring primary cell cultures.

Molecular Diagnosis Using the Polymerase Chain Reaction

Some diagnostic laboratories offer PCR assays for diagnosis of poxvirus infection, which can be both sensitive and, if combined with sequencing, specific. Orthopoxviruses are so similar genetically that PCRs targeted at many orthopoxvirus genes only identify orthopoxviruses to the genus level. PCRs that differentiate between orthopoxvirus species have been described, but such assays tend to be available through research or other specialist laboratories. Of course, in much of Europe, cowpox virus is the only orthopoxvirus known to infect cats and dogs, so identification to the species level is often not necessary. Unlike orthopoxviruses, for which worries over bioterrorism have led to the development of several sensitive and specific PCR assays, molecular assays for parapoxviruses are not widely available.

Direct Electron Microscopy

Electron microscopy of skin lesions is a more rapid approach to diagnosis than cell culture and is fairly sensitive. Negative-stained suspensions of skin lesion material allow typical orthopoxvirus particles to be seen in most cases (Figure 24-2). The diagnosis of parapoxvirus infection usually relies on electron microscopy and visualization of the characteristic parapoxvirus morphology, which resembles a "ball of yarn."

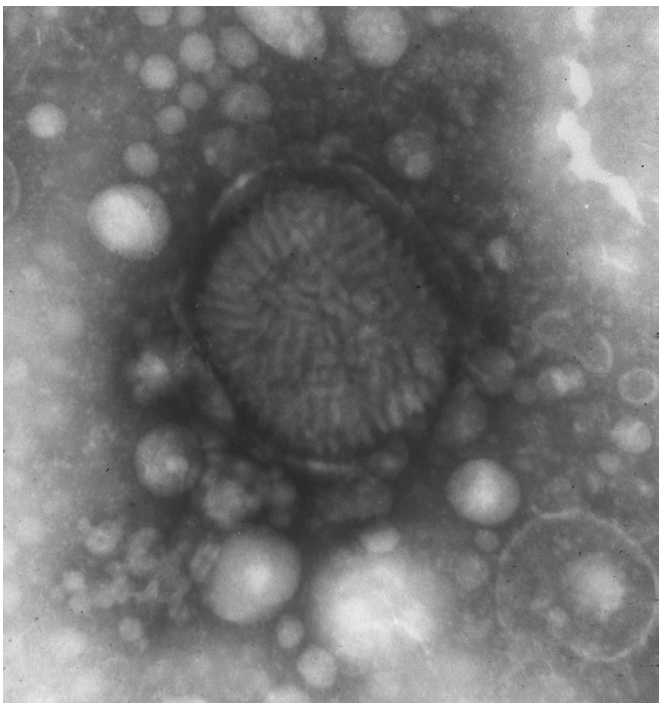

FIGURE 24-2 Electron micrograph of a cowpox virus particle. In contrast, parapoxviruses have the appearance of a new ball of yarn, with threadlike surface tubules arranged in a crisscross fashion.

Serologic Diagnosis

Previous cowpox virus infection can be diagnosed by various serologic assays including immunofluorescent antibody, ELISA, and virus neutralization assays. The prevalence of orthopoxvirus antibodies in domestic cats in Europe is usually only 1% to 2%, so a consistent clinical history combined with an antibody titer is reasonably specific.

VetBooks.ir

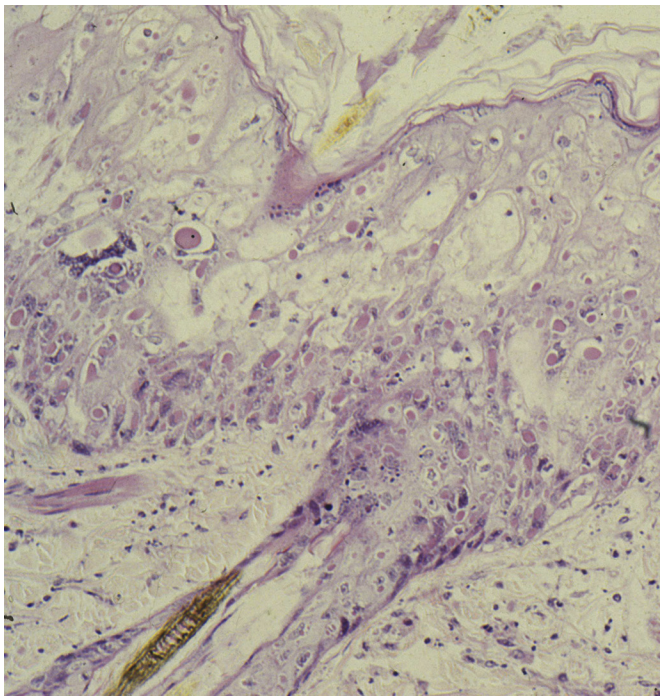

FIGURE 24-3 Histopathology of a feline poxvirus lesion that shows epithelial hyperplasia and large numbers of eosinophilic intracytoplasmic inclusion bodies.

Pathologic Findings

Many cases of cowpox in cats, dogs, and humans are diagnosed by histopathology.[6,12,13] The histology of cowpox is quite characteristic; the virus causes hyperplasia and hypertrophy of the epithelium, with infected cells often containing eosinophilic, intracytoplasmic inclusions that can be readily observed in routine hematoxylin and eosin–stained sections (Figure 24-3). These A-type inclusions comprise virus-encoded protein that forms a protective mass around newly formed virus particles. As the epithelium thickens, cells in the middle layers lyse, which gives rise to fluid-filled lacunae that, when large enough, can be seen with the naked eye as the vesicles (or pocks/pox) from which these viruses get their name. Usually the vesicles quickly ulcerate in cats. Older lesions undergo secondary bacterial infection and subsequent neutrophil infiltration before healing. Immunostaining is useful in histopathologic diagnosis, especially in older lesions or those with secondary bacterial infection.

The histopathology of raccoonpox resembles that of cowpox.[3] Hyperplastic, hypertrophic epithelium is present with eosinophilic, intracytoplasmic A-type inclusion bodies. Because North American orthopoxviruses are quite distinct from "old world" (Eurasian) orthopoxviruses, PCR assays and sequencing can readily characterize the virus, even from fixed material.[11]

Histologic examination of parapoxvirus lesions from the New Zealand cats revealed epithelial hyperplasia giving rise to multiple papillary projections from the skin surface, covered in a thick layer of compacted keratin.[5] Orf virus does not produce the A-type inclusions often seen with orthopoxviruses, but occasional basophilic or amphophilic inclusion bodies may be present (so-called B-type inclusions, which consist of condensed areas of virus replication).

Treatment and Prognosis

Treatment of poxvirus infections is supportive. There are no specific antiviral agents available. Most cats with cowpox recover completely, but some, particularly if immunosuppressed by concurrent infection or treatment with, for example, glucocorticoids, develop larger, persistent skin lesions, and/or pneumonia. Cats that develop pneumonia often die despite supportive care.

Prevention

Housing cats indoors should help to prevent poxvirus infection in cats. No vaccine is available. However, canarypox-vectored vaccines are used to prevent rabies virus and FeLV infection in cats and distemper in dogs.

Public Health Aspects

Cowpox virus infection in humans is usually limited to a skin lesion at the site of inoculation (often on the hand or face) accompanied by local lymphadenopathy and flu-like symptoms. The lesions can be painful, and an important differential diagnosis is cutaneous anthrax. In Europe, most human cases can be traced to contact with an infected cat; infection from rodents or dogs is a much less frequent event. Although most patients recover uneventfully, immunosuppression can lead to more extensive lesions and, rarely, even death.[12,14-16] Although thought not to be zoonotic, a recombinant raccoonpox vaccine caused lesions in a laboratory worker.[17] Orf is readily transmissible to humans, usually from contact with sheep and goats. Although transmission from an infected cat to a human being has not been reported, human orf associated with a cat scratch was reported from Utah in the United States.[13]

CHAPTER 25

Pseudorabies

Jane E. Sykes and Sarah D. Cramer

VetBooks.ir

Overview of Pseudorabies

First Described: 1902 (Hungary, Aujeszky)[1]

Cause: Suid herpesvirus-1 (Family Herpesviridae, subfamily Alphaherpesvirinae, genus *Varicellovirus*)

Affected Hosts: Domestic and feral swine, cattle, horses, sheep, goats, dogs, cats, bears, raccoons, foxes, hedgehogs, opossums, deer, Florida panther, jackals, coyotes, nonhuman primates (macaques, marmosets), chickens, pigeons, geese, ducks, buzzards, sparrow hawks, rabbits, guinea pigs, rats, and mice

Geographic Distribution: Worldwide

Mode of Transmission: Most often ingestion of uncooked pork by-products or pig carcasses

Major Clinical Signs (Dogs): Variable, but may include fever, lethargy, hypersalivation, muscle stiffness, variable facial pruritus, ataxia, behavioral changes, vomiting, diarrhea, and/or respiratory distress

Differential Diagnoses: Rabies, canine distemper, toxicoses (e.g., organophosphates, heavy metals, ethylene glycol, strychnine)

Human Health Significance: Humans appear to be resistant to infection with suid herpesvirus-1.

Etiology and Epidemiology

Pseudorabies (Aujeszky's disease) is a notifiable disease caused by the alphaherpesvirus suid herpesvirus-1 (SuHV-1). Swine are the natural hosts for SuHV-1, but other domestic and wild mammals, including ruminants, dogs, cats, raccoons, rabbits, and rodents, are susceptible to infection and fatal encephalitis. The name *pseudorabies* was applied because the clinical signs caused by the virus in rabbits resemble those of rabies. SuHV-1 has been eradicated from domestic swine through use of vaccination programs in many countries, including Finland, Sweden, Norway, the Netherlands, Denmark, Austria, Switzerland, Germany, Hungary, Slovakia, the United Kingdom, Canada, the United States, and New Zealand. The virus continues to circulate among wild boar and feral swine, which act as a reservoir for the virus.[2] Australia is also free of pseudorabies. Aujeszky's disease is a widespread problem in domestic swine herds in Asia, Latin America, and some parts of Europe.[2]

SuHV-1 is shed in the saliva and nasal discharges of swine, and transmission can occur by direct contact with these discharges or aerosols, or ingestion of infected swine carcasses or other infected animals, especially wildlife. The virus can survive on fomites and in carcasses for several weeks. In swine, clinical signs depend on the age at exposure and virus strain. Subclinical infections and shedding occur commonly. When older pigs do develop signs, they typically develop respiratory disease. Encephalitis occurs in piglets or in adult pigs that are infected with virulent strains. Reproductive disease and fetal loss can occur in pregnant sows. Recovered pigs develop latent infection of neuronal tissues with reactivation and shedding of virus in semen and nasal, oral, or vaginal secretions following stress.

Disease in dogs is uncommonly reported. However, clusters of affected dogs have been described over the past decade, primarily in hunting dogs that contact wild swine from parts of Europe (France, Germany, Belgium) and the southern United States (Florida and Oklahoma).[2-7] This has followed global expansion of wild swine populations. Disease in dogs may be more likely to occur in regions that are densely populated with wild swine, such as the southern United States (Figure 25-1) and parts of Europe such as Germany, France, Spain, Poland, and the Czech Republic.[2] Dogs that reside on swine farms may also become infected.[8] In some reports, packs of dogs have been infected after consumption of uncooked offal from infected pigs or pig carcasses.[9,10] Dogs of any age, sex, and breed can develop disease, but dog-to-dog transmission does not occur. Cats can be infected after ingestion of pork waste or infected rodents, but reports of naturally occurring Aujeszky's disease in cats are extremely rare.[11] Because subclinical infections and nonspecific signs are common in swine, identification of pseudorabies in dogs may be the first indication that disease is present in a swine herd or wild swine population.

Clinical Features

Signs and Their Pathogenesis

After inhalation or ingestion, SuHV-1 replicates in the oropharynx and is taken up by sensory nerve endings. It then travels by retrograde axonal transport to the sensory nerve ganglia and then to the central nervous system (CNS), which results in ganglioneuritis and encephalitis, especially within the brainstem. Infection can also lead to ganglioneuritis of the cardiac autonomic plexuses with associated myocardial degeneration,[12] as well as degeneration of intestinal myenteric ganglia.[10] Clinical signs appear after a short incubation period that typically ranges from 1 to 6 days, but incubation periods up to 10 days have been reported.[9] The duration of signs ranges from 6 to 96 hours.[13] The most commonly reported sign is hypersalivation. This occurs in most affected dogs, although it may not be present early in the course of illness.[10,13,14] Other signs include lethargy, fever, dysphagia, gastrointestinal signs, muscle stiffness, ataxia, head-pressing, vestibular signs (circling, head tilt,

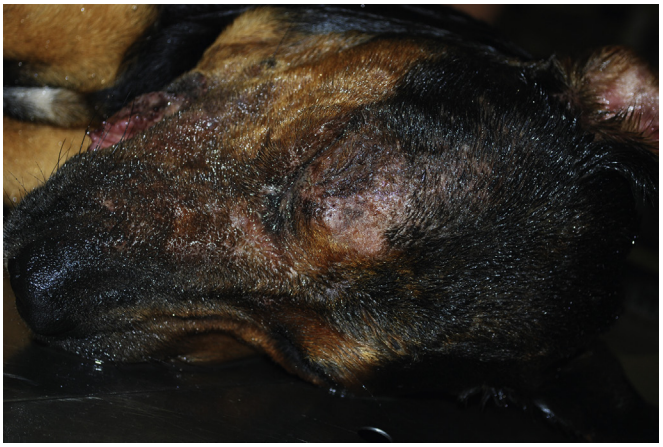

FIGURE 25-2 Evidence of facial self-mutilation in a 2-year-old intact male Catahoula hunting dog with pseudorabies. Severe exudative dermatitis is present over the right eye, external ear canal and muzzle. (Reprinted from Cramer SD, Campbell GA, Njaa BL, et al. Pseudorabies virus infection in Oklahoma hunting dogs. J Vet Diagn Invest 2011;23:915-923.)

BOX 25-1

Clinical Signs in 25 Dogs with Pseudorabies from the United States

Ptyalism: 100%
Anorexia: 84%
Ataxia: 76%
Wandering: 64%
Tachypnea: 64%
Dyspnea: 60%
Vocalization: 56%
Pruritus: 52%
Neck stiffness: 48%
Vomiting: 36%
Muscle spasms: 36%
Aggression: 36%
Trismus: 28%
Dysphagia: 24%
Abnormal pupillary light responses: 20%
Seizures: 16%
Mydriasis: 12%

Monroe WE. Clinical signs associated with pseudorabies in dogs. J Am Vet Med Assoc 1989;195:599-602.

nystagmus), recumbency, intense pruritus and self-mutilation, vocalization, behavior changes such as pacing and aggression, and tachypnea or respiratory distress (Box 25-1). Uncommonly, apparent blindness, facial paralysis, ptosis, photophobia, abnormal facial sensation, and lacrimation occur. Pruritus generally occurs on the face but can also occur on the shoulder and forelimbs.[10,13] The pruritus may result from infection of neurons that innervate those regions.[15] Gastrointestinal signs are common and include vomiting and diarrhea, which may be hemorrhagic (e.g., hematemesis or melena).[6] Seizures and coma may also occur. A variety of cardiac arrhythmias have been reported in experimentally infected dogs, which include ventricular premature complexes, ventricular tachycardia, sinus arrest, atrial tachycardia, atrial fibrillation, wandering pacemaker, second-degree heart block, T- and P-wave abnormalities, and atrioventricular dissociation.[12] Although facial pruritus is considered a classic clinical sign, in one case series, it was present in only 18% of dogs.[14] Death occurs within 96 hours (and usually 48 hours) after the onset of clinical signs. Sudden death may occur, possibly as a result of acute myocarditis.[9,14]

Physical Examination Findings

Physical examination findings in dogs with pseudorabies include mental obtundation, hypersalivation, dehydration, muscle stiffness, tachypnea or respiratory difficulty, and facial pruritus. Cutaneous excoriations and edema due to self-trauma may be identified (Figure 25-2). Other neurologic signs include ataxia, head tilt, circling, hyperesthesia, behavioral abnormalities, anisocoria, mydriasis, nystagmus, slow or absent pupillary light responses, recumbency, and coma. Fever may be present early in the course of infection (up to 108°F or 42°C),[13] but terminally, hypothermia can occur. A variety of cardiac arrhythmias may also be identified.

Diagnosis

Diagnosis of pseudorabies in dogs and cats is based on a compatible history (i.e., exposure to domestic or wild swine in regions where the virus is present), suggestive clinical signs, and histopathology and/or virus detection methods such as immunofluorescent antibody staining, immunohistochemistry, virus isolation, or PCR assay on tissues collected at necropsy (Table 25-1). Antemortem diagnosis of pseudorabies in dogs and cats using virus detection methods has not yet been described.

Laboratory Abnormalities

Laboratory abnormalities in dogs with pseudorabies are nonspecific. Mild anemia and moderate leukocytosis due to a neutrophilia may be present. Affected hunting dogs have also had eosinophilia, hyperglobulinemia, hypoalbuminemia, and hyperglycemia.[7] In these dogs, concurrent gastrointestinal parasitism may have explained the eosinophilia, hypoalbuminemia, and hyperglobulinemia. Analysis of the CSF may reveal increased CSF protein concentration and mononuclear pleocytosis.

VetBooks.ir

TABLE 25-1

Diagnostic Assays Available for Pseudorabies in Dogs and Cats

Assay	Specimen Type	Target	Performance
Histopathology	Necropsy specimens, especially brainstem or ganglia	Meningoencephalitis with eosinophilic intranuclear inclusions; SuHV-1 antigen with IHC, IFA or DNA with in situ hybridization	Necropsy diagnosis
PCR	CNS, tonsils, possibly biopsies of self-traumatized skin or tonsillar swabs	SuHV-1 DNA	Unknown whether PCR could be used for antemortem diagnosis. Not widely available.
Virus isolation	CNS, tonsils, occasionally other tissues such as skin biopsies or lung tissue	SuHV-1	Specialized procedure. False negatives occur commonly.

CNS, Central nervous system; IFA, immunofluorescent antibody; IHC, immunohistochemistry; SuHV-1, suid herpesvirus-1.

Microbiologic Tests

Serologic Diagnosis

Although serology using a variety of antibody detection methods (such as ELISA and virus neutralization) is used to identify exposure in swine herds, it has not been useful for antemortem diagnosis in dogs and cats. This likely reflects the rapid course of disease and insufficient time before death for antibody responses to develop.

Virus Isolation

Although not always successful, SuHV-1 can be isolated from tissues (such as the CNS and tonsils) in pig kidney or Crandell-Rees feline kidney cell monolayers. Immunofluorescent antibody can then be used to confirm the presence of the virus in cells. The sensitivity of virus isolation as an antemortem test (e.g., on saliva or oropharyngeal swabs) is not known. Haired skin from regions of pruritus may also be suitable.

Molecular Diagnosis Using the Polymerase Chain Reaction

Conventional and real-time PCR assays have been described for detection of SuHV-1 in brain tissue collected at necropsy.[7] Whether PCR assays are useful for antemortem diagnosis is not known, but PCR could be attempted on biopsies of pruritic regions or tonsillar swab specimens.

Pathologic Findings

Abnormalities seen on gross postmortem examination in dogs with pseudorabies include facial excoriations, tonsillar enlargement, gastrointestinal mucosal hyperemia and ulceration, myocardial hemorrhage, and pulmonary edema and congestion. On histopathologic examination, perivascular infiltrates of lymphocytes, neutrophils, and macrophages may be present in the brainstem and medulla oblongata, with neuronophagia, neuronal degeneration and necrosis, focal gliosis, and eosinophilic intranuclear inclusion bodies within neurons and astrocytes (Figure 25-3). Involvement of the spinal cord was reported in a cat.[11] Other changes in dogs include suppurative tonsillar inflammation with necrosis, myocardial degeneration, fibrinoid vasculitis, and pulmonary edema. Immunohistochemistry, immunofluorescence, or in situ hybridization can be used to identify virus within neurons.[8]

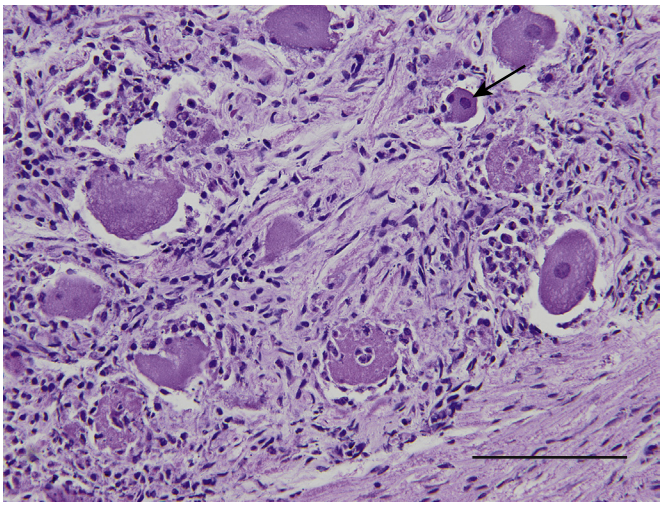

FIGURE 25-3 Histopathology in pseudorabies encephalitis. Trigeminal ganglion of the dog in Figure 25-2. Neutrophilic, lymphocytic, and histiocytic infiltrates are present. Ganglion cells are admixed with necrotic cellular debris, and neuronophagia is prominent. Within a single ganglion cell is an equivocal intracytoplasmic inclusion *(arrow)*. Bar = 50 µm. (From Cramer SD, Campbell GA, Njaa BL, et al. Pseudorabies virus infection in Oklahoma hunting dogs. J Vet Diagn Invest 2011;23:915-923.)

Treatment and Prognosis

Other than supportive care, there is no known treatment for pseudorabies in dogs and cats. Disease is almost always rapidly progressive and fatal.

Immunity and Vaccination

Although vaccines are used in swine to reduce losses where the disease is enzootic, vaccines are not available for dogs and cats, because of the sporadic incidence of the disease.

Prevention

Pseudorabies can be prevented by cooking pork by-products fed to dogs and cats, preventing contact between infected swine

VetBooks.ir

and dogs in regions where the disease is enzootic, and possibly through control of rodents.

Public Health Aspects

Humans appear to be refractory to infection with suid herpesvirus-1.

Viral Papillomatosis

Jane E. Sykes and Jennifer A. Luff

VetBooks.ir

Overview of Papillomatosis in Dogs and Cats

First Described: The transmissibility of canine papillomaviruses was described in the late 1800s; electron microscopic descriptions occurred in the late 1960s[1,2]

Cause: Papillomaviruses (family Papillomaviridae)

Affected Hosts: A variety of animal species, but papillomavirus types are relatively species specific

Geographic Distribution: Worldwide

Mode of Transmission: Cutaneous or mucosal inoculation through trauma

Major Clinical Signs: Exophytic or endophytic papillomas, pigmented plaques, in situ or invasive squamous cell carcinomas

Human Health Significance: Canine and feline papillomavirus types do not appear to infect humans, although some feline papillomavirus types resemble some human papillomavirus types

Etiology and Epidemiology

Papillomaviruses cause warts, or papillomas, in a variety of animal species (Figure 26-1). They are non-enveloped, icosahedral viruses with a circular double-stranded DNA genome. Papillomaviruses have also been associated with malignant transformations within the skin and mucous membranes (Box 26-1).[3] In humans, certain papillomavirus types are more likely than others to induce malignant transformation. Papillomavirus DNA has been detected using PCR assays on the skin of dogs and cats and in the oral cavity of dogs with no signs of papillomas[4-6]; it is not clear whether this represents subclinical infection or just carriage of papillomaviruses.[7] Because of this, the association of papillomaviruses with disease in dogs and cats, especially squamous cell carcinomas (SCCs), remains somewhat unclear. Papillomaviruses are resistant in the environment and survive detergents and high temperatures. Exposure to papillomaviruses is widespread in the dog population based on serologic studies.[8] Congenital or acquired deficiencies in cell-mediated immunity may predispose to papilloma formation.[9-13]

Papillomaviruses are relatively host species specific. The number of different papillomavirus types identified in dogs and cats has expanded dramatically in recent years as a result of the use of molecular techniques. Correlations appear to exist between papillomavirus types and clinical manifestations and progression of disease, although host immune status is also important. Papillomaviruses are classified on the basis of the L1 capsid protein gene sequence. At least nine types occur in dogs; an additional five novel types have been described that are not fully classified (Table 26-1).[14-21] *Canis familiaris* papillomavirus (canine papillomavirus 1) is associated with oral papillomas and rarely with cutaneous endophytic (inverted) papillomas and invasive cutaneous SCCs.[10,22,23] Other canine papillomavirus types have been associated with cutaneous inverted and exophytic papillomas, cutaneous pigmented plaques, or cutaneous in situ SCCs. Papillomavirus DNA has been detected in a few canine oral SCCs.[23,24] However, most oral and cutaneous SCCs in dogs are negative for papillomavirus DNA. The eight canine papillomavirus types have been allocated to three different genera, Lambda, Tau, and Chi.[7,17] Chi papillomaviruses have been associated with cutaneous plaque formation. Cocker spaniels and Kerry blue terriers may be predisposed to cutaneous papillomas, and pug dogs are predisposed to pigmented plaques. Breed predispositions to papillomavirus infections may reflect the presence of congenital defects in cell-mediated immunity; however, this is not yet proven.

Papillomavirus infections are uncommonly reported in cats when compared with dogs. They have been associated with plaque-like lesions (hereafter referred to as feline plaques), dysplastic skin lesions, multicentric Bowenoid in situ SCCs (BISC), cutaneous invasive SCCs, and feline sarcoids (also known as fibropapillomas). The complete viral genome sequence for two feline papillomaviruses types has been described, as well as several stretches of additional novel feline papillomavirus sequences. Feline sarcoids have been associated with *feline sarcoid-associated papillomavirus* (FeSarPV) infection, for which cattle may be a reservoir.[25] Sarcoids have been described in cats from North America, New Zealand, the United Kingdom, Sweden, and Australia, and affected cats are often young (<5 years), male, outdoor cats from rural environments. *Felis domesticus papillomavirus 1* (FdPV-1) has been detected in feline viral plaques.[26,27] *Felis domesticus papillomavirus 2* (FdPV-2)

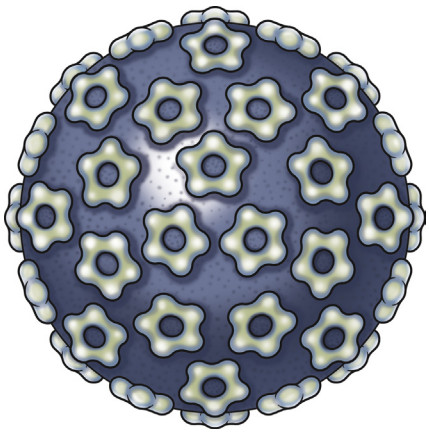

FIGURE 26-1 Structure of a papillomavirus. The virus is non-enveloped and has a icosahedral capsid composed of two different capsid proteins (L1 and L2).

BOX 26-1

Spectrum of Clinical Manifestations Associated with Papillomavirus Infections in Dogs and Cats

Dogs
Oral papillomatosis
Cutaneous exophytic papillomas (warts)
Cutaneous endophytic papillomas (inverted warts)
Pigmented cutaneous plaques
Cutaneous in situ SCCs*
Invasive cutaneous SCCs
Oral SCCs

Cats
Feline viral plaques
Bowenoid in situ carcinomas
Invasive cutaneous SCCs
Feline sarcoids

*SCCs, squamous cell carcinomas. The majority of SCCs in dogs and cats have not been associated with papillomavirus infection.

and other papillomaviruses, including papillomaviruses with homology to human papillomaviruses, have been detected in cats with plaques, BISCs, and invasive SCCs.[27-31] FdPV-2 is strongly associated with feline plaque formation.[32] The finding of papillomavirus DNA with homology to the DNA of human papillomaviruses in cats suggests the possibility of transmission of papillomaviruses between humans and cats; however, additional studies are needed.[30,31]Although papillomavirus DNA has been detected in a feline oral SCC,[33] papillomaviruses do not seem to be responsible for most oral SCCs in cats.[34]

Clinical Features

Signs and Their Pathogenesis

Infection with papillomaviruses follows inoculation of the virus through microabrasions in the skin caused by physical trauma. Initial infection and viral amplification occurs within keratinocytes of the stratum basale.[35] As basal keratinocytes undergo differentiation, early viral proteins (E proteins) are expressed and associate with regulators of the cell cycle to stimulate cell cycle progression.[35] This leads to enhanced proliferation of cells in the stratum spinosum and stratum granulosum, with accumulation of infected cells and papilloma formation (Figure 26-2). With the exception of feline sarcoids, which remain as latent (or nonproductive) infections, late viral products, including the virus capsid proteins (L1 and L2), are first expressed in cells of the stratum spinosum. Papillomaviruses are nonlytic viruses, and mature virions are shed with cells that exfoliate from the stratum corneum or the nonkeratinized cells of the mucous membranes. Infected cells develop a characteristic cytopathic effect, which consists of cytoplasmic vacuolization. Tens of thousands of virus particles are produced by each infected cell. Malignant transformation occurs as a result of the effect of certain viral products (also known as oncoproteins) on host cellular signals that are responsible for regulation of the cell cycle and/or apoptosis.[36] For example, some papillomavirus types produce proteins that degrade p53 and retinoblastoma protein (RB), which are important tumor suppressors.[37] In human

TABLE 26-1

Spectrum of Papillomavirus Types and Disease Associations in Dogs

CPV Type*	Genus	Clinical Manifestation
1	Lambda	Oral papillomas, cutaneous endophytic papillomas, invasive SCCs
2	Tau	Cutaneous endophytic and exophytic papillomas (warts)
3	Chi	Cutaneous pigmented plaques, in situ and invasive SCCs
4, 5	Chi	Cutaneous pigmented plaques
6	Lambda	Endophytic papillomas
7	Tau	Exophytic papillomas and in situ SCC
8	Chi	Cutaneous pigmented plaques
9		Cutaneous pigmented plaques

*CPV, Canine papillomavirus. Five additional types associated with cutaneous pigmented plaques exist that have not yet been definitively classified at the time of writing. (Luff JA, Affolter VK, Yeargan B, et al. Detection of six novel papillomavirus sequences in canine pigmented plaques. J Vet Diagn Invest 2012;24[3]:576-580.)

papillomavirus infections, accidental integration of the human papillomavirus (HPV) genome can occur into host cell DNA, although this does not seem to be necessary for oncogenesis.[36]

Oral papillomas most commonly occur in young dogs and often regress spontaneously over a 4- to 6-week period.[7] They can also occur as a result of immunosuppression, such as after treatment with cyclosporin, less commonly chronic glucocorticoid treatment, or chronic infection with *Ehrlichia canis*. Rarely, papillomas in the caudal oropharynx obstruct respiration (Figure 26-3). Cutaneous pigmented plaques, to which pugs and miniature schnauzers are predisposed, are generally not of clinical significance but in some situations can progress to SCCs.[19,38,39] *Cutaneous exophytic* and *endophytic papillomas* usually occur as solitary masses.[7] Exophytic papillomas are proliferative nodules, whereas endophytic papillomas are cup-shaped lesions with a central, keratin-filled pore (Figure 26-4). *Feline plaques* are flat, often pigmented lesions that resemble canine papillomas histologically. *Feline sarcoids* are tumors that resemble equine sarcoids. *Multicentric BISCs* appear as multiple, hyperpigmented plaquelike lesions.

Physical Examination

Canine Oral Papillomatosis

Oral papillomas can occur on the lips, mucocutaneous junctions, tongue, pharynx, eyelids, and infrequently haired skin[7] (see Figure 26-3; Figure 26-5). They may be accompanied by halitosis, ptyalism, and oral discomfort. Early lesions are smooth and raised, but as they enlarge they may become cauliflower-like. They may be pigmented or nonpigmented.

Canine Cutaneous Exophytic Papillomas

Cutaneous exophytic papillomas are wartlike projections that appear anywhere on the body, but especially the lower limbs and footpads.

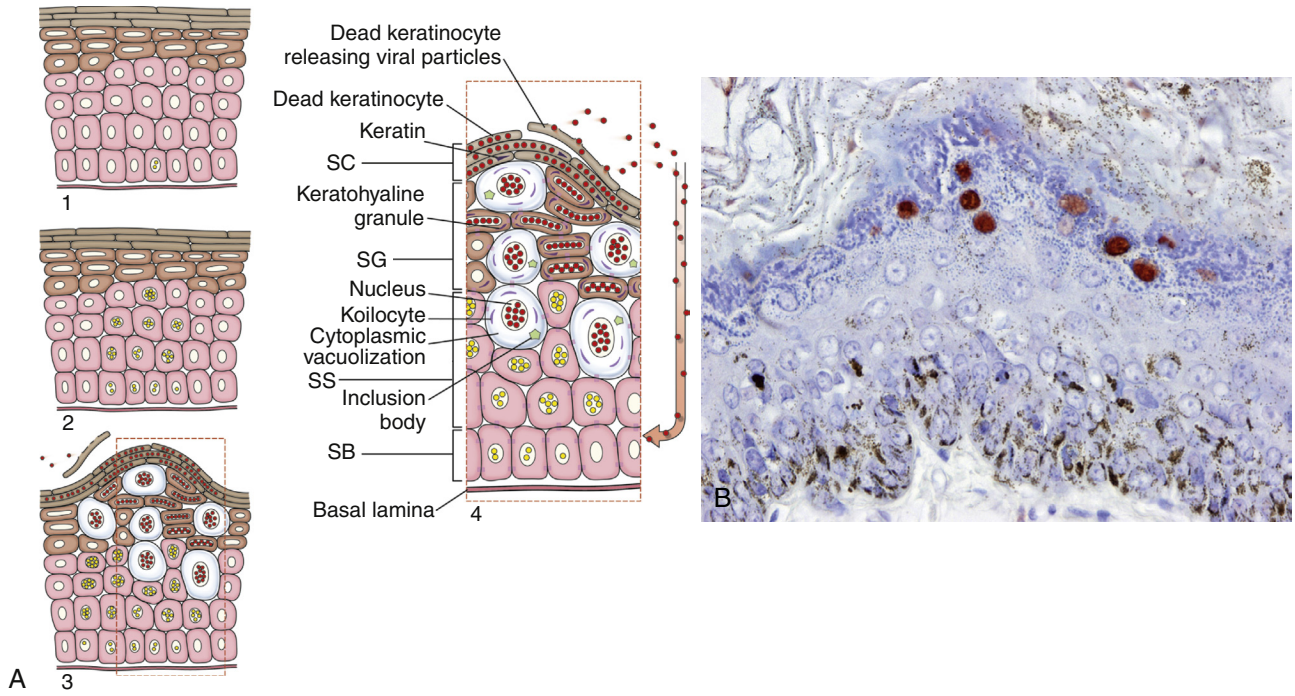

FIGURE 26-2 Schematic representation of the events of papillomavirus infection in the epidermis. **A,** (1) The primary infection occurs in a cell of the stratum basale (SB) after the virus gains entry via a microabrasion. The virus replicates and produces only early proteins, which leads to increased cellular proliferation. (2) Progeny of the initial infected cells migrate laterally and move upwards, where they accumulate in the stratum spinosum (SS) and stratum granulosum (SG). (3) Cellular differentiation ultimately occurs, and large numbers of virions are produced in association with papilloma development. Virions are shed with exfoliating keratinocytes of the stratum corneum (SC). (4) Detail from 3. **B,** Immunoperoxidase staining of papillomavirus antigen in a cutaneous plaque from a dog. (**B** courtesy of Luff J, University of California, Davis. In MacLachlan NJ, Dubovi EJ, eds. Fenner's Veterinary Virology, 4 ed. Burlington, MA: Academic Press [Elsevier]; 2011.)

Canine Endophytic Papillomas

Endophytic (or inverted) papillomas are cup-shaped cutaneous nodules that range in size from 2 mm to 2 cm in diameter with a central depression (see Figure 26-4). Several different variations have been described, but they are rare and poorly understood.[7] Single or multiple lesions can occur anywhere on the body. They have also been described in the interdigital space.[9]

Canine Pigmented Plaques

Pigmented plaques usually range in size from 1 mm to 1 cm, but in one dog progressed to larger sizes (up to 8 cm). Multiple dark, hyperkeratotic flat lesions are typically present on the ventrum or medial aspects of the limbs.[39]

Squamous Cell Carcinomas

SCCs are often ulcerated, nodular masses that may be found alongside pigmented plaques or cutaneous papillomas when malignant transformation occurs (Figure 26-6).

Feline Sarcoids

Feline sarcoids are solitary, firm, ulcerated, or nonulcerated nodules that occur most commonly on the nasal philtrum, nares, upper lip, digits, or tail tip, but have also been reported at other locations such as the eyelids and pinnae (Figure 26-7).[25,40]

Feline Plaques and BISC

In cats, plaques are usually a few millimeters in diameter or linear lesions. They are usually pigmented and occur on the head, neck, dorsal thorax, or abdomen. They can be ulcerated.[41] It may be difficult to differentiate plaques from BISCs, which also appear as pigmented plaques with crusting and ulceration. The two may occur together simultaneously.

Diagnosis

The history and gross appearance of oral papillomas in dogs is generally sufficient for diagnosis. For other papillomas and plaques, the diagnosis can be confirmed with biopsy and histopathology. A full-thickness biopsy that includes adjacent normal skin should be collected. The presence of papillomaviruses can be identified using PCR assays, immunohistochemistry, in situ hybridization, or electron microscopy, although these techniques are primarily used on a research basis. Caution should be used when interpreting the results of PCR assays because papillomaviruses can be detected on normal skin, so results should be interpreted in association with clinical signs. Identification of virus within lesions using immunohistochemistry, in situ hybridization, or electron microscopy is more supportive of causality.

Microbiologic Tests

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays can be used to detect papillomaviruses within biopsy or cytobrush specimens from dogs and cats. Rolling circle amplification has been used on fresh biopsy specimens to amplify whole circular genomic DNA from papillomavirus lesions.[7]

Pathologic Findings

Histopathology of canine exophytic papillomas generally reveals epidermal hyperplasia (acanthosis), extensive hyperkeratosis, and clumped keratohyalin granules in the stratum spinosum. The term *koilocytosis* is used to describe cells with papillomavirus-induced cytopathic effects, which consist of extensive cytoplasmic vacuolation and nuclear pyknosis. Intranuclear inclusion bodies may also be present; these occur in the

VetBooks.ir

upper layers of the epidermis (see Figure 26-3, *C*). Endophytic papillomas are cup-shaped masses of epithelial hyperplasia that occur below the level of the surrounding normal skin. Koilocytosis and intranuclear inclusions are often prominent. Histopathology of pigmented plaques are characterized by locally extensive epidermal hyperplasia, hyperkeratosis, hyperpigmentation, and clumped keratohyalin granules; koilocytes and viral inclusions are generally not observed.[7] Feline sarcoids have dermal fibroplastic proliferations with overlying epithelial hyperplasia that includes long, thin rete ridges that extend into the tumor; they may be confused with sarcomas.[40] Feline plaques exhibit moderate to marked epidermal hyperplasia and koilocytosis. Intranuclear inclusions are sometimes present. In situ SCCs are characterized by epithelial hyperplasia, dysplasia, and increased numbers of mitotic figures, with an intact basement membrane. Loss of the basement membrane and invasion of the dermis indicates invasive SCC.

With the exception of feline sarcoids, immunohistochemistry using antibodies that detect conserved papillomavirus antigens (i.e., group-specific papillomavirus antigens) can confirm the presence of papillomaviruses within lesions. Canine and feline papillomavirus-specific reagents are not widely available. In situ hybridization techniques can also be used. Crystalline arrays of virus can also be identified within lesions with electron microscopy.

Treatment and Prognosis

The outcome of papillomavirus infection depends on the virus strain and host immunity. Oral and cutaneous papillomas in young dogs generally regress spontaneously 4 to 8 weeks, and sometimes 3 months after the onset of clinical signs. However, they may persist in older dogs, or when there is underlying immune compromise, and occasionally progress to malignancy. If possible, underlying immunosuppression should be treated (for example, through removal or tapering of immunosuppressive drug treatment). Lesions can be removed surgically if they cause physical obstruction or for cosmetic reasons, but surgical treatment may be followed by recurrence. Treatment with azithromycin (10 mg/kg PO q24h for 10 days) appeared to be effective in a prospective, randomized, double-blinded placebo-controlled clinical trial that included 12 dogs with oral papillomatosis and 5 dogs with cutaneous papillomatosis.[42] The use of topical or intralesional immunomodulators (such as imiquimod cream) and antiviral drugs (such as cidofovir) has shown promise for treatment of persistent papillomas in humans, but these treatments have not been evaluated in dogs and cats.

Pigmented plaques tend to persist, but most are not associated with malignant transformation. Transformation to a well-differentiated SCC was reported in an affected miniature schnauzer.[43] Feline viral plaques have the potential to transform to Bowenoid SCC in situ and invasive SCCs.[32] Feline sarcoids often recur locally after surgical removal, but metastasis does not occur. As more information becomes available, certain papillomavirus types may be more firmly linked to the presence or absence of malignant transformation, which may aid prognostication.

Immunity and Vaccination

Recovery from oral papillomatosis is associated with papillomavirus type-specific resistance to reinfection. Immunity to papillomaviruses comprises (1) the host immune response to the virus and (2) a cell-mediated immune response to the tumor, which is ultimately responsible for tumor regression. This explains why new tumors may not occur, but old tumors persist and continue to grow in the face of an immune response to the virus, and immunization with the virus does not induce tumor regression. Papillomaviruses can evade the host immune response because infection is limited to the skin, and the immunogenic capsid protein is not expressed until the virus reaches the terminally differentiated outer layer. A variety of other mechanisms of immune evasion have been identified in human papillomavirus infections, such as interference with interferons and inhibition of chemokines such as Il-8 and Il-18 by papillomavirus proteins.[44] Viral persistence is necessary for malignant transformation.

Prevention

No vaccines are available for prevention of papillomatosis in dogs and cats. Prevention of immunosuppressive conditions, such as retrovirus infections in cats, and cautious use of potent immunosuppressive drugs such as cyclosporin can also reduce the chance of papillomatosis.

Public Health Aspects

More than 100 papillomavirus types infect humans. Papillomaviruses are relatively species specific, and there is no evidence that canine papillomaviruses infect humans. However, the DNA of more than one different human papillomavirus type has been detected in epithelial lesions in cats.[30,31] Further work, including whole viral genome sequencing, is required to determine whether cats can be a source of some papillomavirus infections for humans and vice versa.

CASE EXAMPLE

Signalment: "Oscar," an adult male neutered Rottweiler mix (see Figure 26-5)

History: Oscar was brought to the University of California, Davis, Veterinary Medical Teaching Hospital for examination after adoption by a veterinary student as a stray from an Indian reservation in Arizona. The student was concerned about the possibility of malnourishment, a painful mouth, and pruritic skin disease. Since his rescue 5 days previously, the student had been feeding him four times daily with maintenance commercial wet and dry dog foods. His appetite had been ravenous and tapeworm segments had been observed in his feces. He had been isolated from other pets in the household.

Physical Examination:

Body Weight: 25.5 kg

General: Bright and alert with normal mentation, nervous. T = 100.8°F (38.2°C), HR = 90 beats/min, RR = 18 breaths/min, mucous membranes pink, CRT = 1 s.

Integument: A dull haircoat was present. Patchy generalized alopecia with severe scaling, crusting, hyperpigmentation, ulceration, and lichenification was present on the face, pinnae and pinnal margins, shoulders, trunk, and extremities.

Eyes, Ears, Nose, and Throat: Moderate mucoid discharge was present from both eyes. The incisor teeth were severely worn. Oral examination also revealed pain on opening the mouth and multiple pink to gray pedunculated masses that ranged from a few millimeters to over 1 cm in diameter on the buccal mucosa and gingiva, lateral aspect of the tongue, and on the hard and soft palates (see Figure 26-5, *B*). These were consistent with oral papillomatosis.

Musculoskeletal: Body condition score 1/9. Normal gait. No other musculoskeletal abnormalities were noted.

Cardiovascular and Respiratory: No clinically significant abnormalities were detected.

Gastrointestinal and Genitourinary: Abdominal palpation was within normal limits. Intact male with soft, symmetrical testes. Soft feces were noted on rectal examination.

Lymph Nodes: Mandibular and superficial cervical nodes were enlarged (approximately 3 cm); the popliteal nodes were sized within normal limits.

Laboratory Findings:

CBC:

HCT 32.3% (40%-55%)
MCV 64.3 fL (65-75 fL)
MCHC 36.2 g/dL (33-36 g/dL)
WBC 10,390 cells/µL (6000-13,000 cells/µL)
Neutrophils 5995 cells/µL (3000-10,500 cells/µL)
Lymphocytes 1891 cells/µL (1000-4,000 cells/µL)
Monocytes 758 cells/µL (150-1200 cells/µL)
Eosinophils 1704 cells/µL (0-1500 cells/µL)
Platelets 322,000 platelets/µL (150,000-400,000 platelets/µL)
Rare macroplatelets observed.

Serum Chemistry Profile:

Sodium 144 mmol/L (145-154 mmol/L)
Potassium 4.8 mmol/L (3.6-5.3 mmol/L)
Chloride 108 mmol/L (108-118 mmol/L)
Bicarbonate 26 mmol/L (16-26 mmol/L)
Phosphorus 5.1 mg/dL (3.0-6.2 mg/dL)
Calcium 10.1 mg/dL (9.7-11.5 mg/dl)
BUN 26 mg/dL (5-21 mg/dL)
Creatinine 0.7 mg/dL (0.3-1.2 mg/dL)
Glucose 108 mg/dL (64-123 mg/dL)
Total protein 7.7 g/dL (5.4-7.6 g/dL)
Albumin 2.9 g/dL (3.0-4.4 g/dL)
Globulin 4.8 g/dL (1.8-3.9 g/dL)
ALT 48 U/L (19-67 U/L)
AST 30 U/L (19-42 U/L)
ALP 117 U/L (21-170 U/L)
Gamma GT <3 U/L (0-6 U/L)
Cholesterol 210 mg/dL (135-361 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.048; pH 5.0, negative protein (SSA), 1+ bilirubin; no hemoprotein, ketones or glucose; 1-2 WBC/HPF, rare RBC/HPF, rare bilirubin crystals, moderate sperm.

Cytology of Superficial and Deep Skin Scrapings: *Sarcoptes* mites were seen.

Imaging Findings: Lateral and dorsoventral thoracic radiographs were unremarkable. Abdominal ultrasonography revealed a small, 1 cm hypoechoic nodule in the body of the spleen. The remainder of the abdominal structures was within normal limits.

Microbiologic Testing: Lateral flow ELISA assay for antibodies to *Ehrlichia canis, Anaplasma phagocytophilum,* and *Borrelia burgdorferi* and *Dirofilaria immitis* antigen (4Dx SNAP, IDEXX Laboratories, ME, USA): Positive for antibodies to *E. canis*.

Vector-borne disease serology panel (*Babesia canis, A. phagocytophilum, E. canis, Rickettsia* spp. IFA): Positive for antibodies to *E. canis* (1:655,360) and *Rickettsia* spp. (1:40,960).

Fecal flotation: *Giardia* spp. cysts (<1 per 40× field), *Sarcoptes* mites (1 to 10 per 10× field).

Diagnosis: Canine oral papillomatosis; malnutrition; sarcoptic mange; suspected chronic canine monocytic ehrlichiosis; previous exposure to spotted fever group rickettsias; giardiasis; cestodiasis.

Treatment: Oscar was treated with doxycycline (5 mg/kg PO q12h for 6 weeks) for ehrlichiosis, topical selamectin (every 2 weeks for a total of 6 weeks) for sarcoptic mange, praziquantel (5 mg/kg, once) for cestodiasis, cephalexin (22 mg/kg q12h for 4 weeks) for secondary bacterial pyoderma, and fenbendazole (50 mg/kg PO

VetBooks.ir

q24h for 3 days) for giardiasis. The owner was instructed to bathe him with an oatmeal shampoo twice weekly. At a recheck appointment 4 weeks later, Oscar weighed 31.5 kg. The skin lesions had improved, and new hair growth was noted. Pruritus was still present. More oral papillomas were present, and the owner described worsened halitosis. Mandibular lymph nodes remained enlarged. Treatment with cephalexin and doxycycline was continued for an additional 3 weeks. Three weeks later, the dog's bodyweight was 33.4 kg, the oral papillomas and mandibular lymphadenomegaly had resolved, and Oscar was vaccinated with canine distemper virus, canine parvovirus, canine adenovirus, parainfluenza virus, and rabies virus vaccines and neutered.

Comments: The gross appearance of the oral lesions in this dog was sufficient to make a diagnosis of oral papillomatosis. Papillomatosis has been reported in other dogs with chronic *E. canis* infection, but the extent to which ehrlichiosis contributed to papillomatosis in this dog is unknown. The immunosuppression associated with malnutrition may also have played a role. Resolution of lesions occurred within 7 weeks after treatment of the immunosuppressive disorders, but papillomatosis can also resolve spontaneously over the same time period.

CHAPTER 27

Vector-borne and Other Viral Encephalitides

Jane E. Sykes

VetBooks.ir

Overview of Vector-borne Encephalitides in Dogs and Cats

First Described: Eastern equine encephalitis, 1831 (horses, Massachusetts)[1]; West Nile virus infection, 1937 (human, Uganda)[2]; tick-borne encephalitis virus, 1931 (humans, Austria)[3]

Causes: RNA viruses that belong to the families Togaviridae (genus *Alphavirus*), such as eastern equine encephalitis virus; Bunyaviridae, such as La Crosse virus; and Flaviviridae, such as West Nile virus and tick-borne encephalitis virus

Affected Hosts: A variety of animal species including horses, humans, and dogs

Geographic Distribution: Follows that of the vector host. Eastern equine encephalitis virus is found in the eastern and southeastern United States, as well as Central and South America; West Nile virus is found in Africa, Asia, Middle East, Europe, and the United States; tick-borne encephalitis virus is found in continental Europe and Asia

Mode of Transmission: Primarily mosquitos and for tick-borne encephalitis virus, *Ixodes* ticks.

Major Clinical Signs (Dogs): Fever (sometimes >105°F [40.6°C]), lethargy, neurologic signs, and sometimes systemic signs such as anorexia and diarrhea

Differential Diagnoses: Rabies, distemper, pseudorabies; bacterial, protozoal, or fungal meningitis; granulomatous meningoencephalitis; hemic neoplasia with central nervous system involvement

Human Health Significance: Humans are susceptible to disease caused by many arboviruses. Dogs and cats are dead-end hosts and do not serve as reservoirs for human infection. Blood and tissues of affected dogs and cats should be handled with caution.

Etiology, Epidemiology, and Clinical Features

A large number of viruses that are spread by arthropod vectors (sometimes referred to as *arboviruses*, for *ar*thropod-*bo*rne *viruses*) can infect and cause encephalitis in dogs and cats (Box 27-1 and Table 27-1). These viruses are all enveloped RNA viruses that are unstable in the environment and readily inactivated with routine disinfectants. Disease is sporadic and most infected dogs and cats show no clinical signs of illness. For many arboviruses, only subclinical infections have been documented in dogs and cats. Arboviruses are maintained in vectors and small rodent and/or avian reservoir hosts, and some of these reservoir hosts can develop illness in association with infection. Dogs and cats, as well as other domestic animal and human hosts, are generally considered "dead end" hosts and do not maintain sufficient viremia to infect arthropods (Figure 27-1). Arboviruses replicate within the arthropod vector and are transmitted to vertebrate hosts when the vector feeds; this is followed by viremia and, in some cases, viral spread to the central nervous system (CNS) and infection of neurons (neuroinvasion), with subsequent neuronal necrosis and inflammation. When disease occurs, it has important public health significance, because the clinical signs can mimic those of rabies. Because humans have the potential to be infected with these viruses, serologic evidence of infection of dogs and cats can also have public health significance.

Alphavirus Infections (Family Togaviridae)

Alphaviruses are mosquito-borne viruses that belong to the family Togaviridae. Members of this group that are of importance to human and animal health include Eastern, Western, and Venezuelan encephalitis viruses, which primarily cause disease in humans and horses in the Americas; and Ross River virus, which causes disease in humans in Australia and the Pacific islands. Although there is one possible report of encephalitis in a dog due to Venezuelan equine encephalitis virus,[4] only eastern equine encephalitis virus (EEEV) is a significant cause of disease in dogs. Other alphaviruses cause subclinical seroconversion when they infect dogs; in some reports, seropositive cats have also been identified.[5] Dogs have been used as sentinels for the presence of the virus in epidemiologic serosurveys.[6]

EEEV is endemic in swampy areas of the southeastern United States,[7] where it is maintained in a variety of avian reservoir hosts. It causes disease in humans, horses, dogs, and other domestic animal species. Different viral lineages exist that vary in pathogenicity for humans and horses. Human cases occur in the southeastern, eastern, and Great Lakes regions of the United States, but especially Florida, Georgia, Massachusetts, and New Jersey (Figure 27-2, *A*).[8] Most affected dogs are from Georgia, but one affected dog was from New York state.[9] Dogs with signs of encephalitis have always been young (<7 months of age). Disease usually occurs in late spring or summer. Clinical signs include fever, lethargy, inappetence, and diarrhea, with rapid progression (within 1 to 2 days) to recumbency, tachypnea, miosis, nystagmus, tremors, seizures, and death.[7]

Bunyavirus Infections

Important bunyaviruses for animal and human health are the mosquito-borne viruses Rift Valley fever (genus *Phlebovirus*) and La Crosse (genus *Bunyavirus*) viruses; the tick-borne virus

VetBooks.ir

TABLE 27-1

Potential Causes of Vector-borne Viral and Other Viral Encephalitides in Dogs and Cats

Virus	Classification	Vector	Affected Hosts	Geographic Distribution
Eastern equine encephalitis virus	Family Togaviridae, genus *Alphavirus*	Mosquitos	Horses, humans, dogs, other domestic farm animal species	Southeastern (especially Georgia and Florida), eastern, and Great Lakes regions of the United States
Venezuelan equine encephalitis virus	Family Togaviridae, genus *Alphavirus*	Mosquitos	Horses, humans, possibly dogs	Southern United States (Florida), Central and South America (especially Colombia, Venezuela, Trinidad, Peru, Ecuador, Mexico)
La Crosse virus	Family Bunyaviridae	Mosquitos	Humans, dogs	Eastern and Midwestern United States
West Nile virus	Family Flaviviridae	Mosquitos	Horses, humans, birds, dogs	North, Central, and South America; Africa, the Middle East, Europe, Asia, Australia
Tick-borne encephalitis virus	Family Flaviviridae	*Ixodes* ticks	Humans, horses, dogs; domestic animals are generally infected subclinically	Europe, Asia
Borna disease virus	Family Bornaviridae	None known	Horses, cattle, cats, dogs	Primarily Sweden, Austria, Germany, and Japan

BOX 27-1

General Features of Arbovirus Infections as They Relate to Dogs and Cats

- Vector-borne enveloped RNA viruses
- Most often mosquito-borne
- Maintained among small wild vertebrate reservoir hosts, especially birds and/or rodents
- Geographic distribution follows that of vector host
- Seasonal distribution that reflects activity of the vector host
- May cause disease in humans and other domestic animals, especially horses
- Infection of dogs and cats is most often subclinical
- Dogs and cats are "dead end" hosts
- Infection more prevalent in dogs than in cats
- Sporadic reports of disease, especially in young animals (<6 months)
- Neurologic signs accompanied by fever and sometimes other systemic signs (e.g., diarrhea)
- Histopathology shows neuronal necrosis, gliosis, and perivascular cuffing within the brain, which is predominantly nonsuppurative.

Crimean-Congo hemorrhagic fever virus (genus *Nairovirus*); and members of the genus *Hantavirus*, which are not transmitted by vectors and cause hemorrhagic febrile and respiratory illness in humans. Serologic evidence of infection with some these viruses has been documented in dogs and cats.[10,11] La Crosse virus is the only bunyavirus reported to cause disease in dogs under natural circumstances, but this appears to be rare.[12,13] La Crosse virus was named after La Crosse in Wisconsin, where it was first identified as a human pathogen, and is found mostly in the eastern and midwestern United States (see Figure 27-2, *B*). The virus is maintained in rodents, especially Eastern gray squirrels and chipmunks. It is a major cause of human pediatric encephalitis in North America, although mortality is low. Affected dogs have included an adult dog from Florida and three puppies from southern Georgia.[12,13] Mild fever, lethargy, ataxia, vestibular signs, and ultimately seizures occurred in the adult dog, and sudden death was reported in the puppies.

Flavivirus Infections

Vector-borne flaviviruses (*flavi* = "yellow," Latin) of importance to human and animal health are the mosquito-borne viruses Japanese encephalitis virus, yellow fever virus, Murray Valley encephalitis virus, St. Louis encephalitis virus, Wesselsbron virus, Dengue viruses, and West Nile virus (WNV), as well as the tick-borne viruses tick-borne encephalitis (TBE) virus, louping ill virus, and Powassan virus. Antibodies to some of these viruses have been detected in dogs and to a lesser extent, cats in serosurveys,[14-18] but serologic cross-reactivity among flaviviruses can occur. Although uncommon to rare, WNV in the United States and TBE virus in Europe have been reported to cause disease in dogs on more than one occasion. One dog from Africa with fatal encephalitis was initially thought to be infected with Wesselsbron disease virus,[19] but the isolate was later confirmed to be WNV.[20]

West Nile Virus Infection

West Nile virus was first isolated in 1937 from a woman in the West Nile region of Uganda.[21] In the 1950s, the virus was recognized in Israel as a cause of human neurologic disease in the elderly,[22] and subsequently was identified in other parts of Europe and South Africa. In 1999, it appeared in New York state, possibly by transport of infected humans, birds, or

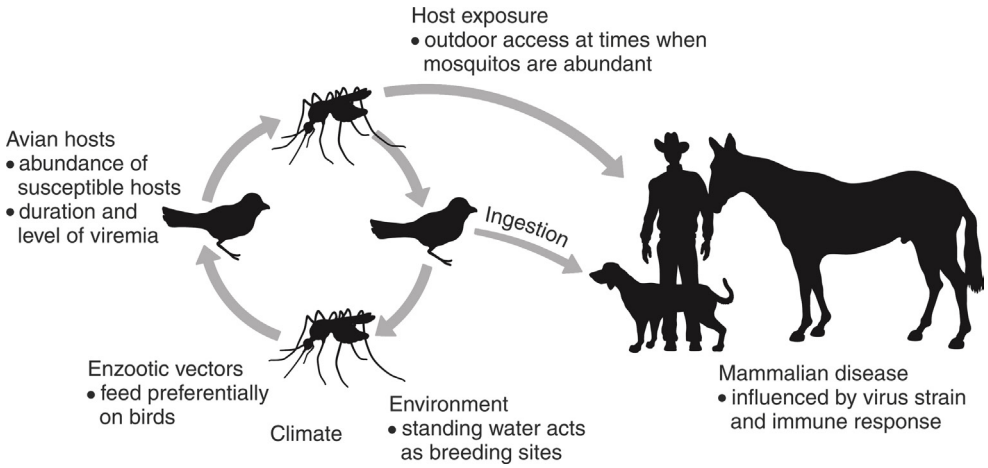

FIGURE 27-1 West Nile virus transmission cycle and factors that influence arbovirus epidemiology.

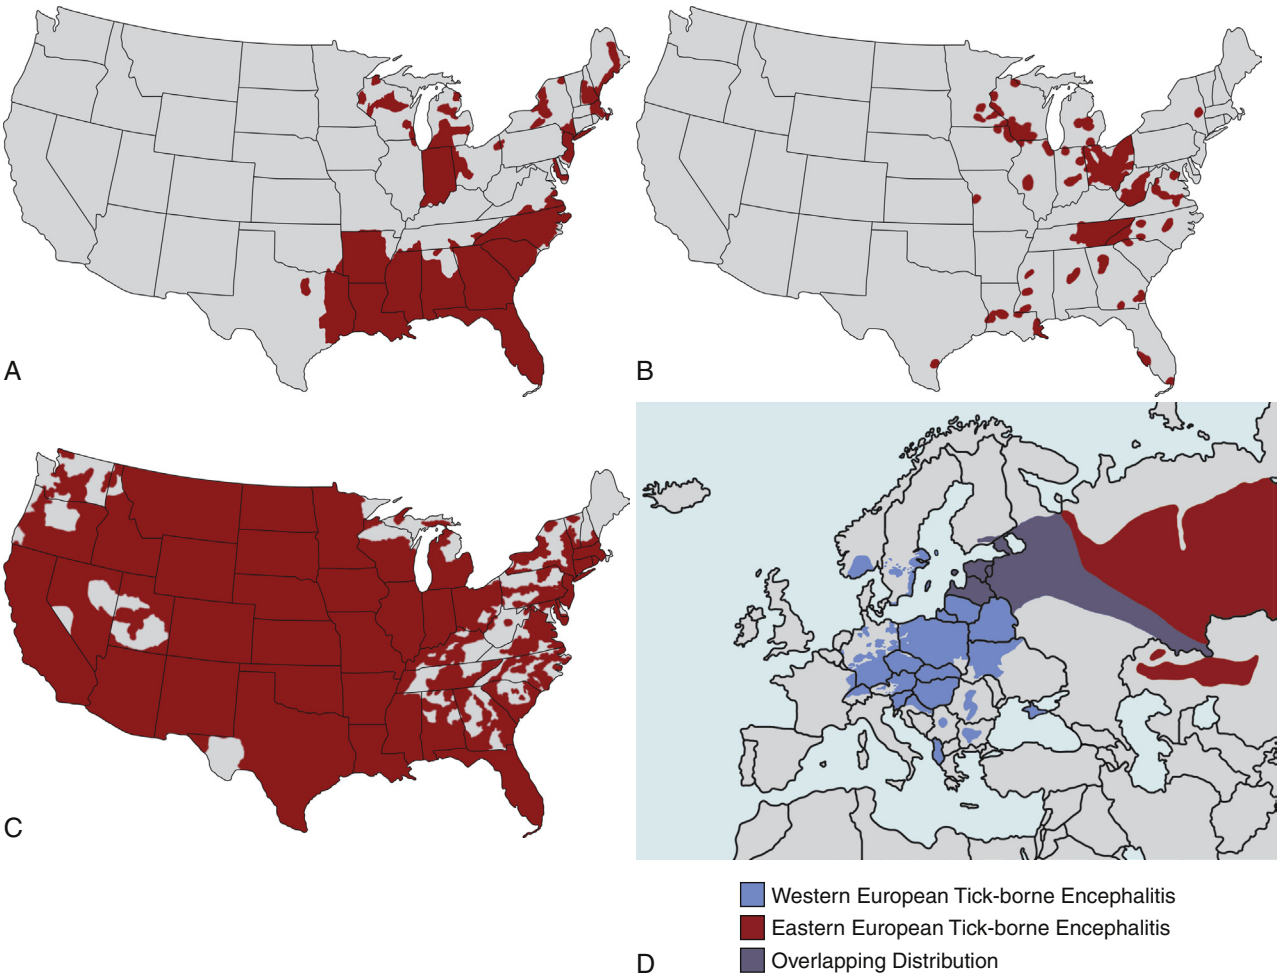

FIGURE 27-2 Geographic distribution of some arboviruses that can cause disease in dogs and cats. **A,** Regions with eastern equine encephalitis virus transmission. **B,** Regions with La Crosse virus transmission. **C,** Regions with West Nile virus transmission. **D,** Regions with tick-borne encephalitis virus transmission.

mosquitos.[23] WNV then spread explosively westward across the United States, and by 2003, disease was detected across the United States to California (see Figure 27-2, *C*). WNV also spread into Canada, Mexico, the Caribbean, and Central and South America.[23,24] Several different variants of the virus exist, which differ in virulence. Strains circulating within the Western hemisphere, Europe, the Middle East, India, Africa, and Australia belong to WNV lineage 1; lineage 2 strains circulate in South Africa and Madagascar. Other lineages have also been reported.

Transmission of WNV by mosquitos increases in the warmer months, with peak activity between July and October. Birds (especially passerines such as crows, jays, and brown sparrows;

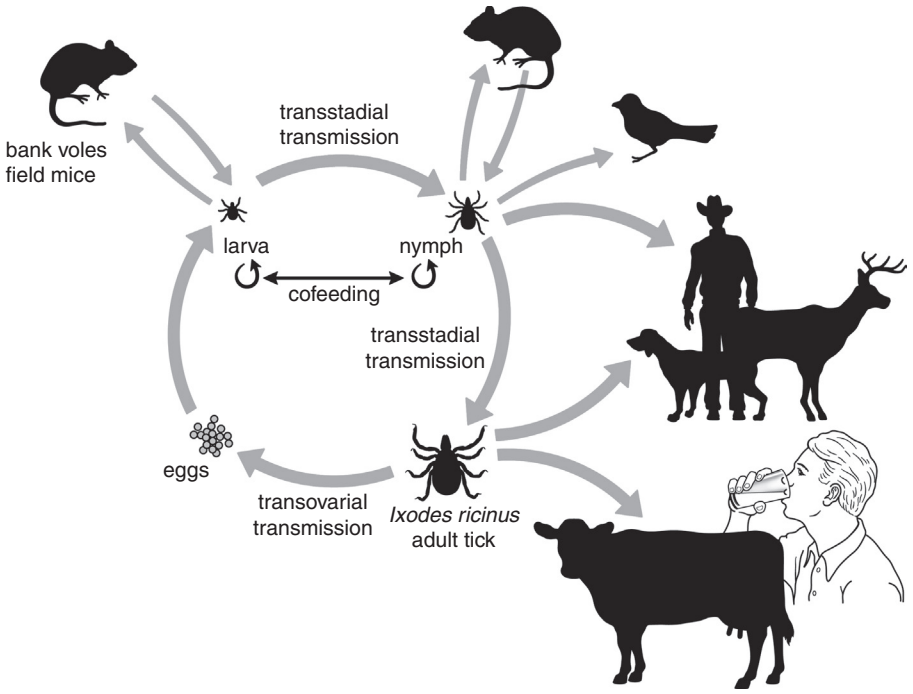

FIGURE 27-3 Transmission cycle for tick-borne encephalitis virus.

shorebirds; owls; and hawks) are important reservoir hosts (see Figure 27-1). Some avian species, such as brown sparrows, maintain high viremias in the absence of clinical signs. Other modes of transmission occur, such as ingestion through predation of infected birds or rodents, blood transfusion, needle-stick injuries, and transplacental transmission. Disease primarily occurs in birds, humans, and horses. When signs occur in humans they are often mild and self-limiting and include fever, headache, myalgia, fatigue, gastrointestinal symptoms, and a transient rash.[25] Rarely, hepatitis, pancreatitis, myocarditis, rhabdomyolysis, orchitis, uveitis, and chorioretinitis can occur. Severe, neuroinvasive disease occurs in fewer than 1% of cases, is most common in the elderly and results in high fever, cervical rigidity, muscle weakness, seizures, and flaccid paralysis. Neurologic signs result from viral invasion of neurons in the brainstem, deep nuclei, and anterior horns within the spinal cord. Clinical signs in horses result from polioencephalomyelitis and include fever and neurologic signs such as ataxia, weakness, and muscle tremors.[26] Approximately two thirds of horses recover. Infected wild birds can exhibit neurologic disease but are usually found dead. Myocarditis and meningoencephalitis are common necropsy findings in these birds.[27]

In dogs, there is widespread serologic evidence of infection, but disease is rare. Cats can become infected and seroconvert, but illness has not been described. Five clinically affected dogs have been described. All, apart from the dog from Africa, resided in various parts of the United States (Missouri, Mississippi, California, and Illinois).[28-31] All of the dogs had signs of fever and progressive neurologic disease. Neurologic signs included generalized tremors, ataxia, a head tilt, bobbing movements, altered mentation, cervical pain, abnormal placing reactions, and tetraparesis. Diarrhea, serous oculonasal discharge, conjunctivitis, abdominal pain, cardiac arrhythmias due to myocarditis, tachypnea, tachycardia, and a stiff gait associated with mild neutrophilic polyarthritis have been reported. For all dogs, diagnosis was made at necropsy.

Tick-Borne Encephalitis Viruses

TBE virus is a notifiable disease that causes potentially fatal neurologic disease in humans in Europe and Asia, where it is the most important tick-borne viral disease of humans.[32] The virus is transmitted transstadially and to a lesser extent transovarially within infected ticks, and ticks can transmit the disease to each other while co-feeding, independent of systemic viremia in vertebrate hosts.[33] Consumption of raw milk from infected ruminants is a lesser mode of transmission to humans (Figure 27-3).

Three subtypes of TBE virus exist, which vary in virulence and geographic distribution. These are designated the European, Siberian, and far-eastern subtypes.[34] The far-eastern subtype occurs in far eastern Russia, Japan, Korea, and China and is the most virulent subtype, with mortality rates in humans that may exceed 20%. In much of Europe, *Ixodes ricinus* ticks spread the European subtype (Western European TBE) whereas *Ixodes persulcatus* ticks transmit the other viral subtypes in northeastern Europe and Asia (Eastern European TBE) (Figure 27-2, *D*).[35] Both Siberian and European subtypes may be found in eastern Europe. The disease was originally detected in 1937 in Austria, but its geographic distribution has expanded rapidly so that the European subtype now occurs throughout Europe as far west as France and possibly Belgium.[17] In Europe, some of the highest incidence rates have occurred in central European countries, especially the Czech Republic.[36] Disease seasonality correlates with the activity of the tick in various parts of Europe. TBE has not been reported in the United Kingdom, but a related tick-borne flavivirus that mainly causes disease in sheep, Louping ill virus, is present. This virus rarely causes encephalitis in dogs.[37,38]

In humans, signs of TBE occur in fewer than 0.5% of infected individuals 4 to 28 days after a tick bite and are biphasic. In the first, viremic phase, fever, malaise, headache, myalgia, and vomiting occur, which resolve within 1 week. In some individuals, after an asymptomatic period that lasts 2 to 10 days, clinical signs return and are accompanied by signs of

meningitis, meningoencephalitis, meningoencephalomyelitis, or meningoencephaloradiculitis. About 1% of cases are fatal, most often in the elderly,[39] but neurologic signs can persist for months or longer than a year. Co-infections with *Borrelia burgdorferi* can occur. Vaccines are currently recommended for prevention of TBE in humans, and national vaccination programs in Austria have greatly reduced the incidence of disease.[40]

Subclinical infection of dogs with TBE virus is widespread, and so dogs have been important sentinels for the presence of the virus in new regions of Europe. Rarely, illness that resembles that in humans can occur in dogs. Affected dogs have been described from Sweden, Switzerland, Austria, Germany, and Italy.[32,41] Several reports have described disease in Rottweilers, but it is not clear whether this represents a true breed predisposition. Signs in dogs include high fever, lethargy, anorexia, and neurologic signs such as decreased mentation, behavioral changes such as aggression, delayed placing reactions, ataxia, flaccid paralysis, reduced segmental reflexes, neck pain, vestibular signs, tremors, tetraparesis, miosis, anisocoria, and generalized seizures.[32,35] These signs progress rapidly over several days to a week, usually culminating in death or euthanasia. Recovery has been described rarely.

Bornaviridae

Borna disease virus (BDV) is an enveloped RNA virus that causes meningoencephalitis primarily in horses in Europe, but also in sheep, cattle, and a variety of other domestic and wild animal species. On rare occasions, cats and dogs are affected.[42,43] BDV has been suggested as a possible but unconfirmed cause of neuropsychiatric illness in humans.[44] The epidemiology of BDV remains mysterious. There is some evidence that small mammals (rodents) act as reservoir hosts. In one study, cats at risk were intact male cats, cats that hunted, and cats that resided in a rural habitat.[45] BDV can be transmitted horizontally among laboratory rodents via urine.[46] Because of seasonal disease occurrence in the spring and summer, an arthropod vector has been suspected, but like rabies virus, BDV is thought to enter the CNS principally via axonal transport from mucosal surfaces, which suggests that direct transmission may be more important. Entrance via the olfactory system has been suggested based on lesions found in horses.[44]

Feline infection was first recognized in Sweden in the early 1970s. The virus has also been detected in cats with neurologic disease from Austria, Switzerland, the United Kingdom, and Japan.[47-49] Some studies have shown a higher prevalence of antibodies to BDV in cats with neurologic signs than in cats without neurologic signs. Affected dogs have been reported from Japan and Austria.[42,43] Serologic evidence of infection has been detected in a low percentage (3.7%) of cats that lacked neurologic disease from the western United States.[50]

The clinical signs of BDV infection can be explained by the predilection of the virus for the limbic system, brainstem, and basal ganglia. In cats, the disease has been referred to as "staggering disease" and is manifested by behavioral changes and increased vocalization, anorexia, lethargy, fever, ataxia, posterior paresis, inability to retract the claws, hypersalivation, and seizures. Clinical signs generally progress over 1 to 6 weeks, which is followed by death or euthanasia or permanent residual neurologic dysfunction. Affected dogs have had anorexia, lethargy, tremors, salivation, mydriasis, circling, and seizures.[42,43]

Diagnosis

Laboratory Abnormalities

Laboratory abnormalities in dogs with vector-borne viral encephalitis are nonspecific. No or minimal abnormalities may be detected in some dogs. Mild anemia, leukopenia, lymphopenia, or leukocytosis due to a neutrophilia (sometimes with a left shift) may occur. The CSF may also be unremarkable, or there may be increased protein concentration and mononuclear pleocytosis.

Microbiologic Tests

Serologic Diagnosis

Serologic assays such as ELISAs are available for detection of antibodies to arboviruses through specialized veterinary diagnostic or research laboratories, and have primarily been used for epidemiologic serosurveys of dogs and cats. Serologic assays have, in general, not been very useful for diagnosis of acute viral encephalitis in dogs and cats. First, because disease is rare, arbovirus infections are often not suspected before death or euthanasia, and euthanasia is often performed early because of suspicion for rabies. Second, incubation periods are often short and disease in dogs progresses rapidly with a high mortality rate, so there is insufficient time for an antibody response to develop. Serologic assays have mainly been used to detect IgG and IgM in dogs with TBE from Europe.[32]

Virus Isolation

Arboviruses can be isolated in a variety of cell lines, and virus isolation has been used to detect WNV, TBE virus, and La Crosse virus in naturally infected dogs with encephalitis and BDV in cats.[12,28,47,51] Fresh or fresh-frozen brain or spinal cord homogenates are suitable specimens. Because viremia occurs, blood, CSF, lung, spleen, and liver might also be useful specimens for isolation.[28,32] Immunofluorescent antibody staining and reverse transcriptase–PCR (RT-PCR) assays are used to confirm the presence of the virus in cell cultures.[7,28,47] Because these viruses can infect humans, specialized biosafety level 3 facilities are generally required. This limits the availability and practicality of virus isolation for routine diagnostic purposes.

Molecular Diagnosis Using the Polymerase Chain Reaction

Conventional and real-time RT-PCR assays have been described for many different arboviral pathogens and BDV. Specialized veterinary diagnostic and research laboratories generally perform these assays. In dogs, RT-PCR assays have been used to detect EEEV, WNV, and BDV in clinical specimens.[7,28,42,43] Because BDV can be detected using PCR assays in tissues in the absence of clinical signs, other methods that localize virus to sites of inflammation, such as immunohistochemistry or in situ hybridization, are necessary for diagnosis of BDV encephalitis.

Pathologic Findings

In general, histopathology of the CNS in dogs with vector-borne viral infections, and cats and dogs with Borna disease, reveals nonsuppurative meningoencephalitis or meningoencephalomyelitis, with multifocal mild to moderate gliosis, neuronal necrosis, and perivascular cuffing with lymphocytes, histiocytes, and plasma cells within Virchow-Robin spaces.[12,32,43] Neutrophils predominate within the meninges of dogs infected with EEEV.[7] Within brain tissue, inflammatory infiltrates in dogs infected with EEEV have been most prominent in the gray

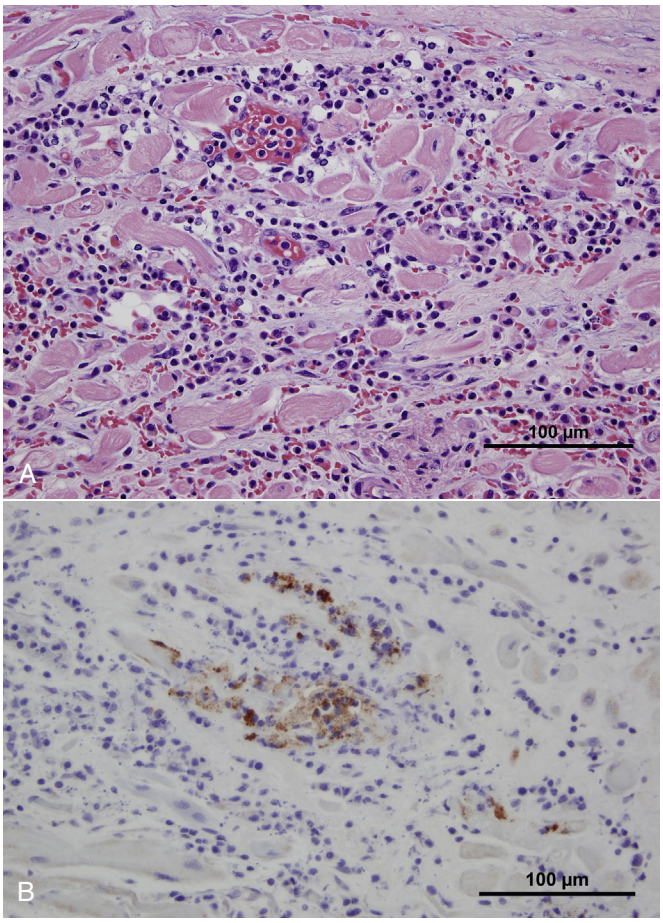

FIGURE 27-5 Severe lymphocytic and neutrophilic myocarditis and vasculitis due to WNV infection with focally extensive hemorrhage and myonecrosis. **A,** H&E stain. **B,** Immunohistochemical stain showing WNV immunoreactivity within neutrophils and histiocytes *(brown).* (From Cannon AB, Luff J, Brault C, et al. Acute encephalitis, polyarthritis and myocarditis associated with West Nile virus infection in a dog. J Vet Internal Med 2006;20:1219-1223.)

matter of the cerebral cortices and midbrains. Gray matter has also been preferentially infected in dogs with WNV encephalitis.[28] Pathologic changes in dogs with TBE are most severe in the brainstem and the cerebellum; meningitis and spinal cord involvement have also been described.[32] BDV preferentially infects the limbic system and brainstem, although the cerebral cortex may also be involved, and one dog had diffuse disease.[39,40,44] Immunohistochemistry has been used to detect antigen of WNV, La Crosse virus, and TBE virus in CNS and other tissues of dogs, and to detect BDV antigen in the CNS of cats and dogs at necropsy (Figure 27-4).[13,28,41-43,47] In situ hybridization has been used to detect BDV RNA in the CNS of dogs and cats.[43,48]

Extraneural lesions have mainly been reported in dogs infected with WNV. Lymphocytic and necrotizing myocarditis was present in several dogs (Figure 27-5). Other findings in dogs with WNV infection have included evidence of hepatic and renal tubular epithelial cell necrosis, neutrophilic pancreatitis, and mild plasmacytic synovitis.[28-31]

Treatment and Prognosis

Treatment of dogs with vector-borne viral encephalitis is supportive only. The prognosis appears to be poor, but because only a handful of infected dogs have been reported, the true prognosis is poorly understood. In virtually all dogs with neurologic signs, diagnosis has been made at necropsy. Some dogs with TBE recover with supportive care.[32] Glucocorticoids have been used to treat some dogs and cats with viral encephalitides, but their use is controversial because of immunosuppression, and controlled studies are not available.

Immunity and Vaccination

Exposure to vector-borne viruses appears to confer immunity to future infections with the same virus. Vaccines are not available for dogs because disease is uncommon to rare. However, vaccines are available and used widely in endemic areas to prevent flavivirus infections in humans (such as TBE, yellow fever, and Japanese encephalitis) and WNV encephalitis in horses.

Prevention

The risk of arboviral infections in dogs and cats can be reduced through control of mosquito and tick vectors. Keeping pets indoors, especially at dawn and dusk when mosquitos are most active, can also reduce exposure, provided mosquitos are excluded through the use of proper screens and windows.

VetBooks.ir

For viruses such as WNV and BDV, prevention of predation on dead birds or rodents may also reduce the risk of infection. Drainage of standing water and removal of containers (tin cans, old tires, flower pots, clogged gutters, bunched tarpaulins) that act as breeding sites are important for mosquito control. Water in birdbaths should be changed at least weekly. Weeds and brush should be reduced. Human mosquito repellents that contain DEET are not recommended for pets, because they can be toxic.[52] Some products labeled for tick prevention in dogs and cats may help to repel mosquitos but are not likely to completely protect against mosquito bites. More information on tick prevention can be found in Chapter 28. Only products specifically labeled for cats should be used on cats or on dogs that are in contact with cats, because of the sensitivity of cats to permethrin toxicosis.[53]

Public Health Aspects

Many arboviruses that cause disease in humans also infect dogs and cats. Dogs and cats are generally not considered reservoirs for transmission of virus to humans because they do not develop high-level or sustained viremia. As noted previously, dogs have been used as sentinels for the presence of these viruses in epidemiologic studies.

CASE EXAMPLE

Signalment: "Paloma," a 13-year-old female spayed golden retriever–Irish setter mix from Vacaville in northern California.

History: Paloma was evaluated at the University of California, Davis, Veterinary Medical Teaching Hospital in September for a 3-day history of inappetence and lethargy. Two days before, physical examination by the referring veterinarian had revealed tachycardia (96 beats/min) and pyrexia (103.1°F or 39.5°C). Results of routine CBC, biochemistry tests, and a urinalysis did not reveal clinically significant abnormalities. The dog was treated with amoxicillin (20 mg/kg PO q12h) and enrofloxacin (10 mg/kg PO q12h), without improvement.

Physical Examination:

Body Weight: 28.6 kg

General: Obtunded, 5% dehydrated. T = 106°F (41.1°C), HR = 140 beats/min, RR = 92 breaths/min, mucous membranes pink, CRT = 1 s.

Integument: No clinically significant abnormalities.

Eyes, Ears, Nose, and Throat: Bilateral enophthalmos, mild serous ocular discharge, conjunctivitis, and nuclear sclerosis were present. Moderate to severe dental disease was present. Examination of the ocular fundus showed no abnormalities.

Musculoskeletal: Body condition score 4/9. Ambulatory on all four limbs, but generalized weakness was noted. Moderate atrophy of the temporalis, quadriceps, and gastrocnemius muscles was present.

Cardiovascular, Respiratory, Gastrointestinal, Urogenital and Lymphoid Systems: Tachypnea and tachycardia were identified. There was mild cranial abdominal discomfort on palpation. All peripheral lymph nodes were normal sized.

Neurologic Examination: Decreased placing reactions were noted in all four limbs, and there was pain on manipulation of the neck.

Laboratory Findings:

CBC:

HCT 37.5% (40%-55%)
MCV 67.3 fL (65-75 fL)
MCHC 34.4 g/dL (33-36 g/dL)
WBC 6050 cells/µL (6000-13,000 cells/µL)
Neutrophils 5627 cells/µL (3000-10,500 cells/µL)
Lymphocytes 363 cells/µL (1000-4000 cells/µL)
Monocytes 61 cells/µL (150-1200 cells/µL)
Adequate platelet numbers (clumped on smear).

Serum Chemistry Profile:

Sodium 144 mmol/L (145-154 mmol/L)
Potassium 4.0 mmol/L (3.6-5.3 mmol/L)
Chloride 110 mmol/L (108-118 mmol/L)
Bicarbonate 16 mmol/L (16-26 mmol/L)
Phosphorus 3.1 mg/dL (3.0-6.2 mg/dL)
Calcium 9.1 mg/dL (9.7-11.5 mg/dl)
BUN 8 mg/dL (5-21 mg/dL)
Creatinine 0.6 mg/dL (0.3-1.2 mg/dL)
Glucose 86 mg/dL (64-123 mg/dL)
Total protein 5.7 g/dL (5.4-7.6 g/dL)
Albumin 2.3 g/dL (3.0-4.4 g/dL)
Globulin 3.4 g/dL (1.8-3.9 g/dL)
ALT 25 U/L (19-67 U/L)
AST 34 U/L (19-42 U/L)
ALP 53 U/L (21-170 U/L)
Gamma GT 3 U/L (0-6 U/L)
Cholesterol 236 mg/dL (135-361 mg/dL)
Total bilirubin 0.3 mg/dL (0-0.2 mg/dL).

Imaging Findings:

Thoracic, Abdominal, Spinal, and Joint Radiographs: No significant abnormalities were noted.

Abdominal Ultrasound: Mild mesenteric and moderate sublumbar lymphadenomegaly was identified. The dog exhibited pain on ultrasound of the right cranial abdomen, but no abnormalities in this region were identified. Impressions: mesenteric and sublumbar lymphadenomegaly.

Microbiologic Testing: Aerobic and anaerobic blood cultures (five sequentially collected specimens): negative

Serology for *Ehrlichia canis*, *Anaplasma phagocytophilum*, and *Borrelia burgdorferi* antibodies (lateral flow ELISA): negative

Treatment: Paloma was treated with lactated Ringer's solution (3 mL/kg/h IV) with potassium chloride supplementation (20 mEq/L), amoxicillin (22 mg/kg PO q8h), enrofloxacin (10 mg/kg PO q24h), and doxycycline (5 mg/kg PO q12h). Physical examination on day 2 revealed persistent pyrexia (105.6°F), tachycardia (108 beats/min), and a stiff gait, but there was no evidence of joint pain or swelling on palpation. Cytologic analysis of synovial fluid collected from both carpal and tibiotarsal joints using arthrocentesis revealed mild suppurative and mononuclear inflammation.

On day 3, the dog became tetraparetic and was unable to stand for longer than a few seconds. Pyrexia (104.5°F) persisted, and treatment with dexamethasone sodium phosphate (0.2 mg/kg IV once) and hydromorphone (0.05 mg/kg IV once) was initiated. Neurologic examination disclosed mental dullness, decreased placing reactions in all four limbs, and

VetBooks.ir

normal segmental reflexes. Further evaluation for neurologic disease, such as imaging of the brain, CSF analysis, or both, was offered, but declined by the owner because of financial limitations. On day 4, the dog was normothermic, and sternally recumbent. Prednisone (1 mg/kg PO q12h) and metronidazole (10 mg/kg PO q8h) were added to the treatment regime. Despite this treatment, by day 5, Paloma was laterally recumbent and obtunded. The owner elected euthanasia.

Necropsy Findings: Histopathologic findings at necropsy consisted of severe acute multifocal necrotizing perivascular and random neutrophilic pancreatitis; severe lymphocytic and neutrophilic myocarditis and vasculitis with myonecrosis; and mild, multifocal gliosis and perivascular to random lymphoplasmacytic and neutrophilic polioencephalomyelitis. The cervical spinal cord was the most severely affected. Mild perivascular plasmacytic synovitis was also present. Aerobic and anaerobic cultures of the liver, spleen, spleen, lung, and synovial fluid were negative. West Nile virus antigen was detected with immunohistochemical stains within foci of encephalomyelitis and myocarditis. The virus was isolated from fresh frozen lung tissue, and WNV RNA was detected using RT-PCR in the synovium, synovial fluid, spinal cord, heart, and kidney tissue.[25]

Diagnosis: Encephalitis, myocarditis, and polyarthritis associated with WNV infection

Comments: This was a rare case of encephalitis and myocarditis associated with WNV infection in a dog. Disease occurred in September, the time of peak activity for virus transmission by mosquitos (July to October).

SECTION 2

Bacterial Diseases

CHAPTER 28

Ehrlichiosis

Jane E. Sykes

Overview of Ehrlichiosis

First Described: *Ehrlichia canis* was first described in 1935 (Algeria).[1] *Ehrlichia ewingii* was described in 1992 (United States).[2] *Ehrlichia chaffeensis* was described in 1991 (United States).[3]

Cause: *E. canis* (canine monocytic ehrlichiosis), *E. ewingii* (canine granulocytic ehrlichiosis), and *E. chaffeensis* (human monocytic ehrlichiosis); an *E. muris*-like organism also may infect dogs in the United States.[4]

Affected Hosts: *E. canis* causes disease in dogs. *E. canis* or a closely related organism may cause disease in cats and humans. *E. ewingii* causes disease in dogs, humans, and goats. *E. chaffeensis* causes disease in humans, possibly dogs and goats. The *E. muris*-like agent causes disease in humans and possibly dogs.

Geographic Distribution: *E. canis* is present worldwide, but especially in tropical and subtropical regions. *E. ewingii* is primarily found in the south-central and southeastern United States. Most reports of *E. chaffeensis* infection are from the southern and south-central United States. The *E. muris*-like agent has been found in the upper Midwest.

Mode of Transmission: *Rhipicephalus sanguineus* ticks (*E. canis*), *Amblyomma americanum* ticks (*E. ewingii* and *E. chaffeensis*).

Major Clinical Signs: The major clinical signs of *E. canis* infection are fever, lethargy, inappetence, weight loss, mucosal hemorrhages, uveitis, pallor, edema, and sometimes neurologic signs. *E. ewingii* primarily causes fever, lethargy, inappetence, and signs of polyarthritis.

Differential Diagnoses: Other tick-borne diseases (such as granulocytic anaplasmosis, Lyme borreliosis and babesiosis), bartonellosis, leptospirosis, lymphoma, multiple myeloma, systemic primary immune-mediated disease

Human Health Significance: All four ehrlichial species can infect and cause disease in humans. The most important human pathogen is *E. chaffeensis*, but the *E. muris*-like agent may also be important.

The ehrlichioses are a group of tick-transmitted diseases caused by intracellular, gram-negative bacteria that include *Ehrlichia canis*, *Ehrlichia ewingii*, and *Ehrlichia chaffeensis*. An organism related to *Ehrlichia ruminantium*, the cause of heartwater disease in cattle, has also been detected in ill dogs from South Africa,[5] and an organism that resembles *E. muris* has been detected in an ill dog and humans from the upper Midwest of the United States.[4] These organisms form morulae (Latin for "mulberry"), a cluster of bacteria, within phagosomes of circulating leukocytes. *Ehrlichia canis* infects monocytes and causes canine monocytic ehrlichiosis (CME), one of the most important infectious diseases of domestic dogs that are exposed to ticks worldwide. *Ehrlichia ewingii* is an unculturable bacterium that infects granulocytes and causes canine granulocytic ehrlichiosis. *Ehrlichia chaffeensis* causes human monocytic ehrlichiosis; dogs are a proposed reservoir for this organism. The geographic distribution of each pathogen is generally restricted to that of their vectors and mammalian reservoir hosts.

Organisms from the genus *Ehrlichia* are grouped within the family Anaplasmataceae. Also within this family are the bacteria *Anaplasma platys* and *Anaplasma phagocytophilum*, which cause canine thrombocytic and granulocytic anaplasmosis, respectively (see Chapter 29); and organisms belonging to the genera *Neorickettsia* (see Chapter 31). *Rickettsia rickettsii*, the cause of Rocky Mountain spotted fever (RMSF), and other spotted fever group rickettsiae belong to a separate family, the Rickettsiaceae (Chapter 30). The families Rickettsiaceae and Anaplasmataceae are phylogenetically related through the order Rickettsiales (Table 28-1). The recent availability of complete genome sequences for these organisms has helped

TABLE 28-1

Members of the Order Rickettsiales of Clinical Importance in Dogs and Cats

Family		Anaplasmataceae		Rickettsiaceae
Genus	*Ehrlichia*	*Anaplasma*	*Neorickettsia*	*Rickettsia*
Species	*E. canis* *E. chaffeensis* *E. ewingii*	*A. phagocytophilum* *A. platys*	*N. helminthoeca* *N. risticii*	*R. rickettsii*

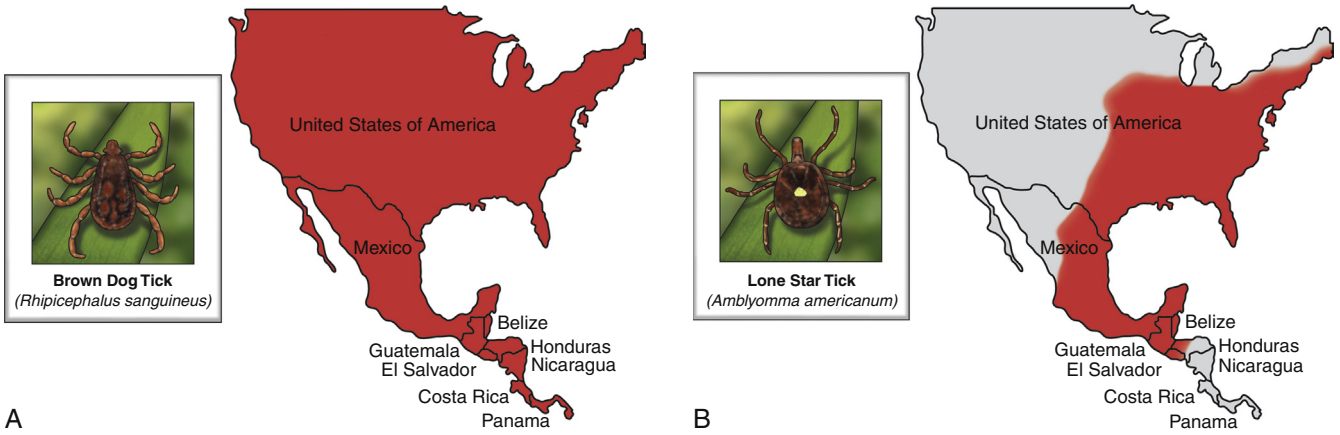

FIGURE 28-1 **A,** Distribution of *Rhipicephalus sanguineus*, which transmits *Ehrlichia canis,* in the United States, Mexico and Central America. **B,** Distribution of *Amblyomma americanum*, which transmits *Ehrlichia ewingii* and *Ehrlichia chaffeensis*. The distribution of *E. ewingii* infections in dogs more closely matches that of *A. americanum* than the distribution of *E. canis* matches that of *R. sanguineus* (highest prevalence in the southern states). This is because of chronic *E. canis* infections that occur in dogs with travel histories to southern states, where the climate is warmer and *R. sanguineus* is more prevalent.

to elucidate mechanisms of pathogenesis and host-pathogen interactions.[5-7]

The severity of clinical signs in animals with ehrlichial infections depends on factors such as the size of the inoculum, host immunity, and organism species and strain. Because of shared arthropod vectors and/or concurrent exposure to multiple vector ticks, co-infections with more than one rickettsial pathogen, as well as other arthropod-borne pathogens such as *Babesia* spp., and *Bartonella* spp., occur commonly in dogs and may complicate the clinical picture.

Ehrlichia canis Infection

Etiology and Epidemiology

E. canis is transmitted primarily by the brown dog tick *(Rhipicephalus sanguineus),* one of the most widely distributed ticks worldwide. Infection has been reported in dogs from Asia, Africa, Europe, and the Americas. Australia appears to be free of *E. canis* infection although occasionally seroreactivity to *E. canis* has been identified in dogs. The DNA of *E. canis* has been detected in other tick species, which include other *Rhipicephalus* species,[8,9] *Ixodes ricinus*,[10] *Haemaphysalis* spp. ticks,[11] and *Dermacentor* spp. ticks[11]; experimental transmission has been accomplished with *Dermacentor variabilis* ticks.[12] Different strains of *E. canis* exist that may vary in virulence. Although *R. sanguineus* is found throughout the United States, it prefers warm climates, and so disease is diagnosed most frequently in dogs living in the southeastern and southwestern states (Figure 28-1). In Europe, *R. sanguineus* is primarily found in Mediterranean regions, but its

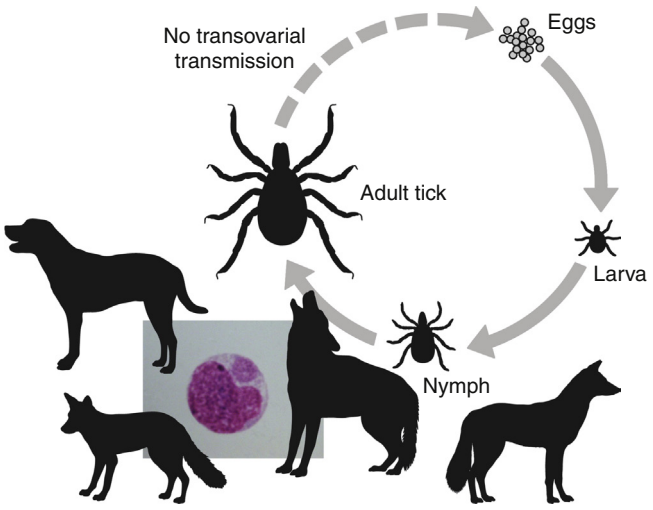

FIGURE 28-2 Life cycle of *Ehrlichia canis*. The organism is transmitted only transstadially (from larva to nymph to adult) within the tick. Jackals, foxes, and possibly coyotes also act as reservoir hosts. A morula is shown within the cytoplasm of a monocyte as seen on a blood smear.

distribution appears to be moving northward, and CME has been reported in dogs that lack travel history as far north as the Netherlands.[13] *E. canis* is the most common pathogen detected in ticks in Israel.[8] Because of chronic, subclinical infection, dogs can be transported to non-endemic regions and subsequently develop disease years later. Tick larvae or nymphs acquire infection when they feed on infected dogs. Jackals, foxes, and possibly coyotes may also act as reservoir hosts. *E. canis* is transmitted transstadially

VetBooks.ir

(i.e., from larva to nymph to adult) within the tick (Figure 28-2).[14] No clear age or sex predilection for CME exists, but German shepherds are reportedly more susceptible, and prognosis may be poorer in this breed. Cross-bred dogs may be less likely to develop disease.[15] Although natural infection of cats with *E. canis* (or one or more closely related organisms) has been described in North and South America,[16-18] clinical ehrlichiosis is rarely reported.

Clinical Features

Signs and Their Pathogenesis

The course of CME has been divided into acute, subclinical, and chronic phases, although in naturally infected dogs, these phases may not be readily distinguishable. Clinical signs of acute disease occur 8 to 20 days after infection. The organism multiplies by binary fission within vacuoles of mononuclear phagocytes; rupture of infected host cells leads to infection of new cells. Immune-mediated mechanisms are important in the pathogenesis of disease, and the presence of the spleen appears to contribute to disease severity.[19] The clinical manifestations vary considerably among dogs, which may reflect factors such as *E. canis* strain variation, host immune response, stage of disease, and concurrent infections. Lethargy, inappetence, fever, and weight loss are most common. Replication of the organism in reticuloendothelial tissues is associated with generalized lymphadenopathy and splenomegaly. Ocular and nasal discharges, peripheral edema, and, less commonly, mucosal and cutaneous petechial and ecchymotic hemorrhages can also occur. Bleeding tendencies result from thrombocytopenia and platelet dysfunction,[20] which may reflect immune-mediated platelet damage.[21] Neurologic signs may result from meningeal inflammation or hemorrhage. Dogs can recover spontaneously from the acute phase within 2 to 4 weeks, after which time they may eliminate the infection or remain subclinically infected. Sequestration of organisms within the spleen may occur, and the organisms may evade the host immune system through antigenic variation.[5] This subclinical phase may persist for months to years.

Chronic CME develops in only some infected dogs. Factors that influence the development of chronic disease are unclear, but genetics may play a role. The presence of pancytopenia typifies the severe chronic form of ehrlichiosis, and results from hypoplasia of all bone marrow cells.[22] Clinical signs range in severity and include lethargy, inappetence, bleeding tendencies, mucosal pallor, fever, weight loss, lymphadenopathy, splenomegaly, dyspnea, anterior uveitis, retinal hemorrhage and detachment, polyuria/polydipsia, and edema.[15,22-24] Polymyositis occurs in some dogs, which can be manifested by diffuse muscle wasting and tetraparesis.[25] Secondary opportunistic infections such as viral papillomatosis, protozoal infections, and bacterial urinary tract infections can also develop, although the precise underlying mechanism of immunosuppression, and how it relates to successful persistence of *E. canis*, has not yet been elucidated (see Figure 26-5).[26,27] Marked granular lymphocytosis and bone marrow plasmacytosis may occur, sometimes accompanied by a monoclonal gammopathy, which may lead to misdiagnosis of lymphocytic leukemia or multiple myeloma, respectively. This has led to the recommendation that all dogs with well-differentiated lymphocytosis or otherwise unexplained monoclonal gammopathy be tested for *E. canis* infection.[28] Protein-losing nephropathy may develop as a result of immune-complex glomerulonephritis.

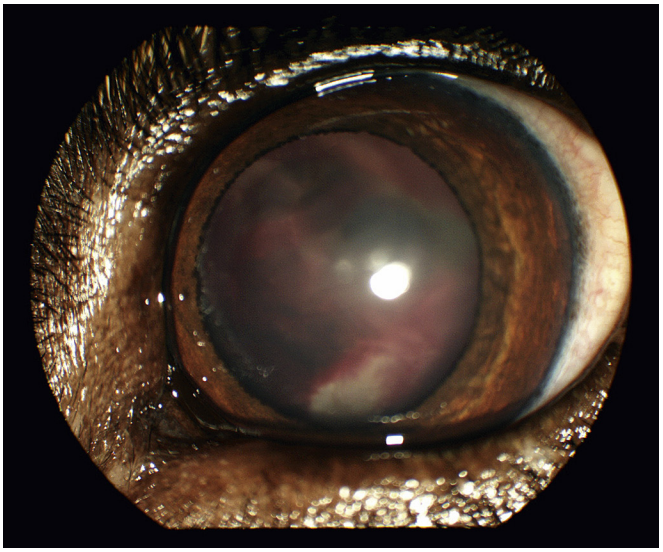

FIGURE 28-3 Retinal hemorrhage and detachment in a 4-year old female spayed Rhodesian ridgeback mix with canine monocytic ehrlichiosis. The dog also had moderate to severe, poorly regenerative, macrocytic hypochromic anemia (16.4% with a reticulocyte count of 49,000), lymphopenia (94 cells/μL), thrombocytopenia (26,000 platelets/μL), and large numbers of circulating nucleated red blood cells (75/100 WBC). Systolic blood pressure was within normal limits. (Courtesy of University of California, Davis Veterinary Ophthalmology Service.)

In reports of feline ehrlichiosis, clinical and laboratory findings have generally been similar to those in dogs; one cat had polyarthritis.[16]

Physical Examination Findings

Common physical examination findings in dogs with CME are lethargy, fever, peripheral lymphadenopathy, and splenomegaly. Ocular and nasal discharge, mucosal petechial hemorrhages, epistaxis, peripheral edema, and/or neurologic signs may be evident. Ocular abnormalities include anterior uveitis, hyphema, retinal hemorrhage, retinal detachment, and optic neuritis, with anterior uveitis being most common (Figure 28-3).[24,29] Neurologic signs include twitching, ataxia, seizures, vestibular signs, hyperesthesia, and cranial nerve defects. Dogs with chronic ehrlichiosis may have thin body condition or diffuse muscle atrophy and mucosal pallor. Findings in cats with ehrlichiosis have been similar to those in dogs, and include lethargy, splenomegaly, lymphadenopathy, petechial hemorrhages, and retinal detachment.[16,17]

Diagnosis

Laboratory Abnormalities

Complete Blood Count

Thrombocytopenia and occasionally mild leukopenia and a nonregenerative anemia occur 1 to 4 weeks after infection with *E. canis*. Mild thrombocytopenia, with increased mean platelet volume, may persist during the subclinical phase. Classically, dogs with chronic CME are pancytopenic, but more commonly, nonregenerative anemia and thrombocytopenia are noted. In some dogs, regenerative anemia or leukocytosis due to a neutrophilia and band neutrophils are present. Lymphopenia occurs in most affected dogs, but in some dogs, moderate to marked granular lymphocytosis (up to 17,000/μL) can occur. Normoblastosis, that can exceed 50 nucleated RBC per 100 WBC, may be present.

VetBooks.ir

In some dogs, morulae are visualized within circulating monocytes (Figure 28-2). The finding of morulae within monocytes using cytologic evaluation of blood smears is insensitive, especially in dogs with chronic infection, and does not distinguish between *E. canis* and *E. chaffeensis* infection. Use of buffy coat smears, thin smears of blood collected from the margin of the pinna, or splenic aspirates increases the sensitivity for detection of morulae. In one study, after careful searching, morulae were found in only 2 of 19 dogs with CME.[22]

Serum Biochemical Tests

Serum chemistry abnormalities in chronic ehrlichiosis include variable hypoalbuminemia, hyperglobulinemia, and elevated ALT and ALP activities. Most often the hyperglobulinemia is due to a polyclonal gammopathy.[15] Monoclonal gammopathy can also develop. Less commonly, increases in serum urea nitrogen and creatinine concentrations are present.[22]

Urinalysis

Transient proteinuria, with urine protein:creatinine ratios that exceed 20 (reference range, <1) have been reported in dogs with acute CME. This can resolve by 6 weeks after infection.[30,31] Dogs with chronic CME may also have evidence of proteinuria. Pyuria, hematuria, and cylindruria may also be present.

Coagulation Profile

In addition to thrombocytopenia, coagulation abnormalities in dogs with CME include prolongation of the buccal mucosal bleeding time (BMBT), decreased platelet aggregation, and prolongation of the APTT.[32,33]

Cerebrospinal Fluid Analysis

Dogs with central nervous system (CNS) involvement may have increased CSF protein concentrations and lymphocytic pleocytosis.[24] Although rarely found, morulae may be detected in cells within the CSF.[34]

Bone Marrow Analysis

In dogs with chronic CME, bone marrow findings include hypoplasia or aplasia of all bone marrow elements, decreased iron stores and marrow plasmacytosis (Figure 28-4). Bone marrow mastocytosis has also been described.[35] Myelofibrosis does not typically develop in chronic CME.[36] Some dogs have normal or hypercellular marrows.

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with CME often show no significant abnormalities, but sometimes bronchointerstitial infiltrates are present. This may reflect an underlying interstitial pneumonia.

Sonographic Findings

Findings on abdominal ultrasonography are nonspecific and include splenomegaly, alterations in splenic echotexture, enlargement and hypoechogenicity of the abdominal lymph nodes, and scant peritoneal effusion. Increased renal echogenicity and decreased corticomedullary definition may occur in dogs with glomerulonephritis.

Microbiologic Tests

Available diagnostic assays for ehrlichiosis in dogs and cats are listed in Table 28-2.

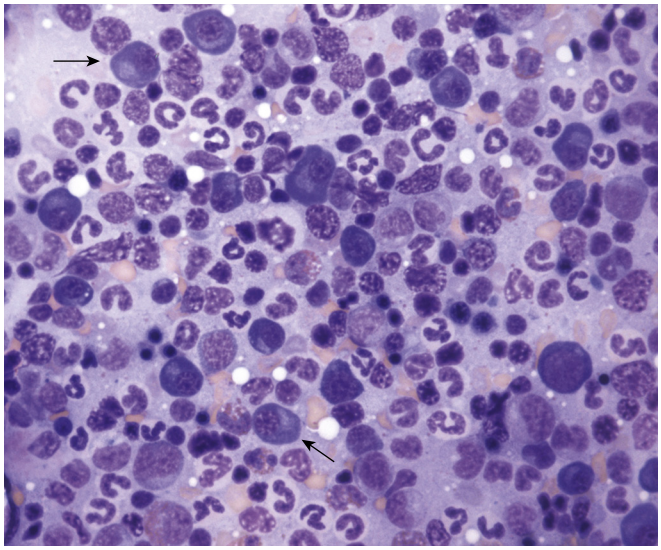

FIGURE 28-4 Bone marrow plasmacytosis in an 8-year-old female spayed Labrador retriever with canine monocytic ehrlichiosis. Serum globulin was 12.1 g/dL (reference range, 2.3-4.4 g/dL), and serum protein electrophoresis revealed a polyclonal gammopathy. Plasma cells have a clock-faced nucleus and a clear area adjacent to the nucleus; two plasma cells are identified with arrows. Mild to moderate megakaryocyte hyperplasia, mild erythroid hypoplasia, and mild mature granular lymphocytosis were also present. Romanowsky stain.

Serologic Diagnosis

Most often, the diagnosis of CME is made using serology, which may be performed using indirect immunofluorescent antibody (IFA) testing, ELISA technology, or Western blotting. Using IFA testing, which is considered the gold standard, antibodies can be detected between 7 and 28 days after initial infection. Dogs with acute ehrlichiosis may have false-negative test results if sufficient time has not elapsed for antibody production to occur. PCR assays may be helpful for diagnosis in this situation. A positive initial serum antibody titer may reflect previous exposure, and not necessarily ehrlichial disease. Retesting should be performed 2 to 3 weeks later to demonstrate seroconversion, and results of serology should be interpreted in light of a dog's clinical signs and the results of testing for other potential causes of the dog's illness. Dogs with chronic *E. canis* infection frequently have extremely high IFA titers, sometimes greater than 1:600,000, and these antibodies may persist in the face of treatment, suggesting persistence of the organism.[22] Seroconversion does not generally occur in dogs with chronic disease, although antibody titers may decline in some dogs with treatment. High titers do not correlate with the severity of hyperglobulinemia, disease in general, or duration of illness. Because of variability of reporting between laboratories, there is no standard "cutoff" titer that is used to separate positive and negative results. Serologic cross-reactivity to other *Ehrlichia* species occurs, which includes *E. ewingii* and especially *E. chaffeensis*. Cross-reactivity to *A. phagocytophilum* antigens can occur to a lesser extent. In areas where other rickettsial agents are endemic, Western blotting has been used in an attempt to confirm that positive antibody titers on IFA are truly to *E. canis* antigens. However, Western blotting is laborious to perform and interpret and not routinely available, and when *E. canis* antigens are the target used, it may be difficult to distinguish between *E. canis* and *E. chaffeensis* infection.[37] As a result, Western blotting has predominantly been used on a research basis.

VetBooks.ir

TABLE 28-2

Diagnostic Assays Available for Ehrlichiosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cell culture	Whole blood	*Ehrlichia canis*; *Ehrlichia ewingii* cannot be cultured	Not widely offered or utilized for routine diagnostic purposes. Requires several weeks' incubation.
Morula detection	Whole blood, buffy coat smears, body fluids, tissue aspirates	*E. canis* or *E. ewingii* morulae	Low sensitivity (especially for chronic *E. canis* infection). *E. canis* morulae cannot be distinguished from those of *E. chaffeensis*, and *E. ewingii* morulae cannot be differentiated from those of *A. phagocytophilum*. Morulae may be confused with platelets, cytoplasmic granules, phagocytized nuclear material, and lymphoglandular bodies.
IFA serology	Serum	Antibodies to *E. canis*	Acute and convalescent serology is required for diagnosis of acute infection, because initial results may be negative in dogs with acute disease, and positive results can reflect previous exposure rather than active infection. Dogs with chronic infection generally do not seroconvert. Cross-reactivity occurs to other ehrlichial species and occasionally to *Anaplasma* spp.
ELISA serology	Serum	Antibodies to *E. canis* or *E. ewingii* antigens	Rapid, inexpensive, can be performed as an in-practice test. Similar limitations as for IFA. Lack of quantitation limits ability to document seroconversion.
Western immunoblotting	Serum	Antibodies to specific *E. canis* or *E. ewingii* antigens	Technically difficult; primarily used on a research basis to identify serologic responses to specific ehrlichial species. May be difficult to distinguish antibody responses to *E. canis* and *E. ewingii*.
PCR	Whole blood; spleen, lymph node or bone marrow aspirates; buffy coat or tissue specimens	*E. canis*, *E. muris*, or *E. ewingii* DNA	Confirms active infection. Sensitivity and specificity may vary depending on assay design and specimen type. Sensitivity for diagnosis of chronic CME may be low. Assays that specifically detect *E. muris* are not widely available on a commercial basis.

CME, Canine monocytic ehrlichiosis; IFA, immunofluorescent antibody.

A variety of ELISA assays have been developed for detection of antibodies to *E. canis*. A point-of-care lateral-flow ELISA device for the simultaneous detection of canine heartworm antigen, antibodies to *E. canis* or *E. ewingii*, antibodies to *Borrelia burgdorferi*, and antibodies to *Anaplasma* spp. in canine serum, plasma, or whole blood has been marketed for use in companion animals (SNAP 4Dx Plus, IDEXX Laboratories, Westbrook, ME), which includes recombinant surface proteins of *E. canis* and *E. ewingii* on a single spot. According to the manufacturer, when IFA and Western blotting were used as the gold standard, the sensitivity and specificity of the *E. canis* antigen for detection of *E. canis* antibodies in 104 samples positive for *E. canis* antibodies and 236 samples negative for *E. canis* antibodies was found to be 96.2% and 100%, respectively. Other point-of-care ELISA assays for detection of *E. canis* antibodies have also been developed. A silicon disc-based assay is available in the United States through Antech Diagnostic laboratories that detects *Dirofilaria immitis* antigen and antibodies to *E. canis*, *Anaplasma* spp., and *B. burgdorferi* (Accuplex 4, Antech Diagnostics, Irvine, CA). The performance of this assay for diagnosis of ehrlichiosis has not been thoroughly investigated at the time of writing. The incidental finding of *E. canis* seroreactivity in dogs screened using these assays for heartworm antigenemia should prompt performance of a thorough physical examination and basic laboratory testing (CBC, chemistry panel, and urinalysis) to evaluate for thrombocytopenia, hyperglobulinemia, and proteinuria. When sick dogs test positive, quantitative serology should be performed so that a titer can be obtained as a baseline for acute and convalescent serologic testing or, for dogs suspected to have chronic CME, to evaluate for titers of very high magnitude that might be consistent with a dysregulated immune response to the organism.

Molecular Diagnosis Using the Polymerase Chain Reaction

Whole-blood PCR assays for *E. canis* DNA is more sensitive for early diagnosis of CME than IFA or ELISA in dogs with acute disease. PCR assays are widely available for routine diagnosis of *E. canis* infection. Several laboratories offer panels that include PCR assays for a variety of different vector-borne pathogens. The results of these assays should be interpreted in light of a dog's history, clinical signs, and the results of appropriate serologic assays; the last should be performed to support the results of PCR testing. PCR assays for *E. canis* may be performed on

VetBooks.ir

blood, lymph node aspirates, splenic aspirates, or bone marrow. Convalescent IFA or ELISA testing is much more sensitive than PCR assays for diagnosis of chronic CME.[22,38,39] The sensitivity of PCR assays for diagnosis of CME when performed on bone marrow in dogs with chronic ehrlichiosis can range from 25% to 68%, depending on the laboratory.[22] The use of PCR assays in the absence of serology is currently not suitable for screening potential blood donors for infection. PCR assays may be useful to confirm infection in the first week of illness, when serologic assays are often negative. Depending on the assay used, when positive, PCR can also be used to confirm the *Ehrlichia* species involved.

Blood Culture

E. canis can be cultured in certain cell lines, such as DH82 cells. This is time-consuming and generally performed only on a research basis.

Pathologic Findings

Gross pathologic findings in CME include widespread petechial and ecchymotic hemorrhages, generalized pallor, edema, lymphadenopathy, and splenomegaly.[40,41] Ascites may also be present. On histopathology, lymphoid and plasma cell hyperplasia, lymphoplasmacytic infiltrates, and vasculitis may be present in numerous organs, such as the brain, eye, spinal cord, spleen, liver, kidneys, lymph nodes, bone marrow, and lungs. Histiocytic infiltrates may be found in lymph nodes. With chronicity, the proportion of plasma cells increases. Non-suppurative meningitis and perivascular cuffing within the CNS can also occur.[40-42] Glomerulonephritis may be evident,[40] although dogs with acute CME have had interstitial nephritis and electron microscopic abnormalities that are more consistent with minimal-change glomerulonephritis, with fusion of podocyte processes.[30] Little information is available in regard to the prevalence and type(s) of glomerulonephritis that develop in dogs with chronic CME.

Treatment and Prognosis

Antimicrobial Treatment

The treatment of choice for CME is doxycycline (10 mg/kg PO q24h) (Table 28-3). It was the consensus of the ACVIM Infectious Disease Study Group that dogs and cats should be treated for a minimum of 28 days.[28] Mixed results have been obtained in studies that have evaluated the efficacy of doxycycline for treatment of *E. canis* infection. One study suggested that acute infection can be eliminated after treatment for just 16 days.[43] Another study that used ticks to infect dogs showed a failure of doxycycline, when given for 14 days, to eliminate the organism from subclinically infected dogs.[44] In another study, dogs with acute and subclinical infections became negative by PCR assay on blood after 28 days of doxycycline treatment, but dogs with chronic infections remained intermittently positive. However, ticks still became PCR positive after they fed on treated dogs, regardless of the stage of disease when treatment was initiated.[45]

Whether or not persistence of infection occurs, most dogs with acute disease show clinical improvement within 24 to 48 hours. Dogs with severe chronic disease may not respond to therapy, or cytopenias may resolve over a period of several months. Strong risk factors for mortality in one study were severe leukopenia (WBC <930 cells/μL), severe anemia (HCT <11.5%), hypokalemia (<3.7 mmol/L), and prolonged APTT (>18.25 s).[46] Platelet counts generally improve and normalize by 2 weeks following institution of therapy. After treatment, titers can decline and become negative in 6 to 9 months. Some dogs retain high titers for several years. Treatment for these dogs should be based on resolution of platelet counts and improvement of hyperglobulinemia, although hyperglobulinemia can resolve over several months after treatment is discontinued. The use of PCR assays on splenic aspirates could be considered to determine if persistent infection is present in these dogs, but whether ongoing treatment with doxycycline changes the outcome for these dogs is unknown. Platelet counts should be reassessed 1 and 3 months after discontinuation of therapy, because of the potential for relapse or reinfection. Other causes of illness (especially other vector-borne diseases such as babesiosis or bartonellosis) should also be considered in dogs that fail to respond to treatment.

TABLE 28-3

Antimicrobial Drug Doses Used for Treatment of Ehrlichiosis in Dogs and Cats

Drug	Dose	Route	Interval (hours)	Minimum Duration (days)
Doxycycline	5 mg/kg	PO, IV	12*	*E. canis* 28 days; *E. ewingii* 14 days
Oxytetracycline	7.5-10 mg/kg	IV	12	Until gastrointestinal signs abate, and then change to oral doxycycline as above

*Or 10 mg/kg PO q24h.

Other drugs used to treat CME with variable success are chloramphenicol, imidocarb dipropionate, and enrofloxacin.[47-50] *Ehrlichia canis* appears to have intrinsic gyrase-mediated resistance to fluoroquinolones,[51] so although their use can be associated with clinical improvement, it is not recommended. The antiprotozoal drug imidocarb dipropionate appeared efficacious for treatment of *E. canis* infection in some studies but not others.[48,49]

At this time, treatment of seroreactive but otherwise healthy dogs that have normal routine bloodwork results is controversial, because it is unknown if treatment changes outcome for these dogs and has the potential to lead to antimicrobial resistance or adverse effects of drug therapy.

Supportive Care

For dogs with CME that are dehydrated or anemic, IV fluids or blood products may be required. Use of erythropoietin and granulocyte colony-stimulating factor together with prednisone was associated with treatment success in a dog with severe chronic ehrlichiosis in one case report.[52] Desmopressin acetate (DDAVP) (1 mcg/kg SC q24h) for 3 days appeared to be efficacious to treat bleeding disorders in a few dogs with CME,[33] and treatment resulted in reduction of the BMBT and APTT. If thrombocytopenia fails to resolve with

doxycycline administration, a short course (up to a week) of therapy with immunosuppressive doses of glucocorticoids could be considered in addition to ongoing therapy with doxycycline.

Immunity and Vaccination

A vaccine for *E. canis* infection is currently not available, but in one study vaccination of dogs with an attenuated strain dramatically reduced disease in dogs challenged with a virulent strain of *E. canis*.[53] The immune response to *E. canis* infection is not well understood. Because *E. canis* is an intracellular pathogen, cell-mediated immune responses are required for pathogen elimination. In one study, dogs with acute infection developed CD8+ lymphocytosis that subsided after several weeks, despite organism persistence.[27] Cytokine studies suggest that the immune response may vary with the strain of *E. canis* involved.[54,55] Genetic factors are also likely to be important determinants of the immune response and outcome of infection.

Prevention

Avoidance of tick-infested areas and routine inspection of dogs for ticks after outdoor activities can help to prevent ehrlichiosis. Early removal of ticks may help to reduce transmission, because of the 24- to 36-hour delay that occurs between tick attachment and feeding. Clients should be instructed to remove ticks properly and avoid handling ticks with bare hands or crushing them, to prevent exposure to infected hemolymph. A variety of devices are available to assist tick removal, which are placed around the area where the mouthparts enter the skin to avoid crushing or squeezing the tick and leaving the mouthparts behind. Fine-tipped tweezers can be used to grasp the tick as close to the skin as possible, followed by steady retraction to remove the tick. The bite wound should then be thoroughly cleaned with a suitable antiseptic solution (such as iodine or chlorhexidine-based antiseptics) or soap and water. Ticks can be disposed in alcohol or tested for vector-borne pathogens using PCR assays.

Topical ectoparasiticides with activity against ticks also prevent tick-borne infectious diseases. Examples of canine ectoparasiticides with activity against ticks include those that contain amitraz, fipronil, pyrethroids (permethrin, etofenprox, pyrethrin, deltamethrin, flumethrin), and selamectin. In one field study, the use of monthly permethrin effectively prevented infection with *E. canis* by kenneled dogs.[56] Products that contain pyrethroids and amitraz have the most potent activity against ticks. Permethrin, deltamethrin, and amitraz cannot be used in cats, and use of these products should be avoided on dogs that co-habitate with cats. Flumethrin collars are available for use on cats (and on dogs) because unlike the other pyrethroids, flumethrin does not require hepatic glucaronidation for metabolism.[57] Products that contain amitraz, a monoamine oxidase inhibitor, should not be used in dogs treated with selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, and pet owners that are receiving SSRIs should also use alternative preventatives for their dogs. Preventatives should be applied consistently at the recommended interval for optimum activity. No preventatives completely protect dogs or cats from tick attachment, especially where tick infestation rates are high. Unfortunately, acaricide-resistant strains of *R. sanguineus* have been reported as a result of indiscriminate use of these drugs.[58]

Low dose doxycycline (6.6 mg/kg q24h PO) has also been used to prevent infection in dogs residing in kennels in which E. canis infection is a problem. Resistance to doxycycline remains a theoretical concern in this situation.

Because of chronic, subclinical infection, blood donor dogs should be screened with serology (or serology and PCR assays) for evidence of *E. canis* exposure or infection. All seropositive dogs should be excluded as donors. Transport of chronically infected dogs to non-endemic regions has the potential to introduce the infection or new strains of *E. canis* to these regions if the appropriate tick vectors are present.

Public Health Aspects

E. canis DNA has been detected in some human patients with clinical signs of human monocytic ehrlichiosis,[59] suggesting that *E. canis* might be a cause of monocytic ehrlichiosis in people. Appropriate precautions should be taken to prevent transmission when handling engorged ticks as well as blood and tissue specimens from infected dogs, and care should be taken to prevent needle-stick injuries.

Ehrlichia ewingii Infection

Etiology and Epidemiology

Ehrlichia ewingii is an unculturable bacterium that causes granulocytic ehrlichiosis in humans and in dogs. It was first recognized in dogs[2] and occurs in North America and more recently has been detected in dogs from Africa and Brazil.[60,61] Infection occurs in the south-central and southeastern parts of the United States, which reflects the distribution of the primary tick vector, *Amblyomma americanum*. Transmission within the tick is transstadial. More than 40% of dogs from an endemic area in Oklahoma and Arkansas were seropositive.[62] In another large study the overall seroprevalence was 14.5% in the central states (Oklahoma, Arkansas, Missouri, and Kansas) and 5.9% in the southeast.[63] In one study, most cases occurred from May through July,[64] but in another, cases occurred throughout the year.[65] In the study from the south-central United States, dogs were more likely to test positive with a PCR assay in August.[62] *E. ewingii* is maintained in white-tailed deer.[66] The DNA of *E. ewingii* has also been found in *Dermacentor variabilis* and *R. sanguineus* ticks,[67] but *A. americanum* is the only proven vector.

Clinical Features

Signs and Their Pathogenesis

In contrast to *E. canis* infection, *E. ewingii* infection appears to cause only acute disease; a chronic phase of disease has not been described. Like *A. phagocytophilum*, *E. ewingii* replicates in neutrophils and delays neutrophil apoptosis, which prolongs the life span of the host cell.[68]

Dogs with *E. ewingii* infection may show no signs, or fever, lethargy, anorexia, and neutrophilic polyarthritis may occur. After experimental infection, signs develop after an incubation period of 3 to 4 weeks.[69-71] Vomiting and diarrhea occur uncommonly. Neurologic signs have been described in some naturally infected dogs,[65] but the possibility of concurrent infections with

other pathogens such as *Rickettsia rickettsii* was not ruled out in these dogs. *E. ewingii* can be found in apparently healthy dogs, so dogs may act as a reservoir for infection.

Physical Examination Findings

On physical examination, dogs with *E. ewingii* infection may have evidence of lethargy, fever, lameness, reluctance to move, a stiff gait, joint effusion, and pain on joint palpation. Reported neurologic signs include anisocoria, tremors, and a head tilt.[65]

Diagnosis

Laboratory Abnormalities

Common laboratory findings in dogs with *E. ewingii* infection are nonregenerative anemia and thrombocytopenia.[65,72] Reactive lymphocytosis can also occur.[65] The biochemistry panel may be unremarkable or show mild nonspecific abnormalities. Synovial fluid analysis reveals neutrophilic polyarthritis. Morulae may be detected within granulocytes in the peripheral blood or synovial fluid, but are indistinguishable from those of *A. phagocytophilum*. Nevertheless, the finding of morulae in granulocytes in *E. ewingii* endemic areas and where *A. phagocytophilum* infection is uncommon or absent is strongly suggestive of *E. ewingii* infection. In experimental infections, morulae are visible in the peripheral blood of some dogs before the onset of clinical signs, around 2 to 3 weeks postinfection.[71]

Microbiologic Tests

Serologic Diagnosis

Serologic diagnosis of *E. ewingii* infection is currently limited to a point-of-care ELISA assay that detects the presence of antibodies to a specific peptide of *E. ewingii* (SNAP 4Dx Plus, IDEXX Laboratories, Westbrook, ME). Because this peptide is combined on a spot with a peptide that detects antibodies to *E. canis*, the antibody response to these pathogens cannot be distinguished from one another. Cross-reactions may also occur to other ehrlichial species such as *E. chaffeensis*. Antibodies appear approximately 1 month after infection.[71] Dogs with acute illness may initially test negative with this assay, and positive test results may reflect the presence of antibodies from previous exposure or subclinical infection. A change from a negative to a positive result over a 2- to 4-week time period may help support a diagnosis of *E. ewingii* infection in endemic areas.

Molecular Diagnosis Using the Polymerase Chain Reaction

Whole-blood PCR assays are available for specific diagnosis of *E. ewingii* infection through some veterinary diagnostic laboratories. The sensitivity of these assays may vary between laboratories. Currently *E. ewingii*–specific PCR assays are the only means to confirm active infection with *E. ewingii* (as opposed to infection with *A. phagocytophilum* or other *Ehrlichia* species). In experimental studies, PCR becomes positive as early as 4 days after inoculation.[71]

Treatment and Prognosis

Antimicrobial Treatment

For *E. ewingii* infection, treatment with doxycycline results in rapid (within 24 to 48 hours) clinical improvement. Treatment for 2 to 4 weeks may be sufficient to eliminate infection. Subclinically infected dogs that test positive with whole-blood PCR assays may spontaneously clear infection within weeks to months. Treatment may not be required for these dogs.

Prevention

Prevention of *E. ewingii* infection involves avoidance of tick exposure and use of tick preventatives (see previously). Early tick removal also has the potential to reduce transmission. Potential blood donor dogs could be screened for infection with *E. ewingii*–specific ELISA and PCR assays. PCR assays alone (i.e., without serology) should not be used to screen blood donors.

Public Health Aspects

Human infection with *E. ewingii* has been rarely described in endemic regions of the United States.[73] Affected people have had headache, fever, and thrombocytopenia, with or without leukopenia, and responded to doxycycline treatment. Most were receiving immunosuppressive drug therapy. Although direct dog-to-human transmission does not occur, blood from affected dogs should be handled with caution.

Ehrlichia chaffeensis Infection

Ehrlichia chaffeensis causes human monocytic ehrlichiosis in North America, an emerging disease that is characterized in human patients by fever, headache, myalgia, thrombocytopenia and leukopenia, and elevations in hepatic transaminases.[74] Gastrointestinal signs, neurologic involvement, and a toxic shock–like syndrome also occur in some infected people. In the United States, it occurs primarily in the south-central, southeastern, and mid-Atlantic states, which reflects the distribution of *A. americanum* and the concurrent presence of white-tailed deer, which are reservoirs for the organism (as for *E. ewingii*). Evidence of *E. chaffeensis* DNA has also been found in humans, dogs, other animal species (including cats[18]), and ticks in Africa, Israel, Central and South America, and Asia. The organism is transmitted transstadially within the tick,[75] which feeds aggressively on humans. In naturally infected dogs, *E. chaffeensis* infection has been associated with clinical signs of lymphadenopathy, anterior uveitis, and epistaxis,[76] but the clinical implications of this infection for dogs are still unclear. Dogs maintain high antibody titers and are PCR positive for months after infection, which supports a possible role of the dog as a reservoir.[77]

Ehrlichia muris-like Infection

Ehrlichia muris was first described in a wild mouse from Japan in the mid-1990s[78,79] and *E. muris* DNA was detected in a febrile person in Russia for the first time in 2008.[80] In 2009, the DNA with strong homology to that of *Ehrlichia muris* was detected in four humans from Minnesota and Wisconsin.[80] These individuals had clinical signs and laboratory abnormalities that resembled those of granulocytic anaplasmosis (see Chapter 29), were seronegative to *A. phagocytophilum*, and showed variable seroreactivity to *E. chaffeensis*. Two of the individuals were solid-organ transplant recipients and the other two people were apparently immunocompetent. Morulae were not seen, but in mice *E. muris* forms morulae in monocytes.[78] In 2012, DNA with homology to *E. muris* was detected in an

ill dog from northern Minnesota that was seronegative for *E. canis* and seroreactive to *A. phagocytophilum*,[4] although the extent to which this organism contributed to the dog's clinical signs was unclear. Because of the geographic distribution of infection, *Ixodes scapularis* is the suspected tick vector (see Chapter 29). *E. muris* DNA has been detected in *I. scapularis* ticks from northern Wisconsin.[81] The extent to which *E. muris* causes disease in dogs and humans in the United States and other countries requires further investigation but it should be considered as a possible cause of unexplained febrile illness in dogs, whether or not they have evidence of antibodies to *E. canis*.

VetBooks.ir

CASE EXAMPLE

Signalment: "Ditto" a 13-year old male neutered border collie mix from Dixon, CA

History: Ditto was brought to the University of California, Davis, because of a 4-day history of lethargy and inappetence. Ditto had been drinking and there was no vomiting or diarrhea. There was no history of exposure to ticks, toxins, or trauma. Ditto was mainly confined to the backyard and did not have access to standing water. The dog had been adopted in Guam and brought to the United States several years ago. There was no other significant travel history. Ditto's diet consisted of a commercial senior dry dog food.

Current Medications: Prednisolone (0.45 mg/kg PO q48h) for allergic skin disease; this had been administered over the preceding 10 days.

Physical Examination:

Body Weight: 22.3 kg

General: Quiet, reluctant to stand. T = 102.2°F (39.0°C), HR = 152 beats/min, panting, mucous membranes pale pink, CRT <2 s. Approximately 5% to 7% dehydrated.

Integument: A sparse hair coat was present; there were no other clinically significant abnormalities. No ectoparasites were noted.

Eyes, Ears, Nose, and Throat: Severe dental calculus was present.

Musculoskeletal: Body condition score was 6/9. The dog would stand but was reluctant to walk.

Cardiovascular and Respiratory Systems: No clinically significant findings were present.

Gastrointestinal and Urogenital Systems: Cranial organomegaly was noted on abdominal palpation. Rectal examination revealed no significant abnormalities.

Lymph Nodes: All peripheral lymph nodes were normal sized.

Laboratory Findings:

CBC:

HCT 28.0% (40%-55%)
MCV 72.4 fL (65-75 fL)
MCHC 30.4 g/dL (33-36 g/dL)
Reticulocyte count 7600 cells/µL (7000-65,000 cells/µL)
Nucleated RBC 1/100 WBC
WBC 19,600 cells/µL (6000-13,000 cells/µL)
Neutrophils 15,876 cells/µL (3000-10,500 cells/µL)
Lymphocytes 392 cells/µL (1000-4000 cells/µL)
Monocytes 1568 cells/µL (150-1200 cells/µL)
Eosinophils 392 cells/µL (0-1500 cells/µL)
Basophils 392 cells/µL (0-50 cells/µL)
Platelets 127,000 platelets/µL (150,000-400,000 platelets/µL)
MPV 20.5 fL (7-13 fL).

Serum Chemistry Profile:

Sodium 141 mmol/L (145-154 mmol/L)
Potassium 4.2 mmol/L (3.6-5.3 mmol/L)
Chloride 105 mmol/L (108-118 mmol/L)
Bicarbonate 18 mmol/L (16-26 mmol/L)
Phosphorus 6.1 mg/dL (3.0-6.2 mg/dL)
Calcium 8.6 mg/dL (9.7-11.5 mg/dl)
BUN 55 mg/dL (5-21 mg/dL)
Creatinine 1.9 mg/dL (0.3-1.2 mg/dL)
Glucose 66 mg/dL (64-123 mg/dL)
Total protein 6.1 g/dL (5.4-7.6 g/dL)
Albumin 2.2 g/dL (3.0-4.4 g/dL)
Globulin 3.9 g/dL (1.8-3.9 g/dL)
ALT 49 U/L (19-67 U/L)
AST 153 U/L (19-42 U/L)
ALP 98 U/L (21-170 U/L)
Creatine kinase 341 U/L (51-399 U/L)
Gamma GT 4 U/L (0-6 U/L)
Cholesterol 282 mg/dL (135-361 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.2 mg/dL)
Magnesium 2.6 mg/dL (1.5-2.6 mg/dL).

Urinalysis: SGr 1.018; pH 7.0, protein 75 mg/dL, no bilirubin, no glucose, hemoprotein 25 erythrocytes/µL, 0-2 WBC/HPF, 0-2 RBC/HPF, rare granular casts

Urine Protein: Creatinine Ratio: 19.3 (reference range, <1)

Plasma Antithrombin: 64% (reference range, 80%-120%)

Imaging Findings:

Thoracic Radiographs: The right cranial mainstem bronchus was slightly widened throughout its visible length and bronchiectasis was suspected. The cardiovascular and remaining pulmonary structures were within normal limits for the age of the patient.

Abdominal Radiographs: An ill-defined soft tissue structure was present that displaced the caudal border of the stomach cranially. The cecum was not well visualized. The liver extended past the costochondral arches with mildly rounded borders, which was interpreted as mild hepatomegaly. The soft tissue structure was thought to represent an enlarged lymph node, pancreas, or spleen.

Abdominal Ultrasound: The liver had normal parenchymal architecture. The gallbladder contained hyperechoic sludge. The spleen was enlarged with rounded edges and a heterogenous, more hypoechoic parenchyma. Both kidneys showed a somewhat thickened cortex with a good distinction between cortex and medulla. The left renal pelvis was mildly dilated, and the papilla was blunted. There were several cystic lesions within the abdomen that measured up to 3.6 cm × 5.4 cm. Septa were visualized within the cystic lesions. The cystic lesions appeared to arise from lymph nodes.

Cytologic Findings: Cytology of ultrasound-guided lymph node aspirate: There was a moderate amorphous basophilic proteinaceous background with low numbers of nucleated cells and erythrocytes. Nucleated cells were composed primarily of a mixed lymphocyte population with lower numbers of macrophages and nondegenerate. neutrophils.

VetBooks.ir

Microbiologic Testing: 4Dx SNAP test serology (IDEXX Laboratories, ME): Positive for antibodies to *Ehrlichia canis*. Weakly positive for antibodies to *Anaplasma* species. Negative for antibodies to *Borrelia burgdorferi* and antigen of *Dirofilaria immitis*.

Vector-borne disease serology (IFA): Positive for antibodies to *Ehrlichia canis* at 1:163,840 and *Anaplasma phagocytophilum* at 1:2560. Negative for antibody to *Rickettsia rickettsii* at <1:40.

Vector-borne real-time PCR panel (whole blood): Positive for *Ehrlichia canis* DNA. Negative for *Anaplasma phagocytophilum, Anaplasma platys, Bartonella* spp., *Rickettsia* spp., and *Borrelia burgdorferi* DNA.

Diagnosis: Canine monocytic ehrlichiosis, characterized by thrombocytopenia, abdominal lymphadenopathy, and protein-losing nephropathy.

Treatment: Ditto was initially treated with IV crystalloids (lactated Ringer's solution supplemented with 20 mEq/L KCl), famotidine (0.5 mg/kg IV q12h), and ampicillin (20 mg/kg IV q8h). The hematocrit dropped to 18%, and 1 unit of packed RBC was administered, which was followed by a transfusion reaction, characterized by hemoglobinuria, vomiting, and icterus. Systolic blood pressure remained within normal limits throughout hospitalization. When the results of serology for *E. canis* were obtained, antimicrobial drug treatment was changed to doxycycline (5 mg/kg PO q12h). Enalapril (0.25 mg/kg PO q24h) and aspirin (0.5 mg/kg PO q24h) were used to manage the protein-losing nephropathy. Two days after initiation of doxycycline treatment, the dog's attitude and appetite improved. At discharge (day 9 of hospitalization), the hematocrit was 26.6%, reticulocytes 150,000 cells/μL, platelet count 496,000/μL, BUN 31 mg/dL, creatinine 1.5 mg/dL, albumin 1.8 g/dL, globulin 5 g/dL, and urine protein:creatinine ratio was 4. At a recheck examination 1 week after discharge, the hematocrit was stable, the platelet count was 635,000 platelets/μL, BUN 41 mg/dL, creatinine 1.3 mg/dL, and albumin 2.2 mg/dL. A kidney biopsy was not performed. Ditto was subsequently managed for protein-losing nephropathy with enalapril and a reduced protein diet for nearly 2 years, at which time hematocrit was 38.9%, platelet count 561,000 platelets/μL, BUN 27, creatinine 1.2 mg/dL, albumin 3.2 g/dL, globulin 3.6 g/dL, and the urine protein:creatinine ratio was 1.6. The spleen had returned to a sonographically normal appearance, and the cystic lymph nodes were markedly reduced in size. Additional serology or follow-up PCR was not performed. He was subsequently lost to follow-up.

Comments: In this dog, active infection with *E. canis* was confirmed through the use of whole-blood PCR assay. Where the dog became infected with *E. canis* was unclear, but infection was most likely acquired many years earlier in Guam, where ticks are abundant and *R. sanguineus* and *E. canis* are present. It is also unclear whether the glucocorticoid treatment played any role in reactivation of chronic infection. The improvement in hematologic and biochemical parameters in association with doxycycline treatment supported a role for *E. canis* in the disease. Hyperglobulinemia may have been initially masked by renal protein loss. In this case, treatment was continued for several months at the owner's request while laboratory parameters and ultrasound findings showed signs of progressive improvement. The seropositivity to *A. phagocytophilum* may have reflected previous exposure to this organism, *Anaplasma platys,* or serologic cross-reactivity between antibodies to *E. canis* and the *A. phagocytophilum* antigen used in the test kit.

CHAPTER 29

Anaplasmosis

Jane E. Sykes and Janet E. Foley

VetBooks.ir

Overview of Anaplasmosis

First Described: First reports of *Anaplasma phagocytophilum* came from sheep in 1951 (Scotland).[1] Canine infection was first reported in the United States (California) in 1982.[2] *Anaplasma platys* was first reported in the United States (Florida) in 1978.[3]

Cause: *Anaplasma phagocytophilum* (granulocytic anaplasmosis), *Anaplasma platys* (thrombocytotropic anaplasmosis)

Affected Hosts: *A. phagocytophilum* causes disease in dogs, cats, humans, ruminants (European strains), horses, and camelids. *A. platys* causes thrombocytopenia in dogs.

Geographic Distribution: In the United States, *A. phagocytophilum* is most prevalent in the upper Midwest, northeast and western states. Infection also occurs throughout continental Europe and the United Kingdom, Asia, and Russia. The organism has been detected in dogs from Africa and South America. *A. platys* occurs throughout the Americas, Europe, Asia, Australia, the Middle East, and Africa.

Mode of Transmission: Tick vectors, primarily *Ixodes ricinus-persulcatus* complex ticks transmit *A. phagocytophilum*. Although unconfirmed, *Rhipicephalus sanguineus* is suspected to be the major vector of *A. platys.*

Major Clinical Signs: The major clinical signs of *A. phagocytophilum* infection are fever, lethargy, inappetence, and lameness due to polyarthritis, although vomiting, diarrhea, cough, and neck pain may occur. *A. platys* usually causes no signs, but fever and lethargy are possible.

Differential Diagnoses: Major differential diagnoses include other tick-borne diseases (such as the ehrlichioses, rickettsioses, Lyme borreliosis and babesiosis), bartonellosis, leptospirosis, primary immune-mediated disease, and lymphoma.

Human Health Significance: *A. phagocytophilum* causes human granulocytic anaplasmosis. Dogs act as a sentinel for human infection and may carry unfed ticks to humans on their coats.

Canine anaplasmosis is caused by *Anaplasma phagocytophilum* (formerly *Ehrlichia equi*, *Ehrlichia phagocytophila*, and, in humans, the human granulocytic ehrlichiosis [HGE] agent) and *Anaplasma platys*. These are tick-borne, gram-negative, obligately intracellular bacteria that belong to the family Anaplasmataceae. *A. phagocytophilum* predominantly infects neutrophils but also eosinophils, where it forms host membrane-enclosed morulae. Ticks that belong to the *Ixodes ricinus-persulcatus* complex are the major vectors for *A. phagocytophilum*. *Anaplasma platys* forms morulae within platelets. The vector of *A. platys* is probably *Rhipicephalus sanguineus*. As with the ehrlichioses, co-infections with other pathogens that are transmitted by the same or other tick species may occur and influence the clinical manifestations of disease.

Anaplasma phagocytophilum Infection

Etiology and Epidemiology

A. phagocytophilum causes granulocytic anaplasmosis in dogs, humans, horses, and, in Europe, domestic ruminants that include sheep, cattle, goats, and deer. Cats and camelids may also be affected. A variety of wild animal species, which include rodents and deer, act as reservoir hosts. For the midwestern and eastern United States, white-footed mice *(Peromyscus leucopus)* and eastern chipmunks may act as reservoirs, whereas in the western states, dusky-footed woodrats, gray squirrels, and chipmunks have been implicated. In Europe, bank voles, wood mice, shrews, and deer are likely reservoirs. Many strains of *A. phagocytophilum* exist that differ in pathogenicity and host tropism. For example, strains that infect domestic ruminants in Europe and white-tailed deer in the United States appear to be distinct from those that infect horses, humans, and dogs. Dogs, cats, and humans are accidental hosts and are not important in the transmission of infection to other host species.

The geographic distribution of the disease follows that of the tick vectors (Figure 29-1). In North America, the tick vectors of *A. phagocytophilum* are *Ixodes scapularis* in the northeastern and upper midwestern states, and *Ixodes pacificus* in the West. In Europe, the primary vector is *Ixodes ricinus*, and the disease has been described in dogs throughout continental Europe and in the UK. *Ixodes persulcatus* and *Dermacentor silvarum* ticks transmit the organism in Asia and Russia. Other *Ixodes* spp. ticks have also been implicated in transmission. Evidence of *A. phagocytophilum* infection has been found in dogs from Brazil and Tunisia, and a closely related organism was found in dogs from South Africa.[4-6] In humans, rare reports exist of direct transmission that followed close contact with blood or respiratory secretions, transplacental spread, or transmission through blood transfusion.

Many seroprevalence studies of dogs have been reported worldwide.[7] The seroprevalence varies with geographic location and whether the dogs studied were sick or healthy. The prevalence of positive antibody titers in dogs from some regions of Europe and North America exceeds 50%. A study that used a commercially available ELISA assay to determine the prevalence

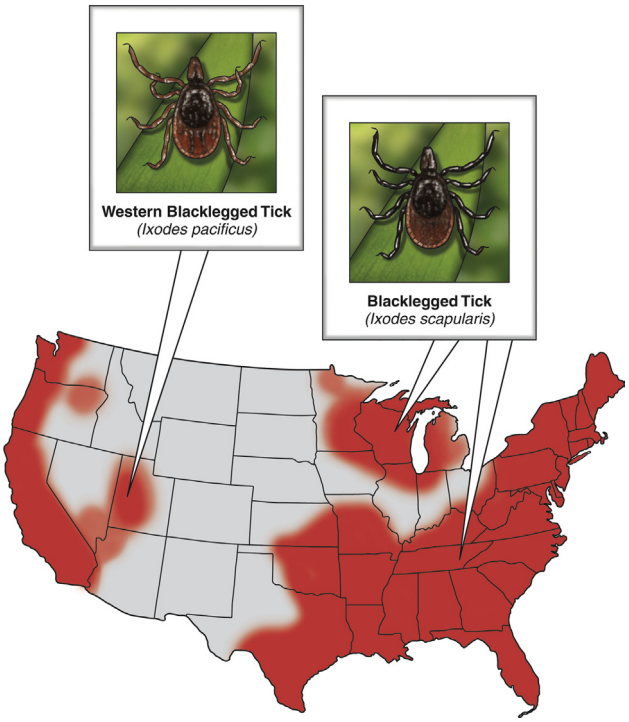

FIGURE 29-1 Distribution of *Ixodes scapularis* and *Ixodes pacificus*, the vectors of *Anaplasma phagocytophilum*, in the United States. The distribution of granulocytic anaplasmosis follows that of the tick vectors.

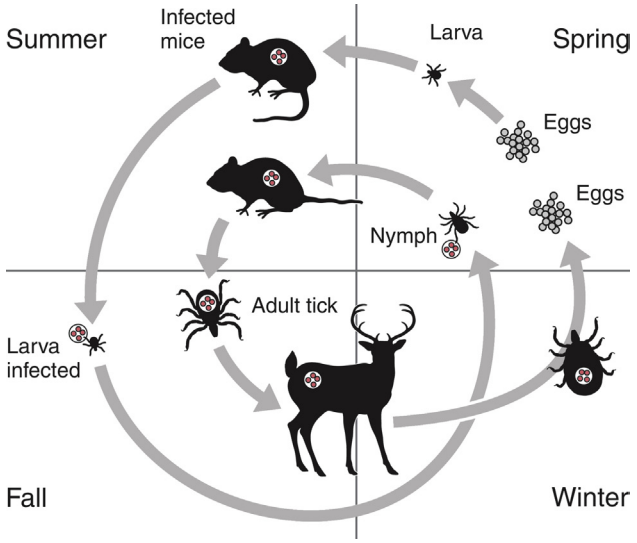

FIGURE 29-2 Life cycle of *Ixodes scapularis* ticks and *Anaplasma phagocytophilum* infection. Uninfected larvae (top right) hatch in the late spring and acquire infection from small rodents in the summer. They then over-winter (often in protected mouse burrows) and then molt into nymphs the following spring. The nymphs feed in the late spring or early summer on a variety of animal species including rodents, humans, deer, and dogs. Nymphs molt into adults in the late summer to fall, which subsequently feed on large mammals such as deer, where they mate and drop off. The females then lay eggs and die. Dogs, cats and humans become infected by nymphs or adult ticks.

of seroreactivity to *A. phagocytophilum* in more than 400,000 dogs from the United States revealed wide variation in seroprevalences. Some counties in the upper Midwest and northeastern United States had seroprevalences that exceeded 40%, although the overall seroprevalence in these regions were 6.7% and 5.5%, respectively.[8] Serologic cross-reactivity with *A. platys* may also influence these data.

The seasonal pattern of disease reflects times of peak nymphal and adult tick activities, as well as periods when humans and their dogs are active outdoors. In the western United States, *A. phagocytophilum* infection occurs most frequently in dogs between April and July, when nymphal ticks are abundant. Some infections occur in October, during early questing of adult ticks. In Minnesota and Wisconsin, most cases are diagnosed in late spring (May, June) and fall (October, November).[9-11] In a study from Berlin, most cases occurred between April and September.[12] The median age of clinically affected dogs is 6 to 8 years (range, 6 months to 14 years).[9,10,12-14] In the upper Midwest of the United States, a bimodal age distribution has been recognized, with 25% of dogs 1 year of age or less, and 50% of dogs at least 8 years of age.[10] Affected cats in the northeastern United States have ranged from 4 months to 13 years of age (mean, 3.7 years).[15] Although no breed predispositions are recognized, in one study, golden retrievers comprised almost half of affected dogs; this may reflect the popularity of these dogs for outdoor activities.[14] Infection with other tick-borne pathogens is a risk factor for *A. phagocytophilum* infection. Co-infection with *Borrelia burgdorferi,* the cause of Lyme disease, is common because *B. burgdorferi* is transmitted by the same *Ixodes* tick species.[8,10,11] In northern California, dogs seroreacted to *A. phagocytophilum* were 18 times more likely to be seropositive for *Bartonella vinsonii* subspecies *berkhoffii* than dogs that were seronegative.[16]

Clinical Features

Signs and Their Pathogenesis

A. phagocytophilum is transmitted transstadially within the tick (i.e., from larva to nymph to adult), and not transovarially (from adult to egg). Dogs and cats thus become infected after exposure to infected nymphs or adult ticks, which acquire infection when they feed on wild animal reservoir hosts as larvae or nymphs (Figure 29-2). Ticks must attach for 36 to 48 hours for transmission to occur. Once *A. phagocytophilum* enters the bloodstream, it attaches to the sialylated ligands on the surface of neutrophils, such as P-selectin glycoprotein ligand-1.[7] The organism then enters the neutrophil through caveolae-mediated endocytosis. *A. phagocytophilum* survives in the harsh neutrophil environment through dysregulation of neutrophil function and by bypassing phagolysosomal pathways. It inhibits neutrophil superoxide production and can reduce neutrophil motility and phagocytosis. *A. phagocytophilum* also reduces neutrophil adherence to endothelium and inhibits neutrophil transmigration into tissues, possibly through downregulation of selectin molecule expression.[7] This may promote its survival in peripheral blood.

Normally, neutrophils circulate for 10 to 12 hours before they enter tissues and undergo death through apoptosis. *A. phagocytophilum* delays neutrophil apoptosis, which allows it to survive longer periods of time within the neutrophil.[7] *A. phagocytophilum* may also infect other cell types, such as bone marrow cells, endothelial cells, and megakaryocytes, although the importance of these cells in the pathogenesis of infection is not clear.

The clinical signs and laboratory abnormalities that occur in dogs and cats with granulocytic anaplasmosis probably vary somewhat in different geographic locations as a result of local strain variation. The vast majority of dogs infected with

A. phagocytophilum show no clinical signs. Some dogs and cats develop a self-limiting febrile illness, which in dogs occurs after an incubation period of 1 to 2 weeks. Lethargy occurs in almost all clinically affected cats and dogs. Fever and inappetence are also common findings. Lameness, reluctance to move, polydipsia, vomiting, diarrhea, and a soft cough can also occur. Generalized lymphadenopathy and splenomegaly develop as a result of reactive lymphoid hyperplasia and, in the spleen, concurrent extramedullary hematopoiesis.[17] Uncommonly, hemorrhage, manifested as mucosal petechiae, melena, or epistaxis, has been reported in naturally infected dogs, but co-infections with other tick-borne pathogens may contribute to these signs in some dogs.[9,12,13,18] Neurologic signs such as seizures, circling, cervical pain, and decreased placing reactions have been described in a few dogs from the upper Midwest with granulocytic anaplasmosis, but one dog with seizures had a history of idiopathic epilepsy.[9,18] Neurologic signs and detection of the organism in the CSF have been uncommonly reported in humans.[19]

Infection with *A. phagocytophilum* results in mild to moderate thrombocytopenia, although other cytopenias may also occur (Table 29-1). The mechanism(s) of these hematologic abnormalities remain unclear. Anti-platelet antibodies occur in serum from humans and dogs with granulocytic anaplasmosis,[12,20] and so immune-mediated mechanisms may contribute to thrombocytopenia. However, thrombocytopenia occurs in acute disease, before antibodies are noted, so other mechanisms may be important. The bone marrow of infected dogs shows megakaryocyte hyperplasia, so platelet destruction may be involved.[21]

Impaired neutrophil function as a result of *A. phagocytophilum* infection may predispose to development of secondary opportunistic infections or influence the outcome of co-infections with other tick-borne pathogens such as *B. burgdorferi*. Although uncommon, opportunistic infections have been occasionally documented in humans and dogs with granulocytic anaplasmosis and are well in small ruminants.[22]

Infection with *A. phagocytophilum* may be self-limiting in dogs and cats, with minimal fatality or chronic disease manifestations. The extent to which *A. phagocytophilum* can persist in tissues and contribute to chronic disease manifestations in humans and dogs has been controversial, and may be dependent on the infecting strain and host immune response to infection. In one study, treatment of dogs that had been experimentally inoculated with *A. phagocytophilum* with prednisolone up to 6 months after infection was followed by the development of positive PCR results for the organism and, in some dogs, thrombocytopenia and reappearance of morulae on blood smears.[23] One dog infected with a California strain of *A. phagocytophilum* was persistently PCR-positive through day 60 postinfection, the last time point evaluated.[23]

Physical Examination Findings

The most common findings on physical examination in dogs include lethargy, fever (up to 106.7°F [41.5°C]), dehydration, tachypnea, mild peripheral lymphadenopathy, and splenomegaly.[7,10] Scleral injection may be noted. Lameness, reluctance to move, swollen joints, and pain on joint manipulation may also be detected in some dogs. Increased lung sounds, abdominal pain, epistaxis, petechial hemorrhages, and neurologic signs such as circling, cervical pain, and decreased placing reactions occur uncommonly.

Physical examination findings reported in cats have been similar to those described in dogs, and include fever, lethargy, tachypnea, increased lung sounds, mild abdominal pain, hepatomegaly, splenomegaly, vomiting, ataxia, hyperesthesia, muscle and joint pain, lameness, conjunctivitis, and ocular discharge.[15,24,25]

Diagnosis

Granulocytic anaplasmosis should be suspected in dogs and cats with acute febrile illness and thrombocytopenia that reside in endemic areas, regardless of tick exposure history. Diagnosis relies on detection of morulae within granulocytes, results of acute and convalescent serology, or molecular testing using PCR assays. The diagnostic criteria for confirmed human granulocytic anaplasmosis are clinical signs and laboratory findings suggestive of granulocytic anaplasmosis together with (1) detection of morulae within neutrophils combined with a single positive reciprocal antibody titer to *A. phagocytophilum* of at least 80; (2) a fourfold increase or decrease in the antibody

TABLE 29-1

Hematologic Abnormalities in Nine Dogs with Granulocytic Anaplasmosis in Northern California*

Test	Reference Range	Number below the Reference Range	Number within the Reference Range	Number above the Reference Range	Range for dogs with Granulocytic Anaplasmosis
Hematocrit (%)	40-55	6	3	0	19-45
Neutrophils (cells/μL)	3000-10,500	0	6	3	3513-18,592
Band neutrophils (cells/μL)	Rare	0	1	8	0-1282
Monocytes (cells/μL)	150-1200	1	7	1	142-1346
Lymphocytes (cells/μL)	1,000-4000	7	2	0	71-2693
Eosinophils (cells/μL)	0-1500	0	9	0	0-328
Platelets (cells/μL)†	150,000-400,000	6	2	0	37,000-262,000

*Diagnosis was based on compatible clinical signs and either morulae within circulating neutrophils and/or a positive real-time PCR assay result for *A. phagocytophilum*.

†Platelets were clumped for one dog.

titer within 4 weeks; (3) a positive PCR test result using specific *A. phagocytophilum* primers; or (4) isolation of *A. phagocytophilum* from blood.[22] These criteria could also be applied to dogs. The use of multiple diagnostic modalities may be needed to confirm the diagnosis of granulocytic anaplasmosis in some dogs.

Laboratory Abnormalities

Complete Blood Count

Thrombocytopenia occurs in approximately 90% of dogs with granulocytic anaplasmosis.[9,10,12,13] The platelet count in thrombocytopenic dogs may occasionally be as low as 5000 platelets/μL, although more often it is mild to moderately decreased (see Table 29-1).[9,10,12-14] The majority of affected dogs are lymphopenic, but lymphocytosis can occur.[9,12,13] Circulating reactive lymphocytes may be present. Anemia is common and typically mild and nonregenerative. Both neutrophilia and neutropenia occur, but most dogs have neutrophil counts that lie in the lower half of the reference range. Low numbers of band neutrophils, as well as mild neutrophil toxicity, are often present. Monocytopenia or monocytosis can occur.[9,12,13] Cytologic examination of blood smears often reveals morulae within granulocytes (Figure 29-3). Morulae were detected in neutrophils from 36%, 56%, 67%, and 100% of dogs in four respective case series.[9,12-14] Morulae appear as early as 4 days after experimental inoculation of dogs and persist for 4 to 8 days.[17] The morulae are indistinguishable from those of *Ehrlichia ewingii*, so serology or PCR assays are needed to confirm *A. phagocytophilum* infection.

In contrast to dogs, thrombocytopenia appears uncommon in cats infected with *A. phagocytophilum*. None of 15 sick, PCR-positive cats from the northeastern United States were thrombocytopenic.[15] The most common hematologic abnormality in cats has been lymphopenia. Morulae have been detected in some cats with granulocytic anaplasmosis.

Serum Biochemical Tests

The most frequent serum biochemistry finding in dogs with granulocytic anaplasmosis is mild to moderate hypoalbuminemia (Table 29-2). Mild hyperglobulinemia, mild electrolyte abnormalities (hypokalemia, hyponatremia, and metabolic acidosis), and a mild increase in the activities of serum ALP and to a lesser extent ALT may occur.[9,10,13,14]

Urinalysis

Urinalysis in dogs with granulocytic anaplasmosis may reveal isosthenuria, hyposthenuria, and proteinuria. Urine protein-to-creatinine ratios in two affected dogs from the United States were

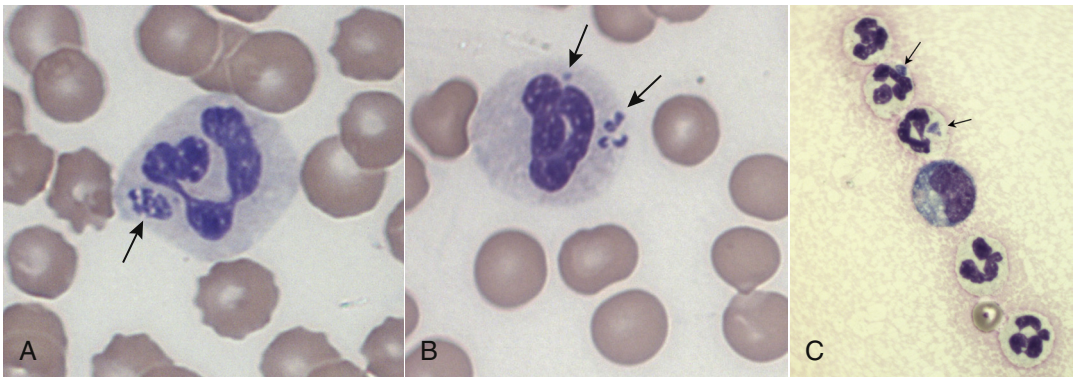

FIGURE 29-3 Intracytoplasmic morula **(A)** and cocci **(B)** of *Anaplasma phagocytophilum (arrows)* within neutrophils of an 8-year-old male neutered golden retriever with granulocytic anaplasmosis; in **(C)**, morulae are present in neutrophils within the synovial fluid of a 5-year-old curly-coated retriever that had polyarthritis.

TABLE 29-2

Findings on Serum Biochemistry Analysis in Nine Dogs with Granulocytic Anaplasmosis in Northern California*

Test	Reference Range	Number below the Reference Range	Number within the Reference Range	Number above the Reference Range	Range for dogs with Granulocytic Anaplasmosis
Sodium (mmol/L)	145-154	4	5	0	142-147
Potassium (mmol/L)	4.1-5.3	2	7	0	3.3-4.9
Bicarbonate (mmol/L)	16-26	3	6	0	11-18
Albumin (g/dL)	2.9-4.2	6	3	0	1.5-3.4
Globulin (g/dL)	2.3-4.4	0	8	1	2.7-6.0
Total bilirubin (mg/dL)	0-0.4	0	8	1	0-1.0
Alanine aminotransferase (U/L)	19-70	0	8	1	26-122
Alkaline phosphatase (U/L)	15-127	0	7	2	26-653

*Diagnosis was based on compatible clinical signs and either morulae within circulating neutrophils and/or a positive real-time PCR assay result for *A. phagocytophilum*.

VetBooks.ir

1.5 and 2.2,[10] but there is no evidence that *A. phagocytophilum* infection causes severe glomerulonephritis in dogs.

Synovial Fluid Analysis

Dogs with granulocytic anaplasmosis can develop neutrophilic polyarthritis. Cytologic examination of synovial fluid in these dogs reveals increased numbers of nondegenerate neutrophils. In some affected dogs, morulae are found within these cells and the synovial fluid can be PCR positive (Figure 29-3,*C*).

Diagnostic Imaging

Plain Radiography

Thoracic radiographs are usually normal in dogs with granulocytic anaplasmosis but may show a mild interstitial infiltrate. Focal alveolar infiltrates occur as well.[26]

Sonographic Findings

Abdominal ultrasound may reveal splenomegaly, with a hypoechoic spleen, or mild abdominal lymphadenopathy.

Microbiologic Tests

Diagnostic assays available for anaplasmosis in dogs and cats are shown in Table 29-3.

Serologic Diagnosis

Diagnosis of granulocytic anaplasmosis can be accomplished with acute and convalescent serology. Many veterinary laboratories perform serologic testing using immunofluorescent antibody (IFA) techniques. IgG antibodies are first detectable approximately 8 days after exposure, 2 to 5 days after morulae appear. As a result, early in the course of illness, antibodies may be undetectable, so PCR assays may be more useful for diagnosis of acute infection in the absence of detectable morulae. Because positive titers can reflect previous exposure, demonstration of a fourfold rise in titer is required. Antibody titers may persist for many months.[14,23] In some human patients, antibody titers have persisted as long as 3 years.[22] In the United States, a silicon disc-based ELISA assay is available commercially for detection of antibodies to *A. phagocytophilum* (Accuplex 4, Antech Diagnostics, Irvine, CA). The performance of this assay when compared with IFA requires further study. An in-clinic lateral-flow ELISA device (IDEXX SNAP 4Dx Plus), which uses a recombinant Msp2/p44 protein, is also available for the detection of antibodies to *Anaplasma* species in dog serum. Positive results obtained with these ELISA assays do not imply that *A. phagocytophilum* is the cause of illness, and as with IFA testing, negative results can occur in dogs with acute illness due to the lag in antibody production relative to the onset of clinical signs.

Serologic cross-reactivity between *Anaplasma* species occurs. Dogs infected with *A. platys* also seroreact to *A. phagocytophilum* antigen; this includes the recombinant Msp2 assay.[8] Serologic cross-reactivity between *A. phagocytophilum* and *E. canis* also occurs, but is relatively uncommon and minor.[13,26,27] Dogs diagnosed with granulocytic anaplasmosis that have antibodies to *A. phagocytophilum* generally lack antibodies to *E. canis* using IFA testing.[7,10]

Molecular Diagnosis Using the Polymerase Chain Reaction

Several conventional and real-time PCR assays for *A. phagocytophilum* exist for detection of *A. phagocytophilum*

TABLE 29-3

Diagnostic Assays Available for Anaplasmosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cell culture	Whole blood	*Anaplasma phagocytophilum*; *Anaplasma platys* cannot be cultured	Not widely offered or utilized for routine diagnostic purposes. Requires several weeks' incubation.
Cytology	Whole blood, buffy coat smears, body fluids, tissue aspirates	*A. phagocytophilum* or *A. platys* morulae	Low sensitivity (especially for *A. platys* infection). Morulae of *A. phagocytophilum* cannot be distinguished from those of *Ehrlichia ewingii*. Morulae may be confused with cytoplasmic granules or stain precipitate.
IFA serology	Serum	Antibodies to *Anaplasma* spp.	Acute and convalescent serology is required for diagnosis of acute infection, because initial results may be negative in dogs with acute disease and positive results may reflect previous exposure rather than active infection. Cross-reactivity occurs between *Anaplasma* spp.
ELISA serology	Serum	Antibodies to *Anaplasma* spp. antigens	Rapid, inexpensive, can be performed as an in-practice test. Similar limitations as IFA. Lack of quantitation limits ability to document seroconversion.
PCR	Whole blood, splenic or lymph node aspirates, bone marrow aspirates, buffy coat specimens, tissue specimens	*A. phagocytophilum* or *A. platys* DNA	Confirms active infection. Sensitivity and specificity may vary depending on assay design and specimen type. Because healthy animals may be PCR positive, positive PCR results must be interpreted in light of the clinical signs.

IFA, Immunofluorescent antibody.

DNA in peripheral blood, buffy coat, bone marrow, or splenic tissue. These can be useful for early diagnosis of granulocytic anaplasmosis in dogs and cats. The sensitivity and specificity of PCR assays may vary depending on the assay design and the laboratory used. Most, but not all, assays detect either the 16S rRNA gene or the outer surface protein gene *msp2* (p44). Assays that detect the *msp2* gene are usually specific for *A. phagocytophilum*, whereas assays that detect the 16S rRNA gene may detect other *Anaplasma* species, and even other bacteria. *A. phagocytophilum* DNA has occasionally been amplified from healthy dogs, so results must be interpreted in light of the clinical signs.[11] In experimentally infected dogs, whole-blood PCR becomes positive several days before and after morulae appear on blood smears.[17,23]

Culture

A. phagocytophilum can be isolated in human promyelocytic leukemia cell lines (HL-60) and tick embryo cell lines. Culture is highly sensitive for diagnosis of acute infection in human patients,[28] but it is not routinely used in dogs for diagnostic purposes because it requires special facilities, technical expertise, and prolonged incubation.

Pathologic Findings

Little information is available regarding the pathology of granulocytic anaplasmosis in dogs. Tissue injury appears to result from the host inflammatory response, rather than the bacterial infection itself.[29] In people, splenic lymphoid depletion, macrophage aggregates and apoptosis within the liver, paracortical lymphoid hyperplasia, and hemophagocytic cells within reticuloendothelial tissues have been described.[30]

Treatment and Prognosis

The treatment of choice for granulocytic anaplasmosis in dogs is doxycycline (5 mg/kg PO q12h). The optimum duration is unknown, but 2 weeks may be sufficient. The prognosis is excellent. Most dogs show clinical improvement within 24 to 48 hours of treatment, although some dogs require more than 1 week of treatment before clinical signs resolve.[10,13] Platelet counts normalize 2 to 14 days after treatment is initiated.[10] In one study, 30% of 23 owners reported that their dog returned to normal activities in 1 to 2 days after treatment was initiated, 30% reported this took 3 to 5 days, 21% 1 to 3 weeks, and 17% reported that it took a month or longer for their dogs to return to normal activity.[10] Death due to granulocytic anaplasmosis has not been described in dogs. Intravenous crystalloid fluids and antiemetics may be required for supportive care until clinical signs improve.

Immunity and Vaccination

The immune response to *A. phagocytophilum* infection is not fully characterized. Both humoral and cell-mediated immune responses appear to be important in clearance of infection. Host cytokines such as IFN-γ may play a role in the initial control of *A. phagocytophilum* infection[31,32] but may also contribute to the inflammatory process associated with disease.[33] In lambs, *A. phagocytophilum* evades the host immune response through differential expression of MSP2, an outer surface protein involved in immune recognition.[34] Variation in MSP2 also occurs in chronically infected woodrats.[35] Further research is required to document whether persistence occurs through similar mechanisms in other host species. It is possible that recovery from natural infection confers long-term protection against development of disease. Reinfection has not been reported in dogs, but was described in one human patient.[36] A vaccine for granulocytic anaplasmosis is not available for companion animals.

Prevention

Infection may be prevented by avoidance of tick exposure, prompt tick removal, and use of topical ectoparasiticides (see Chapter 28). Although not a guaranteed protection, combinations of topical imidacloprid and permethrin, or fipronil, amitraz and (*S*)-methoprene, prevent transmission of *A. phagocytophilum* to dogs from infected ticks.[37,37a]

Public Health Aspects

A. phagocytophilum infection was first recognized in humans in the upper Midwest of the United States in the early 1990s and has since been increasingly recognized in humans from the United States, Europe, and Asia. Human granulocytic anaplasmosis closely resembles the disease in dogs, which has been described as an "influenza-like illness after a tick bite."[38] Men are affected slightly more frequently than women. In Europe, the disease is most commonly reported in from Sweden and Slovenia, where it was first reported in 1997.[39] Morulae are observed less often in humans with granulocytic anaplasmosis in Europe, and the disease may be milder than that described in humans from the United States.

The most common clinical signs reported in human patients are myalgia, headache (which is often severe), malaise, and chills. Anorexia, nausea, arthralgias, and cough may also occur.[22,38,40] The disease typically resolves within 2 months in the absence of appropriate antibiotic treatment. Occasionally more severe disease may occur. In one study, up to 17% of affected humans required admission to an intensive care unit.[38] Death occurs in 1% or fewer clinically affected humans, usually as a result of complications such as a septic or toxic shock–like syndrome, respiratory insufficiency, opportunistic fungal or viral infections, rhabdomyolysis, acute renal failure, hemorrhage, or neurologic disease.[22] Severe illness tends to occur in humans of advanced age or with concurrent immunosuppressive illness or drug therapy. Laboratory testing of peripheral blood typically reveals normal or slightly decreased white blood cell and platelet counts, sometimes with a neutrophilic left shift, and mild to moderate elevation of hepatic transaminase activities. In the United States, the disease is reportable to the Centers for Disease Control and Prevention (CDC). Dogs act as sentinels for human exposure and may be a source of infection through mechanical carriage of infected ticks to humans. Blood from affected dogs should be handled with caution, and needle-stick injuries should be avoided.

Anaplasma platys Infection

Etiologic Agent and Epidemiology

Anaplasma platys infects and forms inclusions within platelets and is the cause of canine cyclic thrombocytopenia, or thrombocytotropic anaplasmosis. It does not appear to infect cats. The organism is very widespread, and infections occur throughout the Americas, Europe, Asia, Australia, the Middle East, and

VetBooks.ir

Africa. *R. sanguineus* ticks are believed to transmit *A. platys*, because the DNA of *A. platys* has frequently been found in *R. sanguineus* ticks worldwide, and dogs infected with *A. platys* are often co-infected with *E. canis*. However, in a single attempt, experimental transmission of *A. platys* by *R. sanguineus* ticks failed.[41] *A. platys* DNA has been found in other tick species, such as *Dermacentor auratus* ticks in Thailand,[42] *Rhipicephalus turanicus* ticks from Israel,[43] and *Haemaphysalis* spp. and *Ixodes nipponensis* ticks from Korea.[44] Different strains of *A. platys* exist that appear to vary in pathogenicity. The organism has never been isolated in cell culture.

Clinical Features

Signs and Their Pathogenesis

Anaplasma platys causes thrombocytopenia in dogs, most often in the absence of other clinical signs, although fever, lethargy, lymphadenopathy, uveitis, pallor, and mucosal hemorrhages have been described.[45,46] Co-infections with other vector-borne pathogens may contribute to clinical signs in some dogs. Thrombocytopenia occurs 1 to 2 weeks after experimental inoculation. This initial episode is associated with the highest number of organisms in platelets, as detected using light microscopic examination of stained blood smears.[47] The platelet count nadir occurs 2 to 3 weeks postinfection and in some dogs may be lower than 20,000 platelets/μL. Visible organisms then disappear from platelets, and the platelet count returns to normal or near-normal limits within 3 to 4 days. This also corresponds with a decrease in organism load and failure to detect the organism in peripheral blood with real-time PCR, although bone marrow and splenic aspirates may remain positive.[48] Cycles of thrombocytopenia and bacteremia then occur at intervals of 7 to 14 days, after which infection and thrombocytopenia persist in some dogs but morulae or inclusions become more difficult to detect within platelets.[47] The mechanism of thrombocytopenia is unknown, but direct damage to platelets, sequestration of platelets in the spleen, and immune-mediated destruction have been hypothesized to play a role.

Co-infection of dogs with *A. platys* and *E. canis* may lead to more severe anemia than occurs with isolated *E. canis* infection.[49] The duration of *A. platys* infection may also be prolonged.

Physical Examination Findings

Most dogs with *A. platys* infection show no clinical signs. Fever, petechial hemorrhages, and uveitis have been reported, but co-infections with other vector-borne pathogens may have contributed to these signs.

Diagnosis

Laboratory Abnormalities

Usually, the only abnormality present on the CBC, biochemistry panel, and urinalysis in dogs with *A. platys* infection is thrombocytopenia. A mild, nonregenerative anemia may be found. The diagnosis can be made when morulae are seen within platelets on blood smears, but this is insensitive, and other inclusions or stain precipitate may be mistaken for organisms.

Microbiologic Tests

Direct Fluorescent Antibody

Direct fluorescent antibody techniques can be used to identify *A. platys* in platelets, but these are not widely available for routine diagnostic purposes. Molecular diagnostic assays have overcome the need for direct fluorescent antibody or immunocytochemical staining.

Serologic Diagnosis

Recent infection with an *Anaplasma* species can be detected through the use of acute and convalescent serology with IFA. Because antibodies to *A. phagocytophilum* bind to *A. platys* antigens it is not possible to distinguish the immune response to each of these pathogens with currently available assays. This can be problematic in geographic regions where both *A. platys* and *A. phagocytophilum* are found. A positive result on commercially available ELISA assays also only indicates previous exposure to an *Anaplasma* species. Dogs with recent infection may be seronegative, because antibodies to *A. platys* are not detectable for 1 to 2 weeks after inoculation. Because a single positive test result only indicates previous exposure, and seroprevalence rates in endemic areas are high, thrombocytopenia in a seropositive dog may be due to an etiology other than *Anaplasma* infection. Cross-reactivity to *E. canis* antigens does not occur in dogs with *A. platys* infections, so positive titers to *E. canis* and *A. platys* may represent previous exposure to both pathogens, or to other *Ehrlichia* or *Anaplasma* species.

Molecular Diagnosis Using the Polymerase Chain Reaction

Several conventional and real-time PCR assays have been described for detection of *A. platys* DNA. In the absence of clearly identifiable morulae within platelets, molecular diagnostic testing with reliable PCR assays that specifically detect *A. platys* DNA (as opposed to *A. phagocytophilum* DNA or *Anaplasma* species DNA) is the only way to confirm active infection. Real-time PCR assays that detect *A. platys* DNA are available commercially and in combination with assays for other vector-borne pathogens. Suitable specimens include whole blood, buffy coats, or bone marrow and splenic aspirates,[48] although it is not clear which of these specimens is optimal. When buffy coats were used, PCR assays for *A. platys* became positive as early 3 to 5 days after experimental infection, but by day 21, negative results occurred in some dogs.[48,49] The use of splenic or bone marrow aspirates may yield positive results when whole blood or buffy coat PCR for *A. platys* is negative yet infection is still suspected.

Pathologic Findings

Pathologic findings have been described in a small number of dogs that were experimentally infected with *A. platys*, and necropsied early in the course of infection.[50] The only gross necropsy finding was generalized lymphadenomegaly. Lesions consisted of reactive lymphoid hyperplasia and erythrophagocytosis by sinusoidal macrophages within lymph nodes and the spleen, crescent-shaped regions of perifollicular hemorrhage in the spleen, mild lymphoplasmacytic infiltrates in the renal interstitium, and multifocal hyperplasia of Kupffer's cells in the liver. Megakaryocyte numbers in the bone marrow were increased in some dogs.

Treatment and Prognosis

The recommended treatment for thrombocytopenic dogs infected with *A. platys* is doxycycline. The optimum dose and duration of treatment is unknown, but it is apparently eliminated using regimens effective for treatment of *E. canis* infection.

Infection could not be detected with PCR for a 3-week follow-up period after just 8 days of doxycycline treatment (10 mg/kg PO q24h), which was initiated in the acute phase of infection.[51] However, one dog remained infected after 2 weeks of treatment with tetracycline. In another study, doxycycline treatment was administered for 28 days, and infection could not be detected after this time point, even after pharmacologic immunosuppression with dexamethasone several months later.[49] Whether the duration of infection at the time of treatment affects treatment efficacy is unknown.

Prevention

See the previous discussion of *Anaplasma phagocytophilum* infection.

Public Health Aspects

Infection with *A. platys* has not been confirmed in humans.

CASE EXAMPLE

Signalment: "Copper," an 8-year old male neutered Labrador retriever from Napa, CA

History: Copper was brought to the University of California, Davis, VMTH emergency service for the problems of lethargy, inappetence, apparent neck pain of 1 week's duration, and fever. The dog had been taken to a local veterinary clinic on the day the illness began, and thrombocytopenia (113,000 platelets/μL) was detected on a CBC. ELISA serology for antibodies to *E. canis*, *B. burgdorferi*, and *A. phagocytophilum* and *Dirofilaria immitis* antigen (4Dx SNAP test, IDEXX Laboratories) was negative. Treatment with enrofloxacin (2.4 mg/kg PO q12h) and metronidazole was instituted, during which time the dog improved clinically, but when the metronidazole was discontinued after 5 days, lethargy, inappetence, and signs of neck pain returned 2 days later. A CBC at that time showed no clinically significant abnormalities. Treatment with enrofloxacin was continued, and methocarbamol (11.6 mg/kg PO q8h) and meloxicam (0.1 mg/kg PO q24h) were instituted for the neck pain. The owner took Copper's rectal temperature at home on the morning he was brought to the VMTH, and it was 105.6°F (40.9°C). Copper lived on a 20-acre winery with a reservoir and had access to wildlife and frequent tick exposure. There had been no known exposure to toxins and no travel history. The dog received monthly heartworm preventative, and flea and tick preventative was used, but only when the owner found ticks. He was normally fed a commercially available dry dog food.

Current Medications: Enrofloxacin (2.4 mg/kg PO q12h), methocarbamol (11.6 mg/kg PO q8h), and meloxicam (0.1 mg/kg PO q24h).

Other Medical History: Nine months previously, Copper was seen by the local veterinary clinic for neck pain. The dog was treated with methocarbamol, a nonsteroidal antiinflammatory drug, and rest, and the pain resolved after 7 days. The owners also reported that Copper had exhibited some weakness of his left pelvic limb for several years.

Physical Examination:

Body weight: 43.1 kg

General: Quiet, alert, responsive, adequately hydrated. T = 103.7°F (39.8°C), HR = 110 beats/min, panting, mucous membranes pink, CRT <2 s.

Integument: No clinically significant abnormalities were identified. No ectoparasites were noted.

Eyes, Ears, Nose, and Throat: Mild gingivitis and dental calculus were present. No other significant abnormalities were noted.

Musculoskeletal: Body condition score 4/9. The dog was ambulatory but had a slightly stiff thoracic limb gait. A decreased range of motion of coxofemoral joints was detected, with the left worst than the right. There was no evidence of joint pain or effusion.

Cardiovascular, Respiratory Systems, Gastrointestinal and Urogenital Systems: No clinically significant findings were identified. Rectal examination revealed no significant abnormalities.

Lymph Nodes: All peripheral lymph nodes were normal sized but slightly firm on palpation.

Neurologic Examination: Mentation and cranial nerve function were within normal limits. The dog was reluctant to move his neck on manipulation, especially to the right side, and palpation of the cervical spine elicited pain. Decreased placing reactions were noted in the left pelvic limb.

Laboratory Findings:

CBC:

HCT 35.8% (40%-55%)
MCV 64 fL (65-75 fL)
MCHC 35.8 g/dL (33-36 g/dL)
Reticulocyte count 10,200 cells/μL (7000-65,000 cells/μL)
WBC 7100 cells/μL (6000-13,000 cells/μL)
Neutrophils 6603 cells/μL (3000-10,500 cells/μL)
Band neutrophils 284 cells/μL
Lymphocytes 71 cells/μL (1000-4000 cells/μL)
Monocytes 142 cells/μL (150-1200 cells/μL)
Platelets 37,000/μL (150,000-400,000 platelets/μL)
MPV 17.2 fL (7-13 fL).

Slight toxicity was detected in neutrophils and band neutrophils, and multiple neutrophils contained basophilic intracytoplasmic inclusions (morulae) (see Figure 29-3).

Serum Chemistry Profile:

Anion gap 23 mmol/L (10-24 mmol/L)
Sodium 145 mmol/L (145-154 mmol/L)
Potassium 3.7 mmol/L (3.6-5.3 mmol/L)
Chloride 115 mmol/L (108-118 mmol/L)
Bicarbonate 11 mmol/L (16-26 mmol/L)
Phosphorus 3.9 mg/dL (3.0-6.2 mg/dL)
Calcium 10.2 mg/dL (9.7-11.5 mg/dl)
BUN 12 mg/dL (5-21 mg/dL)
Creatinine 0.7 mg/dL (0.3-1.2 mg/dL)
Glucose 61 mg/dL (64-123 mg/dL)
Total protein 6.8 g/dL (5.4-7.6 g/dL)

VetBooks.ir

Albumin 3.1 g/dL (3.0-4.4 g/dL)
Globulin 3.7 g/dL (1.8-3.9 g/dL)
ALT 54 U/L (19-67 U/L)
AST 26 U/L (19-42 U/L)
ALP 106 U/L (21-170 U/L)
Creatine kinase 79 U/L (51-399 U/L)
GGT < 3 U/L (0-6 U/L)
Cholesterol 255 mg/dL (135-361 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL)
Magnesium 2.1 mg/dL (1.5-2.6 mg/dL).

Urinalysis: SGr 1.031; pH 8.0, 25 mg/dL protein, no bilirubin, 25 erythrocytes/μL hemoprotein, no glucose, 0-3 WBC/HPF, 15-25 RBC/HPF, no other significant abnormalities were detected.

Imaging Findings:

Spinal Radiographs: Multiple right lateral projections of the spine were reviewed. There were multiple sites of mild ventral spondylosis deformans throughout the thoracolumbar spine. Severe spondylosis was seen at the lumbosacral space with sclerosis of the endplates either side, most likely due to degenerative change. There was severe osseous remodeling of the lumbar articular facets, which was consistent with osteoarthrosis. Small areas of intervertebral disc mineralization were seen at the L2-3 and L4-5 spaces.

Thoracic Radiographs: The cardiovascular and pulmonary structures were within normal limits. There was slightly increased soft tissue opacity in the region of the sternal lymph node on the right lateral projection.

Abdominal Ultrasound: The liver was mildly hypoechoic but normal in size. The spleen was markedly enlarged but had normal echogenicity. The rest of the abdominal organs were within normal limits.

Microbiologic Testing: Aerobic bacterial urine culture: No growth

ELISA serology for vector-borne pathogens (IDEXX 4Dx SNAP test): Positive for antibodies to *A. phagocytophilum*. Negative for antibodies to *E. canis* and *B. burgdorferi*. Negative for *D. immitis* antigen.

IFA serology for vector-borne pathogens: Positive for antibody to *A. phagocytophilum* (1:2560). Negative for antibodies to *R. rickettsia* at <1:40. Negative for antibodies to *Babesia canis* at <1:40. Weak positive for antibody to *E. canis* at 1:40.

Vector-borne real-time PCR panel (whole blood): Positive for *A. phagocytophilum* (Msp gene PCR). Negative for *Anaplasma platys*, *Bartonella* spp., *Borrelia burgdorferi*, *Ehrlichia canis*, and *Rickettsia* spp. DNA.

Diagnosis: Granulocytic anaplasmosis

Treatment: Copper was treated with doxycycline (5 mg/kg PO q12h) the day after admission, when results of the CBC were available. In the interim, pain was managed with meloxicam and hydromorphone, and IV crystalloid fluids were administered. A day later, the fever had resolved and the dog's appetite and neck pain had improved, but thrombocytopenia persisted (36,000 platelets/μL). Two days after initiation of doxycycline treatment, the platelet count was 302,000 platelets/μL, and all other hematologic variables that were abnormal had returned to the reference range. At a recheck examination, 2 weeks after discharge, Copper was doing well, with no evidence of pain or stiffness. A CBC showed a platelet count of 487,000 platelets/μL.

Comments: This was an unusual case of granulocytic anaplasmosis in a dog that developed apparent cervical pain in association with infection. The dog also had osteoarthritis, but clinical signs resolved almost completely once doxycycline was instituted. Although the dog's joints did not appear painful or swollen on physical examination, it is possible that polyarthritis may have contributed to the clinical signs of stiffness. Serology was initially negative because infection was too recent for an antibody response to have developed. The diagnosis of granulocytic anaplasmosis was confirmed with molecular diagnostic testing and supported by seroconversion to *A. phagocytophilum* and identification of morulae within neutrophils. The weak positive IFA test result to *E. canis* may have reflected serologic cross-reactivity. Treatment with enrofloxacin was apparently ineffective. The need for more consistent application of tick preventatives was discussed with the owners.

CHAPTER 30

Rocky Mountain Spotted Fever

Linda Kidd and Edward B. Breitschwerdt

VetBooks.ir

Overview of Rocky Mountain Spotted Fever

First Described: *R. rickettsii* was first described in Montana, United States, 1909[1] (by Ricketts)

Cause: *Rickettsia rickettsii*, a gram-negative, obligately intracellular bacteria

Affected Hosts: Humans and dogs

Geographic Distribution: North, Central, and South America

Primary Mode of Transmission: Ticks (*Dermacentor* spp., *Rhipicephalus sanguineus, Amblyomma* spp.). Most affected dogs lack a history of a tick bite.

Major Clinical Signs: Rocky Mountain spotted fever (RMSF) is an *acute,* generally febrile illness. Clinical signs are consistent with a vasculitis because *R. rickettsii* infects endothelial cells. Major clinical signs include fever, vomiting, ocular signs, lymphadenomegaly, splenomegaly, peripheral edema, cutaneous hyperemia and necrosis, polyarthritis, and neurologic signs. Signs may be complicated by simultaneous infection with other tick-borne pathogens.

Differential Diagnoses: Infection with other tick-borne agents such as *A. phagocytophilum, Ehrlichia* spp., *Bartonella* spp., *Babesia* spp., and *Borrelia burgdorferi* should be considered. Other causes of severe systemic decompensation and vasculitis, such as sepsis and SIRS due to other causes may mimic RMSF. Leptospirosis and other causes of vasculitis and thrombocytopenia may also mimic RMSF. Other differential diagnoses for the neurologic signs seen in RMSF must also be considered. Appropriate antimicrobial treatment with doxycycline must begin before the diagnosis is confirmed by laboratory testing. Misdiagnosis and delayed or inappropriate antimicrobial drug therapy increase morbidity and mortality.

Human Health Significance: Owners and their physicians should be contacted whenever RMSF is diagnosed in any canine patient, because illness in dogs can coincide with or precede illness in humans.

Etiologic Agent

Rocky Mountain spotted fever (RMSF) is caused by *Rickettsia rickettsii,* an obligately intracellular bacteria in the alphaproteobacteria (genus *Rickettsia,* family Rickettsiaceae, order Rickettsiales).[2] The terminology used to describe rickettsial disease is confusing and inconsistent due to multiple changes in the taxonomic classification of organisms in recent years.[3] The terms "rickettsial disease," "rickettsioses," and even the term "*Rickettsia*" have been used to refer to several obligately intracellular organisms including *Rickettsia, Bartonella, Ehrlichia, Anaplasma, Coxiella,* and *Neorickettsia*. Previously, all of these organisms belonged to the order Rickettsiales and most were in the family Rickettsiaceae, based on their fastidious or intracellular nature and other characteristics. Therefore, collectively members of these diverse genera were referred to as "rickettsial organisms."[4,5] Recent advances in molecular biologic techniques have resulted in the reclassification of several of these organisms. Many have been moved out of the family Rickettsiaceae, and others have been moved out of the order Rickettsiales. Now the order Rickettsiales includes only two families, the family Anaplasmataceae, which contains the genera *Anaplasma, Ehrlichia, Wolbachia,* and *Neorickettsia*; and the family Rickettsieaceae, which includes the genera *Rickettsia* and *Orientia*.[2,3,5] Currently, "rickettsial" refers to diseases caused by organisms in the genera *Anaplasma, Ehrlichia, Rickettsia, Neorickettsia,* and *Orientia,* "rickettsioses" refers to diseases caused by organisms in the family Rickettsiaceae (*Rickettsia* and *Orientia*), and the term "*Rickettsia*" refers specifically to members of the genus *Rickettsia*.[3-5]

The genus *Rickettsia* is currently divided into the spotted fever group (SFG) and the typhus group based on phenotypic and, more recently, genotypic characteristics.[3,5] Some of the phenotypic characteristics that have historically been used to group the organisms include the types of vectors that transmit them and the pathophysiologic manifestations of the disease.[3] The SFG rickettsial species are transmitted by arthropod (primarily tick) vectors and infect endothelial cells in mammalian hosts.[5] The two most pathogenic and well-studied SFG rickettsiae are *Rickettsia rickettsii,* the cause of RMSF in the Western Hemisphere, and *Rickettsia conorii,* the cause of Mediterranean spotted fever (MSF) in other areas of the world. The first case of RMSF was described in the late 1800s and the first case of MSF was described in the 1920s.[6] Therefore, these organisms and their associated diseases are the most well characterized among the SFG rickettsiae.[3] Currently, there are 20 or more species of SFG rickettsiae.[3,6] Some species appear to be nonpathogenic endosymbionts of ticks.[6] However, some SFG rickettsiae previously thought to be nonpathogenic, such as *R. parkerii* and *R. massiliae,* have recently been associated with disease in people.[7-9] Previously thought to have rather limited geographic boundaries, many SFG rickettsiae have also been detected in expanding geographic locales around the world.[6] For example, RMSF, originally described in the Bitterroot Valley of Montana, was subsequently found to be a frequent tick-transmitted infection in the eastern United States, but only recently has transmission via the brown dog tick been documented in the southwestern

United States.[10,11] Increasing travel and the effects of climate change on tick populations and habitat are thought to be in part responsible for this phenomenon.[12,13]

Epidemiology

Hosts, Life Cycle, and Transmission

Dogs are sentinels for SFG rickettsioses in people. Both *R. rickettsii* and *R. conorii* infect and cause disease in dogs.[14-20] *Rickettsia rickettsii* infection in dogs can occur before, or coincide with, outbreaks of RMSF in people in the same household or community.[21-24] Several serosurveys in endemic areas have shown an increased risk of MSF in people who live near dogs that are seropositive for SFG rickettsiae.[25-27] Other SFG rickettsial species likely infect dogs, but the extent to which they cause clinical disease has not yet been established. Species implicated in natural infection in dogs include *R. massiliae, R. japonica,* and *R. australis*.[28-31]

Young and purebred dogs are overrepresented in some but not other studies.[17,18] Although some studies suggest male dogs are at increased risk, no sex predilection has been definitively documented.[17,18,32] Severe disease has been reported in English springer spaniels with phosphofructokinase (PFK) deficiency and German shepherd dogs.[18,32] Although antibodies to SFG rickettsiae can be detected in cats that live in endemic areas, the ability of SFG rickettsiae to actively infect and cause disease in cats has not been well characterized.[33] Similarly, the ability of typhus group *Rickettsia* to cause disease both in dogs and cats has also not been well characterized and will not be discussed here.

Rickettsia rickettsii is transmitted by several hard (ixodid) ticks including *Dermacentor variabilis* (the American dog tick) (Figure 30-1, *A*), *Dermacentor andersoni* (the Rocky Mountain wood tick) (Figure 30-1, *B*), *Amblyomma americanum, Amblyomma cajennense, Amblyomma aureolatum,* and *Rhipicephalus sanguineus*.[34-38] *Amblyomma cajennense* and to a lesser extent, *A. aureolatum* transmit the rickettsia in South America. Ticks that transmit *R. rickettsii* feed once during each life stage (Figure 30-2). Both transstadial and transovarial transmission occurs in *Dermacentor* spp. infected with *R. rickettsii,* so these ticks serve as a reservoir of infection.[39,40] *Dermacentor* spp. and *Amblyomma* spp. are three-host ticks. Infection is transmitted among mammalian hosts and ticks when the tick feeds on different hosts during each stage of molting. The sylvatic cycle for *Dermacentor* ticks involves small mammals, such as chipmunks, pine voles, mice, and ground squirrels. After organisms are ingested by the tick, SFG rickettsiae initially replicate in the epithelial cells of the tick midgut, enter the hemolymph and hemocytes, and then multiply in tissues.[40] Once in the salivary glands, the organism is transmitted to a naïve mammalian host on feeding. Transmission can occur within hours of attachment. However, this may be prolonged (up to 48 hours) when changes in virulence occur under conditions such as starvation of the tick. These "dormant" rickettsiae undergo a process called reactivation after the tick begins feeding.[41] Therefore, rapid tick removal can decrease the risk of transmission in many, but not all, circumstances.

Rhipicephalus sanguineus is a one-host tick, with dogs being the preferred host.[42] *Rh. sanguineus* can adapt to hot environments and commonly resides in walls of housing structures in close proximity to humans.[42] It occasionally feeds on humans, especially when ambient temperatures are high.[12] The role of this tick as a reservoir for *R. rickettsii* in nature has yet to be elucidated.

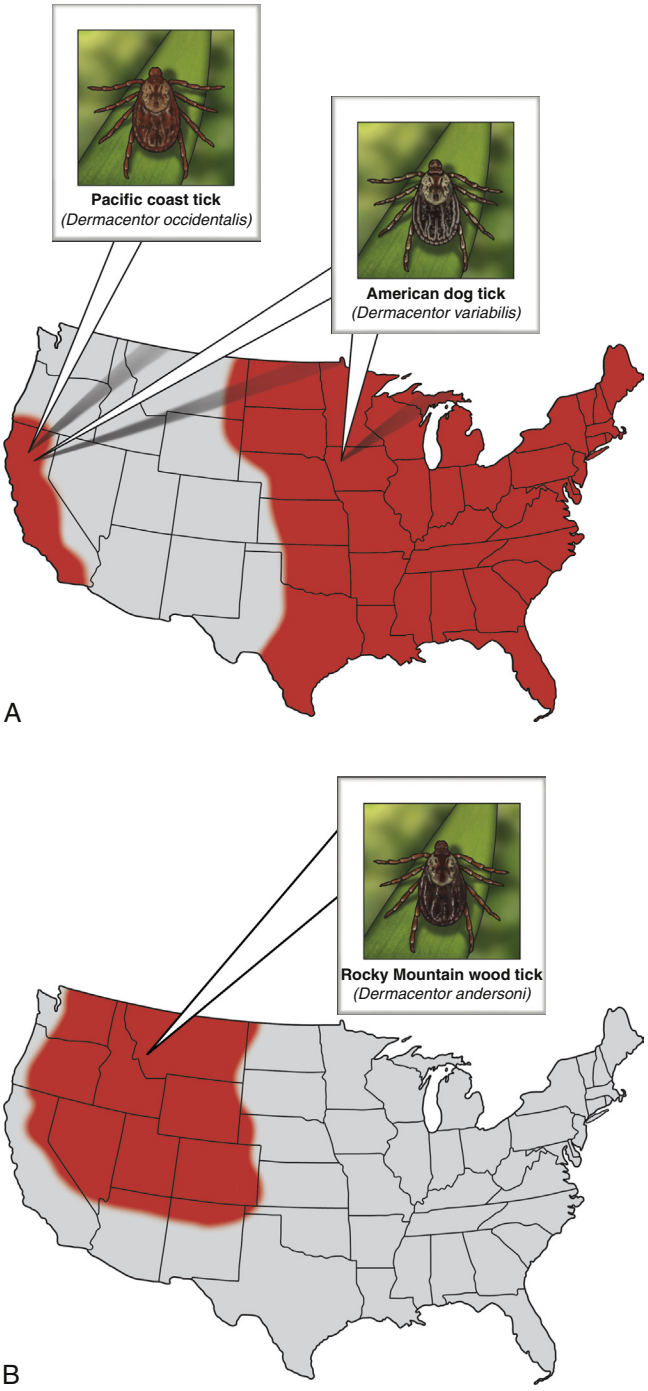

FIGURE 30-1 **A,** Distribution of *Dermacentor variabilis* and *Dermacentor occidentalis* ticks in the United States. **B,** Distribution of *Dermacentor andersoni* ticks in the United States.

The role of dogs as a natural reservoir of infection for *R. rickettsii* is also unknown.[39] Dogs are thought to act as incidental hosts when *Dermacentor* ticks are the vectors, because ticks rarely acquire the organism from rickettsemic dogs.[43] In contrast, all stages of *Rh. sanguineus* acquired infection at a high rate from experimentally infected dogs in one study, but this may have been related to the virulence of the rickettsial strain used.[38] A relatively high infection rate with SFG rickettsiae in naturally infected *Rh. sanguineus* has also been described.[37,44] Therefore, dogs may play a role in maintenance of a reservoir

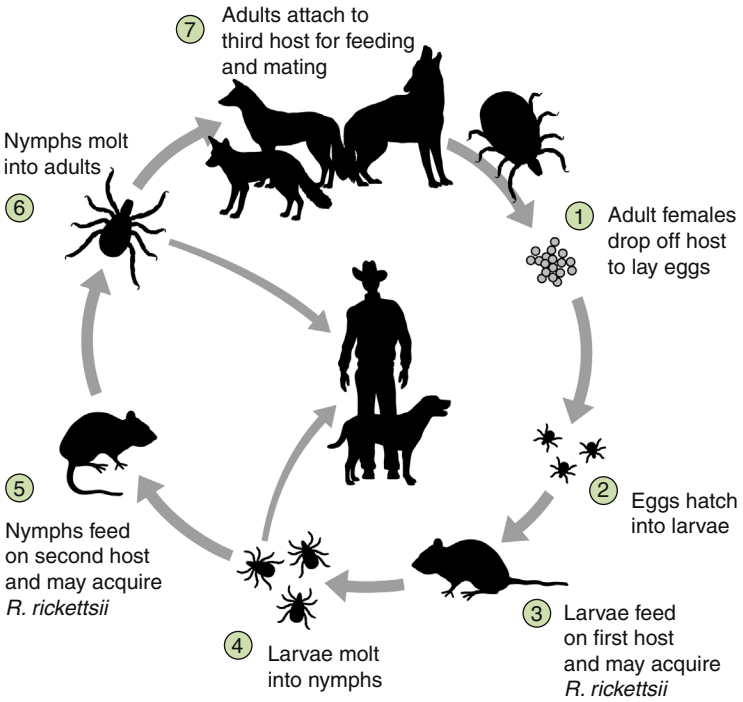

FIGURE 30-2 Transmission cycle of *Rickettsia rickettsii* in tick populations, people, and dogs. After adult female ticks lay eggs and they hatch (1 and 2), *Dermacentor* spp. ticks acquire *R. rickettsii* upon feeding as larvae or nymphs on rodents (3); they then transmit during subsequent feeding as nymphs or adults (4 and 6). Adult ticks feed on a variety of canid species, such as foxes and possibly wolves and coyotes. In addition, *R. rickettsii* infection can be maintained transovarially in *Dermacentor* ticks, so some larvae that hatch from the egg mass already harbor an infection. (Redrawn from Nicholson WL, Allen KE, McQuiston JH, et al. The increasing recognition of rickettsial pathogens in dogs and people. Trends Parasitol 2010;26[4]:205-212.)

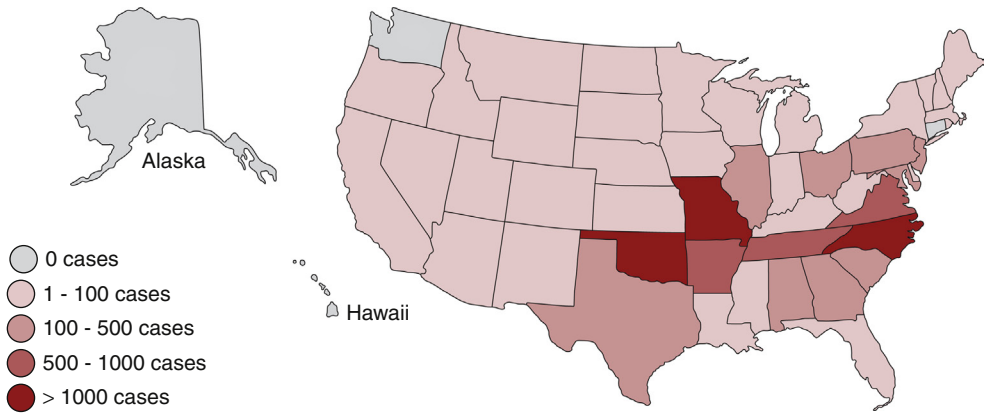

FIGURE 30-3 Geographic distribution of the incidence of spotted fever group rickettsioses in people in the United States, 2005-2009. (Compiled from data from the Centers for Disease Control and Prevention, Morbidity and Mortality Weekly Reports.)

of *R. rickettsii* infection in endemic foci where *Rh. sanguineus* is the primary vector.

Direct transmission of *R. rickettsii* to people has been described in laboratory settings through aerosolization. Direct transmission from blood or other contaminated biologic products also has the potential to occur.

Incidence and Geographic Distribution

Rocky Mountain spotted fever occurs in North, Central, and South America (where it is known as Brazilian spotted fever). In North America, most cases of RMSF occur in the southeastern and south central states (Figure 30-3). Disease distribution in the United States primarily follows the distribution of the primary vectors, *D. variabilis* and *D. andersoni*, although the importance of *D. variabilis* as vectors in endemic areas has recently been questioned.[45] Although disease can occur any time of year, most cases of canine and human RMSF are reported from April through October, months of peak tick activity.[17,46,47] Dogs that live outdoors, particularly those with access to shrubs and high grass, are at increased risk.[17]

In recent years the incidence of RMSF in people has increased.[47] Some of the increase may be due to misdiagnosis of disease caused by species of SFG rickettsiae other than *R. rickettsii*.[48,49] A similar increase in seroprevalence rates has been documented in dogs suspected to have a tick-borne infection in the United States.[50] The geographic distribution of RMSF in the United States has also increased beyond the distribution of *D. variabilis* and *D. andersoni*. *Rhipicephalus sanguineus*

VetBooks.ir

is the main vector for *R. rickettsii* in some parts of the Western Hemisphere, including Mexico and now the southwestern United States. In South America, *Amblyomma* species are the main tick vector. Tick species other than *D. variabilis, D. andersoni,* and *Rh. sanguineus* are also infected with *R. rickettsii* in the United States.[44] For example, *A. americanum* transmitted RMSF to a person in North Carolina.[36] An outbreak in Mexicali, Mexico, was attributed to *R. rickettsii* transmitted by *Rh. sanguineus* ticks associated with dogs.[51] This prompted ongoing surveillance efforts in ticks, dogs, and people in southern California, a nonendemic area for RMSF. Thus far, no *R. rickettsii* has been found in *Rh. sanguineus* ticks from dogs residing in animal shelters located just across the U.S. border from the outbreak.[52,53] This may be due to subtle differences in microenvironment or other factors that affect regional infection rates in ticks.[54]

Clinical Features

Signs and Their Pathogenesis

The endotheliotropism associated with these bacteria results in the characteristic clinical sign of infection, which is disseminated vasculitis. In people, cutaneous macules, papules, and petechiation that occur in association with vasculitis form a rash that looks like "spots," hence the name Rocky Mountain spotted fever.[6] The clinical signs, time course of illness, and response to therapy for RMSF in dogs are very similar, if not identical, to those associated with RMSF in people.[17-20,34] However, cutaneous lesions are not always present in dogs or people ("Rocky Mountain spotless fever"). In people, spotted fever rickettsioses caused by organisms other than *R. rickettsii* are often associated with eschar (an area of cutaneous necrosis) formation.[2,13] Clinicians should keep in mind that dogs from nonendemic areas that have classic signs of RMSF, or those that present with atypical clinical signs, may be infected with *R. rickettsii* or other SFG rickettsial species.

Once the organism is inoculated, it spreads through lymphatics or directly into the bloodstream to the small capillaries. *R. rickettsii* primarily infects endothelial cells, although smooth muscles and monocytes may also be infected.[2,55] The bacterial outer membrane protein A (OmpA) and outer membrane protein B (OmpB) are important for attachment, adhesion, and virulence.[56,57] These proteins are also responsible for differences in serotype, and antibodies to OmpB confer immunity to infection in experimental settings. SFG rickettsiae enter cells by inducing phagocytosis and are released into the cytoplasm through the action of enzymes such as phospholipase D and hemolysin C.[57] The bacteria live in the cytoplasm and the nucleus, deriving nutrients and energy from the host cell.[2,56] They spread from cell to cell by inducing actin to polymerize, which pushes the bacteria directly into adjacent cells.[57,58] This helps them evade the immune response and to disseminate without rupturing the cell. They are also released into circulation when they exit the luminal surface of the cell membrane or when endothelial cell death or detachment occurs.[57] Spotted fever group rickettsiae activate the transcription factor NFκB, which inhibits apoptosis and fosters further growth of the organism.[56,57]

Damage to endothelial cells leads to vasculitis and an increase in microvascular permeability. Mechanisms of cellular damage include oxidative injury through the production of reactive oxygen species, cellular necrosis, and induction of endothelial apoptosis by CD8+ T cells.[55-57,59] Activation of PFK may be important in maintaining vascular integrity and energy metabolism in endothelial cells under hypoxic or oxidative stress,[60,61] which may explain the predisposition of English springer spaniels with PFK deficiency to severe disease. Vasculitis associated with *R. rickettsii* infection manifests as disordered primary hemostasis, tissue edema, hypovolemia, and microthrombosis.

Increased vascular permeability and the associated edema and hypovolemia results from disruption of adherens junctions, endothelial cell death, expression of inflammatory cytokines such as Il1-β, IFN-γ, and TNF-α, and induction of COX-2 with subsequent prostaglandin production.[55] Microthrombosis results from altered platelet adherence to endothelium, increased tissue factor expression, increased plasminogen activator inhibitor, and the release of von Willebrand's factor.[55]

Low numbers of organisms circulate in blood for approximately 13 days after infection, which includes the time that clinical signs are observed.[19,62,63] Organisms are free and also contained within circulating endothelial cells, which are thought to be released from the vessels because of decreased adhesion after rickettsial invasion.[57] Thus, RMSF is an *acute* disease. Chronic infection has not been documented in dogs or people. Co-infection with other vector-borne agents is common and should be considered if the clinical signs are atypical, if there is an incomplete response to doxycycline therapy, or if clinical signs have been present for a week before the time of evaluation.[17,64]

Because of variation in the extent and severity of vascular injury among dogs, a range of signs can occur, and importantly, disease manifestations are initially mild and nonspecific.[15,17,18] Often, there is no known history of a tick bite. Therefore, the clinician (physician and veterinarian) must have a high index of suspicion in order to correctly diagnose and treat this disease. This is very important because a delay in diagnosis and appropriate antimicrobial therapy dramatically increases morbidity and mortality in people and in dogs.[17,46] A "One Health" approach to the management of canine and human RMSF is clearly logical. Lethargy and anorexia are common and may be the only clinical signs. Vomiting and diarrhea occur frequently in dogs and people with RMSF. Melena may be observed, as may a variety of CNS abnormalities including vestibular disease and seizures.[17,18,20] Dramatic and rapid weight loss has been described.[20]

Physical Examination Findings

Fever is present in approximately 80% of naturally infected dogs. Ocular signs are also frequently observed and may include a mucopurulent discharge, scleral and conjunctival injection and hemorrhage, conjunctivitis, uveitis, retinal hemorrhage, and retinitis (Figure 30-4). Lymphadenomegaly and splenomegaly also occur. Respiratory abnormalities include nasal discharge, epistaxis, and tachypnea. Mucocutaneous and cutaneous abnormalities include petechiae, ecchymosis, peripheral edema (which can be localized over a joint, the prepuce, or the mammary chain), hyperemia, and necrosis. Gangrenous necrosis can be so severe as to require reconstructive surgery after successful treatment of the acute febrile illness.[15-18,20,65,66] Orchitis and scrotal edema, hyperemia, and epididymal pain are common in intact male dogs and should prompt consideration of RMSF when present. Generalized myalgia and arthralgia can be observed. Arrhythmias may also be detected. CNS abnormalities can be focal or generalized and include paraparesis, tetraparesis, ataxia, hyperesthesia, ataxia, central or peripheral vestibular signs, stupor, seizures, and/or coma. Neurologic signs are more common in dogs with a high *R. rickettsii* antibody

titer, which suggests a longer duration of illness or a delay in diagnosis.[17] Residual neurologic deficits may occur after infection in severely affected individuals. Microvascular hemorrhage, thrombosis, hypotension, oliguric renal failure, cardiovascular collapse, and coma can occur terminally.

Diagnosis

A combination of diagnostic testing is often necessary to confirm infection by SFG rickettsiae. Active infection is confirmed in a patient with compatible acute clinical signs and demonstration of the organism using PCR assays or immunohistochemistry (IHC), or documentation of seroconversion (Figure 30-5). Importantly, a high index of suspicion based on clinical signs is necessary, because treatment must be instituted before the results of diagnostic tests (including rapid PCR assays) confirm infection.[17,20] Co-infection with other vector-borne disease agents should be considered in patients who fail to respond rapidly to treatment (within the first 24 to 48 hours after initiation of doxycycline treatment).[64] Because direct inoculation into blood or aerosolization can cause infection, all specimens should be handled with care and marked clearly as biohazards. Needle-stick injuries, contact with cuts in the skin, and aerosolization of rickettsemic blood should be avoided.

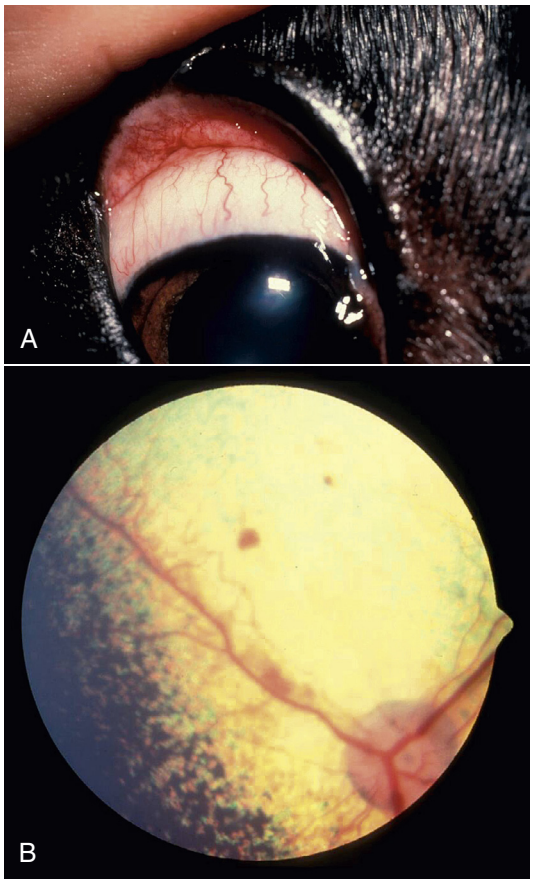

FIGURE 30-4 Ocular complications in dogs with RMSF. **A,** Conjunctival hyperemia and scleral injection. **B,** Retinal hemorrhages.

Laboratory Abnormalities

Complete Blood Count

Thrombocytopenia is common in RMSF and occurs due to vasculitis and immune-mediated platelet destruction.[67] However, it does not occur in all dogs with RMSF.[17,20] The white blood cell count may initially decrease and then tends to increase with duration of illness.[18-20] Neutrophils may have toxic change.[17] Despite the acute nature of this severe illness, a nonregenerative anemia may be present and persist until the dog is treated appropriately and begins to recover.[15,17,20]

Serum Biochemical Tests

Serum biochemical abnormalities can include hypoalbuminemia (due to vasculitis or protein-losing nephropathy), increased ALP activity, hyponatremia, and mild hyperbilirubinemia.[15,17,20,65] Hyponatremia has been associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH) in people with RMSF.

Urinalysis

Urinalysis results in dogs with RMSF are variable and may include proteinuria, hematuria and bilirubinuria, and pyuria. Granular casts can be observed.[17,18]

Coagulation Profile

Coagulation abnormalities include prolonged APTT and increased serum fibrinogen concentration. Less commonly, prolonged PT and increased fibrin degradation products are observed. Although a prothrombotic state can occur during fulminant disease, disseminated intravascular coagulation is uncommon.[15,17]

Body Fluid Cytology

Cytologic examination of aspirates from enlarged lymph nodes in dogs with RMSF is consistent with reactive lymphoid hyperplasia.[17,18] Arthrocentesis may reveal neutrophilic

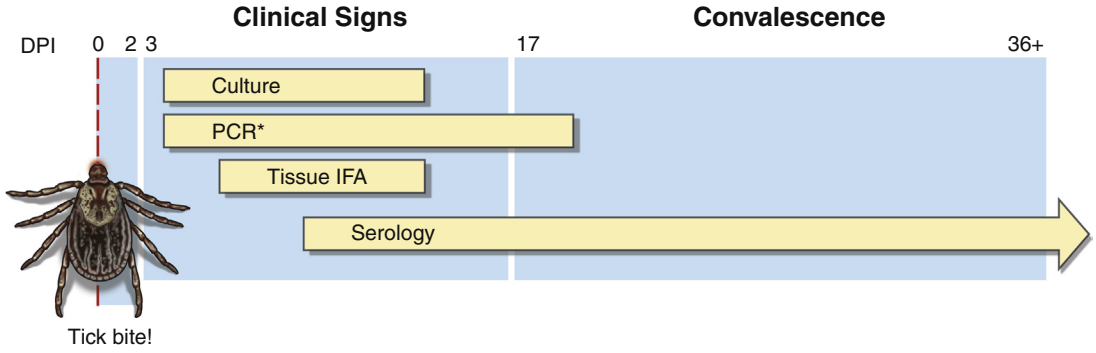

FIGURE 30-5 Timing in relation to day postinfection (DPI) that clinical signs and diagnostic tests for *Rickettsia rickettsii* may be positive in an infected dog[16,62,63,70,76] Further studies are needed to determine exactly how DNA can be detected in peripheral blood after infection.[62,63]

VetBooks.ir

polyarthritis.[17,18] Cerebrospinal fluid analysis in dogs with neurologic signs may reveal a mixed cellular, neutrophilic, or lymphocytic pleocytosis.[17,18,20,68]

Diagnostic Imaging

Thoracic radiographs in dogs with RMSF may show an unstructured interstitial pattern.[18,69] Testicular ultrasound findings may be consistent with orchitis in intact males.[66]

Microbiologic Tests

Diagnostic assays available for RMSF in dogs are shown in Table 30-1. Because of the pathogenesis of the infection, laboratory diagnostics (including serology and PCR assays) may not indicate infection is present at the time that clinical signs manifest (see Figure 30-5). In addition, most diagnostic tests do not differentiate among species of SFG rickettsiae.

Culture

Because of the obligately intracellular and extremely pathogenic nature of *R. rickettsii,* culture is difficult to perform and processing of specimens for isolation is limited to BSL 3 facilities (see Table 1-4). Therefore, culture is not commonly used for routine diagnosis. Currently, *R. rickettsii* is listed as a Category A Bioterrorism agent, so all isolates must be reported to the Centers for Disease Control and Prevention or destroyed immediately.

Serologic Diagnosis

Indirect microimmunofluorescence (MIF) assays that detect IgM and IgG antibodies are most commonly used to document seroconversion in dogs infected with *R. rickettsii*.[19] Because of a lack of specificity, assays that detect IgM alone cannot be used to accurately diagnose acute RMSF.[70] There is extensive serologic cross-reactivity among SFG rickettsiae, and thus a positive titer only indicates exposure to a SFG rickettsial species. In general, the infecting species is presumed based on geographic locale, so RMSF is the presumptive diagnosis in dogs that seroconvert in the southeastern United States. However, other species of SFG rickettsiae may also be present and induce disease.[28,71] Exposure to nonpathogenic SFG rickettsiae, some of which are common endosymbionts in ticks, may be a common cause of positive titers, particularly low and persistent titers, to *R. rickettsii* in healthy people and dogs.[49,72] Serologic cross-reactivity with SFG rickettsiae also may occur in dogs and people infected with *Bartonella henselae*.[73] In addition, previous infection with *R. rickettsii* may result in persistent antibody titers.[70] Thus, infection with *R. rickettsii* cannot be definitively diagnosed based on a single positive titer. However, a single high titer in the context of acute and compatible clinical signs and an appropriate response to therapy suggests infection.[17] Titers are commonly negative early in the course of infection, because clinical signs often occur before seroconversion in naturally and experimentally infected dogs.[20,70,74] Thus, acute and convalescent serology (run in the same laboratory and ideally in the same batch) and documentation of a fourfold change in titer is necessary to confirm acute SFG rickettsiae infection. The convalescent serum specimen should be drawn 2 to 3 weeks after the acute specimen.

TABLE 30-1

Diagnostic Assays Available for Rocky Mountain Spotted Fever in Dogs

Assay	Specimen Type	Target	Performance
Indirect microimmunofluorescence assay (MIF)	Serum	IgM and IgG antibodies against *R. rickettsii*	Demonstration of a fourfold change in titer (seroconversion) is very sensitive. False-negative results are common during the acute phase of infection. A positive antibody response may reflect prior exposure to a nonpathogenic SFG rickettsia, or long-lived circulating antibody from previous infection with SFG rickettsiae. Cross-reactivity to other SFG rickettsiae and to *B. henselae* occurs.
PCR	Whole blood	Gene target varies with testing laboratories	In vitro sensitivity may approach 100%; however, absolute (clinical) sensitivity is lower, approximately 60%, because organisms circulate in blood in low numbers and transiently during the acute phase of infection. Sensitivity is further reduced by antimicrobial drug treatment. Specificity approaches 100%, particularly if the laboratory sequences all PCR amplicons. PCR testing for other tick-borne organisms that cause similar clinical signs is available as PCR panels from some testing laboratories. Only a few PCR assays differentiate among *Rickettsia* species. Negative PCR assay results do not rule out infection.
Histopathology with direct IFA or Gimenez staining	Cutaneous biopsy (inguinal or flank targeting areas with lesions) or necropsy specimens	Characteristic perivascular inflammation and vasculitis with necrosis and presence of the organism	Direct IFA sensitivity is approximately 80% during acute infection. Biopsy of a petechial or ecchymotic lesion may increase sensitivity. False negatives occur if organisms are absent from the lesion because of random chance, timing of specimen collection, or prior antimicrobial treatment. Does not differentiate among species of SFG *Rickettsia*.

VetBooks.ir

Molecular Diagnosis Using Polymerase Chain Reaction

PCR testing of whole blood can be used to confirm infection in seronegative dogs during the acute phase of disease.[62,63,74] A sensitive PCR assay that detects and differentiates among SFG rickettsiae that infect dog blood has been described, and a variety of PCR assays are available through commercial veterinary diagnostic laboratories.[74] However, because *R. rickettsii* circulates in blood in low numbers and only transiently, the sensitivity of any diagnostic assay to detect infection in the bloodstream is limited. One real-time PCR assay, which could detect as few as five copies of organism DNA, had a sensitivity of only 53% for detection of *R. rickettsii* in acute samples from naturally infected dogs with signs of RMSF.[74] The sensitivity of another *R. rickettsii* PCR assay for detection of *R. rickettsii* in experimentally infected dogs ranged from 33% to 100% depending on the day of sampling.[63] Furthermore, false negatives can occur after initiation of appropriate antimicrobial treatment. Therefore, although a positive PCR assay result confirms infection, a negative result does not exclude the diagnosis. Some PCR assays can differentiate among infecting *Rickettsia* species, whereas others only amplify conserved rickettsial DNA targets.[62,74] Clinicians should consult with laboratories to determine the in vitro (analytical) and in vivo (clinical) sensitivity of a PCR assay and its ability to differentiate among infecting *Rickettsia* species.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with RMSF are consistent with vasculitis and may include edema, particularly of the ears, muzzle, and scrotum, and ecchymosis, petechiae, and/or focal hemorrhages of the skin, mucous membranes, and viscera (including the brain). Lymphadenomegaly and splenomegaly are also common findings.[15,16,20,22]

Histopathologic Findings

Microscopically, the predominant lesion is vasculitis. Neutrophils, monocytes, and/or lymphoreticular cells predominate in the inflammatory lesions. The inflammation may surround and invade large small and medium-size vessels of multiple organs and tissues and is frequently accompanied by focal necrosis and hemorrhage. Meningoencephalitis, splenitis, myocardial necrosis, glomerulonephritis, and renal vasculitis have been described.[15,20,22]

Direct IFA can be used to detect organisms in skin and other organs. Identification of abundant SFG rickettsiae within and around small to medium-size vessels and vascular endothelial cells can confirm infection.[20] In experimentally infected dogs, the sensitivity of IHC was 78.3%, and organisms could be visualized between days 7 and 12 of infection (days 3 to 8 of fever).[75] In that study, specimens collected from areas other than the central focus of vasculitis were negative. However, in naturally infected dogs, the sensitivity was 80% for skin specimens from the inguinal region. Half of those specimens lacked gross lesions.[18] Thus, the diagnostic sensitivity of IHC is most likely enhanced by obtaining lesional biopsies, but may not be decreased when a lesion is not biopsied. The sensitivity of direct IHC is decreased by antibiotic therapy. IHC does not differentiate between SFG rickettsial species. Gimenez stain can also be used to visualize rickettsial organisms in tissues or tissue culture isolation attempts, but this stain is not rickettsia specific and does not allow for differentiation among species.

Treatment

Antimicrobial Treatment

Appropriate antibiotic therapy must be immediately instituted based on clinical suspicion, and before diagnostic tests confirm infection. Inappropriate or delayed antibiotic therapy may increase morbidity and mortality.[17,46] Some antimicrobial drugs such as trimethoprim sulfonamides may actually worsen disease progression in human patients.[46] Doxycycline is the treatment of choice (Table 30-2). It effectively eliminates infection and is active against *A. phagocytophilum, Ehrlichia* spp., and *B. burgdorferi,* which may be present in co-infections or cause disease that resembles RMSF. Seven days of treatment is adequate in most cases. Treatment a few days past defervescence is recommended. A longer course of treatment is recommended for dogs that are co-infected with *Ehrlichia* spp. or *B. burgdorferi*. Chloramphenicol was effective in experimentally infected dogs.[76] However, it may be less effective than doxycycline for treating RMSF in people and has less activity in vitro against *Ehrlichia chaffeensis* and *A. phagocytophilum*.[46] Enrofloxacin was effective for treatment of RMSF in experimentally infected dogs.[76] However, enrofloxacin is not effective for treatment of *E. canis* infections.[77] Use of parenteral antimicrobial drugs may be necessary in severely debilitated or vomiting patients.

Supportive Care

Many dogs require hospitalization.[20] Aggressive supportive care for complications such as thrombosis, CNS deficits, and gastrointestinal signs may be necessary. Because of the loss of vascular integrity, fluids should be administered with caution, and colloids may be warranted in some cases. The clinician should avoid exacerbation of interstitial edema, which can contribute to cerebral edema and death. The use of glucocorticoids in dogs with RMSF is controversial. Antiinflammatory and immunosuppressive doses did not affect overall outcome experimentally infected dogs, but rickettsemia was prolonged in dogs concurrently treated with immunosuppressive doses of glucocorticoids and doxycycline.[78] Antiinflammatory doses of glucocorticoids have been used in dogs with severe CNS manifestations and may be necessary topically or systemically for treatment of ocular abnormalities.[68,79]

Prognosis

The response to appropriate antibiotic therapy in dogs with RMSF is rapid (24 to 48 hours). Co-infection with

TABLE 30-2

Antimicrobials Used to Treat Rocky Mountain Spotted Fever in Dogs

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Doxycycline	5	PO, IV	12	7 to 14
Chloramphenicol*	30	PO, IV	8	7 to 14
Enrofloxacin	3† to 5	PO, IV	12	7 to 14

*May cause aplastic anemia in humans (wear gloves); may be less effective than doxycycline.

†Dose used in experimentally infected dogs.[76] Caution required in young animals (see Chapter 8).

VetBooks.ir

B. burgdorferi, Ehrlichia spp., *Babesia* spp., and *Bartonella* spp. should be considered in dogs with severe or prolonged clinical signs or dogs that fail to respond to doxycycline. Residual CNS and other deficits may occur in severely affected patients.[17] The prognosis is good to excellent if the disease is diagnosed and treated with appropriate antibiotics and supportive care early in the course of illness.[17,68]

Immunity and Vaccination

Cell-mediated and innate immunity is important in the clearance of rickettsial infections. CD4+ and CD8+ cells, along with macrophages and dendritic cells, are believed to be sources of inflammatory cytokines such as IFN-γ, TNF-α, Il-1β, and RANTES (CCL5). These cytokines increase production of nitric oxide synthetase and hydrogen peroxide by the endothelial cell, which helps to eliminate the organisms.[56,57] The endothelial cells themselves also produce cytokines such as IL-6, Il-8, and MCP-1 (CCL2) that recruit immune cells and combat infection. Antibodies are not thought to be important initially for clearance of infection because they form after the fulminant stages of disease.[57] However, antibodies are long-lived and together with cell-mediated immunity may prevent subsequent infection. Immunity to reinfection is thought to be lifelong in people, and experimentally infected dogs did not develop illness following rechallenge at 6 months and 3 years after the initial infection. Vaccination is not available for dogs or people currently, but may be in the future.[80]

Prevention

Avoidance of tick-infested areas and routine inspection of dogs for ticks after outdoor activities can help to prevent RMSF. The reader is referred to Chapter 28 for information on tick prevention and safe tick removal. Safe tick removal is especially critical when exposure to *R. rickettsii* is a possibility. In cases where *Rh. sanguineus* is the vector, environmental control of ticks is particularly important.

Public Health Aspects

People living near dogs and with dogs in endemic areas are at increased risk for acquiring RMSF. This is likely due to increased human contact with ticks through interaction with tick-infested dogs. Also, because of transovarial transmission, dogs and people can independently acquire the infection from different ticks questing in the same environment. Because dogs have higher exposure to ticks than their human counterparts, they serve as excellent environmental sentinels for RMSF.[21,22,24,71] In the United States, the diagnosis of SFG rickettsioses in humans is notifiable to public health authorities. Some counties in certain states also require reporting for dogs, particularly during suspected outbreaks.[81] From a public health standpoint, it is important for veterinarians to confirm a diagnosis of RMSF in a dog whenever possible, and to warn the family of the increased risk of acquiring a *R. rickettsii*–infected tick in the same location as the dog acquired the disease. Veterinarians must communicate with owners and physicians that infection in a dog may precede tick-transmitted infection to owners or neighbors. Clients should be instructed to remove ticks properly. Education of owners with regard to the importance of tick control and prevention for both people and pets and the environment is critical. Novel and well-characterized species of SFG rickettsiae are important causes of emerging infectious disease in humans. Furthermore, *R. rickettsii* is considered a potential bioterrorist agent.[80] Because dogs are sentinels for infection, veterinarians play an important role in detecting, defining, and preventing illness in their canine patients and their human companions.

CASE EXAMPLES

Rocky Mountain Spotted Fever in a Dog

Signalment: A 5-year-old MC Australian shepherd from North Carolina

History: The dog was examined by the North Carolina State University veterinary emergency service on April 11 because of recent onset of lethargy, fever, tachypnea, and a stiff gait when walking. Historically the dog had been healthy, had received routine vaccinations, heartworm preventive, and a flea acaricide, and ran approximately 3 miles each evening with the owner, who was a veterinarian. On the day of presentation and several hours after the evening run, the dog became lethargic, refused to eat dog food or treats, and seemed painful upon manipulation. The owner noticed that the dog's heart rate, which was normally 50 to 60 beats/min, was 120 beats/min at rest. Rectal temperature at home just prior to presentation was 104.4°F (40.2°C). Three days before the dog was evaluated, the owner had removed a non-engorged tick from the dog.

Physical Examination: Physical examination findings included a body weight of 21.3 kg, 3%-5% dehydration, pain score of 1 out of 4, rectal temperature of 103.7°F (39.8°C), HR 130 beats/min, tachypnea (42 breaths/min), and a normal CRT. The body condition score was 5/9. The dog stood in a hunched position and had a stiff gait, but localizing pain was not elicited on palpation of the spine, joints, or long bones. There was no nasal or ocular discharge, no petechiae or rash, and no obvious swelling or joint effusion. Popliteal lymph nodes were prominent, but there were no other abnormalities noted on physical examination. Systolic blood pressure was 153 mm Hg, and diastolic and mean blood pressures were 93 mm Hg and 111 mm Hg, respectively.

Laboratory Findings: The hematocrit was 42%, total plasma protein was 6.2 mg/dL, and the platelet count was 120,000/μL. A serum biochemical profile showed only hypoglobulinemia (1.7 g/dL).

Microbiologic Testing: A SNAP 4Dx (IDEXX Laboratories) in-house ELISA assay was negative. Indirect IFA assays for *Babesia canis, Bartonella henselae, Bartonella vinsonii* subsp. *berkhoffii,* and *Ehrlichia canis* were negative (no detectable antibodies at a 1:16 screening dilution). The dog was seroreactive to *Rickettsia rickettsii* antigens at a titer of 1:64. A PCR panel capable of detecting *Anaplasma* spp., *Babesia*

VetBooks.ir

spp., *Ehrlichia* spp., and *Rickettsia* spp. was negative on whole blood. A convalescent *R. rickettsii* antibody titer was 1:256, which supported a diagnosis of SFG rickettsiosis, most likely RMSF.

Treatment: Because of the acute onset of lethargy and fever, the history of recent tick attachment, the documentation of thrombocytopenia, and the relatively high frequency of RMSF in dogs and people in North Carolina, doxycycline (4.8 mg/kg PO q12h) was prescribed for 3 weeks before the results of microbiologic testing became available. The dog responded rapidly after doxycycline treatment, with appetite and behaviors normalizing within 24 to 48 hours after the first dose.

Comment: Although the clinical signs in this dog were relatively nonspecific, the clinical presentation was very typical of RMSF. Because *R. rickettsii* causes generalized vascular injury resulting in increased vascular permeability, fluid and protein leakage out of the intravascular space, and an acute neutrophilic inflammatory response throughout tissue sites within the body, pain that appears to shift in location (back pain, joint pain, abdominal pain, neck pain) is a typical disease manifestation. Also, the hunched appearance reported in this dog is commonly observed in dogs with RMSF. As this dog was owned by veterinarian and a tick had been removed a few days earlier, a clinical diagnosis and appropriate treatment were initiated earlier in the course of illness than is typical of most dogs with RMSF. The rapid initiation of doxycycline may have blunted the humoral antibody response and decreased the convalescent antibody titer to a level that is lower than expected in most cases of RMSF in dogs. It is important to note that PCR assay is insensitive in the early stages of RMSF, as there are often inadequate numbers of organisms in the blood to achieve successful amplification of rickettsial DNA. A very rapid response to doxycycline is expected, unless there has been a delay in diagnosis, accompanied by the onset of neurologic abnormalities. Dogs that develop neurologic complications experience a more prolonged recovery and can have residual neurologic deficits.

Rocky Mountain Spotted Fever in a Human Patient

On May 9, a 61-year-old man, who resided on a farm in Wake County, North Carolina, removed an embedded tick from the hairy portion of his right armpit. Although duration of attachment was unknown, it was likely that the tick was acquired 2 to 3 days earlier while pulling weeds from a hay field. Using a tick identification key, an experienced research technician classified the tick as a male *Amblyomma americanum* and stored the tick in a vial containing alcohol. On May 16, while working on the farm, the patient experienced mild nausea after drinking water and became transiently dizzy. The next morning chills developed, and by the mid-afternoon the patient became febrile (101.2°F [38.4°C]), developed muscle pain, a mild headache and remained in bed until the next morning. These symptoms became progressively more severe during the day and the tick attachment site had developed into an erythematous, circular lesion with induration and a necrotic center, consistent with a rickettsial eschar. Due to the history of tick attachment and fever (maximum temperature 102.9°F [39.4°C]), a spotted fever rickettsiosis, such as RMSF, or neutrophilic or monocytic ehrlichiosis, caused by *Ehrlichia ewingii* and *Ehrlichia chaffeensis*, respectively, was suspected. Neutropenia (2553 cells/μL) was accompanied by a left shift (5% band neutrophils) and thrombocytopenia (148,000/μL). Doxycycline was dispensed with instructions to take 100 mg q12h for 7 days. That evening, after sleeping for 6 hours, the patient ate a small quantity of food, after which he became severely nauseated and fainted, and impact with the floor was associated with a severe blow to the back of the head. The next day (May 19) a maculopapular rash appeared that predominantly involved the inferior portions of the arms and legs. Throughout the day the distribution of the rash spread and the severity progressed from barely visible to obvious over most of the body. At no time did the rash involve the palms or plantar surface of the feet. Fever resolved within 36 hours after the initiation of doxycycline, and the rash began to fade gradually after 48 hours of treatment. Within a week after starting doxycycline, the patient was experiencing no symptoms and had no sequelae as a result of the infection or the fall. A repeat CBC (May 25) identified a normal neutrophil count (4378 cells/μL), no band neutrophils, and a normal platelet count (320,000/μL). Acute-phase serum was collected and stored until the convalescent sample was obtained. *Rickettsia* and *Ehrlichia* spp. PCR was performed immediately. PCR amplicons, obtained from the patient's blood and from the tick, were sequenced, confirming the presence of *R. rickettsii* DNA. PCR for *Ehrlichia* spp. DNA was negative from both the tick and the patient. Subsequently, seroconversion to *R. rickettsii* antigens was identified (1:64 acute titer, convalescent titer 1:512 after 4 weeks). The patient did not seroconvert to *Ehrlichia* spp. antigens.

Comment: Historically, transmission of *R. rickettsii* in North America was attributed solely to *Dermacentor variabilis* in the eastern United States and to *Dermacentor andersoni* in the western United States. However, between 2002 and 2004, researchers at the Centers for Disease Control and Prevention documented *Rh. sanguineus* transmission of *R. rickettsii* to people residing in Arizona. Although this is most likely an infrequent occurrence, this patient was infected with *R. rickettsii* by *A. americanum*. It is important to note the similarities between the historical, physical examination and laboratory findings for the dog discussed previously and the human patient. In several published case reports, dogs develop RMSF before a family member contracts the infection from a tick. Thus, it is important for veterinarians to recognize and confirm a diagnosis of RMSF in dogs and to educate the client as to the risk of tick exposure within their local environment.

CHAPTER 31

Salmon Poisoning Disease

Jane E. Sykes

VetBooks.ir

Overview of Salmon Poisoning Disease

First Described: Northwestern Oregon, United States, 1814 (Astoria)[1]

Cause: *Neorickettsia helminthoeca,* a gram-negative, obligately intracellular bacteria that belongs to the family Anaplasmataceae

Affected Hosts: Dogs, foxes, coyotes, raccoons, captive bears

Intermediate Hosts: Aquatic snails, fish (especially salmonids)

Geographic Distribution: Coastal areas of Washington, Oregon, northern California, British Columbia, Brazil (2004)

Route of Transmission: Ingestion of the infected trematode vector *Nanophyetus salmincola*, most often in salmonid fish

Major Clinical Signs: Fever, lethargy, anorexia, vomiting, diarrhea, lymphadenomegaly

Differential Diagnoses: Lymphoma, canine parvovirus infection, canine distemper virus infection, granulocytic anaplasmosis, ehrlichiosis, leptospirosis, septic shock, disseminated fungal disease (especially cryptococcosis), hemorrhagic gastroenteritis, dietary indiscretion, gastrointestinal foreign body, pancreatitis, hypoadrenocorticism, inflammatory bowel disease. Appropriate antimicrobial treatment with doxycycline must begin before the diagnosis is confirmed by laboratory testing. Misdiagnosis and delayed or inappropriate antimicrobial drug therapy increase morbidity and mortality.

Human Health Significance: *Nanophyetus salmincola* can cause gastrointestinal disturbances and eosinophilia in humans, but *N. helminthoeca* does not cause human disease.

Etiologic Agent and Epidemiology

Salmon poisoning disease (SPD) is caused by the rickettsial pathogen *Neorickettsia helminthoeca*, which, like other *Neorickettsia* spp., resides within a trematode (fluke) vector for the course of the trematode's life cycle. The trematode vector of *N. helminthoeca* is *Nanophyetus salmincola*, thought to be the most common trematode species endemic to the United States.[2] The disease occurs in dogs, foxes, and coyotes and has also been reported in captive bears, but does not occur in domestic cats.[3-5] SPD is geographically restricted to coastal regions of northern California, Oregon, and Washington in the United States, and southern British Columbia in Canada (Figure 31-1). This reflects the distribution of an aquatic snail, *Oxytrema silicula* (also known as *Juga silicula*), which is an intermediate host of the trematode (Figure 31-1). The snail is prevalent in coastal streams. A similar disease has been described in dogs from Brazil.[6,7] Two related yet antigenically distinct organisms have been isolated from dogs with SPD, *N. helminthoeca* and the Elokomin fluke fever (EFF) agent.[8-12] The EFF agent may be a less pathogenic strain of *N. helminthoeca*.

Dogs usually become infected with *N. helminthoeca* when they ingest encysted trematode metacercariae within uncooked or undercooked freshwater fish, most commonly salmonid fish. The Pacific giant salamander is also a competent second intermediate host. Ingestion of encysted metacercariae is followed by maturation of the trematode, which feeds on the intestinal mucosa and inoculates the rickettsia into the host. The fluke has an oral sucker and a ventral sucker, which are used to grasp host intestinal tissue, although the fluke itself does not cause extensive damage to the intestinal wall.[13] Infected trematode ova are shed in the stool for 60 to 250 days.[14] After several months, miracidia develop within the eggs, hatch, swim away, and penetrate the snail. They then develop into rediae, each of which give rise to many free-swimming cercariae. Thousands of cercariae are released intermittently from the snail. These rapidly penetrate the skin of a fish (or are ingested by the fish), and encyst throughout the fish as metacercariae

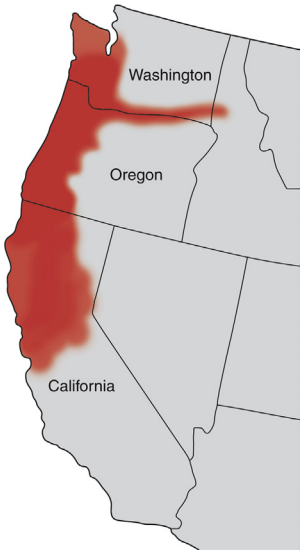

FIGURE 31-1 Geographic distribution of salmon poisoning disease in dogs from the United States. The distribution also extends into the southern portion of British Columbia.

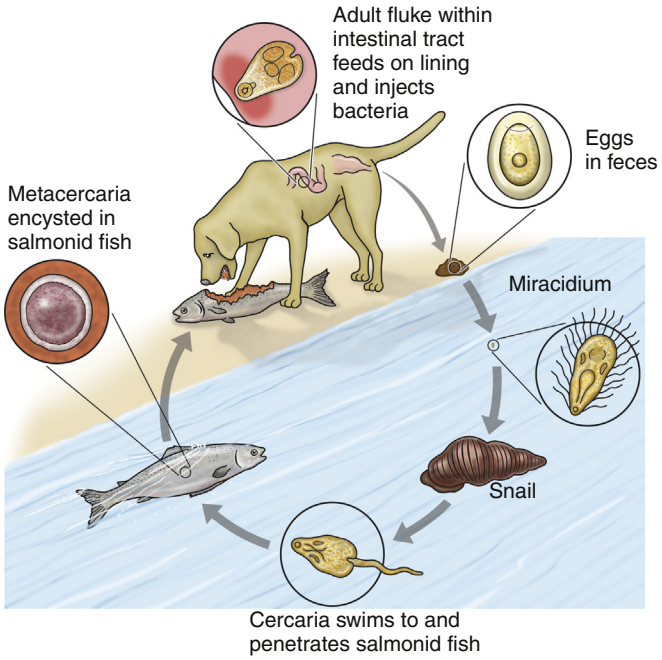

FIGURE 31-2 Life cycle of *Nanophyetus salmincola,* the trematode vector of salmon poisoning disease. The fluke harbors the rickettsial organism throughout its lifecycle.

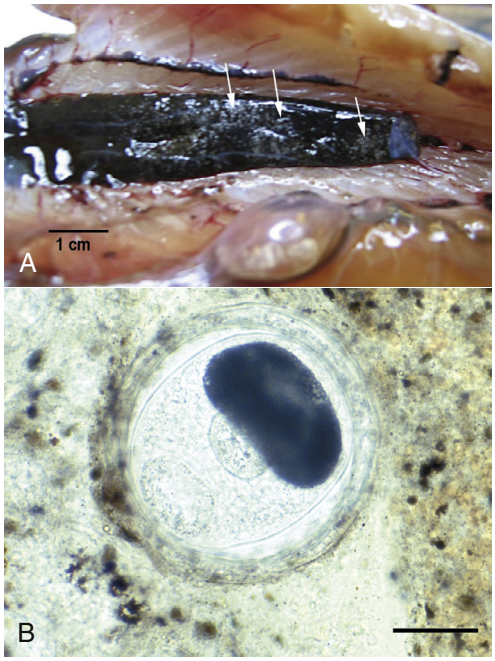

FIGURE 31-3 **A,** "Salt grain" appearance of metacercariae of *Nanophyetus salmincola (arrows)* in the kidneys of a Chinook salmon. (Courtesy Craig Banner, Oregon Department of Fish and Wildlife.) **B,** Wet mount squash of fresh kidney material from a Chinook salmon showing a metacercaria of *N. salmincola*. Bar = 100 µm. (Courtesy Dr. Ronald Hedrick, University of California, Davis.)

(Figures 31-2 and 31-3). Infected fish may contain more than 1000 metacercariae. Infected fish may have visible damage to their skin, and the infection may also interfere with their swimming activity.[15] Dog-to-dog transmission of *N. helminthoeca* has been demonstrated experimentally by mechanical aerosolization or rectal administration of lymph node suspensions or homogenates of rectal mucosa.[16]

Intact male dogs and Labrador retrievers appear to be overrepresented among dogs with SPD,[17] possibly because they are popular with individuals engaged in fishing activities, although dogs of any sex and breed can be affected. Dogs of any age are affected; the median age in one study was 3 years.[17] Dogs develop SPD at any time of year. Occasionally dogs from areas not endemic for SPD develop disease after they ingest fish that is imported from endemic areas.[18]

Most but not all infected dogs have a history of access to or consumption of raw or improperly cooked fish.[17,19] Consumption of any part of the fish, including the entrails and skin, may result in SPD. Supermarket-bought salmon may also be infected.[17] Infection has also been reported after swimming activity, without apparent exposure to fish.[17]

Clinical Features

Signs and Their Pathogenesis

N. helminthoeca replicates within macrophages. This results in a granulomatous inflammatory response within the stomach, intestines, lymph nodes, and spleen. Granulomatous meningitis has also been detected in dogs with SPD.[20,21] The incubation period ranges from 2 to 14 days (median, 7 days), but may be as long as 33 days.[22] The severity of illness varies considerably (Box 31-1). Dogs with peracute infection may be found dead.[17] A marked febrile response is commonly detected (>70% of cases) (Box 31-2) and may reach 107.6°F (42°C).[17]A median rectal temperature of 105°F (40.6°C) was reported in one series of naturally infected dogs.[17] Terminally ill dogs may be hypothermic. Virtually all dogs develop inappetence or anorexia, and lethargy is also common. Vomiting occurs in more than 80% of dogs, and rarely, hematemesis is present.[17] Diarrhea is also common (>70% of dogs) and may be semiformed to liquid in consistency, sometimes containing frank blood, melena, and, less commonly, mucus.[17] Occasionally, a history of diarrhea and vomiting is absent. Other signs include weight loss and increased thirst and urination. Neurologic signs that include mental obtundation, myoclonic twitching, seizures, and apparent neck pain have been reported in fewer than 20% of affected dogs, a primary differential diagnosis being canine distemper virus infection.[17]

BOX 31-1

Signs in the Clinical History of 29 Dogs with Salmon Poisoning Disease

Inappetence or anorexia: 100%
Lethargy: 86%
Vomiting: 86%
Diarrhea: 72%
Hematochezia: 38%
Weight loss: 28%
Melena: 21%
Polyuria and polydipsia: 3%

Physical Examination Findings

Dehydration is frequently noted on physical examination and may be severe. More than 70% of dogs have peripheral

lymphadenomegaly, which may be generalized or involve only some peripheral lymph nodes (see Box 31-2). Lymph nodes may be up to 4 cm in diameter and firm on palpation. Lymphadenomegaly may be absent occasionally, sometimes as a result of lymph node necrosis. Abdominal palpation may reveal pain, and splenomegaly may also be detected. Other abnormalities include tachypnea or labored respirations, tachycardia, scleral or conjunctival injection, and edema that involves the limbs, face, or cervical region.[17] Mucosal pallor, tachycardia, and weak pulses may be present in dogs with hypovolemic shock. Cardiac arrhythmias such as ventricular premature contractions have also been noted, and there may be signs of hemorrhage such as epistaxis and hyphema. Rectal examination may indicate the presence of liquid stool, sometimes accompanied by fresh blood or melena.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

Thrombocytopenia is present in 90% of affected dogs. Anemia is present in up to 40% of dogs with SPD and generally occurs as a result of gastrointestinal hemorrhage. More commonly, the CBC shows evidence of lymphopenia, thrombocytopenia, or neutrophilia, frequently with bandemia (Table 31-1). Uncommonly, neutropenia occurs.[17] Toxic changes may be present within neutrophils, and immature monocytes may occasionally be found in the peripheral blood. Despite the association with helminthiasis, eosinophilia has not been documented.

BOX 31-2

Physical Examination Findings in 29 Dogs with Salmon Poisoning Disease

Peripheral lymphadenomegaly: 74%
Fever: 73%
Dehydration: 65%
Abdominal pain: 28%
Tachypnea or labored respirations: 24%
Tachycardia: 24%
Neurologic signs: 17%
Weak pulses: 17%
Splenomegaly: 14%
Scleral injection: 14%
Mucosal pallor: 10%
Hypothermia: 5%

Serum Chemistry Profile

Hyponatremia and hypokalemia are the most common electrolyte abnormalities in dogs with SPD and result from gastrointestinal losses that occur with vomiting and diarrhea (Table 31-2). Low ionized calcium concentrations may be detected in some dogs, possibly as a result of decreased intestinal absorption. Hypoalbuminemia is present in most (>80%) dogs. Hypoglobulinemia and hypocholesterolemia occur in fewer than 25% of dogs with SPD, but may become profound. Abnormal liver enzyme activities may be present, the most common of which is increased ALP activity,[17,20] but increases in the activity of ALT and AST may also occur. Hyperbilirubinemia is present in fewer than 20% of dogs. Azotemia can be evident in dogs with severe dehydration.

Urinalysis

Bilirubinuria and proteinuria are frequently detected on urinalysis in dogs with SPD.[17] Uncommonly, cylindruria and glucosuria are present, perhaps as a result of renal injury secondary to impaired renal perfusion. Microscopic hematuria occurs in some dogs, possibly reflecting underlying coagulopathies that can occur in dogs with SPD.

Clotting Function

Evaluation of clotting function in some dogs with SPD shows evidence of disseminated intravascular coagulation. Abnormalities include increased PT or APTT, increased fibrin degradation products, and decreased antithrombin activity.[17]

Diagnostic Imaging

Plain Radiography

Abdominal radiographs may be unremarkable or reveal fluid-filled small intestines; decreased serosal detail; and less frequently, hepatomegaly or splenomegaly. Thoracic radiographs

TABLE 31-1

Hematologic Findings in 29 Dogs with Salmon Poisoning Disease

Test	Reference Range	Percent below the Reference Range	Percent within the Reference Range	Percent above the Reference Range	Range for Dogs with Salmon Poisoning Disease	Number of Dogs Tested
Hematocrit (%)	40-55	39	61	0	22-53	23

FIGURE 31-4 Enlarged and hypoechoic abdominal (medial iliac) lymph nodes as detected using abdominal sonographic examination in a 9-year-old male German shepherd dog with salmon poisoning disease.

are typically unremarkable or show reduction in size of the intrathoracic vasculature, consistent with hypovolemia.

Sonographic Findings

Abdominal ultrasound examination of dogs with SPD often shows mild or moderate generalized abdominal or mesenteric lymphadenomegaly, as well as splenomegaly with a mottled splenic echotexture. Some dogs that lack peripheral lymphadenomegaly have abdominal lymphadenomegaly on ultrasound examination,[17] and ultrasound-guided aspiration of enlarged abdominal lymph nodes can be helpful for diagnosis in dogs that lack peripheral lymphadenomegaly. Lymph nodes develop a rounded appearance with a hypoechoic or hypoechoic mottled echogenicity (Figure 31-4). Fluid-distended intestinal loops, sometimes with wall thickening, corrugation, hypermotility, or hypomotility, may be documented. Uncommonly, hepatomegaly or a small amount of free peritoneal fluid is identified.

Microbiologic Tests

Diagnostic assays for SPD are summarized in Table 31-3.

Diagnosis Using Fecal Examination

SPD can be diagnosed when operculated trematode eggs are found in fecal specimens of dogs with consistent clinical signs, which appear within 5 to 8 days after the ingestion of infected fish. Although the sensitivity of centrifugal zinc sulfate fecal flotation for detection of *N. salmincola* ova in dogs with SPD is similar to that of fecal sedimentation, some dogs that test negative by one method test positive using the other, so the sensitivity of fecal examination for diagnosis is maximized by performing both centrifugal zinc sulfate fecal flotations and fecal sedimentation together. In one study, 93% of dogs with SPD tested positive for *N. salmincola* ova using a combination of fecal flotation and fecal sedimentation.[17] False negatives may occur when the duration of illness is shorter than the prepatent period of *N. salmincola* or when light fluke burdens are present. The finding of fluke ova on fecal examination may not be diagnostic of SPD, because dogs may be infected with trematodes that do not harbor the rickettsia, and ova may be shed for months after recovery. Nevertheless, *N. salmincola* ova were detected in only 0.2% of more than 1800 fecal flotations in dogs seen at a teaching hospital in an endemic area, and all positive test results were in dogs suspected to have SPD. Thus, the specificity of fecal examination for a diagnosis of SPD appears to be extremely high.[17]

Centrifugal zinc sulfate fecal flotation may reveal co-infections with other gastrointestinal parasites, which can complicate

the clinical picture. Co-infections with *Dipylidium caninum* and *Trichuris vulpis* have been reported in dogs with SPD.[17]

Cytologic Diagnosis

In addition to fecal examination for trematode ova, SPD can be diagnosed following cytologic examination of peripheral lymph node aspirates, or ultrasound-guided aspirates of abdominal lymph nodes or the spleen. Cytologic findings consist of histiocytic hyperplasia and lymphoid reactivity. Rickettsial organisms are 0.3–µm cocci or coccobacilli and may be seen in large numbers within the cytoplasm of macrophages. They resemble granular to amorphous material of a uniform blue color using Wright's stain, occasionally forming loose clusters of organisms (morulae) (Figure 31-5).[17,22,23] In as many as one quarter to one third of dogs, rickettsial organisms are not identified. The presence of histiocytic hyperplasia should alert the clinician to the possibility of SPD. Organisms may also be absent in dogs with a recent history of antimicrobial therapy.

Serologic Diagnosis

Serologic tests for *N. helminthoeca* antibodies or antigen are not available on a commercial basis for veterinary practitioners. Antibodies to *N. helminthoeca* can cross-react serologically with those of *Ehrlichia* spp., so it is possible that dogs with SPD might test positive using serologic tests for *Ehrlichia* spp. (provided enough time had elapsed for antibody formation to occur).[24] In one study, most dogs with SPD that were tested for antibodies against other rickettsial pathogens did not seroreact to *Ehrlichia canis* or *Anaplasma phagocytophilum*.[17]

Molecular Diagnosis Using the Polymerase Chain Reaction

Specific PCR assays have been used to detect the DNA of *Neorickettsia helminthoeca* in clinical specimens from affected dogs.[17] Real-time PCR assays for *N. helminthoeca* are available from some veterinary molecular diagnostic laboratories and can be performed on blood, lymph-node, or splenic aspirates and possibly fecal specimens from dogs with SPD in order to confirm the diagnosis. More research is required to understand the sensitivity and specificity of PCR assays for diagnosing SPD in dogs, including the optimum specimen type for testing.

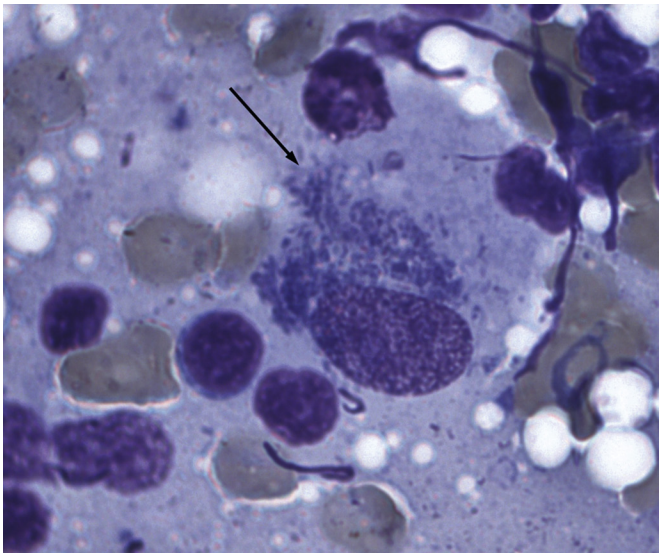

FIGURE 31-5 Lymph node aspirate from a dog with salmon poisoning disease. Note the large histiocyte that contains granular coccoid organisms consistent with *Neorickettsia helminthoeca*.

TABLE 31-3

Diagnostic Assays Available for Salmon Poisoning Disease in Dogs

Assay	Specimen Type	Target	Performance
Fecal sedimentation combined with zinc sulfate centrifugal fecal flotation	Feces	*Nanophyetus salmincola* ova	Specificity nears 100% when performed by a parasitologist. Sensitivity probably >90%. Eggs are light brown, ovoid, operculate at one end and measure 0.087 to 0.097 mm × 0.038 to 0.055 mm.
Cytology	Lymph-node or splenic aspirates	Detection of *Neorickettsia helminthoeca* within macrophages	Sensitivity >70% when performed by a veterinary clinical pathologist. Sensitivity may be improved by examination of aspirates from multiple lymph node. Organisms within macrophages may be confused with debris or hemosiderin. Other changes include lymphocytic reactivity and histiocytic hyperplasia.
Histopathology	Biopsy or necropsy specimens, especially lymph nodes, spleen, gastrointestinal tissues	*N. helminthoeca* within macrophages	Organisms may be stained with Giemsa. Antimicrobial therapy can lead to false-negative results.
PCR	Blood, lymph-node or splenic aspirates, tissue specimens, feces	*N. helminthoeca* DNA	Well validated assays that are specific for *N. helminthoeca* are not available commercially. Optimum specimen type unknown. Antimicrobial therapy may lead to negative PCR results.

Pathologic Findings

Gross Pathologic Findings

Gross necropsy findings in dogs with SPD consist of enlargement of lymphoid tissues, including the tonsils, thymus, lymph nodes, and spleen. Lymph nodes may be yellowish and edematous and may contain white foci that represent foci of granulomatous inflammation. Petechial hemorrhages may be noted on the lymph nodes, the gastrointestinal tract, pancreas, gallbladder, and urinary bladder. The gastrointestinal tract may be thickened and contain white foci. The lumen of the intestinal tract may contain free blood (Figure 31-6, *A*). Flukes are only 0.8 to 1.1 mm long and 0.3 to 0.5 mm wide[25] and may not always be visible grossly.

Histopathologic Findings

Lymphoid tissues show marked depletion of lymphoid follicles, and subcapsular and medullary sinuses are filled with histiocytes, the cytoplasm of which can contain numerous rickettsial organisms, which occasionally form clusters within vacuoles. Organisms are readily appreciated using Giemsa stain (see Figure 31-6, *C*). Lymph node and splenic necrosis may also be present.[17,22] Inflammatory nodules that contain lymphocytes, plasma cells, and infected histiocytes expand the lamina propria of the gastrointestinal tract and extend into the submucosa. Parasites consistent with *N. salmincola* may be found embedded in the mucosa, primarily within the duodenum (see Figure 31-6, *B*).[16,21] Nevertheless, flukes are not always found using histopathology in dogs that die from SPD, even in the absence of anthelmintic therapy.

One dog that died of SPD had widespread and multiple thromboses involving numerous organs with associated tissue infarction. Granulomatous meningitis has been described at necropsy in dogs that were experimentally infected with *N. helminthoeca*.[20]

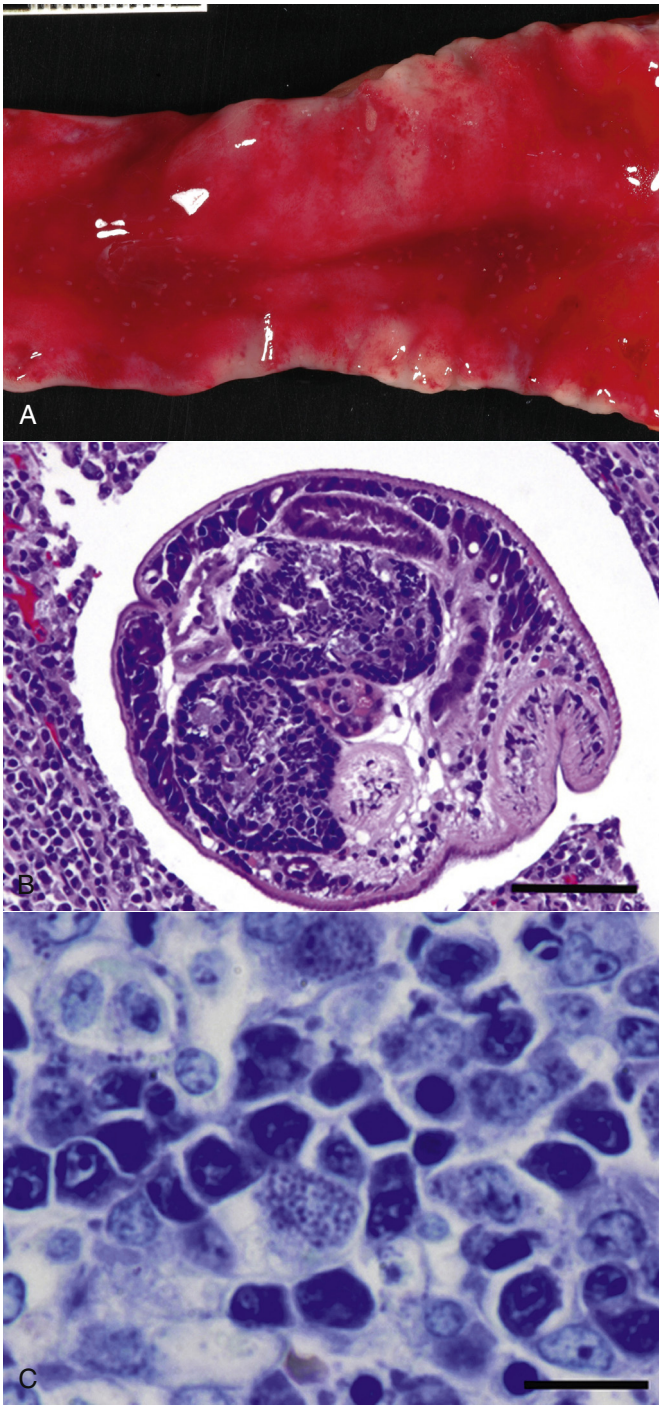

FIGURE 31-6 **A,** Intestinal mucosa of an 8-month-old female spayed Maltese mix dog that died of salmon poisoning disease. The intestinal wall was thickened and the contents were dark red and mucoid. (Courtesy University of California, Davis Veterinary Anatomic Pathology Service.) **B,** Duodenum. A transverse section of an adult *Nanophyetus* fluke is embedded within the intestinal villi. H&E stain. Bar = 200 µm. **C,** Lymph node, medullary sinus from a dog with salmon poisoning disease. Many histiocytes have intracytoplasmic clusters of coccobacilli less than 1 µm in diameter. Giemsa. Bar = 5 µm. (B and C from Sykes JE, Marks SL, Mapes S, et al. Salmon poisoning disease in dogs: 29 cases. *J Vet Intern Med* 2010;24[3]:504-513, 2010.)

Treatment and Prognosis

The treatment of choice for SPD is doxycycline, tetracycline, or oxytetracycline, which should be given for a minimum of 7 days. Administration of tetracyclines is generally associated with clinical improvement within 24 hours, and signs resolve within 1 to 4 days.[17] Dogs that are vomiting may require treatment with parenteral tetracyclines. Clinical improvement has also been reported following treatment with enrofloxacin and parenteral trimethoprim-sulfamethoxazole. Antimicrobials that do not appear to be effective include first-generation cephalosporins, penicillins, aminoglycosides, chloramphenicol, and metronidazole.[17] Although complete clinical recovery may occur without anthelmintic treatment, the fluke infection should be treated with praziquantel after initial recovery from SPD (Table 31-4).

Dogs with mild signs or infrequent vomiting may respond well to treatment with oral tetracyclines alone, whereas those with more severe disease often require hospitalization for IV antimicrobial and crystalloid fluid therapy (see Table 31-4). Oral antimicrobial therapy can be continued once vomiting ceases. The presence of severe hypovolemia or hypoalbuminemia may necessitate treatment with colloids such as fresh frozen plasma, dextrans, or hetastarch. Packed RBC or whole blood may be required for dogs with severe anemia. Treatment with total or partial parenteral nutrition may also be required if vomiting is persistent and does not respond to antiemetics such as metoclopramide, maropitant, or ondansetron. Close monitoring of hematocrit, albumin, electrolytes, acid-base status, renal parameters, and coagulation parameters may be required in some severely affected dogs. Blood cultures should be considered in dogs with severe hemorrhagic diarrhea and

TABLE 31-4

Antimicrobials Used to Treat Salmon Poisoning Disease in Dogs

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Doxycycline	5	PO, IV	12	7-14
Tetracycline	22* 7	PO IV	8 8	7 7
Oxytetracycline	7-10*	PO, IV	8	7
Praziquantel†	10-30	PO	24	1-2

*Reduce dose in renal failure; may cause teeth discoloration in young animals. Monitor for nephrotoxicity (cylindruria).
†For treatment of fluke infection.

abnormal perfusion parameters, after which treatment with broad-spectrum parenteral antimicrobial drugs should be commenced.

Prolonged hospitalization may be required for dogs that develop complications such as cardiac arrhythmias, intussusceptions, adverse reactions to tetracyclines, disseminated intravascular coagulation, or septicemia.[17,19] In a study of dogs evaluated at a tertiary referral hospital, death or euthanasia occurred in 14% of 29 dogs with SPD.[17] The mortality may be lower in dogs seen in primary care practice, providing appropriate treatment can be administered. In general, early treatment is associated with an excellent prognosis. Without treatment, death can occur within 5 to 10 days.

Immunity and Vaccination

Animals that recover from SPD are immune to reinfection with the same strain of *N. helminthoeca*,[22,26,27] but challenge with an alternate strain (then the EFF agent) results in disease, and antibodies fail to cross react with the alternate strain. This may explain why SPD has been reported to occur more than once in some dogs.[17,22] No vaccine is available.

Prevention

N. helminthoeca metacercariae are effectively destroyed by proper cooking or freezing of infected fish. Ingestion of raw fish by dogs in endemic areas should be discouraged, and dog owners in endemic areas should be educated about the disease. Dogs that have eaten raw fish from an endemic area, or those swimming in rivers or lakes in these areas, should be watched carefully for signs of lethargy, vomiting, or decreased appetite that occur within 2 weeks of exposure. If multiple dogs are simultaneously exposed to a source of *N. helminthoeca*, and one dog develops SPD, treatment of the other dogs in the group with 7 days of doxycycline should be considered. Medical equipment used in the treatment of dogs with SPD should not be reused on other patients without proper sterilization.

Public Health Aspects

Human infection with *N. helminthoeca* has not been reported. However, humans may become infected with the fluke, *N. salmincola*, after consumption of poorly cooked fish. Most humans are subclinically infected, although abdominal discomfort, diarrhea, vomiting, weight loss, nausea, and peripheral eosinophilia may occur.[28]

CASE EXAMPLE

Signalment: "Herman," 9-year-old male German shepherd dog from Sacramento, CA (Figure 31-7).

History: Herman's owner reported a 2-day history of inappetence, lethargy, and one episode of vomiting. The dog had been drinking normally. There had been no diarrhea, coughing, sneezing, or increased thirst and urination. The owner also reported that Herman ate turkey and chicken that contained bones 3 days before the onset of illness. He was normally fed a strict diet of rabbit- and potato-based prescription dog food and grilled salmon because of atopic dermatitis. Herman was sometimes fed salmon scraps from the local supermarket, which the owner grilled briefly. He had not traveled out of his local area. He was up to date on vaccinations, which included vaccines for distemper, hepatitis, parvovirus, and rabies.

Current Medications: Lincomycin 29 mg/kg PO q12h; trimeprazine tartrate 0.2 mg/kg PO q48h; prednisolone 0.1 mg/kg q48h for atopic dermatitis.

Other Medical History: Herman had been diagnosed with hip osteoarthritis using pelvic radiography 8 months earlier. Controlled weight loss was the recommended treatment. He was cryptorchid, and the abdominal testicle had been removed when he was a young dog. The descended testicle was still present.

Physical Examination:

Body Weight: 51.5 kg

General: Quiet, alert and responsive. Ambulatory on all four limbs. T = 104.3°F (40.2°C), HR = 108 beats/min, RR = 60 breaths/min, mucous membranes pink, CRT = 1 s.

Integument: A full, shiny haircoat was present and there was no evidence of ectoparasites.

Eyes, Ears, Nose, and Throat: No significant abnormalities were noted. A mild amount of brown waxy debris was present within both ear canals.

Musculoskeletal: A body condition score of 6/9 with symmetrical muscling was noted. Mild to moderate pelvic limb weakness was identified.

Cardiovascular: Strong femoral pulses were noted. No murmurs or arrhythmias were detected on thoracic auscultation.

Respiratory: An increased respiratory rate with increased abdominal effort was present.

Gastrointestinal and Genitourinary: Abdominal palpation revealed a tense abdomen, with abdominal splinting, and splenomegaly. There was one descended testicle, which was smooth with no masses. No abnormalities were detected on

Continued

VetBooks.ir

FIGURE 31-7 "Herman," a 9-year-old male German shepherd dog with salmon poisoning disease.

rectal examination. Soft feces were present in the rectum, and the prostate was palpable and symmetrical.

Lymph Nodes: Marked peripheral lymphadenopathy was present. Mandibular, superficial cervical, and popliteal lymph nodes were all 3-4 cm in diameter and firm.

Laboratory Findings:

CBC:

HCT 40.4% (40-55%)
MCV 65 fL (65-75 fL)
MCHC 36.6 g/dL (33-36 g/dL)
WBC 4240 cells/µL (6000-13,000 cells/µL)
Neutrophils 3689 cells/µL (3000-10,500 cells/µL)
Lymphocytes 466 cells/µL (1000-4000 cells/µL)
Monocytes 42 cells/µL (150-1200 cells/µL)
Platelets 74,000 platelets/µL (150,000-400,000 platelets/µL).

Serum Chemistry Profile:

Sodium 141 mmol/L (145-154 mmol/L)
Potassium 4.0 mmol/L (3.6-5.3 mmol/L)
Chloride 112 mmol/L (108-118 mmol/L)
Bicarbonate 13 mmol/L (16-26 mmol/L)
Phosphorus 2.8 mg/dL (3.0-6.2 mg/dL)
Calcium 9.9 mg/dL (9.7-11.5 mg/dl)
BUN 15 mg/dL (5-21 mg/dL)
Creatinine 1.1 mg/dL (0.3-1.2 mg/dL)
Glucose 86 mg/dL (64-123 mg/dL)
Total protein 6.9 g/dL (5.4-7.6 g/dL)
Albumin 3.6 g/dL (3.0-4.4 g/dL)
Globulin 3.3 g/dL (1.8-3.9 g/dL)
ALT 108 U/L (19-67 U/L)
AST 109 U/L (19-42 U/L)
ALP 105 U/L (21-170 U/L)
Creatine kinase 381 U/L (51-399 U/L)
GGT < 3 U/L (0-6 U/L)
Cholesterol 296 mg/dL (135-361 mg/dL)
Total bilirubin 0.4 mg/dL (0-0.2 mg/dL)
Magnesium 1.7 mg/dL (1.5-2.6 mg/dL).

Urinalysis: SGr 1.048; pH 6.0, 2+ protein (SSA), 1+ bilirubin, 1+ hemoprotein, no glucose, 0-1 WBC/HPF, 20-30 RBC/HPF, rare ammonium biurate crystals, many lipid droplets

Imaging Findings:

Thoracic Radiographs: The cardiovascular and pulmonary structures appeared within normal limits. A mild diffuse bronchial pattern throughout all lung fields was considered consistent with the age of the patient. Marked spondylosis deformans was present throughout the thoracic spine.

Abdominal Ultrasound: The liver had a diffuse, coarse echotexture. The spleen was markedly, diffusely enlarged and had a diffuse hypoechoic, mottled echotexture. The prostate gland was enlarged and had multiple small anechoic cysts within its parenchyma. One testicle was present in the scrotum and had a striated, heterogenous echotexture. A second inguinal or intra-abdominal testis was not observed. Multiple enlarged, hypoechoic inguinal lymph nodes were present (see Figure 31-3). A large (2.5 cm), round, hypoechoic mass with a focal area of mineralization was present in the cranial abdomen caudal to the liver and most likely represented a lymph node. Multiple enlarged, hypoechoic sublumbar lymph nodes were observed. The splenic lymph nodes were enlarged and mildly hypoechoic.

Cytology Findings: Cytology of ultrasound-guided splenic aspirate: splenic stromal clumps contained increased numbers of plump histiocytes and many large clumps of hemosiderin. Histiocytes were also present in moderate numbers throughout the smear, often in clumps, and often mildly vacuolated. They were occasionally erythrophagocytic and often contain hemosiderin. Interpretation: moderate to marked histiocytic inflammation.

Cytology of popliteal lymph node aspirate (see Figure 31-5): moderate reactive lymphoid hyperplasia with pyogranulomatous inflammation was identified. Rare histiocytes were present that contained intracellular small coccoid purple-blue structures that were organized individually and in clusters. These were consistent with *Neorickettsia helminthoeca* organisms.

Fecal examination: Fecal flotation: Negative for parasites.
Fecal sedimentation: *Nanophyetus salmincola* ova, <1 per 10× field

Diagnosis: Salmon poisoning disease

Treatment: Doxycycline, 5 mg/kg PO q12h for 14 days. This was associated with resolution of fever and inappetence within 24 hours of starting treatment. By 7 days after diagnosis, Herman's owner reported that Herman was completely back to his normal self.

Comments: This dog was diagnosed with SPD based on the presence of characteristic cytologic findings on examination of a lymph node aspirate, together with the detection of *N. salmincola* ova in the stool. The case was unusual because the dog was infected after ingestion of incompletely cooked supermarket-bought salmon, which the dog had been fed for years without developing illness. Although the splenic aspirate contained inflammatory cells typical of those seen in SPD, organisms could not be convincingly documented.

CHAPTER 32

Coxiellosis and Q Fever

Jane E. Sykes and Jacqueline M. Norris

VetBooks.ir

Overview of Coxiellosis and Q Fever

First Described: mid 1930s, Queensland, Australia, in slaughterhouse workers (Derrick)[1]

Cause: *Coxiella burnetii,* an obligately intracellular gram-negative bacteria that belongs to the Family Coxiellaceae

Affected Hosts: Humans are most susceptible; reproductive disease can occur in farm animal species such as sheep, goats, cattle, and horses, as well as cats and dogs

Geographic Distribution: Worldwide, with the exception of New Zealand

Major Clinical Signs: Dogs and cats are usually subclinically infected. Abortion, premature birth, and stillbirth may occur.

Differential Diagnoses: Brucellosis, bartonellosis, herpesviral infections, leptospirosis, neosporosis, canine distemper, and canine parvovirus infection. Noninfectious causes of pregnancy loss such as endocrinopathies, genetic disorders, and nutritional deficiency should also be considered.

Human Health Significance: Q fever in people results primarily from contact with infected sheep, goats, and cattle, or indirect contact with surfaces contaminated with secretions or excretions of these animals. However, contact with infected companion animals can also lead to transmission. Q fever in people is most commonly an acute febrile illness, but pneumonia and chronic complications such as endocarditis, granulomatous hepatitis, and chronic fatigue can occur.

Etiology and Epidemiology

Coxiella burnetii is a gram-negative, obligately intracellular, small, pleomorphic rod that causes Q fever in humans, a significant zoonosis worldwide. Sheep, cattle, and goats are the most commonly reported reservoirs for the organism, but infected cats and less commonly dogs have also been implicated in transmission to people.[2-5] Animals other than humans are often subclinically infected, although reproductive complications such as premature birth, abortion, and stillbirth may also occur. Reservoir hosts shed organisms in urine, feces, saliva, and/or milk, and especially in vaginal secretions and the products of parturition because of recrudescence of infection during pregnancy. The placentas of infected animals are heavily infected (up to 10^9 organisms per gram of tissue). At parturition, aerosols are created, which are subsequently inhaled by other animals and humans (Figure 32-1). Ingestion of unpasteurized contaminated milk is a less common and more controversial mode of transmission.[6,7] The term *Q fever* stands for *query* fever, the name it was given when it first emerged in Queensland, Australia, and the underlying cause had not yet been identified. In humans, acute Q fever is characterized by a febrile "flulike" illness, with headaches, and sometimes pulmonary and hepatic involvement. However, infection is initially asymptomatic in 60% of those infected.[8] Chronic Q fever can follow acute Q fever or asymptomatic infection and can be characterized by cardiac disease (endocarditis, pericarditis, myocarditis), fatigue syndromes, skin rash, and neurologic, pulmonary, and hepatic disease. In avian species, systemic illness has been associated with infection by other *Coxiella*-like organisms.[9-11]

Unlike other obligate intracellular pathogens, *C. burnetii* survives prolonged periods in the environment, where it resists high temperature, a variety of disinfectants, and ultraviolet light. The organism exists in two forms: a small cell variant, which survives in the environment, and a large cell variant, which replicates within cells. Survival of the organism for up to 10 months on wool at 15°C to 20°C (59°F to 68°F) has been reported, and it can also survive in tissues that have been stored in formalin for several months. It is inactivated by 5% hydrogen peroxide.[12] Although originally classified within the order Rickettsiales, the availability of sequence information led to its reclassification as a gammaproteobacterium in the order Legionellales, which also includes *Legionella* species. *C. burnetii* undergoes phase variation, which is associated with alterations in its cell wall components. The variants have nominally been called phase 1 and phase 2.[13] The changes in cell surface antigens and the creation of phase variants has clinical implications for serologic testing due to the production of phase 1 and phase 2 antibodies to the bacterium at different stages of natural infection (see Diagnosis, later). The whole genome of *C. burnetii* has been sequenced.[14]

C. burnetii is extremely contagious, and only small numbers of organisms are required to cause disease in people. The epidemiology of Q fever varies geographically. Because of its predilection for domestic ruminant species, Q fever is most commonly reported from rural areas. *C. burnetii* has been detected within a huge variety of different tick and other arthropod species. Within ticks, it replicates in the midgut and it is shed in large quantities in tick feces. Although ticks have the potential to transmit the organism to domestic animal species, the most significant role of ticks appears to be in transmission to wildlife.[15] *C. burnetii* has been identified in fish, wild birds, rodents, marsupials, horses, swine, camels, marine mammals, ducks, turkeys, geese, cats, dogs, and rabbits. Although the mechanism is not clearly defined, cats and dogs may become infected through exposure to infected sheep, cattle, and goats—possibly through ingestion of unpasteurized milk from these species—and

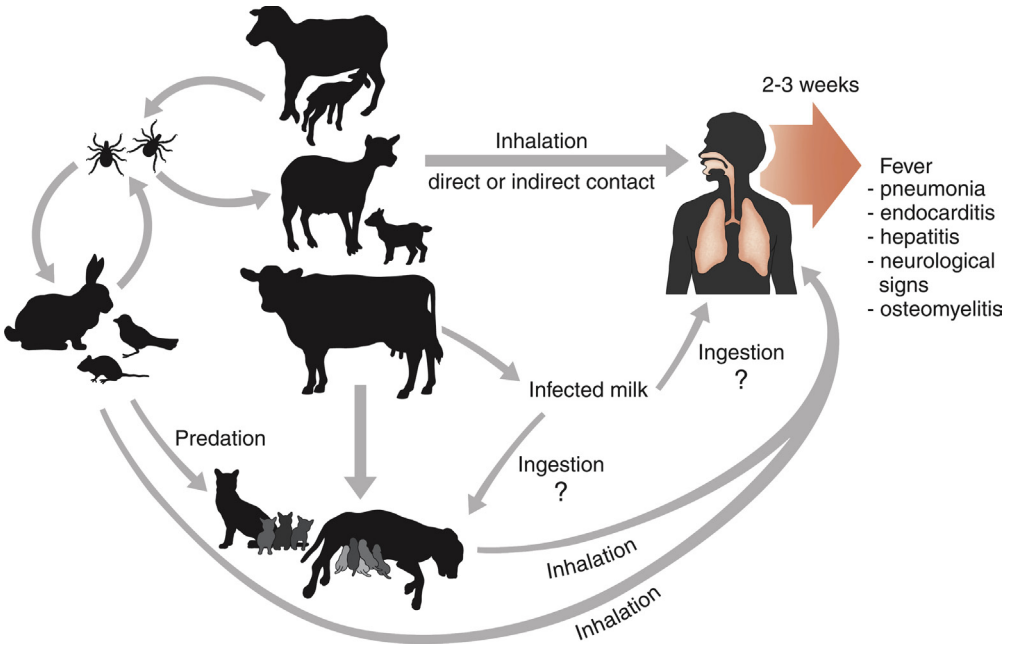

FIGURE 32-1 Transmission of *Coxiella burnetii*. The organism is most often transmitted to humans when animals give birth. People become infected by inhalation when they directly contact the products of parturition or as a result of indirect contact with organisms that survive in the environment. Sheep, cattle, and goats are the most common reservoirs of the organism for human infection, but infected cats and less commonly dogs can also transmit the infection to humans. Ticks also harbor the organism and are thought to maintain transmission to wildlife species, especially rodents (such as small mice) and rabbits, but also birds. Dogs and cats and humans can also become infected when they contact (or ingest) wildlife species. Ingestion of infected milk may be a lesser mode of transmission.

through contact with, or predation of, infected wildlife reservoir hosts such as rodents, birds, and rabbits.

Exposure to stillborn kittens or apparently healthy newborn kittens has been a risk factor for human infection in Africa, Japan, Korea, Canada, and the United States. In a study of intact female cats from Colorado, *C. burnetii* DNA was not detected in vaginal swab specimens or uterine biopsies from 50 shelter cats using a PCR assay, but 4 of 47 uterine biopsies from client-owned cats were positive.[16] Seroprevalence studies suggest that infection is more common in stray cats and dogs than client-owned animals, but further research is required to determine risk factors for exposure in dogs and cats.[17,18] No association has been found between prevalence of Q fever in people and cat or dog ownership.[19] Laboratory-acquired infections have been described in people, and infection can occur as a result of exposure to straw, manure, or dust, such as that from contaminated farm vehicles and contaminated clothing. Q fever has emerged as a disease of U.S. combat arms military personnel who are deployed to Iraq.[20] Studies of a large, 2-year outbreak in the Netherlands showed that dust-accumulating surfaces contained higher levels of *C. burnetii* DNA than vaginal swabs from sheep and goats.[21] The organism can travel for miles as a result of windborne transmission.

Clinical Features

Signs and Their Pathogenesis

After inhalation (and to a lesser extent, ingestion), *C. burnetii* enters mononuclear phagocytes and survives within the harsh environment of the phagolysosome.[22] Remarkably, the acid conditions of the lysosome appear to be a requirement for the metabolic functions of *C. burnetii*. Replication is prolonged, and minimal cytopathic effects occur in infected cells. The organism appears to modulate apoptosis in order to inhibit cell death and promote its own replication.[23] Subsequently, infected cells enter the bloodstream. After experimental infection, bacteremia may be prolonged (up to 1 month) in cats.[24] The organism can persist in a variety of tissues, and in human patients, this contributes to chronic disease manifestations, such as prolonged fever, endocarditis, vasculitis, chronic fatigue, and immune-mediated consequences such as demyelinating polyradiculoneuritis.[25] Appropriate diagnosis and treatment at the acute stage of clinical illness is important in reducing the risk of postacute Q-fever sequelae and development of chronic disease. Reactivation of shedding has been described during pregnancy in humans.[12] Infected cats and dogs usually show no clinical signs of infection, but stillbirth, abortion, and prolonged vaginal bleeding for 3 weeks before delivery have been reported in cats.[4,26] The organism replicates in trophoblasts, and in experimentally infected goats, massive bacterial replication occurs in the placenta just before abortion.[27] An infected rabbit hound dog that transmitted *C. burnetii* to a family in Nova Scotia gave birth to four puppies, all of which died within 24 hours of birth.[5] The importance of *C. burnetii* in reproductive tract disease and chronic disease manifestations such as endocarditis in cats and dogs requires further investigation.

Diagnosis

Microbiologic Tests

Diagnostic assays available for Q fever are listed in Table 32-1.

Culture

C. burnetii can be isolated in a variety of different cell lines. It has also been isolated in a cell-free medium that mimics the phagolysosome environment.[28] Because it is highly infectious

VetBooks.ir

TABLE 32-1

Diagnostic Assays Available for Q Fever

Assay	Specimen Type	Target	Performance
Cell culture	Placental materials, vaginal swabs, blood, urine, feces, milk	*C. burnetii*	Not widely offered or utilized for routine diagnostic purposes. Requires special facilities.
Histopathology	Placental materials	*C. burnetii*	Organisms may be seen when present in large numbers and stain with Gimenez stain. Immunohistochemistry and fluorescence in situ hybridization can be used to identify the organisms as *C. burnetii*.
Serology	Serum	Antibodies to phase 1 or phase 2 *C. burnetii*	Acute and convalescent serology is required for diagnosis of acute infection. At least 1 month may be required for seroconversion. Cross-reactivity may occur to related bacteria. IFA is considered the serologic test of choice in human patients. CFT is the OIE standard in animals but is less sensitive.
PCR	Whole blood, tissue specimens, vaginal swabs, milk, feces	*C. burnetii* DNA	Confirms active infection. Sensitivity and specificity may vary depending on stage of infection, assay design, and specimen type. PCR is most sensitive in acute infections (in the first 2 weeks of illness in humans), but is usually negative in humans with chronic infections. Subclinical shedding in animals is variable but is greatest during parturition.

CFT, Complement fixation test; IFA, immunofluorescent antibody; OIE, World Organization for Animal Health.

to humans, most laboratories do not have the special facilities required to isolate *C. burnetii*. Thus diagnosis of infection is usually performed using immunohistochemistry, serology, or PCR.

Serologic Diagnosis

The World Organization for Animal Health (OIE) reference test for serologic diagnosis of *C. burnetii* infection in animals remains the complement fixation test (CFT),[20] despite the availability of more sensitive serologic tests. A variety of serologic assays have been used to detect antibodies to phase 1 or phase 2 *C. burnetii* antigens in humans and other animals, including immunofluorescent antibody (IFA) assays, ELISA, and the CFT. The CFT is considered the least sensitive and specific method. In human patients, anti–phase 2 antibodies (IgG and IgM) are present in acute Q fever, whereas anti–phase 1 IgG antibodies predominate in chronic infection.[15,29] In humans, the use of IFA assays has been recommended for diagnosis of Q fever.[12] Acute and convalescent serology is required for diagnosis of acute Q fever in people. It can take at least a month before seroconversion occurs; titers peak around 8 weeks after infection.[15] Because infection is usually not clinically detected in dogs and cats, serologic assays have primarily been used in dogs and cats for epidemiologic studies or as part of import requirements to Q fever–free countries such as New Zealand. Low-level cross-reactivity with other bacteria such as *Bartonella* spp. and chlamydiae has been described in some studies, which highlights the need for animal species-specific cutoff values for all serologic methods.[30,31] The concurrent performance of serology for *Bartonella* and *Chlamydia* (i.e., to determine if titers are higher or lower to these organisms than to *Coxiella*) may assist in interpretation of the results.

Molecular Diagnosis Using the Polymerase Chain Reaction

Both conventional and real-time PCR assays have been described for detection of *C. burnetii* DNA. PCR assays are the diagnostic test of choice for organism detection and have revolutionized knowledge of the epidemiology of *C. burnetii* infections. In animals, PCR assays have primarily been used on a research basis. Negative results can occur with PCR assays in chronic infections or even as early as 2 weeks after onset of acute illness in humans, because of undetectable levels of the infection or absence of bacteremia. Because *C. burnetii* is highly infectious to humans, special handling (BSL 3) conditions are required for fresh specimens that are submitted for *C. burnetii* PCR assays (see Table 1-4). When *C. burnetii* is suspected (such as in placentas or aborted material), the laboratory should be contacted in advance, and specimens should be labeled and transported appropriately.

Pathologic Findings

Little information is available about the pathology of *C. burnetii* infection in dogs and cats. In affected livestock, *C. burnetii* causes a necrotizing placentitis with mixed inflammatory cell infiltrate and nonsuppurative vasculitis. In some cases, small, basophilic intracytoplasmic organisms can be seen (Figure 32-2). The organisms stain with Gimenez, Giemsa, and modified acid-fast stains, but not Gram, silver, or periodic acid–Schiff stains.[32] Immunohistochemistry and fluorescent in situ hybridization[33] can be used to identify *C. burnetii* antigen within lesions.

Treatment

Many acute infections in people are self-limiting (or even subclinical), and symptoms respond to nonspecific therapy such as antipyretics and rehydration. However, because of concerns that relate to the development of chronic Q fever, specific antimicrobial therapy is recommended regardless of the severity of acute Q fever. When antimicrobials agents are required, doxycycline for 14 to 21 days, azithromycin for 3 to 5 days,

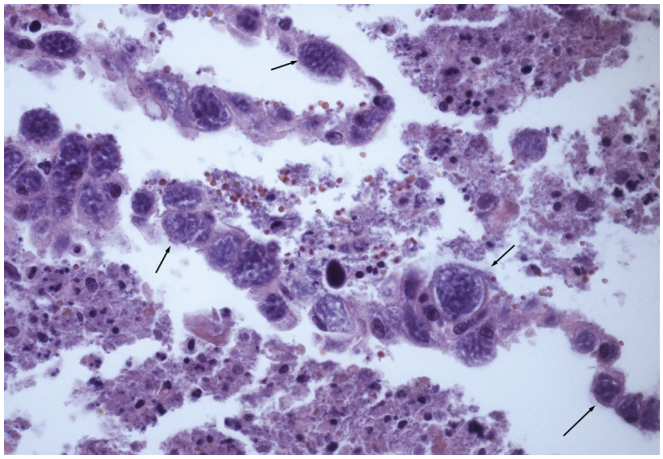

FIGURE 32-2 Histopathology showing severe, acute necrotizing placentitis in the placenta of a goat from which dead fetuses were removed by caesarian section. Trophoblasts are distended with abundant basophilic bacterial organisms *(arrows)*. The organisms were subsequently identified as *Coxiella burnetii* with immunohistochemistry.

or quinolones have been used successfully to treat pneumonia and hepatitis in human patients with *C. burnetii* infection. Combination therapy, such as doxycycline, ciprofloxacin, and rifampin for prolonged periods (e.g., 2 years) or doxycycline and hydroxychloroquine (which alkalinizes phagolysosomes) has been required for treatment of Q fever endocarditis, and valve replacement is frequently needed.[12,15] Antibody titers decrease with successful treatment. Q fever during pregnancy, which may result in abortion when infection occurs in the first trimester, is treated with trimethoprim-sulfamethoxazole for the duration of the pregnancy.[34] Treatment of an infected sheep herd with oxytetracycline on days 100 and 120 of gestation did not prevent shedding of *C. burnetii* in milk, vaginal swabs, or feces as assessed with PCR, nor did it affect the duration of shedding.[35]

Public Health Aspects

In humans, asymptomatic infections with *C. burnetii* are probably widespread. When it occurs, Q fever is most often a systemic febrile illness. Because it mimics a variety of other illnesses, and confirmatory diagnostic tests require a specific index of suspicion by the medical clinician, Q fever is most likely underrecognized. Veterinarians involved in mixed or farm animal practice, slaughterhouse workers, and workers in the livestock industry (farmers, shearers, transporters of animals) are most likely to develop Q fever as a result of direct contact with infected livestock. Person-to-person spread of Q fever is rarely reported, but humans can shed organisms during parturition, and infection of an obstetrician during delivery was described.[36] Transmission during postmortem examinations has also been reported. Between 2005 and 2008, approximately 140 to 170 cases of Q fever were reported to the Centers for Disease Control and Prevention each year, and rates of hospitalization for these cases were around 50%.[37] However, severe cases are more likely to be reported, so actual hospitalization rates are likely much lower. In Australia, 300 to 400 cases are reported annually.[38]

In humans, acute Q fever occurs after an incubation period that ranges from 9 to 39 days, although shorter incubation periods are possible with exposure to high doses of the agent.[12] The incubation period after exposure to an infected cat has ranged from 9 days to 4 weeks.[3,4] Males are predisposed, which relates to an increased likelihood of exposure. Patients who develop pneumonia may also develop severe headache, as well as sweats, chills, fatigue, and myalgia. Other signs include cough, chest pain, nausea and vomiting, sore throat, diarrhea, a rash, and abdominal pain and hematuria.[4] Myocarditis and pericarditis can occur rarely. Blood work often shows a normal white cell count, and thrombocytopenia or marked thrombocytosis can occur. Serum biochemistry testing reveals mild to moderate increases in the activity of hepatic transaminases in almost all patients.[12] Pulmonary infiltrates are present on thoracic radiographs, and in some cases, pleural effusion.[12,15] Q fever pneumonia is rarely fatal. Chronic Q fever may be manifested as endocarditis, optic neuritis, osteomyelitis, granulomatous hepatitis, interstitial pulmonary fibrosis, prolonged fever, and a chronic fatigue syndrome, which has been described in up to 20% of patients who develop acute infection with *C. burnetii*.[39] Endocarditis follows acute Q fever in fewer than 1% of cases,[29] and it may not become apparent for several years after acute illness. Approximately 3% to 5% of human endocarditis cases have been attributed to *C. burnetii*. Host factors seem to be important in whether chronic manifestations of Q fever occur. Cellular immunity and the production of IFN-γ appear to be required for resolution of infection.[29]

Because treatment with tetracyclines does not seem to reduce shedding by reservoir hosts, an emphasis has been placed on the development of effective vaccines for public health purposes. A phase 1 inactivated vaccine (Coxevac) has been used in Europe on an investigational basis to prevent shedding by reservoir livestock species, such as sheep and goats. Vaccination of sheep flocks led to a reduced number of abortions and decreased shedding, but did not completely prevent infection.[29] Vaccination was ineffective in previously infected cattle or naïve pregnant cattle.[40] Another phase 1 whole cell vaccine (Q-VAX, Commonwealth Serum Laboratories, Parkville, Australia) has also been used to protect naïve but at-risk humans, such as livestock workers (farmers, shearers, slaughterhouse workers, animal transporters), veterinarians, and laboratory workers, from infection. A Q-VAX skin test as well as serologic assays are performed as a prescreening of potential vaccine recipients for prior sensitization to Q fever antigens to minimize adverse vaccine reactions; humans with prior exposure to *C. burnetii* should never be vaccinated. It has been recommended that humans not drink raw milk from infected farms. When Q fever is discovered on a farm, sale of milk is forbidden for the year after initial diagnosis. Aborted material and placentas must be buried with lime or incinerated.[29]

CASE EXAMPLE

Signalments: 50-year-old female veterinarian and a 23-year-old female veterinary technician from southeastern Australia

History: A 3-year-old female British shorthair cat with dystocia was brought to a veterinary clinic by the breeder/owner at 8 o'clock in the morning. One kitten was stillborn in the home environment overnight. Safe delivery of the two remaining kittens required a cesarean section. Surgery was performed immediately, and the kittens were delivered and revived by vigorous rubbing with dry towels. The kittens were discolored by yellow-green placental material and were slow to revive. They were able to successfully to suckle once the queen had recovered from general anesthesia. The queen and kittens were returned to the breeder's cattery the same afternoon.

Two weeks after the surgery, the veterinarian and the veterinary technician who had been involved in the cesarean section developed fever, severe headache, neck pain, chills, night sweats, myalgia, and stiffness. The veterinarian sought medical attention. Psittacosis was considered the most likely diagnosis by the attending physician, because psittacine birds were frequently treated in the clinic. A serologic test for chlamydiosis was negative, but nevertheless treatment with doxycycline was commenced. The veterinary technician's clinical signs were more severe and included cough, chest pain, nausea, and vomiting. As a result, she was hospitalized for 3 weeks for further diagnostic testing, treatment, and convalescence. When the technician tested positive by PCR assay for *Coxiella burnetii* DNA on day 10 after the onset of illness, serial diagnostic tests for Q fever were also performed on the veterinarian (Table 32-2).

Comments: Determination of the date of onset of illness is essential in any diagnostic investigation of Q fever in people for correct interpretation of diagnostic test results. In the first 8 to 10 days after the onset of illness, patients are frequently (80%) bacteremic (and therefore PCR positive) but still antibody negative. IgM class antibody to phase 2 antigens, as measured via IFA or ELISA assays, appear as early as 10 to 12 days after the onset of illness, but this may also be delayed, as occurred in the veterinarian in this example. IgM class antibody to phase 1 and IgG class antibody to phase 2 antigens often appear on day 15 to 20, but again this can be delayed. Small animal veterinarians and veterinary technicians or nurses who are exposed to kittens and placental secretions and subsequently develop illness should inform their practitioner of the possibility of exposure to *C. burnetii* because diagnosis requires a high index of suspicion and specific diagnostic assays. Fatigue often persists in patients for months after the onset of illness (as was the case for the veterinary technician in this example) and does not necessarily mean that chronic Q fever has developed.

TABLE 32-2

Results of Diagnostic Assays for Q fever in a Veterinarian and Veterinary Technician after Exposure to an Infected Cat's Reproductive Secretions

Days after the Onset of Illness	Real-Time PCR on Whole Blood		Serology for IgM and IgG to Phase 1 and Phase 2 Antigens*	
	Veterinarian	Technician	Veterinarian	Technician
10	ND	Positive	ND	Negative for IgG and IgM to phase 2 antigen
14	Negative	ND	Negative	ND
20	Negative	Negative	Negative	Positive for IgM to phase 1 and phase 2 antigens, positive for IgG to phase 2 antigen. Positive CFT for antibodies to phase 2 antigen
35	ND	ND	Positive for IgM and IgG to phase 2 antigen. Positive CFT for antibodies to phase 2 antigens	ND

CFT, Complement fixation test; ND, not determined.
*Performed by immunofluorescent antibody unless otherwise specified.

CHAPTER 33

Chlamydial Infections

Jane E. Sykes

VetBooks.ir

Overview of Chlamydial Infections in Dogs and Cats

First Described in Cats: 1944, United States (Baker)[1]

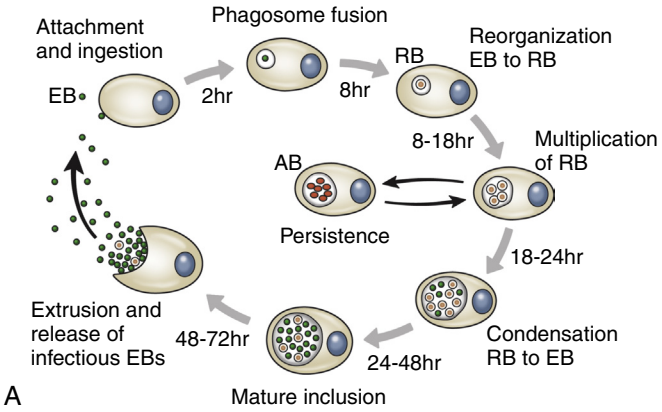
Causes: *Chlamydia felis* (and possibly other chlamydiae such as *Chlamydia pneumoniae*) causes ocular disease in cats; *Chlamydia psittaci* and *Chlamydia abortus* have rarely been detected in association with ocular and respiratory disease in dogs. These are obligately intracellular bacteria that belong to the family Chlamydiaceae.

Geographic Distribution: Worldwide

Mode of Transmission: Direct contact with respiratory secretions and possibly also vaginal secretions and feces

Major Clinical Signs (Cats): Acute and chronic conjunctivitis, chemosis, serous to mucopurulent ocular discharge, and blepharospasm, with or without sneezing and nasal discharge

Differential Diagnoses: The primary differential diagnoses in cats are infections with feline herpesvirus 1, feline calicivirus, *Mycoplasma* spp., and/or *Bordetella bronchiseptica*



Human Health Significance: *C. felis* has rarely been documented as a cause of human conjunctivitis. The importance of cats and dogs as a source of other human chlamydial infections is unclear. *C. psittaci* is generally acquired from avian species and not dogs and cats.

Etiology Agent and Epidemiology

Chlamydiae are obligately intracellular bacteria that belong to the order Chlamydiales. They primarily cause conjunctivitis in cats, but may also play a role in other systemic and reproductive disorders in dogs and cats that remain poorly characterized. Most knowledge of chlamydial infections results from research on human chlamydial pathogens such as *Chlamydia trachomatis*, *Chlamydia pneumoniae*, and *Chlamydia psittaci*, which have significant clinical and public health importance (see Public Health Significance). Chlamydiae structurally resemble gram-negative bacteria, lack peptidoglycan, and have extremely small genomes; they depend on the host cell for many amino acids and nucleotides. They exist in two forms, an infectious elementary body (EB), which is 0.2 to 0.6 µm in diameter and exists outside the cell, and the reticulate body (RB), which is larger (0.5 to 1.5 µm), is noninfectious, and replicates within the cytoplasm of host cells, before it matures and forms EBs (Figure 33-1). The EBs survive only a few days in the environment at room temperature and they are readily inactivated by most disinfectants. Transmission occurs via direct contact or, to a lesser extent, aerosols. Fomites are also likely to be an important means of transmission among group-housed cats in heavily contaminated environments. The chlamydiae at one time were separated into two genera, *Chlamydia* and *Chlamydophila*, based on sequence analysis of the 16S rRNA and 23S rRNA genes. However, there has been disagreement in the field regarding this classification, and reversion to the single genus *Chlamydia* has since been recommended based on the availability of complete genome sequence information.[2]

Chlamydiae persistently infect epithelial cells of the ocular, respiratory, gastrointestinal, and genitourinary systems; chlamydial infections of the synovium have also been reported in a number of different host species. Different chlamydial species tend to associate with certain host species, although evidence has accumulated that some chlamydial species can cause disease in more than one host species (Table 33-1). In addition, more than one chlamydial species can cause similar disease manifestations in a single host species. For example, although the human ocular disease trachoma is caused primarily by *C. trachomatis*, it has now also been associated with infection by *C. pneumoniae* and *C. psittaci*.[3] *Chlamydia felis* is an important cause of conjunctivitis and possibly reproductive disease in cats, but DNA that resembles that of the human pathogen *C. pneumoniae* has now also been detected in ocular swabs from European cats with conjunctivitis.[4] *Chlamydia abortus* DNA was detected in histopathology specimens from 1 of 13 cats with arteriosclerosis.[5] There are rare reports of chlamydial infections in dogs, in association with ocular and respiratory disease, polyarthritis, and atherosclerosis.[6-11] However, chlamydiae were not detected by PCR assay in atherosclerotic lesions from 16 dogs in one study, so the role of chlamydiae in this otherwise rare condition in dogs is uncertain.[5] Respiratory disease associated with *C. psittaci* infection has been reported most frequently among dogs.

The most significant pathogen of cats is *C. felis*, which causes acute and chronic conjunctivitis in cats worldwide. The results of genetic analysis (by multilocus variable-number tandem-repeat and multilocus sequence typing) have revealed that as many as 25 different genotypes of *C. felis* exist, and more than one genotype may circulate in some catteries.[12] Co-infections with more than one strain can occur. The prevalence of infection varies from one group of cats to another and with geographic location, age of the cat population sampled, and presence or absence of clinical illness. Infection occurs most often in multiple-cat households, especially breeding catteries. *C. felis* DNA is uncommonly detected in conjunctival swabs from healthy cats. For example, in clinically healthy household cats, those with a history of past conjunctivitis, and those with active conjunctivitis, 0%, 4.6%,

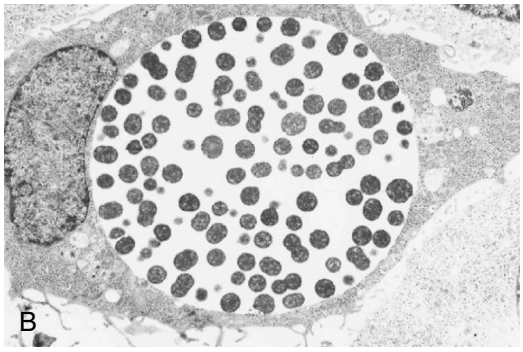


FIGURE 33-1 **A**, Life cycle of chlamydiae. From top left. Electron-dense elementary bodies (EBs) attach to and are taken up by epithelial cells. EBs then differentiate into reticulate bodies (RBs), and RBs divide by binary fission. RBs condense into EBs, and also have the potential to persist in the form of aberrant bodies (AB). EBs are released by cell lysis and infect other cells. **B**, Electron micrograph of chlamydial organisms growing in an inclusion in tissue culture. The larger reticulate bodies (RBs) have more diffuse chromatin. One of the RBs appears to be dividing. The smaller dense bodies are elementary bodies. (B from Mandell GL, Bennett JE, Dolin R. Principles and Practice of Infectious Diseases. Ed 7. Philadelphia, PA: Elsevier, 2012; 2:2440)

and 7.3% had positive PCR assay results, respectively.[13] Isolation rates of up to 30% in household cats with conjunctivitis have been reported.[14] In shelter cats, the prevalence of *C. felis* infection has ranged from 0% to 15%.[15-18] In cats from 218 European rescue shelters, breeding establishments, and private households, the prevalence of infection in cats without respiratory disease was 3%, versus 10% in those with evidence of respiratory disease.[19] Infection with *C. felis* in this European study was associated with suboptimal hygiene. Infection with *C. felis* is more often present in young cats, especially those aged 2 to 12 months; kittens less than 2 months of age may be protected by maternal antibody, although neonatal infections have been described. Cats older than 5 years of age are very unlikely to be infected with *C. felis*. Co-infections with other respiratory pathogens, such as feline herpesvirus 1 (FHV-1) and feline calicivirus (FCV), are common.

The DNA of organisms that belong to the family Parachlamydiaceae has recently been detected in cats with ocular disease. These organisms resemble *Chlamydia* and reside symbiotically within amoebae. Parachlamydial species include *Neochlamydia*, *Parachlamydia*, *Protochlamydia*, *Rhabdochlamydia*, *Criblamydia*, *Simkania*, and *Waddlia* species. DNA that resembles that of *Neochlamydia hartmanellae* has been detected in feline conjunctival brush specimens.[20] This organism is an endosymbiont of the amoeba *Hartmannella vermiformis*, which has been identified as a cause of ocular surface infection in people and may play some role in feline ocular infections. The DNA of *Parachlamydia acanthamoebae* has also been detected with PCR in cats with keratitis and conjunctivitis.[21] As yet, co-infections with amoebae have not been detected in cats. Further studies are required to determine the prevalence and clinical significance of these organisms.

Clinical Features

Signs and Their Pathogenesis

C. felis infection is acquired by cats primarily through close contact, fomites, or to a lesser extent, aerosol transmission. Kittens may be infected from the mother at birth. Whether venereal

TABLE 33-1

Chlamydial Species That Infect Animals and Humans

Species	Major Host(s)*	Major Clinical Manifestations
Chlamydia trachomatis	Humans	Conjunctivitis (serovars A-C); urethritis, cervicitis, proctitis (serovars D-K); lymphogranuloma venereum (serovars L1, L2, and L3)
Chlamydia pneumoniae	Humans	Upper respiratory infection, community-acquired pneumonia, possibly atherosclerosis and asthma
Chlamydia psittaci	Humans, a variety of bird species (e.g., parrots, finches, poultry, pigeons, pheasants, seagulls, egrets, puffins)	Pneumonia, systemic infection
Chlamydia felis	Cats	Conjunctivitis, upper respiratory infection, arthritis?, reproductive disease?
Chlamydia abortus	Sheep, cows, goats, other mammals	Reproductive disease
Chlamydia pecorum	Cattle and sheep	Encephalomyelitis, pneumonia, reproductive tract disease, conjunctivitis, polyarthritis
Chlamydia caviae	Guinea pigs	Keratoconjunctivitis

*Infection may occasionally extend to other host species.

VetBooks.ir

transmission occurs, as reported for other chlamydial species, is unknown, but in some infected cats, the organism is shed in vaginal discharges and from the rectum as well as in ocular discharges. After uptake of EBs, the EB transitions into the RB, which replicates by binary fission in a membrane-enclosed vacuole called an inclusion and avoids lysosomal fusion. The RBs then transition back to the EB form, which is released into the extracellular milieu after cell lysis occurs and subsequently infect other host cells. The entire replication cycle takes about 2 days to complete (see Figure 33-1).[22]

Chlamydiae primarily infect epithelial cells, but they can also infect a variety of other cell types including endothelial cells, smooth muscle cells, lymphocytes, monocytes, and macrophages. *C. felis* replicates in the cytoplasm of conjunctival epithelial cells, but also spreads via the bloodstream to a variety of other tissues, such as the tonsil, lung, liver, spleen, gastrointestinal tract, and kidney.[23] Infection is typically followed 2 to 5 days later by the development of acute, chronic, or recurrent conjunctivitis, with or without signs of rhinitis such as nasal discharge and sneezing. Most cats remain otherwise well and appetent. Lower respiratory tract signs such as cough and dyspnea rarely, if ever, occur. Corneal disease such as keratitis or corneal ulceration is rare and, if present, is likely caused by other or co-infecting pathogens such as FHV-1. Experimental inoculations have also been followed by signs of fever, lethargy, lameness and joint pain (possibly due to polyarthritis), and weight loss, in addition to conjunctivitis.[24] There are also rare reports of gastritis and peritonitis in association with the detection of chlamydia-like organisms in cats.[25,26]

After the initial episode of acute conjunctivitis, infection may persist for many months. This may be accompanied by mild conjunctivitis or, in some cases, no clinical signs of disease. Organisms can be isolated from the conjunctiva for up to 215 days after experimental infection.[27,28] Whether chronic disease is the result of repeated reinfection or the presence of persistent chlamydiae is unclear. Co-infections with other agents such as FCV, FHV-1, *Bordetella,* or *Mycoplasma* may increase the severity of disease and duration of shedding. Other bacteria, including those that normally colonize the healthy conjunctival sac, also act as secondary invaders and worsen disease.

Whether *C. felis* causes reproductive disease in cats remains unclear. The stage of pregnancy at which infection occurs, co-infection with other organisms such as FHV-1, concurrent immunosuppression, route of infection, and the strain involved may be important in determining the ability of *C. felis* to cause reproductive dysfunction, if this indeed occurs in cats.

Chlamydial infections are infrequently described in dogs. *Chlamydia psittaci* has been detected in dogs with respiratory disease, such as pneumonia and pleural effusion, and/or keratoconjunctivitis.[6-8] One group of bitches that had ocular and lower respiratory signs as well as stillbirths and low litter size had nasal, conjunctival, and pharyngeal swab specimens that tested positive for *C. psittaci* with a PCR assay.[6] *Chlamydia abortus* was detected in a dog with keratoconjunctivitis.[9] The DNA of *C. pneumoniae* was detected in atherosclerotic lesions from dogs in Japan,[10] and chlamydia-like organisms were found in a dog from South Africa with polyarthritis.[11]

Physical Examination Findings

Physical examination findings in cats with chlamydiosis include conjunctivitis, chemosis, serous to mucopurulent ocular discharge, and blepharospasm (Figure 33-2). Signs of nasal involvement, such as stertorous respiration, serous or mucopurulent nasal discharge, and sneezing, may accompany conjunctivitis. Mucopurulent vaginal discharge has been reported in some cats that were experimentally infected by topical ophthalmic inoculation.

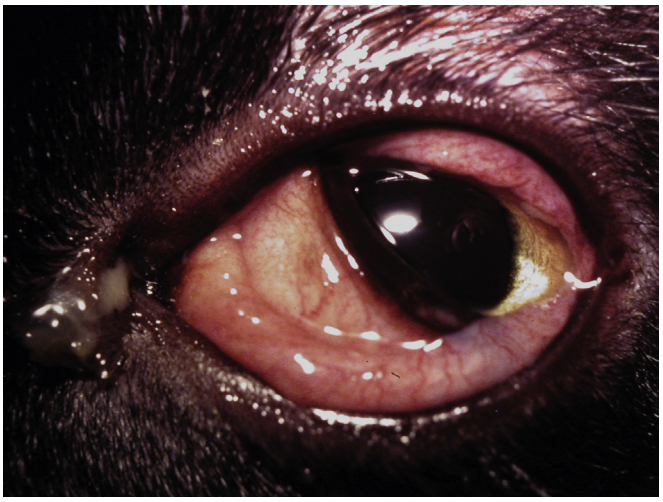

FIGURE 33-2 Domestic shorthair cat with acute chlamydial conjunctivitis. Marked hyperemia and chemosis are present, as well as serous to mucopurulent ocular discharge.

Physical examination findings described in dogs with chlamydiosis have included fever, tachypnea, keratoconjunctivitis with mucopurulent ocular discharge, shifting leg lameness, and lymphadenopathy.[6-9,11]

Diagnosis

There are no clinically significant laboratory abnormalities in cats with chlamydiosis, and there is insufficient information on laboratory abnormalities that might occur in affected dogs. Diagnosis of chlamydiosis is most often based on the results of molecular testing using PCR assays (Table 33-2). For all diagnostic tests that detect chlamydial organisms, sufficient numbers of infected epithelial cells must be collected. This generally involves vigorous swabbing of infected mucosal sites such as the conjunctiva.

Microbiologic Tests

Cytologic Examination for Inclusions

Using light microscopy, chlamydial intracytoplasmic inclusions may be seen in epithelial cells that are present in smears of conjunctival scrapings. Inclusions are made up of basophilic clusters of coccoid bacteria and are up to 10 µm in diameter (Figure 33-3). Giemsa is the preferred staining method. Inclusions are only generally visible early, if at all, during the course of infection, so this method is insensitive. Also, melanin granules in the cytoplasm of conjunctival epithelial cells can yield false-positive results. The use of direct fluorescent antibody staining or immunocytochemical stains that detect *Chlamydia* increases sensitivity and specificity.

Enzyme-Linked Immunosorbent Assay Antigen Detection

A variety of commercial antigen detection enzyme immunoassay kits have been developed and marketed for diagnosis of human chlamydial infections. Nucleic acid amplification tests have now

TABLE 33-2

Diagnostic Assays Available for Chlamydiosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cell culture	Conjunctival swabs	*Chlamydia* spp.	Not widely offered or utilized for routine diagnostic purposes. Requires special chlamydial transport media. False negatives occur when organisms lose viability during transport or in chronic infections, when organism numbers are very low.
Cytology	Conjunctival smears	Chlamydial inclusions	Low sensitivity. Inclusions are most likely to be seen early in infection. False positives can occur when cytoplasmic granules are mistaken for inclusions. Fluorescent or immunoperoxidase antibody techniques may increase sensitivity and specificity.
Serology	Serum	Antibodies to *Chlamydia* spp.	Acute and convalescent serology is required for diagnosis of acute infection. Vaccination may interfere with interpretation of results. Not widely available or utilized worldwide.
PCR	Conjunctival swabs, scrapings, or biopsies	*Chlamydia felis* DNA or *Chlamydia* spp. DNA	Confirms active infection. Assays may be genus or species specific. Sensitivity and specificity may vary depending on assay design and specimen type. Because healthy animals occasionally test PCR positive, positive PCR results must be interpreted in light of the clinical signs. Vaccination with attenuated live chlamydial vaccines has the potential to interfere with results.

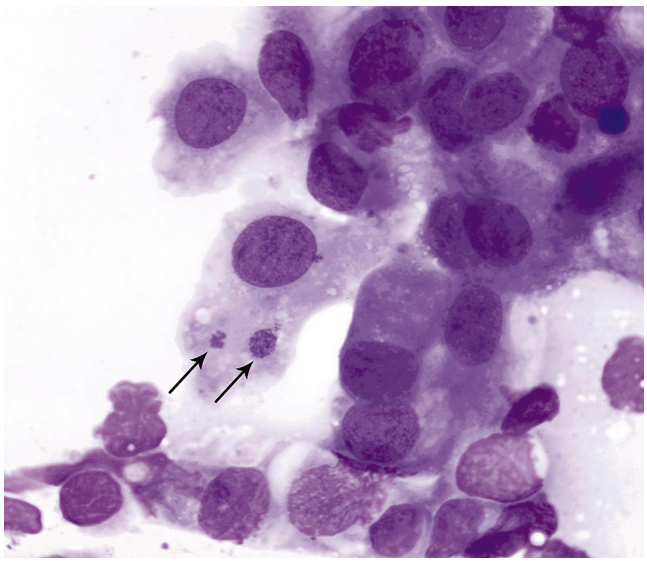

FIGURE 33-3 Conjunctival scraping from a cat with chlamydial conjunctivitis. Inclusions of *Chlamydia felis* are found in an epithelial cell *(arrows)*. Wright's stain, original magnification 1000×. (Courtesy of Judith Taylor, LabVet Consultations, Inc., Guelph, Ontario, Canada and Karen M. Young, University of Wisconsin-Madison. In Young KM, Taylor JJ: Laboratory medicine: yesterday today tomorrow: eye on the cytoplasm, Vet Clin Pathol 35:141, 2006.)

largely replaced the use of these assays for diagnosis of human infections. Antibodies used in ELISA assays that are designed to detect human chlamydial pathogens in swab specimens (such as conjunctival swabs) cross-react with *C. felis* antigen and so have also been used for diagnosis of feline chlamydiosis. Unfortunately, the kits have varied considerably in their sensitivity and specificity. In general, ELISA methods that detect chlamydial antigen have lower sensitivity and specificity than cell culture, direct fluorescent antibody methods, or PCR assays for detection of *C. felis*.

Cell Culture

Cell culture has traditionally been considered the gold standard for chlamydial diagnosis, but is now mostly performed on a research basis. Isolations from cats are usually highest from conjunctival swabs, although nasal and pharyngeal swab specimens may also contain infectious organisms. To enhance organism survival, swabs should be placed immediately in a chlamydial transport medium such as 2SP (0.2 M sucrose and 0.02 M phosphate), which can be obtained from laboratories that perform chlamydial culture. Routine viral transport media should not be used, because it contains antibiotics that inactivate the organisms. The specimen should be refrigerated (4°C) if it is not immediately sent to the laboratory and ideally should reach the laboratory within 24 hours of specimen collection. In the laboratory, organisms are readily grown in the yolk sacs of embryonating eggs or in cell lines such as McCoy or HeLa cells over a period of 2 to 3 days. Fluorescent antibody is then used to identify chlamydial inclusions within the infected cell culture (Figure 33-4).

Molecular Diagnosis Using the Polymerase Chain Reaction

The use of PCR-based assays has revolutionized diagnosis of chlamydial infections in animals and humans, because these assays are rapid, sensitive, and specific and do not require special transport conditions. Sequence analysis of PCR products can be used to differentiate between species of Chlamydiaceae. Both conventional and real-time PCR assays have been used to detect *C. felis* in conjunctival swab specimens from cats,[29-31] and real-time PCR assays that detect *C. felis* are now offered by several commercial veterinary diagnostic laboratories worldwide.

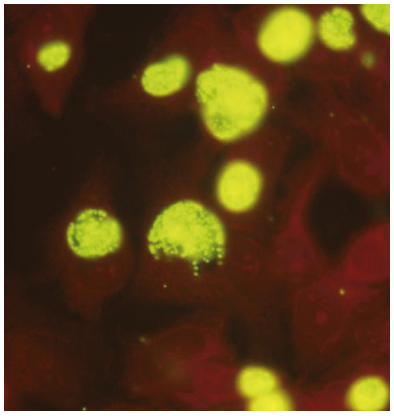

FIGURE 33-4 Chlamydial inclusions stained with fluorescent antibody in a mccoy cell monolayer. (Courtesy of Robert Suchland, Seattle, In Stamm WE, Batteiger BE. Introduction to *Chlamydia* and *Chlamydophila*. In: Mandell GL, Bennett JE, Dolin R, eds. Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases, 7 ed. Philadelphia, PA: Churchill Livingstone Elsevier; 2011.)

Unfortunately, considerable interlaboratory variation in assay performance still exists.[32] In addition, PCR assays for *C. felis* may not detect other chlamydial species, such as *C. pneumoniae*. Genus- or family-specific chlamydial PCR assays must be used to detect these organisms. The laboratory should be consulted to determine the specificity of the assay used. The use of a DNA microarray assay for detection and identification of chlamydiae in cats has also been reported.[5] The microarray assay consists of a chip that carries chlamydial species- and genus-specific probes. DNA within the specimen is first amplified and biotin labeled with PCR, and then reacted with the microarray probes.[33]

PCR assays for *C. felis* are usually more sensitive compared with cell culture for diagnosis of infection in naturally infected cats (see Table 33-1).[29] During antimicrobial treatment of infected cats, PCR assay results continue to be positive for several days.[29,30] Topical ophthalmic solutions such as proxymetacaine and fluorescein did not interfere with the ability of real-time PCR to detect *C. felis*, but there was a slight inhibitory effect when fusidic acid was used.[34] Because cats without signs of conjunctivitis occasionally test PCR positive for *C. felis*, the results of PCR must be interpreted in light of the history, clinical signs present, and response to appropriate treatment.

Serologic Testing

Serologic tests are not widely available for routine diagnosis of chlamydial infections. Assays that detect serum antibodies to chlamydiae, such as IFA or ELISA assays, are of limited benefit for detection of active infection because the IgG antibody titer increase is variable or prolonged, and IgM antibody titers are inconsistently increased. However, very high antibody titers (≥1:512) have been associated with clinical illness and/or chlamydial shedding, and high antibody titers among group-housed cats with conjunctivitis can suggest a role for *C. felis* in disease.[13,23,35] Chlamydial infections persist in the presence of high serum antibody titers, so positive antibody titers after vaccination do not imply protection. Serial titers may be needed to document active infections, and recent vaccination may interfere with interpretation of positive titer results. An ELISA assay that discriminates between the antibody response from vaccination and that from natural infection has been described but is not widely available on a commercial basis.[36]

TABLE 33-3

Suggested Medications for Treatment of Cats with Ocular Chlamydiosis

Drug	Dose	Route	Interval (hours)	Duration
Doxycycline*	10 mg/kg	PO	24	At least 4 weeks, or 2 weeks after resolution of clinical signs
Amoxicillin-clavulanate	12.5	PO	12	4 weeks
Pradofloxacin	5-7.5†	PO	24	6 weeks

*Doxycycline is the treatment of choice. For cats that fail to tolerate doxycycline, amoxicillin-clavulanate should be used. Fluoroquinolones are an option for cats that do not tolerate doxycycline or amoxicillin-clavulanate.

†Dose is for the oral suspension; if tablets are used, the dose is lower (3 mg/kg).

Treatment and Prognosis

Chlamydial infections are generally treated with tetracycline antibiotics. Oral administration of doxycycline at 5 to 10 mg/kg q12h for 3 to 4 weeks results in clinical resolution in most cats. A dose of 10 mg/kg q24h can also be used (Table 33-3).[23] Clinical improvement occurs within 24 to 48 hours after treatment is initiated. In colonies of cats, all cats should be treated for 4 weeks: in one study that used real-time PCR to detect infection, a 3-week course of treatment was insufficient to clear infection in some cats, but treatment for 28 days subsequently cleared infection in all cats.[30] Treatment for up to 6 to 8 weeks may be required. Regardless, treatment should continue for at least 2 weeks after the resolution of clinical signs.

Failure to respond completely to treatment may reflect the concurrent presence of viral upper respiratory tract pathogens. Because administration of doxycycline hyclate can result in esophagitis and esophageal stricture formation, the administration of doxycycline hyclate tablets should be followed by a bolus of water or food (see Chapter 8 for additional information on doxycycline). Ocular infections may initially respond to tetracycline eye ointment applied two or three times daily,[37] but recurrent infections have been documented,[38] likely because systemic infection with chlamydiae can occur in cats with conjunctivitis.

For cats that do not tolerate doxycycline, 4 weeks of amoxicillin-clavulanate is a suitable alternative.[39] In experimentally infected cats, the efficacy of enrofloxacin (5 mg/kg PO q24h for 14 days) was similar to that of doxycycline as determined with direct fluorescent antibody on conjunctival swabs, although a few cats in both the doxycycline and enrofloxacin groups had evidence of persistent infection at the end of the treatment period.[40] Doxycycline is preferred because of concerns that relate to the possibility of retinal toxicity in cats treated with enrofloxacin. Doxycycline was more efficacious than pradofloxacin in experimentally infected cats that were monitored with a PCR assay.[41] Sulfonamides or chloramphenicol are ineffective, and in vitro, penicillin is only inhibitory at higher doses. Treatment with

azithromycin is also incompletely effective when compared with doxycycline.[42]

Immunity and Vaccination

Kittens acquire maternal antibodies to *C. felis* that usually protect them from infection until 7 to 9 weeks of age. Both humoral and cell-mediated mechanisms provide protective immunity in chlamydial infections of other host species. Natural infection seems to confer little protection against reinfection, and this protection appears to be short-lived. However, given the low prevalence of chlamydiosis in older cats, an age-related resistance to chlamydiosis appears to exist. Both inactivated and attenuated live vaccines are available to protect cats from chlamydial respiratory disease. These vaccines do not entirely prevent infection and shedding of chlamydiae after challenge, but they minimize the replication of the organism and hence reduce the severity of clinical signs. Transient fever, anorexia, lethargy, and lameness has been described 1 to 3 weeks after use of combined vaccines containing attenuated live *C. felis* in a low percentage of cats. Chlamydial vaccines are noncore vaccines that are recommended for cats with a high risk of acquiring infection, such as those introduced to or that reside in catteries with documented endemic chlamydiosis. These cats should be vaccinated regularly after initial treatment of all cats with appropriate antimicrobial drugs.

Prevention

Given that chlamydiae survive poorly in the environment and the major route of transmission is close contact, transmission can be minimized by good hygiene, quarantine, single housing, and disinfection practices in cattery situations. Chlamydiae are readily inactivated by detergent solutions.

Public Health Aspects

The most significant chlamydial pathogens of humans are *C. trachomatis*, *C. pneumoniae*, and *C. psittaci*. *C. trachomatis* causes trachoma, the leading cause of infectious blindness worldwide, and it also is the most common bacterial cause of sexually transmitted diseases in humans.[22] *C. pneumoniae* may infect nearly all humans, and is an important cause of community-acquired pneumonia worldwide. It has also been implicated in atherosclerotic cardiovascular disease, although its role in this condition remains unclear. *C. psittaci* causes psittacosis in birds and humans, a potentially life-threatening zoonosis.

C. felis has long been suspected as a cause of conjunctivitis in humans. However, many of the reports of human infection with *C. felis* before the advent of genetic detection methods remain unconfirmed, because diagnosis was based either on culture, without identification to the species level, or on serologic testing, which has the potential to cross-react with other chlamydiae and organisms such as *Bartonella*. More recently, molecular assays have been used to confirm *C. felis* infection in humans. *C. felis* was detected in the conjunctiva of a person with conjunctivitis.[24] The organism was genetically indistinguishable from an isolate later recovered from the patient's cat. Although these associations have been difficult to document, routine precautions should be taken when handling cats with conjunctivitis, especially young cats with chronic conjunctivitis. Proper hand washing and routine cleaning and disinfection are likely to be sufficient to prevent transmission.

The identification of *C. psittaci* in dogs with respiratory disease and *C. pneumoniae* in cats with ocular disease suggests that dogs and cats may have the potential to be a source of these pathogens for humans, although avian species and other infected people, respectively, are likely to be much more significant sources of infection.

CASE EXAMPLE

Signalment: "Sam," a 3-year-old male neutered domestic shorthair cat from Davis, CA

History: Sam was brought to the University of California, Davis, by a veterinary student for evaluation of fever, right thoracic limb lameness, and bilateral conjunctivitis with mucopurulent ocular discharge of 2 days' duration. No coughing, sneezing, vomiting, diarrhea, or abnormal thirst or urination had been noted. Sam lived indoors with 5 other cats, 3 of which had also had severe conjunctivitis, ocular discharge, fever, lethargy, and lameness for the last week. These 3 cats ranged from 8 months to 2.5 years of age. All of the cats had been vaccinated regularly for FHV-1, FCV, and feline panleukopenia virus and tested retrovirus-negative as kittens. They were all fed a commercial dry cat food.

Physical Examination:

Body Weight: 6.7 kg

General: Bright, alert and responsive, hydrated. T = 103.6°F (39.7°C), P = 240 beats/min, respiratory rate 66 breaths/min, mucous membranes pink, CRT = 1 s.

Eyes, Ears, Nose, and Throat: There was no evidence of ocular discharge, but mild conjunctival hyperemia was present. The nasal planum was clean and moist with no discharge; no oral erosions or ulcerations were seen.

Musculoskeletal: Body condition score 7/9. Decreased weight bearing on the left thoracic limb was noted, and the cat sometimes held his left thoracic limb up when sitting. There was possible mild effusion in the left elbow and resentment on flexion of the left carpus and both elbows.

All Other Systems: No clinically significant abnormalities were detected.

Laboratory Findings:

CBC:

HCT 46.3% (30%-50%)
MCV 46.9 fL (42-53 fL)
MCHC 30.7 g/dL (30-33.5 g/dL)
WBC 10,500 cells/μL (4500-14,000 cells/μL)
Neutrophils 7455 cells/μL (2000-9000 cells/μL)
Lymphocytes 2310 cells/μL (1000-7000 cells/μL)
Monocytes 525 cells/μL (50-600 cells/μL)
Eosinophils 210 cells/μL (150-1100 cells/μL)
Basophils 0 cells/μL (0-50 cells/μL)
Platelets 174,000/μL (180,000-500,000 platelets/μL), with moderate macroplatelets.

VetBooks.ir

Serum Chemistry Profile:
Sodium 152 mmol/L (151-158 mmol/L)
Potassium 4.4 mmol/L (3.6-4.9 mmol/L)
Chloride 117 mmol/L (117-126 mmol/L)
Bicarbonate 18 mmol/L (15-21 mmol/L)
Phosphorus 4.0 mg/dL (3.2-6.3 mg/dL)
Calcium 9.5 mg/dL (9.0-10.9 mg/dl)
BUN 21 mg/dL (18-33 mg/dL)
Creatinine 1.6 mg/dL (1.1-2.2 mg/dL)
Glucose 151 mg/dL (63-118 mg/dL)
Total protein 7.1 g/dL (6.6-8.4 g/dL)
Albumin 3.1 g/dL (2.2-4.6 g/dL)
Globulin 4.0 g/dL (2.8-5.4 g/dL)
ALT 48 U/L (27-101 U/L)
AST 8 U/L (17-58 U/L)
ALP 31 U/L (14-71 U/L)
Gamma GT 0 U/L (0-4 U/L)
Cholesterol 154 mg/dL (89-258 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.055; pH 6.5, trace protein, no hemoprotein, glucose, ketones or bilirubin, 0-1 WBC/HPF, 0-2 RBC/HPF, few lipid droplets.

Synovial Fluid Cytology: Synovial fluid from the right stifle, right carpus, left carpus, and right tarsus was examined. All specimens apart from that from the left carpus were markedly blood contaminated and so could not be properly evaluated. The cell counts in those specimens ranged from 2000 to 4000 nucleated cells/μL and consisted predominantly of neutrophils (66%-80%) and small mononuclear cells (7%-18%). The specimen from the left carpus had 2000 nucleated cells/μL, of which 14% were neutrophils, 85% large mononuclear cells, and 1% small mononuclear cells. There were moderate numbers of erythrocytes and blood-associated leukocytes, as well as low numbers of large mononuclear cells of normal morphology, which was consistent with mild blood contamination.

Conjunctival Smear Cytology: Chlamydial inclusions were visualized within several epithelial cells.

Imaging Findings: Radiographs of the left radius and ulna, including carpus and elbow joints: no radiographic abnormalities.

Microbiologic Testing: FeLV antigen and FIV antibody serology: negative
PCR for FCV (oropharyngeal swab specimens): negative
Mycoplasma culture (conjunctival swab specimen): negative

Diagnosis: A tentative diagnosis of chlamydial conjunctivitis and arthritis was made.

Treatment and Outcome: Treatment of all cats in the household with doxycycline (10 mg/kg PO q24h) was initiated. This was associated with rapid resolution of fever, ocular signs, and lameness.

Comments: The cats in this household had conjunctivitis and possibly arthritis in association with chlamydial infection. The major differential diagnosis was FCV infection, which is more widespread than chlamydiosis and for which an association between lameness and infection has been described. Infection with *Mycoplasma* spp. has also been associated with conjunctivitis as well as synovitis in cats (see Chapter 40). Lameness has developed in cats that were experimentally infected with *C. felis*, but there are no reports of lameness in association with natural infection. The negative PCR and culture results for FCV and *Mycoplasma* spp., respectively, could not definitively rule out infection with these agents. The presence of chlamydial inclusions in the conjunctival smear supported a diagnosis of chlamydiosis, but false positives can occur, and unfortunately PCR was not performed to confirm the presence of a chlamydial agent. Nevertheless, the rapid response to doxycycline supported the possibility of a bacterial cause of the arthritis. Interestingly, thrombocytopenia was present (and confirmed on smear evaluation), which has been reported in humans with chlamydial infections.[43]

CHAPTER 34

Streptococcal and Enterococcal Infections

Jane E. Sykes

VetBooks.ir

Overview of Streptococcal and Enterococcal Infections

First Described: Streptococci were first described in Germany in 1868 by Billroth.[1] Enterococci were separated from the genus *Streptococcus* in 1984.[2]

Major Causes: In dogs and cats, the most common causes are *Streptococcus canis*, *Streptococcus equi* subsp. *zooepidemicus, Enterococcus faecium,* and *Enterococcus faecalis,* which are gram-positive coccoid bacteria

Geographic Distribution: Worldwide

Mode of Transmission: Direct contact. Organisms are usually commensals that invade opportunistically.

Major Clinical Signs: Neonatal septicemia, pharyngitis, cervical lymphadenitis, bacteremia and endocarditis, urinary tract infections, postoperative incision or wound infections, otitis externa, keratitis, bronchopneumonia, pyometra or metritis, meningoencephalitis, necrotizing fasciitis and toxic shock syndrome (primarily *S. canis*), rhinitis and necrotizing sinusitis, pyothorax, discospondylitis, arthritis, osteomyelitis, mastitis, cholangiohepatitis, and peritonitis

Differential Diagnoses: Primarily other gram-positive and gram-negative bacterial infections

Human Health Significance: Streptococcal species that infect dogs and cats occasionally infect human patients. Dogs and cats may also have the potential to serve as sources of multidrug-resistant enterococcal infections for humans.

Etiology, Epidemiology, and Clinical Features

Streptococci are catalase-negative, gram-positive cocci that divide along a single axis, forming pairs and chains of organisms (Figures 34-1 and 34-2). They are facultative to strict anaerobes that require complex media for growth, preferably supplemented with blood. More than 40 species of streptococci have been described. Species of streptococci vary in host tropism and virulence properties, and so it is important that they be discussed separately. One of the most important streptococcal pathogens of humans, *Streptococcus pyogenes*, which causes streptococcal pharyngitis ("strep throat"), does not infect dogs and cats to a significant degree (see Public Health Aspects). However, interspecies transmission has been reported for some pathogenic streptococci such as *Streptococcus pneumoniae* and *Streptococcus equi* subsp. *zooepidemicus*. As is the case in humans, streptococci that infect dogs and cats range from commensals of low virulence through to highly virulent organisms that can cause severe disease manifestations and death.

Streptococci have been classified based on their hemolytic properties into β-hemolytic streptococci, which cause complete hemolysis when they grow on blood agar; γ-hemolytic or nonhemolytic streptococci, which do not cause hemolysis; and α-hemolytic streptococci, which reduce hemoglobin, causing a greenish discoloration of the agar around bacterial colonies. Streptococci are also classified from A through W based on their surface antigens (Lancefield classification system) and classified based on phenotypic characteristics (such as pyogenic or viridans group streptococci). Major pathogenic streptococci of dogs and cats belong to Lancefield groups B, C, D, or G (Table 34-1). Pyogenic streptococci are β-hemolytic streptococci that belong to Lancefield groups A *(S. pyogenes)*, B *(Streptococcus agalactiae)*, C (which includes *Streptococcus dysgalactiae* and *S. equi* subsp. *zooepidemicus*), and G (which includes *Streptococcus canis*). Viridans streptococci are often nonhemolytic or α-hemolytic (*viridis* = Latin for green) and tend to be commensals that have low virulence and rarely invade tissues opportunistically. Many group D streptococci have now been classified as enterococci. Molecular typing schemes have revealed that hemolytic reactions, Lancefield antigens, and phenotypic characteristics do not necessarily predict genetic relatedness among

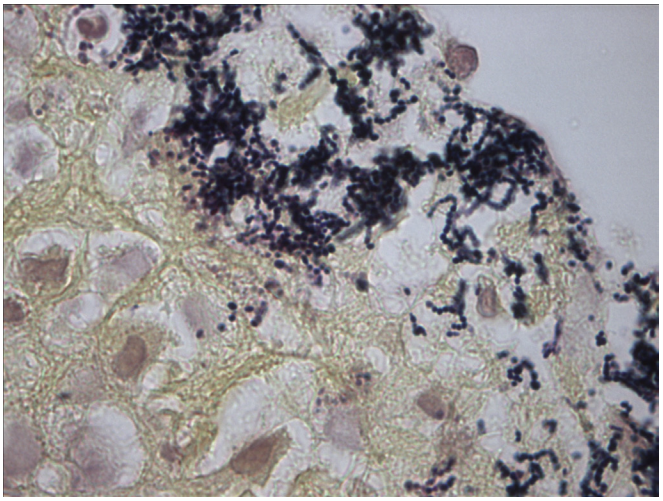

FIGURE 34-1 Histopathology of the serosal surface of the liver of a 12-day-old domestic shorthair kitten that was euthanized after it was found hypothermic and tachypneic. Severe suppurative omphalophlebitis and peritonitis was present. Lesions contained numerous chains of gram-positive cocci. Brown and Benn stain, 1000× oil magnification.

streptococcal strains. Nevertheless, these traditional classification methods are still used by laboratory staff, microbiologists, and clinicians to describe streptococci.

Streptococci invade tissues opportunistically when there is a breach in normal host barriers. This leads to a variety of clinical disease manifestations, such as pyoderma, pneumonia, endocarditis, arthritis, osteomyelitis, meningoencephalitis, cellulitis, and urinary tract infections (UTIs). Severe and life-threatening manifestations of streptococcal infection include necrotizing fasciitis (NF) and streptococcal toxic shock syndrome (STSS). Predisposing conditions for streptococcal infections in dogs and cats may include atopic dermatitis, wounds, foreign bodies (such as migrating grass awns), immunosuppressive drug treatment, and young age (especially neonates).[3] The most common clinical presentation among fetuses and neonates is streptococcal bacteremia and sepsis, which can result in abortion and death. Streptococcal pneumonia may occur in association with infections with other respiratory pathogens, such as respiratory viruses, or occur secondary to bronchitis, hematogenous spread or aspiration. In one study, streptococci were isolated from sick dogs more frequently in summer months.[3]

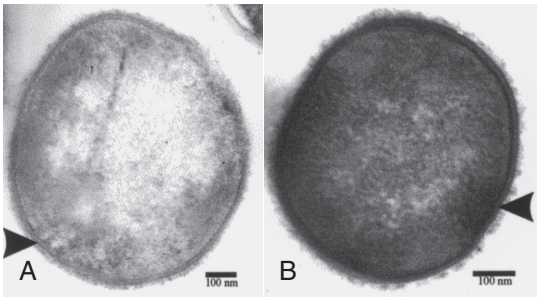

FIGURE 34-2 Electron micrograph of *Streptococcus pyogenes* **(A)** and *Streptococcus canis* **(B)**. Proteinaceous cell surface fibrillae are present on *S. canis* that resemble the M-protein surface fibrils of the human pathogen *S. pyogenes*. M-protein is a key virulence factor of *S. pyogenes*. (From DeWinter LM, Low DE, Prescott JF. Virulence of *Streptococcus canis* from canine streptococcal toxic shock syndrome and necrotizing fasciitis. Vet Microbiol 1999;70:95-110.)

Streptococcus canis

S. canis is the most frequently isolated streptococcus from dogs and cats.[3] It is a β-hemolytic, group G (pyogenic) streptococcus that colonizes the skin, genital, and gastrointestinal tracts of healthy dogs and cats. It has also been isolated from other animal species, such as rats, mice, rabbits, mink, and foxes. Infection with *S. canis* may be associated with neonatal bacteremia, pharyngitis, cervical lymphadenitis, infective endocarditis, UTIs, postoperative incision or wound infections, otitis externa, keratitis, bronchopneumonia, pyometra or metritis, meningoencephalitis, NF, STSS, rhinitis and necrotizing sinusitis, pyothorax, discospondylitis, arthritis, osteomyelitis, mastitis, cholangiohepatitis, and peritonitis. Neonatal infections can occur when organisms are transmitted from the vaginal tract during parturition. The organism can then gain access to the systemic circulation via the umbilical vein. Streptococcal meningitis results from direct extension from the sinuses or middle ear, or from bacteremia. Other embolic complications may accompany bacteremia with group G streptococci. Although opportunistic infections with *S. canis* occur sporadically, outbreaks of group G streptococcal infection have been reported in group-housed animals, which suggested spread of a virulent strain.[4-6]

Severe manifestations of *S. canis* infection, such as STSS and NF, have been increasingly described in dogs and cats in recent years, sometimes in the absence of obvious immunosuppressive underlying conditions or wounds.[6-9] Although toxic shock syndrome can also be caused by staphylococci, STSS is defined as any streptococcal infection associated with the sudden onset of shock and organ failure. Mechanisms of shock and organ failure identified in human group A streptococcal infections include elaboration of pyrogenic exotoxins by streptococci, which act as superantigens. Superantigens stimulate T cell responses through their ability to bind to, and cross-link, the MHC class II complex of antigen-presenting cells, and the T cell receptor, which bypasses normal MHC-restricted antigen processing. This leads to sudden and massive cascade of cytokine release, which in turn causes signs of fever, vomiting, and hypotension, together with tissue damage, disseminated intravascular coagulation

TABLE 34-1

Classification of Streptococci Isolated from Dogs and Cats

Species	Lancefield Antigen(s)	Hemolytic Reactions	Comments
S. canis	G	β	Most common. Dogs and cats are natural hosts. Causes a variety of clinical syndromes. Primary cause of streptococcal toxic shock syndrome and necrotizing fasciitis in dogs and cats.
S. equi subsp. *zooepidemicus*	C	β	Causes pneumonia and sinusitis, primarily in group-housed animals. Has also been associated with meningitis.
S. dysgalactiae	C	β	Uncommon. Has been isolated from dogs with septicemia, dermatitis, or pneumonia.
S. bovis group (*S. gallolyticus* and *S. infantarius*)	D	α or γ	Uncommon. Has been isolated from dogs with urinary tract infections and endocarditis.
S. agalactiae	B	β or γ	Rare. Isolated from dogs and cats with endocarditis and neonatal septicemia.

(DIC), and multiple organ dysfunction.[10] Other streptococcal virulence factors also contribute to proinflammatory cytokine release and the development of hypotension. Laboratory abnormalities include thrombocytopenia, azotemia, hypoalbuminemia, and metabolic acidosis. Death can occur within 48 hours after the onset of illness. Specific criteria are used for diagnosis of STSS in human patients, and similar definitions could be used for diagnosis of STSS in dogs and cats (Box 34-1). Because only a few dogs and cats with STSS have been described, predisposing factors have not been clearly identified. Predisposing conditions in humans include diabetes mellitus, alcoholism, surgical procedures, penetrating and nonpenetrating trauma, viral infections such as varicella, and possibly the use of nonsteroidal antiinflammatory drugs.

NF is a bacterial infection of the deep subcutaneous tissues and fascia, characterized by extensive necrosis and gangrene of the skin and underlying tissues. NF often begins as a minor wound and progresses rapidly over 24 to 72 hours, and it may be accompanied by STSS (Figure 34-3). The popular term "flesh-eating bacteria" has been used to describe the organisms involved. Streptococcal NF has been described in both dogs and cats. Lesions usually involve a limb and are intensely painful, with localized heat and swelling and accumulation of exudate along fascial planes that requires drainage and debridement. In some dogs, extensive sloughing of necrotic skin occurs.[9] Necrotizing myositis, bacteremia, and septic emboli may accompany NF.[8] Outbreaks of NF, arthritis, sinusitis, and meningitis caused by *S. canis* have been reported in cats in shelters[5] and breeding colonies.[11] Molecular typing (by pulsed-field gel electrophoresis) of isolates from one outbreak revealed that isolates were clonally related, which indicated spread of a virulent strain.[12]

Despite the recognition of severe disease manifestations in some dogs and cats, relatively little is known about virulence factors of *S. canis*. A protein analogous to M protein, a major virulence factor of *S. pyogenes*, has been identified in *S. canis* and was shown to bind plasminogen and degrade thrombi.[13] M protein has important antiphagocytic properties. Genes that encode M protein and a streptococcal hemolysin, streptolysin O, have been detected in *S. canis* isolates from dogs with NF and STSS.[14] Genes that encode other virulence factors identified in *S. pyogenes*, such as pyrogenic exotoxins (Spe genes),

BOX 34-1

Criteria Used for Diagnosis of STSS in Human Patients, with Suggested Modifications for Diagnosis of STSS in Dogs and Cats*

I Isolation of Group G streptococci (*Streptococcus canis*)

A. From a normally sterile site
B. From a nonsterile site

II Clinical signs of severity

A. Hypotension: systolic blood pressure <90 mm Hg in dogs and <80 mm Hg in cats
and
B. Two or more of the following signs:
   1. Renal impairment: creatinine above the upper limit of the reference range
   2. Coagulopathy: thrombocytopenia or DIC (prolonged clotting times, low serum fibrinogen concentration, and increased fibrin degradation products)
   3. Liver involvement: serum AST, ALT, or total bilirubin levels at least twice the upper limit of the reference range
   4. Acute respiratory distress syndrome defined as acute onset of diffuse pulmonary infiltrates and hypoxemia in the absence of cardiac failure, or evidence of diffuse capillary leak manifested as acute onset of pulmonary edema, or pleural or peritoneal effusions with hypoalbuminemia
   5. A generalized erythematous macular rash that may desquamate
   6. Soft tissue necrosis, including necrotizing fasciitis or myositis, or gangrene

*An illness that fulfills criteria IA and II is defined as a definite case. An illness that fulfills criteria IB and II is defined as a probable case if no other cause for the illness is identified.

DIC, disseminated intravascular coagulation; STSS, streptococcal toxic shock syndrome.

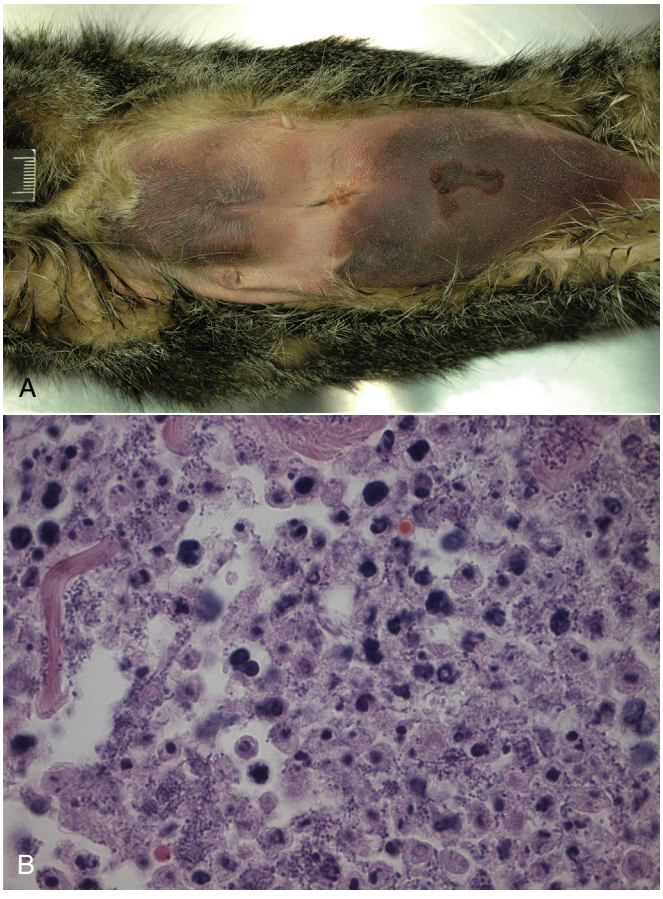

FIGURE 34-3 **A,** Two-year-old female spayed domestic shorthair that was euthanized with necrotizing cellulitis, myositis and fasciitis, and peritonitis that developed after an ovariohysterectomy site became infected with *Streptococcus canis*. **B,** Histopathology showed severe necrotizing cellulitis, myositis, and cellulitis with intralesional cocci that sometimes formed chains. H&E stain, 1000× oil magnification. (Courtesy of the University of California, Davis, Veterinary Anatomic Pathology Service.)

VetBooks.ir

streptococcal superantigen (SSA), streptokinase (Ska), and C5a peptidase (Scp, which cleaves the fifth component of complement) have not been detected.

Streptococcus equi subsp. *zooepidemicus*

S. equi subsp. *zooepidemicus* is a β-hemolytic, group C streptococcus that is a commensal of the upper respiratory and lower genital tracts of horses, and appears to be an emerging pathogen of dogs and cats. Opportunistic infections such as wound infections, respiratory disease, endometritis, and abortion occur in horses. Infections have also been reported in a variety of other animal species, including cattle, sheep, pigs, monkeys, seals, ruminants, dogs, cats, and humans. Different strains of *S. equi* subsp. *zooepidemicus* exist that may vary in pathogenicity and host tropism. Infected horses may have been a source of infection for dogs in some situations,[15,16] but in other situations where infected dogs and cats have been identified, a history of horse contact was not present.

Several outbreaks of hemorrhagic, fibrinosuppurative, and necrotizing pneumonia associated with *S. equi* subsp. *zooepidemicus* infection have been described in group-housed dogs, such as those in kennels and shelter environments, from a variety of geographic locations worldwide (Figure 34-4).[17] The pneumonia progresses rapidly in some dogs can be accompanied by signs suggestive of STSS, such as fever and systemic hypovolemia. In some dogs, severe tachypnea and death occurs within 48 hours of the first signs of respiratory disease, and dogs may be found dead without any preceding clinical signs. Other infected dogs show only mild signs of respiratory disease. *S. equi* subsp. *zooepidemicus* bacteremia and sepsis has been reported in racing greyhounds.[18] Chronic lymphoplasmacytic rhinitis, sometimes with turbinate lysis, has also been described in several dogs in association with *S. equi* subsp. *zooepidemicus* infection, which resolved after specific antimicrobial treatment.[15,16] Outbreaks of pneumonia, purulent rhinosinusitis, and meningoencephalitis have been described in cats.[19,20] *S. equi* subsp. *zooepidemicus* meningoencephalitis occurred in a cat as a result of extension of otitis media/interna.[21]

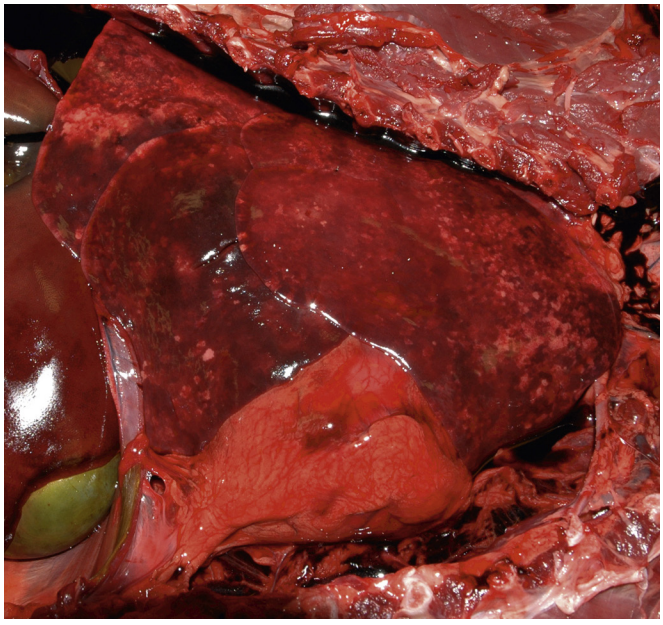

FIGURE 34-4 Pneumonia in a shelter dog caused by *Streptococcus equi* subsp. *zooepidemicus*. The lungs are consolidated and dark red. (Courtesy of Dr. Patricia Pesavento, University of California, Davis.)

The pathogenesis of infection with *S. equi* subsp. *zooepidemicus* in dogs and cats is unclear. Co-infection with other contagious respiratory pathogens can contribute to the severity of disease. Co-infections with canine distemper virus (CDV), canine adenovirus-2 (CAV-2), canine herpesvirus-1 (CHV-1), canine influenza virus (CIV), *Bordetella bronchiseptica*, or *Mycoplasma cynos* have been documented in some, but not all, affected dogs with *S. equi* subsp. *zooepidemicus* pneumonia. Experimentally, co-infection of dogs with both CIV and *S. equi* subsp. *zooepidemicus* is associated with more severe clinical manifestations of disease than when either organism is inoculated alone.[22] Other environmental factors such as overcrowding may also contribute to stress and severe disease manifestations. Superantigen genes have been detected in some isolates of *S. equi* subsp. *zooepidemicus* from dogs,[23,24] but there has been no correlation between the presence of these genes and the severity of histopathologic lesions. However, expression of proinflammatory cytokines such as TNF-α, Il-6, and Il-8 in the lungs of affected dogs suggests that a potent inflammatory response is involved in the pathogenesis of disease.[23]

Other Streptococcal Species

Like *S. equi* subsp. *zooepidemicus, S. dysgalactiae* is a β-hemolytic, group C streptococcus. There are two subspecies, *S. dysgalactiae* subsp. *equisimilis* and *S. dysgalactiae* subsp. *dysgalactiae*. After *S. canis* and *S. equi* subsp. *zooepidemicus, S. dysgalactiae* subsp. *equisimilis* was the third most common β- or γ-hemolytic streptococcal species isolated from dogs at a veterinary teaching hospital in the United States, and was detected in 13 (3.3%) of 393 dogs with streptococcal infections. Affected dogs had bacteremia and sepsis, dermatitis, or pneumonia.[3] *S. dysgalactiae* subsp. *dysgalactiae* has been reported in association with systemic neonatal infections and death in a litter of great Dane puppies.[25]

The porcine streptococcus, *Streptococcus suis*, has been isolated from cats with meningoencephalitis, pyothorax, or dermatitis.[26,27] *S. suis* was also isolated from the urine of a systemically unwell dog in Canada[28] and can be isolated from the tonsils, anus, and skin of healthy dogs and cats.[29] Although contact with pigs was not reported in the sick dogs and cats, the dog was fed commercial pig ear treats. *S. suis* has been classified into serotypes, which have epidemiologic importance. Human infections are usually serotypes 2 and 14. The cases reported in dogs and cats have not belonged to these serotypes.

Other streptococcal species isolated from dogs and cats include the human pathogen *Streptococcus constellatus* (a *Streptococcus anginosus* group organism), which was isolated from a dog with pyoderma;[30] and group B streptococci *(S. agalactiae)*, which have been isolated from dogs and cats with streptococcal disease such as endocarditis and neonatal sepsis. Group B streptococci are important causes of puerperal sepsis and neonatal sepsis and meningitis in humans, as well as mastitis in cattle.

Streptococcus bovis Group (*Streptococcus gallolyticus* and *Streptococcus infantarius*)

Streptococcus bovis group organisms are α- or nonhemolytic and usually possess Lancefield group D antigens. Biotypes that belong to this group, which differ in their biochemical characteristics, have now been reclassified as distinct species, *Streptococcus gallolyticus* and *Streptococcus infantarius*.[31] *S. bovis* group organisms

VetBooks.ir

are commensals of the gastrointestinal tracts of humans and other animals, especially ruminants. They are important causes of bacteremia and endocarditis in humans, accounting for 11% to 17% of all endocarditis cases. They frequently affect multiple valves and are associated with embolic complications. For unknown reasons, fecal carriage of *S. bovis* group organisms by humans has been strongly associated with colorectal cancer. This especially seems to be true for *S. gallolyticus* subsp. *gallolyticus*.[32] Rarely, *S. bovis* group organisms are isolated from dogs and cats with UTIs. They have also been isolated from the blood of dogs with mitral valve endocarditis, one of which also had sternebral osteomyelitis.[33,34]

Enterococcus spp.

Enterococci are α- or nonhemolytic gram-positive bacteria that usually possess Lancefield group D antigens, are commensals of the gastrointestinal tracts of humans and other animals, and are important nosocomial pathogens. They form pairs or short chains of organisms and cannot morphologically be discriminated from streptococci. Enterococci survive harsh environmental conditions; they grow in medium that contains 6.5% NaCl, can grow at temperatures that range from 10°C to 45°C (50°F to 113°F), and hydrolyze esculin in the presence of 40% bile salts. The genus *Enterococcus* was separated from *Streptococcus* in the mid-1980s based on the results of DNA hybridization experiments.[35]

Enterococci are often resistant to a wide variety of different antimicrobial drug classes, and multiple drug resistant (MDR) enterococcal infections, especially those that are also resistant to vancomycin (vancomycin-resistant enterococci or VRE), are a significant problem in human medicine. Of great clinical importance, resistance among enterococci occurs as a result of both intrinsic and acquired resistance mechanisms. Intrinsic resistance to low levels of most β-lactam antimicrobials occurs because enterococci possess low-affinity penicillin binding proteins (PBPs). Thus penicillins are generally bacteriostatic, not bactericidal, against enterococci. Enterococci also have low-level intrinsic resistance to aminoglycosides, which results from decreased drug uptake. However, uptake of aminoglycosides is enhanced when enterococci are exposed to β-lactams, which explains the synergistic activity of this combination. Enterococci are resistant to trimethoprim-sulfamethoxazole because they utilize exogenously produced folate. Thus, even if the organisms appear sensitive to trimethoprim-sulfamethoxazole in vitro (when exogenous folate is lacking), the drug is not effective in vivo. Many laboratories therefore do not report minimum inhibitory concentrations for this organism-drug combination. Enterococcal resistance to other antimicrobials, such as macrolides and vancomycin, can result from acquired resistance mechanisms. Extensive multidrug resistance has been well documented in enterococci isolated from dogs and cats, but there are only a few reports of enterococci with acquired vancomycin resistance from dogs in the literature. These have been from the United Kingdom, New Zealand, and the United States.[36-38] All other isolates examined have been vancomycin susceptible. In contrast, VRE account for about 30% of enterococcal infections in humans from Europe and North America.[39]

Clinical microbiology laboratories often do not differentiate between *Enterococcus* species, because definitive identification can require genetic typing. Some laboratories use biochemical methods to identify *Enterococcus faecalis* and *Enterococcus faecium,* which are the most prevalent species in humans and which differ in their epidemiology, antimicrobial susceptibility, and virulence properties. *E. faecium* is more likely to show high-level resistance to penicillins and carbapenems than *E. faecalis*, and as a result, in humans, the prognosis for serious *E. faecium* infections may be worse than that for *E. faecalis* infections.[40] However, *E. faecalis* is more likely to produce biofilms than *E. faecium*.[41] Although most infections in humans have been *E. faecalis,* a worrisome increase in the prevalence of MDR *E. faecium* infections has occurred. In particular, ampicillin- and fluoroquinolone-resistant *E. faecium* strains that belong to hospital adapted strains known as clonal complex 17 (CC17) have emerged. CC17 isolates have been found in dogs, but their virulence gene profile and antimicrobial susceptibility profiles have differed from those of human isolates.[42]

In healthy dogs and cats, enterococci can be found on the skin and within the oral cavity, nasal cavity, and gastrointestinal tract. In the United States, the most prevalent species in dogs appears to be *E. faecalis,* which comprised 68% of 155 isolates.[43] In the cat, it was *Enterococcus hirae*, which comprised 52% of 121 isolates.[43] Preparations that contain *E. faecium* strain SF68 have been investigated as probiotics in dogs and cats, with mixed results.[44-46] Some studies suggest that supplementation of food with this probiotic can stimulate local and systemic immune function in dogs and cats.[47,48]

Although less pathogenic than many streptococci, important virulence factors have been identified in enterococci that enable them to invade tissues and cause disease. These include a cytolysin, gelatinase, and a serine protease, as well as several surface proteins (e.g., the Ace protein, which allows the organism to adhere to connective tissue components, such as collagen). Enterococci also possess pili that play an important role in adherence. The ability of many enterococci to form biofilms means they can be very difficult to eradicate, because they resist phagocytosis and antimicrobial drugs.[41] As in humans, the two most common species of *Enterococcus* associated with disease in dogs and cats are *E. faecalis* and *E. faecium*.[36,49] Others are shown in Box 34-2.

Because enterococci are naturally resistant to a number of antimicrobials, treatment with broad-spectrum antibiotics (which destroy competing bacteria within the gastrointestinal tract) selects for colonization by enterococci. The development of enterococcal UTIs may be promoted by repeated use of antimicrobial drugs to treat recurrent UTIs, when the underlying cause of infection is not or cannot be resolved. Enterococci can contaminate the hospital environment and survive for long periods on fomites such as doorknobs, stethoscopes, and monitoring devices, as well as the hands, gloves, and clothing of hospital personnel. Inoculation may occur via urinary, intravenous, or other invasive devices, or organisms may enter the body from a damaged gastrointestinal tract. Severe concurrent illness and immunosuppression may predispose to infection. In addition to skin and UTIs, enterococci may be isolated from dogs and cats with UTIs, pyoderma and otitis externa, cholangiohepatitis, pancreatitis, hepatic abscesses, peritonitis, mastitis, bacteremia and endocarditis, wound infections, and discospondylitis. There have been rare reports of gastrointestinal illness in association with enterococcal infection of the gastrointestinal tract in dogs and cats. In affected cats, an association with diarrhea was supported by the presence of large mats of enterococci in association with the gastrointestinal mucosa.[52,53] Frequently, enterococci are isolated from lesions in mixed infections with other gastrointestinal microorganisms.

Physical Examination Findings

Physical examination findings in dogs and cats with *Streptococcus* or *Enterococcus* infections vary with the anatomic site(s) of infection. Streptococcal infections are an important differential diagnosis in sick or fading neonates; dogs that have physical examination findings suggestive of endocarditis; dogs and cats with severe pneumonia and pyothorax; NF; rapid onset of systemic illness in association with a wound; or outbreaks of severe purulent upper respiratory disease, hemorrhagic pneumonia, and systemic illness in group-housed animals.

Findings suggestive of streptococcal or enterococcal endocarditis include fever, lethargy, tachycardia, joint pain and swelling, systolic heart murmurs, and signs of embolic complications such as lameness, limb edema, weak or absent pulses, or neurologic signs. Animals with streptococcal pneumonia may have a fever (up to 106.3°F or 41.3°C), cough, tonsillar enlargement and hyperemia, mucopurulent nasal discharge, and/or tachypnea with increased lung sounds. Lung sounds may be decreased if pleural effusion is present. Animals with NF have variable extents of regional cutaneous erythema, sometimes in association with a wound; cutaneous ulceration, swelling, edema, intense pain, and warmth on palpation of the affected area. In some animals, extensive skin sloughing occurs. Animals with STSS may be obtunded, with weak pulses, tachycardia, tachypnea, and prolonged capillary refill time. Rectal temperatures may exceed 106°F (41.1°C), although the presence of fever is variable. Icterus may be present in animals that develop multiple organ dysfunction syndrome in association with STSS.

Diagnosis

Laboratory Abnormalities

Complete Blood Count, Biochemistry, and Urinalysis Findings

Dogs and cats with severe manifestations of streptococcal infections, such as pneumonia, NF, endocarditis, and STSS, usually have a neutrophilic leukocytosis with a left shift, toxic neutrophils, lymphopenia, and monocytosis. A degenerative left shift or circulating metamyelocytes may be present. STSS may be accompanied by thrombocytopenia as a result of DIC, azotemia and/or increased liver enzyme activities, hypoalbuminemia, and hypoglycemia. The urinalysis of dogs and cats with streptococcal or enterococcal UTIs may reveal pyuria, proteinuria, or hematuria, and cocci in pairs or chains may sometimes be evident on sediment examination.

Clotting Function

Dogs and cats with STSS that develop DIC may have clotting function abnormalities including prolonged coagulation times, increased fibrin degradation product and D-dimer concentrations, and decreased antithrombin concentrations.

Cytologic Abnormalities

Cytologic examination of specimens (respiratory lavage fluid, aspirates of affected tissues, or pus) from dogs and cats with streptococcal or enterococcal infections typically reveals large numbers of degenerate and nondegenerate neutrophils. Coccoid bacteria in pairs or chains may also be seen.

Microbiologic Tests

Isolation and Identification

Streptococci and enterococci that infect dogs and cats are readily isolated on routine bacteriologic media from aspirates, tissue biopsies, body fluids, and lavage specimens. Inoculation of complex media that contain blood is recommended. Streptococci grow well in anaerobic incubation conditions, but these are not required because of their facultative nature. The laboratory may use selective media for specimens that are heavily contaminated with other bacteria. Species are identified based on their phenotypic characteristics (such as colony morphology and hemolytic properties), biochemical reactions, and serotyping with Lancefield antisera; the last is available on a commercial basis. As noted previously, genetic typing may be required to identify some enterococci to the species level. Molecular typing methods such as pulsed-field gel electrophoresis may be required to investigate outbreaks in group-housed animals or hospital environments.

Antimicrobial susceptibility testing for streptococci is often not performed by veterinary diagnostic laboratories, because virtually all strains are penicillin susceptible. Group A streptococci (GAS) that infect humans remain universally susceptible to penicillin, but an increased prevalence of penicillin resistance, which occurs as a result of altered PBPs, has been detected in *S. pneumoniae*, which is primarily a human pathogen.[54] *S. pneumoniae* may also be resistant to other β-lactam drugs and macrolides. Evaluation of antimicrobial susceptibility is of critical importance for enterococci, because of the high prevalence of resistance in this group, and especially among *E. faecium* isolates. Susceptibility testing for aminoglycosides requires high-concentration disk diffusion or broth microdilution methods, which may not routinely be performed by some veterinary microbiology laboratories (see Treatment).

Pathologic Findings

Pathologic findings in *Streptococcus* infections vary depending on the organ system affected. Gross findings in *S. canis* sinusitis include accumulation of purulent material within the frontal sinus with osteolysis, and distortion of the nasal bridge in cats.[5] When meningitis is present, purulent material may be found in association with the meninges (Figure 34-5). Lesions of NF in dogs and cats consist of edema, ecchymoses, and necrosis that extend within the fascia and subcutis in association with

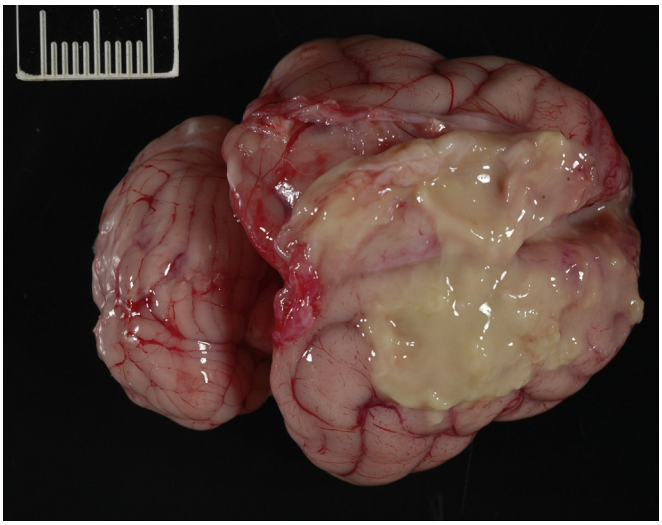

FIGURE 34-5 Accumulation of purulent exudate over the meninges in a shelter cat that died of *Streptococcus canis* meningitis. (Courtesy of Dr. Patricia Pesavento, University of California, Davis.)

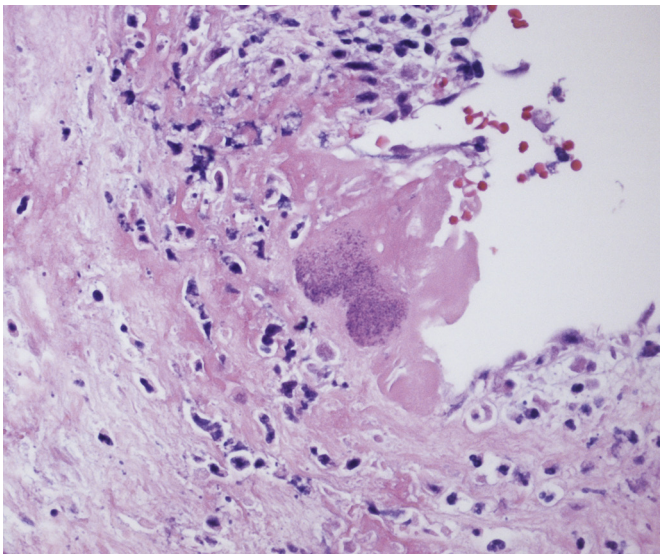

FIGURE 34-6 Histopathology of the mitral valve of an 8-year-old male neutered springer spaniel that was seen for a 1-month history of right thoracic limb lameness, anorexia, and lethargy. There is severe, subacute, fibrinonecrotic endocarditis with intralesional cocci. When the dog was first evaluated, the platelet count was 9000 platelets/μL and the dog was treated with vincristine for immune-mediated thrombocytopenia. Subsequently the dog developed vomiting and diarrhea and became obtunded. Blood cultures grew *Streptococcus canis*. At necropsy, septic emboli were present in the kidneys, spleen, and lymph nodes. Necrotizing fasciitis was also present in multiple limbs, which was thought to have developed as a result of septic embolization.

ulcerative skin lesions (see Figure 34-3). An accumulation of pus may be found between fascial planes. Congestion of a variety of organs may be present in animals that have accompanying STSS. When *S. canis* or Enterococcus endocarditis is present, adherent and friable mass lesions may be seen in association with the mitral and/or, less commonly, the aortic valves. Dogs with streptococcal endocarditis are more likely to have concurrent polyarthritis than dogs with other bacterial causes of endocarditis.[33] On histopathology, valve lesions generally contain large numbers of degenerate and nondegenerate neutrophils, hemorrhage, necrosis, fibrin thrombi, and abundant gram-positive cocci (Figure 34-6). Septic thromboemboli may be present in a variety of organs. Histopathologic lesions in neonates that die of neonatal sepsis include severe inflammation and necrosis, as well as septic emboli in a variety of tissues (see Figure 34-1).

Grossly, the lungs of dogs with *S. equi* subsp. *zooepidemicus* pneumonia may be red, consolidated, and fail to collapse (see Figure 34-4). There may be variable quantities of hemorrhagic pleural effusion, petechial and ecchymotic hemorrhages on pleural surfaces, and bloody exudate within the airways and nasal cavity.[17] Typical histopathologic changes include fibrinous, necrotizing, and/or suppurative pneumonia or bronchopneumonia; fibrin thrombi; and intralesional clusters or chains of coccoid bacteria. Within lymph nodes, marked lymphoid depletion may be present, but lymphoid hyperplasia has also been reported. Occasionally, septic thromboemboli may be present in organs such as the lymph nodes, renal glomeruli, adrenal glands, brain, and splenic sinusoids.[55,56]

Treatment and Prognosis

In general, streptococcal infections should be treated with a β-lactam drug, preferably a penicillin or a cephalosporin (Table 34-2). Early diagnosis and prompt treatment with appropriate antimicrobial drugs is essential to prevent more severe complications such as NF or STSS. In animals that present with severe signs such as septic shock or life-threatening pneumonia, initial treatment should be with a broad-spectrum antimicrobial drug combination, such as a β-lactam and an aminoglycoside, which may also have synergistic activity against some streptococci, such as group C streptococci (*S. equi* subsp. *zooepidemicus*).

Necrotizing Fasciitis, Myositis, and Toxic Shock Syndrome

Prompt surgical exploration and debridement is of critical importance in NF, because shock and organ failure will continue to progress in the face of antimicrobial treatment when necrotic tissue persists. Imaging techniques such as ultrasound may be useful to help characterize the extent of lesions before surgery. Extremely aggressive fluid resuscitation with crystalloids and blood products may also be required, while blood pressure is monitored. In human patients, deep-seated streptococcal infections (NF and STSS) are treated with *both* high-dose penicillin and clindamycin. This is because clindamycin suppresses exotoxin production by GAS, is more active than penicillin in experimental NF, and has a longer half-life than penicillin. However, clindamycin resistance exists in some GAS, whereas all GAS are susceptible to penicillin.[57] Also, penicillin may not be effective in deep-seated streptococcal infections, because stationary-phase organisms do not express PBPs. This tolerance to penicillin has also been observed in group G streptococcal infections.[58] Approximately 10% to 15% of contemporary *S. canis* isolates from dogs in Europe have demonstrated clindamycin resistance.[59,60] Given this finding, the same combination could be used to treat NF in dogs and cats.

Meningitis/Meningoencephalitis

Although high-dose penicillin has been used to treat streptococcal meningitis in human patients, penicillins typically have limited penetration of the CSF. Trimethoprim-sulfamethoxazole was used with apparent success to treat some dogs and cats with streptococcal meningitis.[21,61] See Chapter 90 for additional

VetBooks.ir

TABLE 34-2

Suggested Antimicrobial Drugs for Treatment of Streptococcal Infections in Dogs and Cats

Drug	Dose (mg/kg)	Interval (hours)	Route
Penicillin G potassium or sodium*	20,000-40,000 U/kg	6-8	IV, IM
Ampicillin sodium*	10-20	6-8	IV, IM, SC
Amoxicillin	6.6-20	8-12	PO
Cefazolin sodium	20-35	8	IV, IM
Cephalexin	10-30 (dogs), 15-20 (cats)	12	PO
Trimethoprim-sulfamethoxazole†	30	12	PO, IV

*Consider use with clindamycin, 10 mg/kg q12h IV or IM for necrotizing fasciitis or myositis; consider addition of gentamicin sulfate, 9-14 mg/kg q24h IV, IM, or SC for dogs with *S. equi* subsp. *zooepidemicus* pneumonia because of synergy of this combination for group C streptococci.
†Consider use for treatment of streptococcal meningitis.

TABLE 34-3

Suggested Medications for Treatment of Enterococcal Infections in Dogs and Cats

Drug	Dose (mg/kg)	Interval (hours)	Route
Ampicillin sodium*	10-20	6-8	IV, IM, SC
Amoxicillin*	6.6-20	8-12	PO
Vancomycin†	15	8	IV
Linezolid†	10 (dogs)	8	PO
Chloramphenicol	40-50 (dogs), 12.5-20 (cats)	6-8 (dogs), 12 (cats)	PO, IV, IM
Nitrofurantoin‡	2-3	8	PO

*In human patients, used with gentamicin sulfate, 1 mg/kg q12h IV for systemic enterococcal infections caused by enterococci susceptible to high-level aminoglycosides, because of the synergy of this combination
†For enterococci that show high-level aminoglycoside resistance or when aminoglycosides cannot be used because of toxicity (animals with renal failure). Use in veterinary patients is controversial. Refer to Chapter 8 for additional information on the use of vancomycin.
‡For resistant UTIs

information on treatment of bacterial meningitis. Ceftriaxone has been used as an alternative to benzylpenicillin for treatment of human streptococcal meningitis and attains higher concentrations in the CSF.

Bacteremia and Endocarditis

The reader is referred to Chapter 86 for information on treatment of bacteremia and endocarditis.

Enterococcal Infections

Suggested medications for treatment of enterococcal infections in dogs and cats are shown in Table 34-3. Successful treatment of enterococcal infections requires knowledge of the intrinsic resistance of enterococci to low levels of β-lactams and aminoglycosides, the synergistic effect of high doses of these drugs, the lack of efficacy of trimethoprim-sulfonamide combinations in vivo, and the ability of enterococci to acquire resistance genes to a large number of other antimicrobial compounds. Aminopenicillins such as ampicillin generally have more potent activity against enterococci than does penicillin or the carbapenems. Bactericidal regimens, which consist of a β-lactam and gentamicin (or streptomycin), are used in human patients to treat systemic infections such as endocarditis or bacteremia. Enterococci are usually resistant to aminoglycosides at dilutions used in routine broth microdilution methods (low-level resistance). When the synergistic combination is indicated, but low-level resistance is present, isolates should be tested for high-level resistance (HLR) to aminoglycosides. Aminoglycoside HLR results from production of an aminoglycoside-modifying enzyme by enterococci. It emerged in the 1980s and has been a growing problem in both *E. faecium* and *E. faecalis* isolates from human patients. Aminoglycoside HLR has also been reported in *E. faecium* and *E. faecalis* isolated from dogs and cats,[36,38,62] but most isolates are susceptible to high concentrations of gentamicin. In human patients, a combination of ceftriaxone and ampicillin has been recommended to treat endocarditis caused by aminoglycoside HLR enterococci.[39] When enterococci show penicillin resistance, vancomycin can be substituted for penicillin, but this requires prolonged hospitalization for intravenous administration. Single-agent treatment with linezolid (see Chapter 8) is an oral alternative for treatment of serious penicillin-resistant enterococcal infections, but in human patients it is recommended that this only be used when combinations of β-lactams and gentamicin cannot be used because of resistance, toxicity, or treatment failure.[39] Although most strains

of enterococci isolated from humans are susceptible to linezolid, resistant strains have appeared.[63] Chloramphenicol may be successful for treatment of resistant enterococcal bloodstream infections when administered orally, but it is bacteriostatic, and concerns regarding adverse effects exist (see Chapter 8).

Treatment of enterococcal UTIs with β-lactams such as ampicillin or amoxicillin may be successful even when resistance is documented in the susceptibility panel, because of the high concentrations that these drugs achieve in the urine.[39] Nitrofurantoin has also been useful for treatment of resistant enterococcal UTIs in humans, and routine treatment of subclinical bacteriuria caused by MDR enterococci is not recommended (see Chapter 89).[64] When enterococci are present with other bacteria, especially in the urinary tract, treatment of the nonenterococcal pathogen may be sufficient to resolve the infection.

Prevention

Because outbreaks of streptococcal infections in dogs and cats have been associated with overcrowding, co-infections, and other stressors, appropriate shelter and kennel management and hygiene, as well as vaccination against other respiratory pathogens, may help to prevent streptococcal infections. Proper wound care may prevent serious streptococcal infections such as bacteremia, endocarditis, NF, and STSS. Methods to reduce nosocomial infections by enterococci are outlined in Chapter 11. Resistant enterococcal infections may be prevented through restricted and appropriate use of antimicrobial drugs and proper management of underlying disorders that predispose to bacterial infections.

Public Health Aspects

Streptococci include some of the most important bacterial pathogens of humans. The β-hemolytic group A streptococcus (GAS) *S. pyogenes* causes streptococcal pharyngitis ("strep throat") and scarlet fever, as well as poststreptococcal rheumatic fever, rheumatic heart disease, and glomerulonephritis. It has been estimated that globally, GAS cause 616 million new cases of pharyngitis each year.[65] GAS has also been associated with other disease manifestations, which include NF, STSS, myositis, vaginitis, and bacteremia. As a result, *S. pyogenes* is one of the most extensively studied of all streptococci. There are more than 100 different serotypes, which are classified based on the sequence of the M protein gene (known as *emm* typing). M protein is a filamentous macromolecule that traverses the cell wall and is a key virulence factor of GAS. Transmission between humans primarily occurs through close contact, and chronic subclinical carriage of infection in the oropharynx occurs in some individuals. Although family pets have been implicated as a reservoir in households with recurrent streptococcal pharyngitis,[66,67] colonization or infection of dogs and cats with GAS appears to be rare or nonexistent when accurate streptococcal identification methods have been performed. One study found no evidence of oropharyngeal colonization by GAS in pets that were in contact with children with acute pharyngitis.[68] Even among human family members who are in contact with children with streptococcal pharyngitis, routine culture of asymptomatic individuals is not recommended, because penicillin fails to eradicate streptococcal pharyngeal carriage.[57]

The α-hemolytic streptococcus *S. pneumoniae* is a commensal of the human respiratory tract and can invade opportunistically to cause a variety of clinical manifestations that include otitis media, sinusitis, meningitis, bacteremia, and pneumonia. It possesses no Lancefield group antigens. Although extremely rare in dogs and cats, infections with *S. pneumoniae* have been reported in a dog with meningoencephalitis,[61] a cat with arthritis,[69] and a cat with cellulitis.[70] It is likely that in these reports, the dog and cats acquired the infection from humans, because humans are the natural hosts for *S. pneumoniae*.

Reports of human infection with *S. canis* and *S. equi* subsp. *zooepidemicus* exist. *S. canis* has increasingly been recognized as a cause of soft tissue infections in dog owners and has been isolated from humans with bacteremia, UTIs, osteomyelitis, and pneumonia.[71,72] Rarely, *S. equi* subsp. *zooepidemicus* has been isolated from humans with meningitis, bacteremia, endocarditis, pneumonia, osteomyelitis, septic arthritis, acute nephritis, or STSS. Most human infections with *S. equi* subsp. *zooepidemicus* have been traced to an animal source, such as contact with horses, or consumption of inadequately pasteurized milk products or pork. However, apparent transmission of *S. equi* subsp. *zooepidemicus* from a dog with *S. equi* subsp. *zooepidemicus* pneumonia to a handler, who developed severe systemic illness, has been described.[73]

Dogs and cats are also a potential source for human infection by MDR enterococci. In one study, dogs that left a veterinary intensive care unit were colonized with MDR enterococci with the capacity for biofilm formation and horizontal transfer of antimicrobial resistance genes.[74]

Because of the potential for transmission of streptococci and enterococci between dogs, cats, and humans, preventative measures such as hand washing after pets are handled, household disinfection, and avoidance of close contact (such as allowing pets to lick wounds or mucous membranes) should be considered, especially for immunocompromised pet owners.

CASE EXAMPLE

Signalment: "Jazz" a 6-year-old female spayed miniature Pinscher from Fairfield in northern California

History: Jazz was brought to the University of California, Davis, Veterinary Medical Teaching Hospital for evaluation of anorexia, lethargy, and diarrhea. Two days previously, the dog had been seen by the dermatology service for a focal area of alopecia and scaling on the dorsal midline in the thoracolumbar region that first appeared 7 months previously, enlarged to 6 × 4 cm in diameter over 2 months, and then remained static in size for the subsequent 5 months. Skin scrapings and fungal culture were performed, and four skin biopsies were obtained. An underlying vasculitis was suspected, and treatment with vitamin E (200 U PO q12h) and an oral fatty acid supplement was recommended pending the results of the diagnostic tests. The following day the owner noted edema of the right pelvic limb and discontinued the medications. Over the next 24 hours, the

VetBooks.ir

dog became lethargic, inappetent, and developed liquid diarrhea and polydipsia. Jazz had been vaccinated regularly for canine distemper, adenovirus and parvovirus infections and rabies and normally ate a commercial dry dog food. She was last vaccinated just after the skin lesion first appeared. The dog was mostly indoors, going outside on leash walks only, and there were no other pets in the household.

Other Medical History: Jazz had been spayed 5 weeks previously, at which time pyometra was an incidental finding and was treated with a 7-day course of amoxicillin.

Physical Examination:

Body Weight: 3.3 kg

General: Lethargic, alert and ambulatory, but weak. Vocalized on palpation of the thorax and abdomen. T = 102.2°F (39.0°C), HR = 120 beats/min, RR = 60 breaths/min, mucous membranes pink, CRT = 1 s.

Eyes, Ears, Nose, and Throat: Mild conjunctival hyperemia and bilateral serous ocular discharge were present.

Integument: There was mild subcutaneous edema and a small amount of serosanguineous fluid in the region of the skin biopsies, but sutures remained intact. There was a single, raised erythematous lesion adjacent to the skin biopsies that measured 0.5 × 0.5 cm in diameter. Severe edema was noted in the cranioventral thoracic region, which extended over an area that was 9 × 5 cm in diameter.

Other Systems, Including Peripheral Lymph Nodes: No clinically significant findings.

Laboratory Findings:

CBC:

HCT 53.1% (40%-55%)
MCV 71.2 fL (65-75 fL)
MCHC 36.7 g/dL (33-36 g/dL)
Nucleated RBC 24/100 WBC
WBC 2200 cells/µL (6000-13,000 cells/µL)
Neutrophils 792 cells/µL (3000-10,500 cells/µL)
Band neutrophils 748 cells/µL
Metamyelocytes 88 cells/µL
Myelocytes 44 cells/µL
Lymphocytes 308 cells/µL (1000-4000 cells/µL)
Monocytes 220 cells/µL (150-1200 cells/µL)
Platelets 97,000/µL (150,000-400,000 platelets/µL).
Markedly toxic band neutrophils, metamyelocytes, and myelocytes; moderately toxic neutrophils; and rare reactive lymphocytes were present.

Serum Chemistry Profile:

Sodium 128 mmol/L (145-154 mmol/L)
Potassium 4.4 mmol/L (3.6-5.3 mmol/L)
Chloride 90 mmol/L (108-118 mmol/L)
Bicarbonate 21 mmol/L (16-26 mmol/L)
Phosphorus 8.7 mg/dL (3.0-6.2 mg/dL)
Calcium 10.0 mg/dL (9.7-11.5 mg/dl)
BUN 63 mg/dL (5-21 mg/dL)
Creatinine 0.9 mg/dL (0.3-1.2 mg/dL)
Glucose 75 mg/dL (64-123 mg/dL)
Total protein 5.6 g/dL (5.4-7.6 g/dL)
Albumin 2.2 g/dL (3.0-4.4 g/dL)
Globulin 3.4 g/dL (1.8-3.9 g/dL)
ALT 185 U/L (19-67 U/L)
AST 128 U/L (19-42 U/L)
ALP 539 U/L (21-170 U/L)
Cholesterol 526 mg/dL (135-361 mg/dL)
Total bilirubin 0.5 mg/dL (0-0.2 mg/dL)

Urinalysis: SGr 1.021; pH 5.0, 1+ protein (SSA), 1+ bilirubin, 4+ hemoprotein, no glucose, no ketones, rare WBC/HPF, 0-2 RBC/HPF, few amorphous crystals, no bacteria seen

Imaging Findings: Abdominal ultrasound: Enlargement of the uterine stump was present dorsal to the bladder. There were no cystic structures within the stump and no evidence of fluid in this region or lymphadenopathy.

Cytologic Findings: Needle aspiration of edema fluid from a region adjacent to the right axilla revealed large numbers of cocci, some in pairs, in the absence of significant numbers of leukocytes.

Microbiologic Testing: Aerobic and anaerobic blood culture (three isolator specimens): One colony of coagulase-negative staphylococci was grown on one plate. The other two plates were negative. No anaerobes were cultured. The isolate was resistant to penicillin G, erythromycin, and trimethoprim-sulfamethoxazole, but susceptible to all other antimicrobials tested.

Aerobic bacterial culture (aspirate of edema fluid): Large numbers of *Streptococcus canis* colonies.

Treatment and Outcome: Treatment with IV fluids (0.9% NaCl with 20 mEq KCl/L) was initiated. Ampicillin (20 mg/kg IV q6h), enrofloxacin (5 mg/kg IV q24h), and butorphanol were administered. The dog's body temperature subsequently dropped to 98.0°F (36.7°C) and blood glucose concentration dropped to 30 mg/dL. Fluids were supplemented with dextrose and a warming pad was used, and the dog's temperature returned to normal limits. Within hours the edema had spread to the abdomen, and evidence of bruising appeared on the right thorax and ventrum. The raised erythematous lesion on the dorsum ulcerated, and dehiscence of the biopsy site adjacent to this region became apparent. Blood work showed a hematocrit of 39%, 2700 white cells/µL, 1323 band neutrophils/µL, 702 neutrophils/µL, 162 lymphocytes/µL, 513 monocytes/µL, and 37,000 platelets/µL; serum sodium concentration was 142 mmol/L, potassium 3.7 mmol/L, creatinine 0.4 mg/dL, BUN 23 mg/dL, albumin 1.2 g/dL, globulin 3.1 g/dL, cholesterol 221 mg/dL, and total bilirubin 2.3 mg/dL. The activities of ALT, AST, and ALP were 79 U/L, 136 U/L, and 292 U/L, respectively. Treatment with dextran and plasma was initiated, but systolic blood pressure dropped to 80 mm Hg, and the region adjacent to the biopsy sites became firm and painful and tore when palpated. Ampicillin was substituted with penicillin G (40,000 U/kg IV q6h). Forty-eight hours after admission, the dog was anesthetized and a large portion of necrotic skin was surgically debrided from the dog's dorsum. The debrided region was covered with a stent. During recovery the dog was tachypneic, had increased lung sounds, and systolic blood pressure dropped to 50 mm Hg. The dog developed respiratory arrest, and an endotracheal tube was placed, from which bloody fluid emanated. Cardiac arrest then ensued, and there was no response to closed cardiopulmonary resuscitation efforts.

Necropsy Findings: At necropsy, necrosis extended through the intercostal musculature of the right thoracic wall. Histopathologic lesions included severe, focally extensive, hemorrhagic and necrotizing panniculitis and fasciitis with intralesional bacteria and multifocal thrombi;

Continued

VetBooks.ir

diffuse necrotizing myositis of the right thoracic wall with intralesional bacteria; severe congestion and mild, multifocal hemorrhage and thrombosis within the kidneys; centrilobular congestion and severe bile stasis within the liver; congestion and hemorrhage within the lung; and generalized lymphoid depletion and sinusoidal histiocytosis within lymph nodes. Around the uterine stump, there was focal fibrosis and mild granulomatous serositis. Very small numbers of *S. canis* were cultured from the uterine stump. Histopathology of the biopsy specimens that had been collected before the onset of systemic illness showed severe, diffuse adnexal atrophy; mild, chronic, lymphoplasmacytic mural folliculitis; focal granulomatous furunculosis with hyperkeratosis; and mild, multifocal, perivascular neutrophilic dermatitis. No microorganisms were seen, although only special staining with periodic acid–Schiff (PAS) and Gomori's methenamine silver (GMS) was performed.

Diagnosis: NF, myositis, and STSS associated with *Streptococcus canis* infection

Comments: This rare case description illustrates how rapidly NF can progress and the ineffectiveness of antibiotic treatment in the presence of devitalized tissue. Clinical findings more than satisfied the criteria for diagnosis of STSS in Box 34-1. The source of infection and the role that the uterine stump infection played was unclear. Streptococcal bacteremia was not detected in this case. It is likely that the coagulase-negative staphylococcus represented a contaminant.

CHAPTER 35

Staphylococcus Infections

Jane E. Sykes

VetBooks.ir

Overview of Staphylococcal Infections in Dogs and Cats

First Described: 1882 in Scotland (Alexander Ogsten)[1]

Causes: In dogs and cats, the most common causes are *Staphylococcus pseudintermedius, Staphylococcus schleiferi, Staphylococcus aureus,* and various coagulase-negative staphylococci, which are gram-positive coccoid bacteria.

Geographic Distribution: Worldwide

Mode of Transmission: Direct contact (or through fomites). Organisms are often commensals that invade opportunistically.

Major Clinical Signs: Pyoderma, otitis externa, surgical site infections, osteomyelitis, bacteremia and endocarditis, bronchopneumonia, urinary tract infections, ocular surface infections, rarely necrotizing fasciitis and toxic shock syndrome, pyothorax and peritonitis, discospondylitis, arthritis

Differential Diagnoses: Primarily other gram-positive and gram-negative bacterial infections

Human Health Significance: Humans can become colonized with staphylococcal isolates that colonize or infect dogs and cats. Methicillin-resistant *S. aureus,* which can persistently colonize humans, is of greatest concern, although colonization of dogs with MRSA appears to be transient. *S. pseudintermedius,* which persistently colonizes dogs, has occasionally been isolated from sick and healthy people who are in contact with dogs, and is of concern because of its tendency to show a high degree of multidrug resistance.

Etiology and Epidemiology

Staphylococcus spp. are gram positive, nonmotile, non–spore forming, and usually catalase-positive cocci, which occur singly and in pairs or grapelike clusters (Figure 35-1). Most species are facultative anaerobes. Staphylococci colonize the skin and mucous membranes of an enormous variety of animal species, and disease generally follows a breakdown in normal host defenses. Staphylococci can also contaminate surfaces in the environment, where they may survive for several months.

Staphylococci are classified as *coagulase negative* or *coagulase positive* based on their ability to produce coagulase, an enzyme that cleaves fibrinogen into fibrin and results in coagulation of plasma. There are more than 40 species in the genus *Staphylococcus*,[2] many of which are adapted to live on certain host species. The major coagulase-positive staphylococci that infect dogs and cats are *Staphylococcus pseudintermedius* (previously identified as *Staphylococcus intermedius*) and *Staphylococcus aureus*. *Staphylococcus schleiferi* has also been isolated from dogs (and rarely cats) with pyoderma and otitis externa and has been divided into *S. schleiferi* subsp. *schleiferi,* which is coagulase-negative, and *S. schleiferi* subsp. *coagulans,* which is coagulase-positive. However, these may instead represent a single species, *S. schleiferi,* with variable coagulase production.[3] Coagulase-negative staphylococci (CoNS) tend to be of lower virulence than coagulase-positive staphylococci but occasionally cause disease in immunocompromised hosts. Examples of coagulase-negative staphylococci are *Staphylococcus felis* and *Staphylococcus epidermidis*. *S. felis* has been recognized as a urinary tract pathogen in cats.[4] CoNS are often not identified to the species level by microbiology laboratories.

In recent years, the prevalence of antimicrobial drug resistance has increased in *Staphylococcus* isolates obtained from canine and feline infections. A significant proportion of resistant isolates possess the *mecA* gene, which encodes an altered penicillin binding protein (PBP), known as PBP2a. The *mecA* gene is located on a large genetic element, the *staphylococcal cassette chromosome.* This PBP has low affinity for *all* β-lactam drugs (penicillins, cephalosporins, and carbapenems). As a result, staphylococci that possess this gene are also resistant to the penicillinase-resistant penicillins (oxacillin and methicillin), and so are termed *methicillin-resistant Staphylococcus* (MRS) species. Many MRS also possess resistance genes to other antimicrobial drug classes. There is no evidence that MRS are more virulent than methicillin-susceptible staphylococci, but infections with MRS are more difficult to treat with antimicrobial drugs. The prevalence of MRS isolated from dogs has ranged from 0.6% to as high as 67%, depending on the population sampled (healthy versus disease, hospitalized versus outpatients), geographic location, study dates, and sites of specimen collection. Of 89 staphylococcal isolates from dogs with superficial pyoderma seen in 2010 and 2011 by the University of California, Davis, Veterinary Dermatology service, 38.2% were MRS. This compared with 27.3% of 33 isolates from a primary care clinic in the same region.[5] Methicillin-resistant *S. pseudintermedius* (MRSP) isolates are generally resistant to more antimicrobial drug classes than methicillin-resistant *S. aureus* (MRSA) isolates from dogs and cats. Severe multidrug resistance is also prevalent among CoNS.

Staphylococcus pseudintermedius

S. pseudintermedius is the most common *Staphylococcus* species isolated from dogs. It is a commensal of the skin and mucous membranes of dogs and cats and possibly one of the most common bacterial pathogens treated by veterinarians. It primarily colonizes the anal mucosa and nares of healthy dogs and cats, but it can also be isolated from the mouth, forehead, and

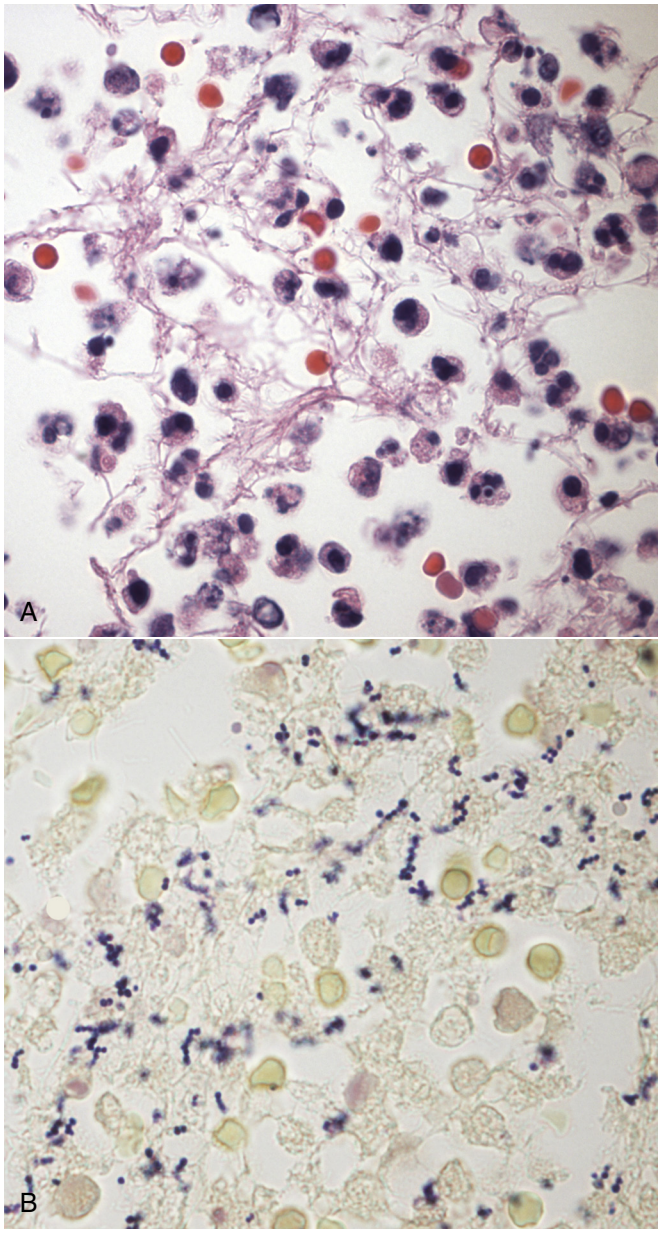

FIGURE 35-1 Histopathology of the integument from the left inguinal region and flank of an 8-year old male neutered boxer dog that had severe, regionally extensive acute neutrophilic cellulitis and panniculitis accompanied by septic shock. A methicillin susceptible *Staphylococcus pseudintermedius* was cultured from an aspirate of cellulitis fluid. The dog had also been treated with prednisone and azathioprine for 4 years to maintain remission for immune-mediated hemolytic anemia and thrombocytopenia. **A,** H&E stain. Large numbers of degenerate neutrophils are present. **B**, Staining with Brown and Benn stain reveals numerous of gram-positive coccoid bacteria, individually, in pairs, and in clusters. 1000× oil magnification.

inguinal region. It can colonize the skin transiently following grooming and licking in dogs with pruritis. Cats have a much lower prevalence of colonization with *S. pseudintermedius* than dogs. *S. pseudintermedius* invades tissues opportunistically and is a major cause of superficial and deep pyoderma, otitis externa, urinary tract infections (UTIs), and wound and surgical site infections, as well as bronchopneumonia, ocular infections, bacteremia, osteomyelitis, and infections of body cavities. An underlying immunosuppressive condition or break in host barriers is present in the majority of infections.

Before 2005, *S. pseudintermedius* were identified as *S. intermedius*. The name *S. pseudintermedius* was defined when isolates from a dog, cat, horse, and parrot were analyzed using molecular methods.[6] Subsequently, a molecular analysis of organisms from dogs and cats that had been previously identified as *S. intermedius* revealed that they were actually *S. pseudintermedius*. *S. pseudintermedius* belongs to the "*S. intermedius* group" (SIG), which comprises the three closely related species *S. intermedius, S. pseudintermedius,* and *S. delphini*. It is difficult to differentiate among these species with phenotypic methods alone; genetic typing methods are required. Because genetic typing methods are not available for routine identification in veterinary diagnostic laboratories, isolates from dogs with phenotypic characteristics typical of *S. intermedius* are now generally identified as *S. pseudintermedius*.[7] However, some laboratories still describe strains from dogs that have biochemical characteristics that do not quite match that typical for the type strain of *S. pseudintermedius* as "SIG organisms."

The whole genome of *S. pseudintermedius* has been sequenced, which is a major contribution to our understanding of the pathogenesis of infections caused by this organism.[8] Like *S. aureus, S. pseudintermedius* possesses numerous mobile genetic elements and potential virulence factors, such as toxin genes that encode for a superantigen, leukotoxin, hemolysins, and exfoliative toxins, as well as an array of proteases.

Methicillin resistance has emerged as a serious and widespread problem in *S. pseudintermedius* isolates from both healthy and sick dogs and cats. Molecular analysis has shown that among dogs, two distinct, major clones of MRSP have spread across Europe and North America, respectively.[9] Many isolates of *S. pseudintermedius* not only are methicillin resistant, but also acquire resistance genes to other classes of antimicrobials, including tetracyclines, trimethoprim-sulfonamides, fluoroquinolones, chloramphenicol, and macrolides. Isolates that are resistant to three or more different *classes* of antimicrobial drugs are defined as multiple drug resistant (MDR) isolates. Currently, many isolates remain susceptible to chloramphenicol and aminoglycosides, but the prevalence of resistance to chloramphenicol has increased among MRSP isolates. MDR *S. pseudintermedius* isolates are no more virulent or difficult to disinfect than susceptible isolates, but they are more difficult to eliminate using antimicrobial drugs. Risk factors for MRSP infection identified in dogs include previous hospitalization, living in an urban environment, older age, and, most consistently, previous antimicrobial drug treatment. Household contacts of dogs and cats with MRSP infection are also frequently colonized with MRSP.[10]

Staphylococcus aureus

S. aureus colonizes the skin and mucous membranes of humans and is one of the most common community-acquired and hospital-acquired bacterial pathogens of people. The anterior nares and the throat are preferred niches for the organism, which can be isolated from the anterior nares of up to 30% of the healthy human population. Methicillin resistance is a growing problem among isolates from humans and animals. Both hospital-acquired methicillin-resistant (HA-MRSA) and community-acquired methicillin-resistant (CA-MRSA) strains have been identified in infected human patients, and invasive *S. aureus* infections are associated with high mortality rates.

When compared with *S. pseudintermedius, S. aureus* tends not to colonize dogs. For example, staphylococci were isolated from 37 of 50 healthy dogs from Pennsylvania, and 6 (12%) of

VetBooks.ir

the dogs were colonized with *S. aureus*; 68% were colonized with *S. pseudintermedius*.[11] MRSA strains that colonize dogs may be identical to those that infect in-contact humans, but sometimes strains found on dogs differ from those found on in-contact humans.[12] The chance that a dog that is in contact with an infected human will be colonized with MRSA decreases with the time after diagnosis of human MRSA infection, which suggests transient carriage of MRSA by dogs. MRSA was not transferred between apparently healthy dogs in a kennel of dogs, and after treatment of an MRSA wound infection in one dog, all dogs tested negative for MRSA within 2 weeks.[13] Although staphylococci are isolated less commonly from cats, colonization with *S. aureus* is more prevalent and certain *S. aureus* strains may be commensals of cats; staphylococci were isolated from 17 of 50 healthy cats, 59% of which were colonized with *S. aureus* and 65% with *S. pseudintermedius*.[14]

In dogs and cats, *S. aureus* infection has been associated with clinical manifestations that include pyoderma, otitis externa, UTIs, surgical site infections, osteomyelitis, and bacteremia. Although MRSA infections are uncommonly diagnosed in dogs and cats, they have been increasingly recognized over the past 2 decades. When canine infections with MRSA do occur, they are often of human hospital origin, but human community-acquired strains have also been isolated. In one study, strong risk factors for MRSA infection (as opposed to methicillin-susceptible *S. aureus* [MSSA] infection) were the number of antimicrobial courses administered, the number of days admitted to veterinary clinics, and a history of surgical implant placement.[15] There has been concern that the use of certain antibiotics, such as cephalosporins and fluoroquinolones, may select for MRSA infections in dogs.

Staphylococcus schleiferi

Coagulase-positive and coagulase-negative *S. schleiferi* have primarily been isolated from dogs with superficial pyoderma and otitis externa, as well as from the ear canals of healthy dogs. Rarely, UTIs and respiratory infections with *S. schleiferi* have been described in dogs.[3] In dogs with pyoderma and otitis externa, *S. schleiferi* is not as prevalent as *S. pseudintermedius* but in most studies has been isolated as often, or more often, than *S. aureus*. Coagulase-negative *S. schleiferi* is a commensal of the human axilla but can cause disease in immunosuppressed humans. Coagulase-positive *S. schleiferi* may be specialized to colonize dogs.

S. schleiferi isolates from dogs with skin disease are often methicillin-resistant as a result of *mecA* gene carriage. In a study of 225 *S. schleiferi* isolates from dogs from the eastern United States, of which 52% were coagulase negative and 42% were coagulase positive, methicillin resistance was identified in 57% of the isolates.[3] Methicillin resistance was more prevalent among coagulase-negative isolates. Isolates from dogs with pyoderma may be more likely to be methicillin resistant than those from dogs with otitis externa.

Clinical Features

Signs and Their Pathophysiology

Staphylococci can cause pyoderma, otitis externa, pneumonia, UTIs, soft tissue infections, surgical site infections, bacteremia, ocular infections, and endocarditis in dogs and cats.

S. aureus and *S. pseudintermedius* possess several adhesins and produce an array of toxins. The clinical effect of these toxins is best characterized for *S. aureus* infections in humans. A number of enterotoxins have been identified in *S. aureus* and *S. pseudintermedius*; these can cause food poisoning in humans but have not been recognized as a cause of disease in dogs and cats. Staphylococcal enterotoxins are heat stable, so they are not inactivated by cooking, even when the bacteria themselves are destroyed. *Staphylococcal toxic shock syndrome* results from the expression of superantigens, which include toxic shock syndrome toxin 1, as well as a large number of enterotoxins and exotoxins that can also act as superantigens. Cellulitis, necrotizing fasciitis, and toxic shock syndrome has been rarely reported in dogs infected with *S. pseudintermedius*.[16,17] Most toxic shock syndrome and necrotizing fasciitis cases in dogs and cats are instead caused by *Streptococcus canis* (see Chapter 34). *Scalded skin syndrome* results from infection of humans with *S. aureus* strains that produce an exfoliative toxin, which hydrolyses the intercellular glycoprotein desmoglein-1. Strains of *S. pseudintermedius* that possess exfoliative toxin genes have been isolated more commonly from dogs with pyoderma than from healthy dogs, so exfoliative toxin may also play a role in canine disease. *Panton-Valentine toxin (PVL)* is a leukocidin that is found in CA-MRSA strains but only a small percentage of HA-MRSA and MSSA strains, and strains that encode PVL have been associated with skin and soft tissue infections and hemorrhagic pneumonia in children and young adults. Although a similar toxin has been identified in *S. pseudintermedius*, the role of PVL in the pathogenesis of staphylococcal infections in dogs and cats is unknown.

Some strains of *S. pseudintermedius* and *S. aureus* produce biofilm, which may contribute to the ability of these organisms to persist in the environment, cause nosocomial infections, and chronic recurrent infections that respond poorly to antimicrobial treatment.[18]

Diagnosis

Laboratory Abnormalities

Complete Blood Count, Biochemistry, and Urinalysis Findings

Dogs with staphylococcal infections of the skin and ear canal often have no clinically significant hematologic or biochemical findings. Systemic infections may be associated with neutrophilia and a left shift, toxic neutrophils, lymphopenia, and monocytosis. The urinalysis of dogs and cats with staphylococcal UTIs may reveal pyuria, proteinuria, or hematuria, and sometimes cocci in clusters may be evident on sediment examination.

Cytologic Abnormalities

Aspirates of affected tissues or pus or respiratory lavage fluid specimens from animals with staphylococcal infections may contain large numbers of degenerate and nondegenerate neutrophils. The presence of cocci in clusters suggests staphylococcal infection.

Microbiological Tests

Isolation and Identification

Staphylococci that infect dogs and cats are readily isolated on routine bacteriologic media from aspirates, tissue biopsies, body fluid, and lavage specimens. Colonies typically appear within 24 hours. Staphylococcal species are identified on the basis of phenotypic and biochemical reactions such as production of coagulase and/or clumping factor, production of hemolysins, ability to ferment carbohydrates, and acetoin production (Vogues-Proskauer reaction). PCR and sequencing of ribosomal

RNA genes (16S or 23S) may be necessary for identification of some species. CoNS are often not identified to the species level because molecular techniques are often required for accurate identification. Because CoNS are of low pathogenicity, they may be contaminants, especially if they are isolated from nonsterile sites, growth is minimal (1+), or another pathogen is present. However, they may occasionally be pathogenic. In particular, isolation of *S. felis* from urine or coagulase-negative *S. schleiferi* from dogs with pyoderma or otitis may have clinical significance.

Evaluation of antimicrobial susceptibility is of critical importance because of the high prevalence of methicillin-resistant and multidrug-resistant staphylococci in some parts of the world. Susceptibility testing for staphylococci should be performed according to recommendations of groups such as the Clinical and Laboratory Standards Institute (CLSI). Oxacillin and cefoxitin are used in the laboratory as a surrogate for detection of methicillin resistance. Laboratories should report methicillin-resistant staphylococci as resistant to all other penicillins, carbapenems, cephalosporins, and β-lactam/β-lactamase inhibitor combinations, regardless of the results of in vitro susceptibility test results for these agents.

Molecular Diagnosis Using the Polymerase Chain Reaction

Real-time PCR assays have been developed that detect and differentiate some *Staphylococcus* species, as well as identify the presence of the *mecA* gene. These assays are available in some laboratories for diagnosis of MRSA infections in humans, but to date have only been used on a research basis to characterize staphylococci isolated from dogs and cats.

Treatment and Prognosis

The approach to treatment of staphylococcal infections depends on the site of infection and the severity of disease; the reader is referred to Chapters 84 to 90 for treatment recommendations for different organ systems. Identification and management of the underlying cause (rather than repeated treatment with antimicrobial drugs) is of paramount importance to minimize selection for resistant organisms. Any foreign material (such as catheters, implants) must be removed. Bathing and topical treatments should be considered for pyoderma as an alternative to antimicrobial drug therapy (see Chapter 84). The use of topical wound treatments such as accelerated hydrogen peroxide, chlorhexidine, or silver sulfadiazine could also be considered provided infection is superficial.

When systemic antimicrobial treatment is necessary, staphylococcal infections should ideally be treated based on the results of culture and susceptibility testing and/or knowledge of the regional prevalence of methicillin resistance and multidrug resistance, because this can vary, not only between countries but also between different states or regions within a state. In regions where methicillin resistance is rare, a β-lactam drug such as cephalexin, clavulanic acid–amoxicillin, or a penicillinase-resistant penicillin could be used empirically (Table 35-1), and culture and susceptibility testing may not be necessary for uncomplicated infections such as newly diagnosed pyoderma or UTIs.

Where methicillin resistance is prevalent in the region, culture and susceptibility testing is recommended. If this is not possible, a reasonable first choice for uncomplicated infections that are not life threatening is clindamycin. Clindamycin is an attractive choice given that many infections are skin, orthopedic, or soft tissue infections (sites to which clindamycin distributes well); it is inexpensive, inhibits toxin production by staphylococci, and is available in oral and intravenous formulations. However, some MRS demonstrate *inducible clindamycin resistance*, a phenomenon whereby the organism is susceptible to clindamycin in vitro but rapidly develops resistance to clindamycin when exposed to macrolides (such as erythromycin) or lincosamides in vivo, owing to bacterial methylation of the ribosomal binding

TABLE 35-1

Suggested Antimicrobial Drugs for Treatment of Staphylococcal Infections in Dogs and Cats

Predicted/Determined Staphylococcal Susceptibility	Drug	Dose (mg/kg)	Interval (hours)	Route
Methicillin-susceptible	Ampicillin sodium	10-20	6-8	IV, IM, SC
	Cefazolin sodium	20-35	8	IV, IM
	Cephalexin	10-30 (dogs), 15-20 (cats)	12	PO
Methicillin-resistant*	Trimethoprim-sulfamethoxazole	30	12	PO, IV
	Clindamycin†	11	12	PO
	Doxycycline	10	12	PO
	Rifampin	5-10	12	PO
	Amikacin	15-30 (dogs), 10-14 (cats)	24	IV, IM, SC
	Vancomycin‡	15	6-8 (dogs), 8 (cats)	IV
	Linezolid‡	10 (dogs)	8	PO, IV
	Nitrofurantoin (macrocrystalline formulation)§	2-3	8	PO

*Susceptibility testing recommended if methicillin resistance is likely based on regional or hospital prevalence data. Many isolates are resistant to clindamycin, trimethoprim-sulfamethoxazole, doxycycline; some are resistant to chloramphenicol. Consider topical antibacterial treatment if possible.
†May not be effective if erythromycin resistance is present on the susceptibility panel due to inducible clindamycin resistance.
‡Reserve for serious infections that are resistant to all other reasonable alternatives, on the basis of culture and susceptibility testing. See Table 8-6 for vancomycin administration protocol.
§For resistant urinary tract infections only.

site for clindamycin.[19] The end result is treatment failure or relapse, although some treatment successes have been reported in human patients infected with *S. aureus* strains that have inducible clindamycin resistance. Staphylococci with inducible clindamycin resistance are resistant to macrolides such as erythromycin and susceptible to clindamycin in routine susceptibility tests. Nevertheless, not all staphylococci with this resistance pattern demonstrate inducible clindamycin resistance. Identification of inducible clindamycin resistance requires a special test known as a *D-zone test*. It involves culture of the organism on agar in the presence of an erythromycin and clindamycin disk. Organisms near to the erythromycin disk express enhanced resistance to clindamycin, which results in a D shape to the zone of inhibition around the clindamycin disk (Figure 35-2). At the time of writing, inducible clindamycin resistance appears to be prevalent in *S. aureus* isolates from dogs and cats (18% in one study of 62 isolates) but is rarely reported in *S. pseudintermedius* (0 of 46 isolates in one study, and 1 of 60 isolates in another study).[20,21] As a result, it is reasonable to assume that disease caused by *S. pseudintermedius* isolates that are susceptible to clindamycin on routine susceptibility testing is likely to respond to treatment with clindamycin. However, in some geographic locations, a high percentage of canine MRSP isolates are overtly resistant to clindamycin, which suggests that clindamycin may not be an ideal empiric treatment choice in these locations. The use of fluoroquinolones to treat staphylococcal infections has been controversial, because they have been associated with treatment failures and development of methicillin resistance in human *S. aureus* infections. In one study, a fluoroquinolone control program in a tertiary human hospital led to a significant reduction in fluoroquinolone-resistant *Pseudomonas aeruginosa* and MRSA rates over 4 years.[22]

If severe and invasive infection with an MRS is a possibility, a combination of clindamycin and an aminoglycoside could be administered parenterally, pending the results of culture and susceptibility testing. Antimicrobials that could be considered for life-threatening methicillin-resistant and multidrug-resistant staphylococcal infections include trimethoprim-sulfamethoxazole, doxycycline, aminoglycosides, rifampin, chloramphenicol, vancomycin, tigecycline, quinupristin-dalfopristin, and linezolid (see Chapter 8). Some MRS are also resistant to trimethoprim-sulfamethoxazole, doxycycline, and chloramphenicol, and toxicity may limit the usefulness of trimethoprim-sulfamethoxazole and chloramphenicol (see Chapter 8). Aminoglycosides must be given parenterally and have the potential to cause nephrotoxicity, and their activity is reduced in the presence of pus. The use of rifampin alone is controversial, because rifampin monotherapy has been associated with development of resistance in *S. aureus* infections.[23] As a result, the use of rifampin in combination with other drugs has been recommended. Minocycline has received attention as an alternative to doxycycline because some doxycycline-resistant strains (strains that possess the tetracycline efflux protein tetK) remain susceptible to minocycline. In contrast, strains that possess tetM (which protects the ribosome from tetracycline binding) are resistant to all tetracyclines. Additional information on the pharmacokinetics and definition of clinical breakpoints for minocycline are required.

Vancomycin, tigecycline, daptomycin, quinupristin-dalfopristin, and linezolid are important drugs for MRSA infections in humans. Whether these drugs should be used to treat companion animals has been debated, given that they are already widely used in humans and that they may be required to save the lives of companion animals. Cost and/or the need for parenteral administration (vancomycin, tigecycline, daptomycin, and quinupristin-dalfopristin) can also limit the usefulness of these drugs in companion animals. At a minimum, their use should be reserved for situations when no other treatment alternatives exist and when the infection is life threatening but has the potential to be resolved with appropriate treatment. The use of vancomycin or linezolid may be indicated in dogs with bacteremia or endocarditis due to MRSA, MRSP, or methicillin-resistant CoNS that are resistant to all options other than aminoglycosides and concerns for aminoglycoside toxicity exist.

FIGURE 35-2 Positive D-zone test for inducible clindamycin resistance in staphylococci. Organisms exposed to erythromycin express enhanced resistance to clindamycin, which leads to distortion of the zone of inhibition around the clindamycin disk. (Courtesy Dr. Scott Weese, University of Guelph.)

Prevention

Prevention of staphylococcal infections involves attention to the underlying cause of disease (such as allergic dermatitis), and strict veterinary clinic and veterinary hospital infection control practices (see Chapter 11). Because canine MRSA infections may be acquired from colonized or infected humans, transmission to dogs may be reduced by hand washing and general surface cleaning and disinfection in the home environment (see Public Health Aspects, next).

Public Health Aspects

Most concern regarding the public health risk of staphylococcal infection or colonization in companion animals has related to MRSA. However, because colonization of dogs with MRSA is transient, other humans are a more significant source of human MRSA infection. Nevertheless, some studies suggest that veterinarians who work with small animals may be at increased risk for colonization with MRSA. Although around 30% of the human population is colonized with *S. aureus*, the prevalence of MRSA colonization is generally much lower than this, less than 2%. In Australia, dog and cat veterinarians had a fivefold higher risk for MRSA carriage when compared with industry and government veterinarians.[24] Small animal veterinarians in the United Kingdom were also at increased risk of colonization.[25] In a study from the United States, 17.3% of veterinarians and veterinary technicians were colonized, and the rate of colonization did not differ

between small- and large-animal veterinarians.[26] In another study, only large-animal practice was associated with colonization.[27]

Regardless of the direction of transmission (human to pet versus pet to human), owners of dogs and cats diagnosed with MRSA infection should be educated about the need to wash their hands after handling their pets, clean and disinfect surfaces that might become contaminated, and not let their pet lick their face or open wounds. Infected sites should be covered with a suitable dressing to minimize contamination of the environment whenever possible. Owners should be instructed to talk to their health care providers if they have concerns about their health or the health of others in their household. In the hospital environment, transmission of MRSA may be prevented through the use of a strict hospital infection control program (see Chapter 11). Routine screening and decontamination is not recommended because dogs appear to resolve infection over time. Topical mupirocin, which has been used for decontamination in humans, is not likely to be effective in dogs and cats given the large size of their nasal cavities, and concerns have been raised regarding the need for and efficacy of decolonization with systemic antibiotics, which may only select for antimicrobial resistance.

Human infections with *S. pseudintermedius* occur occasionally in association with pet contact, although the organism generally tends not to colonize humans. However, colonization with MRSP was reported more frequently in small-animal dermatologists than colonization with MRSA.[28,29] Precautions recommended for MRSA infection are also indicated for MRSP infections.

CASE EXAMPLE

Signalment: "Elliot," a 10-year-old male neutered miniature schnauzer from San Francisco, CA

History: Elliot was seen for a possible pacemaker infection. One month after placement of a dual-chamber pacemaker for sick sinus syndrome, a fluctuant mass was noted around the generator. The seroma was aspirated, and cytologic examination of the aspirate showed many neutrophils. Treatment with clavulanic acid-amoxicillin was initiated (25 mg/kg PO q12h). One month later, there had been no apparent improvement. The wound was flushed with chlorhexidine solution and treatment with chloramphenicol was initiated, but the problem persisted. The chloramphenicol was discontinued, and the dog was referred for further evaluation. The owners reported no vomiting, diarrhea, or decreased appetite. Elliot had also been diagnosed with early myxomatous degeneration of the mitral valve based on the results of echocardiography, associated with a grade III/VI left apical systolic murmur at the time of pacemaker placement.

Physical Examination:

Body Weight: 9.8 kg

General: Quiet, alert, and responsive. Slightly tacky but pink mucous membranes, capillary refill time <2 s, approximately 5% dehydrated, T = 104°F, HR = 160 beats/min, RR = 40 breaths/min.

Eyes, Ears, Nose, and Throat: A mild crusted ocular discharge was present bilaterally, as well as mild serous nasal discharge, and moderate periodontal disease.

Integument: A 1-cm wound that discharged purulent material was present in the region of the right jugular incision, with a draining tract located along the jugular lead that extended to the pacemaker generator over the right cervical region. There was an accumulation of fluid that measured 1 cm in diameter over the generator.

Musculoskeletal: Ambulatory with normal gait, BCS 5/9

Cardiovascular: Heart rate 160 beats/min, regular rhythm, grade III/VI left apical systolic murmur, femoral pulses strong and synchronous

Respiratory: Mild crackles were auscultated in the left and right caudal lung fields.

Abdominal Palpation: Cranial organomegaly was present.

Lymph Nodes: All lymph nodes were normal in size.

Laboratory Findings:

CBC:

HCT 32.2% (40%-55%)
MCV 60.3 fL (65-75 fL)
MCHC 32.3 g/dL (33-36 g/dL)
Reticulocytes 9100 cells/µL (7000-65,000 cells/µL)
WBC 29,680 cells/µL (6000-13,000 cells/µL)
Neutrophils 22,854 cells/µL (3000-10,500 cells/µL)
Lymphocytes 4155 cells/µL (1000-4000 cells/µL)
Monocytes 594 cells/µL (150-1200 cells/µL)
Eosinophils 890 cells/µL (0-1500 cells/µL)
Platelets 446,000 platelets/µL (150,000-400,000 platelets/µL)
Slight toxicity of neutrophils and band neutrophils.

Serum Chemistry Profile:

Sodium 140 mmol/L (145-154 mmol/L)
Potassium 5.6 mmol/L (3.6-5.3 mmol/L)
Chloride 103 mmol/L (108-118 mmol/L)
Bicarbonate 16 mmol/L (16-26 mmol/L)
Phosphorus 7.5 mg/dL (3.0-6.2 mg/dL)
Calcium 11.3 mg/dL (9.7-11.5 mg/dl)
BUN 48 mg/dL (5-21 mg/dL)
Creatinine 1.8 mg/dL (0.3-1.2 mg/dL)
Glucose 81 mg/dL (64-123 mg/dL)
Total protein 7.6 g/dL (5.4-7.6 g/dL)
Albumin 2.7 g/dL (3.0-4.4 g/dL)
Globulin 4.9 g/dL (1.8-3.9 g/dL)
ALT 61 U/L (19-67 U/L)
AST 17 U/L (19-42 U/L)
ALP 190 U/L (21-170 U/L)
Creatine kinase 61 U/L (51-399 U/L)
Gamma GT 3 U/L (0-6 U/L)
Cholesterol 323 mg/dL (135-361 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL)
Magnesium 1.7 mg/dL (1.5-2.6 mg/dL).

Urinalysis: SGr 1.013; pH 6.0, 150 mg/dL protein, no bilirubin, 150 erythrocytes/µL hemoprotein, no glucose, no ketones, 12-18 WBC/HPF, 8-12 RBC/HPF, no other significant findings.

Coagulation Panel: PT 8.7 s (7.0-9.3 s), APTT 14.1 s (10.4-12.9 s), fibrinogen 412 mg/dL (109-311 mg/dL), D-dimers 418 ng/mL (0-186 ng/mL), antithrombin 84% (80%-120%).

Imaging Findings:

Thoracic Radiographs: See Figure 35-3. Mild cardiomegaly was present. The far caudal left pulmonary vasculature

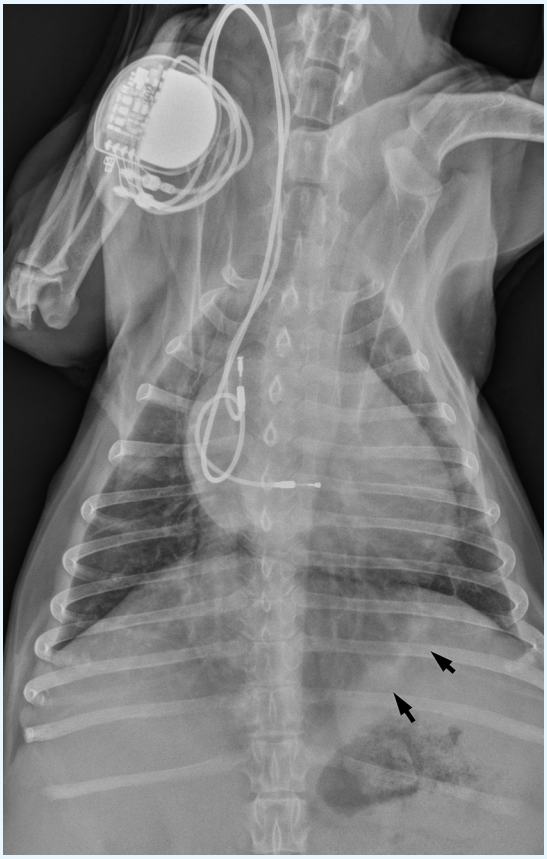

FIGURE 35-3 Dorsoventral thoracic radiograph from a 10-year-old male neutered miniature schnauzer with methicillin-resistant *Staphylococcus* bacteremia and pacemaker infection. There was a bronchointerstitial pattern and mild cardiomegaly. The caudal left pulmonary vasculature was indistinct with patchy infiltrates *(arrows)*, which raised suspicion for septic embolic pneumonia.

was indistinct with region of patchy infiltrates (arrows). The pacemaker was static in appearance with a generator embedded in the tissues dorsal to the cervical spine and two leads extending into the region of the cardiac silhouette—one terminating at the level of the right atrium and the other terminating at the level of the right ventricle. Within the viewable abdomen, the liver was persistently markedly enlarged and rounded. Given the absence of vasculature in the left caudal lung lobe, embolism in this area was suspected.

Echocardiogram (to evaluate for endocarditis): Mild mitral regurgitation was present, with no evidence of endocarditis.

Microbiologic Testing:

Aerobic Blood Culture and Susceptibility: *Bottle 1 (right cephalic catheter):* Direct smear from bottle: small numbers of gram-positive cocci and small numbers of gram-variable rods. Culture: coagulase-negative *Staphylococcus* and *Serratia marcescens*. The CoNS was methicillin resistant and resistant to clindamycin, enrofloxacin, marbofloxacin, erythromycin, trimethoprim-sulfamethoxazole; had intermediate susceptibility to gentamicin (8.00 µg/mL); and was susceptible to amikacin (≤4.00 µg/mL), chloramphenicol (8.00 µg/mL), doxycycline (4.00 µg/mL), rifampin (≤1 µg/mL), daptomycin (≤0.25 µg/mL), linezolid (≤0.5 µg/mL), and vancomycin (≤1.00 µg/mL). The *Serratia marcescens* was resistant to cefazolin, cefoxitin, cephalothin, and doxycycline; and susceptible to amikacin (≤4.00 µg/mL), amoxicillin-clavulanic acid (4.00 µg/mL), ampicillin (≤2.00 µg/mL), cefovecin (1.00 µg/mL), cefpodoxime (≤2.00 µg/mL), enrofloxacin (≤0.25 µg/mL), marbofloxacin (≤1 µg/mL), gentamicin (≤1 µg/mL), imipenem (≤1 µg/mL), ticarcillin (≤8 µg/mL), ticarcillin-clavulanate (≤8 µg/mL), and trimethoprim-sulfamethoxazole (≤0.5 µg/mL).

Bottle 2 (right lateral saphenous vein): Direct smear: small numbers of gram-positive cocci. Culture: coagulase-negative *Staphylococcus*.

Urine aerobic culture and susceptibility (cystocentesis specimen): $>10^5$ organisms/mL coagulase-negative *Staphylococcus*, with an identical antibiogram to that of the isolate from the blood.

Seroma Aerobic and Anaerobic Culture and Susceptibility: Small numbers of coagulase-negative *Staphylococcus*, with an identical antibiogram to that of the isolate from the blood and urine.

Diagnosis: Bacteremia and probable embolic pneumonia due to methicillin-resistant *Staphylococcus* spp. and possibly *Serratia marcescens* associated with pacemaker placement. Skin/soft tissue and urinary tract infection with methicillin-resistant *Staphylococcus* spp.

Treatment: Elliot was hospitalized with full-contact precautions that included the use of gloves and gowns and contact with a limited number of individuals. Treatment was initiated with intravenous fluids, vancomycin (10 mg/kg IV q6h) for the methicillin-resistant staphylococcal infection, and enrofloxacin (10 mg/kg IV q24h) for a possible *Serratia marcescens* infection. After 48 hours of treatment, the pacemaker was removed and replaced with a ventricular (VVIR) epicardial pacemaker, and a Penrose drain was placed at the incision site. A repeat blood culture (four bottles) performed 3 days later showed growth of the CoNS in one bottle. The pulmonary infiltrates resolved, creatinine normalized, and repeat blood and urine cultures were negative after 10 days of vancomycin treatment. The dog was discharged from the hospital. Follow-up cultures after an additional 10 days off antibiotics remained negative. Six months later, Elliot developed right-sided congestive heart failure with ascites and pleural effusion. Aerobic bacterial culture of the ascites fluid was negative. On echocardiography, the tricuspid valve was severely thickened and irregular. Endocarditis was suspected. Additional diagnostics that included blood cultures were declined by the owners, who elected euthanasia without necropsy.

Comments: Vancomycin was used to treat this severe methicillin-resistant staphylococcal infection because the dog had renal failure and there was concern for aminoglycoside toxicity. The *S. marcescens* may have represented a contaminant, but it was treated because of the severity of the dog's condition. Whether the endocarditis that developed was the result of a new infection or persistence of the original staphylococcal infection could not be determined.

CHAPTER 36

Gram-negative Bacterial Infections

Jane E. Sykes

VetBooks.ir

Overview of Gram-negative Bacteria

First Described: Gram-negative bacteria were first described in Berlin by the Danish scientist Hans Christian Gram in 1884 when he used Gram stain to visualize *Klebsiella pneumoniae* in the lungs of people who died of pneumonia.[1]

Causes: Examples include *Escherichia coli, Salmonella, Enterobacter, Citrobacter, Klebsiella, Campylobacter, Pseudomonas,* and *Acinetobacter.*

Geographic Distribution: Worldwide

Mode of Transmission: Direct contact or contact with contaminated fomites; the bacteria often invade opportunistically

Major Clinical Signs: Affected sites include UTIs, wound infections, pneumonia, pyothorax, peritonitis, pyometra, ocular surface infections, otitis externa, pyoderma, bacteremia, and endocarditis, but virtually any body system can be affected.

Differential Diagnoses: Infections with gram-positive bacteria such as *Staphylococcus* spp. and *Streptococcus* spp.; to a lesser extent infections with nonbacterial pathogens such as fungi.

Human Health Significance: Gram-negative bacteria shed by dogs and cats have the potential to colonize humans, especially those with impaired host defenses. They may also be responsible for infections of dog or cat bites.

Etiology, Epidemiology, and Clinical Features

Gram-negative bacteria are widespread causes of opportunistic infections in dogs and cats and primarily cause disease when host defenses are impaired. They are important causes of nosocomial disease. In contrast to gram-positive bacteria, gram-negative bacteria have a complex outer membrane that contains lipopolysaccharide (LPS), as well as structures known as *porins* that regulate transport of molecules in and out of the cell, which includes antimicrobial drugs. Between this outer membrane and the inner (cytoplasmic) membrane is a periplasmic space, which contains the structural polymer peptidoglycan (or *murein*) (Figure 36-1). The peptidoglycan layer of gram-negative bacteria is much thinner than that of gram-positive bacteria, approximately one layer, or 7 to 8 nm thick (compared with many layers, or 20 to 80 nm thick for gram-positive bacteria). The inner cytoplasmic membrane contains many different proteins that are lipoproteins anchored into the outer lipid bilayer leaflet, transmembrane proteins, or peripheral membrane proteins that lie adjacent to the bilayer leaflets.

LPS is a large molecule that varies in composition from one bacterial species and strain to another. It contributes to the structural integrity of gram-negative bacteria and is a potent virulence factor. It consists of the *lipid A* backbone, a *core oligosaccharide,* and the *O antigen* side chain. Lipid A is a phosphorylated disaccharide to which long, hydrophobic fatty acid chains are attached, which anchor the LPS into the outer membrane (Figures 36-1 and 36-2). The lipid A component is also known as *endotoxin* because it is the biologically active portion of the molecule, in that it stimulates a potent host inflammatory response (see Chapter 86). The core oligosaccharide connects lipid A to the O antigen side chain. Its composition differs between bacterial species. The O antigen is a repeating polysaccharide that projects from the surface of the bacterial cell and varies in length from 1 to 60 repeats. It is the antigenic portion of the molecule and is responsible for serogroup classification of gram-negative bacteria.

Gram-negative cocci, such as *Moraxella* or *Neisseria,* are not widely recognized as significant pathogens of dogs and cats. However, they are commensals of the oral cavity of dogs and cats, can cause bite wound infections in humans,[2] and *Neisseria canis* was isolated in pure culture from a deep mandibular abscess from one dog.[3] Gram-negative rods are classified into Enterobacteriaceae and non-Enterobacteriaceae species. Enterobacteriaceae that cause disease in dogs and cats include *Escherichia coli, Proteus, Salmonella, Enterobacter, Citrobacter, Serratia,* and *Klebsiella*. Non-Enterobacteriaceae species include the Pasteurellaceae *(Pasteurella multocida),* as well as *Pseudomonas aeruginosa* and *Acinetobacter*. Other gram-negative bacteria are coccobacilli or spiral-shaped organisms and include *Bartonella, Bordetella, Campylobacter, Francisella, Helicobacter,* and *Brucella*.

Like gram-positive cocci, some gram-negative bacteria have tremendous ability to form biofilms, or bacterial aggregates that are embedded in a matrix of exopolysaccharide (bacterial slime), which form on living or nonliving surfaces. These protect the bacteria, and bacteria in biofilms can resist the effect of antimicrobial drugs and disinfectants.

Enterobacteriaceae

Many of the Enterobacteriaceae contribute to the normal gastrointestinal flora of animals. Organisms that belong to the Enterobacteriaceae possess a capsule *(K antigen)* and may be motile via flagella *(H antigen)*. Some highly encapsulated species, such as *Klebsiella* and *Enterobacter,* have a mucoid appearance when they grow in culture. The flagella project from the bacterial cell and contain the filament-forming protein *flagellin,* which (along with LPS) can stimulate the host inflammatory response. The Enterobacteriaceae also possess fimbriae or pili, which are thinner than flagella and play a role in adhesion and sometimes bacterial aggregation. Finally, they possess a variety of complex

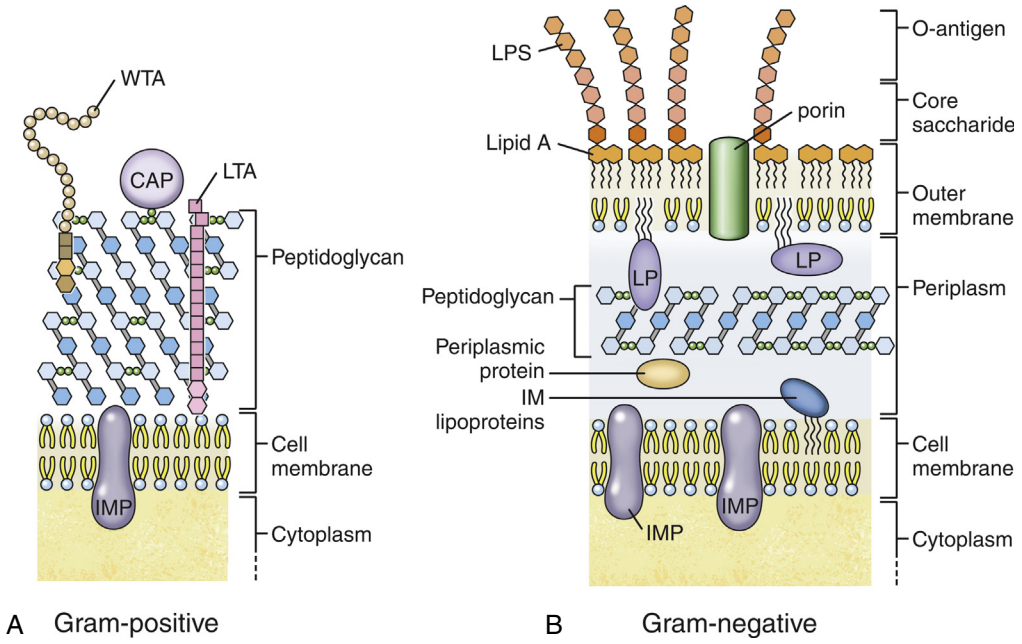

FIGURE 36-1 Structure of the envelope of gram-positive **(A)** and gram-negative **(B)** bacteria. The thickness of the peptidoglycan layer is greater in gram-positive bacteria than in gram-negative bacteria.

secretion systems (type I, II, III secretion systems). These facilitate export of toxins such as hemolysins, and molecules that are inserted into, and form pores in, host cell membranes. The bacteria then use these pores to inject toxins directly into the host cell. The Enterobacteriaceae also have a variety of iron scavenging systems, which are important virulence factors, and transmissible plasmids that contain genes for virulence factors and antimicrobial resistance factors.

Escherichia coli

Escherichia coli is the most common cause of urinary tract infections (UTIs) in dogs and cats and can also be isolated from dogs and cats with pyometra, prostatitis, peritonitis, cholangitis, cholecystitis, bacteremia and endocarditis, bronchopneumonia (such as that secondary to aspiration), and pyothorax. There is one report of necrotizing fasciitis in a dog associated with *E. coli* infection.[4]

Antibiotic resistance in *E. coli* isolates from dogs and cats is an increasing problem; 51% of 376 isolates collected from sick dogs and cats in the United States in 2005 showed resistance to at least one drug, and 29% of the 376 isolates were multiple drug resistant (MDR; defined as resistant to three or more classes of antimicrobial drugs).[5] The prevalence of resistance in 395 isolates from healthy dogs and cats from Canada was lower, 19%.[6] Extended-spectrum β-lactamase enzyme production has also been identified in *E. coli* isolates from dogs and cats in the United States,[7] and a few isolates were found to express New Dehli metallo-β-lactamase (NDM-1), which hydrolyses carbapenems.[8] Nosocomial infections with MDR *E. coli* have also been described in dogs and cats.

In humans, strains of *E. coli* that cause UTIs differ from those that cause diarrhea, and there is some evidence that this may also be true for strains that cause UTIs versus pyometra in dogs and cats.[9-11] Strains of *E. coli* that cause UTIs belong to the pathotype *extraintestinal pathogenic E. coli* (ExPEC). These strains possess a number of virulence factors, such as siderophores, type 1 and P fimbriae, hemolysin, and cytotoxic necrotizing factor. Specific virulence factors, as well as biofilm-forming capacity, have been associated with persistent or relapsing UTIs,[12,13] and uropathogenic *E. coli* can invade and persist within bladder epithelial cells. In one study, canine UTIs associated with *E. coli* were more likely to be recurrent than those associated with other uropathogens.[14] There has been concern that dogs may act as a source of *E. coli* strains that are pathogenic for humans.[11,15] In other extraintestinal *E. coli* infections, *E. coli* more closely resemble commensal strains, and host factors may be more important than bacterial virulence factors. The reader is referred to Chapter 46 for more information on intestinal *E. coli* infections.

Proteus

Proteus mirabilis is a common cause of upper and lower UTIs in dogs as well as otitis externa and uncommonly pyoderma. It produces a potent urease and so may contribute to development of struvite urolithiasis. Uroliths harbor bacteria that can emerge as the uroliths dissolve. *Proteus* has a characteristic swarming motility and may obscure the growth of other co-infecting microorganisms when grown in the laboratory on agar. *Proteus penneri,* an uncommon cause of nosocomial infections in humans, has rarely been isolated from wound infections in dogs seen at the author's hospital.

Klebsiella

The most common species of *Klebsiella* that infects dogs and cats is *K. pneumoniae*. *K. oxytoca* is a nosocomial pathogen in humans and has been reported in association with intravenous catheter colonization in puppies with parvoviral enteritis.[16]

K. pneumoniae primarily causes upper and lower UTIs in dogs and cats, but can also cause pneumonia, sometimes with abscessation (Figures 36-3 and 36-4). It has also been isolated from dogs with hepatic abscesses.[17] Nosocomial infections may be associated with bacteremia, endocarditis, and postoperative skin and soft tissue infections. The capsule of *K. pneumoniae* is

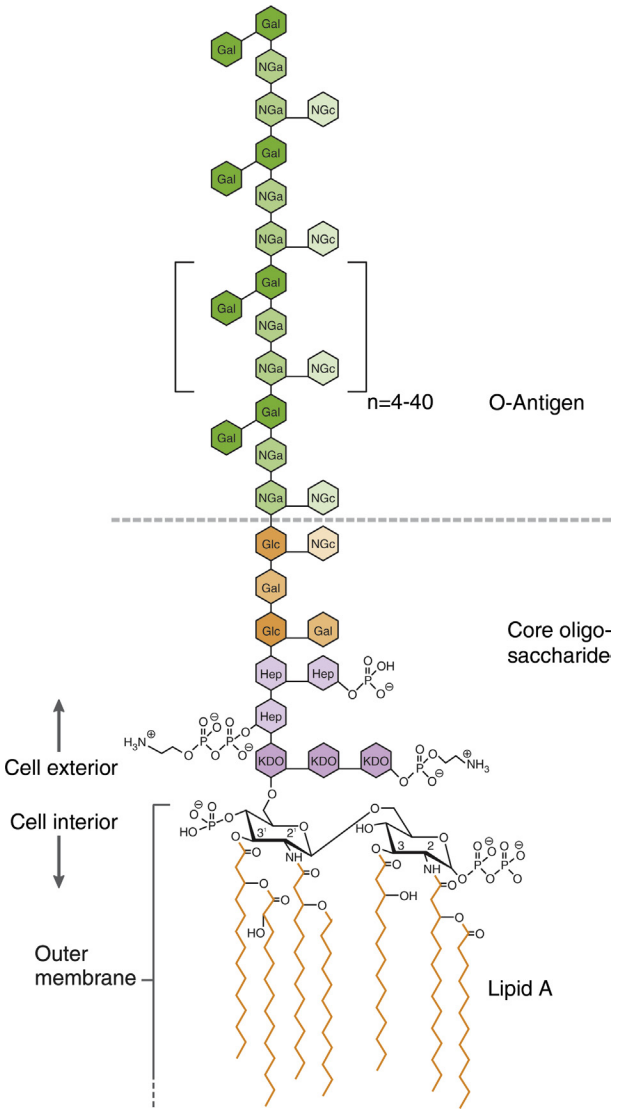

FIGURE 36-2 Structure of bacterial lipopolysaccharide.

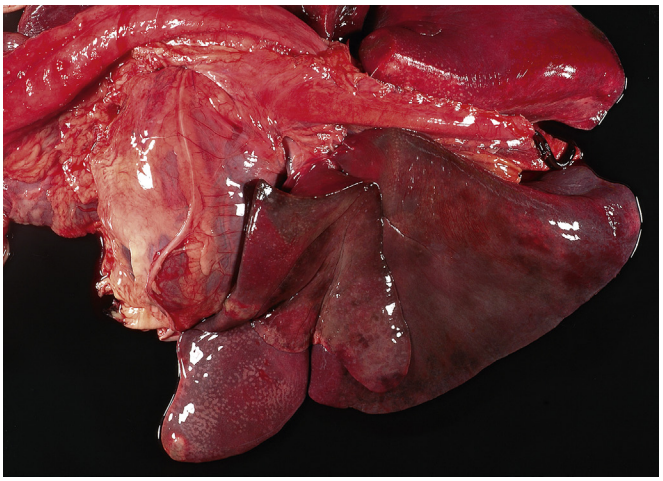

FIGURE 36-3 Lungs of an 11-year-old intact male German shepherd dog with severe, acute, suppurative, necrotizing and hemorrhagic bronchopneumonia due to *Klebsiella pneumoniae* infection. The lung lobes are severely congested. Five days before death, multiple laminectomies had been performed for intervertebral disc disease, and 2 days later the dog developed aspiration pneumonia that necessitated mechanical ventilation. Euthanasia was elected when there was further deterioration in the dog's condition, and bloody exudate was present in the endotracheal tube just before euthanasia.

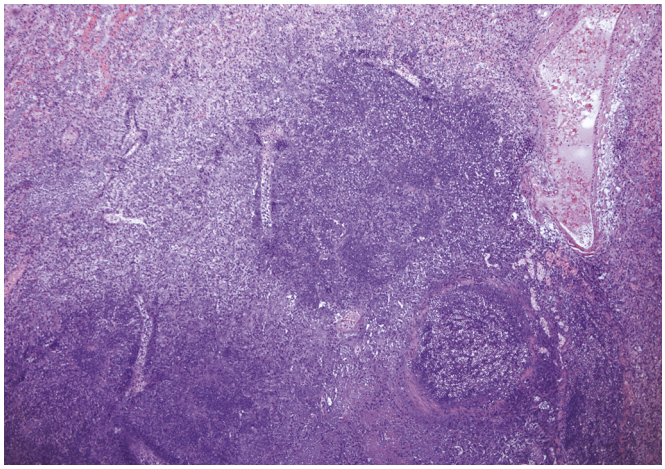

FIGURE 36-4 Histopathology of the lung from a 4-month-old intact male Newfoundland dog with severe, multifocal, necrotizing lung abscesses. Intralesional rod-shaped bacteria were also present. *Klebsiella pneumoniae* was isolated from the lesions. H&E stain, 40× magnification.

a major virulence factor; it inhibits phagocytosis and is responsible for the mucoid appearance of the organism in culture (Figure 36-5, *A*).

All strains of *K. pneumoniae* are resistant to ampicillin, because they possess a chromosomal gene that encodes a penicillin β-lactamase. Some isolates, such as nosocomial isolates or those from persistent UTIs, possess plasmids that contain resistance genes for multiple antimicrobial drugs. Of greatest concern are *Klebsiella* isolates that express extended-spectrum β-lactamase (ESBL) enzymes, which hydrolyze third-generation cephalosporins such as cefotaxime or ceftriaxone. The genes that encode ESBLs are often located on plasmids that also contain genes for aminoglycoside resistance. Although MDR *K. pneumoniae* are not uncommonly isolated from dogs and cats, ESBL-producing *K. pneumoniae* isolates are rarely encountered. Treatment options for MDR *K. pneumoniae* may be limited to aminoglycosides, carbapenems, and sometimes trimethoprim-sulfamethoxazole.

Serratia marcescens

Serratia marcescens is an important cause of nosocomial infections in both human and veterinary medicine. In human patients it is often linked to intravenous drug use. The organism has a tremendous ability to survive in the environment and may contaminate and remain viable in disinfectant solutions.[18] It sometimes grows as a contaminant, such as in blood cultures. Some, but not all, strains of *S. marcescens* produce a red pigment when grown in culture.

In dogs, *S. marcescens* infection has been associated with UTIs, bacteremia and aortic valve endocarditis,[19] catheter-related infections in canine parvoviral enteritis,[14] and necrotizing fasciitis.[20] Contamination of blood products was linked to an outbreak of bacteremia in cats.[21] *Serratia* is resistant to ampicillin and first-generation cephalosporins as a result of a chromosomal β-lactamase. It may also acquire plasmid-mediated resistance to other antimicrobial drugs.

Enterobacter

Enterobacter cloacae and, to a lesser extent, *Enterobacter aerogenes* represent the majority of *Enterobacter* species isolated

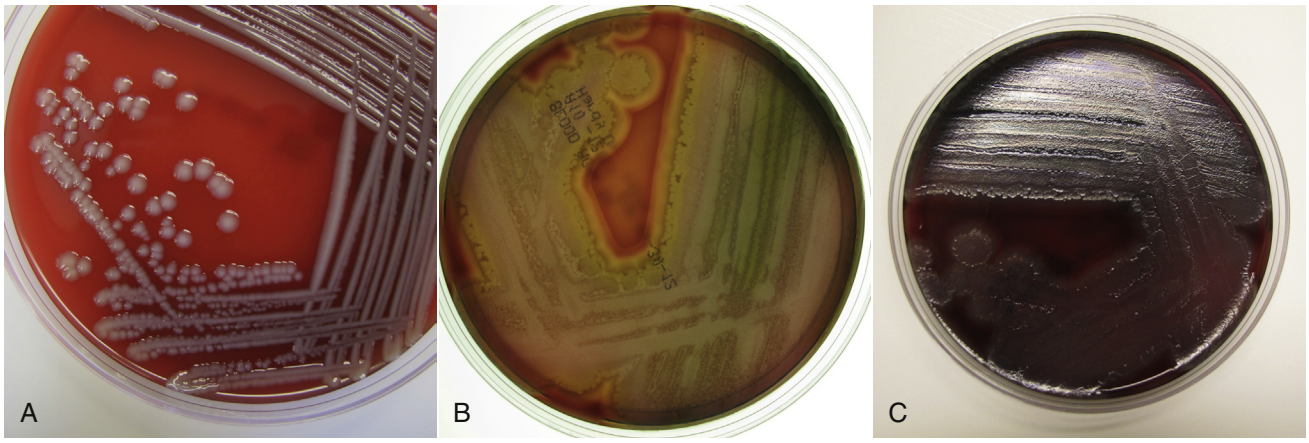

FIGURE 36-5 Gram-negative aerobic bacteria growing on blood agar. **A,** Mucoid colonies of *Klebsiella pneumoniae*. **B,** *Pseudomonas aeruginosa*. Transillumination using a light box revealed the presence of hemolysis and production of a green pigment (pyoverdin). **C,** The plate in **(B)** had a fruity odor and a "mother-of-pearl" appearance when not transilluminated.

from dogs and cats in the author's hospital. *Enterobacter* spp. are mainly isolated from dogs and cats with UTIs but occasionally cause wound or catheter-related infections. They generally are intrinsically resistant to ampicillin and first-generation cephalosporins and may also be resistant to multiple other antimicrobial drug classes.

Citrobacter

Citrobacter species are named for their ability to use citrate as a sole carbon source. *Citrobacter freundii* is most commonly isolated from dogs and cats with UTIs but can also cause catheter-related infections, bacteremia, and endocarditis.[22,23] *Citrobacter koseri* was isolated from puppies with myocarditis.[24] Like *Enterobacter* and *Serratia, Citrobacter* are usually resistant to ampicillin and first-generation cephalosporins and may acquire a number of plasmid-mediated resistance genes, including those that encode ESBLs and resistance to fluoroquinolones.

Non-Enterobacteriaceae

Pasteurella

Bacteria that belong to the family Pasteurellaceae are small, fastidious, nonmotile bacilli or coccobacilli that are commensals of the oral cavities and upper respiratory tracts of dogs and especially cats. The most common species of *Pasteurella* associated with disease in dogs and especially cats is *Pasteurella multocida*. Other species include *Pasteurella canis, Pasteurella dagmatis,* and *Pasteurella stomatis*. *Pasteurella* spp. have been associated with a wide variety of disease manifestations that include pyothorax, upper respiratory tract infections (usually secondary to viral infections or chronic rhinosinusitis), bronchopneumonia, UTIs, ocular surface infections, wound infections, cutaneous abscesses, otitis externa, bacteremia, and, rarely, infective endocarditis. They may be found in mixed infections with other bacteria, such as *Streptococcus canis,* other gram-negative bacteria, or anaerobes. In humans, they are an important cause of animal bite wound infections.[2] *Pasteurella* spp. are usually broadly susceptible to antimicrobial drugs, and the treatment of choice is a penicillin such as penicillin G, ampicillin, or amoxicillin.

Pseudomonas aeruginosa

Pseudomonas aeruginosa is the main pathogenic species in the family Pseudomonaceae. It is known for its ability to produce a variety of pigments when grown in culture, such as pyocyanin (blue), pyorubin (red), pyomelanin (black), and pyoverdin (yellow-green to yellow-brown and fluorescent), and for its characteristic "corn taco" or "grape"-like odor (see Figure 36-5, *B* and *C*). *P. aeruginosa* has one polar flagellum and is covered in thin, hairlike pili (Figure 36-6). It can also produce an extracellular

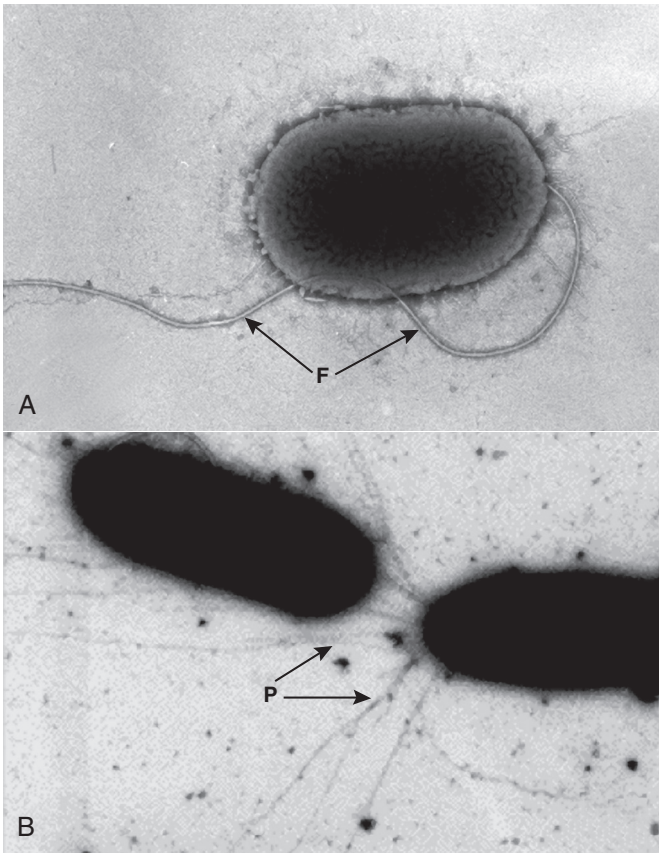

FIGURE 36-6 Electron micrograph of *Pseudomonas aeruginosa* showing ultrastructural features. **A,** Single cell with polar flagellum (*F*) with part of the flagellum running under the cell body. **B,** Two cells showing thin, hair-like pili (*P*). VetBooks.ir

polysaccharide known as *alginate,* which results in a mucoid colony appearance.

Pseudomonas aeruginosa is widespread in the environment and can grow in a huge variety of different conditions, reflecting its importance as a nosocomial pathogen. It is commonly found on plants, water, and soil. It can survive in disinfectants and grow in diesel and jet fuel. It is occasionally isolated from the skin, mucous membranes, and feces of healthy animals and humans. Almost any site of the body that is subject to injury can become colonized and subsequently infected. In humans, community-acquired infections can occur as a result of exposure to contaminated hot tubs, swimming pools, and contact lens solutions. In the hospital environment, *P. aeruginosa* often colonizes moist environments such as sinks, endotracheal tubes, and ventilator equipment. It also colonizes damp, macerated tissues such as the ear canals, damaged cornea, traumatized skin (such as wounds and burns), and the interdigital space. Because the organism can be resistant to a large number of different antimicrobial drugs, repeated treatment of secondary bacterial infections in sites where impaired host defenses exist with a variety of antimicrobials can select for MDR *P. aeruginosa* infection at these sites. Examples of such conditions in dogs and cats include recurrent aspiration pneumonia and/or bronchiectasis, cystitis, chronic feline rhinosinusitis, and otitis externa/media.

Pseudomonas aeruginosa possesses virtually every type of bacterial virulence factor, including exotoxins, a type III secretion system, lipopolysaccharide, pili, flagella, several proteases, phospholipases, iron-scavenging mechanisms such as pyoverdin production, and the ability to form extensive biofilms. Alginate protects the organism from phagocytosis, and the pigment pyocyanin produces reactive oxygen species, which in turn damage host cells. Multidrug resistance results from the production of specific β-lactamase enzymes (which can include ESBLs), antibiotic efflux pumps, enzymes that modify aminoglycosides or alter antibiotic binding sites (such as DNA gyrase for fluoroquinolones), and decreased bacterial permeability.

Infections with broadly susceptible *P. aeruginosa* isolates could be treated with an antipseudomonal β-lactam (e.g., ticarcillin, a carbapenem, cefepime, ceftazidime) alone or in combination with an aminoglycoside or a fluoroquinolone. The combination of an aminoglycoside and an antipseudomonal penicillin has synergistic activity against some *P. aeruginosa* infections. Currently, most MDR *P. aeruginosa* isolates from dogs and cats remain susceptible to carbapenems (such as meropenem) and aminoglycosides (especially amikacin), and so the usual treatment of choice is 1) a combination of these two drugs, 2) removal of any foreign or necrotic material and, 3) if possible, resolution or management of any other underlying cause for impaired host defenses. Because parenterally administered aminoglycosides do not effectively penetrate airway mucus, nebulized tobramycin has been used to treat resistant *P. aeruginosa* infections of the airways in human patients, but these may not adequately penetrate consolidated lung tissue.[25] Effective treatment of MDR *P. aeruginosa* infections when they occur in locations such as the feline nasal cavity may be extremely difficult, if not impossible, because of irreversible turbinate loss, the requirement for injectable antimicrobial drugs, poor penetration of aminoglycosides to the site of infection, and an inadequate ability to effectively treat all surfaces of the nasal cavity with topical aminoglycosides.

Investigation of suspected nosocomial outbreaks of *P. aeruginosa* infection generally requires typing of isolates from affected animals and the environment with molecular methods such as pulsed-field gel electrophoresis or multilocus sequence typing. Use of antibiograms alone does not adequately discriminate between strains.

Acinetobacter

Like *P. aeruginosa, Acinetobacter* is an important nosocomial opportunistic pathogen. *Acinetobacter* is present in soil and water and can be found in frozen foods, pasteurized milk, and an enormous array of inert objects in the hospital environment, where it may persist for months. It colonizes the skin and mucous membranes of healthy humans as well as those of dogs and cats.[26,27] The main species that cause disease in animals are *Acinetobacter baumannii* and, to a lesser extent, *Acinetobacter lwoffii* and *Acinetobacter calcoaceticus*. Multidrug resistant isolates of *A. baumannii* have been responsible for outbreaks of nosocomial infections in veterinary hospitals[28,29] and, like MDR *P. aeruginosa*, may be resistant to a huge variety of antimicrobial drug classes. Carbapenem-resistant *A. baumannii* have been isolated from humans as well as animals.[29,30] Clinical manifestations of *Acinetobacter* infections in dogs and cats include nosocomial UTIs (e.g., after invasive urinary procedures such as catheterization), surgical wound infections, pneumonia, catheter-related bacteremia, and, rarely, endocarditis. Necrotizing fasciitis associated with *A. baumannii* infection was described in a cat.[31] When *Acinetobacter* is grown from a specimen, care should be taken to differentiate infection from contamination. Most veterinary isolates are susceptible to aminoglycosides and carbapenems; some are susceptible to trimethoprim-sulfamethoxazole and fluoroquinolones.[28]

Diagnosis

Laboratory Abnormalities

Complete Blood Count, Biochemistry, and Urinalysis Findings

Dogs and cats with superficial gram-negative infections of sites that drain to the exterior, such as wounds, the external ear canal, the nasal cavity, and the lower urinary tract, often have no clinically significant laboratory abnormalities. Deep tissue or systemic infections with gram-negative bacteria may be associated with marked neutrophilia and a left shift, toxic neutrophils, or a degenerative left shift, sometimes with circulating metamyelocytes. Thrombocytopenia may be present in dogs and cats that develop disseminated intravascular coagulation (DIC). Anemia of inflammatory disease, lymphopenia, and monocytosis may be present. The urinalysis of dogs and cats with gram-negative bacterial UTIs may reveal pyuria, proteinuria, hematuria, and sometimes bacterial rods on sediment examination.

Coagulation Profile

Systemic gram-negative bacterial infections may be associated with evidence of DIC due to activation of the coagulation cascade by endotoxin.

Cytologic Abnormalities

Aspirates of affected tissues or pus, or transtracheal wash or bronchoalveolar lavage fluid specimens from dogs and cats with gram-negative bacterial infections may contain large numbers of degenerate and nondegenerate neutrophils, sometimes with bacterial rods.

VetBooks.ir

TABLE 36-1

Examples of Systemic Antimicrobial Drugs That Could Be Selected for Treatment of Gram-Negative Bacterial Infections in Dogs and Cats (See Also Chapter 8)

Infecting Species	Drug	Dose (mg/kg)	Interval (hours)	Route
Pasteurella	Amoxicillin	20	8	PO
	Ampicillin	20	6-8	IV, IM, SC
	Penicillin G	20,000-40,000 U/kg	6-8	IV, IM
Susceptible Enterobacteriaceae	Trimethoprim-sulfamethoxazole	30	12	PO, IV
	Amoxicillin–clavulanate potassium	20	8	PO
	Ciprofloxacin	20-30	24	PO
		10	24	IV
MDR Enterobacteriaceae, *Pseudomonas*, or *Acinetobacter*	Amikacin*	15-30 (dogs), 10-14 (cats)	24	IV, IM, SC
	Gentamicin*	9-14 (dogs), 5-8 (cats)	24	IV, IM, SC
	Ticarcillin disodium, ticarcillin-clavulanate	33-50	4-6	IV
	Meropenem	12	8	SC
		25	8	IV
	Ceftazidime	30	6	IV

*Use aminoglycosides in combination with an antipseudomonal β-lactam such as ticarcillin, meropenem, or a third-generation cephalosporin.

Microbiologic Tests

Isolation and Identification

Gram-negative bacteria are readily isolated from aspirates, tissue biopsies, body fluid, blood, and lavage specimens. MacConkey and blood agar are usually used to isolate gram-negative bacteria, which usually grow within 24 to 48 hours and are subsequently differentiated on the basis of colony morphology and biochemical reactions. *Pasteurella* spp. are more fastidious, and species that infect dogs and cats do not grow on MacConkey agar. Evaluation of antimicrobial susceptibility is important for all Enterobacteriaceae, *P. aeruginosa*, and *Acinetobacter* spp., given their propensity to develop resistance to many antimicrobial drug classes.

Treatment and Prognosis

The approach to treatment of gram-negative infections depends on the site of infection and the severity of disease (Table 36-1); the reader is referred to Chapters 84 to 90 for treatment recommendations for different organ systems. Identification and management of the underlying cause are also important to minimize selection for resistant organisms. Any foreign material (such as catheters, implants) must be removed, and necrotic tissue debrided. When systemic antimicrobial drug treatment is required, it should preferably be based on the results of susceptibility testing, although *Pasteurella* spp. are generally susceptible to penicillin or aminopenicillins such as amoxicillin. Because gram-negative bacteria have higher minimum inhibitory concentrations (MICs) to penicillins than do gram-positive bacteria, the high end of the dose range and more frequent administration may be necessary. Some Enterobacteriaceae are intrinsically resistant to ampicillin and first-generation cephalosporins, and initial treatment of serious infections while awaiting the results of susceptibility testing should include an aminoglycoside, a third-generation cephalosporin, or a fluoroquinolone. Trimethoprim-sulfamethoxazole, amoxicillin, or clavulanic acid–amoxicillin are reasonable initial choices for treatment of UTIs associated with bacterial rods.[32] Treatment should also be based on knowledge of local resistance patterns among gram-negative bacteria, which may vary from region to region and practice to practice.

Prevention

Prevention of gram-negative infections involves resolution of impairment in host defenses and strict hospital infection control practices (see Chapter 11).

Public Health Aspects

Strains of *E. coli* and other MDR gram-negative bacteria harbored by dogs resemble pathogenic strains isolated from humans.[15,30] As a result, concern has been raised that companion animals may be a source of organisms for human infection, especially those that reside with humans with compromised host defenses.

Pasteurella multocida is the most commonly isolated organism from human dog and cat bite wounds.[2] *Pasteurella* spp. can also colonize the respiratory tracts of humans with underlying respiratory disease such as bronchiectasis or chronic sinusitis, and they occasionally have been reported in association with peritonitis, bacteremia, and endocarditis. Most of these humans have had contact with domestic animals in the household, and isolates from affected humans have been shown by molecular methods to be identical to those colonizing animals in the household.[33]

Thus, immunocompromised owners or those with impaired anatomic barriers should be instructed to wash their hands after handling their pet and perform regular household cleaning and disinfection. Companion animals should not be allowed to lick open wounds or the owner's face.

CASE EXAMPLE

Signalment: "Lottie", a middle-aged, female spayed domestic shorthair from northern California

History: Lottie was evaluated for chronic nasal discharge. Since her rescue as a stray 2.5 years earlier, intermittent sneezing and bilateral mucopurulent nasal discharge had been noted, and the discharge sometimes contained blood. Ten months before the evaluation, Lottie had been anesthetized for a nasal flush at a local veterinary clinic, but developed respiratory distress on recovery and was hospitalized with oxygen supplementation for 24 hours. She was ataxic, leaned to one side, and did not eat well for days, but over the subsequent months the ataxia and leaning gradually resolved. For the two weeks before the evaluation Lottie had stertorous respiration and intermittent episodes of open-mouth breathing. For the past 9 months, Lottie had been treated with marbofloxacin and prednisolone. Before that, treatments for the nasal discharge included clavulanic acid–amoxicillin, doxycycline, or azithromycin, as well as L-lysine supplementation. Lottie lived with six other cats, all of which had access to the outdoors, and she was fed commercial canned and dry cat food. The FeLV and FIV status of these cats was unknown.

Current medications: marbofloxacin (5 mg/kg PO q24h) and prednisolone (1 mg/kg PO q24h)

Physical Examination:

Body Weight: 4 kg

General: Bright, alert and responsive, hydrated. T = 100.3°F (37.9°C), P = 220 beats/min, purring, body condition score 7/9.

Eyes, Ears, Nose, and Throat: Mucopurulent nasal discharge was present that was most profuse on the left side. Nasal airflow was absent on the left side. Mild dental calculus was present, but there were no oral masses or ulceration.

Respiratory: An inspiratory stertor was present, and referred upper airway noises were detected on auscultation of the thorax.

Cardiovascular, Gastrointestinal and Genitourinary, and Lymph Nodes: No clinically significant abnormalities were detected. It was difficult to palpate abdominal structures due to the presence of abdominal fat.

Neurologic Examination: There was a mild, intermittent, left-sided head tilt. No other abnormalities were detected on full neurologic examination.

Laboratory Findings:

CBC:

HCT 39.1% (30%-50%)
MCV 44.7 fL (42-53 fL)
MCHC 29.9 g/dL (30-33.5 g/dL)
Reticulocytes 111,400 cells/µL (7000-60,000 cells/µL)
WBC 21,210 cells/µL (4500-14,000 cells/µL)
Neutrophils 16,713 cells/µL (2000-9000 cells/µL)
Lymphocytes 4115 cells/µL (1000-7000 cells/µL)
Monocytes 297 cells/µL (50-600 cells/µL)
Eosinophils 64 cells/µL (150-1100 cells/µL)
Basophils 0 cells/µL (0-50 cells/µL)
Platelets 316,000/µL (180,000-500,000 platelets/µL).

Serum Chemistry Profile:

Sodium 151 mmol/L (151-158 mmol/L)
Potassium 3.7 mmol/L (3.6-4.9 mmol/L)
Chloride 113 mmol/L (117-126 mmol/L)
Bicarbonate 19 mmol/L (15-21 mmol/L)
Phosphorus 5.8 mg/dL (3.2-6.3 mg/dL)
Calcium 10.2 mg/dL (9.0-10.9 mg/dl)
BUN 49 mg/dL (18-33 mg/dL)
Creatinine 1.4 mg/dL (1.1-2.2 mg/dL)
Glucose 128 mg/dL (63-118 mg/dL)
Total protein 8.7 g/dL (6.6-8.4 g/dL)
Albumin 3.6 g/dL (2.2-4.6 g/dL)
Globulin 5.1 g/dL (2.8-5.4 g/dL)
ALT 33 U/L (27-101 U/L)
AST 21 U/L (17-58 U/L)
ALP 36 U/L (14-71 U/L)
Gamma GT 0 U/L (0-4 U/L)
Cholesterol 192 mg/dL (89-258 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL).

Urinalysis: USG 1.044, pH 6, 75 mg/dL protein, no glucose, bilirubin or ketones, 250 erythrocytes/µL hemoprotein, >100 RBC/HPF (traumatic cystocentesis), 0-1 WBC/HPF.

Imaging Findings:

Thoracic Radiographs: Cardiovascular structures were within normal limits. There was a small amount of air in the cervical esophagus (likely due to aerophagia) and a mild diffuse bronchointerstitial pattern that was attributed to an obese body condition.

Skull Computed Tomography Scan: Contiguous transverse 0.6-mm collimated images of the skull were available for review without contrast administration. There was moderate turbinate destruction of both right and left nasal passages with lobular soft tissue attenuating material present along their length (Figure 36-7, *A*). There was stenosis of both frontal sinuses to the point where the left frontal sinus was completely occluded. The right frontal sinus was almost completely filled with soft tissue attenuating material. The ear canals were within normal limits bilaterally. The mandibular lymph nodes were prominent but symmetrical.

Rhinoscopy: Severe turbinate destruction with diffuse hyperemia and large accumulations of inspissated green mucus was present throughout the nasal passages (Figure 36-7, *B*). Several biopsies of the right and left nasal cavities were obtained for histopathology.

Microbiologic Testing: Aerobic bacterial culture and *Mycoplasma* culture (nasal brush specimen): a direct smear showed moderate numbers of neutrophils, but no organisms were seen. Moderate numbers of *Pseudomonas aeruginosa* were isolated. The *P. aeruginosa* was resistant to amoxicillin–clavulanic acid, ampicillin, cefazolin, cefovecin, cefoxitin, cefpodoxime, ceftiofur, chloramphenicol, doxycycline, enrofloxacin, marbofloxacin, ticarcillin, ticarcillin–clavulanic acid, and trimethoprim-sulfamethoxazole. It was susceptible only to amikacin (≤4 µg/mL), gentamicin (2 µg/mL), and imipenem (≤1 µg/mL).

Histopathology of Nasal Biopsy Specimens: The submucosa was markedly expanded and multifocally effaced by sheets of lymphocytes and plasma cells, with neutrophils and fewer numbers of mast cells surrounding irregular spicules of woven bone extending from primary turbinates. Less affected sections contain similar, predominately lymphoplasmacytic infiltrates that separated submucosal glands and elevated the superficial epithelium. Pathologic diagnosis: severe, chronic, and extensive lymphoplasmacytic and neutrophilic rhinitis with turbinate remodeling.

Continued

VetBooks.ir

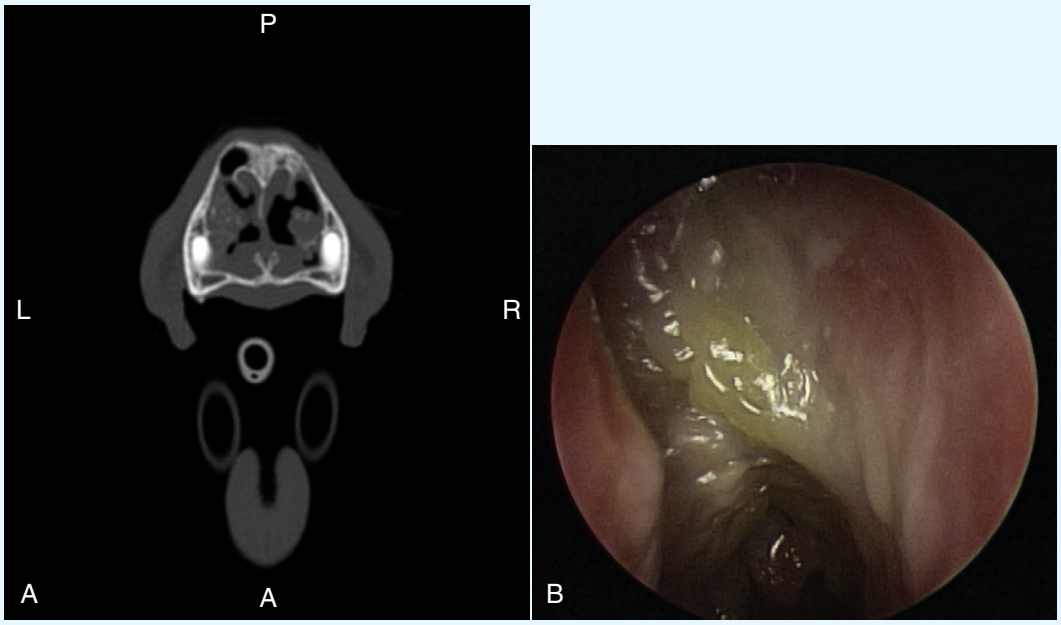

FIGURE 36-7 Nasal cavity of a middle-aged, female spayed domestic shorthair with chronic rhinosinusitis and secondary infection with multidrug-resistant *Pseudomonas aeruginosa.* **A,** Computed tomographic scan showing destruction of the turbinates of the left and right nasal passages. **B,** Rhinoscopic findings included severe turbinate destruction, hyperemia, and accumulations of thick green mucus.

Diagnosis: Feline chronic rhinosinusitis with suspected opportunistic MDR *P. aeruginosa* infection.

Treatment and Outcome: The nasal cavity was lavaged. The prednisolone was tapered over 1 week, then discontinued, and 7 days later, treatment with piroxicam was commenced (0.3 mg/kg PO q24h for 7 days, then q48h thereafter). Other medications discussed with the owner were *N*-acetylcysteine and intranasal gentamicin drops, but the prognosis given for disease resolution was poor.

Comments: The underlying cause of feline chronic rhinosinusitis is poorly defined, but infection of kittens with respiratory viruses such as feline herpesvirus 1 (FHV-1) is suspected to play a role. Severe turbinate destruction predisposes to secondary opportunistic infections with a variety of bacteria, which include staphylococci, *Bordetella bronchiseptica, Streptococcus canis, Mycoplasma* spp., *E. coli, Pasteurella multocida,* and *P. aeruginosa*. In this cat, selection for MDR *P. aeruginosa* likely resulted from repeated and chronic use of a variety of antimicrobial drugs. The reticulocytosis and increased serum BUN concentration likely was secondary to chronic epistaxis and swallowed blood. The cat's neurologic signs and head tilt were thought to be due to peripheral vestibular disease, possibly due to otitis media, but there was no evidence of middle ear disease on the CT scan.

CHAPTER 37

Anaerobic Bacterial Infections

Jane E. Sykes

VetBooks.ir

Overview of Anaerobic Bacterial Infections

First Described: 1860s (Louis Pasteur)[1]

Causes: *Bacteroides, Prevotella, Porphyromonas, Peptostreptococcus, Fusobacterium, Clostridium, Propionibacterium,* other species

Geographic Distribution: Worldwide

Mode of Transmission: Direct contact, and opportunistic invasion of tissues by commensal bacteria

Major Clinical Signs: Abscess formation in a variety of tissues, pyothorax, peritonitis, pyometra, periodontal disease, osteomyelitis, bacteremia

Differential Diagnoses: Primarily bacterial infections caused by gram-positive and gram-negative aerobes, but also neoplasia (when discrete abscessation is present).

Human Health Significance: Anaerobes of the oral cavities of dogs and cats are an important component of animal bite wound infections in humans. Enteric clostridial infections of dogs and cats may also have public health significance (see Chapter 48).

Etiology and Epidemiology

An *anaerobe* is an organism that requires an environment that is reduced in oxygen for growth and does not grow in air. Anaerobic bacteria represent a significant component of the normal flora of the upper and lower gastrointestinal tracts of dogs and cats as well as their genital tracts; in addition, anaerobes play an important role in the regulation of the bacterial composition of the normal flora. Aerobes and facultative organisms that reside alongside anaerobes use oxygen present in these sites and reduce the local oxidation-reduction potential, which permits survival and growth of anaerobes. Sites that are protected from oxygen such as the gingival crevices also favor anaerobes. The metabolic activity of anaerobic bacteria prevents colonization of mucosal surfaces by potentially more pathogenic microbes (this is known as *colonization resistance*). Finally, anaerobes are important for the maintenance of normal mucosal barrier function.

Anaerobic bacteria can cause disease when they gain access to normally sterile sites. This occurs when mucosal barriers are disrupted, or when anaerobes gain access to subcutaneous tissues as a result of a contaminated penetrating wound. Anaerobic bacterial infections are often mixed infections owing to the concurrent presence of other anaerobes, as well as aerobes and facultative bacteria such as *Pasteurella* spp., *Escherichia coli,* streptococci, or staphylococci. Although there are hundreds of anaerobes that comprise the normal flora, the anaerobic bacterial species most often identified in disease are the gram-negative anaerobes *Fusobacterium* spp., *Bacteroides* spp., *Prevotella* spp., and *Porphyromonas* spp., and the gram-positive anaerobes *Clostridium* spp. and *Peptostreptococcus* spp. (Box 37-1).[2] An accurate understanding of the epidemiology of anaerobic bacterial infections in dogs and cats has been hampered by difficulties associated with culture of anaerobes. The use of molecular methods such as PCR has begun to shed more light on this topic. The reader is referred to Chapters 48 and 54 for information on gastrointestinal *Clostridium perfringens* and *Clostridium difficile* infections, and disease caused by the toxins of *Clostridium tetani* and *Clostridium botulinum*, respectively.

Clinical Features

Signs and Their Pathogenesis

Anaerobes can cause disease in a variety of different organs. Often, their presence is associated with abscess formation and necrosis at the site of inoculation, which contains a mixed population of anaerobic as well as facultative bacteria. The possession of virulence factors by anaerobes contributes to their ability to cause disease after host barriers are disrupted. These include capsular polysaccharides, extracellular proteases, endotoxin (gram-negative anaerobes), and a variety of other toxins. Capsular polysaccharides play an important role in the stimulation of

BOX 37-1

Major Anaerobic Bacterial Pathogens Isolated from Dogs and Cats

Gram-Positive Cocci
Peptostreptococcus spp. (especially *Peptostreptococcus anaerobius*)

Gram-Positive Rods
Clostridium spp.
Propionibacterium spp. (especially *Propionibacterium acnes*)

Gram-Negative Rods
Bacteroides spp. (e.g., *Bacteroides fragilis*)
Fusobacterium spp. (e.g., *Fusobacterium necrophorum* and *Fusobacterium nucleatum*)
Prevotella spp. (e.g., *Prevotella heparinolyticus*)
Porphyromonas spp.

VetBooks.ir

abscess formation by certain anaerobes such as *Bacteroides, Porphyromonas, Fusobacterium,* and *Prevotella* species. Just as aerobic bacteria potentiate the survival of anaerobes through local consumption of oxygen, anaerobic bacteria produce metabolites such as short-chain fatty acids, which inhibit phagocytosis and promote survival of co-infecting facultative organisms.

Anaerobes of the oral cavity are important contributors to periodontal disease, tooth root abscesses and mandibular osteomyelitis, retrobulbar abscesses, and bite wound infections. Anaerobes are frequently isolated from the lungs and pleural cavities of dogs or cats with aspiration pneumonia and pyothorax, respectively. Intestinal anaerobes may be isolated from the abdominal cavities of animals with septic peritonitis secondary to intestinal perforation. The female genital tract is also heavily colonized with anaerobic bacteria, and pyometra may sometimes be associated with mixed aerobic and anaerobic infections that include the anaerobic species *Bacteroides, Prevotella, Fusobacterium,* and *Peptostreptococcus* species.

Plant awn migration in dogs and cats can lead to abscess formation in a variety of tissues, including retroperitoneal tissues and the brain. These abscesses usually contain a mixed population of aerobes and anaerobes, especially *Fusobacterium, Actinomyces,* and *Bacteroides* species. Brain abscessation can follow direct extension of anaerobic bacterial infection from otitis or tooth root infection. Alternatively, hematogenous spread may occur (Figure 37-1).

Periodontal Disease

Periodontal disease is one of the most common disorders seen by small animal veterinarians and may result in chronic pain, decreased appetite, and loss of teeth. It begins with formation of dental plaque as a result of poor oral hygiene and other host factors. Dental plaque is a bacterial biofilm composed primarily of gram-positive facultative anaerobes. Subsequently there is proliferation of pathogenic bacteria, which include gram-negative rods and especially anaerobes. These secrete toxins and incite an inflammatory response. Anaerobes implicated in canine and feline periodontal disease (such as *Porphyromonas gulae*) differ from those implicated in human periodontal disease *(Porphyromonas gingivalis)*.[3-6] Periodontal disease is manifested as gingival erythema, edema, gingival bleeding, and halitosis, with accumulation of calculus, gingival recession, alveolar bone loss, and sometimes the presence of purulent exudate (Figure 37-2).

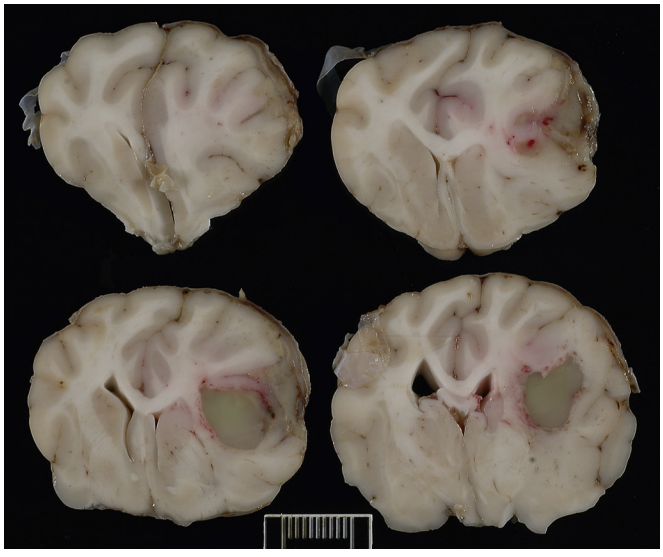

FIGURE 37-1 Abscess in the white matter of the right frontal lobe of a 2-year-old female spayed Chihuahua that had a 1-month history of difficulty chewing food and lethargy and a 3-week history of progressive obtundation, neck pain, and tetraparesis. Signs initially improved following treatment with prednisone, but then recurred as the prednisone dose was reduced. The abscess in the frontal lobe communicated with the overlying meninges, which were expanded by a chronic and fibrosing suppurative inflammatory infiltrate. Another abscess was present in the midbrain, which suggested hematogenous spread of infection. Although no bacteria were seen within the lesions with special stains, *Actinomyces canis* and *Fusobacterium nucleatum* were cultured from the lesions. (Courtesy of the University of California, Davis Veterinary Anatomic Pathology Service.)

Retrobulbar Abscesses

Retrobulbar or orbital abscesses can result from tooth root abscessation, penetrating foreign bodies such as grass awns, or penetrating trauma to the orbit. Clinical signs include unilateral exophthalmos, protrusion of the nictitans, conjunctival hyperemia, serous to mucopurulent ocular discharge, inappetence, fever, and pain on opening the mouth (Figure 37-3). A fluctuant swelling or draining tract posterior to the last ipsilateral molar may be present on examination of the oral cavity. In one study, *Bacteroides* spp. and *Clostridium* spp. were the most frequent anaerobes isolated from 34 dogs with retrobulbar abscesses; other frequently isolated bacteria were *Staphylococcus* spp., *Pasteurella* spp., and *Escherichia coli*. In cats, the most frequent anaerobe was *Bacteroides vulgatus,* and the most common nonanaerobe was *Pasteurella* spp.[7]

Skin and Soft Tissue Infections

Cat bite abscesses are one of the most common reasons that cats are brought to small animal clinics. Clinical signs include fever, lethargy, inappetence, pain, and firm or fluctuant subcutaneous swellings that may rupture and drain purulent material. Oral anaerobes and *Pasteurella multocida* are frequently isolated from these abscesses.[8] Anaerobic species involved include *Peptostreptococcus anaerobius, Porphyromonas* spp., *Clostridium villosum, Fusobacterium* spp., *Bacteroides* spp. (especially *Bacteroides tectum*), and *Prevotella* spp.[9] Despite the widespread occurrence of cat bite abscesses, studies that use molecular methods to identify the types and relative prevalences of anaerobes in cat bite abscesses are lacking.

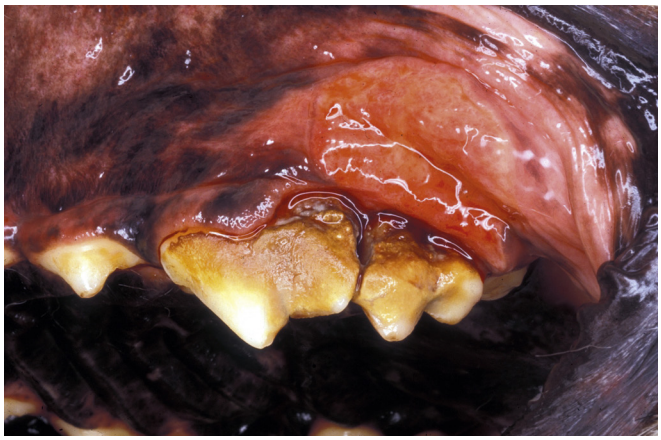

FIGURE 37-2 Periodontitis in a dog. There is significant gingival inflammation, plaque and calculus accumulation, and purulent exudate. Gingival recession and contact ulceration of the buccal mucosa are also present. (Courtesy of Dr. Frank Verstraete, University of California, Davis Dentistry and Oral Surgery Service.)

Other skin and soft tissue infections associated with a variety of anaerobes include foreign body penetrating wounds and dog bite wounds (see Chapter 57).

Pneumonia and Pyothorax

Anaerobes such as *Fusobacterium* spp., *Peptostreptococcus anaerobius, Prevotella* spp., and *Porphyromonas* spp. are frequently isolated from dogs and cats with aspiration pneumonia, foreign body pneumonia (especially that due to plant awn migration), and pyothorax.[10] Dogs with plant awn migration develop multifocal necrotizing pneumonia with abscess formation. In some cases, aspiration pneumonia is followed by lung abscess formation (Figure 37-4). In human patients, a period of 6 to 7 days is required for necrosis and abscess formation to occur after aspiration, and so aspiration pneumonia with lung abscess formation is generally a chronic disease process.

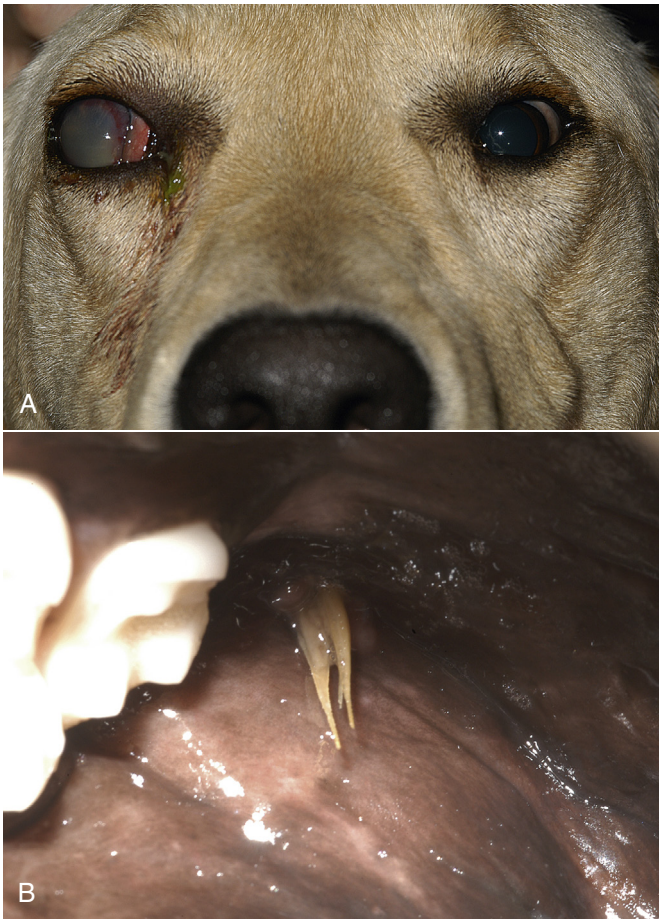

FIGURE 37-3 Retrobulbar abscess and endophthalmitis secondary to a migrating grass awn foreign body in a 10-month-old intact male Labrador retriever. **A,** Note the mucopurulent ocular discharge from the right eye, as well as buphthalmos (enlargement of the eye) and exophthalmos. The nictating membrane and conjunctiva are hyperemic, and there is diffuse corneal edema. Hypopyon and iris bombe were also present. Globe retropulsion was reduced and painful on the right side. **B,** Multiple grass awns were present all over the dog's haircoat, and an awn (shown) was removed from the gingiva posterior to the last right maxillary molar tooth. The right eye was subsequently enucleated. No additional grass awns were found. Histopathology of the globe showed severe chronic fibrinosuppurative panophthalmitis with focal, 0.3-cm scleral rupture in the caudal sclera near the optic nerve, regional orbital granulation tissue, and rupture of the lens. (Courtesy of the University of California, Davis Veterinary Ophthalmology Service.)

The reader is referred to Chapter 87 for more information on bacterial pneumonia and pyothorax.

Peritonitis

Septic peritonitis that involves anaerobes may result from perforation of the intestinal tract, especially the cecum or colon. *Bacteroides* and *Clostridium* species are most often isolated from these infections. *Fusobacterium* and *Propionibacterium* species may also be isolated.[11] Disease that results from bowel perforation often contains a population of organisms that reflect the bowel flora at the site of perforation, including anaerobes, facultative gram-positive anaerobes (especially *Enterococcus* spp.), *Candida* spp., and facultative gram-negative anaerobes such as *Escherichia coli*. Rupture of the female genital tract secondary to pyometra may also result in anaerobic bacterial peritonitis.

Bacteremia

Anaerobes are occasionally isolated from dogs and cats with bloodstream infections, usually as polymicrobial infections with aerobic bacteria. In a European study of 66 bacteremic cats, 12% of bacteria isolated from the bloodstream were obligate anaerobes.[12] In a study of 140 bacteremic dogs, anaerobes comprised 9% of the isolates.[13] Of 39 dogs and 10 cats with critical illness and bacteremia from Colorado, anaerobes were isolated from 31% of the dogs and 40% of the cats. The most common anaerobe isolated from the 39 dogs was *C. perfringens* (9 dogs), followed by *Bacteroides* species (2 dogs).[14] The cats were infected with *Bacteroides* or *Fusobacterium* species. The possibility of mixed aerobic-anaerobic bacterial bloodstream infection should be considered in dogs with systemic grass awn migration. However, anaerobic bacteria appear to be a very rare cause of endocarditis in dogs (see Chapter 86).[15]

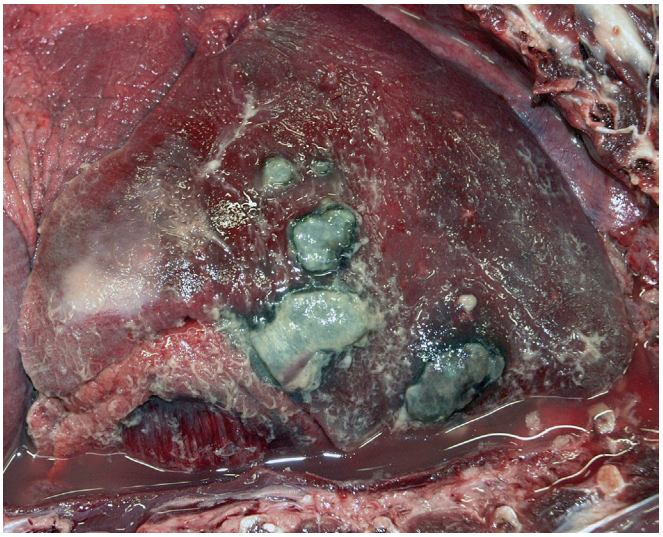

FIGURE 37-4 Necropsy findings in an 11-year-old male neutered Labrador retriever with severe aspiration pneumonia secondary to laryngeal tie-back surgery for laryngeal paralysis, which occurred 2 months before death. Aspiration led to bronchopneumonia with multifocal abscessation, pleural rupture, pyothorax, and pneumothorax. There are multiple to coalescing black to dark gray, soft, irregular foci in the lungs that measured up to 4.5 cm in diameter. On cut surface, dark gray to black material oozed from the parenchyma. Aerobic bacterial culture yielded large numbers of bacteria that included *Streptococcus canis,* nonfermenter group 3 organisms, and *Pasteurella canis*. Anaerobic culture yielded large numbers of *Peptostreptococcus anaerobius.* (Courtesy of the University of California, Davis, Veterinary Anatomic Pathology Service.)

Diagnosis

Abnormalities that suggest an anaerobic bacterial infection include a putrid odor, discolored purulent discharge, gas production within tissues (especially with *C. perfringens* infections) (Figure 37-5), a bite or puncture wound, penetrating foreign bodies, abscessation, pyothorax, aspiration pneumonia, damage to mucosal surfaces with which anaerobes are usually associated, and/or necrotic or gangrenous tissue (Box 37-2). However, absence of these features does not rule out infection with anaerobes, and some of these abnormalities occur with pure aerobic bacterial infections. For example, although anaerobes such as *Clostridium* spp. may be involved in emphysematous cystitis in humans and dogs, the most common cause of emphysematous cystitis is *E. coli*.

Laboratory Abnormalities

Complete Blood Count, Biochemistry, and Urinalysis Findings

No specific CBC, biochemistry, or urinalysis findings suggest anaerobic infection. Infections may be associated with leukocytosis due to a neutrophilia with a left shift and toxic neutrophils.

Cytologic Analysis

Cytologic analysis of exudate in aerobic bacterial infections typically reveals neutrophilic inflammation accompanied by bacteria of mixed morphology and gram staining characteristics. This and/or the presence of filamentous rod-shaped bacteria within these exudates should increase suspicion for an anaerobic infection (Figure 37-6).

Microbiologic Tests

Bacterial Isolation and Identification

Optimal techniques for isolation of anaerobic bacteria are described in Chapter 3. The decision to request anaerobic bacterial culture should be considered carefully, because anaerobes are difficult to culture, tend to have predictable susceptibility to antimicrobial drugs, and can contaminate specimens, which can lead to misleading results. If anaerobic culture is performed, the best specimens to collect are tissues or body fluids that are normally sterile. Fluids (e.g., 1 to 2 mL) or tissue specimens are preferable to swab specimens. Specimens should immediately be placed in an anaerobic transport medium and shipped to the laboratory as soon as possible, because even brief exposure to oxygen impairs isolation. Growth is often slow when compared to other facultative organisms, and cultures should be incubated for 7 days. Because most anaerobe infections also involve aerobes, aerobic bacterial culture should always be requested concurrently.

Extensive antimicrobial susceptibility testing is not routinely performed for anaerobes because it is laborious, expensive, and can have a long turnaround time. Because infections are polymicrobial (two or more anaerobe species as well as facultative organisms present), susceptibility testing for all pathogens present is often cost prohibitive to

BOX 37-2

Disease Processes That Suggest the Possibility of Anaerobic Bacterial Infection

- Abscess formation
- Putrid odor
- Necrotic tissue
- Negative cultures despite the presence of bacteria on cytologic examination
- Exposure to plant foreign bodies such as grass awns
- Interdigital or retrobulbar soft tissue involvement
- Dental infections
- Aspiration pneumonia
- Pyothorax
- Gastrointestinal perforation
- Pyometra
- Bite wound infections

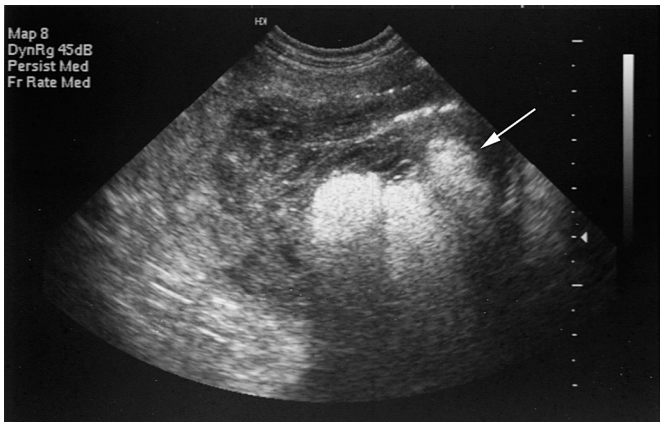

FIGURE 37-5 Splenic abscess in an 11-year-old male neutered Labrador mix that also had duodenal lymphoma. Ultrasound image of a large splenic mass that contains numerous hyperechoic foci and shadowing, consistent with the presence of gas. Necropsy showed severe, focally extensive, neutrophilic, and necrotizing splenitis. The duodenum was perforated at the site of the neoplasm. *Escherichia coli, Bacteroides tectum,* and a *Prevotella heparinolyticus*–like organism were cultured from the splenic abscess.

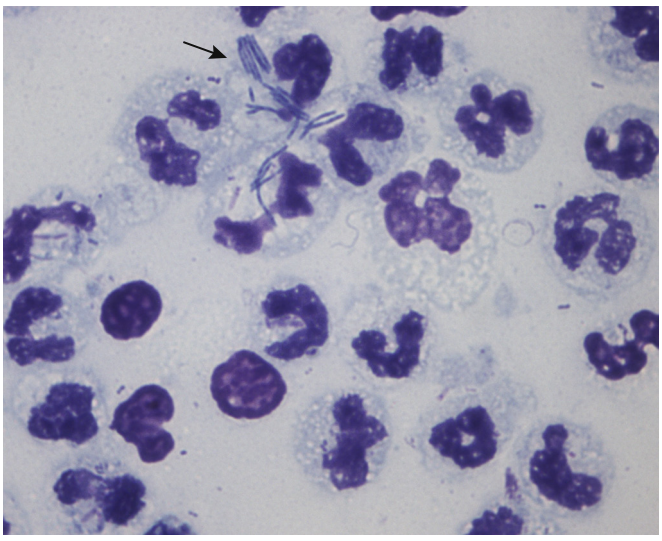

FIGURE 37-6 Cytology of pleural fluid collected using thoracocentesis from an 8-year-old female spayed domestic shorthair with pyothorax. A mixed population of bacteria that includes filamentous organisms suggestive of anaerobes *(arrow)* is present. Aerobic and anaerobic bacterial culture yielded a mixed growth of *Prevotella* spp., *Peptostreptococcus anaerobius*, *Fusobacterium* spp., and an unidentified anaerobic gram-positive rod. Wright's stain, 1600× magnification.

TABLE 37-1

Suggested Antimicrobial Drugs for Treatment of Anaerobic Bacterial Infections in Dogs or Cats*

Drug	Dose (mg/kg)	Interval (hours)	Route
Amoxicillin–clavulanate potassium	12.5-25	12	PO
Ampicillin-sulbactam	10-20†	8	IV, IM
Metronidazole	15 15	12 12 (dogs), 24 (cats)	IV PO
Clindamycin hydrochloride, clindamycin phosphate	11 10	12 (dogs), 24 (cats) 12	PO IV‡, IM
Chloramphenicol, chloramphenicol sodium succinate	40-50 (dogs), 12.5-20 (cats)	6-8 (dogs), 12 (cats)	PO, IV, IM§
Pradofloxacin	3 (dogs), 5-10 (cats)	24	PO‖

*The concurrent presence of aerobes should also be considered when selecting antimicrobial drugs.
†Dose according to ampicillin component.
‡For IV administration, dilute 1:10 in 0.9% saline and administer over 30-60 minutes.
§See Chapter 8 for warnings about chloramphenicol use.
‖Use of pradofloxacin in dogs at high doses has been associated with myelosuppression and is extra-label in the United States. Doses shown for cats are for the oral suspension; a dose of 3 mg/kg is recommended for the tablet formulation.

pet owners. In addition, anaerobes that infect dogs and cats generally have predictable drug susceptibilities. Nevertheless, because antimicrobial resistance has increased among anaerobes that infect humans, the possibility of drug resistance should be considered when infections do not respond to treatment with drainage and appropriate antimicrobial drugs. Some veterinary diagnostic laboratories perform rapid tests for β-lactamase enzyme production by anaerobes (see Case Example).

Treatment and Prognosis

Treatment of anaerobic bacterial infections involves surgical removal of necrotic tissue, drainage of abscesses through surgical or imaging-guided approaches, restoration of blood supply, and medical management with antimicrobial drugs (Table 37-1). Antimicrobial drugs with activity against most anaerobes are β-lactam/β-lactamase inhibitor drug combinations (such as clavulanic acid–amoxicillin or ampicillin-sulbactam), clindamycin, metronidazole, chloramphenicol, and carbapenems. Although penicillin and first-generation cephalosporins may be effective, some pathogenic anaerobes that infect dogs and cats (especially *Bacteroides* but also a significant percentage of *Prevotella, Porphyromonas,* and *Fusobacterium* isolates) may be resistant to these drugs through the production of β-lactamase enzymes. Approximately 20% of *Bacteroides* and *Clostridium* isolates are resistant to clindamycin, but other anaerobes are susceptible.[2] Factors such as tissue penetration should be considered when selecting antimicrobial drugs, and the concurrent presence of aerobic bacteria must also be taken into account. Thus a combination of a β-lactam/β-lactamase inhibitor drug or clindamycin and a drug with activity against gram-negative bacteria, such as a fluoroquinolone or an aminoglycoside, is a reasonable choice for initial treatment of serious infections while awaiting the results of susceptibility testing for aerobic bacteria when mixed aerobic-anaerobic infections are suspected. For infections that do not require parenteral therapy, pradofloxacin also has potent activity against a variety of aerobes, anaerobes and mycoplasmas (see Chapter 8).

With the exception of newer generation fluoroquinolones such as pradofloxacin, anaerobes are resistant to fluoroquinolones. Anaerobes are also generally resistant to trimethoprim-sulfamethoxazole and have unpredictable resistance to tetracyclines. Aminoglycosides are remarkable for their complete inactivity against anaerobes.

Prevention

Prevention of anaerobic bacterial infections involves management or prevention of underlying conditions that predispose to these infections. Vaccines for prevention of anaerobic bacterial infections are not available. An inactivated, whole-cell *Porphyromonas denticanis, Porphyromonas gulae,* and *Porphyromonas salivosa* vaccine was available for several years for prevention of periodontal disease in dogs but was withdrawn from the market because of apparent lack of efficacy.

Public Health Aspects

Anaerobes that reside in the oral cavity of dogs and cats are important causes of bite wound infections in humans, next to *Pasteurella* species. The reader is referred to Chapter 57 for more information on the public health significance of bite wound infections.

VetBooks.ir

CASE EXAMPLE

Signalment: "Cocoa," a 4-month-old intact female Labrador retriever from Gonzales in northern California

History: Cocoa was brought to the University of California, Davis, Veterinary Medical Teaching Hospital for evaluation of seizures. Approximately 6 weeks before referral, the dog was seen for left ocular exophthalmos. She was treated with amoxicillin–clavulanic acid for 1 week, and the exophthalmos resolved, but subsequently right ocular exophthalmos developed. This resolved after another 1-week course of amoxicillin–clavulanic acid. One month later, Cocoa appeared painful on opening her mouth. She was treated with cephalexin and meloxicam with no apparent improvement. Two days later she became inappetent. When the owners offered her food by hand, she ate, became ataxic, fell over, her thoracic limbs stiffened, and foamy saliva was noted around her mouth. She was taken to an emergency clinic, and she vomited in the car. At the emergency clinic she had three generalized seizures that were treated with diazepam. She was also treated with enrofloxacin (5 mg/kg IV, once).

Cocoa's diet normally consisted of commercial dog food, and she had been vaccinated for distemper, hepatitis, and parvoviral enteritis at 8 and 12 weeks of age. There had been no coughing, sneezing, diarrhea, exposure to ticks or toxins, trauma, or travel outside California.

Physical Examination:

Body Weight: 15.3 kg

General: Quiet but alert and responsive. Hydrated. T = 102.8°F (39.3°C), HR = 110 beats/min, panting, mucous membranes pink, CRT = 1 second.

Eyes, Ears, Nose, and Throat: No clinically significant abnormalities were noted. There was no evidence of pain on opening the mouth provided neck movement was prevented during the examination.

Integument, Musculoskeletal, Cardiovascular, Gastrointestinal, Genitourinary Systems, and Peripheral Lymph Nodes: No clinically significant findings.

Neurologic Examination: Mild obtundation was noted. The dog held her head down and was reluctant to move her neck. There was moderate to marked ataxia that involved all four limbs, with the pelvic limbs most severely affected, and the right pelvic and thoracic limbs more severely affected than the left. Cranial nerve examination revealed only a decreased corneal reflex on the right side. Decreased placing reactions were noted in all four limbs, with the right limbs more severely affected. There was severe pain on palpation of the cervical spine and moderate pain on palpation of the lumbosacral spine. Multifocal CNS lesions were suspected.

Laboratory Findings:

CBC:

HCT 34.4% (40%-55%)
MCV 64.9 fL (65-75 fL)
MCHC 34.9 g/dL (33-36 g/dL)
Reticulocytes 22,000 cells/µL (7000-65,000 cells/µL)
WBC 17,780 cells/µL (6000-13,000 cells/µL)
Neutrophils 12,979 cells/µL (3000-10,500 cells/µL)
Band neutrophils 533 cells/µL
Lymphocytes 3023 cells/µL (1000-4000 cells/µL)
Monocytes 1245 cells/µL (150-1200 cells/µL)
Platelets 392,000 platelets/µL (150,000-400,000 platelets/µL).

Serum Chemistry Profile:

Sodium 143 mmol/L (145-154 mmol/L)
Potassium 4.6 mmol/L (3.6-5.3 mmol/L)
Chloride 102 mmol/L (108-118 mmol/L)
Bicarbonate 23 mmol/L (16-26 mmol/L)
Phosphorus 6.9 mg/dL (3.0-6.2 mg/dL)
Calcium 11.1 mg/dL (9.7-11.5 mg/dl)
BUN 7 mg/dL (5-21 mg/dL)
Creatinine 0.4 mg/dL (0.3-1.2 mg/dL)
Glucose 95 mg/dL (64-123 mg/dL)
Total protein 6.1 g/dL (5.4-7.6 g/dL)
Albumin 2.8 g/dL (3.0-4.4 g/dL)
Globulin 3.3 g/dL (1.8-3.9 g/dL)
ALT 35 U/L (19-67 U/L)
AST 52 U/L (19-42 U/L)
ALP 103 U/L (21-170 U/L)
Creatine kinase 556 U/L (51-399 U/L)
Gamma GT 4 U/L (0-6 U/L)
Cholesterol 262 mg/dL (135-361 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.013; pH 6.5, negative for protein, glucose, ketones, bilirubin, hemoprotein, WBC, RBC, casts, and bacteria.

Imaging Findings:

Thoracic Radiographs: Cardiopulmonary structures were within normal limits.

Abdominal Ultrasound: The gastric wall was mildly thickened with bright, echogenic speckles within the muscularis layer. The submucosa of the stomach was echogenic. These changes were suggestive of gastritis. The remainder of the abdominal ultrasound was unremarkable.

Spinal Radiographs: Open physes were present within the vertebral column. No abnormalities were identified.

Brain MRI: In the precontrast brain study, a flattened, fusiform extradural structure was identified in the dorsal part of the foramen magnum that caused moderate dorsoventral compression of the spinal cord (see arrow in Figure 37-7). This structure was hypointense to brain but hyperintense to CSF on the T1-weighted images and moderately hyperintense on dual echo and fluid-attenuated inversion recovery (FLAIR) images. The postcontrast brain study showed diffuse meningeal enhancement that involved the spinal cord and brain, with the most prominent enhancement noted along the ventral brainstem and left cerebral hemisphere. This contrast enhancement pattern was consistent with meningitis. A discrete rim of enhancement surrounded the aforementioned fusiform structure, which gave it a cystic appearance. The structure had partial fluid characteristics, and, in light of the meningeal enhancement, an abscess was suspected.

Analysis of CSF (Lumbar CSF): CSF protein: 726 mg/dL (reference range, <25 mg/dL)

Total RBC: 5 cells/µL (reference range, 0 cells/µL)

Total nucleated cells: 7500 cells/µL (reference range, <2 cells/µL)

Differential: 88% neutrophils, 12% large mononuclear cells

Microscopic evaluation: The specimen was highly cellular and contained a large number of nondegenerate neutrophils. A few pyknotic forms were noted. Lower numbers of

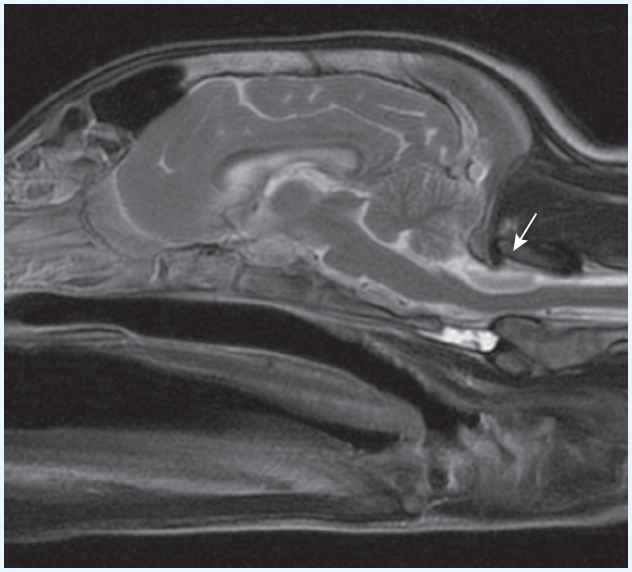

FIGURE 37-7 Postcontrast brain MRI, 4-month-old intact female Labrador retriever with *Bacteroides fragilis* meningitis and an epidural abscess located in the dorsal part of the foramen magnum. There is a flattened, fusiform structure in the dorsal part of the foramen magnum associated with moderate dorsoventral compression of the spinal cord *(arrow)*. Diffuse meningeal enhancement and a discrete rim of enhancement surrounding the fusiform structure are present.

monocytoid cells, large reactive lymphocytes, and rare eosinophils also were observed. Interpretation: Marked neutrophilic pleocytosis (purulent inflammation).

Cytologic Analysis of CSF (Cisternal): A direct smear of cisternal CSF contained disrupted cells and mildly to moderately degenerate neutrophils. These were admixed with low numbers of monocytoid cells and intermediate-sized reactive lymphocytes. Rare neutrophils were observed with intracellular rod-shaped bacteria. Few free rod-shaped bacteria were noted in the background.

Microbiologic Testing: Aerobic urine culture: No growth was detected.

Aerobic and anaerobic blood cultures: No growth was detected.

Aerobic and anaerobic CSF culture: Small numbers of *Bacteroides fragilis*, positive for β-lactamase production.

Diagnosis: *Bacteroides fragilis* meningitis with extradural abscess formation

Treatment and Outcome: Cocoa was treated with ticarcillin (50 mg/kg IV q6h), metronidazole (10 mg/kg IV q8h), and crystalloid fluids (LRS with 20 mEq/L KCl at 50 mL/h, IV). The following day her mentation improved and she became more willing to move. On day 3 after starting antibiotics, treatment was changed to clavulanic acid–amoxicillin (16 mg/kg PO q8h) and metronidazole (16 mg/kg PO q12h). On day 4, Cocoa was less ataxic and had normal placing reactions, but had a seizure while on a walk outside. The seizure lasted 45 seconds and was manifested by jaw chomping and defecation, but Cocoa did not fall over or lose consciousness. Potassium bromide (40 mg/kg PO q8h for 4 days, then 40 mg/kg PO q24h) was added to the treatment regimen, and Cocoa was discharged from the hospital.

At a recheck 3 weeks later, Cocoa's owners reported that she had shown steady clinical improvement and for the last week she had been acting like a normal puppy. There had been no seizures. She had received the final set of the puppy vaccine series 1 week earlier. No abnormalities were detected on neurologic examination. A CBC showed persistent mild nonregenerative anemia (hematocrit 34.8%), 5253 neutrophils/μL, and 228 band neutrophils/μL. A repeat MRI showed a decrease in the meningeal enhancement and marked reduction in the size of the cystic structure, although there was persistent mild spinal cord compression. Analysis of CSF revealed a CSF protein concentration of 37 mg/dL, <1 RBC/μL, 24 nucleated cells/μL, with 12% neutrophils, 51% small mononuclear cells, and 37% large mononuclear cells. Microscopic examination of the CSF revealed a heterogenous population of lymphocytes that included small mature lymphocytes, larger reactive lymphocytes, and many plasmacytoid lymphocytes along with mature plasma cells and moderately vacuolated macrophages. A few nondegenerate neutrophils were present. Antimicrobial drug treatment was continued and a recheck was recommended in 3 months, but the dog was subsequently lost to follow-up.

Comments: The history of exophthalmos increased suspicion for an anaerobic bacterial infection of the CNS in this dog and was the reason that anaerobic culture of the CSF and blood was performed. Given the young age of this dog, a migrating foreign body (e.g., plant awn) was suspected. The history, together with the distribution of lesions in the CNS and the lack of lesions elsewhere, suggested direct extension of the infection from the retrobulbar location to the meninges, rather than hematogenous spread of infection. Because the dog was treated with antibiotics before culture was performed, the concurrent presence of other facultative organisms or other anaerobic species may have been obscured. The identification of β-lactamase production by the *B. fragilis* isolate was not surprising, because of the high (>90%) prevalence of β-lactamase production by this species. *B. fragilis* is also known for its propensity to form abscesses.

CHAPTER 38

Bordetellosis

Jane E. Sykes

VetBooks.ir

Overview of Canine and Feline Bordetellosis

First Described: 1911 (*Bacillus bronchicanis*, Ferry).[1] The genus *Bordetella* was named after Bordet, who first described *Bordetella pertussis* (Bordet and Gengou, 1906).[2]

Cause: *Bordetella bronchiseptica,* an aerobic gram-negative motile bacterium (family Alcaligenaceae)

Affected Hosts: Dogs, cats, wild carnivores, pigs, horses, rabbits, rodents, turkey, humans. Dogs and cats share the same strains.

Geographic Distribution: Worldwide

Mode of Transmission: Aerosol, contact with contaminated fomites and water sources

Major Clinical Signs: Sneezing, serous to mucopurulent nasal discharge, harsh or honking cough (especially dogs). Dogs and cats with bronchopneumonia can develop fever, lethargy, inappetence, tachypnea, productive cough, and mucopurulent nasal and ocular discharge.

Differential Diagnoses: Upper and lower respiratory diseases such as collapsing trachea, viral respiratory infections, fungal pneumonia, protozoal pneumonia, respiratory tract neoplasia, airway foreign bodies, chronic bronchitis, eosinophilic bronchopneumopathy or granulomatosis, parasitic infections (such as *Filaroides, Oslerus, Capillaria, Paragonimus, Dirofilaria*), bronchopneumonias secondary to conditions such as laryngeal paralysis or ciliary dyskinesia, left-sided congestive heart failure

Human Health Significance: *B. bronchiseptica* is closely related to *B. pertussis* and *Bordetella parapertussis*, which cause whooping cough in humans. Uncommonly, it has been associated with respiratory disease in humans and rarely systemic infections such as peritonitis, septicemia, and meningitis. It primarily causes disease in the immunocompromised. Contact with dogs and cats has been associated with human infections, but host specificity may also be strain related.

Etiologic Agent and Epidemiology

Bordetella spp. are small, pleomorphic, gram-negative coccobacilli. They have fimbriae (pili) and can be motile by means of flagella. There are at least nine different bacterial species in the genus *Bordetella* (Table 38-1).[3] The only species known to cause disease in dogs and cats is *Bordetella bronchiseptica*, but *B. bronchiseptica* is closely related to *B. pertussis* and *B. parapertussis*, which cause pertussis (whooping cough) in humans. In fact, there is evidence that *B. pertussis* evolved from a distinct, human-associated lineage of *B. bronchiseptica*,[4] and it has been recommended that *B. bronchiseptica*, *B. pertussis*, and *B. parapertussis* be reclassified as subspecies of the "*B. bronchiseptica* cluster."[5] *B. pertussis* can colonize puppies in the absence of clinical signs of respiratory disease.[6]

Worldwide, *B. bronchiseptica* is an important cause of respiratory disease in dogs and cats; it also infects and causes respiratory illness in many different animal species including wild carnivores, pigs, rabbits, and occasionally horses, other herbivores, rodents, turkeys, and humans. There are a large number of different strains of *B. bronchiseptica* that vary in virulence and host specificity. Nevertheless, the results of molecular typing efforts have shown that strains that infect dogs can be passed to cats and vice versa.[7-9] The whole genome of *B. bronchiseptica* has been sequenced.[10] Its genome is larger than that of its close relatives, and it possesses several plasmids, some of which mediate antimicrobial drug resistance.[11]

Like viral respiratory infections, bordetellosis is especially prevalent in dogs and cats in shelter, pet stores, boarding facilities, and other situations where large numbers of potentially stressed animals may have been in close contact with one another. Infections with *B. bronchiseptica* frequently occur in concert with respiratory viral and/or *Mycoplasma* spp. infections (see Chapters 17, 23, and 40). Unlike *B. pertussis* and *B. parapertussis*, *B. bronchiseptica* can persist in the environment for at least 10 days and can grow in natural water sources,[12] but is susceptible to most disinfectants provided they are used correctly.

The prevalence of *B. bronchiseptica* infections in group-housed animals, including shelters, varies from group to group, even in the same geographic region. *B. bronchiseptica* can be isolated from apparently healthy cats and cats with respiratory disease, but is more likely to be isolated from cats with respiratory disease. In one European study that included 1748 cats from private multicat households, shelters, and breeding catteries, the more cats in the group, the greater the chance that *B. bronchiseptica* would be detected. In rescue shelters, increased seroprevalence has been associated with poor hygiene.[13] In a study of 742 cats in the United Kingdom, *B. bronchiseptica* was isolated from 0% of pet cats, 19.5% of cats from rescue shelters, and 13.5% of cats from research colonies.[14] *B. bronchiseptica* was cultured from 3.1% of 614 cats from four shelters in Louisiana,[15] 5.1% of nasal swabs from 59 cats with acute respiratory disease in Colorado,[16] and none of 22 cats with respiratory disease in a shelter in California.[17] However, the prevalence of infection was nearly 50% in nasal

VetBooks.ir

TABLE 38-1

Species That Belong to the Genus *Bordetella*

Species	Host(s)	Disease
Bordetella bronchiseptica	Dogs, cats, pigs, horses, rabbits, rodents, humans	Rhinitis, tracheobronchitis, bronchopneumonia
Bordetella pertussis	Humans	Whooping cough
Bordetella parapertussis	Humans, sheep	Whooping cough (humans); ovine-adapted strains cause respiratory disease in sheep
Bordetella holmesii	Humans	Upper respiratory tract disease, bacteremia
Bordetella trematum	Humans	Otitis media and wound infections
Bordetella avium	Poultry (especially turkey)	Rhinotracheitis
Bordetella hinzii	Birds, rarely humans	Normal flora of birds, bacteremia, cholangitis in humans
Bordetella petrii	Environment, rarely humans	None, osteomyelitis
Bordetella ansorpii	Humans	Bacteremia, skin infection

swabs from 40 cats with rhinitis from a shelter in Colorado.[18] Similarly, a high prevalence (26%) of infection was detected with a PCR assay in 100 cats with upper respiratory disease from central Italy.[19]

Only a few studies have examined the epidemiology of *B. bronchiseptica* infection in dogs. In a case review from the eastern United States, *B. bronchiseptica* was isolated from 32 (49%) of 65 pet dogs under 1 year of age with radiographic and microbiologic evidence of bacterial bronchopneumonia. Most of these dogs had originated from breeders (40%) or pet stores (41%), and only 8% were from shelters. Dogs infected with *B. bronchiseptica* were younger (7 to 35 weeks of age), had been owned for a shorter period of time (median, 18 days), were more likely to have originated from a pet store and were less likely to have originated from a breeder than dogs with pneumonia caused by other organisms. *B. bronchiseptica* was isolated from dogs with respiratory disease as well as from healthy dogs in a rehoming kennel in the United Kingdom.[20]

Clinical Features

Signs and Their Pathogenesis

Transmission of *B. bronchiseptica* occurs primarily by the airborne route, but contact with contaminated fomites and water sources may also be important. The organism is highly contagious. Much of what is known about *B. bronchiseptica* pathogenesis is based on studies of infections in host species other than the dog or cat. *B. bronchiseptica* is inhaled, adheres to respiratory cilia, evades the immune system, and secretes toxins that damage the respiratory epithelium (Figure 38-1). Adhesion of virulent strains of *B. bronchiseptica* to respiratory cilia occurs by means of fimbrial adhesins (FIM), a filamentous hemagglutinin (FHA), pertactin, and cell wall lipopolysaccharide. *Bordetella* colonization factor A (BcfA) is another outer membrane protein that appears to be important for tracheal colonization by *B. bronchiseptica*.[21] *B. bronchiseptica* possesses genes that encode for pertussis toxin, an important adhesin in *B. pertussis*. These genes are not expressed in vitro, but there is some evidence for pertussis toxin expression in vivo.[22] Evasion of host defenses is mediated by the organism's outer capsule (which is absent in *B. pertussis* and *B. parapertussis*), adenylate cyclase toxin, and pertactin. The capsule protects it from phagocytosis and destruction by complement. Adenylate cyclase toxin catalyzes the conversion of ATP to cAMP, which inhibits the migration and activation of phagocytes and T-lymphocytes. Pertactin allows the organism to resist neutrophil-mediated clearance.[23] A type VI secretion system also appears to play a key role in persistence of *B. bronchiseptica*.[24] Other virulence determinants present in the outer membrane include lipopolysaccharide and the Brk protein (*B*ordetella *r*esistance to *k*illing), which allow the organism to resist complement-mediated destruction. At least two other important exotoxins damage respiratory epithelial cells and cells of the immune system, and incite cytokine production: tracheal cytotoxin (TCT) and dermonecrotic toxin (DNT). *B. bronchiseptica* also possesses a type III secretion system that allows it to inject as-yet-undefined effector proteins into cellular targets.[5]

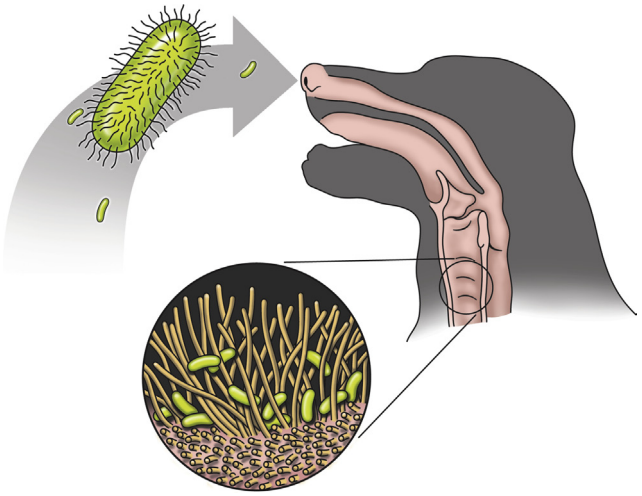

FIGURE 38-1 *Bordetella bronchiseptica* infection. *B. bronchiseptica* is inhaled, adheres to respiratory cilia by means of fimbrial adhesins, evades the immune system and secretes a variety of toxins that damage the respiratory epithelium.

The inflammation and altered cell function that occur as a result of *B. bronchiseptica* infection lead to increased fluid and mucus secretion, and impairment in host innate immune defenses predisposes to opportunistic viral and bacterial infections. Clinical signs vary in severity and may reflect factors such as the bacterial strain involved, host immunity, and the presence of co-infections. The incubation period ranges from 2 to 10 days. Rhinitis and tracheobronchitis may be associated with serous to mucopurulent nasal discharge, sneezing, stertor, and, especially in dogs, a persistent, often paroxysmal harsh cough. In some dogs, development of bronchopneumonia leads to fever, productive cough, lethargy, and decreased appetite.

VetBooks.ir

FIGURE 38-2 Kitten with *Bordetella bronchiseptica* conjunctivitis and bronchopneumonia. The kitten was tachypneic and had mucopurulent ocular discharge.

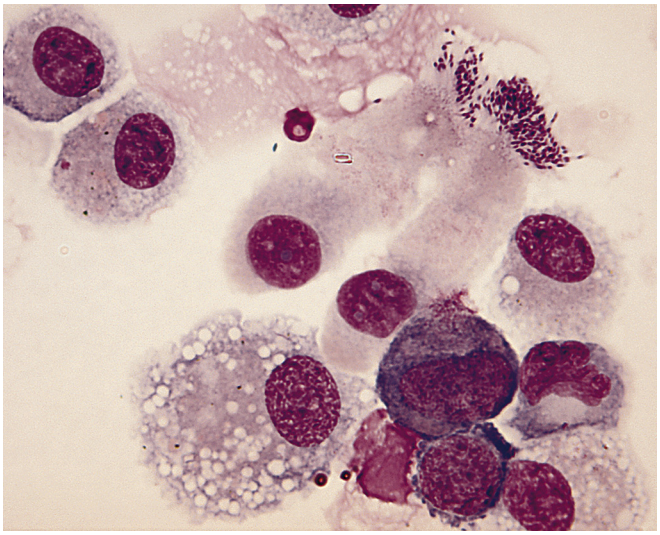

FIGURE 38-3 Bronchoalveolar lavage cytology from a dog infected with *Bordetella bronchiseptica*. Numerous coccobacilli are adhered to the cilia of columnar epithelial cells. Wright stain, 1000× oil magnification. (Courtesy of Michael Scott, Michigan State University. In Raskin RE, Meyer D, eds. Canine and Feline Cytology: A Color Atlas and Interpretative Guide, 2 ed, St. Louis, MO: Saunders; 2010.)

Bronchopneumonia may be due to *B. bronchiseptica* itself or it may result from co-infection with other respiratory pathogens, such as canine distemper virus (CDV). In cats, infection is significantly associated with sneezing, and cough is uncommon.[14] Cats with pneumonia may develop tachypnea, cyanosis, and death.

Shedding of *B. bronchiseptica* by both dogs and cats can continue intermittently for at least a month and sometimes several months after infection. Evasion of the immune system through survival inside phagocytes may explain the persistent infection that occurs. In contrast, *B. pertussis* is rapidly destroyed by macrophages.[25]

Physical Examination Findings

On physical examination, dogs with uncomplicated bordetellosis are bright, alert, and active with a paroxysmal cough that can occur throughout the examination. The cough is often easily elicited on tracheal or laryngeal palpation. Conjunctivitis and serous to mucopurulent ocular and nasal discharge may be present in affected dogs and cats (Figure 38-2). Dogs and cats with complicated *Bordetella* bronchopneumonia may be pyrexic, lethargic, and tachypneic with increased respiratory effort. There may also be increased lung sounds and/or referred upper airway noises on thoracic auscultation, and mucopurulent nasal discharge.

Diagnosis

Laboratory Abnormalities

There are no specific laboratory abnormalities in uncomplicated bordetellosis. Usually the CBC is normal. Dogs with bronchopneumonia can also have a normal CBC,[26] or a mild to moderate neutrophilia, bandemia, and toxic neutrophils may be present. Cytologic examination of transtracheal lavage (TTL) or bronchoalveolar lavage (BAL) specimens may reveal a suppurative or mixed exudate, and sometimes intracellular and extracellular coccobacilli are visible (Figure 38-3).

Diagnostic Imaging

Plain Radiography

Plain thoracic radiographs in dogs with uncomplicated bordetellosis may be unremarkable or show a mild diffuse interstitial or bronchointerstitial pattern. *Bordetella* bronchopneumonia may be characterized by development of peribronchial and alveolar infiltrates and lobar consolidation.

Microbiologic Tests

The main assays used for diagnosis of bordetellosis in dogs and cats are aerobic bacterial culture and PCR assays, which can be performed on nasal or oropharyngeal swabs, TTL or BAL specimens, or respiratory tract tissue collected at necropsy (Table 38-2). In some studies, *B. bronchiseptica* has been detected in nasal but not oropharyngeal swabs, but in other studies, the use of oropharyngeal swabs was more sensitive. Collection of swab specimens from the nasal cavity or posterior nasopharynx is preferred for diagnosis of pertussis in humans because these regions have ciliated epithelial cells, for which *B. pertussis* has affinity.[27] False-negative results occur when organism numbers in secretions are low, and depending on the sensitivity of the PCR assay used and the viability of the bacteria in the specimen, culture may be positive when PCR is negative and vice versa. Although the detection of *B. bronchiseptica* in TTL or BAL specimens is diagnostic for bordetellosis, it may be more difficult to interpret the significance of a positive culture or PCR assay result from nasal or oropharyngeal swabs, especially among group-housed dogs and cats when the background prevalence of infection is high. Co-infections with viral respiratory pathogens should always be considered when *B. bronchiseptica* is detected, as well as the presence of other comorbidities that suppress the innate or adaptive immune system that could predispose to bordetellosis (e.g., ciliary dyskinesia or brachycephalic obstructive syndrome in dogs, retroviral infections in cats).

Bacterial Culture

B. bronchiseptica can usually be isolated on routine aerobic bacterial culture media, such as MacConkey agar and blood agar.

VetBooks.ir

TABLE 38-2

Diagnostic Assays Available for Bordetellosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Aerobic bacterial culture	Nasal and oropharyngeal swabs, transtracheal and bronchoalveolar lavage specimens, airway and lung specimens collected at necropsy	*B. bronchiseptica*	False negatives can occur when specimens contain no or low numbers of organisms, or after antimicrobial treatment. Allows subsequent susceptibility testing. The clinical significance of positive culture results from nasal and oropharyngeal swab specimens may be difficult to interpret.
PCR assays	See Aerobic bacterial culture	*B. bronchiseptica* DNA	Sensitivity and specificity can vary depending on assay design. False negatives can occur when specimens contain no or low numbers of organisms, or after antimicrobial treatment. Testing specimens from multiple different anatomic sites or combining PCR assays with other diagnostic tests can increase sensitivity. Avirulent live vaccine organisms may be detected for several weeks after intranasal vaccination. Because of subclinical shedding, the clinical significance of a positive result may be difficult to interpret.
Serology	Serum	Antibodies against *Bordetella* antigens	Interpretation complicated by previous vaccination and widespread exposure.

Charcoal-based medium that is supplemented with cephalexin is preferred for isolation of *B. pertussis*, which is more fastidious. For *B. bronchiseptica*, use of methicillin or oxacillin in selective media can prevent overgrowth by contaminating microflora.[5] The laboratory should be informed when bordetellosis is on the differential diagnosis list. In one study, *B. bronchiseptica* was isolated from cats using nasal swabs but not oropharyngeal swabs.[16] The use of Dacron, rayon, or calcium alginate swabs is preferred for culture of *B. pertussis*, because growth is inhibited when cotton swabs are used.[27] Unlike PCR assays, successful detection of *B. bronchiseptica* using culture allows susceptibility testing, which assists in rational antimicrobial drug selection.

Molecular Diagnosis Using the Polymerase Chain Reaction

Sensitive and specific real-time PCR assays that detect *B. bronchiseptica* DNA have been described,[13,28] and assays are available through several commercial veterinary diagnostic laboratories. Some laboratories offer panels that also detect other respiratory pathogens, which can be useful for detection of coinfections. As with culture, negative results can occur when organism numbers are low in the specimen, or when there has been recent antimicrobial drug use; however, PCR assays may be more likely to be positive than culture in these situations. Positive PCR assay results can occur for at least 3 weeks after intranasal vaccination.[29] A conventional PCR assay that differentiates between field strains and one vaccine strain of *B. bronchiseptica* has been described,[29] but commercially available real-time assays that distinguish between field and vaccine strains are needed.

Serologic Diagnosis

Antibodies to *B. bronchiseptica* can be detected using bacterial agglutination or recombinant or whole-cell ELISA assays, but serology is of limited use for diagnosis because of the high prevalence of antibodies in the dog and cat population and the influence of vaccination, which is routinely performed on entry to most shelters. Serology has primarily been used to study the epidemiology of infection and to examine immune responses as they relate to vaccination.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with uncomplicated bordetellosis are usually minimal. There may be an accumulation of mucopurulent exudate in the airways.

Histopathologic Findings

Microscopic findings in dogs or cats with bordetellosis consist of a suppurative inflammatory response that is usually confined to the ciliated portions of the respiratory tract. Cilia are mostly intact, but regional bronchial epithelial necrosis may be present. Mild lymphoid hyperplasia may be present. Depending on the stage and severity of infection, aggregates of bacteria may be observed in association with the cilia.[30]

Treatment and Prognosis

Antimicrobial Treatment

B. bronchiseptica isolates from dogs and cats have the propensity to exhibit multidrug resistance (i.e., resistance to three or more antimicrobial drug classes). Resistance to amoxicillin and trimethoprim-sulfamethoxazole is common. Many infections are mild or self-limiting, and so antimicrobial drug treatment should be reserved for animals with confirmed *B. bronchiseptica* infection that have persistent clinical signs (>7 to 10 days) or those with more severe clinical signs and radiographic abnormalities that suggest bronchopneumonia. Young kittens and puppies (<6 to 8 weeks of age) are candidates for early initiation of treatment because disease in neonates may progress rapidly to pneumonia and death. Treatment should be based whenever possible on the results of culture and susceptibility testing.

VetBooks.ir

When susceptibility results are not available, or when they are pending and bordetellosis is strongly suspected, the initial drug of choice is doxycycline. At the time of writing, doxycycline resistance is uncommon among isolates from dogs and cats,[31-33] and doxycycline effectively penetrates lung tissue. Unfortunately, doxycycline is not the best choice for other secondary bacterial pneumonias because it is bacteriostatic and parenteral doxycycline can be expensive and difficult to administer. This reinforces the need for culture whenever feasible in animals with evidence of pneumonia. Bacterial shedding may continue despite resolution of clinical signs, so affected dogs and cats should remain in isolation from other animals whenever possible for at least 2 months after treatment.

Rarely, treatment with systemic antimicrobial drugs fails to resolve clinical signs of bordetellosis, and the organism persists despite documented susceptibility to the antimicrobial drug selected. In this situation, a short period of nebulized aminoglycosides could be considered. Because this can cause airway irritation, its use should probably be restricted for dogs with refractory bronchopneumonia, or severe and persistent tracheobronchitis (for example, >4 weeks in duration).

Supportive Care and Prognosis

The prognosis for dogs with uncomplicated bordetellosis is excellent. Cats and dogs with bronchopneumonia usually require other supportive treatments, such as IV fluid therapy, appropriate nutritional support, supplemental oxygen, and nebulization (see Chapters 17 and 23). In one study, bronchopneumonia associated with *B. bronchiseptica* infection was more severe than that associated with other bacterial agents, and affected dogs also had higher $PvCO_2$ values, were more likely to require supplemental oxygen, and had longer mean hospitalization times (7.2 days compared with 4.9 days).[26]

Immunity and Vaccination

Antibodies to outer surface molecules of *B. bronchiseptica,* especially IgA in mucosal secretions, are important for bacterial clearance. Several avirulent live, mucosal (intranasal or oral) *B. bronchiseptica* vaccines are available for dogs, some of which also contain canine parainfluenza virus with or without canine adenovirus 2. These vaccines are designed to stimulate mucosal immunity and provide protection within 3 days after a single dose of vaccine.[34] Protection with intranasal vaccines also occurs in the face of maternal antibody and can last at least 1 year.[35,36] Inactivated parenteral *B. bronchiseptica* vaccines are also available for dogs, but two doses administered 3 to 4 weeks apart are required to stimulate maximal immunity, which occurs 1 week after the second dose. The rapid onset of protection that follows the use of intranasal vaccines makes them the vaccine type of choice for puppies and animals introduced into heavily contaminated environments, such as shelters, when immunization in advance of entry is usually not possible. Mucosal vaccines should not be given to animals treated with antimicrobial drugs (because they inactivate bacteria in the vaccine), and administration of intranasal vaccines to aggressive animals without sedation may not be feasible. Transient signs of mild to moderate respiratory disease occur in a small percentage of vaccinated dogs and cats several days after mucosal vaccination. In shelters, it may not be possible to differentiate between postvaccinal disease and infectious respiratory disease due to field pathogens, which complicates decisions that relate to isolation practices. Inadvertent parenteral administration of intranasal vaccines has the potential to lead to injection site reactions, hepatic necrosis, and even death in some dogs.[37] Subcutaneous fluids should be administered at the site of vaccination, and immediate treatment with antimicrobial drugs is indicated. It has been suggested that gentamicin sulfate solution be instilled into the affected area (2 to 4 mg/kg gentamicin sulfate in 10 to 30 mL of saline), and dogs should then be treated with oral doxycycline for 5 to 7 days.[38] Special packaging has been developed by some vaccine manufacturers in an attempt to prevent inadvertent parenteral administration of the intranasal vaccine.

Concerns have been raised that intranasal *B. bronchiseptica* vaccines may cause respiratory disease in immunosuppressed humans who inhale the vaccine during administration or who contact vaccine organisms shed by recently immunized dogs.[39,40] However, as yet, there has been no molecular proof that the *B. bronchiseptica* strains isolated from affected human patients match vaccine strains. In fact, in one report of *B. bronchiseptica* pneumonia in an infant that was temporally related to intranasal vaccination of a pet dog, genetic analysis (ribotyping) showed that the vaccine was not the source of the infant's exposure.[41] The organism matched to another *B. bronchiseptica* strain that had previously been isolated from a human patient.

Intranasal *B. bronchiseptica* vaccination is followed by the development of low titers of serum IgG, whereas serum IgG responses are higher after parenteral vaccination (as might be expected). Parenteral whole-cell vaccines, and more recently acellular vaccines that include virulence factors such as pertactin, FIM, FHA, and pertussis toxin, are widely used to prevent pertussis in humans.[26] Fewer scientific data are available on the efficacy of parenteral *B. bronchiseptica* vaccines in dogs when compared with intranasal vaccines. One study showed that an intranasal vaccine was more effective than a parenteral antigen extract vaccine.[42] Additional challenge studies are required that directly compare the efficacy of intranasal and parenteral *B. bronchiseptica* vaccines for dogs.

In some countries, intranasal *B. bronchiseptica* vaccines are available for cats, which can reduce signs of disease after challenge as long as 1 year after vaccination.[43] Because disease is rarely severe in cats more than 6 weeks of age, vaccination of cats has not been recommended on a routine basis,[43] but could be considered as an adjunct to management strategies such as reduction of overcrowding and proper disinfection if outbreaks of bordetellosis are a problem in group-housed cats. Vaccination of immunocompromised cats is not recommended.[44]

Prevention

In the absence of management strategies to reduce stress, overcrowding, and comorbidities, vaccination is unlikely to completely prevent bordetellosis. The reader is referred to the sections on prevention in Chapters 17 (dogs) and 23 (cats) for more additional information on prevention and management of outbreaks of respiratory infections in group-housed animals.

Public Health Aspects

B. bronchiseptica is an uncommon cause of respiratory disease in humans, but has been isolated from humans without clinical signs and humans with mild to severe respiratory disease, including pneumonia.[45] Most, but not all, affected humans have underlying immunosuppressive conditions that predispose them

to infection. *B. bronchiseptica* peritonitis has been reported in human patients receiving continuous peritoneal dialysis.[46,47] Bacteremia and meningitis have also been reported.[48] Recent exposure to cats and to dogs with signs of "kennel cough" has been noted in most human cases,[45,49] but airborne transmission between humans can occur in hospital settings.[50] At least in mouse models, human acellular pertussis vaccines appear to cross-protect against *B. bronchiseptica*.[51] Infections with *B. bronchiseptica* may be underrecognized in people, because the direct fluorescent antibody test used for diagnosis of pertussis may not distinguish between *B. pertussis* and *B. bronchiseptica*. Clinically, recognition of *B. bronchiseptica* infections in humans is important, because *B. bronchiseptica* is resistant to macrolides, which are first-line agents for pertussis.[41] Until more is understood about the risks of canine mucosal *B. bronchiseptica* vaccines for immunocompromised people, parenteral vaccination of at-risk dogs owned by seriously immunocompromised humans is probably warranted, and the owners of these dogs should be instructed to avoid or minimize situations in which their dogs could come into contact with large numbers of other dogs.

CASE EXAMPLE

Signalment: 7-week-old intact female Persian kitten from California

History: A research colony kitten was examined for a 3-day history of respiratory signs. Three days previously, sneezing was observed in this kitten and one of its littermates. A day later, the kitten developed lethargy, inappetence, and respiratory distress, and the littermate was found dead. The kitten had been treated with lactated Ringer's solution (6 mL SC q24h) and azithromycin suspension (0.7 mg/kg PO q24h) since it became unwell. Two other kittens in the litter remained unaffected, and one had mild nasal discharge. All of the cats had tested negative for FeLV antigen and FIV antibody using a commercially available in-house ELISA kit.

Physical Examination:

Body Weight: 0.37 kg

General: Alert, open-mouth breathing. T = 97.5°F (36.4°C), HR = 220 beats/min, RR = 40 breaths/min, mucous membranes pale pink.

Eyes, Ears, Nose, and Throat: No abnormalities were noted.

Musculoskeletal: Body condition score 4/9.

Respiratory: Markedly increased inspiratory and expiratory effort, tachypnea, and open-mouth breathing were noted. Increased lung sounds were detected on auscultation.

Cardiovascular, Gastrointestinal, and Genitourinary Systems and Lymph Nodes: No clinically significant abnormalities were detected.

Imaging Findings: Thoracic radiographs: There was collapse of the left cranial lung lobe and partial volume loss in the left caudal lung lobe with evidence of mediastinal shift to the left, possibly secondary to a bronchial mucus plug. A focal increase in opacity was noted in the area of the right middle lung lobe with hyperinflation of the right cranial and caudal lung lobes. There were regions of gas trapping, and the bronchi were enlarged. Emphysema was suspected, possibly congenital. Consolidation in the area of the right middle lung lobe was compatible with pneumonia.

Outcome: The kitten was treated with oxygen supplementation, terbutaline (0.01 mg/kg SC q6h), ticarcillin-clavulanate (50 mg/kg IV q8h), LRS with 5% dextrose (1 mL/hr IV), a single dose of dexamethasone (1 mg/kg IV), and a single dose of furosemide (2 mg/kg IV). Euthanasia was performed 24 hours later due to lack of improvement and the poor prognosis.

Necropsy Findings: An endotracheal wash was performed immediately after euthanasia. This revealed marked, septic, suppurative inflammation and mild to moderate epithelial hyperplasia. Bacteria were present in large numbers extracellularly, within degenerate neutrophils, and in large mats.

Gross necropsy findings consisted of diffuse lung lobe collapse with multiple firm dark red areas throughout the parenchyma. On histopathology, there was severe, multi-focal to coalescing, acute necrosuppurative bronchopneumonia with abundant clusters of gram-negative bacteria. Examination of the upper respiratory tract showed mild, multifocal neutrophilic rhinitis and mild, multifocal, lymphocytic tracheitis. The other kitten was also necropsied, with similar findings.

Microbiologic Testing (Endotracheal Wash Specimen): Culture for aerobic bacteria, *Mycoplasma* spp., and virus isolation revealed only moderate numbers of *Bordetella bronchiseptica*.

Diagnosis: *Bordetella bronchiseptica* bronchopneumonia.

Comments: This outbreak of severe bordetellosis in a research cat colony resulted in the death of several kittens, which deteriorated rapidly even in the face of supportive care. Co-infections were not detected, although PCR testing was not performed and the negative *Mycoplasma* culture and virus isolation results did not rule out the possibility of co-infection. Although susceptibility testing was not performed, resistance to the antimicrobials that were used can occur in *B. bronchiseptica*. Furthermore, the dose of azithromycin used as reported in the medical record was subtherapeutic.

CHAPTER 39

Cell Wall–Deficient Bacterial Infections

Jane E. Sykes

VetBooks.ir

Overview of Cell Wall–Deficient Bacterial Infections

First Described: 1935, London (Kleineberger)[1]

Causes: Cell wall–deficient strains of a variety of gram-positive and gram-negative bacteria

Geographic Distribution: Worldwide

Major Clinical Signs: Chronic draining or ulcerated soft tissue and skin lesions, polyarthritis, possibly other chronic pyogenic and pyogranulomatous lesions

Differential Diagnoses: Infections due to other fastidious bacteria such as *Mycoplasma*, *Nocardia*, *Mycobacterium*, *Bartonella*, *Brucella*, nutritionally variant streptococci such as *Granulicatella*, or, for animals with polyarthritis, *Borrelia burgdorferi*; fungal infections (e.g., due to *Sporothrix schenckii* or *Coccidioides immitis*); persistence of a foreign body; neoplasia; congenital immunodeficiency; primary immune-mediated disease

Human Health Significance: Likely similar to that for the corresponding walled (or "normal") variant of the bacterial species involved

Etiologic Agent and Epidemiology

Cell wall–deficient bacteria (CWDB), also known as *L-phase* or *L-form* bacteria, are bacterial variants that lack a cell wall, although they may in fact possess small amounts of peptidoglycan.[2] The name *L-form* was given to these bacteria because they were discovered at the Lister Institute in London. L-form bacteria are distinct from mycoplasmas, because *Mycoplasma* spp. do not originate from bacteria that normally possess a cell wall. A huge variety of gram-positive and gram-negative bacterial species may become CWDB when exposed to certain stressors in the laboratory (such as antimicrobial drugs) (Box 39-1). Some of these bacteria remain as CWDB (stable L-forms), whereas others revert back to possession of a cell wall (unstable L-forms). CWDB assume a spherical or pleomorphic shape, and are susceptible to osmotic lysis. However, they resist β-lactam drugs such as penicillin, and may be able to evade the innate immune response. Thus, it has been proposed that reversion to cell wall–deficient forms may be a mechanism of bacterial persistence. Although the formation of CWDB has been well documented in the laboratory, the role that CWDB play in disease remains controversial.[3]

Clinical Features

In human patients, CWDB have been implicated in culture-negative endocarditis, bacteremia, uveitis, pneumonia, osteomyelitis and arthritis, urinary tract infections, soft tissue infections, and meningitis.[3] In cats, CWDB have been implicated as a cause of subcutaneous abscesses and arthritis.[4,5] A cell wall–deficient *Nocardia* sp. was isolated from a dog with polyarthritis that was refractory to antibiotics,[6] and a *Pseudomonas aeruginosa* L-form was isolated from the blood of a dog after antibiotic treatment for *P. aeruginosa* endocarditis.[7]

Diagnosis

Physical examination and laboratory findings in cats and dogs infected with CWDB may be similar to those for other chronic, persistent bacterial infections. Infection with CWDB should be considered in cats and dogs with culture-negative pyogranulomatous or suppurative inflammatory lesions, or when a bacterial etiology is suspected on the basis of clinical signs but routine

BOX 39-1

Examples of Medically Important Bacteria That May Become Cell Wall–Deficient When Subjected to Appropriate Stressors

Staphylococcus spp.
Streptococcus spp.
Enterococcus spp.
Escherichia coli
Serratia marcescens
Pasteurella multocida
Pseudomonas aeruginosa
Proteus mirabilis
Salmonella typhimurium
Lactobacillus spp.
Nocardia spp.
Actinomyces spp.
Bacillus spp.
Brucella spp.
Corynebacterium spp.
Borrelia burgdorferi
Leptospira interrogans

TABLE 39-1

Assays Available for Diagnosis of Cell Wall–Deficient Bacterial Infections in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Biopsies, body fluids, wash specimens	Cell wall–deficient bacteria (CWDB)	Requires special L-form bacterial (hyperosmolar) media
Cytology or histopathology	Biopsies, smears of affected tissues	CWDB	Organisms usually not visible owing to the lack of a cell wall, but may be gram-variable. Low sensitivity and cannot be used to identify absence of a cell wall (although the presence of organisms that stain strongly with Gram stain indicates the presence of walled bacteria).
Electron microscopy	Biopsies	CWDB	Confirms the presence of CWDB in lesions. May not distinguish CWDB from *Mycoplasma* spp. Often expensive and not readily available for routine diagnostic purposes.
Broad-range bacterial PCR assay and sequencing	Biopsies, body fluids, wash specimens	16S ribosomal subunit DNA of CWDB	Confirms presence of bacteria in lesions when culture is negative. False positives may occur if contaminating bacteria are present. Does not distinguish between CWDB and their walled counterparts. Sensitivity and specificity may vary between assays.

cultures are negative. Definitive diagnosis is difficult because the organisms are not always readily visualized using light microscopy, and passage through special hypertonic laboratory media is required for growth of CWDB in culture (Table 39-1). Electron microscopy has been used to identify the organisms in lesions. The use of broad-range bacterial PCR assays that detect bacterial 16S ribosomal subunit DNA in tissues may be useful to detect L-form bacteria in tissues in the future when routine culture methods are negative, although this method does not distinguish between CWDB and their walled counterparts. Infection with CWDB could also be suspected when lesions resolve after treatment with tetracyclines.

Treatment and Prognosis

CWDB are generally susceptible to tetracyclines such as doxycycline. Other antimicrobial drugs that act through cell wall–independent mechanisms, such as fluoroquinolones, chloramphenicol, and macrolides, may also be active against some L-form bacteria.

Public Health Aspects

The role that CWDB play in zoonotic disease is unclear, but it is reasonable to believe it is similar to that of the corresponding walled (or normal) variant of the bacterial species implicated. A single report described isolation of an L-form of *Streptococcus sanguinis* from a vascular graft of a hemodialysis patient.[8] The affected person's pet dog was reported to often lick the graft site, and *S. sanguinis* was also isolated from the dog's oral cavity. Although this was suggestive of zoonotic transmission, the identity of the isolates was not confirmed with molecular methods.

CHAPTER 40

Mycoplasma Infections

Jane E. Sykes

VetBooks.ir

Overview of Mycoplasma and Ureaplasma Infections

First Described: Dogs, Japan 1934 (Shoetensack).[1] Reports of human *Mycoplasma* infections also occurred around this time.[2]

Causes: *Mycoplasma cynos* and *Mycoplasma felis* have been most commonly associated with disease, but many other *Mycoplasma* species infect dogs and cats

Geographic Distribution: Worldwide

Mode of Transmission: Direct contact, fomite transmission in overcrowded environments. Opportunistic invasion of commensal mycoplasmas also occurs.

Major Clinical Signs: Conjunctivitis, sneezing and nasal discharge (cats); cough, tachypnea, fever, weight loss (lower respiratory disease); swollen, painful joints (polyarthritis); subcutaneous abscesses; neurologic signs (meningoencephalitis); prostatitis, epididymitis-orchitis, or lower urinary tract signs (dogs)

Differential Diagnoses: Primarily gram-positive and gram-negative bacterial infections. Differential diagnoses for suspected mycoplasma respiratory disease include viral infections, fungal and parasitic causes of pneumonia, aspiration pneumonia, and neoplasia.

Human Health Significance: Canine and feline mycoplasma species have rarely been detected in immunocompromised humans with mycoplasmosis who have had contact with pet cats and dogs.

Etiology and Epidemiology

Mycoplasmas are fastidious bacteria that lack a cell wall. They belong to the class Mollicutes (which translates to "soft skin"), and are the smallest known free-living organisms. Many require sterols for growth, and *Ureaplasma* species require urea for fermentation. Mycoplasmas measure only 0.3 to 0.8 μm in size. More than 120 different species of *Mycoplasma* and 7 species of *Ureaplasma* have been identified. The spectrum of mycoplasma species that infect or colonize dogs and cats is incompletely understood because precise species identification has been difficult (Box 40-1).[3-7] Additional mycoplasma species are likely to be discovered with the application of molecular methods in the future. Some *Mycoplasma* spp. infect multiple host species. Mycoplasmas are often difficult to grow on cell-free media, and some, such as the hemotropic mycoplasmas, have never been successfully cultured in the laboratory (see Chapter 41). The remainder of this chapter refers only to nonhemotropic mycoplasma species.

BOX 40-1

Nonhemotropic *Mycoplasma* and *Ureaplasma* Species Found in Dogs and Cats[3-7]

Dogs	Cats
M. cynos	*M. felis*
M. canis	*M. gateae*
M. molare	*M. arginini*
M. arginini	*M. feliminutum*

M. edwardii	*M. cynos**
M. feliminutum	*M. lipophilum**
M. felis	*M. hyopharyngis**
M. gateae	*U. felinum*
M. maculosum	*U. cati*
M. opalescens	*Acholeplasma laidlawii*
M. spumans	
M. sp. HRC689	
M. sp. VJC358	
U. canigenitalium	
Acholeplasma laidlawii	

*Identified on the basis of DNA sequencing of small segments of the 16S rRNA gene; sequence analysis of longer fragments may reveal these are in fact other mycoplasma species.

Mycoplasmas are commensal bacteria found widely in association with mucous membranes of all mammalian species. Simultaneous colonization with more than one *Mycoplasma* species is common. Mycoplasmas have also been associated with keratoconjunctivitis and/or upper respiratory tract disease (URTD) in cats; reproductive disease and urinary tract infections (UTIs) in dogs; and lower respiratory tract disease, skin and soft tissue infections, meningoencephalitis, and arthritis in both cats and dogs (Box 40-2).[8-18] Because mycoplasmas are commonly isolated from the upper respiratory and genital tracts of healthy dogs and cats, their role in ocular, upper respiratory tract, and urogenital tract disease has been difficult to determine. Several studies have now identified an increased prevalence of mycoplasmas in cats with conjunctivitis or URTD when compared with healthy cats.[13,19,20] Mycoplasmas can act as secondary invaders when other pathogenic viruses and bacteria are present, or when normal host defenses are impaired by factors such as underlying neoplasia or immunosuppressive drug

VetBooks.ir

BOX 40-2

Diseases That May Be Associated with Mycoplasma Infections in Dogs and Cats

Cats
Conjunctivitis
Upper respiratory tract disease
Pyothorax

Dogs
Urinary tract infections
Prostatitis
Epididymitis and orchitis

Both Cats and Dogs
Bronchopneumonia
Skin and soft tissue infections (abscesses)
Meningoencephalitis
Polyarthritis

therapy. When mycoplasmas are associated with systemic disease or pneumonia, young animals (less than 1 year of age) are often involved. Some mycoplasma species appear to be more pathogenic than others. For example, evidence has accumulated that *Mycoplasma cynos* is associated with lower respiratory disease in dogs.[21,22] In one study, *M. cynos* infection was associated with increased severity of canine infectious respiratory disease, younger age, and longer time spent in a kennel.[22] Experimental infection with *M. cynos* leads to respiratory disease in dogs, but infection with *Mycoplasma gateae, Mycoplasma canis,* and *Mycoplasma spumans* does not.[23] The role of mycoplasmas in feline lower urinary tract disease and lymphoplasmacytic pododermatitis has been investigated using molecular techniques, but no association was found.[24,25]

Clinical Features

Signs and Their Pathogenesis

In order to colonize mammalian hosts, mycoplasmas must adhere to host cells. Mycoplasma species that infect humans are known to possess specific adhesins, but these have not been well characterized in mycoplasmas from dogs and cats. Invasion of deeper tissues and disease occurs as a result of immunosuppression or disruption of normal host barriers. Some mycoplasmas, such as the human pathogen *Mycoplasma pneumoniae,* produce toxins, but whether similar virulence factors are present in mycoplasmas isolated from dogs and cats is unknown. A number of pathogenic mycoplasma species of humans can invade cells, which may contribute to organism persistence and difficulties associated with isolation in the laboratory. Transmission of pathogenic mycoplasmas such as *M. cynos* may occur in overcrowded environments as a result of close contact or fomite spread. The finding of identical strains in multiple dogs from a kennel environment (using molecular typing methods) supports the concept of transmission between dogs in this environment.[26] The extent to which mycoplasmas survive in the environment varies among mycoplasma species and has not been determined for mycoplasmas that infect dogs and cats.

FIGURE 40-1 Ulcerative keratitis in a 4-year-old female spayed Persian. Involvement of feline herpesvirus-1 was suspected, and *Mycoplasma* spp. was isolated from a corneal swab. The significance of the *Mycoplasma* infection was unclear, but the ulcer healed after topical treatment with topical ofloxacin and azithromycin drops. (Courtesy of the University of California, Davis, Veterinary Ophthalmology Service.)

Conjunctivitis and Upper Respiratory Tract Disease

Mycoplasma spp. are commonly detected in cats in association with conjunctivitis and URTD. Concurrent infections with other upper respiratory pathogens (such as *Bordetella bronchiseptica*, *Chlamydia felis*, and feline respiratory viruses) may contribute to clinical signs. Stressors such as overcrowding and unhygienic conditions may promote proliferation of mycoplasmas and their transmission between cats. Ulcerative keratitis has been reported in association with *Mycoplasma* infection, but the presence of corneal involvement may reflect the concurrent presence of feline herpesvirus 1 (FHV-1) or other factors that predispose to secondary invasion by *Mycoplasma* spp. (Figure 40-1).

Pneumonia and Pyothorax

Virtually all dogs and cats harbor mycoplasmas in their upper respiratory tracts. Fewer than 25% of healthy dogs harbor mycoplasmas in their trachea or lungs. In one study mycoplasmas were detected in tracheobronchial lavage specimens from 21% of 28 cats with pulmonary disease, but not from 18 healthy cats.[27,28] Mycoplasmas can be isolated from the lower airways and lungs of dogs and cats with pneumonia, sometimes in pure culture.[29] Factors that predispose to the development of mycoplasma pneumonia are not always apparent.[30] Clinical signs include variable fever, cough, tachypnea, lethargy, and decreased appetite. Concurrent signs of URTD have been reported in some affected cats.[30] Rarely, mycoplasmas can be cultured from the pleural fluid of cats and dogs with pyothorax, in pure culture or in mixed infections with other organisms.[31-33]

Urogenital Tract

Mycoplasma and *Ureaplasma* spp. have been found in the semen and urine of dogs with infertility and purulent epididymitis.[34] The role of mycoplasmas in reproductive tract disease in dogs and cats is unclear because they are commonly isolated from the urogenital tract of healthy dogs and cats. Large numbers of mycoplasmas (>10^5 CFU/mL) can occasionally be isolated in pure culture from urine collected by cystocentesis from dogs with prostatitis and lower urinary tract signs.[14,34] Dogs with mycoplasma UTIs often have other comorbidities that impair

VetBooks.ir

normal urinary defenses, such as urinary tract neoplasia, calculi, or neurologic disease.[14]

Arthritis and Bacteremia

Isolated case reports exist of polyarthritis due to infection with *M. spumans* or *Mycoplasma edwardii* (dogs) and *M. gateae* or *M. felis* (cats). Synovial fluid analysis usually reveals the presence of large numbers of neutrophils. This may lead to diagnostic confusion with primary immune-mediated polyarthritis. Systemic signs such as lethargy, fever, and inappetence usually accompany lameness. Evidence of immune compromise, such as underlying neoplasia or surgery, young age, or a history of glucocorticoid treatment, has generally been present in dogs and cats with mycoplasma polyarthritis. *M. felis* has also been isolated from cats with monoarthritis, possibly secondary to bite wound infections.[17]

Meningoencephalitis

Mycoplasmas may gain access to the central nervous system after penetrating wounds, ascending infection from the middle ear, or hematogenous spread. Meningoencephalitis associated with *M. felis* infection was described in a 10-month-old cat that showed signs of lethargy, fever, a head tilt, nystagmus, and tetraparesis.[12] *M. felis* was isolated in pure culture from the CSF. The cat also had evidence of otitis media-interna at necropsy, but the role this played in development of the mycoplasma infection was unclear. *M. edwardii* was isolated from the brain of a 6-week-old dog with a sudden onset of seizures.[8] Suppurative and histiocytic meningitis was detected at necropsy, in conjunction with evidence of a possible penetrating wound to the skull. Recently, infection with *Mycoplasma canis* has been associated with some cases of granulomatous meningoencephalomyelitis and necrotizing meningoencephalitis in dogs,[35] which requires further study.

Physical Examination Findings

Physical examination findings in dogs and cats with mycoplasma infections depend on the organ affected, as well as underlying disease processes that facilitate opportunistic invasion by mycoplasmas. Ocular infections in cats are characterized by serous to mucopurulent ocular discharge, conjunctival hyperemia, and possibly keratitis. Upper respiratory tract infections may result in nasal discharge and sneezing, with or without conjunctivitis. Fever, tachypnea, and increased lung sounds may be present with pneumonia. Urinary tract infections may lead to clinical signs of lower urinary tract disease, such as hematuria or stranguria. *Mycoplasma* arthritis may be manifested by fever, joint pain and swelling, and sometimes local lymphadenopathy.[9-11]

Diagnosis

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Findings on the CBC, serum biochemistry panel, and urinalysis in dogs or cats with *Mycoplasma* infections are nonspecific and influenced by underlying immunocompromising disease processes. Dogs and cats with pneumonia, mycoplasma bacteremia, and polyarthritis may have a neutrophilia with a left shift and neutrophil toxicity, a degenerative left shift, mild nonregenerative anemia, hypoalbuminemia, and evidence of organ dysfunction such as increased liver enzyme activities and azotemia.[9,10,15]

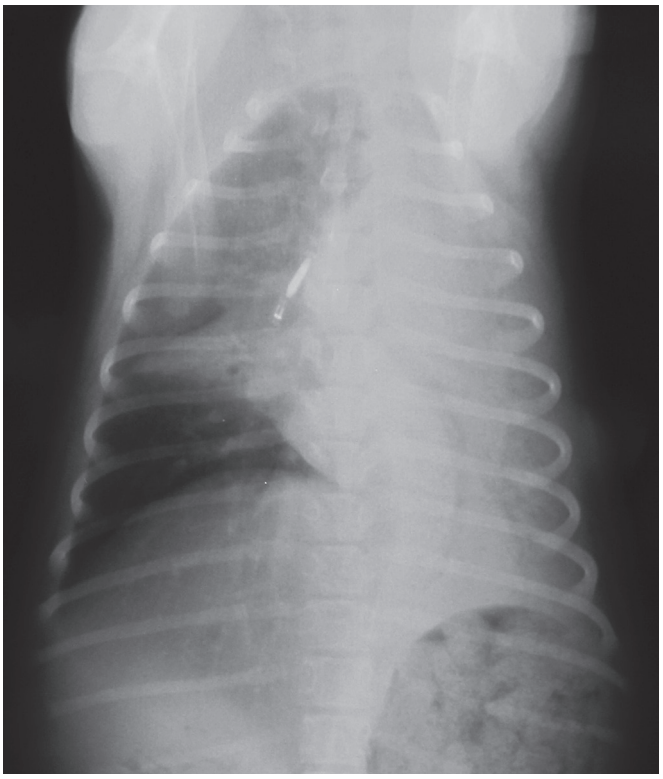

FIGURE 40-2 Ventrodorsal thoracic radiograph from a 3-month-old intact female pug with *Mycoplasma cynos* pneumonia. There is consolidation of the lung lobes associated with the left hemithorax and the right middle lung lobe. A diffuse interstitial pattern is present in the remainder of the right lung fields.

Diagnostic Imaging

Plain Radiography

Mycoplasma pneumonia may be characterized by interstitial to alveolar patterns or lung lobe consolidation (Figure 40-2); sometimes, mild pleural effusion is present. Radiographs of the joints of dogs and cats with mycoplasma polyarthritis may reveal periarticular soft tissue swelling. Erosive changes to the subchondral bone have also been described.[9]

Microbiologic Tests

Assays available for diagnosis of mycoplasma infections in dogs and cats are shown in Table 40-1.

Cytologic Examination

Mycoplasma spp. are often not visible by light microscopy because of their small size. They do not stain with Gram stain because they lack a cell wall. Cytologic examination of affected body fluids (such as bronchoalveolar lavage fluid, synovial fluid, and CSF) usually reveals a predominance of neutrophils with fewer histiocytes and lymphocytes.[9,10,12,29,30]

Isolation and Identification

Specimens suitable for mycoplasma culture include synovial fluid, blood, CSF, urine collected by cystocentesis, pleural fluid, semen, and tracheobronchial or bronchoalveolar lavage specimens. Swabs of the nasal cavity, conjunctiva, cornea, urethra, vagina, or cervix can also be submitted, but interpretation of results from these sites is difficult. If swabs are used, the swab should be rubbed vigorously on the mucosa, because mycoplasmas are cell associated. Rapid transport to the laboratory is

TABLE 40-1

Assays Available for Diagnosis of Mycoplasma Infections in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Swabs, body fluids, lavage specimens, tissue obtained at necropsy	Cultivable mycoplasma species	Some organisms grow on blood agar, but others require special mycoplasma media. The presence of uncultivable mycoplasmas may lead to false-negative results. Turnaround time may be slow (several days to weeks); species differentiation and antimicrobial drug susceptibility testing is often not performed. The significance of positive results from the upper respiratory and genital tract may be unclear.
PCR assays	Swabs, body fluids, lavage specimens, tissue obtained at necropsy	*Mycoplasma* DNA	Allows rapid detection of mycoplasmas. More sensitive than culture for detection of fastidious or uncultivable mycoplasmas, although sensitivity and specificity may vary between assays. Some assays are designed to only detect certain pathogenic *Mycoplasma* species, such as *Mycoplasma cynos*. Sequencing of the PCR product may permit species identification. The clinical significance of positive results may be unclear.

important, because mycoplasmas are susceptible to deterioration in the environment. The use of special transport media (e.g., Stuart's medium or Amies medium without charcoal) for swab or tissue specimens may increase yield of fastidious mycoplasma species if a delay of several hours is likely between collection of specimens and transport to the laboratory. Specimens should be refrigerated if delayed transport is unavoidable. If the delay is likely to be longer than 24 hours, specimens in transport media should ideally be frozen at –80°C. Some mycoplasma species will still grow in the laboratory if specimens are kept refrigerated for 2 to 3 days.

Some mycoplasmas grow on blood agar under routine aerobic or anaerobic conditions. Others require special mycoplasma media, and some fail to grow under any laboratory conditions. The rate of growth in culture varies from one *Mycoplasma* species to another; for some mycoplasmas, colonies are visible in 2 or 3 days, whereas others require several weeks of incubation before colonies appear. Examination of plates under the light microscope may be required for detection of *Mycoplasma* colonies, because the colonies range in size from 15 to 300 µm in diameter. The colonies of many mycoplasma species have a characteristic "fried egg" appearance (Figure 40-3). Biochemical properties can then be used to subgroup mycoplasmas, but species identification has traditionally required the use of species-specific antisera. Because cross-reactions can occur between species even when antisera are used, molecular typing methods (such as 16S rRNA gene or 16S/23S rRNA intergenic spacer region PCR assays and sequence analysis of the respective PCR products) are now the method of choice for species identification.[3] Most veterinary diagnostic laboratories currently report only growth of a *Mycoplasma* species and do not identify organisms to the species level unless specifically requested. It is difficult to interpret the significance of a positive mycoplasma culture from mucosal sites that can normally be colonized by mycoplasmas, including the lower respiratory tracts of dogs, so results must be interpreted in light of the clinical findings and the results of other diagnostic tests.

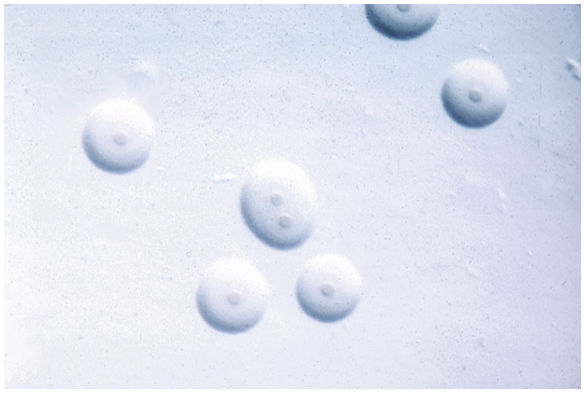

FIGURE 40-3 Colonies of *Mycoplasma bovirhinis* showing the "fried egg" appearance that is typical of the growth of some *Mycoplasma* spp. in culture. (From The genera *Mycoplasma* and *Ureaplasma*. In Songer JG Post KW, eds. Veterinary Microbiology Bacterial and Fungal Agents of Animal Disease, 2 ed, St. Louis, MO: Saunders; 2005.)

Antimicrobial susceptibility testing for mycoplasmas is labor intensive and not routinely performed, and established breakpoints are not available. When performed, the most widely used method is microbroth dilution (see Chapter 3).[36]

Molecular Diagnosis Using the Polymerase Chain Reaction
