Some veterinary diagnostic laboratories offer PCR assays that directly detect mycoplasma DNA in clinical specimens, without the need for culture. Several conventional and real-time PCR assays have been used to detect mycoplasmas of dogs and cats.[37-40] These assays may be specific for certain mycoplasma species (such as *M. cynos* or *M. felis*) or they may be genus-specific assays that detect a variety of mycoplasma species. PCR assays may be more sensitive than culture for detection of fastidious mycoplasma species. Sequencing of the PCR product generated from genus-specific PCR assays may be used to identify the infecting species present, provided the PCR amplicon is sufficiently long. As with culture, the significance of a

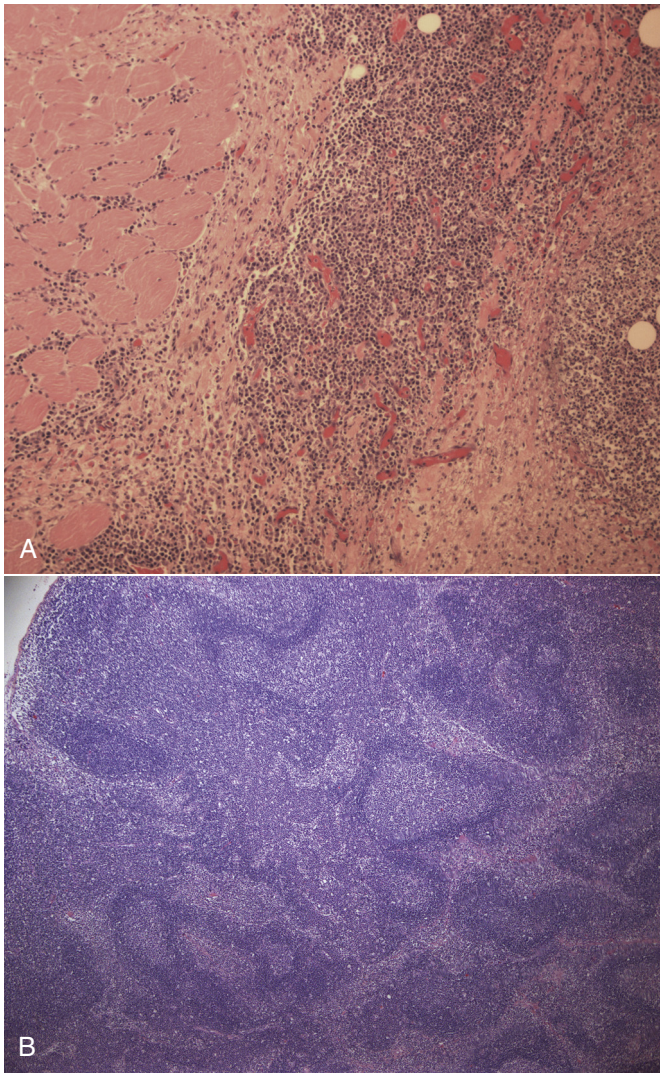

FIGURE 40-4 Histopathology of the inguinal subcutaneous tissues **(A)** and sublumbar lymph node **(B)** from a 6-month-old, retrovirus–negative, male neutered domestic shorthair with severe suppurative cellulitis, steatitis, dermatitis, and myositis of the scrotal skin and subcutaneous tissue. A pure culture of a *Mycoplasma* species was obtained from the lesion. The cat had been neutered 13 days previously and was evaluated for a 2-day history of lethargy and reluctance to move. Physical examination revealed fever (104.6°F [40.3°C]), conjunctivitis, generalized peripheral lymphadenomegaly, and firm mass lesions in the inguinal area. In addition to suppurative cellulitis and myositis, marked systemic lymph-node hyperplasia was present. Hyperplasia was most profound in the sublumbar lymph nodes, which were 4 cm in diameter.

positive PCR test result for *Mycoplasma* spp. may be unclear given the role the frequent colonization of healthy animals with mycoplasmas, so results must be interpreted with the underlying disease process and the results of other diagnostic tests.

Pathologic Findings

Gross pathology in dogs and cats with mycoplasmal diseases usually reveals purulent material in affected tissues. Histopathology shows predominantly neutrophilic inflammation, although histiocytes may also be present. Reactive lymphadenopathy may also be evident as a result of immune stimulation (Figure 40-4).

TABLE 40-2

Suggested Antimicrobial Drug Treatment for Mycoplasma Infections in Dogs and Cats

Drug	Dose (mg/kg)	Route	Interval (hours)
Doxycycline	5 to 10	PO or IV	12 to 24
Enrofloxacin*	5	PO or IV	24
Marbofloxacin	2.75 to 5.5	PO	24
Pradofloxacin†	5 to 10 (cats) 3 mg/kg (dogs)	PO	24

*For cats, use enrofloxacin only when other alternatives are not possible because of risk for irreversible blindness.
†Use of pradofloxacin is extra-label in dogs in the United States (see Chapter 8). The dose for cats is for the oral suspension. The dose for the tablet formulation is 3 mg/kg.

Treatment and Prognosis

Treatment of mycoplasma infections involves specific antimicrobial therapy (Table 40-2) as well as management of other underlying disorders that predisposed to invasion by mycoplasmas. Tetracyclines or fluoroquinolones are active against most mycoplasma isolates. The optimal duration is unknown, but treatment for at least 2 weeks is reasonable. In a prospective study of shelter cats with URTD and *M. felis* infection, a 14-day course of doxycycline was more effective in causing reduction in *M. felis* load as determined with real-time PCR than a 7-day course, but there was no overall significant difference in the reduction in clinical signs between the two groups.[41] Nevertheless, 25% of the cats treated for 14 days were still infected after that time. In another study of cats with conjunctivitis, three weeks of treatment with pradofloxacin or doxycycline was required to eliminate *Mycoplasma* DNA.[40] β-Lactam drugs are not active against mycoplasmas, because they lack any peptidoglycan. Mycoplasmas are also intrinsically resistant to trimethoprim-sulfonamide combinations and rifampin. Some species are resistant to macrolides.

Immunity and Vaccination

Mycoplasma spp. persist in tissues in the face of the immune response. Mechanisms to evade the host immune response such as antigenic variation of outer surface proteins have been identified in several mycoplasma species. Innate, humoral (especially IgA), and cell-mediated immune responses may be required to clear mycoplasma infections, with humoral mechanisms of critical importance. Vaccines to limit disease caused by pathogenic mycoplasma species such as *M. cynos* are currently not available, although mycoplasma vaccines have been used with success in food production animal species.

Prevention

Prevention of mycoplasma infections involves management or reversal of disorders that predispose to opportunistic invasion by mycoplasmas. Reduction of overcrowding and concurrent infections in shelter environments may also reduce the incidence and severity of mycoplasma infections (see Chapter 11).

Routine disinfectants are sufficient to inactivate mycoplasmas that persist in the environment.

Public Health Aspects

The vast majority of mycoplasma species associated with disease in humans are different from those found in dogs and cats. However, pharyngeal colonization with *M. canis* was reported in a family and their pet dog.[42] *Mycoplasma felis* was isolated from the joints of a woman with common variable immunodeficiency who developed septic arthritis.[43] The woman had worked in an animal shelter, lived with a cat, and had been bitten on the hand by a healthy cat 6 months before she was evaluated. A mycoplasma was also isolated from a cat scratch wound on the hand of a veterinarian.[44] Although *Staphylococcus aureus* was initially isolated from the wound, it failed to resolve completely after treatment with erythromycin. Subsequently, tenosynovitis developed, and a mycoplasma was isolated. The identity of the mycoplasma could not be determined using biochemical and serologic methods, and whether a cat was truly the source of this infection was not proven.

CASE EXAMPLE

Signalment: "Delilah", a 3-month old intact female pug dog from Reno, NV

History: Delilah was brought to the University of California, Davis, Veterinary Medical Teaching Hospital for evaluation of pneumonia. She had been purchased from a pet store 3 weeks before the date of evaluation. The owner noticed nasal and ocular discharge when the dog was brought home from the store, as well as a dry, nonproductive cough. Delilah was taken to a local veterinary clinic where a diagnosis of "kennel cough" was made. She was then treated with clavulanic acid–amoxicillin (15 mg/kg PO q12h) for 2 weeks. However, the cough persisted, and Delilah's respiratory effort increased. She was hospitalized at the local veterinary clinic and treated with ticarcillin-clavulanate (50 mg/kg IV q8h), supplemental oxygen, nebulization, and coupage. Radiographs showed infiltrates in the left lung lobes and right middle lung lobe that worsened over the course of hospitalization, so she was referred for further evaluation and treatment. There had been no decrease in appetite, vomiting, or diarrhea. She was fed a commercial puppy food and had no history of ticks, travel, trauma, or toxin exposure. The owner was not aware of previous vaccinations.

Physical Examination:

Body Weight: 2.2 kg

General: Quiet, alert, hydrated. T = 101.0°F (38.3°C), HR = 220 beats/min, RR = 60 breaths/min, slightly tacky mucous membranes with a normal capillary refill time.

Eyes, Ears, Nose, and Throat: Mild serous oculonasal discharge was present bilaterally. Conjunctival hyperemia and chemosis were present, as well as scleral injection.

Musculoskeletal: BCS 4/9. Fully ambulatory with no evidence of muscle atrophy. Poor body conformation was present, characterized by medial deviation of the tarsi and hyperextension of the carpi.

Respiratory: Tachypnea was present with marked abdominal effort. Lung sounds were markedly increased, especially on the left side. There were no crackles or wheezes. A nonproductive cough occurred several times during the examination.

All Other Systems: No clinically significant abnormalities were detected.

Laboratory Findings:

Venous Blood Gas: pH = 7.348, pCO_2 44 mm Hg, pO_2 44.7 mm Hg, HCO_3 23.2 mmol/L, base excess −1.4 mmol/L, ionized calcium 1.43 mmol/L, lactate 3.3 mmol/L.

CBC:

HCT 35.4% (40%-55%)
MCV 68.6 fL (65-75 fL)
MCHC 31.1 g/dL (33-36 g/dL)
WBC 31,580 cells/μL (6000-13,000 cells/μL)
Neutrophils 6948 cells/μL (3000-10,500 cells/μL)
Band neutrophils 9790 cells/μL
Lymphocytes 9158 cells/μL (1000-4000 cells/μL)
Monocytes 4737 cells/μL (150-1200 cells/μL)
Eosinophils 947 cells/μL (150-1100 cells/μL)
Platelets 307,000 platelets/μL (150,000-400,000 platelets/μL).
Band neutrophils and mature neutrophils had evidence of toxic changes.

Serum Chemistry Profile:

Sodium 147 mmol/L (145-154 mmol/L)
Potassium 4.9 mmol/L (3.6-5.3 mmol/L)
Chloride 104 mmol/L (108-118 mmol/L)
Bicarbonate 24 mmol/L (16-26 mmol/L)
Phosphorus 8.0 mg/dL (3.0-6.2 mg/dL)
Calcium 10.5 mg/dL (9.7-11.5 mg/dl)
BUN 10 mg/dL (5-21 mg/dL)
Creatinine 0.5 mg/dL (0.3-1.2 mg/dL)
Glucose 110 mg/dL (64-123 mg/dL)
Total protein 5.9 g/dL (5.4-7.6 g/dL)
Albumin 2.5 g/dL (3.0-4.4 g/dL)
Globulin 3.4 g/dL (1.8-3.9 g/dL)
ALT 12 U/L (19-67 U/L)
AST 38 U/L (19-42 U/L)
ALP 144 U/L (21-170 U/L)
Gamma GT 0 U/L (0-6 U/L)
Cholesterol 188 mg/dL (135-361 mg/dL)
Total bilirubin 0.0 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.045; pH 7.0, no protein, glucose, ketones, bilirubin, WBC, or RBC were present. Rare triple phosphate and a few sodium urate crystals were noted.

Imaging Findings:

Thoracic Radiographs: There was complete consolidation of the lung lobes associated with the left hemithorax (see Figure 40-2). Prominent air bronchogram formation was noted in these lobes and in the right middle lung lobe, which also appeared consolidated. Diffuse interstitial markings were present in the remainder of the right lung fields.

Thoracic Ultrasound: Complete consolidation of the left lung was the only abnormality detected.

Cytologic Findings: Transtracheal lavage: One direct smear was evaluated that was highly cellular and contained a minimal amount of mucus. Cells were essentially all neutrophils,

Continued

VetBooks.ir

which were primarily nondegenerate but occasionally mildly to moderately degenerate. A single extracellular rod and two neutrophils with intracellular structures that resembled bacteria were found. Interpretation: Marked suppurative inflammation.

Microbiologic Testing: Gram-stained direct smear of transtracheal lavage fluid: Large numbers of neutrophils were seen.

Aerobic and anaerobic bacterial culture and *Mycoplasma* culture (transtracheal wash fluid): Large numbers of *Mycoplasma* spp.; DNA sequence analysis revealed 100% identity to *Mycoplasma cynos*. No other aerobic or anaerobic organisms were isolated.

Direct fluorescent antibody for distemper virus antigen (conjunctival smear): Negative

Centrifugal zinc sulfate fecal flotation: Negative

Diagnosis: *Mycoplasma cynos* bronchopneumonia

Treatment: Before the culture results were available, Delilah was treated with supplemental oxygen, nebulization, coupage, and IV fluids. Treatment with ticarcillin-clavulanate was continued for 3 days, then changed to enrofloxacin (5 mg/kg PO q24h) and amoxicillin-clavulanate (19 mg/kg PO q12h). Daily nebulization with gentamicin was also initiated, because there had been no improvement and persistent bordetellosis was considered possible. The following morning, lung sounds were improved and Delilah was playful. Her nasal discharge resolved and the frequency of cough reduced. The CBC showed a regenerative anemia (hematocrit 33.2%, with 95,300 reticulocytes); 14,112 slightly toxic neutrophils/μL; 1008 band neutrophils/μL; 5796 lymphocytes/μL; and 3780 monocytes/μL. Growth of *Mycoplasma* spp. was reported 5 days after specimens were submitted for culture. Oxygen supplementation was withdrawn, and Delilah was discharged on day 8 of hospitalization, although significant radiographic improvement was not yet evident and an occasional productive cough was still present. Treatment with enrofloxacin, amoxicillin-clavulanate, coupage, and exercise restriction was continued at home. At a recheck 3 weeks later, Delilah had gained weight (3.5 kg). An intermittent, moist, but nonproductive cough was present only in the morning. Her appetite was normal, and there was no evidence of exercise intolerance or oculonasal discharge. A physical examination was unremarkable. A CBC showed persistent mild regenerative anemia, with 7260 neutrophils/μL and 330 band neutrophils/μL. Thoracic radiographs showed improved aeration of the left lung lobes, and near complete resolution of the right-sided infiltrates. The amoxicillin-clavulanate was discontinued. Further improvement in the cough and pulmonary infiltrates was observed at a recheck 3 weeks later. After an additional 7 weeks of treatment, the cough had resolved, but partial atelectasis of the cranial portion of the left lung lobe persisted.

Comments: The isolation of a pure culture of *Mycoplasma cynos* from this dog's airways, the lack of response to β-lactam antibiotics, and a prompt response to enrofloxacin treatment supported a diagnosis of mycoplasma pneumonia (and possibly also URTD) in this dog. The concurrent presence of respiratory viruses remains possible because other than direct fluorescent antibody testing for canine distemper virus, diagnostic tests for respiratory viruses were not performed, and co-infection with multiple respiratory pathogens in dogs from pet stores and shelter environments is common. Resolution of the cough and radiographic changes occurred over several months. Concern existed in regard to cartilage toxicity in such a young dog due to prolonged treatment with enrofloxacin, but no adverse effects occurred. The regenerative anemia was interesting and may have reflected pulmonary hemorrhage or immune-mediated hemolysis. Reticulocytosis has been reported in human patients with community-acquired pneumonia due to *Mycoplasma pneumoniae*.

Hemoplasma Infections

Jane E. Sykes and Séverine Tasker

VetBooks.ir

Overview of Hemoplasma Infections

First Described: Feline hemoplasmas, South Africa, 1942 (Clark)[1]; canine hemoplasmas, Germany, 1928 (Kikuth)[2]

Cause: *Mycoplasma haemofelis,* '*Candidatus* Mycoplasma haemominutum,' '*Candidatus* Mycoplasma turicensis' (cats). The most prevalent hemoplasmas in dogs are *Mycoplasma haemocanis* and '*Candidatus* Mycoplasma haematoparvum.'

Affected Hosts: Cats and wild felids, dogs and wild canids; other hemoplasma species cause disease in a variety of other animal species.

Geographic Distribution: Worldwide

Mode of Transmission: Experimentally, transmission can occur through ingestion or injection of infected blood; the mode of transmission in the field uncertain. Biting or aggressive interactions are a suspected mode, and possibly vertical transmission. Ticks are suspected to transmit *Mycoplasma haemocanis*. Other unidentified arthropod vectors may also be involved.

Major Clinical Signs: Fever, lethargy, inappetence, weakness, pallor.

Differential Diagnoses: Cytauxzoonosis, FIV infection, FeLV infection, feline infectious peritonitis, primary immune-mediated hemolytic anemia, Heinz body hemolytic anemia, inherited erythrocyte disorders such as pyruvate kinase deficiency and the red cell fragility disorder of Abyssinian and Somali cats

Human Health Significance: DNA sequences that match those found in *Mycoplasma haemofelis* were detected in a human co-infected with HIV and *Bartonella henselae.* DNA sequences of other animal hemoplasmas have also been detected in humans.

Etiology and Epidemiology

Hemotropic mycoplasmas (hemoplasmas) are small (0.3-0.8 µm), unculturable mycoplasmas that reside on the surface of erythrocytes and can cause variable degrees of hemolytic anemia in infected hosts. Hemoplasmas infect a wide variety of mammalian species, including humans, and have a worldwide distribution. Although previously classified as *Haemobartonella* and *Eperythrozoon* spp., sequence analysis of the 16S rRNA genes of these organisms has shown that they are closely related to the pneumoniae group of mycoplasmas, which includes the human mycoplasmal pathogens *Mycoplasma pneumoniae* and *Mycoplasma genitalium*.

At least three hemoplasma species infect domestic as well as wild cats, *Mycoplasma haemofelis*, '*Candidatus* Mycoplasma haemominutum,' and '*Candidatus* Mycoplasma turicensis.' The '*Candidatus*' prefix is applied to newly discovered hemoplasmas until more information is available to support their classification. This is because hemoplasmas cannot be cultured in the laboratory, which limits full characterization of these organisms. *M. haemofelis* (previously the Ohio strain, or large form of *Haemobartonella felis*) is the most pathogenic organism and can cause moderate to severe hemolytic anemia in immunocompetent cats. The resulting disease has been referred to as *feline infectious anemia*. Using cytologic evaluation of blood smears, *M. haemofelis* organisms are cocci that sometimes form short chains of three to six organisms (Figure 41-1). *M. haemofelis* is the least prevalent of the three feline hemoplasmas. It has been found using PCR in 0.5% to 5% of sick cats at veterinary hospitals. The whole genome sequences of *M. haemofelis* and *M. haemominutum* have been determined.[3-5]

'*Ca.* M. haemominutum' (previously the California strain or small form of *H. felis*) is generally smaller than *M. haemofelis* and has not clearly been associated with disease in immunocompetent cats. Using cytologic evaluation of blood smears, '*Ca.* M. haemominutum' are small cocci, 0.3 to 0.6 µm in diameter, although *M. haemofelis* and '*Ca.* M. haemominutum' cannot

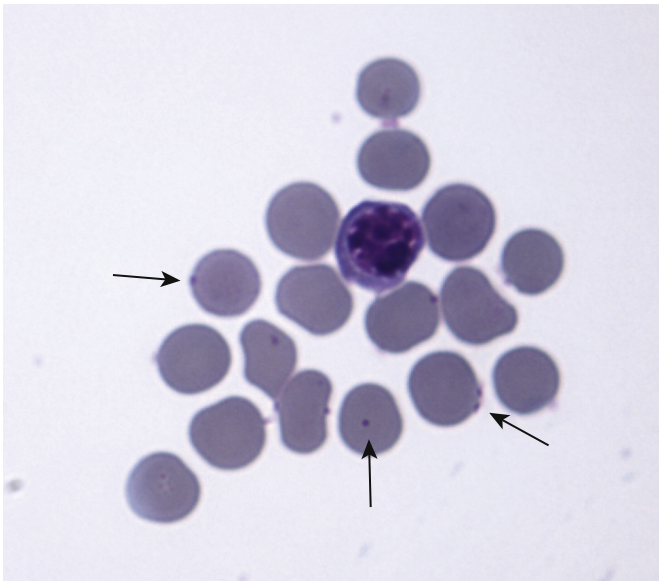

FIGURE 41-1 Romanowsky-stained blood smear from an 8-year-old male neutered domestic shorthair cat showing epierythrocytic bacteria typical of *Mycoplasma haemofelis (arrows).*

VetBooks.ir

always reliably be distinguished by this method. '*Ca*. M. haemominutum' is common in the cat population worldwide, infecting as many as 20% of cats that visit veterinary hospitals.[6-8] Infection of cats with '*Ca*. M. haemominutum' results in a mild decrease in hematocrit. There is some evidence that '*Ca*. M. haemominutum' may play a role in disease. For example, cats that are co-infected with FeLV and '*Ca*. M. haemominutum' develop more significant anemia than cats infected with '*Ca*. M. haemominutum' alone, and progression to FeLV-induced myeloproliferative disease occurred more rapidly.[9] There are also descriptions of cats with hemolytic anemia in which the only recognized cause of anemia was '*Ca*. M. haemominutum.'[10] '*Ca*. M. haemominutum' is commonly found in co-infections with '*Ca*. M. turicensis' or *M. haemofelis*. Mixed infections with all three feline hemoplasma species also have been described.

'*Ca*. M. turicensis' was first described in a cat from Switzerland that had severe intravascular hemolysis (*turicensis* pertains to Turicum, the Latin name of Zurich).[11] Infections with '*Ca*. M. turicensis' have since been detected worldwide.[8,12-14] '*Ca*. M. turicensis' has never been seen using light microscopic examination of blood smears, and organism loads in infected cats are typically low. Infection with '*Ca*. M. turicensis' is slightly more prevalent in the cat population than infection with *M. haemofelis*. Most studies show a prevalence of 0.5% to 10% in sick cats that visit veterinary hospitals. The pathogenic potential of this organism is not fully understood. Inoculation of an immunosuppressed cat with '*Ca*. M. turicensis' resulted in severe anemia,[11] but little or no anemia occurs in immunocompetent cats after inoculation with '*Ca*. M. turicensis.' Cofactors, such as co-infection with other hemoplasmas or concurrent immunosuppression, may influence the development of anemia in cats infected with '*Ca*. M. turicensis.'

Infection of cats by hemoplasmas is strongly associated with male sex, nonpedigree status, and outdoor access (Box 41-1).[8,12,15,16] Infection with '*Ca*. M. haemominutum' is more prevalent in older cats, presumably because the chance of acquiring persistent subclinical infection increases over time. In contrast, young cats may be more likely to develop disease after infection by *M. haemofelis*. Some studies, but not others, have shown an association between retrovirus and hemoplasma infections. Cats infected with *M. haemofelis* in the United States were 6 times more likely to be FIV infected than cats negative for hemoplasmas.[15]

Several hemoplasma species also infect dogs. Infection with *Mycoplasma haemocanis* (previously *Haemobartonella canis*) has been associated with hemolytic anemia in splenectomized dogs, and rarely in dogs with other immunosuppressive disease or concurrent infections. The 16S rRNA gene of *M. haemocanis* has the same sequence as *M. haemofelis*, but the whole genome sequence of *M. haemocanis* distinguishes it as a different species.[17] *M. haemocanis* is a coccoid organism that often forms long chains of organisms (Figure 41-2). The prevalence of this infection is particularly high in kennel-raised dogs, which are often infected subclinically.[18] In the southwestern United States, infection was also prevalent among coyotes.[19]

Three additional hemoplasma species have been detected in dogs. '*Candidatus* Mycoplasma haematoparvum' is a small (0.3 µm) coccoid organism that resembles '*Ca*. Mycoplasma haemominutum' morphologically as well as genetically (Figure 41-3). '*Ca*. M. haemominutum' has also been detected in several dogs using PCR assays, and organisms that resemble '*Ca*. M. haematoparvum' and '*Ca*. M. haemominutum' have been detected in European wolves and bush dogs from Brazil.[20] The ovine hemoplasma *Mycoplasma ovis* was detected in the spleens of a small number of dogs from the southeastern United States, and the bovine hemoplasma '*Ca*. Mycoplasma haemobos' was detected in a dog from northern Australia.[21,22] The clinical importance of these hemoplasma species in dogs remains unclear.

The mode of transmission of hemoplasmas remains unclear. To some extent, fleas and other arthropod vectors may be capable of transmitting feline hemoplasmas,[23] but experimental evidence for vector-borne transmission of feline hemoplasmas is weak. Transmission of *M. haemocanis* by the brown dog tick, *Rhipicephalus sanguineus*, has been demonstrated experimentally, although this was before PCR assays were available to confirm infection.[24] Geographic variation in the prevalence of

hemoplasma infection in dogs and cats supports a role for arthropod vectors in transmission. For example, in Europe, infection with *M. haemocanis* is more prevalent in Mediterranean countries, which follows the distribution of *Rh. sanguineus*. Vertical (e.g., transplacental) spread has also been hypothesized and has been documented for bovine hemoplasmas. Biting has been suggested as a means of transmission of feline hemoplasmas, and the strong male sex predilection, recent history of cat bite abscessation in some cats, and association with FIV infection in some studies supports this mode. Additionally, studies in Switzerland found that subcutaneous inoculation of blood that contained '*Ca.* M. turicensis' resulted in transmission, whereas inoculation of saliva that contained '*Ca.* M. turicensis' did not.[25] This suggests that hemoplasma transmission by social contact (saliva via mutual grooming etc.) is less likely than transmission by aggressive interaction (blood transmission during a cat bite incident). Because infection can also be transmitted by ingestion of blood, it may be that the biting cat (rather than the bitten cat) is most at risk for acquisition of infection. Transmission of *M. haemocanis* through ingestion of infected blood has also been described,[26] so aggressive interactions between dogs may also have the potential to transmit hemoplasmas; however, this mode of transmission remains to be proven in field circumstances. Transmission can also occur following blood transfusion.

Clinical Features

Signs and Their Pathogenesis

Because only *M. haemofelis* infection is associated with significant anemia in cats, only the pathogenesis of disease induced by this species is described here. After experimental infection, there is a delay of 2 to 34 days before the onset of clinical signs. Anemia then occurs and persists for about 18 to 30 days (acute phase), although its severity and chronicity vary considerably between infected cats. Anemia predominantly results from extravascular hemolysis, and the onset of anemia is usually followed by a strong regenerative response with reticulocytosis. The organism resides in an indentation on the erythrocyte surface (Figure 41-4). Production of both cold and warm reactive erythrocyte-bound antibodies, increased osmotic fragility, and decreased erythrocyte life span have been noted in infected cats.[27-29] The organisms can also "bridge" adjacent erythrocytes, which might promote splenic trapping and removal of red blood cells. In contrast, erythrocyte-bound antibody formation and significant reticulocytosis have not been documented in cats infected with '*Ca.* M. haemominutum' or '*Ca.* M. turicensis.'

Anemia can result in signs of lethargy, inappetence, pallor, and weakness. Some owners report that their cats eat dirt or litter or lick cement (pica). Weight loss and dehydration can occur. Rapid development of anemia may result in neurologic signs, vocalization, collapse, and death. In some infected cats, cyclical changes in the hematocrit and numbers of infected erythrocytes occur, with sharp declines in the hematocrit correlating with appearance of large numbers of organisms in blood smears.[30-32] The proportion of erythrocytes associated with visible organisms on blood smears can decline from 90% to less than 1% in less than 3 hours.[33,34] These dramatic fluctuations in organism numbers appear to result from rapid replication of *M. haemofelis*, followed by rapid clearance from the blood as a result of the host's immune response. Repeated antigenic variation in *M. haemofelis* may allow the organism to again proliferate in the face of this immune response, which contributes to ongoing fluctuations in organism numbers.

In cats that survive the acute phase, the hematocrit then returns to normal or near-normal (recovery phase), and organisms can no longer be visualized in blood smears. It is possible that at least some of these recovered cats remain persistently infected, whereby the organism evades the host immune system, and that recrudescence of anemia may follow stress, pregnancy, intercurrent infection, or neoplasia.[32,33] However, evidence is

accumulating that differences may exist in the ability of hemoplasmas to persist within the host, the carrier state being more frequent for '*Ca*. M. haemominutum' but less frequent for *M. haemofelis* and '*Ca*. M. turicensis.' In cats, splenectomy has a variable effect on the course of hemoplasmosis. Recrudescence of anemia and bacteremia has been documented in some chronically infected cats after splenectomy, although other studies suggest that splenectomy increases the number of visible organisms in blood smears without causing significant anemia.[32,34] Infection of splenectomized cats with '*Ca*. M. haemominutum' does not appear to enhance the pathogenicity of this organism.[35]

Dogs that develop clinical hemoplasmosis have usually had a history of splenectomy or, less commonly, concurrent immunosuppressive illness or drug treatment or co-infections with other bloodborne pathogens such as *Babesia* spp. and *Ehrlichia canis*. Clinical signs include weakness, lethargy, and pallor, and some dogs are inappetent.

Physical Examination Findings

Physical examination findings in cats with acute *M. haemofelis* infection include fever, weakness, mucosal pallor, tachypnea, tachycardia, and weak or bounding femoral pulse quality. Other physical examination abnormalities can include dehydration, cardiac murmurs, splenomegaly, and occasionally mild icterus (Figure 41-5). Moribund cats may be hypothermic.

Dogs with hemoplasmosis can show lethargy and mucosal pallor. Fever is usually absent.

Cats infected with '*Ca*. M. haemominutum' or '*Ca*. M. turicensis,' and dogs infected with '*Ca*. M. haematoparvum' generally appear healthy unless concurrent disease is present.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

The most characteristic CBC abnormality in dogs and cats infected with *M. haemocanis* and *M. haemofelis*, respectively, is regenerative anemia, with macrocytosis, anisocytosis, reticulocytosis, polychromasia, Howell-Jolly bodies, and, especially in cats, sometimes marked normoblastemia. Manual reticulocyte counts should be interpreted with caution in cats infected with *M. haemofelis*, because both hemoplasma-infected erythrocytes have the same appearance as reticulocytes in blood smears stained with methylene blue. Autoagglutination may be noted in blood smears. Nonregenerative anemia can be present when sufficient time for a regenerative response has not yet elapsed, or as a result of concurrent FeLV infection or any other disease that suppresses the regenerative response. Concurrent occult hemoplasma infection should be considered in any anemic FeLV-positive cat, even in the absence of reticulocytosis. Neutrophil counts may be normal, elevated, or low, and lymphopenia may be present. Thrombocytopenia can also occur in affected dogs and cats, but often the platelet count is within the reference range.

Serum Biochemical Tests

The serum chemistry profile in cats with hemoplasmosis may reveal increased activities of ALT and AST as a result of hypoxia; metabolic acidosis; mild to moderate hyperbilirubinemia; and prerenal azotemia. Hyperproteinemia may be seen in some cats.

Urinalysis

The urinalysis is usually unremarkable; bilirubinuria may be present in hyperbilirubinemic cats.

FIGURE 41-5 Mild icterus of the nictating membrane in an 8-year-old male neutered domestic shorthair with hemolytic anemia secondary to *Mycoplasma haemofelis* infection.

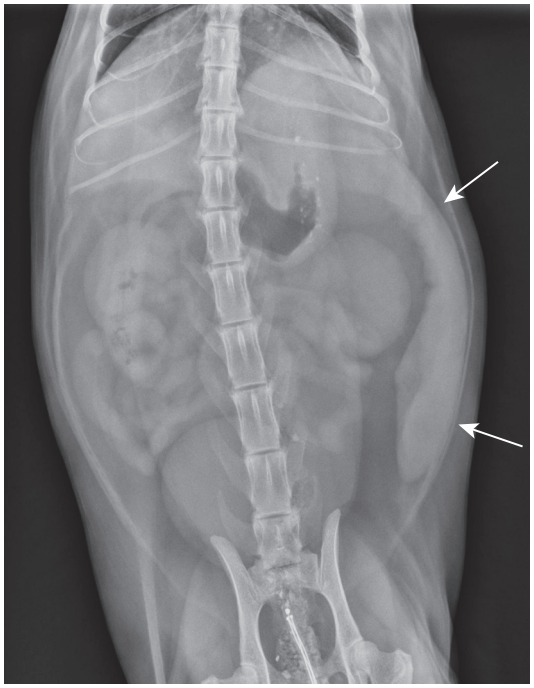

FIGURE 41-6 Ventrodorsal abdominal radiograph from an 8-year-old male neutered domestic shorthair cat with hemolytic anemia secondary to *Mycoplasma haemofelis* Infection. There is marked splenomegaly (*arrows*).

Diagnostic Imaging

The most common radiographic finding in cats with hemoplasmosis is splenomegaly (Figure 41-6). The spleen may be absent in affected dogs because of previous splenectomy.

Microbiologic Tests

Assays available for diagnosis of hemoplasmosis in dogs and cats are listed in Table 41-1.

Cytologic Examination of Blood Smears

Cytologic detection of hemoplasmas has low sensitivity and specificity, especially for diagnosis of feline infectious anemia. *M. haemofelis* is visible less than 50% of the time in acutely infected cats, because organisms can disappear for days before

VetBooks.ir

TABLE 41-1

Assays Available for Diagnosis of Hemoplasmosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Blood smears	Hemoplasmas	Poor sensitivity, especially in affected cats. Organisms are seen on blood smears in fewer than 50% of sick cats. False positives can occur when stain precipitate, drying artifact, basophilic stippling, and Howell-Jolly bodies are misinterpreted as hemoplasmas.
PCR	Whole blood, blood smears	Hemoplasma DNA	Sensitivity and specificity can vary depending on assay design. Results must be interpreted in light of the species detected and the clinical findings. *Mycoplasma haemofelis* and *Mycoplasma haemocanis* are most likely to be associated with anemia.

reappearing on blood smears over the course of infection. Because organisms detach from erythrocytes within hours of blood collection, fresh blood smears should be submitted. False-positive diagnoses occur when stain artifacts such as precipitate are confused with organisms; thus, careful staining with a properly prepared, uncontaminated Romanowsky-type stain solution is essential. Organisms also need to be distinguished from basophilic stippling and Howell-Jolly bodies. '*Ca.* M. haemominutum' is small and is not usually visible in chronically infected cats. '*Ca.* M. turicensis' has never been seen on blood smears with light microscopy. Hemoplasmas are visible in many clinically affected dogs, and because *M. haemocanis* tends to form chains, it is more readily differentiated from stain artifacts and erythrocyte morphologic changes than is *M. haemofelis*. However, hemoplasmas are not usually visible in chronically infected dogs or in dogs infected with '*Ca.* M. haematoparvum.'

Culture

Attempts to isolate and grow feline hemotropic mycoplasmas in the laboratory have been unsuccessful, so blood culture cannot be used for diagnosis of hemoplasmosis.

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays are currently the tests of choice for diagnosis of hemoplasmosis in dogs and cats. Numerous assays have been described to date, which are generally based on detection of the 16S rRNA gene. These are significantly more sensitive than blood smear evaluation, although they occasionally do not detect infection in apparently healthy carrier cats when organism numbers in the blood are below the detection limit of the PCR assay.[6,30,36,37] Both conventional and real-time PCR assays have been described. Some conventional PCR assays do not differentiate between *M. haemofelis* and '*Ca.* M. turicensis,' because the primers used in the assay generate the same-sized PCR product when either or both of these species are present. Real-time PCR assays are usually species specific. Because the pathogenic potential of each hemoplasma species differs, the laboratory should be consulted to determine the species specificity of the assay(s) offered. Alternative causes of anemia should always be considered, especially in cats that test positive for '*Ca.* M. haemominutum' or '*Ca.* M. turicensis,' because infection with these organisms is not commonly associated with anemia. Indeed, *all* PCR results should be interpreted in conjunction with the patient's clinical signs, the degree and nature of the anemia present, and any concurrent signs or diseases present that could be contributing to the clinical signs. Dried blood smears can also be tested but are less sensitive than liquid whole blood specimens.[38] PCR assays designed to detect *M. haemofelis* generally also detect *M. haemocanis* because of the high 16S rRNA gene sequence homology between these species, but a separate assay is required for detection of '*Ca.* M. haematoparvum.'

Serologic Diagnosis

The development of serologic tests for diagnosis of hemoplasmosis has been hampered by the inability to culture hemoplasmas in the laboratory. However, the application of molecular techniques has led to the identification of antigens for serologic assay development. Specifically, an ELISA that detects antibodies to an immunodominant protein of *M. haemofelis*, DnaK, has been developed. Cats produce antibodies to this antigen after infection,[39,40] and in a study that examined the immune response to '*Ca.* M. turicensis' infection, antibody titers to DnaK declined with antimicrobial drug treatment.[39] Serologic cross-reactivity occurs to this antigen for all three feline hemoplasma species[40]; therefore, the assay does not discriminate between infection with *M. haemofelis* and other hemoplasmas, but determination of acute and convalescent titers may be helpful to distinguish acute from chronic infection. Currently this assay is available only on a research basis.

Pathologic Findings

Generalized pallor, splenomegaly, and, in some cats, icterus are the main gross necropsy finding in cats that die or are euthanized as a result of hemoplasmosis. Histopathologic findings include extramedullary hematopoiesis, follicular hyperplasia, and erythrophagocytosis within the spleen.

Treatment and Prognosis

Treatment is indicated for cats and dogs with clinical signs and laboratory abnormalities consistent with hemoplasmosis. Although controversial, treatment could also be considered for apparently healthy cats that test positive for *M. haemofelis* in view of the potential for recrudescence of disease with this hemoplasma species. It may be difficult or impossible to eradicate infection with some hemoplasma species or strains, especially '*Ca.* M. haemominutum.' Indeed, no antibiotic treatment regime consistently eliminates hemoplasma infection in cats.

The treatment of choice for hemoplasmosis is doxycycline for a minimum of 2 weeks (see Chapter 8 for information on doxycycline) (Table 41-2); some have suggested using longer courses of treatment (6 to 8 weeks) to ensure that infection is

VetBooks.ir

TABLE 41-2

Suggested Drug Dosages for Treatment of Hemoplasmosis in Cats

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration
Doxycycline	10	PO	24	2 weeks
Marbofloxacin	2.75 to 5.5	PO	24	
Pradofloxacin*	5 to 10	PO	24	
Enrofloxacin†	5	PO	24	

*Dose listed is for the oral suspension for cats.
†Only when other alternatives are not available because of potential for irreversible blindness when enrofloxacin is used in cats.

eliminated. Real-time PCR could be used to monitor response to antibiotic treatment if quantitative information is available. Fluoroquinolones are an alternative; marbofloxacin and pradofloxacin,[41] when available, are both efficacious. Enrofloxacin is also usually effective,[42] but diffuse retinal degeneration and acute blindness have been reported following the use of this fluoroquinolone and, although this is rare, caution must be exercised with its use in cats. The response of the different hemoplasma species, and indeed different strains of the same species, to antibiotics varies. Most successful studies that have demonstrated treatment efficacy have evaluated the response of *M. haemofelis* to treatment. Affected dogs and cats may also require supportive treatment with IV crystalloids or blood products. Clinical improvement usually occurs within 2 to 3 days. The use of immunosuppressive doses of glucocorticoids to suppress the associated immune-mediated hemolytic process is controversial, given that glucocorticoids can cause reactivation of latent infection, but may be necessary in cats that fail to respond to antimicrobial therapy alone, or when the diagnosis is uncertain, especially if erythrocyte-bound antibodies are identified.

Doxycycline is the drug of choice for treatment of *M. haemocanis* infection. Treatment of a splenectomized dog with oxytetracycline for approximately 1 month was associated with clinical improvement, but infection persisted as determined with quantitative PCR, and relapse occurred when treatment was withdrawn.[43] Infection also persisted after treatment with enrofloxacin, despite eventual recovery from anemia. In contrast, in *M. haemocanis*–infected dogs with intact spleens, doxycycline treatment for 4 weeks appeared to result in resolution of infection as determined by PCR assay, whereas '*Ca.* M. haematoparvum'–infected dogs remained PCR positive.[19] A splenectomized dog was apparently cured of *M. haemocanis* infection after 12 weeks of doxycycline treatment.[44]

Immunity and Vaccination

Little information is available in regard to the immune response to hemoplasma infection, and no vaccines are available. Because co-infections with multiple hemoplasma species occur, infection with one species does not appear to protect against infection with other species.

Prevention

Inadvertent transmission of hemoplasmas by transfusion of blood from carrier cats has been documented, and so all blood donor dogs and cats should be tested for hemoplasmas with PCR assays. In the future, screening with serologic assays may also be used to identify potential donor animals. Whenever possible, cats and dogs that are PCR negative for any of the known hemoplasma species should be excluded as donors. Given the high prevalence of subclinical '*Ca.* M. haemominutum' infection among cats, in some circumstances it may not be possible to find a donor that is '*Ca.* M. haemominutum' negative. At this time, it is unclear whether transfusion of blood from cats that are infected with '*Ca.* M. haemominutum' is associated with adverse outcome, but it remains a possibility. Keeping cats indoors is also likely to prevent infection, as outdoor access has been identified as a risk factor. Control of fleas and ticks is recommended.

Public Health Aspects

Organisms that resembled hemoplasmas were identified in human blood smears decades ago. Molecular techniques that were originally designed for detection of canine and feline hemoplasmas have since been applied to human blood, and a variety of hemoplasma species have now been identified. In addition, application of these methods to archived human blood smears believed to contain hemoplasmas based on cytological evaluation yielded negative results, suggesting the possibility of historical misdiagnosis.[45] Infection with a novel hemoplasma, designated '*Ca.* Mycoplasma haemohominis,' has been identified in a person with hemolytic anemia.[46] *M. haemofelis* DNA was identified in a person from Brazil who was co-infected with HIV and *Bartonella henselae*.[47] In addition, DNA of *Mycoplasma ovis* was detected in a Texas veterinarian who was co-infected with *B. henselae*.[48] *Mycoplasma suis* DNA has been found in farm workers from China.[49] The identification of the DNA of animal hemoplasmas in humans should be viewed cautiously because only a small portion or portions of the hemoplasma genome was detected in each of these case reports. *M. haemocanis* and *M. haemofelis* have identical 16S rRNA gene sequences, but different host tropisms, and so the organisms detected in these humans may not necessarily be the same as those that infect domestic animal species. Until further information is available, veterinarians should handle blood from animals with caution.

VetBooks.ir

CASE EXAMPLE

Signalment: "Shadow," an 8-year-old male neutered domestic shorthair from Fairfield, CA

History: Shadow was brought to the University of California, Davis, Veterinary Medical Teaching Hospital emergency service for treatment of severe anemia. The owners reported that he had disappeared 5 days previously. The evening that he was brought to the emergency service, he was found splayed across a fence and was unwilling to move, and vocalizing and salivating profusely. He was immediately taken to a local emergency clinic where he was found to be obtunded, pale, and severely dehydrated. His pulse was 180 beats/min, respiratory rate was 60 breaths/min, and temperature was 94.0°F (34.4°C). A systolic blood pressure was 80 mm Hg. A PCV was 12%. Shadow's condition was stabilized after treatment with supplemental oxygen, active warming, and IV crystalloid fluids (Normosol-R, 50 mL over 30 minutes, then 25 mL/hr). He tested negative for FIV antibody and FeLV antigen with an in-practice ELISA assay. Shadow was an indoor-outdoor cat that was acquired as a stray kitten from the owner's backyard. There had been no previous history of illness.

Physical Examination:

Body Weight: 6 kg

General: Obtunded, laterally recumbent. T = 97.8°F (36.6°C), HR = 150 beats/min, RR = 60 breaths/minute, purring, pale and tacky mucous membranes with no detectable capillary refill, weak pulses.

Integument: No ectoparasites were noted. The pinnae and ventral abdominal skin were icteric.

Eyes, Ears, Nose, and Throat: Moderate dental calculus was present. Pallor and mild icterus of the mucous membranes, nictitans, and sclera was noted (see Figure 41-5).

Musculoskeletal: Body condition score was 7/9.

Cardiovascular: Weak pulses. No other clinically significant abnormalities were detected. No murmurs were detected but the heart sounds were difficult to auscultate because of persistent purring.

Respiratory: Tachypneic; auscultation was limited because of purring.

Gastrointestinal and Genitourinary: Nonpainful abdomen. Moderate cranial organomegaly. Urinary bladder not palpable.

Neurologic: A full neurologic examination was not performed but no abnormalities were detected on examination of cranial nerve functions.

Lymph Nodes: No clinically significant abnormalities detected.

Laboratory Findings:

PCV/TPP: 14%/7.3 g/dL, icteric plasma.

Saline Slide Agglutination Test: Negative for autoagglutination.

Blood Smear Examination: Marked polychromasia, normoblastosis, and mild anisocytosis were present. Coccoid bodies that resembled hemoplasmas were present in association with erythrocytes (see Figure 41-1).

Electrolyte/Acid-Base Panel (Venous Blood): HCO_3 = 14 mmol/L, pH = 7.365, pCO_2 = 21.9 mm Hg, pO_2 = 35.4 mm Hg, Hb = 2.8 g/dL, O_2 = 59.5%, potassium = 4.0 mmol/L, sodium = 144 mmol/L, ionized calcium = 1.2 mmol/L, glucose = 157 mg/dL, lactate = 8.4 mmol/L, base excess = −12.2 mmol/L.

Imaging Findings:

Thoracic Radiographs: No clinically significant abnormalities were detected.

Abdominal Radiographs: The spleen was markedly enlarged (See Figure 41-6). The liver was mildly enlarged. Small mineral densities were present within ingesta and feces in the stomach and colon, respectively.

Treatment: The cat was placed on a heating pad and transfused with 1 unit of packed RBC, and supplemental oxygen was administered, after which heart rate increased to 200 beats/min and respiratory rate decreased to 40 breaths/min. Rectal temperature increased to 103.7°F (39.8°C) during the transfusion, and so dexamethasone was administered because of the concern for a transfusion reaction (0.2 mg/kg IV once). The cat was also treated with enrofloxacin (5 mg/kg IV q24h) (see comments section later) for suspected hemoplasmosis. The results of laboratory testing after transfer to the internal medicine service the day after admission are shown here.

CBC (Post Transfusion and Antimicrobial Treatment):

HCT 12.7% (30%-50%)
MCV 76.5 fL (42-53 fL)
MCHC 26.8 g/dL (30-33.5 g/dL)
Reticulocytes 155,600 cells/μL (7000-60,000 cells/μL)
Nucleated RBC 39/100 WBC (0/100 WBC)
Corrected WBC 9800 cells/μL (4500-14,000 cells/μL)
Neutrophils 8134 cells/μL (2000-9000 cells/μL)
Band neutrophils 98 cells/μL
Lymphocytes 784 cells/μL (1000-7000 cells/μL)
Monocytes 784 cells/μL (50-600 cells/μL)
Eosinophils 0 cells/μL (150-1100 cells/μL)
Basophils 0 cells/μL (0-50 cells/μL)
Platelets 142,000/μL (180,000-500,000 platelets/μL).
Cytologic examination revealed marked anisocytosis, marked polychromasia, few Howell-Jolly bodies, and many macrocytes and microcytes. No hemoplasmas were identified.

Serum Chemistry Profile:

Sodium 143 mmol/L (151-158 mmol/L)
Potassium 5.2 mmol/L (3.6-4.9 mmol/L)
Chloride 107 mmol/L (117-126 mmol/L)
Bicarbonate 11 mmol/L (15-21 mmol/L)
Phosphorus 6.6 mg/dL (3.2-6.3 mg/dL)
Calcium 9.6 mg/dL (9.0-10.9 mg/dL)
BUN 47 mg/dL (18-33 mg/dL)
Creatinine 1.2 mg/dL (1.1-2.2 mg/dL)
Glucose 98 mg/dL (63-118 mg/dL)
Total protein 7.2 g/dL (6.6-8.4 g/dL)
Albumin 3.0 g/dL (2.2-4.6 g/dL)
Globulin 4.2 g/dL (2.8-5.4 g/dL)
ALT 166 U/L (27-101 U/L)
AST 201 U/L (17-58 U/L)
ALP 24 U/L (14-71 U/L)
GGT 0 U/L (0-4 U/L)
Cholesterol 75 mg/dL (89-258 mg/dL)
Total bilirubin 6.1 mg/dL (0-0.2 mg/dL)
Magnesium 3.4 mg/dL (1.5-2.5 mg/dL)
Creatine kinase 446 U/L (73-260 U/L).

VetBooks.ir

Urinalysis: USG 1.040, pH 6, 75 mg/dL protein, no glucose, 5 mg/dL ketones, 6 mg/dL bilirubin, 250 erythrocytes/μL hemoprotein, 0-1 RBC/HPF, 0 WBC/HPF, rare transitional epithelial cells.

Microbiologic Testing: Real-time PCR for *Mycoplasma haemofelis,* '*Candidatus* Mycoplasma haemominutum,' and '*Candidatus* Mycoplasma turicensis' (blood smear): Positive for *M. haemofelis* DNA

Diagnosis: Feline infectious anemia (*Mycoplasma haemofelis* infection)

Additional Treatment and Outcome: Treatment was changed to doxycycline (10 mg/kg followed by 5 mL of water PO q24h for 3 weeks). Treatment with IV crystalloid fluids was continued and oxygen supplementation was discontinued. Two days after admission, the PCV was 16% and the cat became aggressive and began eating. The cat was discharged the following day with a PCV of 18%, and a recheck at the local veterinary clinic that included a CBC was recommended 1 week later. The owner subsequently elected to house Shadow indoors.

Comments: This represents a typical case of hemoplasmosis in a male neutered cat with access to the outdoors. Specific testing for hemoplasmas with PCR was performed on blood smears because treatment with packed RBC and antibiotics had been initiated immediately on admission and whole blood was not saved before treatment was instituted. Although PCR on blood smears has lower sensitivity than when whole liquid blood is used, in this case sufficient organisms were present to generate a positive result, which confirmed the diagnosis of hemoplasmosis. Because the cat was hypovolemic on admission, parenteral antimicrobial treatment was chosen. Subsequently, treatment with oral doxycycline was initiated. Although continued treatment with oral enrofloxacin may have been a suitable alternative to doxycycline, retinal degeneration was a possible adverse effect of continued treatment with enrofloxacin. Retesting for retroviruses was indicated 2 months after the first test was performed at the local veterinary clinic, as the cat may have been exposed to retroviruses but not yet have developed positive test results (see Chapters 21 and 22).

CHAPTER 42

Actinomycosis

Jane E. Sykes

VetBooks.ir

Overview of Actinomycosis

First Described: Actinomycosis was first described in 1877 (in cattle) (Otto Bollinger, Germany)[1]

Causes: *Actinomyces* spp. and *Arcanobacterium* spp. (order Actinomycetales, family Actinomycetaceae)

Geographic Distribution: Worldwide, but especially regions where plant awns are prevalent

Mode of Transmission: Opportunistic invasion of commensal bacteria following disruption of cutaneous or mucosal barriers

Major Clinical Signs: Subcutaneous masses and draining skin lesions (cervicofacial and cutaneous-subcutaneous disease); pulmonary nodules, masses, and/or effusion with cough and tachypnea (thoracic disease); abdominal effusion or masses (abdominal disease); thoracolumbar pain or pelvic limb paresis/paralysis (retroperitoneal disease); rarely neurologic signs due to meningitis or brain abscesses (central nervous system disease).

Differential Diagnoses: Mycobacterial infections, streptomycosis, nocardiosis, bartonellosis, fungal infections, neoplasia

Human Health Significance: Direct transmission of disease from animals to humans does not occur, but humans have developed actinomycosis after bites from healthy dogs or cats.

Etiology and Epidemiology

Actinomycosis is caused by anaerobic or microaerophilic, filamentous, gram-positive bacteria that belong to the genus *Actinomyces* (and to a lesser extent, the related genus *Arcanobacterium*). These organisms are normal inhabitants of mucous membranes, especially of the oropharynx, but also the genital and gastrointestinal tracts, and cause opportunistic infections. Together with other oral commensal bacteria, actinomycetes colonize the periodontal mucosal surfaces and adhere to the tooth surface to form plaque. Numerous *Actinomyces* species have been cultured from the mucous membranes, dental plaque, and saliva of healthy dogs and cats. Organisms isolated from ill dogs and cats with actinomycosis are shown in Box 42-1.[2-15]

Usually, actinomycosis develops when *Actinomyces* spp. are inoculated into tissues along with other bacteria, often as a result of a deeply penetrating wound or foreign body migration. Young adult to middle-age large-breed dogs that have outdoor access are often affected, especially retriever and hunting breeds.[16,17] There is no clear sex predisposition, and the median age of dogs with actinomycosis is approximately 5 years.[18] Actinomycosis in outdoor dogs is often related to exposure to penetrating plant foreign bodies such as grass awns. In cats, actinomycosis usually follows bite wounds and so is more commonly diagnosed in males.[18,19] In the author's hospital, two-thirds (11 of 17) cats with actinomycosis are male. However, underlying retrovirus infection is uncommonly present and does not appear to predispose to disease.

Because *Actinomyces* species are difficult to culture and are susceptible to antimicrobial drugs that are often used empirically, the prevalence of actinomycosis in dogs and cats is probably underestimated.

Clinical Features

Signs and Their Pathogenesis

After ingestion or inhalation, plant awns become contaminated with *Actinomyces* spp. and other bacteria from the oropharynx, and then migrate to various sites and act as a nidus of infection. Alternatively, organisms can be introduced into tissues at the time of a bite wound injury. The latter is the most common route of infection in cats, and can manifest as pyothorax, peritonitis, or cellulitis.[18,19] Other co-infecting aerobic and anaerobic bacteria

BOX 42-1

Actinomyces and _Arcanobacterium_ Species Isolated from Dogs and Cats with Actinomycosis

Dogs

Actinomyces viscosus[2-4]
Actinomyces bowdenii[5]
Actinomyces hordeovulneris[6]
Actinomyces canis[7]
Actinomyces odontolyticus[8]
Actinomyces catuli[9]
Actinomyces turicensis[10]
Actinomyces hyovaginalis[11]
Actinomyces urogenitalis[11]
Arcanobacterium pyogenes[12]

Cats

Actinomyces viscosus[13,14]
Actinomyces bowdenii[5]
Actinomyces hordeovulneris[11]
Actinomyces meyeri[15]
Actinomyces odontolyticus[14]
Arcanobacterium pyogenes[12]

from the oral cavity or intestinal tract ("companion microbes") undermine normal host defenses and reduce oxygen tension, which allows *Actinomyces* spp. to persist. *Actinomyces* spp. that possess fimbriae can bind to specific cell surface receptors on other bacteria, especially streptococci. This bacterial co-aggregation inhibits the ability of neutrophils to phagocytize the organisms.[20] Dense colonies of *Actinomyces* spp. form, and these, together with other associated bacteria, are surrounded by neutrophils, macrophages, and plasma cells, with slowly progressive pyogranulomatous inflammation (Figure 42-1). Large aggregations of organisms form "sulfur granules," which are tan to yellow colonies of actinomycetes, which can be microscopic or visible grossly. Proteolytic enzymes from the associated bacteria, macrophages, and degranulated neutrophils destroy connective tissue, which facilitates extension of the disease through normal tissue planes. Less often, organisms spread hematogenously to distant sites. In some cases, the inflammatory reaction is accompanied by mass formation and extensive fibrosis. The center of the lesions can eventually suppurate and soften, or draining tracts may develop. The tracts can close and reappear over weeks to months as infection gradually spreads through tissues.

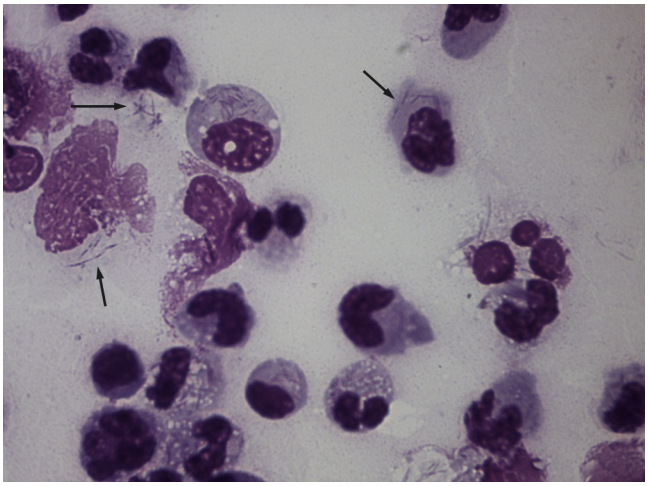

FIGURE 42-1 Abdominal fluid cytology from a 3-year-old male neutered domestic longhair cat with a 1-week history of progressive lethargy and anorexia, ascites, hyperbilirubinemia, and hypoproteinemia. Abdominal fluid analysis revealed a total protein of 2.2 g/dL, and 75,500 nucleated cells/μL, with 92% neutrophils and 8% large mononuclear cells. High numbers of moderately degenerative neutrophils were present with low numbers of macrophages. Moderate numbers of filamentous beaded bacteria were present both in the background and within phagocytes *(arrows)*. *Actinomyces* spp. and *Fusobacterium nucleatum* were isolated from the peritoneal fluid. Necropsy revealed severe, chronic peritonitis with intralesional filamentous bacteria.

The most common clinical forms of actinomycosis in cats and dogs involve the cervicofacial region, thorax, abdomen, and subcutaneous tissue, but central nervous system (CNS) infections (meningitis and meningoencephalitis) and ocular infections (keratitis and endophthalmitis) can also occur.[21,22] *Cervicofacial actinomycosis* can follow bite wounds, perforation of the oropharynx by a foreign body, or chronic periodontal disease. The mandibular, submandibular, and ventral or lateral cervical areas are most frequently affected, but infections that involve the face, retrobulbar space, and temporal area also occur (Figure 42-2, *A* and *B*). *Cutaneous-subcutaneous actinomycosis* typically involves the lateral thoracic wall, flank region, and occasionally the limbs. Lesions on the thoracic or abdominal walls may represent extensions of thoracic, abdominal, or retroperitoneal actinomycosis.

Thoracic actinomycosis may be limited to the lung parenchyma but can involve other thoracic structures, such as the mediastinum, pleura, pericardium, and thoracic wall. It usually follows aspiration of oropharyngeal material, often together with a contaminated grass awn. Alternative routes of thoracic infection include mediastinal involvement after esophageal perforation or direct extension of subcutaneous or abdominal disease. Clinical signs include cough and less commonly hemoptysis, tachypnea, respiratory distress, and subcutaneous

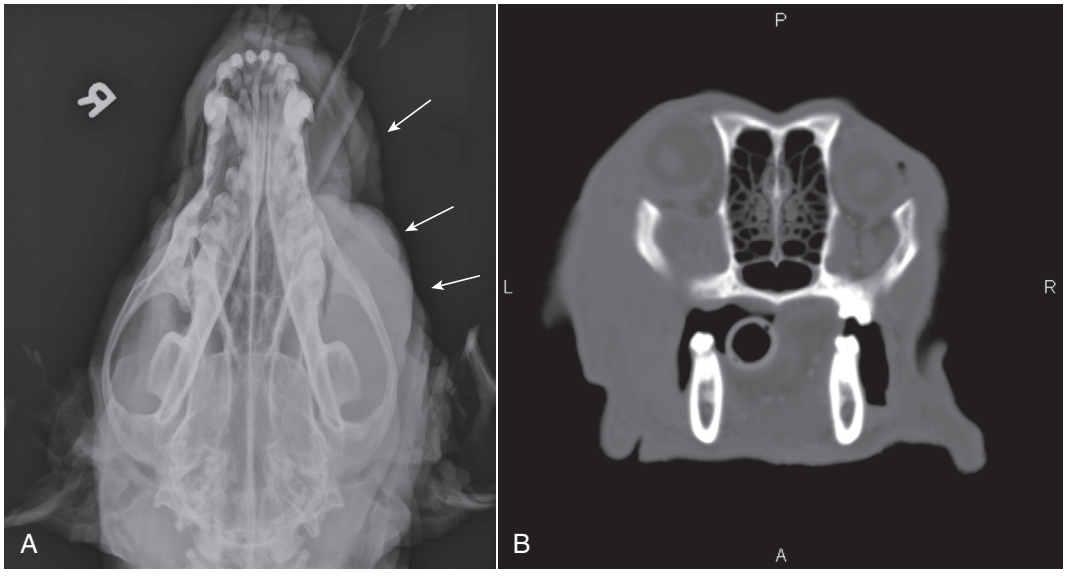

FIGURE 42-2 Cervicofacial actinomycosis in an 8-year-old female spayed Labrador retriever with slowly progressive, left-sided facial swelling. Skull radiograph **(A)** and computed tomographic scan **(B)**. There was severe, regional soft tissue swelling over the left side of the face, which involved the left masseter muscle and zygomatic salivary glands and extended into the retrobulbar space, with secondary exophthalmos. Multiple premolars and molars of the left maxillary arcade were missing. Biopsy of the lesion revealed severe, diffuse, pyogranulomatous cellulitis with intralesional gram-positive, acid-fast negative bacilli. Culture yielded *Actinomyces hordeovulneris* (based on 16S rRNA gene sequencing), *Pasteurella multocida* subsp. *multocida*, *Neisseria canis* (based on 16S rRNA gene sequencing) and an *Eikenella*-like organism.

soft tissue masses or draining skin lesions on the thoracic wall. Sometimes there is a history of neck pain, gagging, or hypersalivation before the onset of tachypnea, possibly due to passage of a penetrating foreign body.

Abdominal actinomycosis develops when ingested foreign bodies penetrate the gastrointestinal tract, which leads to the formation of intra-abdominal mass lesions and ascites.[2,16,23] Abdominal involvement may also follow direct extension from subcutaneous tissues or hematogenous spread of the organism to abdominal organs such as the liver. Although dogs are more often affected than cats, intra-abdominal actinomycotic masses can occur in cats.[24,25] *Retroperitoneal actinomycosis* in dogs often follows the migration of plant awns through the lung and up the crus of the diaphragm to its dorsal attachment. Initially, fever of unknown origin may be the only clinical sign. Ultimately, progression can lead to osteomyelitis and compression fractures of the vertebral bodies, with spinal pain and paresis or paralysis of the pelvic limbs (Figure 42-3).[3,26,27]

Although rare, actinomycosis of the brain and meninges can also occur in dogs (Figure 42-4).[28-30] Brain abscesses may follow hematogenous dissemination from a distant site, or meningitis may result from extension of infection from an adjacent site, such as the middle ear.[29,31] In humans, risk factors for CNS actinomycosis include dental disease or tooth extraction, head trauma, gastrointestinal tract surgery, and chronic otitis, mastoiditis, or sinusitis. CNS actinomycosis has been reported in dogs in association with concurrent otitis media/interna[30] and head trauma,[28] and in cats in association with retrobulbar abscesses[31] and cutaneous abscesses of the tail base.[13,32]

Rarely, *Actinomyces* infections of the urinary bladder,[12,33] gallbladder,[34,35] and heart valve[4,10,36,37] have been recognized in dogs, cats, and human patients.

Physical Examination Findings

Lesions in dogs and cats with cervicofacial or cutaneous-subcutaneous actinomycosis may fluctuant or firm, indurated, have draining sinuses, and rarely are ulcerated. Pain and fever are variable. Thoracic or abdominal actinomycosis is often accompanied by a thin body condition and fever. Dogs and cats with thoracic actinomycosis may show tachypnea or respiratory distress, and thoracic auscultation may reveal decreased lung sounds if pyothorax or intrathoracic mass lesions are present. Masses and/or ascites may be detected on abdominal palpation of dogs with abdominal actinomycosis. Dogs with retroperitoneal actinomycosis can show pain on palpation of the abdomen or spine; signs of pelvic limb paralysis or paresis may be also present, such as pelvic limb ataxia, delayed or absent placing reactions, increased segmental reflexes, and loss of pain sensation. Neurologic signs in dogs with *Actinomyces* meningitis or encephalitis include altered behavior, decreased consciousness, cervical pain, vision loss, ataxia, tetraparesis, and seizures.

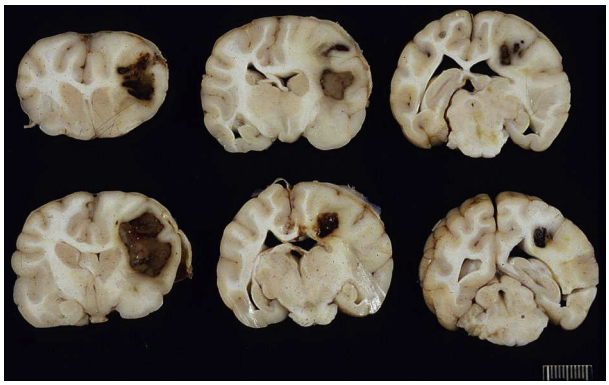

FIGURE 42-4 Necropsy findings in a 1-year-old male neutered Yorkshire terrier with suspected CNS actinomycosis. Three weeks previously, surgery to correct an extrahepatic portosystemic shunt and remove a urate cystolith had been performed. The dog's appetite and activity level did not improve after the surgery, and for the week before the dog was reexamined, disorientation and weakness was noted. The dog deteriorated rapidly after it was hospitalized, and euthanasia was performed. Three separate abscesses were found in the left cerebral cortex. Histopathology revealed neutrophilic inflammation, hemorrhage, and granular mats of material that contained gram-positive, acid-fast negative branching bacteria (consistent with *Actinomyces* spp.), as well as a dense population of gram-negative, Giemsa-positive cocci. (Courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

FIGURE 42-3 Left lateral spinal radiograph from a 3-year-old female Border collie with retroperitoneal actinomycosis. The dog was seen for a 3-day history of lethargy, fever, abdominal pain, and progressive pelvic limb paresis. Severe, smoothly marginated ventral spondylosis bridges the L1-L4 space. There is also marked irregular osteolysis of the 2nd, 3rd, and 4th lumbar vertebrae. There is loss of visualization, narrowing, and irregularity of the intervertebral disc spaces at L2-3 and L3-4. There is marked loss of detail within the retroperitoneal space, and the colon is displaced slightly ventrally. Irregular mineral foreign bodies are present in the stomach and colon.

Diagnosis

In the human literature, actinomycosis has been referred to as the "most misdiagnosed disease."[38] Fibrous masses are frequently mistaken for neoplastic lesions, although reports of *Actinomyces* spp. infections that complicate neoplasia exist in human medicine.[39,40] Aspiration of firm lesions is often unrewarding, organisms are often difficult to isolate from lesions, and short periods of antimicrobial drug treatment are ineffective, which all serve to further mislead the clinician to a diagnosis of neoplasia. Actinomycosis should be considered on the list of differential diagnosis in any animal with a history of penetrating plant awn foreign bodies, draining skin lesions, chronic fibrous masses, persistent bite wounds, pyothorax, retroperitoneal abscesses, or focal neurologic signs, especially when young-adult to middle-aged dogs are affected. Ultimately, diagnosis is based on clinical signs, identification of organisms with typical morphology with cytology or histopathology, and culture.

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Animals with extensive, chronic actinomycosis may have mild to moderate nonregenerative anemia, leukocytosis with a mild to moderate left shift and monocytosis, hypoalbuminemia, and hyperglobulinemia, which may be marked. Dogs with body cavity effusions may be hypoglycemic. There are usually no specific urinalysis findings.

Cytologic Examination of Body Fluids

Cytologic examination of aspirates of abscesses, effusions, or CSF from animals with actinomycosis typically reveals a suppurative to pyogranulomatous inflammatory response (>75% neutrophils). Total protein in pleural fluid is generally greater than 3.0 g/dL, with erythrocyte and nucleated cell counts often greater than 70,000 cells/µL. CSF from dogs and cats with cerebral actinomycosis can grossly resemble pus. Aspirates of firm masses may yield only a small amount of blood. Sulfur granules may be visible in effusion fluid or purulent material from cutaneous lesions, grossly as white to tan to gray granules, or microscopically as dense clusters of organisms. When bacteria are visualized, they may be filamentous rods suggestive of *Actinomyces* spp., or "companion" microorganisms. Actinomycetes are gram-positive, non-acid-fast filamentous organisms that are occasionally branched. The filaments are less than 1 µm wide, vary in length, and can stain irregularly, producing a beaded appearance (see Figure 42-1). *Nocardia* spp., *Corynebacterium* spp., and *Mycobacterium* spp. can be confused with *Actinomyces* species.

Diagnostic Imaging

Plain Radiography

Radiographs of cervicofacial or cutaneous-subcutaneous lesions may show evidence of adjacent osteomyelitis and/or periosteal new bone formation. Pulmonary involvement may manifest as interstitial or alveolar infiltrates, sometimes with consolidation (Figure 42-5, *A*). Air bronchograms may be seen within pulmonary mass lesions, which suggests the presence of a nonneoplastic

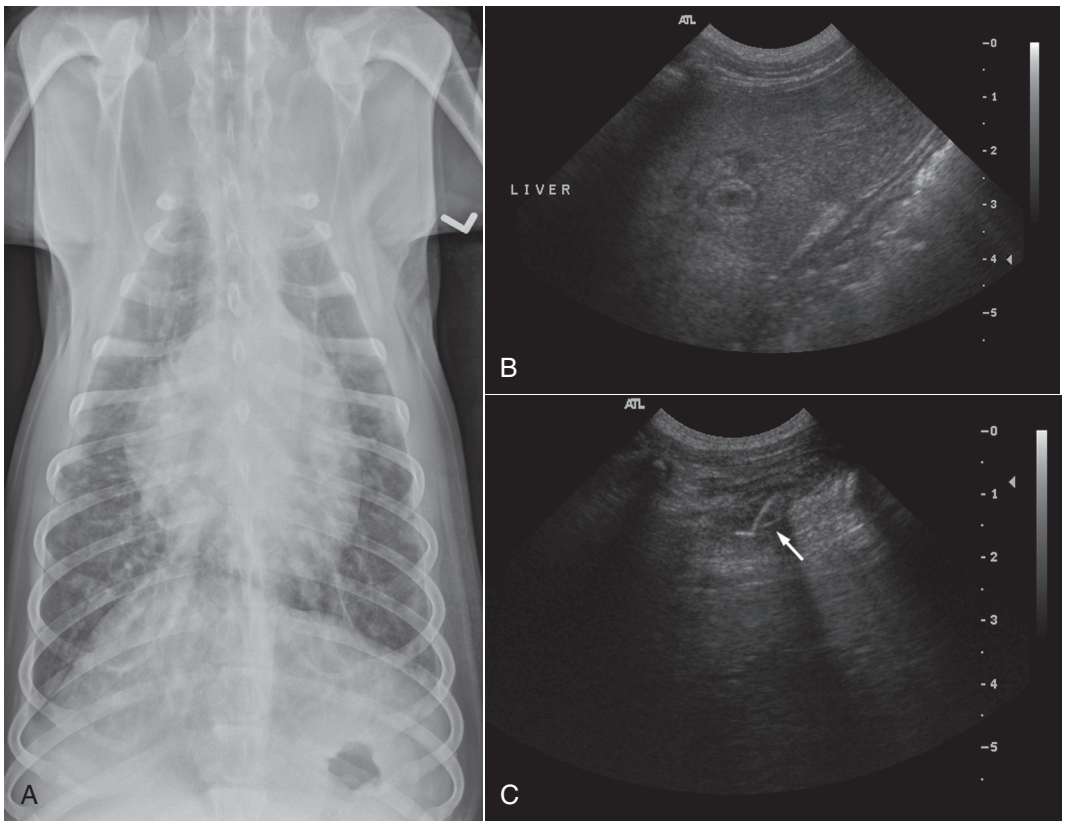

FIGURE 42-5 Imaging findings in a 1-year-old female spayed Labrador retriever with systemic actinomycosis secondary to grass awn migration. **A,** Dorsoventral thoracic radiograph. Patchy diffuse interstitial opacities were present in all lung fields. **B,** Ultrasound image of the liver. Within the left liver, there were focal, ill-defined heteroechoic or hypoechoic nodules. One of these areas (shown) had a hyperechoic rim with echogenic luminal contents. The nodules were consistent with multifocal hepatic abscesses. **C,** Ultrasound image of the thoracic wall. A linear plant awn foreign body was identified *(arrow)*.

process. Other variable findings include pleural thickening, pleural effusion, widening of the mediastinum, pleural mass lesions, enlargement of the cardiac silhouette (with pericardial involvement), and periosteal new bone formation or osteomyelitis involving adjacent ribs, vertebral bodies, or sternebrae. Dogs with retroperitoneal actinomycosis may have periosteal new bone formation on the ventral aspects of two or three adjacent vertebral bodies (usually T13 through L4) on abdominal radiography; involvement of disc spaces is uncommon (see Figure 42-3). Abdominal actinomycosis may be characterized by loss of abdominal detail due to peritoneal effusion and intra-abdominal mass lesions.

Sonographic Findings

Ultrasonography in dogs with actinomycosis can be useful to identify linear grass awn foreign bodies (see Figure 42-5).[41,42] Sonographic abnormalities in dogs with abdominal disease include variable amounts of flocculent ascites fluid, abdominal lymphadenopathy, and nodular or mass lesions that incorporate or displace adjacent structures. New bone formation may be detected on interrogation of the ventral aspects of the vertebral bodies in dogs with retroperitoneal disease.

Advanced Imaging

For animals with CNS involvement, MRI may reveal meningeal thickening, contrast enhancement, and/or intraparenchymal contrast-enhancing mass lesions.[18] MRI may also be useful for detection of grass awn foreign bodies. Advanced imaging allows assessment of the extent of actinomycosis (see Figure 42-2), which can assist with surgical planning.

Microbiologic Tests

Diagnostic assays available for *Actinomyces* infection in dogs and cats are shown in Table 42-1.

Isolation and Identification

Because *Actinomyces* is a commensal of the oral cavity, it is commonly swallowed, inhaled, and transferred by licking; therefore, culture of the organism from the airways, gastrointestinal tract, or skin does not necessarily constitute infection. Consistent cytologic or histopathologic findings (pyogranulomatous inflammation with or without the presence of filamentous bacteria) and the presence of companion microorganisms support the diagnosis of actinomycosis.

Specimens for culture can be collected through fine-needle aspiration or, if possible, biopsy. Because *Actinomyces* species are susceptible to many antimicrobial drugs, treatment of animals before obtaining specimens for culture can also prevent recovery of the organisms. Culture may be negative or yield only "companion" microorganisms, which can obscure the presence of *Actinomyces* spp. As a result, diagnosis is often based only on cytologic or histologic identification of the organism in specimens from animals with appropriate clinical signs.

Most *Actinomyces* spp. that cause disease in dogs and cats are facultative anaerobes, but a few *(A. bovis, A. israelii, A. meyeri)* are obligate anaerobes.[5,7,9,43] The facultative anaerobes can grow under aerobic conditions, and some, such as *A. viscosus,* grow best in these conditions. In addition, "companion" microorganisms are often obligate anaerobes or other aerobes. Therefore, both aerobic and anaerobic cultures should be requested when an *Actinomyces* spp. infection is suspected, and the laboratory should be notified that *Actinomyces* spp. may be present. Tissue specimens, aspirates of pus, or sulfur granules are ideal specimens for anaerobic culture.

Visible growth of *Actinomyces* spp. can occur within 48 hours but usually requires 5 to 7 days. It may be necessary to hold plates 2 to 4 weeks. Species identification using traditional biochemical tests is difficult. PCR amplification and DNA sequence analysis of the 16S rRNA gene may be necessary for precise species identification. In the future, matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) mass spectrometry may prove most useful for identification of *Actinomyces* species (see Chapter 3).[44]

In addition to actinomycetes, one to five other associated bacteria are often recovered from properly handled specimens. The most commonly isolated organisms are resident flora of the oral cavity or intestinal tract and include the anaerobes *Fusobacterium*, *Peptostreptococcus*, *Prevotella*, or *Bacteroides* spp.; and *Pasteurella multocida, Escherichia coli,* and *Streptococcus* spp. Occasionally, pure cultures of *Actinomyces* spp. are isolated, but this does not exclude the concurrent presence of other organisms, especially strict anaerobes.

TABLE 42-1

Diagnostic Assays Available for *Actinomyces* Infection in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Aspirates of purulent material (e.g., abscesses, pleural effusion), whole blood, CSF, tissue specimens obtained by biopsy or at necropsy (e.g., subcutaneous tissue, heart valve, lung tissue), sulfur granules	*Actinomyces* spp.	Some organisms require anaerobic conditions. Requires several weeks' incubation, and overgrowth by companion bacteria may occur. Because *Actinomyces* spp. are mucosal commensal bacteria, isolation from contaminated sites does not imply disease causation. PCR and sequencing may be required to identify the species present.
Cytology or histopathology with organism detection using special stains	Aspirates or tissue specimens	*Actinomyces* spp. organisms	Organisms are gram positive, do not take up acid-fast stain, and are often accompanied by other bacteria and sulfur granules. Definitive diagnosis requires culture because *Nocardia* can resemble *Actinomyces* spp.

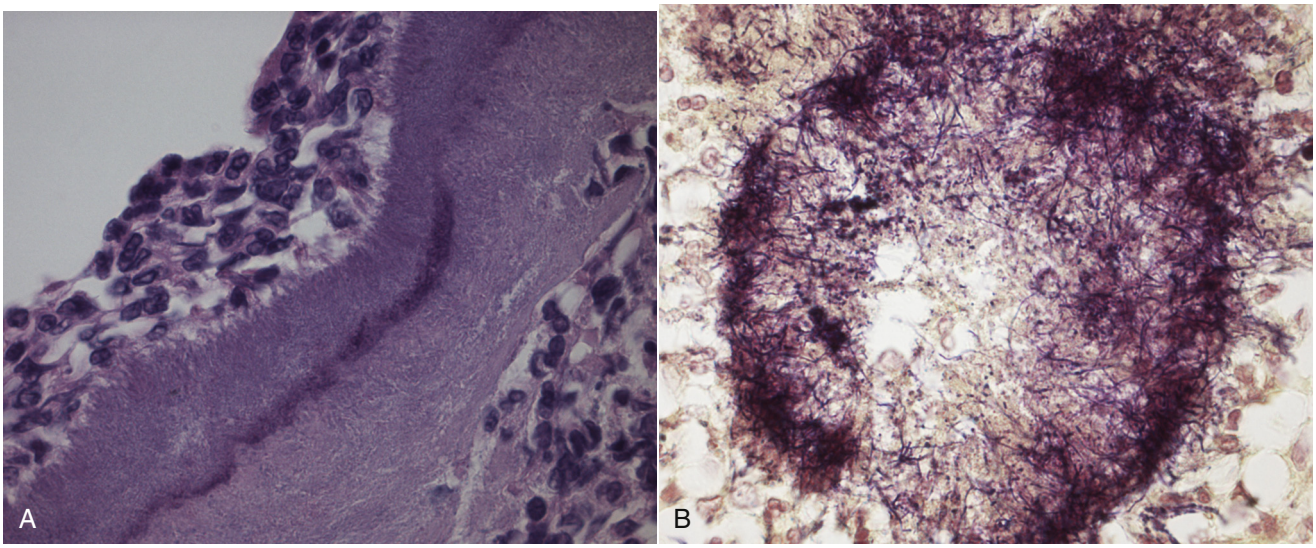

FIGURE 42-6 Histopathology of a biopsy specimen from the xiphoid of a 10-year-old intact male English pointer dog with actinomycosis due to a migrating plant awn foreign body. The dog had a 1-month history of a ventral thoracic wall mass. **A,** Dense, granular mats of branching bacteria were present in a background of extensive granulation tissue and embedded plant material (not shown). H&E stain. **B,** Brown and Benn (gram) stain revealed colonies of gram-positive, filamentous, branching bacteria. *Actinomyces bowdenii* (based on 16S rRNA gene sequencing), *Pasteurella canis, Porphyromonas canoris, Propionibacterium acnes,* a *Bacteroides gingivalis*–like organism, and a *Bacteroides ureolyticus*–like organism were isolated from the lesion.

Molecular Diagnosis Using the Polymerase Chain Reaction

Specific PCR assays for *Actinomyces* spp. have been developed and used for diagnosis of human actinomycosis[45] but are not commercially available for veterinary diagnosis.

Pathologic Findings

Gross lesions in animals with actinomycosis often consist of one or more poorly defined, indurated masses of the subcutaneous tissues, thoracic cavity, lungs, abdominal cavity, or retroperitoneal space, which incorporate adjacent structures. Masses may contain pockets of a reddish-brown exudate. Fistulas, plant material, and sulfur granules may be found. Abdominal or thoracic effusions are often reddish-brown and can contain sulfur granules. Animals with thoracic and abdominal infections may also have a diffuse, red, velvety to granular thickening of the pleura or peritoneum and omentum. Rarely, abscesses are present in the brain, or purulent meningitis is identified.

Histopathology of affected tissues reveals abscesses with a core of neutrophils encapsulated by granulation tissue that contains macrophages, plasma cells, and lymphocytes in a dense, fibrous tissue matrix. When present, sulfur granules are generally in the center of microabscesses, but multiple tissue sections may be needed to find them. In tissue sections stained with hematoxylin and eosin, the granules are round, oval, or scalloped amphophilic solid masses (Figure 42-6). They vary in size from 30 to 3000 µm in diameter and often are rimmed by partially confluent radiating eosinophilic club-shaped structures collectively known as the *Splendore-Hoeppli phenomenon*. This phenomenon can also occur with zygomycosis, sporotrichosis, parasitic infections, foreign body reactions, and hypereosinophilic syndrome.[46,47] Antigen-antibody complexes, complement, and major basic protein of eosinophils have been detected within the Splendore-Hoeppli phenomenon. Special stains (Gram stains, Giemsa and silver stains) are required to stain *Actinomyces* spp. and reveal clumps of tangled, intermittently branched, thin (<1 µm) filaments (see Figure 42-6, *B*). Other nonfilamentous bacteria and/or plant material may also be present. *Actinomyces* are not acid fast. With the rare exception of some *Nocardia* spp. that are not acid fast, other fungi and bacteria that produce tissue granules can be distinguished from *Actinomyces* based on their staining and morphologic properties.

Treatment and Prognosis

Treatment of actinomycosis usually requires prolonged antimicrobial drug treatment. Penicillin is the antimicrobial drug of choice because isolates are uniformly susceptible to penicillins (Table 42-2). High-dose therapy for weeks to months is generally required for animals with chronic infections and extensive fibrosis. In human patients with actinomycosis, high doses of penicillin are given parenterally for 2 to 6 weeks, followed by oral therapy with amoxicillin for 6 to 12 months.[48] If the animal is stable clinically, oral therapy can be tried from the outset.[8,49] Treatment must be extended for weeks to months beyond resolution of measurable disease to prevent relapse; in some cases, treatment for longer than a year may be required.[8,16] However, when actinomycosis is associated with foreign body migration, shorter durations of treatment may be possible if the foreign body is removed, drainage is established, and extensive scar tissue has not formed. Alternative antimicrobial drug choices include clindamycin, doxycycline, chloramphenicol, carbapenems, and ceftriaxone.[48] It is recommended that cephalexin, metronidazole, and aminoglycosides be avoided for treatment of human actinomycosis.[48] Infections associated with companion microbes also usually resolve with penicillin, but on occasion they require broader spectrum antibiotics during the initial treatment period followed by long-term administration of penicillin.

Excepting when foreign body material is present (Figure 42-7), surgery has a controversial role in the treatment of actinomycosis, but may be required if there is extensive fibrous tissue formation or large accumulations of purulent material to facilitate

VetBooks.ir

TABLE 42-2

Medications That Could Be Used to Treat *Actinomyces* spp. Infections in Dogs and Cats with Actinomycosis

Drug	Dose	Route	Interval (hours)
Penicillin G	100,000 U/kg	IV, IM	6-8
Ampicillin sodium	20	IV, IM, SC	6-8
Amoxicillin	20	PO	8
Clindamycin*	11	PO	12 (dogs), 24 (cats)
Doxycycline†	5-10	PO	12-24

*For IV administration of clindamycin phosphate, see Chapter 8.
†10 mg/kg q12h preferred if tolerated without gastrointestinal adverse effects. Doxycycline hyclate or clindamycin should always be administered with a bolus of water to avoid esophagitis.

FIGURE 42-7 One-year-old female spayed Labrador retriever with systemic actinomycosis secondary to a plant awn foreign body after surgical removal of the plant awn and placement of a grenade drain.

drug penetration (see Chapter 87 for information on management of pyothorax). In human medicine, an initial attempt to control disease with aggressive medical therapy alone has been suggested, with surgical therapy if the response to treatment is inadequate.[48] In animals with pulmonary abscesses, removal of affected lung lobes may be required. Fibrotic lesions are often extensively vascularized and may obliterate tissue planes, which complicates dissection. In dogs with solitary masses that involve the thoracic and abdominal walls, radical surgical excision is often curative, but repeat surgeries may be needed. An initial period of antibiotic therapy may reduce the size of lesions and improve lesion definition, which facilitates surgery followed by continued antimicrobial drug treatment at a later date. Surgery is also required if a nidus such as a grass awn is present.

Appropriate treatment of actinomycosis results in a cure rate of greater than 90%.[8,16,50] Cure rates with meningitis/meningoencephalitis and advanced thoracic or peritoneal disease with extensive mass lesions may be lower.

Prevention

Prevention of actinomycosis involves restriction of access to areas with extensive grass awn formation and avoidance of fighting and biting activity between animals. When wounds occur, they should be carefully examined for foreign material and cleaned promptly. Plant awns found on animals' coats should be removed and discarded as soon as possible and the finding of one should prompt a thorough search for others.

Public Health Aspects

No reports exist of actinomycosis being transmitted from clinically infected animals to humans or other animals; however, humans bitten by dogs, cats, or other people can develop actinomycosis (see Chapter 57).[51] The most common species that infects humans is *A. israelii*.[48] This is a commensal of the canine oral cavity but has not been isolated from dogs or cats with actinomycosis. Nevertheless, *A. viscosus, A. odontolyticus,* and *A. meyeri* have been isolated from canine and feline as well as human actinomycosis.

CASE EXAMPLE

Signalment: "Penny", a 1-year-old, female spayed Labrador retriever from Herald in northern California

History: Penny was evaluated by the University of California, Davis, veterinary emergency service for a 1-week history of progressive inappetence, weight loss, lethargy, and fever. Two days before she was evaluated, Penny vomited up some kibble, and had not eaten anything since. The owner reported that her feces had been formed and there were no changes in thirst or urination. Earlier the same day, Penny had been evaluated at another veterinary clinic where a grade IV/VI left-sided cardiac murmur was auscultated and thoracic radiographs showed a bronchoalveolar and interstitial lung pattern. She was treated with cefazolin (27 mg/kg IV) and furosemide (1 mg/kg SC) and referred. Penny had been fully vaccinated for canine distemper virus, canine parvovirus, canine adenovirus, and rabies. She had missed some doses of heartworm prophylaxis medication recently and received no other medications. She lived with three other healthy

VetBooks.ir

Labrador retrievers. She roamed on 8 acres of land, and there was a pond on the property where she swam and was known to eat crayfish and frogs. Her usual diet consisted of a commercial dry puppy food. Seven months earlier, she had been evaluated at another veterinary clinic for vomiting and inappetence. At that time she was moderately azotemic; an exploratory laparotomy was performed for a suspected foreign body, but no foreign body was found.

Physical Examination:

Body Weight: 22.5 kg

General: Quiet, alert, responsive and wagging tail. Approximately 5% dehydrated. T = 105.2°F (40.7°C), HR 160 beats/min, RR = 42 breaths/min. Pink, slightly tacky mucous membranes, CRT < 2 s.

Integument: Full clean haircoat, no evidence of ectoparasites.

Eyes, Ears, Nose, and Throat: No clinically significant abnormalities were noted.

Musculoskeletal: BCS 3/9. Generalized mild muscle atrophy was present.

Cardiovascular: A grade II/VI left systolic murmur was auscultated. Femoral pulses were strong, regular, and synchronous.

Respiratory: Increased breath sounds were present bilaterally and diffusely. There was a mild increase in respiratory effort.

All Other Systems: No clinically significant abnormalities were noted.

Laboratory Findings:

CBC:

HCT 24.0% (40%-55%),
MCV 65.6 fL (65-75 fL)
MCHC 35.0 g/dL (33-36 g/dL)
WBC 29,850 cells/µL (6000-13,000 cells/µL)
Neutrophils 16,119 cells/µL (3000-10,500 cells/µL)
Lymphocytes 2985 cells/µL (1000-4000 cells/µL)
Monocytes 7761 cells/µL (150-1200 cells/µL)
Eosinophils 0 cells/µL (0-1500 cells/µL)
Basophils 0 cells/µL (0-50 cells/µL)
Platelets 98,000 platelets/µL (150,000-400,000 platelets/µL)
MPV 20.1 fL (7-13 fL).
A few slightly toxic band neutrophils and moderate numbers of macroplatelets were present.

Serum Chemistry Profile:

Sodium 144 mmol/L (145-154 mmol/L)
Potassium 4.3 mmol/L (3.6-5.3 mmol/L)
Chloride 114 mmol/L (108-118 mmol/L)
Bicarbonate 15 mmol/L (16-26 mmol/L)
Phosphorus 5.3 mg/dL (3.0-6.2 mg/dL)
Calcium 9.6 mg/dL (9.7-11.5 mg/dL)
BUN 22 mg/dL (5-21 mg/dL)
creatinine 0.8 mg/dL (0.3-1.2 mg/dL)
Glucose 44 mg/dL (64-123 mg/dL)
Total protein 7.8 g/dL (5.4-7.6 g/dL)
Albumin 2.5 g/dL (3.0-4.4 g/dL)
Globulin 5.3 g/dL (1.8-3.9 g/dL)
ALT 31 U/L (19-67 U/L)
AST 76 U/L (19-42 U/L)
ALP 612 U/L (21-170 U/L)
Gamma GT 5 U/L (0-6 U/L)
Cholesterol 292 mg/dL (135-361 mg/dL)
Total bilirubin 0.8 mg/dL (0-0.2 mg/dL)

Urinalysis: SGr 1.016; pH 5.0, 1+ protein (SSA), 1+ bilirubin, 2+ hemoprotein, 1+ glucose, 0-1 WBC/HPF, 0-3 RBC/HPF, rare granular casts, many amorphous crystals, rare bilirubin crystals, many lipid droplets

Coagulation Panel: PT 7.7 s (7.5-10.5 s), APTT 15.2 s (9-12 s), fibrinogen 232 mg/dL (90-255 mg/dL), D-dimer 1.0-2.0 µg/mL (0-0.25 µg/mL).

Imaging Findings:

Thoracic Radiographs (3 View): There were patchy diffuse unstructured interstitial opacities in all lung lobes (see Figure 42-5, *A*). Cardiovascular structures appeared within normal limits. The liver was markedly enlarged.

Echocardiography: The left ventricle was eccentrically hypertrophied. The papillary muscles had normal shape and echogenicity. There was no enlargement of the left atrium. There was no evidence of endocarditis. Decreased fractional shortening (26%; reference range, approximately 34%-46%) and increased end systolic diameter (3.9 cm; reference range, approximately 1.8-3.5 cm) and E-point septal separation (6.8 mm) were indicative of systolic dysfunction, which could also be appreciated subjectively. There was mild tricuspid regurgitation and trivial pulmonic insufficiency. Conclusions: Moderate systolic dysfunction. It was recommended that the dog's diet and taurine blood/plasma levels be evaluated. It was also considered possible that the dog's febrile state was responsible for some of abnormalities observed on the echocardiogram.

Abdominal Ultrasound: The liver was diffusely mottled, particularly in the left caudal region (see Figure 42-5, *B*). Within the left caudal liver, there was a focal, ill-defined heteroechoic area approximately 1 cm in diameter. Other smaller, ill-defined hypoechoic nodules were also present within the left liver. One of these areas had a well-demarcated, hyperechoic rim with irregular echogenic luminal contents and measured approximately 0.5 cm in diameter. Multiple large mesenteric lymph nodes were just caudal to the liver; the largest measured 1.3 cm by 4.5 cm. There was a small amount of anechoic free abdominal fluid. The spleen was moderately enlarged, but the echotexture and echogenicity appeared within normal limits. There was mild renal pyelectasia bilaterally, but the renal papillae appeared within normal limits.

Microbiologic Testing: Aerobic and anaerobic blood cultures (five specimens): Negative

IFA serology for serum antibody to *Ehrlichia canis, Anaplasma phagocytophilum, Rickettsia rickettsii,* and *Babesia canis*: Negative

IFA serology for serum antibody to *Bartonella vinsonii* subsp. *berkhoffii, Bartonella clarridgeiae,* and *Bartonella henselae*: Negative

Bartonella culture (whole blood): Negative

Serology for *Coccidioides* serum antibodies: Negative

Cytologic Findings:

Splenic Aspirate (Ultrasound-Guided): Two smears were examined that contained a large amount of blood in the background and were highly cellular. Several small clumps of splenic stromal cells were noted. A large heterogeneous population of lymphocytes was found, with a moderate increase in plasma cells. A moderate number of hematopoietic cells was also present, including

VetBooks.ir

megakaryocytes, myeloid, and erythroid precursors. Interpretation: Moderate reactive lymphoid hyperplasia and extramedullary hematopoiesis.

Liver Aspirate (Ultrasound-Guided): Smears contained a diffusely stippled background with abundant nuclear debris and were highly cellular. A large population of mildly to markedly degenerate neutrophils were observed. Degenerate cells ranged from highly pyknotic to severely karyolytic. A few neutrophils contained small intracellular bacterial rods. Interpretation: Marked suppurative inflammation with bacterial sepsis.

Further Microbiologic Testing:

Aerobic and Anaerobic Culture (Ultrasound-Guided Liver Aspirate): Small numbers of suspect *Actinomyces* spp. No anaerobes cultured. Partial 16S rRNA gene PCR and sequence analysis revealed 99% identity to *Actinomyces bowdenii*.

Diagnosis: Systemic *A. bowdenii* infection with hepatic involvement

Treatment: Immediately on admission, Penny was treated with IV lactated Ringer's solution with 20 mEq/L KCl and 5% dextrose at 75 mL/hr. After the specimens for blood culture were collected, treatment with enrofloxacin (10 mg/kg IV q24h) and ampicillin (22 mg/kg IV q8h) was initiated. Within 24 hours, the dog's rectal temperature had decreased to 101.3°F (38.5°C), the blood glucose had increased from 41 mg/dL to 107 mg/dL, and Penny began eating. The liver aspirate was submitted for culture on day 2 of hospitalization. A recheck abdominal ultrasound examination on day 3 showed progressive abscessation of the left liver and further enlargement of the gastrohepatic lymph nodes. By day 4 of hospitalization, growth of an organism resembling an *Actinomyces* sp. was reported. On day 5, antimicrobial drug treatment was changed to clavulanic acid–amoxicillin (17 mg/kg q8h). However, later in the day, Penny's temperature increased to 103.6°F (39.8°C), and so the initial antimicrobial drug prescription was reinstated. The dog's hematocrit had also dropped to 19%. Thoracic radiographs were repeated and showed almost complete resolution of the patchy pulmonary infiltrates. A follow-up echocardiogram was unchanged. Abdominal ultrasound examination was again repeated and showed persistent hypoechogenicity of the left liver lobe, but during the procedure a hyperechoic lesion that was consistent with a plant awn foreign body was discovered in the subcutaneous tissue in a caudoventral intercostal space. On day 6, surgery was performed to remove the plant awn. Packed red cells were administered during the procedure, and a 16F thoracostomy tube was placed because the thoracic cavity was entered during the search for the foxtail, which, with the assistance of intraoperative ultrasound examination, was eventually located under the 13th rib just outside the pleural space. Sulfur granules were found embedded in the tissue during surgery. A closed suction grenade drain was also placed (see Figure 42-7). The thoracostomy tube was removed later in the day. Treatment with enrofloxacin and ampicillin was continued, as well as with oxymorphone (0.04 mg/kg SC q6h) to control pain. On day 7, Penny's temperature was 100.7°F (38.2°C), and the drain was removed. Aerobic and anaerobic culture of the foxtail revealed small numbers of penicillin-susceptible *Enterococcus faecalis* and an organism resembling a *Streptomyces* sp. No anaerobes were cultured. Penny was discharged on day 8 with instructions to continue treatment with clavulanic acid–amoxicillin for an additional month. The dog had no further clinical signs of illness.

Comments: This is an unusual case of disseminated *A. bowdenii* infection that led to hematogenous pneumonia and hepatic abscessation. Although there was an initial defervescence with antimicrobial drug treatment, anemia and pyrexia persisted, which led to a search for an abscess that might require drainage or a plant awn. Fortunately, a plant awn was ultimately identified with ultrasound and removed, after which the dog's illness resolved completely. *E. faecalis* was isolated from the plant awn and represented a "companion microbe," but whether dissemination of this organism occurred was unclear. The *Streptomyces* sp. may have been a contaminant, or the *Actinomyces* sp. that was misidentified. The owner was warned that additional plant awns might still be present. The cause of the cardiomyopathy was not determined; plasma and whole blood taurine concentrations were within normal limits, and follow-up examination was not performed.

CHAPTER 43

Nocardiosis

Jane E. Sykes

VetBooks.ir

Overview of Nocardiosis

First Described: 1888, Alfort, France (Edmond Nocard)[1]

Causes: *Nocardia* spp. (order Actinomycetales, family Nocardiaceae)

Geographic Distribution: Worldwide, although infections in dogs and cats are most commonly reported from Brazil, the western United States, and Australia

Mode of Transmission: Inhalation or cutaneous inoculation of organisms in the environment, with opportunistic proliferation in the face of impaired host immune defenses

Major Clinical Signs: Lethargy, weight loss, inappetence; subcutaneous masses and nonhealing, crusted, or draining skin lesions; pulmonary nodules, masses and/or effusion with cough and tachypnea; signs of dissemination (neurologic signs, chorioretinitis, abdominal effusion or masses, lameness)

Differential Diagnoses: Actinomycosis, streptomycosis, mycobacteriosis, bartonellosis, fungal infections, neoplasia, leishmaniosis

Human Health Significance: Direct transmission of disease from animals to humans does not occur, but humans have developed disease after bites or scratches from healthy dogs or cats.

Etiology and Epidemiology

Nocardia are filamentous, branching, gram-positive bacteria that belong to the family Nocardiaceae (Figure 43-1). More than 50 *Nocardia* species have been recognized since the advent of molecular identification methods, approximately half of which are human and animal pathogens.[2] The advent of molecular methods has also led to extensive revision of the taxonomy of *Nocardia* spp. Species that belong to the former *N. asteroides* complex are now considered distinct species and include *Nocardia cyriacigeorgica* (formerly *N. asteroides* sensu stricto), *Nocardia abscessus*, *Nocardia nova*, *Nocardia farcinica*, and *Nocardia otitidiscaviarum*.[2] Knowledge of the species involved is clinically important, because each *Nocardia* species differs in its antimicrobial susceptibility patterns, epidemiology, and pathogenicity. They also differ in their cell wall mycolic acid content, which affects their ability to stain with acid-fast stains.

Like actinomycosis, nocardiosis is a suppurative to granulomatous, localized, or disseminated opportunistic infection caused by filamentous bacteria. However, unlike *Actinomyces* spp. (which are commensals of mucous membranes), *Nocardia* spp. are ubiquitous soil saprophytes that degrade organic matter. They are also found in fresh and salt water, in dust, and on decaying plants and fecal matter.[2] They can be carried mechanically on the claws or skin. Infections are acquired via inhalation of organisms or inoculation via puncture wounds. Transfer of infection between animals does not occur.

Nocardiosis is much less frequently reported in dogs and cats than actinomycosis, although nocardiosis is increasingly recognized in both human medicine and companion animals in association with immunocompromise, such as occurs with potent immunosuppressive drug therapy (especially cyclosporine).[3-5] Where vaccination for canine distemper virus (CDV) is inadequate or not widely instituted, nocardiosis in dogs has been associated with CDV-induced immunosuppression.[6]

The prevalence of nocardiosis and the predominant *Nocardia* species that cause disease vary geographically. For example, within the United States, human nocardiosis has been most commonly reported from the southwestern states. Dry, dusty, and windy conditions in these areas may facilitate aerosolization and dispersal of nocardiae.[7] Dogs and cats from Australia and the western United States are most commonly infected with *Nocardia nova*.[8-10] Other species isolated from dogs and cats are shown in Table 43-1.[11-16] In humans, *Nocardia brasiliensis* is the most common species isolated from patients that reside in tropical locations such as the southwestern United States, Central and South America, and Australia.

More than 60% of people with nocardiosis have underlying immunosuppressive disorders such as AIDS, chronic obstructive pulmonary disease, autoimmune diseases that require immunosuppressive drug therapy, solid organ transplantation, diabetes

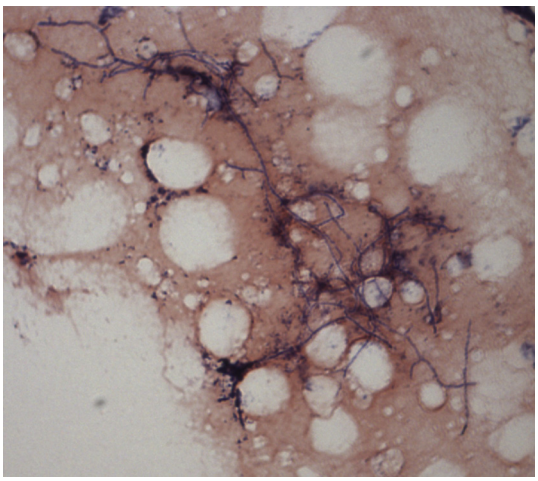

FIGURE 43-1 Gram-stained smear showing *Nocardia* spp. The organisms are gram-positive, filamentous, branching, and slightly beaded.

Nocardia Species Isolated from Dogs and Cats with Nocardiosis

Host Species	Dogs	Country
Dogs	*N. nova*	United States, Australia[8,9]
	N. paucivorans	United States[9]
	N. asiatica	United States[9]
	N. abscessus	United States[5]
	N. otitidiscaviarum	Brazil[6]
	N. farcinica	Australia[8]
Cats	*N. nova*	United States, Australia[9]
	N. cyriacigeorgica	Australia[8]
	N. africana	Japan,[11] Brazil[12]
	N. elegans	Japan[13]
	N. brasiliensis	United States[14]
	N. otitidiscaviarum	Spain[15]
	N. tenerifensis	United States[16]

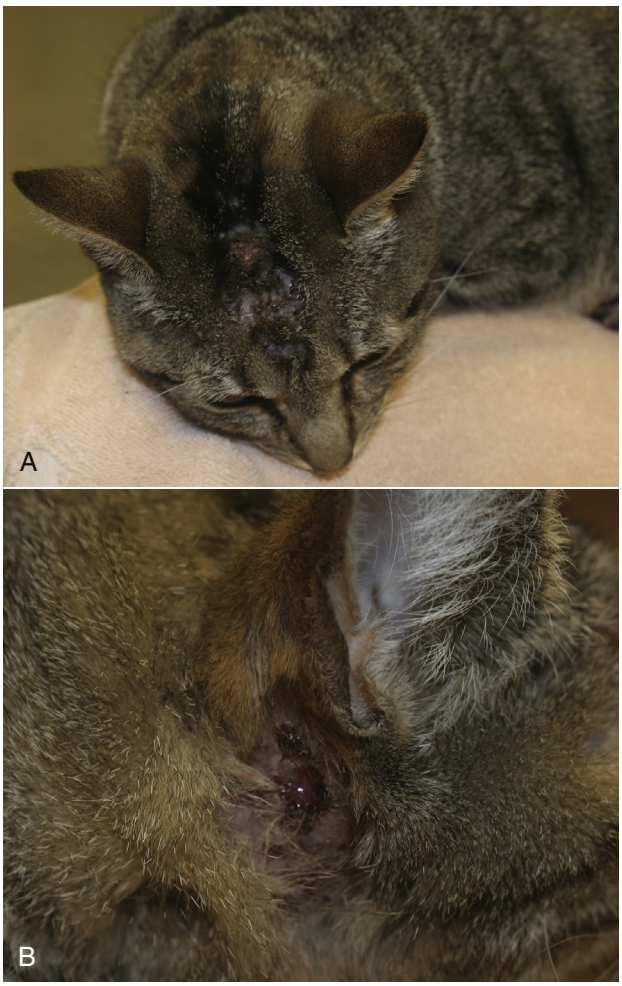

FIGURE 43-2 Six-year-old male neutered domestic shorthair cat with cutaneous-subcutaneous nocardiosis. The lesions progressed over at least a year after a cat bite abscess that was initially treated with amoxicillin-clavulanic acid. They consisted of nodular and crusted lesions on the head **(A)** and cervical region **(B)** that drained fluid and extended down the cervical region to the cranioventral thorax. The cat tested negative for retroviruses. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

mellitus, and hemic neoplasia.[17] Underlying immunosuppressive disease or drug treatment also seems to predispose dogs to nocardiosis. Nocardiosis has been documented in several dogs treated with cyclosporine and in a dog with lymphoma.[3-5,9] Most affected cats have cutaneous infections that develop after scratch or bite wounds.[8,18] Accordingly, more than 75% to 80% of affected cats are male; in the author's hospital, 9 of 10 affected cats were male.[8,9,19] Cats of any age can be affected, and no breed predilection has been identified.[8] Some cats have underlying disorders that predispose them to nocardiosis, such as a history of renal transplantation, underlying retroviral infection, or glucocorticoid administration. Others have no obvious underlying immunosuppressive disease.

Clinical Features

Signs and Their Pathogenesis

The pathogenicity of *Nocardia* spp. is influenced by the strain and growth phase of the organism, and host susceptibility. Virulent *Nocardia* strains are facultative intracellular pathogens that inhibit phagosome-lysosome fusion, neutralize phagosomal acidification, resist oxidative burst, secrete superoxide dismutase, and alter lysosomal enzymes within neutrophils and macrophages.[17] These effects are partly related to the content and structure of mycolic acids within the bacterial cell wall, which vary among strains and throughout the growth phase. Filamentous log-phase cells in the environment can be highly resistant to phagocytosis. Some strains have a greater propensity to invade the central nervous system (CNS).[19,20]

The normal host response to infection is characterized by an initial pyogenic inflammatory response, but a cell-mediated immune response is necessary to destroy the organisms. Diminished host resistance, especially impaired cell-mediated immunity (CMI), is a primary factor in susceptibility to nocardiosis and the extent to which dissemination occurs.

Cutaneous-subcutaneous nocardiosis, the most common form in cats (>75% of affected cats), is characterized by slow and progressive circumferential spread of a nonhealing, draining wound (Figure 43-2). Lesions are typically subacute to chronic. Infections of feeding tube sites can also occur.[21] Mycetoma-like lesions in the inguinal area resemble those described for rapidly growing mycobacterial infections (see Chapter 44), with multiple draining sinuses. These may result from contamination of "raking" injuries inflicted by the hindlimbs during fighting behavior,[8] or contamination of traumatic wounds from penetrating plant material. Cutaneous-subcutaneous nocardiosis was documented in 8 of 9 dogs from Brazil[6] but represents the minority of canine nocardiosis cases in California and Australia.[8,9] Dogs with cutaneous involvement typically develop draining wounds and masses, often on the head and limbs. Osteomyelitis can occur in association with cutaneous lesions.

The pathogenesis of *pulmonary or disseminated nocardiosis* is similar to that of the deep mycoses. Branching nocardial filaments fragment into small, unicellular particles that are aerosolized and inhaled, possibly in dust. Once within the lung, *Nocardia* spp. proliferate in the face of immune suppression, which leads to formation of intrapulmonary masses or pneumonia, hilar lymphadenopathy, and/or extrapulmonary masses and pyothorax (Figure 43-3, *A*). Pulmonary nocardiosis is the most common form of nocardiosis in humans and also occurs in dogs and less commonly in cats. In dogs, it can have a peracute onset characterized by tachypnea, hemoptysis, hypothermia,

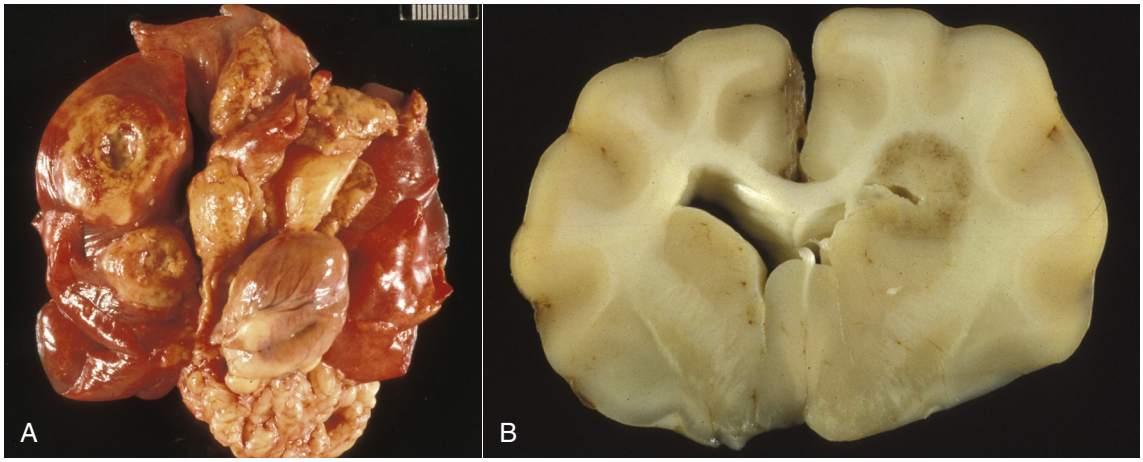

FIGURE 43-3 Gross necropsy findings in a 4-year-old male neutered domestic shorthair cat with disseminated nocardiosis caused by *Nocardia nova*. The cat was a renal transplant recipient. **A,** Multifocal to coalescing large, white to gray, caseous pulmonary masses are present within the lungs. **B,** The brain contained multifocal, white to gray foci that histologically consisted of large numbers of neutrophils and filamentous bacteria. (Courtesy University of California, Davis Veterinary Anatomic Pathology Service.)

collapse, and death; however, subacute to chronic clinical signs are more common.[22-25] Co-infection with CDV is occasionally reported.[6,26,27] Disseminated nocardiosis occurs when organisms in the lung erode into blood vessels and spread systemically, with abscess formation in a variety of organs. This results in signs of lethargy, fever, inappetence, and signs that relate to the location of the infectious process. Disseminated disease occurs in cats as well as in dogs. The most frequently involved extrathoracic organs after dissemination are skin and subcutaneous tissue, kidney, liver, spleen, lymph nodes, CNS, eye, bone, and joints. In dogs and cats, CNS lesions can result in seizures or neurologic signs that relate to the local effects of abscesses or granulomas in the brain, meninges, or spinal cord (see Figure 43-3, *B*). CNS involvement is common in human nocardiosis. Peritoneal nocardiosis has rarely been reported in cats, possibly as a result of penetrating wounds to the abdomen.[8,28]

Physical Examination Findings

Physical examination findings in animals with cutaneous-subcutaneous disease consist of chronic, sometimes crusted, ulcerated, nonhealing draining wounds, and in cats may involve the extremities, inguinal area, flank, head, bridge of the nose, and neck (see Figure 43-2). Animals with pulmonary or systemic involvement may have a thin body condition, lethargy, and fever. Tachypnea and cough may be present, and lung sounds may be increased (with bronchopneumonia) or decreased (with pyothorax). Involvement of the liver, spleen, and lymph nodes may result in hepatomegaly, splenomegaly, and/or peripheral or abdominal lymphadenomegaly. Ophthalmic examination may reveal chorioretinitis. Bone or joint infection results in focal limb swelling and lameness. Animals with CNS involvement may show mental obtundation, anisocoria, decreased menace and pupillary light responses, head tilt, nystagmus, decreased gag reflexes, and/or delayed or absent placing reactions.

Diagnosis

A diagnosis of nocardiosis is usually suspected based on the presence of persistent pyogenic to pyogranulomatous inflammatory lesions and the presence of filamentous bacteria, together with a history of immunosuppression, although the last is not always present. Confirmation of the diagnosis requires culture.

Laboratory Abnormalities

Complete Blood Count and Serum Biochemical Tests

Hematologic abnormalities in nocardiosis are similar to those with actinomycosis (nonregenerative anemia, neutrophilic leukocytosis with a left shift, monocytosis, and sometimes marked hyperglobulinemia). However, in immunosuppressed animals, lymphopenia, monocytopenia, and eosinopenia may be present. Hypercalcemia associated with granulomatous disease was reported in a cat with nocardiosis.[29]

Cytologic Examination of Body Fluids

Examination of pleural effusion, bronchoalveolar lavage fluid, and aspirates of abscesses from animals with nocardiosis typically reveals suppurative to pyogranulomatous inflammation, with large numbers of degenerate neutrophils. Gram-positive, often partially or weakly acid-fast, beaded, filamentous organisms that branch at right angles may be observed individually or in loose aggregates (see Figure 43-1). The filaments may also fragment to form rods and coccoid forms. In contrast, *Actinomyces* spp. is not acid fast, and *Mycobacterium* spp. do not branch. When the infecting *Nocardia* sp. is not acid fast, it may not be distinguishable from an *Actinomyces* sp. organism. With Romanowsky-type stains, organisms are eosinophilic or basophilic and have a beaded appearance. They are usually around 0.5 µm in diameter and up to 30 µm long, but thicker organisms were described in a dog infected with *N. abscessus* (2 µm).[5] Macroaggregates (i.e., sulfur granules) occur infrequently in effusions. In contrast to actinomycosis, mixed bacterial populations in deep tissue sites are rarely present.

Diagnostic Imaging

Plain Radiography

Radiographs of cutaneous-subcutaneous lesions can reveal soft tissue swelling with or without associated bone lysis and periosteal proliferation. The radiographic appearance of pulmonary lesions varies and includes multiple, diffuse pulmonary nodules; intrapulmonary or extrapulmonary solitary masses; focal or diffuse bronchointerstitial to alveolar infiltrates; lobar

consolidations; pleural effusions; and, often, dramatic hilar lymphadenopathy (Figure 43-4).

Sonographic Findings

Abdominal ultrasound findings in dogs and cats with disseminated nocardiosis have not been described in detail because disseminated disease with abdominal organ involvement is rare. However, intraparenchymal mass lesions and flocculent ascites fluid might be expected.

Advanced Imaging

Nodular lung lesions similar to those described in humans were identified with computed tomography in one dog with disseminated nocardiosis.[5] Computed tomographic and MRI abnormalities in dogs and cats with confirmed CNS nocardiosis have not been reported. One dog with suspected nocardiosis based on histopathology had a large, T2-hyperintense circumscribed lesion in the occipital cortex that was consistent with a brain abscess, together with widespread cerebral edema and herniation of the cerebellum through the foramen magnum.[4]

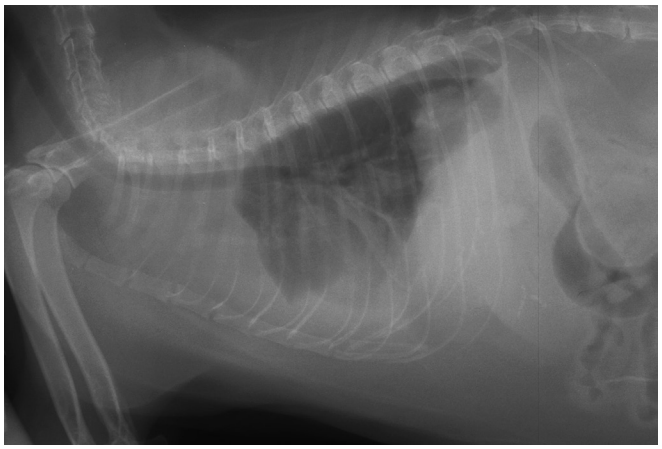

FIGURE 43-4 Lateral thoracic radiograph of a 4-year-old male neutered domestic shorthair cat with disseminated nocardiosis. Pleural effusion is present and obscures the cardiac silhouette. A mass is associated with the caudal aspect of the left caudal lung lobe.

Microbiologic Tests

Diagnostic assays available for *Nocardia* infection in dogs and cats are shown in Table 43-2.

Isolation and Identification

Nocardia spp. grow aerobically at a wide temperature range on simple media (e.g., Sabouraud's glucose agar, blood agar). Organisms are usually recovered in pure cultures, and colonies are often visible after 2 days. However, in some cases, 2 to 4 weeks of incubation may be necessary, and the organism may be overgrown by contaminating bacteria. Thus, the laboratory should be alerted if nocardiosis is suspected, so that selective media and long incubation times are used. Colonies are smooth and moist, or rugose with a powdery surface due to aerial filamentation, and may be pigmented. Organisms may then be identified based on their microscopic appearance and their ability to take up acid fast stains. However, not all pathogenic strains of *Nocardia* species are acid fast.[19,20,30] L-form *Nocardia* spp., which are cell wall–deficient variants, have been associated with disease in people and a dog.[31] These bacteria require special media for isolation and culture, similar to mycoplasmas (see Chapter 39).

Traditionally, *Nocardia* species have been distinguished based on their growth characteristics and antibiotic susceptibility patterns; however, molecular methods provide a more reliable and rapid means of speciation. Sequence analysis of PCR products from the 16S rRNA gene identifies most pathogenic *Nocardia* spp., but differentiation of closely related species may require analysis of other genes, multilocus sequence typing, or DNA-DNA hybridization.[2,17] DNA-DNA hybridization is considered the gold standard for nocardial species determination.[2] Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry shows promise for rapid and reliable identification of *Nocardia* species in clinical microbiology laboratories.[32] PCR assays have also been used to directly detect *Nocardia* spp. in clinical specimens, without prior isolation.[2]

Because *Nocardia* organisms are ubiquitous in soil and may be inhaled by healthy animals, the isolation of small numbers of organisms from ulcerated skin lesions or the respiratory tract may not be clinically significant and must be interpreted in conjunction with clinical signs and history of immune compromise. Repeated positive cultures, pure cultures, or isolation of large

TABLE 43-2

Diagnostic Assays Available for *Nocardia* Infection in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Aspirates of purulent material (e.g., abscesses, pleural effusion); whole blood; tissue specimens obtained by biopsy or at necropsy (e.g., subcutaneous tissue, lung tissue)	*Nocardia* spp.	Grows on most simple media. May require several weeks' incubation. Because *Nocardia* spp. are soil saprophytes, isolation from skin lesions does not imply disease causation. PCR and sequencing may be required to identify the species present.
Cytology or histopathology with organism detection using special stains	Aspirates or tissue specimens	*Nocardia* spp. organisms	Organisms are gram-positive, variably acid-fast, and are not typically accompanied by sulfur granules, other bacteria, or the Splendore-Hoeppli phenomenon. Definitive diagnosis requires culture because non–acid-fast *Nocardia* can resemble *Actinomyces* spp.

numbers of the organism also suggest nocardiosis, and isolation of a single colony from a normally sterile site is significant. Visualization of gram-positive filamentous bacteria in cytology specimens in association with acute inflammatory cells also assists in determination of clinical significance.

The susceptibility of *Nocardia* spp. to antimicrobial drugs varies considerably between different *Nocardia* species, and so species identification can be used to guide antimicrobial drug selection (see Treatment, later) (Table 43-3). Susceptibility testing for *Nocardia* spp. is difficult and should be done by laboratories with special expertise. Susceptibility testing may be helpful when there is a failure to respond to therapy or relapse occurs from drug resistance. It may also be useful if there are concerns that relate to adverse drug reactions to sulfonamides, the initial treatment of choice (e.g., in dogs with immune-mediated disease that is complicated by cyclosporine-associated nocardiosis). Testing is also indicated when *N. farcinica* is present, which tends to be highly resistant to antimicrobial drugs, or when a nocardial species with unpredictable susceptibility is isolated.

Pathologic Findings

Nocardiosis is characterized by suppurative necrosis and abscess formation and infrequently granulomas (see Figure 43-3). Gross lesions in organs such as the spleen, lung, liver, and the brain typically consist of numerous small (1 mm) to large (several centimeters), discrete or coalescing, intraparenchymal white or gray-white nodules. On cut section, nodules appear caseous to purulent. Lymph nodes are enlarged, often massively, and are firm to fluctuant with a caseous to purulent core. A reddish-brown exudate may be present in the pleural or peritoneal space or within abscesses. Although formation of sulfur granules by *Nocardia* spp. is uncommon compared with *Actinomyces* spp., small granules are occasionally found in skin lesions and pleural and peritoneal fluid.[10,22,28,33]

Histopathology usually reveals a central region of necrosis and suppuration, which, depending on the host immune response, may be surrounded by macrophages, lymphocytes, and plasma cells (Figure 43-5, *A*). In chronic cutaneous-subcutaneous infections, pyogranulomatous foci may be interspersed within dense fibrous tissue. Plant material may be observed if plants were involved in inoculation of *Nocardia* spp. into tissues, but this is more common with actinomycosis.

Nocardia filaments are usually present in abundance within regions of necrosis and suppuration. They are poorly visible in tissue sections stained with hematoxylin and eosin or with Gridley's fungal or periodic acid–Schiff. Organisms can be stained with Gram stain (see Figure 43-5, *B*) or methenamine silver preparations,[5] especially with prolonged silver nitrate exposure. They are usually partially acid fast and have the same appearance described previously in the Cytology section. In chronic skin infections, tissue granules characterized by colonies arranged in large, rosette-like arrays have been described. In contrast to actinomycosis, other bacteria and the Splendore-Hoeppli phenomenon are not generally present.

Treatment and Prognosis

Treatment

Successful treatment of nocardiosis relies on the combination of appropriate antimicrobial therapy combined with the

TABLE 43-3

Suggested Antimicrobial Drug Selection for Treatment of Pathogenic *Nocardia* spp. Based on Minimum Inhibitory Concentration Data

Nocardia Species	Appropriate Antimicrobial Drug Choices	Antimicrobial Drugs to Avoid
N. abscessus	Ampicillin, amoxicillin–clavulanic acid, ceftriaxone, linezolid, amikacin and gentamicin, sulfamethoxazole	Imipenem, ciprofloxacin, clarithromycin
N. brevicatena/paucivorans complex	Ampicillin, amoxicillin–clavulanic acid, ceftriaxone, amikacin, sulfamethoxazole, ciprofloxacin	Gentamicin, clarithromycin
N. nova complex (includes *N. nova*, *N. africana*)	Ampicillin, sulfamethoxazole, erythromycin, clarithromycin, ceftriaxone, imipenem, amikacin	Amoxicillin–clavulanic acid
N. farcinica	Amikacin, sulfamethoxazole, ciprofloxacin (most isolates), imipenem (most isolates)	Ampicillin, broad-spectrum cephalosporins, clarithromycin, aminoglycosides other than amikacin
N. cyriacigeorgica	Ceftriaxone, amikacin, imipenem	Ampicillin, amoxicillin–clavulanic acid, clarithromycin, ciprofloxacin
N. brasiliensis	Minocycline, amoxicillin–clavulanic acid, sulfamethoxazole	Ampicillin, ciprofloxacin, clarithromycin
N. otitidiscaviarum	Gentamicin, amikacin, sulfamethoxazole, ciprofloxacin	All β-lactam antibiotics

Data from Brown-Elliott BA, Brown JM, Conville PS, et al. Clinical and laboratory features of the *Nocardia* spp. based on current molecular taxonomy. Clin Microbiol Rev 2006;19:259-282.

use of surgical drainage or debridement. Chronic, extensive lesions may require surgical debridement or resection. Appropriate antimicrobial therapy that includes surgical drainage is not always effective, possibly because of an inadequate host immune response.[8] Existing immunosuppressive drug treatment should be discontinued or reduced, provided it does not cause relapse of a life-threatening underlying disease process.

The initial selection of an antimicrobial drug or drug combination should take into account the site of the infection, the host immune status, the infecting *Nocardia* species (see Table 43-3), and, if available, susceptibility test results.[17] However, in vitro susceptibilities do not always translate into a clinical response in vivo. Sulfonamides, including trimethoprim-sulfonamide combinations (TMS), are the first line antimicrobial drugs for treatment of nocardiosis (Table 43-4). Treatment durations from 1 to 3 months are recommended in people with cutaneous infections, up to 6 months for uncomplicated pulmonary infections, and 12 months or longer for systemic infections or infections in those who are immunocompromised.[17] Clinical improvement is generally observed within 7 to 10 days of starting treatment. High doses of trimethoprim-sulfas given for long periods to dogs (and to a lesser extent, cats) can produce a variety of adverse effects such as keratoconjunctivitis sicca and myelosuppression (see Chapter 8). If adverse drug reactions occur, selection of drugs other than TMS should ideally be based on susceptibility test results. If these are not available, choices should be made based on published susceptibility data for different *Nocardia* species (see Table 43-3). *Nocardia nova* is susceptible to amoxicillin but resistant to amoxicillin-clavulanic acid because of induction of chromosomal β-lactamase by clavulanic acid.[8,10] Substitution of antimicrobial drugs within a drug class may not provide effective treatment; for example, although susceptible to amikacin, *N. farcinia* isolates are resistant to gentamicin, and although susceptible to minocycline, *N. brasiliensis* isolates are mostly resistant to doxycycline.[34] Two- or three-drug combinations including TMS, amikacin, and either ceftriaxone or imipenem have been used, pending the results of susceptibility tests to treat severe nocardiosis in human patients.[2] A combination of amikacin and imipenem should be effective against all isolates. Combination treatment with amikacin and TMS was suggested for cats with *N. farcinica* infections, which generally require an aggressive, combination drug treatment.[8] After susceptibility testing, monotherapy with linezolid has consistently been used with success to treat some refractory *Nocardia* infections in humans.[35] *Nocardia* isolates from dogs and cats have high minimum inhibitory concentrations for fluoroquinolones,[36] which are not generally recommended for treatment.

If CNS disease is present, either high doses of TMS given parenterally, or drugs with excellent CNS penetration, which include third-generation cephalosporins, carbapenems, or linezolid should be considered. The use of linezolid in veterinary patients is controversial because it is an important drug for resistant bacterial infections in humans (see Chapter 8).

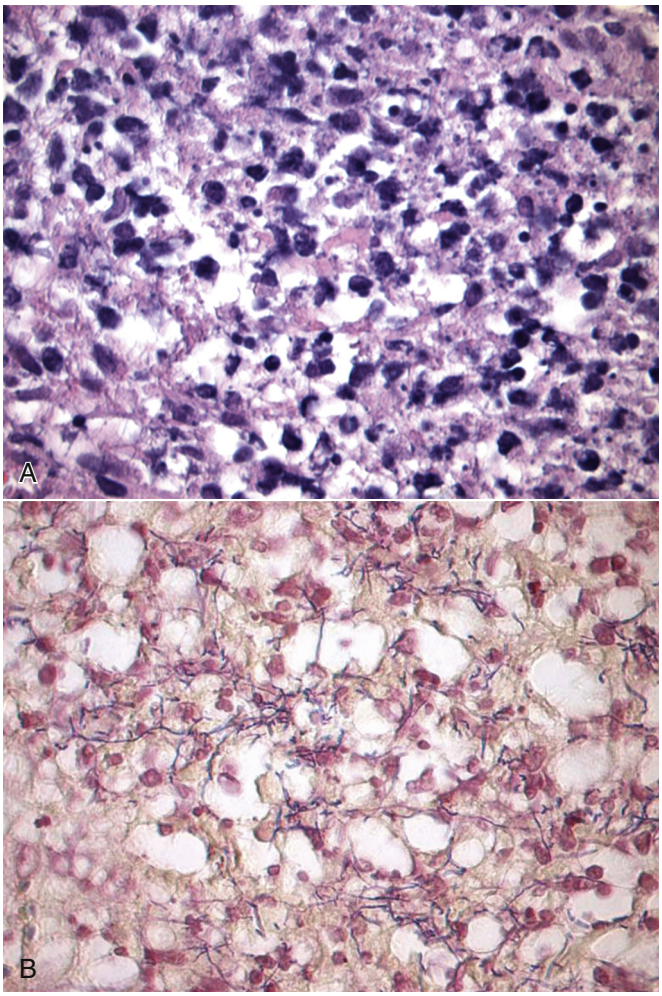

FIGURE 43-5 Histopathologic findings in nocardiosis. **A,** Severe, necrotizing pyogranulomatous inflammation is present with intralesional bacteria, which are barely visible. H&E stain. **B,** Gram staining revealed tangles of filamentous, branching gram-positive bacteria. Brown and Benn stain.

Prognosis

In a review of 53 dogs with nocardiosis, 50% of the dogs died and 39% were euthanized.[24] Of 36 cats with nocardiosis, 16 were either euthanized or died.[8] The high mortality rate may relate to underlying immunosuppressive disease or immunosuppressive

TABLE 43-4

Medications That Could Be Used to Treat Dogs and Cats with Nocardiosis *

Drug	Dose (mg/kg)	Route	Interval (hours)
Trimethoprim-sulfamethoxazole	30	PO, IV	12

†Amikacin and imipenem-cilastatin are generally used in combination with each other or with trimethoprim-sulfamethoxazole.

drug treatment, delayed diagnosis, and inappropriate treatment. With earlier diagnosis and more aggressive, multidrug therapy, mortality of nocardiosis in animals may decrease to the rate reported in people. Only 20% of humans with primary infections died, whereas 42% of patients with predisposing conditions and more than 50% of patients with systemic or CNS nocardiosis died.[19]

Immunity and Vaccination

Immunity to nocardiosis is dependent on intact CMI. There are no vaccines for nocardiosis.

Prevention

Prevention of nocardiosis in cats involves housing cats indoors and limiting their fighting or biting activity. Any wounds should be carefully examined for foreign material and cleaned promptly. Disease in both dogs and cats may be prevented by avoidance of excessive immunosuppression with potent drugs such as cyclosporine.

Public Health Aspects

No cases of human nocardiosis acquired from direct contact with an animal have been reported; however, several cases of cutaneous nocardiosis transmitted to people by cat scratches have been documented.[37-40] Humans with impaired CMI (such as those receiving immunosuppressive drug therapy or those with HIV infection) should wear gloves and practice hand washing after handling pets with nocardiosis, or another individual in the household should treat these animals.

CASE EXAMPLE

Signalment: "Bob," a 6-year-old male neutered domestic shorthair cat from San Francisco, CA

History: Bob, a renal transplant recipient, was evaluated for a 2-week history of decreased activity and progressive inappetence and lethargy. He was taken to a local emergency clinic where blood work showed only mild hyponatremia (130 mmol/L) and a white cell count of 19,000 cells/µL. No abnormalities were detected on abdominal ultrasound examination. Bob was treated overnight with IV fluids and sent home with instructions to administer amoxicillin-clavulanic acid (12.5 mg/kg PO q12h). However, the cat's condition failed to improve, and so he was taken to a local veterinary clinic 3 days later. Further laboratory testing showed hyponatremia, hypoalbuminemia, and mild hyperbilirubinemia. Urinalysis showed a specific gravity of 1.054, 3+ bilirubin, 1+ hemoprotein, 0-2 WBC/HPF, 6-10 RBC/HPF, and no bacteria or casts. Aerobic bacterial urine culture was negative. The following day Bob became tachypneic and pleural effusion was identified. In-house examination of the effusion fluid revealed cloudy fluid that contained large numbers of erythrocytes, degenerate neutrophils, and macrophages. No bacteria were seen with Gram stain. Bob was then referred to the University of California, Davis, Veterinary Medical Teaching Hospital for further evaluation.

Bob had received a renal transplant at 3.5 years of age and since then had been treated with prednisone (0.5 mg/kg PO q12h) and cyclosporine (4 mg/kg PO q12h). A recent whole blood trough cyclosporine concentration was 1100 ng/mL.

Physical Examination:

Body Weight: 5.1 kg

General: Severely obtunded, T = 100.8°F (38.2°C), HR = 240 beats/min, RR = 55 breaths/min, mild generalized icterus, mucous membranes pink to icteric, CRT = 1 s, hydrated.

Eyes, Ears, Nose, and Throat: The only clinically significant abnormalities related to the eyes. Anisocoria was present with the left pupil larger than the right. Direct and consensual pupillary light reflexes were present, and the cornea and anterior chamber were clear with no ocular discharge. Fundoscopic examination showed focal areas of tapetal hyperreflectivity and focal dark and dull lesions with peripheral hyperreflectivity.

Musculoskeletal: BCS 7/9, with generalized weakness, recumbency and unwillingness/inability to walk.

Respiratory: Tachypnea with a shallow respiratory pattern was identified. Decreased lung sounds were present ventrally.

All Other Systems: No clinically significant abnormalities were present. The transplanted kidney could be palpated in the right abdomen. The urinary bladder was small.

Neurologic Examination:

Mentation: Obtunded.

Gait/Posture: The cat had a tendency to lean to the right, but could not or would not walk more than a few steps.

Cranial Nerves: Menace responses were absent bilaterally.

Postural Reactions: Delayed placing reactions were identified in all four limbs.

Spinal Reflexes and Panniculus Reflex: Normal.

Neuroanatomic Location: Cerebrothalamic, possibly right sided.

Laboratory Findings:

CBC:

HCT 30.4% (30%-50%), MCV 46.5 fL (42-53 fL)
MCHC 32.6 g/dL (30-33.5 g/dL)
Reticulocytes 18,000 cells/µL (7000-60,000 cells/µL)
WBC 22,860 cells/µL (4500-14,000 cells/µL)
Neutrophils 19,660 cells/µL (2000-9000 cells/µL)
Band neutrophils 2286 cells/µL
Lymphocytes 457 cells/µL (1000-7000 cells/µL)
Monocytes 229 cells/µL (50-600 cells/µL)
Eosinophils 229 cells/µL (150-1100 cells/µL)
Basophils 0 cells/µL (0-50 cells/µL).

Platelets clumped but adequate. Neutrophils had slight toxic change, and band neutrophils had marked toxic change.

Serum Chemistry Profile:

Sodium 136 mmol/L (151-158 mmol/L)
Potassium 3.5 mmol/L (3.6-4.9 mmol/L)
Chloride 98 mmol/L (113-121 mmol/L)
Bicarbonate 18 mmol/L (15-21 mmol/L)

Continued

VetBooks.ir

Phosphorus 4.3 mg/dL (3.2-6.3 mg/dL)
Calcium 8.3 mg/dL (9.4-11.4 mg/dl)
BUN 48 mg/dL (18-33 mg/dL)
Creatinine 0.8 mg/dL (1.1-2.2 mg/dL)
Glucose 140 mg/dL (73-134 mg/dL)
Total protein 4.8 g/dL (6.6-8.4 g/dL)
Albumin 1.4 g/dL (1.9-3.9 g/dL)
Globulin 3.4 g/dL (2.9-5.3 g/dL)
ALT 19 U/L (28-106 U/L)
AST 27 U/L (12-46 U/L)
ALP 5 U/L (14-71 U/L)
Gamma GT 0 U/L (0-4 U/L)
Cholesterol 141 mg/dL (89-258 mg/dL)
Total bilirubin 1.5 mg/dL (0-0.2 mg/dL).

Imaging Findings:

Thoracic Radiographs: See Figure 43-4. There was a moderate amount of pleural effusion. A mass was associated with the caudal aspect of the left caudal lung lobe. The cardiac silhouette was completely obscured on the lateral projection. On the ventrodorsal projection, there appeared to be a mass effect superimposed over the caudal border of the cardiac silhouette that deformed the left and right caudal lung lobes.

Abdominal Ultrasound: The native kidneys were markedly diminished in size, were irregular in contour, and had a markedly irregular parenchyma with a lack of corticomedullary distinction. The transplanted kidney appeared within normal limits. The muscularis layer of the small intestine was mildly thickened diffusely. A Y-shaped region of mineralization was identified within the right liver lobes, which was likely associated with the biliary system.

Treatment and Outcome: Thoracocentesis was performed, and 35 mL of turbid red fluid was removed. Unfortunately, the cat became progressively more agitated and tachypneic, thoracocentesis was aborted, and Bob was placed in a cage with oxygen supplementation. Preliminary cytologic examination of the fluid yielded results that were consistent with referring veterinarian's findings. Treatment with IV crystalloid fluids (0.9% NaCl with 20 mEq/L KCl at 12 mL/hr), enrofloxacin (2.5 mg/kg IV q12h), and ampicillin (22 mg/kg IV q8h) was initiated, and pleural fluid was submitted to the laboratory for cytologic examination and aerobic and anaerobic bacterial culture. The plan was to stabilize Bob with this treatment until additional thoracocentesis and chest tube placement could be performed. Differential diagnoses considered were cryptococcosis, toxoplasmosis, FIP, a systemic bacterial infection, or neoplasia. However, 10 hours after admission, Bob developed respiratory and cardiac arrest. The owner elected euthanasia.

Necropsy Findings: Gross necropsy findings consisted of 120 mL of flocculent, serosanguinous fluid within the thoracic cavity and multifocal to coalescing, variably sized, white to gray, firm to caseous nodules that largely effaced the caudal lung lobes and extended through the pleural surface, with adhesions to the thoracic diaphragm and pleura (see Figure 43-3, *A*). A 3-mm nodule was also present in the wall of the left ventricle. The peritoneal cavity contained multiple adhesions from the small intestines to the omentum and the stomach to the left abdominal wall. The right medial liver lobe contained a focal, white to gray mass that was 10 cm in diameter and oozed purulent material when cut. The spleen contained multiple, white, raised, pinpoint foci. The native kidneys were shrunken, pale, irregular, and had loss of corticomedullary definition. The right transplanted kidney contained 3-4, tan, firm, homogenous cortical nodules that ranged from 2 to 4 mm in diameter. On cut section, the brain contained multifocal, randomly distributed, soft, white to gray, homogenous foci that measured 1-4 mm in diameter (see Figure 43-3, *B*). Histopathology of the lung, pleural, myocardium, thoracic diaphragm, spleen, liver, transplanted kidney, adrenal medulla, stomach, salivary gland, brain, and meninges revealed chronic, severe, necrotizing pyogranulomatous inflammation with intralesional branching filamentous bacteria. There was also chronic, moderate, multifocal and necrotizing pyogranulomatous choroiditis and cyclitis in both eyes. The bacteria were gram positive but were not acid fast (see Figure 43-5, *B*).

Microbiologic Testing: Aerobic and anaerobic bacterial culture (liver, lung specimens collected at necropsy): Small numbers of *Nocardia nova*. No other bacteria were cultured.

Diagnosis: Disseminated *Nocardia nova* infection

Comments: In this case, nocardiosis followed a rapid clinical course, as can occur in human patients with severe immunodeficiency. The trough whole blood cyclosporine concentration was high; the goal of treatment is to obtain blood concentrations of approximately 300 to 500 ng/mL, although the optimum concentration that achieves adequate but not excessive immunosuppression in cats is not known.[18] Treatment with antimicrobial drugs was not effective given the advanced nature and severity of the disease in this cat.

CHAPTER 44

Mycobacterial Infections

Jane E. Sykes and Danièlle A. Gunn-Moore

VetBooks.ir

Overview of Mycobacterial Infections in Dogs and Cats

First Described: Evidence of tuberculosis in humans dates back to 2400 to 3400 BC, but the causative agent was not demonstrated until 1882 (Robert Koch).[1]

Causes: *Mycobacterium* spp. (order Actinomycetales, family Mycobacteriaceae)

Geographic Distribution: Worldwide, but the distribution of different mycobacterial species varies.

Major Clinical Signs: Cutaneous nodular, ulcerated, or draining skin lesions; peripheral or internal lymphadenopathy; pneumonia with cough and/or tachypnea; osteomyelitis; granulomatous or pyogranulomatous infiltrates in a variety of abdominal organs and, rarely, the central nervous system and eye.

Differential Diagnoses: Neoplasia (especially lymphoma), feline infectious peritonitis (cats), tularemia, nocardiosis, actinomycosis, rhodococcosis, bartonellosis, leishmaniasis, and fungal infections

Human Health Significance: Transmission of mycobacteria from dogs or cats to humans has not been reported. However, the potential for transmission of *M. tuberculosis* and *M. bovis* to humans exists. Humans acquire infection by other mycobacteria from environmental sources.

Mycobacterium spp. are aerobic, nonmotile, non–spore-forming, gram-positive, acid-fast pleomorphic bacilli that cause chronic infections in humans and animals. *Mycobacterium* spp. have a high cell wall mycolic acid content, which causes them to retain a pink color when stained with acid-fast stains such as Ziehl-Neelsen or Kinyoun stains and examined under the microscope. As a result, the term "acid-fast bacilli" (AFB) is often associated with mycobacteria, although *Nocardia* is variably acid fast (see Chapter 43).

Mycobacterium spp. belong to the family Mycobacteriaceae and are grouped into those that belong to the *Mycobacterium tuberculosis* complex (MTBC), the *Mycobacterium avium* complex (MAC), the lepromatous mycobacteria, and nontuberculous mycobacteria other than *M. avium* (Table 44-1). Disease caused by these groups of microorganisms differs in its epidemiology, pathogenesis, clinical presentation, zoonotic potential, and response to antimicrobial treatment. Accordingly, each group is considered separately in this chapter.

Mycobacterium tuberculosis Complex

Etiology and Epidemiology

MTBC bacteria include the slowly growing, host-associated bacteria *Mycobacterium tuberculosis*, *Mycobacterium bovis*, *Mycobacterium microti*, *Mycobacterium africanum*, *Mycobacterium pinnipedii*, *Mycobacterium caprae*, and *Mycobacterium canettii*. These organisms cause tuberculosis in humans and animals. Only *M. tuberculosis*, *M. bovis*, and *M. microti* infect dogs and cats (Table 44-2). *M. africanum* and *M. canettii* are rare causes of human tuberculosis in Africa, *M. pinnipedii* infects seals, and *M. caprae* is primarily a ruminant pathogen. MTBC organisms share greater than 95% DNA-DNA homology, and so are difficult to differentiate from one another, even with many molecular methods. Unlike other mycobacterial species, MTBC bacteria do not survive well in the environment, although *M. bovis* can survive months in feces or carcasses.

Humans are the only reservoir host for *M. tuberculosis*, which is responsible for more than 90% of tuberculosis in humans. Cats are resistant to infection with *M. tuberculosis*. Disease due to *M. tuberculosis* has been reported in dogs that reside in various parts of the United States, Africa, France, and Switzerland.[2-9] Affected dogs from Europe have had travel histories; one was from western Africa and the other was a stray from southern Europe.[2,3] Dogs are usually infected after prolonged aerosol exposure to contaminated human respiratory secretions, so the disease is a "reverse zoonosis" (or *anthropozoonosis*). Thus, disease occurs in dogs where tuberculosis occurs in humans. In the United States, *M. tuberculosis* infection is most prevalent in humans from the northeast/mid-Atlantic states, southern states, Alaska, California, and Nevada (Figure 44-1). Dogs have not transmitted *M. tuberculosis* infection to humans despite prolonged close contact in some situations,[7] possibly because the pulmonary cavitary lesions that are required for transmission do not develop to the same extent in dogs as they do in humans. However, organisms have been detected in dogs' sputum, so transmission remains possible.

Cats are most often infected with *M. microti* or *M. bovis*.[10] Rodents (especially voles and shrews) are reservoir hosts for *M. microti*, and cattle and a variety of wildlife species are reservoir hosts for *M. bovis*. The overwhelming majority of feline infections with *M. microti* and *M. bovis* have been reported from the United Kingdom, where *M. microti* infection is endemic in voles, wood mice, and shrews, and *M. bovis* infection is endemic in Eurasian badgers and cattle. Infections with *M. microti* and *M. bovis* comprise a third of feline infections with culturable mycobacteria in the United Kingdom.[10] Cats infected with *M. bovis* tend to be young adult cats (median age 3 years),

TABLE 44-1

Mycobacterial Pathogens of Clinical Significance in Dogs and Cats

Group	Mycobacterial Species	Description
M. tuberculosis complex	*M. tuberculosis, M. bovis, M. microti*	Host-associated, slow-growing species. Cause cutaneous and disseminated granulomatous disease in dogs (all three species) and cats (*M. bovis* and *M. microti*)
M. avium-intracellulare complex	*M. avium* subsp. *avium, M. avium* subsp. *hominissuis*	Opportunistic, environmental, slow-growing species. Cause cutaneous and disseminated granulomatous disease in dogs (subsp. *hominissuis*) and cats (subsp. *avium*). Some may cause leprosy syndromes in cats.
Lepromatous mycobacteria	*M. lepraemurium,* the CLG organism, and other unnamed species, some with genetic resemblance to known nontuberculous mycobacteria	Highly fastidious or unculturable mycobacteria. Cause nodular granulomatous to pyogranulomatous cutaneous disease in cats (all species) or dogs (CLG organism).
Rapidly growing nontuberculous mycobacteria	*M. fortuitum, M. smegmatis, M. abscessus, M. chelonae, M. thermoresistibile, M. goodii, M. flavescens, M. alvei*	Opportunistic, environmental, rapidly growing species. Cause pyogranulomatous panniculitis, pneumonia, or disseminated infections in cats or dogs
Slowly growing nontuberculous mycobacteria other than *M. avium*	*M. kansasii, M. ulcerans, M. genavense, M. malmoense, M. celatum, M. terrae, M. simiae, 'M. visibile'**	Opportunistic, environmental, slowly growing species. Cause pyogranulomatous cutaneous or disseminated disease in dogs or cats.

CLG, Canine leproid granuloma.
*The exact position of '*M. visibile*' is not clear; it has also been grouped within the lepromatous mycobacteria.

TABLE 44-2

Organisms of the *Mycobacterium tuberculosis* Complex of Clinical Significance in Dogs and Cats

Species	Host(s)	Major Reservoir Hosts	Geographic Distribution of Reported Cases in Companion Animals	Clinical Signs	Human Health Significance
M. tuberculosis	Dogs	Humans	United States, Africa, southern Europe	Pneumonia and tracheobronchial lymphadenopathy; rarely dissemination to the CNS, liver, kidney	Primary cause of tuberculosis in humans. Reverse zoonosis. Transmission back to humans not reported but may be possible.
M. bovis	Cats, rarely dogs	Cattle, Eurasian badgers, other wildlife species	Southwestern England and Wales, New Zealand, Argentina, rarely United States	Cutaneous lesions, peripheral lymphadenopathy, occasionally dissemination to abdominal lymph nodes and other organs, osteomyelitis	Rare cause of tuberculosis in humans but transmission from animals to humans theoretically possible
M. microti	Cats, very rarely dogs	Voles, wood mice, shrews, camelids	Southwestern Scotland, northern and southern England, western Europe	Cutaneous lesions, peripheral lymphadenopathy, less often pneumonia, arthritis, osteomyelitis, ocular lesions	Very rare cause of tuberculosis in humans

whereas the median age of cats infected with *M. microti* is 8 years.[10] All affected cats have been more than 1 year of age, which likely reflects the long incubation period associated with these infections. Retroviral infection does not appear to predispose to infection.

M. bovis infections mainly occur in cats that reside in Wales and southwestern England and that have access to the outdoors (Figure 44-2).[10] Feline *M. bovis* infections also occur in New Zealand, where brushtail possums act as reservoir hosts[11]; Argentina, where stray cats are often fed raw cattle

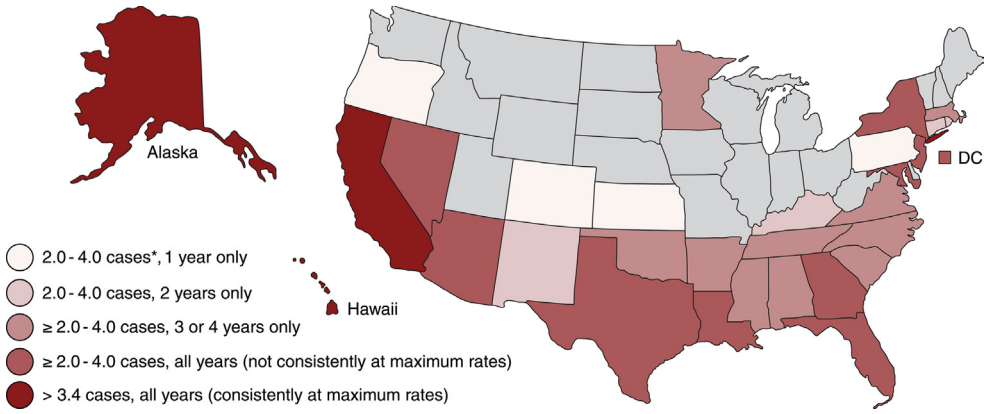

FIGURE 44-1 Geographic distribution of human cases of *Mycobacterium tuberculosis* infection in the United States, 2005-2011. Compiled from Morbidity and Mortality Weekly reports data on trends in human tuberculosis, years 2005, 2007, 2008, 2010, and 2011. *The intensity of the red color reflects the absolute number of cases/year, and whether case numbers were persistently high or varied among the 5 years evaluated. Thus the states that persistently have the highest rates of *M. tuberculosis* infection are Alaska, Hawaii, California, and New York (Long Island).

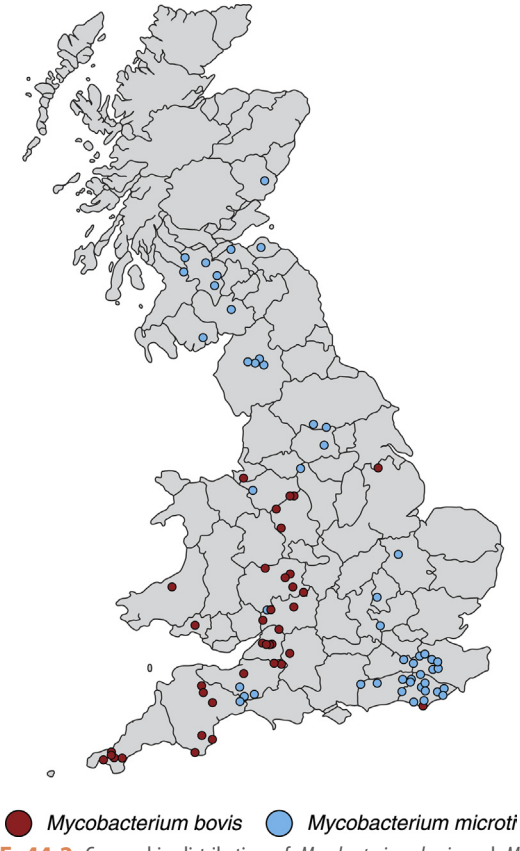

FIGURE 44-2 Geographic distribution of *Mycobacterium bovis* and *Mycobacterium microti* isolates from cats in the United Kingdom. (Redrawn from Gunn-Moore DA, McFarland SE, Brewer JI, et al. Mycobacterial disease in cats in Great Britain: I. Culture results, geographical distribution and clinical presentation of 339 cases. J Feline Med Surg 2011;13:934-944.)

lung[12]; and rarely the United States.[13] In the United Kingdom, spillover of infection from cattle, badgers, and possibly small rodents to cats is suspected. Aggressive interactions between cats and infected badgers may also be a route of transmission, especially as most cutaneous lesions occur at sites where fight and bite wounds often occur.[10,14] Ingestion of unpasteurized milk by cats is no longer a common route of transmission. A study from the United States showed no evidence of transmission of *M. bovis* to cats or dogs that lived on infected cattle farms.[15] Major wildlife reservoirs in North America, which include white-tailed deer, bison, and elk, are less likely than small mammals to interact with cats, which may explain why fewer *M. bovis* infections are reported in cats from North America when compared with the United Kingdom. Dogs are uncommonly infected with *M. bovis*.[16-18] Wounds inflicted by badgers or a squirrel have preceded disease in affected dogs.[16] In recent years, disease in dogs has been restricted to southwestern England or Ireland.

M. microti infections mainly occur in cats with outdoor access from the United Kingdom, with major clusters in southwestern Scotland/northern England and southern England (see Figure 44-2).[10,19] Spillover of disease from voles to cats is suspected.[19] Vole and llama genotypes of *M. microti* have been identified. Cats in the United Kingdom and one in Switzerland have been infected with the vole type.[20] A dog from France was infected with the llama type.[21]

Clinical Features

Signs and Their Pathogenesis

MTBC organisms are inhaled (*M. tuberculosis* and possibly *M. bovis*), ingested (*M. bovis* or *M. microti*), or inoculated into the skin (*M. bovis* or *M. microti*) and replicate locally. Organisms are then ingested by macrophages but survive and replicate within these cells. Macrophage destruction leads to recruitment of lymphocytes and additional monocytes, which initiates tubercle formation. Infected macrophages also travel to local lymph nodes, with development of a *primary complex* lesion. If cell-mediated immunity (CMI) is defective, dissemination to distant sites can occur. Delayed type hypersensitivity (DTH) responses can control the initial infection or may lead to central necrosis and calcification of the primary complex lesions, with persistence of organisms in the center of the lesions.

Clinical signs in dogs with pulmonary tuberculosis due to *M. tuberculosis* are slowly progressive. They consist of chronic, productive, or nonproductive cough, as well as inappetence, weight loss, and lethargy.[4,7] Rarely, dissemination to nonpulmonary sites such as the central nervous system (CNS), liver,

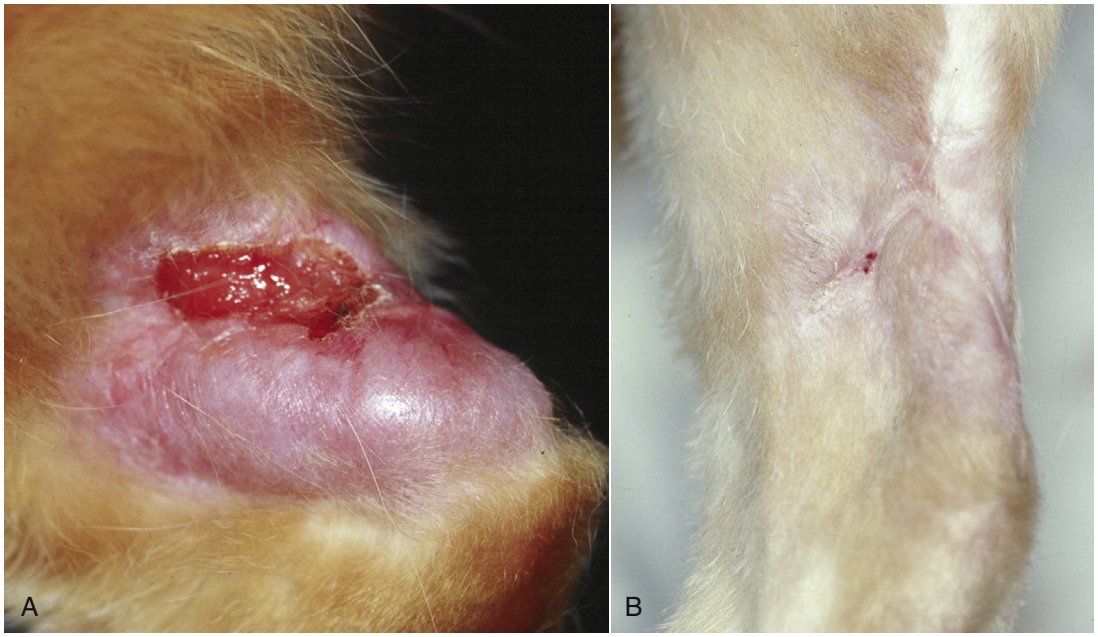

FIGURE 44-3 Ulcerative skin lesion due to *Mycobacterium microti* infection in a 6-year-old male neutered domestic shorthair. **A,** Before treatment. **B,** After 2 months of treatment with a combination of marbofloxacin, azithromycin, and rifampin.

or kidney leads to neurologic signs, weight loss, vomiting, or diarrhea.[2,3,9] Involvement of the lungs, liver, kidneys, and/or lymph nodes can occur in dogs infected with *M. bovis*.[16,18,22] Isolated lung and tracheobronchial node involvement similar to that often reported for *M. tuberculosis* was described in one dog that was infected with *M. bovis*.[18]

Most (>75%) cats infected with *M. bovis* and *M. microti* have had cutaneous nodular lesions with or without mandibular lymphadenopathy. Multifocal peripheral lymphadenopathy may be present.[23] Mesenteric lymphadenopathy, pneumonia, ocular lesions, and arthritis occur in some cats infected with *M. microti*.[20,23-25] Dissemination may result in weight loss, fever, and inappetence. Lung involvement may be associated with tachypnea, dyspnea, or cough.[18]

Physical Examination Findings

Dogs with pulmonary involvement caused by *M. tuberculosis* may show fever, increased lung sounds, and cough. Other physical examination findings that relate to dissemination of infection are present less often, such as thin body condition, neurologic signs, or hepatomegaly. Abnormal findings on examination of the respiratory tract and/or abdominal organs may also be detected in dogs with disseminated *M. bovis* or *M. microti* infection.

The most common physical examination findings in cats (and to a lesser extent, dogs) that are infected with *M. bovis* or *M. microti* are single or multiple firm cutaneous nodules, and enlargement of one or more peripheral lymph nodes (Figures 44-3 and 44-4). Cutaneous nodules may be mobile or fixed to underlying tissues (muscle and bone) and can ulcerate or drain purulent fluid. Skin lesions are most prevalent on the head but can also occur on the limbs and the trunk.[20,23] Enlarged mesenteric lymph nodes, spleen, and/or liver may be detected on abdominal palpation. Involvement of internal lymph nodes is more common with *M. bovis* infections (21% of cats) than with *M. microti* infections (9% of cats).[10] Lameness may be present in cats with skeletal involvement.

FIGURE 44-4 Mandibular lymphadenopathy in a cat infected with *Mycobacterium microti*.

Diagnosis

Diagnosis of MTBC infection relies on suggestive history, clinical signs, and radiographic abnormalities, combined with the results of histopathology, molecular tests, and culture. When mycobacterial infection is suspected, clinical specimens should be divided into portions—one for histopathology (in formalin), one for mycobacterial culture, one for routine cultures for other bacterial species, and one for mycobacterial PCR (fresh or frozen). The laboratory should be informed that mycobacterial infection is a possibility.

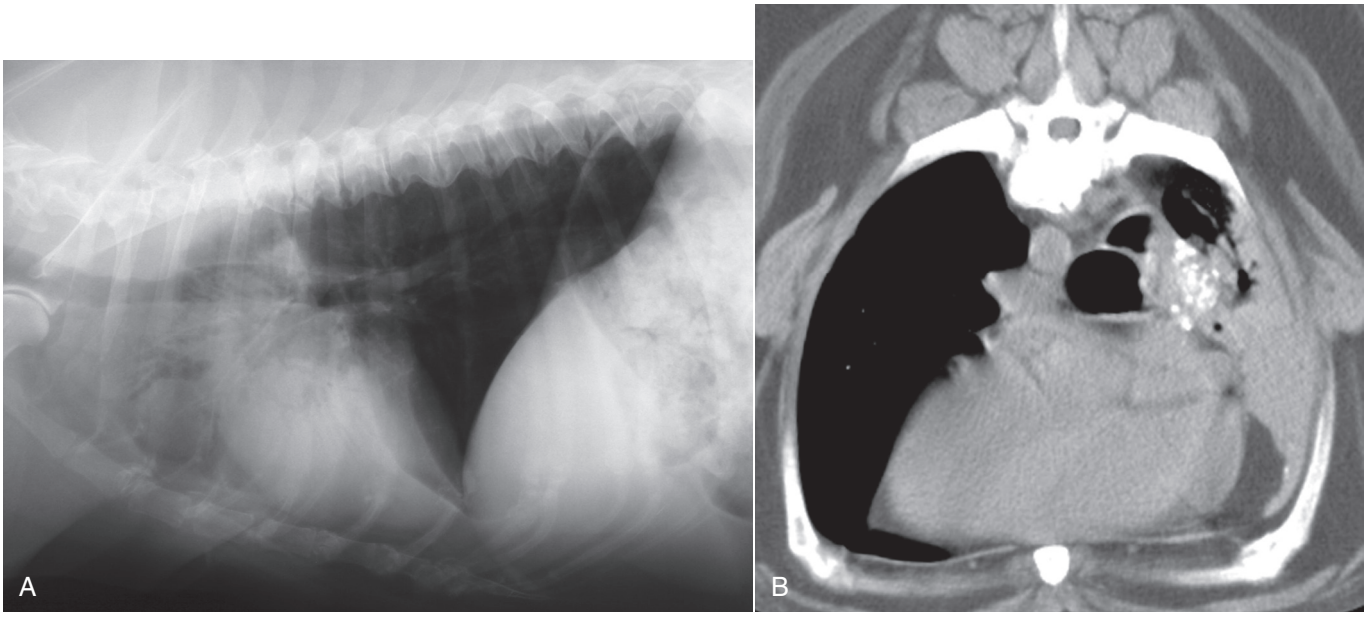

FIGURE 44-5 Lateral thoracic radiograph **(A)** and 7-mm collimated computed tomography (CT) image immediately cranial to the carina **(B)** from a 9-year-old female spayed golden retriever with pulmonary tuberculosis. **A,** Consolidation of the right cranial lung lobe is present together with interstitial to alveolar infiltrates in the right middle lung lobe. **B,** On the CT scan, the right cranial lung lobe is consolidated and markedly volume reduced. Air bronchograms are present centrally that extend dorsally toward a focal region of aerated lung. The granular mineral opacity adjacent to the right margin of the trachea represents mineralized lymphadenopathy of the right tracheobronchial lymph nodes. (From Sykes JE, Cannon AB, Norris AJ, et al. *Mycobacterium tuberculosis* complex infection in a dog. J Vet Intern Med 2007;21:1108-1112.)

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Laboratory abnormalities in dogs and cats infected with MTBC organisms are nonspecific. Mild anemia of inflammatory disease and neutrophilic leukocytosis, sometimes with a left shift, and monocytosis are often present. The serum chemistry profile may show hypoalbuminemia and hyperglobulinemia. Hypercalcemia of granulomatous disease can also occur in dogs or cats.[10,17] Increased serum liver enzyme activities have been reported in dogs with hepatic involvement.[3]

Diagnostic Imaging

Plain Radiography

Findings on plain thoracic radiography in dogs infected with *M. tuberculosis* or *M. bovis* include tracheobronchial or mediastinal lymphadenopathy,[3,4,7] interstitial to alveolar infiltrates,[22] pleural effusion,[3] and lobar consolidation (Figure 44-5, *A*).[7,22] Similar abnormalities can occur in cats infected with *M. microti* and *M. bovis* (Figure 44-6). Bronchial, alveolar, nodular interstitial, and unstructured interstitial patterns predominate in cats, and perihilar lymphadenopathy can be present.[20,26] Calcification of pulmonary lesions or lymph nodes may be evident in dogs or cats. Hepatomegaly, splenomegaly, or lymphadenopathy, with or without ascites, may be present on abdominal radiography, or abdominal radiographs may be unremarkable.[26] Radiographic evidence of osteomyelitis (especially osteolysis) can occur in cats infected with *M. microti* or *M. bovis*, often in association with overlying cutaneous lesions.[26]

Computed Tomography

Thoracic CT findings have been reported for a dog infected with *M. tuberculosis*.[7] Lung lobe consolidation, multifocal stellate opacities, bronchial stenosis, bronchiectasis,

FIGURE 44-6 Pneumonia in a 6-year-old male neutered oriental shorthair with suspected *Mycobacterium microti* infection. Bronchoalveolar lavage revealed pyogranulomatous inflammation, but acid-fast stains were negative. Results of an IFN-γ assay suggested infection by *M. microti*.

VetBooks.ir

TABLE 44-3

Assays Available for Diagnosis of Mycobacterial Infections in Dogs and Cats

Assay	Specimen Type	Target	Performance
Acid-fast staining	Tissue aspirates, buffy coat smears, body fluids, airway lavage specimens, tissues obtained at biopsy or necropsy	Acid-fast bacteria	Insensitive, especially for some mycobacterial species such as MTBC bacteria. Other bacteria, such as *Rhodococcus* and *Nocardia*, may also be acid fast, so positive results are not specific for *Mycobacterium* spp.
Gamma-interferon response assay	Whole blood (peripheral blood mononuclear cells)	Cell-mediated immune response to mycobacterial antigens	Not yet well validated, but show promise for discrimination between *M. bovis* and *M. microti* infections in the United Kingdom. Variable responses to *M. avium*.
Mycobacterial culture	See acid-fast staining; avoid use of aspirates or swabs if possible	Culturable *Mycobacterium* spp.	Some mycobacterial species are unculturable. Growth of MTBC organisms and slowly growing nontuberculous mycobacteria may take weeks to months, and identification requires special expertise. Allows detailed molecular typing and susceptibility testing.
PCR	See acid-fast staining	Mycobacterial DNA	Permits rapid identification of mycobacterial infection and differentiates MTBC from other mycobacteria, so appropriate precautions can be instituted. False-negative results can occur with insufficient specimen size, if there are very few bacteria present, or if degradation of DNA occurs. False-positive results are possible as a result of laboratory contamination.

tracheobronchial wall thickening, and partially mineralized masses consistent with enlarged mediastinal and tracheobronchial lymph nodes were present (Figure 44-5, *B*). In this dog, the mineralization was not visible on plain thoracic radiographs. CT in human patients with tuberculosis is considered more sensitive than plain radiography for detection of pulmonary lesions and enlarged lymph nodes and provides better visualization of calcifications.

Sonographic Findings

Abdominal sonography in animals with MTBC infections may be unremarkable or reveal hepatomegaly, splenomegaly, abdominal lymphadenopathy, and/or ascites. A dog with disseminated *M. tuberculosis* infection had multifocal hypoechoic masses within the kidneys and liver and mineralization of the hepatic and renal parenchyma.[4]

Cytologic Examination

Cytologic examination of aspirates, effusion, or lavage specimens from the respiratory tract of dogs with pulmonary tuberculosis typically reveals a mixed population of often heavily vacuolated histiocytes and smaller numbers of degenerate or nondegenerate neutrophils and small lymphocytes.[3,7,22] Intracytoplasmic, nonstaining bacilli were seen in macrophages in a bronchoalveolar lavage specimen from a dog infected with *M. bovis*.[22] Moderate anisocytosis or anisokaryosis of exfoliated respiratory epithelial cells can be present, which might cause suspicion for pulmonary neoplasia.[7] The presence of cholesterol crystals, caseous debris, and concentrically laminated crystalline structures known as calcospherite bodies can be a clue for the presence of MTBC infection.[7,22]

Microbiologic Tests

Assays available for diagnosis of mycobacterial infections are listed in Table 44-3.

Acid-Fast Stains

Acid-fast stains can be applied to smears or tissue sections for detection of tuberculous mycobacteria. Organisms are faintly beaded bacilli, and are often within macrophages. The presence of AFB suggests mycobacterial infection, but is not specific for infection with MTBC organisms. Acid-fast staining of smears or Cytospin preparations can be insensitive for detection of MTBC organisms, and negative results do not rule out infection.

Immunologic Assays

Intradermal inoculation of tuberculin (a purified protein derivative from *M. tuberculosis*), or the *Mantoux test,* is well validated and widely used in human medicine for diagnosis of, and screening for, infection with MTBC organisms. Infected individuals develop a cutaneous DTH reaction at the site of inoculation 48 to 72 hours later. False-negative test results can occur as a result of underlying immunosuppression. False-positive results occur as a result of nontuberculous mycobacterial infection. Cats do not respond reliably to tuberculin skin testing. In dogs, tuberculin testing has been performed on the medial surface of the pinna, but false-positive results have been documented with a variety of other bacterial infections. Tests for anti-mycobacterial antibodies are also not specific.[27] Cell-based assays (ELISA and ELISPOT), which measure IFN-γ production by patient peripheral blood mononuclear cells in response to specific mycobacterial antigens, have been used for diagnosis of tuberculosis in humans and cattle. These assays have been adapted for use in cats and have the potential to rapidly distinguish infection with

VetBooks.ir

M. bovis from that with *M. microti* when responses to different mycobacterial antigens are compared.[28]

Bacterial Isolation and Identification

Routine aerobic, anaerobic, fungal, and mycoplasma cultures are negative when performed on specimens collected from animals with MTBC infections. Mycobacterial culture is required and is the gold standard for diagnosis of MTBC infection. The use of laboratories with expertise in isolation of MTBC is recommended. Respiratory specimens such as respiratory lavages are usually treated with the mucolytic *N*-acetylcysteine and a sodium hydroxide solution to destroy contaminating bacteria. Specimens from normally sterile sites, such as pleural fluid, are not decontaminated so that viable mycobacteria are preserved as much as possible. Specimens are then inoculated onto special liquid or solid media for isolation of mycobacteria, such as 7H11 agar or Lowenstein-Jensen media (an egg-based medium). Modifications to the media composition may be required on the basis of the mycobacterial species suspected, so good communication between the clinician and the microbiology laboratory can optimize the chance of successful culture. Growth is evident 1 to 3 weeks after inoculation of liquid media, and 3 to 8 weeks after inoculation of solid media. However, inoculation of solid media is still required, because some strains grow only on solid media, and growth on solid media allows assessment of colony morphology. Once growth is evident, nucleic acid–based assays, mycolic acid analysis with high-performance liquid chromatography, or mass spectrometry (MALDI-TOF)[29] can be used to determine whether the organism belongs to the MTBC. Antimicrobial drug susceptibility testing can also be performed.

Currently, performance of a series of phenotypic (biochemical) assays on cultured isolates is the gold standard method for differentiation of mycobacterial species that belong to the MTBC. Molecular techniques such as PCR-restriction endonuclease analysis, DNA probing, and 16S rRNA gene sequencing do not differentiate among MTBC species. Specialized molecular techniques for further typing of MTBC isolates include mycobacterial interspersed repetitive unit-variable-number tandem repeat (MIRU-VNTR) typing and spoligotyping. Spoligotyping is a PCR-hybridization typing method that targets the direct repeat region of MTBC strains. This region contains multiple DNA sequence repeats interspersed with nonrepetitive spacer sequences. MTBC species vary in the numbers of repeats and the presence or absence of some spacers and can be differentiated on the basis of their hybridization patterns. Spoligotyping also allows identification of prevalent *M. tuberculosis* genotypes, such as the Beijing genotype, an aggressive, highly transmissible strain that has been associated with multiple drug resistance. MIRU-VNTR is often combined with spoligotyping for identification of MTBC organisms. Spoligotyping has been performed on several MTBC isolates from dogs and cats.

Molecular Diagnosis Using the Polymerase Chain Reaction

Real-time PCR-based assays are available on a commercial basis in some countries for rapid detection of *Mycobacterium* spp. DNA in clinical specimens from dogs and cats. An understanding of the range of mycobacterial species detected by an assay is of paramount importance for proper interpretation of the results. Genus-specific *Mycobacterium* spp. assays are available, as well as assays that detect mycobacteria other than tuberculosis (MOTT) organisms. These assays can be used in combination to determine whether an MTBC organism is present. A positive result with a genus-specific assay but a negative result with an assay for MOTT organisms implies the presence of an MTBC organism. The results of mycobacterial PCR assays should be interpreted in light of clinical findings, and PCR assays should always be used with mycobacterial culture, which is the only way to confirm the mycobacterial species involved and allows antimicrobial drug susceptibility testing. The latter is important given the public health implications of MTBC infections.

Pathologic Findings

Gross Pathologic Findings

The most frequent gross pathologic findings in dogs infected with *M. tuberculosis* are pulmonary congestion, lobar consolidation, or granulomatous mass formation and sometimes massive enlargement of tracheobronchial and mediastinal nodes. Lymph nodes may contain multifocal gritty, yellow, caseous material.[4,7,22] Pleural effusion may also be present.[3] In dogs with disseminated disease, pale nodular lesions may be found in abdominal organs such the liver, peritoneal surfaces, and kidneys.[2,4,22] In one unusual case, a dog from Africa had nodular lesions that were confined to the liver and brain.[2] Dogs infected with *M. bovis* have abnormalities similar to those infected with *M. tuberculosis*.[16-18] In addition to cutaneous lesions and peripheral lymphadenomegaly, cats with disseminated *M. bovis* or *M. microti* infections may have abdominal lymphadenomegaly and multifocal tumor-like, grayish-white masses within parenchymal organs that can have hemorrhagic margins and/or a soft purulent center. Pulmonary lesions are often grayish red and may be accompanied by serosanguineous pleural effusion.

Histopathologic Findings

Histopathologic findings are similar for all MTBC diseases. Characteristic tubercles or granulomas are present in tissues, which vary in size and may coalesce (Figure 44-7). Tubercles consist of abundant epithelioid macrophages and lesser numbers of neutrophils. Multinucleated giant cells are rarely present in dogs or cats.[4,30] The inflammatory foci are surrounded by a layer of macrophages, neutrophils, lymphocytes, and plasma cells and an outer layer (or background) of granulation tissue. The center of the tubercle may be necrotic. Central mineralization and lipid accumulation occurs in some dogs infected with *M. tuberculosis*,[7,22] but mineralization is rare in cats infected with *M. microti* or *M. bovis*. Acid-fast stains reveal low numbers of AFB in tubercle centers in most cases, but a careful search may be required (Figure 44-8).[4,7]

Treatment and Prognosis

Dogs and cats with suspected MTBC infection should be placed in isolation, and aerosol precautions are indicated (see Chapter 11). Treatment of dogs and cats with MTBC infection is controversial because of concerns that relate to zoonotic potential. It should only be performed after owners have been fully educated about the potential risks of disease transmission. Most affected dogs have been euthanized without specific treatment, but occasionally euthanasia of animals with non-MTBC mycobacterial infection has occurred before a diagnosis of MTBC was confirmed. Combination drug therapy with the antimycobacterial drugs ethambutol, isoniazid, rifampin, and pyrazinamide is used to treat human patients. Ethambutol and isoniazid interfere with mycobacterial cell wall synthesis; the mechanism of action of pyrazinamide is not known, and *M. bovis* is naturally resistant

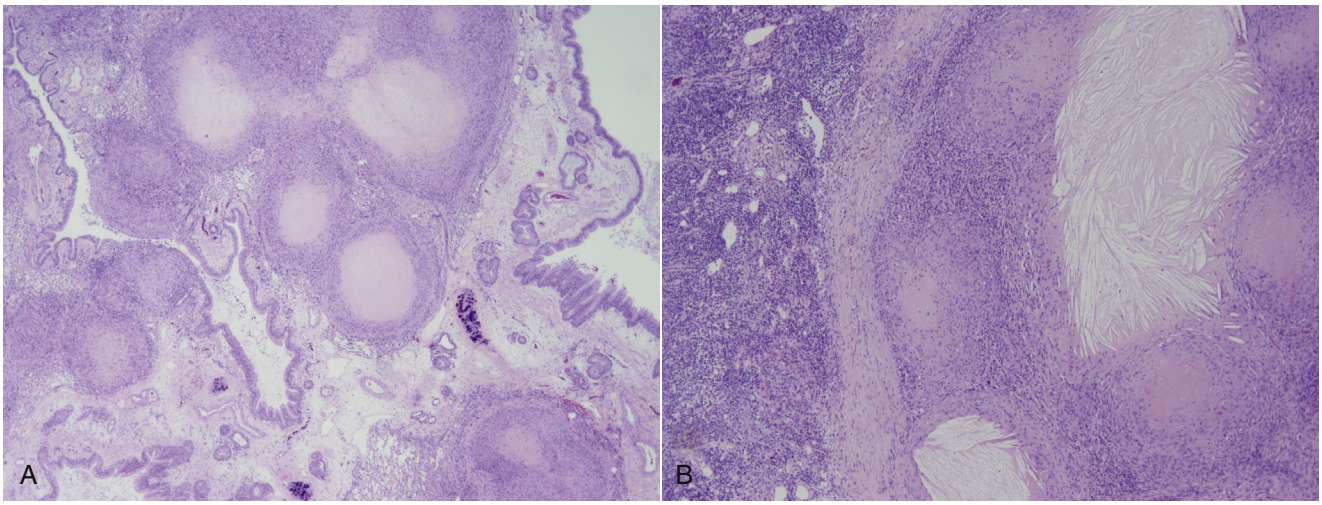

FIGURE 44-7 Multifocal granuloma formation in the lung **(A)** and thoracic lymph node **(B)** of a 9-year-old female spayed golden retriever with pulmonary tuberculosis. The granuloma within the lymph node contains a lake of lipid and necrotic cellular debris, surrounded by an internal layer of epithelioid macrophages, a thick layer of fibrosis, and an external layer of lymphocytes, plasma cells, and histiocytes. Fite and Ziehl-Neelsen acid-fast stains revealed scant numbers of acid-fast positive bacteria in areas of central necrosis (not shown).

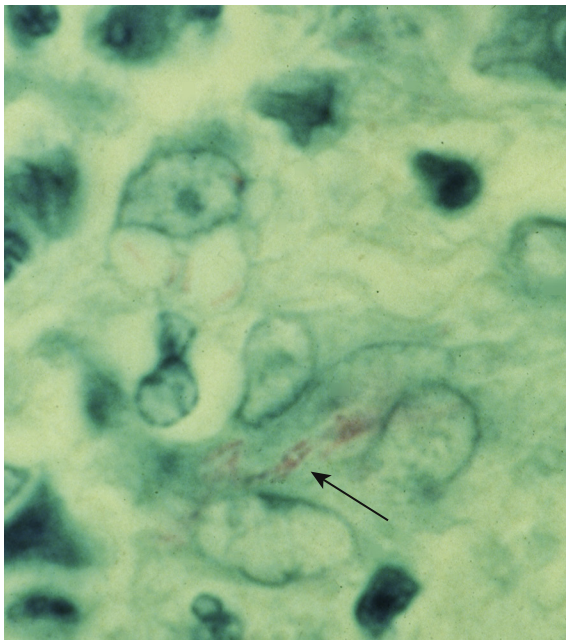

FIGURE 44-8 Rare acid-fast bacteria in a biopsy specimen from a cat infected with *M. microti*.

to it. Treatment of a dog with *M. tuberculosis* infection was attempted with rifampin, isoniazid, and clarithromycin, but the dog was euthanized after seizures developed.[7] The seizures were suspected to be an adverse effect of isoniazid administration.

Successful treatment of cats with cutaneous and/or pulmonary MTBC infections has been achieved with combinations of fluoroquinolones, clarithromycin or azithromycin, doxycycline, and a rifamycin; most successfully treated cases have received a fluoroquinolone, clarithromycin or azithromycin, and a rifamycin (Table 44-4). Surgical excision of small skin lesions can be curative if dissemination is not present, but lesions may dehisce and progress if resection is not complete, and it may not always be possible to determine whether dissemination has occurred. The use of three drugs has been recommended for the first 2 months of treatment (e.g., rifampin, clarithromycin, and a fluoroquinolone), followed by a continuation period with two drugs (usually the macrolide and the fluoroquinolone, because rifamycins are more often associated with adverse effects). Esophagostomy tube placement may be necessary to facilitate treatment and reduce the chance of exposure of the owner to the infection through bite or scratch wounds.

Immunity and Vaccination

There are no vaccines available for prevention of mycobacterial disease in animals.

Prevention

Prevention of *M. tuberculosis* infections in dogs relies on appropriate control and treatment of *M. tuberculosis* infections in affected humans that are in close contact with dogs. Prophylaxis with a single antimycobacterial drug such as isoniazid could be considered for dogs that reside with affected humans, but isoniazid has the potential to cause adverse effects such as seizures in dogs. The possibility of chronic infection by potentially zoonotic pathogens such as *M. tuberculosis* should be considered before stray dogs are adopted from underdeveloped countries.

In cats, prevention of *M. bovis* and *M. microti* infections can be achieved when cats are housed indoors and rodent populations controlled. The feeding of raw cattle or game (e.g., deer, elk) also has the potential to transmit *M. bovis* to dogs or cats and should be discouraged.

Public Health Aspects

Disease caused by MTBC bacteria is usually notifiable to public health authorities. More than 90% of human tuberculosis is caused by *M. tuberculosis*. Only 1% of cases result from *M. bovis* infection, and human infection with *M. microti* is very rare.[31] Factors such as HIV infection, homelessness, and intravenous drug use predispose humans to *M. tuberculosis* infection. Tuberculosis continues to be an important public health problem worldwide and especially in Africa. It is second only to HIV as a cause of death worldwide from a single infectious

VetBooks.ir

TABLE 44-4

Suggested Drug Doses for Treatment of Mycobacterial Infections*

Drug	Dose (mg/kg)	Route	Interval (hours)	Major Adverse Effects in Dogs and Cats
Isoniazid	5-10	PO	24	Hepatotoxicity, seizures. Start at a low dose; do not exceed 300 mg/day. Monitor liver enzymes.
Ethambutol	10-25	PO	48-72	Unknown; neuropathies, especially optic neuritis with visual disturbances occur in humans.
Rifampin	5-10	PO	12-24	Gastrointestinal, hepatotoxicity, orange discoloration of urine, tears, sclera, mucous membranes, feces. Monitor liver enzymes.
Clarithromycin	7.5	PO	12	Rare; hepatotoxicity and gastrointestinal signs possible.
Doxycycline	10	PO	12	Gastrointestinal
Enrofloxacin	5-10 (dogs only)†	PO	24	Gastrointestinal
Marbofloxacin	2.75-5.5	PO	24	Gastrointestinal
Clofazimine	25 mg/cat, 4-8 mg/kg (dogs)	PO	24	Cutaneous photosensitization,‡ orange pigmentation to the skin, gastrointestinal. May be difficult to obtain in some countries.

*See text for recommended drug combinations for each mycobacterial species and additional drugs that may be useful.
†The use of other fluoroquinolones such as marbofloxacin or pradofloxacin is preferred in cats because of the risk of retinal toxicity (see Chapter 8).
‡Bennett S. Photosensitisation induced by clofazimine in a cat. Aust Vet J 2007;85:375-380.

agent,[32] and drug resistance is emerging globally. Over the past 2 decades, case numbers have decreased to the lowest levels in history in the United States.[33] In the United States, the incidence rate is highest among non-Hispanic Asians, non-Hispanic blacks, and Hispanics, which is 25, 8, and 7 times greater, respectively, than the rate for non-Hispanic whites.[33] Disease in immigrants to the United States results from reactivation of disease acquired in other countries.

Public health authorities should be notified if a diagnosis of MTBC infection is made in a dog or cat. An investigation may be performed by these authorities in order to identify the source of infection, and it may be necessary to perform one or more Mantoux tests on individuals with significant contact with infected animals. Although transmission of *M. tuberculosis* from infected dogs to humans has not been reported as a result of direct contact, veterinary staff were infected when a necropsy of an infected dog was performed, possibly following aerosolization of infected brain tissue when the skull was sectioned with an electric saw.[2] Properly fitted high-density surgical masks (N95 masks) should be worn if surgery or necropsy is performed on a dog or cat suspected to have tuberculosis.

Mycobacterium avium Complex

Etiology and Epidemiology

The *Mycobacterium avium* complex (MAC) consists of two closely related species, *M. avium* and *Mycobacterium intracellulare*. There are four subspecies of *M. avium*: *hominissuis, avium, paratuberculosis,* and *silvaticum*. *M. avium* subsp. *hominissuis* causes most human infections. The distribution of subspecies in affected dogs and cats is currently not clear, because molecular methods are required for identification at the subspecies level. *M. avium* subsp. *hominissuis* infections have been identified in several dogs from continental Europe,[34,35] whereas *M. avium* subsp. *avium* was isolated from an affected cat.[36] The DNA of *M. avium* subsp. *paratuberculosis* was detected in intestinal biopsies from dogs with chronic gastrointestinal signs, but the role of this organism in disease was not clear.[37] Unlike MTBC organisms, which are associated with reservoir hosts, MAC organisms are environmental saprophytes with a worldwide distribution. They can be found in soil, dust, and aquatic environments that include showers, faucets, household drinking water, swimming pools, and hot tub spas.[38] The organisms also infect free-living amoebae and form biofilms, which may promote environmental persistence. In the United Kingdom, a spatial cluster of infection has been identified in cats from eastern England.[10] Subclinical infections with *M. avium* subsp. *avium* are common among birds, and *M. avium* subsp. *avium* is the main cause of avian tuberculosis.[39] Ingestion of infected birds or bird feces may be a route of transmission to cats or dogs, but this requires clarification.

MAC organisms cause opportunistic infections in immunocompromised individuals. Most affected dogs and cats are 1 to 5 years of age. In dogs, disease occurs sporadically in any breed, but basset hounds, miniature schnauzers, and possibly Yorkshire terriers may be predisposed, possibly because of an inherited CMI deficiency. In cats, retrovirus infection or treatment with potent immunosuppressive drugs may predispose to MAC infection, although most cats have no identifiable immunodeficiency. Siamese cats as well as Abyssinians and Somalis may be predisposed.[40,41] Disseminated MAC infection has also been reported in feline renal transplant recipients[42,43] and in a cat treated with chemotherapy for lymphoma.[44] Infection is not transmissible from one infected individual to another, but disease may initially be indistinguishable from that caused by MTBC bacteria. In the United States, although still rare, infection of cats and dogs with MAC organisms is more common than infection with MTBC organisms. In the United Kingdom, *M. avium* accounted for only 15% of 159 culturable mycobacterial infections in cats (73% were MTBC infections).[10] The median age of affected cats is 8 years.

FIGURE 44-9 Five-year-old female spayed husky dog with *Mycobacterium avium* lymphadenitis. Swellings in the mandibular region are apparent.

FIGURE 44-10 Digital osteomyelitis in an 8-year-old female spayed Yorkshire terrier dog with *Mycobacterium avium* infection. The first and second phalanges of the fifth digit are destroyed, and there is irregular mineralization within a large soft tissue swelling in this region. There is also moderate soft tissue swelling at the second digit. The third and fourth digits had been previously amputated at the mid-metacarpal bones, which are now fused at their distal aspect.

Clinical Features

Signs and Their Pathogenesis

Disease due to MAC organisms occurs when organisms in soil, water, or dust are inhaled, ingested, or inoculated into skin wounds in the face of host immunocompromise. Disseminated infection often leads to nonspecific signs such as fever, lethargy, inappetence, and weight loss, together with signs that relate to specific organ involvement. In cats, disease resembles that caused by *M. bovis* or *M. microti,* with cutaneous lesions (especially on the head and limbs) in some cats, osteomyelitis, pulmonary involvement with tachypnea or cough, peripheral and abdominal lymphadenomegaly, and gastrointestinal, liver, splenic, renal, omental, and uncommonly CNS or marrow involvement.[41,42,44-50] Gastrointestinal involvement may initially manifest as weight loss despite a good appetite.[41]

Dogs with MAC infections often develop marked peripheral or abdominal lymphadenopathy, tonsillar enlargement, hepatosplenomegaly, and/or osteomyelitis. In some dogs, mandibular or cervical lymphadenopathy may be so severe that respiratory distress and dysphagia occur (Figure 44-9).[51] At necropsy, AFB and associated inflammatory lesions may also be found in the small and large intestines, liver, spleen, lung and pleura, bone marrow, and rarely the spinal cord.[34,52-56] Involvement of the gastrointestinal tract may lead to chronic vomiting, diarrhea, hematochezia, melena, inappetence, and weight loss. Intestinal rupture in one dog led to bacterial peritonitis. Even though inflammatory lesions with intralesional AFB have been detected in the lung at necropsy, pulmonary involvement is not a prominent clinical feature of MAC infections in dogs, which may help to distinguish the disease from *M. tuberculosis* infection.

Physical Examination Findings

Physical examination of cats with MAC infections may reveal fever, a thin body condition, cutaneous lesions similar to those described for MTBC infection, peripheral or abdominal lymphadenopathy, renomegaly, hepatomegaly, tachypnea, and/or increased lung sounds. Rarely, neurologic signs such as nystagmus occur.[41] In dogs, low-grade fever, a thin body condition, dehydration, mucosal pallor, tonsillar enlargement, lymphadenomegaly (especially of the mandibular or abdominal nodes), hepatosplenomegaly, and/or abdominal pain may be found. Melena or hematochezia may be detected on rectal examination. Osteomyelitis may be associated with lameness or mass lesions in association with underlying bone involvement (Figure 44-10). A dog with spinal cord involvement had pelvic limb paresis.[53]

Diagnosis

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Findings on routine laboratory tests in dogs and cats with MAC infections are similar to those described for MTBC infection. Most affected dogs or cats have had mild to moderate nonregenerative anemia, neutrophilia with bandemia, lymphopenia, hypoalbuminemia, hyperglobulinemia or hypoglobulinemia, and sometimes hypercalcemia, hyperbilirubinemia, and increased liver enzyme activities.[48,54,57] An absence of hematologic or biochemical abnormalities has also been described.

Diagnostic Imaging

Plain Radiography

When radiographic abnormalities are present in cats infected with *M. avium*, they often consist of diffuse interstitial or bronchointerstitial pulmonary patterns.[41,48] Diffuse interstitial patterns may be present in the absence of clinical signs of respiratory involvement. Thoracic lymphadenopathy or mediastinal

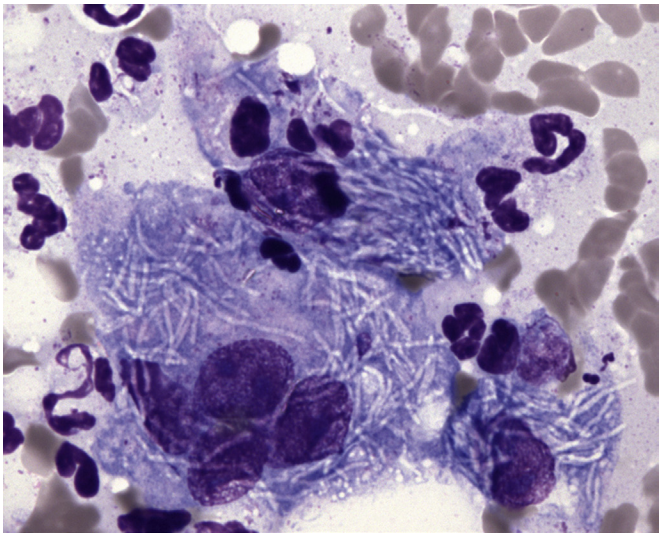

FIGURE 44-11 Aspirate cytology from a cutaneous mass in a cat that developed after prolonged (>1 year) treatment with cyclosporine. Large numbers of negatively stained mycobacterial organisms are present. (Image courtesy Dr. William Vernau, University of California, Davis Veterinary Clinical Pathology Service.)

masses may be present in dogs.[35] Abdominal radiographs may show abdominal masses or hepatosplenomegaly in both dogs and cats. Radiographs of affected bone may reveal soft tissue swelling and bony lytic lesions or periosteal proliferation (see Figure 44-10).

Sonographic Findings

Abdominal sonography in animals with MAC infections may be unremarkable or reveal hepatomegaly, splenomegaly, hypoechoic nodules within the liver or spleen, intestinal wall thickening, hyperechoic mesentery, or enlarged, hypoechoic, or heteroechoic abdominal nodes.[58]

Cytologic Examination

Cytologic examination of aspirates from lymph nodes, abdominal organs, or respiratory lavage specimens from cats or dogs with *M. avium* infection reveals large numbers of histiocytes with nonstaining intracellular bacteria (Figure 44-11) and lower numbers of neutrophils.

Microbiologic Tests

For assays available for diagnosis of mycobacterial infections in dogs and cats, see Table 44-3.

Acid-Fast Stains

Application of acid-fast stains to smears or tissue sections can be used to identify MAC organisms in clinical specimens. In general, AFB are identified more readily in MAC infections when compared with MTBC infections, and most reports of affected dogs and cats report the detection of organisms in cytology specimens stained with acid-fast stains.

Bacterial Isolation and Identification

See the previous discussion of MTBC infection for information on mycobacterial culture. Like MTBC organisms, MAC organisms grow slowly in culture. Up to 6 weeks of incubation may be required for visible growth. MAC species are then identified using commercial DNA probe-based assays or PCR analysis. Subspecies determination requires specialized typing techniques such as IS*1245* restriction fragment length polymorphism typing, MIRU-VNTR, or the use of PCR assays that detect gene fragments present in some *M. avium* subspecies but not others.[34,36,59]

Molecular Diagnosis Using the Polymerase Chain Reaction

See the previous discussion of MTBC infection for information on mycobacterial PCR assays.

Pathologic Findings

In general, pathologic findings in cats or dogs with MAC infection consist of focal, multifocal, or generalized lymphadenomegaly (up to 5 cm in diameter), and nodules in the spleen, liver, lungs, omentum, intestinal wall, and occasionally the kidneys. Nodules are white, gray, or yellow and may be caseous on cut section. Gastrointestinal mucosal hemorrhage may be evident in dogs.[54]

Histopathology in MAC infections typically reveals large numbers of histiocytes and lesser numbers of neutrophils, which in some cases surround necrotic foci. Multinucleated giant cells are rarely seen, and mineralization has not been described. Moderate to large numbers of AFB are usually present within histiocytes (Figure 44-12).

Treatment and Prognosis

Treatment of MAC infections in dogs or cats is challenging, but apparent cure has been reported in a few cats.[36,41,48] As for infection with MTBC organisms, the use of two or three drugs in combination is recommended to prevent emergence of resistance. The availability of macrolides (especially clarithromycin) has greatly improved outcome for human patients with MAC infections, so inclusion of clarithromycin or azithromycin is important. The currently recommended treatment for humans with MAC infections consists of a rifamycin, ethambutol, and a macrolide such as clarithromycin. Treatment of a dog with a combination of drugs that did not include a macrolide was unrewarding.[51] Various combinations of clarithromycin, clofazimine, doxycycline, rifamycins, and fluoroquinolones have been used to treat affected cats (see Table 44-4). Clofazimine is an antimycobacterial drug with an unknown mechanism of action. In human patients, it has primarily been used to treat lepromatous or rapidly growing opportunistic mycobacteria, but may have some activity against MAC organisms. It may be difficult or impossible to obtain in some countries.

Public Health Aspects

Like dogs and cats, humans acquire MAC infections from the environment; direct transmission from animals to people has not been described. Ownership of caged birds by immunocompromised humans has been discouraged in the past because of the potential that these birds might shed MAC organisms. However, human disease is caused by *M. avium* subsp. *hominissuis* and not the avian organism (subsp. *avium*), so the feces of caged birds may not represent a significant source of infection. Three clinical forms of MAC disease occur in people: localized pulmonary disease (which includes "hot tub lung disease," a hypersensitivity pneumonitis), cervical lymphadenitis, and disseminated disease.[60] Disseminated disease occurs most often in HIV-infected humans, but children with congenital

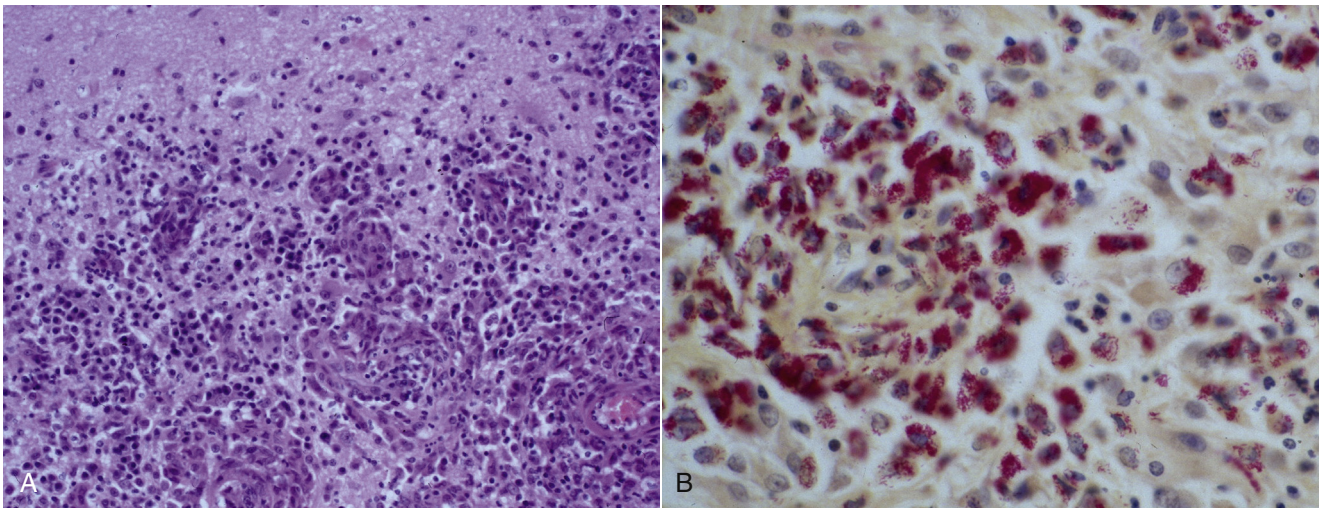

FIGURE 44-12 **A,** Granulomatous inflammation in the brain of a 10-year-old male neutered Siamese mix cat with disseminated *Mycobacterium avium* infection. H&E stain. **B,** Section from the same cat stained with Ziehl-Neelsen (acid-fast) stain. There are large numbers of intracellular acid-fast bacteria.

immunodeficiencies can also be affected. Prophylactic antimycobacterial drug treatment is recommended for HIV-infected humans with CD4+ T cell counts that are less than 50 cells/mm^3.[60] Cervical lymphadenitis is an uncommon disease of children less than 3 years of age.

Although transmission of MAC organisms from diseased dogs and cats to humans should not, in theory, occur by direct contact, it may not be possible to distinguish infection with *M. avium* from infection with MTBC organisms (especially *M. bovis*) based on clinical presentation. Thus, in regions where *M. bovis* infections occur, animals suspected to have MAC infections should be isolated until the results of PCR assays confirm MAC infection. Cytologic or histopathologic evidence of large numbers of organisms also suggests MAC as opposed to MTBC infection. Veterinary staff should take care to avoid needle-stick injuries or cutaneous inoculation when collecting specimens (such as lymph node aspirates) from dogs and cats with *M. avium* infections because of the possibility that disease might occur after cutaneous inoculation. Sedation is recommended whenever lymph node aspiration is indicated for an animal with an unknown cause of lymphadenopathy. When mycobacterial disease is suspected, care should also be taken not to aerosolize tissues at necropsy (as occurs with electric saws).

Lepromatous Mycobacteria

Etiology and Epidemiology

Lepromatous mycobacteria are highly fastidious or unculturable mycobacteria that cause nodular cutaneous lesions in dogs or cats. Feline leprosy is caused by *Mycobacterium lepraemurium* and probably several other mycobacterial species. In fact, with the recent discovery of these other mycobacterial species, localized nodular cutaneous disease in cats caused by MAC organisms, or organisms that resemble other nontuberculous mycobacteria (NTM), has fallen under the general heading of feline leprosy syndromes.[61-63]

Feline leprosy has been described in the Netherlands, the United Kingdom, the United States, western Canada, Australia, New Zealand, Italy, and Greece. Affected cats range in age from 1 year to 14 years and are often from rural or semirural environments. Inoculation of organisms into the skin through rodent bites or cat fight wounds is the suspected mode of transmission.

Disease in dogs is known as canine leproid granuloma syndrome (CLGS). It has mainly been reported from the western United States and coastal regions of Australia.[64-66] The organism that causes CLGS has only been partially characterized by the use of PCR sequencing. It has never been isolated in culture and does not yet have a Latin name, but is often referred to as the "CLG organism." A similar, and possibly the same, organism has also been detected using PCR in cats with leprosy.[63] Boxer dogs or their crosses are predisposed, and possibly also German shepherd dogs.[65,66] The mode of transmission to dogs is unknown. Transmission by biting insects has been hypothesized because most lesions occur on the pinnae and head.

Clinical Features

Lepromatous mycobacteria cause single or multiple nodular cutaneous or subcutaneous lesions, which may ulcerate. In cats, lesions are usually on the head or forelimbs, but can also occur at other body sites. Affected cats are usually systemically well. Two pathologic variants of feline disease have been described.[62,63] The first form, "tuberculoid feline leprosy," is characterized by multifocal to coalescing pyogranulomas with central caseous necrosis, as well as increased numbers of lymphocytes and plasma cells in the dermis and panniculus. Multinucleate giant cells may or may not be present, and acid-fast stains reveal variable numbers of AFB, primarily in regions of necrosis. The second form, "lepromatous feline leprosy," is characterized by pyogranulomatous dermatitis and panniculitis with sheets of epithelioid macrophages and neutrophils, moderate to abundant multinucleate giant cells, and large numbers of AFB with minimal necrosis. Organisms that resemble *M. lepraemurium* can be detected in both these clinical forms, whereas the CLG organism has only been detected in cats with the tuberculoid form.[63] The distribution of histopathologic types may vary geographically.

In dogs, CLGS is characterized by the development of firm cutaneous nodules that range in diameter from millimeters to several centimeters. Larger lesions may ulcerate. Most lesions are found on the pinnae, but they may also be found on the head, muzzle, forelimbs, and trunk (Figure 44-13). Histopathology

VetBooks.ir

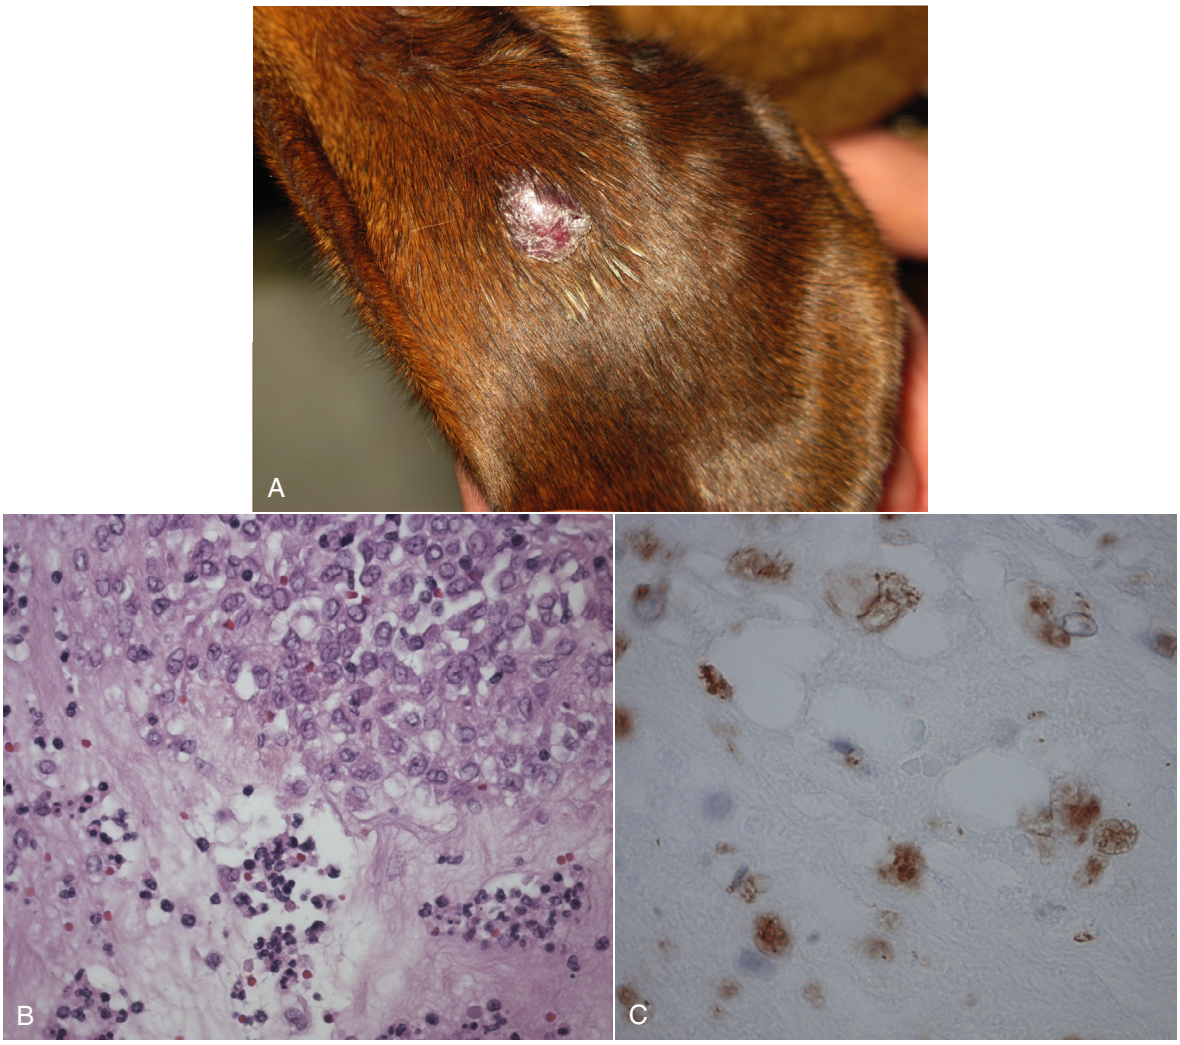

FIGURE 44-13 **A,** Pinna of a 5-year-old male neutered boxer dog with CLGS. A crusted lesion was present that measured 1 × 2 cm in diameter. **B,** Histopathology of CLGS lesions reveals pyogranulomatous inflammation. **C,** A BCG immunostain (brown) identified the presence of intracellular *Mycobacterium* spp. organisms.

reveals coalescing accumulations of histiocytes and neutrophils, with fewer numbers of lymphocytes and plasma cells.[64,66] Multinucleate giant cells may be present, and there may be large numbers of intracellular AFB.

Diagnosis

Diagnosis of leproid syndromes is based on the presence of typical skin lesions, absence of signs of dissemination or systemic illness, suggestive cytologic and histopathologic findings, negative mycobacterial culture results, and positive 16S rRNA gene PCR assay results where PCR assays are available. Cytologic examination of fine-needle aspirates usually reveals pyogranulomatous inflammation with intracellular, negatively stained bacteria, which subsequently stain with acid-fast stains. Sequence analysis of PCR products that are generated from biopsy specimens is required to determine the likely species present.

Treatment

Treatment of feline leproid lesions with a combination of clofazimine and clarithromycin is often successful (see Table 44-4). Wide surgical excision could be considered for small, localized lesions, but has the potential to be followed by dehiscence and extension of disease. If necessary, antimicrobial drug treatment for several weeks followed by surgery may be most successful. In dogs, granulomas may resolve spontaneously within 1 to 3 months. In dogs with progressive or widespread CLGS, a combination of clarithromycin and a rifamycin may be effective.[67]

Prevention and Public Health Aspects

Mycobacterial organisms that cause canine and feline lepromatous disease are not transmitted directly to humans. However, lesions may resemble those caused by *M. microti* and *M. bovis*, so where these diseases are endemic, precautions should be taken until a causative organism is identified with molecular methods.

Nontuberculous Bacteria Other Than *Mycobacterium avium-intracellulare*

Etiology and Epidemiology

NTM species include a variety of opportunistic, environmental mycobacteria that have been classified based on their rate

VetBooks.ir

TABLE 44-5

Cutaneous and Disseminated Disease in Dogs and Cats Caused by Slow-Growing Opportunistic Nontuberculous Mycobacteria

Mycobacterial Species	Species Affected	Clinical Abnormalities	Geographic Location
M. kansasii	Dog	Chronic pleural effusion with pulmonary arterial and pleuroperitoneal shunt infection	North Carolina, USA[83]
M. simiae	Cat	Disseminated disease with generalized lymphadenopathy, lung and skin involvement, and granulomatous chorioretinitis	Switzerland[84]
M. genavense	Cat (FIV+)	Disseminated disease with involvement of lungs, liver, lymph nodes, skin, kidney, spleen	New South Wales, Australia[85]
	Dog	Disseminated disease with involvement of lymph nodes and possibly liver and spleen	New York, USA[86]
M. xenopi	Cat	Cutaneous lesion	Australia[87]
	Cat	Disseminated disease with kidney, lymph node, pancreatic, and marrow involvement	Florida, USA[88]
	Cat	Disseminated disease with lymphadenopathy, gastrointestinal involvement, and ascites	Wisconsin, USA[89]
M. xenopi-like	Cat (FIV+)	Tracheal granuloma	Italy[90]
M. ulcerans	Dog	Cutaneous ulcerating lesions on distal limbs or tail base	Victoria, Australia[91]
	Cat	Mass on nasal bridge	Victoria, Australia[92]
'*M. visibile*' (originally '*M. visibilis*')	Cat	Cutaneous and disseminated disease with involvement of the eyes, skeletal muscle, and a variety of other organs except the liver and kidneys	Western Canada and United States[93]
M. malmoense	Cat	Cutaneous involvement	United Kingdom[10]
M. celatum	Cat	Cutaneous involvement and fever	United Kingdom[10]
M. terrae	Cat	Cutaneous involvement	United Kingdom[94]

of growth in culture (rapid, intermediate, or slow) (see Table 44-1). They are found in soil and a variety of water sources and cause cutaneous, pulmonary, or disseminated disease in dogs and cats. Rapidly growing mycobacteria (RGM) grow in culture within 7 days and include several groups of organisms to which *M. fortuitum, M. septicum, M. abscessus, M. chelonae, M. smegmatis, M. thermoresistibile, M. goodii,* and *M. mucogenicum* belong. Slowly growing mycobacteria require more than 7 days (and sometimes many months) before significant growth occurs in culture. Other than MAC organisms, examples include *M. kansasii, M. terrae, M. xenopi, M. ulcerans, M. malmoense, M. simiae,* and *M. genavense*.

Rapidly Growing Mycobacteria

RGM are responsible for the vast majority of cutaneous mycobacterial disease in cats in the United States and Australia, but infections have also been described in the United Kingdom, Canada, western Europe, and New Zealand. The most commonly isolated species in both the United States and Australia are *M. fortuitum* and *M. smegmatis*, but infections with other RGM also occur (see Table 44-1).[68-71] These organisms have a tropism for adipose tissue, and when inoculated into the skin by means of cat fight injuries (bites or scratches) or other penetrating wounds (and rarely surgical wounds),[72] mycobacterial panniculitis develops. Most affected cats are female spayed cats. Underlying immunosuppressive disease is usually not present. Cutaneous disease occurs less often in dogs and results from infection with *M. fortuitum, M. smegmatis, M. abscessus*, or *M. goodii*.[72-75] No age, breed, or sex predisposition has been recognized, but most dogs are in good body condition or obese. Some dogs have a history of bite wounds or trauma.[73] Concurrent hyperadrenocorticism was described in one dog.[75]

M. fortuitum can cause pulmonary disease in dogs[76-79] as well as bacteremia.[72] Lipoid mycobacterial pneumonia rarely occurs in cats and may arise in association with lactulose or paraffin treatment for furballs.[80] Pneumonia was also described in a cat infected with *M. thermoresistibile*.[81] Disseminated RGM infections are very rare. Disseminated disease that resembled MAC infection was described in a basset hound infected with *M. smegmatis*.[82]

Slowly Growing Mycobacteria

A variety of slowly growing mycobacteria cause cutaneous or disseminated disease in dogs and cats that resembles disease caused by MAC organisms (Table 44-5).[83-94] These include the known human pathogens *M. kansasii, M. simiae, M. genavense, M. xenopi, M. celatum, M. malmoense, M. terrae*, and *M. ulcerans*. Some, but not all affected cats have been infected with FIV, and one cat had CD4+ lymphopenia.[88] *M. ulcerans* causes ulcerative skin lesions in humans, cats, or dogs in certain parts of Australia.

Clinical Features

Rapidly Growing Mycobacteria

In cats, mycobacterial panniculitis occurs most often in the inguinal fat pad, but lesions may also be found elsewhere

VetBooks.ir

on the lateral abdomen, perineum, dorsum, and pelvic limbs (Figure 44-14). The subcutis becomes thickened and adheres to the dermis, after which nodular and draining skin lesions develop. The majority of affected cats are otherwise well; the development of systemic illness is rare. In dogs, nodular lesions or nonhealing wounds with draining tracts often occur in the inguinal region, cervical region, and/or other proximal body locations.

Pneumonia due to RGM generally results in signs of fever, lethargy, decreased appetite, cough, and tachypnea, with increased lung sounds on thoracic auscultation. Thoracic radiographs frequently reveal lung lobe consolidation and alveolar patterns. In the cat with *M. thermoresistibile* pneumonia, extensive pulmonary mineralization developed.[81] The dog with disseminated *M. smegmatis* infection had granulomatous hepatitis and lymphadenitis.

Slowly Growing Mycobacteria Other Than MAC

Clinical features of slowly growing mycobacterial infections other than MAC infections have varied from one case to another and are summarized in Table 44-5. Animals with disseminated disease can have clinical abnormalities that are indistinguishable from those caused by *M. avium*.

Diagnosis

Diagnosis of RGM infection is usually based on the presence of consistent clinical abnormalities, and the results of cytology, histopathology, and mycobacterial culture (see Table 44-3). Cytologic examination of fine needle aspirates or lavage specimens generally reveals pyogranulomatous inflammation. However, airway lavage fluid from a dog with *M. fortuitum* pneumonia contained mostly neutrophils.[76] Heavily vacuolated macrophages and lipid vacuoles may be present in aspirates from animals with panniculitis. Organisms may or may not be visible with routine stains or acid-fast stains. Histopathology shows pyogranulomatous inflammation without tubercle formation or necrosis. Large lipid vacuoles that contain acid-fast bacilli may be present. Although molecular assays are often used for speciation, direct use of PCR assays on clinical specimens is often not required for diagnosis because RGM grow readily on routine culture media (blood agar). Culture also allows subsequent antimicrobial drug susceptibility testing to be performed at specialized facilities.

Cytology and histopathology findings for slow-growing NTM are similar to those for MAC infections. Diagnosis of slow-growing mycobacterial infection requires specialized mycobacterial culture or the use of PCR assays. *M. xenopi* requires culture at higher temperatures (42°C to 44°C), whereas other mycobacterial species require lower temperatures (28°C or 30°C). Organisms such as *M. genavense* and *M. ulcerans* can be difficult to grow on solid media, and so molecular methods may be required to identify these species.

Treatment and Prognosis

Treatment options for RGM infections include doxycycline, fluoroquinolones, clarithromycin, aminoglycosides, sulfonamides, or carbapenems (see Table 44-4 and Chapter 8). Many cutaneous and pulmonary infections respond well to treatment with doxycycline, aminoglycosides, and/or a fluoroquinolone.[74-78] Multidrug-resistant isolates are more difficult to treat; moxifloxacin, pradofloxacin, or linezolid could be considered when other treatment options are not possible.[95] As for lepromatous

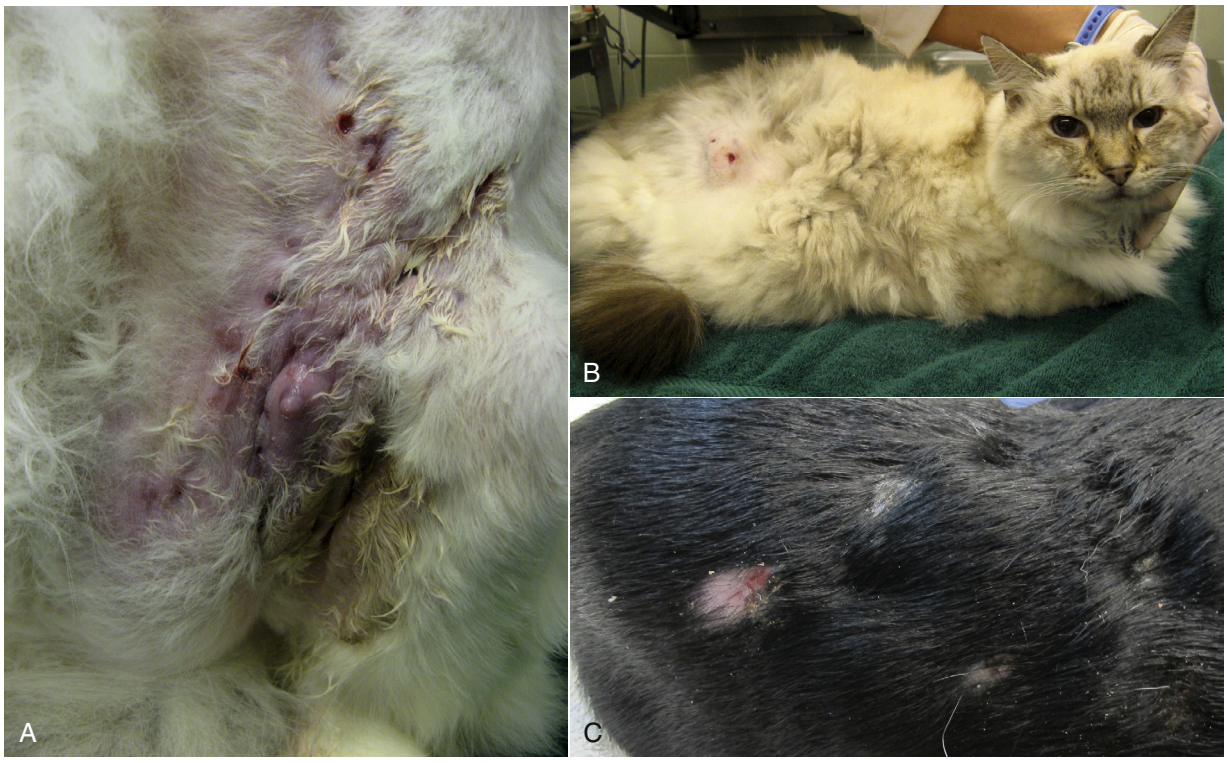

FIGURE 44-14 Cutaneous-subcutaneous infections with rapidly-growing mycobacteria. **A** and **B,** Thirteen-year-old male neutered Siamese cat with mycobacterial panniculitis. There are multiple nodular lesions in the inguinal region **(A)** and lateral flank and dorsal lumbar regions **(B)**. In this cat, lesions progressed slowly over 8 years despite treatment with antimicrobial drugs. **C,** Dorsum of an 8-year old dachshund mix with a multidrug resistant *Mycobacterium abscessus* infection. Multiple draining wounds and extensive scarring are present.

VetBooks.ir

disease, surgical excision of cutaneous lesions is often followed by dehiscence and progression if resection is not complete. However, radical surgical excision by an experienced surgeon could be considered after antimicrobial drug treatment if lesions reduce in size but fail to resolve. Intraoperative treatment of affected cats with an aminoglycoside has been suggested.[96] Treatment should continue for 2 months beyond complete resolution of the lesions and is generally required for at least 4 to 12 months.

M. ulcerans infections generally respond to monotherapy with clarithromycin or a fluoroquinolone.[91,92] For animals with slowly growing mycobacterial infections, options similar to those used to treat MAC infections are indicated—that is, combinations of clarithromycin, a rifamycin, and a fluoroquinolone. In human patients, *M. kansasii* infections are treated with rifampin and ethambutol, with or without isoniazid.[97] The prognosis for disseminated infections in dogs and cats appears to be guarded to poor.

Public Health Aspects

NTM are opportunistic, environmental mycobacteria that are not usually transmitted from animals to humans. Disease in humans resembles that in dogs and cats. Localized cutaneous and soft tissue infections with NTM have occurred after traumatic wounds and lacerations, including after dog and cat bites.[98-100] Infections with RGM can occur after surgical procedures such as liposuction, LASIK surgery, and acupuncture.[97] Catheter-related infections have also been described. Disseminated disease caused by NTM almost always occurs in humans with HIV infection or other immunosuppressive illness or drug therapy.

CASE EXAMPLE

Signalment: "Sarah", a 5-year-old female spayed husky dog from Santa Cruz in coastal northern California

History: Sarah was evaluated for a 1-month history of protrusion of the anus, swelling of the neck, progressive lethargy, and inappetence. She had been diagnosed with zinc-responsive dermatitis 3 years prior, and symmetrical lupoid onychodystrophy 6 months prior. There were two other dogs and three cats in the household, none of which were unwell. The dogs lived in a suburban household and occasionally traveled to southern California, and were normally fed a commercial dry maintenance dog food. There was no known history of tick or toxin exposure or interactions with other wildlife or domestic farm animal species. The owner was a white non-Hispanic male who had been sick for some months. His doctor believed he had acquired the illness from Sarah.

Current Medications: Zinc (2.5 mg/kg q12h PO), tetracycline (25 mg/kg q12h PO), niacinamide (25 mg/kg q12h PO), fish oil capsules (1 capsule PO q12h), and vitamin E (20 IU/kg PO q12h) for the zinc-responsive dermatitis and onychodystrophy. Fipronil with S-methoprene was used for flea and tick control on a monthly basis.

Physical Examination:

Body Weight: 20 kg

General: Quiet to lethargic, hydrated, responsive, preferred to lie down but was ambulatory. T=102.9°F (39.4°C), HR = 140 beats/min, RR = 70 breaths/min

Integument: No abnormalities were detected.

Eyes, Ears, Nose, and Throat: A small amount of purulent ocular discharge was present from the left eye. A fundic examination was unremarkable. Moderate dental calculus.

Musculoskeletal: Body condition score was 4/9, with symmetrical muscling. Moderate ventral cervical and submandibular swelling was present.

Cardiovascular: No murmurs or arrhythmias, femoral pulses adequate. Mucous membranes were pale pink, with a CRT of 2 s.

Respiratory: Referred upper airway noises were auscultated.

Gastrointestinal/Genitourinary: The dog's abdomen was nonpainful. The rectal mucosa was proliferative and hyperemic and protruded from the anus. A rectal examination revealed a nodular diffusely thickened mucosa with a granular texture and prominent sublumbar lymph nodes. There was evidence of melena and frank blood on the glove. No vulvar discharge was noted.

Neurologic: Palpebral, menace, and papillary light responses were intact bilaterally. No neurologic deficits were apparent. A full neurologic examination was not performed.

Lymph Nodes: Generalized peripheral lymphadenopathy was present. The mandibular nodes were 5-6 cm in diameter, lobular and firm. The superficial cervical nodes were 3 cm in diameter, and the inguinal nodes were enlarged at 2 cm, with the left larger than the right. The popliteal nodes were enlarged at 2-3 cm bilaterally.

Laboratory Findings:

CBC:

HCT 22% (40%-55%)
MCV 52 fL (65-75 fL)
MCHC 30 g/dL (33-36 g/dL)
Reticulocyte count 25,200 cells/µL
WBC 40,510 cells/µL (6000-13,000 cells/µL)
Neutrophils 29,977 cells/µL (3000-10,500 cells/µL)
Band neutrophils 2431 cells/µL
Lymphocytes 2026 cells/µL (1000-4000 cells/µL)
Monocytes 2431 cells/µL (150-1200 cells/µL)
Eosinophils 3646 cells/µL (0-1500 cells/µL)
Platelets 387,000 platelets/µL (150,000-400,000 platelets/µL).
Band and mature neutrophils were slightly toxic.

Serum Chemistry Profile:

Sodium 132 mmol/L (145-154 mmol/L)
Potassium 3.5 mmol/L (3.6-5.3 mmol/L)
Chloride 103 mmol/L (108-118 mmol/L)
Bicarbonate 17 mmol/L (16-26 mmol/L)
Phosphorus 4.1 mg/dL (3.0-6.2 mg/dL)
Calcium 8.6 mg/dL (9.7-11.5 mg/dl)
BUN 6 mg/dL (5-21 mg/dL)

Continued

VetBooks.ir

Creatinine 0.6 mg/dL (0.3-1.2 mg/dL)
Glucose 93 mg/dL (64-123 mg/dL)
Total protein 4.3 g/dL (5.4-7.6 g/dL)
Albumin 2.1 g/dL (3.0-4.4 g/dL)
Globulin 2.2 g/dL (1.8-3.9 g/dL)
ALT 43 U/L (19-67 U/L)
AST 51 U/L (19-42 U/L)
ALP 115 U/L (21-170 U/L)
Creatine kinase 202 U/L (51-399 U/L)
GGT < 3 U/L (0-6 U/L)
Cholesterol 146 mg/dL (135-361 mg/dL)
Total bilirubin 0 mg/dL (0-0.2 mg/dL)
Magnesium 2.0 mg/dL (1.5-2.6 mg/dL).

Urinalysis: SGr 1.005; pH 7.5; no protein, bilirubin, hemoprotein, or glucose; rare WBC/HPF, 0 RBC/HPF, few lipid droplets.

Imaging Findings:

Thoracic Radiographs: No abnormalities were detected.

Abdominal Ultrasound: All abdominal lymph nodes were enlarged and irregular. There were focal regions of thickening and irregularity within the small bowel. The liver and spleen were unremarkable.

Aspiration Cytology (Mandibular Lymph Node): Multiple, variably sized aggregates of macrophages were scattered along with numerous karyolytic and degenerated neutrophils and a residual lymphoid population in a light pink background that contained low numbers of erythrocytes and lysed cells. The macrophages were large and distended with intracellular, negatively staining thick, relatively short, rod-shaped bacteria. Intracellular organisms were noted within neutrophils and large multinucleated giant cells, as well as being located extracellularly. The bacilli were acid fast. Interpretation: Pyogranulomatous inflammation due to infection with *Mycobacterium* spp.

Microbiologic Testing: Real-time PCR assay for *Mycobacterium* genus organisms (lymph node aspirate): Positive

Real-time PCR assay for *M. avium* complex organisms (lymph node aspirate): Positive

Mycobacterial culture and susceptibility testing (National Jewish Laboratories, Denver, CO): Positive for *M. avium* after incubation for 26 days. The organism was identified by HPLC. The organism was tentatively designated as resistant to ciprofloxacin, rifabutin, and rifampin; of intermediate susceptibility to clofazimine, kanamycin, amikacin, ethambutol, streptomycin, and moxifloxacin; and susceptible to clarithromycin. The organism was susceptible to ethambutol and of intermediate susceptibility to rifampin when the two drugs were used in combination.

Diagnosis: Disseminated *M. avium* infection.

Treatment: Before the availability of culture results, the dog was treated with a combination of enrofloxacin, clarithromycin, and ethambutol. The tetracycline and niacinamide combination was discontinued because of the potential for underlying immunosuppression. The lymph nodes ruptured after the aspirates were collected and drained purulent exudate. Unfortunately, this was followed shortly afterward by the development of fever, lethargy, and dysphagia secondary to severe lymphadenomegaly, and the owners elected euthanasia.

Comments: This dog was suspected to have mycobacterial infection caused by an organism other than a MTBC organism from the outset, based on the dog's background, clinical presentation, and the presence of large numbers of AFB on cytology. *M. tuberculosis* most often causes pulmonary disease in dogs. *M. bovis* infections have been described in the Hispanic population in southern California and rarely in cattle from California,[101] so *M. bovis* infection was possible but seemed highly unlikely based on exposure history and the epidemiology of this disease in dogs. The use of PCR assays allowed rapid confirmation that the organism belonged to *M. avium*.

CHAPTER 45

Salmonellosis

Jane E. Sykes and Stanley L. Marks

VetBooks.ir

Overview of Salmonellosis

First Described: Washington, DC, United States, 1885 (Theobald Smith and Daniel Salmon)[1]

Cause: *Salmonella* spp. (gram-negative rods that belong to the Enterobacteriaceae)

Affected Hosts: A large variety of warm-blooded animals and humans; cold-blooded animals may be subclinically infected

Geographic Distribution: Worldwide

Primary Mode of Transmission: Fecal-oral

Major Clinical Signs: Fever, lethargy, anorexia, diarrhea, vomiting, and less commonly reproductive failure, neurologic and/or respiratory signs

Differential Diagnoses: Differential diagnoses for suspected *Salmonella* enterocolitis include canine and feline parvovirus infection, canine distemper virus infection, campylobacteriosis, clostridial diarrhea, salmon poisoning disease, giardiasis, tritrichomoniasis (cats), cryptosporidiosis, whipworms, leptospirosis, dietary indiscretion, gastrointestinal foreign body, pancreatitis, inflammatory bowel disease, lymphoma, hypoadrenocorticism, hyperthyroidism, toxins (including drugs)

Human Health Significance: Important zoonosis. Dogs and cats may be a source of human infection with some *Salmonella* serotypes, some of which may be resistant to multiple antimicrobial drugs.

Etiology and Epidemiology

Salmonella are gram-negative, motile, non–spore-forming facultative anaerobic rods that belong to the family Enterobacteriaceae. Most *Salmonella* exist in two phases, which differ in composition of their flagellar antigens.

Salmonella are ubiquitous organisms that can be isolated from the intestinal tracts of an enormous variety of animal species and are a major cause of enterocolitis and sometimes severe systemic illness in humans and animals. Infections can be transferred between animal species and are zoonotic. Many infections are food borne, especially in association with milk, meat, and eggs. *Salmonella* spp. have a remarkable ability to survive long periods of time (weeks to years) in the environment, and so fomite transmission is important. In addition, *Salmonella* can multiply rapidly in contaminated food left at room temperature and can survive freezing for several weeks.[2]

The genus *Salmonella* comprises two species, *Salmonella enterica* and *Salmonella bongori*, each of which contains multiple serotypes.[3] Serotypes of *S. bongori* are generally associated with cold-blooded animals and rarely have been isolated from warm-blooded animals, including a dog with diarrhea.[4] There are six subspecies of *S. enterica* (Table 45-1) and approximately 2500 different serotypes. These are identified on the basis of agglutination reactions of their O (somatic) and H (flagellar) antigens (see Chapter 36). Subspecies I serotypes, which are responsible for almost all disease in humans and warm-blooded animals worldwide, are assigned names such as *S.* ser. Typhimurium. Unless named before 1966, serotypes that belong to other subspecies are designated using antigenic formulas. The formulas describe the subspecies, O antigens: H antigens (phase 1): and if present, H antigens (phase 2) (e.g., *S.* IV 45:g,z_{51}:—).

Certain serotypes of *Salmonella* are host restricted, whereas others infect a broad range of host species. *Salmonella* serotype Typhi, for example, is adapted to humans, causing typhoid fever, and does not infect animals. Other serotypes are adapted to certain host species, with rare transmission to other hosts. *Salmonella* serotype Typhimurium is the most commonly isolated serotype from diseased humans and animals.

Infection of dogs and cats with *Salmonella* has been associated with the feeding of raw meat diets,[5-9] although commercial dry and raw dog food and pig ear pet treats have also become contaminated with the organism.[5,10-13] Occasionally, co-infections with multiple *Salmonella* serotypes occur.[14] Outbreaks of *S.* ser. Typhimurium infection in cats have been associated with seasonal bird migrations ("songbird fever").

Salmonella is generally isolated less than 1% of the time from the feces of dogs and cats that are fed processed commercial

TABLE 45-1

Classification of Salmonellae

Salmonella Species	*Salmonella* Subspecies	Example Serotypes
Salmonella enterica	*enterica* (I)	*Salmonella* ser. Typhimurium *S.* ser. Typhi *S.* ser. Choleraesuis
	salamae (II)	*S.* ser. Greenside
	arizonae (IIIa)	*S.* IIIa 18:z_4,z_{23}:—
	diarizonae (IIIb)	*S.* IIIb 60:k:z

pet foods,[15-19] although one study of household pet dogs in Ontario, Canada revealed a shedding prevalence of 23%.[20] The highest rates of infection have been found in group-housed dogs, especially those fed raw meat diets, such as racing sled dogs and greyhound breeding facilities, where prevalences have exceeded 75%.[8,21] *Salmonella* was isolated from the feces of 18 of 26 (69%) healthy pre-race Alaskan sled dogs, and 19 of 30 (63%) diarrheic racing Alaskan sled dogs, which underscored the lack of an association between the isolation of *Salmonella* and clinical diarrhea.[8] Coprophagic behavior may also contribute to salmonellosis in dogs. In cats, the feeding of raw poultry may increase risk for *Salmonella* infection,[22] and occasionally, high prevalences of infection have been detected in group-housed cats[18] and shelter cats. Ingestion of infected wild bird species by cats during seasonal bird migrations can also lead to salmonellosis (songbird fever). In a study of diarrheic and nondiarrheic shelter cats in Florida, the prevalence of *Salmonella* shedding as determined by PCR assay was 6% and 4%, respectively.[23] Susceptibility to shedding and disease is highest in immunosuppressed dogs and cats, including young animals, pregnant animals, those in overcrowded conditions, and those with underlying immunosuppressive illness (such as neoplasia, diabetes mellitus, retroviral infection, and immune-mediated disease) or immunosuppressive drug therapy.[24,25]

Clinical Features

Signs and Their Pathogenesis

After ingestion, salmonellae that survive the acidic environment of the stomach gain access to the intestine, where they disrupt tight junctions and actively invade (1) enterocytes; (2) M cells within the ileum (which sample luminal antigens); and (3) dendritic cells, which send protrusions into the gut lumen between intestinal epithelial cells. Interaction of *Salmonella* with immune cells and epithelial cells within the gut leads to production of cytokines and chemokines, with massive influx of lymphocytes, macrophages, and neutrophils, sometimes with severe epithelial injury and mucosal sloughing.[26] Localization in the mesenteric lymph nodes, Peyer's patches, solitary intestinal lymphoid tissues, and intestinal epithelium, along with evasion of the host immune response, is followed by persistent shedding, often for several weeks, after which animals can become latently infected. Reactivation of shedding, with or without clinical illness, may occur, sometimes as a result of stress or immunosuppression.[27,28]

If the organism has properties that allow it to spread systemically and host defenses are impaired, bacteremia and extraintestinal infection follows.[29] More virulent strains have a greater ability to multiply intracellularly in nonphagocytic cells. Fever, hypoglycemia, and leukopenia occur. The *Salmonella* lipopolysaccharide (LPS) can then induce endotoxic shock, with hypotension and activation of the complement and coagulation cascade. The coagulation cascade is also activated with exposure to *Salmonella* porins, which are hydrophobic outer membrane proteins. Disseminated intravascular coagulation (DIC) follows.

Dogs and cats infected with *Salmonella* spp. may show no signs or they may develop enterocolitis, focal suppurative infection, or severe systemic illness. The majority of dogs are chronically and subclinically infected. When disease occurs, signs often begin 3 to 5 days after infection or onset of immunosuppression. Fever (occasionally as high as 106°F [41°C]), lethargy, and anorexia may be followed by abdominal pain, vomiting, and watery to mucoid, often hemorrhagic diarrhea, and dehydration. Weight loss may be seen. Diarrhea may take several weeks to resolve. Rarely, chronic intermittent diarrhea that lasts up to 8 weeks develops.[30]

Severely affected animals develop signs of septic shock (see Chapter 86). Neurologic signs, and signs that relate to endocarditis, arthritis, pancreatitis, pneumonia, peritonitis, and cholecystitis occur in some animals. Infected cats may develop severe enterocolitis, with fever, pancytopenia, and hyperbilirubinemia. Some cats show persistent fever and anorexia with no diarrhea. Conjunctivitis has been described in cats in association with *Salmonella* infection.[31]

Occasionally salmonellae localize in a particular organ, such as the lungs or urinary tract (Figure 45-1). Signs of dysfunction of that organ system may follow, even when enteric signs or positive fecal culture results are absent.[32] Abortion and stillbirth can occur after transplacental infection, and the dam may also infect her neonates, which leads to fading puppies.[33-35]

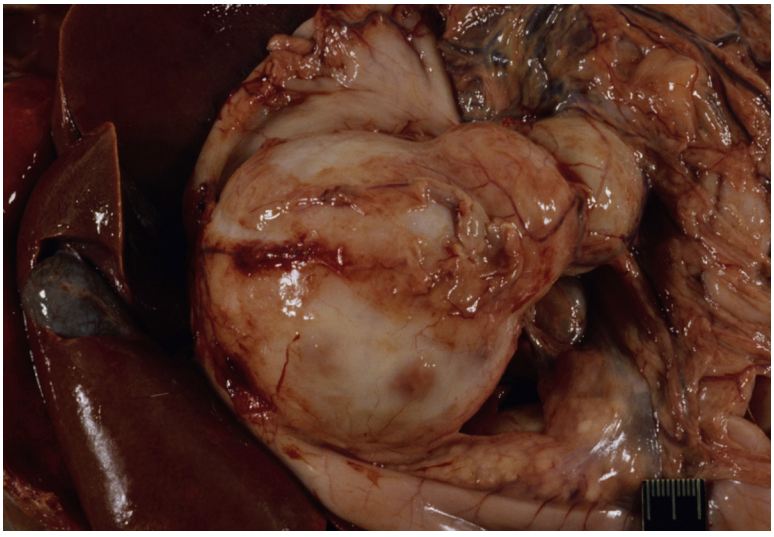

FIGURE 45-1 Large, chronic pancreatic abscess due to *Salmonella* Typhimurium associated with a pancreatic adenocarcinoma in a 15-year-old castrated male domestic shorthair cat. The mass was multicystic and fluctuant, and when cut open was filled with cloudy fluid and lined by thick tan debris. (Courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

VetBooks.ir

Diagnosis

The traditional diagnosis of canine and feline salmonellosis is made based on culture of the organism in conjunction with clinical signs and assessment of potential risk factors, such as hospitalization, age, environmental exposure, and antibiotic administration. Diagnostic assays available for salmonellosis in dogs and cats are shown in Table 45-2.

Laboratory Abnormalities

Complete Blood Count

The CBC in dogs or cats with salmonellosis may be unremarkable or may show a neutrophilia with a left shift; in bacteremic animals, anemia, a degenerative left shift, toxic neutrophils, lymphopenia, and thrombocytopenia are usually present. Rarely, intracellular bacteria are seen within neutrophils.

Serum Chemistry Profile

In animals with severe salmonellosis, changes on the serum chemistry profile include elevated liver enzyme activities, hyperbilirubinemia, azotemia, hypoalbuminemia, hypocholesterolemia, hypoglycemia, and electrolyte abnormalities.

Urinalysis

Salmonella spp. occasionally localize in the kidneys, with associated isosthenuria, pyuria, proteinuria, casts, and bacteriuria.

Clotting Function

Dogs and cats that develop DIC may have clotting function abnormalities that include prolonged coagulation times, increased fibrin degradation product concentrations, and decreased antithrombin concentrations.

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in animals with salmonellosis may reveal bronchointerstitial to alveolar infiltrates in animals with pneumonia, or pleural effusion with pyothorax. Abdominal radiographs can reveal fluid-filled intestines, decreased serosal detail, and/or mild hepatomegaly.

Sonographic Findings

Depending on the severity of the infection, abdominal ultrasound may be unremarkable in dogs and cats with salmonellosis, or show changes that include abdominal lymphadenomegaly, intestinal wall thickening, fluid-filled bowel segments, hepatomegaly, splenomegaly, or ascites.

Microbiologic Testing

Bacterial Isolation

A diagnosis of salmonellosis can be made when *Salmonella* is isolated from a normally sterile site, such as the blood, bronchoalveolar lavage specimens, synovial fluid, or urine specimens collected by cystocentesis. Isolation of *Salmonella* from feces does not confirm that the organism is the cause of disease, but it can raise suspicion that *Salmonella* may be playing a role in enterocolitis, and it has zoonotic significance (see Public Health Aspects, later). Isolation also allows antimicrobial susceptibility testing, which is important because many isolates of *Salmonella* are resistant to multiple antimicrobial drugs.

Salmonella grow readily at 37°C on routine bacteriologic media from specimens that have been collected from a normally sterile site. Selective media are required for specimens that are heavily contaminated with other bacteria such as feces. Examples of selective media include enrichment broths such as tetrathionate broth or Selenite F broth. After enrichment, subculturing is performed on a medium such as deoxycholate, which also favors growth of *Salmonella*. Many veterinary laboratories incorporate such protocols for isolation of *Salmonella* as part of a panel for detection of enteropathogenic bacteria. Once *Salmonella* is isolated, the organism can be identified based on biochemical reactions and serotyping, which involves agglutination testing with O and H antisera. In the future, use of whole cell matrix-assisted laser desorption ionization-time-of-flight (MALDI-TOF) mass spectrometry in veterinary clinical microbiology laboratories should allow identification of *Salmonella* at the species and subspecies level within minutes.[36] It also can identify some important *S. enterica* subsp. *enterica* to the serovar level, and could reduce the need for laborious subtyping procedures.[37]

Molecular Diagnosis Using the Polymerase Chain Reaction

Some veterinary diagnostic laboratories offer PCR assays for *Salmonella*, some of which have been shown as highly sensitive and specific when compared with culture.[38,39] PCR is more rapid than culture but currently does not provide information on antimicrobial susceptibility. It has been recommended that PCR assay after overnight enrichment in a nonselective broth be adopted as the gold standard for diagnosis, and that all specimens that test positive by PCR assay be cultured using selective

TABLE 45-2

Diagnostic Assays Available for Salmonellosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Bacterial isolation	Feces, blood, synovial fluid, tissue aspirates, bronchoalveolar lavage fluid, peritoneal or pleural effusions, urine, CSF, tissues obtained at necropsy	*Salmonella* species	Sensitive and specific. False negatives may occur, especially following antimicrobial therapy. Isolation from feces does not imply that *Salmonella* is the cause of disease. Allows subsequent antimicrobial susceptibility testing.
PCR	As for isolation	*Salmonella* DNA	Rapid (within hours); can be highly sensitive and specific. Positive results from feces do not imply that *Salmonella* is the cause of disease. Does not allow susceptibility testing or typing for epidemiologic purposes.

enrichment to isolate and identify the infecting organism.[40] As with culture, detection of the organism in feces using PCR assays does not prove that it is the cause of gastrointestinal illness.

Pathologic Findings

Gross Pathologic Findings

Gross necropsy findings in dogs and cats with severe salmonellosis include widespread petechial and ecchymotic hemorrhages, hemorrhagic enteritis, abscesses within parenchymal organs, enlarged mesenteric lymph nodes, and fibrinohemorrhagic ascites fluid. Pulmonary consolidation and edema may also be present.

Histopathologic Findings

Histopathologic lesions in dogs and cats with salmonellosis are highly variable. Changes in severely affected animals may include suppurative pneumonia, necrotizing hepatitis, and necrotizing and fibrinohemorrhagic enterocolitis, typhlitis, and cholecystitis. More chronic lesions such as chronic cholecystitis have also been described.[41,42] Sometimes, gram-negative bacilli are identified within lesions with tissue Gram stains (Figure 45-2).

Treatment and Prognosis

The movement of dogs and cats that test positive for *Salmonella* should be limited, and if possible, hospitalized animals should be isolated. The mere detection of *Salmonella* in the feces of dogs and cats with uncomplicated diarrhea does not warrant antimicrobial administration, and supportive care only is recommended. Most of these animals have self-limiting disease and shedding, and injudicious antimicrobial administration has the potential to prolong the carrier state and contribute to antimicrobial resistance. Treatment of an animal with uncomplicated diarrhea is also not advocated if the owner is immunocompromised, although appropriate husbandry recommendations and barrier control must be enforced.

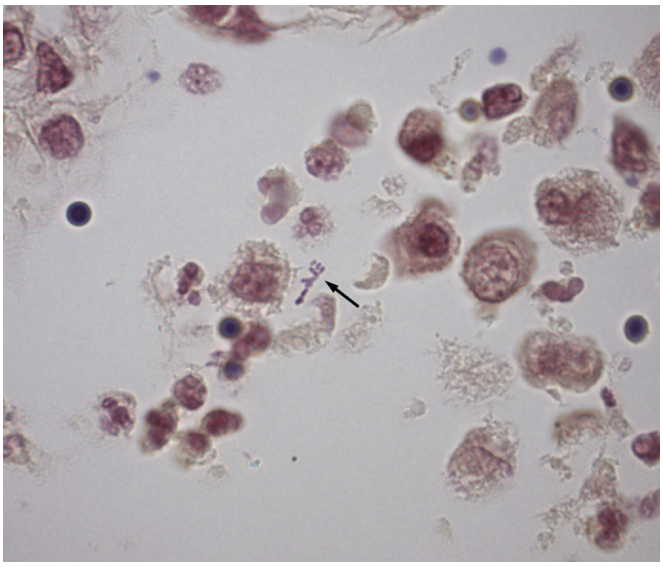

FIGURE 45-2 Gram-negative bacilli (*arrow*) in the lungs of a cat with suppurative cholecystitis and pneumonia due to *Salmonella arizonae*. The cat had been treated with prednisone and cyclosporine for immune-mediated hemolytic anemia. Brown and Benn stain, 1000× magnification.

Dogs and cats with systemic salmonellosis may require aggressive intravenous fluid therapy and colloidal support with hydroxyethyl starch or plasma, together with parenteral antimicrobial drugs. The choice of antimicrobial drugs should be based on the results of culture and susceptibility, because of the potential for resistance to multiple antimicrobial drugs through plasmid transfer. In the event of systemic disease, administration of a combination of ampicillin and a fluoroquinolone is advocated as empiric therapy while awaiting results of culture and susceptibility. Because of the importance of endotoxin in the pathogenesis of sepsis due to gram-negative bacteria such as *Salmonella*, considerable effort has been invested in development and application of drugs targeting endotoxin.[43] Clear benefit through reduction in mortality has not yet been demonstrated for these treatments, and to date they have not been widely used in dogs and cats. Most recently, investigations have been focused on antagonists of Toll-like receptor 4, which is the LPS receptor.[44] Eritoran tetrasodium (E5564) and TAK-242 are examples of TLR4 antagonists that have been used in clinical trials involving septic humans.[45]

Immunity and Vaccination

Salmonella spp. can persist in the host by interfering with dendritic cell function in the intestinal tract. The organism penetrates dendritic cells and avoids lysosomal degradation, which prevents subsequent antigen presentation by dendritic cells on molecules of the major histocompatibility complex.[46] Reduced intracellular proliferation of the organism within antigen-presenting cells may also limit antigen presentation and the development of an effective immune response.[47] Although *Salmonella* vaccines have been developed, none are available for dogs and cats.

Prevention of Enteric Bacterial Infections

Prevention of enteric bacterial infections includes feeding dogs and cats properly cooked foods, hand washing before and after handling pets and pet food, and prevention of coprophagic behavior. Proper handling and storage of pet foods can also limit the potential for food contamination during storage by rodents, insects, and human hands.

Within the hospital setting, fomites such as food dishes, endoscopes, proctoscopes, and rectal thermometers should be disinfected between uses, and single-use disposable thermometer covers should be used. Cages should be cleaned and properly disinfected (see Chapter 11) between animals. Blood donors should not be housed with the regular hospital population, as they may be a source of *Salmonella* infection.

Dogs and cats diagnosed with salmonellosis or *Salmonella* shedding should be isolated from other animals until shedding stops. Fecal cultures should be repeated every 2 weeks, and termination of shedding is identified when three successive negative cultures have been obtained.

Public Health Aspects

All enteric bacterial infections of dogs and cats have the potential to infect and cause illness in humans. Nontyphoid salmonellosis (salmonellosis other than that caused by *S.* ser. Typhi) can be transmitted from domestic animals to humans and cause serious enterocolitis, with fever, severe abdominal pain,

diarrhea, nausea, inappetence, chills, and headache. Serious complications tend to occur in children, the elderly, or otherwise immunocompromised individuals such as those infected with HIV. The majority of cases result from ingestion of improperly cooked foods of animal origin, such as meat, milk, and eggs. Most, if not all, pet reptiles carry *Salmonella*, and there has been considerable effort to educate the public about the hazards of reptile-associated salmonellosis. Dogs, and to a lesser extent cats, are less commonly incriminated as a source of *Salmonella*. Of particular concern, multidrug-resistant *Salmonella* strains, such as *S.* ser. Typhimurium strain DT 104, have been isolated from dogs, cats, and reptiles.[20,48] People exposed to dogs and cats that are fed raw meat diets are at increased risk of exposure.

Proper hand washing after handling pets, pet food, and fomites such as bedding and food dishes can help prevent zoonotic transmission of *Salmonella*. Reptile ownership by families with children younger than 5 years of age or among the immunosuppressed is discouraged by public health authorities.[49] Proper food handling practices, including separating raw meat from vegetables and proper cooking of meat, can also reduce salmonellosis in humans.

CASE EXAMPLE

FIGURE 45-3 "Sampson", a 3-year-old male castrated shepherd mix with salmonellosis.

Signalment: "Sampson," a 3-year-old male castrated shepherd mix from Fresno in southern California (Figure 45-3).

History: Sampson was brought to a veterinarian for evaluation of a 3-month history of bilateral tarsal joint swelling. Some clinical improvement had been noted after treatment with oral tetracycline (28 mg/kg PO q8h) for 2 weeks. Subsequently, he was treated with oral prednisone (1.1 mg/kg PO q12h). Two weeks after the prednisone treatment was initiated, Sampson became nonambulatory in his pelvic limbs, and all of his peripheral joints became swollen and he was referred to the University of California, Davis, Veterinary Medical Teaching Hospital. A mass had been removed from his left dorsolateral thorax 3 weeks before referral that was assumed to be a foxtail abscess. Sampson had a good appetite. Increased thirst and urination had been noted after the prednisone treatment was initiated. There had been no coughing, sneezing, vomiting, or diarrhea. He was fed a duck- and potato-based diet for food allergy dermatitis and had been treated intermittently with prednisone, 4 mg PO q24h, for this condition since he was 6 months old. He had not traveled outside his local area, but he lived on a ranch and was known to consume horse feces and dead wild animals. There was no known tick exposure. He was up to date on vaccinations including canine distemper, adenovirus, parvovirus, and rabies vaccines.

Current medications: Prednisone 0.9 mg/kg PO q12h

Physical Examination:

Body Weight: 35.8 kg

General: Quiet, alert and responsive, 5% to 7% dehydrated. Recumbent. T = 102.9°F (39.4°C), HR = 140 beats/min, panting, mucous membranes pink and tacky, CRT = 1 s.

Integument: Multifocal epidermal collarettes were present and the haircoat was dry. A shaved area was present on the left lateral thoracic wall.

Eyes, Ears, Nose, and Throat: Moderate periodontal disease was present. A fundic examination was within normal limits.

Musculoskeletal: Body condition score was 5/9 with pelvic limb muscle atrophy. Pain and effusion of the carpi, tarsi, and stifles with decreased range of motion was noted. Spinal and pericervical pain was detected on palpation of these regions.

Cardiovascular: Weak but synchronous femoral pulses were noted. No murmurs or arrhythmias were auscultated.

Respiratory: There were moderately increased breath sounds in all lung fields.

Gastrointestinal/Genitourinary: The abdomen was tense on palpation and moderate hepatomegaly was detected. The dog urinated a large amount of odiferous urine during the examination. No abnormalities were detected on rectal examination.

Lymph Nodes: Moderate peripheral lymphadenopathy was present. Mandibular, superficial cervical, and popliteal lymph nodes were all 1.5 to 2.5 cm in diameter.

Laboratory Findings:

CBC:

HCT 35.4% (40%-55%)
MCV 67 fL (65-75 fL)
MCHC 35.6 g/dL (33-36 g/dL)

Monocytes 79 cells/μL (150-1200 cells/μL)
Platelets 419,000 platelets/μL (150,000-400,000 platelets/μL).
Neutrophils, band neutrophils, and metamyelocytes all showed moderate toxic changes.

Serum Chemistry Profile:

Sodium 148 mmol/L (145-154 mmol/L)
Potassium 4.4 mmol/L (3.6-5.3 mmol/L)
Chloride 105 mmol/L (108-118 mmol/L)
Bicarbonate 14 mmol/L (16-26 mmol/L)
Phosphorus 5.8 mg/dL (3.0-6.2 mg/dL)
Calcium 10.3 mg/dL (9.7-11.5 mg/dl)
BUN 10 mg/dL (5-21 mg/dL)
Creatinine 0.4 mg/dL (0.3-1.2 mg/dL)
Glucose 111 mg/dL (64-123 mg/dL)
Total protein 6.1 g/dL (5.4-7.6 g/dL)
Albumin 2.3 g/dL (3.0-4.4 g/dL)
globulin 3.8 g/dL (1.8-3.9 g/dL)
ALT 560 U/L (19-67 U/L)
AST 72 U/L (19-42 U/L)
ALP 3318 U/L (21-170 U/L)
Creatine kinase 197 U/L (51-399 U/L)
Gamma GT 59 U/L (0-6 U/L)
Cholesterol 212 mg/dL (135-361 mg/dL)
Total bilirubin 0.3 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.010; pH 8.0, 1+ protein (SSA), 3+ hemoprotein, no bilirubin or glucose, 25-35 WBC/HPF, 10-15 RBC/HPF, many rods.

Imaging Findings:

Thoracic Radiographs: The cardiovascular and pulmonary structures appeared within normal limits.

Right and Left Carpal, Stifle, and Tarsal Radiographs: Intracapsular soft tissue swelling was associated with all joints.

Spinal Radiographs: No abnormalities were detected.

Abdominal Ultrasound: The liver was enlarged and hyperechoic. There was echogenic sediment in the urinary bladder.

Echocardiogram: Thickening and hyperechogenicity of the posterior leaflet of the tricuspid valve was noted (arrowhead) which raised suspicion for endocarditis (Figure 45-4).

Cytology Findings: Arthrocentesis of right and left carpi, right tarsus and right stifle: Purulent inflammation was noted in the right tarsus, right stifle, and left carpus, with approximately 85% neutrophils and the remaining cells were a mixture of small and large mononuclear cells. In the right stifle, degenerate neutrophils are visualized, and some contained intracellular rod-shaped bacteria.

Microbiologic Testing: Serologic testing: An in-clinic ELISA for antibodies to *Borrelia burgdorferi*, *Anaplasma phagocytophilum*, and *Ehrlichia canis* was negative. Serum IFA for antibodies to *Bartonella vinsonii* subspecies *berkhoffii* was negative. Serology for *Coccidioides* spp. antibodies was also negative.

FIGURE 45-4 Thickening and hyperechogenicity of the posterior tricuspid valve leaflet (*arrowhead*) in a dog with *Salmonella arizonae* bacteremia.

Aerobic bacterial culture of blood, joint fluid, and urine collected by cystocentesis: *Salmonella arizonae*, susceptible to all antimicrobials tested.

Diagnosis: *Salmonella arizonae* septic polyarthritis, bacteremia, and possible tricuspid valve endocarditis.

Treatment: Before obtaining susceptibility results, Sampson was treated with intravenous crystalloids, opioids for pain control, enrofloxacin (5 mg/kg IV q24h), and ampicillin (30 mg/kg IV q8h). The ampicillin was discontinued when the susceptibility results became available. The prednisone was tapered over a 3-day period and discontinued. The dog was moved to an isolation ward on diagnosis of salmonellosis. During hospitalization, Sampson's appetite declined initially, and he remained very painful for 6 days. After that time, he was able to sit up, began eating, and was discharged 8 days after admission.

Comments: *Salmonella arizonae* infections in humans have been associated with direct or indirect contact with reptiles. Reptile-associated salmonellosis is an increasing problem in humans in the United States and is especially a problem in infants and immunocompromised adults in contact with snakes and iguanas, or those who eat sun-dried rattlesnake meat for medicinal purposes. Horse feces from the farm were cultured for *Salmonella* and were negative. It is possible that the infection in this dog occurred as a result of ingestion of wild reptiles. The long history of glucocorticoid therapy for atopic dermatitis in this dog may have contributed to immunosuppression and predisposition to systemic salmonellosis.

Enteric *Escherichia coli* Infections

Jane E. Sykes and Stanley L. Marks

VetBooks.ir

Overview of Enteric *Escherichia coli* Infections

First Described: Germany, 1885 (Theodor Escherich)[1]

Cause: *Escherichia coli* (gram-negative rods that belong to the Enterobacteriaceae)

Affected Hosts: Humans and a large variety of animals

Geographic Distribution: Worldwide

Primary Mode of Transmission: Fecal-oral

Major Clinical Signs: Fever, lethargy, inappetence, diarrhea, vomiting

Differential Diagnoses: Differential diagnoses for suspected *E. coli* enterocolitis include canine and feline parvovirus infection, canine distemper virus infection, salmon poisoning disease, campylobacteriosis, clostridial diarrhea, salmonellosis, giardiasis, tritrichomoniasis (cats), cryptosporidiosis, whipworms, pythiosis, histoplasmosis, leptospirosis, dietary indiscretion, gastrointestinal foreign body, pancreatitis, inflammatory bowel disease, lymphoma, hypoadrenocorticism, hyperthyroidism (cats), toxins (including drugs).

Human Health Significance: Dogs and cats may be a source of human infection with some *E. coli* serotypes.

Etiology and Epidemiology

Escherichia coli are pleomorphic gram-negative, non–spore-forming rods that belong to the family Enterobacteriaceae. Like *Salmonella, E. coli* can survive long periods of time in feces, dust, and water. They are part of the normal flora of the gastrointestinal tract but can be associated with enterocolitis in the presence of bacterial virulence factors and impaired local or systemic immunity. As with *Salmonella* infections, *E. coli* infections can be transferred between animal species and some may be zoonotic; many infections are food borne.

There are more than 170 serogroups of *E. coli* based on the identity of the bacterial O (somatic) antigen, the sugar that is on the most external portion of the bacterial lipopolysaccharide (LPS) (see Chapter 36). Organisms are also identified on the basis of their H (flagellar) antigens—for example, O157:H7 *E. coli*. Both the bacterial LPS (endotoxin) and the flagellar antigens are bacterial virulence factors. Other virulence factors in *E. coli* include adhesins, bacterial exotoxins such as cytotoxic necrotizing factor (CNF), hemolysins, heat-labile (LT) and heat-stable (ST) enterotoxins, and the capsular polysaccharide (K).

E. coli strains that cause gastrointestinal disease have been divided into seven distinct pathogenic categories (pathovars). Each pathovar is defined by a characteristic set of virulence factors that act in concert to determine the clinical, pathologic, and epidemiologic features of the disease they cause. The seven pathovars include enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enterohemorrhagic *E. coli* (EHEC), necrotoxigenic *E. coli* (NTEC), enteroinvasive *E. coli* (EIEC), enteroaggregative *E. coli* (EAEC), and adherent-invasive *E. coli* (AIEC) (Table 46-1). Currently, the epidemiology of many of these strains and their role in disease causation is not well defined in small animals, with most work having been done in humans and farm animal species. Many strains have been isolated from both nondiarrheic and diarrheic dogs and cats. An association between EPEC and EHEC (including H7:O157) infection and diarrhea in dogs has been detected.[2,3] In addition, AIEC strains have been well associated with granulomatous colitis in boxer dogs.[4]

Clinical Features

Signs and Their Pathogenesis

EPEC strains carry the *eae*A gene on their chromosome (*E. coli* attaching effacing), which is located in a "pathogenicity island" referred to as LEE (locus of enterocyte effacement). The *eae*A gene encodes a 94-kDa protein, intimin, which allows the organism to adhere intimately to intestinal epithelial cells. This leads to local effacement of the microvilli and formation of numerous, actin-rich pedestals on which the bacteria reside (Figure 46-1).[5] The bacteria secrete their own receptor, the Tir receptor, and Tir-intimin interactions are involved in pedestal formation. The pedestals may help the bacteria to remain extracellular, and thus escape immune recognition by the host. The resulting characteristic histopathologic lesions on enterocytes have been referred to as "attaching and effacing lesions." Subsequent signal transduction events induced by EPEC may be associated with loss of tight junction integrity and altered electrolyte transport, with associated watery diarrhea. The EPEC pathovar does not produce Shiga toxin, Shiga-like toxin, or verotoxins. EPEC serotypes that have been associated with diarrhea in humans have been identified in dogs and cats.[6,7]

ETEC are a major cause of diarrhea in human infants in developing countries and are the agents most frequently responsive for traveler's diarrhea. ETEC pathovars have been associated with up to 31% of cases of canine diarrhea, particularly in young dogs.[8-10] Most of the canine ETEC strains express ST enterotoxin, whereas ETEC strains that produce LT enterotoxin are rarely found. The bacteria adhere to the proximal small intestinal mucosa and produce plasmid-encoded LT and ST enterotoxins. LT is related to cholera toxin and is taken up by enterocytes. Once within intestinal epithelial cells, it activates adenylate cyclase, which leads to increased concentrations of intracellular cyclic AMP with resultant secretion of electrolytes

VetBooks.ir

TABLE 46-1

Pathogenic Strains of *Escherichia coli* That Cause Enterocolitis

Strain	Lesion	Signs	Virulence Characteristic
Enteropathogenic *E. coli* (EPEC)	Attaching and effacing lesions (effacement of microvilli and pedestal formation)	Watery diarrhea	*eaeA* gene (encodes intimin)
Enterotoxigenic *E. coli* (ETEC)	Adhere using fimbria and produce heat-labile (LT) and/or heat-stable (ST) toxins	Diarrhea	LT and ST production
Enterohemorrhagic *E. coli* (EHEC); also known as Shiga-toxin–producing *E. coli* (STEC) or verotoxin-producing *E. coli* (VTEC)	Produce Shiga-like toxins (verotoxins) that cause vascular endothelial damage, also produce attaching and effacing lesions	Diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome	Shiga-like toxin production, see also EPEC
Necrotoxigenic *E. coli* (NTEC)	Produce cytotoxic necrotizing factors (CNFs)	Diarrhea, bacteremia, urinary tract infections in humans	CNFs
Enteroinvasive *E. coli* (EIEC)	Actively invade colonic epithelial cells	Large bowel diarrhea	Plasmid-encoded invasion genes such as *ipaH*
Adherent-invasive *E. coli* (AIEC)	Invade colonic epithelial cells using unknown virulence mechanisms	Granulomatous/histiocytic ulcerative colitis in dogs (especially boxers)	None known
Enteroaggregative *E. coli* (EAEC)	Adhere to intestinal epithelium via fimbriae and aggregate in bricklike fashion	Persistent watery diarrhea in humans	*aggR* gene

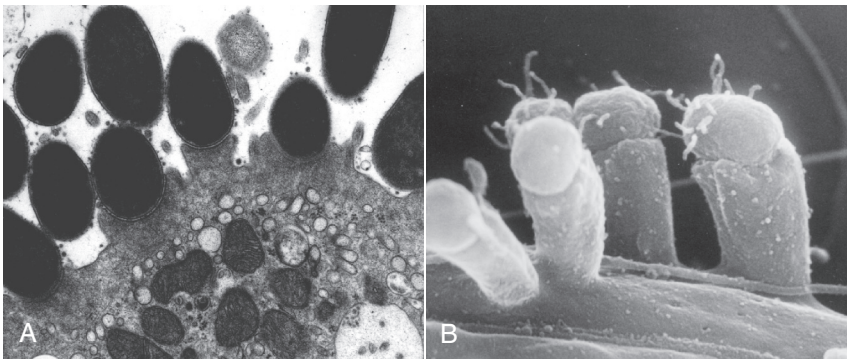

FIGURE 46-1 Scanning and transmission electron micrographs showing actin pedestals induced by enteropathogenic and enterohemorrhagic *Escherichia coli* (EPEC and EHEC). **A,** EPEC generates attaching and effacing (AE) lesions on the intestinal epithelium after infection of gnotobiotic piglets. Note the pedestal-like structures on host cells beneath attached bacteria. (From Campellone KG, Leong JM. Tails of two Tirs: actin pedestal formation by enteropathogenic *E. coli* and enterohemorrhagic *E. coli.* Curr Opin Microbiol 2003;6(1):82-90.) **B,** Actin pedestals that resemble AE lesions formed in vivo are also generated on cultured epithelial (HeLa) cells. (Courtesy of Knutton S. In: Knutton S, Rosenshine L, Pallen, MJ, et al. A novel EspA-associated surface organelle of enteropathogenic *Escherichia coli* involved in protein translocation into epithelial cells. EMBO J. 1998;17:2166-2176.)

and water that lead to diarrhea, hypovolemia, and metabolic acidosis. LT may also downregulate innate host immune responses and promote ETEC adherence. In contrast, ST binds to the extracellular domain of guanylyl cyclase C, which leads to accumulation of intracellular cyclic GMP and ultimately secretion of chloride and decreased absorption of NaCl, with resultant osmotic diarrhea. Two different ST enterotoxins have been identified, STa and STb. ST-producing ETEC have been detected in young dogs with diarrhea.[8-10]

In addition to producing attaching and effacing lesions similar to those created by EPEC, EHEC (Shiga-toxin–producing *E. coli*, or STEC) produce Shiga-like toxins (also known as verotoxins). They cause diarrhea, hemorrhagic colitis, and hemolytic-uremic syndrome (HUS) (e.g., *E. coli* strain O157:H7). Shiga-like toxins are absorbed from the intestinal lumen and cause vascular endothelial damage, which may lead to a multiorgan thrombotic process in the absence of bacteremia. EHEC can also produce other toxins that contribute to the pathogenesis of the disease. HUS in humans is characterized by renal failure, widespread microthrombotic damage to a variety of organs, hemolytic anemia, and sometimes diarrhea. Similar syndromes have been described in dogs, but an associated *E. coli* infection was not demonstrated.[11,12] HUS has been reproduced experimentally in dogs with a non-O157:H7 *E. coli* serotype.[13] Based on the similarity

VetBooks.ir

of renal lesions to those described in HUS, and the practice of feeding predominantly raw meat diets to greyhounds, it has been hypothesized that cutaneous and renal glomerular vasculopathy of greyhounds (also known as "Alabama rot" or "Greenetrack disease") may result from infection with EHEC strains such as O157:H7.[14] A similar condition was described in a great Dane from Germany.[15] Some dogs develop cutaneous lesions in the absence of renal failure; other dogs develop renal failure before the onset of cutaneous lesions.

NTEC produce two toxins: CNF and cytolethal distending toxin. Multiple CNF types have been identified (CNF1, CNF2, and CNF3). NTEC have been associated with diarrhea, bacteremia, and urinary tract infections in human patients, as well as with diarrhea in dogs.[16]

EIEC actively invade colonic epithelial cells. This, together with the associated inflammatory response, leads to hemorrhagic, large bowel diarrhea. In human patients, the EIEC pathovar is uncommonly detected compared with EPEC and ETEC. AIEC, which lack the virulence genes that identify EIEC, have been associated with granulomatous colitis in boxer dogs and infrequently in the French bulldog and Border collie. This infection typically affects young adult boxer dogs that show signs of severe colitis, with colonic thickening and ulceration, and weight loss that is often marked.[4,17] It has been suggested that a heritable anomaly in boxer dogs predisposes them to the infection, given the marked breed predisposition for the disease.[18]

The EAEC pathovar is considered an emerging pathogen in human patients. It adheres to epithelial cells of the terminal ileum and colon using fimbriae in a characteristic "stacked brick" pattern. Expression of these fimbriae is encoded by a plasmid gene known as *aggR*. Bacterial aggregation is followed by damage and a subsequent inflammatory response, which leads to development of persistent watery diarrhea. Occasionally, EAEC strains also produce toxins, such as verocytotoxin.[19] Their role in dogs and cats requires further investigation.

Physical Examination Findings

Physical examination may reveal dehydration and abdominal pain in puppies with *E. coli* diarrhea. Dogs with HUS have had cutaneous erythema and well-demarcated, multifocal cutaneous ulcers of the limbs. Fever and peripheral edema have also been described. Boxer dogs with granulomatous colitis may have poor body condition. A thickened and irregular rectal wall may be detected on rectal palpation, and the feces may contain fresh blood and mucus.

Diagnosis

Diagnosis of intestinal *E. coli* infections, with the exception of granulomatous colitis of boxer dogs, is difficult or impossible with currently available diagnostic assays, because of the fact that healthy dogs and cats shed *E. coli*, and it is a combination of bacterial virulence factors and host immune competence that contributes to the development of clinical signs. This section therefore focuses primarily on the more specific clinical syndromes caused by EHEC and AIEC.

Laboratory Abnormalities

Complete Blood Count

CBC changes in dogs with *E. coli* diarrhea are generally mild and nonspecific. Leukocytosis may be present. Dogs infected with EHEC may be thrombocytopenic and have evidence of microangiopathic hemolysis. Microcytic anemia may be present in boxer dogs with granulomatous colitis.

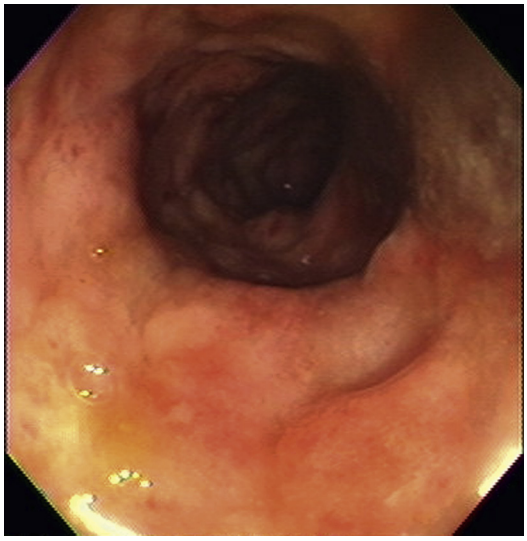

FIGURE 46-2 Ulcerated and erythematous colon of a 2-year-old intact male boxer dog with granulomatous colitis as viewed during colonoscopy. The dog had a 7-month history of marked weight loss and severe diarrhea, with increased frequency of defecation and hematochezia.

Serum Chemistry Panel and Urinalysis

Laboratory abnormalities in dogs with *E. coli* diarrhea could include electrolyte abnormalities and prerenal azotemia in dogs with severe diarrhea. Dogs infected with EHEC have had variable evidence of hypoalbuminemia, prerenal azotemia, increased activities of ALT and creatine kinase, hematuria, proteinuria, and isosthenuria. Boxer dogs with granulomatous colitis are commonly hypoalbuminemic.

Diagnostic Imaging

Findings on abdominal radiography and abdominal ultrasound are typically unremarkable or show fluid-filled intestinal loops. Abdominal ultrasound in boxer dogs with granulomatous colitis often reveals mild or moderate mesenteric or sublumbar lymphadenomegaly, and the colonic wall can appear thickened.

Endoscopic Findings

Proctoscopy or colonoscopy is usually performed in order to obtain colonic biopsies from boxer dogs suspected to have granulomatous colitis. Proctoscopy requires less fastidious colonic preparation compared to colonoscopy, can be performed under heavy sedation, and is more cost effective compared to colonoscopy. Most boxer dogs with granulomatous colitis have involvement of the descending colon, underscoring the diagnostic utility of proctoscopy. Common changes in appearance to the colonic wall include erythema, irregularity, and ulceration of the rectal wall (Figure 46-2).

Microbiologic Testing

Bacterial Isolation and Typing

E. coli is commonly isolated on routine bacteriologic media from feces of both healthy and diarrheic dogs. A differential medium such as MacConkey agar is often used. Apart from dogs with granulomatous colitis, attempts to specifically identify *E. coli* as a cause of diarrhea are generally performed only

by reference or public health laboratories when an outbreak has occurred, or for research purposes. *E. coli* can be isolated from colonic biopsies of dogs with granulomatous colitis, which permits subsequent antimicrobial susceptibility testing.[20] Serologic identification, which is performed using specific O and H antisera, can be costly and is generally performed by large public health laboratories in epidemiologic investigations.

Virulence Assays

Immunoassays are available for detection of Shiga toxin, ST, and LT. A Vero cell cytotoxicity assay has been used to detect verocytotoxin. Identification of EPEC and AIEC often relies on assays that assess adherence in tissue culture. In research settings, molecular diagnostic techniques using DNA probes or PCR assays have revolutionized the ability to detect and differentiate between pathogenic and nonpathogenic strains of *E. coli*. EPEC characteristically possess the *eaeA* gene. Detection of genes that encode LT, ST, and Shiga-like toxin allows identification of ETEC and EHEC. EIEC are identified based on the presence of invasion-associated genes such as *ipaH*. The *aat* gene is a diagnostic marker for EAEC detection.[19]

Pathologic Findings

The most significant pathologic findings in intestinal *E. coli* infections occur with EHEC and AIEC infections.

EHEC

Cutaneous ulcerative lesions in dogs with suspected HUS are characterized histopathologically by fibrinoid vascular necrosis, with dermal thrombosis and leukocytoclastic vasculitis. Grossly, the kidneys may be swollen and have cortical petechiae. Histopathology reveals hyaline fibrinous thrombi in glomerular capillaries and afferent arterioles, glomerular and multifocal tubular necrosis, and leukocytoclastic vasculitis with fibrinoid necrosis.

AIEC

Histopathologic lesions in boxers and French bulldogs with granulomatous colitis are pathognomonic and include neutrophilic inflammation, epithelial ulceration, crypt hyperplasia and distortion, decreased goblet cell numbers, and abundant macrophages that stain positive with periodic acid–Schiff (PAS) stain (Figure 46-3). The presence of *E. coli* within macrophages can be confirmed using fluorescence in situ hybridization, which has been recommended as part of the diagnostic work-up of dogs suspected to have histiocytic ulcerative colitis.[5,18]

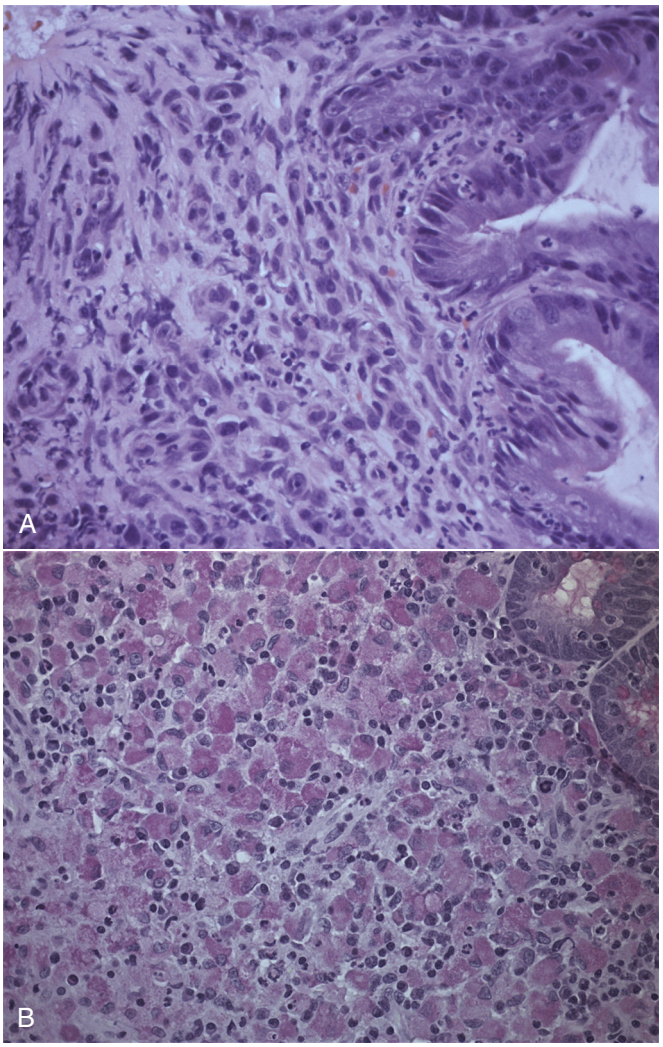

FIGURE 46-3 **A,** Histopathology showing severe, chronic, histiocytic colitis in a 2-year-old male boxer dog. The inflammatory infiltrate is comprised of large, epithelioid macrophages and lesser numbers of neutrophils, plasma cells, and lymphocytes. **B,** Histiocytes in the lamina propria contain PAS-positive material.

Treatment and Prognosis

Dogs and cats with severe diarrhea due to pathogenic *E. coli* may require intravenous fluid therapy. Dogs with granulomatous colitis can show dramatic responses to treatment with enrofloxacin (10 mg/kg PO q24h), and a minimum treatment duration of 8 weeks is recommended.[18] Administration of fluoroquinolones is usually associated with rapid resolution of clinical signs and resolves cellular infiltration characteristic of this disorder on colonic biopsy. Because enrofloxacin resistance has been documented in some isolates from dogs with granulomatous colitis, attempts to isolate *E. coli* from colonic biopsies before treatment is recommended so that antimicrobial susceptibility testing can be performed.[20] Antimicrobials that penetrate intracellularly, such as fluoroquinolones, chloramphenicol, rifampin, or trimethoprim-sulfonamides, should be chosen for treatment based on the results of susceptibility testing.

Immunity and Vaccination

Currently, no vaccines for *E. coli* infections are available for dogs and cats. Vaccines for EPEC, ETEC, and EHEC have been investigated for animals and humans on a research basis,[21-23] including a transdermal LT vaccine for prevention of travelers' diarrhea.[24]

Prevention

The reader is referred to Chapter 11 and Chapter 45 for information on prevention of enteric bacterial infections.

Public Health Aspects

Pathogenic *E. coli* that cause diarrhea have been particularly prevalent in children in developing countries and in travelers to developing countries. EHEC can be acquired following

ingestion of undercooked ground hamburger meat, vegetables, and nonchlorinated drinking and swimming water that have been contaminated with fecal material. Infection has also been reported following contact with animals housed in petting zoos.[25] HUS is reported as the most common cause of acute renal failure in children. Clinical signs in humans consist of gastrointestinal signs, often with profuse, bloody diarrhea, abdominal cramps, pallor, weakness, and oliguria or anuria.[26] Dogs have been suggested as a source of human infection with EPEC and EHEC.[27,28]

The possibility of zoonotic transmission of multidrug resistant *E. coli* that are shed by dogs and cats is an emerging concern. A variety of resistance mechanisms have been identified in *E. coli* isolates from dogs and cats, which include production of efflux pumps and extended-spectrum and AmpC β-lactamase enzymes. There is some evidence that *E. coli* strains shed by healthy companion animals can be shared with humans that reside in the same household,[29-32] but more studies are required to determine the extent to which this occurs and its zoonotic significance. Transfer of plasmids that carry resistance genes from canine or feline *E. coli* isolates and those of humans also has the potential to occur.

For hospitalized animals, staff should use contact precautions for any dog or cat suspected to have enteropathogenic illness, including the use of warning signs, gloves, and gowns, hand washing, and cleaning with bleach-based or accelerated hydrogen peroxide-based disinfectants. Endoscopes should be disinfected thoroughly between uses. Veterinarians should discuss the zoonotic implications of enteropathogenic bacterial infection with pet owners, especially in relation to the presence of young children or otherwise immunocompromised individuals in the household.

CASE EXAMPLE

Signalment: "Caesar", 2-year-old male boxer dog from Tulare, CA (Figure 46-4)

History: Caesar was evaluated for chronic diarrhea, which had been present since he was 6 months of age. His feces were loose and contained a small amount of frank blood. He strained to defecate many times a day, and the owner sometimes noticed mucus in the diarrhea. Every few months, Caesar's appetite and energy level declined and the diarrhea became more severe. His signs transiently improved after treatment with subcutaneous fluids and metronidazole. The owners had tried a variety of different diets such as fiber-supplemented diets and elimination diets that contain novel, single protein sources, but these strategies did not help. His current diet was a digestible commercial diet, and his appetite was good. He was up to date on vaccinations, including those for rabies, canine distemper, canine parvovirus, canine adenovirus, and *Bordetella bronchiseptica*. He was primarily an indoor dog with access to a suburban backyard.

Physical Examination:

Body Weight: 23.4 kg

General: Bright, alert, and responsive. Ambulatory on all four limbs. T = 102.5°F (39.2°C), HR = 102 beats/min, panting, mucous membranes pink, CRT = 1 s.

Integument, Eyes, Ears, Nose, and Throat: No significant abnormalities were noted. A moderate amount of dental calculus was present.

Musculoskeletal: Body condition score was 3/9 with symmetrical muscling.

All Other Systems: On rectal examination, the walls of the rectum were smooth. There was fresh blood on the glove following palpation. No other clinically significant abnormalities were noted.

Laboratory Findings:

CBC:

HCT 54.4% (40%-55%)
MCV 76.8 fL (65-75 fL)
MCHC 32.9 g/dL (33-36 g/dL)
WBC 12,590 cells/μL (6000-13,000 cells/μL)
Neutrophils 9631 cells/μL (3000-10,500 cells/μL)
Lymphocytes 1674 cells/μL (1000-4000 cells/μL)
Monocytes 781 cells/μL (150-1200 cells/μL)
Platelets were clumped but appeared adequate in number.

Serum Chemistry Profile:

Sodium 155 mmol/L (145-154 mmol/L)
Potassium 4.2 mmol/L (3.6-5.3 mmol/L)
Chloride 116 mmol/L (108-118 mmol/L)
Bicarbonate 23 mmol/L (16-26 mmol/L)
Phosphorus 4.4 mg/dL (3.0-6.2 mg/dL)

FIGURE 46-4 "Caesar," a 2-year-old male boxer dog from Tulare, CA, that was diagnosed with granulomatous colitis following colonoscopy and biopsy.

VetBooks.ir

Calcium 10.4 mg/dL (9.7-11.5 mg/dl)
BUN 18 mg/dL (5-21 mg/dL)
Creatinine 1.1 mg/dL (0.3-1.2 mg/dL)
Glucose 105 mg/dL (64-123 mg/dL)
Total protein 6.5 g/dL (5.4-7.6 g/dL)
Albumin 2.9 g/dL (3.0-4.4 g/dL)
Globulin 3.6 g/dL (1.8-3.9 g/dL)
ALT 68 U/L (19-67 U/L)
AST 46 U/L (19-42 U/L)
ALP 86 U/L (21-170 U/L)
GGT 5 U/L (0-6 U/L)
Cholesterol 200 mg/dL (135-361 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL).

Fecal Examination: Centrifugal fecal flotation: Negative for parasites.

Colonoscopy: The entire mucosal surface of the colon was erythematous and irregular, with multifocal areas of mucosal ulceration (see Figure 45-1).

Histopathology of Colonic Biopsies: Severe, chronic, histiocytic and ulcerative colitis. Histiocytes in the lamina propria contained PAS-positive material (see Figure 46-3).

Diagnosis: Granulomatous colitis of boxer dogs

Treatment: Enrofloxacin, 6 mg/kg PO q24h for 8 weeks and a commercial low-residue dry and canned dog food. This was associated with clinical improvement within a week after starting the medication. At a recheck 4 weeks later, the owner reported that Caesar's feces were completely normal in consistency and frequency.

Comments: In this dog, the diagnosis of granulomatous colitis was made solely based on histopathologic findings. Culture of a biopsy specimen could also have been performed and is now recommended given the emergence of fluoroquinolone-resistant AIEC strains of *E. coli.*

CHAPTER 47

Campylobacteriosis

Jane E. Sykes and Stanley L. Marks

VetBooks.ir

Overview of Campylobacteriosis

First Described: Germany, 1886 (Theodor Escherich)[1]; the organism was not isolated until the 1950s

Cause: *Campylobacter* spp. (curved to spiral gram-negative bacteria that belong to the Campylobactereaceae)

Affected Hosts: Humans and a large variety of other animal species

Geographic Distribution: Worldwide

Primary Mode of Transmission: Fecal-oral

Major Clinical Signs: Fever, lethargy, anorexia, large bowel diarrhea

Differential Diagnoses: Differential diagnoses for suspected *Campylobacter* enterocolitis include canine and feline parvovirus infection, canine distemper virus infection, salmon poisoning disease, *Escherichia coli* infection, clostridial diarrhea, salmonellosis, giardiasis, tritrichomoniasis (cats), cryptosporidiosis, whipworms, leptospirosis, dietary indiscretion, gastrointestinal foreign body, pancreatitis, inflammatory bowel disease, lymphoma, hyperthyroidism (cats), hypoadrenocorticism, toxins (including drugs).

Human Health Significance: Important zoonosis. Dogs and cats may be a source of human infection with *Campylobacter*, some of which may be resistant to antimicrobial drugs.

Etiology and Epidemiology

Campylobacter are thin, gram-negative, curved, S-shaped or spiral rods that are often motile by means of a single polar flagellum at one or both ends (Figure 47-1). They are microaerophilic (i.e., they grow best when levels of oxygen are lower than that present in the atmosphere), and are widespread in the gastrointestinal tracts of animals. *Campylobacter* spp. have the potential to be zoonotic and are an important cause of foodborne illness in humans, especially in association with poultry products. They can survive weeks to months in water. More than a dozen species have been identified in dogs and cats (Box 47-1). All species are commonly isolated from both healthy and diarrheic dogs and cats. The prevalence of shedding by clinically healthy dogs, for example, ranges from 15% to 87%,[2] and as high as 58% of non-diarrheic and diarrheic cats shed *Campylobacter* as determined by PCR assay.[3] *Campylobacter jejuni* is most commonly incriminated as a cause of diarrhea. The evidence for disease causation by other species, such as *Campylobacter upsaliensis* and *Campylobacter helveticus*, is less certain, because the isolation rates of these species are often similar in healthy and diarrheic dogs and cats. In one study, *Campylobacter* species were isolated more commonly from healthy cats than from cats with diarrhea.[3]

C. jejuni, *C. helveticus*, and *C. upsaliensis* are the species most frequently isolated from the stool of dogs and cats, with *C. helveticus* and *C. upsaliensis* being the predominant isolates in some studies.[3,4] Other commonly identified species in dogs and cats include *Campylobacter coli*, *C. helveticus*, and *Campylobacter lari*. In one study, up to 12 *Campylobacter* species were present simultaneously in dogs,[5] and coinfection with multiple *Campylobacter* species was detected in 47% of 74 cats from which *Campylobacter* was isolated.[3] The prevalence of *Campylobacter* carriage is particularly high in young dogs and cats and those housed with large numbers of other animals such as in kennels or shelters. Increased isolation rates are also observed in the spring, summer, and fall months, depending on study location.[6,7] Cats less than 1 year of age were significantly more likely to shed *Campylobacter* than cats older than a year of age, and median duration of shedding was around 6 weeks in a study from the upper Midwestern United States.[7] Young age and the feeding of homemade cooked food to dogs was associated with *Campylobacter* carriage in dogs from eastern Canada.[2] Ownership of puppies and kittens is a significant risk factor for development of campylobacteriosis by humans, especially young children.[8,9]

Clinical Features

Signs and Their Pathogenesis

Campylobacter colonize the lower intestinal tract, including the jejunum, ileum, and colon. In contrast to other enteropathogenic bacteria, *Campylobacter* possess relatively few virulence factors, and host factors are important in determining the severity of clinical signs that develop. *Campylobacter* can invade intestinal epithelial cells and produce cytolethal distending toxin, which causes cell cycle arrest and apoptosis, and in humans, stimulates Il-8 production, which leads to an inflammatory response. The organism can produce a polysaccharide capsule, which may also be a virulence factor.[10] Puppies and kittens less than 6 months of age are most likely to show diarrhea in association with *Campylobacter* infection, and stress, overcrowding, and concurrent gastrointestinal infections with other bacteria, protozoa, and helminth parasites may also contribute to clinical signs. The severity of diarrhea can range from mild diarrhea with loose stools through to watery, bloody, or mucoid diarrhea, with lethargy, inappetence, and, less commonly, vomiting. Other signs of large bowel diarrhea such as tenesmus may also be present. Fever may occur in severe acute campylobacteriosis in puppies and kittens. Diarrhea is generally self-limiting within a 1- to 2-week period, although chronic diarrhea can also occur in dogs.[11,12] Rarely, extraintestinal *Campylobacter* infections in dogs have been

reported, specifically cholecystitis, bacteremia, and abortion.[13,14] These have also been described in humans.[15,16]

Physical Examination Findings

Physical examination findings in severely affected young animals with campylobacteriosis are variable and include lethargy, dehydration, fever, and abdominal pain. Diarrhea, sometimes with fresh blood or mucus, may be found on rectal examination in dogs.

Diagnosis

Laboratory Abnormalities

Complete Blood Count and Chemistry Panel

Basic laboratory testing in puppies and kittens with *Campylobacter* diarrhea generally reveals mild and nonspecific changes. A leukocytosis may be present. Animals with systemic campylobacteriosis and cholecystitis may show neutrophilia or neutropenia with increased circulating band neutrophils and biochemical evidence of cholestasis and hepatic dysfunction (see Case Example).

Diagnostic Imaging

Findings on plain abdominal radiography and abdominal ultrasound are typically unremarkable or show fluid-filled intestinal loops. A thickened gallbladder wall may be seen using ultrasound in animals with *Campylobacter* cholecystitis (Figure 47-2).

Microbiologic Testing

Microbiologic assays available for diagnosis of campylobacteriosis in dogs and cats include microscopic examination, culture, and PCR assays (Table 47-1). Because of the high prevalence of *Campylobacter* colonization in healthy dogs and cats, it is difficult to interpret the significance of positive test results on feces. The results must always be considered in light of the patient signalment, history, clinical signs, and exclusion of other causes of diarrhea. Specific identification of *C. jejuni,* as opposed to other *Campylobacter* species, may also add support to the role of *Campylobacter* in disease.

Microscopic Examination

Although not diagnostic for campylobacteriosis, a direct fecal smear may reveal large numbers of fine, S-shaped or gull-shaped organisms following staining with Gram or Romanowsky stains (Figure 47-3). Detection of these organisms only suggests the presence of *Campylobacter*-like organisms and should *not* be used as the sole method to diagnose campylobacteriosis because of the inability to differentiate between similar-appearing organisms such as *Arcobacter* or nonpathogenic campylobacters. Fecal leukocytes may also be present. More advanced microscopic techniques that have been used to identify *Campylobacter* in the feces include darkfield and phase-contrast microscopy, which are used on fresh fecal specimens and show the characteristic morphology and darting motility of the organism. These are generally not performed routinely in clinical situations and require significant technical expertise.

Bacterial Isolation

Campylobacter cannot be isolated on routine bacteriological media. Fecal enteric panels designed to detect bacterial enteropathogens in feces generally include isolation on selective media such as charcoal- or blood-based *Campylobacter* media, which often contain antimicrobials to eliminate other bacteria (such as cefoperazone). The inoculated medium is incubated

VetBooks.ir

TABLE 47-1

Diagnostic Assays Available for Campylobacteriosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Bacterial isolation	Feces, blood, bile, intestinal tissues collected at necropsy	*Campylobacter* organism	False negatives may occur, especially following antimicrobial therapy, and some species may not grow under routine conditions used to isolate *Campylobacter*. Isolation from feces does not imply that *Campylobacter* is the cause of disease. Allows subsequent antimicrobial susceptibility testing.
Polymerase chain reaction	As for isolation	*Campylobacter* DNA	Rapid (within hours); can be highly sensitive and specific. Positive results from feces do not imply that *Campylobacter* is the cause of disease. Some assays do not differentiate between *Campylobacter* species, but others are species specific (e.g., only *Campylobacter jejuni* or only *Campylobacter coli*). Check with the laboratory to determine what assays are offered.

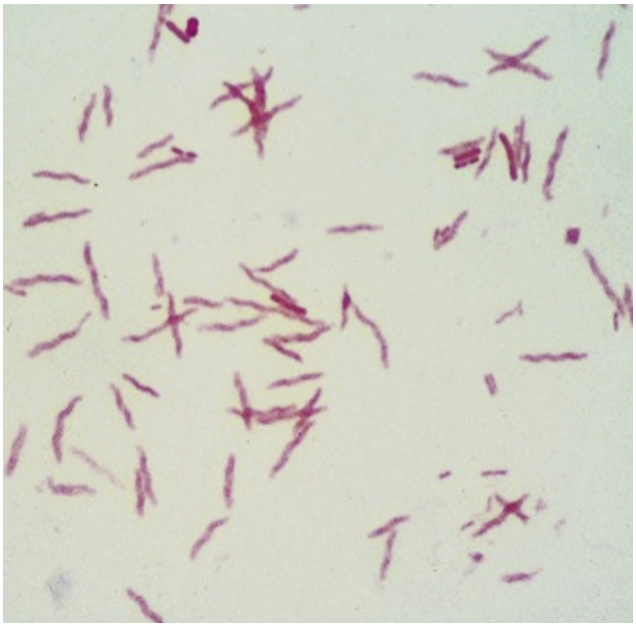

FIGURE 47-3 Cytology showing *Campylobacter* organisms. Gram stain, 1000× magnification.

in a microaerophilic environment for 72 to 96 hours. Incubation is frequently carried out at 42°C to select for thermophilic *Campylobacter*; however, a temperature of 37°C should also be used to ensure isolation of variable or nonthermophilic species. The use of direct plating onto charcoal-based media may be most sensitive for isolation of *Campylobacter* from pets, but use of a combination of isolation methods increases sensitivity further.[17] Some strains require more hydrogen than others and do not grow under routine conditions used for *Campylobacter* isolation. Species identification can then be performed on the basis of biochemical testing or the use of PCR followed by sequencing of the PCR product. Biochemical testing can be highly variable, resulting in inaccurate identification. Serotyping has been traditionally used to identify strains of *C. jejuni* for epidemiologic studies, and more recently, molecular methods such as pulsed-field gel electrophoresis and PCR-based typing methods (including multilocus sequence typing), have been used.[18-20] Techniques based on matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry also show promise for rapid identification of *Campylobacter* species and strains (see Chapter 3).[21,22] Isolation of *Campylobacter* in culture permits subsequent antimicrobial susceptibility testing, although this is not routinely performed by most veterinary laboratories.

Molecular Diagnosis Using the Polymerase Chain Reaction

Both conventional and real-time PCR-based assays have been developed for direct detection of *Campylobacter* in stool, and some are available commercially for use in dogs and cats. An advantage of PCR is that it can detect species that grow poorly in culture, and it overcomes problems relating to overgrowth of other fecal bacteria.[3] Both *Campylobacter* genus-specific and species-specific assays (such as those that only detect *C. jejuni*) have been developed. In human patients, a real-time PCR assay for detection of *C. jejuni* was at least as sensitive as culture.[23]

Pathologic Findings

Gross Pathologic Findings

Gross necropsy findings in puppies with campylobacteriosis include fluid-filled intestinal loops with mucosal congestion and edema, especially within the distal jejunum, ileum, cecum, and colon.[12,24] Mesenteric lymphadenomegaly may also be present.

Histopathologic findings

Campylobacter infection can result in villous blunting and fusion, epithelial hyperplasia, and congestion and lymphoplasmacytic inflammation of the lamina propria. Crypts contain filamentous bacteria that stain with silver stains such as Warthin-Starry (Figure 47-4). Immunohistochemistry can be used to identify *Campylobacter* within intestinal crypts.[12]

Treatment and Prognosis

Uncomplicated campylobacteriosis is generally self-limiting and resolves with supportive therapy. Because isolation of *Campylobacter* even from diarrheic feces does not necessarily imply causation for the clinical signs, specific treatment may not be warranted and may further disrupt the intestinal microflora. Treatment could be considered for severely ill dogs and cats. Macrolides (such as erythromycin or azithromycin) and fluoroquinolones (such as enrofloxacin, 5 mg/kg q24h for 5 to 7 days) are often efficacious, although resistance to these antimicrobials has been documented in some *Campylobacter* isolates.[25,26] Treatment failures could

reflect resistance to the antimicrobial used or infection with a nonpathogenic *Campylobacter* species and persistence of clinical signs from another unidentified cause. Recrudescence of infection has been documented in human patients after treatment.[27]

Immunity and Vaccination

Innate, humoral, and cell-mediated immune responses are critical for clearance of *Campylobacter* infection.[28] Short-term protection that is somewhat serotype specific can result from frequent exposure to *Campylobacter*, but immunity wanes with time, and reinfection is possible. Considerable effort has been expended into development of vaccines for humans and poultry.[29-31] No vaccine currently exists for prevention of *Campylobacter* infection in dogs and cats.

Public Health Aspects

Campylobacter is the most common bacterial cause of enteric illness in humans worldwide. Over 90% of human campylobacteriosis in industrialized countries results from consumption of contaminated chicken products, as well as beef and milk. Drinking water and swimming water may also be a source of infection. To a lesser extent, contact with other food animal species, wild birds, and pet dogs and cats has been associated with human campylobacteriosis.[32] Ingestion of as few as 500 organisms can lead to infection. When clinical signs occur, early signs develop after an incubation period of 1 to 7 days and include fever, myalgia, vomiting, and headache, which generally last 1 to 3 days, followed by up to one week of watery to bloody diarrhea and abdominal pain. Illness may be mild to severe, requiring hospitalization. Severe illness is more likely to occur in the immunosuppressed. Reactive arthritis and Guillain-Barré syndrome, an acute inflammatory demyelinating polyneuropathy, are late-onset immune-mediated consequences that can sometimes occur in association with infection and may persist for weeks or years.[32] In fact, *C. jejuni* is the most common infection that precedes Guillain-Barré syndrome, which occurs in 1 in 1000 infected individuals.[25] Extraintestinal infections that have been described include bacteremia, hepatitis, cholecystitis, pancreatitis, peritonitis, abortion and neonatal sepsis, urinary tract infections, myocarditis, and meningitis, although these are very rare in immunocompetent individuals. *Campylobacter* enteritis has also been identified as a risk factor for inflammatory bowel disease.[33]

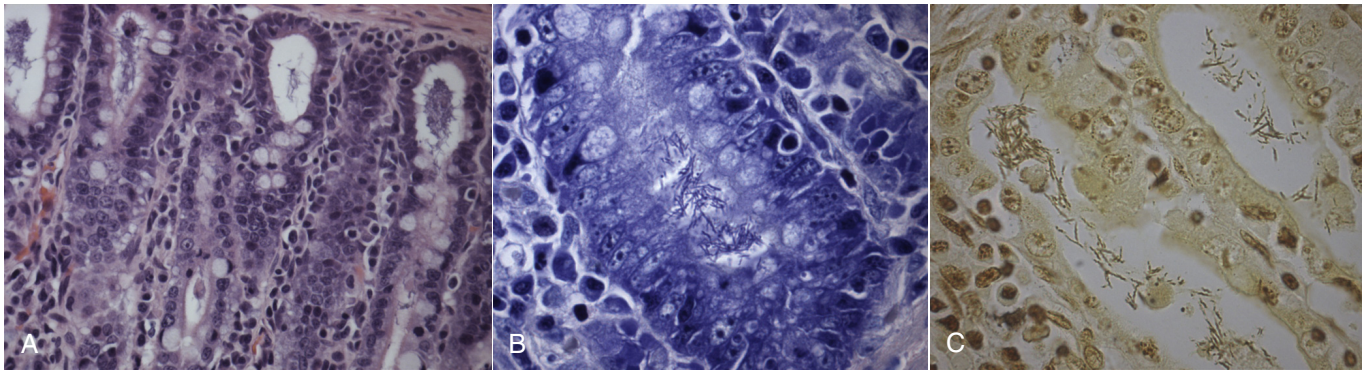

FIGURE 47-4 Histopathology of an intestinal section from a 3-month-old Chihuahua puppy with *Campylobacter jejuni*–associated diarrhea. Abundant filamentous, spiral bacteria pack the crypts and there is an associated lymphoplasmacytic enterocolitis. **A,** H&E stain; **B,** Giemsa stain; **C,** Warthin-Starry silver stain.

CASE EXAMPLE

Signalment: "Henry," a 10-year-old intact male Brittany spaniel from Dixon in northern California

History: Henry was brought to an emergency clinic for a 1-day history of anorexia, lethargy, and fever. The owner, a retired veterinarian, noted that Henry's rectal temperature was 106°F (41.1°C). There had been no vomiting or diarrhea, and the dog had been drinking normally. Henry was a field trial dog and was hunting a week before becoming ill. He was housed in an outdoor run with no access to foreign objects other than gravel. There were nine other apparently healthy dogs in the household. The dogs were fed a commercial dry and canned diet.

Physical Examination:

Body Weight: 17.8 kg

General: Quiet, alert and responsive, 5% to 7% dehydrated. Ambulatory. T = 106.4°F (41.3°C), HR = 140 beats/min, RR = 40 breaths/min, mucous membranes pale pink and tacky, CRT = 2 s.

Integument, Eyes, Ears, Nose, and Throat: A large amount of dental calculus was noted. There was moderate waxy debris in both ear canals and pinnal erythema.

Musculoskeletal: Body condition score was 4/9, and the dog was ambulatory with symmetrical muscling.

Cardiovascular: The femoral pulses were fair and synchronous. No murmurs or arrhythmias were auscultated.

Respiratory: Harsh breath sounds were bilaterally noted on thoracic auscultation, which were loudest in the ventral lung fields.

Gastrointestinal and Genitourinary: The abdomen was tense on palpation and moderate hepatomegaly was noted. The urinary bladder was large. No abnormalities were detected on rectal examination.

Lymph Nodes: All were within normal limits.

Laboratory Findings:

CBC:

HCT 42.9% (40%-55%)
MCV 70 fL (65-75 fL)
MCHC 34.5 g/dL (33-36 g/dL)

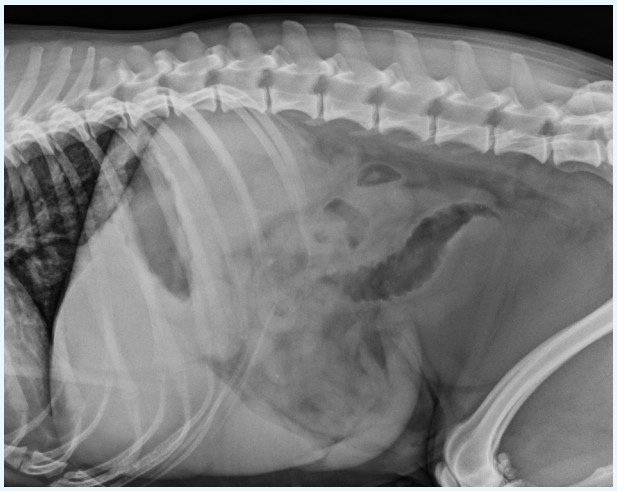

FIGURE 47-5 Abdominal radiograph from a 10-year-old intact male Brittany spaniel with *Campylobacter* bacteremia, gastroenteritis, and probable cholecystitis that shows hepatomegaly and corrugation of the colonic wall.

2 nucleated red blood cells/100 WBC
WBC 6600 cells/μL (6,000-13,000 cells/μL)
Neutrophils 2904 cells/μL (3000-10,500 cells/μL)
Band neutrophils 2838 cells/μL
Metamyelocytes 330 cells/μL
Lymphocytes 330 cells/μL (1000-4000 cells/μL)
Monocytes 198 cells/μL (150-1200 cells/μL)
Eosinophils 0 cells/μL (0-1500 cells/μL)
Platelets 144,000/μL (150,000-400,000 platelets/μL).
Neutrophils, band neutrophils, and metamyelocytes showed mild toxic changes.

Serum Chemistry Profile:
Sodium 146 mmol/L (145-154 mmol/L)
Potassium 4.1 mmol/L (3.6-5.3 mmol/L)
Chloride 116 mmol/L (108-118 mmol/L)
Bicarbonate 15 mmol/L (16-26 mmol/L)
Phosphorus 3.9 mg/dL (3.0-6.2 mg/dL)
Calcium 8.6 mg/dL (9.7-11.5 mg/dl)
BUN 21 mg/dL (5-21 mg/dL)
Creatinine 0.8 mg/dL (0.3-1.2 mg/dL)
Glucose 86 mg/dL (64-123 mg/dL)
Total protein 5.0 g/dL (5.4-7.6 g/dL)
Albumin 2.7 g/dL (3.0-4.4 g/dL)
Globulin 2.3 g/dL (1.8-3.9 g/dL)
ALT 794 U/L (19-67 U/L)
AST 275 U/L (19-42 U/L)
ALP 461 U/L (21-170 U/L)
GGT 37 U/L (0-6 U/L)
Cholesterol 273 mg/dL (135-361 mg/dL)
Total bilirubin 0.7 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.013 (after fluid bolus), pH 7.5, 2+ protein (SSA), 1+ bilirubin, 1+ hemoprotein, no glucose, rare WBC/HPF, rare RBC/HPF, rare granular casts.

Imaging Findings:

Thoracic and Abdominal Radiographs: The cardiovascular and pulmonary structures were within normal limits. The liver was moderately enlarged. The colon was mildly gas distended and had a corrugated appearance (Figure 47-5).

Abdominal Ultrasound: There was moderate enlargement of the liver and spleen. The gallbladder wall was thickened and mildly irregular. There was moderate peritoneal effusion. The stomach and duodenal wall were mildly thickened. Moderate mesenteric lymphadenopathy was identified, particularly around the liver and ileocolic junction. The prostate was enlarged with multiple small parenchymal cysts, but was symmetric and smoothly margined. A sample of orange, somewhat turbid abdominal fluid and an aspirate of a mesenteric lymph node were obtained using ultrasound guidance.

Cytology Findings: Abdominal fluid: Modified transudate. TP = 4.8 g/dL, 20,000 RBC/μL, 460 nucleated cells/μL, with 72% neutrophils, 21% small mononuclear cells, and 7% large mononuclear cells. The nucleated cells were primarily nondegenerate neutrophils with smaller numbers of lymphocytes and macrophages. The lymphocytes were a heterogenous population of small mature lymphocytes and scattered granular lymphocytes. Several pyknotic cells and rare erythrophagocytic macrophages were present. No infectious organisms were seen.

Mesenteric lymph node: Mild lymphoid reactivity.

Microbiologic Testing: Vector-borne disease serologic testing (IFA): Positive for serum *Babesia canis* antibodies (1:160), negative for antibodies to *Rickettsia rickettsii, Anaplasma phagocytophilum,* and *Ehrlichia canis*.

Aerobic and anaerobic bacterial culture of abdominal fluid: No growth.

Aerobic bacterial urine culture (cystocentesis specimen): No growth.

Aerobic and anaerobic blood culture (four specimens collected over 5 hours, the first inoculated into a blood culture bottle and the remainder into isolator tubes): Direct smear of blood culture bottle contents showed rare small curved gram-negative rods. Anaerobic culture of first specimen showed small curved gram-negative rods suspicious for *Campylobacter* spp. Partial sequencing of the 16S rRNA gene revealed 100% identity to *Campylobacter jejuni*. All other specimens yielded no growth.

Fecal enteric panel: *Clostridium difficile* TcdA and TcdB toxin ELISA negative. ELISA negative for *Clostridium perfringens* enterotoxin. No *Salmonella* spp. cultured. No *Clostridium difficile* cultured. Small numbers of *Campylobacter* spp. cultured (*C. jejuni* using partial 16S rRNA gene sequencing).

Diagnosis: *Campylobacter jejuni* bacteremia and probable cholangiohepatitis/cholecystitis

Treatment and Outcome: Henry was hospitalized and treated aggressively with intravenous fluids, and before culture results became available, enrofloxacin (5 mg/kg IV q12h) and ampicillin (22 mg/kg IV q8h). Shortly after admission he vomited and developed mucus-containing diarrhea, and subsequently melena was observed. Over the next 48 hours his temperature gradually normalized, but he continued to vomit intermittently. Neutropenia persisted, and his platelet count dropped to 105,000. He also became icteric, and there were progressive increases in the activities of liver enzymes (ALT 1179 U/L, AST 946 U/L, ALP 1088 U/L, GGT 15 U/L, total bilirubin 3.9 g/dL). By day 4 after presentation, vomiting and diarrhea ceased and he began eating a bland diet. Laboratory testing showed resolution of neutropenia and thrombocytopenia. He was discharged from the hospital and treated with enrofloxacin (10 mg/kg PO q24h) for 4 weeks. One week after discharge, Henry was doing well and had a normal appetite and

activity level. The owner reported that another dog in the household subsequently developed vomiting and diarrhea, and *Campylobacter* spp. were cultured from the dog's feces.

Comments: This was an unusual case of *C. jejuni* bacteremia and probable cholangiohepatitis/cholecystitis in a dog that required blood culture for definitive diagnosis. Culture of bile was not performed, but might also have been helpful. Had *C. jejuni* only been isolated from the dog's feces, its clinical significance would have been less apparent. Whether or not the other dog in the household truly had campylobacteriosis is unknown.

CHAPTER 48

Enteric Clostridial Infections

Jane E. Sykes and Stanley L. Marks

VetBooks.ir

Overview of Clostridial Diarrhea

First Described: 1978 (*C. difficile*, causative role in pseudomembranous colitis in humans)[1]; 1892 (*C. perfringens*, by Nuttall and Welch).[2] Evidence for a role of *C. perfringens* in food-borne illness was gathered over 50 years later.[3]

Cause: *Clostridium difficile* and *Clostridium perfringens* (gram-positive, spore-forming anaerobic rods)

Affected Hosts: Humans and a variety of other animals

Geographic Distribution: Worldwide

Primary Mode of Transmission: Fecal-oral; disease can result from toxin production by organisms resident in the gastrointestinal tract

Major Clinical Signs: Lethargy, anorexia, diarrhea, occasionally fever

Differential Diagnoses: Differential diagnosis for suspected clostridial enterocolitis include canine and feline parvovirus infection, canine distemper virus infection, salmon poisoning disease, campylobacteriosis, salmonellosis, giardiasis, tritrichomoniasis (cats), cryptosporidiosis, whipworms, leptospirosis, dietary indiscretion, gastrointestinal foreign body, pancreatitis, inflammatory bowel disease, lymphoma, hypoadrenocorticism, toxins (including drugs)

Human Health Significance: Dogs and cats have the potential to be a source of human infection with *C. difficile*, because they can harbor strains (ribotypes) that have been detected in humans. The role of dogs and cats as a source of *C. perfringens* infection is poorly understood.

Etiology and Epidemiology

Clostridium difficile and *Clostridium perfringens* are gram-positive, spore-forming, obligately anaerobic rods that are capable of toxin production. Clostridial spores are spherical to oval and distend the bacterial cells when they form within them (Figure 48-1). *Clostridium* species are found in soil and the intestinal tracts of a variety of different animal species, including those of healthy dogs and cats. Their spores are very resistant to disinfection and can persist in the environment, including within hospitals, for years. Despite their similarities, many differences exist between *C. difficile* and *C. perfringens* that relate to epidemiology, interpretation of diagnostic test results, and treatment.

C. difficile is the most common cause of hospital and antimicrobial-associated diarrhea in humans and has also been associated with nosocomial diarrhea in dogs and cats in veterinary hospitals.[4,5] In one study, living with an immunocompromised human was a risk factor for *C. difficile* infection in dogs, but strains present in dogs differed from those in the household environment.[6] Dogs that visit human health care facilities are also at risk of acquiring *C. difficile* infections.[7] The emergence of "hypervirulent" *C. difficile* strains in people has resulted in an increased incidence of disease, increased mortality rates, increased relapse rates, and recognition of community-associated disease.[8] A similar change has not been observed in animals; however, a hypervirulent strain (North American pulsotype 1 or NAP1) was identified in a dog.[9] *C. difficile* strains have been classified on the basis of PCR-based typing of their ribosomal RNA genes (PCR-ribotyping). In one study, multiple animals in shelter environments were colonized with a single PCR-ribotype (SLO 066, 045, and 010 in three different shelters, respectively).[10] More detailed genetic analysis of the *C. difficile* strains isolated by multilocus variable number of tandem repeat analysis (MLVA) suggested that horizontal transmission of strains 045 and 010 occurred within the shelter.

C. perfringens is especially widespread in soil and dust and consists of five biotypes, A to E, based on the possession of one or more of four major toxin genes (encoding alpha, beta, epsilon, and iota toxins). Each biotype can also express a subset of at least 10 other established toxins, including *C. perfringens* enterotoxin (CPE). Almost all infections in dogs and cats are *C. perfringens* biotype A, which also causes the majority of clostridial food-borne illness in humans. The zoonotic potential of *C. difficile* and *C. perfringens* is still incompletely understood.

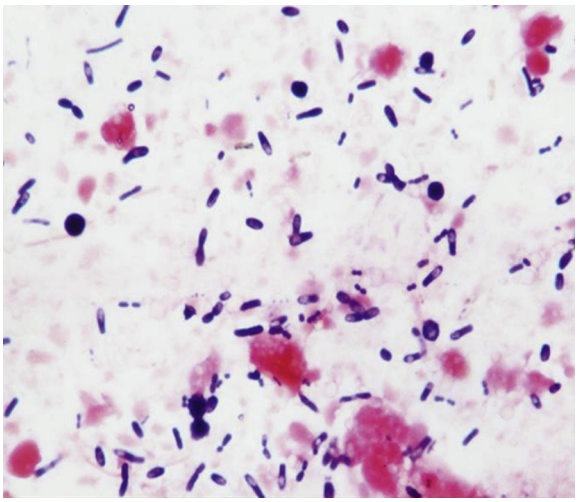

FIGURE 48-1 Fecal smear from a dog with diarrhea showing spore-distended clostridial rods, leading to a characteristic "safety pin" and "tennis racquet" appearance.

The importance of *C. perfringens* and *C. difficile* as causes of diarrhea in dogs and cats has been controversial, because they can be isolated from both diarrheic and healthy animals. For example, *C. perfringens* can be isolated using culture from the feces of more than 70% of both diarrheic and nondiarrheic dogs.[11,12] The prevalence of *C. perfringens* colonization of healthy cats appears to be lower than that in dogs, with isolation rates of 43% to 63%.[13] Similarly, toxin production can be detected in both healthy and diarrheic dogs and cats, although most studies have shown a correlation between production of certain clostridial toxins and diarrhea.[11]

Clinical Features

Signs and Their Pathogenesis

Both *C. difficile* and *C. perfringens* cause diarrhea by producing toxins. The diarrhea can be mild and self-limiting or severe, acute, and hemorrhagic, with life-threatening consequences that relate to dehydration and hypovolemic shock. Inappetence, vomiting, fever, and abdominal pain have also been described in cats with *C. difficile*-associated diarrhea.[14] Vomiting can also occur in dogs. Although clostridial diarrhea is often described as a large bowel–type diarrhea, clinical manifestations of both small and large bowel diarrhea have been well documented.

C. difficile can produce up to five toxins, the most well studied being toxin A (TcdA), toxin B (TcdB), and *C. difficile* binary toxin (CDT, an ADP-ribosyltransferase that is made up of two components). CDT-positive strains have not been reported in dogs and cats. In contrast to humans, a history of antibiotic use does not always seem to be necessary for colonization and disease in dogs and cats, although in one study administration of antimicrobials before admission and the use of immunosuppressive drugs during hospitalization were risk factors for nosocomial colonization.[4] Toxins A and B are thought to be most important in the pathogenesis of diarrhea.[15] These are large toxins that inactivate the Rho family of GTPases, which regulate intracellular actin dynamics. The result is a disruption of the cell cytoskeleton, with subsequent rounding and death of intestinal epithelial cells, and loss of tight junctions. The two toxins also cause release of inflammatory cytokines from mast cells, macrophages, and epithelial cells.[15]

In dogs, *C. perfringens* infection has been associated with nosocomial diarrhea,[16] hemorrhagic enteritis,[17-19] and acute and chronic large bowel diarrhea. *C. perfringens* diarrhea in dogs and cats is thought to occur subsequent to massive proliferation and sporulation of resident clostridial organisms in the intestinal lumen following an alteration in local intestinal conditions. Decreased peristalsis, the effects of antimicrobial drugs on the resident intestinal microflora, diet changes, and/or co-infections with other intestinal pathogens has the potential to trigger sporulation. *C. perfringens* produces CPE on sporulation, but other toxins and bacterial virulence factors may also be involved in the pathogenesis of diarrhea, because diarrhea can occur in the absence of CPE production. CPE is a pore-forming protein toxin that is released when vegetative clostridial cells lyse and release their spores. It binds primarily to claudin, a component of epithelial tight junctions, which leads to increased paracellular permeability.[20] The role of CPE in the development of diarrhea in dogs and cats is unclear, because CPE is detected in 34% of diarrheic dogs, and in 5% to 14% of nondiarrheic dogs.[11,12] There may be an association between the detection of CPE in dogs with acute hemorrhagic diarrheal syndrome (AHDS), as CPE was detected in 8 of 12 dogs (67%) with AHDS.[18]

FIGURE 48-2 Abdominal ultrasound image showing thickening and corrugation of the small intestinal wall of a 2-year-old intact male chihuahua with *Clostridium perfringens*–associated vomiting, hematemesis, diarrhea, and hematochezia. Large numbers of spore-forming gram-positive rods were seen on a fecal smear. *C. perfringens* enterotoxin was detected in the feces using an ELISA assay.

The prevalence of *C. perfringens*–associated diarrhea in cats is much lower than in dogs, and CPE has been detected at a similar rate in diarrheic and nondiarrheic cats (2% to 4.1%).[13] In another study, CPE was detected with ELISA in 19.6% of 46 diarrheic dogs versus 2.1% of 48 healthy dogs, and in 8.3% of 48 diarrheic cats versus 0% of 39 healthy cats.[21] In a PCR-based study of cats and dogs in an animal shelter in Florida, the *C. perfringens* alpha toxin gene was detected in 64% of 50 diarrheic dogs and 40% of 50 nondiarrheic dogs, which was significantly different.[22] In contrast, it was detected in 42% of 50 diarrheic and 50% of 50 nondiarrheic cats in the same shelter.[23] Thus the role that *C. perfringens* plays in feline diarrhea, if any, remains unclear.

Physical Examination Findings

Physical examination findings in dogs and cats with severe clostridial diarrhea include dehydration, fever, and abdominal pain, with or without signs of hypovolemic shock. Rectal examination may reveal loose or watery stools, sometimes with fresh blood and mucus.

Diagnosis

Laboratory Abnormalities

Complete Blood Count and Chemistry Panel

Basic laboratory testing in dogs and cats with clostridial diarrhea usually reveals mild and nonspecific changes. A neutrophilic leukocytosis with a left shift and toxic changes may be present in dogs and cats with acute clostridial gastroenteritis. In addition, a discordant hematocrit and serum total protein concentration can be identified in some dogs with *C. perfringens* and *C. difficile*-associated diarrhea. The hematocrit can be markedly increased in the face of a normal or low-normal total protein.

Diagnostic Imaging

Findings on plain abdominal radiography and abdominal ultrasound examination in animals with clostridial diarrhea are typically unremarkable or show fluid-filled intestinal loops. Mild thickening and corrugation of the small intestinal or colonic wall may be detected on ultrasound examination (Figure 48-2).

VetBooks.ir

TABLE 48-1

Diagnostic Assays Available for Clostridial Enterocolitis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Bacterial isolation	Feces	*C. perfringens* and *C. difficile*	Isolation from feces does not imply that *Clostridium* is the cause of disease. Allows genotyping and subsequent antimicrobial susceptibility testing if needed. False negatives may occur, especially for *C. difficile*, which requires strict anaerobic conditions.
Common antigen test	Feces	*C. difficile*	Excellent negative predictive value for *C. difficile* (i.e., a negative test result suggests *C. difficile* is not present). A positive test result does not imply that *C. difficile* is the cause of disease.
Toxin immunoassays	Feces	*C. perfringens* enterotoxin (CPE); *C. difficile* toxin A and toxin B	Positive test results may occur in dogs and cats that do not have diarrhea; negative results do not rule out clostridial diarrhea, as other toxins may be involved and CPE is relatively labile.
PCR	Feces	*Clostridium* toxin gene DNA	Rapid (within hours). Positive results from feces do not imply that *Clostridium* is the cause of disease. Toxin gene PCR assays may be useful for diagnosis in conjunction with positive ELISA results for toxin production. Negative results may occur if other toxin genes are important or if inhibitors of PCR are present.

Microbiologic Testing

Diagnostic assays available for clostridial enterocolitis in dogs and cats are shown in Table 48-1. Because organisms and their toxins can be found in healthy and diarrheic animals, the results must be interpreted in light of the history, clinical signs, and diagnostic testing to rule out other causes of disease.

Microscopic Examination

Spore-forming rods may be identified on microscopic examination of fecal smears that have been stained with Wright stains (see Figure 48-1). Rods that contain endospores have the appearance of "tennis racquets" or "safety pins." However, there is no association between fecal endospore counts and the presence of diarrhea, or between endospore counts and the detection of CPE in fecal specimens. Detection of fecal endospores is thus an unreliable test for diagnosis of *C. perfringens* diarrhea in dogs and cats and should not be used as a stand-alone test to make clinical inferences in diarrheic dogs and cats.[11,24]

Bacterial isolation. Both *C. difficile* and *C. perfringens* can be isolated from feces of dogs and cats using strict anaerobic conditions for incubation. *C. perfringens* is more tolerant of oxygen than *C. difficile* and therefore may be easier to isolate (hence the name *difficile*, because of its difficulty to isolate in the laboratory).

C. difficile can be isolated from 0% to 40% of diarrheic and healthy dogs. When fecal culture for *C. difficile* is performed on a viable fecal specimen by a reputable laboratory, a negative result suggests that *C. difficile* is not present. However, a positive culture does not differentiate between toxigenic and nontoxigenic strains, and further testing for toxin is warranted.

Because of the high carriage rate of *C. perfringens* in both healthy and diarrheic dogs (>70% in both groups), routine isolation of *C. perfringens* is not recommended for diagnosis, unless epidemiologic studies that require genetic typing are undertaken in outbreak situations. Quantitative stool spore counts have been used to aid diagnosis of *C. perfringens* diarrhea in humans. The stool is treated with heat or alcohol after which it is cultured anaerobically and colonies are counted. Median spore counts of greater than 10^6 per gram of feces collected within 48 hours after the onset of illness are suggestive of infection.[25] Such counts can still be detected in humans with no signs of illness, and the method, when used without assessment of toxin production, has not proven useful for diagnosis of *C. perfringens* diarrhea in dogs.[12]

ELISA for *C. difficile* Antigen

C. difficile antigen ELISA is easy to perform, rapid, and highly sensitive. The antigen test detects "common antigen" (glutamate dehydrogenase; GDH) that is predominantly present in toxigenic and nontoxigenic *C. difficile* strains and a few uncommon *Clostridium* spp. This test has the same limitations as culture in terms of detection of nontoxigenic strains, although a negative test for GDH can virtually rule out infection with *C. difficile*.

Assays for Toxin Production

Several commercial serologic assays are available for detection of *C. difficile* toxin A and toxin B in feces. Fecal swab specimens generally do not contain a sufficient quantity of stool for these assays. Even when performed on larger volumes of stool, the sensitivities and specificities of these assays vary considerably, and the etiologic predictive values are relatively low for all tests. In other words, a positive result does not prove that a clostridial infection is the cause of a dog or cat's diarrhea. Currently, assays based on ELISA methodology have shown the best correlation in dogs between clostridial toxin detection and the presence of diarrhea in dogs.[11,16,24] Panels should include assays for both *C. difficile* toxin A and toxin B, because TcdA-negative, TcdB-positive strains have been documented in dogs, and production of both toxins is not needed for disease causation.[26] The reference standard in human medicine for *C. difficile* toxin production is a cell culture cytotoxicity assay, which uses Vero cells and neutralizing antibody to inhibit cytopathic effects.[27,28] However, culture followed by molecular detection of toxin genes within the isolated strains (also known as "toxigenic culture") appears to be a more sensitive reference standard.[28] Both of these assays

VetBooks.ir

are time consuming and expensive, require specific technical expertise, and are of limited availability. The use of multiple assays in sequence has been advocated for diagnosis of *C. difficile* infection in humans.[29] Specifically, fecal isolation of *C. difficile* or detection of common antigen should be followed with ELISA testing for toxin A and toxin B. Detection of toxin but failure to identify *C. difficile* should be interpreted with caution, considering the relatively high sensitivity of organism or common antigen detection methods compared to toxin ELISA.

Detection of *C. perfringens* enterotoxin in stool is the most widely used diagnostic tool for *C. perfringens* infection in both humans and animals. Two commercially available immunoassays are currently used in veterinary diagnostic laboratories: a reverse passive latex agglutination assay (RPLA) and an ELISA. The assays have not been validated in animals to date. In addition, the RPLA has been associated with false-positive results when compared to several different ELISA methods.

Molecular Diagnosis Using the Polymerase Chain Reaction

Real-time PCR assays are commercially available for detection of *C. perfringens* and *C. difficile* toxin genes in the feces of dogs and cats. It is important to recognize that the presence of clostridial toxin genes within fecal specimens does not prove that clostridia are the cause of an animal's diarrhea, because they do not prove that the organism is actively producing toxin within the intestinal tract of a patient. Conversely, a negative PCR result for clostridial toxin genes does not rule out clostridial diarrhea, as clostridia may be present that possess other virulence factors, and inhibitors of PCR are common in fecal specimens. Real-time PCR assays for *C. difficile* toxin genes have been developed for diagnosis of *C. difficile* diarrhea in humans.[30] Some assays can detect mutations within the toxin gene that correlate with increased toxin production. However, it is still not well understood how well the results of these assays correlate with clinical illness. Similarly, detection of the *cpe* gene has been used to diagnose *C. perfringens* diarrhea in humans.[31] In one study, fecal specimens from diarrheic dogs were more likely to be positive for CPE as detected using ELISA and PCR for the *cpe* gene (28%) when compared with nondiarrheic dogs (4%). Such a combination of testing for the toxin (CPE) via ELISA and the enterotoxin gene (*cpe*) via PCR is likely superior to either test alone.[12] At the time of writing, real-time PCR assays that provide quantitative information on toxin gene copy numbers are available through some veterinary diagnostic laboratories. The degree to which toxin gene copy numbers correlate with clinical signs requires further study.

Treatment and Prognosis

Animals with suspected clostridial enterocolitis that are systemically ill (fever, hemorrhagic gastroenteritis, inflammatory or toxic leukogram) merit appropriate antimicrobial therapy (Table 48-2). There is no documented evidence for a benefit of antimicrobial therapy in dogs with uncomplicated *Clostridium*-associated diarrhea, and most of these animals can be managed supportively to ensure adequate hydration status without antimicrobial therapy. In fact, a prospective, blinded study that randomized dogs with hemorrhagic gastroenteritis that showed no signs of sepsis to two groups, one treated with clavulanic acid–amoxicillin for 7 days and one treated with placebo, showed no difference in mortality rate, dropout rate, duration of hospitalization, or severity of clinical signs, either on any individual day or over the course of disease.[32]

Metronidazole is the drug of choice for treatment of complicated *C. difficile* infections. Oral vancomycin (which is not absorbed from the gastrointestinal tract) is occasionally used in human medicine to treat metronidazole-resistant isolates. The vast majority of *C. perfringens* isolates from dogs are sensitive to metronidazole, ampicillin, amoxicillin, tylosin, and macrolides such as erythromycin.[33] Because of the infrequency of resistance to these drugs, the lack of known breakpoints for veterinary anaerobes, and the lack of relationship between positive stool cultures and disease, antimicrobial susceptibilities are not performed on a routine basis for these organisms when isolated from dogs and cats. Most animals with complicated clostridial enterocolitis can be successfully treated with antimicrobials for 5 to 7 days, and appropriate treatment is generally associated with clinical improvement within 24 to 36 hours.

Immunity and Vaccination

No vaccines are available to prevent clostridial diarrhea in dogs and cats.

Public Health Aspects

C. difficile is increasingly recognized as an important cause of nosocomial diarrhea and pseudomembranous colitis in humans, especially the elderly, which is induced by antimicrobial treatment (especially ampicillin, amoxicillin, clindamycin, cephalosporins, and fluoroquinolones)[34] or disruption of the normal gastrointestinal flora. Humans with *C. difficile* infection develop bloating, and often foul-smelling diarrhea with abdominal pain, usually 5 to 10 days after starting antibiotics.

TABLE 48-2

Antimicrobials That Can Be Used to Treat Complicated Clostridial Diarrhea in Dogs and Cats*

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Metronidazole	10	PO	12	5-7
Ampicillin	22	PO	8-12	5-7
Amoxicillin	22	PO	12	5-7
Tylosin	5 to 10	PO	24	5-7
Erythromycin	15	PO	8	5-7

*Antimicrobial treatment of uncomplicated clostridial diarrhea is not recommended.

VetBooks.ir

Other signs include fever, nausea, anorexia, and malaise. Rare and life-threatening complications of pseudomembranous colitis include acute toxic megacolon, an acute dilatation of the colon with signs of obstruction, and colonic perforation. Hypervirulent strains (such as PCR-ribotype 027) that produce CDT, toxin A, and toxin B have been increasingly identified recently that cause a more severe disease, higher relapse rates, and increased mortality.[35] Efforts are underway to develop vaccines for *C. difficile* infections in humans.[36] There is evidence that dogs may shed *C. difficile* strains similar to those that infect humans. Human colonization and disease usually occurs in hospital situations, and community-acquired infection is uncommon, although concerns have been raised regarding the role of meat and companion animal food products in transmission of the organism.[6,37]

C. perfringens infections are associated with sporadic and antimicrobial-associated diarrhea in humans and CPE is one of the most commonly identified causes of food poisoning in the industrialized world.[38] Clinical signs of infection include foul-smelling, frothy diarrhea, cramping and abdominal pain, and occasionally nausea and vomiting, usually 7 to 15 hours after eating suspected food, especially meat products that have been cooked with improper cooling and reheating.[39] Vegetative cells are then ingested, and this can be followed by massive sporulation with toxin production in the intestinal tract. The zoonotic potential of *C. perfringens* isolates from dogs and cats requires further investigation.

CASE EXAMPLE

Signalment: "Bradley", 2-year old male Chihuahua from Grass Valley in northern California

History: Bradley was brought to an emergency clinic for evaluation of a 12-hour history of hematemesis and diarrhea. He initially vomited up dog food, after which he continued to vomit hourly, and the vomiting progressed to hematemesis. He also developed bloody diarrhea. He had been inappetent and not drinking, and the owner felt he was much quieter than usual. He primarily resided indoors and in the owner's backyard, and there was no history of travel or access to toxins. There were two other apparently healthy dogs in the household. He was up to date on vaccinations for canine parvovirus, distemper virus, canine adenovirus, and rabies. His diet consisted of commercial dry dog food, dog bones, and table scraps.

Physical Examination:

Body Weight: 3.4 kg

General: Quiet, alert and responsive, ambulatory, 5% to 7% dehydrated. Recumbent. T = 100.0°F (37.8°C), HR = 100 beats/min, RR = 30 breaths/min, mucous membranes pink and tacky, CRT = 2 s.

Integument: A full coat with a small amount of flea excrement was present. Bloody diarrhea contaminated the hair in the perianal region.

Eyes, Ears, Nose, and Throat: No abnormalities were noted.

Musculoskeletal: Body condition score was 4/9.

Cardiovascular: The femoral pulses were fair and synchronous. No murmurs or arrhythmias were auscultated.

Respiratory: Normal breath sounds were present in all lung fields.

Gastrointestinal and Genitourinary: The dog was nonpainful on abdominal palpation, but defecated red, jelly-like material several times in the room following the examination. He also urinated a large amount of odiferous urine during the examination. No abnormalities were detected on rectal examination apart from the abnormal stool color and consistency.

Lymph Nodes: All lymph nodes were within normal limits on palpation.

Laboratory Findings:

CBC:

HCT 46% (40%-55%)
MCV 68 fL (65-75 fL)
MCHC 36.3 g/dL (33-36 g/dL)
WBC 11,030 cells/µL (6000-13,000 cells/µL)
Neutrophils 7280 cells/µL (3000-10,500 cells/µL)
Band neutrophils 1324 cells/µL
Lymphocytes 1655 cells/µL (1000-4000 cells/µL)
Monocytes 772 cells/µL (150-1200 cells/µL)
Eosinophils 0 cells/µL (0-1500 cells/µL)
Platelets 273,000/µL (150,000-400,000 platelets/µL).
Neutrophils and band neutrophils showed mild to moderate toxic changes.

Serum Chemistry Profile:

Sodium 147 mmol/L (145-154 mmol/L)
Potassium 4.5 mmol/L (3.6-5.3 mmol/L)
Chloride 111 mmol/L (108-118 mmol/L)
Bicarbonate 29 mmol/L (16-26 mmol/L)
Phosphorus 3.9 mg/dL (3.0-6.2 mg/dL)
Calcium 9.6 mg/dL (9.7-11.5 mg/dl)
BUN 15 mg/dL (5-21 mg/dL)
Creatinine 0.4 mg/dL (0.3-1.2 mg/dL)
Glucose 123 mg/dL (64-123 mg/dL)
Total protein 5.1 g/dL (5.4-7.6 g/dL)
Albumin 3.1 g/dL (3.0-4.4 g/dL)
Globulin 2.0 g/dL (1.8-3.9 g/dL)
ALT 68 U/L (19-67 U/L)
AST 31 U/L (19-42 U/L)
ALP 30 U/L (21-170 U/L)
GGT < 3 U/L (0-6 U/L)
Cholesterol 168 mg/dL (135-361 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.042, pH 6.0, 1+ protein (SSA), 1+ bilirubin, no hemoprotein, no glucose, 1-2 WBC/HPF, 0 RBC/HPF, rare granular casts.

Coagulation Panel: PT 8.9 s (7.5-10.5 s), APTT 18.1 s (9-12 s); fibrinogen 349 mg/dL (90-255 mg/dL).

Imaging Findings: Abdominal ultrasound: Mild mesenteric and sublumbar lymphadenopathy was identified. The small intestines had mild wall thickening and a corrugated appearance (see Figure 48-2). The colon was fluid filled.

VetBooks.ir

Fecal Examination: Fecal flotation: Negative for parasites. Fecal sedimentation: Negative for parasites.

Microbiologic Testing: Parvovirus fecal antigen ELISA: Negative.

Fecal direct smear: Large numbers of gram positive rods were present, some with spores.

Fecal enteric panel: *Clostridium difficile* toxin A and toxin B antigen ELISA negative. ELISA positive for *Clostridium perfringens* enterotoxin. No *Salmonella* spp. cultured. No *Clostridium difficile* cultured. No *Campylobacter* spp. cultured.

Diagnosis: Suspected *C. perfringens*–associated gastroenteritis.

Treatment: Bradley was initially hospitalized and treated with intravenous fluids, nothing by mouth, and metronidazole (7.5 mg/kg IV q12h). Vomiting did not continue, but red gelatinous diarrhea continued every hour for the next 12 hours. Within 24 hours, he had become bright and alert and was offered a bland diet, which he ate well. He was discharged and treated with metronidazole for an additional 5 days, with gradual reintroduction of his regular food.

Comments: Infection by *C. perfringens* was strongly suspected in this case based on the combination of consistent clinical signs, negative assay results for other pathogens, a positive toxin ELISA assay, and response to treatment with metronidazole. However, because the feces of healthy dogs can contain *C. perfringens* enterotoxin, a definitive diagnosis of *C. perfringens* enterocolitis could not be made.

CHAPTER 49

Gastric *Helicobacter*-like Infections

Jane E. Sykes and Stanley L. Marks

VetBooks.ir

Overview of *Helicobacter* Infections in Dogs and Cats

First Described: 1881 by Rappin (France),[1] who observed spiral bacteria in a dog's stomach; the association between *H. pylori* infection and disease in humans was made in 1983 by Warren and Marshall (Australia).[2]

Cause: Various species of non–*H. pylori* helicobacters, rarely *H. pylori* in cats (gram-negative spiral-shaped bacteria that belong to the family Helicobacteraceae)

Primary Mode of Transmission: Fecal-oral and oral-oral transmission proposed, possibly water-borne. Transmission through contact with vomitus may also occur.

Affected Hosts: Humans and a variety of other animals are colonized by helicobacters; an association with disease is clearest for humans and ferrets

Geographic Distribution: Worldwide

Major Clinical Signs (Dogs and Cats): Possibly chronic vomiting (gastric helicobacters) or diarrhea (intestinal helicobacters), although evidence for a causative role in disease is weak

Differential Diagnoses: Dietary indiscretion, gastrointestinal foreign body, chronic pancreatitis, inflammatory bowel disease, food-responsive enteropathy, eosinophilic fibrosing gastritis (cats), bilious vomiting syndrome, gastrointestinal neoplasia (lymphoma, mast cell neoplasia, gastric adenocarcinoma), chronic infiltrative infectious diseases of the gastrointestinal tract (including feline infectious peritonitis, mycobacteriosis, canine cryptococcosis, pythiosis), hypoadrenocorticism, hyperthyroidism, toxins (including drugs), gastric helminthiasis (e.g., *Physaloptera* and *Ollulanus* spp.)

Human Health Significance: Dogs and cats may be a source of human infection with non–*H. pylori* helicobacters that have been associated with gastritis, gastroduodenal ulceration, and low-grade mucosa-associated lymphoid tissue (MALT) lymphoma in humans.

Etiology and Epidemiology

Helicobacter spp. are flagellate, gram-negative, microaerophilic, curved to spiral-shaped motile bacteria. They are grouped into gastric, hepatic, and intestinal *Helicobacter* species, with intestinal species residing primarily in the large intestine.[3,4] In humans, gastric *Helicobacter* spp. are an important cause of gastritis and gastroduodenal ulceration and increase the risk for development of gastric adenocarcinoma and lymphoma. In contrast, the extent to which *Helicobacter* spp. cause disease in dogs and cats is not fully understood, and newly discovered organisms in dogs and cats have drawn most attention in regard to their zoonotic potential.[5]

Helicobacter pylori, the type organism, is the most important species infecting humans. *H. pylori* infection is extremely rare in cats and has only been identified in one colony of cats to date.[6] It has not been described in dogs. Dogs and cats are generally infected with gastric non–*H. pylori* helicobacters (also referred to as gastric helicobacter-like organisms, or GHLOs).[5] These are much larger than *H. pylori* (5 to 10 µm long versus 1.5 to 3 µm long for *H. pylori*), and species cannot be differentiated from one another based on their light or electron microscopic appearance alone (Figure 49-1). The nomenclature of non–*H. pylori* helicobacters is complicated. Species identified in dogs and cats are listed in Table 49-1.[4,7-16] Before their genetic characterization, non–*H. pylori* helicobacters were originally referred to as "*Gastrospirillum hominis*" and later "*Helicobacter heilmannii.*" Subsequent analysis of multiple gene sequences from a variety of "*H. heilmannii*" from dogs and cats has revealed that "*H. heilmannii*" is not one but a group of organisms that includes *H. felis*, *H. bizzozeronii*, *H. salomonis*, and an organism that has been confusingly named *H. heilmannii*. These organisms have also been implicated in human disease, albeit less commonly than *H. pylori*.[5]

Depending on the study, between 60% and 100% of dogs and cats carry non–*H. pylori* helicobacters, and gastric *Helicobacter* spp. can be found in apparently healthy animals and dogs and cats without signs of vomiting.[5,17-22] *H. felis* infection has been associated with gastric pathology in dogs in some studies[23] but not others.[24] Dogs and cats are probably colonized shortly after birth, as a result of fecal-oral and oral-oral transmission.[25] Transmission through contact with vomitus may also occur. Water-borne transmission may play a role in spread of *H. pylori* to humans.[26] Shelter and colony dogs and cats may have a higher prevalence of colonization, most likely due to the close proximity of animals to one another. One *Helicobacter* species may be able to suppress the presence of another, so that dogs and cats are primarily colonized with a single species, although in some animals, the simultaneous presence of multiple species has been found.[27-30] The organisms have a remarkable ability to survive the low pH of the stomach, which they resist by living deep in the mucus glands of the stomach and through production of the enzyme urease. The urease catalyzes the hydrolysis of urea to carbon dioxide and ammonia, which raises the pH of the organism's milieu. In dogs and cats, the organisms are also found within the canaliculi and the cytoplasm of parietal cells.[25,30,31]

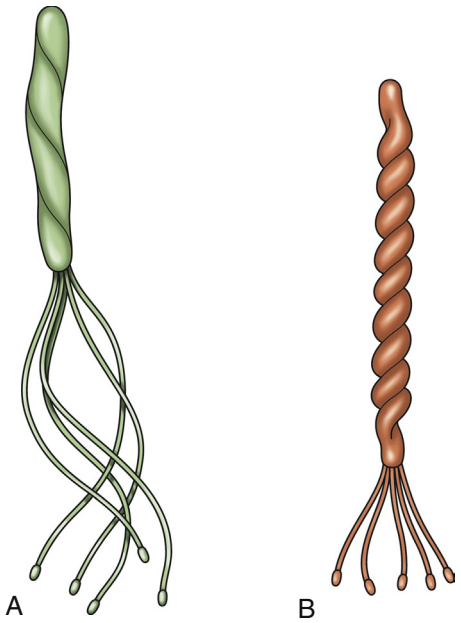

FIGURE 49-1 Structure of gastric *Helicobacter* species. Note the terminal bunches of flagellar filaments. **A,** *Helicobacter pylori*. **B,** Gastric helicobacter-like organism.

TABLE 49-1

***Helicobacter* Species Identified in Dogs, Cats, and Humans**[4,7-16]

Species	Location	Host
H. bizzozeronii	Stomach	Dog, humans
H. salomonis	Stomach	Dog
H. cynogastricus	Stomach	Dog
H. heilmannii	Stomach	Dog, cat, humans
H. felis	Stomach	Dog, cat, humans
H. pametensis	Stomach	Cat
H. baculiformis	Stomach	Cat
H. pylori	Stomach	Cat
"*Flexispira rappini*"	Stomach, intestine	Dog, cat
H. bilis	Stomach, intestine	Dog, cat
H. cinaedi	Intestine	Dog, cat
H. fennelliae	Intestine	Dog, cat
"*H. colifelis*"	Intestine	Cat
H. marmotae	Intestine	Cat
H. canis	Intestine, liver	Dog, cat, humans

Clinical Features

Signs and Their Pathogenesis

The majority of dogs and cats infected with *Helicobacter* spp. show no clinical signs. *Helicobacter* infection of some dogs and cats has been hypothesized to cause chronic intermittent vomiting, inappetence, pica, belching, weight loss, fever, and polyphagia.[31] Unfortunately, strong evidence that supports an association with such disease in dogs and cats is lacking. Clinical signs in some animals with biopsy-confirmed infection resolve following specific therapy for gastric helicobacter infection,[31-33] although the results of one study were difficult to interpret because an elimination diet was administered concurrently.[31] Experimental and natural infection of dogs and cats with non–*H. pylori* helicobacters has been associated with chronic lymphoplasmacytic gastritis and lymphoid follicular hyperplasia. Gastroduodenal ulceration and marked alterations in the gastric acid secretory axis, as occur in humans, have not been observed in dogs and cats.[24,33,34] However, not all animals infected with non–*H. pylori* helicobacters have histopathologic evidence of gastritis, and no correlation has been observed between the severity of gastric pathology and the degree of colonization by helicobacters. More severe gastritis with marked lymphoid follicular hyperplasia and neutrophilic inflammatory infiltrates has been reported in cats and acutely in puppies experimentally infected with *H. pylori*.[35,36] The puppies developed gastrointestinal signs, including vomiting and loose stool, shortly after inoculation. It is possible that the degree of bacterial invasion and gastritis in dogs and cats varies with the infecting *Helicobacter* species or even strain.[30] In humans, gastric pathology has been associated with possession of a number of pathogenicity genes by *H. pylori,* including *cag*A (cytotoxin-associated gene A), *vac*A (vacuolating cytotoxin), and *ice*A (induced by contact with epithelium).[37] The degree of vacuolating cytotoxin production can also vary among strains.[38]

In human patients, *H. pylori* infection has been well associated with gastric low-grade, B-cell, mucosa-associated lymphoid tissue (MALT) lymphoma. Eradication of *H. pylori* achieves complete remission in some patients with *H. pylori*–positive early-stage gastric MALT lymphoma.[39] One study suggested a possible association between *Helicobacter* spp. infection and gastric lymphoma in cats,[40] but additional studies are required to determine the role of *Helicobacter* spp. infection in feline gastric disease.

Non–*H. pylori* helicobacters have been detected in the hepatobiliary system of cats with neutrophilic cholangitis[41] and lymphocytic cholangitis,[42] although this may reflect ascending bacterial infection secondary to an underlying disease process. *H. canis* was detected in the liver of a 2-month-old puppy with multifocal necrotizing hepatitis that had acute weakness and vomiting, and died within hours.[43] *H. canis* was also detected in a colony of Bengal cats with diarrhea, but its role as a causative agent was uncertain.[44] Abundant organisms that genetically resembled *H. canis* were detected microscopically throughout the large intestine of a 2-month-old kitten with severe diarrhea, vomiting, dehydration, weight loss, and inappetence.[3] In one study, the presence of heavy colonic infection with enterohepatic *Helicobacter* spp. infection in a group of laboratory dogs was associated with the presence of mucosal atrophy and fibrosis, and a possible role of *Helicobacter* spp. infection in canine inflammatory bowel disease was suggested.[29]

Diagnosis

Microbiologic Testing

Clinical diagnosis of *Helicobacter* infection in dogs and cats has most commonly been based on histopathology, cytology, rapid urease testing, and, to a lesser extent, PCR on gastric biopsies (Table 49-2). Other tests such as the urea breath and blood tests, fecal PCR, and serologic tests are primarily used in human patients and in the research arena.

Diagnosis Using Cytology and Histopathology

Spiral organisms can be readily detected in touch impression smears of gastric tissue obtained following biopsy or necropsy,

VetBooks.ir

TABLE 49-2

Diagnostic Assays Available for Gastric *Helicobacter* Infection in Dogs and Cats*

Assay	Specimen Type	Target	Performance
Bacterial isolation	Gastric biopsies	*Helicobacter* organisms	Can take up to 10 days. Low sensitivity for non–*H. pylori* helicobacters, which can be difficult to culture. Patchy distribution may also lead to false negatives. Allows typing and antimicrobial susceptibility testing.
Cytology	Impression smears of gastric biopsies or cytology brush specimens	*Helicobacter* organisms	Rapid and sensitive, but false negatives can occur. Patchy distribution may also lead to false negatives. Does not provide information on inflammatory or architectural changes in underlying tissue.
Histopathology	Gastric biopsies	*Helicobacter* organisms	Less sensitive than cytologic examination. Patchy distribution may also lead to false negatives. Use of silver stains increases sensitivity when organism numbers are low. Allows determination of associated gastric histopathology.
Rapid urease testing	Gastric biopsies	*Helicobacter* urease	Rapid and very sensitive. Patchy distribution and low organism loads may lead to false negatives. Very rare false positives with other urease-producing organisms.
PCR	Gastric biopsies	*Helicobacter* DNA	Rapid (within hours); can be highly sensitive and specific. Sequence analysis can determine the species involved. Primarily used on a research basis.
Serology	Serum	Antibodies to *Helicobacter* spp.	Moderate sensitivity in dogs and cats. Results do not correlate well with gastric histopathology and do not always correlate with active infection. Primarily used in research settings.
Urea breath and blood testing	Breath, blood	Radiolabeled carbon dioxide derived from the activity of *Helicobacter* urease	Requires specialized detection equipment. Although sensitive, false negatives may occur, such as following acid suppression. In dogs and cats, has been primarily used in research settings to date.

*For all tests, positive results do not imply that *Helicobacter* is the cause of disease.

after staining with Gram or Diff Quik stains (Figure 49-2). A cytology brush can also be used to obtain a specimen during endoscopy. Several biopsies or brush specimens may need to be evaluated from different regions of the stomach (fundus, cardia, antrum/pylorus) when the distribution of organisms is patchy. When organism burdens are high, the organisms can be detected using histopathology, which allows assessment of concurrent gastric pathology (Figures 49-3 and 49-4). The use of silver stains (such as Warthin-Starry stain or Steiner stain), Giemsa, or toluidine blue stain, as well as immunostaining, dramatically increases sensitivity for organism detection (see Figures 49-3, *C*, and 49-4, *C*).[45]

Bacterial Isolation

Isolation of gastric helicobacters is difficult and has low sensitivity. Growth typically requires incubation on selective media in microaerobic conditions for 5 to 10 days. Isolation is advantageous in research settings because it allows subsequent identification of the organism using conventional biochemical testing, whole-cell protein profiling, and DNA analysis.[21,46] It also allows antimicrobial susceptibility testing, which has recently been recommended before treating humans for *H. pylori* infection because of the increasing prevalence of antimicrobial resistance.[47] Resistance to antimicrobials has also been documented in non–*H. pylori* helicobacters isolated from dogs and cats.[48]

Rapid Urease Testing

The rapid urease test involves incubating a gastric biopsy in a urea broth that contains the pH indicator phenol red. If gastric helicobacters are present, helicobacter urease breaks down the urea; with the release of ammonia, a rise in pH and a color change occur. The change in color can occur within 1 to 3 hours, although the broth is generally incubated at room temperature for 24 hours. The test is very sensitive, but false-negative results can occur if the distribution within the stomach is patchy or if organism loads are low. False-positive results have rarely been reported when other urease-producing bacteria are present in the stomach, such as *Proteus* spp.

Detection of *Helicobacter* DNA

PCR assays have been extensively used to detect *Helicobacter* species in tissues on a research basis, including those from dogs and cats. Sequence analysis of the PCR products can allow identification of the *Helicobacter* species present. Fluorescent in situ hybridization (FISH) has also been used to detect, localize, and identify *Helicobacter* species infection in tissues from dogs and cats.[4,32,40,49]

VetBooks.ir

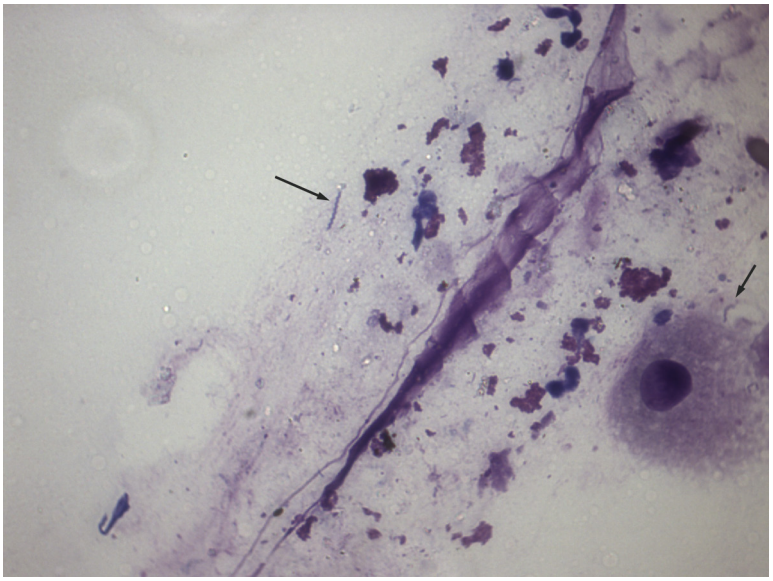

FIGURE 49-2 Spiral-shaped gastric *Helicobacter*-like organisms visible in a Diff Quik–stained smear *(arrows)* of a gastric biopsy from a 2-year-old male neutered Cavalier King Charles spaniel with chronic vomiting and regurgitation for which no other cause was apparent (1000× magnification).

Serology

A variety of serum ELISA and immunoblotting assays have been used in humans to detect antibodies and screen for *H. pylori* infection, and some can be used to some extent to monitor the success of therapy.[50,51] Serologic assays have been used on a research basis to noninvasively detect non–*H. pylori* helicobacter infection in dogs and cats, in some studies demonstrating moderate sensitivity and good specificity.[52-54]

Urea Breath and Blood Testing

Diagnosis and monitoring of the extent of *H. pylori* infection in human patients can also be accomplished noninvasively using urea breath and blood testing, which involves oral administration of urea containing ^{14}C or the stable isotope ^{13}C. After ingestion, the labeled urea is converted to ammonia by *Helicobacter* urease, and the released carbon is absorbed systemically, where it can be measured in the blood. Subsequently, the labeled carbon dioxide is exhaled and can be measured in the breath. Acid suppression interferes with test results by decreasing *Helicobacter* urease activity, and so testing is generally performed several days after discontinuing treatment. False positives can also occur.[55] Urea breath and blood testing has been used with success in dogs,[56] and breath testing has been used in cats[20,57] both before and following specific treatment for *Helicobacter* infection.

Stool Antigen Assays

Assays that detect *H. pylori* antigen in feces have been used in human patients,[55] but their use in dogs and cats has not been described.

Pathologic Findings

Infection with non–*H. pylori* helicobacters in dogs and cats has primarily been associated with chronic lymphocytic or lymphoplasmacytic gastritis, with lymphoid follicular hyperplasia (see Figures 49-3, *A*, and 49-4, *A*), although the extent of inflammation varies dramatically from absent to severe.[19,58,59] An eosinophilic inflammatory component has been described in some cats.[58] Neutrophil and eosinophil infiltrates can accompany mononuclear inflammation in some cats infected with *H. pylori*.[58,60] Organisms may be found in the superficial mucus and crypts, and sometimes within parietal cells see Figures 49-3 and 49-4).

Histopathologic findings in a cat infected with an intestinal helicobacter included large numbers of densely packed spiral bacteria covering the intestinal mucosa and present within the crypts, and minimal inflammatory changes. Hepatic changes in a dog with *H. canis* infection consisted of randomly distributed and coalescing hepatocellular necrosis with associated neutrophilic and mononuclear infiltrates.[43]

Treatment and Prognosis

Whether antimicrobial treatment should be used for *Helicobacter* infections in dogs and cats is unknown. Humans with *H. pylori* infections are typically treated with a combination of a proton pump inhibitor, amoxicillin, and clarithromycin, with or without bismuth subsalicylate. Treatment of humans is reserved for symptomatic individuals; the development of antimicrobial resistance by *H. pylori* is increasingly of concern.[61] Treatment should be reserved for dogs and cats with gastrointestinal signs that have no other identifiable cause of illness, after a diagnosis of gastritis and *Helicobacter* infection has been confirmed using biopsy. A 2-week course of combination therapy with antimicrobials and a proton pump inhibitor or an H_2 antagonist does not reliably eliminate gastric helicobacters in dogs and cats, although clinical signs often resolve.[33,56,62,63] Reinfection can occur in some animals after treatment. This theory is underscored by a study of 20 dogs that were naturally infected with *Helicobacter* spp. and treated with triple therapy (clarithromycin, amoxicillin, and lansoprazole) for 7 days. The dogs were then randomized into a control group kept in isolation, and an experimental group, which was placed in contact with *Helicobacter*-positive dogs for 60 days. Triple therapy was effective in 100% of the dogs; however, recurrence of infection occurred in 80% of dogs in

VetBooks.ir

TABLE 49-3

Antimicrobials Used with Success to Treat *Helicobacter* spp. Infection in Dogs and Cats

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Metronidazole	10-15	PO	12	14-21
Amoxicillin	22	PO	12	14-21
Bismuth subsalicylate	0.22 mL/kg	PO	6-8	14-21
Clarithromycin	5-10	PO	12	14-21
Omeprazole	0.7-1.0	PO	24	14-21
Famotidine	0.5-1.0	PO	12	14-21

The first three drugs are administered as a combination. Alternatively, clarithromycin can be combined with amoxicillin and administered with either omeprazole or famotidine. Bismuth compounds should be avoided in cats. Omeprazole should be given on an empty stomach 30 minutes before a meal.

the experimental group, and in none of the dogs in the control group after 60 days.[64] A 3-week course of amoxicillin, metronidazole, and bismuth subsalicylate (Table 49-3) cleared gastric helicobacters in dogs and cats, with resolution of vomiting, but histopathologic evidence of gastritis did not resolve.[32] Metronidazole could be substituted with clarithromycin.[21] One study showed that concurrent use of an H_2 antagonist in dogs did not change outcome.[33] This is consistent with the lack of abnormalities in the gastric acid secretory axis in dogs infected with non–*H. pylori* helicobacters.[24,34]

Immunity and Vaccination

Gastric helicobacters persist in the stomach despite a vigorous humoral immune response. Research has been underway to develop an effective vaccine for *H. pylori* infection in humans, and a variety of *H. pylori* antigens induce protection in healthy human volunteers or mouse models.[65] No vaccine is available for *Helicobacter* infection in dogs and cats, and a greater understanding of the role of gastric helicobacters in canine and feline disease will be required in order to assess the need for effective vaccines against these organisms.

Public Health Aspects

At least 50% of the world's human population is infected with *H. pylori*, although the prevalence of infection has decreased in developed countries.[66] In the Western world, 1% to 10% of people develop gastroduodenal ulceration as a result of chronic *H. pylori* infection. A smaller percentage of infected people (<3%) develop gastric adenocarcinoma or MALT lymphoma in association with infection. Duodenal ulceration results from increased gastrin release in response to *H. pylori*–induced gastric antral inflammation. Factors that influence outcome are not well understood, but an individual's immune response to

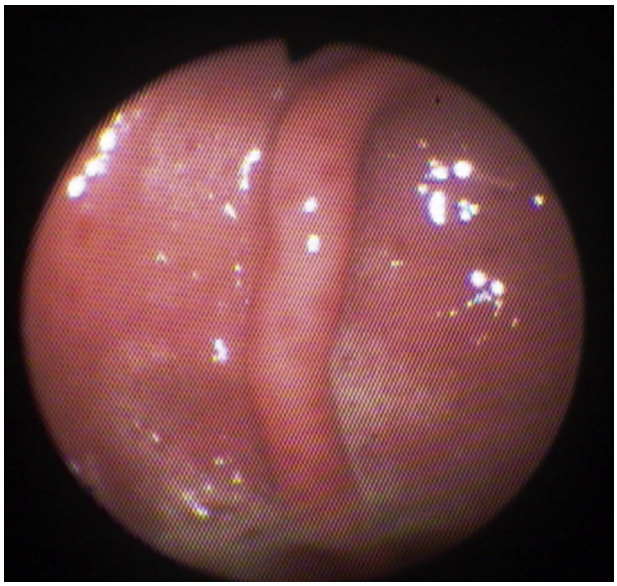

FIGURE 49-5 Endoscopic image of lymphoid follicular gastritis in a 2-year-old maltese terrier with chronic vomiting and regurgitation that was associated with the presence of large numbers of gastric helicobacter like-organisms. Note the 'goose pimple' appearance of the mucosa.

the organism, as well as the possession of virulence factors by *H. pylori* strains, appears to play an important role.[66] Eradication of infection using antimicrobial therapy can cure gastroduodenal ulceration and MALT lymphoma, but gastric adenocarcinoma generally persists despite treatment.[67] Although *H. pylori* has been documented to infect a colony of cats, infection of cats with this species is extremely rare, and exposure to pets is not a risk factor for *H. pylori* infection in humans.

Non–*H. pylori* gastric helicobacter infection is uncommon in humans compared with *H. pylori* infection. Nevertheless, these helicobacters have also been associated with chronic active gastritis, gastroduodenal ulceration, and MALT lymphomas in people. Disease is generally less severe than that caused by *H. pylori*.[5] Clinical signs in humans may be absent or consist of nausea, epigastric pain, vomiting, hematemesis, heartburn, and decreased appetite. Treatment with triple antibiotic therapy and bismuth subsalicylate can resolve infection and gastritis. Pets have been suggested as a source of these helicobacters for humans,[5,7,68-71] and close contact with dogs and cats is a risk factor for infection.[72] Licking has been suggested as a mode of transmission, based on the presence of non–*H. pylori* helicobacter DNA in the oral cavity of dogs.[25] Pigs play an even more important role in zoonotic transmission of non–*H. pylori* gastric helicobacters, the swine helicobacter *H. suis* being the most prevalent species identified in humans.[5]

Intestinal helicobacters found in dogs and cats, especially *H. cinaedi*, have been associated with enteric disease and bacteremia in immunocompromised humans.[73] The relative role of dogs and cats in transmission of these organisms to humans is unknown. Nosocomial spread of *H. cinaedi* was suggested among immunocompromised humans in one report.[74]

CASE EXAMPLE

Signalment: "Mochi," a 2-year-old female spayed Maltese terrier from Dixon, CA

History: Mochi had been vomiting and regurgitating intermittently since she was 1 year of age. As a puppy, the owner (a veterinary student) reported intermittent episodes of "burping." The vomiting occurred 2 to 5 times throughout the day and was not associated with eating, drinking, or exercise. The vomitus usually consisted of brown fluid with no recognizable food particles. Dietary changes that included a digestible elimination diet containing a novel, single protein source followed by a fat-restricted prescription diet had not resulted in improvement in her clinical signs. Therapy with cisapride (3 mg PO q8h) and famotidine (2.5 mg PO q24h) or omeprazole (3.5 mg PO q24h) resulted in only slight improvement in the frequency of vomiting. Her appetite was appropriate, and there had been no weight loss or diarrhea. She primarily lived indoors with one cat. She was up to date on vaccinations, which included those for rabies, distemper, parvovirus, and canine adenovirus.

Physical Examination:

Body Weight: 3 kg

General: Bright, alert and responsive, hydrated, nervous. Ambulatory on all 4 limbs. T = 100.4°F (38.0°C), HR = 120 beats/min, RR = 28 breaths/min, mucous membranes pink and moist, CRT = 1 s.

Integument, Eyes, Ears, Nose, and Throat: No clinically significant abnormalities were noted.

Musculoskeletal: The dog's body condition score was 4/9 with symmetrical muscling.

Cardiovascular, Respiratory, and Lymph Nodes: No clinically significant abnormalities were noted.

Gastrointestinal and Genitourinary: Abdominal palpation was unremarkable. "Burping" behavior was observed in the room, which occurred without any prodromal signs or abdominal effort. Lip-smacking behavior occurred immediately afterwards. Rectal examination was normal.

Laboratory Findings:

CBC:

HCT 46.5% (40%-55%)
MCV 64.4 fL (65-75 fL)
MCHC 35.9 g/dL (33-36 g/dL)
WBC 5700 cells/µL (6000-13,000 cells/µL)
Neutrophils 3112 cells/µL (3000-10,500 cells/µL)
Lymphocytes 1830 cells/µL (1000-4000 cells/µL)
Monocytes 257 cells/µL (150-1200 cells/µL)
Eosinophils 479 cells/µL (0-1500 cells/µL)
Platelets 277,000/µL (150,000-400,000 platelets/µL).

Serum Chemistry Profile:

Sodium 147 mmol/L (145-154 mmol/L)
Potassium 4.4 mmol/L (3.6-5.3 mmol/L)
Chloride 111 mmol/L (108-118 mmol/L)
Bicarbonate 23 mmol/L (16-26 mmol/L)
Phosphorus 5.3 mg/dL (3.0-6.2 mg/dL)
Calcium 10.6 mg/dL (9.7-11.5 mg/dl)
BUN 22 mg/dL (5-21 mg/dL)
Creatinine 1.1 mg/dL (0.3-1.2 mg/dL)
Glucose 95 mg/dL (64-123 mg/dL)
Total protein 5.7 g/dL (5.4-7.6 g/dL)
Albumin 4.0 g/dL (3.0-4.4 g/dL)
Globulin 1.7 g/dL (1.8-3.9 g/dL)
ALT 42 U/L (19-67 U/L)
AST 45 U/L (19-42 U/L)
ALP 52 U/L (21-170 U/L)
GGT < 3 U/L (0-6 U/L)
Cholesterol 241 mg/dL (135-361 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.040, pH 7.0, no protein, glucose, or ketones, trace hemoprotein, 0-1 WBC/HPF, 0-1 RBC/HPF, moderate lipid droplets.

Serum Pancreatic Lipase Immunoreactivity: <30 µg/L (reference range 0-200 µg/L)

Imaging Findings:

Abdominal Radiographs: A moderate amount of gas was identified within multiple small intestinal loops, but an obstructive pattern was not identified.

Thoracic Radiographs: The cardiopulmonary structures were within normal limits. A small amount of gas was visualized within the esophagus on the left lateral projections.

Esophagram: Unremarkable study.

Abdominal Ultrasound: No abnormalities were identified.

Gastroduodenoscopy: Gross findings were suggestive of diffuse lymphoid follicular hyperplasia, with a mild "goose pimple" appearance to the gastric mucosa (Figure 49-5). Multiple biopsies of all regions of the stomach and multiple duodenal biopsies were obtained and submitted for histopathology.

Histopathology: Stomach: Moderate, lymphofollicular, eosinophilic, and lymphoplasmacytic gastritis with intralesional spiral bacteria (see Figure 49-3). Duodenum: Mild, chronic, lymphofollicular, eosinophilic, and lymphoplasmacytic duodenitis and ileitis. Jejunum: Diffuse, mild, eosinophilic, and lymphoplasmacytic enteritis.

Diagnosis: Chronic gastritis associated with *Helicobacter* spp. infection; mild eosinophilic and lymphoplasmacytic enteritis.

Treatment: Treatment for the *Helicobacter* infection was initiated with metronidazole (30 mg PO q12h), amoxicillin (60 mg PO q12h), and bismuth subsalicylate for 2 weeks. The owner reported almost complete resolution of the vomiting following treatment, but signs returned after treatment was discontinued, and an additional course of treatment was instituted. Treatment with a fat-restricted prescription diet was continued. The frequency of vomiting then decreased to once a week.

Comments: Whether the *Helicobacter* spp. infection in this dog contributed to clinical signs or was an incidental finding in a dog with underlying enteritis was not clear. The failure to respond to multiple diet changes, including an elimination diet, and the dramatic response to triple therapy supported a possible role for *Helicobacter* spp. infection, or a diagnosis of antibiotic-responsive gastroenteropathy that was unrelated to *Helicobacter* spp. infection.

CHAPTER 50

Leptospirosis

Jane E. Sykes

VetBooks.ir

Overview of Leptospirosis

First Described: Heidelberg, Germany, 1886 (Adolf Weil)[1]

Cause: *Leptospira* spp. (a spirochete)

Affected Hosts: Dogs, rarely cats, more than 150 other mammalian species

Geographic Distribution: Worldwide

Major Clinical Signs: Fever, lethargy, reluctance to move, anorexia, polyuria and polydipsia, vomiting, diarrhea, icterus, respiratory difficulty

Major Differential Diagnoses: Nephrotoxicoses (e.g., NSAIDs, grapes and raisins, ethylene glycol), Lyme nephritis, acute glomerulonephritides, bacterial pyelonephritis, acute pancreatitis, canine monocytic ehrlichiosis, Rocky Mountain Spotted Fever, bacterial sepsis, leishmaniosis

Human Health Significance: Zoonosis. Human infection results from direct or indirect contact with contaminated urine. No signs, a mild influenza-like illness, or severe illness with multiorgan failure (Weil's disease) have the potential to occur.

Etiologic Agent and Epidemiology

Leptospirosis is a widespread zoonotic disease caused by systemic infection by pathogenic spirochetes of the genus *Leptospira*. *Leptospira* spp. are thin (0.1 µm in diameter), flexible, motile, spiral-shaped bacteria that have a hook-shaped end (*leptos* = "thin," *spira* = "coiled"). A huge variety of different mammalian species may be infected by leptospires. These hosts can shed the organism in their urine and contaminate the environment. Infection of incidental hosts results in disease that varies in severity from a mild febrile illness to severe multisystemic disease. Both dogs and cats can develop leptospirosis, but cats appear to be relatively resistant to development of clinical illness. As a result, leptospirosis is uncommonly described in cats.[2-5]

Both pathogenic and saprophyte *Leptospira* species exist in nature. Saprophytic species, such as *Leptospira biflexa*, live in water and soil and do not infect animal hosts. Disease in dogs is primarily caused by the pathogenic species *Leptospira interrogans* and *Leptospira kirschneri*. Within the genus *Leptospira*, more than 250 different serovars of pathogenic leptospires are recognized, which are distinguished based on differences in their lipopolysaccharide (LPS) O antigens. The serovars are grouped into more than 20 antigenically related serogroups (Table 50-1). At least 10 serovars have been associated with disease in dogs worldwide. Each serovar is adapted to one or more wild or domestic animal reservoir host species (see Table 50-1).

Recently, PCR-based DNA typing methods have been used to identify *Leptospira* strains on the basis of their genotype, instead of using the serovar classification method. Specific genotypes appear to associate more strongly with particular reservoir hosts and disease manifestations than has been found for serovars.[6,7] Multiple different leptospiral serovars have been isolated from single outbreaks of human leptospirosis associated with specific clinical manifestations (such as pulmonary hemorrhage).[8] Therefore, virulence factors other than outer surface antigens (which define serovars) may more important determinants of clinical manifestations of disease than the identity of the infecting serovar.

Pathogenic *Leptospira* species do not replicate outside the host and are readily inactivated in the environment when exposed to excessive heat, ultraviolet irradiation, a variety of disinfectants, and freezing conditions. However, when conditions are optimal, pathogenic leptospires can survive in water and wet soil for weeks to months.[9] Dogs that drink from, swim, or wade in environmental water sources can become infected; exposure to wildlife or farm animals and their urine is also a risk factor. In developing countries, dogs may be infected as a result of access to sewage.[10] Although the "classic" signalment for a dog with leptospirosis is a large-breed, outdoor, intact male dog, dogs of any age, breed, and sex may be affected. For example, geriatric, small-breed dogs that live in urban or suburban areas and that contact rodents or rodent urine can develop the disease. Indeed, over the past decade, residence in urban areas has emerged as a risk factor for *Leptospira* infection in dogs in some parts of North America, possibly due to exposure to urban wildlife species.[11] Cats may be infected after ingestion of infected prey, so outdoor exposure and hunting behavior may be risk factors for cats.[2]

Outbreaks of disease in dogs have been correlated with periods of high annual rainfall and may occur approximately 3 months after wet weather.[12-14] The peak seasonal distribution in parts of North America where freezing winters occur is late fall,[11,15,16] but in more temperate regions, peak seasonal distribution occurs after months of high rainfall (such as in the winter in northern California).[13] Leptospirosis is most prevalent in parts of the world where there is higher annual rainfall and a warm climate, but the presence of infected reservoir hosts also influences the geographic distribution of leptospirosis. Within North America, dogs that live in or travel to Hawaii, northern California, Oregon, Washington, the upper Midwest and Midwest, parts of Texas, Colorado, and the northeastern and mid-Atlantic coastal regions may be more likely to develop infection.[17] Leptospirosis also occurs in dogs in the southeastern United States,[18] and the disease has been widely reported in dogs from Ontario in Canada.[16] Numerous reports describe leptospirosis in dogs from across Europe.[19] Major disease foci among people include the Caribbean, Central and South America, India, Southeast Asia, South America, and Oceania.

TABLE 50-1

Selected Serovars of *Leptospira interrogans* and *Leptospira kirschneri* that Infect Dogs *

Species	Serogroup	Serovar	Potential Reservoir Hosts	Country
Leptospira interrogans	Icterohaemorrhagiae	Icterohaemorrhagiae	Rats	United States, France
	Canicola	Canicola	Dogs	India, United States
	Pomona	Pomona	Horses, cattle, sea lions	United States
	Australis	Bratislava	Pigs, hedgehogs, horses	United States
	Sejroe	ND	Mice	Germany
	Ballum	Ballum	Mice, gray squirrels, muskrats, opossums	United States
Leptospira kirschneri	Grippotyphosa	Grippotyphosa	Raccoons, fox squirrels, muskrats, bobcats, voles, mice, rats, cattle, horses	United States

*Isolated from dogs with naturally-occurring leptospirosis, or that induce disease in dogs after experimental inoculation.

Worldwide, the most common serovars thought to infect dogs before the introduction of canine *Leptospira* vaccines several decades ago were Icterohaemorrhagiae and Canicola.[20] Since that time, widespread seroconversion to other serovars, especially Grippotyphosa and Pomona in North America, has been noted in sick dogs. Increased testing for these serovars may have contributed to this phenomenon, as well as increased contact between dogs and wildlife and farm animal reservoir hosts for these serovars.[21] Serovars that currently cause disease in the dog population are poorly understood, because the results of serology do not accurately predict the infecting serovar,[22] and culture and identification of leptospiral serovars is insensitive, requires significant technical expertise, and is not widely available (see Diagnosis, later).[23]

FIGURE 50-1 Uveitis in an Australian shepherd with leptospirosis with leakage of serum bilirubin into the aqueous humor.

Clinical Features

Signs and Their Pathogenesis

Pathogenic leptospires penetrate intact mucous membranes or abraded skin. They multiply rapidly in the bloodstream as early as 1 day postinfection, which may be followed by the development of vasculitis and multiorgan failure. The spirochetes can produce a variety of toxins, including phospholipases, sphingomyelinases, and pore-forming proteins. Infection follows direct contact with infected urine or, more commonly, contact with soil, water, food, or other fomites that have been contaminated with infected urine. Transmission has also occurred as a result of bite wound inoculation (such as from infected rodents), ingestion of infected tissues, and venereal and placental transfer.

The incubation period for acute leptospirosis is approximately 7 days, but may be shorter or longer depending on the dose and strain virulence of the leptospires involved, and the host immune response.[24] Dogs can also develop signs of chronic kidney disease months or more than a year after acute kidney injury. Early renal damage in this situation may be associated with transient or undetected clinical signs, which are subsequently followed by either clearance or persistence of infection and progression of renal damage. Longer incubation periods might occur in cats,[2] but further study is required.

Leptospirosis varies considerably in severity, which may contribute to underrecognition of the disease. Many dogs probably show no signs of illness or develop only a mild, transient febrile illness. Severe clinical signs and death result from renal failure and/or injury to the liver and lungs. Leptospirosis should be suspected in dogs that develop signs of acute febrile illness, kidney and hepatic injury, uveitis, or pulmonary hemorrhage; it should also be suspected in breeding dogs with abortion, stillbirths, or neonatal deaths.[20] Clinical signs in affected cats resemble those in dogs, although some cats have lacked evidence of hepatic injury.[2]

Fever occurs only at the onset of illness and is often accompanied by shivering, reluctance to move, and generalized muscle tenderness that may result from myositis. This may be followed by signs of lethargy, polyuria and polydipsia, inappetence, vomiting, and diarrhea.[24-27] Gastrointestinal signs in some dogs may result from pancreatitis and enteritis, in addition to acute renal and liver damage. Polyuria and polydipsia may result from a decreased responsiveness of the inner medullary connecting ducts to antidiuretic hormone (acquired nephrogenic diabetes insipidus). However, some dogs show decreased thirst and urination. Liver involvement leads to icterus in some dogs (Figure 50-1). Components of leptospiral endotoxin such as oleic and linoleic acid are thought to interfere with hepatic transport pumps, which leads to functional hepatic impairment.[28] Hepatocyte apoptosis and injury to hepatocyte membranes is also suspected

*Diagnosis based on results of acute and convalescent phase serology together with consistent clinical signs.

to occur; leptospirosis in humans and guinea pig models is associated with loss of the cellular adhesion molecule E-cadherin on hepatocytes.[20]

Less commonly, uveitis, myocardial damage, or reproductive complications occur. Leptospiral DNA can be detected in the aqueous humor of human patients with leptospiral uveitis, and the development of uveitis may be delayed up to 18 months after the onset of acute illness.[29] ECG alterations can occur in dogs that suggest myocardial damage.[30] Abortion can occur during pregnancy.[31] Stillbirth and neonatal deaths have also been described.

Bleeding tendencies in dogs with leptospirosis may be manifested as petechial hemorrhages, hematuria, hematemesis, epistaxis, hematochezia, or melena.[25,30,32] Although the precise mechanisms are unknown, bleeding tendencies may reflect the presence of endothelial damage and disordered coagulation. In human patients, thrombocytopenia (≤100,000 platelets/μL) and prolonged PT have been associated with bleeding.[33,34] Tachypnea may be noted as a result of severe pulmonary hemorrhage syndrome (SPHS).[35,36] SPHS is recognized commonly in humans with severe leptospirosis, is not associated with significant lung colonization by the spirochete, and seems to have an immune-mediated pathogenesis.[37] The prevalence of SPHS in dogs appears to be particularly high in continental Europe. For example, pulmonary complications occurred in more than two thirds of dogs with leptospirosis in Berlin.[36] Vasculitis can also contribute to the development of peripheral edema and mild pleural and peritoneal effusions. In human patients, aseptic meningitis is a common complication of leptospirosis and results in signs of severe headache, delirium, and less commonly seizures and altered sensory perception.[38] Whether meningitis occurs in dogs is unknown.

The extent to which leptospires can cause chronic hepatic injury in dogs is also unknown. In one report from France, leptospires were detected in bile canaliculi of young dogs with chronic hepatitis using immunohistochemistry and electron microscopy. These dogs showed signs of poor growth, weight loss, and ascites.[39,40] Attempts to detect *Leptospira* DNA in liver tissue from dogs with chronic active hepatitis have been unrewarding.

Physical Examination Findings

Findings on physical examination of dogs with leptospirosis vary with disease severity, chronicity, and the infecting leptospiral strain. Severely affected dogs may show fever, dull mentation, dehydration, mild generalized peripheral lymphadenopathy, diffuse muscle pain, and pain on palpation of the abdomen or kidneys. Fever is typically only present early in the course of infection. In oliguric or anuric dogs that have been treated aggressively with intravenous fluids, evidence of overhydration may be present. Rarely, arrhythmias are detected on cardiac auscultation. Careful ophthalmologic examination may reveal conjunctivitis, scleral injection, and occasionally uveitis. Mild pallor, petechial or ecchymotic hemorrhages, and, less commonly, epistaxis may be present. Respiratory difficulty, tachypnea, and harsh lung sounds may be evident in dogs that develop pulmonary complications. Dogs with liver involvement may be icteric. Rectal examination occasionally reveals melena or hematochezia.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

The hemogram in dogs with leptospirosis may reveal neutrophilia, sometimes with bandemia; nonregenerative anemia; lymphopenia; and/or thrombocytopenia (Table 50-2). Thrombocytopenia occurs in up to 53% of dogs.[25,26,30,41] The mechanism is unclear; disseminated intravascular coagulation (DIC) or immune-mediated mechanisms may be involved.

Serum Biochemical Tests

Findings on the serum chemistry panel vary depending on leptospiral strains that circulate in a particular geographic region (Table 50-3). In all geographic locations, a combination of azotemia and elevated liver enzyme activities, especially when thrombocytopenia is present, should raise suspicion for leptospirosis. Azotemia is generally present in more than 80% to 90% of dogs,[25,26,30,42] although in one European study, increased serum creatinine concentration was present in only 57% of affected dogs.[41] Uncommonly, dogs exhibit increased liver enzyme activities in the absence of azotemia. Signs of hepatic dysfunction are associated with minimal histologic damage to the liver and include variable, and generally mild to moderate, increases in serum ALT, AST, and ALP activities and total bilirubin concentration.

CK (U/L)	46-320	31	8	62	5-258,720	13

*Diagnosis based on results of acute and convalescent phase serology together with consistent clinical signs.

Other findings on the serum chemistry panel include hypoalbuminemia and a variety of electrolyte abnormalities. Hyponatremia, hypochloremia, or hyperphosphatemia occur in most dogs. Decreased expression of sodium transporters by proximal convoluted tubule cells contributes to impaired sodium resorption, increased distal sodium delivery, and potassium wasting.[43] As a result, dogs with acute oliguric renal failure may have paradoxical hypokalemia.

Moderately and occasionally markedly increased serum CK activity is present in some dogs due to myositis. Increased serum troponin concentrations have been found in some dogs with leptospirosis, which suggests myocardial damage.[30] Increased serum pancreatic lipase immunoreactivity may occur, probably as a result of pancreatitis.

Urinalysis

Findings on urinalysis in dogs with leptospirosis include isosthenuria, occasionally hyposthenuria, and variable glucosuria, proteinuria, pyuria, cylindruria, and bilirubinuria.[20,26,30,42] Urine protein to creatinine (UPC) ratios may be increased. Glucosuria was present in 77% of 44 dogs with leptospirosis at the author's institution, and in 21 dogs that had UPC ratios measured, the ratios ranged from 0.4 to 11.6 (median, 3, reference range less than 0.5). Most proteins in the urine are of low molecular weight, which supports a tubular rather than glomerular origin of these proteins.[30,44] Leptospires are not visible in urine sediment by routine light microscopy.

Coagulation Function

Aside from thrombocytopenia, analysis of hemostatic function in dogs with leptospirosis shows variable increases in fibrinogen, D-dimer, and fibrinogen degradation product concentrations. Antithrombin activity may be decreased. Prolongations in PT and PTT have been present in up to 15% of tested dogs.[20,26,30] PT prolongations are associated with mortality in human patients.[34] In some dogs, a shortened PT is present,[42] possibly because of DIC. In human patients, leptospirosis has been associated with an imbalance between coagulation and fibrinolysis.[34]

Diagnostic Imaging

Plain Radiography

Plain thoracic radiography in dogs with leptospirosis may show no abnormalities, or mild to severe, diffuse interstitial pulmonary patterns may be present. Thoracic radiographs from dogs with SPHS can show severe nodular to diffuse interstitial and alveolar patterns (Figure 50-2). Uncommonly, mild pleural effusion is present.

Sonographic Findings

Findings on abdominal sonography include mild renomegaly, increased renal cortical echogenicity, mild pyelectasia, perirenal fluid accumulation or mild ascites, and a medullary band of increased echogenicity within the kidneys (Figure 50-3).[45] None of these signs are specific for leptospirosis. Ultrasonographic changes suggestive of pancreatitis are occasionally present, such as enlargement and hypoechogenicity of the pancreas. Thickening of the gastric, and less commonly small intestinal wall may also be present. Mild to moderate hepatomegaly and splenomegaly with mottling of the splenic echotexture may be detected, with or without evidence of mild abdominal lymphadenomegaly.

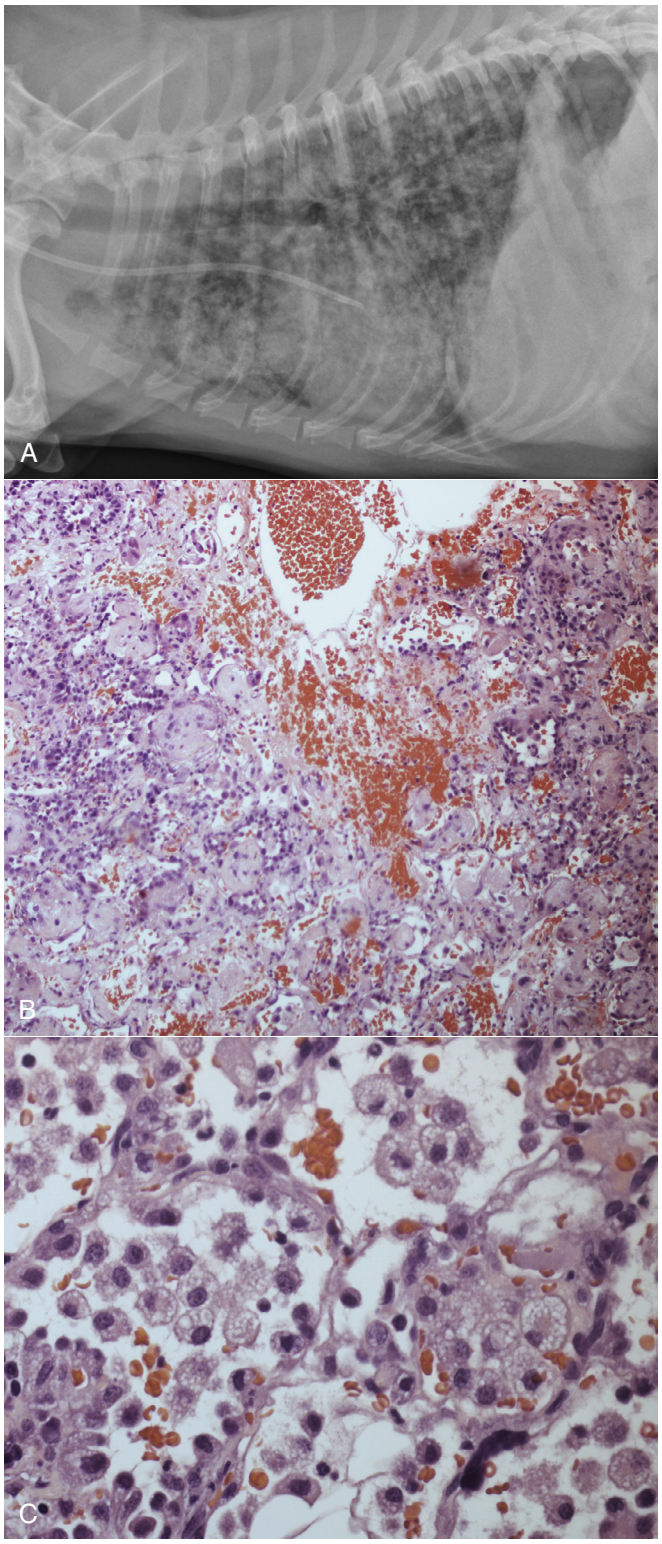

FIGURE 50-2 Clinical images from a 4-year-old male neutered Havanese terrier with severe leptospiral pulmonary hemorrhage syndrome and anuric renal failure. **A,** Right lateral thoracic radiograph. A severe, diffuse alveolar pattern is present. Mechanical ventilation was needed and ultimately euthanasia was performed because of respiratory failure. Histopathology of a lung biopsy showed severe pulmonary hemorrhage **(B)** and marked alveolar histiocytosis **(C)**.

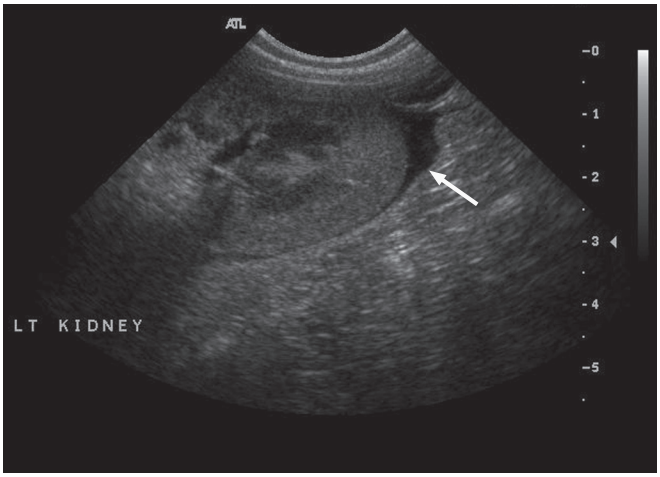

FIGURE 50-3 Abdominal sonogram image showing perirenal fluid accumulation in a 1.5-year-old male neutered kelpie with renal failure due to acute leptospirosis.

Microbiologic Tests

Diagnostic assays available for leptospirosis in dogs are described in Table 50-4. Most often, diagnosis is based on acute and convalescent phase serology.

Darkfield Microscopy

Examination of urine sediment using darkfield microscopy is insensitive for diagnosis of leptospirosis. Considerable experience is required to accurately identify the spirochetes, so false positives also have the potential to occur.

Culture

Culture of leptospires is not routinely performed, because it is slow, can be insensitive, and is not widely available. Special leptospira growth media is required, such as Ellinghausen-McCullough-Johnson-Harris (EMJH) medium. Cultures must be incubated for up to 3 to 6 months, and overgrowth with other bacteria can occur if cultures become contaminated. Venous blood and/or urine should be collected using aseptic technique before initiating antimicrobial drug treatment. Ideally, a few drops of blood or urine are inoculated directly into culture medium alongside the patient. In humans, blood is optimally collected during the initial febrile period; urine can be collected after the first week of illness. Because the exact time of infection may be unknown, submission of both blood and urine can increase the chance of a positive test result.

Only certain reference laboratories have expertise in culture of leptospires and the ability to identify leptospires to the serovar level, which is performed using a cross agglutinin absorption test. Genetic typing methods such as pulsed field gel electrophoresis can also be performed.[23] Despite the difficulties associated with culture and identification of leptospires, a proper understanding of the epidemiology of leptospirosis depends on the use of these methods.

Serologic Diagnosis

Currently the test of choice for diagnosis of leptospirosis is serology using the microscopic agglutination test (MAT).[20] In this assay, the laboratory mixes serial dilutions of patient sera with a panel of live leptospiral serovars. The laboratory then reports the agglutinating antibody titer for each of the serovars tested,

VetBooks.ir

TABLE 50-4

Diagnostic Assays Available for Leptospirosis in Dogs

Assay	Specimen Type	Target	Performance
Darkfield microscopy	Urine	*Leptospira* organisms	Low sensitivity and specificity. Requires considerable technical expertise to interpret correctly.
Culture	Whole blood, urine	Leptospires	Low sensitivity. Special media and prolonged incubation times required. Difficult and not widely available. Antimicrobial therapy may lead to false-negative results. Currently the only method that permits accurate serovar identification.
Serology (MAT)	Serum	Antibodies against various leptospiral serovars	False negatives can occur early in the course of illness or with immunosuppression. False positives can occur with a history of vaccination or with previous exposure. Paired titers performed at the same laboratory generally required for diagnosis. Interlaboratory variation in results may occur.
Histopathology	Kidney tissue collected via biopsy or necropsy	Leptospires	Organisms may be visualized with silver stains, immunohistochemistry, or fluorescence in situ hybridization. Antimicrobial therapy may lead to false-negative results.
PCR	Blood, urine, tissue specimens	*Leptospira* DNA	Sensitivity and specificity unclear and may vary between assays offered by different laboratories. Antimicrobial therapy may lead to negative PCR results.

which is the highest dilution of serum that causes the organisms to agglutinate as assessed using darkfield microscopy. Seropositive dogs can have high titers to multiple serovars tested because of serologic cross-reactivity. The highest titer does not necessarily predict the infecting serovar.[22] The serovar that produces the highest titer may also change when serology is repeated over the course of illness.[20]

Documentation of a fourfold or greater increase in titer to at least one serovar over time is usually required for diagnosis using the MAT, because titers are often low or negative in the first few days of illness, and a single high titer can result from previous exposure or a history of vaccination for leptospirosis. Later in the course of illness, a fourfold decrease in titer may also be appropriate for diagnosis. Traditionally, convalescent titers are performed 2 to 4 weeks after the acute titer, although seroconversion can sometimes occur as early as 3 to 5 days after the initial titer is obtained. Nevertheless, successive titers should be spaced at least 1 week apart, and it is critically important to use the same laboratory for each set of titers.[20] Antimicrobial treatment has the potential to blunt a rise in titer, but dogs usually seroconvert despite antimicrobial treatment.[42] Titers that result from previous vaccination, previous exposure or chronic infection generally change by one dilution over time (e.g., from 1:400 to 1:800) or remain static. Titers persist for at least 1 year after natural infection, although they often decline by 4 months after vaccination.[46] Nevertheless, postvaccinal titers can persist for longer than a year and be maintained at high levels (≥1600), especially if ongoing exposure to field strains occurs. Thus, although single positive titers can raise suspicion for the disease, they cannot be used to confirm the diagnosis of leptospirosis. After immunization, paradoxical cross-reactivity to serogroups other than those used in the vaccine can occur,[46] so titers to non-vaccinal serovars in vaccinated dogs do not necessarily imply natural exposure to field strains.

False-negative titers have the potential to occur if the infecting serovar (or a related serovar) is not included in the panel of serovars used to perform the test. Assays for diagnosis of human leptospirosis generally include a larger panel of serovars (>20) than those used routinely in veterinary diagnostics (5 to 7 serovars). Assays should optimally include serovars from serogroups that are known to circulate in the local dog population, although this information is not often readily available.

The MAT is widely available and relatively inexpensive, but is complex to perform and interpret. Performance of the test is hazardous to laboratory workers because live pathogenic serovars are used, and the test is difficult to standardize. Considerable interlaboratory variation in results can occur, in terms of both the magnitude of the titers reported and the pattern of seroreactivity to each serovar included in the test.[47] The identity of serovars used in the assay must be verified periodically to ensure that cross-contamination or culture deterioration has not occurred. A leptospirosis proficiency testing scheme is offered by the International Leptospirosis Society (ILS) to assist laboratories in the maintenance of quality

assurance for the MAT.[48,49] Veterinarians should strive to use laboratories that participate in this quality assurance scheme.

Other serologic assays under investigation for diagnosis of leptospirosis include ELISA assays for IgG and IgM antibodies that are directed against leptospiral surface antigens.[50-53] The performance of such assays have the potential to vary geographically based on the serogroups that are prevalent in the region. In Europe, a lateral-flow assay that detects IgM (Test-it, Royal Tropical Institute/Life Assay Diagnostics) is available for diagnosis of acute canine leptospirosis.[50] This assay appeared to have high clinical sensitivity for diagnosis of leptospirosis in dogs in the Netherlands (100%) and the West Indies (78%), with a low rate of false positives in healthy dogs from the Netherlands, the West Indies, and Mexico (<5%).

Molecular Diagnosis Using the Polymerase Chain Reaction

Several veterinary diagnostic laboratories in the United States and Europe offer PCR assays for the detection of the DNA of pathogenic leptospires in blood and/or urine. The sensitivity and specificity of these assays in dogs with leptospirosis has not been thoroughly assessed and have the potential to vary geographically, because of differences in shedding patterns for different serovars. Assay performance also is likely to vary from one laboratory to another. PCR assays have the potential to be advantageous for diagnosis early in the course of illness, when serologic tests are negative, or in dogs that possess residual antibody after vaccination. Specimens for PCR testing are best obtained before initiation of antimicrobial drug treatment, and both blood and urine should be submitted in order to optimize sensitivity. Negative results do not rule out a diagnosis of leptospirosis. Because subclinically infected dogs can shed leptospires, a positive PCR test result on urine may not necessarily correlate with illness. Vaccination of healthy dogs with inactivated *Leptospira* vaccines should not lead to positive PCR assay results,[54] so a history of *Leptospira* vaccination should not interfere with PCR diagnosis. Currently available PCR assays do not provide information on the infecting serovar or serogroup.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with leptospirosis include jaundice, petechial and ecchymotic hemorrhages, and sometimes fibrin thrombi throughout the body. The lungs of dogs with SPHS may be wet, mottled, heavy, and dark-pink to red in color.[36] Ascites and/or pleural or pericardial effusion may be present, and the intestinal lumen may be filled with blood or contain melena. The kidneys of dogs with acute disease may be mildly enlarged, pale and sometimes mottled or petechiated; they may also contain infarcts. Dogs with chronic renal injury secondary to the infection can have kidneys that are shrunken and irregular (Figure 50-4).

FIGURE 50-4 Shrunken, irregular kidneys from a 16-year-old male neutered Jack Russell terrier. The dog was treated for severe acute leptospirosis at 12 years of age. At that time, after six dialysis treatments, the dog was discharged from the hospital with a creatinine of 4.2 mg/dL. Four years later, the dog died for reasons unrelated to renal injury but had evidence of chronic renal injury at necropsy. (Image courtesy UC Davis Veterinary Anatomic Pathology Service.)

Histopathologic Findings

Infection of the kidneys by leptospires leads to an interstitial nephritis, with mixed inflammatory infiltrates. Acute tubular necrosis can also occur as a result of vasculitis and renal ischemia (Figure 50-5, *A*).[36] Histopathologic changes in the liver are often mild and include mild random hepatic necrosis, mild neutrophilic periportal hepatitis, cholestasis, or liver plate disarray (Figure 50-6). Multifocal, random, neutrophilic, and necrotizing myocarditis can also occur; myonecrosis is occasionally described in skeletal muscle. Lung pathology in dogs with SPHS resembles that described in human patients and consists of intra-alveolar hemorrhage, pneumocyte necrosis, and hyaline membrane formation, in the absence of significant inflammation.

Silver stains such as Warthin-Starry stain and immunohistochemistry can be used to visualize bacteria within tissue specimens (see Figure 50-5, *B*). Fluorescence in situ hybridization has also been used to identify and localize leptospires within the kidneys (see Figure 5-1).

Treatment and Prognosis

Antimicrobial Drugs

Penicillins or doxycycline are recommended for initial treatment of humans and dogs with leptospirosis. Treatment should be initiated as early as possible, before the results of diagnostic assays become available. In hamster models, doxycycline clears spirochetes from all tissues, including the kidney, within 3 days of infection; ampicillin is less effective at clearing organisms from the kidney.[55] Based on current evidence, the ACVIM Consensus Statement on leptospirosis in dogs

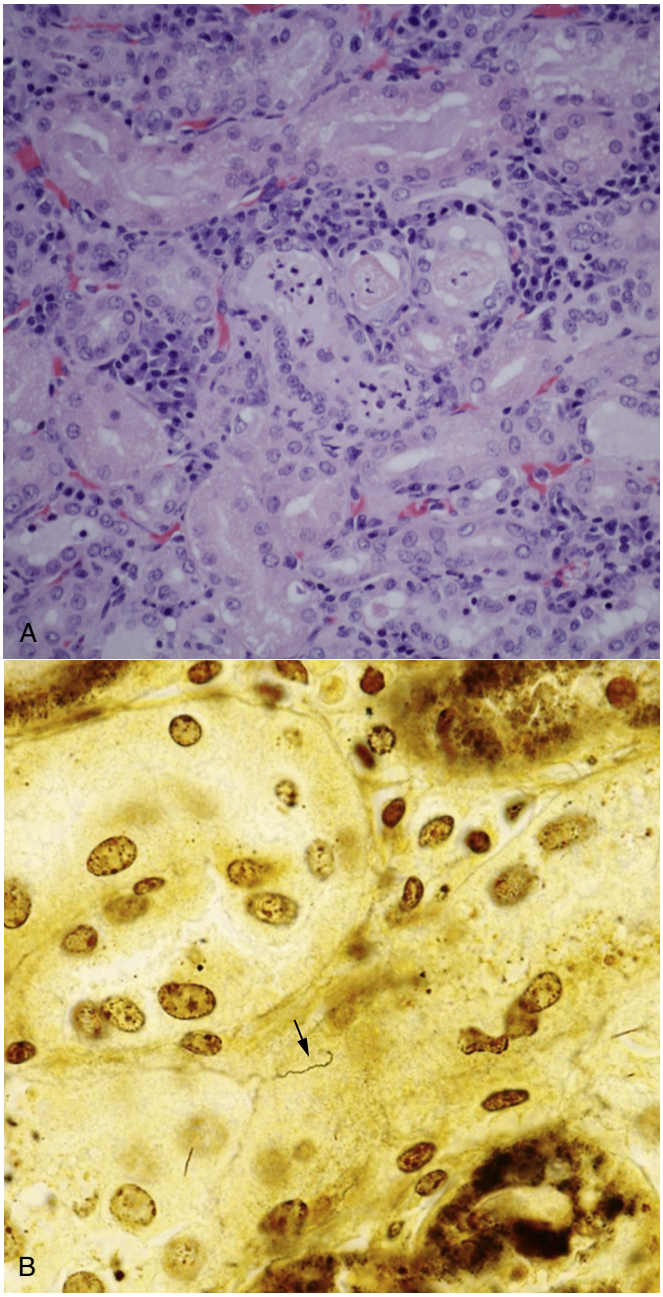

FIGURE 50-5 **A,** Histopathology of the kidney of a dog that died of leptospirosis. Acute tubular necrosis and interstitial nephritis is present. H&E stain. **B,** Warthin-Starry showing low numbers of leptospires in the renal interstitium *(arrow)*. (Images courtesy Dr. Patricia Pesavento, University of California, Davis Veterinary Anatomic Pathology Service.)

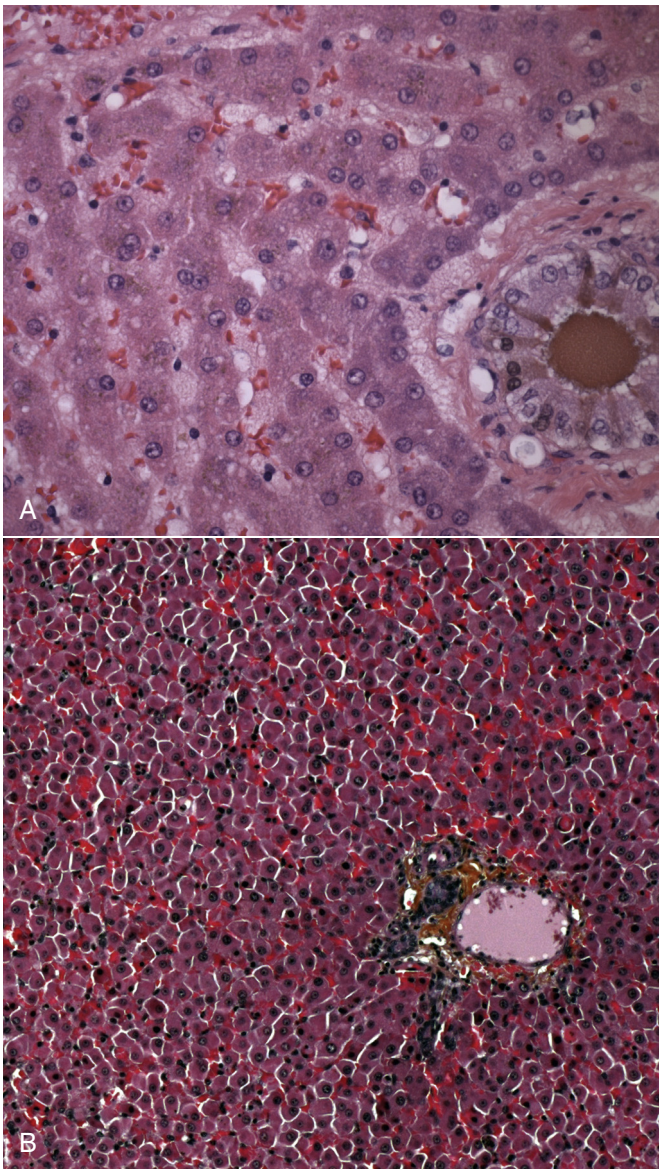

FIGURE 50-6 Histopathology of the liver in leptospirosis. **A,** Minimal hepatic changes and severe cholestasis in an 8-year-old male neutered Australian shepherd mix that was euthanized because of anuric leptospirosis. The activity of serum ALP and the serum total bilirubin concentration were mildly increased, and the dog seroconverted with the highest titer to serovar Pomona (1:400 to >1:3200 12 days later). **B,** Liver plate disarray with hepatocellular dissociation in a dog with leptospirosis. (B, Image courtesy John Cullen, North Carolina State University and Jean-Jacques Fontaine, École Nationale Vétérinaire d'Alfort)

recommends that all dogs with leptospirosis should be treated with doxycycline, 5 mg/kg q12h PO or IV for 2 weeks.[20] If vomiting or other adverse reactions preclude the use of doxycycline, parenteral ampicillin or penicillin G can be used (Table 50-5). Dogs initially treated with a penicillin derivative should be treated with doxycycline for 2 weeks after gastrointestinal signs resolve. Fluoroquinolones are not highly efficacious for clearance of leptospires from tissues.[56] Other antimicrobials that have been efficacious in clinical trials involving human patients with leptospirosis include ceftriaxone, cefotaxime, and azithromycin.[57,58]

TABLE 50-5

Antimicrobials Recommended for Treatment of Leptospirosis in Dogs

Drug	Dose	Route	Interval (hours)	Duration (days)
Doxycycline	5 mg/kg	PO, IV	12	14
Ampicillin	20 mg/kg*	IV	6	Variable
Penicillin	25,000-40,000 U/kg	IV	12	Variable

*Reduce dose in renal failure.

Supportive Care

Dogs with severe disease require aggressive treatment with IV crystalloids, potassium supplementation, antiemetics, antihypertensives, antacids, blood products, and parenteral or enteral nutrition, with attention to precautions to minimize zoonotic transmission (see Public Health Aspects, later). Referral to a 24-hour care facility, ideally with access to dialysis, should be considered for severely ill dogs because of the need for intensive monitoring and close observation. Electrolyte and acid-base status may require frequent monitoring.

Fluid therapy is critical and should be calculated based on measurement of "outs and ins," together with careful attention to body weight, respiratory rate, lung sounds, blood pressure, and if possible, central venous pressure. Dogs with polyuric renal failure may require extremely high fluid rates. For dogs with oliguric or anuric renal failure, high fluid rates can lead to overhydration and respiratory failure. Urine output in dogs with oliguria or anuria should be closely monitored through use of a closed, indwelling urinary catheter and collection bag system. Diuretics such as furosemide and mannitol may be indicated. Failure of urine production after adequate hydration is achieved is an indication for dialysis (see Renal Replacement Therapy, next). Once recovery of kidney values has occurred, fluids should be tapered slowly before they are discontinued to ensure that proper hydration status is maintained. In some dogs, possibly because of enteritis or pancreatitis, inappetence persists for several days after kidney and liver values normalize. Continued nutritional support is required during this period.

Dogs with SPHS may require oxygen therapy and, rarely, mechanical ventilation. The optimum treatment for dogs with SPHS is unknown. Human patients with SPHS have had improved outcome following cyclophosphamide therapy and plasma exchange.[59]

Renal Replacement Therapy

Early hemodialysis results in improved survival and shorter hospital stays in human patients with leptospirosis.[60] Renal replacement therapy is indicated for dogs with inadequate urine output that develop volume overload, hyperkalemia, a BUN greater than 80 mg/dL, or signs of uremia that do not respond to medical management.[20] Approximately 50% of 89 dogs with leptospirosis at the University of California, Davis, VMTH in the past 10 years received hemodialysis; the median number of hemodialysis treatments required was 3 (range, 1 to 14). Recovery of adequate renal function usually occurs within 2 to 4 weeks of starting dialysis.

Prognosis

When the treatment is initiated early and aggressively, the prognosis for recovery from acute leptospirosis is excellent. Survival rates are in excess of 50%,[41] and in centers where hemodialysis is available, survival rates can exceed 80%. Precise survival rates for dogs with SPHS are unknown but may be lower. Successful treatment is associated with normalization of the platelet count, serum BUN and creatinine concentrations, and serum liver enzyme activities within 10 to 14 days. Icterus may be slow to resolve, and urine-concentrating ability may not return for at least 4 weeks. Some dogs have residual permanent renal damage after recovery.

Immunity and Vaccination

Recurrence of leptospirosis in dogs after recovery from natural infection appears to be rare, but the duration of immunity after natural infection is unknown. Immunity after vaccination with inactivated vaccines is serogroup specific and possibly serovar specific, although partial immunity to heterologous serogroups was shown in one report.[61] A live attenuated LPS mutant *L. interrogans* serovar Manilae vaccine was shown to induce strong protection in hamsters against challenge either with the same or a serologically unrelated (Pomona) serovar.[62] After challenge with serovar Pomona, survival rates were 100% in hamsters immunized with the attenuated live vaccine, compared with only 40% for those immunized with an inactivated serovar Manilae vaccine.

Current vaccines for dogs are inactivated bacterins. Bivalent vaccines that contained only serovars Icterohaemorrhagiae and Canicola were first introduced for prevention of leptospirosis in dogs. In the United States, these have now been replaced with four-serovar vaccines that contain serovars Icterohaemorrhagiae, Canicola, Grippotyphosa, and Pomona. In Europe, serovar Icterohaemorrhagiae and Canicola vaccines are still available, but vaccines that contain serovar Icterohaemorrhagiae, Canicola, and Grippotyphosa (Pfizer Animal Health) and serovar Copenhageni (serogroup Icterohaemorrhagiae), Portland-vere (serogroup Canicola), Bratislava (serogroup Australis), and Dadas (serogroup Grippotyphosa) (MSD Animal Health) have been introduced. Leptospiral vaccines effectively prevent disease and reduce shedding after challenge with the serovar included in the vaccine. The duration of immunity following vaccination is at least 12 months.[32,63,64] Leptospirosis has occurred in North American dogs immunized with bivalent vaccines; however, disease is rare in dogs immunized with four-serovar vaccines.[13]

In the past, vaccination for with *Leptospira* vaccines has been associated with type I hypersensitivity reactions such as anaphylaxis, especially in small-breed dogs. Anecdotal evidence from industry and veterinary practitioners in North America suggests that the prevalence of these reactions has considerably reduced in recent years (to <1%) following efforts from industry to remove constituents that have been associated with vaccine reactivity.[20]

Immunization is recommended for dogs at risk of exposure. In some regions, this may be dogs that contact wildlife or farm animals, or dogs that swim, wade, or drink from environmental water sources. In other regions, dogs in urban or suburban backyards may be at risk if there is significant exposure to wildlife or rodents in the immediate home environment. Immunization may be optimally performed a few months before the onset of the peak season for leptospirosis in a given geographic region. There is no evidence that the initial series needs to be readministered to dogs that are overdue for an annual booster. For dogs that experience natural infection, immunization could commence a year after recovery, although the duration of immunity after natural infection and the degree and duration of cross-protection to heterologous serovars that follows natural infection requires further investigation.

Prevention

Leptospirosis can be prevented by restricting dogs' access to potential reservoir host species or environmental water sources. Access to wildlife and farm animals can be reduced through fencing and rodent control. Where this is not possible, immunization is recommended.

Public Health Aspects

In humans, leptospirosis occurs after an incubation period of 2 to 20 days (mean, 10 days). In 90% of infections, it is a mild, influenza-like illness. Less commonly, it is manifested by severe multiorgan failure, with renal failure, hepatic failure, or SPHS. Abortion can occur during pregnancy. Weil's disease, which is characterized by impaired renal and hepatic function, usually occurs a week after an initial illness characterized by fever, myalgia, headache, chills, and conjunctivitis.[1]

In developed countries, most human leptospirosis cases follow recreational activities that involve water, such as houseboating or participation in triathlons, caving, or white-water rafting.[65,66] Individuals who contact farm animals can also develop leptospirosis. Contact with wild rodents adopted as pets has also led to human disease.[67] In developing countries, stray dogs may be a source of human infection, although rodents are also important in this situation.[68] The extent to which domestic cats might serve as reservoir hosts is not understood.

Reports of transmission from clinically affected incidental hosts (as opposed to subclinically infected reservoir hosts) to other animals are rare, and there are no reports that document transmission of leptospires from pet dogs to humans with the support of molecular typing methods. Appropriate antimicrobial therapy may also reduce the possibility of transmission to humans. Nevertheless, precautions should be taken in the hospital environment to minimize zoonotic transmission (see Chapter 11). All dogs with acute renal failure should be handled as leptospirosis suspects until an alternative diagnosis is established. Suggested precautions are shown in Box 50-1. Urine from dogs with leptospirosis can be inactivated with a variety of disinfectant solutions, including iodine-based disinfectants, quaternary ammonium solutions, and accelerated hydrogen peroxide. Large volumes of urine can be inactivated by 1:1 dilution with a 10% solution of household bleach. In dogs with indwelling urinary catheters, 10% bleach should be injected directly into the collection bag before disposal. All blood, urine, and tissues from dogs should be treated as medical waste. If a dog dies or is euthanized, individuals who are to handle the remains should be alerted of the possibility of leptospirosis.

Owners of affected dogs should be educated in regard to the zoonotic nature of the disease. The risk of infection to owners is probably low, because urinary shedding generally does not occur until 7 to 10 days after the onset of illness, and doxycycline treatment likely results in clearance of bacteria from the kidneys and urine within 2 to 3 days. Nevertheless, until antimicrobial therapy is completed, owners should avoid contact with their dog's urine. Routine household disinfectants and gloved hands should be used to clean up urinary accidents that occur indoors. Dogs should be taken to urinate in a place that is away from water and away from other pets and people, especially children. Owners should wash their hands after they handle their pets. Veterinarians should recommend that owners seek medical attention if illness occurs around the time their dog is diagnosed with leptospirosis, or if they have any questions about the disease in humans. Immunocompromised humans should be referred to their medical practitioners for advice. Owners should also be informed that environmental sources of infection may represent an ongoing risk, not only to other dogs in the household but also to humans. If other dogs in the household may have been exposed at the same time as the dog diagnosed with leptospirosis, those dogs should be treated with doxycycline for 2 weeks, because subclinical infection and shedding may have occurred.[20]

Veterinarians should contact their local or state health department or the Centers for Disease Control and Prevention if additional questions arise regarding the public health risks and zoonotic transmission of leptospirosis.[20]

BOX 50-1

Suggested In-Hospital Precautions for Dogs with Known or Suspected Leptospirosis

- Warning signage on the cage or run
- Minimize movement around the hospital, avoiding transport along common hallways
- Gloves and disposable gowns
- Protective eyewear and face shields if aerosolization of urine likely
- Handwashing before and after handling
- No pregnant or immunocompromised staff to work with the patient
- Prompt disinfection of urine and urine spills
- Treatment with appropriate antimicrobial drugs
- Indwelling rather than intermittent urinary catheterization for monitoring urine output
- Dogs walked or gurneyed outside to urinate frequently if urinary catheter not in place
- Urination outside in a designated area that can be easily disinfected
- Warnings to others who handle the dog or specimens from the dog

CASE EXAMPLE

FIGURE 50-7 "Makalu," a 1.5-year-old male neutered kelpie dog that developed leptospirosis.

Signalment: "Makalu," a 1.5-year-old male neutered kelpie dog from Dixon in northern California (Figure 50-7).

History: Makalu had a 1-day history of lethargy and inappetence. The owner, a veterinarian, took his temperature at home and it was >104°F (40°C). There had been no vomiting, diarrhea, coughing, sneezing, or increased thirst and urination. Makalu lived on a property with another dog, three cats, sheep, goats, and a pot-bellied pig. He normally ate a commercial dry dog food; he consumed a rawhide the day before he became ill. There was no history of previous travel, toxins, trauma, medications, or tick exposure. He was 3 months overdue for vaccination but had been vaccinated as a puppy for distemper, hepatitis, parvovirus, rabies, and leptospirosis. The owner did not recall which *Leptospira* vaccines he received.

Physical Examination:

Body Weight: 22.4 kg

General: Quiet, alert and responsive. Ambulatory on all four limbs, T = 103.7°F (39.8°C), HR = 80 beats/min, RR = 20 breaths/min, mucous membranes pink, CRT = 1 s. Estimated to be 7% to 8% dehydrated based on skin turgor.

Integument, Eyes, Ears, Nose, and Throat: Mild scleral injection and chemosis were present bilaterally.

Musculoskeletal: Appeared stiff, but there was no evidence of synovial effusion. Vocalized on flexion of the right thoracic limb.

Cardiovascular: Strong femoral pulses. No murmurs or arrhythmias auscultated. Systolic blood pressure was 145 mm Hg.

Respiratory: Quiet bronchovesicular sounds were present in all lung fields.

Gastrointestinal and Genitourinary: A tense abdomen was noted, with abdominal splinting noted on palpation. No abnormalities were detected on rectal examination.

Lymph Nodes: No abnormalities were detected.

Laboratory Findings:

CBC:

HCT 41.4% (40%-55%)
MCV 70.2 fL (65-75 fL)
MCHC 36.0 g/dL (33-36 g/dL)
WBC 8820 cells/µL (6000-13,000 cells/µL)
Neutrophils 7673 cells/µL (3000-10,500 cells/µL)
Lymphocytes 353 cells/µL (1000-4000 cells/µL)
Monocytes 441 cells/µL (150-1200 cells/µL)
Platelets 74,000 platelets/µL (150,000-400,000 platelets/µL).

Serum Chemistry Profile:

Sodium 143 mmol/L (145-154 mmol/L)
Potassium 3.7 mmol/L (4.1-5.3 mmol/L)
Chloride 104 mmol/L (105-116 mmol/L)
Bicarbonate 17 mmol/L (16-26 mmol/L)
Phosphorus 5.1 mg/dL (3.0-6.2 mg/dL)
Calcium 9.6 mg/dL (9.9-11.4 mg/dl)
BUN 90 mg/dL (8-31 mg/dL)
Creatinine 4.6 mg/dL (0.5-1.6 mg/dL)
Glucose 110 mg/dL (70-118 mg/dL)
Total protein 5.1 g/dL (5.4-7.4 g/dL)
Albumin 2.4 g/dL (2.9-4.2 g/dL)
Globulin 2.7 g/dL (2.3-4.4 g/dL)
ALT 42 U/L (19-67 U/L)
AST 146 U/L (21-54 U/L)
ALP 73 U/L (15-127 U/L)
Creatine kinase 1387 U/L (46-320 U/L)
GGT 2 U/L (0-6 U/L)
Cholesterol 189 mg/dL (135-345 mg/dL)
Total bilirubin 0.4 mg/dL (0-0.4 mg/dL).

Urinalysis: SGr 1.013; pH 7.5, 2+ protein (SSA), 1+ bilirubin, 3+ hemoprotein, 2+ glucose, 0 WBC/HPF, 20-30 RBC/HPF, rare transitional epithelial cells.

Coagulation Profile: PT 8.8 (7.5-10.5), APTT 16.8 (9-12), fibrinogen 280 (90-255).

Serum Ethylene Glycol Assay: Negative.

Imaging Findings:

Thoracic Radiographs: The cardiovascular and pulmonary structures appeared within normal limits.

Abdominal Ultrasound: The liver and spleen were both enlarged. The tail of the spleen had a mildly mottled echotexture. Both kidneys were mildly enlarged, and measured approximately 8 cm in length. The renal cortices were mildly echogenic. A small amount of subcapsular and retroperitoneal fluid was noted in association with both kidneys. The mesenteric lymph nodes were prominent.

Microbiologic Testing: Aerobic bacterial culture of blood and urine: No growth.

Leptospira serology (MAT): Day 2 after the onset of illness, negative for antibodies to serovars Canicola, Grippotyphosa, Hardjo, Icterohaemorrhagiae, and Pomona at 1:100. Positive for antibodies to serovar Bratislava at 1:100. Day 10 after the onset of illness, negative for antibodies to serovar Canicola. Positive for antibodies to serovars Grippotyphosa (1:400), Hardjo (1:100), Icterohaemorrhagiae (1:800), Pomona (1:12,800), and Bratislava (1:3200).

Diagnosis: Leptospirosis.

Treatment: Makalu was aggressively treated with intravenous fluids, mannitol, famotidine, a metoclopramide, and ampicillin (20 mg/kg IV q6h). Despite this treatment and administration of furosemide, urine output remained at <0.8 mL/kg/hr. After 18 hours of hospitalization, dialysis was initiated. After a second dialysis treatment 2 days later, polyuria ensued (Table 50-6). On day 3, DIC developed, with further prolongation of the PT (14.3 s) and APTT (21.1 s), hypofibrinogenemia (<90 mg/dL), and a positive D-dimer assay. The dog was treated with multiple

VetBooks.ir

units of fresh frozen plasma. Treatment with ondansetron was also initiated on day 3 because of persistent vomiting, and total parenteral nutrition was instituted on day 4. Makalu's mentation improved on day 5 and he began eating on day 8.

Comments: Antibody titers in this dog were very low or negative initially because insufficient time had elapsed for antibody production to occur. The diagnosis of leptospirosis was based on consistent clinical signs together with seroconversion on day 10. Liver enzyme activities were not increased in this dog on admission, but increased subsequently. Without dialysis, this dog would have died from the disease.

TABLE 50-6

Serial Changes in Clinicopathologic Variables in a Hospitalized Dog with Leptospirosis That Was Treated with Hemodialysis

Variable	Day 1	Day 3	Day 4	Day 5	Day 8	Day 10
ALT (U/L)	62	ND	105	110	82	71
ALP (U/L)	83	ND	97	97	79	75
Bilirubin (mg/dL)	0.4	ND	0.5	0.8	0.3	0.3
BUN (mg/dL)	105 (27)*	144 (30)	54	47	35	27
Creatinine (mg/dL)	5.6 (2.2)	12.9 (3.1)	4.8	3.3	2.1	1.6
Albumin (g/dL)	2.2	2.4	2.5	2.9	3.0	3.1
Platelets (x1000/μL)	74	ND	26	91	92	clumped
Urine output (mL/kg/hr)	<0.8	0.25	10	10	7	ND

*Values in parentheses are postdialysis values. ND, not done.

CHAPTER 51

Lyme Borreliosis

Jane E. Sykes

VetBooks.ir

Overview of Lyme Borreliosis

First Described: Connecticut, USA, 1982 (Burgdorfer)[1]

Cause: *Borrelia burgdorferi* sensu lato (a spirochete)

Primary Mode of Transmission: *Ixodes* spp. ticks

Affected Hosts: Humans and a large variety of animals; disease occurs in dogs, humans, horses, cattle

Geographic Distribution: North America, Europe, Asia

Major Clinical Signs: Fever, lethargy, inappetence, lameness due to polyarthritis. Signs of Lyme nephropathy include vomiting, weight loss, and polyuria and polydipsia.

Differential Diagnoses: Differential diagnoses for suspected Lyme polyarthritis includes bilateral cruciate ligament rupture, primary immune-mediated polyarthritis, septic polyarthritis, and polyarthritis secondary to infection with other pathogens such as *Ehrlichia ewingii, Bartonella* spp., *Ehrlichia canis, Anaplasma phagocytophilum, Rickettsia rickettsii,* and fungal organisms. Differential diagnosis for suspected Lyme nephritis include leptospirosis, bacterial pyelonephritis, primary immune-mediated glomerulonephritis, familial nephropathies, amyloidosis, and glomerulonephritis secondary to other chronic infections such as *Dirofilaria immitis, Babesia canis, E. canis,* and *Leishmania* spp. infections.

Human Health Significance: Dogs and cats are not a direct source of human infection but may bring unfed infected ticks into the house. Evidence of canine exposure to *B. burgdorferi* is a sentinel for human exposure.

Etiologic Agent and Epidemiology

Lyme borreliosis, or Lyme disease, is a vector-borne spirochetosis caused by the motile, corkscrew-shaped bacterium *Borrelia burgdorferi* sensu lato. Lyme disease occurs in North America, Europe, and Asia. It was named after Old Lyme in Connecticut, where clusters of the disease were first recognized in children with juvenile rheumatoid arthritis in 1976.[2] However, chronic cutaneous manifestations of infection were recognized in human patients in Germany as far back as 1883.[3] The spirochete was first detected in ticks by Burgdorfer in 1982.[1] A variety of different mammalian hosts and humans may be infected. The disease has been increasingly recognized and is now the most common vector-borne infectious disease of humans in the United States and Europe. Reforestation of farmland and proliferation of deer and tick populations may have contributed to emergence of the disease in humans.[4] Cats can be infected and seroconvert, but appear to be relatively resistant to development of disease.[5] Dogs can develop fever, arthritis, and renal disease, but most infected dogs show no signs of illness.

More than 15 different species of *B. burgdorferi* sensu lato have been described, some of which are nonpathogenic (Table 51-1). *Borrelia turicatae,* the cause of tick-borne relapsing fever in humans, has been detected in sick dogs from Texas.[6] The DNA of *Borrelia lonestari,* which is thought to be nonpathogenic, has been detected in dogs from Arkansas.[7] In North America, Lyme disease is caused by *Borrelia burgdorferi* sensu stricto, whereas in Europe and Asia, other species that belong to *Borrelia burgdorferi* sensu lato are more important, specifically *Borrelia afzelii* and *Borrelia garinii*. This may account for differences in clinical manifestations that occur in human patients in Europe compared with those in North America (see Public Health Significance, later). Some strains of *B. burgdorferi* appear to have increased virulence, such as *B. burgdorferi* OspC type A within the United States.[8]

B. burgdorferi sensu lato is transmitted by *Ixodes ricinus-persulcatus* complex ticks (Table 51-2). The geographic distribution of Lyme disease reflects that of the vector ticks as well as the competency of the reservoir hosts involved. In the United States, the vectors are *Ixodes scapularis* in the east and upper Midwest, and *Ixodes pacificus* in the West (see Chapter 29). Major foci of infection exist in the upper Midwest, Northeast, mid-Atlantic, and parts of northern California (Figure 51-1).[9] In some endemic areas, seroprevalence in dogs is nearly 90%,[10] although seroprevalence in a study that used a C6 ELISA assay (see Diagnosis, later) was lower than this in endemic areas such as Connecticut and Massachusetts, around 20%.[11] Infection is passed transstadially within the tick (i.e., from larva to nymph to adult), and not transovarially (from adult to egg). Reservoirs for the spirochete in the Northeast and the upper Midwest are *Peromyscus leucopus,* the white-footed mouse, which can harbor large numbers of the organism without overt signs of illness,[12] as well as shrews and chipmunks.[13] In the western United States, the western gray squirrel is the primary reservoir host.[14] Lyme disease is less prevalent in the western United States because *I. pacificus* prefers to feed on the western fence lizard, a poor reservoir for the spirochete. Similarly, the low prevalence of Lyme disease in the southeastern United States, is because *I. scapularis* ticks feed primarily on lizards in this region.[15] *B. burgdorferi* is primarily transmitted to humans by nymphal ticks, because they are extremely small and often enough go unnoticed. Adult ticks may be more important for transmission of infection to dogs.[16] The nymphs of *I. scapularis* quest in the late spring and summer, when humans and dogs are often outdoors and become exposed. The peak questing times for *I. scapularis* adult ticks are in the spring and fall. Other

TABLE 51-1

Pathogenic and Nonpathogenic Species That Belong to *Borrelia burgdorferi* sensu lato and Their Geographic Distributions

	United States	Europe	Asia
Pathogenic	*B. burgdorferi* sensu stricto	*B. burgdorferi* sensu stricto *B. afzelii* *B. garinii*	*B. afzelii* *B. garinii*
Non-pathogenic or questionable pathogenicity	*B. bissettii* *B. andersonii* *B. californiensis* *B. carolinensis* *B. americana* *B. kurtenbachii*	*B. valaisiana** *B. bissettii** *B. spielmanii** *B. lusitaniae* *B. bavariensis*	*B. bissettii** *B. japonica* *B. turdi* *B. tanukii* *B. sinica* *B. yangtze*

**B. valaisiana* and *B. bissettii* have been isolated from single cases of Lyme borreliosis; *B. spielmanii* has been detected in early skin lesions (Stanek G, Reiter M. The expanding Lyme *Borrelia* complex—clinical significance of genomic species? Clin Microbiol Infect 2011;17:487-493).

TABLE 51-2

Vectors of Lyme Disease Worldwide

Geographic Location	Tick Species	Common Name	Reservoir host for *Borrelia*
Western United States	*Ixodes pacificus*	Pacific black-legged tick	Western gray squirrel
Northeastern and upper Midwestern United States	*Ixodes scapularis*	Black-legged tick	White-footed mouse, shrews, chipmunks
Europe	*Ixodes ricinus*	Castor bean or sheep tick	Squirrels, thrushes, chipmunks, mice, shrews, hedgehogs, rats, hares, pheasants, voles
Asia	*Ixodes persulcatus*	Taiga tick	Voles

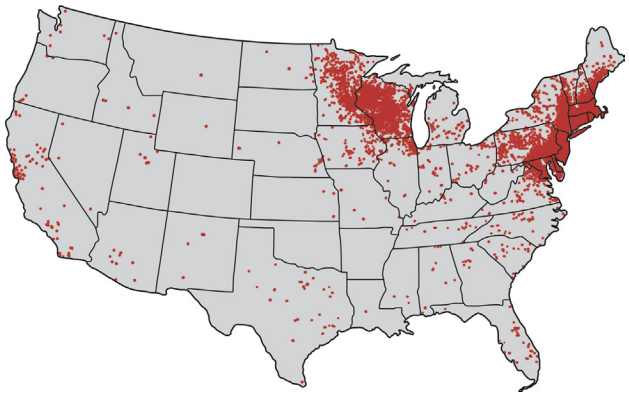

FIGURE 51-1 Approximate geographic distribution of Lyme borreliosis in humans (and dogs) in the United States.

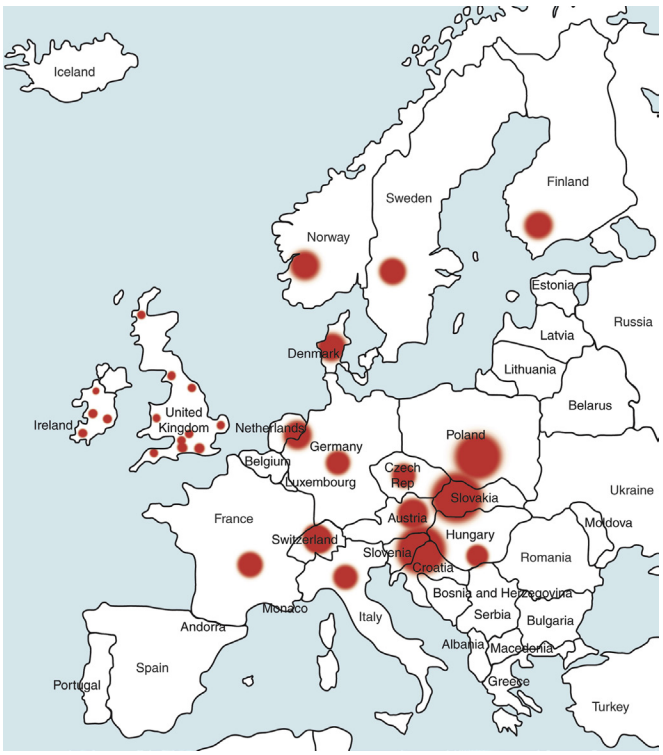

FIGURE 51-2 Countries and regions where Lyme borreliosis occurs in Europe. The size of the red dot correlates with the relative prevalence of the infection in those areas.

vector-borne pathogens, such as *Anaplasma phagocytophilum,* may be co-transmitted and complicate the clinical picture. There is some evidence that co-infection with *A. phagocytophilum* can enhance the pathogenicity of *B. burgdorferi*.[17]

In continental Europe, Lyme disease is most prevalent in central and eastern Europe, especially Poland, Slovakia, and Slovenia, but also Germany, Switzerland, Austria, and southern Scandinavia (Figure 51-2). *B. garinii* was detected in a dog from the Czech republic with meningoencephalitis,[18] and *B. afzelii* has been detected in dogs from Poland.[19] Evidence of infection has also been found in dogs from the British Isles,[20] where endemic areas include the Scottish Highlands, Ireland, Wales, the Lake District, the Yorkshire Moors, Exmoor, Wiltshire, Berkshire, and particularly the New Forest, the South Downs, and the Thetford Forest region. A huge variety of reservoir hosts appear to be involved in Europe. Small rodents such as squirrels appear to be an important reservoir host for *B. afzelii*, and birds such as blackbirds and song thrushes are important reservoir hosts for *B. garinii*.[21]

The complete genome of *B. burgdorferi* has been sequenced. The organism expresses different outer-surface lipoproteins at different stages of infection, which allows it to adapt to dramatically different environments within the arthropod vector and the mammalian host. This property of the organism has been exploited for the purpose of diagnostic assay and vaccine development. Outer surface proteins of importance include OspA, OspC, and VlsE. Over the fall, winter, and spring, the spirochete remains dormant within the nymphal tick and expresses OspA, which allows it to adhere to the tick midgut. When the tick ingests mammalian blood in the late spring and summer, OspA expression is downregulated by the spirochete, and OspC expression is upregulated.[22] The spirochete then moves to the tick hemolymph

VetBooks.ir

and salivary glands. OspC binds a tick salivary gland protein, which may help the organism evade the host immune response. OspC also binds to mammalian plasminogen and helps the spirochete to disseminate within the mammalian host.[23] VlsE undergoes recombinational shuffling of its genetic code, which further allows the spirochete to evade the immune response.[24] Finally, *B. burgdorferi* may undergo metamorphosis into a spherical shape when it encounters unfavorable conditions within the host, such as when it is exposed to antibiotics, nutrient deprivation, and changes in pH.[25] This may also contribute to its ability to evade the immune system and resist antimicrobial drug treatment.

Clinical Features

Signs and Their Pathogenesis

Transmission is thought to require tick attachment for a minimum of 24 hours,[26] but in some cases transmission may occur at earlier time points.[27] The spirochete replicates at the site of tick attachment, then disseminates to multiple locations. Although it can be transiently found in blood, the organism primarily replicates and spreads through connective tissue (Figure 51-3). It binds proteins such as plasminogen, β_3 integrins such as the platelet integrin $\alpha_{IIb}\beta_3$, glycosaminoglycans, fibronectin, laminin, and decorin (a collagen proteoglycan).[28] After invasion, the organism can persist in dogs for over a year, through evasion of host immune responses.[29]

In contrast to human Lyme disease, dogs do not develop an early skin rash (erythema migrans). It has been estimated that only 10% of affected dogs show overt signs of illness. Initial signs in dogs occur 2 to 5 months after a tick bite and consist of variable fever, inappetence, thrombocytopenia, and lameness due to neutrophilic polyarthritis. In a study of experimentally infected dogs, the first joint to be affected was the joint closest to the site of the tick bite, which supports the notion that spirochetes reach the joints as a result of spread through connective tissue.[29,30] Subsequently, other joints can be affected, and dogs may develop shifting lameness. It is not clear whether dogs develop other clinical manifestations seen in humans such as persistent, antibiotic-refractory Lyme arthritis; uveitis; carditis; or encephalopathy. Complete heart block was described in a seropositive dog from Connecticut that had pathologic changes at necropsy consistent with Lyme carditis.[31]

Lyme nephritis is a syndrome of membranoproliferative glomerulonephritis that has been recognized in dogs in association with exposure to *B. burgdorferi*. Rare reports of a similar disease in human patients exist.[32] Golden and Labrador retriever breeds appear to be overrepresented,[33] and it has been suggested that Shetland sheepdogs and Bernese mountain dogs might also be predisposed.[34-36] Dogs with Lyme nephritis are younger than dogs with other glomerular diseases. In one study, more than 50% of dogs with Lyme nephritis were 5 years of age or younger.[33] Many affected dogs are also thrombocytopenic, and some also have polyarthritis.[33] The pathogenesis of Lyme nephritis is uncertain; immune-mediated mechanisms have been proposed.[37] The DNA or antigen of the spirochete cannot be consistently detected within renal biopsies.[37,38] Subendothelial deposits of IgM, IgG, and C3 can be detected within the glomeruli.[33] Clinical signs result from proteinuria and renal failure and include inappetence, lethargy, weight loss, vomiting, and polyuria and polydipsia.

Physical Examination Findings

Physical examination findings in dogs with Lyme arthritis include lethargy, fever, lameness, and swollen, warm, painful joints. Mild generalized peripheral lymphadenopathy may be present. Dogs with Lyme nephritis may have a thin body condition, dehydration, and show evidence of peripheral edema, pleural effusion, or ascites, especially after crystalloid fluid administration. Complications of hypertension can sometimes occur, such as retinal detachment.

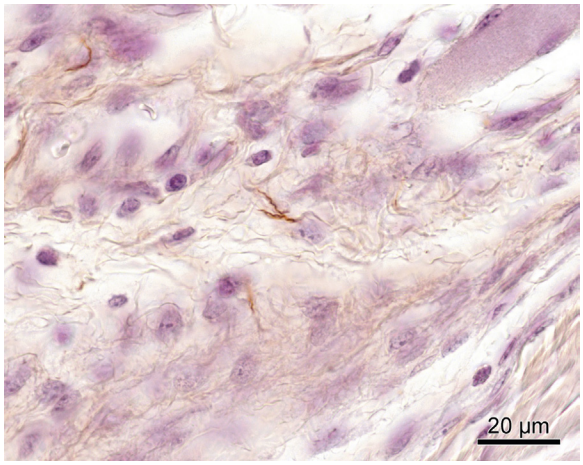

FIGURE 51-3 *Borrelia burgdorferi* in the metatarsal tendon sheath of a mouse with severe combined immunodeficiency. (Courtesy Dr. Stephen Barthold, Center for Comparative Medicine, University of California, Davis.)

Diagnosis

Diagnosis of Lyme disease is notoriously difficult. The overwhelming majority of infected dogs experience subclinical infection, after which positive antibody titers may persist for months or years. Because only a small percentage (e.g., <10%) of infections result in disease, it is important to distinguish between diagnosis of *infection* or previous exposure to the spirochete and diagnosis of Lyme *disease*. Dogs with positive antibody titers may develop unrelated illnesses, which results in diagnostic confusion. As in human patients, the diagnosis must be established based on characteristic clinical signs, a history of exposure in an endemic area, and a positive antibody response to *B. burgdorferi*.[39] A history of tick exposure may not always be present.

Laboratory Abnormalities

Complete Blood Count

The most common finding on the CBC of dogs with Lyme polyarthritis or nephritis is mild to moderate thrombocytopenia. The mechanism of thrombocytopenia is not known, but it may be immune mediated, because treatment of dogs with Lyme nephritis with immunosuppressive drugs can result in normalization of the platelet count. Mild to moderate anemia and leukocytosis due to a mature neutrophilia may be present in dogs with Lyme nephritis, but white cell counts may also be normal. Lymphopenia and mild neutropenia can also occur.

Serum Biochemical Tests

Dogs with polyarthritis typically have minimal changes on serum biochemistry testing. Dogs with Lyme nephritis may show azotemia, mild to marked hypoalbuminemia, metabolic acidosis, and electrolyte changes such as hyperphosphatemia, hypochloremia, and mild hyperkalemia or hypokalemia. Uncommonly, hypercholesterolemia is present.

Urinalysis

The urinalysis in dogs with Lyme nephritis generally reveals isosthenuria and proteinuria. Pyuria and microscopic hematuria

VetBooks.ir

may also be present. Urine protein to creatinine ratios are often greater than 5 and may be above 15 in some dogs.

Coagulation Profile

Dogs with Lyme nephritis may have low antithrombin activities as a result of glomerular antithrombin loss, which may lead to hypercoagulability syndromes. Sometimes, abnormalities such as a shortened PT, prolonged APTT, and increased fibrinogen and D-dimer concentrations are present.[40]

Synovial Fluid Cytology

Dogs with Lyme arthritis may have normal synovial fluid cytology,[30] or there may be markedly increased numbers of nondegenerate neutrophils within the synovial fluid of distal joints (>5000 and frequently >10,000 cells/μL). Because not all joints may be affected, synovial fluid should be collected from at least three and preferably four peripheral joints.

Diagnostic Imaging

Plain Radiography

Lyme arthritis is a nonerosive polyarthritis, so the only changes visible on plain radiography of the joints are increased periarticular soft tissue opacity. Thoracic radiography is generally unremarkable, but pleural effusion is occasionally identified in severely hypoalbuminemic dogs with Lyme nephritis.

Sonographic Findings

Abdominal sonographic examination is normal in dogs with Lyme arthritis. In dogs with nephritis, thickening and increased echogenicity of the renal cortices, decreased renal corticomedullary distinction, and peritoneal effusion may be seen.

Microbiologic Tests

Specific diagnostic assays available for Lyme borreliosis in dogs are described in Table 51-3.

TABLE 51-3

Diagnostic Assays Available for Lyme Borreliosis in Dogs

Assay	Specimen Type	Target	Performance
Bacterial isolation	Skin biopsy close to the tick bite site; synovial fluid	*B. burgdorferi* spirochete	Low sensitivity, requires special media, and may take several weeks. Isolation does not imply that *B. burgdorferi* is the cause of disease.
Serology (C6 assay)	Serum	Antibodies against *B. burgdorferi* C6 protein	Positive serology does not equate with Lyme disease, so test results must be interpreted in light of clinical findings. False positives can occur in regions of low prevalence. False negatives are rare, because antibodies are present by the time dogs develop illness. Cross-reactivity with vaccine antibodies does not occur.
Serology (whole cell IFA and ELISA)	Serum	Antibodies against *B. burgdorferi* antigens	As for C6 serology except that cross-reactivity with vaccine antibodies occurs, and false positives may also occur with other inflammatory diseases, and other spirochete infections.
Serology (Western immunoblot)	Serum	Antibodies against *B. burgdorferi* antigens	Used to confirm the serological response to natural infection in dogs that test positive with whole-cell ELISA and IFA. Technically difficult to perform and requires expertise to interpret. Positive serology does not equate with Lyme disease, so test results must be interpreted in light of clinical findings.
Serology (multiplex fluorescent bead assay)	Serum	Antibodies against *B. burgdorferi* OspA, OspC, and OspF	Antibodies to OspC appear only early in infection, whereas those to OspF reflect chronic infection and appear to correlate with the C6 antibody response. Sensitivity and specificity in dogs with naturally occurring Lyme disease unknown. Positive serology does not equate with Lyme disease, so test results must be interpreted in light of clinical findings.
Serology (multi-target silicon disc–based assay)	Serum	Antibodies against *B. burgdorferi* OspA, OspC, and OspF, SLP, and P39	Sensitivity and specificity in dogs with naturally occurring Lyme disease requires further study. PCR	As for isolation	*B. burgdorferi* DNA	Rapid but insensitive. Synovial fluid from dogs with polyarthritis may be the best specimen, but further study is needed. Assay performance can vary between laboratories.

VetBooks.ir

Culture

B. burgdorferi can be isolated from tissue specimens in Barbour-Stoenner-Kelly medium. The optimal specimen for culture is a skin biopsy collected from a site adjacent to the tick bite, which is rarely identifiable in affected dogs. Incubation of cultures for several weeks may be required. Because of these factors, culture is not generally used on a routine basis for diagnosis.

Serologic Diagnosis

Serologic tests for antibody are the main assays used for diagnosis of Lyme disease in humans and also in dogs, but it is critical to recognize that positive serology does not necessarily equate with the presence of Lyme disease. In Europe, infection with nonpathogenic variants of *B. burgdorferi* sensu lato can result in positive serologic results, which further complicates diagnosis. Because the infection is chronic and persistent, and the incubation period is long, paired serology is generally not performed, because seroconversion may not occur. However, paired serology using serologic panels that include *B. burgdorferi* may be required for diagnosis of other vector-borne diseases that might be present. Positive test results in regions of low prevalence are more likely to be false positives than in regions of high prevalence, so interpretation of positive results should be performed with care in low-prevalence regions.

Currently, one of the most widely used serodiagnostic tests for canine Lyme disease is based on a C6 ELISA, which detects antibodies against a portion of the VlsE lipoprotein. The advantages of the C6 ELISA assay are that (1) it detects IgG antibodies 3 to 5 weeks after the time of infection, so by the time dogs develop clinical signs they are virtually always seropositive,[41] and (2) it is negative in dogs that have been vaccinated for Lyme disease, because the antigen is not expressed by organisms used in Lyme vaccines. The C6 ELISA is available as an in-practice lateral-flow assay, in combination with serodiagnostic spots for *Ehrlichia canis/Ehrlichia ewingii* antibody, *Anaplasma* spp. antibody, and *Dirofilaria immitis* antigen (SNAP 4Dx Plus, IDEXX Laboratories, ME) and as a quantitative ELISA (Quant C6), which is performed at IDEXX central veterinary diagnostic laboratories. There is no correlation between the magnitude of the C6 ELISA titer and disease severity. In a study from Europe, positive test results did not correlate with disease.[36] Another rapid immunochromatographic ELISA assay has recently become available in the United States (Abaxis VetScan Canine Lyme Rapid Test) that detects antibodies to a different portion of the VlsE lipoprotein, OspC and p41; these are combined on a single line.

Other serologic assays that are available include whole-cell ELISA or immunofluorescent antibody (IFA) assays and Western blotting (WB; see Chapter 2 for a description of these techniques). WB has traditionally been considered the gold standard assay. False positives using whole-cell ELISA and IFA have the potential to occur in patients with other spirochete infections, with other inflammatory disorders, and in vaccinated dogs. In human patients, a two-tiered approach is recommended for diagnosis.[39] Serum from patients who test positive for IgM or IgG with ELISA is then subjected to WB, because WB has increased specificity. WB has been used to differentiate the response to immunization and natural infection in dogs (Figure 51-4).[42] It has also been used to identify "dual status" dogs, that is, dogs that have been both immunized and naturally infected. WB is more time-consuming to perform than ELISA and IFA and experience is required to interpret it correctly.[43]

A multiplex fluorescent bead assay has been marketed in North America for detection of antibodies to three antigens of *B. burgdorferi:* OspA, OspC, and OspF.[43] The assay uses tiny beads to which OspA, OspC, and OspF are coupled. Dog serum is added to the beads, and if present, antibodies in the serum bind to the antigens and can be detected using a fluorescent conjugate. The pattern of reactivity to each antigen can be used to differentiate among the response to vaccination, early infection, and chronic infection. The presence of anti-OspA antibodies suggests previous vaccination, because vaccines contain OspA, and the spirochete rarely expresses OspA within

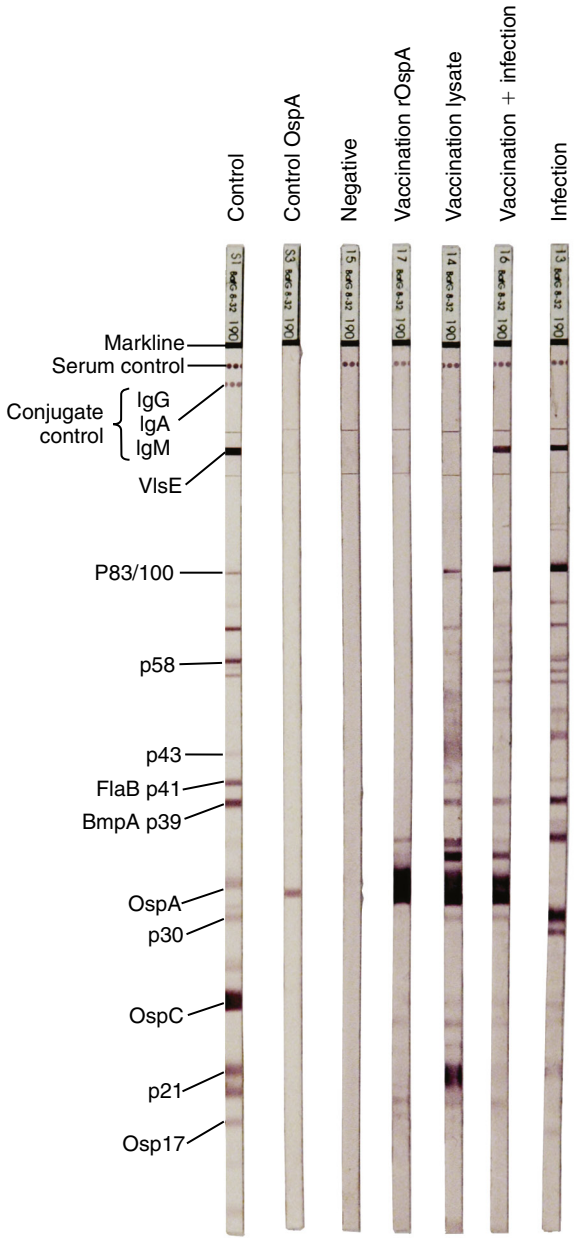

FIGURE 51-4 Western immunoblots of sera from dogs not infected with *B. burgdorferi* (Negative); immunized with recombinant OspA (vaccination rOspA); Immunized with a whole cell lysate vaccine (vaccination lysate); immunized and infected with *B. burgdorferi* (vaccination + infection); and infected only with *B. burgdorferi* (infection). The left strip shows all major signals available on the blot (control); the second strip from the left is stained with a monoclonal antibody against OspA (control OspA). (Courtesy R. Straubinger, Ludwig-Maximillians-Universitat, Munich, Germany. In: Greene CE: Infection Diseases of the Dog and Cat. 4th ed. St. Louis: Elsevier/Saunders; 2012.)

the host. OspC is expressed as the spirochete moves to the tick salivary glands and shortly after it enters the host. Thus an antibody response to OspC may suggest recent infection; titers decline and become undetectable beyond 3 months after infection.[44] Antibodies to OspC appear as early as 3 weeks after experimental infection of dogs, and OspF as early as 5 weeks.[44] OspF is expressed in more chronic infections, and can be detected together with the C6 antibody response in naturally exposed dogs (Figure 51-5).[44,45] In dogs, when WB was used as the gold standard, the sensitivities of the OspA, OspC, and OspF assays were 83%, 62%, and 82%, and the specificities were 90%, 89%, and 86%, respectively. The use of WB as the gold standard was questioned, and it was suggested that in fact, the fluorescent bead assay may have greater sensitivity and specificity than WB. The performance of the fluorescent bead assay is yet to be thoroughly evaluated in dogs with naturally occurring Lyme disease.

A novel silicon disc–based serologic assay is available in the United States for detection of antibodies to *B. burgdorferi, E. canis,* and *A. phagocytophilum* and antigen to *Dirofilaria immitis* (Accuplex 4, Antech Diagnostics, Irvine, CA). The assay for *B. burgdorferi* detects antibodies to the spirochete proteins OspA, OspC, OspF, P39, and SLP and is performed at central veterinary diagnostic laboratories. Preliminary data suggests that laboratory analysis of the response to these proteins correlates with the results of WB and can differentiate between the responses to natural infection and vaccination, and acute and chronic infection.[46]

Molecular Diagnosis Using the Polymerase Chain Reaction

As with culture, PCR assays are best performed on skin biopsy specimens collected from a region adjacent to the tick bite site. In human patients, the use of PCR assays for diagnosis of Lyme borreliosis on blood has low sensitivity, and so false negatives are common when *B. burgdorferi* PCR assay is used as part of a whole-blood vector-borne infection PCR panel. Synovial fluid or synovial membrane biopsies may be the optimum specimen for diagnosis of Lyme arthritis in dogs. This is also true in human patients.[47] However, in a study of experimentally infected dogs, PCR assay of the synovial fluid was insensitive.[30] The sensitivity and specificity of PCR assays when used on specimens such as synovial fluid for diagnosis of canine Lyme borreliosis requires further study.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with Lyme arthritis include peripheral lymphadenomegaly, joint swelling, and synovial effusion.[29] The synovial fluid may be yellow-tinged and cloudy, with decreased viscosity. In dogs with nephritis, the kidneys are diffusely light tan and may have pinpoint red foci over the cortical surfaces.[33] In addition, evidence of systemic edema, thrombosis and infarction, and uremia (such as parathyroid hyperplasia, ulcerative stomatitis, and gastritis) may be present.

Histopathologic Findings

Histopathology of the joints of dogs that have been experimentally infected with *B. burgdorferi* reveals fibrinosuppurative or lymphoplasmacytic inflammation of the synovial membranes, joint capsules, and tendon sheaths.[29,30] Inflammation can sometimes be found in the joints even when a history of lameness is not present.[29] In human patients, organisms have been demonstrated in the synovium using immunostains and electron

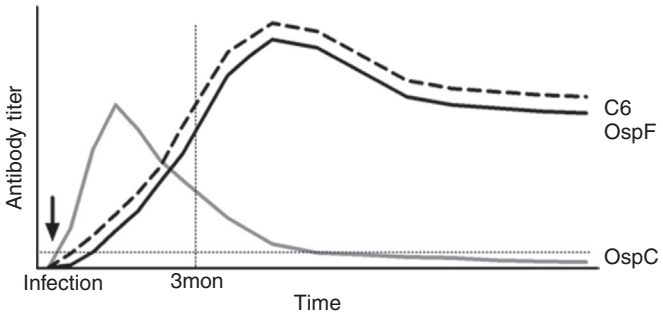

FIGURE 51-5 Proposed canine antibody response to OspC, OspF, and C6 antigens of *B. burgdorferi* during early and late infection. Data were obtained by fluorescent bead multiplex analysis. The lines for the first 3 months after infection are based on multiplex results from experimentally infected dogs. After 3 months the lines are projected from data obtained from patient sera. The horizontal dotted line shows the cutoff value for the multiplex assay. The vertical dotted line indicates 3 months after infection. (Modified from Wagner B, Freer H, Rollins A, et al. Antibodies to *Borrelia burgdorferi* OspA, OspC, OspF, and C6 antigens as markers for early and late infection in dogs. Clin Vaccine Immunol 2012;19:527-535.)

microscopy.[48] Other findings in experimentally infected dogs include periarteritis and perineuritis, especially within joint capsules and the skin, as well as lymphoid hyperplasia within peripheral lymph nodes. Mild, focal meningitis and encephalitis was identified in dogs that were infected with *B. burgdorferi* and immunosuppressed with dexamethasone.[49]

Renal histopathology in dogs with Lyme nephritis reveals diffuse membranoproliferative glomerulonephritis (Figure 51-6), dilation of the cortical renal tubules, tubular necrosis and regeneration, and mild to moderate, diffuse interstitial lymphoplasmacytic inflammation.[33] Periglomerular or diffuse interstitial fibrosis may be present in dogs with end-stage disease.

Treatment and Prognosis

Antimicrobial Treatment

Antibiotic treatment is recommended for seropositive dogs that have clinical illness consistent with Lyme disease. There is no evidence that treatment of healthy seropositive dogs is beneficial and it may lead to drug adverse effects and contribute to antimicrobial resistance in other bacteria and antimicrobial shortages. The antibiotic of choice for Lyme arthritis is doxycycline. The optimal dose and duration of treatment is unknown. Recommended doses have included 5 mg/kg PO q12h and 10 mg/kg PO q12h or 10 mg/kg PO q24h.[34,50] Four weeks of treatment has been recommended[34] because the clinical manifestations of disease resemble those of late-stage disease in human patients, for which relapses occur when treatment durations of less than 30 days are used.[39] Dogs with polyarthritis generally respond clinically to doxycycline treatment within 24 to 48 hours. Other differential diagnoses for polyarthritis should be considered if an inadequate response to treatment occurs. On the other hand, a clinical response to doxycycline treatment is not sufficient to make a diagnosis of Lyme arthritis. This is because there are other doxycycline-responsive causes of infectious polyarthritis in dogs; signs of primary immune-mediated polyarthritis can wax and wane; and doxycycline has antiinflammatory properties that may contribute to clinical improvement. For dogs that do not tolerate doxycycline, amoxicillin can be used, which also has activity against *B. burgdorferi* (Table 51-4). Azithromycin and third-generation cephalosporins have also been used to treat Lyme disease in human patients.[39] Doxycycline treatment

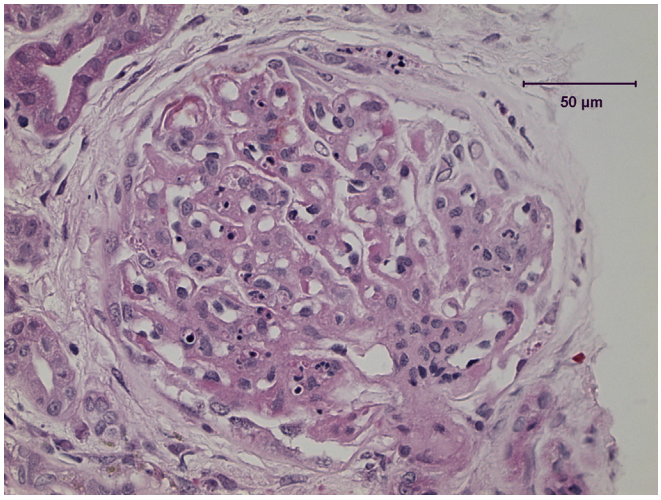

FIGURE 51-6 Membranoproliferative glomerulonephritis in a 6-year-old, intact male golden retriever dog that was seropositive for *B. burgdorferi* C6 protein antibodies and had clinical and biochemical evidence of protein-losing nephropathy. The morphologic diagnosis was moderate to severe, diffuse, global membranoproliferative glomerulonephritis with moderate chronic-active tubulointerstitial nephritis. The capillary walls are thickened and there is mesangial cell proliferation. There was also evidence of focal arteriolar mural disorganization, lamination, and sclerosis in this biopsy specimen. (Image courtesy Dr. George Lees, Texas A&M University.)

is also recommended for dogs with Lyme nephritis, although clinical improvement generally does not occur with antimicrobial treatment alone (see Supportive Care).

Although treatment leads to clinical improvement and a reduction in antibody titers, *B. burgdorferi* can persist in tissues after treatment is discontinued. Studies in mouse and primate models have shown that despite negative cultures after treatment, PCR assays remain positive, and infection can be transmitted from PCR-positive to naïve animals.[51,52] Regardless of the serologic test used, antibody titers can persist for months or years after resolution of clinical signs and antimicrobial drug treatment, so the results of antibody testing are not consistently useful to guide further treatment when clinical resolution of arthritis has occurred.

Supportive Care

Dogs with arthritis usually respond rapidly to treatment with antibiotics, and additional treatment may not be necessary. Severe pain associated with arthritis may be treated with nonsteroidal antiinflammatory drugs or opiate analgesics such as tramadol. Because Lyme arthritis can be reactivated in some dogs by administration of glucocorticoids more than a year after exposure,[53] glucocorticoids are not recommended for their antiinflammatory effects.

Dogs with Lyme nephritis require management for protein-losing nephropathy, which may include treatment with intravenous crystalloids and colloids, angiotensin-converting enzyme inhibitors such as enalapril or benazepril, low-dose aspirin in an attempt to reduce thrombotic events, and nutritional support with a reduced protein diet. Placement of an esophagostomy or gastrostomy tube for feeding purposes may be required. Blood pressure should be monitored and if necessary, antihypertensive drugs such as amlodipine should be administered and titrated to effect. Anecdotally, improved outcomes have been noted in dogs with Lyme nephritis after immunosuppressive drug treatment (Table 51-5). The optimum protocol is yet to be determined. Dogs treated with immunosuppressive drugs should be carefully monitored for adverse effects of drug therapy.

TABLE 51-4

Suitable Antimicrobials for Treatment of Lyme Disease in Dogs

Drug	Dose	Route	Interval (hours)	Duration (days)
Doxycycline	5 to 10 mg/kg	PO	12	28
Amoxicillin	20 mg/kg	PO	8	28

TABLE 51-5

Immunosuppressive Drug Protocols That Could Be Considered for Treatment of Lyme Nephritis in Dogs in Conjunction with Antimicrobial Drug Treatment

Drug	Dose	Route	Interval and Duration
Methylprednisolone sodium succinate with either cyclophosphamide, mycophenolate mofetil, or azathioprine below	5 mg/kg	IV	24 hours for 2 days
Cyclophosphamide	200 mg/m^2	IV	Every 14 days for a maximum of 6 cycles. Recheck CBC 1 week after each treatment.
Mycophenolate mofetil	10 mg/kg	IV or PO	12 hours until remission occurs, then consider tapering
Azathioprine	1-2 mg/kg	PO	24 hours for 7 days, then every 48 hours until remission occurs, then consider tapering

Prognosis

It is estimated that more than 90% of dogs that are infected with *B. burgdorferi* show no signs of illness. Dogs with Lyme arthritis generally recover rapidly with antimicrobial treatment and do not develop relapse of disease. It is not clear whether the "antibiotic-refractory arthritis" that occurs in a small percentage of genetically predisposed human patients also occurs in dogs. Seropositive dogs with antibiotic-refractory polyarthritis may have other unrelated causes of their disease, such as primary immune-mediated polyarthritis.

The prognosis for dogs with Lyme nephritis is guarded to poor. In the past, it was noted that most dogs die or are euthanized within days to weeks.[34] Death often results from systemic thrombosis or oliguric or anuric renal failure. Anecdotally, longer survival times of months to over a year have been noted in

some dogs treated with immunosuppressive drugs in addition to doxycycline and other supportive treatments.

Immunity and Vaccination

Borrelia spp. can evade the host immune response through modification of outer surface proteins and possibly metamorphosis to a resistant spherical form.[54] Interference with B-cell responses by the spirochete also seems to occur.[55] Humoral immunity is most critical for resolution of infection, although T-cell responses may be important for resolution of cell-mediated consequences of infection, such as carditis in human patients.[56]

Several vaccines are available in North America for reduction of Lyme disease in dogs. Lyme vaccines stimulate the formation of borreliacidal antibodies that are directed against the surface proteins normally expressed by the spirochete when it resides within the tick. When the tick ingests dog blood that contains these antibodies, complement-mediated lysis of the bacteria occurs *within the tick*. Thus, bacteria are inactivated before they invade the host. A canine recombinant OspA vaccine is available that induces the formation of antibodies only against OspA. This subunit vaccine is similar to a Lyme disease vaccine that was previously available for prevention of human Lyme borreliosis (LYMErix, GlaxoSmithKline). In humans, the vaccine was shown to be safe and efficacious, conferring immunity on 76% of adults and 100% of children with a low prevalence of local injection site reactions and flu-like symptoms.[57] However, this vaccine was withdrawn in February 2002 because of concerns that it may trigger autoimmune disease as a result of molecular mimicry in sensitive individuals, despite a lack of scientific justification for these concerns.[58,59]

Two inactivated whole spirochete vaccines are also available for dogs. One contains two strains of *B. burgdorferi*, one of which expresses high levels of OspC. The other vaccine is a single-strain vaccine. The potential advantage of these vaccines is that they stimulate immunity not only to OspA, but also to other surface proteins expressed by the spirochete. This may provide the opportunity to neutralize *B. burgdorferi* when OspA is downregulated, such as when the organism is in the salivary glands and after it enters the host. Concern has been expressed that whole-cell vaccines may be more likely to trigger autoimmune consequences in dogs than the subunit vaccine, especially in dogs that have been previously exposed to *B. burgdorferi*.[34] However, no strong evidence exists that these types of adverse reactions occur. Both OspA and whole-cell vaccines provide protection against infection and disease that results from experimental challenge.[60,61] A study in an endemic area for Lyme disease found a reduced prevalence of C6 seropositivity in dogs that had been vaccinated with a whole-cell bacterin when compared with dogs that had not been vaccinated, suggesting the possibility of protection from natural infection.[62] The dual-strain bacterin has been shown to have a 1-year duration of immunity.[63] Although no Lyme vaccine can be relied on to provide complete protection, side-by-side comparisons of canine Lyme vaccines that are available on the market have not been performed. In addition, whether Lyme vaccination protects against, or contributes to, the most severe consequence of infection, Lyme nephritis, is unknown. Finally, whether there are any advantages or disadvantages of vaccinating dogs that are already seropositive as a result of natural infection remains to be elucidated. The recent identification of reinfection (as opposed to relapse) as a cause of recurrent clinical signs of borreliosis in human patients[64] suggests that vaccination of previously exposed individuals may offer some benefit, because the protection induced by vaccination (anti-OspA antibodies) differs from that induced by natural infection (no anti-OspA antibodies). However, whether recurrent Lyme disease occurs in dogs as a result of reinfection is not known.

Prevention

Avoidance of tick-infested areas, use of topical ectoparasiticides, and routine inspection of dogs for ticks after outdoor activities can help to prevent Lyme disease. Ticks should be removed within 24 hours of attachment, before transmission of the spirochete can occur, but removal up to 60 hours after attachment may still reduce the chance of transmission.[65] Refer to Chapter 28 for general information on tick prevention and removal. Although treatment with a single dose of doxycycline after a known *Ixodes* tick bite can prevent Lyme disease in humans[66] and mice,[67] it is controversial because of the very low risk of infection after a tick bite.[68] A study in mice showed that treatment 2 or more days after tick removal was ineffective.[67]

For healthy dogs that test positive for antibodies to *B. burgdorferi* during a heartworm screen with assays that include a *B. burgdorferi* ELISA, a urinalysis could be offered in order to assess for proteinuria.[34] If proteinuria is detected, further work-up that includes a urine protein to creatinine ratio, aerobic bacterial culture of the urine, serum biochemistry panel, and imaging may be indicated. However, whether treatment of seropositive, proteinuric dogs with doxycycline influences the progression of Lyme nephropathy is not known, so this is controversial. Similarly, a CBC or platelet count could be performed, but whether treatment of thrombocytopenic dogs is necessary is also unknown. At a minimum, tick control for seropositive, apparently healthy dogs should be recommended.

Public Health Aspects

Lyme disease is the most common vector-borne disease of humans in the Northern Hemisphere, and the prevalence of the disease has increased progressively.[69] In humans, the first sign of disease in 80% to 90% of infected individuals is erythema migrans, which is a characteristic "bull's-eye" rash that occurs 3 to 30 days after a tick bite and moves outward from the bite site at a rate of approximately 1 cm/day. In some people, the rash is pruritic or painful, and it may be accompanied by headache and malaise. Early disseminated disease can appear as multiple erythema migrans rashes; myocardial disease that is usually characterized by atrioventricular block; or neuroborreliosis. Neuroborreliosis is more common in Europe and may be characterized by the development of cranial nerve palsies or signs of meningitis and polyradiculoneuritis. Arthritis is a manifestation of late Lyme disease. A small percentage of infected individuals, especially those of certain human leukocyte antigen (HLA) types, can develop chronic, antibiotic-refractory arthritis, which may result from persistence of spirochete residues in tissues.[70] European strains, particularly *B. afzelii*, can also induce a chronic skin manifestation known as acrodermatitis chronica atrophicans.[71]

Dogs do not pose a direct zoonotic risk to humans in the household. However, they may carry infected, unfed ticks into the household that could subsequently attach to humans. The presence of antibodies in dogs can also indicate increased human risk as a result of common exposure to infected ticks in the environment (sentinel exposure).

CASE EXAMPLE

Signalment: "Dako", a 7-year-old MC Doberman Pinscher dog from Amador County in northern California

History: Dako was evaluated for a 2-day history of lethargy, apparent blindness, inappetence, and inability to walk. He was taken to a local emergency clinic within 24 hours of illness, where a neurologic examination was considered abnormal and an intracranial lesion was suspected. He was treated with intravenous fluids and given a single dose of ampicillin (1 g). The following day his mentation and thoracic limb strength had improved, but he remained unable to walk and developed urinary incontinence. He lived on a farm and had contact with sheep, horses, llamas, chickens, geese, cats, and four other dogs, all of which were currently healthy, although an additional dog had died of acute renal failure 1 month earlier. There was no travel history or toxin exposure, but frequent exposure to ticks occurred. Dako's diet consisted of commercial dry dog food, and occasionally pieces of cooked steak and raw goose eggs. He had not received a Lyme vaccine in the past but had been vaccinated regularly for distemper, adenovirus, parvovirus, parainfluenza, and rabies. Dako had been diagnosed several years previously with color dilution alopecia.

Current Medications: Monthly topical flea and tick preventative (fipronil and *S*-methoprene), monthly oral heartworm preventative (ivermectin and pyrantel).

Physical Examination:

Body Weight: 43.1 kg

General: Quiet, alert, and responsive. Hydrated. Ambulatory on all four limbs but appeared very painful. T = 101.9°F (38.8°C), HR = 78 beats/min, RR = 24 breaths/min, mucous membranes pink, CRT = 1 s.

Integument, Eyes, Ears, Nose, and Throat: A thin haircoat with scaling was noted. Mild episcleral injection was present bilaterally. Moderate dental calculus and gingivitis were also present.

Musculoskeletal: Body condition score was 5/9 and the dog was symmetrically well muscled. Multiple distal joints were severely swollen and painful on palpation, including both carpi, tarsi, stifle, and elbow joints. The dog appeared painful when rising from recumbency and when walked, with pronounced right pelvic limb lameness.

Cardiovascular, Respiratory, Gastrointestinal, and Genitourinary: No clinically significant abnormalities were detected. The dog had a large bladder, and actively urinated a large amount during the examination. Rectal examination was unremarkable.

Lymph Nodes: Bilateral popliteal lymphadenomegaly (3 cm in diameter) was noted. The remaining peripheral lymph nodes measured 2 cm in diameter. All nodes were soft on palpation.

Neurologic Examination: No neurologic abnormalities were detected.

Laboratory Findings:

CBC:

HCT 48.4% (40%-55%)
MCV 69.6 fL (65-75 fL)
MCHC 34.9 g/dL (33-36 g/dL)
WBC 17,100 cells/μL (6000-13,000 cells/μL)
Neutrophils 15,561 cells/μL (3000-10,500 cells/μL)
Lymphocytes 171 cells/μL (1000-4000 cells/μL)
Monocytes 1026 cells/μL (150-1200 cells/μL)
Eosinophils 342 cells/μL (0-1500 cells/μL), platelets clumped.

Serum Chemistry Profile:

Sodium 148 mmol/L (143-151 mmol/L)
Potassium 3.5 mmol/L (3.6-4.8 mmol/L)
Chloride 115 mmol/L (108-116 mmol/L)
Bicarbonate 20 mmol/L (20-29 mmol/L)
Phosphorus 3.1 mg/dL (2.6-5.2 mg/dL)
Calcium 10.0 mg/dL (9.6-11.2 mg/dL)
BUN 11 mg/dL (11-33 mg/dL)
Creatinine 0.8 mg/dL (0.8-1.5 mg/dL)
Glucose 102 mg/dL (86-118 mg/dL)
Total protein 6.1 g/dL (5.4-6.9 g/dL)
Albumin 3.6 g/dL (3.4-4.3 g/dL)
Globulin 2.5 g/dL (1.7-3.1 g/dL)
ALT 17 U/L (21-72 U/L)
AST 36 U/L (20-49 U/L)
ALP 60 U/L (14-91 U/L)
Creatine kinase 217 U/L (55-257 U/L)
GGT 1 U/L (0-6 U/L)
Cholesterol 167 mg/dL (139-353 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL)
Magnesium 1.8 mg/dL (1.9-2.5 mg/dL).

Urinalysis: SGr 1.018; pH 8.0, negative protein (SSA), negative bilirubin, negative glucose, 0-1 WBC/HPF, 0-2 RBC/HPF.

Imaging Findings:

Thoracic Radiographs: Unremarkable.

Abdominal Ultrasound: The liver was diffusely hypoechoic but was normal in size. There was mild bilateral adrenomegaly (0.9 cm). The urinary bladder was very large and was in a pelvic location.

Microbiologic Testing: 4Dx SNAP test (IDEXX Laboratories): Positive for *B. burgdorferi* antibodies; negative for antibodies to *Anaplasma* spp. and *E. canis*; negative for *Dirofilaria immitis* antigen.

Cytology of Synovial Fluid Obtained via Arthrocentesis

	Right Carpus	Left Carpus	Right Tarsus	Left Stifle
Cell count (cells/μL)	23,730	29,370	ND	1020
Neutrophils (%)	85	94	76	12
Small mononuclear cells (%)	2	0	1	41
Large mononuclear cells (%)	13	6	23	47
Interpretation	Marked purulent inflammation with nondegenerate neutrophils			Very mild purulent inflammation with nondegenerate neutrophils

ND, not done.

VetBooks.ir

Lyme C6 Quant antibody ELISA (IDEXX Laboratories): 153 U/mL (normal, <30 U/mL).
PCR for *B. burgdorferi* on synovial fluid: Negative.

Diagnosis: Neutrophilic polyarthritis; possibly secondary to *B. burgdorferi* infection.

Treatment: Dako was treated with doxycycline (5 mg/kg PO q12h) and tramadol (2 mg/kg PO q8h) and showed dramatic clinical improvement within 24 hours of initiating treatment. A physical examination was normal 2 weeks later.

Comments: The positive serology and response to doxycycline suggested the possibility of Lyme arthritis, although it is possible there was some other cause that was not identified and the presence of C6 antibodies was not related to this dog's illness. It may have been too early in the course of illness for this dog to have seroconverted to other vector-borne pathogens such as *A. phagocytophilum*. Other diagnostic assays that might have been useful in this dog (and in this geographic location) include serology for *Bartonella* spp.; PCR on blood for vector-borne pathogens such as *A. phagocytophilum, Rickettsia* spp., and *Ehrlichia canis;* aerobic bacterial culture of the synovial fluid; and convalescent serology for vector-borne pathogens. The negative synovial fluid PCR result did not rule out the possibility of Lyme arthritis, because organism numbers within the synovial fluid of animals with Lyme arthritis may be extremely low. The dog had been treated with ampicillin before it was seen, which also may have reduced organism numbers further.

CHAPTER 52

Bartonellosis

Jane E. Sykes and Bruno B. Chomel

VetBooks.ir

Overview of Bartonellosis in Dogs and Cats

First Described: Peru, 1905 (Alberto Barton Thompson) (*Bartonella bacilliformis*).[1] Identification of *Bartonella* as the cause of cat scratch disease in humans did not occur until 1983.[2]

Causes: The most common species in cats are *Bartonella henselae* and *Bartonella clarridgeiae*; in dogs, they are *Bartonella vinsonii* subsp. *berkhoffii* and *B. henselae*.

Geographic Distribution: Worldwide, with highest prevalence in subtropical and tropical regions

Major Mode of Transmission: Fleas (*Ctenocephalides felis*); possibly other flea species (such as *Pulex* spp.) and vectors such as ticks, lice, biting flies

Major Clinical Signs: Signs that relate to infective endocarditis (lethargy, fever, cardiac murmur, cough, tachypnea, lameness, neurologic signs) are the most frequent and well understood manifestations of bartonellosis in dogs. *Bartonella* can also cause endocarditis and myocarditis in cats and is suspected to cause (or contribute to) caudal stomatitis and possibly other systemic inflammatory disorders such as uveitis.

Differential Diagnoses: Cats: major differential diagnoses are other bacterial causes of endocarditis and feline infectious peritonitis. Dogs: other bacterial causes of endocarditis, other vector-borne diseases such as ehrlichiosis, anaplasmosis, borreliosis and babesiosis, and immune-mediated inflammatory diseases.

Human Health Significance: *Bartonella* causes cat scratch disease in immunocompetent humans as well as vasculoproliferative disorders in immunocompromised humans.

Etiology and Epidemiology

Bartonella spp. are fastidious, intraerythrocytic gram-negative bacteria that infect a wide range of domestic and wild mammalian host species. Different *Bartonella* species have adapted to specific mammalian reservoir hosts and can infect and occasionally cause disease in alternative, incidental hosts. More than 10 species of *Bartonella* infect cats or dogs worldwide (Tables 52-1 and 52-2). *Bartonella* infections are important because cats are the principal reservoir host for *Bartonella henselae*, the main cause of cat scratch disease (CSD) in humans, and subclinical bacteremia in cats is widespread (8% to 56% of healthy cats worldwide).[3]

Cat fleas *(Ctenocephalides felis)* play a major role in the transmission of feline *Bartonella* infections. The presence of cat fleas is essential for maintenance of the infection within the cat population.[4] *B. henselae* can multiply in the digestive system of the flea and survive several days in flea feces.[5] The main source of infection appears to be flea feces that are inoculated by contaminated cat claws.[6] There is some evidence that *Bartonella* is present in the saliva of cats, but shedding of *B. henselae* in cat saliva has not been clearly documented. Other potential vectors, such as *Pulex* flea species, ticks, lice, and biting flies, also harbor *Bartonella* DNA, and experimental transmission of *Bartonella birtlesii* has been accomplished with *Ixodes ricinus* ticks.[7] There is epidemiologic evidence that ticks may transmit *Bartonella* to dogs.

Because *Bartonella* infections are often subclinical in dogs and cats, the full extent to which *Bartonella* spp. cause *disease* in naturally infected dogs and cats remains unclear. *Bartonella* spp. have been widely studied for their role in a number of idiopathic inflammatory disorders of cats, including uveitis, lymphadenopathy, caudal stomatitis, and rhinitis, without definitive evidence of disease causation. Without doubt, they are important causes of endocarditis in dogs and occasionally cause endocarditis and myocarditis in cats (Table 52-3 and Box 52-1).

Epidemiology of *Bartonella* in Cats

The most common *Bartonella* species isolated from cats is *B. henselae*. Less commonly, cats are infected with *Bartonella clarridgeiae* or *Bartonella koehlerae*, which also have been linked to human disease.[5,8] Young cats (≤1 year) are more likely than older cats to be bacteremic, and stray or feral cats are more likely to be bacteremic than pet cats.[5,9,10] Older cats are more likely to be seropositive than young cats, which likely reflects the increased chance of exposure over time. The prevalence of *Bartonella* bacteremia in cats is also highest in warm, humid climates (e.g., 68% in the Philippines), whereas it is low in colder climates (e.g., 0% in Norway).[5] At least two genotypes of *B. henselae* infect cats, type Houston-1 (type I) and type Marseille (type II). *B. henselae* type Marseille predominates among cats in the western United States, western continental Europe, the United Kingdom, and Australia; type Houston-1 is dominant in Asia (Japan and the Philippines).[5] However, within a given country, the prevalence of these types varies among cat populations, and type Houston-1 is more often isolated from humans with bartonellosis, even when type Marseille is more prevalent in the cat population. Some molecular typing methods reveal an even broader genetic diversity among feline strains, and most of the strains that infect humans cluster in a limited number of groups.

TABLE 52-1

Species of *Bartonella* Known to Infect Cats

Bartonella Species	Primary Reservoir	Primary Vector
B. henselae	Cats	Cat flea (*Ctenocephalides felis*)
B. clarridgeiae	Cats	Cat flea
B. koehlerae	Probably cats	Cat flea
B. quintana	Human	Human body louse (*Pediculus humanus*)
B. bovis	Ruminants (cattle, deer)	Biting flies?
B. vinsonii subspecies *berkhoffii*	Coyotes, domestic dogs	Unknown (fleas, ticks?)

TABLE 52-2

Species of *Bartonella* Known to Infect Dogs

Bartonella Species	Primary Reservoir	Primary Vector
B. henselae	Domestic cats	Cat flea (*Ctenocephalides felis*)
B. vinsonii subsp. *berkhoffii*	Coyotes, domestic dogs, foxes	Unknown (fleas, ticks?)
B. rochalimae	Wild carnivores, domestic dogs	Fleas (*Pulex irritans*)
B. clarridgeiae	Domestic cats	Cat flea
B. koehlerae	Domestic cats	Unknown
B. quintana	Human	Body louse (*Pediculus humanus*) (in humans)
B. washoensis	California ground squirrel	Unknown
B. bovis	Ruminants (cattle, deer)	Unknown
B. elizabethae	Rats	Oriental rat flea (*Xenopsylla cheopis*)
B. grahamii	Wild mice	Rodent fleas (*Ctenophthalmus nobilis*)
B. taylorii	Wild mice	Rodent fleas (*Ctenophthalmus nobilis*)
B. vinsonii subsp. *arupensis*	White-footed mouse	Unknown
B. volans–like	Southern flying squirrel	Unknown
"*Candidatus B. merieuxii*" (strain HMD)	Dogs, jackals	Unknown

TABLE 52-3

Examples of Clinical Manifestations That May, in Some Circumstances, Be Associated with *Bartonella* Infection in Naturally Infected Cats

Strength of Association	Clinical Manifestation	*Bartonella* Species
Definite	Endocarditis[26]	*B. henselae*
	Myocarditis and diaphragmatic myositis[27]	
Probable	Osteomyelitis[28]	*B. v. berkhoffii*
	Systemic reactive angioendotheliomatosis[29]	
Possible*	Caudal stomatitis[32-37]	Unknown
	Lower urinary tract disease[32,36]	
	Uveitis[30,31]	
	Lymphadenopathy[37]	
	Fever[38]	

*Results of experimental studies are conflicting or there is insufficient evidence to prove an association with disease.

Epidemiology of *Bartonella* in Dogs

Dogs are most commonly infected with *Bartonella vinsonii* subsp. *berkhoffii* or *B. henselae*. Domestic and wild dogs are thought to be the natural reservoir for *B. v. berkhoffii*, because *B. v. berkhoffii* establishes prolonged bacteremia in dogs. In California, 35% of coyotes *(Canis latrans)* tested were seropositive, and 28% of coyotes from a highly endemic region were bacteremic.[5] Other *Bartonella* species have also been detected in dogs (see Table 52-2). Novel species also have been identified in dogs from Thailand, Sri Lanka, and the Mediterranean.[11-13]

Because it is often difficult to culture *Bartonella* from domestic dog blood, prevalence studies in dogs are usually based on antibody detection. Unfortunately, this correlates poorly with bacteremia. In addition, serologic cross-reactivity occurs among *Bartonella* species so seroprevalence studies cannot be *Bartonella* species-specific. The prevalence of antibodies to *B. v. berkhoffii* in dogs is highest in tropical or subtropical regions. For example, seroprevalences as high as 47% were detected in stray dogs from Morocco.[14] In the southeastern United States, the prevalence of *B. henselae* antibodies in healthy dogs was 10%; a higher prevalence (27%) was found in sick dogs.[15] Risk factors identified in dogs in the southeastern United States were tick exposure, residence in a rural environment, roaming, and outdoor exposure.[16] The prevalence of *B. henselae* antibodies in sick dogs from the western United States is less than 2%.[17]

Clinical Features

Signs and Their Pathogenesis

After infection, *Bartonella* replicates in erythrocytes and can also infect endothelial cells and bone marrow progenitor cells.[18] It then establishes chronic, often subclinical bacteremia, which can last for weeks, months, or even more than a year and may be a specific adaptation to a mode of transmission by blood-sucking

BOX 52-1

Descriptive Case Reports or Small Case Series Where *Bartonella* Has Been Detected within Lesions in Dogs using Culture or PCR

Endocarditis
B. v. berkhoffii[45-47]
B. henselae[45,48]
B. clarridgeiae[46]
B. koehlerae[48]
B. quintana[49]
B. rochalimae[50]

Chronic lymphocytic hepatitis with copper accumulation (Doberman)
B. clarridgeiae[51]

Systemic pyogranulomatous disease, hyperviscosity syndrome
Bartonella spp.[52]

Pyogranulomatous lymphadenitis
B. henselae[53]

Granulomatous hepatitis
B. henselae[51]

Peliosis hepatis
B. henselae[54]

Systemic granulomatous disease and sialometaplasia
B. henselae
B. v. berkhoffii[55]

Chronic erosive polyarthritis
B. henselae
B. v. berkhoffii[56]

Massive post-traumatic seroma
B. henselae
B. v. berkhoffii[57]

Hemangiopericytoma
B. v. berkhoffii or *B. henselae*[29]

Epistaxis
B. v. berkhoffii or *B. henselae*[58]

Meningoradiculoneuritis and pyogranulomatous dermatitis or panniculitis
B. v. berkhoffii[59]

Bacillary angiomatosis
B. v. berkhoffii[60]

arthropods.[19] Infection of endothelial cells may be more likely to occur in incidental hosts and appears to be necessary for the development of disorders such as vasculoproliferative disease and endocarditis. *Bartonella* is thought to cause vasculoproliferative disease via cytokine-induced stimulation of endothelial cell proliferation and inhibition of endothelial cell apoptosis. Virulence factors characterized in *Bartonella* species include adhesins, heme acquisition mechanisms, type IV secretion systems, and a low-potency lipopolysaccharide, among others.[20] Host immunocompromise, such as due to genetic susceptibility (e.g., breed-related immunodeficiency syndromes), poor nutrition, overcrowding, co-infections with other pathogens, immunosuppressive drug treatment, or defects in normal host barriers (such as congenital valvular disease in dogs with endocarditis), may also influence whether disease ultimately develops in infected dogs and cats.

The vast majority of infected dogs and cats show no overt clinical signs of illness when bacteremic. In some situations, disease manifestations that occur in *Bartonella* spp.–infected dogs and cats are otherwise uncommon to rare and/or known to be associated with *Bartonella* infection in human patients; organisms may also have been visualized with silver stains using light microscopy in affected tissues (e.g., endocarditis or myocarditis lesions). In other situations, nonspecific clinical signs are present (e.g., uveitis, gingivostomatitis, chylothorax, polyarthritis, chronic rhinitis, idiopathic lower urinary tract disease, lymphadenopathy, reproductive disease, or neurologic disorders), and it has been impossible to clearly assign a role to *Bartonella* in disease causation. A clear understanding of the role of *Bartonella* in disease causation has also been thwarted by limitations of diagnostic tests available for detection of infection.

Clinical Manifestations in Cats

Experimental infections of specific pathogen free cats with *Bartonella* have shed light on disease processes that can follow infection of cats with *Bartonella*. Cats infected with *B. henselae* develop a small papule at the site of inoculation, and transient fever and lymphadenopathy.[21-24] Transient neurologic signs (such as staring and behavioral abnormalities) and reproductive disorders can also occur. Some cats infected with *B. henselae* and/or *B. clarridgeiae* show no clinical signs, and gross lesions are lacking at necropsy. However, histopathology reveals peripheral lymph node hyperplasia, splenic follicular hyperplasia, lymphocytic cholangitis/pericholangitis, lymphocytic hepatitis, lymphoplasmacytic myocarditis, and/or interstitial lymphocytic nephritis.[21,23]

In naturally infected cats, *Bartonella* can rarely cause endocarditis and myocarditis. Generally speaking, infective endocarditis is rare in cats, but a few of the reported cases have been associated with *Bartonella* infection. *B. henselae* DNA has been amplified from aortic valvular vegetative lesions of cats, with visualization of the organism in lesions using silver stains.[25,26] Dramatic pyogranulomatous myocarditis and diaphragmatic myositis were associated with *B. henselae* infection in two cats that died in a North Carolina shelter, and organisms were detected in lesions with silver stains and immunohistochemistry (IHC) (Figure 52-1).[27] Carpal and metacarpal osteomyelitis was also associated with a *B. v. berkhoffii* infection in a cat; *Bartonella* DNA was detected in bone lesions as well as in the blood.[28] The DNA of *B. v. berkhoffii* and *B. henselae* was also detected in cardiac tissues of several cats with systemic reactive angioendotheliomatosis.[29]

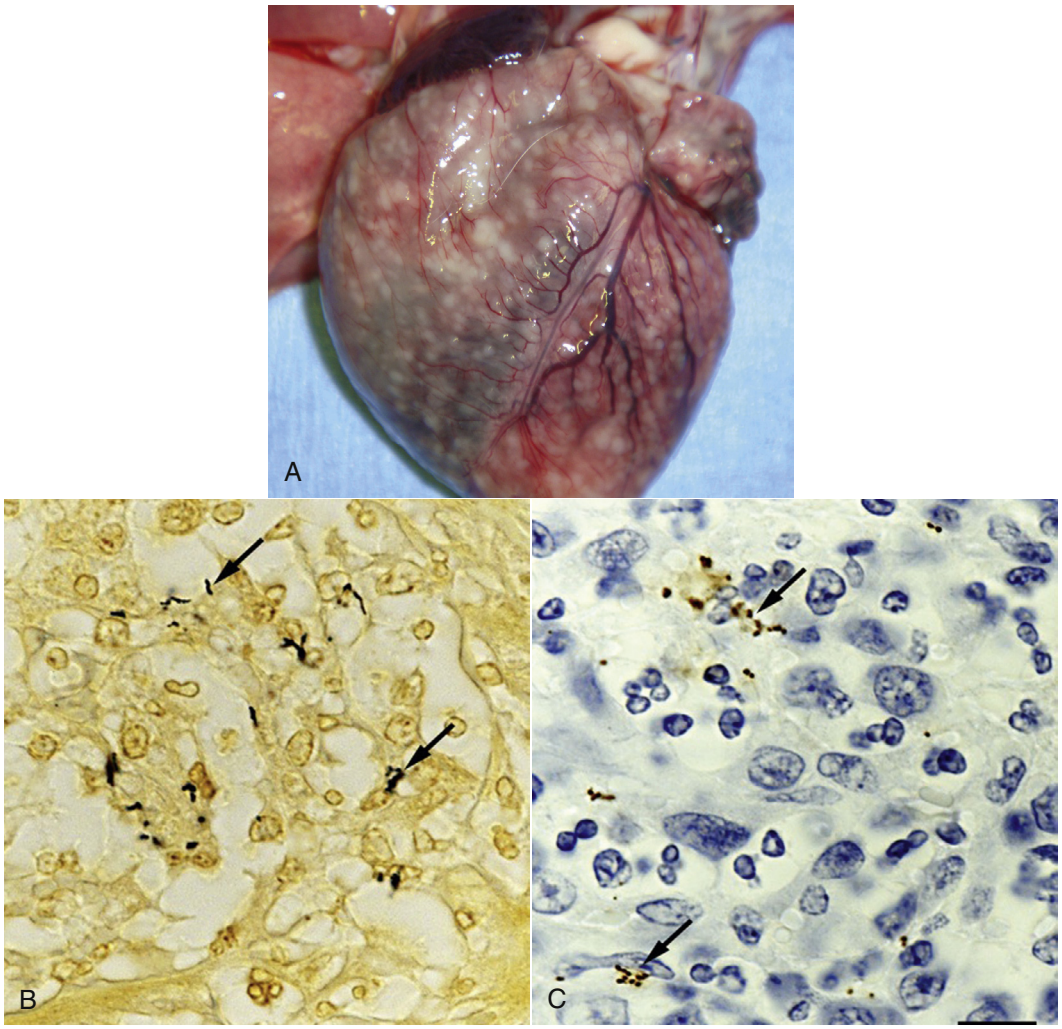

FIGURE 52-1 **A,** Granulomatous myocarditis associated with *Bartonella henselae* infection in an 8-week-old female domestic shorthair introduced to a shelter that was ridden with fleas. **B,** Histopathology of the heart of the affected cat showing intralesional agyrophilic bacteria *(arrows)*. Warthin-Starry stain. **C,** Short bacilli *(arrows)* in an inflammatory focus are immunoreactive *(brown)* for *Bartonella henselae*–specific monoclonal antibody. Immunohistochemistry with diaminobenzidine chromogen, hematoxylin counterstain. (**A,** Courtesy Drs. Jack Broadhurst and Edward Breitschwerdt. From Varanat M, Broadhurst J, Linder KE, et al. Identification of *Bartonella henselae* in 2 cats with pyogranulomatous myocarditis and diaphragmatic myositis. Vet Pathol 2012;49:608-611.)

Bartonella has been investigated for its role in a large number of idiopathic conditions in cats (see Table 52-3).[26-38] These include uveitis,[30-32] caudal gingivostomatitis,[32-37] fever of unknown origin,[38] lower urinary tract disease,[32,36,39] chronic kidney disease,[32,36] pancreatitis,[40] lymphadenopathy (Figure 52-2),[37] neurologic disease,[32,41,42] pododermatitis,[43] and chronic idiopathic rhinosinusitis.[44] There is currently no convincing and repeatable scientific evidence that *Bartonella* infection causes any of these conditions. Studies have varied in the methodology used to detect infection (serology, culture, and/or PCR assays), and many of the conditions investigated likely have multifactorial etiologies. An understanding of the significance of *Bartonella* in these conditions will probably require prospective study of large numbers of cats with clearly defined clinical illness using *Bartonella* culture and/or PCR assays.

Clinical Manifestations in Dogs

Bartonella spp. are important causes of blood-culture–negative endocarditis in dogs (see Box 52-1).[25,29,45-60] Infection with *Bartonella* was identified in 6 (19%) of 31 dogs with culture–negative endocarditis in California.[61] Worldwide, the DNA of several *Bartonella* species has been detected in the heart valves of dogs with endocarditis. The most common species identified has been *B. v. berkhoffii*. In dogs, *Bartonella* endocarditis usually involves the aortic valve, although the mitral valve is occasionally affected, so the possibility of bartonellosis should not be ruled out in dogs with mitral valve endocarditis. Dogs with *Bartonella* endocarditis are more likely to be afebrile and more likely to have congestive heart failure than dogs with other causes of endocarditis, and their median survival time is shorter (Figure 52-3).[61] Complications of *Bartonella* endocarditis include thromboembolic disease and neutrophilic polyarthritis.

Bartonella, or *Bartonella* DNA, has been detected in lesions from dogs with a variety of chronic pyogranulomatous or granulomatous inflammatory and vasculoproliferative diseases (see Box 52-1). *Bartonella* was detected in a dog with peliosis hepatis and a dog with bacillary angiomatosis, rare conditions that are strongly associated with *Bartonella* infection in humans.[54,60] Peliosis hepatis and bacillary angiomatosis are vasculoproliferative diseases characterized by the presence of blood-filled proliferations of vascular tissue in the liver and skin, respectively. Based on case reports and seroprevalence studies, *Bartonella* is suspected to cause polyarthritis, epistaxis, thrombocytopenia,

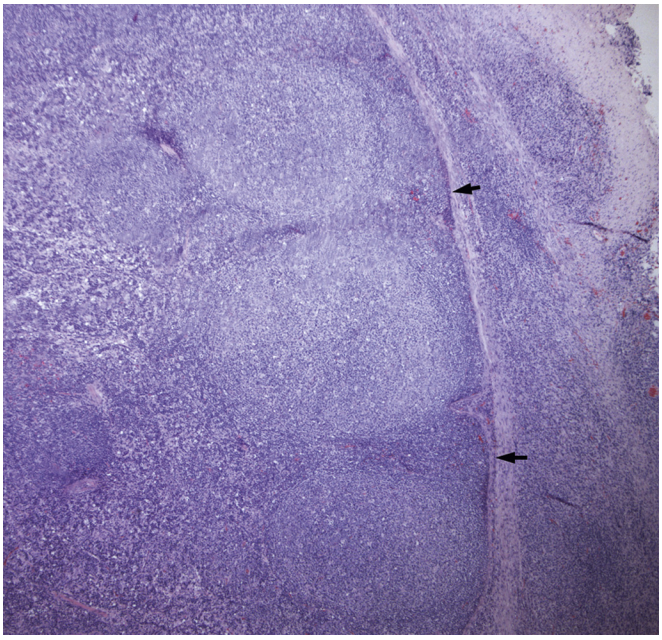

FIGURE 52-2 Lymph node of a 1-year-old, retrovirus-negative, flea-ridden cat with a 3-month history of fever, mild lethargy, and generalized peripheral lymphadenopathy but a normal appetite. The right axillary and both mandibular lymph nodes measured 3 cm in diameter; the remaining peripheral lymph nodes were 2 cm in diameter. A serum chemistry profile revealed hyperglobulinemia (6.5 g/dL). Serum protein electrophoresis revealed a polyclonal gammopathy. Histopathology of the right axillary, right mandibular and right popliteal lymph node showed lymphofollicular hyperplasia and marked neutrophilic, lymphocytic, and histiocytic capsulitis and perilymphadenitis. Note the florid capsulitis to the right of the arrows, which indicate the outer extent of the lymph node parenchyma. Silver stains (Warthin-Starry and Steiner stains) showed a small amount of granular staining within cells, which possibly represented intracellular agyrophilic bacteria. The DNA of *Bartonella henselae* and *Bartonella clarridgeiae* was detected in the lymph node using PCR, and blood cultures were positive for *B. henselae*. Interestingly, the cat was seronegative to *B. henselae* and *B. clarridgeiae*.

and/or splenomegaly in dogs.[17] However, these associations could also reflect the presence of other detected or undetected, co-transmitted vector-borne pathogens that cause these disorders. *Bartonella* has been investigated for its role in canine lymphoma[62]; neurologic disease[63]; splenic disorders including lymphoid nodular hyperplasia, hemangiosarcoma, and fibrohistiocytic nodules[64]; idiopathic cavitary effusion[65]; and idiopathic rhinitis.[66] As for cats, the role that *Bartonella* plays in these conditions, if any, is unclear and requires further study.

Physical Examination Findings

In dogs with *Bartonella* endocarditis, physical examination findings include lethargy, inappetence and thin body condition; lameness or recumbency due to thromboembolic complications, weakness, or polyarthritis; joint effusion; and, uncommonly, fever (as high as 104.9°F [41°C]). Evidence of cardiac disease and congestive heart failure is often present, including respiratory distress, cough, increased lung sounds, and systolic and/or diastolic heart murmurs, cardiac arrhythmias, and pulse deficits. Neurologic signs such as anisocoria and obtundation can occur in dogs with thromboembolism that involves the central nervous system. There may also be evidence of flea or tick infestations in some dogs. Other physical examination findings that might be present in dogs with other manifestations of bartonellosis are mass lesions that involve the nasal cavity, lymph nodes, or salivary glands; splenomegaly or hepatomegaly; cavitary effusions; peripheral edema; epistaxis; or nodular skin lesions.

Physical examination findings in cats with *Bartonella* endocarditis or myocarditis have included fever, lethargy, respiratory distress, cardiac murmurs, and arrhythmias.[26,27]

Diagnosis

Diagnosis of bartonellosis is based on the presence of consistent clinical abnormalities (especially endocarditis or myocarditis, but also other systemic inflammatory or vasculoproliferative diseases), histopathologic findings, and positive culture or PCR

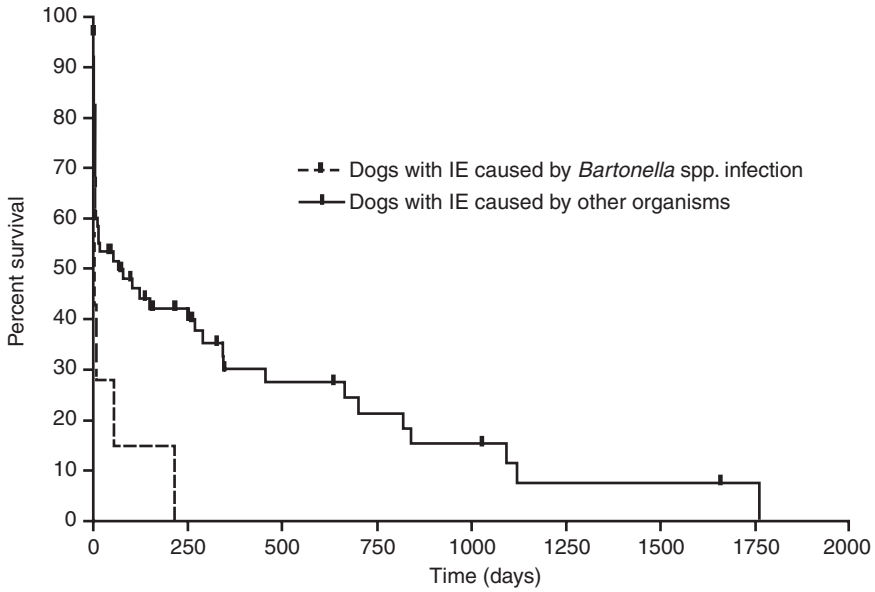

FIGURE 52-3 Kaplan-Meier survival curve comparing survival of dogs with *Bartonella* infectious endocarditis (IE) with that of dogs with IE caused by other pathogens. (From Sykes JE, Kittleson MD, Pesavento PA, et al. Evaluation of the relationship between causative organisms and clinical characteristics of infective endocarditis in dogs: 71 cases (1992-2005). J Am Vet Med Assoc 2006;228:1723-1734.)

TABLE 52-4

Diagnostic Assays Available for *Bartonella* Infection in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Whole blood, tissue specimens obtained at necropsy (e.g., heart valve, myocardium) or by biopsy (e.g., liver biopsy, skin biopsy)	*Bartonella* spp.	Confirms infection and allows species identification. Specialized culture conditions required; best performed in laboratories with special expertise. Requires several weeks' incubation. Sensitivity is especially low in dogs because of low-level or intermittent bacteremia. Use of BAPGM enrichment media followed by PCR may increase sensitivity but may increase the chance of false-positive results due to PCR-related contamination. Positive culture results alone do not apply disease causation, because healthy dogs and cats can have *Bartonella* in their blood.
Histopathology with organism detecting using silver stains or IHC	Tissue specimens obtained by biopsy or necropsy	*Bartonella* spp. organisms	Low sensitivity, but supports disease causation when positive and properly performed and interpreted.
Serology	Serum	Antibodies to *Bartonella* spp.	Variable cross-reactivity between *Bartonella* species; species-specific assays are required. Immunofluorescent antibody, ELISA, and Western immunoblot assays are available. Results correlate poorly with bacteremia. Positive results do not imply disease causation, because a significant proportion of healthy dogs and cats are seropositive. Positive titers are usually present in dogs and cats with endocarditis.
PCR	Whole blood, splenic or lymph node aspirates, tissue specimens obtained at necropsy or biopsy	*Bartonella* spp. DNA	Confirms active infection more rapidly than culture. Sensitivity and specificity may vary depending on assay design and specimen type; may not necessarily be more sensitive than culture. Because healthy animals may be PCR positive, positive PCR results must be interpreted in light of the clinical signs. False positive results may occur as a result of PCR-related contamination.

assay results on blood and affected tissues (Table 52-4). It may be impossible to identify *Bartonella* as the cause of disease if the organism is detected only in the blood and if affected tissues (e.g., valvular vegetations) cannot be obtained for analysis, because healthy dogs and especially cats can be bacteremic. Other possible causes of disease must also be investigated, and a response to antibiotic treatment could be evaluated (see Case Example).[67] It is even more difficult to establish a definitive diagnosis based on serology, but when culture and PCR assay results are negative, positive serologic test results *in dogs* may be of some value in the presence of consistent clinical abnormalities. More specifically (and as occurs in humans), dogs with *Bartonella* endocarditis usually have high antibody titers to *Bartonella* spp. Organism detection tests are insensitive in dogs because dogs tend to have very low levels of bacteremia when compared with cats.

Laboratory Abnormalities

Hematologic and biochemistry abnormalities in dogs and cats with *Bartonella* endocarditis are nonspecific and often mild. The CBC may show a mild nonregenerative anemia (31% to 39%), variable leukocytosis primarily due to neutrophilia (up to 43,000 neutrophils/μL), and mild thrombocytopenia (usually above 100,000 platelets/μL). In a few dogs, low to moderate numbers of circulating band neutrophils, lymphocytosis, and/or monocytosis are present.[49,68,69] The biochemistry panel may reveal mild azotemia (creatinine <3 mg/dL), mild hypoalbuminemia, and, less often, hyperglobulinemia. Isosthenuria, proteinuria, cylindruria, and slightly increased urine protein-to-creatinine ratios have been present in the urine of some affected dogs. Dogs with hepatic disorders associated with *Bartonella* infection have had moderately increased activities of serum ALT and/or ALP.[51,54]

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with *Bartonella* endocarditis often show evidence of congestive heart failure, with venous engorgement and pulmonary edema (Figure 52-4). Lung lobe consolidation and hilar lymphadenopathy were described in a dog with systemic granulomatous disease and sialometaplasia.[55]

Abdominal Ultrasound

Ultrasound of dogs with systemic granulomatous or pyogranulomatous disease may reveal lymphadenomegaly and organomegaly,[52] and mixed echogenic patterns within the liver.[51] The dog with peliosis hepatis had ascites and multiple, small nodular masses and hypoechoic cystic lesions within the liver.[54]

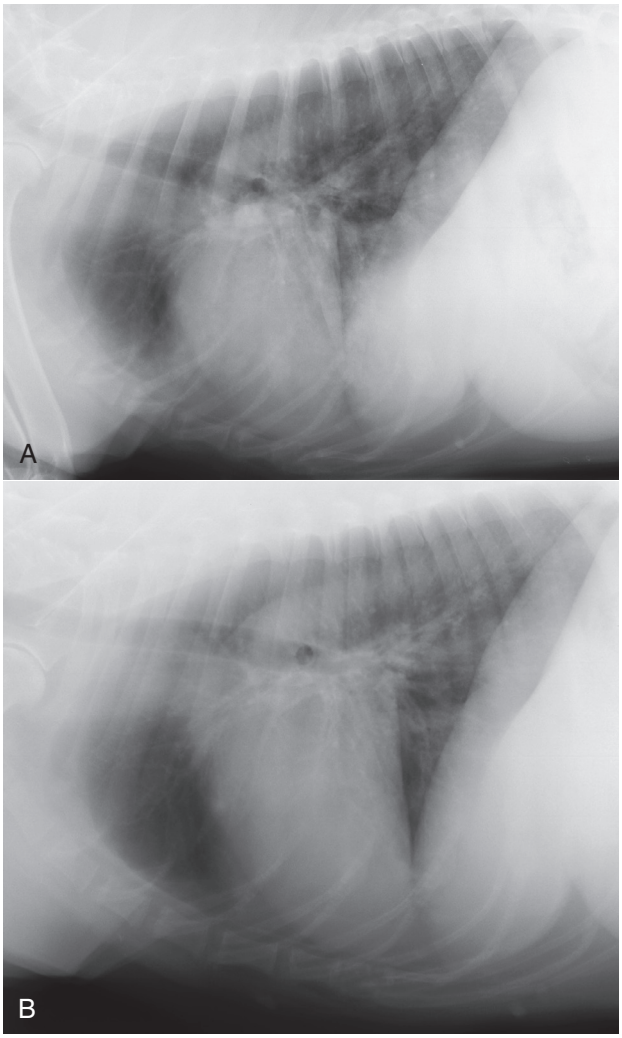

FIGURE 52-4 Lateral thoracic radiograph from a 3-year-old female spayed Doberman pinscher with early congestive heart failure due to endocarditis, before (A) and after (B) treatment with furosemide. The dog was seroreactive to *Bartonella vinsonii* subsp. *berkhoffii* with a titer of 1:256 and *Bartonella henselae* with a titer of 1:64. **A,** There is mild cardiomegaly with left atrial enlargement. There is increased pulmonary interstitial opacity that is most pronounced in the accessory lung lobe, as well as cranial to the heart. **B,** Pulmonary infiltrates have significantly resolved.

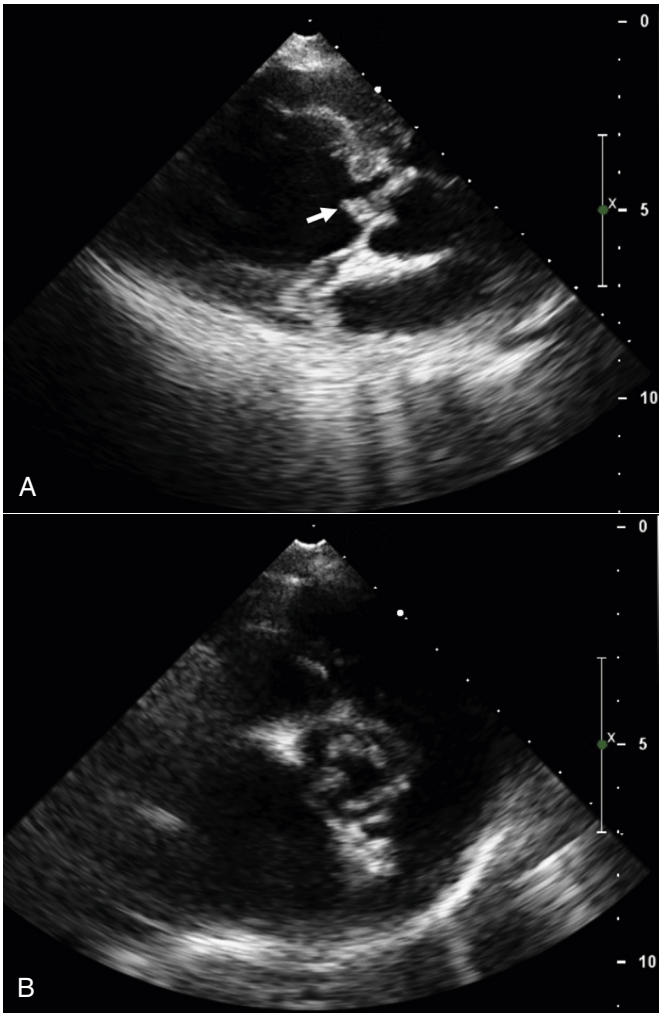

FIGURE 52-5 Echocardiogram images from a 13-year old German shepherd dog with blood culture–negative endocarditis. The dog also had biopsy-confirmed glomerulonephritis. IFA serology for *Bartonella vinsonii* subsp. *berkhoffii*, *Bartonella clarridgeiae*, and *Bartonella henselae* were positive at titers of 1:512, 1:1024, and 1:128, respectively. On the long-axis view **(A)** there is an irregular hyperechoic lesion attached to the aortic valve cusps *(arrow),* and the cusps appear thickened. On the short-axis view **(B)**, the normal "Mercedes Benz" sign has been destroyed by the aortic valvular thickenings.

Echocardiography

Echocardiography in dogs and cats with *Bartonella* endocarditis reveals oscillating valvular vegetations or thickened and hyperechoic valve leaflets, which usually involve the aortic valve (Figure 52-5). There may be evidence of aortic regurgitation or insufficiency and eccentric hypertrophy of the left ventricle in some dogs.

Microbiologic Tests

Culture

Culture of blood or other tissues for *Bartonella* allows definitive diagnosis of infection. However, blood culture requires special techniques and can be insensitive because of the relapsing nature of bacteremia. In contrast to the situation in cats, culture has especially low sensitivity in dogs because of the low level of bacteremia in dogs (especially when they act as incidental hosts and develop disease). Blood for culture should be obtained using sterile technique and the blood placed in EDTA-containing tubes, and then chilled or frozen during shipment. Collection of blood into plastic EDTA tubes allows the tubes to be frozen directly, which releases organisms from erythrocytes after which they are plated onto special media. Blood should be sent to laboratories familiar with the culture of these fastidious organisms, and the laboratories should be contacted for specific instructions regarding specimen collection and submission. Special media (such as fresh chocolate agar, or brain-heart infusion agar enriched with 5% to 10% blood) and culture conditions (5% CO_2, temperatures of 35°C to 37°C) are used to enhance the likelihood of isolation of *Bartonella*.[62] Extended incubation times of up to 6 to 8 weeks are often required. Serial *Bartonella* blood cultures may enhance the chance of a positive result. The use of an insect growth medium (*Bartonella* Alpha Proteobacteria Growth Medium, or BAPGM) that is enriched with multiple micronutrients and defibrinated sheep blood for pre-enrichment culture of blood and potentially other tissues, followed by PCR assay of the liquid culture and subinoculation of the liquid culture onto agar plates, may enhance the sensitivity of culture for

diagnosis of *Bartonella* infections of dogs. It also has the potential to yield other fastidious organisms not cultured under routine conditions that may play a role in endocarditis.[70]

Molecular Diagnosis Using the Polymerase Chain Reaction

A variety of PCR-based assays have been developed for rapid detection of *Bartonella* DNA in blood or other tissues. Some veterinary diagnostic laboratories offer real-time PCR assays for detection of *Bartonella* species as a component of vector-borne PCR panels. Some assays detect all species of *Bartonella*, whereas others are species-specific. Genetic analysis of the resultant PCR products can also be performed to identify the infecting species. The clinical performance of many of these assays when compared with culture has not been well studied. When used directly on blood specimens, PCR assays may be no more sensitive than culture for detection of *Bartonella*, and detection of DNA does not always equate to detection of living organisms. False-positive PCR assay results due to laboratory contamination have the potential to occur.

Serologic Diagnosis

Immunofluorescent antibody (IFA), ELISA, and Western immunoblot assays are available for detection of antibodies to *Bartonella* species. Some degree of cross-reactivity occurs among *Bartonella* species, but multiple species-specific assays still should be performed to increase the chance of antibody detection. Paired titers are not valuable because disease typically results from chronic and persistent infection. If serologic testing is performed in dogs, at a minimum it should include testing for *B. henselae, B. v. berkhoffii, B. rochalimae,* and *B. clarridgeiae.* Measurement of serum antibodies to *Bartonella* has a limited ability to help determine whether a sick animal has an active *Bartonella* infection. In both cats and dogs, bacteremia can occur in the absence of detectable antibodies (see Figure 52-2), and seropositive cats and dogs are not always bacteremic. Fewer than half of antibody-positive cats are bacteremic, and 3% to 15% of antibody-negative cats are bacteremic.[67] Because of this, serology is not recommended for routine diagnosis of *Bartonella* infection in cats. Because of the low sensitivity of PCR and culture in dogs, serology could be considered when these assays and routine blood cultures are negative (or in conjunction with PCR and culture) to support a diagnosis of *Bartonella* endocarditis (which is usually associated with high antibody titers).

Pathologic Findings

Gross necropsy of dogs and cats with *Bartonella* endocarditis may reveal evidence of congestive heart failure, with lung congestion and edema. Single or multiple, variably sized nodules are typically present on the periphery of valvular leaflets, which may be small and firm or large, granular, and friable (Figure 52-6). White plaques may be found adherent to the adjacent endocardial surfaces. Histopathology reveals chronic inflammation, with fibrous tissue and extensive mineral deposits. The presence of valvular mineralization should raise suspicion for *Bartonella* endocarditis, because mineralization is uncommonly associated with endocarditis caused by other bacteria.[61] Small bacilli may be seen within lesions with silver stains or immunohistochemical stains for *B. henselae*.[26,27,60] Silver stains must be interpreted with caution, because necrotic debris and nuclear material can mimic positive staining. Gross lesions in the dog with peliosis hepatis consisted of multiple, 0.1- to 0.3-cm cysts in the liver that were filled with cloudy, serosanguineous fluid.[54] The cysts were lined with endothelial cells, and there was evidence of telangiectasia

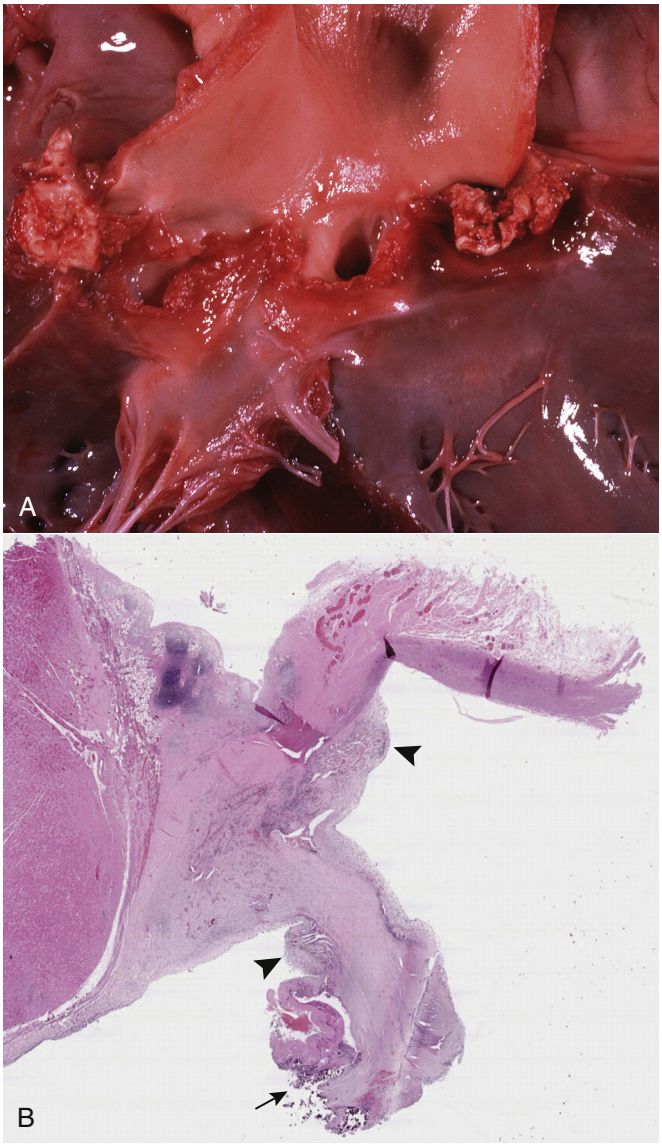

FIGURE 52-6 Gross pathologic findings (A) and histopathology (B) of the aortic valve from a dog with *Bartonella* endocarditis. **A,** The periphery of the valve is eroded. Variably sized, mineralized nodules expand the valve leaflet. There are multifocal, slightly raised, dull white plaques on the surface of the adjacent aorta and ventricular endocardium. **B,** Aortic valve, aorta, and ventricular septum. The distal leaflet is fragmented and contains mineral deposits *(arrow)* and hemorrhage. At the base of the valve, the endothelial surface is lifted and there are broad bands of loose connective tissue, small vessels, and endothelial-lined clefts *(arrowheads)*. H&E stain. Bar = 180 µm. (Reprinted from Pesavento PA, Chomel BB, Kasten RW, et al. Pathology of *Bartonella* endocarditis in six dogs. Vet Pathol 2005;3:370-373.)

scattered through other parts of the liver. Nodular granulomatous or pyogranulomatous lesions in lymphoid or other tissues (such as the liver, lymph nodes, and nasal cavity) have also been described in dogs with bartonellosis,[47,51,71] and nodular pyogranulomatous inflammatory lesions with intralesional bacteria were described in the myocardium and diaphragm of cats with *Bartonella* myocarditis and diaphragmatic myositis.[27]

Treatment and Prognosis

Efficacy has not been established for any antimicrobial that could be used to eliminate *Bartonella* bacteremia in cats or dogs. In humans, doxycycline, erythromycin, and rifampin are the most

VetBooks.ir

TABLE 52-5

Medications That Could Be Used to treat *Bartonella* spp. Infections in Sick Dogs and Cats Suspected to have Bartonellosis

Drug	Dose (mg/kg)	Route	Interval (hours)
Ampicillin sodium	10-20	IV	6-8
Gentamicin sulfate*	9-14 (dogs), 5-8 (cats)	IV, IM, SC	24
Amoxicillin-clavulanate	12.5-25	PO	8
Doxycycline	10	PO	12
Rifampin†	5	PO	12
Azithromycin	5-10	PO	24
Marbofloxacin	2.75-5.5	PO	24
Enrofloxacin‡	5 (cats), 5-20 (dogs)	PO	24

*Use in combination with ampicillin for initial treatment of endocarditis; other aminoglycosides could be substituted for gentamicin (such as amikacin). Monitor renal values during treatment.
†Use in combination with doxycycline; avoid monotherapy with rifampin because of the potential for rapid selection for resistant bacteria. May cause gastrointestinal adverse effects.
‡Other fluoroquinolones are preferred in cats due to the higher risk of retinal toxicity with enrofloxacin. Doses of 5 mg/kg q24h should never be exceeded in cats.

frequently recommended antimicrobials for treatment of *Bartonella* infection, but clinical improvement has been reported after the use of penicillin, gentamicin, ceftriaxone, ciprofloxacin, or azithromycin. Treatment for 2 weeks is recommended for immunocompetent patients (e.g., for CSD), and for a minimum of 6 weeks in immunocompromised humans. Relapses in bacteremia, fever, or other disease manifestations have been reported in immunocompromised humans, despite a 6-week treatment regimen.

The prognosis for *Bartonella* endocarditis in dogs and cats is generally poor. Supportive care and medications such as furosemide to manage congestive heart failure are often required. A combination of a β-lactam and an aminoglycoside or doxycycline is recommended for treatment of *Bartonella* endocarditis in human patients, and valve replacement is usually indicated (see Chapter 86).[72] Oral antimicrobial alternatives for dogs that are stable include high-dose doxycycline, alone or in combination with rifampin; azithromycin; or fluoroquinolones, alone or in combination with amoxicillin (Table 52-5). Resistance of *B. henselae* to azithromycin and fluoroquinolones has been documented.[73] Data from experimentally or naturally infected cats indicate that a high dose of doxycycline may be necessary to eliminate *Bartonella* infection in cats. Amoxicillin–clavulanic acid may also be an appropriate choice for treatment of infected cats when a definitive diagnosis is not known. If there is no response after 7 days, a change to a fluoroquinolone or azithromycin could be considered.[67] Extreme care should be taken to avoid scratches or bites when administering drugs to bacteremic cats.

Immunity and Vaccination

There are no vaccines for prevention of bartonellosis in cats or dogs. *Bartonella* evades the host immune system and establishes a persistent intracellular infection. Dogs and cats can be coinfected with multiple different *Bartonella* species and genotypes. Vaccination and challenge with the same or different *Bartonella* species results in variable protection, and protection is generally species specific.[74-76]

FIGURE 52-7 A crop of cutaneous bacillary angiomatosis lesions on the elbow of an AIDS patient. All lesions involuted with doxycycline treatment. (From Slater LN, Welch DF. *Bartonella*, including cat-scratch disease. In: Mandell GL, Bennett JE, Dolin R, eds. Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases, 7 ed. Philadelphia, PA: Churchill Livingstone Elsevier; 2010:2995-3009.)

Prevention

Prevention of *Bartonella* infections in cats and dogs is best accomplished by avoiding exposure to arthropod vectors. Flea control measures, such as use of ectoparasiticides, can interrupt transmission of *B. henselae* among cats and should be maintained year-round.[67,77] Housing cats indoors may also reduce exposure to fleas. *B. henselae* and *B. clarridgeiae* have been transmitted through inoculation of infected cat blood; therefore, cats of unknown *Bartonella* status or cats that are positive by culture, serology, and/or PCR for *Bartonella* should be excluded as blood donor cats.

Public Health Aspects

Cats are the major reservoirs for *B. henselae*, the principal cause of CSD in immunocompetent humans. CSD is characterized by formation of a pustule at the site of inoculation (a cat scratch) within 14 days, followed by development of local lymphadenopathy and malaise 1 to 3 weeks after the scratch (or bite), which can persist for weeks to months. Most cases of CSD are self-limiting after several months and respond minimally to antimicrobial drug treatment. Occasionally CSD is complicated by other disorders such as encephalopathy, relapsing bacteremia, osteomyelitis, neuroretinitis, or endocarditis, which require

antimicrobial drug treatment. Vasculoproliferative diseases such as bacillary peliosis (e.g., peliosis hepatis) and bacillary angiomatosis (Figure 52-7) are among the most common complications in immunocompromised humans.[20] Young cats are most often implicated in transmission to humans, because young cats are more likely to be bacteremic than older cats. Dogs are less likely to act as reservoirs for human disease when compared with cats, because the prevalence of *Bartonella* infection and the magnitude of bacteremia in dogs are lower than that in cats. Nevertheless, dogs have occasionally been implicated in transmission of *Bartonella* to humans through bite wounds or scratches, and to date, all *Bartonella* species identified in sick dogs are also pathogenic or potentially pathogenic in humans. Immunocompromised humans should preferably choose adult, well-socialized cats over kittens as pets and should be properly educated in regard to the need for flea prevention. Cats' claws should be trimmed regularly, but there is no evidence that declawing prevents transmission. Animal scratches or bites should be avoided, and if they occur, they should be washed thoroughly with soap and water, after which prompt medical attention should be sought. The Guidelines for Preventing Opportunistic Infections among HIV-Infected Persons (United States Public Health Service and Infectious Diseases Society of America) state "No evidence indicates any benefits to cats or their owners from routine culture or serologic testing of the pet for *Bartonella* infection."[78] There is also no antimicrobial drug treatment that reliably eliminates bacteremia from cats, and administration of antimicrobial drugs to cats may result in unnecessary bites, scratches, and contact with cat saliva. Pros and cons for the testing of healthy cats for *Bartonella* infection are shown in Box 52-2.[67]

Bartonella has the potential to be transmitted to veterinarians as a result of scratches or bite wounds as well as needlestick injuries.[79,80] Because of the high prevalence of *Bartonella* bacteremia in stray and young cats, veterinarians should take care to avoid these injuries (consider use of sedation whenever possible if necessary), thoroughly wash wounds that occur, and seek medical attention early if necessary. Gloves should be worn if skin contact with animal blood or saliva is anticipated.

Although cats and dogs are important reservoirs of *Bartonella*, humans can also develop bartonellosis through other routes of transmission, such as via other arthropods and possibly through blood transfusions.[81] Human body lice primarily transmit *B. quintana* among humans (especially the homeless), which causes relapsing fever (trench fever) and endocarditis.

BOX 52-2

Advantages and Disadvantages of Routine Testing of Healthy Cats for *Bartonella* spp. Infection

Advantages

Cats with positive *Bartonella* test results can be eliminated as blood donors or breeding animals

Cats with negative *Bartonella* test results (serology *and* culture or PCR) may be safer pets than cats that test positive

Testing cats for *Bartonella* spp. may allow veterinarians to avoid claims or litigation

Disadvantages

Bartonella serology and PCR can be falsely positive

Some cats with positive serologic test results may have eliminated infection and be immune to reinfection

Cats with negative test results may still be bacteremic, or become bacteremic within the near future

Detection of positive *Bartonella* spp. test results in some situations may lead to needless euthanasia

A focus on testing may lead to underappreciation of the need for other relevant health care such as flea control

There is no treatment that reliably eliminates bacteremia in healthy cats, and antimicrobial drug treatment of cats has not been shown to prevent human infection

Treatment of positive cats may increase the risk of human infection due to an increased risk of bites and scratches

Treatment of positive cats may lead to unnecessary life-threatening adverse drug reactions such as esophageal strictures (doxycycline) or blindness (fluoroquinolones); it also selects for antimicrobial-resistant bacteria

CASE EXAMPLE

Signalment: "Pesto," a 16-month-old female spayed domestic medium hair cat from Rio Vista in northern California

History: Pesto was evaluated at the University of California, Davis, Veterinary Medical Teaching Hospital for progressive lethargy over the previous month. Since obtained as a kitten, she had shown intermittent signs of upper respiratory tract disease, characterized by sneezing, serous to mucopurulent nasal and ocular discharges, inappetence, blepharospasm, tachypnea, and a cough, for which she had been treated with amoxicillin or doxycycline on at least three separate occasions. Between episodes she appeared healthy, but she had always been thin. There had been no vomiting, diarrhea, or changes in thirst or urination. Pesto was obtained as a stray kitten, tested negative for FeLV and FIV, and had been housed indoors ever since. She was neutered at 8 months of age without complication. Five months earlier, she traveled briefly to Oregon with the owner. She lived with a dog and a retrovirus-negative kitten that was introduced 5 months ago. One other sibling had died of FIP, which was confirmed on necropsy. Pesto was up to date on vaccinations for respiratory viruses, panleukopenia virus, and rabies. She was not receiving any medications.

Physical Examination:

Body Weight: 2.9 kg.

General: Quiet, alert, responsive, and hydrated. T = 103°F (39.5°C), HR = 240 beats/min, RR = 40 breaths/minute, moist and pink mucous membranes, CRT <2 s.

Integument: No ectoparasites were noted. The haircoat was full and lustrous.

Eyes, Ears, Nose, and Throat: In the left eye, mild conjunctivitis with moderate serous ocular discharge was

Continued

present. Mild corneal opacity was present in the right eye. No abnormalities detected on examination of the oral cavity. There was no evidence of nasal discharge or abnormal nasal airflow.

Musculoskeletal: Body condition score 4.5/9, ambulatory, adequate muscle mass.

All Other Systems: No clinically significant abnormalities were detected. A full neurologic examination was not performed.

Ophthalmologic Examination: Pesto behaved as if visual and was relatively comfortable with mild blepharospasm. The menace response, palpebral reflexes, and pupillary light reflexes were normal. There was no evidence of eyelid abnormalities or episcleral or conjunctival injection. Mild chemosis was present bilaterally. There was no aqueous flare, the lenses were normal, and a fundic examination was normal. The dorsal third of the right cornea had superficial vessels that extended from the limbus and a 2- to 3-mm central area where ghost vessels were present, which may have represented a previous dendritic ulcer. A rose Bengal stain was negative for ulceration.

Laboratory Findings:

CBC:

HCT 31% (30%-50%)
MCV 37.8 fL (42-53 fL)
MCHC 34.2 g/dL (30-33.5 g/dL)
Reticulocytes 29,000 cells/µL (7000-60,000 cells/µL)
WBC 7030 cells/µL (4500-14,000 cells/µL)
Neutrophils 4570 cells/µL (2000-9000 cells/µL)
Lymphocytes 2179 cells/µL (1000-7000 cells/µL)
Monocytes 141 cells/µL (50-600 cells/µL)
Eosinophils 70 cells/µL (150-1100 cells/µL)
Basophils 70 cells/µL (0-50 cells/µL)
Platelets clumped but adequate. A few Dohle bodies were seen within neutrophils.

Serum Chemistry Profile:

Sodium 146 mmol/L (151-158 mmol/L)
Potassium 4.5 mmol/L (3.6-4.9 mmol/L)
Chloride 110 mmol/L (117-126 mmol/L)
Bicarbonate 18 mmol/L (15-21 mmol/L)
Phosphorus 5.1 mg/dL (3.2-6.3 mg/dL)
Calcium 9.8 mg/dL (9.0-10.9 mg/dl)
BUN 20 mg/dL (18-33 mg/dL)
Creatinine 1.0 mg/dL (1.1-2.2 mg/dL)
Glucose 119 mg/dL (63-118 mg/dL)
Total protein 12.0 g/dL (6.6-8.4 g/dL)
Albumin 2.4 g/dL (2.2-4.6 g/dL)
Globulin 9.6 g/dL (2.8-5.4 g/dL)
ALT 42 U/L (27-101 U/L)
AST 25 U/L (17-58 U/L)
ALP 8 U/L (14-71 U/L)
GGT 9 U/L (0-4 U/L)
Cholesterol 134 mg/dL (89-258 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.2 mg/dL).

Serum Protein Electrophoresis: Results were consistent with a polyclonal gammopathy.

Imaging Findings:

Thoracic Radiographs: No clinically significant abnormalities were noted.

Abdominal Ultrasound: Lymph nodes were moderately enlarged throughout the abdomen, including the gastric, splenic, and jejunal nodes. Hepatic and sublumbar nodes were enlarged to a lesser degree. The echotexture of the enlarged nodes was homogeneous. The left adrenal gland was moderately enlarged, measuring 0.66 cm in thickness. The right adrenal gland could not be differentiated from multiple enlarged nodes. No free fluid was identified.

Microbiologic Testing: In-clinic FeLV antigen and FIV antibody ELISA assay: Negative.

Feline coronavirus serum antibody IFA assay: Positive at 1:25,600.

Treatment: Pesto was treated with L-lysine (500 mg PO q12h), for possible FHV-1 infection, and doxycycline (10 mg/kg PO q24h, immediately followed by a bolus of water), for possible chlamydiosis or mycoplasmosis. The owner could not administer the L-lysine, only the doxycycline, and reported improvement in Pesto's activity level and appetite several days after starting the doxycycline.

Additional Diagnostics and Outcome: Pesto was evaluated again 2 weeks later for possible lymph node aspiration or biopsy under sedation. Abdominal ultrasound showed persistent abdominal lymphadenomegaly. Cytologic examination of an ultrasound-guided aspirate of a mesenteric lymph node revealed mild to moderate lymphoid reactivity. Plasma cells were increased in number and were admixed throughout the specimen with rare mast cells and eosinophils. Low numbers of vacuolated macrophages and nondegenerate neutrophils were also observed. RT-PCR for feline coronavirus RNA on the lymph node aspirate was negative. IFA serology for antibodies to *B. clarridgeiae* was negative, whereas serology for antibodies to *B. henselae* was positive at 1:64. *B. henselae* was cultured from the blood. Treatment was changed from doxycycline to azithromycin, and again there was mild improvement in Pesto's attitude. However, several days later the cat became lethargic again, and her appetite decreased further. After 3 weeks of treatment with azithromycin, Pesto was reexamined. Because of the cat's fractious temperament, sedation was required. No abnormalities were detected on physical examination. A CBC showed a hematocrit of 23%, MCV of 39.2 fL, MCHC of 32.6 g/dL, reticulocyte count of 23,200 cells/µL, 8220 slightly toxic neutrophils/µL, 788 band neutrophils/µL, 1239 lymphocytes/µL, 788 eosinophils/µL, and 298,000 platelets/µL. A biochemistry panel showed similar abnormalities to those previously present (mild hyponatremia, hypochloremia, and hyperglycemia and low creatinine), and the globulin had increased to 12.4 mg/dL, with a total protein of 14.4 mg/dL. IFA serology and culture for *Bartonella* were repeated and showed a titer of 1:1024 to *B. clarridgeiae* and 1:4096 to *B. henselae*; *Bartonella* spp. culture was negative. An ultrasound-guided biopsy of an enlarged mesenteric lymph node was obtained. Histopathology showed a mixed, dense inflammatory infiltrate composed of neutrophils, lymphocytes, and plasma cells. Some of the macrophages present stained positive using immunohistochemistry for feline coronavirus antigen. Treatment with prednisone (1 mg/kg PO q12h for 5 days, then 1 mg/kg PO q24h thereafter) was initiated. Four days later, the cat became anorectic and tachypneic and was euthanized. A necropsy was not performed.

VetBooks.ir

Diagnosis: Feline infectious peritonitis and concurrent *B. henselae* bacteremia

Comments: *Bartonella* infection in this cat was initially suspected because of fever and lymphadenopathy, and infection with *B. henselae* was confirmed with *Bartonella* culture. Ultimately, an alternate diagnosis (FIP) was made based on the presence of the combination of marked hyperglobulinemia, a very high feline coronavirus titer, and histopathology of a mesenteric lymph node and IHC for coronavirus antigen. There was also minimal response to antimicrobial drugs with activity against *Bartonella*. Thus, the *Bartonella* bacteremia was an incidental finding. *Bartonella* bacteremia was detected in the face of doxycycline treatment, which highlights the fact that antimicrobial drug treatment does not always clear bacteremia. The cat was fractious and the owner could not effectively administer the L-lysine twice daily, but assured the veterinarian that Pesto had received the doxycycline. The owner may have been exposed to *Bartonella* during treatment. Treatment with azithromycin was followed by a single negative culture, but antibody titers increased, so the *Bartonella* infection may have been relatively recent.

CHAPTER 53

Canine Brucellosis

Autumn P. Davidson and Jane E. Sykes

VetBooks.ir

Overview of Brucellosis in Dogs

First Described: *B. canis* was first isolated from dogs by Leland Carmichael in 1966 (USA)[1]

Causes: *Brucella canis*; rarely *Brucella suis, Brucella melitensis,* or *Brucella abortus*

Geographic Distribution: Worldwide, but infections are most often reported from the southwestern United States, Central and South America, China, and Japan

Major Clinical Signs: No signs or infertility, abortion, nonpainful scrotal enlargement and dermatitis, testicular atrophy, lymphadenopathy, splenomegaly, signs related to discospondylitis (spinal pain, pelvic limb paresis, or paralysis), uveitis, chorioretinitis, rarely osteomyelitis and meningoencephalitis.

Major Mode of Transmission: Direct exposure to contaminated body fluids (oral, nasal, conjunctival, venereal)

Differential Diagnoses: Bartonellosis, mycobacterial infections, chronic vector-borne diseases associated with splenomegaly such as ehrlichiosis and babesiosis, coxiellosis, other bacterial and fungal causes of discospondylitis, intervertebral disc disease, hemic neoplasia (such as lymphoma or multiple myeloma). Additional differential diagnoses for dogs with ophthalmitis include deep mycoses, rickettsial diseases, leptospirosis, and toxoplasmosis.

Human Health Significance: *B. canis* can be transmitted to humans and most often causes mild, influenza-like illness.

Etiology and Epidemiology

Canine brucellosis is caused by *Brucella canis*, a small, gram-negative, non–spore-forming aerobic coccobacillus. *Brucella abortus*, *Brucella melitensis*, and *Brucella suis* occasionally cause canine infections but are comparatively rare.[2,3] *B. canis* infections are zoonotic, but other species of *Brucella* present a greater risk to human health.[4,5]

Brucellosis is the primary contagious infectious venereal disease of concern in canine reproduction. *Brucella canis* causes reproductive failure in both male and female dogs. Screening for *B. canis* infection is an important part of the pre-breeding evaluation of any dog and should be included in the initial diagnostics in any case of canine abortion, orchitis, epididymitis, and apparent infertility in bitches or dogs. Because the incidence of canine brucellosis is low in many geographic locations, breeder compliance with regular screening can wane, which makes continued veterinarian vigilance important. Notably, neutered and maiden or virgin dogs can also be infected. *B. canis* can also cause systemic disease (such as discospondylitis) in dogs not used for reproduction. Dogs with *B. canis* discospondylitis are typically medium- to large-breed dogs, with body weights that range from 14 to 64 kg; dogs have ranged in age from 1 to 8 years, with a median of 4 years in one study.[6-9] Of 22 dogs with *B. canis* discospondylitis known to the authors, 18 (82%) were intact male dogs, 3 (14%) were female spayed, and 1 (4%) were male neutered.[6,8-10] Three dogs described in the literature with *B. canis* ophthalmitis did not fit this signalment; one dog was a Pomeranian and none were intact males.[11]

Transmission of *B. canis* occurs through direct exposure to body fluids that contain sufficient numbers of bacteria to cause infection (2×10^6 CFU), most often semen, lochia, aborted fetuses/placentas, milk, and/or urine. Transmission is therefore primarily oral, nasal, or conjunctival and secondarily venereal (i.e., through the mucous membranes). Oronasal and conjunctival exposure follows the ingestion or aerosolization of infectious materials. The aerosol route is especially important in crowded kennel conditions. Transplacental transmission and direct cutaneous inoculation can also occur. Although fomite-associated transmission can occur under appropriate circumstances, *B. canis* is short-lived outside the host and is readily inactivated by common disinfectants, such as quaternary ammonium compounds, 1% sodium hypochlorite, 70% ethanol, iodine/alcohol solutions, and glutaraldehyde.[12]

Members of the Canidae family are the natural hosts of *B. canis*. Canine brucellosis occurs most commonly as outbreaks in large commercial kennels, and less commonly in privately owned dogs. Although the geographic distribution of canine brucellosis is not fully understood, outbreaks of canine brucellosis have geographic orientation, with increased incidence seen in the southernmost United States and commonly in Mexico, Central and South America, the People's Republic of China, and Japan. There are sporadic reports of disease in Canada and throughout Europe.[7,13-17] Australia and New Zealand appear to be free of the disease. However, because infection with *B. canis* is chronic and subclinical, the organism can readily be imported into regions where the prevalence of disease is low through the movement of infected dogs. The increased practice and success of canine semen processing for exportation (chilling and cryopreservation) for the purpose of artificial insemination now makes canine brucellosis a concern worldwide, as direct mucosal contact among dogs is no longer necessary for transmission.

Clinical Features

Signs and Their Pathogenesis

Brucella organisms attach to and penetrate mucous membranes; the severity of disease is proportional to the infectious dose. After

FIGURE 53-1 Midterm abortion from a *Brucella canis* affected bitch diagnosed by AGID. Note the variation in fetal development indicating that death occurred at different stages. (Courtesy Patricia Olson, DVM, PhD, DACT.)

FIGURE 53-2 *Brucella* discospondylitis at the T7-T8 junction with ventral spondylosis and collapse of the intervertebral disc space. (Courtesy Anna Park, DVM, and James Lavely, DVM, DACVIM [Neurology].)

replication in regional lymph nodes, bacteremia occurs within 7 to 30 days after exposure with subsequent dissemination to reticuloendothelial cells, the prostate, uterus, and placenta. *B. canis* has a predilection for steroid-dependent (reproductive) tissues. The organism survives facultatively within monocytes and macrophages of the reticuloendothelial system. *Brucella* organisms can survive and multiply in reticuloendothelial cells because they inhibit the bactericidal myeloperoxidase-peroxide-halide system through the release of 5′-guanosine and adenine. Early in infection, polymorphonuclear cells and macrophages kill intracellular *B. canis* relatively ineffectually.[18]

Brucella organisms can be found in the rough endoplasmic reticulum of placental trophoblastic giant cells in an infected bitch's gravid uterus. Severe necrotizing placentitis with infarction of the labyrinth region, coagulation necrosis of the chorionic villi, and necrotizing arteritis result in fetal death. The organism can be found in the gastric contents of aborted fetuses. Necrotizing vasculitis and granulomatous inflammation results in epididymal and subsequent testicular and prostatic pathology.[3,19]

Brucellosis in dogs is associated with a high morbidity but low mortality. The clinical systemic signs are often subtle and include suboptimal athletic performance, lumbar pain, lameness, weight loss, and lethargy. The primary clinical sign of canine brucellosis in the breeding bitch is pregnancy loss, which can occur early (day 20) in gestation resulting in fetal resorption, or more commonly (75% of dogs) later in gestation (generally 4 to 59 days), which results in abortion (Figure 53-1). Bitches with pregnancy loss early in gestation can appear to be infertile (fail to conceive) unless early ultrasonographic pregnancy evaluation is performed to identify pregnancy. Nongravid bitches can show no signs or can show regional lymphadenopathy (pharyngeal if orally acquired, inguinal and pelvic if venereally acquired).

The primary acute clinical signs of canine brucellosis in the male dog involve the portions of the reproductive tract that participate in the maturation, transport, and storage of spermatozoa. Epididymitis is common, with associated orchitis and scrotal dermatitis, and resultant deterioration of semen quality and fertility. Chronically, testicular atrophy and infertility can occur. The organism can be found in the prostate gland and urethra and is shed intermittently in the urine. Anti-sperm antibodies develop in association with brucellosis-induced epididymal granulomas and further contribute to infertility. Pyospermia develops 3 to 4 months postinfection. Chronic infections in either sex can result in uveitis or endophthalmitis, lymphadenitis, splenomegaly, or discospondylitis; occasionally, dermatitis and meningoencephalitis have been reported (Figure 53-2).[3,8,11,20] Owners of dogs with discospondylitis most often describe episodic neck pain or lameness, which can occasionally be accompanied by lethargy or decreased activity. Bacteremia can persist for years, and subclinically infected dogs can remain infectious for long intervals. Infection of the bone that surrounded a total hip replacement was described in two dogs 9 and 12 months after surgery.[21]

Large numbers of organisms are shed in the vulvar discharge of bitches 4 to 6 weeks postabortion. The highest concentration of organisms is shed in the semen of infected dogs 2 to 3 months postinfection, with lesser amounts for years. Urine can serve as a contaminated vehicle because of the proximity of the urinary and genital tracts in the dog, with shedding present for months to years, and is more prevalent in males. Organisms can also be shed in milk.[22-24]

Spontaneous apparent recovery can occur 1 to 5 years postinfection, but true clearance of the organism is difficult to document. Bitches that have been treated with antimicrobial drugs can produce normal litters after multiple abortions, but can remain infectious to their offspring. Dogs may remain infertile because of irreparable damage to the spermatogenic apparatus.[3,23]

Physical Examination Findings

For dogs with clinical *B. canis* infections, fever is rarely present. Affected male dogs may have an enlarged but nonpainful scrotum and secondary scrotal pyoderma, which results from excessive licking. Enlargement of the epididymis is often present. Some chronically infected male dogs have small, soft testicles due to testicular atrophy. Other dogs have generalized peripheral lymphadenomegaly, and splenomegaly may be detected on abdominal palpation. The most common finding in dogs with discospondylitis is spinal pain.[8,9] Other findings

TABLE 53-1

Diagnostic Assays Available for *Brucella* Infection in Dogs

Assay	Specimen Type	Target	Performance
Culture	Whole blood, urine, disc aspirates or bone fragments, tissue specimens obtained at necropsy (e.g., spleen, uterus, prostate), aborted fetuses and placental tissue, seminal fluid	*Brucella* spp.	Confirms infection but is insensitive. Antibiotic treatment can lead to false-negative results.
Histopathology with organism detection using IHC	Tissue specimens obtained by biopsy or at necropsy	*Brucella* spp. organisms	IHC may have low sensitivity depending on the tissue examined, but supports disease causation when positive and properly performed and interpreted.
Serology, rapid slide agglutination test (RSAT), and mercaptoethanol RSAT	Serum	Antibodies to *Brucella* spp.	Rapid and inexpensive. False positives are common as a result of cross-reactivity with other bacterial species and require confirmation with an alternative test. Positive results do not imply active infection. False-negative results with RSAT can occur in dogs with discospondylitis. The sensitivity of the RSAT may be higher than that of the ME-RSAT.
Serology, tube agglutination test	Serum	Antibodies to *Brucella* spp.	See RSAT. Usually positive by 2 weeks after infection. Titers ≥ 1:200 tend to correlate with bacteremia.
Serology, agar gel immunodiffusion	Serum	Antibodies to *Brucella* spp.	See RSAT. Requires special expertise and is time-consuming to perform. May not be positive until 12 weeks after infection. Cytoplasmic antigen assays are more specific for *Brucella* spp. antigens.
Serology, indirect immunofluorescent antibody (IFA)	Serum	Antibodies to *Brucella* spp.	See RSAT. Requires expertise to perform and interpret. May have lower specificity and sensitivity when compared with ELISA assays or the tube agglutination test.
Serology, ELISA	Serum	Antibodies to *Brucella* spp.	Has the potential to be sensitive and specific, but assays vary in performance. A standard, accepted assay is not currently available.
PCR	Whole blood, splenic or lymph node aspirates, disc aspirates, tissue specimens obtained at necropsy, vaginal swabs, seminal fluid, urine, placental materials, or fetuses	*Brucella* spp. DNA	Confirms active infection and has the potential to be more sensitive than culture. Sensitivity and specificity may vary depending on assay design, specimen type, and quality assurance practices in the laboratory. Results should be interpreted with caution and in light of the clinical picture and the results of serologic tests and/or culture.

IHC, immunohistochemistry.

include lameness, delayed placing reactions, ataxia, pelvic limb hyperreflexia, and, uncommonly, pelvic limb paresis or tetraparesis. Meningoencephalitis may result in behavioral changes, anisocoria, ataxia, circling, or a head tilt. For unknown reasons, ocular abnormalities are often unilateral and include blepharospasm, conjunctival hyperemia, and evidence of uveitis, such as aqueous flare, miosis, iris hyperpigmentation, loss of the normal contour of the iris surface, hypopyon, posterior synechiae, and secondary glaucoma.[11] Corneal edema, vitreous opacities, swelling and hyperemia of the optic disc, and evidence of multifocal granulomatous chorioretinitis have also been described. Ocular abnormalities and discospondylitis are frequently present in the absence of other systemic signs of illness. However, some, but not all dogs with discospondylitis have other, subtle physical examination abnormalities that suggest brucellosis, such as dermatitis, uveitis, small testicles, or lymphadenopathy.[8]

Diagnosis

The diagnosis of canine brucellosis is based on suggestive clinical signs and the results of serology; culture of blood, urine, or tissues; histopathology; and/or PCR assays. Because no single antemortem test has 100% sensitivity, and serologic assays lack specificity, a combination of diagnostic assays is often required to make a diagnosis (Table 53-1). When multiple dogs with infertility problems are present in a household or kennel, as many dogs as possible should be tested with serology and blood culture to increase the chance of a reliable diagnosis.

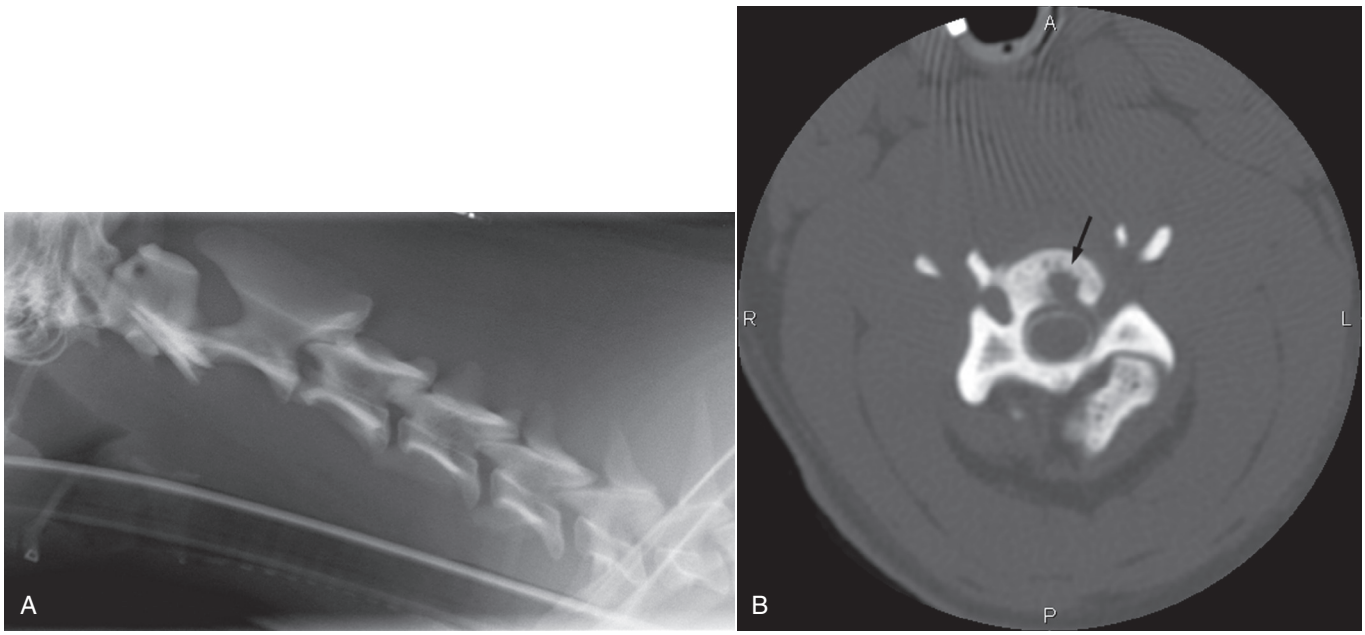

FIGURE 53-3 Radiographic images from a 1-year-old female spayed labradoodle with *Brucella canis* discospondylitis that was evaluated for cervical pain. CSF analysis revealed a CSF protein concentration of 31 g/dL, with 3 nucleated cells/μL, 89% of which were small mononuclear cells and 11% of which were large mononuclear cells (marginal lymphocytic pleocytosis). *Brucella canis* was isolated from 5 of 5 blood culture specimens. Urine culture was negative. Of significance, a *B. canis* rapid slide agglutination test was negative. The dog was treated successfully with antimicrobial drugs (doxycycline and clavulanic acid–amoxicillin) and lesions resolved radiographically. **A,** Plain lateral radiograph of the cervical spine. There is endplate lucency associated with cranial endplate of C3 at the C2-3 articulation. The C2-3 disc space appears narrowed. **B,** Computed tomography image. Central lysis of the end plates at C2-3 is present *(arrow),* compatible with discospondylitis at C2-3.

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

The results of routine laboratory tests are often within reference ranges in dogs with brucellosis. The CBC may show leukocytosis due to a neutrophilia.[11] Degenerate left shifts, monocytosis, and/or lymphopenia have been uncommonly reported.[9,20] The chemistry panel is often normal, but hyperglobulinemia and hypoalbuminemia may be present. A lack of abnormalities on routine laboratory testing or the presence of splenomegaly or abdominal lymphadenomegaly in dogs with discospondylitis should raise suspicion for *B. canis* infection. Urinalysis is generally within normal limits, even when *B. canis* bacteriuria is present.

Cytologic Analysis of Tissue Aspirates

Aspirates of the spleen or lymph nodes of dogs with brucellosis reveal lymphoid reactivity, sometimes with plasmacytosis. Prostatic aspirates in one dog with prostatitis showed granulomatous inflammation with intracellular gram-negative coccobacilli.[7]

Cytologic Analysis of Body Fluids

CSF analysis in dogs with *Brucella* discospondylitis is usually unremarkable. A dog with meningoencephalitis had neutrophilic pleocytosis and increased CSF protein concentration.[3] Aspirates of ocular fluids (aqueous or vitreous humor) from a dog with panophthalmitis revealed pyogranulomatous inflammation with extracellular and intracellular small gram-negative cocci.[11]

Semen Examination

Diminished sperm counts (oligospermia), poor motility (asthenospermia), and increased morphologic abnormalities (teratospermia) are characteristic of semen in dogs infected with *Brucella*. Detached sperm heads, proximal and distal cytoplasmic droplets, and acrosomal deformities are the most common morphologic abnormalities. Sperm head-to-head agglutination suggests the presence of anti-sperm antibodies. An absence of sperm in the ejaculate (azoospermia) can also be found.

Diagnostic Imaging

Plain Radiography and Advanced Imaging

Plain radiography may show evidence of either multifocal or focal discospondylitis (see Figure 53-2; Figure 53-3, *A*). Advanced imaging (CT or MRI) may be more sensitive than plain radiographs for detection of endplate lucency (see Figure 53-3, *B*; see also Chapter 85).

Sonographic Findings

Abdominal ultrasound examination of dogs with brucellosis may show no abnormalities, or abdominal lymphadenomegaly and splenomegaly may be present. Ultrasound of the prostate may reveal prostatic irregularity, hyperechogenicity, and cavitation.[7]

Microbiologic Tests

Serologic Diagnosis

There are two reasons to perform serologic tests for brucellosis in dogs: (1) as part of a routine screening program in breeding kennels, whereby healthy dogs are screened for infection, and (2) for diagnosis of active infection in sick dogs that are suspected to have brucellosis because of infertility, reproductive losses, epididymitis, discospondylitis, osteomyelitis, or ophthalmitis.

Assays used for screening purposes are usually rapid and inexpensive, but can suffer from low specificity (a high rate of false-positive test results) due to strong cross-reactivity between

VetBooks.ir

surface lipopolysaccharide (LPS) antigens of *B. canis* and those of other nonpathogenic infectious agents. Up to 50% to 60% of dogs can have false-positive test results because of cross-reacting antibodies to microorganisms such as *Bordetella, Pseudomonas, Escherichia coli,* and *Moraxella* spp. Even when the antibodies detected truly represent anti-*Brucella* antibodies, the presence of these antibodies does not indicate active infection with *Brucella* because dogs can remain seropositive for months after they clear the infection. Antibodies to *Brucella* do not become detectable until 2 to 12 weeks after infection, so a window of time exists in which an infected dog eludes serologic diagnosis with any assay used. False negatives also occasionally occur in dogs with chronic sequestered infections. Beyond the first 3 months of infection, the sensitivity of screening assays is generally believed to be high, but in some scenarios it might be lower than previously thought.[25] Examples of screening assays include the rapid slide agglutination test (RSAT); the semiquantitative 2-mercaptoethanol modified RSAT (ME-RSAT); the semiquantitative tube agglutination test (TAT); agar gel immunodiffusion (AGID) assays; and indirect IFA or ELISA assays. Veterinarians need to understand the limitations of the assays available to them through local veterinary diagnostic laboratories. The RSAT uses *Brucella ovis* as the antigen, whereas the ME-RSAT uses *B. canis* antigen, which may improve specificity. However, in one study, the sensitivity of the ME-RSAT was only 32%, when compared with 71% for the RSAT, so the RSAT may be preferable for screening.[25] In the TAT, a titer of more than 1:200 correlates well with positive blood cultures, but lower titers are more difficult to interpret. The performance of AGID assays requires trained laboratory personnel and special media. Two types of AGID assay are available: an assay that uses cell wall antigens as the substrate (cell wall AGID assay) and an assay that uses cytoplasmic antigens of *Brucella* as the substrate (cytoplasmic AGID assay). The cell wall assay has from the same low specificity as other assays that detect antibodies to *Brucella* LPS, and the sensitivity may be lower than that of the RSAT.[25] In contrast, the cytoplasmic assay is specific for antibodies to *Brucella*, so, when available, it is a useful confirmatory assay for dogs that test positive with other rapid serologic assays. Indirect IFA has lower sensitivity than many other serologic assays. A number of ELISA assays have been developed to overcome difficulties that relate to the low specificity of serologic assays for *B. canis* and the limited availability of other assays. The performance of these ELISA assays has varied, but sensitive and specific ELISA assays have been developed that may prove useful for rapid serologic testing in the future.[26]

In practice, for screening purposes, healthy bitches are tested at least 1 month before a planned breeding or introduction to a breeding kennel with a serologic assay of low specificity such as the RSAT because these assays are rapid, readily available, and inexpensive. Healthy, fertile stud dogs should be tested annually with the RSAT. If the test result is negative, in cases of subfertility or if recent exposure is suspected, a second test is performed a month later, to assess for seroconversion (which would be expected if the dog was early in the course of infection when first tested). If the test result is positive, a confirmatory assay should be performed. This could include the TAT or a more specific assay, such as the cytoplasmic AGID assay, a specific ELISA assay, blood culture, or a reliable PCR assay, although blood culture can lack sensitivity.[13,15] Usually the assay(s) selected is based on test availability and financial resources of the owner. Positive serologic test results for dogs with discospondylitis or other disease manifestations suggestive of brucellosis should be confirmed using culture or a reliable PCR assay whenever possible. Although false-negative serologic test results are uncommon in dogs with discospondylitis, negative serologic test results in dogs with discospondylitis do not rule out infection with *Brucella* spp., and attempts should also be made to detect the organism with culture or PCR assays. Of various dogs with *B. canis* discospondylitis or ophthalmitis, 15 of 18 were positive with the RSAT, 16 of 16 were positive with the TAT, and 6 of 7 were positive with AGID assays.[6,8-11] The 3 dogs that were negative with the RSAT had discospondylitis. One was positive by blood culture, and the other 2 dogs tested positive with the TAT at a later date.[8,10]

Isolation and Identification

Despite improvements in serologic diagnostic methods, confirmatory blood cultures are still indicated when brucellosis is suspected. *B. canis* is readily isolated from the blood of bacteremic individuals for several months after infection. Specimens for blood culture should be collected as detailed in Chapter 3. A positive *B. canis* culture has been advocated as the best diagnostic test in the first 2 months of the disease; however, dogs can become abacteremic 27 to 64 months after infection but remain infected. Occasionally *B. canis* can be isolated from urine, tissue specimens such as aborted fetuses or placental material, necropsy specimens (especially spleen, prostate, and uterus), vaginal swabs, or disc aspirates. Of dogs with *Brucella* discospondylitis or ophthalmitis, 6 of 15 dogs tested positive by blood culture, 3 of 13 by urine culture, and 4 of 6 by culture of disc material or bone chips from the intervertebral disc space obtained at surgery.[6,8-10]

B. canis is an aerobe, but unlike other *Brucella* species, added CO_2 (5% to 10%) can be inhibitory. Multiplication is slow at the optimum temperature of 37°C, and enriched medium (tryptose or trypticase soy media) is occasionally needed to support adequate growth. *Brucella* colonies become visible in 2 to 3 days. Growth of *Brucella* can be identified on the basis of rough (as opposed to smooth) colony morphology, staining characteristics, and slide agglutination with anti-*Brucella* serum. Identification to the species level is best done in a specialized laboratory. Differentiation between *B. canis* and *B. suis* can be difficult.[13] In the United States, the New York State Diagnostic Laboratory at Cornell University, the Tifton Veterinary Diagnostic and Investigational Laboratory in Georgia, and the University of Florida are recognized to be reliable for definitive testing made necessary by positive *B. canis* screening tests in dogs intended for breeding, or for clinically affected dogs undergoing evaluation for infertility or abortion, or when outbreaks are being managed.[3,27] Susceptibility testing can be performed, but in vitro test results may not correlate well to the in vivo treatment response.

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays have been used to successfully identify *B. canis* in semen from dogs with negative culture results, which suggests that this may ultimately be the most sensitive method of testing as part of the male dog pre-breeding evaluation, especially in cases where management of an outbreak is the concern.[28] PCR assays were also used to detect *B. canis* in the aqueous humor of dogs with endophthalmitis[11] and in lymph node aspirates.[29] Assays have been designed that differentiate between the *Brucella* species present.[30] A real-time PCR assay was used to detect *B. canis* in tissue specimens, urine, buffy coat, and intervertebral disc material

of a dog with discospondylitis when culture of intervertebral disc material, blood, and urine was negative.[7] Some veterinary diagnostic laboratories in the United States now offer real-time PCR assays for detection of *B. canis* on a commercial basis.

Pathologic Findings

The main pathologic findings of *B. canis* infections consist of lymphoplasmacytic to lymphohistiocytic follicular hyperplasia in lymphoid tissues, lymphohistiocytic to neutrophilic endophthalmitis, and mild lymphohistiocytic meningitis. Occasionally, mild lymphoid and histiocytic infiltrates are present in other tissues, such as the liver and lung.[15] A mixed lymphohistiocytic inflammatory response is also present in the uterus (endometritis) of females and the testicles, epididymis and spermatic cord, and prostate of male dogs. Prostatic and testicular fibrosis may be found. Placental trophoblasts can contain large numbers of gram-negative bacteria, and coagulative necrosis may be present. In male dogs, lesions are more likely to be restricted to the reproductive system. Immunohistochemistry has been used to confirm the presence of *Brucella* spp. in placental tissues.[13]

Treatment and Prognosis

In certain jurisdictions, brucellosis is a reportable disease in dogs or in humans. Infected dogs and bitches should be removed from breeding programs and quarantined. Eradication of the disease in kennel situations has not been successful without removal (culling) of all current or historically infected dogs. Because of the zoonotic potential of the disease and difficulty in eradicating the infection, euthanasia of affected dogs has been recommended. Infection in household or small hobby kennel dogs often results in client requests for alternatives to euthanasia. Neutering decreases the amount of organism shed in semen and uterine discharge, but does not eradicate infection. Urine shedding can persist, and the organism can be found in internal organs and the bloodstream.

Antibiotic therapy has historically not been rewarding, likely because the organism is intracellular and bacteremia is periodic. Antimicrobial drug treatment can reduce antibody titers without clearing infection. Relapses are common. Combination therapy should be used whenever possible, preferably with tetracyclines (high-dose doxycycline or minocycline) for at least 1 to 2 months and an aminoglycoside (streptomycin or gentamicin) for the first 1 to 2 weeks of treatment (Table 53-2). Some also advocate use of two 1-week courses of aminoglycoside treatment spaced 1 month apart, or treatment with streptomycin every other week for 8 weeks.[11] Combination therapy with tetracyclines and streptomycin is thought to be the most successful treatment, but unavailability of streptomycin, nephrotoxicity, parenteral therapy requirements, and expense may be problematic.[31-33] In addition, aminoglycosides do not provide adequate ocular or CNS penetration for dogs with ophthalmitis or meningitis. A combination of doxycycline and rifampin has been used to treat human brucellosis but may not be well tolerated by dogs because of gastrointestinal adverse effects. The use of three or four drugs in combination (e.g., streptomycin, enrofloxacin, doxycycline with or without rifampin) was efficacious for treatment of ophthalmitis in dogs.[11] Topical 1% prednisolone acetate and atropine ointment may be required for management of uveitis.[11]

One study reported a possible benefit of therapy with enrofloxacin (5 mg/kg q12h PO for 4 weeks, often for multiple courses) in a small group of infected dogs and bitches. Enrofloxacin did not completely eliminate *B. canis*, but it maintained fertility and avoided the recurrence of abortions, transmission of the disease to subsequently whelped puppies, and dissemination of microorganisms during parturition. Ultimately, however, most treated individuals remained culture positive.[34] Combinations of enrofloxacin and doxycycline may be a more effective alternative for dogs unable to tolerate aminoglycoside or rifampin treatment and for dogs that have ocular or CNS involvement, but studies are lacking.

TABLE 53-2

Medications That Could Be Used to Treat *Brucella* spp. Infections in Dogs

Drug	Dose (mg/kg)	Route	Interval (hours)
Doxycycline*	10-15	PO	12
Streptomycin	20	IM	24
Gentamicin sulfate	9-14	IV, IM, SC	24
Rifampin	5	PO	12
Enrofloxacin	5-10	PO	24

*Use in combination with one of the other drugs listed. Combinations of drugs are preferred for treatment where possible.

Vaccination and Immunity

Serum agglutinating antibodies do not protect against infection in the dog, and immunity likely depends on cell-mediated immunity. Presently, the development of a vaccine is considered undesirable because the *Brucella* vaccines evaluated have offered only moderate protection, and immunized dogs develop antibodies that confound serodiagnosis.

Prevention

Prevention of infection and elimination of infected dogs should be the principal control strategy in kennels. Prevention requires at least yearly testing of all breeding stock and the testing of all dogs to be introduced into a kennel. Ideally, two negative screening tests performed at least a month apart should occur before a dog or bitch is introduced into a breeding facility. *Confirmed* positive dogs should be isolated (euthanasia is advised by many authors), neutered, treated, and tested monthly (AGID, culture, or reliable PCR assay) until two consecutive negative tests occur, although occult infection can still be present.

Private breeders should require serologic screening of all bitches offered for breeding and confirmatory negative test results if positive results occur during screening before they accept a bitch into their kennel. Stud dogs should be screened at least annually. Because of the potential for nonvenereal transmission, screening of maiden dogs and bitches before breeding is also recommended.[35,36]

Public Health Aspects

Humans can become infected with *B. canis*, although they are relatively resistant to infection and other *Brucella* species account for the majority of human disease. Approximately 40

VetBooks.ir

cases of human infection have been reported worldwide; however, the actual number is unknown. Serologic assays used for diagnosis of brucellosis in humans often do not detect antibodies to *B. canis*, so the disease may be overlooked. Transmission to humans most commonly occurs through contact with an infected dog's semen, vulvar discharge from an infected bitch, or aborted fetuses or placentas, or through direct, accidental laboratory exposure.[8] Thus, disease is more likely to occur in people who are in contact with breeding dogs, but disease occasionally occurs in the owners of pet dogs with discospondylitis.[10] Immunocompromised humans, children, and those who are pregnant may be at greater risk for development of disease. Infection of humans with *B. canis* typically results in nonspecific, persistent clinical signs of fever, muscle aches, night sweats, and general malaise. Rarely, granulomatous hepatitis, hepatosplenomegaly, osteomyelitis, pulmonary disease, and endocarditis have been reported. In one case report, disease occurred in an HIV-infected dachshund dog breeder who reported infertility in one of the dogs, which had been tested by a veterinarian and was seropositive with a screening assay. Confirmatory testing with AGID performed at a university veterinary diagnostic laboratory yielded a negative result, so brucellosis was not thought to be present. However, subsequent blood culture of all of the dogs in the household was positive in one other dog.[37] Affected humans are typically treated successfully with combinations of doxycycline and either aminoglycosides (for the first week) or rifampin, but monotherapy has been associated with unacceptable rates of relapse.

Prevention of human disease involves eradication of the disease in dog kennels; precautions such as the wearing of gloves and protective clothing when in contact with aborted material; and hand washing after handling dogs and before eating. Although it is preferable that immunocompromised individuals do not participate in dog breeding activities, if necessary, these individuals should take special care if they interact with breeding dogs. Contact with dogs with reproductive problems or their secretions should be avoided whenever possible, and if aborted material must be handled, gloves, gowns, and face protection should be worn, all protective wear should be disposed of properly, and hands should be washed thoroughly.

CASE EXAMPLE

Signalment: "Sadie", a 6-year-old female spayed Border collie mix from northern California

History: Sadie was brought to her local veterinarian for listlessness and reluctance to jump noted during the previous 48 hours. She had been adopted from a local humane shelter as an ovariohysterectomized 11-month-old. She lived in a rural agricultural area in northern California and was the only dog in the household.

Physical Examination: Sadie's vital signs were within normal limits, mucous membrane color was pink, and she was quiet and alert on physical examination. Body weight was 25 kg. Mild dental tartar was evident. Thoracic auscultation and abdominal palpation were normal, pulses were synchronous, and no peripheral lymphadenomegaly was evident. Palpable dorsal thoracolumbar pain was demonstrated. She was reluctant to rise but was ambulatory. The neurologic examination including a fundoscopic examination was normal.

Laboratory Findings: A complete blood count, chemistry panel, and urinalysis were performed. Mild neutropenia (2958 cells/μL; reference range, 3000-11,500 cells/μL) was found, and the chemistries and urinalysis were normal with no proteinuria.

Imaging Findings: Radiographs of the spine revealed evidence of disc space collapse, spondylosis, and discospondylitis at the T7-T8 disc space (see Figure 53-2).

Microbiologic Testing: A SNAP 4DX test (IDEXX Laboratories) for antigen of *Dirofilaria immitis* and antibodies to *Ehrlichia canis*, *Anaplasma phagocytophilum*, and *Borrelia burgdorferi* was negative. Aerobic bacterial urine culture was negative. Serum was submitted for a *Brucella canis* IFA, which was positive at a titer of 1:200. A *B. canis* AGID was submitted and was also positive.

Treatment: Sadie was treated with tramadol (1-2 mg/kg PO q8h) and carprofen (3 mg/kg PO q12h). Once the serologic test results were available, a tentative diagnosis of *B. canis* discospondylitis was made, and she was treated with enrofloxacin (5.5 mg/kg PO q12h). Clinical improvement was reported in 2 weeks, and repeat radiographs were performed in 1 and 5 months. Equivocal change was reported in the appearance of T7-T8 at 1 month, but the 5-month radiograph showed no progression, suggesting the lesion was no longer active. The owners were advised of the zoonotic potential of this disease and the potential hazard of transmission to other dogs. The potential need for lifelong antibiotic therapy with risk of relapse was also discussed.

Comments: Dogs with *Brucella* discospondylitis frequently are brought to their veterinarian for clinical signs of spinal pain or lameness that resemble common musculoskeletal injuries such as intervertebral disc disease or rupture of the cranial cruciate ligament. Although not typical, this case illustrates the fact that *B. canis* disease can occur in female spayed, nonbreeding dogs and often occurs in the absence of fever or significant abnormalities on routine laboratory testing. A diagnosis of *Brucella* discospondylitis was strongly suspected based on positive serologic test results with multiple assays. Blood culture was not performed, but urine culture was negative. Monotherapy with fluoroquinolones has been associated with high rates of relapse in human patients once antimicrobial drug treatment has been discontinued, so it is generally not recommended. Nevertheless, it can occasionally be successful.

CHAPTER 54

Tetanus and Botulism

Jane E. Sykes

VetBooks.ir

Overview of Tetanus and Botulism

First Described: The etiology of tetanus was identified in the late 1800s in Germany (Nicolaier).[1] *C. botulinum* and its toxin were first described in Belgium in 1897 (van Ermengem).[2] Before that, descriptions of both diseases had been recorded; tetanus was described by Hippocrates more than 2000 years ago.

Causes: Toxins of *Clostridium botulinum* (botulism) or *Clostridium tetani* (tetanus)

Geographic Distribution: Worldwide

Major Mode of Transmission: Ingestion of preformed toxin (botulism) or cutaneous inoculation of spores into a wound (tetanus)

Major Clinical Signs: Spastic paralysis (tetanus) or flaccid paralysis (botulism)

Differential Diagnoses: Differential diagnoses for suspected botulism include polyradiculoneuritis, paralytic rabies, tick paralysis, coral snake poisoning, myasthenia gravis, and ionophore toxicity. For tetanus they include strychnine toxicosis, hypocalcemia, metaldehyde toxicity, and extraocular myositis

Human Health Significance: Botulism and tetanus are not directly transmissible from animals to humans, but care should be taken when handling specimens from animals with botulism.

Etiology and Epidemiology

Tetanus and botulism are neurologic diseases caused by the toxins of *Clostridium tetani* and *Clostridium botulinum* that occur worldwide. These organisms are gram-positive, sluggishly motile, anaerobic spore-forming bacilli. The spores of *C. tetani* and *C. botulinum* are extremely resistant in the environment and resist boiling and disinfection with alcohol or formalin.

Botulism

In dogs and especially cats, botulism is rare and usually follows ingestion of preformed neurotoxin within carrion, especially waterfowl or poultry carrion. Disease in dogs can coincide with outbreaks of botulism in waterfowl. Botulism outbreaks in dogs have been reported in hunting foxhounds.[3,4] Most affected dogs are medium- to large-breed, intact male or intact female dogs that vary in age. The only report of botulism in cats was an outbreak of disease that occurred after several cats were fed pelican carrion.[5] The relative resistance of dogs and cats to botulism has been hypothesized to reflect an adaptive response to a carnivorous lifestyle. *C. botulinum* produces seven related toxins: A, B, C, D, E, F, and G. Most human botulism is caused by types A, B, and E.[6] Botulism in dogs and cats almost always results from ingestion of toxin C,[3,5,7-9] with the exception of a few dogs in the Senegal that had type D intoxication.[10]

Tetanus

C. tetani is widespread in the soil and feces of animals. It produces two toxins, *tetanospasmin* and *tetanolysin*. Tetanolysin does not appear to have clinical significance. Humans and horses are most susceptible to tetanus, and so widespread vaccination against the disease is performed in these species. Disease occurs occasionally in dogs and is rare in cats. The development of tetanus in dogs and cats usually follows introduction of spores into a penetrating wound, but more than one third of affected dogs have no known wound history *(cryptogenic tetanus)*.[11] Traumatic wounds of the feet, claws, or head; draining tracts associated with grass awn migration; animal bite wounds; tick bite wounds; bleeding claw trim wounds; wounds that result from chronic protozoal or fungal infections of the skin; teething wounds in dogs; and surgical wounds (which include spay and neuter operations) have all been implicated.[11-14] Although dogs of any age, breed, or sex develop tetanus, disease occurs most often in young, large-breed, active, intact male dogs.[11,13,14] Disease is seen in puppies as young as 8 weeks of age; some studies describe a significant proportion of affected dogs as less than 1 year of age. Disease is also more severe in young dogs.[11] Cats are often young cats with outdoor access, but cats of any age have been affected.[15]

Clinical Features

Signs and Their Pathogenesis

The toxins of *C. tetani* and *C. botulinum* have similar structures and mechanisms of action, even though they cause diseases that contrast sharply with one another. Both toxins are among the most potent toxins known and act at femtomolar concentrations. They consist of two polypeptide chains, a heavy (H) chain and a light (L) chain, joined by a disulfide bond (Figure 54-1). The heavy chain attaches to presynaptic nerve terminal membrane receptors, although the precise receptors have not been identified because of the extremely low concentrations at which these toxins act. Variation in receptor binding affinities may explain differences in species susceptibility to clostridial neurotoxins. The toxin is then internalized via receptor-mediated endocytosis into the presynaptic nerve terminal, where it has a local impact on nerve cell function (botulinum toxin) and also travels by retrograde axonal transport to the nerve cell body

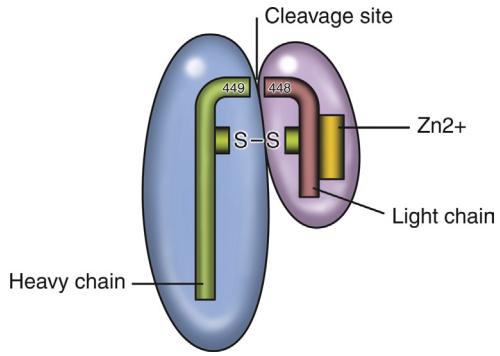

FIGURE 54-1 Schematic of the structure of *Clostridium tetani* and *Clostridium botulinum* toxins.

and diffuses into inhibitory interneurons, where it impacts inhibitory interneuron function (tetanospasmin). The L chain, a zinc-dependent matrix metalloproteinase, is released from the vesicle and subsequently cleaves one or more *docking proteins*. These proteins are critical for the release of neurotransmitters from synaptic vesicles into the synaptic cleft and are located on the membrane of synaptic vesicles *(synaptobrevin)* or the presynaptic cell membrane (*syntaxin* and *SNAP-25*). Synaptobrevin binds to the docking proteins located on the presynaptic membrane. The resulting complex (the SNARE complex) docks the synaptic vesicle at the proper location for fusion and exocytosis of neurotransmitter molecules into the synaptic space (Figure 54-2). Tetanospasmin cleaves synaptobrevin, whereas botulinum neurotoxin C cleaves syntaxin; other botulinum neurotoxins cleave synaptobrevin or SNAP-25. The process of recovery involves the sprouting of new presynaptic terminals, followed by recovery of the original synapse, after which new terminal outgrowths retract.[16]

Botulism

C. botulinum spores germinate in anaerobic conditions and produce toxin. They grow best in temperatures that range from 30°C to 37°C. The toxin is ingested, survives the acid stomach conditions, and is absorbed into the bloodstream from the small intestine. It then travels to peripheral cholinergic synapses, which include the neuromuscular junction and autonomic synapses, and inhibits release of acetylcholine (ACh). This leads to ascending symmetrical flaccid paralysis, development of megaesophagus, and signs of autonomic dysfunction. Clinical signs usually occur within 12 to 72 hours after ingestion of botulinum toxin and may be complicated by signs of dietary indiscretion, although gastrointestinal signs may also reflect the presence of autonomic dysfunction. Disease progresses rapidly over 1 or 2 days, and then begins to resolve with supportive care. Death can result from respiratory muscle paralysis or aspiration of intestinal contents. Abnormalities in affected cats were ascending flaccid paralysis, lethargy, hypothermia, tachypnea, dehydration, and urinary incontinence.[5]

Tetanus

C. tetani spores are introduced into tissues where they germinate, replicate locally, and produce toxin in anaerobic conditions. Ingestion is not a route of transmission, because tetanospasmin is destroyed by gastrointestinal secretions. The toxin is produced as a single polyprotein that is cleaved extracellularly by a bacterial protease into the L and H chains, which remain connected by the disulfide bond. It then binds to presynaptic terminals of lower motor neurons and is internalized, travels up axons by retrograde axonal flow, and enters inhibitory interneurons in the brain and spinal cord, where it interferes with release of γ-aminobutyric acid (GABA) and glycine inhibitory neurotransmitters (Figure 54-2, *B*). Toxin can also spread hematogenously to the central nervous system (CNS) from the wound site. The result is unhindered excitation of motor neurons, spastic paralysis, and dysfunction of the sympathetic and parasympathomimetic nervous systems. Clinical signs occur 3 days to 3 weeks after a wound in both cats or dogs. Shorter incubation periods occur when the wound is proximal to the CNS and when a large amount of toxin is present. Paralysis may initially be localized to the wound site but can then generalize. Involvement of the head is common in dogs, and often owners of dogs with tetanus first notice an unusual appearance to their dog's eyes, a "swollen" face, or evidence of dysphagia.[11] Regurgitation or vomiting of food occurs in less than 20% of affected dogs, and a voice change or dysuria may be noted. Death occurs in severely affected dogs due to paralysis of respiratory muscles; infectious complications such as pneumonia; upper airway obstruction; the development of severe hyperthermia with disseminated intravascular coagulation (DIC), multiple organ failure, and/or pulmonary thromboembolism; and cardiac arrhythmias.[11,13,14] Hiatal hernia and coxofemoral joint luxations have also been described as complications of tetanus in dogs.[11,14,17] Disease in cats is usually localized to the limbs, but generalized tetanus can occur.[15,18-21] Many affected cats have an initial history of disappearance for days to a week or more, after which lameness is noted.

Physical and Neurologic Examination Findings

Dogs and cats with botulism or tetanus are usually alert, afebrile, and in good body condition, but lethargy and anorexia occur in some animals. Hyperthermia can occur with severe tetanus.

Botulism

Physical examination findings in dogs with botulism depend on the severity of intoxication. Fever is absent unless aspiration pneumonia has developed. Mildly affected dogs show only ataxia or pelvic limb paresis, whereas dogs with severe intoxication are quadriplegic with absent voluntary motor activity and are unable to rise from lateral recumbency. The ability to wag the tail is often retained.[3,8,9] Neurologic examination can reveal decreased cranial nerve function, especially facial nerve function and a decreased gag reflex, sometimes accompanied by ptyalism.[3,7,9,22] A weak blink reflex can result in corneal ulceration. A mucopurulent ocular discharge may be present. Mydriasis with sluggish pupillary light reflexes has been described.[3,22] Segmental reflexes may be intact, decreased, or absent, but pain sensation is preserved. Occasionally tachycardia and tachypnea are present. Tachypnea may result from diaphragmatic muscle weakness or secondary aspiration pneumonia. Increased lung sounds may also be present on thoracic auscultation of dogs with secondary aspiration pneumonia. Physical examination findings in one affected cat consisted of hypothermia, lethargy, dehydration, quadriplegia, and decreased segmental reflexes.[5]

Tetanus

In dogs with tetanus, involvement of the head and generalized disease occurs more often than occurs in cats. A wound may or

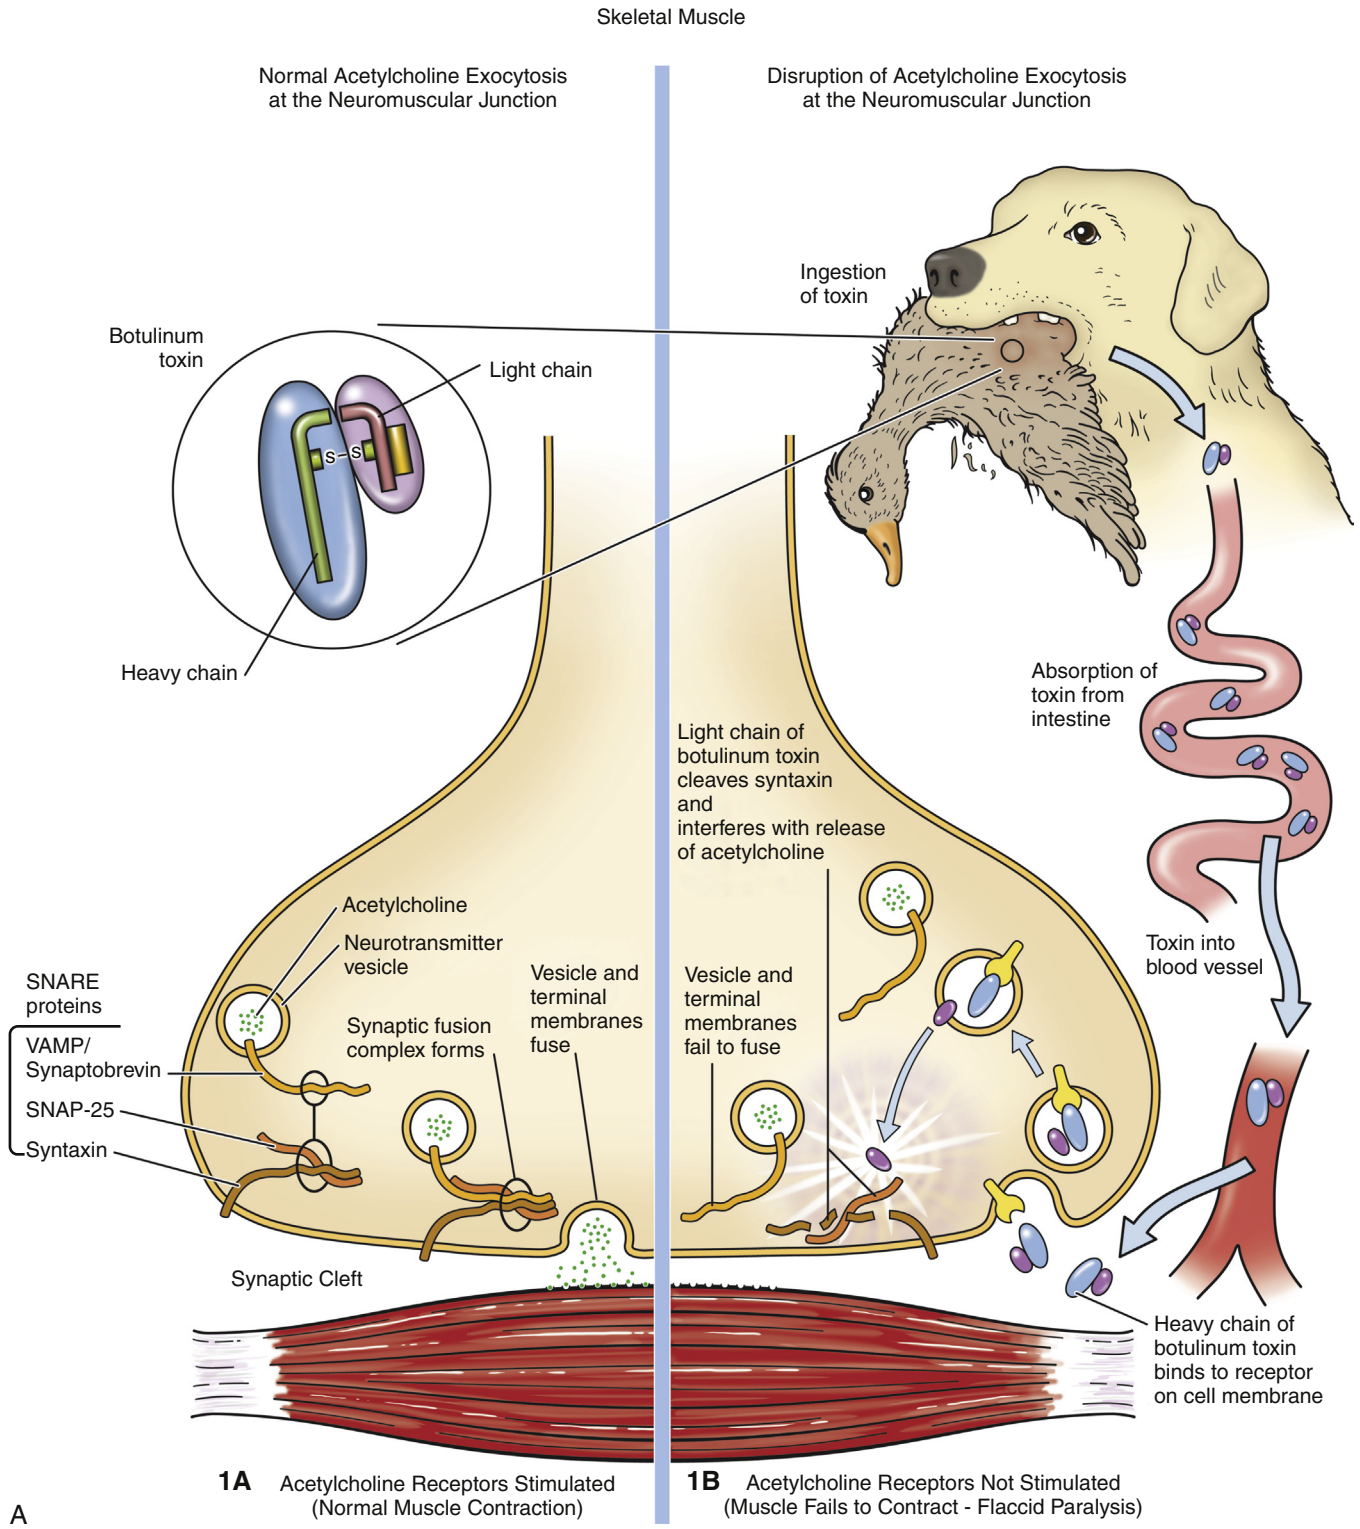

FIGURE 54-2 Action of clostridial neurotoxins. **A,** Botulism Toxin.

Continued

may not be found. Dogs with localized forelimb tetanus have caudal retraction of the limb with extension of both the elbow and carpus.[15] In dogs with generalized tetanus, a wrinkled forehead, erect ears, retracted lips *(risus sardonicus),* and prolapsed third eyelids are almost always present, usually in association with generalized muscle stiffness (see Figure 54-3, *A*). Miosis may be present. It may be difficult or impossible to open the mouth. Dogs that are ambulatory walk slowly with a stiff, stilted gait and can have a wide-based or "sawhorse" stance; voluntary movement of the head may occur slowly or appear difficult, and the tail may be erect. Laryngeal spasm and hypersalivation occur in approximately half of affected dogs.[13,14] Reflexes are exaggerated or difficult to elicit. Severely affected dogs are anxious and hypersensitive, develop opisthotonos, vocalize, tremble or

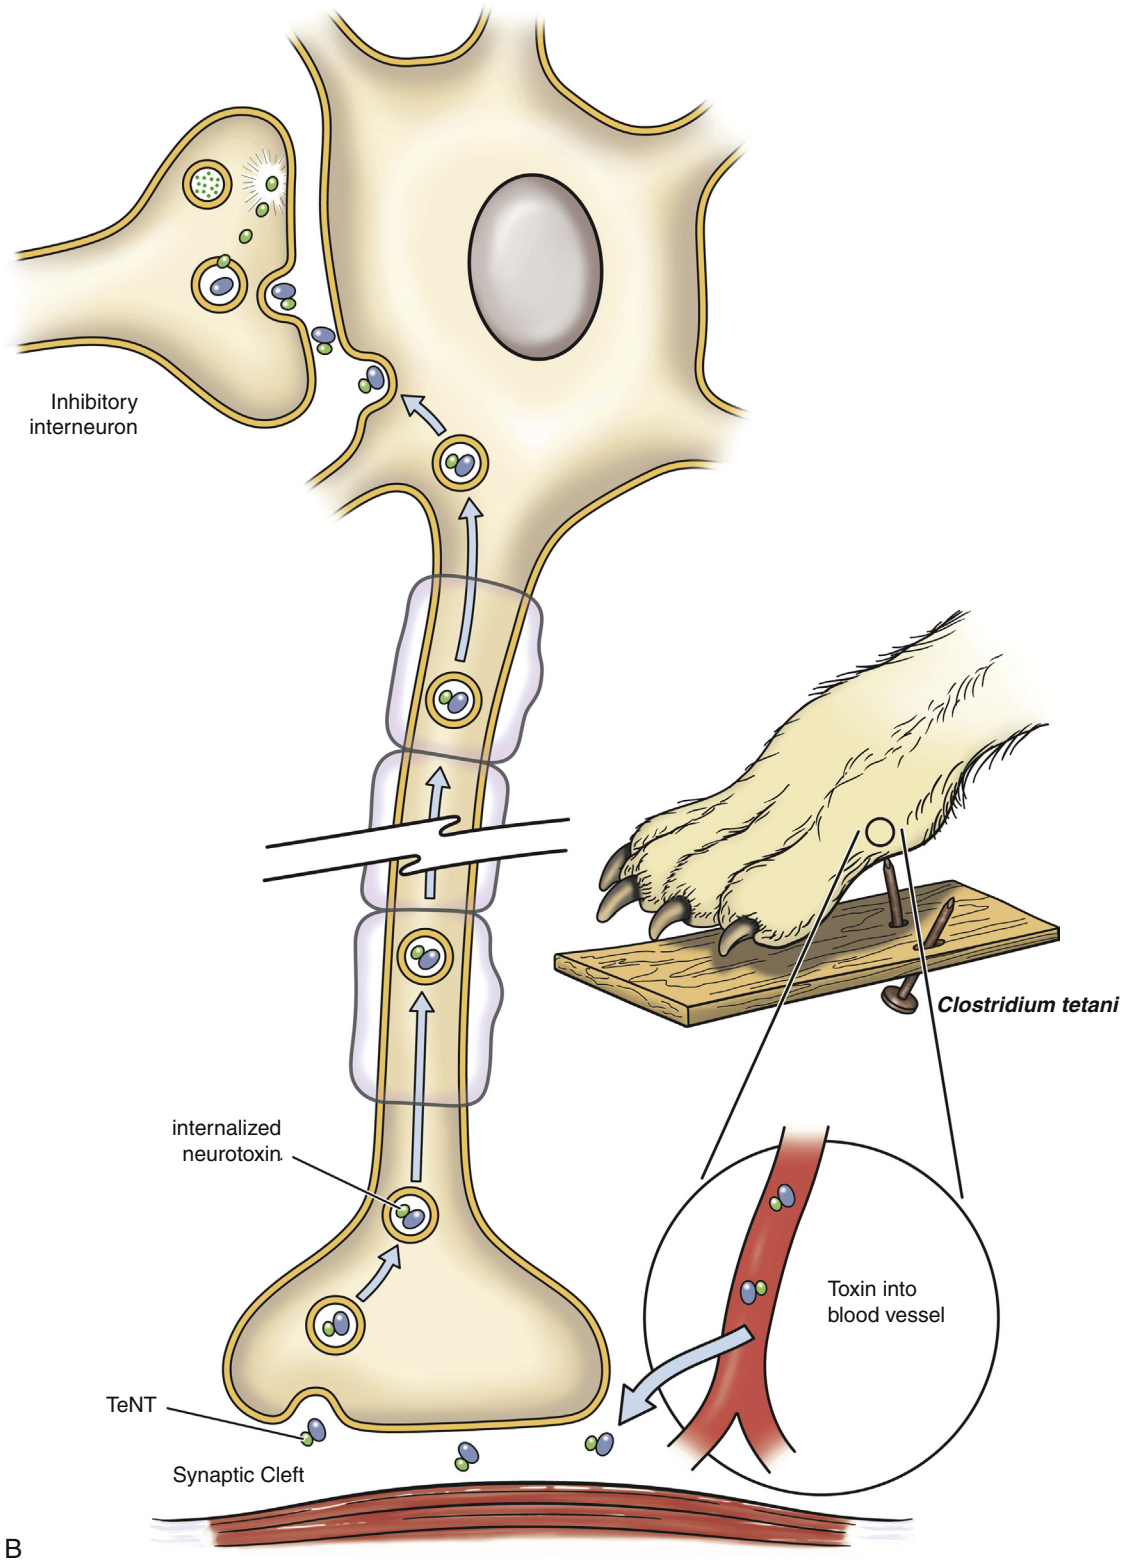

FIGURE 54-2, cont'd. **B,** Tetanospasmin.

even have a seizure when stimulated, and may be hyperthermic due to increased muscle activity (up to 111°F or 43.9°C).[11] A semicomatose state may even result. Abdominal palpation may reveal an enlarged bladder that is difficult to express, or palpation may not be possible because of abdominal muscle spasm. Hypoventilation may be present, or tetanic spasms may trigger episodes of dyspnea. At least a third of dogs are bradycardic or have bradyarrhythmias (which include atrioventricular block or sinus arrest), with heart rates that range from 40 to 60 beats/min; another third of dogs are tachycardic (>150 beats/min) or have variable heart rates, which may reflect autonomic dysfunction or pain.[11]

Cats with localized tetanus often have extensor rigidity of a single limb, on which a wound may be identified. When the forelimb is affected, spasm of the triceps muscle results in caudal extension of the limb with carpal flexion (in contrast to dogs) and elbow extension (Figure 54-3, *B*).[20,23,24] The head and neck may be deviated toward the affected limb.[15] When disease generalizes, the contralateral limb and subsequently all four limbs may be affected.[20] Affected cats may be reluctant to move or hyperesthetic. Lockjaw *(trismus)*, protrusion of the third eyelid, retracted lips *(risus sardonicus)*, wrinkling of the forehead, or opisthotonos can occur in cats with generalized tetanus. Segmental reflexes may be exaggerated, or it may not be possible to elicit reflexes because of severe muscle spasticity. Dyspnea, tachypnea, and open-mouth breathing may occur.[12] Cranial nerve responses are usually normal. Miosis may be present.

FIGURE 54-3 **A,** Image of a Weimaraner with generalized tetanus. The dog walked with a stiff gait and was salivating profusely. Risus sardonicus is evident. **B,** Three-year-old female domestic shorthair cat with localized tetanus that was seen for a 3-day history of right thoracic limb lameness. Extension of the shoulder and elbow and partial flexion of the carpal joint is present. (From Langner KFA, Schenk HC, Leithaeuser C, et al. Localised tetanus in a cat. Vet Rec 2011;169:126.)

Diagnosis

Diagnosis of tetanus and botulism in dogs and cats is most often based on a consistent history and clinical abnormalities, exclusion of the few other possible causes of disease (e.g., with assays for myasthenia gravis in dogs with botulism), and sometimes electrodiagnostic testing. The primary differential diagnoses for botulism are acute polyradiculoneuritis and myasthenia gravis; paralytic rabies should also be considered. There are few other disorders other than strychnine poisoning that truly mimic tetanus. Serologic assays have been used to detect an antibody response to botulinum toxins. Finally, specific assays that detect botulinum toxin in serum, gastrointestinal contents, or food can be performed (Table 54-1).

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Routine laboratory test results in animals with tetanus or botulism are often normal, but stress hyperglycemia, mild to severe increases in the activity of serum creatine kinase (usually <20,000 U/L but sometimes >200,000 U/L, reference range 46-320 U/L), mildly increased AST activity, and myoglobinuria may be present in animals with tetanus.[11,14] Dehydration may result in hemoconcentration or prerenal azotemia. Animals with wounds or aspiration pneumonia may have an inflammatory leukogram. Severe hyperthermia in dogs with tetanus may lead to laboratory evidence of multiple organ dysfunction, with moderate to severe hypoalbuminemia, azotemia, and/or increased liver enzyme activities and hyperbilirubinemia. Thrombocytopenia and coagulation test abnormalities consistent with DIC may also be present in these dogs.

CSF Analysis

CSF analysis in dogs and cats with botulism and tetanus typically shows no abnormalities.

TABLE 54-1

Laboratory Assays Available for Diagnosis of Botulism

Assay	Specimen Type	Target	Performance
Mouse inoculation bioassay	Feces, vomitus, intestinal contents, serum, foodstuffs	Botulinum toxin	Gold standard for diagnosis. False negatives can occur if toxin degradation occurs. Slow turnaround time means diagnosis is generally retrospective. Laborious and requires the use of laboratory animals.
ELISA toxin assays	Feces, vomitus, intestinal contents, serum, foodstuffs	Botulinum toxin	Rapid and inexpensive. Standard ELISA toxin assays have a lower sensitivity than the mouse inoculation assay.
ELISA assays that detect the antibody response to botulinum toxin	Serum	Anti–botulinum toxin antibodies	Negative antibody titers occur early in the course of disease, so acute and convalescent titers must be performed. Thus, diagnosis is retrospective.

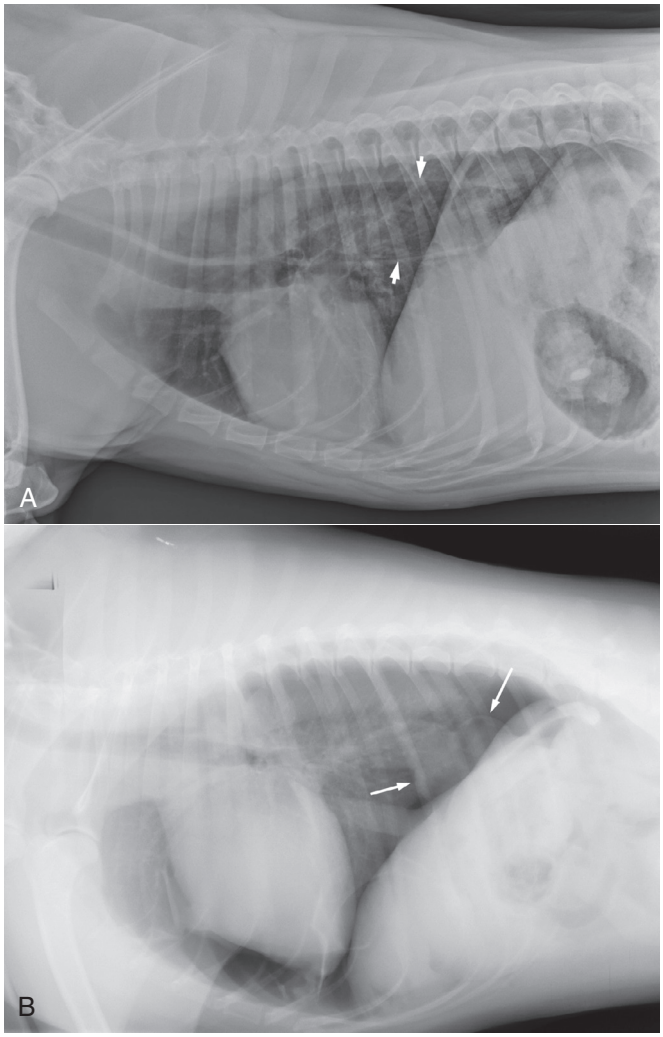

FIGURE 54-4 Radiographic findings in dogs with botulism (A) and tetanus (B). **A,** Lateral thoracic radiograph from a 6-year-old female spayed Labrador retriever with botulism. Megaesophagus is present. The *white arrows* delineate the dorsal and ventral esophageal wall. **B,** Lateral thoracic radiograph from a 3-year-old female spayed English springer spaniel with tetanus that was seen for vomiting, dysuria, respiratory distress, and a stiff gait. Pneumothorax and a hiatal hernia *(arrows)* can be appreciated. Before the radiographs were taken, an exploratory laparotomy had been performed because a foreign body was suspected. The pneumothorax developed postoperatively for reasons that were unclear. A foxtail wound was later found on the left distal pelvic limb between the digits. The dog was hospitalized for 19 days, during which time all radiographic abnormalities resolved.

Diagnostic Imaging

Thoracic radiographs in dogs with botulism may be unremarkable, or megaesophagus may be present (Figure 54-4, *A*). Evidence of carrion bones are occasionally present in the stomach. Changes consistent with aspiration pneumonia in dogs with botulism or tetanus may also be apparent.[11,22] Rarely, dogs with tetanus have evidence of a hiatal hernia on thoracic radiography, which appears as a soft tissue mass in the caudal thorax (see Figure 54-4, *B*). Abdominal ultrasound examination may be normal, or mild abdominal lymphadenopathy may be identified.

Electrodiagnostic Tests

Electromyography (EMG) and electroneurography can be useful to support a diagnosis of botulism in some dogs (Table 54-2). Sedation or anesthesia for electrophysiologic testing is generally not advisable in dogs with megaesophagus and aspiration pneumonia, although EMG can be performed without anesthesia.[3] Electroneurography studies involve electrical stimulation of one or more motor nerves and assessment of the resultant electrical activity in the innervated muscle. Electroneurography findings in dogs with botulism include normal F waves (late waves that disappear in acute polyradiculoneuritis) and decreased magnitude of the compound muscle action potential.[3,22,25] Repetitive nerve stimulation at low frequencies can result in decremental responses, but repetitive nerve stimulation at high frequencies in dogs with botulism has no effect on the muscle response.[22] In humans with botulism, an incremental response to repetitive nerve stimulation occurs at high frequencies.[26] Motor nerve conduction velocity (MNCV) is normal or decreased. On EMG, the primary finding is prolonged or increased insertional activity in botulism.[3,22] Fibrillation potentials and positive sharp waves have also been described.[3,25] Animals with tetanus have had normal EMGs and MNCVs as well as motor unit potentials and pathologic spontaneous muscle activity,[14,20,21,24] but electrodiagnostic testing is not specific for a diagnosis of tetanus and is usually not required.

Microbiologic Tests

Isolation and Identification

Attempts to culture *C. tetani* from wounds are not recommended because the presence of *C. tetani* in a wound does not necessarily imply toxin production. In addition, this is insensitive.[11,13]

Serologic Diagnosis

ELISA assays that detect the antibody response to botulinum neurotoxin are available and were used to confirm a diagnosis of botulism in one dog.[7] A convalescent specimen collected 3 weeks after the onset of illness was positive, but specimens collected at the time the dog was first evaluated and 10 days later were negative. Thus, the diagnosis is generally retrospective with this method because most dogs have recovered by the time seroconversion occurs. The antibody response to tetanospasmin is not significant.

Toxin Detection

Botulinum toxin can be detected in feces, vomitus, gastrointestinal contents collected at necropsy, carrion, or serum. Specimens should be held at 4°C, marked with a warning label, and shipped immediately to the laboratory. The most sensitive assay is a mouse inoculation assay, in which untreated mice and mice treated with serotype-specific antitoxin are inoculated with the specimen to determine if the antitoxin is protective.[27] However, several days are required to run this assay. Toxin type–specific ELISA assays are available for rapid detection of neurotoxin C, but standard ELISA assays lack sensitivity when compared with mouse inoculation. Research efforts have been focused on the development of a variety of novel, rapid, highly sensitive, and inexpensive diagnostic assays that detect minute quantities of botulinum toxins.[27]

Pathologic Findings

There are no specific gross or histopathologic findings associated with botulism or tetanus. Evidence of complications such as aspiration pneumonia, pulmonary thromboembolism, or DIC may be present in dogs with tetanus.

Treatment and Prognosis

Specific Treatment

There is no readily available specific treatment for botulism in dogs. In the United States, heptavalent equine antitoxin is

VetBooks.ir

TABLE 54-2

Pathophysiologic, Clinical, and Electrophysiologic Features of Botulism, Polyradiculoneuritis, and Myasthenia Gravis

	Botulism	Polyradiculoneuritis	Acquired Myasthenia Gravis
Pathophysiology	Inhibition of acetylcholine release by botulinum toxin	Inflammatory disorder of nerve roots	Antibody formation to acetylcholine receptors at the neuromuscular junction
Neurologic abnormalities	Decreased reflexes, progressive tetraparesis, respiratory compromise, autonomic signs, dysphonia, megaesophagus	Decreased reflexes, progressive tetraparesis, facial weakness, dysphonia, respiratory compromise, with or without hyperesthesia	Normal reflexes, muscle weakness and rapid fatigue, megaesophagus
EMG	Normal/subnormal	Abnormal	Normal
Electroneurography	Decreased CMAP amplitudes, normal F-waves, decremental response to repetitive nerve stimulation at low frequency (and incremental response at high frequency in humans)	Decreased CMAP amplitudes, absent F-waves, usually normal MNCV	Usually normal CMAP amplitudes, decremental response to repetitive nerve stimulation at low frequency

TABLE 54-3

Suggested Dosages of Medication for Specific Treatment of Tetanus

Drug	Dose	Route	Interval (hours)	Duration (days)
Metronidazole	15 mg/kg	IV, PO	12	10
Tetanus equine antitoxin	100-1000 units/kg 500 units	IV, IM* SC near wound site	NA NA	Once Once
Human tetanus immune globulin	500 units	IM near wound if found	IM	Once

NA, Not applicable.
*IV use is preferred. Administer 0.1 mL intradermally as a test dose before infusion. The full dose should then be given slowly over 10 minutes.

available from the Centers for Disease Control and Prevention for treatment of human botulism. However, its availability is tightly controlled, so it may be impossible to obtain for treatment of dogs or cats.[28] Tetanus antitoxin is more widely available and should be administered as a single dose IV (equine antitoxin) or IM (human antitoxin) after an initial intradermal test dose to evaluate for allergic reactions (Table 54-3). Dogs that react to the test dose should be premedicated with diphenhydramine and a low dose of dexamethasone. Adverse reactions to antitoxin include vomiting, retching, or tachypnea and may occur even in premedicated dogs.[11] Reduction in the rate of antitoxin administration or discontinuation of treatment leads to resolution of clinical signs. Administration of antitoxin does not reverse existing paralysis because it is unable to enter nerve terminals, but it may neutralize free toxin. A small amount of antitoxin can be administered locally if a wound is identified. The efficacy of tetanus antitoxin is controversial, and the optimal dose is not known. In one study, early IV administration of equine tetanus antitoxin did not influence disease progression or mortality as opposed to administration later in the course of disease.[11]

For animals with tetanus, treatment with antimicrobials that have activity against *C. tetani* is also recommended. This is not indicated for animals with botulism, because ingested toxin is preformed. Appropriate antimicrobials for treatment of tetanus include intravenous metronidazole or penicillin G. Metronidazole is preferred because of its improved penetration into purulent material and the fact that penicillin can antagonize GABA. Studies in human patients have also shown improved outcome with metronidazole as opposed to procaine penicillin.[29] Once antitoxin has been administered and spasms are controlled (see Supportive Care), wounds should also be debrided or flushed extensively with hydrogen peroxide solution. Earlier appropriate antimicrobial treatment and wound debridement may not influence progression or mortality.[11]

Supportive Care

For both tetanus and botulism, supportive care is an essential part of management. The extent of care required depends on the severity of illness. Intravenous fluids, soft bedding, frequent turning to prevent decubital ulcers, application of ocular lubricant to prevent corneal ulceration, bladder expression or urinary catheterization (ideally intermittent), enemas to relieve constipation, and nutritional support in the form of hand feeding, feeding tubes, or total parenteral nutrition may be required. Force feeding is not recommended because it is unlikely to satisfy caloric needs and can contribute to the development of aspiration pneumonia. Occasionally (<10% of affected dogs with tetanus), mechanical ventilation is required to support respiration.[11] For dogs with botulism, antimicrobial drugs should only be used if infection develops (e.g., bacterial pneumonia or urinary tract infection). Aminoglycosides should be avoided because they may contribute to neuromuscular blockade.

VetBooks.ir

Dogs or cats with generalized tetanus should be placed in a quiet, dimly lit environment away from excessive visual or auditory stimuli. Cotton balls can be used as earplugs. Sedatives and/or muscle relaxants such as acepromazine, diazepam, midazolam, or methocarbamol may be useful. Severely affected animals may require a constant-rate infusion of drugs such as pentobarbital, phenobarbital, or propofol. Barbiturates are no longer recommended for treatment of tetanus in humans; benzodiazepines are preferred. If human disease is severe, drugs that cause neuromuscular blockade such as vecuronium are used, but this necessitates mechanical ventilation.[30] Methocarbamol often appears ineffective and requires frequent administration.[11,13] Benzodiazepines are preferred to methocarbamol because they are GABA agonists and also provide some sedation. Successful control of muscle spasms relieves pain and hyperthermia. If used, opioids should be administered with caution because they may contribute to constipation or gastrointestinal adverse effects. The use of fans and cool fluids may also be beneficial for dogs with tetanus-induced heat stroke. Administration of atropine may be required for animals with bradyarrhythmias (HR <60 beats/min). Rarely, upper respiratory obstruction has necessitated tracheostomy,[14] or bradyarrhythmias have required temporary pacemaker placement.[11]

Prognosis

Provided complications do not occur, prognosis is generally good for animals with tetanus or botulism. The overall 28-day survival rate for dogs with tetanus in one study was around 80%,[11] whereas in another study of 20 dogs it was only 50%.[13] A classification system has been developed to assess the severity of tetanus in dogs for the purpose of prognostication (Table 54-4).[11] The survival rate for dogs that progressed to tetanus severity classes I or II was 100%, but it dropped to 60% for dogs that progressed to tetanus severity class III or IV.[11] However, at the time of initial evaluation, only 11% of 37 dogs were in classes III or IV, and dogs progressed to higher classes unpredictably, with 47% of the dogs categorized in class III or IV when the highest recorded class was assigned. Dogs with severe tetanus are more likely to develop complications such as aspiration pneumonia or multiple organ dysfunction than dogs with mild tetanus. In a few dogs that recover (<10% of dogs that develop tetanus), intermittent localized muscle spasm continues to occur for many months, which may be noticed by the owner during activities such as sleeping or eating.[11]

Immunity and Vaccination

Given the relative rarity of tetanus and botulism in dogs and cats, vaccination is not recommended for these species. Recurrent tetanus or botulism has been documented in human patients, so recovery from natural disease does not necessarily result in protection from future episodes of disease. Thus, preventative measures should be discussed with owners of pets that recover from tetanus or botulism.

Prevention

Prevention of botulism involves limiting access of cats and dogs to carrion and feeding heat-processed commercial diets that are unspoiled. Although botulinum toxin can be denatured through boiling, spores can survive this treatment. Thus, cooked food should not be allowed to stand for long periods before it is fed to pets. The spores of *C. botulinum* are inactivated by pressure-cooking foods.

For tetanus, control of (1) roaming, (2) exposure to plant awns, and (3) aggressive interactions with other animals may reduce the chance that wounds develop. If wounds are noticed, they should be cleaned promptly with soap and water. Surgical instruments should always be sterilized properly before use so that tetanus spores are inactivated, and needles should never be reused. Tetanus spores can be inactivated with iodine, glutaraldehyde, hydrogen peroxide, or autoclaving at 121°C and 15 psi for 15 minutes.

TABLE 54-4

Tetanus Severity Classification System for Dogs

Class	Clinical Signs
I	Absence of class II, III or IV signs *and* any or all of: • Miosis, enophthalmos, risus sardonicus, erect ears, or trismus • Hypersensitivity to noise, light or touch • Ambulatory
II	Absence of class III or IV signs *and* any or all of: • Dysphagia • Stiff gait, sawhorse stance, erect tail • Ambulatory
III	Class I or class II signs, absence of class IV signs, *and* any or all of: • Recumbency • Muscle fasciculations or spasms • Seizures
IV	Class I, II, or III signs *and* any or all of: • Bradycardia (HR ≤60 beats/min) or bradyarrhythmia • Sinus tachycardia (HR ≥140 beats/min) or tachyarrhythmia • Labile hypertension or hypotension (mean arterial blood pressure ≤60 mm Hg or ≥ 130 mmHg, or systolic arterial blood pressure ≤80 mm Hg or ≥150 mm Hg) • Periods of apnea or respiratory arrest

Modified from Burkitt JM, Sturges BK, Jandrey KE, et al. Risk factors associated with outcome in dogs with tetanus: 38 cases (1987-2005). J Am Vet Med Assoc 2007;230:76-83.

Public Health Aspects

Animals with botulism or tetanus cannot transmit these conditions directly to humans who handle them. Nevertheless, feces, tissues, or body fluids from animals with botulism should be handled with care and marked with warning labels before they are submitted to the laboratory because the toxin is so potent. The main risk that dogs with tetanus pose to humans is through bite wounds, which can occur when owners attempt to administer medications.

Three forms of botulism occur in people: infant botulism, wound botulism, and food botulism.[26] Infant botulism occurs as a result of local production of botulinum toxin within the intestinal tract by *C. botulinum* in the absence of the competing intestinal

VetBooks.ir

microflora that are normally found in adults. Wound botulism occurs almost exclusively as a result of injection of contaminated heroin into the skin by intravenous drug users. Botulinum toxin preparations are used to treat conditions such as strabismus, esophageal achalasia, cervical dystonia, axillary hyperhydrosis (excessive sweating), or blepharospasm. There are rare reports of iatrogenic botulism after such use.[31] Life-threatening iatrogenic botulism has also occurred after use of botulinum preparations that were unlicensed for cosmetic treatment of wrinkles.[32] Significant concerns have been raised about the possible use of botulinum toxin as an agent of bioterrorism. This has stimulated considerable research on the disease, which is otherwise very rare.

Tetanus in humans is rare in developed countries, because most children are immunized against the disease. When it occurs, it is most often in people older than 60 years of age because of waning immunity.[30] Worldwide, the vast majority of cases occur in neonates from sub-Saharan Africa because of lack of immunization.

CASE EXAMPLE

Signalment: "Jenny," a 6-year-old female spayed Labrador retriever from Winters in northern California

History: Jenny was brought to the University of California, Davis, veterinary emergency service early in the morning for a 2-hour history of inability to stand. Her owners awoke to find her in another room, unable to get up for her morning walk. She appeared anxious and was breathing with increased effort, but was still wagging her tail. She also did not want to eat breakfast. There had been no known history of travel, toxins, trauma, or tick exposure. Over the past 2 months, she had been treated with prednisone (1 mg/kg PO q24h for 5 days, followed by 0.74 mg/kg PO q24h thereafter) for allergic dermatitis. Three weeks before the onset of illness she was treated with a short course of cephalexin after an aural hematoma was repaired. Jenny had been regularly vaccinated with rabies, distemper, hepatitis, and parvovirus vaccines.

Physical Examination:

Body Weight: 27.2 kg

General: Bright, alert, responsive, and hydrated. Laterally recumbent and anxious. HR = 140 beats/min, T = 101°F, panting.

Integument, Eyes, Ears, Nose, and Throat: Sutures were present on the pinna of the right ear from the recent aural hematoma repair. Moderate dental calculus and gingivitis was present. There were no other abnormalities noted.

Musculoskeletal: BCS 5/9. The dog was unable to use the pelvic limbs to bear weight.

Cardiovascular, Respiratory, Gastrointestinal, Genitourinary, and Lymph Nodes: No clinically significant abnormalities were present.

Neurologic Examination:

Mentation: Appropriate, anxious.

Gait/Posture: The dog was nonambulatory, but voluntary movement was present in all four limbs. She was unable to stand and support weight, but could crawl and shuffle. She attempted to bear weight on her thoracic limbs and could maintain sternal recumbency. When supported to stand, the pelvic limbs collapsed and the thoracic limbs were minimally able to bear weight.

Cranial Nerves: Slightly reduced palpebral reflexes and gag reflex. Absent corneal reflexes. No other deficits were noted.

Postural Reactions: These were difficult to assess because of the dog's inability to stand, but appeared decreased.

Segmental Reflexes: Reduced muscle tone was present in the thoracic limbs. Triceps, patella, and gastrocnemius reflexes were decreased. Reduced thoracic limb withdrawal reflexes were noted, but pelvic limb withdrawal reflexes were intact. Panniculus and perineal reflexes were also intact. Pain perception remained intact.

Spinal Palpation: No apparent pain was present on palpation or cervical manipulation.

Neuroanatomic Location: Neuromuscular disease.

Laboratory Findings:

CBC:

HCT 41.0% (40%-55%)
MCV 69 fL (65-75 fL)
MCHC 36.6 g/dL (33-36 g/dL)
WBC 5800 cells/µL (6000-13,000 cells/µL)
Neutrophils 3671 cells/µL (3000-10,500 cells/µL)
Lymphocytes 1769 cells/µL (1000-4000 cells/µL)
Monocytes 197 cells/µL (150-1200 cells/µL)
Eosinophils 145 cells/µL (0-1500 cells/µL)
Platelets clumped but adequate (150,000-400,000 platelets/µL).

Serum Chemistry Profile:

Sodium 146 mmol/L (145-154 mmol/L)
Potassium 3.9 mmol/L (3.6-5.3 mmol/L)
Chloride 107 mmol/L (108-118 mmol/L)
Bicarbonate 21 mmol/L (16-26 mmol/L)
Phosphorus 2.3 mg/dL (3.0-6.2 mg/dL)
Calcium 11.4 mg/dL (9.7-11.5 mg/dl)
BUN 15 mg/dL (5-21 mg/dL)
Creatinine 0.9 mg/dL (0.3-1.2 mg/dL)
Glucose 105 mg/dL (64-123 mg/dL)
Total protein 7.1 g/dL (5.4-7.6 g/dL)
Albumin 4.2 g/dL (3.0-4.4 g/dL)
Globulin 2.9 g/dL (1.8-3.9 g/dL)
ALT 64 U/l (19-67 U/L)
AST 25 U/L (19-42 U/L)
ALP 129 U/L (21-170 U/L)
Creatine kinase 57 U/L (51-399 U/L)
GGT 4 U/L (0-6 U/L)
Cholesterol 204 mg/dL (135-361 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.025; pH 7.0, trace protein (SSA), 1+ bilirubin, no hemoprotein, glucose, ketones, WBC/HPF, RBC/HPF, bacteria or crystals in the sediment. Many lipid droplets were present.

VetBooks.ir

Imaging Findings:

Thoracic Radiographs: The cardiopulmonary structures were within normal limits. There were mineral opacities within the stomach. There was a small amount of gas in the midthoracic esophagus.

Abdominal Ultrasound Examination: Mild mesenteric lymphadenopathy was identified. No other abnormalities were present.

Neuromuscular Testing: Edrophonium response test for myasthenia gravis: negative

Treatment: Jenny was admitted to the intensive care unit and treated with supportive care that included IV fluids (lactated Ringer's solution with 20 mEq/L KCl at 75 mL/hr), soft bedding, intermittent manual bladder expression, physical therapy (massage and passive range-of-motion exercises), and frequent turning. Treatment with prednisone was discontinued. Respiratory function was monitored continuously by observation, serial examination, and serial venous pCO_2 measurements. After repeated inspections for ticks, fipronil was applied in case the signs resulted from tick paralysis. Serum was submitted for an acetylcholine receptor antibody titer, and feces were submitted for a botulinum toxin assay. Over the subsequent 12 to 18 hours, Jenny became anxious after she was fed canned food and began to retch and hypersalivate. Thoracic radiographs were repeated and showed megaesophagus (see Figure 54-4, *A*). Severe tachycardia also developed (HR = 210 beats/min). An ECG showed ventricular tachycardia followed by supraventricular tachycardia. Systolic blood pressure was 145 mm Hg. Acepromazine was administered (0.01 mg/kg IV once), after which her heart rate decreased to 90 beats/min, with a normal sinus rhythm. A second neurologic examination showed progression of disease with reduced cervical tone and an inability to hold up the head, tetraplegia with absence of all segmental reflexes, and a reduced tail wag. The owners were warned that mechanical ventilation may be needed should the disease progress. Over the course of the next day, dysphonia and a mild cough developed, and Jenny regurgitated several times. Gastrostomy or jejunostomy tube feeding or parenteral nutrition were offered to the owner, but were declined. Four days after admission, improvement in the triceps reflex was noted, and on day 5, some voluntary movement was noted in the pelvic and thoracic limbs. At that time Jenny was successfully fed meatballs of canned food by hand. She was kept in sternal recumbency for 30 minutes after eating to minimize further aspiration. On day 7, the acetylcholine receptor antibody and botulinum toxin assay results became available.

Serum acetylcholine receptor antibody titer: 0.05 nmol/L (reference range, <0.6 nmol/L)

Botulinum toxin C mouse bioassay (fecal specimen): Positive for type C botulinum toxin. An extract from the fecal specimen was lethal in the bioassay. The effects were eliminated by heating the extract at 80°C for 10 minutes, which indicated that the toxic effects were due to a heat-labile toxin. Mice were also protected from the effects by anti–type C botulinum antisera but not by anti–type A botulinum antisera.

Diagnosis: Botulism.

Outcome: On day 8 after hospitalization, thoracic radiographs showed resolution of megaesophagus and no evidence of pneumonia. By day 10, Jenny began to shuffle along the floor. All segmental reflexes had returned but remained reduced. The dog was discharged from the hospital with instructions for continuation of care in the home environment. By day 15, Jenny's owners reported that her normal bark had returned, and she could walk 20 steps and defecate and urinate unassisted. A month after discharge she was reexamined and no abnormalities were detected.

Comments: The main differential diagnoses considered for this dog were myasthenia gravis and botulism. Initially, polyradiculoneuritis was also considered, but the subsequent development of megaesophagus was not consistent with this disorder. Ultimately, a diagnosis of botulism was confirmed through assay of the stool for botulinum toxin. A history of carrion ingestion was not known, but the dog lived in a semirural area, and the presence of mineralized stomach contents suggested that it had occurred. Prednisone administration may have contributed to polyphagia and ingestion of carrion by this dog.

CHAPTER 55

Yersinia pestis (Plague) and Other Yersinioses

Jane E. Sykes and Bruno B. Chomel

VetBooks.ir

Overview of Plague

First Described: Descriptions of plague date back to around 1300 BC. The causative agent was isolated in 1894, in Hong Kong (Alexandre Yersin).[1]

Cause: *Yersinia pestis*, a gram-negative coccobacillus (family Enterobacteriaceae)

Affected Hosts: *Y. pestis* causes disease in rodents, rabbits, wild carnivores, domestic dogs and cats, and humans. Goats, deer, antelope, camelids, and nonhuman primates can also develop illness.

Geographic Distribution: Southwestern United States; foci also exist in Asia, Africa, and South America

Major Mode of Transmission: Flea-borne, via an enormous variety of rodent flea species; ingestion of infected rodents or rabbits by cats and dogs

Major Clinical Signs: Fever, lethargy, inappetence, lymphadenopathy, subcutaneous abscesses

Differential Diagnoses: Tularemia, cat bite abscesses, *Streptococcus* spp. infections, feline infectious peritonitis

Human Health Significance: A small percentage (10%) of human plague cases result from exposure to infected cats, through bites, scratches, or respiratory droplet inhalation from cats with pneumonic plague. Dogs and cats can also expose humans through the carriage of infected fleas into households (especially sleeping areas).

Etiology and Epidemiology

The genus *Yersinia* includes 11 different species, three of which are pathogenic in humans, cats, and dogs: *Yersinia pestis* and the enteropathogenic species *Yersinia pseudotuberculosis* and *Yersinia enterocolitica*. *Yersinia* spp. are nonmotile, gram-negative coccobacilli that belong to the family Enterobacteriaceae. Only *Y. pestis* is transmitted by arthropod vectors.

Yersinia pestis causes plague, which is maintained in wild burrowing rodents in rural regions of Asia, Africa, and the Americas (Figure 55-1). There is no plague in Australia, and the last case of plague in Europe was reported after World War II. The organism is transmitted between rodents by rodent fleas; humans, dogs, and cats are usually accidental and "dead-end" hosts (although direct transmission can occur through aerosols in humans and cats with pneumonic disease). Fleas become infected when they feed on heavily bacteremic rodents. The organism replicates in the flea intestine and creates a blockage of the intestinal tract, which causes the "starved" flea to repeatedly and aggressively feed and regurgitate bacteria into the bite site of a new host.[2] A large number of flea species can transmit *Y. pestis*, but some flea species, such as the Oriental rat flea *(Xenopsylla cheopis)* worldwide and the ground squirrel flea *(Oropsylla montana)* in the western United States are particularly efficient vectors. Although nowhere near as efficient as these two fleas as a vector, the cat flea *(Ctenocephalides felis)* can infest rodent reservoirs and also has the potential to transmit *Y. pestis*.[3] *Y. pestis* attains very high concentrations in rodent blood (10^8 organisms/mL) before death of the rodent occurs, which allows fleas to acquire sufficient numbers of bacteria for efficient transmission to other rodents.[4] Fleas can remain infected for more than a year, which permits transmission long after the death of an infected rodent.

Plague is transmitted to cats or dogs when they ingest infected mammals (especially rodents or rabbits) or less commonly, after the bite of a rodent flea. Humans are infected by (1) the bite of an infected flea; (2) direct contact with contaminated tissues (such as handling dead rodents, rabbits, or other dead wild mammalian carnivores); or rarely (3) inhalation of respiratory secretions by infected animals, especially cats (Figure 55-2). Death of a rodent from plague can cause the rodent's fleas to bite humans and other animals in a search for an alternative blood meal.

In the United States, plague in humans, dogs, and cats is now uncommon, although it is likely underrecognized in dogs and cats. Cats are considerably more susceptible to disease than dogs. Affected cats can be of any age, breed, and sex, with a mean age of 3 years in one case series.[5] Most plague cases in humans and cats occur in the southwestern United States, particularly northern New Mexico, but also southern Colorado, northern Arizona, and to a lesser extent California, southern Oregon, and western Nevada (especially in the Sierra Mountain ranges) (Figure 55-3). The probability of an area in the United States being a high-risk plague habitat increases with elevation up to 2300 meters and declines as elevation increases thereafter.[6] Rodent or rabbit species associated with human cases include white-tailed antelope squirrels, ground squirrels, rock squirrels, cottontail rabbits, jack rabbits, prairie dogs, deer mice, Colorado chipmunks, and wood rats.[2] The prevalence of antibodies to *Y. pestis* in a survey of 4115 dogs and 466 cats from California in the mid-1990s was less than 5% in both species.[7]

In general, plague has a seasonal distribution that correlates with the timing of epizootics that lead to a die-off of susceptible rodents. In the United States, most plague cases occur from February through August, when rodents and their fleas are most active and humans and their companion animals are more likely to be outdoors. In general, the organism does not survive well in the environment outside infected hosts, with survival less than

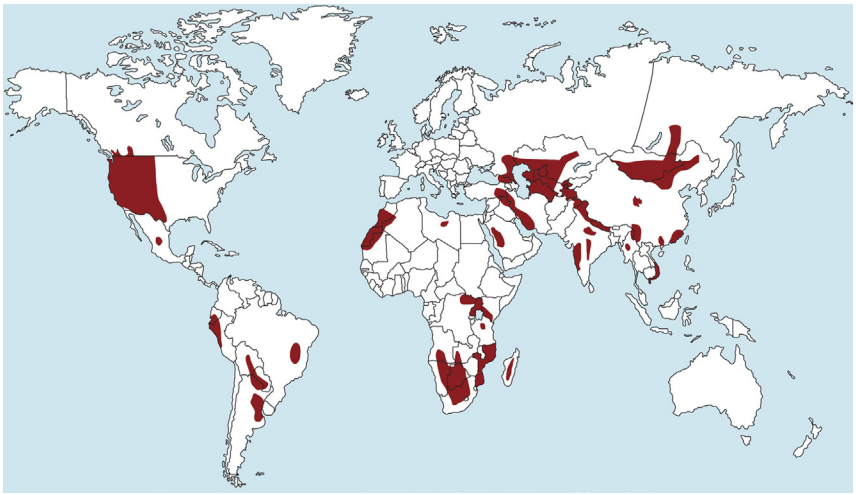

FIGURE 55-1 Worldwide distribution of plague endemic areas. (Data compiled from the World Health Organization, Centers for Disease Control and Prevention, and other sources. From Centers of Disease Control and Prevention. Prevention of plague: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep 1996;45:1-15. In: Mandell GL, Bennett JE, Dolin R, eds. Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases, 7th ed. Philadelphia, PA, Churchill Livingstone, Elsevier, 2011.)

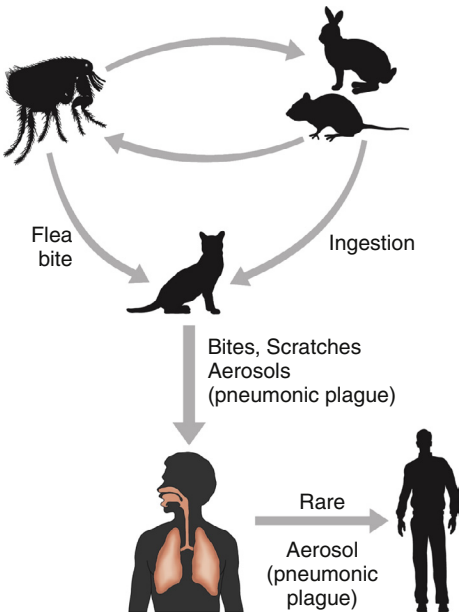

FIGURE 55-2 The role of the cat in transmission of *Yersinia pestis* to humans. Most humans are infected by direct contact with wildlife reservoir hosts or a bite from an infected flea, but infections can also occur as a result of cat bites or direct exposure to cats that have pneumonic plague. Dogs can also be infected but are less susceptible than cats to disease and shedding. Direct aerosol transmission from one human to another is rare and only occurs in humans that have terminal pneumonic plague.

72 hours on hard surfaces.[8] However, *Y. pestis* survived at least 24 days in blood-contaminated soil that was protected from UV light.[9] The extent to which environmental survival of *Y. pestis* contributes to the geographic distribution and epidemiology of the disease requires further clarification.

Clinical Features

Signs and Their Pathogenesis

After inoculation into the mammalian host by fleas, *Y. pestis* is taken up by mononuclear cells, in which it survives, replicates, and produces F1 capsular envelope antigen. The envelope allows it to further resist phagocytosis. Cats and dogs usually become infected after they ingest bacteremic rodents or other wildlife species that may have died of plague. In this situation, the organism has already produced a capsule and disseminates more rapidly than occurs after flea-borne transmission. Organisms are carried by lymphatics to regional lymph nodes. In more than half of affected cats, this results in an intense neutrophilic inflammatory response, variable fever, inappetence, and formation of the *bubo*, which is an enlarged and tender lymph node that occasionally forms an abscess and drains purulent material. This form of disease is known as *bubonic plague* and is the least fatal form of the disease. The location of the bubo(es) depends on the initial site of infection. In cats that ingest infected rodents, the mandibular or retropharyngeal lymph nodes are usually involved, and affected cats shed bacteria from the oropharynx. Less often (around 20% of cats with bubonic plague), other peripheral lymph nodes are involved; this may follow flea-borne transmission that occurs at sites distant to the head.[5]

In some cats, bubo formation is accompanied by bacteremia, with associated endotoxemia and sepsis, and formation of hemorrhagic, neutrophilic, and necrotizing lesions in many organs. Disseminated intravascular coagulation and multiple organ failure can then ensue. Signs of severe sepsis or septic shock in affected cats include tachypnea, vomiting, tachycardia or bradycardia, and weak pulse quality. In some situations, bacteremia and multiple organ involvement occurs in the absence of identifiable buboes *(septicemic form),* which has a high mortality rate. *Pneumonic plague* occurs in about 10% of affected cats as a result of hematogenous spread of bacteria to the lungs or, less often, by inhalation of organisms and can result in dyspnea and cough. The incubation period for plague is estimated to be 1 to 6 days, with shorter incubation periods after ingestion or inhalation of the organism, and death can occur in as few as 2 to 3 days in the absence of appropriate treatment; occasionally the clinical course extends for 2 to 3 weeks. Some (<20%) of cats show no signs of illness, or there may be transient fever, decreased appetite, and recovery. Transient febrile illness is also common in dogs.

Physical Examination Findings

Physical examination in cats with plague reveals lethargy (82% of cats), fever (71% of cats; mean rectal temperature of 105.1°F [40.5°C]), dehydration, a thin body condition, and lymphadenopathy. Lymphadenopathy most often involves the mandibular nodes. In one case series, 33% of 67 cats with bubonic

plague had bilateral lymphadenopathy, 32% had left-sided lymphadenopathy, and 13% had right-sided lymphadenopathy; in the remainder of cats, the location was not known.[5] Bilateral disease occurred only when the mandibular and cervical nodes were involved. Lymph nodes may be markedly enlarged (up to 8 cm, with a mean of around 4 cm); may be edematous, abscessated, and painful on palpation; and may drain purulent material. Drainage was reported in 6 (15%) of 40 cats with bubonic plague. Dyspnea or tachypnea can be present in cats with pulmonary involvement or possibly as a result of painful lymphadenopathy. Other reported physical examination abnormalities in cats with plague include ocular or nasal discharge (14% of cats) and abscesses that involve sites other than the lymph nodes, such as the sublingual region or the tongue, oral cavity, face, limbs, or trunk. Physical examination findings in dogs suspected to have plague have included fever, lethargy, mandibular or cervical bubo formation, oral ulceration and ptyalism, and cough.[10]

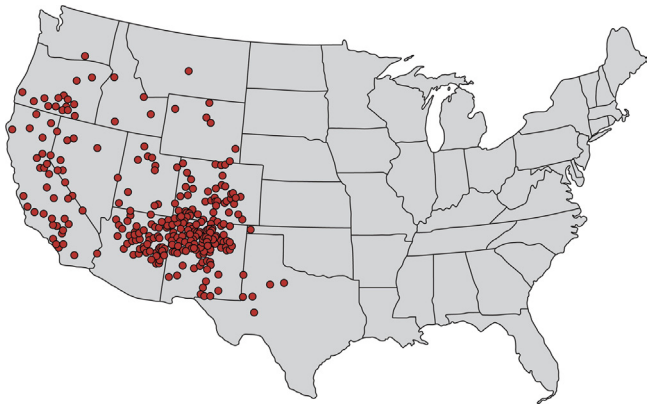

FIGURE 55-3 Approximate distribution of human plague cases in western United States, 1970 to 2012. Each dot represents a case, with the dot placed randomly in the county of exposure. (Modified from Dennis DT, Mead PS. *Yersinia* species, including plague. In: Mandell GL, Bennett JE, Dolin R, eds. Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases, 7th ed. Philadelphia, PA, Churchill Livingstone, Elsevier, 2011. Data from 2007-2012 collated from ProMed-Mail reports, http://www.promedmail.org/. Last accessed February 5, 2013).

Diagnosis

Diagnosis of plague is based on a history of residence in an endemic area as well as contact with, or predation of, wild mammals (especially rodents or lagomorphs). Duration of illness, physical examination findings, and lymph node aspirate cytology also support the diagnosis. There is a relative lack of information available on laboratory abnormalities in dogs and cats with plague because the disease is rare. Ultimately, a diagnosis of plague can only be confirmed by culture, direct fluorescent antibody testing, and/or serologic testing. Confirmation of the diagnosis may ultimately take weeks, so a high level of suspicion for the disease is needed in endemic areas.

Laboratory Abnormalities

Hematologic abnormalities in naturally infected cats most often consist of mild to moderate neutrophilia, usually with a mild to moderate left shift, and occasionally lymphopenia and monocytopenia.[5] Mild leukopenia can occur in cats with pneumonic plague. Platelet counts have not been widely reported in naturally infected cats but may be low in cats with severe sepsis. The serum biochemistry panel may show hypoalbuminemia, hyperglycemia, azotemia, electrolyte abnormalities, and increased liver enzyme activities.[11]

Diagnostic Imaging

Plain Radiography

Findings on thoracic radiography in cats with pneumonic plague have not been described in detail, but include diffuse interstitial, alveolar, and often nodular lung opacities.

Sonographic Findings

Abdominal ultrasound findings in cats with plague have not been reported. Based on pathologic findings, they might include abdominal lymphadenomegaly, splenomegaly, and hepatomegaly.

Microbiologic Tests

Diagnostic assays currently available for plague in dogs and cats are described in Table 55-1.

TABLE 55-1

Diagnostic Assays Currently Available for Plague in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Lymph node aspirates, blood, tissues collected at necropsy	*Yersinia pestis*	Recent antibiotic treatment may cause false-negative results. May take 48 hours for colonies to appear. Hazardous to laboratory personnel and should be sent to laboratories with appropriate expertise when possible.
Cytology	Lymph node aspirates	*Y. pestis* organisms (bipolar staining bacilli)	Low sensitivity. Recent antibiotic treatment may cause false-negative results.
Direct IFA	Lymph node aspirates, tissues collected at necropsy	*Y. pestis* F1 antigen	Increases sensitivity for detection of *Y. pestis* over cytology alone, but false negatives can still occur. Recent antibiotic treatment may cause false-negative results. Must be performed by laboratories with expertise in plague diagnosis.
Serology	Serum	Antibodies to *Yersinia pestis*	Acute and convalescent serology is required for diagnosis of acute infection, because initial results may be negative, and positive results may reflect previous exposure rather than active infection.

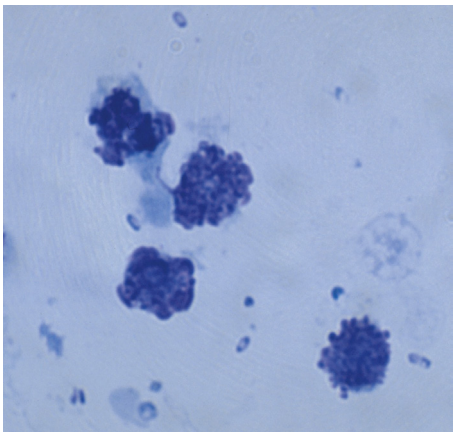

FIGURE 55-4 Lymph node aspirate cytology from a cat with bubonic plague. Bipolar rods are scattered throughout the field. (From Nelson RW, Couto CG, eds. Small Animal Internal Medicine, 4 ed. St. Louis, MO: Mosby; 2009.)

Cytologic Demonstration of Bacteria

Y. pestis is usually found in large numbers in tissues. If plague is suspected, aspirates of buboes or other affected tissues should be collected and smears prepared in isolation while wearing protective clothing, including eye protection and properly fitted high-density face masks (see Chapter 11). The smears should be heat fixed or immediately immersed in fixative solution to inactivate any organisms present. Cytologic examination shows massive numbers of neutrophils and a monomorphic population of coccobacilli with bipolar staining (Figure 55-4). This is in contrast to cat bite abscesses, where a mixture of bacteria is usually present.

Direct Immunofluorescent Antibody and Antigen ELISA Assays

Heat-fixed slides prepared from lymph node aspirates can be submitted to approved testing facilities for application of immunofluorescent antibody against the F1 envelope antigen. Local public health authorities should be contacted for information on recommended testing facilities if immunofluorescent antibody (IFA) testing is required. IFA can also be applied to impression smears from tissues obtained at necropsy. However, negative IFA results do not rule out plague, so culture and serology should also be considered.[5] A lateral-flow dipstick assay has been described for rapid (within 15 minutes), sensitive, and specific in-clinic diagnosis of plague in human patients, although false negatives may still occur.[12,13] This assay detects F1 antigen in body fluids such as sputum, lymph node aspirates, serum, and urine and has an estimated shelf life of about 2 years at room temperature. It has not been validated for diagnosis of plague in cats.

Isolation and Identification

Y. pestis can be grown from clinical specimens on routine media used for isolation of organisms that belong to the Enterobacteriaceae. The organism grows slowly, and colonies are smaller than those of other Enterobacteriaceae, so cultures must be held for at least 48 hours. If plague is suspected, specimens should never be shipped to routine veterinary diagnostic laboratories. Instead, local public health authorities should be contacted immediately for instructions regarding how and where to submit specimens for culture of *Y. pestis*.

Serology

Acute and convalescent serology is required for serologic diagnosis of plague in dogs and cats. The most widely used serologic test is a passive hemagglutination inhibition (HI) assay (see Chapter 2), which is available through public health laboratories approved for plague diagnosis. Because of the extremely short incubation period, a significant proportion of affected cats and dogs may have negative titers when they first are brought to the veterinarian, so convalescent serum should be submitted at least 10 to 14 days after the initial titer. Some cats may die before a rise in antibody titer occurs.[11] A fourfold increase in titer together with consistent clinical abnormalities confirms the diagnosis of plague. Titers in affected cats in one study ranged from less than 1:4 for acute specimens to 1:8192 for convalescent specimens.[5]

TABLE 55-2

Suggested Antimicrobial Drugs for Treatment of Plague in Cats

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration
Doxycycline	10	IV or PO*	24	10 days
Gentamicin	5-8	IV, IM, SC	24	10 days

*Oral administration should be avoided for at least the first 72 hours of treatment to minimize exposure of the caregiver to *Y. pestis*. For IV doxycycline administration, dilute in 100 mL of lactated Ringer's saline and administer over 2 hours; if fluid overload is a concern, consider parenteral tetracycline or use of an aminoglycoside.

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays have been described for detection of *Y. pestis* DNA and are an attractive means of diagnosis because of their sensitivity and rapid turnaround time. In addition, the organism can be deliberately inactivated before specimens are submitted to the laboratory for PCR testing, which reduces the risk of laboratory-acquired infection. Real-time PCR assays have been validated for use on clinical specimens from humans,[13] but to date assays have not been validated for diagnosis of the disease in cats or dogs. Real-time PCR was considerably more sensitive for diagnosis of human plague in Africa than the lateral-flow dipstick antigen assay or culture.

Pathologic Findings

Gross pathologic findings in cats with plague include enlarged lymph nodes or abscesses with associated edema and hemorrhage, focal (up to 1 cm) lung lesions, and hemorrhages in a variety of organs. Histopathology reveals hemorrhage, necrosis, neutrophilic infiltrates, and often very large numbers of small coccobacilli in tissues.

Treatment and Prognosis

Treatment of cats and dogs with plague involves supportive care, abscess drainage, and antimicrobial drug administration (Table 55-2). Animals suspected to have plague should be housed in isolation at least for the first 72 hours of antimicrobial drug therapy and handled by as few individuals as possible. Public health authorities should be notified immediately. Gowns, gloves, and suitable face protection (eye protection and a properly fited high-density surgical mask) should be worn, and protective wear should be properly removed and disposed of after handling affected cats. Cats and dogs

FIGURE 55-5 Axillary bubo with ulceration and eschar formation at the site of an infected flea bite. (Centers for Disease Control and Prevention.) (From Dennis DT, Mead PS. *Yersinia* species, including plague. In: Mandell GL, Bennett JE, Dolin R, eds. Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases, 7 ed, Philadelphia, PA: Churchill Livingstone, Elsevier; 2010.)

with plague should also be treated for fleas. Abscesses should be lanced and flushed with chlorhexidine solution. Any biohazardous waste should be double bagged and disposed of correctly. Routine disinfectants can be used to inactivate the organism in the environment. Antimicrobials with activity against most isolates of *Y. pestis* are aminoglycosides or tetracyclines such as doxycycline. Trimethoprim-sulfamethoxazole and chloramphenicol also have activity against *Y. pestis*. Parenteral aminoglycosides such as gentamicin are preferred for seriously ill animals. Mortality rates in naturally infected cats that are not treated with antimicrobial drugs can reach 75%, but most (>90%) of cats treated with antimicrobial drugs survive.[5] The time between antimicrobial drug treatment and recovery of affected cats ranged from 1 to 10 days in one study (mean, 4.4 days).[5]

Immunity and Vaccination

There are no plague vaccines for dogs and cats. Although vaccines have been used to prevent plague in highly at-risk humans, these did not protect against pneumonic plague. Currently there are no vaccines approved for use in the United States. Because *Y. pestis* is a potential agent of bioterrorism, efforts have been focused on development of subunit vaccines. However, *Y. pestis* has also been considered an unlikely agent of bioterrorism because in general it does not survive well in the environment, and person-to-person transmission requires close contact with a dying person, usually on the last day of life.[2,14]

Prevention

Prevention of plague in dogs and cats involves housing cats indoors in endemic areas and discouragement of predation or exposure to/consumption of wild animal carcasses. Dogs should not be allowed to dig around rodent burrows in endemic areas. Flea preventatives should reduce the chance that dogs and cats will carry infected fleas into the house. Rodent control in the environment (e.g., removal of garbage and food scraps) should also be performed.

Public Health Aspects

The clinical course of plague in humans closely resembles that in cats (Figure 55-5). Three major pandemics of plague have occurred in humans: Justinian plague, which occurred in the Mediterranean basin during the sixth century Byzantine era; the "Black Death," which began in 1347 and spread throughout Europe; and modern plague, which began in China in the 1860s and was subsequently spread by ship rats to all continents inhabited by humans. Currently, more than 95% of human plague cases reported to the WHO originate from sub-Saharan Africa and Madagascar.[15] From 1970 to 2007, 415 cases were reported in the United States, with 59 deaths.[16] In endemic regions, humans who have close contact with rodents or their canine or feline predators are at risk. The vast majority of humans are infected as a result of contact with rodent fleas. Human disease has also been reported after skinning of rabbits or contact with wild carnivores. Fewer than 10% of human plague cases result from exposure to cats, with infection transmitted from cats to humans after a bite, scratch, or inhalation of respiratory droplets from cats with pneumonic plague.[17-19] However, exposure to cats often results in pneumonic plague, which has the worst prognosis and can progress to death within as little as 24 hours after the onset of symptoms. Occasionally, dogs or cats carry rodent fleas into the house, which may then transmit the infection to humans. Sleeping with a dog may also increase the risk of infection.[20] Exposure to infected fleas carried into a household by a dog was suspected in a report of two affected humans in Oregon, one of whom slept in the same bed with the pet dog during the 2 weeks before onset of illness.[21] The dog seroconverted to *Y. pestis*.

Flea control and reduction of pet exposure to rodents also serve to reduce plague in humans. Pet owners should be made aware that pets can carry fleas (and ticks) into the house and that flea control may reduce the chance of arthropod-transmitted human disease. Adoption of wild animals should be discouraged. In the veterinary hospital situation, plague can be prevented if there is a high index of suspicion for the disease and appropriate precautions are taken (see Treatment and Prognosis). Owners of pets suspected to have plague should be advised to contact their physicians without delay. Humans with exposure to affected animals are generally treated with prophylactic doxycycline for 7 days.

Other Yersinioses

Y. pseudotuberculosis and *Y. enterocolitica* are enteropathogenic bacteria that are distributed worldwide. They are classified into serotypes based on their O antigens, with different classification systems used for the two pathogens. Enteropathogenic yersiniae are maintained in a variety of food animal and wild animal reservoirs and are well known causes of food-borne febrile gastrointestinal illness in humans. Pigs are a major reservoir for *Y. enterocolitica,* and outbreaks have followed consumption of undercooked pork products. *Y. enterocolitica* can also grow in food held at refrigeration temperatures. Affected human patients frequently exhibit right lower abdominal pain due to mesenteric adenitis or ileitis, which can mimic appendicitis. A small proportion of patients develop complications such as secondary polyarthritis and erythema nodosum (panniculitis).[16] Children are most susceptible. Immunocompromised humans (such as those with diabetes mellitus, malignancy, or immunosuppressive drug therapy) can occasionally develop bacteremia with systemic

spread and abscesses in a variety of different organs. The mortality rate in this situation is at least 50%.[16]

Dogs and cats can shed *Y. enterocolitica* and *Y. pseudotuberculosis* in their feces in the absence of clinical signs.[22,23] *Y. enterocolitica* was also isolated from 19% of 144 tonsils from stray dogs in Ireland.[24] Strains found in dogs can resemble those implicated in human disease,[25] and in several reports, dogs were suspected as a source for human infection and disease. *Y. enterocolitica* infection was associated with hepatitis in a 2-year-old Pekingese dog from Korea[26] and hepatitis and myocarditis in a 4-month-old Rottweiler.[24] It has also been isolated from young dogs with hemorrhagic diarrhea. There have been several reports of *Y. pseudotuberculosis* infection in cats, with microabscess formation in a variety of abdominal organs.[27-29] A young adult dog evaluated at the authors' hospital for hemoptysis and lung consolidation had pulmonary *Y. pseudotuberculosis* infection.

Enteropathogenic *Yersinia* species are usually susceptible to doxycycline, trimethoprim-sulfamethoxazole, chloramphenicol, aminoglycosides, and fluoroquinolones. Some organisms produce β-lactamase enzymes.

In dogs and cats, prevention of enteropathogenic yersiniosis involves feeding properly cooked foods and preventing predation. Other measures to reduce zoonotic transmission include hand washing after handling dogs and cats (especially before eating), wearing gloves when contact with saliva or feces is anticipated, and preventing dogs from licking the face or open wounds.

CASE EXAMPLE

Refer to Chapter 56, Tularemia, for a case example.

Tularemia

Jane E. Sykes and Bruno B. Chomel

VetBooks.ir

Overview of Tularemia

First Described: 1911, Tulare County, California[1]

Cause: Virulent strains of *Francisella tularensis*, a gram-negative coccobacillus (family Francisellaceae)

Major Vectors: Ticks (especially *Dermacentor andersoni, Dermacentor variabilis,* and *Amblyomma americanum* in the eastern United States), biting flies (western United States), mosquitos (Scandinavia)

Affected Hosts: Some 190 mammalian species, which include rodents, rabbits, wild carnivores, domestic dogs and cats, sheep, horses, nonhuman primates, and humans

Geographic Distribution: Northern Hemisphere between 30 degrees and 71 degrees of latitude; most disease is reported from the United States, where virulent strains are most prevalent

Major Clinical Signs: Fever, lethargy, inappetence, lymphadenopathy, subcutaneous abscesses, splenomegaly, hepatomegaly

Differential Diagnoses: Plague, cat bite abscess, *Streptococcus* spp. infections, feline infectious peritonitis, mycobacterial infections, lymphoma, sepsis caused by other gram-negative bacteria

Human Health Significance: Cats and less commonly dogs can transmit tularemia to humans after they are exposed to infected rodents or rabbits. Cat bites are most commonly implicated.

Etiologic Agent and Epidemiology

Tularemia (also known as rabbit fever, hare fever, deerfly fever, and lemming fever) is an extremely infectious but uncommon zoonotic disease caused by *Francisella tularensis*, a small (0.2 × 0.2 × 0.7 µm), nonmotile, aerobic, encapsulated gram-negative coccobacillus. The name "tularemia" comes from the first isolation of the organism from sick rodents in Tulare County, California, in 1911. There are four subspecies of *F. tularensis: tularensis, holarctica, novicida,* and *mediasiatica*. Subspecies *tularensis* (also known as type A) and *holarctica* (type B) cause most disease in humans. Subspecies *mediasiatica* is only found in Asia and the former Soviet Union. Subspecies *novicida* can cause illness in severely immunosuppressed humans and is widely studied as a model for tularemia because of its low virulence to laboratory workers.

F. tularensis subsp. *tularensis* has the greatest degree of virulence for humans and predominates in North America, whereas the less virulent subspecies *holarctica* predominates in Europe. Additional genetic variation within type A and type B subpopulations of *F. tularensis* correlates with geographic distribution of cases and the severity of disease.[2] Molecular subtyping has further divided type A into subpopulations A1a, A1b, A2a, and A2b. The highest mortality in humans, 24%, results from infections by A1b.[3]

Tularemia occurs primarily in the Northern Hemisphere, especially between 30 degrees and 71 degrees of latitude (Figure 56-1). Human disease caused by a subspecies *novicida*–like organism was reported from the Northern Territory in Australia in 2003.[4] Even in North America, where *F. tularensis* subsp. *tularensis* predominates, tularemia is a rare disease, and most human cases occur in the central and north-central United States, especially Arkansas, Missouri, Kansas, South Dakota, and Oklahoma, with an additional focus in Massachusetts (especially Martha's Vineyard) (Figure 56-2). Despite its rarity, tularemia is a reportable disease in the United States because *F. tularensis* is considered a potential agent of bioterrorism. In western Europe, tularemia is endemic in Scandinavia but has emerged in new parts of Sweden and is increasingly reported in humans from more southern locations, such as Germany, France, and Spain.[5] Tularemia has been absent from the United Kingdom, with the exception of travel-related disease. It also occurs in Russia and Japan.[6]

Canine and feline disease due to *F. tularensis* has only been reported from the United States. Young adult cats and dogs are usually affected. As with plague, cats are more susceptible than dogs. Cases are reported most often from Oklahoma[7-9] and Kansas,[10] but also from other locations that include Montana,[11] Missouri,[12] Massachusetts,[13] central Virginia,[14] and eastern Oregon,[15] which mirrors the distribution in humans. Tularemia is likely underdiagnosed in cats and dogs because clinical signs

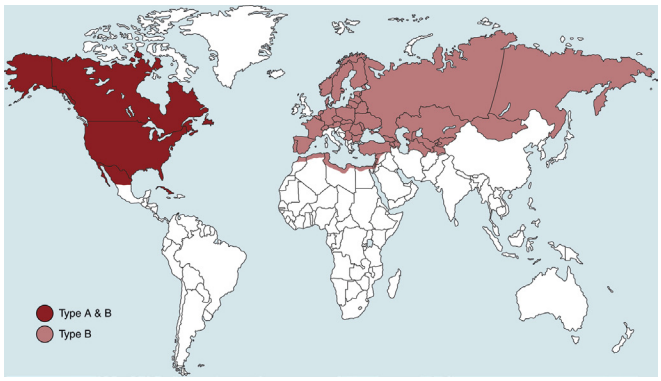

FIGURE 56-1 Global distribution of tularemia (Centers for Disease Control and Prevention).

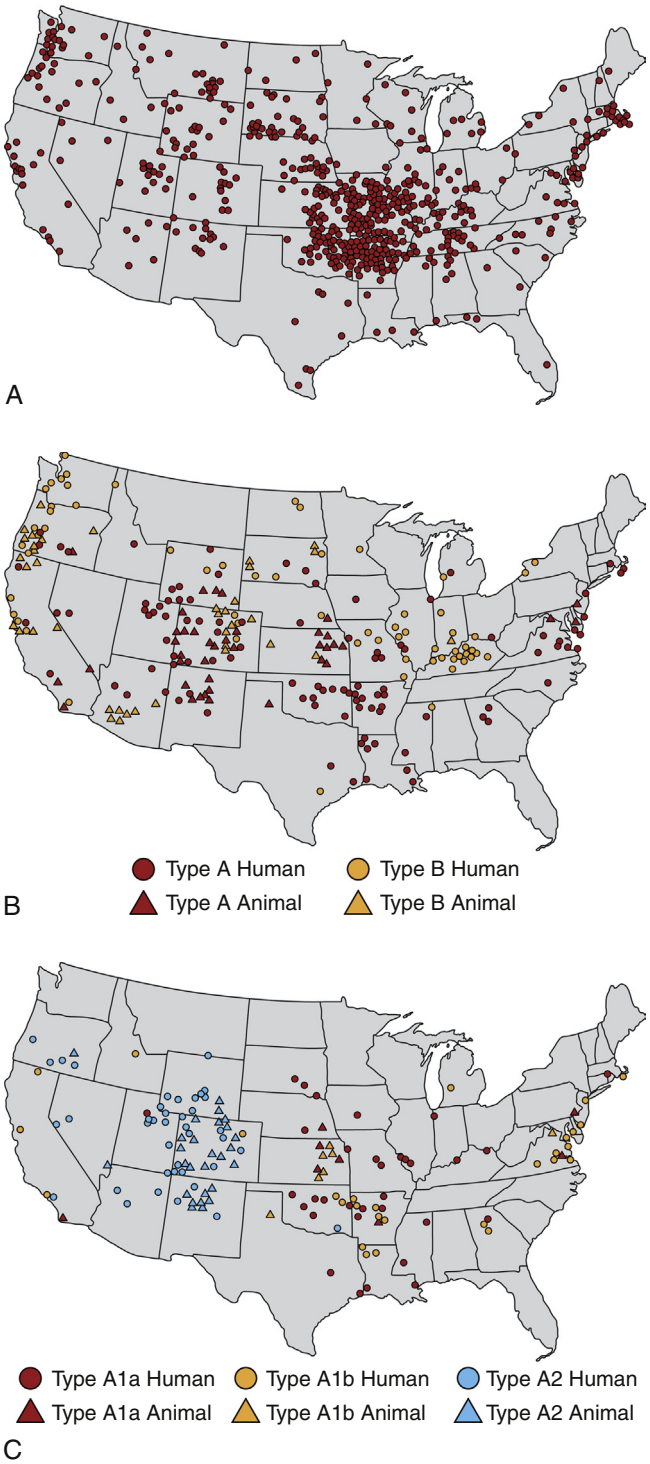

FIGURE 56-2 Geographic distribution of tularemia in the USA. Compare this with the geographic distribution of plague (Figure 55-3). **A,** Overall distribution of human tularemia cases. **B,** Distribution of type A and type B isolates from humans and animals. **C,** Distribution of isolates from humans and animals by molecular subtype. Note that the geographic distribution of human type A cases follows the distribution of subtype A1, the most virulent subtype being A1b. (**A** and **B** modified from Kugeler KJ, Mead PS, Janusz AM, et al. Molecular epidemiology of Francisella tularensis in the United States. Clin Infect Dis 2009;48:863-870.)

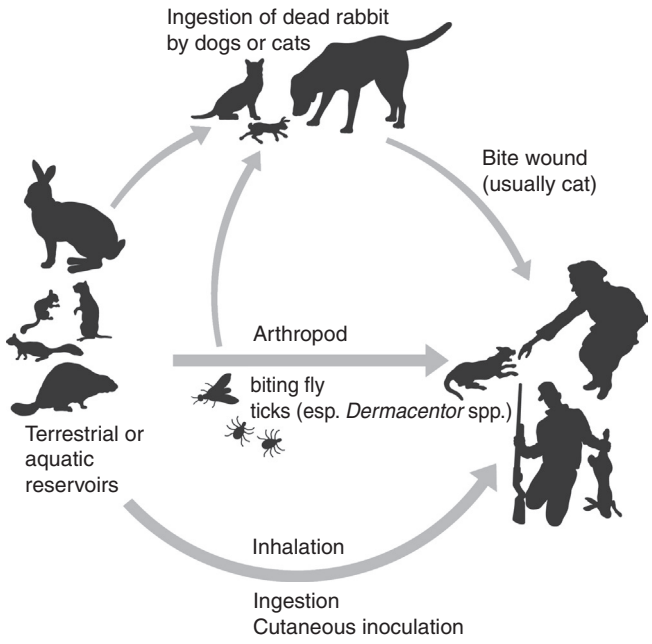

FIGURE 56-3 Transmission cycle for *Francisella tularensis.*

are nonspecific. Many cats with tularemia are diagnosed with tularemia at necropsy.[7,10] The seroprevalence in pet cats from Connecticut and New York state was 12%.[16]

F. tularensis is maintained in the environment by a huge variety of terrestrial and aquatic mammals, which include rabbits, hares, ground squirrels, prairie dogs, lemmings, voles, beavers, muskrats, water rats, and other rodents.[6] It often causes severe disease in these species, although subclinical carriage may also occur. It can be transmitted by arthropod bites, inhalation or ingestion of the organism, and direct skin contact with infected tissues (probably when there are minute breaks in the skin) (Figure 56-3). Inhalation of as few as 10 organisms can cause human disease, whereas larger numbers of organisms (10^8) must be ingested for disease to occur. Cats and dogs become infected when they hunt rodents or lagomorphs; a history of rabbit ingestion was most often described in association with the few reported feline and canine cases.[7-9] In the western United States (Utah, Nevada, and California), the most common arthropod vectors are biting flies, whereas ticks (especially *Dermacentor* ticks and *Amblyomma americanum*) are the most common vectors east of the Rocky Mountains. In Europe, *Dermacentor* ticks and *Ixodes ricinus* are the main tick vectors; mosquitos are important vectors in Scandinavia.[17] *F. tularensis* is well known for its ability to survive up to several months in fresh water sources, and survival in brackish water has also been demonstrated.[18] Survival and replication of *F. tularensis* within free-living amoebae such as *Hartmannella vermiformis* may contribute to the organism's ability to persist in water sources.[19] The organism can also survive for years in frozen rabbit meat.

Clinical Features

Signs and Their Pathogenesis

The clinical manifestations of tularemia depend on the virulence of the infecting strain, the route of inoculation, and host immunity. Although tularemia may rapidly progress to death in cats, protracted illness has also been described.[15]

VetBooks.ir

F. tularensis survives in macrophages through evasion of cellular destruction by phagosomes and inhibition of the respiratory burst. Several different virulence factors of *F. tularensis* have been identified, which include bacterial lipopolysaccharide (LPS), pili, a capsule, and a series of acid phosphatase enzymes. The endotoxic activity of the LPS of *F. tularensis* is 1000-fold less potent than that of *Escherichia coli*.[20,21] Production of acid phosphatase enzymes may be key to the organism's ability to inhibit the respiratory burst and survive in macrophages.[22] Many stages of the organism's intracellular lifestyle depend on a pathogenicity island (group of virulence genes) known as the *Francisella* pathogenicity island.

For the first few days after cutaneous inoculation, *F. tularensis* replicates locally and can produce a papule that may then ulcerate. It then disseminates to local lymph nodes, which may be followed by bacteremia and sepsis, with infection of systemic, primarily reticuloendothelial tissues. The organism invades not only macrophages but also nonphagocytic cells such as hepatocytes and alveolar epithelial cells,[23] with induction of a profound inflammatory response and necrosis. Incubation periods that range from 1 to 5 days have been suspected in naturally occurring tularemia in dogs and cats, but longer incubation periods (up to 21 days) can occur in humans. Clinical signs typically manifest as a sudden onset of fever, lethargy, and inappetence. Other manifestations in affected cats have included a thin body condition, icterus, hepatomegaly, vomiting, dehydration, peripheral and/or abdominal lymphadenomegaly, splenomegaly, and oral and/or lingual ulceration. Hypothermia and bradycardia can occur in moribund cats[7]; one cat had seizures and was nonresponsive.[14] A single cat with localized cutaneous tularemia had a chronic (1-year duration) draining skin lesion in the region of (but not involving) the mandibular lymph nodes, in the absence of systemic signs.[15] In the rare reports of naturally affected dogs, clinical signs have included fever, anorexia, and peripheral lymphadenopathy.[8,24] One dog also had bilateral mucoid ocular discharge and mild conjunctival hyperemia,[8] and another had tonsillitis.[24]

Physical Examination Findings

Physical examination in cats with tularemia may reveal lethargy, fever (up to 105.1°F [40.5°C]) or hypothermia, a thin body condition, and dehydration.[7,9,11-13] Ulceration of the oral mucous membranes or tongue may be present.[7,13] Icterus may also occur.[25] Moribund cats may be hypothermic and bradycardic and may have weak pulse quality. Mild to marked peripheral lymphadenopathy is present in most but not all cats. Lymphadenopathy may be restricted to the lymph nodes of the head and neck[13] or may be generalized.[7,9] Abdominal palpation may reveal hepatomegaly or splenomegaly, or abdominal lymph nodes may be palpable. Fever, lethargy, peripheral lymphadenopathy, mucoid ocular discharge, and tonsillitis may be present in dogs.[8,24]

Diagnosis

Tularemia should be considered in cats and dogs with lymphadenopathy and fever that have a history of residence in or recent travel to an endemic area, as well as contact with or predation of wild mammals (especially lagomorphs). Plague is the major differential diagnosis of zoonotic importance in the southwestern United States (Table 56-1). Ultimately, the diagnosis can be confirmed by culture, PCR, and/or serologic testing. With the exception of PCR, access to approved laboratories that practice biosafety level 3 procedures is required to perform these tests when tularemia is suspected. Local public health authorities should be contacted to report suspicion for the disease and for information on recommended testing facilities.

Laboratory Abnormalities

Complete Blood Count, Biochemistry Profile, and Urinalysis

Leukocyte counts in a limited number of cats with tularemia have been normal, decreased (as low as 1300 cells/μL), or increased with evidence of neutrophil toxicity.[7,9,13,14] Moderate to marked bandemia may be present.[9,13] Thrombocytopenia is a common finding (as low as 41,000 platelets/μL).[7,9] The serum biochemistry panel may show hypoglycemia, azotemia, and electrolyte abnormalities, increased liver enzyme activities, and hyperbilirubinemia (up to 7.6 mg/dL).[7,9,14] Bilirubinuria and hemoglobinuria may be present.[7] Mature neutrophilia, lymphopenia, and increased serum ALP activity were present in a dog with tularemia.[8] In human patients, abnormalities include thrombocytopenia, elevated serum transaminase activities, increased serum creatine kinase activity, myoglobinuria, and pyuria.[26]

Cytologic Examination of Lymph Node Aspirates

Cytologic examination of lymph node aspirates in cats with tularemia may reveal lymph node hyperplasia.[9] Lymph nodes may also contain necrotic debris and increased numbers of macrophages and/or degenerate neutrophils.[7,13] Because *F. tularensis* is tiny and stains only faintly, organisms are less likely to be visualized than those of *Yersinia pestis* (see Chapter 55).

Diagnostic Imaging

Plain Radiography

Findings on thoracic radiography in cats with tularemia have not been well described; one cat had normal thoracic radiographs.[9] Findings on abdominal radiography have included hepatomegaly and fluid-filled intestinal loops.[9]

Sonographic Findings

Abdominal ultrasound findings in cats with tularemia could include abdominal lymphadenomegaly, splenomegaly, and/or hepatomegaly. Abdominal lymphadenomegaly was described in one cat.[9]

Microbiologic Tests

Diagnostic assays currently available for tularemia in dogs and cats are described in Table 56-2.

Direct Detection

Heat-fixed slides can be submitted to experienced laboratories for direct immunofluorescent antibody (IFA) staining for *F. tularensis*. Alternatively, IFA or immunoperoxidase stains can be applied to tissues obtained at necropsy.[10] Negative results do not rule out tularemia, but in some cases IFA may detect the organism when culture is negative.[27] Fluorescence in situ hybridization (FISH) has also been used to detect *F. tularensis* in tissues and differentiate between subspecies.[28] As for plague, lateral-flow assays have been described for rapid detection of *F. tularensis* LPS antigen in clinical specimens such as urine.[29] The use of these assays in dogs and cats has not been described.

Isolation and Identification

F. tularensis can be grown from clinical specimens, but it is very fastidious, grows slowly, is hazardous to laboratory personnel,

VetBooks.ir

TABLE 56-1

Differences and Similarities between Plague and Tularemia in Cats and Dogs in the United States

	Plague	Tularemia
Organism	Gram-negative bacillus (Enterobacteriaceae). Survives relatively poorly in the environment. Grows on routine culture media used for gram-negative bacteria.	Gram-negative coccobacillus (Francisellaceae). Can persist in the environment and water sources for months. Fastidious growth in culture; often requires special media and prolonged incubation.
Major Arthropod vectors	Diverse variety of rodent and rabbit fleas	*Dermacentor* spp. and *Amblyomma americanum* ticks
Geographic location	Southwestern United States	Western, southwestern, central, and eastern United States
Affected hosts	Cats > dogs	Cats > dogs
Usual history	Rodent contact or exposure to rodent fleas	Rodent and especially rabbit contact; ingestion often reported
Clinical signs	Acute disease with high fever and lymphadenopathy, most often of the mandibular and/or retropharyngeal lymph nodes. Hyperbilirubinemia and icterus do not appear to be common in affected cats.	Acute or more chronic disease (sometimes associated with a thin body condition) with oral ulceration, lymphadenopathy of the mandibular and/or retropharyngeal lymph nodes, or generalized lymphadenopathy and abdominal organomegaly. Hyperbilirubinemia is frequent in affected cats, and icterus has been described.
Lymph node aspirate cytology	Neutrophilic inflammation; monomorphic population of bipolar staining bacilli often present	Lymphoid reactivity or neutrophilic to pyogranulomatous inflammation and necrosis; bacteria often not visualized
Antimicrobial drugs	Aminoglycosides, doxycycline, chloramphenicol, trimethoprim-sulfamethoxazole	Aminoglycosides are the treatment of choice. Doxycycline, chloramphenicol, and fluoroquinolones may be effective but may be followed by relapse.
Zoonotic potential	Exposure to cats with pneumonic plague can lead to human infection; bites and scratches have also been implicated. Human pneumonic plague usually results from exposure to infected cats and can progress to death within a few days. Exposed humans may require prophylaxis with doxycycline.	Most often follows bites from affected cats, less often scratches. Course of disease longer and mortality may be lower than occurs with pneumonic plague. Medical attention should be sought if bites or scratches occur.

TABLE 56-2

Diagnostic Assays Currently Available for Tularemia in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Lymph node aspirates, blood, tissues collected at necropsy	*Francisella tularensis*	Recent antibiotic treatment may cause false-negative results. May require special media and takes at least 48 hours for colonies to appear. Hazardous to laboratory personnel and should be sent to laboratories with appropriate expertise when possible.
Direct immunofluorescent antibody	Lymph node aspirates, tissues collected at necropsy	*F. tularensis* antigen	May be positive when culture is negative. False negatives can still occur. Recent antibiotic treatment may cause false-negative results.
Serology	Serum	Antibodies to *F. tularensis*	Acute and convalescent serology is required for diagnosis, because initial results may be negative and positive results may reflect previous exposure rather than active infection. Seroconversion may take up to 3 weeks.

and does not always grow on media used for routine isolation of gram-negative bacteria such as MacConkey agar (in contrast to *Y. pestis*). The use of cysteine-supplemented media (such as cysteine heart agar) and incubation in a CO_2-supplemented environment enhances recovery of the organism. Growth generally occurs 48 to 72 hours after inoculation, but cultures must be held for 7 to 10 days. Overgrowth of contaminating bacteria can occur unless the media is supplemented with antibiotics that inactivate these organisms. *F. tularensis* may grow from blood specimens after inoculation of routine blood culture media. The organism is identified on the basis of biochemical testing with or without the use of molecular methods such as 23S rRNA gene PCR sequencing (which allow subspecies determination). Whole-cell matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry, which measures the mass of peptides and small proteins from whole cells, has also been used for identification of *F. tularensis* isolates to the subspecies level.[30]

Serology

As for plague, acute, and convalescent serology, with a fourfold increase in titer, is required for serodiagnosis of tularemia in affected dogs and cats and is less hazardous to human health than culture. Tube agglutination and microagglutination assays are the standard methods for serodiagnosis, but ELISA assays have also been developed. Because of the extremely short incubation period, affected cats and dogs may have negative titers when they first are brought to the veterinarian, so convalescent serum should be submitted at least 2 to 3 weeks after the initial titer if the animal survives. Some cats die from the disease before a rise in antibody titer occurs. In addition, high titers may persist after recovery from infection, so a single positive titer is not diagnostic for tularemia.

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays that detect *F. tularensis* DNA represent an attractive means of diagnosis because of their sensitivity, rapid turnaround time, low risk to laboratory personnel, and the ability of some assays to differentiate between subspecies and genotypes of *F. tularensis*.[31] A PCR assay was used to detect *F. tularensis* in tissues at necropsy in a cat.[12] A number of real-time PCR assays have been used to detect *F. tularensis* in human clinical specimens. Despite the sensitivity of PCR assays, false negatives can still occur. Real-time PCR assays for *F. tularensis* are offered on a commercial basis by some veterinary diagnostic laboratories in the United States.

Pathologic Findings

Gross pathologic findings in cats with tularemia include icterus, oral ulceration, lymphadenomegaly, splenomegaly, and hepatomegaly. Multifocal to coalescing irregular yellow, gray, or white foci (usually 1 to 5 mm in diameter) are present in these organs, and sometimes other organs such as the lung and myocardium.[7,12,13] When examined histopathologically, the nodules represent well-circumscribed but non-encapsulated masses of caseous necrosis, with abundant cellular debris, surrounded by infiltrates of degenerate neutrophils, macrophages, and/or fibroblasts. Lesions are centered on the splenic white pulp and cortical lymphoid follicles within lymph nodes. Necrosis and hemorrhage of lymphoid follicles within the gastrointestinal tract may be present.[7,11] Organisms may be discernible with silver staining as tiny coccobacilli[11] or can be demonstrated with immunoperoxidase or immunofluorescence methods.[10,27]

TABLE 56-3

Suggested Antimicrobial Drugs for Treatment of Tularemia in Cats*

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration
Gentamicin	5-8	IV, IM, SC	24	14 days
Doxycycline	5	PO†	12	2-3 weeks
Marbofloxacin	2.75-5.5	PO	24	2-3 weeks

*The same antimicrobial drugs could be used to treat dogs; doses shown are for cats.
†Parenteral aminoglycosides are preferred for at least the first 72 hours of treatment to minimize exposure of the caregiver to *F. tularensis* during treatment.

Treatment and Prognosis

Treatment of cats (and, although less commonly affected, dogs) with tularemia involves supportive care and antimicrobial drug administration (Table 56-3). As for plague, animals suspected to have tularemia should be housed in isolation at least for the first 72 hours of antimicrobial drug therapy and handled by as few individuals as possible. Public health authorities should be notified. Gowns, gloves, and suitable face protection (eye protection and a properly fitted high density surgical mask) should be worn, and protective wear should be properly removed and disposed of after handling affected cats. Any biohazardous waste should be double bagged and disposed of correctly. Routine disinfectants should be used to inactivate the organism in the environment. The drug of choice for initial treatment of tularemia is a parenteral aminoglycoside such as gentamicin. Doxycycline can also be used but is associated with a higher relapse rate in humans than occurs with aminoglycosides.[26] Fluoroquinolones are active against *F. tularensis* in vitro, but like tetracyclines, they may be associated with relapse in vivo.[32] Extension of the course of treatment from 2 weeks to 3 weeks when fluoroquinolones or doxycycline is used has been effective for treatment of human tularemia.[25] Other drugs with in vitro activity against *F. tularensis* include chloramphenicol and erythromycin.[33]

Immunity and Vaccination

Natural infection by *F. tularensis* is followed by protection against reinfection. Because *F. tularensis* is facultatively intracellular, cell-mediated immune responses are required for pathogen clearance, although humoral immunity is also important.[23] As a result, inactivated vaccines have not been effective for prevention of tularemia, because they primarily induce humoral immunity. An attenuated live vaccine that contained *F. tularensis* subsp. *holarctica* (live vaccine strain, or LVS) has been available for prevention of serious disease in people at high risk of exposure. However, this remains unlicensed because of concerns regarding efficacy and the route of administration, which is by scarification.[34] Since then there has been strong interest in vaccine development for prevention of human tularemia, because of concerns that the organism will be used as a weapon of bioterrorism.[23] Vaccines are not likely to be available for dogs and cats given the rarity of disease in these species and the minor role that they play in transmission of disease to humans.

Prevention

Prevention of tularemia in dogs and cats involves housing cats indoors and discouragement of predation or exposure to dead wild rodents and rabbits. Use of tick preventatives also reduces the chance that dogs and cats will carry infected ticks into the house. Rodent control in the environment (e.g., removal of garbage) should also be performed.

Public Health Aspects

Humans are most commonly infected by *F. tularensis* after arthropod bites or handling infected wild animals. In the United States, disease is most commonly reported in late spring and summer. Occupations associated with an increased risk of tularemia include farming, hunting, landscaping, meat handling, working with sheep, veterinary practice, and laboratory work. Severe illness is most often reported in young children (5 to 9 years) and the aged (>75 years). Men are more likely to be affected than women.[26]

Several overlapping forms of disease have been described in humans, the development of which depends on the route of inoculation and the virulence of the infecting strain: ulceroglandular, glandular, oculoglandular, oropharyngeal, typhoidal, and pneumonic.[26] Ulceroglandular tularemia results from cutaneous inoculation, oropharyngeal disease follows ingestion and pneumonic tularemia can result from aerosol inhalation. Pneumonic tularemia has been described in people after activities such as lawn mowing or brush cutting in tick-infested areas. Infection of humans from dogs and cats can occur after these animals carry *F. tularensis* in their mouths after ingestion of wild prey. Human-to-human transmission does not occur.

Clinical signs in humans consist of acute onset of a flu-like illness, with fever, chills, and malaise. Sore throat, abdominal pain, vomiting, diarrhea, lymphadenopathy, and a cough may also occur. Infection with less virulent strains may result in transient flu-like illness followed by recovery. Without treatment, clinical signs can persist for several months, with chronic lymphadenopathy, weight loss, and debilitation.[26] Disease in chronically affected humans can resemble cat scratch disease.

Ulceroglandular tularemia is the most common form of tularemia seen in humans. It consists of a red and painful papule at the site of skin infection, with associated lymphadenopathy (Figure 56-4). The papule then undergoes necrosis, forming an ulcer, which can take weeks to heal. In some individuals, lymph nodes may suppurate and become fluctuant. Multiple lesions can occur on the hands when infected animals have been handled, whereas tick bites typically result in single lesions elsewhere on the body.[26] Only lymphadenopathy may be present if the ulcer heals before the time of evaluation *(glandular tularemia)*. *Oculoglandular tularemia* occurs when organisms gain access through the conjunctiva and is characterized by conjunctivitis, conjunctival ulceration, lacrimation, and associated lymphadenopathy.[26] *Oropharyngeal tularemia* is characterized by fever and severe throat pain; tonsillitis, oral ulceration, and associated lymphadenopathy may be present, which resembles the disease described in dogs and cats (which usually acquire infection via ingestion). Oropharyngeal tularemia tends to occur in children who ingest contaminated food or water and can resemble "strep throat."[26] *Typhoidal tularemia* is a febrile illness in the absence of prominent lymphadenopathy and may be associated with sore throat, abdominal pain, diarrhea, vomiting, icterus, and, with more chronic illness, hepatomegaly and splenomegaly. *Pneumonic tularemia* is the most severe form and results from inhalation of the organism or hematogenous spread of the organism to the lung, with clinical signs such as cough, chest pain, and hemoptysis. Thoracic radiographs can reveal lobar infiltrates, hilar lymphadenopathy, pleural effusion, and miliary infiltrates.[26] Changes resemble those seen in other chronic pneumonias, such as tuberculosis or fungal disease.

FIGURE 56-4 Papule undergoing central necrosis with desquamation on the thigh of a middle-aged man infected with *Francisella tularensis*. (Courtesy of Dr. Joseph A. Bocchini, Louisiana State University Health Sciences Center, Shreveport, LA. In: Mandell GL, Bennett JE, Dolin R, eds. Principles and Practice of Infectious Diseases, 7th ed, Philadelphia, PA: Churchill Livingstone; 2010:2927-2937.)

Although not the most common route of infection for humans, cat-bite–associated tularemia has been described (including among veterinary staff), and cats that live in rural endemic areas are important vectors of the most virulent strain of *F. tularensis*, type A1b.[25] Disease in humans can mimic *Pasteurella multocida* cellulitis, the most common bacterial infection after a cat bite, but treatment with amoxicillin or clavulanic acid–amoxicillin is ineffective. Less commonly, human disease follows cat scratches or casual contact with cats.[27] In some cases, cats had recent contact with or ingested wild rabbits or rodents. Both apparently healthy and sick cats have been involved. Aerosol exposure to organisms on the coats of dogs (such as occurs when dogs shake their coats after contact with infected rabbits) has rarely been suspected in clusters of human disease.[35-37] In summary, tularemia should especially be considered in humans who develop illness in endemic areas within 3 weeks after a bite from a cat that is a stray or that has had a recent history of wild rabbit or rodent contact.

VetBooks.ir

CASE EXAMPLE

Signalment: "Sam," a 5-year-old male neutered domestic shorthair cat from Woodland in northern California

History: Sam was brought to the University of California, Davis, veterinary emergency service for evaluation of fever and inappetence. The owner first noticed he was ill 4 days previously, when he regurgitated a small amount of pink fluid about 1 hour after eating. The following day he was not eating and lethargic, and his water consumption was reduced. On day 3, he was taken to a local veterinary clinic where he was found to be febrile (105°F [40.5°C]), icteric, and had a mass on the left side of his neck. He was treated with enrofloxacin (4.5 mg/kg SC, once), ketoprofen (1.9 mg/kg SC), and clavulanic acid–amoxicillin (12 mg/kg PO q12h). The results of a CBC showed a mild neutrophilia (13,083 cells/μL; reference range, 2500-12,500 cells/μL) with slightly toxic neutrophils and a mild lymphopenia (1176 cells/μL; reference range, 1500-7000 cells/μL). A biochemistry panel showed hyponatremia (133 mEq/L; reference range, 147-156 mEq/L), hypochloremia (99 mEq/L; reference range, 111-125 mEq/L), hypokalemia (3.4 mEq/L; reference range, 3.9-5.3 mEq/L), hyperglycemia (214 mg/dL; reference range, 70-150 mg/dL), hyperbilirubinemia (3.7 mg/dL; reference range, 0-0.4 mg/dL), increased serum CK activity (1858 U/L; reference range, 64-440 U/L), and a mild metabolic acidosis (bicarbonate 12 mEq/L; reference range, 13-25 mEq/L). ELISA serology for FeLV antigen and FIV antibody and IFA serology for FCoV antibody were negative. On receipt of the laboratory test results, the local veterinarian recommended referral.

Sam had been fed commercial dry and canned cat food and was treated monthly with fipronil. He had been acquired at 6 weeks of age, at which time he was neutered. He had been vaccinated annually by the owner for feline respiratory viruses and feline panleukopenia virus, and was vaccinated for rabies for the first time 4 months earlier. He lived with three other cats, three dogs, and two rabbits, and the owner had brought home a wild mouse from the Lake Tahoe (Sierras) region several weeks before Sam became ill. The rabbits were acquired by the owner 6 months ago, were kept indoors, and did not receive flea control. The owner fostered cats and occasionally dogs for the local animal shelter and cared for a colony of feral cats, which did not interact with the household cats. The household cats lived harmoniously indoors.

Physical Examination:

Body Weight: 5.4 kg

General: Lethargic but responsive. Resented handling. T = 105.9°F [41.1°C], RR = 60 breaths/min, HR = 176 beats/min, CRT <2 s.

Integument: Mild scaling was present throughout the haircoat, but no ectoparasites were visible.

Eyes, Ears, Nose, and Throat: No clinically significant abnormalities were present.

Musculoskeletal: Body condition score 6/9. There was a 2 × 2 × 6 cm firm subcutaneous mass alongside the trachea on the left side.

Cardiovascular: There were no murmurs or arrhythmias detected on cardiac auscultation. Pulses were strong and synchronous.

Respiratory: Tachypnea was present with a shallow respiratory pattern. Normal bronchovesicular sounds were present in all lung fields.

Abdominal Palpation: No clinically significant abnormalities were identified. The urinary bladder was palpable but small.

Lymph Nodes: The left mandibular lymph node was enlarged at 2 cm. All other lymph nodes appeared to be within normal limits.

Laboratory Findings:

CBC:

HCT 20.3% (30%-50%)
MCV 42.9 fL (42-53 fL)
MCHC 33.0 g/dL (30-33.5 g/dL)
Reticulocytes 9500 cells/μL (7000-60,000 cells/μL)
WBC 23,120 cells/μL (4500-14,000 cells/μL)
Neutrophils 18,958 cells/μL (2000-9000 cells/μL)
Band neutrophils 3699 cells/μL
Lymphocytes 231 cells/μL (1000-7000 cells/μL)
Monocytes 231 cells/μL (50-600 cells/μL)
Eosinophils 0 cells/μL (150-1100 cells/μL)
Basophils 0 cells/μL (0-50 cells/μL)
Platelets 102,000/μL (180,000-500,000 platelets/μL).

Serum Chemistry Profile:

Anion gap 18 mmol/L (13-27 mmol/L)
Sodium 143 mmol/L (151-158 mmol/L)
Potassium 3.2 mmol/L (3.6-4.9 mmol/L)
Chloride 110 mmol/L (117-126 mmol/L)
Bicarbonate 18 mmol/L (15-21 mmol/L)
Phosphorus 3.0 mg/dL (3.2-6.3 mg/dL)
Calcium 8.8 mg/dL (9.0-10.9 mg/dL)
BUN 15 mg/dL (18-33 mg/dL)
Creatinine 0.8 mg/dL (1.1-2.2 mg/dL)
Glucose 151 mg/dL (63-118 mg/dL)
Total protein 6.6 g/dL (6.6-8.4 g/dL)
Albumin 2.5 g/dL (2.2-4.6 g/dL)
Globulin 4.1 g/dL (2.8-5.4 g/dL)
ALT 30 U/L (27-101 U/L)
AST 39 U/L (17-58 U/L)
ALP 5 U/L (14-71 U/L)
GGT < 3 U/L (0-4 U/L)
Cholesterol 134 mg/dL (89-258 mg/dL)
Total bilirubin 2.1 mg/dL (0-0.2 mg/dL)
Magnesium 2.0 mg/dL (1.5-2.5 mg/dL)
Creatine kinase 586 U/L (73-260 U/L).

Urinalysis: SGr 1.014; pH 8.0, trace protein (SSA), 1+ bilirubin, 2+ hemoprotein, 2+ glucose, rare WBC/HPF, 7-12 RBC/HPF, few lipid droplets.

Imaging Findings:

Thoracic Radiographs and Abdominal Ultrasound: No clinically significant abnormalities were present.

Cervical Ultrasound: There was moderate to severe enlargement of the retropharyngeal lymph nodes bilaterally and of the left mandibular salivary gland.

Microbiologic Testing: Cytologic examination of lymph node aspirates (mandibular and retropharyngeal): A slightly bloody background was admixed with markedly increased numbers of variably degenerate neutrophils. Low numbers of lymphocytes and scattered macrophages are also observed. Interpretation: marked suppurative inflammation.

Continued

VetBooks.ir

Comments: Although no intracellular bacteria were seen, the number of neutrophils and their variably degenerate nature suggested sepsis as the primary differential diagnosis.

Aerobic and anaerobic bacterial culture and susceptibility (lymph node aspirate): No growth.

PCR for *Francisella tularensis* DNA (lymph node aspirate): Negative.

Diagnosis: Severe suppurative lymphadenitis and fever; suspect plague or tularemia.

Treatment: Sam was transferred to isolation, during which time he bit a clinician, and treated with intravenous fluids (lactated Ringer's solution and 20 mEq/L KCl at 15 mL/h IV) and antimicrobial drugs (ampicillin, 20 mg/kg IV q8h and gentamicin, 5 mg/kg IV q24h). Public health officials were contacted. The cat's rectal temperature initially increased to 107°F (41.6°C); dark brown diarrhea was also noted. On the second day of hospitalization, Sam's rectal temperature was 105°F (40.5°C), and by day 3 it had normalized and Sam began to eat. It increased again to 103.9°F (40.0°C) the following day, and the right mandibular and retropharyngeal lymph nodes became palpably enlarged. Subsequently, the cat's rectal temperature normalized, laboratory abnormalities improved, and the lymph nodes decreased in size and were soft on palpation. The cat was discharged with instructions to continue treatment with oral amoxicillin and subcutaneous gentamicin for 7 days, with a recheck planned at that time for an examination and convalescent *Y. pestis* and *F. tularensis* serology. The owner did not bring Sam back for a recheck examination, but a follow-up telephone conversation indicated that Sam had recovered completely.

Comments: A diagnosis of plague or tularemia was never confirmed in this cat, although strongly suspected based on the history of wild rodent and rabbit exposure (with the rodent adopted from a plague endemic region), and the clinical abnormalities that were present. The findings of hyperbilirubinemia, thrombocytopenia, and increased serum CK activity were perhaps more suggestive of tularemia than plague, although hyperbilirubinemia and thrombocytopenia can occur in human plague. The history of antibiotic treatment may have contributed to the negative cytology, culture, and PCR results. Culture was requested on site shortly after admission because plague and tularemia were initially overlooked as likely diagnoses. Once these diseases were considered, an attempt was made to send specimens out to a public health laboratory for additional testing, but this was complicated by concerns that related to the potentially hazardous nature of the specimens. Handling of the cat was limited to as few individuals as possible and was difficult because the cat was aggressive. The clinician who was bitten by the cat immediately saw her physician, who prescribed doxycycline for 7 days. Rabies quarantine was also instituted because the cat was incompletely vaccinated for rabies. The owner was educated about the possibility of plague or tularemia and the implications for human health. Although flea control was used, not all of the animals received flea prevention, and there was significant turnover of a variety of wildlife and domestic animal species in the household. Continued adoption of wild animals by the owner was discouraged.

CHAPTER 57

Bite and Scratch Wound Infections

Jane E. Sykes

VetBooks.ir

Overview of Bacterial Bite Wound Infections

Causes: A variety of aerobic and anaerobic bacteria that include mycoplasmas and mycobacterial species. *Pasteurella* spp. are commonly isolated.

Geographic Distribution: Worldwide

Major Clinical Signs: Fever, lethargy, inappetence, hyperesthesia, puncture wounds, cutaneous swellings, lacerations, tissue avulsions, and signs that relate to damage and/or infection of other structures (such as the thorax, abdomen, and brain and spinal cord)

Differential Diagnoses: Other traumatic injuries, cutaneous neoplasia, sterile nodular panniculitis (dogs), plague, tularemia

Human Health Significance: Cat and dog bite wound infections are common in humans and may be life threatening in the immunocompromised. They also can be associated with transmission of potentially serious bloodborne bacterial diseases such as bartonellosis and tularemia.

Etiology and Epidemiology

Bite wounds are one of the most common reasons that dogs or cats are brought to veterinary hospitals for care. Despite this, there is surprisingly little information available on their epidemiology in comparison to the plethora of publications on animal bite wounds in people (see Public Health Aspects). Bite wounds often result in bacterial infection, but can also result in systemic viral infection (especially in the case of bitten cats), and less often, fungal or bloodborne protozoal infections such as babesiosis (Table 57-1).

Bacterial pathogens that cause bite wound infections are usually members of the normal oral cavity flora of the biting animal species, but organisms in the environment can also contaminate bite or scratch wounds (e.g., *Clostridium tetani*, *Mycobacterium* spp., or *Nocardia* spp.). Bite wounds are instantly contaminated with millions of bacterial species from the oral cavity, but only a small proportion of these species possess virulence properties that allow them to proliferate within the wound and cause disease. The degree to which proliferation occurs also depends on host factors such as underlying immunocompromise. The bacterial species that cause bite wound infections in dogs and cats differ from those that cause dog or cat bite wound infections in human patients, so data from human studies cannot be extrapolated to dog or cat bite wound infections.

Dogs

Bite wounds in dogs most often result from aggressive dog-dog interactions. The dog breeds affected depend on regional variation in dog breed popularity. Younger adult, male dogs and especially intact male dogs appear to be predisposed, but studies that compare affected dogs to a control (or "background") population have not been reported.[1-3] Bite wounds in dogs can also result from the bites of other domestic and wild animal species, but the epidemiology of infections that result from these wounds is not well described.

Approximately 20% of dog-dog bite wounds become *infected*, as opposed to *contaminated*. The likelihood that a wound becomes infected increases with the time lag between the aggressive interaction and when veterinary attention is sought.[2,3] Infection develops 8 to 24 hours after the bite occurs and is less likely to be develop if the wound is limited to the dermis.[3] The distribution of bacterial species involved varies from one study to another and may be influenced by whether infected or only contaminated wounds were evaluated. The most common bacterial species isolated from dog-dog bite wounds are *Staphylococcus pseudintermedius*, *Enterococcus* spp., *Pasteurella* spp., streptococci, and *Escherichia coli*.[1-3] *Staphylococcus aureus* and *Capnocytophaga canimorsus*, which are important pathogens in humans that are bitten by dogs, are rarely isolated from bitten dogs,[2,3] although the prevalence of *C. canimorsus* is probably underestimated because it is very difficult to grow in culture. In the author's hospital, *Pasteurella* spp. accounted for 17% of 41 bacterial species cultured from 33 dog bite wounds, followed by a variety of staphylococci (some methicillin-resistant) (15%), *E. coli* (12%), *Enterococcus* spp. (7%), and *Bacteroides* spp. (7%). Other organisms were *Peptostreptococcus* spp., *Clostridium* spp., and *Pseudomonas aeruginosa* (each 5%); and *Streptococcus viridans*, *Actinomyces* spp., *Acinetobacter* spp., *Serratia marcescens*, *Klebsiella pneumoniae*, *Myroides* spp., *Prevotella* spp., *Fusobacterium* spp., *Aeromonas* spp., *Mycobacterium smegmatis*, and *Mycoplasma* spp. (one isolate each or 2%). Obligate anaerobes were isolated from 5 dogs (15%), and in all 5 of these dogs, multiple bacterial species were isolated.

Cats

Most bite wounds in cats result from aggressive interactions with other cats, but nonfatal dog bite wounds can also occur. Occasionally, cats are bitten by a variety of other small wildlife species that vary geographically based on the local fauna present. In contrast to dogs, which often crush and tear tissues with their teeth, cats deliver deep puncture wounds that create an environment where obligate and facultative anaerobes flourish. Thus, anaerobic bacterial infections are more prevalent in cat bite abscesses than in dog bite wounds, and accordingly, polymicrobial infections are

*The term 'aerobe' refers to facultative anaerobes and obligate aerobes.

present more often in closed cat bite abscesses than in dog bite wounds. In a study of 36 closed cat bite abscesses, 168 bacterial strains were isolated, of which 72% were obligate anaerobes and 28% were facultative anaerobes.[4] The most prevalent anaerobes isolated from cat bite abscesses include *Porphyromonas, Bacteroides, Prevotella, Peptostreptococcus,* and *Fusobacterium*. *Pasteurella multocida,* a commensal of the oral cavity of virtually all cats, is the most common facultative anaerobe present.[4-6] *Porphyromonas* spp. appear to be particularly prevalent; in one study of 15 abscesses in Australian cats, they accounted for 92% to 99% of all the facultative and obligate anaerobes present.[7] Less often *Actinomyces,* β-hemolytic streptococci, lactobacilli, and *Propionibacterium* spp. have been isolated.

Clinical Features

Dogs

Among dogs, dog bite wounds consist of abrasions, lacerations, avulsions (i.e., skin flaps), crushing injuries, and deep puncture wounds (Figure 57-1). Abscesses can also develop. Dog bite wounds may also penetrate body cavities and cause pneumothorax or damage the esophagus, vertebral column, or gastrointestinal tract. Pyothorax or bacterial peritonitis can also occur. Most dogs have between 1 and 5 wounds. Rarely, more than 10 wounds are present.[1-3] The majority of bite wounds occur cranial to the diaphragm, especially on the head and neck (Figure 57-2). The location of the bite wounds also depends on the size of the bitten

FIGURE 57-1 Dog bite wounds. **A,** Multiple puncture wounds, abrasions and lacerations to the abdomen of a 10-year-old female spayed mixed breed dog. A portion of the jejunum had perforated and had herniated into the subcutaneous tissue. The dog developed cardiac arrest after 2 days of aggressive treatment that included surgery and was euthanized. **B,** Five-year-old male neutered Pomeranian dog with a bite wound to the lateral cervical region from a pit-bull terrier dog that resulted in tissue avulsion. **C,** Inguinal region of a 6-year-old intact male German shepherd dog with severe bite wounds and tissue avulsion that resulted in extensive exposure of muscle and bone. The dog had been attacked by four other dogs. The dog survived with aggressive medical treatment and surgery that included amputation of the right pelvic limb. (Courtesy of the University of California, Davis Veterinary Emergency and Critical Care Service.)

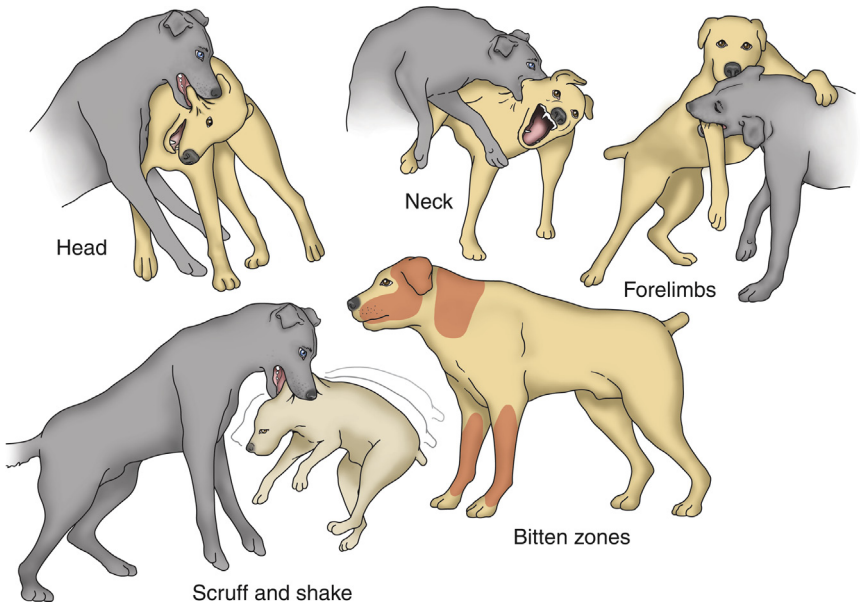

FIGURE 57-2 Common anatomic distribution of dog-to-dog bite and fight wounds.

dog; large-breed dogs are more likely to have wounds on the neck and face, but small-breed dogs often have wounds on their dorsum. Injury to underlying tissue is frequently dramatically more severe than is apparent on the surface. Classification systems have been used to describe the severity of dog-dog bite wounds based on the type of injury (laceration vs. puncture wound) and the presence or absence of dead space or abscessation.[1-3] Abscessation is rarely associated with dog bite wounds as compared with cat bite wounds.[3] The presence of pus, fever, erythema, subcutaneous emphysema, and/or a foul odor suggests that infection has occurred. Uncommonly, hematogenous spread of bacteria leads to signs of severe sepsis or septic shock (see Chapter 86).

Cats

In cats, cat bite wounds may be difficult to identify on the surface, but infection can extend to penetrate bone, joints, tendon and muscle.[5] Cat bite wounds are most often located on the forelimbs, lateral aspect of the face, and near the base of the tail (Figure 57-3).[8] In contrast, scratches are often found on the bridge of the nose, pinna, and inguinal region. Cat bite abscesses are characterized by the presence of firm or fluctuant subcutaneous swellings or masses, with or without fever, lethargy, inappetence, and hyperesthesia. Some cats are brought to the veterinarian solely because of lethargy, and a careful physical examination is required before an abscess or cellulitis is detected. One or more scabs may be found on top of the abscess, or the overlying skin may lack hair and have a gray, necrotic appearance. If the abscess ruptures, cream-colored or red-brown purulent material may be identified on the haircoat, sometimes in association with a foul odor (Figure 57-4). Alternatively, the haircoat may be matted over the site. Lameness may be apparent if the limbs are involved, and especially if there is extension to the bone or a joint. Involvement of the thoracic cavity may be associated with fever, lethargy, tachypnea, and decreased lung sounds due to pyothorax (see Chapter 87). Bite wounds to the calvarium can result in neurologic signs such as circling, disorientation, head pressing, mental obtundation, delayed or absent placing reactions, tetraparesis, anisocoria,

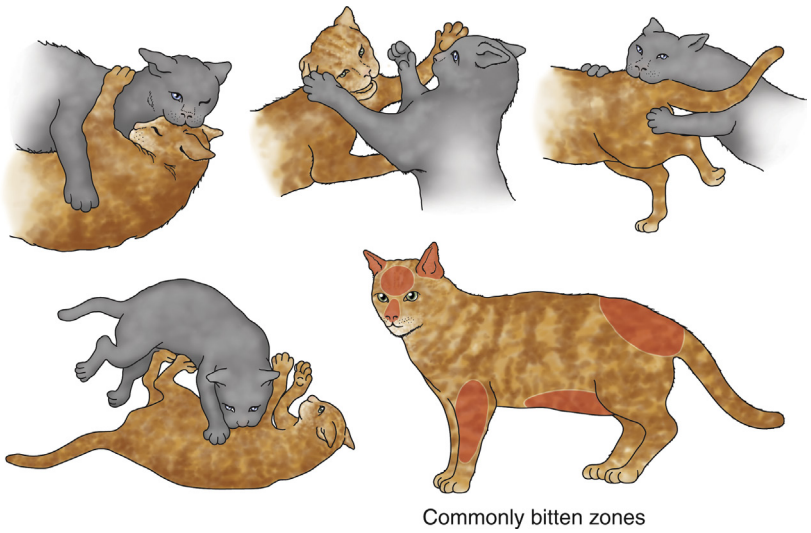

FIGURE 57-3 Common anatomic distribution of cat-to-cat bite and fight wounds ("wound cat"). (Adapted from Malik R, Norris J, White J, et al. "Wound cat." J Feline Med Surg 2006;8:135-140.)

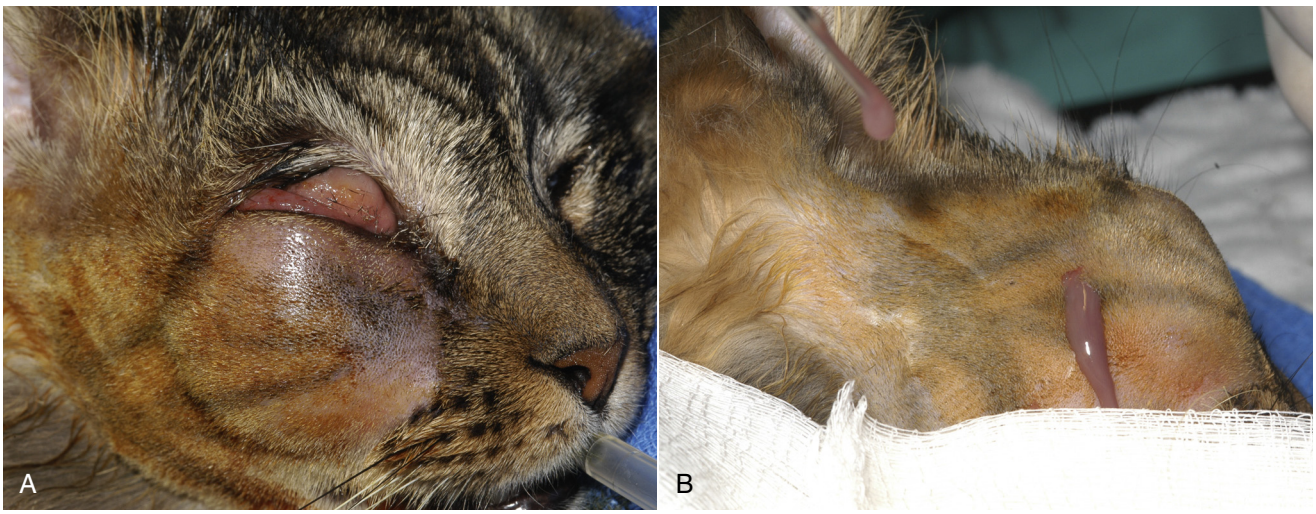

FIGURE 57-4 **A,** Six-year-old female spayed domestic shorthair cat with a cat bite abscess adjacent to the right eye that was associated with marked chemosis and periocular swelling. **B,** Purulent material discharged from the abscess when it was drained surgically. (Images courtesy University of California, Davis Veterinary Ophthalmology service.)

absent menace responses, and seizures.[9] Penetration of the caudal vertebral column and spinal cord can lead to vertebral fractures, osteomyelitis, bacterial meningitis, and signs of pelvic limb paralysis (Figure 57-5). As in dogs, progression to severe sepsis or septic shock can occur, but most cat bite abscesses rupture and resolve spontaneously.

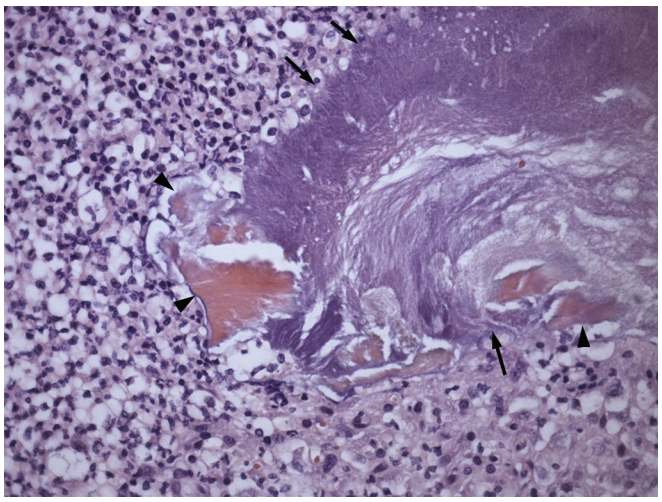

FIGURE 57-5 Histopathology of the vertebral column of a young adult, male domestic shorthair that was found with a bite wound to the base of the tail that drained purulent material and pelvic limb paralysis with absent deep pain sensation. Multiple fractures of caudal vertebrae 4 and 5 were present in association with suppurative osteomyelitis *(arrowheads)*, cellulitis, ascending meningitis, and masses of intralesional bacteria *(arrows)*. Multiple anaerobes were cultured from the lesion. H&E stain.

Cats with dog bite wounds often have life-threatening injuries. Fractures, severe hemorrhage, and hypovolemic shock can dominate the clinical picture. Penetrating injury of cervical structures, the thorax, abdominal organs, brain, or spinal cord can occur (Figure 57-6). Death most often results from trauma rather than infection, but occasionally deep-seated infections or bacteremia develops if the cat survives the initial traumatic episode.

Diagnosis

A diagnosis of bite wound infections is based on history of a fight or bite and physical examination findings that suggest that infection has developed. Cytologic examination of a wound may also assist in diagnosis of infection. The veterinarian should record whether the wound was provoked or unprovoked and note time and location that the wound occurred and the biting animal species involved. Depending on the extent and location of bite wounds, radiographs of the affected region should be considered to assess for underlying damage to bone or body cavities. All cats with cat fight wounds should be tested for FeLV and FIV infection, and the test should be repeated 2 months later because transmission may have occurred at the time of the fight wound (see Chapters 21 and 22).

Laboratory Abnormalities

Laboratory abnormalities in cats or dogs with wound infections are variable and depend on the degree of tissue trauma, the underlying organs involved (if any), and the severity and type of infection. The CBC may show nonregenerative or regenerative anemia, neutrophilia with bandemia, toxic neutrophils,

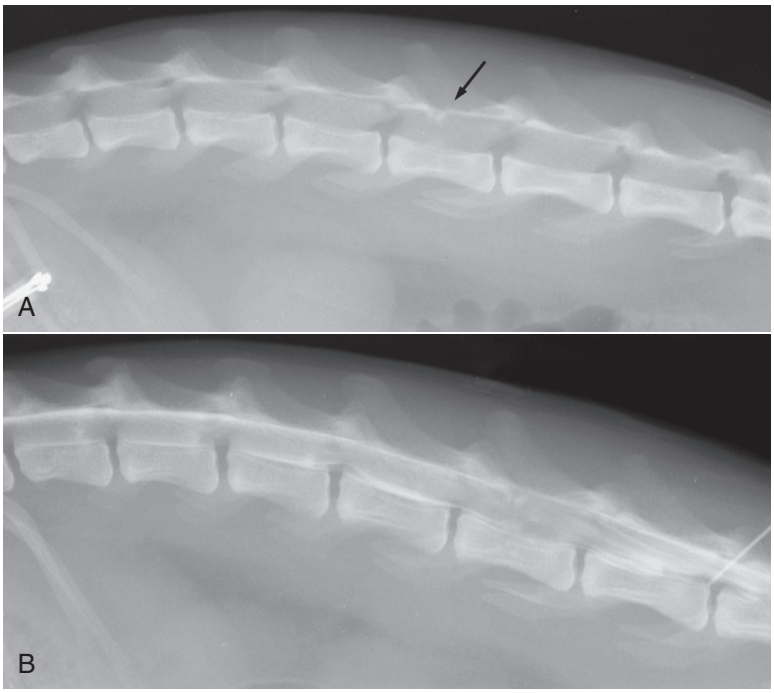

FIGURE 57-6 **A,** Lateral radiograph of the lumbar spine of a 3-year-old female Siamese cat with a dog bite wound to the lumbar spine. The cat was unable to stand and had absent placing reactions in the pelvic limbs. Patellar reflexes were also absent. Two osseous densities are superimposed at the level of the dorsal spinal canal at the level of the fourth lumbar vertebra (L4) *(arrow)*. The dorsoventral view showed deviation of the spinous process of L4 (not shown). CSF analysis revealed mild suppurative inflammation. **B,** Myelogram. A spinal needle is inserted at L5-6 for injection of contrast agent. Spinal cord widening with associated thinning of the contrast column circumferentially is identified over the body of L4. Dorsal deviation and splitting of the ventral contrast column is present over L2-3 as a result of disc protrusion in this region. A decompressive hemilaminectomy over L4 to L6 was performed and a bone fragment was removed; the cat ultimately recovered.

VetBooks.ir

monocytosis, and lymphopenia or lymphocytosis. Animals with severe sepsis or septic shock may be thrombocytopenic. Findings on the chemistry panel include hypoalbuminemia and evidence of muscle damage (increased activities of CK, AST, and sometimes mild increases in serum ALT activity). Increased muscle enzyme activities may be a clue to an underlying cat bite wound in cats with fever of unknown origin. Prolongations of the PT and/or APTT may be present in animals with septic shock and disseminated intravascular coagulation.

Diagnostic Imaging

Plain Radiography

Radiographs of the thorax in dogs or cats with bite wounds may show fractured ribs, pneumothorax, evidence of pulmonary contusions, mediastinal emphysema, diaphragmatic herniation, or pleural effusion due to hemothorax or pyothorax. Abdominal radiographs may show a lack of serosal detail due to hemoabdomen or bacterial peritonitis. Radiographs of the axial or appendicular skeleton may reveal fractures or tooth foreign bodies. In more chronic bite wound infections, evidence of osteomyelitis or septic arthritis may be present, with soft tissue swelling and bony lysis (see also Chapter 85).

Sonographic Findings

Ultrasound of soft tissues can be useful to assess the extent of bite wound infections. Abdominal ultrasound is indicated for animals with bite wounds to the abdomen to assess for evidence of peritonitis or trauma to abdominal organs. Findings in dogs or cats with peritonitis include a hyperechoic mesentery with an irregular outline and free peritoneal fluid, which is typically echogenic (see Chapter 88).

Advanced Imaging

Findings on MRI in cats with brain abscesses secondary to cat bite wounds include space-occupying lesions with well-defined margins that are hyperintense on T2-weighted images, and hypointense T1-weighted images.[9] Marked ring enhancement is usually present. Evidence of brain herniation may be detected.[9]

Cytologic Examination

Cytologic examination of swab or fluid specimens collected from infected wounds typically reveals large numbers of degenerate neutrophils with intracellular bacteria, which may include cocci, rods, or long, filamentous organisms (which are usually anaerobes).

Microbiologic Tests

Isolation and Identification: Dogs

Aerobic bacterial culture and susceptibility and anaerobic bacterial culture are indicated whenever possible from dogs that are suspected to have infected bite wounds. Culture lacks sensitivity for detection of anaerobes, and anaerobic bacterial infections respond predictably to treatment, so anaerobic culture could be considered optional if client finances are limited (see Chapter 37).

The skin around the wound should be clipped and cleaned with chlorhexidine solution, and an aspirate, swab, or devitalized tissue specimen should be collected from as deep within the wound as possible while the animal is sedated or anesthetized. When pockets of purulent material extend subcutaneously away from an open wound, collection of aspirates percutaneously with a needle and syringe can avoid contamination by surface bacteria. Because a positive culture from a wound does not imply infection, results must be interpreted in light of the physical examination and laboratory findings. Susceptibility test results for isolated bacteria can then be used to guide antimicrobial drug treatment. Blood cultures should be considered for dogs with evidence of severe sepsis or septic shock.

Isolation and Identification: Cats

In general, culture of cat bite abscesses in cats is not routinely performed because they almost always respond to drainage with or without systemic antibacterial drug treatment. Cytologic examination and culture are indicated for cat bite abscesses/cellulitis if clinical signs of infection are persistent or recurrent in the face of treatment, or if severe infections that involve underlying bones, joints, or body cavities occur. Culture is also recommended for draining skin lesions in the inguinal region, which may result from infection with rapidly growing mycobacteria (see Chapter 44). Blood cultures are indicated for cats with signs of severe sepsis or septic shock.

Treatment and Prognosis

Surgical Management: Dogs

Dogs with dog bite wounds should be muzzled and the wound(s) covered with a clean, dry bandage immediately after the injury occurs to prevent further contamination of the wound until the animal's condition can be stabilized if necessary. If possible, the dog should then be sedated or anesthetized and a wide area of skin around the wound clipped in order to determine the extent of injury and prepare for surgery. Frequently, this leads to detection of additional full-thickness puncture wounds or lacerations. The skin around the wound should be scrubbed with chlorhexidine or povidone-iodine solution. Full-thickness punctures and lacerations should then be explored, debris and devitalized tissue removed, and specimens collected for culture if infection is suspected. If the abdominal or thoracic cavity has been penetrated, surgical exploration of these cavities is typically required to identify and treat damaged viscera. Wounds should be lavaged extensively with copious quantities of sterile saline or lactated Ringer's solution under moderate pressure (such as using a 60-mL syringe attached to an 18-gauge needle). The use of antibiotics or antiseptics to lavage the wound is not generally recommended, as they can be toxic to tissue and provide minimal benefit for treatment of established wound infections. If used, 0.05% chlorhexidine diacetate (1 part 2% chlorhexidine to 39 parts water) is preferred because it has antibacterial activity in the presence of organic debris, residual antibacterial activity, and minimal systemic absorption and toxicity.

In general, infected wounds that are limited to the subcutaneous tissues and muscle are subsequently managed as open wounds in order to optimize drainage and debridement. Closure of infected wounds can lead to dehiscence and persistence of infection. Whenever possible, the wound is covered with bandages that absorb fluid, reduce dead space, prevent movement and contamination of the wound, and assist in debridement. Hydrophilic bandages are often used for the first 3 to 5 days. Wound closure may be possible for noninfected wounds that are in the "golden period" (first 6 to 8 hours after injury). The reader is referred to small animal surgical texts for additional information on surgical management of bite wound infections and bandaging.[10]

VetBooks.ir

TABLE 57-2

Suitable Antimicrobial Drugs for the Treatment of Bite Wound Infections in Dogs and Cats*

Drug	Species	Dose (mg/kg)	Interval (hours)	Route
Amoxicillin-clavulanic acid	D, C	12.5-20	8-12	PO
Ampicillin-sulbactam	D, C	10-20†	8	IV, IM
Pradofloxacin‡	D	3	24	PO
	C	5-7.5	24	PO
Enrofloxacin	D	5-20	24	IV, IM, PO
Marbofloxacin	D	2.75-5.5	24	PO
Gentamicin	D	9-14	24	IV, IM
Amikacin	D	15-30	24	IV, IM
Metronidazole	D, C	10	8	PO, IV

C, Cat; D, dog.

*Doses of antimicrobial drugs that have activity primarily against gram-negative aerobes are listed for dogs, because isolation of gram-negative aerobes from cat bite abscesses is very rare.

†Dose according to ampicillin component.

‡The pradofloxacin dose for dogs is for the tablet formulation available in Europe. The dose for cats is for the oral suspension. The use of pradofloxacin in dogs may be associated with myelosuppression and is off-label in some countries.

Surgical Management: Cats

As for open dog bite wounds, a wide area of skin around cat bite abscesses should be clipped and scrubbed. The abscess should then be lanced and specimens collected for culture if desired. The abscess cavity should then be lavaged, necrotic tissue debrided, and a placement of a drain should be considered to optimize drainage and prevent early wound closure. Whenever possible, the wound and drain should then be covered with a bandage. The drain is removed in 3 to 5 days. For cats with pyothorax, placement of chest tubes with or without surgical exploration may be required (see Chapter 87). Cats with abscesses that involve the central nervous system have the potential to recover with craniectomy, drainage of purulent material within the abscess, removal of any tooth fragments present, and closure of subcutaneous tissue and the skin.[9]

Antimicrobial Treatment

Contaminated Wounds (First 8 Hours after Injury)

The need for antimicrobial treatment in contaminated, noninfected wounds is controversial, because there is no evidence that it prevents infection of the wound and it may select for infection with bacteria that are resistant to the antimicrobial drug used. Proper wound cleaning and debridement are likely to have the greatest impact on whether infection subsequently develops. Antimicrobial treatment could be considered for deep punctures or large, dirty wounds that require extensive debridement. If deemed necessary, the drug of choice for contaminated wounds is amoxicillin–clavulanic acid, because it has efficacy against most oral cavity commensals of the dog and cat mouth such as *Pasteurella* spp. and a variety of anaerobes, including those that produce β-lactamase enzymes.

Infected Wounds

For severely infected dog bite wounds, initial treatment should consist of parenteral antimicrobial drugs that have activity against gram-negative and gram-positive aerobic and anaerobic bacteria, which includes methicillin-resistant staphylococci (in regions where methicillin-resistant *S. pseudintermedius* is prevalent). Appropriate combinations include ampicillin-sulbactam and an aminoglycoside, or a combination of ampicillin, metronidazole, and an aminoglycoside (Table 57-2). Where methicillin-resistant *S. pseudintermedius* is not prevalent, a fluoroquinolone could be substituted for the aminoglycoside. Subsequent treatment should be based on the results of culture and susceptibility. Amoxicillin-clavulanic acid is the drug of choice for treatment of cat bite abscesses once drainage has been established (although many cat bite abscesses will likely heal with drainage alone). Because *Pasteurella* spp. are not susceptible to clindamycin or first-generation cephalosporins, monotherapy with these drugs should be avoided. Pradofloxacin is also a suitable choice, because it has activity against anaerobes as well as a variety of aerobic bacterial species.

Antimicrobial drug treatment of infected bite wounds that are localized to the skin, subcutaneous tissue, and muscle should continue for 3 to 5 days after signs of infection are no longer evident. The reader is referred to Chapters 85, 87, and 88 for information on the management of osteomyelitis, septic arthritis, pyothorax, and peritonitis.

Rabies Prophylaxis

In regions where rabies occurs, bite wounds may need to be reported to local public health authorities. If the biting animal has an unknown vaccination history, or the bite was from a wild animal that was unavailable for testing, a rabies booster should be administered and the animal monitored for 45 days. If the bitten animal is unvaccinated or has a lapsed vaccination status, additional quarantine or euthanasia may be required (see Chapter 13).

Prognosis

The prognosis for bite wound infections depends on the severity and extent of injury, the immune status of the host, and the organisms involved. Recurrent infections may result from underlying osteomyelitis, foreign bodies, immunodeficiency, or the presence of atypical organisms such as *Mycobacterium* spp., *Nocardia* spp., or *Mycoplasma* spp. (which do not respond to β-lactam drugs). Failure to respond to appropriate treatment should prompt a thorough physical examination; testing for retroviruses in cats; imaging of the affected area; and culture for aerobic and

anaerobic bacteria and mycoplasmas. If the clinical picture is suggestive, culture for mycobacteria may also be indicated.

Prevention

Prevention of bite wounds involves education of pet owners in regard to housing cats indoors and use of secure collars and leashes for walking dogs. Intact male dogs should be neutered if they are not to be used for breeding. Proper handling and socialization of puppies as well as behavior training should be encouraged. Pet owners should be instructed to avoid or closely supervise interactions between their dogs and unfamiliar dogs that are breeds of known aggressive tendency, such as American pit bull terriers, Rottweilers, German shepherds, blue heelers, chow chows, and Jack Russell terriers. Special caution is warranted for small-breed dogs, which may provoke larger breed dogs and are more likely to develop life-threatening injuries. Dogs that are unfamiliar with one another or dogs with a history of fighting with one another should never be left together without proper supervision.

Public Health Aspects

Epidemiology of Dog and Cat Bite Wounds

In 2012, the American Pet Products Association estimated that there are 78.2 million owned dogs and 86.4 million owned cats in the United States, and that 39% of households own at least one dog and 33% own at least one cat.[11] In the United Kingdom, around 22% of households own a dog and 18% own a cat.[12] German shepherds, Rottweilers, and Jack Russell terriers are among the top 10 dog breeds owned. Dog and cat bite wounds account for approximately 1% of emergency department visits by humans in the United States, and similar numbers are reported in Europe. Dog bites accounted for more than 70% and cat bites accounted for 13% of animal bite visits to emergency rooms in New York City.[13] The median age of bitten people in one study was 15 years, and in another study it was 28 years.[14,15] Many bites occur in children, especially boys aged 5 to 9 years.[16] Children often have dog bites to the face, neck, and head. Women and the elderly are at risk for cat bite injuries. Patients who seek medical attention more than 8 hours after injury usually have infected wounds.

Dog Bite Infections

Between 3% and 20% of dog bite wounds in humans become infected.[17,18] The infecting organisms generally reflect the flora of the canine oral cavity, but may also derive from the environment or the bitten person's skin or oral cavity. Many infections are polymicrobial, but the organism that most often contributes to dog bite wound infections is *Pasteurella* spp., which is found in 50% of wounds (Table 57-3).[14,19-27] The most common species is *P. canis,* but *P. multocida* (subspecies *multocida, septica,* and *gallicida*), *P. stomatis,* and *P. dagmatis* may also be present. Other common isolates from dog bite wounds include streptococci (especially the α-streptococcus *S. mitis* and *S. pyogenes; S. canis* is rarely isolated), staphylococci, *Corynebacterium* spp., *Neisseria* spp., and anaerobes.[19] Of the staphylococci, *S. aureus* is isolated most often (20% of infections). Infections with *S. pseudintermedius* occur rarely. Anaerobes are present in approximately 70% of infections and are almost always present in combination with other anaerobes and aerobic bacteria.

Cat Bite Infections

Although cat bite wounds are less traumatic to tissue, they are more likely to become infected and progress to infection more rapidly than dog bite wounds.[14] The upper extremities are often affected. As in dog bite wounds, *Pasteurella* spp. are the most common organisms isolated and are present in 75% of wounds.[14,19] The predominant species are *P. multocida* subsp. *multocida* and *P. multocida* subsp. *septica*. Streptococci (including *S. pyogenes*) and staphylococci are also often present, but *S. aureus* is isolated less frequently from cat bite wounds than dog bite wounds. *Neisseria* and *Moraxella* are also often isolated from cat bite wounds (see Table 57-3). The prevalence of infection with anaerobes in cat bite wounds is similar to that in dog bite wounds.[14]

Clinical Manifestations

Infection of bite wounds in humans most often results in localized cellulitis, pain, purulent discharge, a black to gray appearance, and, less often, fever and local lymphadenopathy. Extension to underlying bones or joints can lead to osteomyelitis or septic arthritis, which is especially likely to occur after penetrating cat bite wounds to the hand (Figure 57-7). Rarely, necrotizing fasciitis, bacteremia, meningitis, endocarditis, peritonitis, or brain abscesses develop.[19,28]

Most of the serious consequences of dog or cat bite wound infections occur in immunocompromised humans and involve *P. multocida* or *Capnocytophaga canimorsus*. Severe disease manifestations have also occurred after exposure of wounds to dog or cat saliva through licking, or after invasive medical supplies (such as dialysis tubing) were chewed or licked by a pet.[29] In a few cases, patients have had a history of contact with animals but no known bite or scratch wound.[30-32] Life-threatening infections with *P. multocida* tend to occur in infants, pregnant women with animal contact, patients on chronic glucocorticoid therapy, HIV-infected people, organ-transplant recipients, and patients with chronic liver disease.[28]

Capnocytophaga canimorsus is a capnophilic (carbon dioxide–loving), facultatively anaerobic, filamentous gram-negative bacterial rod that is commonly found in the oral cavity of dogs and cats.[33] Although rarely reported as a cause of illness in dogs or cats, this organism can cause cellulitis, gangrene, bacteremia, meningitis, and endocarditis in humans.[28,33] *C. canimorsus* bacteremia is rare, but humans who are immunocompromised, especially those with chronic alcoholism, cirrhosis, or a history of splenectomy, are at risk for life-threatening *C. canimorsus* infections that progress rapidly, with a mortality of 31%. The virulence factors that contribute to these severe infections are not well understood. The organism does not cause endotoxemia but appears to evade recognition by the immune system and resist phagocytosis.[28] In one series of humans with *C. canimorsus* sepsis, 56% of cases followed a dog bite and 10% of cases followed exposure of a wound to dog saliva by licking.[34] Veterinarians have also developed corneal infections with *C. canimorsus* when dog tooth fragments have struck them in the eye during dental extractions.[35,36] Most affected humans are older than 40 years of age. Clinical manifestations of *C. canimorsus* sepsis include fever, myalgia, and a petechial rash that involves the skin and mucous membranes, which may progress from purpura *(purpura fulminans)* to gangrene over a period of several days. Because *C. canimorsus* is very difficult to grow, early diagnosis and successful treatment require clinical suspicion and early treatment with effective antimicrobial drugs, such as β-lactam/β-lactamase inhibitor combinations, which are also active against *Pasteurella* spp.

Prevention

Veterinarians play an important role in educating the public about prevention of cat and dog bite wounds. Provision of information to clients who intend to purchase a new dog about dog breeds, puppy socialization, dog behavior training, and how to prevent and manage aggression and avoid bites or scratches (to themselves and to others) is encouraged. Veterinarians can also engage in community activities (especially in schools) where young children can be educated about pet ownership and how to avoid wounds and wound infections from their own or someone else's dog or cat. Immunocompromised individuals should be educated about the potential benefits and risks of pet ownership and precautions that can be taken to minimize infections. Finally, care should be taken in the veterinary practice situation to avoid bites or scratches to veterinary staff. Veterinary staff should be educated about the types of infections that can occur in the workplace; likelihood of these infections; risk factors for infection; appropriate preventative measures; and protocols to follow should a bite or scratch wound occur (see General Animal Handling Precautions, Chapter 11). Routine hand-washing practices should be enforced, and licking by dogs or cats should be discouraged. Face protection should be worn by veterinary staff when dental procedures are performed. Bites and scratches may need to be reported to public health authorities, and all staff should be educated about the need to ensure that tetanus and rabies immunizations are not overdue.

CASE EXAMPLE

Signalment: "Murphy", a 5-year-old intact male boxer dog from Vacaville in northern California

History: Murphy was evaluated by the University of California, Davis, veterinary emergency service for dog bite injuries after a fight with another dog in the household. The owner had returned home a few hours earlier to find Murphy bleeding from the neck. The other dog, a 5-year-old male neutered boxer mix, was found hiding and unable to stand with several "scratches" on his body. Murphy had a history of fights with other dogs. Both dogs in the household were fully vaccinated for canine distemper virus, parvovirus, adenovirus, and rabies. There was no other pertinent medical history.

Initial Physical Examination:

Body Weight: 46.2 kg.

General: Quiet, alert, responsive and hydrated. T = 102.1°F (38.9°C), HR = 110, panting, pink and moist mucous membranes, CRT = 1 s.

Integument: The haircoat was full, thick, and dirty. There was a 1-cm superficial laceration on the ventral aspect of the pinna, and approximately 10 puncture wounds on the left ventral cervical region. A 2-cm superficial laceration was present at the cranial aspect of the dorsal midline, and a 5-cm superficial laceration was present on the left flank. No ectoparasites were seen.

Eyes, Ears, Nose, and Throat: Bilateral conjunctival hyperemia and a mucoid ocular discharge were present. No other significant abnormalities were noted.

Musculoskeletal: BCS 6/9, ambulatory.

Cardiovascular, Respiratory, Gastrointestinal, Genitourinary, Lymph Nodes, and Neurologic: No clinically significant abnormalities were detected. Cranial nerve examination was unremarkable. A full neurologic examination was not performed.

Initial Treatment: Murphy was sedated with hydromorphone and dexmedetomidine. The left neck was clipped with a no. 40 clipper blade from the midpoint of the dorsal aspect of the head to the ventral aspect of the left ear and the thorax. The skin was cleaned with 0.05% chlorhexidine solution, and all puncture sites were probed and flushed with sterile saline. The sites were found to be relatively superficial. Drain sites were created with a no. 11 scalpel blade for three wounds, and a 3 × 0.75 inch Penrose drain was placed across a wound site that had the greatest amount of dead space and secured with a single interrupted suture. The dog was sent home with instructions for the owner to administer amoxicillin-clavulanic acid (16 mg/kg PO q12h) and tramadol (2.4 mg/kg PO q8-12h), to monitor the wound for development of excessive discharge, bleeding, swelling, or redness, and to keep the area clean with a washcloth soaked in warm water. Instructions were provided to return in 3 days to have the wound reevaluated and the drain removed.

The owners returned 7 days later for drain removal. At that time, they reported that Murphy had been eating normally, but had been drinking more than usual. His activity level had been normal, but they believed his neck was had become swollen and tender. They had been administering the medications as directed.

Continued

VetBooks.ir

Physical Examination (Day 7):

Body Weight: 46.2 kg.

General: Quiet, alert, responsive, and hydrated but anxious. T = 103.1°F (39.5°C), HR = 114, RR = 36, pink and moist mucous membranes, CRT 1 s.

Integument: There were marked crusts and scabs on the left lateral and ventral aspect of the neck. The Penrose drain was present with minimal amounts of discharge. Serous to purulent discharge was draining from the ventral puncture wounds. There was moderate crusting of the dorsal aspect of the left pinna.

Other Systems: No change from the previous examination.

Treatment (Day 7): The dog was again sedated and purulent material was collected for culture and susceptibility. The eschars were gently removed with forceps and the skin scrubbed with 0.05% chlorhexidine and water. Ultrasound of the neck region revealed pockets of hypoechoic material beneath the skin, and surgical debridement of the area under general anesthesia was recommended. Subsequently Murphy was anesthetized and the wound was explored. No abscesses were found. The devitalized tissue was excised, the wounds flushed vigorously, and two Penrose drains were placed. The neck was bandaged initially, but this interfered with the dog's ability to breathe comfortably, so the bandage was removed. The dog was hospitalized overnight and treated with hydromorphone (0.05 mg/kg, IV, q4h) and warm compresses to the neck (q6h for 5 minutes). He was then sent home with instructions to administer tramadol as previously prescribed, clindamycin (20 mg/kg PO q12h), and enrofloxacin (10 mg/kg PO q24h), and to warm compress the neck every 4 to 6 hours for the next 3 days. They were also instructed to return in 3 to 5 days for reevaluation and drain removal.

Microbiologic Testing:

Direct Smear and Gram Stain: Rare numbers of gram-positive cocci.

Aerobic and Anaerobic Culture and Susceptibility (Swab from Wound): Isolate 1: Methicillin-resistant *Staphylococcus aureus,* resistant to all β-lactams and clindamycin; susceptible to amikacin (≤4 µg/mL), chloramphenicol (8 µg/mL), doxycycline (≤2 µg/mL), enrofloxacin (≤0.25 µg/mL), gentamicin (≤1 µg/mL), marbofloxacin (≤0.25 µg/mL), rifampin (≤1 µg/mL), and trimethoprim-sulfamethoxazole (≤0.50 µg/mL).

Isolate 2: *Enterococcus faecium* (intrinsic resistance to low-level aminoglycosides, cephalosporins, clindamycin, fluoroquinolones, trimethoprim-sulfamethoxazole), resistant to chloramphenicol and rifampin. Intermediate susceptibility to doxycycline (8 µg/mL), erythromycin (1 µg/mL), ticarcillin (64 µg/mL), and ticarcillin-clavulanate (64 µg/mL). Susceptible to ampicillin (1 µg/mL), clavulanic acid–amoxicillin (≤4 µg/mL), penicillin (4 µg/mL), and imipenem (≤1 µg/mL).

Isolate 3: *Pseudomonas aeruginosa,* resistant to ampicillin, amoxicillin-clavulanic acid, all cephalosporins tested, chloramphenicol, and doxycycline. Susceptibility to clindamycin was not reported because this species is usually resistant. Susceptible only to amikacin (≤4 µg/mL), gentamicin (2 µg/mL), enrofloxacin (0.50 µg/mL), imipenem (≤1 µg/mL), ticarcillin (16 µg/mL), ticarcillin–clavulanic acid (16 µg/mL). The MICs for trimethoprim-sulfamethoxazole and marbofloxacin were 2 µg/mL and ≤0.25 µg/mL, respectively.

Anaerobic culture: Moderate numbers of mixed growth that included *Bacteroides ureolyticus* group (β-lactamase negative), *Peptostreptococcus anaerobius,* and *Bacteroides* spp./*Prevotella* spp. (β-lactamase negative).

Diagnosis: Polymicrobial bite wound infection with anaerobes and multiple drug-resistant aerobic gram-positive and gram-negative bacteria.

Outcome: On receipt of the culture and susceptibility test results, the clindamycin was substituted with amoxicillin-clavulanic acid (16 mg/kg PO q12h). Treatment with enrofloxacin was continued and the owners were educated in regard to the public health significance of the infection and the need to wear gloves when handling the wound and for scrupulous hand-washing practices. The dog returned 4 days after surgery for drain removal. The owners reported that the drains had been producing considerable amounts of purulent material and that Murphy was doing well. He was afebrile and the wound was unchanged in appearance. He was again sedated, the area was scrubbed, and crusts were removed. The drains were removed. Murphy recovered uneventfully and the sutures were removed 10 days later at a local veterinary clinic. Five months later he was seen again for multiple bite wounds to the thoracic limbs and right thorax.

Comments: In this dog, bite wound injuries were complicated by infection with multiple gram-negative and gram-positive drug-resistant aerobic bacteria as well as anaerobes. The *S. aureus* and *P. aeruginosa* were resistant to amoxicillin-clavulanic acid, which had been used to prevent infection when the dog was first seen. In contrast, the anaerobes and the *E. faecium* were susceptible to amoxicillin-clavulanic acid, but presumably were able to proliferate and persist in the face of antimicrobial drug treatment as a result of the presence of the other drug-resistant bacteria, purulent material, and dead space. Bite wounds to the neck can be a challenge to manage because of the mobility of this area, which contributes to the maintenance of the dead space. The use of a bandage can reduce dead space, avoid further contamination, and reduce exposure to multidrug-resistant bacteria, but attempts to bandage the wound were not tolerated by this dog. Client education was an important part of management. The owners were instructed to separate the dogs when unattended to avoid further fights. Neutering may also have been of benefit.

SECTION 3

Fungal and Algal Diseases

CHAPTER 58

Dermatophytosis

Jane E. Sykes and Catherine A. Outerbridge

Overview of Dermatophytosis

First Described: Dermatophytosis was described independently by several scientists in the 1830s and 1840s,[1] but probable descriptions of ringworm date back to ancient Greek times. Dermatophytes were more fully characterized in the early 1900s by Sabouraud.[2]

Causes: *Microsporum* and *Trichophyton* species (especially *Microsporum canis, Microsporum gypseum,* and *Trichophyton mentagrophytes*) (teleomorph name, *Arthroderma* spp.)

Geographic Distribution: Worldwide, especially warm and humid climates

Mode of Transmission: Direct contact with other infected hosts, fomite transmission

Major Clinical Signs: Cutaneous lesions include alopecia, erythema, crusting and scaling, and sometimes nodular or draining lesions (kerions and dermatophytic mycetomas).

Differential Diagnoses: Alopecic lesions must be differentiated from self-traumatic alopecia secondary to allergic dermatitis, sarcoptic mange, or demodicosis. If scale and crusting are also present, bacterial folliculitis, superficial pyoderma, and pemphigus foliaceus are differential diagnoses. Nodular lesions must be differentiated from eosinophilic granuloma, feline acne (cats), and mast cell tumors (dogs).

Human Health Significance: Dermatophytosis is a zoonosis. Young children and the immunocompromised can develop extensive cutaneous lesions.

Etiology and Epidemiology

Dermatophytosis (ringworm or tinea) is a superficial cutaneous infection with one or more of the keratinophilic fungi that belong to the genera *Microsporum*, *Trichophyton*, or *Epidermophyton*. Transmission of dermatophytes occurs by close contact with other infected animals or through contact with contaminated fomites (which includes the haircoats of animals and arthropods such as fleas or houseflies). Dermatophyte spores survive more than a year in the environment under optimal conditions of temperature and humidity, and they resist most routinely used hospital disinfectants, which facilitates transmission. Dermatophytes are somewhat host species specific and are classified as *geophilic*, *zoophilic*, or *anthropophilic* (Table 58-1).[3-8] Geophilic dermatophytes are soil saprophytes. The most common geophilic dermatophyte that infects dogs or cats is *Microsporum gypseum*, which is most prevalent in warm, humid tropical and subtropical environments. Zoophilic dermatophytes are adapted to animal hosts and are rarely found in soil. The most common zoophilic dermatophyte that infects dogs and especially cats is *Microsporum canis*; this organism accounts for more than 90% of dermatophyte isolates from cats worldwide and more than 60% of isolates from dogs.[3,9,10] Sylvatic dermatophytes are zoophilic dermatophytes that are adapted to rodents or hedgehogs. The most common sylvatic dermatophyte that infects dogs and cats is *Trichophyton mentagrophytes*. Anthropophilic dermatophytes are adapted to human hosts and do not survive in the soil; they include *Microsporum audouinii*, *Trichophyton tonsurans*, *Trichophyton rubrum*, and *Epidermophyton floccosum*. Rarely, these species infect or contaminate dogs or cats that have a history of close contact with infected humans.[4,11-16] Mixed infections with multiple dermatophyte species occur rarely in dogs.[10]

Risk factors for dermatophytosis in dogs and cats include young age and concurrent immunosuppressive disorders, especially endogenous or iatrogenic hyperadrenocorticism. Dermatophytosis is more common in cats than in dogs, but the prevalence varies with geographic location. Positive dermatophyte cultures occurred in 6% of submissions from dogs or cats in the southern United States (3.8% for dogs and 14.9% for cats),[17] and in the United Kingdom, 16% were positive (10% for dogs and 16% for cats).[9] Higher prevalences of detection (19% to 43%) have been reported in some studies

TABLE 58-1

Zoophilic and Geophilic Dermatophyte Species Reported to Infect Dogs and/or Cats[3-8]

Dermatophyte Species	Classification	Primary Reservoir	Species Affected	Geographic Distribution
Microsporum canis	Zoophilic	Cats, dogs, horses	All mammals	Temperate and tropical locations worldwide
Microsporum gypseum	Geophilic	Soil	All mammals	Worldwide
*Microsporum persicolor**	Zoophilic	Voles, field mice	Dogs, cats	Europe
Trichophyton mentagrophytes	Zoophilic	Rodents	All mammals	Worldwide
Trichophyton erinacei	Zoophilic	Hedgehogs	Dogs	Europe and New Zealand
Trichophyton simii	Zoophilic	Primates	Dogs, cats	India and the Far East
*Trichophyton terrestre**	Geophilic	Soil	All mammals	Worldwide

*Do not invade hair; the role of *T. terrestre* in disease causation is controversial.

of cats and dogs, with and without skin lesions, from parts of continental Europe.[3,5,10] Dermatophytosis (especially geophilic dermatophytosis) is more prevalent in regions with high warmth and humidity. Shelter cats, the vast majority of which lack skin lesions, are more likely to carry dermatophytes on their haircoats than healthy pet cats. Dermatophytes were cultured from 5.5% and 19% of all shelter cats depending on geographical region,[18,19] whereas the prevalence of *M. canis* isolation from healthy pet cats is generally less than 2.5%.[18] Animals admitted to breeding or boarding facilities that have a history of dermatophytosis are also at risk of infection, whereas dermatophytes are generally not detectable on the haircoats of animals in facilities without a history of infection.[20] Retrovirus-infected cats are no more likely to carry dermatophytes than retrovirus-negative cats,[21] but retrovirus-infected cats carry a greater range of species and may be more likely to develop skin lesions (dermatophytosis). Genetic factors may also be important. Persian and Himalayan cats and Yorkshire and Jack Russell terriers appear to be predisposed to dermatophytosis.[3,9,17] In particular, Persian cats are thought to be at greater risk for development of dermatophytic mycetomas (see Clinical Features). Dogs that hunt and burrow in soil may be at increased risk for infection by geophilic or sylvatic dermatophytes, which may explain the common distribution of lesions on the face and distal thoracic limbs for these dermatophyte species (Figure 58-1).

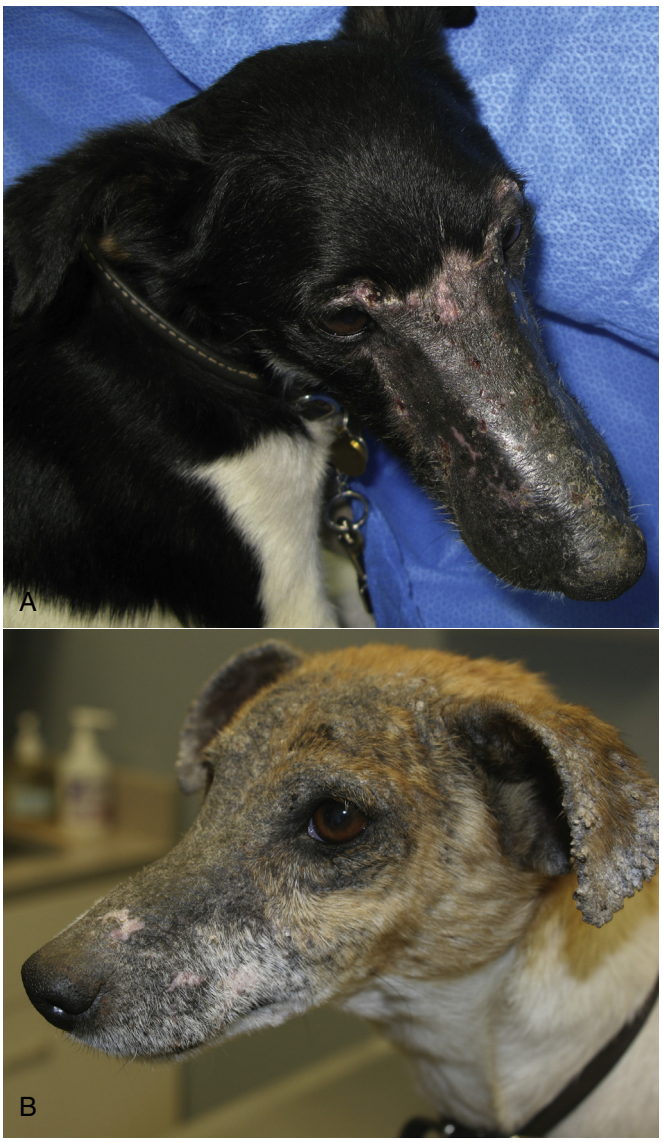

FIGURE 58-1 Chronic *Trichophyton mentagrophytes* infections. There is alopecia, crusting, hyperpigmentation, and ulceration of the muzzle and periocular skin. **A,** Four-and-a-half-year-old male neutered fox terrier. **B,** Six-year-old female spayed Jack Russell terrier. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

Clinical Features

Signs and Their Pathogenesis

Pathogenic dermatophytes invade keratinized tissue that has been macerated or traumatized. Infections are localized to the stratum corneum, hair shafts, and claws. The clinical expression of the disease is affected by the fungal species and strain involved and the host response to infection.[22] Infectious arthrospores, which are formed by the segmentation and fragmentation of fungal hyphae, adhere to the surfaces of skin and nails, germinate, and secrete proteases. These proteases, such as subtilisins, fungalysins, and a variety of acidic proteases,[22,23] digest keratin into short peptides or amino acids, which are then used by the fungus as a source of nutrition. The pattern of proteases secreted by different dermatophyte strains may influence the clinical expression of disease. On the host, dermatophytes reproduce asexually through production of conidia.

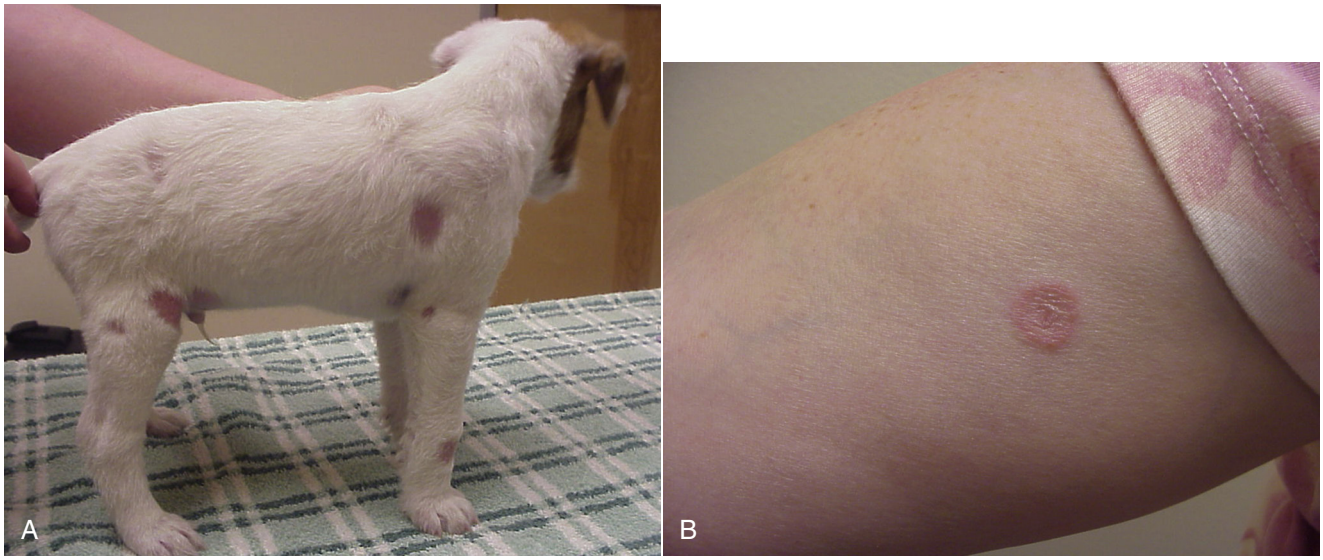

FIGURE 58-2 **A,** Jack Russell terrier puppy with multifocal classic well-circumscribed lesions caused by infection by *Microsporum canis.* **B,** On questioning, the owner of the affected litter of puppies revealed that she also had a lesion on her arm. (Courtesy Dr. Terry Nagle.)

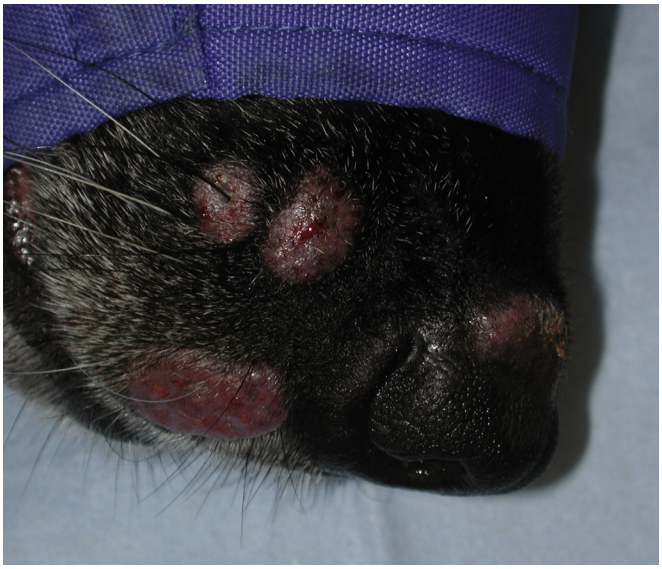

FIGURE 58-3 Nine-year-old female spayed labrador retriever with multiple kerions on the muzzle due to *Microsporum canis* infection. Another dog in the household had similar lesions that were less severe. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

Dermatophyte lesions form after an incubation period of 1 to 3 weeks. Classically, lesions are single or multiple and consist of circular regions of alopecia with an erythematous margin, superficial scale and crust, and follicular papules and pustules (Figure 58-2). Central healing may occur, sometimes with hyperpigmentation or hair regrowth in the center of the lesion. Pruritis is variable. Infection by *T. mentagrophytes* in dogs can result in progressive alopecia, with dramatic scaling and/or crusting and inflammation and in some cases scarring (see Figure 58-1). A *kerion* or *kerion reaction* (also known as nodular dermatophytosis) is a localized, nodular inflammatory lesion that results from dermatophyte infection and may be associated with infection by *M. gypseum, T. mentagrophytes,* or *M. canis* (Figure 58-3).[10,24,25]

Longhaired cats may develop a poor haircoat, shed excessively, and vomit hairballs more frequently, because infected hair shafts are friable and prone to breakage. Persian and Himalayan cats (and very rarely, domestic longhair cats and dogs) with *M. canis* infections can develop dermatophytic mycetomas, which are coalescing subcutaneous nodular lesions that often drain purulent fluid (Figure 58-4).[26-31] These develop when dermatophytes invade the dermis and subcutaneous tissues, presumably after traumatic implantation of fungal organisms from the haircoat of an already colonized or infected animal. These lesions have also been referred to as granulomatous dermatitis, Majocchi's granuloma, or "pseudomycetomas," although use of the last term was not recommended by the International Society for Human and Animal Mycology (ISHAM) committee for nomenclature of fungal diseases.[32] In contrast to true mycetomas (eumycetomas), dermatophytic mycetomas are not caused by soil saprophytes, and lesions are often multiple and coalescing, rather than single and localized.[10]

Physical Examination Findings

In dogs, dermatophytosis can occur anywhere on the body but most often occurs on the face, distal limbs, and tail. Dogs are more likely than cats to present with classical, localized, well-circumscribed lesions. Claw infection is manifested by erythema and thickening of the ungual fold, deformity and friability of the claw, and sometimes footpad involvement (Figure 58-5). Kerions most commonly develop on the muzzle or distal limbs, and with digital pressure they typically have a boggy or exudative appearance (see Figure 58-4).

Lesions in cats are extremely pleomorphic and can consist of one or more areas of partial alopecia with scale and crusts, especially on the pinnae and pinnal margins, nasal bridge, distal limbs, or tail (Figure 58-6). Some lesions resemble miliary dermatitis or are focal, pruritic lesions that resemble eosinophilic plaques. Cats with dermatophytic mycetomas have focal (and rarely disseminated) nodular, sometimes ulcerated cutaneous lesions, usually on the dorsum or neck, which may drain serous or purulent fluid (see Figure 58-4).

Diagnosis

Diagnosis of dermatophytosis is based on clinical suspicion together with the results of Wood's lamp examination, skin and hair cytology, skin scrapings (to evaluate for demodicosis), and/or fungal culture (Table 58-2). In both dogs and cats, lesions are rarely symmetric. This asymmetry can help differentiate dermatophytosis from other diagnoses that more commonly cause symmetrical lesions. However, diagnosis that is solely based on the appearance of lesions and/or Wood's lamp examination is not recommended, because it can lead to misdiagnosis and unnecessary treatment that may be expensive and even harmful. In addition, mixed processes can occur, such as co-infections with dermatophytes and staphylococci or dermatophytes and *Demodex* mites. Because dermatophytosis can take on a wide range of appearances in cats, it should be considered a possible differential diagnosis in cats with *any* skin disease.[33]

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

The results of routine laboratory testing in dogs and cats with dermatophytosis are typically unremarkable or show abnormalities associated with predisposing disease conditions (such as hyperadrenocorticism).

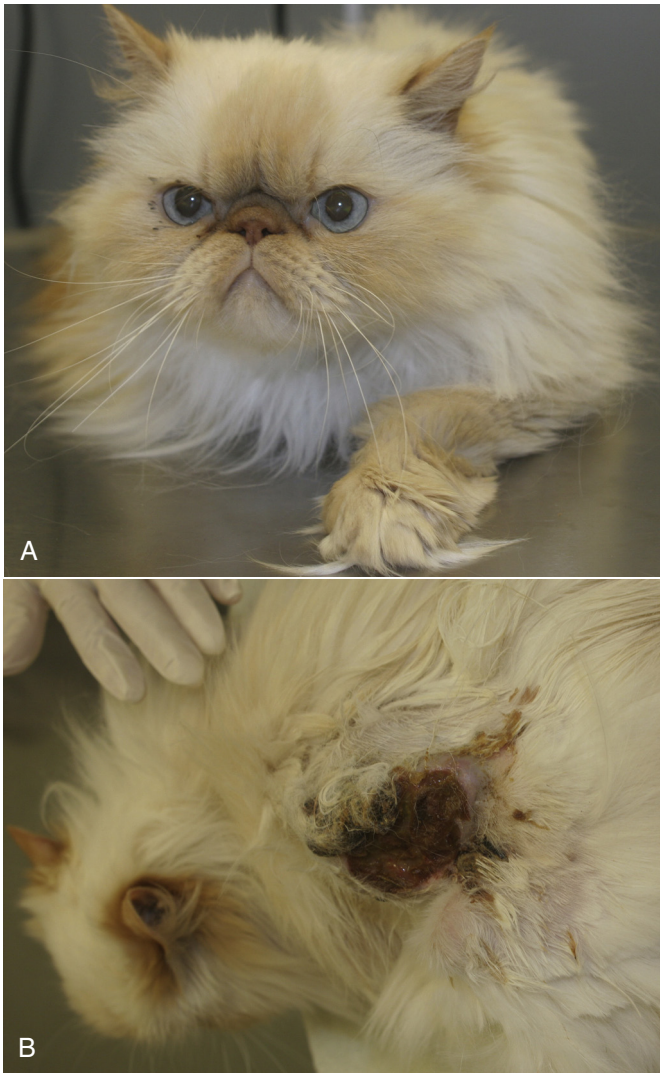

FIGURE 58-4 **A** and **B,** Twelve-year-old female spayed Himalayan with a dermatophytic mycetoma. Ulceration and fistulation are present. Ultimately, surgical excision of the mycetoma was required. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

Microbiologic Tests

Wood's Lamp Examination

A positive Wood's lamp examination is characterized by the presence of apple-green fluorescence along the length of a hair shaft (Figure 58-7). The fluorescence results from tryptophan metabolites produced by some *M. canis* strains when they grow within the hair shaft; the metabolite is not produced when the organism grows on scale or the claw. A significant proportion of *M. canis* infections do not fluoresce,[3,9] and other dermatophyte species of veterinary significance do not produce fluorescent metabolites, so the sensitivity of Wood's lamp examination is low. The lamp should be allowed to warm up for several minutes before it is used, and the lights should be turned off during the examination. False-positive results can occur if topical ointments, scale, lint, keratinized debris, or sebum are present and incorrectly interpreted as dermatophyte fluorescence. Hairs that fluoresce can be plucked and submitted for cytologic examination and fungal culture.

Cytologic Examination

Cytologic examination of hairs plucked from lesions or the circumference of lesions may reveal fungal hyphae or chains of arthroconidia (ectothrix spores) in some affected animals; macroconidia, which form in culture, are not seen (Figure 58-8). Addition of a clearing agent such as 10% or 20% potassium hydroxide (KOH) or chlorphenolac is recommended, which removes scale and debris that can interfere with organism identification. Potassium hydroxide solutions must be gently heated with the hair for 10 minutes for clearing to occur, or incubated

FIGURE 58-5 Foot of a 9-year-old intact male terrier mix with dermatophytosis caused by *Microsporum gypseum*. The dog competed in rodent hunting events that occurred in underground tunnels. Severe, chronic dermatitis with ulceration and alopecia that involved multiple distal limbs and claws was present. The claws were irregular and discolored. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

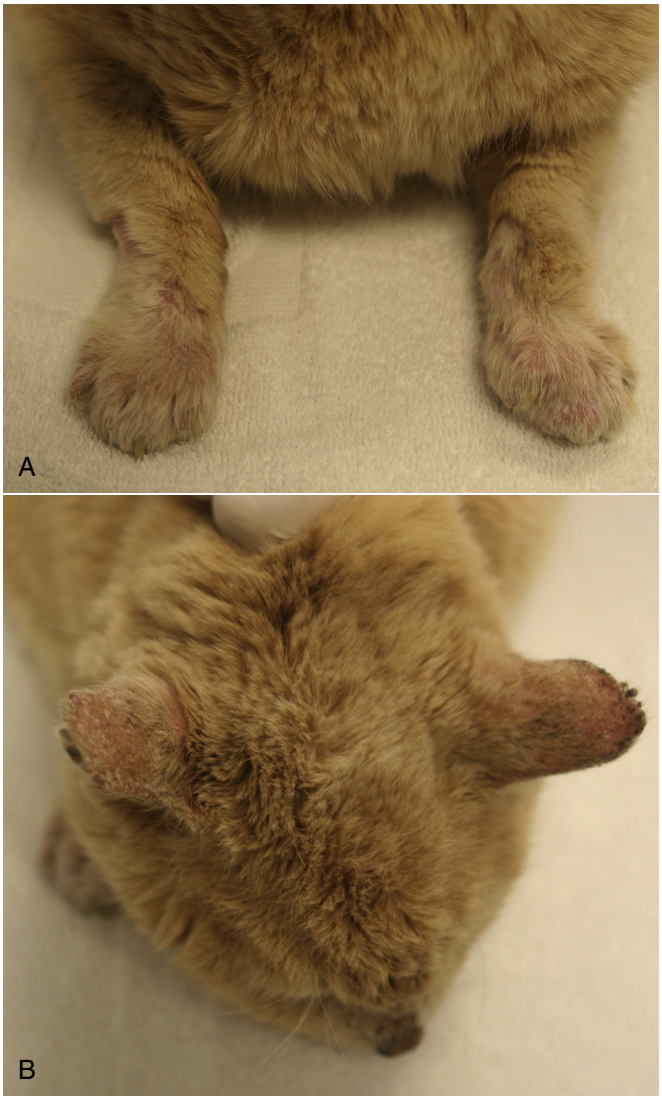

FIGURE 58-6 Eighteen-year-old male neutered domestic shorthair cat with dermatophytosis caused by *Trichophyton mentagrophytes*. The paws **(A)**, pinnae **(B)**, and nasal bridge were involved. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

overnight at room temperature. Chlorphenolac, which is composed of chloral hydrate, phenol, and lactic acid, is not readily available and is toxic, but it does not require heating or prolonged incubation. Examination of hairs mounted in mineral oil can still yield positive results in the absence of a clearing agent.[25] Cytologic examination has low sensitivity when compared with culture, and experience is required for proper organism identification.

Fungal Culture

Culture is the gold standard for diagnosis of dermatophytosis. Ten to 12 hairs (ideally those that appear damaged or broken) should be plucked from the edge of lesions with sterile forceps and placed in a clean, dry paper envelope (preferably) or a sterile tube or container at room temperature. Scrapings of crusts from the edge of lesions or nail clippings (after cleaning the nail with 70% alcohol) can also be submitted (see also Chapter 4 for specimen collection methods for dermatophytes). Alternatively, a brand-new toothbrush (out of the package) can be used to collect specimens from lesions or the entire coat of a suspect animal by vigorous brushing for several minutes. The toothbrush is then submitted to the laboratory. Macerated tissue cultures can be performed on biopsy specimens from animals that have nodular dermatophytosis or dermatophytic mycetomas.

The most commonly used media for culture are Dermatophyte Test Medium (DTM) or Sabouraud's dextrose agar. In-house DTM cultures, if performed, should be interpreted with caution. Flat Petri plates (as opposed to vials) should be used in order to facilitate inoculation and species identification. Inoculated media should be incubated at 24°C to 30°C; incubation at room temperature is more likely to result in false negatives.[34] Growth occurs within 14 days, and often within 5 to 7 days, but may take up to 21 days (particularly for treated animals). Dermatophyte colonies, which are white or cream and powdery (Figure 58-9), should not be confused with those of saprophytic molds, which may be brown, green, black, gray, or mixed in color. The DTM turns red when the first dermatophyte colony is visible. Color changes that occur after the first colony appears may result from growth of saprophytic fungi. All suspicious colonies must be confirmed as dermatophytes and speciated based

TABLE 58-2

Diagnostic Assays Available for Dermatophytosis

Assay	Specimen Type	Target	Performance
Wood's lamp examination	Haircoat	Fluorescent *Microsporum canis* strains in hair	Low sensitivity (around 50%) for detection of *M. canis* when performed properly. Other dermatophyte species do not fluoresce. The presence of scale, sebum, debris, and topical ointments may lead to false positive results. When positive, allows identification of suitable specimens for cytology and/or culture.
Cytology	Hair pluck specimens	Dermatophyte hyphae and arthrospores	When positive, allows early institution of treatment. Low sensitivity. Incubation with clearing agents may increase sensitivity, but these may not be readily available. Other fungal conidia that contaminate the haircoat or debris may be mistaken for dermatophyte elements.
Culture	Plucked hair specimens, scale and nail clippings	All dermatophyte species	Gold standard for diagnosis of dermatophytosis. Prolonged incubation times may be required.
Histopathology	Skin biopsies	Dermatophytes	Organisms may be visualized with silver stains, periodic acid–Schiff stain, or immunohistochemistry.

on spore morphology through the use of microscopy (see Figure 58-9). Spores form after 7 to 10 days of growth. The individual performing the identification should wear gloves. Tape is placed over the colony and transferred to a slide, on which a drop of stain is applied. A coverslip is then applied. Lactophenol cotton blue or new methylene blue are suitable stains. Dysgonic strains of *M. canis* have been described that have atypical morphology in culture, but these are rare.[27,35] Whenever possible, submission to a veterinary diagnostic laboratory that follows Clinical and Laboratory Standards Institute (CLSI) guidelines is recommended to ensure proper quality assurance for culture and identification of dermatophytes. This also minimizes the risk of laboratory-acquired infections and contamination of the practice environment. Matrix-assisted laser desorption/ionization–time of flight mass spectrometry (MALDI-TOF) offers promise for rapid identification of dermatophytes in veterinary diagnostic microbiology laboratories in the future.[36]

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays have been developed that detect and differentiate between dermatophytes that infect dogs and cats.[37,38] Sensitive real-time PCR assays have been described for use in humans,[39,40] but their use has not been reported for the diagnosis of dermatophytosis in dogs or cats. PCR assays have the potential to be

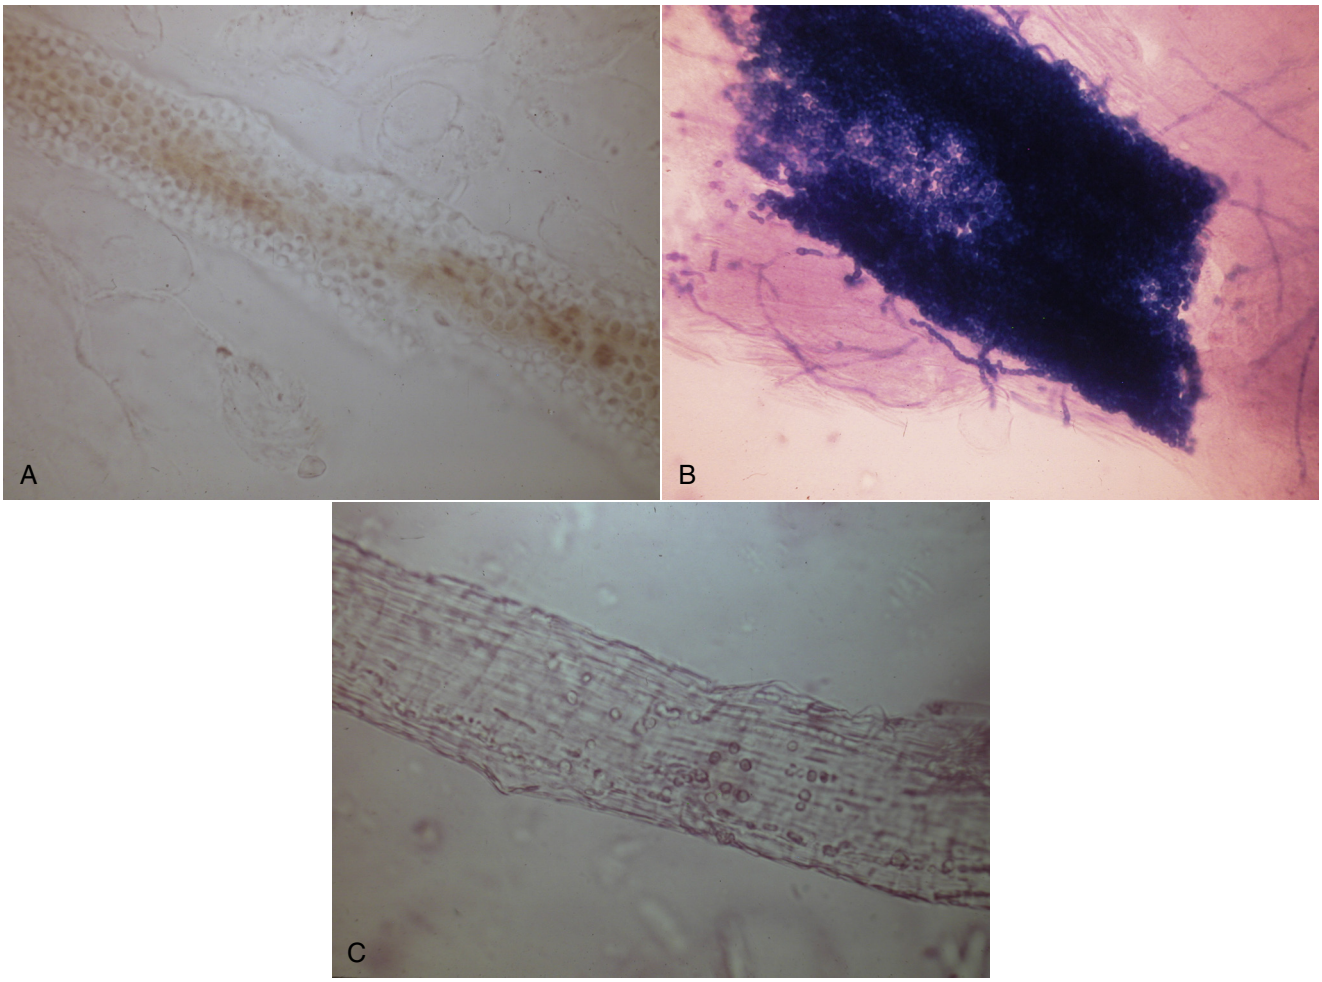

FIGURE 58-8 Cytology images of hairs infected with dermatophytes. **A,** Unstained preparation. Large numbers of *Microsporum canis* spores are seen that surround the hair shaft. **B,** Parker ink-KOH stain. Arthrospores and hyphae can be seen. **C,** Unstained preparation of a hair infected by *Microsporum gypseum.*

more sensitive than culture, with a more rapid turnaround time, and have the potential to facilitate assessment of treatment efficacy and control of disease in group-housed animals.

Pathologic Findings

Histopathology of biopsy specimens from dogs or cats with dermatophytosis may reveal spores and hyphae within intrafollicular hair shafts, in association with a variable pyogranulomatous inflammatory response (Figure 58-10). Special stains such as periodic acid–Schiff (PAS) or Gomori's methenamine silver can increase the sensitivity for detection of fungal elements.[41] Immunohistochemical stains have also been used to detect *M. canis* within lesions.[26] Occasionally, dermatophytes produce a superficial pustular histologic lesion. Acantholytic keratinocytes can be seen in biopsies from some dogs, which may lead to misdiagnosis of pemphigus foliaceus.[41] Histopathology of representative skin biopsies is especially useful for diagnosis of dermatophytic mycetomas, kerions, and fungal paronychia, because organisms are typically present in low numbers in these lesions and culture may be negative. Histopathology of dermatophytic mycetomas reveals pyogranulomatous inflammation and PAS-positive fungal elements that are embedded in an eosinophilic amorphous material within the dermis.

Treatment and Prognosis

Most otherwise healthy animals with dermatophytosis clear the infection without specific antifungal treatment within 3 months of diagnosis. Nevertheless, treatment is strongly recommended for animals that reside in multianimal households and those that live with immunocompromised humans (which includes children and older people, e.g., 60+ years of age) because of the highly contagious nature of the infection. The general approach to treatment includes the use of systemic antifungal drugs, with or without topical treatment, together with environmental decontamination. Lesions should be mapped and photographed before treatment is initiated so that progress can be monitored over time.

Management of dermatophytosis in multicat households can be frustrating, because (1) all in-contact cats must be treated; (2) some cats are colonized and have no visible lesions; and (3) testing and treatment require considerable energy, time, monitoring, and expense. For group-housed animals, all in-contact animals should be examined and cultured using the toothbrush technique. Ideally all animals with positive cultures (and definitely those with clinical signs) should be treated with both systemic and topical antifungal therapy, whereas all unaffected, culture-negative animals should be monitored for development of lesions and treated with topical antifungal drugs (ideally lime sulfur).

Topical Antifungal Drug Treatment

Topical antifungal drug treatment is not as effective as systemic treatment, but inactivates fungal spores on the haircoat and reduces environmental contamination. Spot treatments are not recommended, because spores are distributed all over the haircoat even when skin lesions are localized. The two most effective topical treatments are lime sulfur (1:16 dilution, or 237 mL in 3.6 L of water) or 0.2% enilconazole, both of which should be applied twice weekly.[42-44] Miconazole-chlorhexidine shampoos are also an option but may not be as effective as lime sulfur.[45,46] Lime sulfur shampoos, sprays, or dips have a foul odor and can

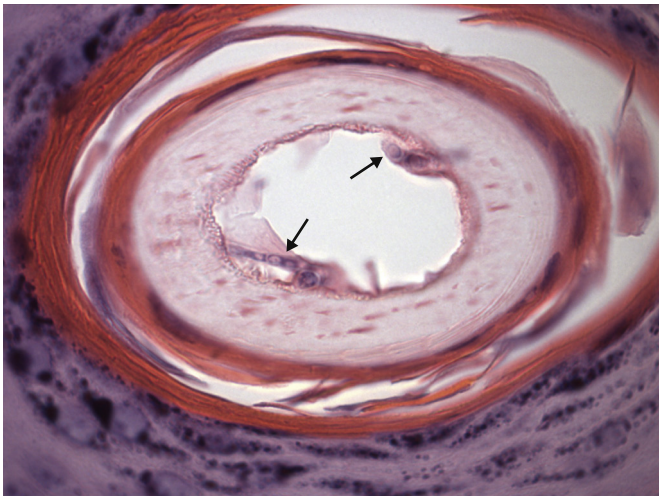

FIGURE 58-10 Histopathology that shows a cross-sectional view of a hair shaft from a 3-year-old female spayed Boston terrier. Fungal hyphae are visible within the hair shaft *(arrows)*.

TABLE 58-3

Antimicrobial Drugs That Can Be Used for Systemic Treatment of Dermatophytosis*

Drug	Dose (mg/kg)	Route	Interval (hours)
Itraconazole†	5	PO	12-24
Fluconazole	5-10	PO	12-24
Ketoconazole	10	PO	12
Terbinafine†	30-40	PO	24
Griseofulvin† (microsized)	25	PO	12
Griseofulvin (ultramicrosized)	15	PO	12

*See also Chapter 9 for more information on adverse reactions and drug administration before use.
†Administer itraconazole capsules, terbinafine, and griseofulvin with food. Reduce dose of itraconazole to 3 mg/kg q24h if using the suspension in cats.

stain light-colored haircoats but are safe for all age groups. A reformulated lime sulfur product with an odor-masking agent was not as effective in one clinical trial as a traditional lime sulfur preparation.[46] Lime sulfur products are most commonly used in the United States but may not be readily available in other parts of the world. Anecdotally, lime sulfur solutions have been reported to cause oral ulcerations in cats, but these were not detected in studies that evaluated cats that were allowed to lick their coats after treatment.[46,47] Ingestion of enilconazole can cause hypersalivation, anorexia, and vomiting, and there are rare anecdotal reports of severe adverse effects that include death.[11] Use of an Elizabethan collar is recommended to prevent cats from licking topical solutions from the haircoat until the treatment has dried. Chlorhexidine alone or povidone-iodine are not sufficiently active against spores and are not recommended. Whether or not the haircoat should be clipped before application of these treatments is controversial. Clipping removes contaminated hair and facilitates penetration of topical treatments, but may also serve to contaminate the environment and may create or exacerbate skin lesions if clipping disrupts the skin. It is recommended that clipping be used for longhaired cats and all cats in an affected Persian or Himalayan cattery. Clippers must be thoroughly disinfected with 10% bleach or concentrated accelerated hydrogen peroxide solutions afterward.

Systemic Antifungal Drug Treatment

Systemic antifungal drug treatment decreases the duration and severity of feline dermatophytosis (Table 58-3).[42] However, it should be used in conjunction with topical treatment and environmental decontamination when groups of animals are affected. Antifungal drugs with activity against dermatophytes are griseofulvin, ketoconazole, fluconazole, itraconazole, and terbinafine (see Chapter 9 for additional information on these drugs). Itraconazole is the drug of choice for treatment of dermatophytosis, because adverse reactions are uncommon and it has equal or greater efficacy when compared with griseofulvin.[48] Fluconazole is less active than other azole antifungal drugs against dermatophytes in vitro (as is the case for other fungi),[49,50] but controlled clinical trials that compare the efficacy of fluconazole to that of itraconazole for treatment of dermatophytosis are needed. The chitin inhibitor lufenuron (traditionally administered orally to prevent flea infestations) has been evaluated for treatment of dermatophytosis,[51,52] but its efficacy has been questioned and its use is no longer recommended.[10,11,24]

Environmental Decontamination

In some situations, environmental decontamination is extremely difficult or impossible because of the hardiness of dermatophyte spores and their widespread dispersal on surfaces that cannot be adequately disinfected. Even concentrated (1:10) bleach solutions are not 100% active against dermatophyte spores; complete disinfection requires undiluted household bleach or 1% formalin. Both are too toxic and caustic for routine use.

All potentially contaminated beds and blankets should be either discarded or washed with bleach through the use of a hot cycle and a hot dryer. Leashes, collars, and grooming equipment should be discarded, and carpets and furniture should be vacuumed to remove all visible hair and then steam cleaned. Because vacuum cleaners are a source of recontamination, they may need to be replaced after initial cleaning efforts; at the very least the vacuum bag should be discarded. Disinfection of hard surfaces should be performed with 1:10 to 1:100 bleach solution, 0.2% enilconazole solution, or (where available) an enilconazole fogger. Vehicles and carriers used to transport animals must also be appropriately cleaned. According to label information, concentrated (1:16) accelerated hydrogen peroxide solutions may also inactivate dermatophytes and reduce environmental contamination, but this requires further evaluation (see Chapter 11).

Duration of Treatment

The duration of treatment of dogs and cats with dermatophytosis is based on serial physical examinations and importantly, follow-up culture results. Usually, several months of treatment are required. In general, animals should be examined and a culture performed at least monthly (and no more frequently than weekly) during treatment. Treatment should be continued until two successive cultures are negative and active lesions have resolved. For group-housed animals, at least three successive negative cultures are suggested. Some authors advocate once-weekly cultures because this may permit earlier discontinuation of treatment.[11] If serial cultures are not possible because of financial limitations, treatment should be continued for 2 to 4 weeks after complete resolution of clinical signs. Typically, treatment is continued for at least 10 to 12 weeks.

Prognosis

The prognosis is good for resolution of dermatophytosis in young animals, especially in households with only a single animal or very low numbers of animals. Complicated disease

VetBooks.ir

such as dermatophytic mycetomas are difficult to resolve and require very long treatment durations; in some cats with mycetomas, surgery may ultimately be required for complete lesion resolution. The prognosis for rapid resolution of dermatophytosis may also be worse for animals with irreversible underlying immunocompromise. Hair regrowth may not occur in regions of scarring.

Immunity and Vaccination

Resolution of dermatophytosis depends on a delayed type-hypersensitivity immune response, which involves the activity of macrophages and IFN-γ.[22] Less invasive dermatophytes may evade the host immune response by limiting their presence to the superficial corneal epithelial cells and hair shafts. A vaccine for prevention of feline *M. canis* infections was licensed in the United States in the mid-1990s but was not sufficiently efficacious and is no longer available.

Prevention

Prevention of dermatophytosis relies on avoidance of contact with infected or carrier animals or fomites, but this may be impossible in some situations. For scenarios that involve group-housed animals, clean (culture-negative) animals, incoming animals, and animals undergoing treatment (culture-positive) must be kept in separate rooms, and ideally in individual cages. Once animals in the contaminated room are culture negative, they are moved to the clean room, and the contaminated room is thoroughly disinfected. Culture and topical treatment should be considered for any incoming animals to a clean facility.

In veterinary hospitals, animals with known dermatophytosis should be scheduled for examination late in the day and should be carried directly from the parking lot to an appropriate examination room that can subsequently be easily cleaned (the animal should not wait in the reception area). Strict attention to barrier precautions is required (see Chapter 11). If hospitalization is necessary, animals with suspected or documented *M. canis* infections should be housed in isolation.

Public Health Aspects

Forms of human dermatophytosis include tinea capitis (scalp), tinea pedis ("athlete's foot"), tinea barbae (bearded area), tinea cruris ("jock itch"), tinea corporis (body), tinea imbricata (a variant of tinea corporis), tinea manuum (hand), tinea faciei (face), and tinea unguium (nails).[1] Dermatophyte species that cause disease in dogs and cats have the potential to cause human disease. *Microsporum canis* is the most common zoophilic dermatophyte implicated. Zoophilic dermatophytes are most often associated with tinea capitis or tinea corporis. A high prevalence of infection with *M. canis* has been reported in children that have tinea capitis (scalp infection) from continental Europe and Asia.[53-55] *M. canis* is now a rare cause of tinea capitis in the United States, with most cases caused by anthropophilic dermatophytes such as *T. tonsurans*.[56]

FIGURE 58-11 Boy with multiple lesions of dermatophytosis on the face and body. The boy had juvenile rheumatoid arthritis. The boy's cat had a lesion on the right side of its face. (Courtesy Dr. Richard Malik.)

Young children and the immunocompromised (e.g., transplant recipients) are most susceptible to dermatophytosis and may develop deep, recalcitrant, and/or disseminated lesions as a result of contact with infected pets.[57,58] Disease has been described in veterinarians and veterinary students.[11,35] In general, zoophilic and geophilic species evoke a more profound inflammatory response than anthropophilic dermatophytes; the latter tend to cause more chronic infections in people.[1] Typical "ringworm" lesions in humans are erythematous, circular lesions with a raised margin (Figure 58-11), but atypical forms that mimic other skin diseases such as atopic dermatitis and lupus have been described.[59] Humans who handle infected animals should wear protective clothing and gloves. Young children or the immunocompromised should avoid any contact with these animals. Toothbrush cultures should be considered for cats that are adopted from shelters or multicat households before they are introduced to households where immunocompromised individuals reside.

VetBooks.ir

CASE EXAMPLE

Signalment: "Jack", a 4.5-year-old male neutered smooth-coated fox terrier from northern California

History: Jack was evaluated for chronic diarrhea, a distended abdomen, and loss of hair on the face. Jack's owners adopted him when he was 14 months old, at which time he had no clinical signs of illness. At 2 years of age, the owners noted that Jack began to rub his muzzle on objects. The intensity of this behavior at times resulted in excoriations that would bleed. Jack had been seen at another veterinary clinic where he was treated with a diet that was "hypoallergenic." The owners then continued to try to feed a variety of different diets for the skin problem, with a change to a new diet approximately every 3 months. The most recently fed diets were a prescription intestinal diet and a prescription venison and potato diet. Diet trials were never strict elimination trials, because the dog was fed the same treats throughout the diet trial process. There was no improvement in the skin lesions, which progressed to cause alopecia that involved the entire aspect of his face (see Figure 58-1, *A*). Approximately 18 months before Jack was evaluated, intermittent diarrhea had developed. The diarrhea was brown, occurred once or twice a day, and was sometimes accompanied by tenesmus. It occasionally contained mucus but never blood, and varied from soft to watery in consistency. In addition to this history, over the preceding 2 years, Jack had been treated intermittently with prednisone (0.5 to 0.75 mg/kg PO q12h) for the pruritus. The prednisone never improved the skin condition but was occasionally associated with resolution of the diarrhea. Other medications used at various time points over the previous 2 years included hydroxyzine, metronidazole, tylosin, cephalexin, and a topical otic preparation that contained thiabendazole, neomycin, and dexamethasone. Although Jack's appetite was generally good, he was described as a picky eater and had intermittent lethargy when his diarrhea was severe. The owners reported that over the most recent few weeks he had lost weight and muscle mass and had developed a distended abdomen. Jack lived on a ranch with multiple other dogs (the owner bred poodles and shelties), cats, and horses, none of which were unwell or had skin lesions. He spent most of his time outdoors on the farm and loved to dig in rodent holes.

Current medications: Prednisone, 1.4 mg/kg PO q12h

Physical Examination:

Body Weight: 7.1 kg.

General: Bright, alert, responsive, hydrated. T = 100.3°F (37.9°C), HR = 120 beats/min, RR = 40 breaths/min, mucous membranes pink/pigmented, CRT <2 s.

Integument: A dull, unkempt haircoat was noted. An area of partial alopecia with crusts was present over the right caudal tarsus. Diffuse, complete alopecia with serocellular and hemorrhagic crusting and multifocal, discrete ulcerations was present over the entire dorsal muzzle (see Figure 58-1, *A*). The skin within the alopecic area was hyperpigmented and had a shiny appearance compatible with scarring. Periocular alopecia with crusts was also present bilaterally and was confluent with the erythematous, advancing edge of the facial lesion. The skin on the ventral abdomen was thin with prominent subcutaneous vessels.

Eyes, Ears, and Throat: No clinically significant abnormalities of the eyes or ears were noted. On oral examination, the dentition was severely worn, and there was mild to moderate periodontal disease.

Musculoskeletal: Normal ambulation. Body condition score was 3/9.

Cardiovascular and Respiratory Systems: No clinically significant abnormalities were noted.

Gastrointestinal and Genitourinary: The abdomen was moderately distended with a palpable fluid wave. Rectal examination revealed only a moderate amount of formed but soft feces.

Lymph Nodes: No peripheral lymphadenopathy was detected.

Laboratory Findings:

CBC:

HCT 39.8% (40%-55%)
MCV 69.7 fL (65-75 fL)
MCHC 34.2 g/dL (33-36 g/dL)
WBC 18,810 cells/µL (6000-13,000 cells/µL)
Neutrophils 16,177 cells/µL (3000-10,500 cells/µL)
Band neutrophils 188 cells/µL
Lymphocytes 376 cells/µL (1000-4000 cells/µL)
Monocytes 1693 cells/µL (150-1200 cells/µL)
Eosinophils 376 cells/µL (0-1500 cells/µL)
Platelets clumped, rare nucleated RBC/100 WBC.

Serum Chemistry Profile:

Sodium 144 mmol/L (145-154 mmol/L)
Potassium 4.1 mmol/L (3.6-5.3 mmol/L)
Chloride 115 mmol/L (108-118 mmol/L)
Bicarbonate 24 mmol/L (16-26 mmol/L)
Phosphorus 1.9 mg/dL (3.0-6.2 mg/dL)
Calcium 6.6 mg/dL (9.7-11.5 mg/dL)
BUN 10 mg/dL (5-21 mg/dL)
Creatinine 0.5 mg/dL (0.3-1.2 mg/dL)
Glucose 108 mg/dL (64-123 mg/dL)
Total protein 2.9 g/dL (5.4-7.6 g/dL)
Albumin 1.5 g/dL (3.0-4.4 g/dL)
Globulin 1.4 g/dL (1.8-3.9 g/dL)
ALT 85 U/L (19-67 U/L)
AST 109 U/L (19-42 U/L)
ALP 23 U/L (21-170 U/L)
Creatine kinase 309 U/L (51-399 U/L)
GGT < 3 U/L (0-6 U/L)
Cholesterol 88 mg/dL (135-361 mg/dL)
Total bilirubin < 0.1 mg/dL (0-0.2 mg/dL)
Magnesium 1.8 mg/dL (1.5-2.6 mg/dL).

Serum Vitamin B_{12} and Folate: Vitamin B_{12} 314 ng/L (272-875 ng/L), folate 9.1 ng/mL (6.5-18.6 ng/mL).

Serum Ionized Magnesium Concentration: 0.44 mmol/L (0.40-0.52 mmol/L).

Urinalysis (Cystocentesis): SGr 1.018; pH 6.5, no protein, bilirubin, hemoprotein, or glucose, 0-2 WBC/HPF, no RBC/HPF, no crystals or bacteria, rare granular casts, few lipid droplets.

Imaging Findings:

Thoracic Radiographs: No abnormalities were detected in the thorax. In the portion of visible abdomen, there was decreased serosal detail.

Abdominal Ultrasound: There was marked thickening of the mucosal layer of the small intestine diffusely, with

VetBooks.ir

hyperechoic striations. A moderate volume of anechoic peritoneal effusion was present.

Cytologic Findings: Abdominal effusion: the fluid was colorless with a total protein of 0.3 g/dL, low numbers of erythrocytes, and 380 nucleated cells/μL (38% neutrophils, 2% small mononuclear cells, and 60% large mononuclear cells). Nucleated cells were a mixture of nondegenerate neutrophils and mononuclear cells of normal morphology. One large cluster of reactive mesothelial cells was observed. The fluid was interpreted as a transudate.

Microbiologic Testing: Skin scrapings and hair pluck cytology (trichogram) (from face and tarsus): Large numbers of dermatophyte hyphae and spores were present. No mites were seen.

Fungal culture (hair specimens from periphery of lesions on face and tarsus): Small numbers of *Trichophyton mentagrophytes* grew after 4 days.

Diagnosis: Protein-losing enteropathy (suspect lymphangiectasia), likely iatrogenic hyperadrenocorticism, and dermatophytosis due to *T. mentagrophytes* infection.

Treatment: Before the results of the fungal culture became available, fluconazole (7 mg/kg PO q24h) was prescribed based on the high index of suspicion from cytologic identification of fungal elements, together with an oatmeal shampoo to be used twice weekly. The dose of prednisone was reduced to 0.5 mg/kg PO q12h and strict instructions were given to feed a prescription low-fat diet and no other foods (including treats). At a recheck 3 weeks later, the owners reported that Jack was doing very well. His diarrhea, abdominal distention, and facial pruritus had resolved; he was more energetic; and his appetite had improved. Physical examination revealed resolution of crusts and evidence of new hair growth. Body weight had reduced to 6.2 kg and no evidence of abdominal distention was present. The only abnormalities on the chemistry panel were mild hypoproteinemia (5.1 g/dL) and hypocholesterolemia (110 mg/dL). Albumin was 3.1 g/dL and globulin was 2.2 g/dL. Abdominal ultrasound examination showed resolution of ascites. The prednisone dose was decreased to 0.4 mg/kg PO q24h, but diarrhea returned, so the dose was increased again to 0.4 mg/kg PO q12h. A repeat fungal culture (hair pluck specimen) 3 months after starting treatment was negative; culture was not performed earlier because lesions still appeared active, even though they had improved. Additional follow-up showed complete resolution of abnormalities on the serum chemistry panel and serum B_{12} and folate concentrations in the middle of the reference range. Ultimately management of the diarrhea required a cottage cheese and rice–based diet (balanced by a veterinary nutritionist) and a low dose of prednisone (0.4 mg/kg PO every 4 days). However, despite resolution of crusts and pruritis, hair cultures continued to periodically grow small numbers of *T. mentagrophytes* 1 year later, and fluconazole was never discontinued.

Comments: Persistent dermatophytosis in this dog was likely due to underlying immunosuppressive disease/drug treatment that could not be completely reversed, and possibly reinfection. The dog was likely exposed as a result of digging in rodent holes, based on the history and the dermatophyte species isolated. Poor client compliance and client financial limitations were factors that may also have contributed to an inability to control the infection.

CHAPTER 59

Malassezia Infections

Jane E. Sykes, Terry M. Nagle, and Stephen D. White

VetBooks.ir

Overview of *Malassezia* Dermatitis

First Described: 1874, in France, by Louis-Charles Malassez (the fungus was initially named *Pityrosporum ovale*)[1]

Cause: *Malassezia pachydermatis*; less commonly, lipid-dependent species such as *Malassezia globosa, Malassezia sympodialis, Malassezia nana, Malassezia slooffiae,* and *Malassezia furfur* are involved.

Affected Hosts: Dogs and to a lesser extent cats

Geographic Distribution: Worldwide

Mode of Transmission: Direct contact and opportunistic proliferation of commensal organisms

Major Clinical Signs: Cutaneous erythema, pruritus, alopecia, scaling, greasy exudation, hyperpigmentation, lichenification, malodor

Differential Diagnoses: Dermatophytosis, demodicosis, allergic dermatitis, drug eruptions, pyoderma

Human Health Significance: *M. pachydermatis* does not normally colonize human skin but can rarely infect immunosuppressed adults and cause catheter-related infections in neonatal intensive care units.

Etiology and Epidemiology

Malassezia spp. (formerly *Pityrosporum* spp.) are lipophilic yeasts that normally colonize animal and human skin in low numbers. At least 13 species of *Malassezia* exist. The vast majority of species are classified as lipid dependent: when grown in the laboratory, these species have an absolute requirement for long-chain fatty acids, which are used as a source of carbon. In contrast, *Malassezia pachydermatis*, the most commonly isolated yeast species from the skin and ears of healthy dogs and cats, is non–lipid dependent when grown in the laboratory. Lipid-dependent species, including *Malassezia globosa*, *Malassezia sympodialis*, *Malassezia nana*, *Malassezia slooffiae*, and *Malassezia furfur*, can colonize the skin of healthy cats.[2-5]

In healthy dogs, *Malassezia* spp. are most commonly found in the ear canals, on the lips, axillae, interdigital spaces, anal sacs, and occasionally the nose and vagina. It has been suggested that a symbiotic relationship exists between *Malassezia* spp. and commensal staphylococci; each maintains a local microenvironment that benefits the other.

Malassezia spp. are common opportunistic contributors to chronic dermatitis and otitis externa in dogs, and to a lesser extent in cats. They are isolated more frequently from the ears of dogs and cats with otitis externa than from the ears of healthy dogs and cats.[6,7] Dogs with skin disease can have 100- to 10,000-fold increases in skin population densities of *Malassezia* spp. compared with healthy dogs.[8] Species and strains of *Malassezia* vary in virulence and tropism for different anatomic sites and host species.[9,10] A variety of lipid-dependent *Malassezia* spp. occasionally have been isolated from dogs and cats with otitis externa.[6,7,11-14]

Malassezia spp. infection can occur in dogs and cats of any age, breed, and sex, but some dog breeds are thought to be predisposed, including American cocker spaniels, West Highland white terriers, basset hounds, poodles, and Australian silky terriers.[15] Sphynx and Devon Rex cats have high rates of *Malassezia* spp. colonization when compared with domestic shorthair cats.[16]

Clinical Features

Signs and Their Pathogenesis

Malassezia spp. proliferate opportunistically, becoming pathogenic with alterations in host defenses or the skin surface microclimate. Examples of underlying diseases include allergic dermatitis, endocrinopathies, intertrigo, primary keratinization/cornification disorders, and, in cats, underlying neoplasia or retrovirus infections.[17,18] A history of treatment with antibiotics was a predisposing factor in one study.[19] Prolonged glucocorticoid treatment can also lead to yeast proliferation. The yeasts adhere to the cells of the stratum corneum and secrete lipases, proteinases, phospholipases, and acid sphingomyelinases.[20] The resulting skin lesions may be localized or generalized, are thought to result from inflammation, and, in some animals, hypersensitivity reactions to yeast antigens.[21,22] The more erythematous the interdigital region is in an atopic dog, the more likely a *Malassezia* spp. infection is present.[23]

The most commonly affected anatomic sites are the ear canals, skin folds (including the periocular and perioral skin, ventral neck, axillae, inguinal regions, and perineum), and interdigital skin (Figure 59-1). Clinical signs include erythema, pruritus, alopecia, scaling, and a greasy exudate. The claw beds may develop a reddish-brown stain. Chronicity results in hyperpigmentation, lichenification, and stenosis of the ear canal, and a pungent, offensive odor develops. Pruritus may result in excoriations. Devon Rex and Sphynx cats can develop a greasy dermatitis associated with increased numbers of *Malassezia* spp., which can respond dramatically to antifungal drug treatment.[8]

Physical Examination

A thorough physical and dermatologic examination aids diagnosis of *Malassezia* spp. infection and provides important clues

FIGURE 59-1 Five-year-old male neutered pug with a 1 year history of otitis externa and generalized pruritus. *Malassezia* dermatitis and bacterial pyoderma secondary to underlying atopic dermatitis was diagnosed. Note the distribution of lesions, which affect the facial folds and ventral neck **(A)** and axillae **(B)**.

as to the underlying disorder leading to opportunistic proliferation of *Malassezia* spp. It also allows identification of lesions consistent with concurrent pyoderma (see Chapter 84).

Diagnosis

Diagnosis of *Malassezia* spp. dermatitis is based on clinical signs, findings on cytologic examination, and a positive response to antifungal drug treatment.

Microbiologic Testing

Skin Scrapings

Skin scrapings are important in animals suspected to have *Malassezia* spp. dermatitis in order to rule out demodicosis, which can mimic *Malassezia* spp. dermatitis.

Cytologic Examination

Cytology is an important tool for diagnosis and is generally performed using clear (not frosted) acetate (Scotch) tape preparations of the skin. The tape is pressed to the skin, dipped in the final step basophilic (blue) Diff-Quik solution, rinsed, and applied to a slide on which a drop of immersion oil has been placed. Alternatively, the tape is pressed against the affected skin several times and then placed on a dry glass slide, and a small amount of the basophilic Diff-Quik solution is injected under the tape. The tape is then examined using a light microscope, with an additional drop of immersion oil to allow identification of bacteria and *Malassezia* spp. using the 100× objective. The yeasts stain deeply basophilic and exhibit wide-based budding, resembling "footprints," "peanuts," or "snowmen" (Figure 59-2). An inflammatory cellular response is often not present, even when *Malassezia* spp. contribute to disease progression.

Estimation of yeast counts, although only semiquantitative, may help to determine the role of *Malassezia* in otitis and dermatitis, but there are no clear guidelines as to what constitutes a normal yeast population size. In addition, yeast counts do not take into account other factors, such as strain variation in virulence or host hypersensitivity.[10,24] For *Malassezia* spp. dermatitis, mean counts of 1 or more yeast per oil immersion field (1000× magnification) are considered abnormal in dogs.[25] For ears, a mean yeast count of approximately 5 or more organisms per oil immersion field has been suggested as abnormal.[25] Cats may be colonized with higher numbers of yeasts, and 12 or more organisms per high dry field has been suggested as abnormal in feline ear canals in another study.[26] The ear canals of healthy dogs and cats have mean counts of 2 or fewer yeasts per high dry field (400× magnification), and intermediate counts represent a gray zone.[26]

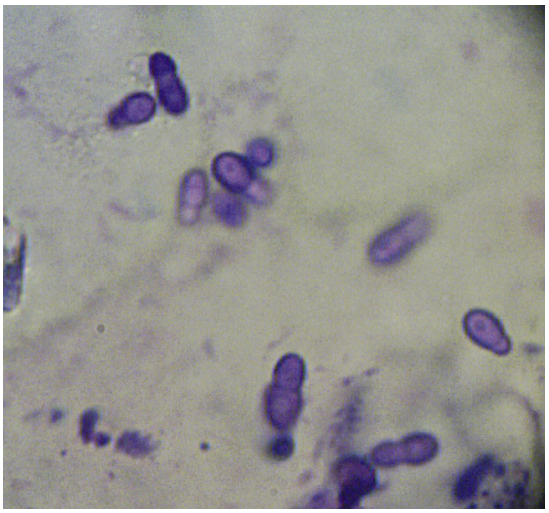

FIGURE 59-2 Tape preparation from the skin of a dog with *Malassezia* dermatitis. Note broad-based budding yeasts, which have the appearance of a footprint. Modified Wright's stain, 1000× oil magnification.

Fungal Culture

Fungal culture and susceptibility testing for *Malassezia* spp. is not routinely performed for clinical diagnostic purposes,

VetBooks.ir

TABLE 59-1

Systemic Antifungal Drugs Used for Treatment of *Malassezia* Dermatitis and Otitis Externa in Dogs

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Ketoconazole	5 to 10	PO	12	3 to 4 weeks or until cytologic resolution
Itraconazole	5*	PO	24	
Fluconazole	5	PO	24	
Terbinafine	30	PO	24	

*Dose applies to the capsules. Reduce dose to 3 mg/kg if using the suspension.

although methods that use broth dilution or E-testing for susceptibility testing have been described. The organism can be cultured from a tape preparation, which in the laboratory is mounted on a drop of olive oil that has been placed on fungal isolation media.[25] Growth occurs within 7 days of incubation. Currently, most *Malassezia* spp. infections are broadly susceptible and respond well to treatment of the yeast infection and any underlying disorders present. One azole-resistant isolate of *M. pachydermatis* was identified in a dog with dermatitis, but this was not associated with resistance in vivo.[27]

Treatment and Prognosis

Treatment of *Malassezia* spp. dermatitis and otitis requires identification and, if possible, treatment of the underlying cause, in addition to antifungal drug treatment. Because *Malassezia* spp. infection is superficial, topical treatments may be adequate to resolve infection. A variety of topical otic preparations are available for treatment of *Malassezia* otitis. These contain antifungals such as clotrimazole, miconazole, or posaconazole, which are generally combined with a glucocorticoid and an antibacterial (see Chapter 84). There is good evidence that *Malassezia* dermatitis can be successfully treated with twice-weekly shampooing with a 2% miconazole/2% chlorhexidine shampoo (e.g., Malaseb, DVM Pharmaceuticals) for 3 weeks,[24] and this can also prevent recurrence. A 3% chlorhexidine shampoo may be equally efficacious.[28] Systemic antifungals that have been shown to have efficacy for treatment of *Malassezia* infections include ketoconazole, itraconazole, fluconazole, and terbinafine, which are generally administered for 3 weeks (Table 59-1).[29,30] Longer periods of treatment may be required for severe infections or infections of the claw bed.[8] Administration of terbinafine on two consecutive days each week (i.e., in a pulsatile fashion) may be as effective as daily administration, but more studies are required.[31] Treatment should be monitored through serial dermatologic examinations and cytologic evaluation of tape preparations. The prognosis for resolution depends on the ability to identify and address the underlying cause for proliferation of *Malassezia* spp.

Public Health Aspects

In human beings, *Malassezia* infections most commonly result from infection by *M. furfur*. This organism belongs to the normal human cutaneous flora and proliferates opportunistically following immunocompromise. Yeast proliferation can lead to *Malassezia* folliculitis, seborrheic dermatitis, catheter-related fungemia, and a variety of other invasive infections.[32] Administration of lipid-containing total parenteral nutrition solutions is a risk factor for disseminated infections in humans, which often occur in neonates.[33,34]

M. pachydermatis is not part of the normal human cutaneous microflora. Human disease associated with *M. pachydermatis* infection occurs rarely. Nosocomial infections with *M. pachydermatis* have been reported in neonates in intensive care units.[35] One epidemic was associated with colonization of health care workers' pet dogs with a strain identical to that causing disease, as determined by molecular typing with pulsed-field gel electrophoresis.[36] Cutaneous infections have also been reported in adults with underlying immunosuppressive disease.[30] Owners of dogs with atopic skin disease were 11 times more likely to carry *M. pachydermatis* on their hands than owners of healthy dogs, as determined using culture (39% vs. 6%).[25] The owners of both groups of dogs were equally likely to carry the yeast on their hands as determined by PCR testing (93% and 94%). It was concluded that mechanical carriage of the organism by dog owners appears to be of low risk to human health, given how rarely disease due to *M. pachydermatis* occurs. Hand washing is likely to reduce the rate of carriage of *M. pachydermatis*, but this has not been well studied.

CASE EXAMPLE

See case example in Chapter 84.

CHAPTER 60

Blastomycosis

Jane E. Sykes and Lindsay K. Merkel

VetBooks.ir

Overview of Blastomycosis

First Described: 1894, in the United States by Thomas Casper Gilchrist.[1] The organism was initially mistaken for a protozoan parasite.

Cause: *Blastomyces dermatitidis* (an ascomycete, teleomorph *Ajellomyces dermatitidis*)

Affected Hosts: Primarily humans and dogs, but also other mammalian species that include cats, horses, ferrets, and sea lions

Geographic Distribution: Primarily North America, especially the south-central and upper midwestern states of the United States; Canadian provinces that border the Great Lakes; and a small area of the northeastern United States and southeastern Canada near the St. Lawrence river

Mode of Transmission: Inhalation of conidia from the environment; rarely cutaneous inoculation

Major Clinical Signs: Fever, inappetence, weight loss, cough, tachypnea, respiratory difficulty, nodular or ulcerative cutaneous lesions, ocular lesions (uveitis, chorioretinitis, panophthalmitis), lameness, neurologic signs

Differential Diagnoses: Neoplasia, other deep mycoses, protothecosis, mycobacterial infections, systemic protozoal infections (leishmaniasis, toxoplasmosis, neosporosis), aspiration or foreign body pneumonia

Human Health Significance: *B. dermatitidis* causes disease in humans, but direct transmission from animals to humans does not occur (with the exception of rare bite wound transmission from infected dogs). Dogs are a sentinel for human exposure.

Etiology and Epidemiology

Blastomyces dermatitidis is a dimorphic fungus that grows as a mycelial form in the environment and as a thick-walled budding yeast in tissues (at 37°C). Hyphae within soil produce conidia that are 2 to 10 µm in diameter. The conidia are thought to be aerosolized and inhaled by the host, where they transform into yeasts and produce a localized pulmonary or disseminated disease known as blastomycosis (Figure 60-1). The organism's name *(dermatitidis)* stems from the fact that the skin is a common site to which the organism disseminates.

B. dermatitidis is primarily found in the eastern parts of the United States, especially around the Great Lakes, along the Ohio and Mississippi river valleys, and in the southeastern states (Figure 60-2). A smaller focus of endemicity exists in the St. Lawrence river region in the northeast, which extends up into Ontario, Canada. Disease may also be seen in parts of Canada around the Great Lakes and has also been reported from Saskatchewan.[2,3] Occasionally disease appears in nontraveled dogs that reside in non-endemic parts of the United States, such as in Wyoming and South Dakota. Canine blastomycosis has also been reported from India.[4] Human blastomycosis occurs in Africa, but a different serotype is involved. Interestingly, reports of canine disease from Africa are absent from the literature. Blastomycosis was described in Europe in a dog with a travel history to the United States.[5]

The ecologic niche of *B. dermatitidis* appears to be warm, moist, sandy soil that is rich in organic debris such as decaying vegetation. However, this has not been thoroughly defined because the fungus is difficult to isolate from the environment. No consistent seasonality has been linked to disease. Genetic differences have been reported among isolates of *B. dermatitidis* within the United States. Using PCR-based typing methods, several different genotypes have been described (A, B, C, D, and E).[6] Analysis by microsatellite typing suggests the existence of at least two genetically distinct groups, group 1 and group 2, the geographic distributions of which overlap.[7] In human patients, group 2 isolates may be more likely to be associated with disease in older patients with comorbid conditions, and group 2 isolates are also more likely to be associated with dissemination than group 1 isolates.[8]

Young adult, large-breed (>15 kg) dogs are predisposed to blastomycosis, and a slight male predisposition has been

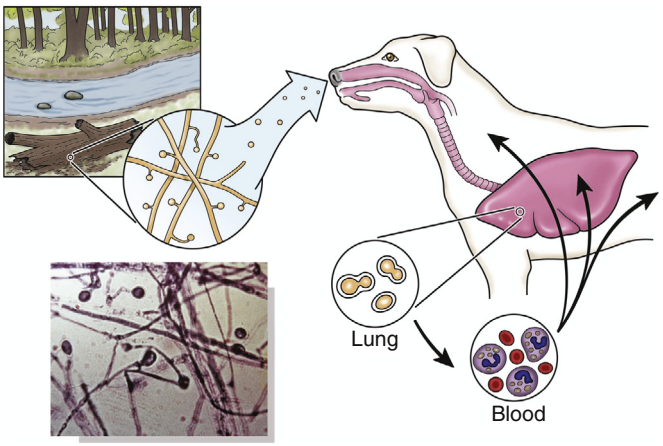

FIGURE 60-1 Life cycle of *Blastomyces dermatitidis*. From the lung, the organism can disseminate to a variety of tissues, but especially the eye, lymph nodes, skin, and bones.

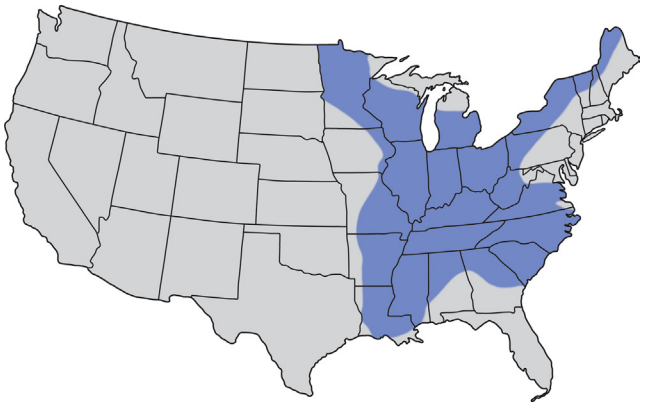

FIGURE 60-2 Approximate geographic distribution of *Blastomyces dermatitidis* in the United States.

identified in some studies.[9] Overrepresented breeds include coonhounds, pointers, Weimaraners, Labrador retrievers, golden retrievers, and Doberman pinschers.[9,10] This may reflect the increased likelihood of exposure of these dog types to organisms in the environment, because they are more likely to be used in outdoor activities such as hunting. Dogs younger than 6 months of age and as old as 17 years may be affected, but dogs in the 2- to 4-year age group have the highest risk of infection with the 4- to 6-year age group a close second.[9,10] Residence less than 400 m from a body of water increased the risk of blastomycosis by a factor of 10 in one study from Louisiana,[10] and exposure to sites of soil disturbance or excavation may also increase the risk of infection. In one report, *B. dermatitidis* was isolated from a woodpile near the Wisconsin River; over 14 years, 4 of 9 dogs housed in a kennel close to the woodpile developed blastomycosis.[11] Most affected dogs are immunocompetent. Blastomycosis is rarely reported in cats from endemic regions of the United States and, as with other soil-borne mycoses such as histoplasmosis and cryptococcosis, blastomycosis can occur in cats that have been housed entirely indoors.[12,13] In one study, 10% of 41 affected cats tested positive for FeLV antigen.[14]

Clinical Features

Signs and Their Pathogenesis

Infection most often results from inhalation of conidia in the environment. Direct inoculation of organisms followed by localized cutaneous disease and/or osteomyelitis *(inoculation blastomycosis)* occurs rarely in dogs and human patients.[15,16] Once within the host, the conidia transform into yeasts that can resist destruction by neutrophils. The yeasts trigger a pyogranulomatous inflammatory response. Important virulence factors include a cell surface glycoprotein known as BAD-1 (previously known as WI-1), and other cell wall components such as α-1,3-glucan and possibly melanin.[17,18] BAD-1 is an adhesin that binds to host cell receptors on macrophages. It may also contribute to the yeast's ability to evade the host immune response by influencing cytokine secretion and impairing complement activation.[17,19] In some animals, the organism spreads hematogenously from the lungs to associated lymph nodes and other extrapulmonary sites. Extrapulmonary sites of predilection include the skin, eye, bone, reproductive tissues (prostate and testes), and the central nervous system (CNS). However, virtually any tissue in the body may be affected, and infection has been reported in the mammary glands, nasal or oral cavities, cardiac tissues (myocardium, endocardium, and pericardium), and very rarely in the kidneys, liver, spleen, peritoneum, gastrointestinal tract, and urinary bladder.[20]

Clinical signs are variable. Dogs may develop subclinical infections, acute or chronic disease that is localized to the lungs and associated lymph nodes, or severe and progressive signs that result from dissemination of the organism to multiple extrapulmonary sites. The incubation period is variable and not precisely known, but is estimated to range from 5 to 12 weeks. Nonspecific signs of illness such as lethargy, weakness, fever, inappetence, and weight loss are common (Table 60-1). Other common clinical manifestations (between 20% and 50% of affected dogs) include signs of respiratory involvement (such as cough and increased respiratory rate), lymphadenopathy, ocular manifestations, cutaneous lesions, and lameness.[10,21] Lameness may result from fungal osteomyelitis, arthritis, or rarely, hypertrophic osteopathy.[22] Gastrointestinal signs (vomiting, diarrhea, hematemesis, and melena); polyuria or polydipsia; mammary gland masses; laryngeal masses; nasal discharge, sneezing and/or epistaxis; testicular masses; dysuria or hematuria secondary to prostatic involvement; cardiac arrhythmias; and neurologic signs due to meningoencephalitis or ependymitis occur less frequently.[10,23-29] Neurologic involvement secondary to extension of intranasal or retrobulbar *Blastomyces* granulomas through the calvarium can also occur.[25,29] Rarely, thromboembolic disease has been reported.[30]

TABLE 60-1

Physical Examination Findings in 115 Dogs with Blastomycosis[9]

Clinical Sign	Percent of Dogs
Fever	62
Lymphadenopathy	56
Harsh lung sounds	50
Skin lesions	49
Chorioretinitis	43
Anterior uveitis	42
Cough	32
Emaciation	25
Retinal detachment	23
Cutaneous mass	16
Glaucoma	16
Tachypnea	16
Dehydration	15
Bony mass/swelling	14
Nasal discharge	8
Neurologic signs	6
Prostatomegaly	5
Mammary mass	3
Orchitis	2
Synovial effusion	2

FIGURE 60-3 Disseminated blastomycosis in a labrador retriever. Nodular cutaneous lesions are present on the muzzle **(A)**. There are also multiple, ulcerated, and draining skin lesions on the distal limbs **(B)** and digit **(C)**. (Courtesy Dr. Sheila Torres, University of Minnesota.)

In cats, clinical signs of blastomycosis are similar to those in dogs, although neurologic and gastrointestinal involvement may be more prevalent.[31]

Physical Examination Findings

Physical examination abnormalities in dogs with blastomycosis commonly include fever, thin body condition, dehydration, and signs of respiratory involvement. Fever is present in approximately 50% of affected dogs and is usually low grade (103°F to 104°F or 39.4°C to 40.0°C) but occasionally exceeds 106°F (41.1°C).[20,27] Respiratory signs include cough, tachypnea, increased respiratory effort, and increased lung sounds on thoracic auscultation. Other common findings on physical examination are firm cutaneous or subcutaneous masses, draining or ulcerated skin lesions, and peripheral lymphadenopathy. Careful palpation of the entire skin surface can reveal small skin lesions. Cutaneous and subcutaneous lesions are frequently found on the trunk, limbs, and digits and can also involve the muzzle (Figure 60-3). Lesions of the tongue, gingiva, or mucocutaneous junctions may also be present (Figure 60-4). Facial swelling, exophthalmos, or facial deformity has been described in some affected dogs.[25,32] Dogs with nasal cavity involvement can have stertorous respiration, decreased nasal airflow, or nasal discharge. Ocular signs may be unilateral or bilateral and include chorioretinitis (sometimes with retinal detachment); lesions consistent with optic neuritis; endophthalmitis or panophthalmitis; uveitis with aqueous flare, iris bombé, synechia, and miosis; cataract formation; conjunctivitis; keratitis;

FIGURE 60-4 Nodular and ulcerated lesions of the tongue in a dog with disseminated blastomycosis. (Courtesy Dr. Sheila Torres, University of Minnesota.)

FIGURE 60-5 Cutaneous lesions in a cat with disseminated blastomycosis that involved the footpads **(A)**, interdigital folds **(B)**, and lips **(C)**. (Courtesy Dr. Sheila Torres, University of Minnesota.)

and photophobia.[33,34] Severe ocular involvement may result in increased intraocular pressures and/or loss of vision. Dogs with musculoskeletal involvement may be lame, have firm swellings associated with long bones, or exhibit joint swelling, warmth, and/or pain. Dogs with testicular blastomycosis may have scrotal swelling or palpable testicular masses. Neurologic signs are present in fewer than 5% of affected dogs and can include seizures, hypermetria, decreased placing reactions, tetraparesis, circling, ataxia, blindness, decreased or absent menace and/or pupillary light reflexes, nystagmus, and decreased facial sensation.

Physical examination findings in cats with blastomycosis are similar to those described in dogs. These include fever, thin body condition, peripheral lymphadenopathy, tachypnea, increased or decreased lung sounds, ocular abnormalities (chorioretinitis with retinal detachment, uveitis, panophthalmitis, and secondary glaucoma), nodular or draining skin lesions (Figure 60-5), and a variety of neurologic signs that include obtundation, ataxia, pelvic limb paresis, circling, hyperesthesia, decreased placing reactions, and blindness.[13,31,35-37]

Diagnosis

A diagnosis of blastomycosis is usually suspected based on the presence of suspicious clinicopathologic abnormalities in a dog or cat from an endemic area. The diagnosis is usually confirmed through cytologic examination of fine needle aspirates of affected tissues (especially skin lesions and lymph nodes), impression smears of draining skin lesions, respiratory lavage specimens (transtracheal washes or bronchoalveolar lavage), or body fluids (especially CSF or ocular fluid, but also synovial fluid or urine sediment). Other methods of diagnosis include histopathology (e.g., of bone or tissue biopsies), fungal culture, and PCR-based assays (Table 60-2). Serologic assays that detect antigen and antibody are also available, but when used alone, these do not confirm a diagnosis of blastomycosis.

VetBooks.ir

TABLE 60-2

Diagnostic Assays Currently Available for Blastomycosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, body fluids, impression smears of skin lesions	*Blastomyces dermatitidis* yeasts	Organisms are usually present in variable numbers but occasionally may not be visualized. Organisms may appear disrupted after treatment with antifungal drugs.
Fungal culture	Aspirates or biopsies of affected tissues, body fluids	*B. dermatitidis*	Rarely indicated. Sensitive and specific and may be required for animals when cytologic examination is negative. Risk of laboratory-acquired infections. Slow turnaround time (may require several weeks of incubation).
Antibody serology (gel ID)	Serum	Antibodies to *B. dermatitidis*	When present in conjunction with consistent clinical signs, positive test results usually indicate active infection, but the potential for false positives exists. Negative test results occur commonly in dogs and cats with blastomycosis (low sensitivity).
Antigen assay (ELISA)	Urine, serum	*B. dermatitidis* antigen	Highly sensitive (>90%) when urine is used as the test specimen. False positives are extremely rare in dogs that lack fungal disease, but cross-reactivity with other fungal pathogens may occur (especially *Histoplasma*), so positive results are not diagnostic for blastomycosis.
Real-time PCR assays	Whole blood	*B. dermatitidis* DNA	Not yet validated in adequate numbers of dogs or cats with blastomycosis; usefulness requires further evaluation.
Histopathology	Biopsy specimens from affected tissues	*B. dermatitidis* yeasts	Sensitive, but yeasts may be difficult to find in some infections. Special stains may assist organism detection.

Laboratory Abnormalities

Complete Blood Count

The hemogram of dogs or cats with blastomycosis can be unremarkable. However, a mild, normocytic, normochromic nonregenerative anemia is present in many affected animals. Mild to moderate neutrophilia is also present in many dogs and may be accompanied by a mild to moderate bandemia.[10,38] Mild monocytosis, lymphocytosis, or lymphopenia may be detected.

Serum Biochemical Tests

Serum biochemistry findings in animals with blastomycosis include mild to moderate hyperglobulinemia due to a polyclonal gammopathy, hypoalbuminemia, and, uncommonly, mild hypercalcemia.[10,38] Hypoalbuminemia was present in 70 of 91 (77%) of dogs in one study, hyperglobulinemia in 58%, and hypercalcemia in 14% of dogs.[10]

Urinalysis

The urinalysis is usually unremarkable in animals with blastomycosis, but occasionally proteinuria, pyuria, hematuria, or cylindruria are present. Rarely, *B. dermatitidis* yeasts are identified in the sediment.

Cerebrospinal Fluid Analysis

CSF analysis in dogs with CNS blastomycosis can reveal increased total nucleated cell counts and increased CSF protein concentration.[39] Nucleated cells typically consist of a mixture of small and large mononuclear cells and neutrophils.

Diagnostic Imaging

Plain Radiography

Radiographic patterns in dogs with blastomycosis vary considerably and include unstructured, miliary, or nodular interstitial patterns; a bronchointerstitial pattern; alveolar or mixed alveolar-interstitial patterns; pulmonary mass lesions (>3 cm in diameter); or single or multiple large (0.5 to 2.9 cm) pulmonary nodules that can resemble metastatic pulmonary neoplasia (Figure 60-6).[10,40,41] Tracheobronchial lymphadenopathy is present in approximately 25% of dogs.[40] Pleural thickening and mild pleural effusion are uncommonly identified (≤10% of

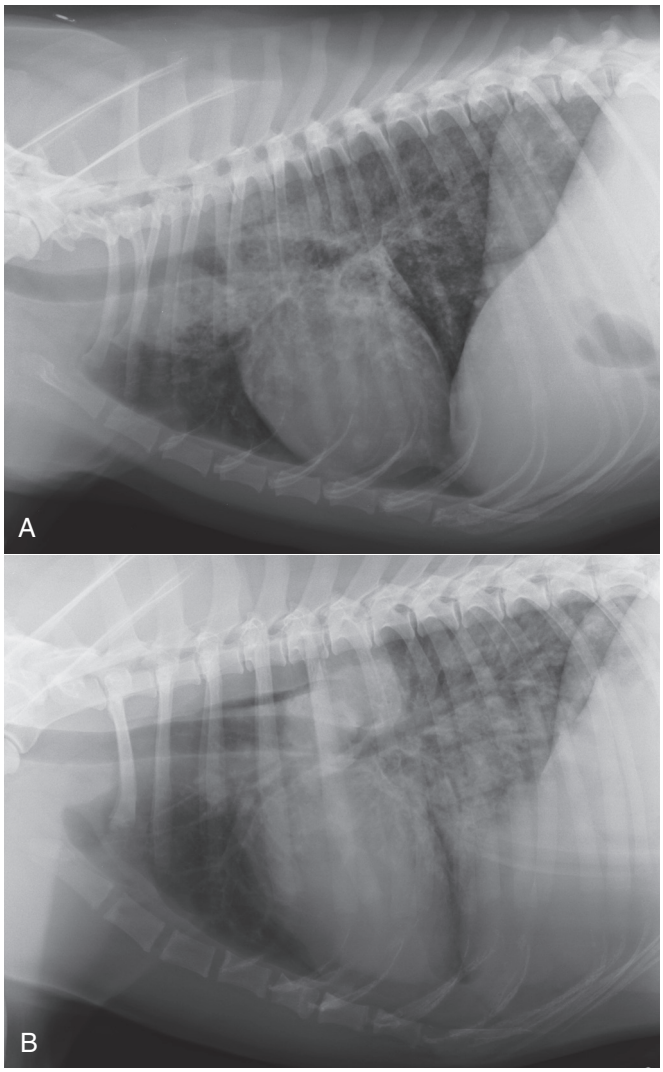

FIGURE 60-6 Radiographic patterns in pulmonary blastomycosis. **A,** Lateral thoracic radiograph from a 2-year-old female spayed Labrador retriever with a 1-week history of cough and inappetence. A diffuse miliary nodular interstitial pattern is present. **B,** Lateral thoracic radiograph from a 5-year-old female spayed German shepherd dog with lethargy and inappetence. An alveolar pattern is present in the caudal lung lobes, along with marked hilar lymphadenopathy. There is also a nodular lesion in the cranial lung lobes just ventral to the trachea. (Courtesy Daniel Cronk, University of Minnesota.)

affected dogs). Focal bronchiectasis has also been described. In one study, only 2 of 125 dogs with blastomycosis had no visible abnormalities on thoracic radiography. Findings in affected cats include diffuse miliary or nodular interstitial patterns, lobar consolidation, and/or pleural effusion.[13,31]

Radiographs of affected bone typically show osteolysis, often accompanied by periosteal proliferation and soft tissue swelling. Pathologic fractures may be identified (Figure 60-7). Evidence of hypertrophic osteopathy was present bilaterally along the humerus, radius, ulna, metacarpi, and phalanges of a dog with a mass lesion in the right middle lung lobe.[22]

Advanced Imaging

Computed tomographic findings in dogs with CNS blastomycosis include intra-axial, intranasal, or retrobulbar mass lesions that are uniformly or heterogeneously contrast enhancing.[25] An intra-axial contrast-enhancing mass lesion was also described in a cat.[42] Intranasal or retrobulbar mass lesions can invade the cribriform plate or other parts of the skull, with associated osteolysis. Meningeal or periventricular contrast enhancement may also be present.[25,26] MRI findings have not been extensively described. One dog had a retrobulbar mass lesion that extended through the calvarium; the lesion was iso- to hypointense on T2-weighted images, slightly hypointense on T1-weighted images, and showed strong homogenous contrast enhancement.[29]

Microbiologic Tests

Cytologic Examination

Cytologic examination of fine-needle aspirates, respiratory wash specimens, or body fluids frequently reveals large numbers of *B. dermatitidis* yeasts. The yeasts are 8 to 15 µm in diameter, have a thick, refractile cell wall, and exhibit broad-based budding (Figure 60-8). Daughter cells are nearly as large as the parent cell when they detach. A pyogranulomatous inflammatory response is usually present. Occasionally, organisms are not seen; the sensitivity of transtracheal lavage for diagnosis of pulmonary blastomycosis in two studies of 17 and 39 dogs was 76% and 69%,[38,41] whereas the sensitivity of fine-needle aspiration of the lung was 46 of 57 (81%).[38]

Serologic Diagnosis

Serologic assays that detect antibody and those that detect *B. dermatitidis* antigen are available on a commercial basis in North America. The most widely available antibody assay uses gel immunodiffusion (ID) (see Chapter 2), which detects antibodies to the *B. dermatitidis* A antigen. Unfortunately, gel ID assays have variable and generally unacceptable sensitivity for diagnosis of blastomycosis in dogs and cats, which has ranged from 17% to 91%.[10,31,38,43-45] An enzyme immunoassay that used crude mold-phase *B. dermatitidis* as the antigen had a sensitivity of 76.1%,[43] and a radioimmunoassay designed to detect antibody responses to the BAD-1 antigen had a sensitivity of 92%.[45] The specificity of the gel ID assay exceeds 95% based on limited studies of healthy dogs or dogs with diagnoses other than blastomycosis.[44,45] However, because false-positive test results have the potential to occur as a result of exposure and recovery in endemic areas or as a result of cross-reactivity to other infectious agents, diagnosis based on positive antibody serology alone is not recommended.

An assay that detects *Blastomyces* cell wall galactomannan antigen (MiraVista Diagnostics, Indianapolis, IN) has largely replaced antibody assays for serologic diagnosis of canine blastomycosis. The performance of this assay was evaluated in 46 dogs with confirmed blastomycosis.[43] When urine was used, the sensitivity was 93.5%, whereas when serum was assayed, sensitivity was 87%. Only 1 of 43 control dogs without blastomycosis had a positive test result. In human patients, the sensitivity of urine galactomannan antigen testing was 90%, and specificity was 99% in patients without fungal infections. However, 96% of humans with histoplasmosis tested positive as a result of cross-reactivity.[46] Positive test results can also occur in dogs and cats that have histoplasmosis, although the extent to which this occurs requires further study. It is possible that cross-reactivity may also occur when other mycoses are present.

Fungal Culture

B. dermatitidis can be isolated from clinical specimens on routine fungal media in the laboratory. Growth of a white mold

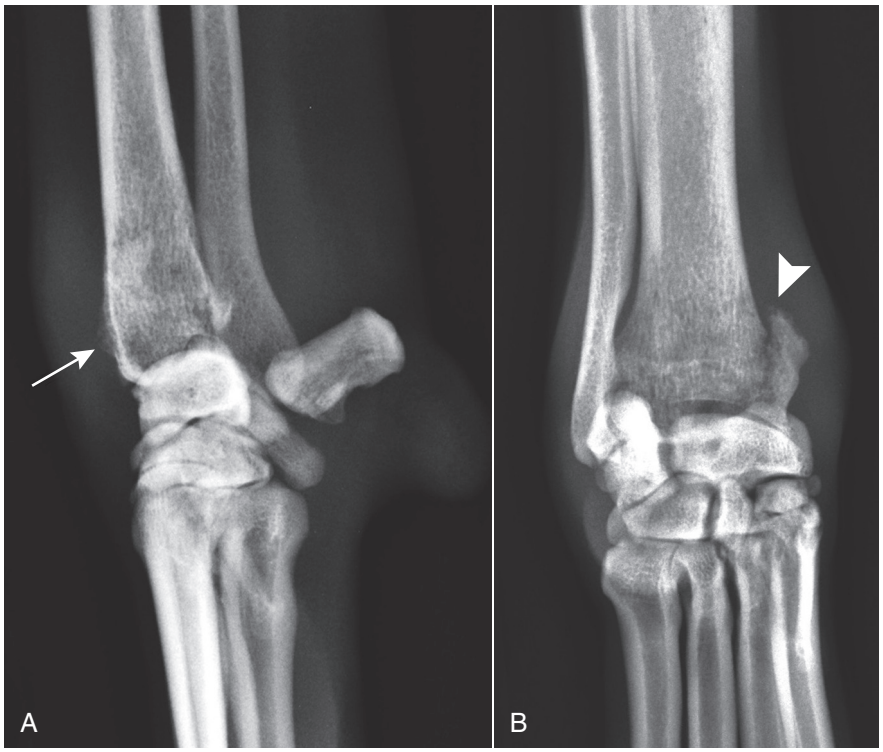

FIGURE 60-7 Lateral **(A)** and anteropalmar **(B)** radiograph of the right carpus showing an osteolytic and osteoproductive *(small arrow)* lesion with a pathologic fracture *(arrowhead)* and associated soft tissue swelling in the distal radius of a 6-year-old male neutered Labrador retriever with disseminated blastomycosis. (Image courtesy Daniel Cronk, University of Minnesota.)

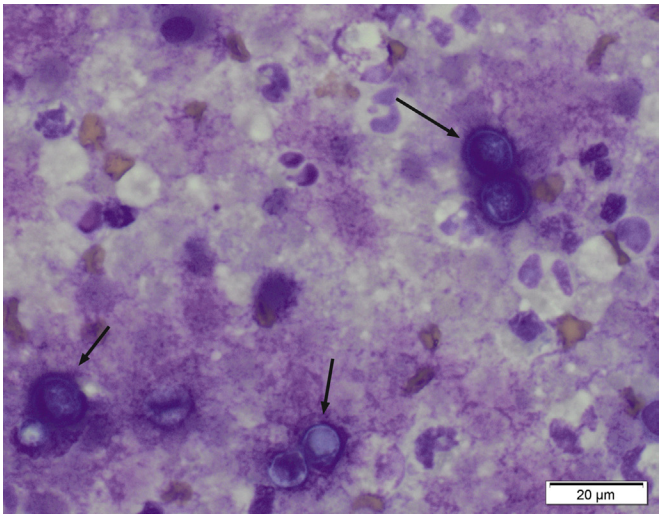

FIGURE 60-8 Cytology of a fine-needle aspirate of a skin lesion from a dog with blastomycosis. *Blastomyces* yeasts *(arrows)* have a thick wall and exhibit broad-based budding. A pyogranulomatous inflammatory response is also present. (Image courtesy Dr. Jed Overmann, University of Minnesota.)

typically appears after incubation for 1 to 3 weeks, but occasionally incubation periods of up to 5 weeks are required. The organism is identified based on the morphology of its conidia, which are round to oval and attached to hyphae (see Figure 60-1). Because *B. dermatitidis* grows as a mycelium in the laboratory, culture is a laboratory health hazard and should be performed only if necessary. The laboratory should be warned of the possibility of a dimorphic fungal infection, so that appropriate precautions are taken.

Molecular Diagnosis Using the Polymerase Chain Reaction

Real-time PCR assays have been developed that rapidly detect *B. dermatitidis* in clinical specimens from humans,[47,48] but are not currently used routinely for diagnosis in dogs and cats. The sensitivity of one assay was 86% when compared with culture of clinical specimens.[48] PCR assays have not been widely applied to the diagnosis of blastomycosis in dogs and cats.

Pathologic Findings

Gross pathologic findings in dogs with blastomycosis include thin body condition; characteristic skin lesions; bony proliferations that may be accompanied by pathologic fracture; enlargement of the peripheral and/or tracheobronchial lymph nodes; ocular lesions; lung consolidation; and firm, pale, pulmonary nodules or masses that range in size from 1 mm to several centimeters in diameter. Masses may be caseous on cut surface. Animals with CNS involvement may have masses within the brain, secondary hydrocephalus, or retrobulbar or caudal nasal cavity granulomas that may invade the cribriform plate and extend along optic nerves.[27,39] Rarely, pleural and/or peritoneal effusion and nodular lesions within abdominal viscera have been reported.[20] Testicular and prostatic masses can also be found.[27] Histopathology reveals granulomatous or pyogranulomatous inflammatory infiltrates in a variety of organs, often with intralesional budding yeasts (Figure 60-9). Multinucleated giant cells, fibroblasts, and large numbers of lymphocytes may also be present. Ocular lesions include uveitis, choroiditis, retinal detachment, retinal degeneration, lens rupture, cataracts, optic

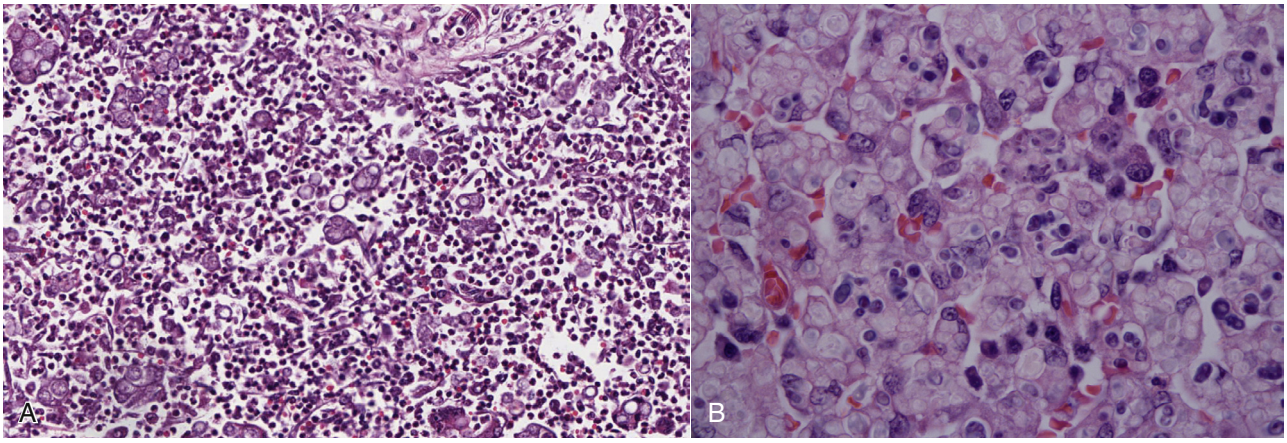

FIGURE 60-9 Histopathologic findings in dogs with blastomycosis. **A,** Histopathology of the lymph node from a 10-year-old female spayed Australian shepherd dog with blastomycosis. Severe pyogranulomatous lymphadenitis is present with moderate numbers of large yeast organisms. (Image courtesy Dr. Catherine Benson, University of Minnesota.) **B,** Histopathology of the lung of another Australian shepherd dog that had a pulmonary and a mediastinal abscess due to *Blastomyces dermatitidis*. neuritis, and vitritis.[27,34] Secondary hepatic and renal amyloidosis was described in one dog.[49]

Organisms are not always detected in lesions, even in untreated dogs. Special stains such as silver stains, periodic acid–Schiff, and immunohistochemical stains can assist in the identification of *B. dermatitidis* yeasts within sections,[34,49,50] but failure to detect yeasts does not rule out blastomycosis.

Treatment and Prognosis

Antimicrobial Treatment

The most widely used treatment for blastomycosis in dogs is itraconazole, which is effective as a single agent in many dogs.[38,51] Itraconazole has largely replaced the use of ketoconazole for treatment of blastomycosis. The recommended dose of itraconazole for dogs is 5 mg/kg PO q24h. This dose has an equivalent efficacy as a dose of 5 mg/kg PO q12h and a lower rate of adverse effects such as anorexia.[51] The duration of azole treatment should be based on serial monitoring of clinical signs and radiographic lesions (e.g., every 4 to 8 weeks). Most dogs require at least 3 to 6 months of treatment, and some dogs require treatment for more than 1 year, especially those with osteoarticular infections or widespread dissemination. Because fluconazole is less active, its use is not recommended for treatment of human blastomycosis, unless itraconazole is not tolerated.[52] Treatment with deoxycholate amphotericin B or lipid-complexed amphotericin B is also effective and could be considered for dogs with severe disease with widespread dissemination, for animals that do not respond to azole mono therapy, or for those that do not tolerate itraconazole (see Box 9-1).[38,53] Cats with blastomycosis have also been treated with variable success with combinations of amphotericin B and azoles or amphotericin B alone.[13,31] In human patients, the use of deoxycholate or lipid-complexed amphotericin B is recommended for severe pulmonary or disseminated disease, followed by step-down itraconazole therapy after there has been a satisfactory clinical response.[52] Whether protocols that include amphotericin B offer a survival advantage over azole monotherapy for dogs or cats has not been well studied in a prospective fashion. Other drugs that have been used successfully to treat human blastomycosis include voriconazole and posaconazole.[54,55] Because of its ability to penetrate the CNS and eye, voriconazole has been recommended for treatment of human CNS blastomycosis after initial treatment with lipid-complexed amphotericin B.[55]

Urine *Blastomyces* galactomannan antigen concentration declines with effective antifungal drug treatment.[43] It is not yet clear whether treatment should be continued until antigenuria is undetectable when radiographic lesions resolve earlier. It is possible that the immune system of some dogs may continue to clear antigen even after treatment is discontinued.

Supportive Care

Other treatments that may be required for treatment of dogs or cats with severe pulmonary blastomycosis are supplemental oxygen, nebulization and coupage, intravenous fluid therapy, and, in some cases, mechanical ventilation.[38] Mechanical ventilation was used to treat 5 (4%) of 125 dogs with pulmonary blastomycosis in one report, none of which survived.[38] Dogs with CNS involvement may require treatment with anticonvulsants in order to control seizure activity. The concurrent use of systemic glucocorticoids should also be considered to control brain inflammation and edema, although whether this ultimately improves outcome is not known. For animals that lack CNS involvement, NSAIDs can be used to control pyrexia. Topical anti-inflammatory and antiglaucoma agents may be indicated if ocular involvement is present. Enucleation may ultimately be required if endophthalmitis is present to control ocular pain and eliminate infection. Treatment of osteomyelitis or large pulmonary granulomas that are refractory to antifungal chemotherapy may require surgical treatment by amputation or lung lobectomy, respectively.

Prognosis

Cure rates of 50% to 75% have been reported in dogs with blastomycosis.[51,56] An additional 20% of dogs experience relapse of disease after treatment is discontinued.[51] Clinical signs and radiographic lesions can worsen in the first few days of treatment in some affected dogs,[40] possibly as a result of the inflammatory response to dying organisms. The median time for resolution of primary radiographic patterns in dogs with

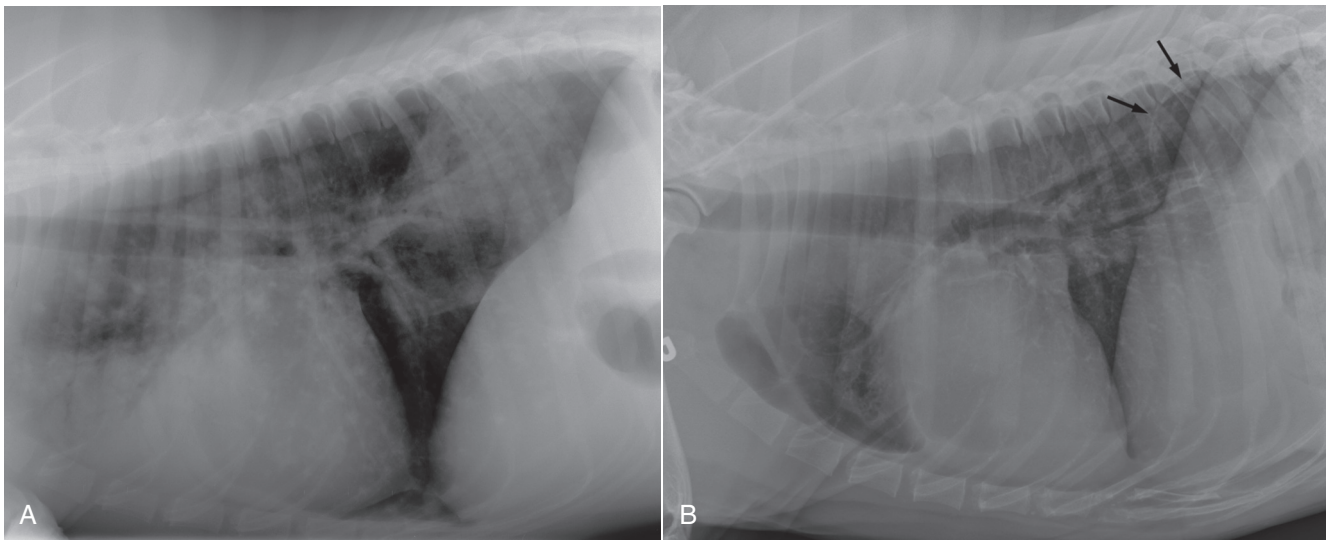

FIGURE 60-10 Lateral thoracic radiographs from a young adult male neutered golden retriever with blastomycosis. **A,** A nodular soft tissue pattern is present diffusely throughout all lung lobes, which coalesces to alveolar infiltrates in the left caudal lung lobe and right cranial lung lobe. **B,** Residual pulmonary infiltrates are present in the right cranial lung lobe after 14 months of itraconazole treatment. There is also a large bulla in the left caudal lung lobe *(arrows)*.

pulmonary blastomycosis in one study was 186 days (range, 4 to >355 days).[40] Significantly longer mean treatment durations were required for radiographic improvement of large pulmonary masses when compared with alveolar and interstitial patterns. The most common radiographic sequela to pulmonary blastomycosis is development of one or more pulmonary bullae. Unstructured interstitial patterns may also persist, presumably as a result of pulmonary fibrosis (Figure 60-10).[40]

Involvement of the CNS, severe lung disease, and a high band neutrophil count are negative prognostic factors.[38,51,56] In one study, the median band neutrophil count in dogs that did not survive was 1200 cells/μL (range, 0 to 3980 cells/μL), whereas that in survivors was 0 cells/μL (range, 0 to 2380 cells/μL).[38] In that study, 63% of 125 dogs with blastomycosis survived. The prognosis for survival in animals with neurologic involvement is particularly poor. The prognosis for resolution of endophthalmitis is also poor; only 20% of eyes with endophthalmitis respond favorably to antifungal drug treatment.[33] Nevertheless, eyes that do not undergo enucleation can ultimately progress to phthisis bulbi after completion of treatment, without recurrence of systemic infection.[33]

Immunity and Vaccination

Immunity to blastomycosis is initially dependent on phagocyte function, especially neutrophils and alveolar macrophages, which can clear conidia. However, once the organisms have transitioned to the yeast form, control of infection also depends on T lymphocytes, which stimulate macrophages to kill the yeasts.[52] Humoral immunity is not essential for resolution of infection. An experimental vaccine that includes a genetically engineered, live-attenuated BAD-1 deletion mutant *B. dermatitidis* strain protected mice from experimental infection, was safe in 25 beagles and 78 foxhounds in a field trial, and induced specific immune responses to *B. dermatitidis* antigens.[57,58] Although further study is required, this vaccine holds promise for prevention of blastomycosis in dogs that reside in hyperendemic regions of the United States.

Prevention

Avoidance of specific foci of hyperendemicity where other dogs or humans have contracted blastomycosis may prevent blastomycosis, but this is not always possible.

Public Health Aspects

Like dogs, humans acquire *B. dermatitidis* infection from the environment. Dogs are considered sentinels for human exposure and infection,[59] although whether strains that infect dogs also infect humans requires further study. The incidence of blastomycosis in dogs is approximately 8 times that in humans, and disease has been reported in humans and dogs that reside in the same household.[59,60] Approximately 50% of human infections are asymptomatic.[52] When illness develops, it typically occurs 30 to 45 days after exposure and is often a mild, self-limiting influenza-like illness with fever and cough. Blastomycosis is suspected in endemic areas when respiratory signs persist and fail to respond to treatment with antibacterial drugs. Radiographic abnormalities resemble those in dogs, although hilar lymphadenopathy is not often seen. Chronic pulmonary blastomycosis can resemble pulmonary neoplasia or tuberculosis. Rarely, blastomycosis-associated acute respiratory distress syndrome (ARDS) develops, which is associated with mortality rates that exceed 50%.[52] Dissemination to extrapulmonary sites similar to those involved in dogs occurs in 20% to 25% of affected humans. Serious infections can occur in immunocompromised patients such as those with AIDS, solid organ transplant recipients, and humans treated with TNF-α blockers (used to treat inflammatory diseases such as Crohn's disease, psoriasis, and rheumatoid arthritis).[52,61,62]

Inoculation blastomycosis that involves the skin and underlying bone has been described in veterinary personnel after sharps injuries or bite wounds from dogs with blastomycosis. One involved a needle-stick injury after a lung aspirate in a dog with suspected blastomycosis, and another was an accident that occurred during a necropsy.[63,64] Bite wounds from dogs with

VetBooks.ir

blastomycosis can result in localized disease; disseminated disease occurred in a renal transplant recipient.[65-67] A veterinary technician developed pulmonary blastomycosis after *B. dermatitidis* was cultured unexpectedly in a veterinary clinic in-house laboratory.[68] Although these routes of transmission are rare, prevention of sharps injuries, avoidance and proper management of bite wounds, and use of accredited veterinary laboratories for isolation of microorganisms from dogs and cats may reduce the risk of inoculation or laboratory-acquired blastomycosis in veterinary staff. The bandaging of skin lesions has been discouraged because it has the potential to promote transition of the organism to the mold form, but this has not been documented to occur. The body of deceased pets with blastomycosis should be disposed of promptly and by cremation.

CASE EXAMPLE

Signalment: "Sam," a 3-year-old male neutered golden retriever from Burlingame in northern California

History: Sam was evaluated by the Veterinary Emergency and Critical Care Service at the University of California, Davis, for pulmonary blastomycosis, which had been diagnosed at a local veterinary clinic. Sam had a 1-week history of lethargy and inappetence. The day after illness was noted, Sam was taken to a local veterinary clinic. Routine blood work showed only anemia (hematocrit 34%), thrombocytosis (554,000 platelets/μL), and a mildly increased serum alkaline phosphatase activity (199 U/L). Thoracic radiographs showed hilar lymphadenopathy, a mild diffuse miliary interstitial pattern, and focal alveolar infiltrates in the right cranial and left caudal lung lobe. Cytologic examination of a transtracheal lavage specimen showed pyogranulomatous inflammation with moderate numbers of yeasts that had morphology consistent with *Blastomyces dermatitidis*. Serology (gel immunodiffusion) for detection of antibodies to *B. dermatitidis* was negative. Treatment with itraconazole (5 mg/kg PO q24h) was commenced, and after 2 days the dose was increased to 10 mg/kg PO q24h because of lack of clinical improvement. Subsequently the dog's rectal temperature increased to 105°F (40.6°C) and a day later, radiographs showed an increase in the severity of the alveolar infiltrates. Treatment with carprofen (2.4 mg/kg PO q12h) was initiated, and subcutaneous fluids were administered. This was associated with resolution of pyrexia, but the dog remained lethargic and exercise intolerant and the owners noted right pelvic limb lameness. The dog was referred for further evaluation.

Approximately 6 weeks before he became ill, Sam had been taken to Georgian Bay in Ontario, Canada, for 1 week. He had also been in the Vermont region for 2 months before that time. Other travel had been limited to various bayside and mountainous parts of northern California. The owner's brother's dog, which had traveled with Sam to Ontario and Vermont, had also been diagnosed with blastomycosis 3 weeks earlier.

Physical Examination:

Body Weight: 41.5 kg.

General: Quiet, alert and responsive. T = 103.5°F (39.7°C), HR = 120 beats/min, panting, CRT <2 s, mucous membranes were moist and slightly cyanotic.

Eyes, Ears, Nose, and Throat: No clinically significant abnormalities were detected. A fundoscopic examination with dilated pupils was unremarkable.

Musculoskeletal: BCS 4/9; no obvious lameness or pain on palpation was appreciated.

Respiratory: Increased respiratory effort was present. Lung sounds were increased diffusely on thoracic auscultation and partially obscured the heart sounds. Markedly increased respiratory effort was evident when the dog's gait was assessed as part of an orthopedic examination. An intermittent nonproductive cough was also appreciated.

All Other Systems: No clinically significant abnormalities were detected. No obvious neurologic deficits were noted, but a full neurologic examination was not performed.

Laboratory Findings: Blood oxygen saturation (pulse oximetry) = 91%, improved to 95% with flow-by supplemental oxygen

CBC:

HCT 37.3% (40%-55%)
MCV 71.2 fL (65-75 fL)
MCHC 35.1 g/dL (33-36 g/dL)
WBC 14,640 cells/μL (6000-13,000 cells/μL)
Neutrophils 11,273 cells/μL (3000-10,500 cells/μL)
Band neutrophils 586 cells/μL
Lymphocytes 1318 cells/μL (1000-4000 cells/μL)
Monocytes 1318 cells/μL (150-1200 cells/μL)
Eosinophils 146 cells/μL (0-1500 cells/μL)
Platelets 387,000 platelets/μL (150,000-400,000 platelets/μL)
Rare slight toxicity of band neutrophils was reported.

Serum Chemistry Profile:

Sodium 148 mmol/L (145-154 mmol/L)
Potassium 5.0 mmol/L (4.1-5.3 mmol/L)
Chloride 116 mmol/L (105-116 mmol/L)
Bicarbonate 15 mmol/L (16-26 mmol/L)
Phosphorus 6.6 mg/dL (3.0-6.2 mg/dL)
Calcium 9.9 mg/dL (9.9-11.4 mg/dL)
BUN 11 mg/dL (8-21 mg/dL)
Creatinine 0.5 mg/dL (0.5-1.6 mg/dL)
Glucose 81 mg/dL (60-104 mg/dL)
Total protein 5.6 g/dL (5.4-7.4 g/dL)
Albumin 1.8 g/dL (2.9-4.2 g/dL)
Globulin 3.8 g/dL (2.3-4.4 g/dL)
ALT 15 U/L (19-67 U/L)
AST 32 U/L (21-54 U/L)
ALP 148 U/L (15-127 U/L)
GGT 0 U/L (0-6 U/L)
Cholesterol 318 mg/dL (135-345 mg/dL)
Total bilirubin 0.4 mg/dL (0-0.4 mg/dL).

Urinalysis: SGr 1.015; pH 5.0, no protein (SSA), 1+ bilirubin, no hemoprotein, no glucose, no WBC, rare RBC/HPF, rare transitional epithelial cells, and a few amorphous crystals were seen.

Continued

VetBooks.ir

Imaging Findings:

Thoracic Radiographs: A nodular soft tissue pattern was present diffusely throughout all lung lobes, which coalesced to alveolar infiltrates in the left caudal lung lobe and right cranial lung lobe (see Figure 60-10). The cardiac silhouette was mildly enlarged. Increased soft tissue opacity was noted in the perihilar region.

Abdominal Ultrasound: The spleen was mildly enlarged, and there was mild mesenteric lymphadenopathy.

Diagnosis: Acute, severe pulmonary blastomycosis.

Treatment: Sam was placed in an oxygen cage with an inspired oxygen concentration (FiO_2) of 40% to 60%. An arterial blood gas revealed a pH of 7.301, pCO_2 of 36.6 mm Hg, pO_2 of 79.1 mm Hg, HCO_3 of 16.8 mmol/L, base deficit of 7.8 mmol/L, and measured O_2 saturation of 92.8%. The dog was also treated with crystalloid fluids (lactated Ringer's solution with 20 mEq/L KCl; 80 mL/hr, IV) and nebulization and coupage (q6h). For the first 24 hours, respiratory rate ranged from 90 to 105 breaths/min and a nonproductive cough occurred every few hours. The dog drank water, but was inappetent. Treatment with lipid-complexed amphotericin B was initiated (1 mg/kg IV on a Monday-Wednesday-Friday basis) and carprofen administration continued. By day 4, Sam was afebrile, eating, and oxygen saturation was 96% with an FiO_2 of 46%. However, increased respiratory effort developed when oxygen supplementation was discontinued, and arterial blood gas analysis showed a pH of 7.335, pCO_2 of 27.2 mm Hg, pO_2 of 65.8 mm Hg, HCO_3 of 13.9 mmol/L, and base deficit of 10.6 mmol/L (room air). By day 5, Sam was playing with toys in the oxygen cage, and his appetite was excellent. Treatment with itraconazole (5 mg/kg PO q24h) was resumed in addition to the amphotericin B. By day 8, oxygen saturation was 95% with an FiO_2 of 30%. Thoracic radiographs showed persistent radiographic abnormalities, organization of the alveolar infiltrates, and apparent bronchiectasis. Survey radiographs of the appendicular skeleton showed no evidence of osteomyelitis. The dog was discharged after 11 days of hospitalization (cumulative amphotericin B dose of 6 mg/kg). An additional seven treatments of amphotericin B were then administered at the local veterinary clinic. Serial renal panels showed no evidence of nephrotoxicity.

At a recheck 1 month after the date of first evaluation, Sam remained somewhat lethargic and exercise intolerant, but had gained 3 kg. The frequency of cough had decreased from approximately 8 times a day to once or twice daily over the previous 2 weeks. An arterial blood gas showed a pO_2 of 93.5 mm Hg, hematocrit was 27.8% with 39,400 reticulocytes/μL, and there was persistent hypoalbuminemia (2.0 mg/dL) and hyperglobulinemia (4.8 mg/dL). There was mild radiographic improvement in the pulmonary lesions. Treatment with itraconazole was continued for an additional 14 months, with serial monitoring of thoracic radiographs at 1, 2, 3, 8, and 14 months. At the 14-month time point, Sam had returned to his normal energetic self, weighed 45 kg, but had persistent mild infiltrates in the right cranial lung lobe on thoracic radiographs and a bulla in the left cranial lung lobe. There was also a mild to moderate generalized interstitial pattern with multiple small soft tissue opaque nodules that had not changed from the previous evaluation. One month after the itraconazole was discontinued, thoracic radiographs remained unchanged. Relapse did not occur. Sam was ultimately euthanized at 8 years of age as a result of an unrelated neoplastic disease.

Comments: This case is an example of acute pulmonary blastomycosis that followed travel to an endemic area. Another dog that traveled to the same area also developed disease. Sam appeared to require more aggressive therapy than itraconazole alone, so amphotericin B was instituted, which was followed by gradual recovery from the infection. Although lipid-complexed amphotericin B was used, treatment with deoxycholate amphotericin B may also have led to cure. No evidence of dissemination was clearly identified. The lameness observed by the client may have represented weakness or exercise intolerance, but it is possible that bone involvement was present but not evident radiographically. The case also illustrates the residual pulmonary lesions that can develop in dogs with pulmonary blastomycosis, and the need for serial radiographic evaluations to assess these lesions. Although not performed in this dog, serial monitoring of antigenuria may also ultimately help determine the most appropriate time to discontinue therapy.

CHAPTER 61

Histoplasmosis

Jane E. Sykes and Joseph Taboada

VetBooks.ir

Overview of Histoplasmosis

First Described: 1905, Panama (by Samuel Darling), in a person from Martinique, where it was initially mistaken for a protozoal pathogen.[1]

Cause: *Histoplasma capsulatum* (an ascomycete)

Affected Hosts: Many mammalian species including dogs, cats, and humans

Geographic Distribution: Worldwide; but especially the Ohio, Missouri, Tennessee, and Mississippi river valleys of the United States; and Latin America

Mode of Transmission: Inhalation of microconidia from the environment

Major Clinical Signs: Cough, tachypnea, organomegaly, gastrointestinal signs, pallor; signs are often non-specific in cats.

Differential Diagnoses: Other deep mycoses, protothecosis, mycobacterial infections, hemic neoplasia, leishmaniosis, histiocytic colitis

Human Health Significance: *H. capsulatum* also causes disease in humans but direct transmission from animals to humans does not occur

Etiology and Epidemiology

Histoplasma capsulatum is a dimorphic, soil-borne fungus that is found worldwide, but especially along the Mississippi, Missouri, Tennessee, and Ohio river valleys of the United States, as well as in Latin America (Figure 61-1). Endemic areas within the United States span the central portion of the United States from western Virginia to central Texas. Disease has also been reported in cats or dogs from northern California[2]; Brazil[3]; Italy[4]; Queensland in Australia[5]; Japan[6]; and western Canada.[7,8] Eight clades of the organism have been identified by genetic analysis: North American (class 1 and class 2), Latin American (group A and group B), and one each of Australian, Indonesian, Eurasian, and African. These may vary in virulence. All except the Eurasian clade, which is derived from the Latin American group A clade, may be distinct phylogenetic species.[9] A possible ninth clade, which is related to, but distinct from, North American class 1 also appears to infect cats in North America outside the accepted endemic range.[10] Three variants have also been described based on pathogenicity and morphology—*H. capsulatum* var. *capsulatum*, *H. capsulatum* var. *duboisii*, and *H. capsulatum* var. *farciminosum*—although the phylogenetic value of these variants has been debated.[6,9] *H. capsulatum* var. *duboisii* occurs primarily in Africa and Japan. *H. capsulatum* var. *farciminosum* infections occur primarily in horses, but have also been reported in humans and dogs.

H. capsulatum grows best in soil where temperatures are between 22°C and 29°C, where annual rainfall is 35 to 50 inches, and where relative humidity is 67% to 87%. These conditions are typically found between latitudes of 45 degrees north to 30 degrees south.[11] *H. capsulatum* can be found in the intestinal tracts and guano of bats, which are the primary reservoir of the organism and serve to disseminate it geographically.[12] Bat caves can maintain perfect growth conditions for *H. capsulatum*. Although *H. capsulatum* can be found in high concentrations in decaying avian guano (especially around blackbird or starling roosts and chicken coops), it is not found in fresh feces or shed in the feces of birds.

Cats are as susceptible, or slightly more susceptible, to histoplasmosis than dogs. Affected cats can be as young as 2 months and, in some cases, older than 15 years.[13] The mean age of affected cats has varied from around 4 years to 9 years.[14] For dogs, a mean age of 4.3 years was reported (range, 5 months to 10 years).[15] Dogs in the 2- to 4-year and 4- to 7-year age groups were more likely to develop histoplasmosis than dogs less than 2 years of age.[16] Sporting or working dogs may be at greater risk of infection because of increased exposure; in a study using the Veterinary Medical Database, pointers were strongly overrepresented.[16] Weimaraners and Brittany spaniels were also at increased risk. Among cats, Persian cats may be slightly overrepresented. A sex predisposition has not been clearly identified in dogs or cats, but more female than male dogs were affected in some case series.[14,15,17-19] This contrasts to human histoplasmosis and other systemic mycoses in dogs, which affect males more often than females.[20] The overwhelming majority of cats with histoplasmosis are retrovirus negative, but a significant percentage of cats in two studies (16% and 28%, respectively) were co-infected with FeLV.[13,14] A small percentage of cats have underlying comorbidities such as lymphoma, feline infectious peritonitis, or a history of glucocorticoid treatment.[13] Comorbidities described in dogs include dirofilariasis[15] and metastatic carcinoma.[6] Disease can occur in cats that are housed exclusively indoors.

Clinical Features

Signs and Their Pathogenesis

In the soil, the mycelial phase of *H. capsulatum* forms macroconidia and microconidia (Figure 61-2). The microconidia are thought to be the form inhaled by mammalian hosts, because

VetBooks.ir

they are small enough (2 to 5 µm) to enter the terminal bronchioles and alveoli. Within the lungs (i.e., at a temperature of 37°C), the microconidia transition to a unicellular yeast, which replicates by budding. The fungus binds to CD11-CD18 integrins on alveolar macrophages and is phagocytized. It then replicates within these cells through control of the phagolysosomal environment and ultimately destroys them, with subsequent replication in other resident alveolar macrophages and inflammatory phagocytes that are recruited to the lung.[21] Acquisition of iron by the fungus is essential for growth in vivo.[22] Some animals control the initial infection but remain latently infected with small numbers of yeasts. Subsequent immune suppression can lead to reactivation of infection years later. Thus, the incubation period can range from 2 to 3 weeks to as long as several years.

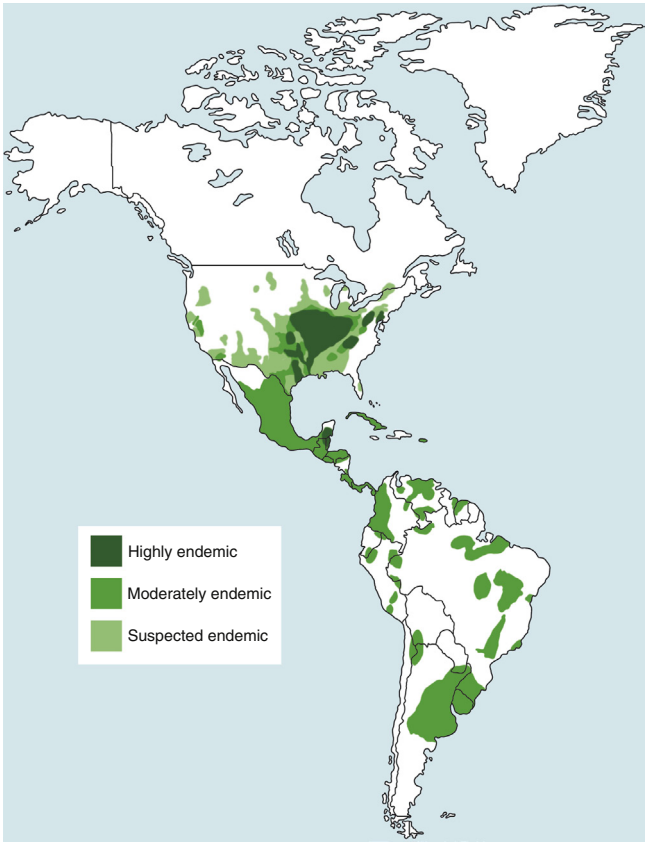

FIGURE 61-1 Approximate geographic distribution of histoplasmosis in the Americas.

The clinical manifestations and rate of disease progression depend on the host immune response to infection, the infectious dose, and the *Histoplasma* strain, which can vary geographically. The vast majority of infections are probably subclinical.[23] Replication of the organism leads to a granulomatous inflammatory response in the lungs. Occasionally, the inflammatory response is followed by fibrosis and scarring. The yeasts migrate to local lymph nodes (such as the hilar lymph node) and other tissues that contain mononuclear cells, such as the liver and spleen. When the cell-mediated immune response is defective or absent, disseminated disease occurs (referred to in human patients as *progressive disseminated histoplasmosis* [PDH][20]), which may be acute or chronic. In addition to lymph nodes, liver, and spleen, other common sites of dissemination are the bone marrow, small and/or large intestinal tract, pancreas, skin, bones, central nervous system (CNS), and eyes. Dogs with histoplasmosis in the United States appear to be particularly susceptible to intestinal involvement. Severe infiltration of the small and large intestines leads to malabsorption, diarrhea, severe weight loss, and hematochezia, often without evidence of respiratory involvement.

Clinical signs in cats are commonly vague and nonspecific, such as weight loss, inappetence, weakness, dehydration, and fever.[13,14] Approximately 40% of cats show respiratory signs such as dyspnea and tachypnea, and to a lesser extent, cough and nasal discharge. However, respiratory signs may be absent

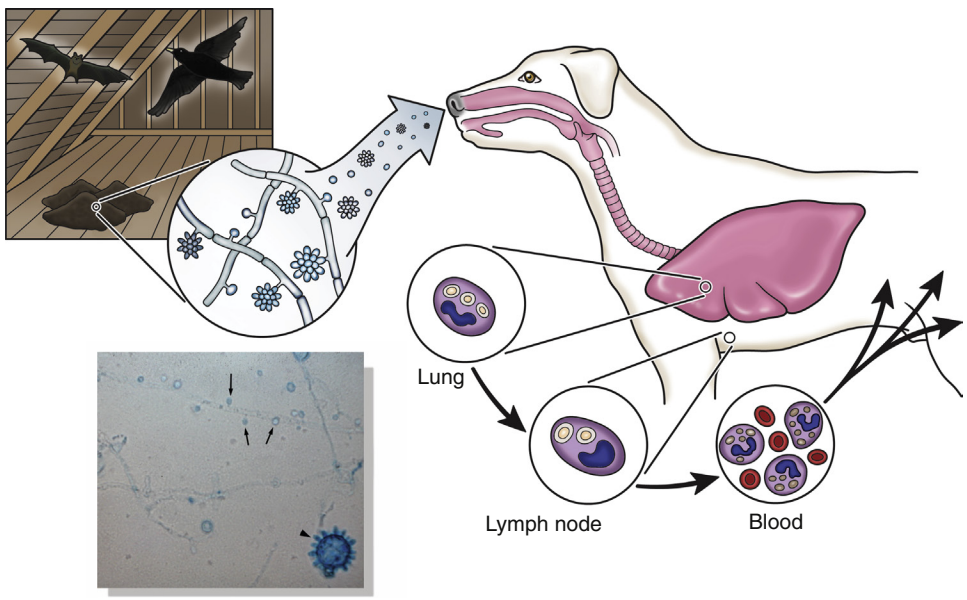

FIGURE 61-2 Life cycle of *Histoplasma capsulatum*. In the environment, the organism forms macroconidia (*arrowhead*, inset) and microconidia (*arrows*, inset). The microconidia are thought to be inhaled into the lungs of mammalian hosts. Within the lung, the organisms transform into yeasts that infect alveolar macrophages and then disseminate to local lymph nodes and the systemic circulation.

in some cats with dissemination of infection to nonpulmonary sites. Ocular signs such as chorioretinitis and/or posterior or anterior uveitis occur in approximately one quarter of cats with histoplasmosis, and around 20% of cats have signs of skeletal involvement.[13,14,17] Nodular or ulcerated and draining skin lesions, peripheral lymphadenopathy, vomiting, diarrhea, oral ulceration, myelopathy, and/or hematuria due to bladder wall involvement have also been reported.[4,14,17,24-29] Clinical signs associated with gastrointestinal involvement are much less likely to occur in cats than in dogs. A high proportion of affected cats that were necropsied had severe disseminated disease.[13]

In dogs, diarrhea, decreased appetite, weight loss, lethargy, fever (up to 40°C or 104°F), and mucosal pallor are the most common clinical signs.[7,8,15,18] In addition to inappetence, weight loss, and diarrhea, other clinical signs referable to the gastrointestinal tract include melena, tenesmus, hematochezia, dyschezia, and/or increased frequency of defecation.[8,15,18] Profuse diarrhea may be chronic and persist for several months. Hilar lymphadenopathy is common, and may be an incidental finding on thoracic radiographs, or it may be severe and contribute to signs of cough. Other signs include respiratory difficulty, icterus, vomiting, hepatomegaly, lymphadenomegaly, nasal discharge, ocular signs, polyuria and polydipsia, lameness due to osteomyelitis, and neurologic signs such as seizures or paralysis/paresis.[8,15,30-32] Affected dogs in Japan have had chronic cutaneous or gingival lesions in the absence of pulmonary or gastrointestinal involvement,[33-36] although disseminated disease has also been described.[6] Skin nodules were also reported in an Australian dog with histoplasmosis.[5] Varied clinical manifestations of histoplasmosis in different parts of the world as a result of strain variation in *H. capsulatum* also occur in humans.[20]

Physical Examination Findings

Physical examination findings in cats with histoplasmosis can be minimal or can include thin body condition or emaciation; fever; pale and/or rarely icteric mucous membranes; peripheral lymphadenopathy; respiratory signs such as dyspnea, tachypnea, and increased or decreased lung sounds; single or multiple cutaneous nodules, ulcerations, and/or draining tracts (Figure 61-3); lameness; and detection of organomegaly, abdominal masses, and/or pain on palpation of the abdomen. Ocular signs include chorioretinitis, optic neuritis, anterior uveitis, retinal detachment, panophthalmitis, and glaucoma (Figure 61-4).

In dogs, lethargy, fever, thin body condition, and pale mucous membranes are most often found on physical examination. Other physical examination abnormalities include dehydration, hepatomegaly, icterus, and/or ascites; tachypnea, increased respiratory effort, and increased lung sounds; lymphadenomegaly that involves one or more peripheral lymph nodes; abnormal stool quality on rectal examination (diarrhea, hematochezia, or melena); nasal and ocular discharge; tachycardia; tongue lesions; and cutaneous nodules, ulceration, or draining tracts.[5,8,15,18,30,37,38] Ocular examination can reveal uveitis, evidence of optic neuritis, or chorioretinitis with retinal detachment.[18,39,40] One dog was seen for lameness, hyperemia, and edema of the left pelvic limb because of a sclerosing pyogranulomatous inflammatory mass in the inguinal region that resulted in venous occlusion.[37] Rarely, neurologic signs such as ataxia, obtundation, head tilt,

VetBooks.ir

nystagmus, strabismus, seizures, facial paralysis, and tetraparesis may be present on physical examination as a result of hepatic encephalopathy or meningoencephalitis.[40-42]

Diagnosis

Laboratory Abnormalities

Complete Blood Count

The CBC in dogs and cats with histoplasmosis reflects the presence of systemic inflammation, gastrointestinal hemorrhage, and/or bone marrow infiltration by fungal organisms. In both dogs and cats, anemia is a common abnormality, may be mild to severe, and is usually normocytic, normochromic, and nonregenerative.[14,15,17,18,43,44] Increased numbers of nucleated erythrocytes occur in some affected dogs.[8,44] The total white cell count or neutrophil count may be normal, increased, or decreased.[15,17,18,43] Most affected cats have a normal or decreased white cell count,[14,43] but leukocytosis due to neutrophilia and monocytosis may be more common in affected dogs.[15,44] Increased numbers of band neutrophils with toxic neutrophils, lymphopenia, monocytopenia, and thrombocytopenia can be present in some severely affected animals.[14,17,18,43,45] Thrombocytopenia can be a result of platelet consumption, sequestration, and/or myelophthisis. Rarely, eosinophilia is present.[46]

Serum Biochemical Tests

Mild to severe hypoalbuminemia is present in most (>75%) affected dogs and cats. Cats with liver involvement may have increased activities of serum ALT and AST.[17,43] Hyperbilirubinemia and increased serum ALP activity are rarely reported.[17] Hypercalcemia and hyperglobulinemia have been described in a few affected cats.[17] Hyperglobulinemia; mild to moderate increases in the activity of serum ALT, AST, ALP, and GGT; and hyperbilirubinemia can be found in dogs.

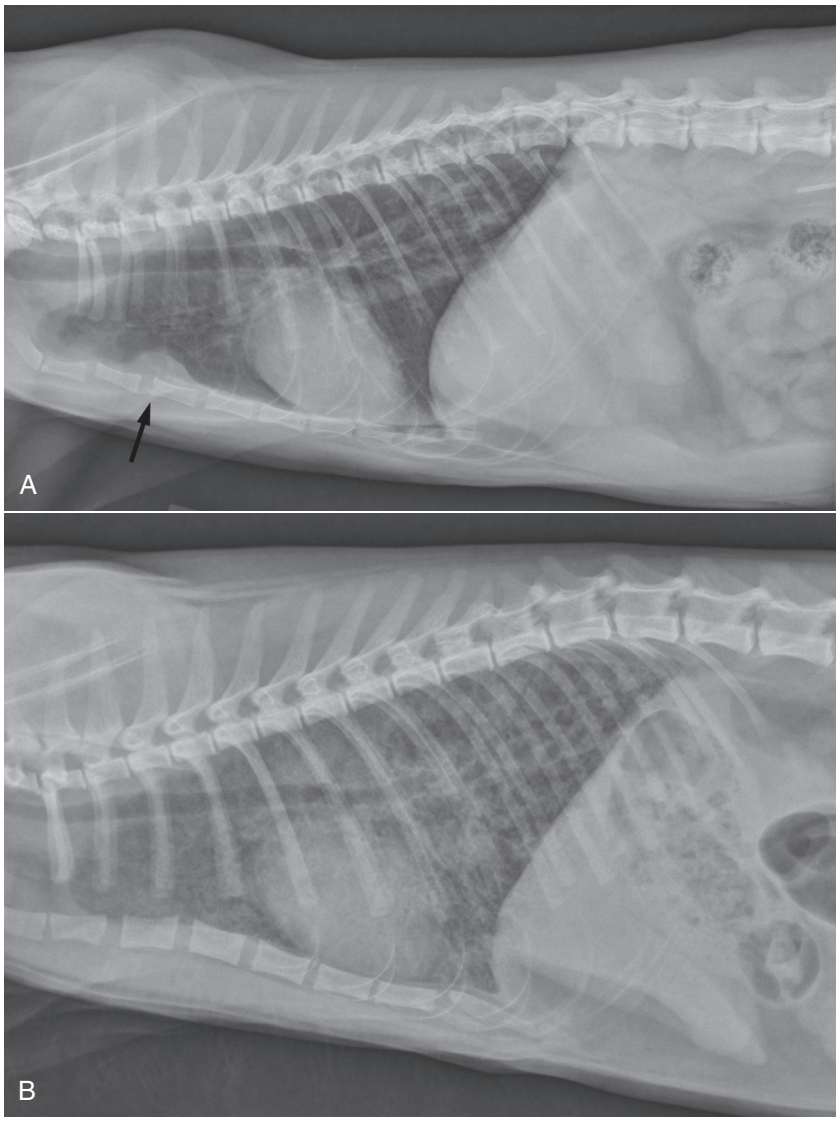

FIGURE 61-5 Radiographic abnormalities in feline pulmonary histoplasmosis. **A,** Lateral thoracic radiograph from an 8-month-old intact male domestic shorthair cat with disseminated histoplasmosis. There is a diffuse bronchointerstitial pulmonary pattern and evidence of sternal lymphadenopathy *(arrow)*. In the viewable abdomen, marked splenomegaly can be appreciated. **B,** Lateral thoracic radiograph from a 7-month-old male neutered domestic shorthair cat with histoplasmosis that was evaluated for tachypnea and dyspnea of 10 days duration. There is a diffuse, severe, interstitial-to-coalescing and patchy pulmonary pattern that obscures visualization of the pulmonary vasculature and cardiac contours. (Courtesy of Lorrie Gaschen, Louisiana State University.)

VetBooks.ir

Urinalysis

Results of urinalysis are usually within normal limits, but low urine specific gravity and bilirubinuria may be present in dogs with hepatic involvement.

Coagulation Testing

A few dogs with acute PDH have had coagulation abnormalities characterized by increased PT and PTT and fibrin degradation product or D-dimer concentrations.[31,44] Coagulation abnormalities in dogs with histoplasmosis may result from disseminated intravascular coagulation and possibly severe hepatic involvement (see also Canine Case Example).

Diagnostic Imaging

Plain Radiography

In cats, thoracic radiographic findings in histoplasmosis usually consist of diffuse, linear, nodular, or miliary interstitial patterns, but mixed interstitial-alveolar-bronchial patterns, pleural effusion, or an absence of abnormal findings can also occur (Figure 61-5).[14,19,43,47] Plain thoracic radiographs in dogs may show alveolar, interstitial, and/or bronchial patterns, tracheobronchial lymphadenopathy, lung lobe consolidation, and/or rarely pleural effusion.[31,45,47,48] Lesions in dogs sometimes mineralize, which does not seem to occur in cats. Abdominal radiographs may show hepatomegaly, splenomegaly, or decreased serosal detail due to ascites. Radiographic evidence of osteomyelitis may be present in cats, with associated soft tissue swelling and sometimes pathologic fractures. Osteomyelitis is rarely described in dogs.[30,32]

Sonographic Findings

Findings on abdominal sonographic examination of dogs with histoplasmosis include hepatic enlargement and hypoechogenicity, abdominal lymphadenopathy, splenomegaly, and ascites. A thickened intestinal wall may be present with disruption of bowel wall architecture. Adrenomegaly, abdominal lymphadenopathy, and occasionally renomegaly have been described in cats.[14]

Endoscopy

Colonoscopic findings in dogs with colonic histoplasmosis include irregularity, ulceration, and increased granularity and friability of the colonic wall (Figure 61-6).

Microbiologic Tests

Diagnostic assays currently available for histoplasmosis in dogs and cats are described in Table 61-1.

Cytologic Examination

Cytologic examination of aspirates or impression smears of affected tissues (e.g., fine-needle aspirates of liver, spleen, lymph nodes, lung, bone marrow), rectal scrapings, or Cytospin preparations of lung wash specimens or body fluids (e.g., CSF, synovial fluid, ascites, or pleural effusion) usually reveals pyogranulomatous or granulomatous inflammation. *H. capsulatum* yeasts can be seen extracellularly and intracellularly (usually within mononuclear phagocytes). Most extracellular organisms are probably an artifact of smear preparation. Occasionally one or more organisms are seen in circulating monocytes, neutrophils, or eosinophils in severely ill animals with disseminated disease (Figure 61-7). Cytologic evidence of fungemia was detected in nearly 20% of affected cats in one study.[13] The bone marrow is a common site to yield organisms in cats, even when hematologic abnormalities are minimal.

Cytologically, the yeasts are 2 to 4 µm in diameter, oval, have a basophilic center, and are surrounded by a clear halo, which results from shrinkage artifact (see Figure 61-7). They are similar in size to *Sporothrix* spp., although different in shape. A variety of stains can be used, such as Diff-Quik and Wright stains. The organism is not encapsulated, despite its name. Organisms may not be identified within chronic, fibrosing lesions.[37,49]

Serologic Testing

Both antibody and antigen (ELISA) assays are available for serodiagnosis of histoplasmosis. Antibody assays for *Histoplasma capsulatum* are based on gel immunodiffusion or complement fixation and have had poor diagnostic sensitivity.[13,15,17] False positives reportedly occur in recovered animals, although the specificity of antibody assays in dogs and cats is not well documented. In human patients, acute and convalescent antibody testing is useful for diagnosis of acute pulmonary histoplasmosis, and a single positive antibody titer is used as an aid for diagnosis of chronic histoplasmosis. In particular, a positive CSF antibody titer can be useful for diagnosis of culture-negative chronic *H. capsulatum* meningitis. An ELISA assay for *H. capsulatum* antigen (MiraVista Diagnostics, Indianapolis, IN) is widely used in human patients for diagnosis of histoplasmosis, and urine is the preferred specimen for testing because it results in a higher sensitivity than when serum is assayed.[49] In human patients with AIDS and severe PDH, the sensitivity of the assay is 95% when urine is used, and 86% when serum is used.[49] The sensitivity is lower in human patients with pulmonary histoplasmosis, but use of a combination of urine antigen and serum antigen increases sensitivity to 83%.[50] False positives occur in people with other disseminated mycoses, including blastomycosis, penicilliosis, and coccidioidomycosis,[51,52] so the

TABLE 61-1

Diagnostic Assays Currently Available for Histoplasmosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, bone marrow aspirates, sometimes blood smears or buffy coat preparations, body fluids	*Histoplasma capsulatum* organisms (usually in large numbers) within mononuclear phagocytes and granulocytes	Organisms are usually present but, in the absence of experience, may be confused with protozoa such as *Leishmania* or other fungi such as *Sporothrix schenckii*. False negatives can occur in animals with very chronic clinical manifestations.
Fungal culture	Aspirates or biopsies of affected tissues, body fluids, whole blood	*H. capsulatum*	Rarely indicated. Sensitive and specific and may be required for animals with chronic histoplasmosis when cytologic examination is negative. Risk of laboratory-acquired infections. Slow turnaround time (several weeks of incubation may be required).
Antibody serology (complement fixation or gel immunodiffusion)	Serum	Antibodies to *H. capsulatum*	Positive test results indicate exposure but do not indicate active infection or correlate with clinical disease. Negative test results occur commonly in animals with histoplasmosis (low sensitivity).
Antigen assay (ELISA)	Urine, serum	*H. capsulatum* antigen	Sensitivity and specificity require further evaluation in dogs and cats, although the assay appears to be sensitive and specific in cats when urine is tested. Cross-reactivity with other fungal pathogens may occur, so positive results are not diagnostic for histoplasmosis. Cross-reactivity is seen with blastomycosis, a systemic fungal infection with an overlapping geographic range.
Real-time PCR assays	See fungal culture	*H. capsulatum* DNA	Not yet validated in adequate numbers of dogs or cats with histoplasmosis; usefulness requires further evaluation.
Histopathology	Biopsy specimens from affected tissues	*H. capsulatum* yeasts	Yeasts can be difficult to find in chronic infections. Special stains may assist organism detection.

assay must always be used in conjunction with other diagnostic assays in order to determine the identity of the infecting fungal pathogen. Antigen levels become undetectable with successful treatment.[53] The antigen assay has also been used for the diagnosis of histoplasmosis in cats and dogs.[37,54] In one study, the urine of 17 of 18 cats with confirmed histoplasmosis was positive, whereas none of 26 cats with other diagnoses were positive.[54] Additional studies that evaluate larger numbers of cats and dogs with and without confirmed histoplasmosis, as well as those with other fungal infections, are required to further establish the sensitivity and specificity of this assay.

Fungal Culture

H. capsulatum can be isolated from clinical specimens on routine fungal media. There is a risk of laboratory-acquired infection when the organism grows in the mycelial form on artificial media, so culture should be performed only if necessary, and the laboratory should be warned of the possibility of a dimorphic fungal infection, so that appropriate precautions are taken. Although most cultures are positive within 2 or 3 weeks, growth may require up to 6 weeks of incubation. The organism is identified based on morphology (see Figure 61-2).

Molecular Diagnosis Using the Polymerase Chain Reaction

Real-time PCR assays have been developed for rapid detection of *H. capsulatum* in clinical specimens from affected humans[55,56] but currently are not used routinely for diagnosis. The sensitivity of one assay was 73% when compared with culture of clinical specimens.[55] PCR assays have not been widely applied to the diagnosis of histoplasmosis in dogs and cats; further studies are required to determine their usefulness.

Pathologic Findings

Gross pathologic findings in dogs and cats with histoplasmosis consist of miliary nodules or larger focal lesions in the lungs and other organs, and enlarged lymph nodes, which may be mineralized in dogs with chronic disease. In dogs, the intestinal tract may be thickened and focal or diffuse mucosal hemorrhage may be present. The liver and spleen may be enlarged with rounded borders, and the liver may be mottled with a reticulated appearance. Pleural and peritoneal effusions are occasionally described.[45] Histopathology yields pyogranulomatous or granulomatous inflammation with intralesional yeasts in a variety of organs (Figure 61-8). Lymphocytes and plasma cells may be present, and in some animals with chronic histoplasmosis, histologic evidence of fibrosis or (in dogs) mineralization is apparent.[37,45] Special stains such as Gomori's methenamine silver or periodic acid–Schiff can aid detection of the yeasts in tissues.

Treatment and Prognosis

Antimicrobial Treatment

Antifungal drugs with activity against *H. capsulatum* include the azole antifungal drugs ketoconazole, itraconazole, and fluconazole

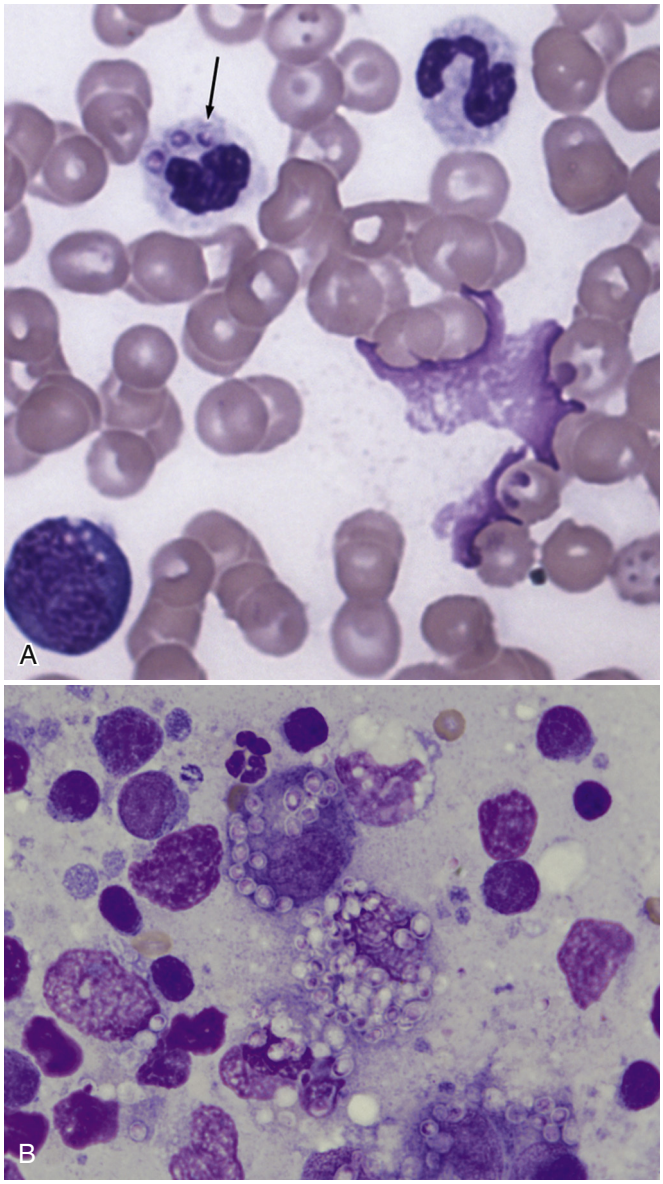

FIGURE 61-7 **A,** Blood smear from a dog with *Histoplasma capsulatum* fungemia. Three organisms can be seen in a circulating neutrophil *(arrow)*. Wright's stain, 1000× magnification. **B,** Fine-needle aspirate cytology from the right popliteal lymph node of the cat in Figure 61-5, *A*. There is pyogranulomatous inflammation with large numbers of intracellular yeast organisms with morphology consistent with that of *H. capsulatum*. Wright's stain, 1000× magnification. (Courtesy Angela Royal, Louisiana State University.)

(see Chapter 9 for more information and dosing for antifungal drugs). Itraconazole and fluconazole are preferred to ketoconazole since they are more effective and less likely to cause toxicity.[17] In human patients, itraconazole has consistently been more effective than fluconazole. An increased efficacy of itraconazole when compared with fluconazole is likely in dogs and cats as well, although in the authors' experiences, some animals may be cured with fluconazole monotherapy. Limited data suggest that posaconazole may be an effective salvage treatment in human patients with histoplasmosis that fail to respond to treatment with other antifungal drugs, including fluconazole, itraconazole, amphotericin B, and voriconazole.[57] Development of resistance to fluconazole and voriconazole has been documented during treatment of human patients with fluconazole, but not with posaconazole.[58]

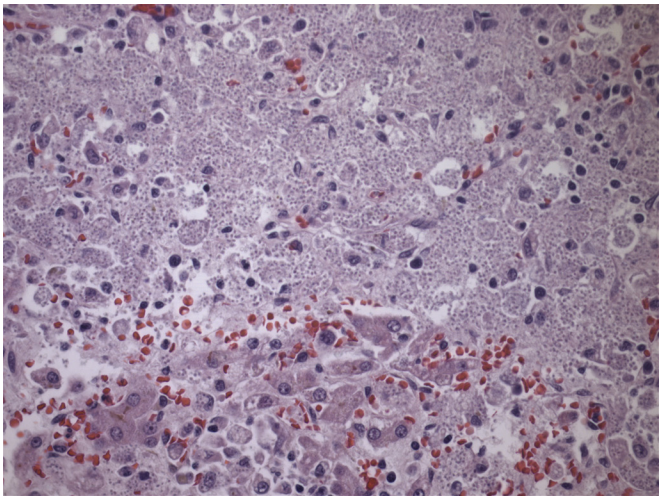

FIGURE 61-8 Histopathology of the liver of a 5-month-old intact male redbone coonhound with disseminated histoplasmosis. There is severe granulomatous inflammation with massive numbers of intrahistiocytic yeast organisms.

Deoxycholate or lipid-complexed amphotericin B should be used initially to treat dogs or cats with severe acute pulmonary, acute disseminated, or CNS disease, after which treatment should be continued with itraconazole. If funds or patient factors do not permit itraconazole treatment, fluconazole can be used as a second-line agent.

The length of treatment and prognosis depend on the severity and chronicity of disease and the immune status of the host. At least 6 months of treatment is generally required. Many animals require treatment for 12 months or longer, and those with chronic disease may require treatment for more than 2 years. The decision to discontinue treatment should be based on lesion resolution (which may require serial imaging studies). Resolution of positive urine antigen titers might also be used to decide when to discontinue treatment, but further study is required to determine whether serial monitoring of *H. capsulatum* antigenuria is useful in making treatment decisions.

Supportive Treatment

Other supportive treatments that may be required depend on the extent of infection and include intravenous crystalloid fluids, supplemental oxygen, blood transfusions for severely anemic animals, nutritional support, antiemetics, and medications to manage consequences of hepatic failure such as hepatic encephalopathy. Topical glucocorticoids and atropine may be required for animals with uveitis, and enucleation may be required to manage persistent ocular infection and pain. The role of systemic glucocorticoids for treatment of chronic manifestations of histoplasmosis is controversial, and they are not recommended for treatment of active or disseminated histoplasmosis.

Immunity and Vaccination

Immunity to *H. capsulatum* is dependent on a Th1 immune response. Production of IFN-γ activates macrophages to destroy the fungus.[59] There is currently no vaccine for prevention of histoplasmosis, but there is interest in development of a vaccine for at-risk human patients because of increasing incidence of the disease.

Prevention

Prevention of histoplasmosis involves avoidance of bat caves and areas previously inhabited by avian species in endemic areas. Nevertheless, histoplasmosis has occurred in animals housed exclusively indoors, and widespread exposure and recovery likely occurs in endemic areas.

Public Health Aspects

As many as 80% of young adults in endemic areas have been previously infected by *H. capsulatum*, but only 1% develop symptoms.[49] Risk factors identified for human histoplasmosis include exposure to soil disrupted as a result of excavation, exploration of caves inhabited by bats, or renovation of buildings inhabited by birds or bats. Males are predisposed in a 4:1 ratio.[20] Several forms of the disease have been described, which include acute pulmonary histoplasmosis, chronic pulmonary histoplasmosis (which may be cavitary or noncavitary), and acute or chronic PDH.[20] Complications of pulmonary histoplasmosis include granulomatous mediastinitis (characterized by enlargement and sometimes calcification of mediastinal lymph nodes, with compression of adjacent structures) or mediastinal fibrosis (characterized by fibrosis of caseous mediastinal lymph nodes). The clinical picture of PDH in humans is similar to that described in dogs; rare clinical manifestations include meningitis, endocarditis, and vascular infections.[20,49] Humans with AIDS or those treated with immunosuppressive drugs (such as tumor necrosis factor antagonists) are at risk for severe PDH, and smokers are predisposed to chronic pulmonary histoplasmosis. Itraconazole prophylaxis is considered for immunosuppressed patients who are at risk for development of the disease.[20]

Transmission of *H. capsulatum* from dogs or cats to humans has not been reported, but disease in dogs and cats may signal the potential for human infection as a result of exposure to the same source of infection; outbreaks have been described that involved both humans and dogs.[60] The bodies of deceased pets with histoplasmosis should be disposed of promptly and by cremation.

CANINE CASE EXAMPLE

Signalment: "Murphy," a 5-month-old intact male redbone coonhound from northern California.

History: Murphy was evaluated at the University of California, Davis, Veterinary Medical Teaching Hospital for a 1-week history of increased respiratory effort, hypersalivation, a single episode of vomiting, and lethargy. After the first day of illness he was taken to a local veterinary clinic where fever (103.2°F or 39.6°C), pale mucous membranes, and a cranial abdominal mass were noted on physical examination. Abdominal radiographs revealed moderate hepatomegaly and mild splenomegaly. He was treated with vitamin K, a single dose of prednisone (2 mg/kg SC), and cephalexin (20 mg/kg PO q8h). Considerable improvement in his mentation was noted. However, after 5 days, anorexia, hypersalivation, vomiting, and liquid diarrhea occurred, and he returned to the local veterinary clinic, where he was hospitalized and treated with intravenous fluids. The following day, obtundation and facial twitching developed, and Murphy was referred for further diagnostics and treatment.

Other Medical History: Murphy had been coughing a week before he became systemically ill, but this subsequently resolved. He was treated for a roundworm infection at that time, which was diagnosed by fecal flotation. Murphy was obtained from a breeder in Oklahoma at 4 months of age. He had always appeared "slow" to the owner, his appetite had never been very good, and he seemed unthrifty. The other puppies in the litter were apparently healthy. There was no known exposure to toxins. The breeder administered his first vaccines, and he was revaccinated for distemper, parvovirus, adenovirus, parainfluenza virus, and *Leptospira* by the local veterinarian when he was acquired.

Physical Examination:

Body Weight: 12.2 kg.

General: Obtundation was noted; the dog was in lateral recumbency and apparently unaware of his surroundings. Facial twitching occurred throughout the examination. T = 102.2°F (39.0°C), HR = 140 beats/min, RR = 50 breaths/min, mucous membranes were moist and pink.

Eyes, Ears, Nose, and Throat: Moderate conjunctivitis was present. There was a mild bilateral serous nasal discharge. No other abnormalities were detected.

Musculoskeletal: Appeared small in stature, BCS 3/9.

Cardiovascular, Respiratory and Lymph Nodes: No clinically significant abnormalities were detected.

Abdominal Palpation: Cranial organomegaly was present.

Laboratory Findings:

Blood Glucose: 70 mg/dL.

Plasma Fasting Ammonia Concentration: 509 µg/dL (0-92 µg/dL).

Canine Distemper Virus Direct Immunofluorescent Antibody (Urine Sediment): Negative.

CBC:

HCT 30.2% (40%-55%)
MCV 61 fL (65-75 fL)
MCHC 36.1 g/dL (33-36 g/dL)
Reticulocytes 49,200/µL (7000-65,000/µL)
WBC 22,000 cells/µL (6000-13,000 cells/µL)
Neutrophils 10,340 cells/µL (3000-10,500 cells/µL)
Band neutrophils 7040 cells/µL
Metamyelocytes 880 cells/µL
Lymphocytes 1100 cells/µL (1000-4000 cells/µL)
Monocytes 1100 cells/µL (150-1200 cells/µL)
Eosinophils 880 cells/µL (0-1500 cells/µL)
Platelets 28,000/µL (150,000-400,000 platelets/µL).
Moderately toxic neutrophils and markedly toxic band neutrophils and metamyelocytes were present. Occasional organisms with morphology consistent with *Histoplasma capsulatum* were seen within both neutrophils and monocytes. The myeloid series was shifted to the myelocyte stage with rare progranulocytes noted. Rare nucleated erythrocytes (metarubricytes) were also present. Many lymphocytes were reactive. Numerous macroplatelets were noted.

Serum Chemistry Profile:

Total protein 5.8 g/dL (5.4-7.4 g/dL)
Albumin 2.1 g/dL (2.9-4.2 g/dL)
Globulin 3.7 g/dL (2.3-4.4 g/dL)
ALT 31 U/L (19-70 U/L)
AST 217 U/L (15-43 U/L)
ALP 195 U/L (15-127 U/L)
GGT 24 U/L (0-6 U/L)
Cholesterol 363 mg/dL (135-345 mg/dL)
Total bilirubin 1.1 mg/dL (0-0.4 mg/dL).

Urinalysis (Cystocentesis): SGr 1.044; pH 5.0, 1+ bilirubin, no hemoprotein, no glucose, no protein, 0-1 RBC/HPF, rare WBC/HPF; no crystals, casts, or bacteria seen.

Coagulation Panel: PT 10.7 s (7.5-10.5 s), PTT 24.4 s (9-12 s), fibrin degradation products > 40 µg/mL (<10 µg/mL).

Imaging Findings:

Thoracic Radiographs: There was a diffuse bronchointerstitial pulmonary pattern, especially in the region of the cranial right middle lung lobe. The heart and pulmonary vasculature were slightly small. In the viewable abdomen, the liver was moderately enlarged.

Abdominal Ultrasound: Severe hepatomegaly was present with normal hepatic echogenicity. A large, folded spleen and sublumbar and mesenteric lymphadenomegaly were present.

Microbiologic Testing:

Fecal Flotation: Positive for *Ancylostoma* ova.

Aspiration Cytology (Ultrasound-guided Liver Aspirate): The specimen was bloody and moderately cellular with numerous clusters of platelets and inflammatory cells. Occasional small clusters of hepatocytes were noted, which showed mild to moderate vacuolar degeneration. A few hepatocytes contained intracytoplasmic blue-green pigment consistent with bile. Inflammatory cells consisted primarily of activated macrophages that contained abundant intracellular yeast organisms consistent with *Histoplasma* spp. Lower numbers of nondegenerate neutrophils, mixed lymphocytes, and occasional eosinophils and basophils were also found. Interpretation: *Histoplasma* infection with marked pyogranulomatous inflammation. Mild to moderate hepatic vacuolar degeneration and cholestasis.

CSF Analysis (Cisternal): The fluid was clear and colorless. The protein concentration was 17 mg/dL (reference range, <25 mg/dL). There was fewer than 1 RBC/µL (reference range, <1200 RBC/µL) and 25 nucleated cells/µL (reference range, <2 cells/µL). The differential cell count consisted of 1% neutrophils, 6% lymphocytes, and 93% large mononuclear cells. The cytofuge specimen was cellular, and large, foamy macrophage-like cells predominated. Vacuoles within the cytoplasm contained digested debris, but no organisms could be discerned. Low numbers of small lymphocytes were also noted. Interpretation: Mononuclear pleocytosis.

Diagnosis: Acute progressive disseminated histoplasmosis with suspected *Histoplasma* meningitis; hookworm infestation.

Treatment: Murphy was hospitalized in the intensive care unit and treated with intravenous crystalloids (lactated Ringer's solution with 25 mEq/L KCl and 2.5% dextrose, 75 mL/h), plasma, vitamin K, and heparin (100 units/kg SC q8h). The hookworm infection was treated with fenbendazole (50 mg/kg PO q24h for 3 days). Seizures were controlled with diazepam as needed and phenobarbital (2 mg/kg IM q12h). Hepatic encephalopathy was treated with a warm water enema followed by a 3 mL/kg lactulose enema, then oral lactulose (1 mL/kg PO q8h). Profuse watery diarrhea ensued. Treatment with lipid-complexed amphotericin B was then initiated (2 mg/kg IV over 2 hours, every other day). Initially, clinical signs improved, and Murphy appeared brighter and began eating small amounts of a reduced protein diet. A CBC showed a hematocrit of 30%, 19,988 neutrophils/µL, 263 band neutrophils/µL with slight toxicity, 2367 lymphocytes/µL, 2367 monocytes/µL, 1315 eosinophils/µL, and 65,000 platelets/µL. No *Histoplasma* organisms were seen. The results of a biochemistry profile were similar to those reported at hospitalization, but electrolytes and glucose had normalized and total bilirubin was 2.6 mg/dL.

On day 4 of hospitalization, Murphy developed increased respiratory effort, weakness, and a head tremor. Thoracic radiographs showed a diffuse miliary interstitial infiltrate in the perihilar region and in the region of the right cranial lung lobe, which was slightly more severe than that seen at the time of hospitalization. By day 7 of hospitalization, he remained extremely weak and inappetent, and the owners elected euthanasia because of financial limitations. At necropsy, there was severe hepatomegaly and splenomegaly; the lungs were firm and mottled dark red to pink, and cut surfaces oozed white froth and blood. Histopathology revealed severe, diffuse, granulomatous inflammation with intrahistiocytic yeasts in the lungs, liver, spleen, bone marrow, sublumbar lymph nodes, and tracheobronchial lymph nodes (see Figure 61-8). In the kidneys there was severe, multifocal, granulomatous interstitial nephritis with intrahistiocytic yeasts. Multifocal granulomatous inflammatory lesions with intrahistiocytic yeasts were present in the pancreas, duodenum, jejunum, thyroid glands, and peritoneal fat. Within the brain there was minimal, focal, granulomatous meningitis.

Comments: In this dog, the diagnosis of disseminated histoplasmosis with fungemia was straightforward because organisms were seen in a peripheral blood smear. The dog likely acquired infection in Oklahoma where the fungus is endemic. Overwhelming infection suggested a possible underlying immunodeficiency, although severe disease is common without obvious immunodeficiency in dogs. The dog had evidence of disseminated intravascular coagulation, hepatic encephalopathy, and granulomatous meningitis. Had treatment with amphotericin B, azole antifungal drugs, and additional supportive care continued, recovery might have occurred, but the costs of this treatment without guaranteed success led the owners to elect euthanasia. Clearly the burden of intact fungal organisms at necropsy was still massive despite several treatments with amphotericin B. Even in human patients, overall cure rates for *H. capsulatum* meningitis are no better than 50%.

FELINE CASE EXAMPLE

Signalment: "Shaq," an 8-month-old intact male domestic shorthair cat from east central Louisiana.

History: Shaq was evaluated at the Louisiana State University (LSU) Veterinary Medical Teaching Hospital for a 3-week history of lethargy and intermittent anorexia. Occasional right pelvic limb lameness had been noted. He was taken to a local veterinary clinic, where fever and an enlarged right popliteal lymph node were noted on physical examination. A bite wound was suspected at the local veterinarian's clinic, and Shaq was treated with an injectable long-acting cephalosporin and oral amoxicillin. After 2 weeks of continued waxing and waning lethargy, Shaq was brought to the emergency service at LSU.

Current Medications: Amoxicillin.

Other Medical History: Shaq was an indoor/outdoor cat who has always lived in Louisiana. He ate a commercial kitten food and was vaccinated at 3 to 4 months of age, which included an FIV vaccination. FeLV and FIV infection status was unknown.

Physical Examination:

Body Weight: 3.2 kg.

General: The cat was quiet but alert and responsive. His mucous membranes were pink and moist, and his CRT was less than 2 s. Rectal temperature was 104.9°F (40.5°C), and heart rate was 216 beats/min.

Eyes, Ears, Nose, and Throat: Normal; no fundic examination abnormalities were noted.

Musculoskeletal: Normal; no pain was noted on palpation of the right pelvic limb. The right popliteal lymph node was moderately enlarged, movable, and nonpainful.

Cardiovascular: No murmurs or arrhythmias were auscultated, and a strong pulse quality was present.

Respiratory: Tachypnea was present but no significant abnormalities were detected on auscultation.

Abdominal Palpation: Cranial organomegaly (splenomegaly) was present.

Lymph Nodes: Other than the right popliteal lymph node, lymph nodes were palpably normal.

Laboratory Findings:

CBC:

HCT 28.6% (30%-48%)
MCV 33 fL (41-57 fL)
MCHC 30.0 g/dL (30-35 g/dL)
Reticulocytes 22,100/µL
WBC 10,300 cells/µL (6000-10,000 cells/µL)
Neutrophils 6500 cells/µL (2500-12,500 cells/µL)
Lymphocytes 3700 cells/µL (1500-7000 cells/µL)
Monocytes 100 cells/µL (0-800 cells/µL)
Eosinophils 0 cells/µL (0-1500 cells/µL)
Platelets 515,000/µL (190,000-368,000 platelets/µL)
WBC and RBC morphology were considered normal.
Plasma protein 8.2 g/dL (6-7.5 g/dL).

Serum Chemistry Profile:

Sodium 164 mmol/L (150-165 mmol/L)
Potassium 3.7 mmol/L (4.0-5.0 mmol/L)
Chloride 126 mmol/L (121-126 mmol/L)
Phosphorus 6.5 mg/dL (3.1-7.5 mg/dL)
Calcium 10.3 mg/dL (8.8-9.3 mg/dL)
BUN 28 mg/dL (16-22 mg/dL)
Creatinine 1.1 mg/dL (1.7-1.9 mg/dL)
Glucose 125 mg/dL (77-96 mg/dL)
Total protein 7.8 g/dL (6.5-7.1 g/dL)
Albumin 3.0 g/dL (2.8-3.1 g/dL)
Globulin 4.8 g/dL (37.-4.1 g/dL)
ALT 77 U/L (24-44 U/L)
AST 16 U/L (0-36 U/L)
ALP 41 U/L (33-72 U/L)
Total bilirubin 0.2 mg/dL (0-0.4 mg/dL).

Urinalysis: Not performed.

Imaging Findings:

Thoracic Radiographs: There was a diffuse mild bronchointerstitial pulmonary pattern that was somewhat patchy in the caudodorsal lung fields. A smooth, broad-based soft tissue opaque structure that was sharply marginated by the surrounding lung was evident dorsal to sternebrae 3 to 4; this was consistent with sternal lymphadenopathy. In the visible abdomen, the spleen was moderately enlarged (see Figure 61-5, *A*).

Abdominal Ultrasound: A large spleen was present with diffusely heterogenous echogenicity.

Microbiologic Testing:

Fecal Flotation: Negative.

FeLV/FIV ELISA Serology: Negative for FeLV antigen, positive for FIV antibody.

Aspiration Cytology (Popliteal Lymph Node Aspirate): Smears contained large numbers of adequately preserved nucleated cells with a low number of erythrocytes. The nucleated cell population consisted of high numbers of small lymphocytes (75%), low numbers of neutrophils (20%), and highly vacuolated macrophages (5%). The macrophages contained large numbers of oval, 2- to 3-µm–diameter yeast that were surrounded by a thin clear halo and had small, eccentric, crescent-shaped purple nuclei. Interpretation: Pyogranulomatous inflammation with intracellular *Histoplasma* spp. yeasts (see Figure 61-7, *B*).

Histoplasma *Quantitative Antigen EIA (Urine):* 9.3 ng/mL (positive).

Diagnosis: Disseminated histoplasmosis.

Treatment: Shaq was hospitalized in the intensive care unit and treated with intravenous crystalloids (Normosol-R with 25 mEq/L KCl, 8 mL/h) and his temperature was monitored. The fungal infection was treated with itraconazole oral solution (10 mg/kg PO q24h). His temperature fluctuated between 103.6°F and 105.3°F (39.8°C and 40.7°C) over the next 48 hours, but he maintained a good appetite and was bright and alert. On day 3, Shaq was discharged from the hospital with instructions to continue the itraconazole treatment. He was still febrile but was bright and alert and eating well. Recommendations were to recheck monthly at the local veterinary clinic for exam and chemistry panel. A urinary *Histoplasma* Quantitative Antigen EIA was repeated after 2 months of treatment and was 2.0 ng/mL, which was still positive but indicated a probable treatment response. Recheck at 6 months revealed a normal physical examination, thoracic radiograph, CBC, and chemistry panel with the exception of an increased serum ALT activity

VetBooks.ir

at 221 U/L (0-90 U/L). It was recommended that the local veterinarian repeat the *Histoplasma* antigen assay and discontinue itraconazole if negative.

Comments: In this cat, a diagnosis of disseminated histoplasmosis was straightforward because organisms were seen in a lymph node aspirate. If they had not been present on cytologic examination of the lymph node aspirate, cytologic examination of a splenic or a bone marrow aspirate would have been most likely to reveal organisms. The vague presentation with mild respiratory signs is typical of infection in cats. The positive result for FIV antibody was likely due to the previous vaccination. Treatment is probably best continued until the result of the urine antigen assay is negative, but if the titer remains low and clinical signs have resolved, discontinuation of itraconazole treatment may be appropriate with retesting for antigenuria. An increase in urine antigen concentration may indicate relapse and need for further therapy. The increased ALT (221 U/L) was likely due to itraconazole therapy and did not necessitate alteration in treatment as long as the cat otherwise appeared normal.

CHAPTER 62

Cryptococcosis

Jane E. Sykes and Richard Malik

VetBooks.ir

Overview of Cryptococcosis

First Described: 1894, in a human patient in Germany (independently by Busse and Buschke)[1]

Causes: *Cryptococcus gattii*, *Cryptococcus neoformans*, rarely other cryptococcal species (a basidiomycete, teleomorph *Filobasidiella* spp.)

Affected Hosts: Cats, dogs, humans, and a variety of other domestic and wild animal species

Geographic Distribution: Worldwide

Major Mode of Transmission: Inhalation of basidiospores from the environment

Major Clinical Signs: Nodular or ulcerative cutaneous lesions, upper respiratory tract signs, chorioretinitis, neurologic signs secondary to meningoencephalitis. In dogs, *Cryptococcus* can also disseminate to abdominal organs and cause gastrointestinal signs such as vomiting, diarrhea, and inappetence.

Differential Diagnoses: For cats, differential diagnoses for cutaneous lesions include other deep mycoses (especially sporotrichosis), mycobacteriosis, nocardiosis, neoplasia (especially squamous cell carcinoma), herpetic dermatitis and eosinophilic granuloma complex. Differential diagnoses for suspected cryptococcal rhinitis include nasal lymphoma, foreign bodies, sinonasal/sino-orbital aspergillosis, oronasal fistulae and neutrophilic rhinitis. For ocular and central nervous system lesions, differential diagnoses include neoplasia (especially lymphoma), toxoplasmosis, feline infectious peritonitis, and otogenic bacterial meningitis. For dogs, differential diagnoses include other disseminated mycoses (especially histoplasmosis and blastomycosis), mycobacteriosis, actinomycosis and nocardiosis, other causes of rhinitis (such as foreign bodies, nasal aspergillosis, oronasal fistulas, lymphoplasmacytic rhinitis, rhinosporidiosis), neoplasia (especially round cell neoplasia), toxoplasmosis, neosporosis, severe inflammatory bowel disease, and pancreatitis.

Human Health Significance: Human infections occur as a result of exposure to organisms in the environment and are often associated with underlying immune compromise.

Etiology and Epidemiology

Cryptococcosis is an important fungal infection of people and animals worldwide and the most common systemic mycosis of cats. The infection is acquired from the environment, and disease transmission from one animal to another has not been reported. Occasional outbreaks of cryptococcosis in people and animals may result from exposure to common environmental sources.[2,3] Various domestic and native mammals may be infected, which include cats, dogs, ferrets, horses, camelids, goats, sheep, cattle, dolphins, birds, koalas, and other marsupials.[4-10] The incidence of cryptococcosis in cats is eightfold higher than that in dogs.[11]

The genus *Cryptococcus* contains at least 19 encapsulated yeast species. *Cryptococcus neoformans* and *Cryptococcus gattii* (formerly *C. neoformans* var. *gattii*) cause the vast majority of infections in dogs, cats, and humans. *C. gattii* has emerged as a pathogen of immunocompetent humans in temperate regions of North America, in particular on the west coast of the United States and in British Columbia, Canada. Other species, particularly *Cryptococcus laurentii* and *Cryptococcus albidus*, rarely cause disease in people and animals, but may be emerging as a result of immunocompromise.[12-14] *Cryptococcus magnus* was isolated from the external ear canal of a cat with otitis externa,[15] and *C. laurentii* has been isolated from the external ear canal of dogs.[16]

Cryptococcus spp. are dimorphic, basidiomycetous fungi. The life cycle of the fungus is thought to involve growth in host tissues as an encapsulated haploid budding yeast, combined with the ability to undergo a transition to a filamentous form (or teleomorph) in the environment. Two mating types of *Cryptococcus* spp. exist, α and **a**. The α-type is vastly more prevalent in environmental and clinical samples. Under appropriate laboratory conditions, the two mating types fuse and adopt a dikaryotic filamentous state, also known as the *perfect state*. This is followed by production of basidia, which are small, club-shaped structures on which basidiospores form (Figure 62-1).[17] Cells of the α mating type can also undergo asexual reproduction via a process known as monokaryotic fruiting, which also involves filamentation and spore formation.[17-19] Although they have never been observed in nature, basidiospores (or possibly desiccated yeasts) are thought to be the main form that, when inhaled, gives rise to mammalian disease.[20] In animal tissues, basidiospores convert to the yeast form, which is round to oval with a variably sized capsule. The capsule is primarily (90% to 95%) composed of a polysaccharide known as glucuronoxylomannan (GXM), with smaller amounts of galactoxylomannan. The capsule enlarges after infection of mammalian hosts and protects the fungus from phagocytosis and environmental insults such as desiccation. Within tissues, *Cryptococcus* reproduces by forming one or two daughter cells (buds) that are connected to the parent cell by a narrow base (Figure 62-2).

Historically, five serotypes of *Cryptococcus* (A, B, C, D, and AD) were recognized on the basis of antigenic differences in the capsular polysaccharide. Based on the results of molecular

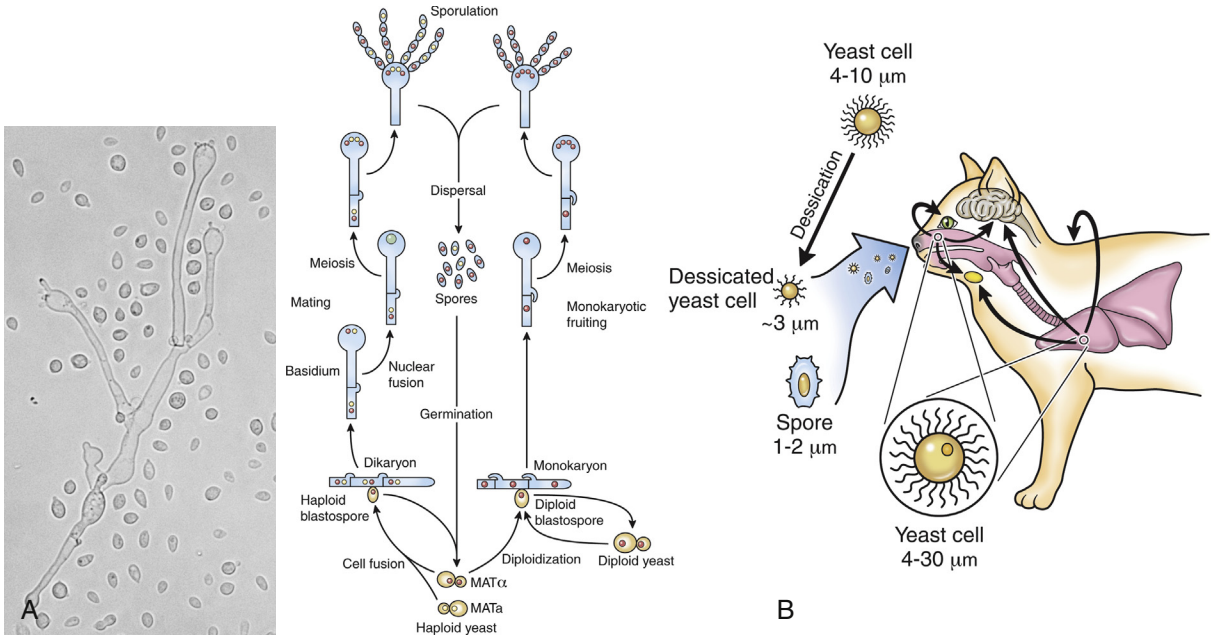

FIGURE 62-1 Life cycle of *Cryptococcus* spp. **A,** Spores result from either mating between cells of opposite mating types (MATa or MATα) and subsequent formation of dikaryotic hyphae or unisexual mating of MATα cells (monokaryotic fruiting). In both cases, sexual development within the filamentous form results in meiosis and basidiospore formation. The spores germinate to produce haploid, yeast-like cells that divide by budding. **B,** Spores, and potentially desiccated yeast cells, are inhaled. Germination of spores or vegetative growth of yeast cells in the upper or lower respiratory tract results in the proliferation of budding yeasts. Dissemination to a variety of tissues can then occur, but especially to the lymph nodes, nasal cavity, skin, and CNS. (Modified from Kronstad JW, Attarian R, Cadieux B, et al. Expanding fungal pathogenesis: *Cryptococcus* breaks out of the opportunistic box. Nat Rev Microbiol 2011;9:193-203. Basidiospore image courtesy Patrik Inderbitzen, University of California, Davis.)

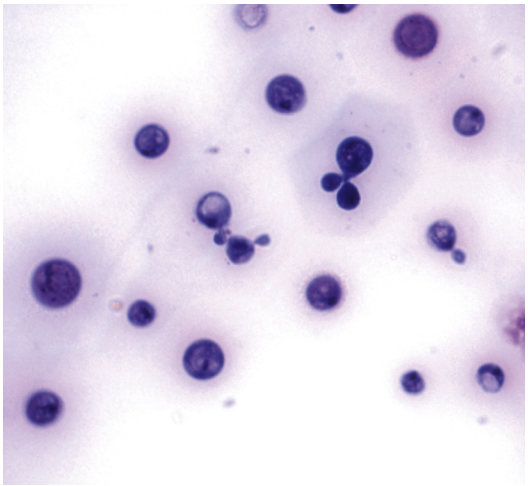

FIGURE 62-2 CSF cytology from an 8-year-old male neutered domestic shorthair cat with cryptococcal meningitis. Large numbers of budding cryptococcal yeasts are present.

typing methods such as PCR fingerprinting and multilocus sequence typing, cryptococcal strains from around the world are divided into eight major molecular types: VNI and VNII (*C. neoformans* serotype A); VNIII (*C. neoformans* serotype AD); VNIV (*C. neoformans* serotype D), and VGI, VGII, VGIII, and VGIV (*C. gattii*, serotypes B and C).[21] Hybrid strains also exist. Differences in epidemiology, pathogenicity, clinical features, and drug susceptibility have been associated with each species and molecular type.

Cats of all ages may be affected,[22] but young adult cats appear to be at increased risk. In dogs, cryptococcosis is diagnosed predominantly in young adult dogs. In one study, the median age of cats and dogs was 6 and 4 years, respectively.[11] No clear sex predisposition exists. Siamese, birman, and ragdoll cats have been predisposed in Australian studies but were not found to be at risk in the United States.[11,23] Similarly, German shepherd dogs, Doberman pinschers, and great Danes appear to be predisposed in Australia, whereas in the United States, American cocker spaniel dogs are strongly predisposed.[5,11,22,24,25]

Most cats and dogs with cryptococcosis do not have identifiable underlying immunosuppressive illness. The prevalence of retrovirus infection in cat populations with cryptococcosis does not differ from that in cat populations without cryptococcosis.[11,22] However, some cats with cryptococcosis that are co-infected with FeLV appear to respond more slowly to treatment and may be more likely to have relapses.[26] Cryptococcosis is occasionally reported in cats treated with immunosuppressive therapy or chemotherapy for malignancy.[11,27] Concurrent opportunistic infections have been reported in other cats (e.g., toxoplasmosis), as well as in dogs (e.g., neosporosis or papillomatosis), suggesting underlying immunodeficiency.[11,28]

Cryptococcus neoformans

C. neoformans has a worldwide distribution. It primarily infects human patients who are immunocompromised, especially AIDS patients. The realized environmental niche for *C. neoformans* is weathered bird (especially pigeon) guano, in which it mates prolifically.[29] It can also be found in decaying plant matter in hollows of certain trees.[30] The organism can remain viable for at least 2 years in environments such as pigeon lofts. The majority of human cryptococcal infections result from infection with *C. neoformans* var. *grubii* (VNI). *C. neoformans* var. *grubii* is the most common *Cryptococcus* species isolated from dogs and cats in southeastern Australia and accounts for more than 70% of infections.[22,23,25] Across the United States, most dogs with cryptococcosis are infected with *C. neoformans*, but infection of cats with this species is rare.[11,31]

Cryptococcus gattii

C. gattii is endemic in Australia, New Zealand, Papua New Guinea, Southeast Asia, parts of Latin America, California, Mexico, Hawaii, Central and South Africa, and, to a lesser extent, certain parts of Europe (Austria, Germany, France, Italy, Greece, and Spain).[32,33] Since 1999, an epidemic of infections with *C. gattii* has occurred in humans and domestic and wild animals in British Columbia in Canada, especially Vancouver Island, and the Pacific Northwest of the United States.[34-36] The main molecular types identified in this epidemic have been molecular types VGIIa and, to a much lesser extent, VGIIb and, in Oregon, also VGIIc. *C. gattii* molecular type VGII can be found on living tree bark (Garry oak, maple, cedar, and pine) and in air, and has also been found in freshwater and seawater. Proximity to areas with soil disturbance was a risk factor for dogs and cats.[37] In California, almost all cats are infected with *C. gattii* VGIII, with occasional VGII infections.[11,31] The ecologic niche of this molecular type in the United States remains unclear. Approximately 25% of affected cats are housed exclusively indoors.[11]

In eastern Australia, 20% to 30% of human, feline, and canine cryptococcosis is caused by C. *gattii*,[23,38] whereas in western Australia, approximately 50% of cats and dogs are infected with *C. gattii*.[5] Most *C. gattii* isolates from eastern Australia belong to VGI; VGII predominates in southwestern and northern Australia.[5,39] C. *gattii* VGI in Australia is exclusively associated with dead plant material in eucalyptus tree hollows. Cats in rural environments are at risk of infection.

In contrast to *C. neoformans, C. gattii* isolates from the Pacific northwest and British Columbia can infect apparently immunocompetent humans.[40] *C. gattii* molecular type VGIII infections have been reported in immunosuppressed humans in southern California.[41] When disease occurs in immunocompetent hosts, it is often characterized by the presence of pulmonary mass lesions (cryptococcomas) and sometimes intracranial cryptococcomas.[42] As a result, pulmonary cryptococcomas are more commonly described in human patients infected with *C. gattii* compared with those infected with *C. neoformans*.[43]

Clinical Features

Signs and Their Pathogenesis

Based on the small size of basidiospores, the lung is thought to be the primary site of infection in humans. In cats, dogs, and koalas, the nasal cavity may be the primary site of infection (see Figure 62-1); significant pulmonary parenchymal involvement in these species is rare. Colonization of the nasal cavity may be followed by development of cryptococcal rhinitis in some (but not all) dogs and cats. However, some nasal cavity involvement may result from hematogenous dissemination, because injection of *Cryptococcus* spp. into the carotid artery of cats can lead to development of lesions on the bridge of the nose. Some localized cutaneous lesions may result from direct cutaneous inoculation (e.g., after a cat scratch), but skin lesions are usually interpreted as the result of dissemination or extension from the nasal cavity.

The pathogenesis of cryptococcosis depends on the size of the inoculum, virulence of the cryptococcal strain, and host immunity. *Cryptococcus* has been aptly described as "a sugar-coated killer with designer genes."[44] *Cryptococcus* has several important virulence factors, including its polysaccharide capsule, laccase (which makes melanin), and other enzymes such as phospholipase, urease, and superoxide dismutase.[17,42] Capsular polysaccharide is continuously shed into the host's extracellular fluid, which includes blood, urine, and CSF. The capsule inhibits phagocytosis, depletes complement, and is well known for its ability to inhibit effective T cell responses. The ability of *C. neoformans* and *C. gattii* to grow at mammalian body temperature is also an important virulence factor and is lacking in other species of *Cryptococcus*.

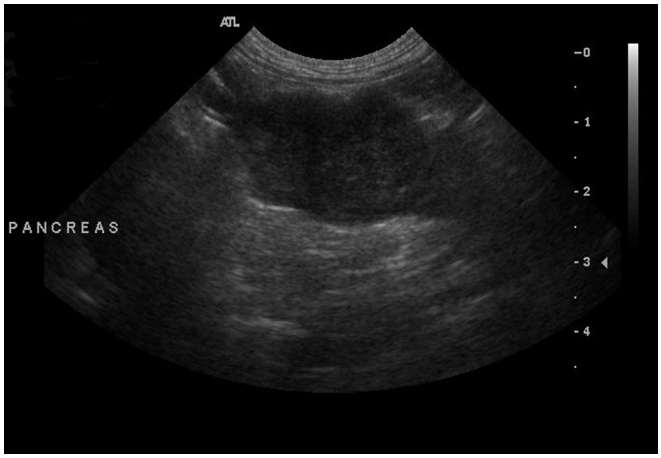

FIGURE 62-3 Ultrasound image that shows an enlarged and hypoechoic pancreas in a 7-year-old female spayed basset mixed-breed dog with systemic cryptococcosis caused by *Cryptococcus neoformans* var. *grubii* (molecular type VNI). The dog was evaluated for gastrointestinal signs that were associated with severe cryptococcal pancreatitis and enteritis. The dog's lungs, heart, kidneys, liver, mesenteric lymph nodes, peritoneum, brain, and meninges were also involved at necropsy.

The incubation period can range from 2 to 13 months.[45,46] Exposure and self-limiting infection may occur in some individuals, with reactivation of viable cryptococci in residual granulomatous foci months or years later with immunosuppressive drug therapy or illness.[42] Because of this delay, a travel history to areas where *Cryptococcus* is highly endemic (such as British Columbia or the west coast of the United States) may be present in animals and humans residing in non-endemic regions. After infection is established within the lung or nasal cavity, the organism can spread hematogenously to other sites, particularly the lymph nodes, eye, skin, and central nervous system (CNS) (see Figure 62-1). *Cryptococcus* spp. has a strong tendency to invade the meninges and typically causes meningitis or meningoencephalitis. In humans, cerebral cryptococcosis is often associated with increased intracranial pressure, and this probably also occurs in cats and dogs. Spread of infection to the eye, either along the optic nerves from the brain or as a result of hematogenous spread, may result in concurrent cryptococcal optic neuritis and chorioretinitis. In animals with nasal cavity involvement, extension of infection into the brain may also follow osteomyelitis of the cribriform plate or of the ventral wall of the frontal sinus. Middle ear involvement can also occur.[47] Infection also often spreads from the nasal cavity to the mandibular lymph nodes.

Multifocal cutaneous involvement in cats and dogs reflects hematogenous dissemination from the primary site of infection, as do lesions in bone (e.g., digits) or periarticular soft tissues. Dogs infected with *C. neoformans* often develop widely disseminated disease, with involvement of sites such as the gastrointestinal system, pancreas, mesenteric lymph nodes, kidneys, myocardium, and thyroid gland (Figure 62-3).[11,24,48,49] In contrast, dogs infected with *C. gattii* molecular type VGII in the

United States tend to have isolated caudal nasal cavity cryptococcomas, which can extend through the cribriform plate into the brain (Figure 62-4).

Clinical Features in Cats

Cryptococcosis is often a chronic infection in cats, and affected cats are usually otherwise well but occasionally have mild lethargy and inappetence. Fever is rare, and when it occurs, it tends to be low-grade. Upper respiratory tract signs due to nasal cavity involvement are common, sometimes with associated mandibular lymphadenopathy. Single or multifocal ulcerated or nonulcerated cutaneous masses may also be present (Figure 62-5).

Lower respiratory tract signs such as tachypnea are uncommon but can occur as a result of pleural effusion or severe mediastinal lymphadenomegaly. Neurologic signs vary depending on the location of lesions in and around the CNS (see Physical Examination Findings), and, rarely, cats with CNS involvement lack obvious neurologic signs. Optic neuritis and chorioretinitis develop in as many as one third of affected cats and almost always indicate CNS involvement.

Other signs include peripheral lymphadenomegaly (which may be unassociated with skin lesions and is often asymmetric), lameness due to osteomyelitis or cryptococcal arthritis, and swollen digits. Rarely, involvement of the abdominal lymph nodes, kidneys, spleen, liver, thyroid, and salivary glands occur.

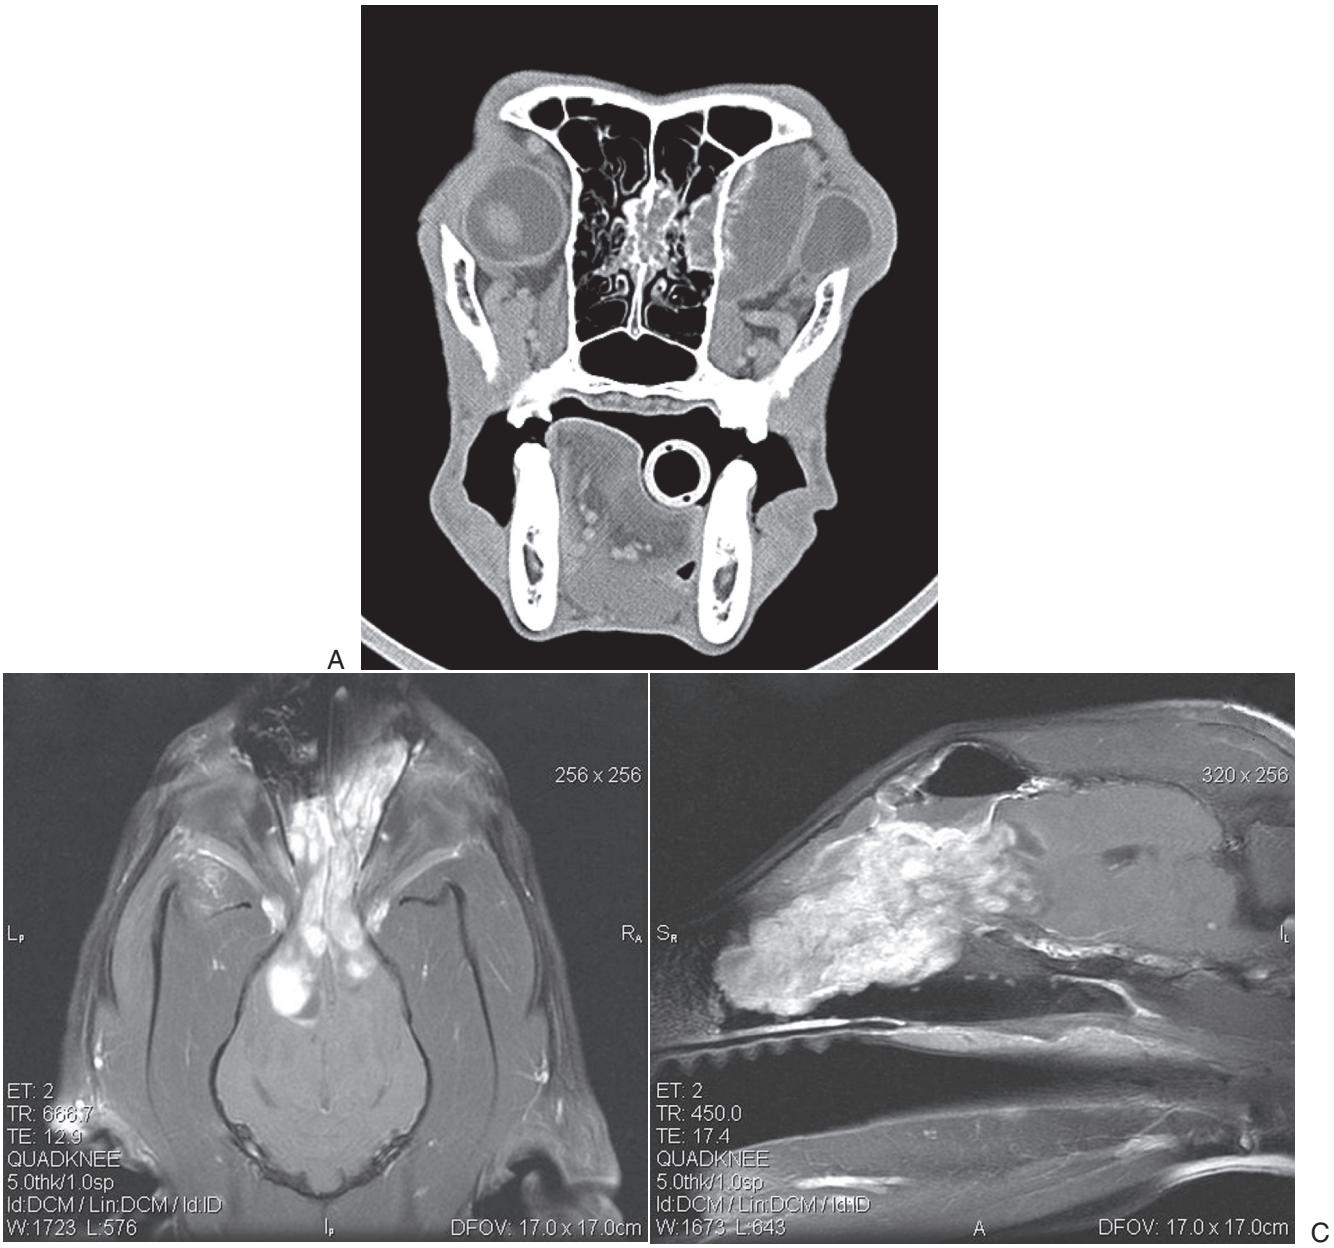

FIGURE 62-4 Caudal nasal cryptococcosis in dogs infected with *Cryptococcus gattii*. **A,** CT scan showing a large caudal nasal cavity cryptococcoma at necropsy that invaded the cribriform plate and retrobulbar space in a 5-year-old Doberman pinscher infected with *C. gattii* molecular type VGIIa. There is a palisading periosteal response along the lateral margin of the right frontal and lacrimal bones. **B** and **C,** Postcontrast magnetic resonance images of the head of a 2-year-old intact male malamute with a 1-week history of abnormal behavior and seizures. *Cryptococcus gattii* was isolated from the nasal cavity. A large, contrast-enhancing mass is present in the caudal nasal cavity that invades the cribriform plate and extends into the brain. (Courtesy Dr. Stacey Hoffman.)

Clinical Features in Dogs

In contrast to cats, dogs frequently develop severe disseminated disease. In one study, 80% of dogs had involvement of multiple anatomic sites, and 50% of dogs had involvement of sites other than the nasal cavity, skin, lungs, lymph nodes, kidney, eye, and CNS.[11] Weight loss, lethargy, and inappetence are common nonspecific findings. Rhinosinusitis from cryptococcosis may be subclinical in dogs, so its incidence may be underestimated.[11,25] However, sneezing and mucopurulent nasal discharge can also occur. Neurologic signs were present in two thirds of affected dogs from California.[11] Dogs can also primarily show signs of gastrointestinal or pancreatic involvement, such as vomiting, diarrhea, and abdominal pain.

Cutaneous involvement is uncommon in dogs but, as in cats, may be a marker for disseminated disease. Although rarely detected antemortem, more than half of dogs have lower respiratory involvement at necropsy.[11] Other clinical signs that are infrequently present in dogs include peripheral lymphadenomegaly or lameness (due to osteomyelitis or arthritis).

FIGURE 62-5 Multiple ulcerated skin lesions in a cat from northern California with disseminated cryptococcosis caused by *Cryptococcus gattii* molecular type VGIII.

Physical Examination Findings

Cats

Upper respiratory tract signs are common physical examination findings in cats with cryptococcosis. These include sneezing; snuffling; and mucopurulent, serous, or hemorrhagic nasal discharge that is unilateral or bilateral. In some cats, a fleshy mass protrudes from the nostril. Other cats have one or more firm to fluctuant, ulcerated or nonulcerated, subcutaneous swellings over the bridge of the nose. These swellings may communicate with the frontal sinus or nasal cavity, and palpation of the lesions may reveal crepitus due to subcutaneous emphysema. Cats with nasopharyngeal cryptococcosis develop stertor, stridor, and, occasionally, otitis media. Mandibular lymphadenopathy is often present. Ulcerated or proliferative lesions of the buccal mucosa can also be found. Multifocal skin lesions consist of nodules or masses that are fluctuant to firm, up to several centimeters in diameter, and may ulcerate (see Figure 62-5).

Neurologic examination abnormalities in cats with CNS involvement include obtundation; atypical behavior; slow menace, palpebral, or pupillary light responses; mydriasis or anisocoria (Figure 62-6, *A*); twitching or tremors; and seizures, circling, head pressing, ataxia, paresis, abnormal placing reactions, head tilt, nystagmus, and spinal pain.[9] Fundoscopic examination may reveal granulomatous chorioretinitis, exudative retinal detachment, papilledema, evidence of optic neuritis, and/or retinal hemorrhage (Figure 62-6, *B*). Severe ocular

TABLE 62-1

Diagnostic Assays Currently Available for Cryptococcosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, body fluids, impression smears of skin lesions or biopsies	*Cryptococcus* organisms	High sensitivity, but occasionally organisms are not visualized (such as in the CSF of some animals with CNS cryptococcosis).
Fungal culture	Aspirates or biopsies of affected tissues, body fluids such as CSF and urine	*Cryptococcus* spp.	Generally sensitive and specific, but false negatives are possible if specimen size is low. Requires several days' incubation. Allows species identification and antifungal drug susceptibility testing.
Antigen assay (latex agglutination)	Serum, CSF	*Cryptococcus* polysaccharide antigen	Sensitivity and specificity exceed 90%. False negatives can occur in dogs and with localized infections in cats. False positives are generally of low magnitude (<1:200 and usually <1:16). Titers vary between kits.
Real-time PCR assays	Biopsies, body fluids, aspirates	*Cryptococcus* DNA	Not yet validated in adequate numbers of dogs or cats with cryptococcosis; usefulness requires further evaluation.
Histopathology	Biopsy specimens from affected tissues	*Cryptococcus* spp. yeasts	High sensitivity, with rare false negatives. Special stains such as Mayer's mucicarmine and immunohistochemical stains facilitate organism detection and identification.

lesions or optic neuritis may result in blindness with dilated and unresponsive pupils.

Dogs

Many dogs with cryptococcosis are lethargic or obtunded because of disseminated disease and/or CNS involvement. When fever occurs, it is typically low grade. Other CNS signs in dogs include absent or slow menace, gag, pupillary light responses, nystagmus, mydriasis, head tilt, strabismus, anisocoria, facial paralysis, paraparesis, abnormal placing reactions, ataxia, circling, seizures, twitching or tremors, reluctance to open the mouth, absent or decreased segmental reflexes, and, commonly, cervical hyperesthesia.[9,24] Some dogs show signs that resemble those of cervical disc herniation. The most common ocular abnormalities are chorioretinitis, papilledema, evidence of optic neuritis, and retinal detachment. Decreased nasal airflow may be present in dogs with nasal cavity cryptococcomas. Nodules, masses, or ulcers may involve any portion of the integument, and the nose, tongue, buccal mucosa, hard palate, lips, or nail beds.

Diagnosis

Definitive diagnosis of cryptococcosis is usually straightforward and based on evaluation of representative tissue specimens with cytology, culture, and occasionally histopathology, with or without serologic detection of cryptococcal antigen in body fluids (Table 62-1). Suitable specimens include nasal swabs, nasal washings, needle aspirates from mass lesions or enlarged lymph nodes, bronchoalveolar lavage specimens, pleural fluid, CSF, and urine.

Laboratory Abnormalities

Complete Blood Count, Serum Chemistry Profile, and Urinalysis

Changes in the CBC, chemistry panel, and urinalysis in animals with cryptococcosis are generally mild and nonspecific. Mild to moderate nonregenerative anemia; leukocytosis, often with monocytosis; and eosinophilia are the most common findings. Dogs with disseminated disease may have a neutrophilia with a left shift. The serum biochemical profile reflects specific organ involvement in animals with disseminated disease. Occasionally, cryptococcal yeasts are found on examination of the urine sediment.

Cerebrospinal Fluid Examination

The CSF in cats and dogs with neurologic signs due to cryptococcosis may have an increased protein concentration (usually between 10 and 140 mg/dL in cats, but may be several hundred or rarely more than 1000 mg/dL in dogs).[9] Leukocyte counts can range from 2 to more than 1000 cells/μL in both dogs and cats. A mixed cellular pleocytosis is generally present, with neutrophils or large mononuclear cells generally outnumbering other cell types. Some dogs have a marked eosinophilic pleocytosis. Cryptococcal yeasts are visible in most but not all animals with cryptococcal meningitis (see Figure 62-2).[9] Marked deterioration in neurologic status occasionally occurs in animals with CNS cryptococcosis immediately after CSF collection. Many animals have intracranial mass lesions or increased CSF pressure, which can increase the risk of cerebellar herniation following a cisternal tap. Wherever possible, attempts to make a diagnosis with serum antigen testing or collection of specimens from other anatomic sites should be considered as an alternative to diagnosis by CSF analysis.

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs and cats are often normal. In some animals, interstitial to alveolar infiltrates or small nodular lesions are present. Occasionally, large pulmonary nodules, hilar lymphadenopathy, a mediastinal granuloma, or pleural effusion are found.[41]

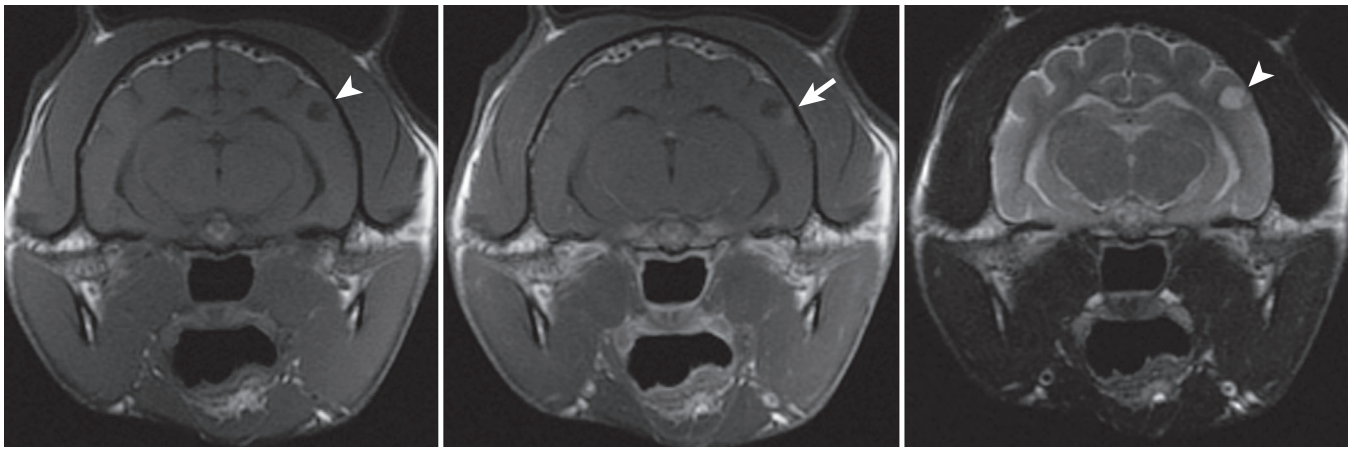

FIGURE 62-7 Transverse T1-weighted pre-contrast *(left)*, T1-weighted post-contrast *(center)*, and T2-weighted *(right)* MRI of the brain of an 8-year-old male neutered domestic shorthair with cryptococcosis. There is a focal lesion in the gray matter of the right cerebral cortex at the junction of the parietal and occipital lobes *(arrowhead)*. The lesion is T2 hyperintense, T1 hypointense, and rim-enhancing *(arrow)*. These signal characteristics were consistent with a pseudocyst lesion.

Computed Tomography

In cats with nasal cryptococcosis, computed tomography (CT) of the nasal cavity can reveal soft tissue and fluid opacification of the nasal cavity or frontal sinus, peripherally contrast-enhancing mass lesions of the nasal planum, and lysis of the nasal bones or of the cribriform plate.[11] In dogs, CT findings in the nasal cavity include peripherally contrast-enhancing mass lesions within the frontal sinuses, caudal nasal cavity, nasopharynx, or the retrobulbar space and associated osteomyelitis (see Figure 62-4, *A*). CNS abnormalities such as ventricular dilation and intra-axial contrast-enhancing mass lesions have been described in dogs using CT.[9] However, MRI is more sensitive for detection of CNS lesions in human patients,[42] and the same is probably true for dogs and cats.

Magnetic Resonance Imaging

MRI abnormalities in cats with CNS cryptococcosis consist of single or multifocal contrast-enhancing mass lesions that tend to be hyperintense on T2-weighted images and hypointense on T1-weighted images, as well as mild to moderate, diffuse or focal meningeal enhancement.[9] Some cats have lesions that appear fluid-filled on T2-weighted images but have a greater T1-weighted intensity than expected for acellular fluid ("high T2, low T1 lesions") (Figure 62-7).[9] MRI in dogs may show contrast-enhancing mass lesions that are hyperintense on T2-weighted images and of variable intensity on T1-weighted images, as well as meningeal enhancement (see Figure 62-4, *B*). Ventriculomegaly and/or cribriform plate osteomyelitis may also be evident.

Sonographic Findings

Over 80% of cats with cryptococcosis have normal abdominal ultrasound examinations. Cats with kidney involvement can have iso- to hypoechoic intraparenchymal mass lesions on ultrasound, with or without associated renal failure. These sometimes involve the renal pelvis. However, cats with renal involvement can also have normal abdominal ultrasound examinations.[11]

Ultrasonographic findings in dogs include intra-abdominal lymphadenomegaly, multifocal gastric and small intestinal thickening, changes suggestive of pancreatitis, renal mass lesions, and/or ascites (see Figure 62-3).[11,48]

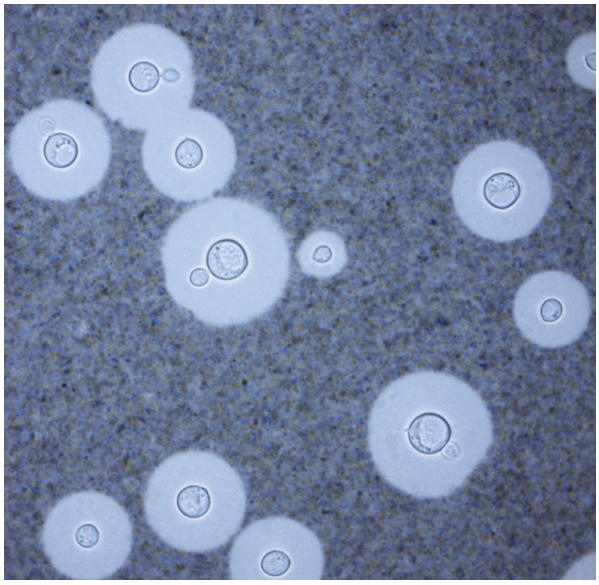

FIGURE 62-8 India ink stained preparation of *Cryptococcus gattii* yeasts that had been grown in culture. 1000× oil magnification. (Courtesy Greg Hodges and George Thompson III, University of California, Davis.)

Microbiologic Tests

Cytologic Examination

Cytologic examination can be performed on aspirates, body fluids, or impression smears of biopsy specimens. Romanowsky-type stains, new methylene blue, and Gram stain are all satisfactory for making a cytologic diagnosis. India ink can be used to examine CSF for cryptococcal yeasts, which appear unstained and silhouetted against a black background. India ink staining of CSF is still used routinely in the diagnosis of human cryptococcal infections (Figure 62-8).[42] However, lymphocytes and fat droplets can sometimes be confused with the organism.

Although cytologic examination of nasal or cutaneous exudates, aspirates, or body fluids for organisms is a rapid and sensitive test for cryptococcosis, negative test results do not eliminate the possibility of cryptococcosis. Generally, organisms are found only by cytologic examination of CSF in 60% to 80% of dogs and cats.[11] If a sufficient index of suspicion exists,

VetBooks.ir

additional diagnostic tests such as histopathology, antigen testing, and/or fungal culture are indicated.

Fungal Culture

Cryptococcus spp. are readily cultured from aspirates, exudate, CSF, urine, and tissue specimens. Attempts to culture the organism are recommended whenever possible before treatment is initiated, because isolation confirms the diagnosis, can be used to differentiate *C. gattii* from *C. neoformans*, and permits antifungal susceptibility testing for cases that subsequently fail to respond adequately to antifungal drug treatment. Some veterinary diagnostic laboratories still report all *Cryptococcus* isolates as *C. neoformans* in the absence of tests to discriminate between *C. neoformans* and *C. gattii*. If the report lists *C. neoformans* as the isolate, the laboratory must therefore be consulted to determine whether *C. neoformans* was differentiated from *C. gattii*. However, whether the clinician needs to know whether the isolate is *C. neoformans* or *C. gattii* is debatable because at this time, species identification does not clearly influence treatment recommendations or prognosis. If *Cryptococcus* is isolated from a contaminated site such as the nasal cavity, a diagnosis of cryptococcosis should be supported with cytologic or histopathologic evidence of active infection. This is because subclinical colonization occurs in some animals.

C. neoformans and *C. gattii* grow on almost all laboratory media, but fungal isolation media (such as Sabouraud's dextrose agar) and incubation temperatures of 25°C or 30°C in addition to incubation at 37°C are preferred when fungi are being considered in the differential diagnosis. Antibiotics are added to the medium for isolation of *Cryptococcus* spp. from contaminated sites, such as the nasal cavity. Colonies usually are visible in 2 to 3 days, but sometimes incubation for up to 10 days is required. Unlike other dimorphic fungi, *Cryptococcus* grows as a yeast, rather than a mold, on routine fungal media and so is less likely to represent a laboratory hazard than organisms that grow as molds. The organisms form white, creamy colonies. Often *C. gattii* colonies are more mucoid than *C. neoformans* colonies. The organism is identified based on its microscopic morphology and response to biochemical tests in commercial yeast identification kits (see Chapter 4). Canavanine-glycine-bromothymol blue (CGB) agar is used to differentiate between *C. neoformans* and *C. gattii*.[50] Unlike *C. neoformans*, *C. gattii* grows on CGB agar and turns the media a brilliant deep blue (Figure 62-9). Fungal culture of the CSF is frequently positive in patients with CNS cryptococcosis and should be performed even if the organism cannot be demonstrated cytologically or serologically. Culture of urine specimens collected using cystocentesis is also indicated when cryptococcosis is suspected, even when obvious renal involvement is not present and cytologic abnormalities are not present. Identification of molecular types for epidemiologic purposes requires specialized techniques such as multilocus sequence typing or PCR fingerprinting. However, matrix-assisted laser desorption/ionization–time of flight mass spectrometry (MALDI-TOF) can also rapidly differentiate between *Cryptococcus* species as well as molecular types, and may be used in veterinary clinical microbiology laboratories in the future.[51]

Most cryptococcal isolates from dogs or cats are susceptible to amphotericin B, 5-flucytosine, and azoles. Rarely, resistance to 5-flucytosine and azole antifungal drugs (especially fluconazole) is detected. In general, minimum inhibitory concentrations (MICs) for fluconazole are higher than those for other azole drugs, and this does not imply resistance in vivo. In the human literature it has been suggested that when the MIC rises during treatment, or if the initial MIC is at least 16 µg/mL for fluconazole, or at least 128 µg/mL for flucytosine, failure of antifungal drug treatment may result from drug resistance.[42]

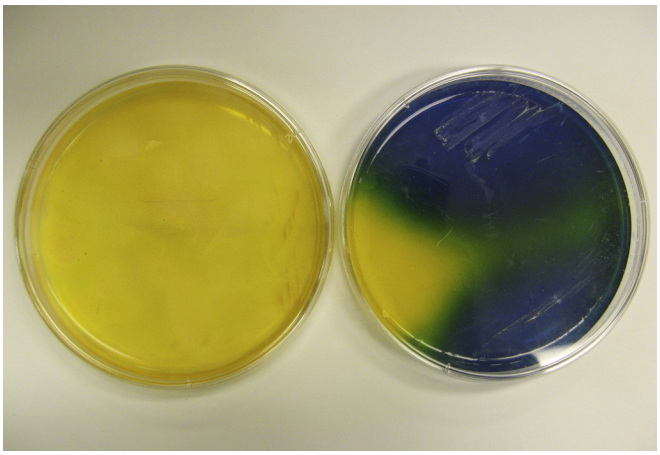

FIGURE 62-9 Growth of *C. neoformans (left)* and *C. gattii (right)* on canavanine-glycine-bromothymol blue agar. *Cryptococcus neoformans* does not grow well in the presence of canavanine and does not utilize glycine, so the medium color remains unchanged. *Cryptococcus gattii* grows in the presence of L-canavanine and utilizes glycine as the sole carbon and nitrogen source, which raises the pH of the medium and causes the bromothymol blue indicator in the medium to turn the agar a vivid cobalt blue color.

Serologic Testing

Latex agglutination assays for detection of cryptococcal polysaccharide capsular antigen are widely used for diagnosis of cryptococcosis in veterinary patients and are sensitive and specific.[11,52,53] ELISA assays are also available, and the performance of a rapid lateral-flow assay (CrAg, IMMY Diagnostics, Norman, OK) is under investigation in the authors' laboratories. Serologic assays detect the antigen of all *C. gattii* and *C. neoformans* molecular types and can be used on serum or CSF. These can provide a rapid diagnosis when organisms cannot be visualized or cultured. When positive, serum cryptococcal antigen assays can be advantageous in animals with neurologic signs when CSF collection is unacceptably risky or if a diagnosis of cryptococcosis is unlikely but requires additional evidence for exclusion.

In human patients, commercial kits typically have at least 90% sensitivity and specificity.[42] Results have been similar for small animal patients,[11,52,53] although false negative results may be more common in dogs than in cats.[11] False positive test results are reduced when test specimens are pretreated in the laboratory with pronase (a proteinase).[42] In human patients, titers below 1:8 can represent false-positive results, although false-positive titers of up to 1:200 have rarely been detected in cats.[11] These cats had other causative etiologies identified that explained their clinical signs. In some cats these low positive titers may represent subclinical colonization. Attempts to obtain cytologic or histopathologic confirmation of infection in animals with titers of 1:200 or less are recommended.

Antigen titers are frequently extremely high (>1:65,536) in cats and dogs with cryptococcosis, but even a titer of 1:2 can indicate cryptococcal infection.[52] Titer results from different kits vary considerably; therefore, the methodology should not be altered when monitoring the response to treatment. A good prognosis is indicated by a decrease in antigen titer, whereas

VetBooks.ir

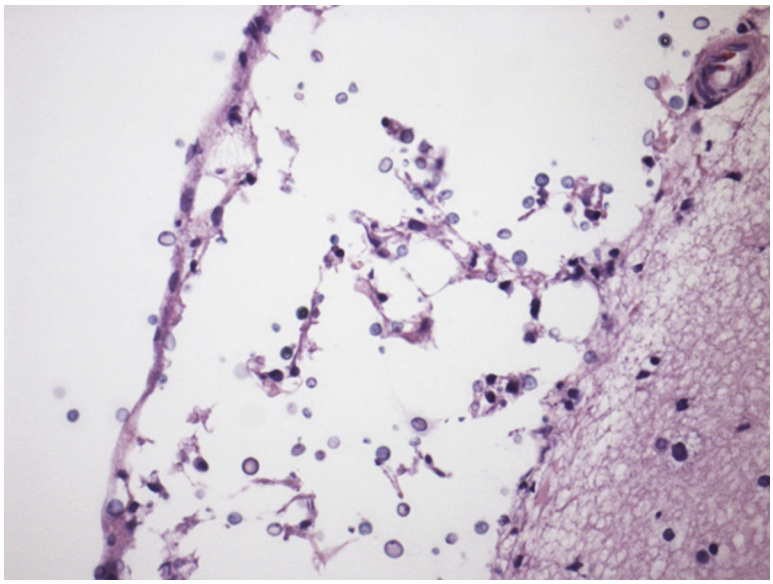

FIGURE 62-10 Histopathology showing the meninges of a cat with cryptococcosis. Numerous round yeast organisms occupy the meningeal spaces. H&E stain.

a persistent titer after treatment suggests continued infection. Reductions in the titer typically lag behind clinical improvement. No correlation has been found between pretreatment antigen titer and outcome.

Because the sensitivity of cryptococcal antigen testing is not 100%, cryptococcosis should not be ruled out on the basis of a negative antigen titer alone. This is especially important in dogs, because false negatives are more common in dogs than in cats.[11] False negatives are most common in animals with localized ocular, CNS, or solitary cutaneous lesions. For dogs and cats suspected to have cryptococcal meningoencephalomyelitis that have negative serum antigen titers, CSF should be submitted for cytologic examination, antigen titers, and fungal culture.

Molecular Diagnosis Using the Polymerase Chain Reaction

Real-time PCR assays for *Cryptococcus* spp. are offered on a commercial basis by some veterinary diagnostic laboratories. These assays can confirm the presence of *Cryptococcus* DNA in tissues or body fluids when other means fail. However, because a diagnosis of cryptococcosis is usually apparent based on the methods described earlier, PCR is currently not regarded as a routinely useful clinical tool. Because *Cryptococcus* DNA has been detected using PCR assays in small intestinal contents from healthy dogs and dogs with chronic enteropathies,[54] positive results on intestinal biopsies may not reflect cryptococcosis. Similarly, because subclinical nasal cavity colonization can occur, positive results on nasal biopsies may not represent invasive disease. Because false positives also have the potential to occur as a result of contamination in the PCR laboratory, a PCR diagnosis of cryptococcosis should always be supported by cytologic or histopathologic evidence of infection and/or culture of *Cryptococcus* spp. from a normally sterile site.

Pathologic Findings

Lesions associated with cryptococcosis vary from gelatinous masses that consist almost exclusively of organisms to well-ordered granulomas or pyogranulomas that typically occur in patients with improved cell-mediated immune (CMI) responses. The gelatinous appearance is a reflection of the large amount of capsular polysaccharide present in lesions. In sections stained with hematoxylin-eosin, *Cryptococcus* yeasts are faint, eosinophilic, round to oval bodies that are surrounded by a clear halo (the unstained capsule). The organism is more easily visualized with periodic acid–Schiff, methenamine silver, or Fontana-Masson stain, although the capsule still does not stain well with these methods. With Mayer's mucicarmine stain, the cryptococcal capsule takes on a rose-red color, and the organism appears pink against a blue background. Other fungi with similar morphologic features do not stain with Mayer's mucicarmine. Some *Cryptococcus* strains have poorly developed capsules. If necessary, immunohistochemistry can be used to differentiate *Cryptococcus* from other fungi and some reagents can provide information on the identity of the species and serotype present.[55]

Cats

In cats that die or are euthanized as a result of cryptococcosis, histopathology of lesions within the nasal cavity may reveal granulomatous rhinitis. CNS cryptococcosis consists of either meningitis[41] or meningoencephalomyelitis, with single or multiple cerebral granulomas (Figure 62-10). Extension of infection from the meninges along perforating arteries into the Virchow-Robin spaces can result in cystic collections of yeast organisms known as gelatinous pseudocysts.[9] Ocular lesions include pyogranulomatous to granulomatous chorioretinitis, optic neuritis, uveitis, endophthalmitis, panophthalmitis, and retinal separation. Other affected organs include skin and subcutaneous tissues, kidneys, and lymph nodes. Renal granulomas have been found in some cats with disseminated disease. Granulomas can also occasionally be found in the spleen, adrenal glands, thyroid glands, and liver.

Dogs

Dogs that die or are euthanized because of cryptococcosis often have CNS infection, ocular involvement, or widely disseminated disease. The lesions consist of granulomatous or pyogranulomatous meningoencephalitis, sometimes with pseudocyst formation; neuritis of the optic, facial, or vestibular nerves; and pyogranulomatous or granulomatous chorioretinitis. Inflammatory lesions that contain *Cryptococcus* yeasts may also be

present in the lungs, nasal cavity, kidneys, pancreas, liver, myocardium, gastrointestinal tract, and spleen. Less commonly, involvement of the peritoneum, thyroid, tongue, prostate, pleura, joints, mediastinum, urinary bladder, and adrenal gland has been detected at necropsy.

Treatment and Prognosis

Treatment recommendations for dogs and cats with cryptococcosis have been based on evidence-based studies performed in human patients and clinical experiences; evidence-based studies are lacking for veterinary patients. The most common problems encountered are the high cost of therapy, requirement for multiple hospital visits, and the need for regular medication of pets for a protracted period. Immunocompromised animals (which may include purebred dogs with no obvious underlying immunodeficiency) are especially likely to have persistent or progressive infection in the face of treatment. In many affected animals, treatment must be continued for years or the life of the animal. Surgical debulking could be considered before treatment for large cryptococcomas to improve drug penetration. However, even large cryptococcomas can resolve with medical treatment alone, and surgery should only be performed if lesions can be easily and safely resected. The reader is referred to Chapter 9 for detailed information on antifungal drugs.

Cats

Cats with localized cutaneous disease can sometimes be treated successfully with azole monotherapy. The initial drug of choice is fluconazole (10 mg/kg PO q12h), because of its good penetration of the brain, eye, and urinary tract; low cost; and minimal adverse effects.

Treatment should be continued until there is complete lesion resolution and the cryptococcal antigen titer becomes negative. A four- to fivefold reduction in the antigen titer suggests an adequate response. In cats with *C. gattii* molecular type VGI or *C. neoformans* infections, this typically takes 2 to 12 months (median, 4 months),[56] although longer periods of therapy may be required for some cats. For recovered animals that achieve an antigen titer of 0, the titer can be monitored every 3 to 6 months, so that any recurrence is diagnosed early. However, in the authors' experience, many cats with *C. gattii* molecular type VGII and VGIII infections in North America fail to respond completely to fluconazole treatment, antigen titers persist at high levels, and relapse occurs after an initial treatment response. In some of these cats, treatment with itraconazole (5-10 mg/kg PO q24h [capsules] or 3-5 mg/kg PO q24h [solution]) or ketoconazole can lead to clinical remission. Liver enzyme activities should be monitored monthly during treatment with azole antifungal drugs to monitor for hepatotoxicity (see Chapter 9).

Amphotericin B is the most effective anticryptococcal agent. Penetration of the CNS and vitreous is poor, but clinical responses still occur in cats and dogs with CNS and ocular cryptococcosis, presumably because the blood-brain barrier is compromised. A combination of amphotericin B and 5-flucytosine (250 mg PO q8h) is considered the optimal therapy for cats (and humans, but not dogs) with CNS cryptococcosis, or for those that fail to respond to azole drugs. Fluconazole can be substituted for 5-flucytosine if 5-flucytosine is unaffordable. However, 5-flucytosine shows synergy when combined with amphotericin B and effectively penetrates the blood-brain barrier. Because resistance can develop rapidly when 5-flucytosine is used alone, it is used chiefly to improve the efficacy of other antifungal drugs. Lipid-complexed amphotericin B preparations are not necessarily more effective but are less nephrotoxic, which may translate into greater efficacy because higher doses can be used, although at a substantially increased cost. In human patients, higher doses of amphotericin B more effectively sterilize the CSF. The reader is referred to Chapter 9 for dosing protocols for various formulations of amphotericin B. Treatment with 5-flucytosine (or fluconazole) and amphotericin B is continued for 2 to 4 weeks (ideally 4 weeks) or until azotemia develops, after which treatment is continued with azole monotherapy. Additional courses of amphotericin B may be required to maintain clinical remission in some cats. Although controlled trials have not been performed, some cats with CNS cryptococcosis have shown apparent response to addition of terbinafine to the treatment regimen, when other drugs failed to resolve clinical signs.[57]

Dogs

If affordable to the owner, dogs with disseminated disease or CNS involvement should be treated initially with deoxycholate or lipid-complexed amphotericin B and fluconazole. Dogs treated with flucytosine frequently develop toxic epidermal necrolysis, typically 10 to 14 days after starting therapy, which precludes treatment with flucytosine in this species.[58] Some dogs with CNS involvement respond to azole monotherapy, although residual neurologic signs may persist.[9] Other potential outcomes include incomplete recovery, with persistent active infection despite therapy, or relapse after prolonged clinical remission. In one dog, surgical debridement of an extradural spinal cord granuloma combined with fluconazole treatment controlled spinal cord infection.[59] Again, azoles are fungistatic and rely on a CMI response and phagocytosis to remove cryptococcal yeasts from the host, which may be lacking in some dogs with cryptococcosis. Treatment of a dog with intestinal cryptococcosis with terbinafine was associated with long-term disease resolution when treatment with azoles, surgical debulking, and amphotericin B failed.[48]

Other Antifungal Drugs

Other antifungal drugs that are effective for treatment of cryptococcosis include voriconazole and posaconazole, although these can be unaffordable for many clients. Voriconazole penetrates the CNS and so is potentially advantageous for treatment of cryptococcal meningoencephalitis. However, virtually all cats and some dogs do not tolerate voriconazole treatment because of gastrointestinal, neurologic, and cardiac adverse effects. In humans, posaconazole is well tolerated, and it has been used to treat other fungal infections without complication in cats (see Chapter 9), so it could be an option for cats with refractory disease. Unpredictable serum levels have led to increased interest in therapeutic serum level determination in humans.

Supportive Care

Because many cats and dogs with CNS involvement deteriorate clinically during initial treatment with antifungal drugs as a result of the inflammatory response to dying yeasts, anti-inflammatory doses of short-acting glucocorticoids may be necessary to support animals with CNS cryptococcosis for the first few days to weeks of treatment and may increase survival rate at 10 days after initiation of treatment.[9] Deterioration of neurologic status in the first few days of treatment is not a negative

VetBooks.ir

prognostic indicator if the animal can be supported through this phase. Supportive care with IV fluid therapy, tube feeding, and antiseizure medications may be necessary. Rarely, dogs or cats require supplemental oxygen because of respiratory involvement.

Prognosis

In general, cats show significant clinical improvement within 1 to 2 weeks of starting therapy. In studies from Australia, around 75% of cats were treated successfully.[5,56] As many as 60% of cats may be cured after an initial course of therapy, although some cats that show an initial favorable response to therapy can relapse, sometimes as long as 10 years after therapy is discontinued.[56] In one study, the median survival time of cats with CNS cryptococcosis was only 13 days (range, 0 to 4050 days), but a median survival time was never reached if cats survived at least 3 days after diagnosis, so supportive care during this phase may be critical.[9]

The prognosis is more guarded for dogs. Six of 11 dogs with cryptococcosis in Australia were treated successfully.[56] In a study from the western United States[9] and another from southwestern Australia,[5] the success rate was lower, around 30%. The median survival time for dogs with CNS cryptococcosis was 7 days (range, 0 to 3680 days).[9]

In human patients with cryptococcosis, negative prognostic indicators include underlying immunosuppressive disease or drugs, abnormal mental state, high organism burden at presentation (as defined by large numbers of yeasts in the CSF and/or high antigen titers), and a poor anti-inflammatory response in the CSF (<20 cells/μL).[60] The presence of CNS disease appears to negatively affect outcome in both cats and dogs.[56,61] In dogs and cats with CNS involvement, the presence of altered mental status at first evaluation was associated with increased mortality ($P = 0.03$).[9]

Immunity and Vaccination

Cryptococcosis can occur in apparently immunocompetent or in immunodeficient individuals, although those with deficiencies of cell-mediated immunity are most commonly infected. Production of Th1 type cytokines such as Il-2, TNF-α, and IFN-γ and a granulomatous inflammatory response are important for elimination of infection, and decline in the CD4+ T cell count to less than 50 to 100 cells/μL correlates well with the risk of infection in HIV-infected humans.[42] No vaccines are available.

Prevention

Prevention of cryptococcosis may be possible through avoidance of exposure to ecologic niches of the organism, such as pigeon feces. Nevertheless, cryptococcosis occurs in animals housed exclusively indoors, and widespread exposure and recovery likely occurs in endemic areas.

Public Health Aspects

Cryptococcosis is an important opportunistic fungal infection of people with AIDS, in particular those who are not treated with highly active antiretroviral therapy. Human infection is acquired from the environment and not by direct contact with infected animals, although intense exposure to avian excrement has been associated with some cryptococcosis cases in HIV-infected humans.[62] Malignancy, chemotherapy, immunosuppressive drug therapy, diabetes mellitus, splenectomy, cirrhosis, or sarcoidosis can also predispose to the disease. Severe meningitis and disseminated infections can develop in immunodeficient patients.

The organism does not aerosolize from sites of tissue infection, so the disease cannot spread among people or animals. The major public health significance of infected pets is that cats may act as a sentinel for infection of human beings, because of their susceptibility to infection. In the diagnostic laboratory, culture of *Cryptococcus* is not a significant health hazard, because only the yeast form is grown routinely, and this form does not aerosolize from media. During handling of infected tissues or cultures, precautions should be taken to prevent inadvertent cutaneous inoculation of the organism. Veterinarians should consider patient sedation for procedures that involve fine-needle aspiration in order to avoid inadvertent needle-stick injuries, which have caused localized cutaneous infection in the human health care setting.[63] Because sporotrichosis is a major differential diagnosis for cats with cutaneous lesions, gloves should always be worn and hand hygiene performed when handling cats with suspicious lesions (see Chapter 64).

CASE EXAMPLE

Signalment: "Simon," an 8-year-old male neutered domestic shorthair cat from northern California

History: Simon was evaluated by the University of California, Davis, Veterinary Medical Teaching Hospital (VMTH) for a 5-week history of progressive weakness, inappetence, and weight loss. Initially the owners noted that he was reluctant to jump and had a low tail carriage, and intermittent episodes of head shaking and sneezing were also noted. He also had episodes of clenching the furniture with his claws. Three weeks before he was brought to the VMTH, Simon was seen at a local veterinary clinic where a physical examination was unremarkable. Broad-spectrum antimicrobial drugs were prescribed (amoxicillin-clavulanic acid and enrofloxacin for 7 days), and he was treated with subcutaneous fluids (lactated Ringer's solution, 150 mL, once). Over the following 5 days his clinical signs lessened, but then anorexia developed. Physical examination 2 days after the onset of anorexia revealed a rectal temperature of 102.5°F (39.2°C) and weight loss (3.7 kg at the previous visit to 3.2 kg). A CBC and biochemistry panel showed mild lymphopenia (1157 cells/μL, reference range 1500-7000 cells/μL). Treatment with metronidazole (39 mg/kg PO q24h) and prednisone (3 mg/kg PO q24h) was instituted. Three days before he was brought to the VMTH, he began panting and vocalizing. The metronidazole was discontinued and the prednisone dose was reduced to 1.5 mg/kg PO q24h. The following day, the owners noted that Simon's eyelids were twitching, and he urinated and defecated on himself in the litter box. Clindamycin (6 mg/kg PO q12h) was prescribed

Continued

VetBooks.ir

for suspected toxoplasmosis, and Simon was referred for further evaluation.

Simon had no other previous medical or surgical history apart from being neutered as a kitten. He had access to the outdoors and there were no other cats in the household. There had been no changes in his thirst or urination, no vomiting or diarrhea, and he was last vaccinated at 5 years of age. He had killed a large rat approximately 5 weeks earlier and had not been himself since.

Physical Examination:

Body Weight: 2.9 kg.

General: Obtunded but responsive, estimated as 5% dehydrated. T = 100.2°F (37.9°C), HR = 200 beats/min, RR = 60 breaths/min, CRT <2 s.

Eyes, Ears, Nose, and Throat: Bilateral mydriasis and absent pupillary light reflexes were noted. There was no evidence of nasal discharge and nasal airflow was normal. Mucous membranes were pink and slightly tacky. Fundic examination was within normal limits.

Musculoskeletal: Body condition score 4/9, ambulatory. The cat had a slow gait with a short stride.

Respiratory: Tachypnea was present with a normal respiratory effort. Normal breath sounds were present on auscultation.

Cardiovascular, Gastrointestinal, Genitourinary and Lymph Nodes: No clinically significant abnormalities were detected. The urinary bladder was small.

Neurologic Examination: The cat was mildly obtunded, walked with a crouched stance and behaved as if nonvisual. Bilateral mydriasis and absent menace and pupillary light reflexes were confirmed. Intermittent horizontal nystagmus with the fast phase to the left was present. Cranial nerve examination was otherwise normal. Placing and hopping reactions were delayed in the left pelvic limb. There was a decreased left patellar reflex, but other segmental reflexes were intact. There was no apparent pain on spinal palpation, but the cat appeared painful when the tail was raised. Neuroanatomic location: Multifocal CNS disease.

Laboratory Findings:

CBC:

HCT 27.2% (30%-50%)
MCV 48.3 fL (42-53 fL)
MCHC 29.8 g/dL (30-33.5 g/dL)
Reticulocytes 8400 cells/µL (7000-60,000 cells/µL)
WBC 12,360 cells/µL (4500-14,000 cells/µL)
Neutrophils 11,000 cells/µL (2000-9000 cells/µL)
Lymphocytes 828 cells/µL (1000-7000 cells/µL)
Monocytes 445 cells/µL (50-600 cells/µL)
Eosinophils 87 cells/µL (150-1100 cells/µL)
Basophils 0 cells/µL (0-50 cells/µL)
Platelets 357,000/µL (180,000-500,000 platelets/µL).

Serum Chemistry Profile:

Sodium 150 mmol/L (151-158 mmol/L)
Potassium 4.3 mmol/L (3.6-4.9 mmol/L)
Chloride 115 mmol/L (117-126 mmol/L)
Bicarbonate 19 mmol/L (15-21 mmol/L)
Phosphorus 5.4 mg/dL (3.2-6.3 mg/dL)
Calcium 10 mg/dL (9.0-10.9 mg/dl)
BUN 21 mg/dL (18-33 mg/dL)
Creatinine 1.2 mg/dL (1.1-2.2 mg/dL)
Glucose 136 mg/dL (63-118 mg/dL)
Total protein 7.5 g/dL (6.6-8.4 g/dL)
Albumin 3.8 g/dL (2.2-4.6 g/dL)
Globulin 3.7 g/dL (2.8-5.4 g/dL)
ALT 37 U/L (27-101 U/L)
AST 28 U/L (17-58 U/L)
ALP 8 U/L (14-71 U/L)
GGT < 3 U/L (0-4 U/L)
Cholesterol 177 mg/dL (89-258 mg/dL)
Total bilirubin < 0.1 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.018; pH 7.0; 25 mg/dL protein; no bilirubin, hemoprotein, glucose; rare WBC/HPF, 0 RBC/HPF, few amorphous crystals, few lipid droplets.

ELISA for FeLV Antigen and FIV Antibody: Negative.

Latex Agglutination for Cryptococcus Antigen: Positive at 1:32,768.

Imaging Findings:

Plain Thoracic and Abdominal Radiographs: The only abnormality present was mild lateral spondylosis of the caudal lumbar spine.

Abdominal Ultrasonography: The liver was mildly enlarged and contained multiple small hyperechoic foci. In the kidneys, mild cortical hyperechogenicity and decreased corticomedullary distinction were present.

Magnetic Resonance Imaging (Brain): Precontrast images showed a well-defined, round T2-hyperintense, T1-hypointense lesion in the gray matter of the right cerebral cortex at the junction of the parietal and occipital lobes (see Figure 62-7). Postcontrast images showed moderate contrast enhancement of this lesion. There was mild contrast enhancement of the meninges ventral to the right preoptic area. There was moderate, focal contrast enhancement of the gray matter at the lateral aspect of the right pyriform lobe. There was contrast enhancement of the medial aspect of both pyriform lobes adjacent to the hypophysis. Impressions: Multifocal contrast-enhancing lesions with T2 hyperintensity and a cystic lesion in the right cerebral cortex.

Cytologic Findings: CSF analysis (cisternal): Protein concentration 29 mg/dL (reference range, <25 mg/dL). The specimen had a moderate increase in cellularity with a low number of erythrocytes. Numerous thick-capsuled yeast organisms with frequent narrow budding forms were noted, consistent with *Cryptococcus* spp. Nucleated cells consisted of nondegenerate neutrophils admixed with low numbers of variably vacuolated macrophages and small lymphocytes. The differential cell count was 83% neutrophils, 7% small mononuclear cells, and 10% large mononuclear cells.

Microbiologic Testing: Fungal culture (CSF): *Cryptococcus gattii*. Multilocus sequence typing revealed the organism belonged to *C. gattii* molecular type VGIIa.

Diagnosis: *Cryptococcus gattii* meningoencephalitis.

Treatment: Simon was treated with deoxycholate amphotericin B (0.25 mg/kg in 30 mL 5% dextrose IV over 30 minutes on Monday, Wednesday, and Friday for five treatments). Before and after this treatment, 0.9% NaCl was administered at twice maintenance rate and kidney analytes were monitored. Flucytosine (62.5 mg PO q8h) and prednisone (2.5 mg PO q24h) were also administered. An esophagostomy tube was placed for enteral nutrition because of persistent inappetence. By day 7, Simon appeared more alert, pupillary light reflexes and menace

VetBooks.ir

responses were present but weak, and nystagmus had resolved. He was discharged from the hospital on day 12, with instructions to continue treatment with fluconazole (50 mg PO q12h) and prednisone (2.5 mg PO q48h), in addition to esophagostomy tube feeding. On day 24, he was reevaluated for lethargy of several days' duration. Physical examination showed resolution of cranial nerve abnormalities, but delayed hopping reactions in all limbs were present. He was treated with six additional amphotericin B treatments over 2 weeks. He began eating, and the esophageal feeding tube was removed on day 40. Three months after diagnosis, his neurologic signs had almost completely resolved with the exception of occasional tremors, persistent mild placing reaction deficits, and lumbosacral pain. A cryptococcal antigen titer was positive at 1:65,536. The fluconazole was replaced with itraconazole solution (3 mg/kg PO q12h). After an additional month, the antigen titer was 1:1024, a serum chemistry profile was unremarkable, and the owners felt that Simon was a normal cat. The prednisone treatment was discontinued thereafter. A year later, the antigen titer was 1:20. At a recheck examination 2 years later the cat was neurologically normal. The owner declined further antigen testing and chose to continue treatment with itraconazole.

Comments: This cat had CNS cryptococcosis caused by *Cryptococcus gattii* molecular type VGIIa, a hypervirulent molecular type that emerged in British Columbia and the Pacific Northwest. The treatment plan was limited by client financial concerns, which meant that the initial course of amphotericin B and flucytosine treatment was short, and a second course of amphotericin B was required. Subsequently, treatment with fluconazole was associated with limited improvement, but a change to itraconazole was followed by dramatic clinical improvement and reduction in antigen titers.

CHAPTER 63

Coccidioidomycosis

Jane E. Sykes

VetBooks.ir

Overview of Coccidioidomycosis

First Described: 1892 (by the medical student Alejandro Posadas), in a person from Buenos Aires, Argentina, where it was initially mistaken for a protozoan (*Coccidia*)[1]

Cause: *Coccidioides immitis* and *Coccidioides posadasii* (ascomycetes, no known teleomorph)

Affected Hosts: Primarily humans and dogs, but also a variety of other animals that include cats, domestic farm animal species, and a variety of wildlife hosts

Geographic Distribution: Southwestern United States, Mexico, and parts of Central and South America (northeastern Brazil, Argentina, Paraguay, and Bolivia)

Mode of Transmission: Inhalation of arthroconidia from the environment; rarely cutaneous inoculation

Major Clinical Signs: Cough, fever, inappetence, weight loss, tachypnea, increased respiratory effort, lameness, subcutaneous masses or draining skin lesions, lymphadenopathy, neurologic signs, ascites due to right-sided heart failure (pericarditis), ocular lesions (uveitis, chorioretinitis, endophthalmitis)

Differential Diagnoses: Neoplasia, other deep mycoses, mycobacteriosis, actinomycosis or nocardiosis, toxoplasmosis or neosporosis, systemic immune-mediated disease

Human Health Significance: Direct transmission from animals to humans does not usually occur, although sharps injuries or bite wounds from affected animals may be a source of human infection. Dogs are a sentinel for human exposure.

Etiology and Epidemiology

Coccidioides spp. are dimorphic, soil-borne fungi that exist in the environment as a mycelium and in tissues (at 37°C) as peculiar structures known as *spherules*. The mycelium consists of chains of haploid, multinucleated, barrel-shaped arthroconidia (or arthrospores) that alternate with smaller, thin-walled, nonviable cells. The arthroconidia remain viable in the soil for long periods. They ultimately fragment from each other and are subsequently aerosolized and inhaled by animal hosts (Figure 63-1). This can be followed by the development of coccidioidomycosis, a localized pulmonary disease or a serious multisystemic disease if dissemination occurs in the face of inadequate immune responses.

In the environment, *Coccidioides* spp. are distributed in the lower Sonoran life zone, regions characterized by semiarid to arid soils, low elevations above sea level, and hot summers. Worldwide, *Coccidioides* spp. are found in the southwestern United States, Mexico, and parts of Central and South America, specifically Colombia, Guatemala, Honduras, Venezuela, northeastern Brazil, Argentina, Paraguay, and Bolivia (Figure 63-2). In the southwestern United States, highly endemic regions are the south-central valley of California, especially Bakersfield ("valley fever") and Arizona, especially Tucson and Phoenix.[2] Infections also occur in non-endemic regions in dogs and humans that have a travel history to endemic regions.

Two species of *Coccidioides* have been identified, *C. posadasii* and *C. immitis*. These appear to cause similar clinical manifestations and have similar antifungal drug susceptibilities, but further studies are required.[3] The geographic range of *C. immitis* is largely limited to the central valley of California, whereas *C. posadasii* is found elsewhere.[4] However, there may be some overlap in the distribution of these organisms.

Infection of animals and humans with *Coccidioides* spp. often follows a cycle of moist conditions (required for growth of the organism in the soil), a dry period, then soil disruption, such as may occur with heavy rainfall, earthquakes, dust storms, prolonged droughts, or construction.[5-7] Dogs of any breed, age, or sex may be affected, although large-breed, young adult dogs predominate in case series.[8,9] In dogs seen at the University of California Veterinary Medical Teaching Hospital, boxers, poodles, pointers, Labrador and golden retrievers, German shepherds, Australian shepherds, Dalmatians, Scottish terriers, dachshunds, and beagles are overrepresented when compared with the hospital patient population.[10] Risk factors for infection in dogs from Arizona include being housed outdoors during the day rather than indoors, roaming areas more than 1 acre, and walking in the desert.[11] Latent infections may also occur in dogs, and these can reactivate after treatment with immunosuppressive drugs, such as corticosteroids and chemotherapeutic agents, including after previous recovery from coccidioidomycosis.

Although not as prevalent as in dogs, coccidioidomycosis also occurs in cats.[12] In a study of 48 cats from Arizona, cats ranged in age from 1 to 15 years (median, 5 years) and there was no obvious sex or breed predisposition.[12] One cat was infected with FIV, and all cats tested were FeLV negative. Interestingly, a search of the author's hospital and pathology database from 1990 to 2012 revealed not a single cat with coccidioidomycosis, which might suggest cats are less susceptible to *C. immitis* infection than to *C. posadasii* infection.

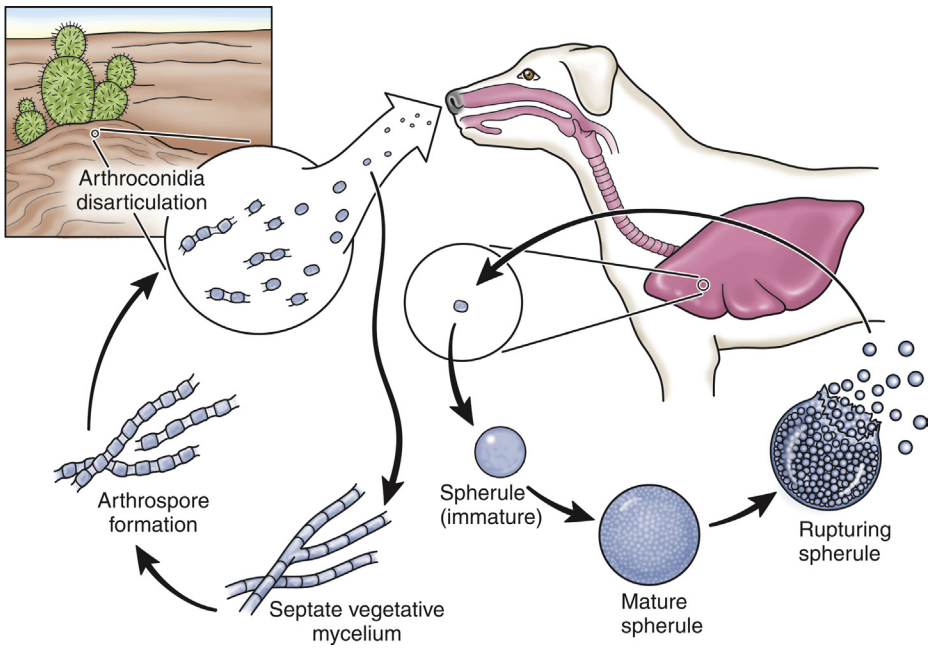

FIGURE 63-1 Life cycle of *Coccidioides* spp. Hyphae fragment into arthroconidia, which are inhaled and form spherules in tissues. The spherules rupture and release endospores, which form new spherules. In some dogs, the organism disseminates from the lungs to a variety of other tissues, but especially local lymph nodes, bone, skin, the pericardium, the eye, and the central nervous system.

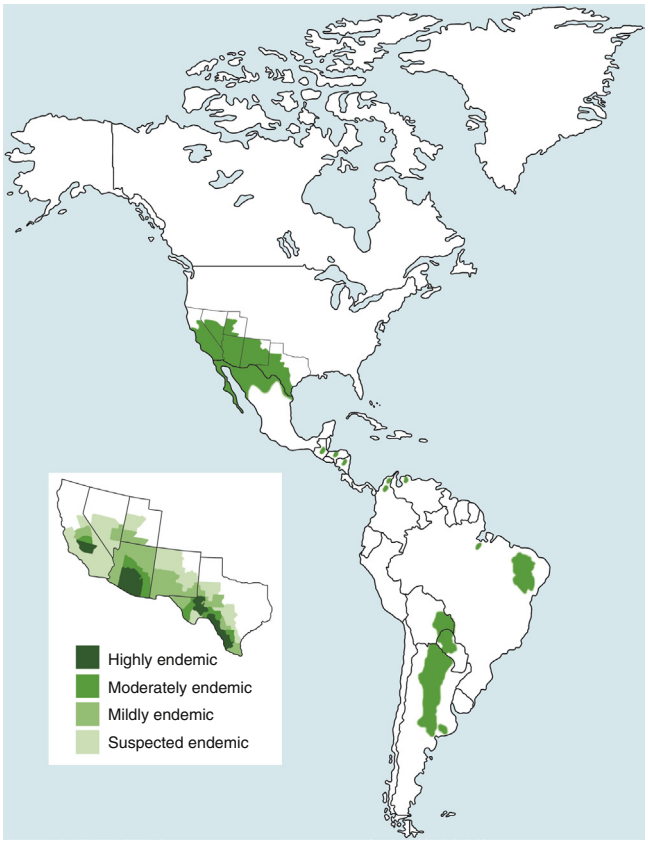

FIGURE 63-2 Geographic distribution of *Coccidioides* spp. worldwide. The inset shows the distribution of *Coccidioides* species in the southwestern United States.

Clinical Features

Signs and Their Pathogenesis

The clinical signs of coccidioidomycosis depend on factors such as the infectious dose and the immune status of the host. Arthroconidia are inhaled and are phagocytosed by alveolar macrophages. They then enlarge into a spherule, which measures 8 to 100 µm in diameter. Hundreds of endospores then develop within the spherule, which are released when the mature spherule ruptures. These attract neutrophils, which leads to a pyogranulomatous inflammatory response. Each released endospore that escapes immune destruction then enlarges into a new spherule, and the cycle continues. Endospores can revert to mycelial growth when removed from the site of infection. In hosts that are unable to mount an effective immune response, endospores disseminate by lymphatics to tracheobronchial lymph nodes and hematogenously to a variety of body sites. Inoculation coccidioidomycosis can rarely occur, and generally results in lesions that are localized to the site of the wound. In one report, it followed removal of a foxtail from a wound.[13]

Most infections in endemic areas are subclinical.[14] Development of clinical signs often follows a subacute to chronic course, with variable and often mild systemic signs such as intermittent fever, lethargy, inappetence, and weight loss.[8,15] Many dogs otherwise appear healthy, with occasional periods of inappetence.[8] Clinical signs may be present for days to years before veterinary attention is sought.[9] Signs of respiratory tract involvement include a harsh cough, increased respiratory effort, tachypnea and/or exercise intolerance.[9,15] Cough may be chronic and is sometimes associated with gagging or retching; occasionally it results from bronchial compression by enlarged tracheobronchial lymph nodes. Rarely, diffuse pneumonia follows a fulminant course, with signs that resemble acute bacterial pneumonia or septic shock, as reported in immunocompromised human patients.[2]

FIGURE 63-3 Draining skin lesion on the left elbow of a 5-year-old shepherd mix with disseminated coccidioidomycosis. Radiography revealed a mixed productive and destructive lesion of the distal humerus and proximal ulna. Productive lesions of the sixth and seventh ribs were also present. Arthrocentesis revealed suppurative inflammation with no growth on culture. Diagnosis was ultimately made by biopsy of the synovium and serology. The *Coccidioides* titer was 1:64.

A smaller percentage of infected dogs develop disseminated infections. Sites of dissemination often include osteoarticular sites, the central nervous system (CNS), skin, peripheral lymph nodes, eyes, testes, prostate, and the pericardium.[9,10] Rarely, sites such as the liver, spleen, gastrointestinal tract, or urinary system are affected.[8] Sometimes dissemination to only one anatomic site is evident; in other dogs multiple sites are involved. A history of respiratory signs may be absent.[8] Bone involvement may manifest as lameness and/or one or more firm swellings associated with the appendicular or axial skeleton. Dogs with skin involvement may have subcutaneous masses ulcerated skin lesions that drain serosanguineous fluid (Figure 63-3).[8] Skin lesions may overlie sites of osteomyelitis. Neurologic signs result from meningoencephalitis and include obtundation, blindness, nystagmus, absent menace reflexes, diminished gag responses, ataxia, abnormal placing reactions, pacing, circling, cervical pain, tetraparesis, and seizures.[9,16,17] Ocular manifestations of coccidioidomycosis include chorioretinitis, uveitis, optic neuritis, and endophthalmitis.[9,18,19] Involvement of abdominal organs such as the liver and gastrointestinal tract can lead to inappetence, vomiting, and/or diarrhea.[8] Pericarditis may lead to signs of right-sided cardiac failure, with ascites and pleural effusion.[8]

Physical Examination Findings

Fever is present in up to two thirds of dogs with coccidioidomycosis (range, 103°F to 106°F) on physical examination. Other common findings in dogs are lethargy, weakness, thin body condition or profound muscle atrophy, tachypnea, increased respiratory effort, inducible or spontaneous cough, and/or increased lung sounds.[9] Lameness and firm, often painful bony swellings with associated muscle atrophy may be present in dogs with osteomyelitis. Less often, focal or (very rarely) generalized peripheral lymphadenomegaly, subcutaneous masses or draining skin lesions, or swollen joints are present. Dogs with pericardial coccidioidomycosis may have abdominal distention with a palpable fluid wave, tachycardia, tachypnea, jugular pulses, muffled breath and heart sounds due to pleural effusion, mucosal pallor, prolonged capillary refill time, and weak pulses.[20] Neurologic signs, when present, include obtundation, apparent blindness, ataxia, nystagmus, spinal pain, circling, and tetraparesis. The most common ocular abnormality is uveitis, but keratitis, conjunctivitis, granulomatous chorioretinitis, optic neuritis, retinal detachment, and endophthalmitis with secondary glaucoma have also been described.[9,18,19]

Of 48 cats with coccidioidomycosis, fever was present in 31%. Skin lesions were present in more than 50% of 48 affected cats and included draining skin lesions, subcutaneous granulomas, and abscesses.[12] Tachypnea or increased respiratory effort was present in 25% of affected cats, and lameness in fewer than 20% of cats. Ocular abnormalities were present in 13% of cats. Conjunctival masses, periorbital swellings, chorioretinitis, retinal detachment, endophthalmitis, and/or anterior uveitis have been described.[21,22] A small percentage of cats have neurologic signs such as hyperesthesia, posterior paresis, seizures, and ataxia. Dissemination to abdominal organs such as the spleen can occur.[23]

Diagnosis

Coccidioidomycosis is usually suspected based on a history of travel to or residence in an endemic region, and consistent clinical signs and radiographic findings. Because the disease is not prevalent in some endemic regions (such as coastal southern California), early diagnosis requires a high index of suspicion in these regions. The diagnosis can be confirmed with cytologic examination of aspirates or body fluids, serologic assays that detect antibodies to *Coccidioides* spp., histopathology, and/or fungal culture (Table 63-1).

Laboratory Abnormalities

Complete Blood Count

CBC findings in dogs with coccidioidomycosis are nonspecific and resemble those of other deep mycoses. Most affected dogs have mild, normocytic, normochromic, nonregenerative anemia and mild leukocytosis. Leukocytosis results from a neutrophilia, occasionally with a left shift and evidence of neutrophil toxicity.[9,20] A monocytosis and lymphopenia may also be present, but in contrast to human infections, eosinophilia is not typically present.

Serum Biochemical Tests

Almost all dogs with coccidioidomycosis have hypoalbuminemia, and approximately half of affected dogs and cats have hyperglobulinemia (up to 7.8 mg/dL in one study).[9,12] Hypoalbuminemia is usually mild to moderate, but rarely may be more severe (<1.5 g/dL). Uncommonly, mild hypercalcemia is present. Increased activity of serum ALP may be present in some dogs, possibly as a result of bone involvement.

Urinalysis

The urinalysis is often normal, but significant proteinuria (urine protein-to-creatinine ratios as high as 9.5, reference range <1) has been reported in some dogs with coccidioidomycosis.[9] It is not clear whether proteinuria of this magnitude results from glomerulonephritis secondary to chronic immune stimulation or another comorbidity.

VetBooks.ir

TABLE 63-1

Diagnostic Assays Currently Available for Coccidioidomycosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, body fluids, impression smears of skin lesions	*Coccidioides* spherules and/or endospores	Low sensitivity and organisms may be difficult to accurately identify in some specimens. Immature spherules may be mistaken for other fungi or cellular aggregates or debris.
Fungal culture	Aspirates or biopsies of affected tissues, body fluids such as CSF or pleural effusion, transtracheal or bronchoalveolar lavage specimens	*Coccidioides* spp.	Generally sensitive and specific, but false negatives are possible if specimen size is low. Can require several weeks' incubation. A significant laboratory health hazard.
Antibody serology (gel immunodiffusion)	Serum, CSF	IgG or IgM antibodies to *Coccidioides* spp.	Sensitivity is close to 100%. Quantification of an IgG antibody titer is possible. Titers decline with successful treatment. In hyperendemic areas, titers as high as 1:16 have the potential to exist in subclinically infected or recovered dogs, so positive serology should be supported with other diagnostic tests for coccidioidomycosis.
Serology for *Coccidioides* antigen	Serum, urine	*Coccidioides* spp. galactomannan antigen	Low sensitivity (≤20%); false positives can occur in dogs with histoplasmosis or blastomycosis. Not recommended.
Real-time PCR assays	Biopsies, body fluids, respiratory lavage specimens, aspirates	*Coccidioides* DNA	Not yet validated in adequate numbers of dogs or cats with coccidioidomycosis; usefulness requires further evaluation.
Histopathology	Biopsy specimens from affected tissues, such as bone biopsies	*Coccidioides* spp. spherules	Limited sensitivity in dogs; submission of multiple biopsies is recommended when possible. Often only one or two spherules are visualized. Special stains such as periodic acid–Schiff and silver stains facilitate organism detection.

Cerebrospinal Fluid Analysis

CSF analysis in dogs with CNS coccidioidomycosis usually reveals an increase in protein concentration (generally <300 mg/dL, reference range <25 mg/dL) and a mild to moderate increase in the nucleated cell count (usually <50 cells/μL, reference range <2 cells/μL).[9] The differential cell count may show mixed, predominantly lymphocytic, mixed mononuclear, or neutrophilic pleocytosis. Organisms are generally not observed.

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with disseminated coccidioidomycosis are often unremarkable. The most common radiographic finding in dogs with pulmonary coccidioidomycosis is mild to severe hilar lymphadenomegaly (Figure 63-4, *A*), which was present in 10 of 19 dogs with coccidioidomycosis from California.[9] Hilar lymphadenopathy can also be present in affected cats.[12] Although hilar lymphadenopathy can be the only finding, most dogs with hilar lymphadenopathy also have pulmonary infiltrates, which are usually mild to moderate and interstitial. Nodular interstitial, interstitial-alveolar, bronchointerstitial infiltrates, and/or sternal lymphadenomegaly can also be present (Figure 63-4, *B* and *C*).[9,15] Dogs with pericarditis can have cardiomegaly and pleural effusion, with hepatomegaly and decreased abdominal detail.[20]

Radiographs of affected bones in both dogs and cats with *Coccidioides* osteomyelitis reveal local periosteal proliferation as well as osteolysis and soft tissue swelling. Lesions can resemble osteosarcomas (Figure 63-5).[8,12]

Sonographic Findings

Abdominal ultrasound examination of dogs with coccidioidomycosis is typically unremarkable. Mild hepatosplenomegaly and abdominal lymphadenomegaly have been described in a small proportion of dogs.[9] Ascites, hepatomegaly, and distended hepatic veins may be evident in dogs with pericarditis.[20]

Echocardiography in dogs with *Coccidioides* spp. pericarditis can reveal thickening and mass lesions of the pericardium, adherence of the pericardium to the epicardium, pericardial and pleural effusion, and evidence of cardiac tamponade (see Figure 86-3).[20]

Advanced Imaging

Advanced imaging findings in dogs with coccidioidomycosis have not been extensively reported in the literature. Focal, contrast-enhancing intra-parenchymal mass lesions in the brain or osteomyelitis of the skull may be identified on computed tomography (CT) of the head.[24] Thoracic CT findings include contrast-enhancing miliary nodular pulmonary lesions; single or multifocal larger nodules or masses; tracheobronchial, sternal,

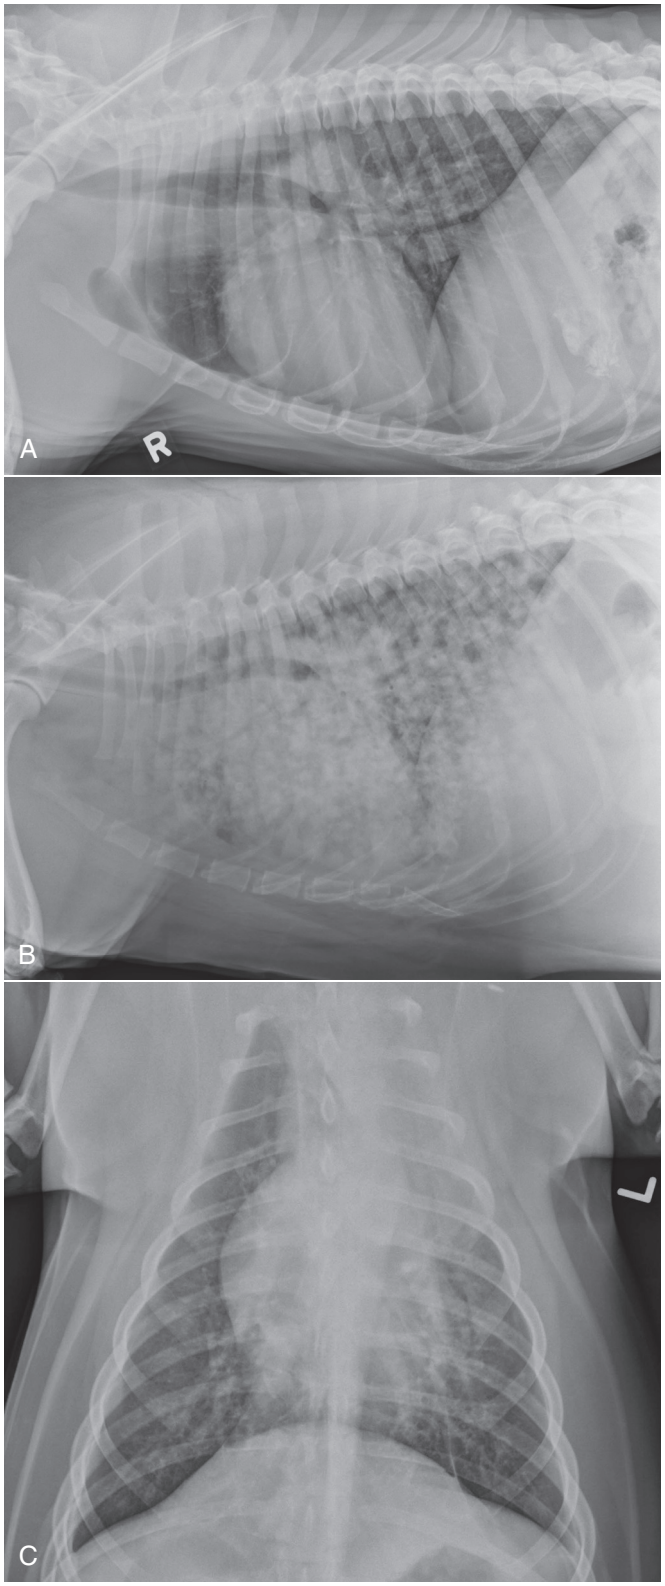

FIGURE 63-4 Thoracic radiographic patterns in coccidioidomycosis. **A,** Lateral thoracic radiograph from a 7-year-old intact male English pointer that shows several tracheobronchial lymphadenomegaly and focal pulmonary infiltrates. **B,** Lateral thoracic radiograph from a 3-year-old intact female Rottweiler with cough, anorexia, and respiratory distress. There are diffuse nodular and peribronchial infiltrates throughout the pulmonary parenchyma and possible hilar lymphadenopathy. Necropsy revealed necrogranulomatous interstitial pneumonia with intralesional spherules. The spleen, liver, and kidney were also involved. **C,** Dorsoventral thoracic radiograph from a 2-year-old female spayed Labrador retriever with cough and inappetence. There is an alveolar pattern in the left cranial lung lobe.

or mediastinal lymphadenopathy; focal regions of alveolar or peribronchial infiltrates; lobar consolidation; pleural or mediastinal thickening; and, rarely, pleural effusion (Figure 63-6).

MRI of the brain in dogs with CNS coccidioidomycosis may show focal hyperintense lesions within the brain on T2-weighted images (Figure 63-7). These are typically isointense on T1-weighted images and enhance with contrast. Other findings include ventricular dilation and/or meningeal enhancement.

Microbiologic Tests

Cytologic Examination

Cytologic examination of aspirates of affected tissues, pleural effusion, or respiratory lavage specimens typically reveals granulomatous or pyogranulomatous inflammation, sometimes with rare multinucleated giant cells, scattered eosinophils, and/or a reactive lymphocyte population. However, occasionally a suppurative inflammatory response predominates. Spherules may be visualized as round, deeply basophilic, double-walled, slightly crinkled structures that range in diameter from 8 to 70 µm. Spherules are generally low in number, frequently associated with cellular aggregates, but often they are not evident or easily identified. Usually their internal structure is not easily discernible, but occasionally endospores are seen in association with ruptured spherules (Figure 63-8). The endospores are 2 to 5 µm in diameter, are surrounded by a thin, nonstaining halo, and have small, round to oval, densely aggregated, eccentric nuclei. Endospores may be found extracellularly or within phagocytes. In one report, only endospores were visualized in a fine-needle aspirate from a bone lesion; intact spherules were not seen.[13]

Because cytology is relatively insensitive for diagnosis of coccidioidomycosis when compared with other deep mycoses, serologic testing for coccidioidomycosis should always be considered when cytology of tissue aspirates, body fluids, or lung washes reveals pyogranulomatous, suppurative, or granulomatous inflammation but organisms are not seen, and exposure to *Coccidioides* is possible based on the history.

Serologic Diagnosis

Serologic assays that detect antibodies to *Coccidioides* spp. are important diagnostic tests for coccidioidomycosis because organism detection assays have low sensitivity. Most diagnostic laboratories screen serum specimens with qualitative gel immunodiffusion (ID) assays for IgG or IgM antibodies (see Chapter 2). Detection of IgM (tube precipitin) or IgG (complement fixating) antibodies is reported, depending on the antigen preparation used in the assay. In dogs, IgM is detectable within 2 to 5 weeks of infection, and IgG appears after 8 to 12 weeks.[10] Quantification of an IgG antibody response can then be performed by quantitative ID, whereby serial dilutions of patient serum are subjected to gel ID.[14] In human patients, the complement fixation test is often used to quantify IgG antibody, but frequent false-positive results have been described with this method in dogs as a result of anticomplementary properties of canine serum.[25] The complement fixation test is positive in most cats with coccidioidomycosis; titers have ranged from 1:2 to 1:128.[12]

False-negative serologic test results are extremely rare in dogs with coccidioidomycosis tested at the author's institution,[9,20] but they have been described in dogs from Arizona.[26,27] Antibody titers usually range from 1:2 to 1:256; the median titer was 1:32 in one study.[9] There is no clear correlation between the magnitude of the IgG titer and the severity of illness in dogs.

Severe osteolysis is present. **B,** Right humerus of a 4-year-old female spayed shepherd mix. There is a mixed productive and lytic lesion of the distal diaphysis of the right humerus. **C,** Lesion in **(B)** at necropsy. (Courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

FIGURE 63-6 Computed tomography scan of the thorax of a 2-year-old intact male Labrador retriever with coccidioidomycosis. There are infiltrates in the caudal aspect of the right cranial lung lobe that extend from the mediastinum to the pleural surface. The walls of the right cranial bronchus and associated airways are thickened. Bronchial lymphadenomegaly was also identified.

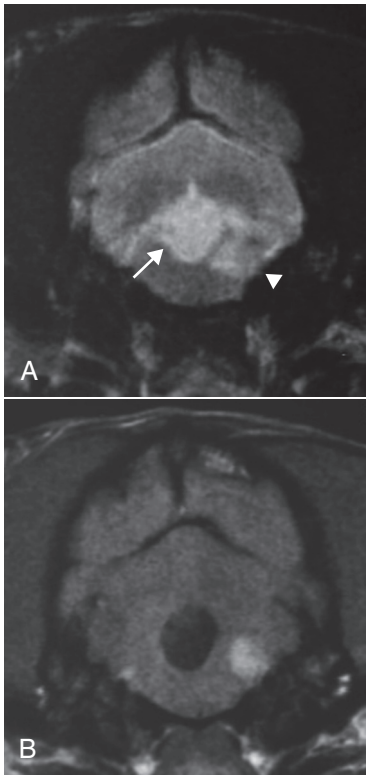

FIGURE 63-7 MRI scan of the brain of a 7-year-old male neutered shih tzu with disseminated coccidioidomycosis. **A,** A small focus of increased signal intensity on T2-weighting is present in the left lateral aspect of the brainstem *(arrowhead)*. Ventricular dilation is also present *(arrow)*. **B,** T1-weighted image after administration of gadolinium. The lesion in the brainstem is contrast enhancing.

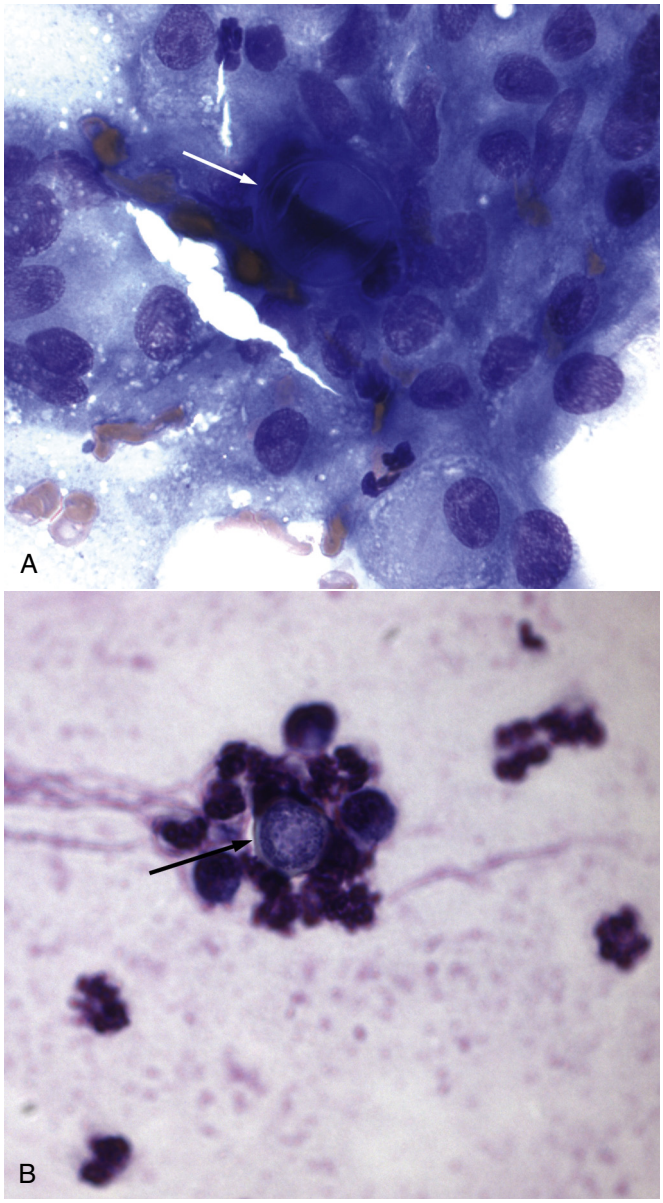

FIGURE 63-8 Cytologic appearance of *Coccidioides* spp. spherules. **A,** Spherules often appear as deeply basophilic, crinkled, intact, or ruptured ball-like structures *(white arrow)*. **B,** Sometimes, a refractile spherule wall is appreciated *(arrow)* and endospores are visualized as granular material within the spherule.

Dogs with active infection can have titers as low as 1:2, and healthy dogs in hyperendemic areas in Arizona can have titers as high as 1:16.[14] As a result, positive titers of 1:16 or lower must be interpreted in light of clinicopathologic abnormalities, and in hyperendemic areas, other diagnostic tests (such as culture, cytology or histopathology) should be used to confirm the diagnosis if possible. Latex agglutination and ELISA (EIA) assays for detection of anti-*Coccidioides* antibody have also been developed, but these are not widely used in veterinary medicine, and their use has been associated with a significant number of false-positive reactions in humans.[2,25,28]

A serologic assay that detects *Coccidioides* antigen in urine is available for diagnosis of coccidioidomycosis in human patients, such as in immunocompromised patients who lack the ability to produce significant quantities of antibody. However, preliminary data suggest that this assay has unacceptable sensitivity (≤20%) for diagnosis of coccidioidomycosis in dogs when serum, urine, or both specimens are tested, and false-positive reactions occur in a small proportion of dogs with blastomycosis or histoplasmosis.[29]

Fungal Culture

Coccidioides spp. can be isolated from clinical specimens on routine fungal media in the laboratory, but a negative culture result does not rule out coccidioidomycosis. Growth of a gray-white, downy mold that is tan to brown when visualized through the bottom of the plate usually appears after incubation for several days. Isolates can be identified based on their light microscopic appearance, with or without molecular methods. Culture of *Coccidioides* spp. is a serious laboratory health hazard and should only be performed if necessary and by suitably equipped laboratories. The clinician should warn the laboratory of the possibility of dimorphic fungal infection if suspected.

Molecular Diagnosis Using the Polymerase Chain Reaction

Real-time PCR assays have been used for rapid detection of *Coccidioides* spp. in respiratory specimens or CSF from affected humans, although sensitivity has been limited.[2,30] PCR assays have also been used in epidemiologic studies to identify major growth sites of *Coccidioides* spp. in soil.[31] PCR assays have not yet been widely applied to the diagnosis of coccidioidomycosis in dogs and cats.

Pathologic Findings

Gross pathologic findings in dogs with coccidioidomycosis include mottling and consolidation of the pulmonary parenchyma; single or multiple pale masses, nodular lesions, or emphysematous bullae within the lungs (Figure 63-9); enlarged and firm tracheobronchial, mediastinal, or sternal lymph nodes; plaque-like lesions on the pleura; and pleural and pericardial effusion. The interior of masses or nodules may be firm, caseous, or liquefied. The pericardium and epicardium may be thickened with mass lesions and adhesions between the pericardium and epicardium.[20] Ascites may also be present in dogs with pericarditis. Dogs with disseminated disease may have diffuse muscle atrophy, one or more enlarged peripheral lymph nodes, irregular bony swellings with associated draining skin lesions, and/or evidence of arthritis and synovitis. Meningoencephalitis may be evident as mass lesions within the brain parenchyma, ventricular dilation secondary to obstruction of CSF flow by inflammatory lesions, regional discoloration within the brain, and/or discoloration and thickening of the meninges. Rarely, prostatic enlargement, hepatic congestion and friability, multifocal nodular lesions within the myocardium or other parenchymal organs, and ocular lesions are present (see Physical Examination Findings for a description of ocular lesions).

Histopathology of affected tissues reveals large numbers of neutrophils and macrophages and sometimes marked fibrosis, with occasional endosporulating or non-endosporulating spherules. Multinucleated giant cells may be present and can contain spherules.[26] Spherules have a thick wall, and endospores may be visualized in mature spherules (Figure 63-10). Often only one or two spherules are visualized, and in some cases they are not found at all. Use of special stains such as periodic acid–Schiff and Gomori's methenamine silver can enhance organism identification within lesions. The presence of large numbers of spherules has been described in some affected cats.[23,32] Chronic, diffuse glomerulonephritis was present in 3 of 13 dogs with

VetBooks.ir

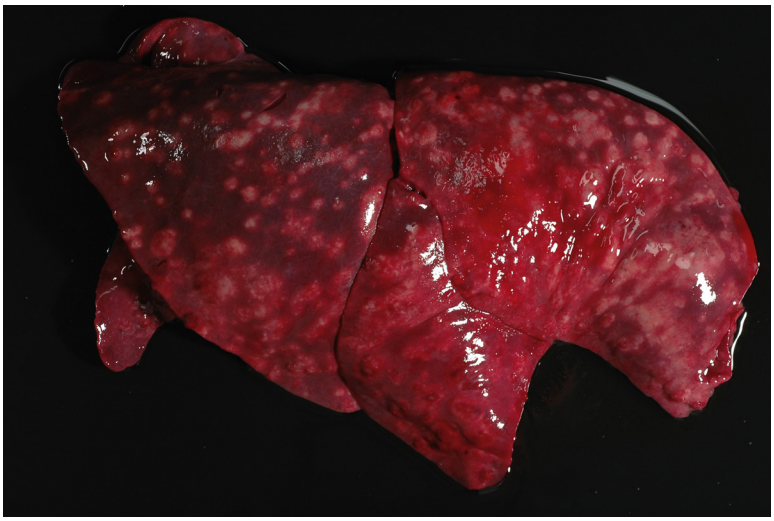

FIGURE 63-9 Lungs of the dog in Figure 63-4, *B*. Multiple pale nodules are present throughout the lung parenchyma.

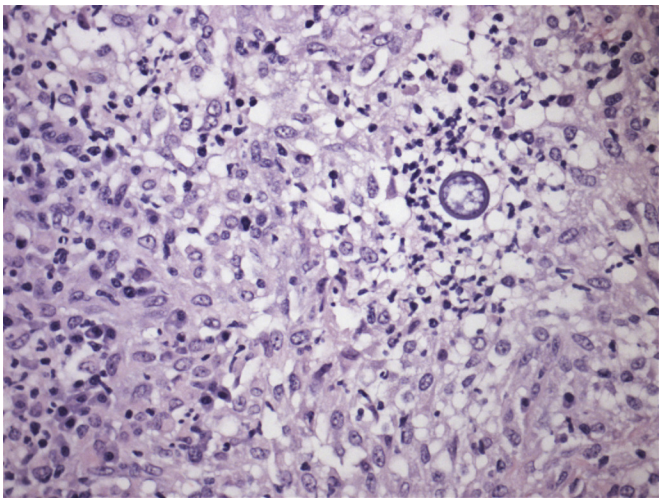

FIGURE 63-10 Histopathology of the tarsus of the dog in Figure 63-5, *A*. A single mature spherule is surrounded by a pyogranulomatous inflammatory response. The spherule contains many endospores.

coccidioidomycosis that had full necropsy examinations at the author's hospital; an additional dog with renal lesions had multiple renal pyogranulomas with intralesional spherules.[24]

Treatment and Prognosis

Successful treatment of coccidioidomycosis is limited by the high cost of treatment and the often advanced nature of the disease by the time it is diagnosed in some dogs. Treatment consists of a combination of antifungal drug therapy and supportive care; in some cases, surgery is required. Usually a minimum of 6 months of treatment is required.

Antimicrobial Treatment

Animals with coccidioidomycosis can respond well to azole monotherapy with fluconazole or itraconazole. Ketoconazole has been used successfully to treat dogs and cats in the past but is no longer the drug of first choice owing to its lower activity and increased rate of adverse effects. Fluconazole is the least expensive azole and may be a better choice than itraconazole for dogs with CNS involvement, because of its superior penetration of the CNS. The dose of fluconazole used by the author is 5 mg/kg PO q12h. Itraconazole (5 mg/kg PO q24h) is preferred for animals with bone involvement and may be effective in dogs that fail to respond to treatment with fluconazole. In human patients, itraconazole demonstrated a greater response rate in a blinded comparison with fluconazole.[33] Compounded formulations of itraconazole should be avoided. Small dogs are best treated with itraconazole solution (10 mg/mL), which has higher bioavailability than the capsules (see Chapter 9). If capsules are used, they should be administered with food. If clinical signs do not improve with azole treatment, therapeutic drug monitoring could be considered to ensure that serum drug concentrations are adequate. Periodic monitoring of liver enzymes is recommended for animals treated with azole antifungals.

Treatment with deoxycholate or lipid-complexed amphotericin B is recommended either alone or in combination with an azole for dogs with refractory or severe disease (see Chapter 9 for dosing protocols). However, studies that compare amphotericin B to azole monotherapy in dogs have not been performed. Voriconazole and posaconazole have been used to treat refractory coccidioidomycosis in human patients, but they are not considered first-line drugs.[2] Their use for treatment of affected dogs or cats is limited by expense. Voriconazole could be considered for treatment of refractory meningoencephalitis if client finances permit its use, because it has excellent penetration of the CNS.

Surgical Management

Ultimately, some dogs with severe and persistent osteomyelitis require amputation to control the infection, and enucleation may be required for dogs with endophthalmitis. Successful treatment of *Coccidioides* pericarditis has been reported after subtotal pericardiectomy and epicardial excision, which should be performed in conjunction with antifungal drug therapy. Referral to a specialist surgeon with experience with the technique is strongly recommended. The perioperative mortality rate in one study was reported as 24%, and the 2-year survival rate after discharge was 82%.[20]

Supportive Care

Other treatments that may be required for dogs with severe pulmonary coccidioidomycosis are similar to those described

VetBooks.ir

for blastomycosis and include oxygen supplementation, nebulization and coupage, drainage of thoracic effusions, nutritional support, anti-inflammatory drugs, and intravenous fluid therapy. Concurrent treatment with glucocorticoids and antiseizure medications may be necessary to reduce the severity of neurologic signs in dogs with CNS coccidioidomycosis. Topical prednisolone acetate solution and antiglaucoma agents may be required for dogs with ocular lesions.

Prognosis

The prognosis for resolution for coccidioidomycosis depends on the severity of infection and the extent of dissemination. The duration of treatment ranges from 6 months to many years, and in some cases, lifelong treatment is needed. IgG antibody titers decrease with successful treatment, which in general should be continued until lesions resolve and the titer is 1:2 or lower. Residual radiographic opacities may be present in some dogs as a result of scar tissue formation. Dogs with localized pulmonary infection have the best prognosis; the prognosis appears to be poor for dogs with CNS involvement. Dogs with *Coccidioides* osteomyelitis may require lifelong treatment with itraconazole.

Immunity and Vaccination

Immunity to *Coccidioides* spp. depends primarily on cell-mediated immunity, specifically T lymphocytes. No vaccine is currently available commercially for prevention of the disease.

Prevention

Prevention of coccidioidomycosis requires avoidance of hyperendemic areas (especially parts of Arizona and south-central California), which may not be possible. In endemic areas, dogs should be kept away from sites of soil disturbance (such as construction sites) and housed indoors during dust storms; digging should be discouraged. Housing dogs indoors during the day in endemic regions may reduce the chance of infection. Nevertheless, it should be remembered that clinical infections develop in only a minority of exposed dogs.

Public Health Aspects

Coccidioidomycosis is a serious infection in human patients and has similar clinical manifestations to those described in dogs. The incidence of human coccidioidomycosis has increased in Arizona in the last decade, possibly as a result of population growth, immigration of immunologically naïve people, and construction. Construction and agricultural workers, archeologists, and excavators are at high risk for coccidioidomycosis.[2] African American and Filipino patients, as well as patients with AIDS and women in the third trimester of pregnancy, are at highest risk for disseminated disease, which occurs in approximately 0.5% of infected humans.

Because of their susceptibility to infection, dogs have been used as a sentinel for human exposure to environmental sources of *Coccidioides* spp. in seroprevalence studies.[34] Direct transmission between infected veterinary patients and humans has not been reported. However, fatal coccidioidomycosis occurred in a veterinary resident after necropsy of a horse with disseminated disease.[35] Inoculation coccidioidomycosis was reported in a veterinary technician from Arizona after a bite from a cat that was later diagnosed with disseminated disease.[23] Inoculation coccidioidomycosis also has the potential to occur if sharps injuries occur during aspiration of affected tissues, surgical procedures, or necropsy examinations. Proper sedation or anesthesia should always be used if coccidioidomycosis is suspected in dogs or cats seen at veterinary clinics and the potential for a sharps injury exists. If accidental inoculation occurs, immediate attention should be sought from a physician. Prolonged fluconazole prophylaxis is generally recommended with monitoring of *Coccidioides* serology and liver function tests. Bandaging of skin lesions should be avoided. Necropsies should be performed without delay with suitable protective clothing, and the carcasses of animals that die from coccidioidomycosis should immediately be incinerated, because conversion of the organism to a mycelial form can occur after death of an animal. For the same reason, burial is not recommended because of the potential for contamination of the environment. Fluconazole prophylaxis is also indicated after accidental laboratory exposure to inocula.[36]

CASE EXAMPLE

Signalment: "Jenny", a 2-year-old female spayed Labrador retriever from Oxnard in southwestern California

History: Jenny was evaluated for a 2-month history of cough, inappetence, and lethargy. For the first 3 days of illness, the owner noted only an intermittent harsh, nonproductive cough. On day 4, the dog became lethargic and inappetent, so she was taken to a local veterinary clinic. Thoracic radiographs revealed alveolar infiltrates in the left cranial lung lobe. A diagnosis of bacterial pneumonia was suspected, so Jenny was treated with enrofloxacin (6 mg/kg PO q24h), amoxicillin-clavulanic acid (12.5 mg/kg PO q12h), and metronidazole (8 mg/kg PO q12h) for 2 weeks. After the first week of treatment, there was no improvement, so a long-acting cephalosporin was administered (cefovecin, 8 mg/kg SC once). Two days later, treatment with prednisone (0.3 mg/kg PO q12h) was initiated, which was followed by mild improvement in the clinical signs. Jenny's owner then sought a second opinion on day 20 after onset of clinical signs, and *Coccidioides* serology was performed. The titer was positive for IgG at 1:64. The prednisone was discontinued, and treatment was initiated with fluconazole (6.7 mg/kg PO q12h). However, after 1 month of treatment, thoracic radiographic abnormalities were unchanged. The fluconazole was substituted with a compounded itraconazole formulation (5 mg/kg PO q12h). However, after an additional 2 weeks of treatment, there had been no further improvement in the cough, so the owner was referred to the University of California, Davis.

Continued

VetBooks.ir

According to the owner, Jenny had a poor appetite for dog food but was eating home-cooked chicken, rice, and vegetables. Her activity level had been low. The cough occurred many times throughout the day and was unrelated to exercise and eating. Occasionally she had paroxysms of cough with a terminal retch. Other medical history included canine parvovirus infection when she was 8 weeks old and "kennel cough" when she was 9 months old, which resolved after 10 days. The owners lived in a semirural area just north of Los Angeles. The only travel had been to Atascadero, further north on the California coast. She was the only animal in the household. There had been ongoing construction around the house to replace a septic system with a sewer, which began 4 to 6 weeks before the onset of clinical signs.

Physical Examination:

General: Quiet but alert and responsive, hydrated. T = 102.6°F (39.2°C), HR = 100 beats/min, RR = 24 breaths/min, CRT = 1 s.

Eyes, Ears, Nose, and Throat: No abnormalities were noted. A dilated fundoscopic examination was unremarkable.

Musculoskeletal: Body condition score was 4/9. The dog was ambulatory with no lameness or muscle atrophy.

Respiratory: Harsh breath sounds were present in all lung fields. A harsh cough with a terminal retch was readily elicited on tracheal palpation.

Cardiovascular, Gastrointestinal, Genitourinary, and Lymph Nodes: No clinically significant abnormalities were detected.

Imaging Findings: Thoracic radiographs were compared to the two-view thoracic study performed 2 weeks previously, which was available for review. The initial radiographs showed a dense alveolar pattern throughout the left cranial lung lobe and increased opacity in the region of the hilar lymph nodes with splaying of the mainstem bronchi (see Figure 63-4, *C*). These abnormalities had improved slightly in the 10-day recheck interim, but alveolar infiltrates were still present throughout the left cranial lung lobe. There was a persistent, mild, diffuse pulmonary interstitial pattern in the remaining pulmonary parenchyma, which was most severe in the caudodorsal lung fields. This was considered excessive for the age of the patient. The cardiovascular structures were within normal limits.

Microbiologic Testing: *Coccidioides* serology: positive by qualitative gel immunodiffusion for complement-fixing antibody (IgG), negative for IgM. Quantitative immunodiffusion revealed an IgG titer of 1:128.

Serum itraconazole concentration: <0.31 µg/mL (undetectable).

Diagnosis: Pulmonary coccidioidomycosis.

Treatment: The itraconazole capsules prescribed at the previous veterinary clinic were examined and found to contain a white powder rather than granules. Treatment was changed to brand-name itraconazole (Sporanox), because compounded formulations can be unstable. Instructions were given to administer the itraconazole (5 mg/kg PO q24h) with food to improve absorption. Aspirin was also prescribed (12 mg/kg PO q12h). One month later Jenny's cough and activity level had improved considerably. A CBC was within normal limits, and a biochemistry panel showed hypoalbuminemia (3.3 g/dL, reference range 3.4-4.3 g/dL) and hyperglobulinemia (3.4 g/dL, reference range 1.7-3.1 g/dL). Liver enzyme activities were within reference ranges. Thoracic radiographs showed resolution of hilar lymphadenopathy with persistence of the alveolar infiltrates in the left cranial lung lobe. The IgG antibody titer to *Coccidioides* was 1:64. Three months later, the cough had resolved completely, and after 6 months of treatment, there was complete resolution of thoracic radiographic abnormalities and the titer was 1:32. At this point, the owner switched to a generic formulation of itraconazole because of financial concerns. After an additional 3 and 6 months of treatment, the IgG titer was 1:16 and 1:8, respectively, with no further clinical signs. Treatment was continued for an additional 3 months (i.e., total of 15 months of treatment), and the dog remains alive and apparently healthy at the time of writing.

Comments: This is an interesting case of pulmonary coccidioidomycosis that occurred outside the hyperendemic central valley region in California. Exposure may have resulted from soil disturbance as a result of sewer work. Because of the low suspicion for the disease, the disease was mistaken for bacterial pneumonia. The owner had limited financial resources, so an extensive respiratory work-up (including respiratory lavage with cytology and culture) was declined. When *Coccidioides* serology was positive, fluconazole was prescribed, but there was no improvement. The decision to treat with compounded itraconazole was made because of client financial limitations, but serum drug levels with this treatment were undetectable. Fortunately, disease ultimately resolved with a change to a noncompounded formulation, and there was progressive decline in serial IgG titers (which were always performed by the same laboratory). Whether treatment beyond complete resolution of the radiographic abnormalities was necessary is unknown.

CHAPTER 64

Sporotrichosis

Jane E. Sykes

VetBooks.ir

Overview of Sporotrichosis

First Described: 1896, in Maryland, USA, by Benjamin Schenk[1]

Cause: *Sporothrix schenckii* complex fungi (ascomycetes, teleomorph *Ophiostoma stenoceras*)

Affected Hosts: Cats, dogs, humans, and a variety of other mammalian and avian species

Geographic Distribution: Tropical and temperate zones worldwide

Mode of Transmission: Cutaneous inoculation or inhalation of conidia

Major Clinical Signs: Cutaneous nodules or draining skin lesions, lymphadenopathy

Differential Diagnoses: Other deep mycoses (especially cryptococcosis in cats), mycobacterial infections, nocardiosis or actinomycosis, leishmaniosis, squamous cell carcinoma, feline eosinophilic granuloma complex, feline herpesviral dermatitis, foreign body granulomas

Human Health Significance: Many human infections are acquired from the environment, but direct transmission can follow contact between infected cats and humans, and especially cat bites or scratches.

Etiology and Epidemiology

Organisms that belong to the *Sporothrix schenckii* species complex are dimorphic, saprophytic fungi that cause sporotrichosis, a subacute to chronic disease that most often results from cutaneous or subcutaneous inoculation of the organism through a puncture wound, but can also follow inhalation of the fungus. Sporotrichosis has been described in cats, dogs, humans, and a variety of other domestic and wild animal hosts that include equine species, ruminants, swine, rats, mice, hamsters, armadillos, domestic fowl, chimpanzees, and dolphins.

Sporothrix species thrive in humid conditions (92% to 100%) and at mean temperatures between 25°C and 30°C. They prefer moist soil that is rich in decaying vegetation, as well as sphagnum moss, wood, thorns, or hay, where they grow as mycelia. The fungus is distributed worldwide in tropical and temperate zones but is most prevalent in tropical or subtropical regions of the Americas. Regions of endemicity include Mexico, Brazil, Uruguay, Peru, Japan, India, and South Africa; sporotrichosis is uncommon in Europe. Although all *Sporothrix* isolates have in the past been grouped into one species, multiple genotypes exist that vary in virulence and geographic distribution.[2-4] As a result, an *S. schenckii* species complex has been identified, which includes at least six species: *S. schenckii* sensu stricto, *Sporothrix brasiliensis, Sporothrix globosa, Sporothrix mexicana, Sporothrix albicans,* and *Sporothrix luriei*.[5-7] The epidemiology of the various members of the complex is as yet incompletely understood. *S. globosa* has a worldwide distribution, whereas *S. brasiliensis* appears to be limited to Brazil. *S. schenckii, S. brasiliensis,* and *S. albicans* have been isolated from cats, and *S. schenckii* and *S. luriei* have been isolated from dogs.[8]

Cats are more susceptible to sporotrichosis than dogs and are thought to facilitate spread of organisms in the environment.[9] Contaminated claw or bite wounds, as well as autoinoculation during grooming, are thought to be important modes of transmission.[10] Male cats are overrepresented in most studies (60% to 70% of affected cats), which may reflect the tendency of male cats to roam outdoors and be involved in aggressive interactions.[10-13] In Rio de Janeiro, a large outbreak of sporotrichosis has occurred over the past decade, which has involved more than 1000 humans, 60 dogs, and 1500 cats.[1] Of affected cats in this outbreak, *Sporothrix* spp. were isolated from 100% of 76 cutaneous lesions, 66% of 71 swab specimens from the nasal cavity, 41% of 79 oral swab specimens, and 40% of 38 nail fragments.[14] The fungus was also isolated from 3 of 84 apparently healthy cats that were in contact with affected animals. Twenty percent of cats were positive for antibodies to FIV, 1% of cats were positive for FeLV antigen, and 1% of cats were positive for both FIV antibodies and FeLV antigen.[10] More than 85% of affected cats were less than 4 years of age. Of isolates from affected humans in the outbreak, most were *S. brasiliensis,* but *S. schenckii* sensu stricto and *S. globosa* were also isolated.[7]

In dogs, sporotrichosis is relatively rare. Cutaneous introduction of the organism with plant foreign bodies has been suggested in some cases. In one dog, the portal of entry was thought to be an alligator bite wound.[15] In the Brazilian outbreak, contact with cats appeared to be an important mode of transmission to dogs.[16] No clear breed or sex predisposition has been identified, and dogs in the Brazilian outbreak ranged in age from 6 months to 12 years (median, 4 years). Mixed sporotrichosis and cryptococcosis was reported in a dog from Ontario.[17]

Clinical Features

Signs and Their Pathogenesis

Transmission of *Sporothrix* primarily results from cutaneous inoculation of organisms in the environment, but can also result from inhalation of conidia. Direct contact with cats that have sporotrichosis (without an apparent break in the skin) can also result in transmission.[10] Once within tissues, the organism

VetBooks.ir

TABLE 64-1

Proposed Classification Scheme for Clinical Forms of Sporotrichosis in Human Patients[1]

Group	Subcategory	Relevance to Cats and Dogs
Cutaneous	Fixed (or localized) Lymphocutaneous Multifocal (or disseminated)	All forms described in cats and dogs, but fixed or multifocal disease most common
Mucosal	Ocular Nasal Other	Occurs in cats and dogs
Extracutaneous	Pulmonary Osteoarticular Meningeal Generalized (or disseminated)	Pulmonary and generalized disease is primarily described in cats. Pulmonary, generalized, and osteoarticular disease occur rarely in dogs.
Special forms	Spontaneous regression Hypersensitivity (erythema nodosum, erythema multiforme)	Spontaneous regression has been described in cats and especially dogs

converts into a yeast form. The yeast form has a cell wall that contains glucans, a glycoprotein fraction known as peptidorhamnomannan, and galactose-containing polysaccharides. The cell wall also contains melanin, which may protect the yeast from oxidative damage.[1,9] Adhesins on the surface of the organism bind fibronectin, which appears to be important for virulence.[18] Organisms that are thermotolerant (able to survive at temperatures closer to body temperature, or 37°C) may be more likely to cause invasive disease.[9]

Several clinical forms of sporotrichosis are recognized in human patients. The clinical form of disease that develops depends on host factors and the virulence of the infecting *Sporothrix* strain. A suggested classification system for human sporotrichosis categorizes the distribution of lesions into cutaneous, mucosal, or extracutaneous (Table 64-1). Cutaneous lesions are crusted, plaque-like, or nodular lesions that often ulcerate or drain serosanguineous fluid. They may be fixed (localized), track along the course of lymphatics (lymphocutaneous), or be multifocal (sometimes referred to as disseminated cutaneous disease) (Figures 64-1 and 64-2). More than 50% of human patients develop the lymphocutaneous form and the infection spreads proximally along lymphatics, with formation of multiple secondary nodules (also known as gummata) that may ulcerate. This form has not been clearly recognized in cats and appears to be uncommon to rare in dogs.[16] Up to 80% of cats with sporotrichosis have multiple, widely distributed cutaneous lesions.[10,13] These may develop as a result of autoinoculation during grooming, or they can be a manifestation of a disseminated (or generalized) systemic infection.

Extracutaneous disease follows inhalation of conidia or hematogenous spread of *Sporothrix* from sites of cutaneous

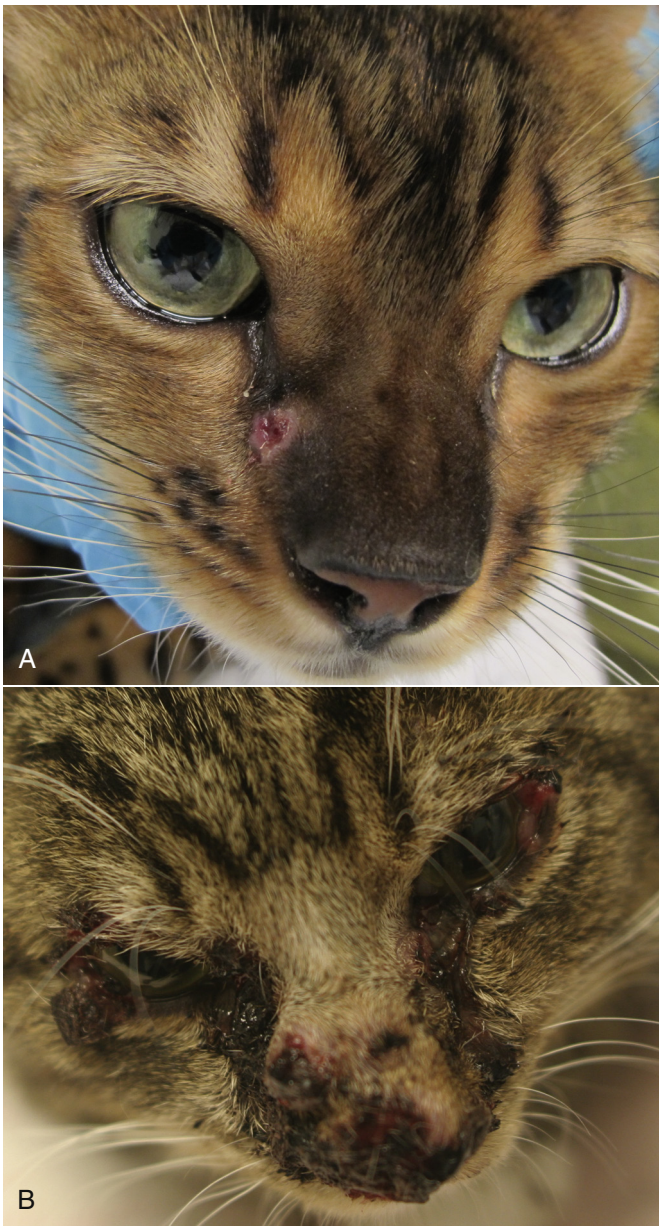

FIGURE 64-1 Cutaneous and mucosal sporotrichosis. **A,** 2-year-old female spayed Bengal that had ulcerated lesions of the face, thoracic limb, and tail. **B,** Cutaneous and conjunctival sporotrichosis in a 1-year-old male neutered domestic shorthair. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

inoculation. Transmission by inhalation is thought to occur in some cats, because pulmonary and nasal cavity disease with associated respiratory signs are common in cats.[10-13,19] Respiratory signs include sneezing, cough, tachypnea, increased respiratory effort, stertor, and/or nasal discharge. Respiratory signs were present in 44% of 347 cats in the Brazilian outbreak[10] and can also occur in dogs.[13,16] Sneezing may occur before the onset of cutaneous lesions in cats, and some cats or dogs show only respiratory signs. Cats also can develop generalized disease, with involvement of multiple organ systems, which include the lungs, liver, spleen, kidneys, lymph nodes, and testicles.[13,20] Co-infection with FIV does not appear to be a risk factor for dissemination.[21] Isolation of *Sporothrix* species from the blood of 35% of 49 cats with focal or multifocal cutaneous involvement was reported.[21] Clinical signs of systemic involvement include fever, generalized

TABLE 64-2

Diagnostic Assays Currently Available for Sporotrichosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of cutaneous nodules, impression smears of skin lesions or biopsies	*Sporothrix* yeasts	High sensitivity (approximately 80%) in cats. Sensitivity is lower in dogs.
Fungal culture	Aspirates, swabs, or biopsies of affected tissues	*Sporothrix* spp.	Generally sensitive (around 75%), but false negatives can occur if specimen size is low. Most specific method. Requires several weeks' incubation. Allows species identification via molecular methods and antifungal drug susceptibility testing.
Histopathology	Biopsy specimens from affected tissues	*Sporothrix* spp. yeasts	Sensitivity is higher (>60%) in cats when compared with dogs (<20%). Special stains such as Gomori's methenamine silver and immunohistochemical stains facilitate organism detection and identification.

lymphadenomegaly, anorexia, dehydration, vomiting, and weight loss. These signs were each reported in fewer than 20% of cats with sporotrichosis; vomiting occurred in fewer than 5% of the cats.[10] Weight loss, vomiting, or anorexia can also occur in dogs.[13,16] Other rare forms of extracutaneous sporotrichosis described in humans include osteoarticular and meningeal sporotrichosis. Osteoarticular sporotrichosis occurs rarely in dogs and may manifest clinically as lameness and synovial effusion.[12,22]

Physical Examination Findings

In cats, cutaneous lesions are most often found on the head (especially the bridge of the nose and the nasal planum, eyelids, and/or pinnae) and have a similar appearance to those caused by *Cryptococcus* spp. (see Figure 64-1).[10,12,23] Other common sites for skin lesions are the distal limbs, digits, and tail, but lesions can also be found elsewhere on the body. Swelling of the conjunctiva or lesions in the oral cavity or nasal cavity can be present in some affected cats (see Figure 64-1). Cutaneous or subcutaneous lesions are often firm nodules that sometimes enlarge to form soft cutaneous masses. Nodules can ulcerate and drain serosanguineous to purulent fluid, but are usually not painful or pruritic.[12] In some cases, ulcerations and draining skin lesions are not associated with the formation of discrete nodules. Lesions range in diameter from a few millimeters to several centimeters. Extensive zones of necrosis with exposure of underlying muscle and bone have also been described.[10] Regional lymphadenomegaly may be detected. Other less frequent physical examination findings in cats are fever, nasal discharge, decreased nasal airflow, tachypnea, increased respiratory effort, dehydration, and thin body condition.

In dogs, lesions consist of single or multiple ulcers or nodules on the head, trunk, forelimbs, and/or digits (see Figure 64-2). Rarely, they course along lymphatics.[12,13,16,24] The nasal planum was affected in 59% of 44 dogs in one study, and 21% of dogs had nasal mucosal involvement.[16] Regional lymphadenomegaly is common.

Diagnosis

Diagnosis of sporotrichosis rests on identification of the organism by cytologic or histopathologic evaluation, or by fungal culture of lesions (Table 64-2). A high degree of suspicion is required for the disease in non-endemic regions. Sporotrichosis should be considered in any dog or cat with cutaneous lesions suggestive of cryptococcosis or other deep mycoses, and especially any cat with ulcerative or nodular lesions of the face.

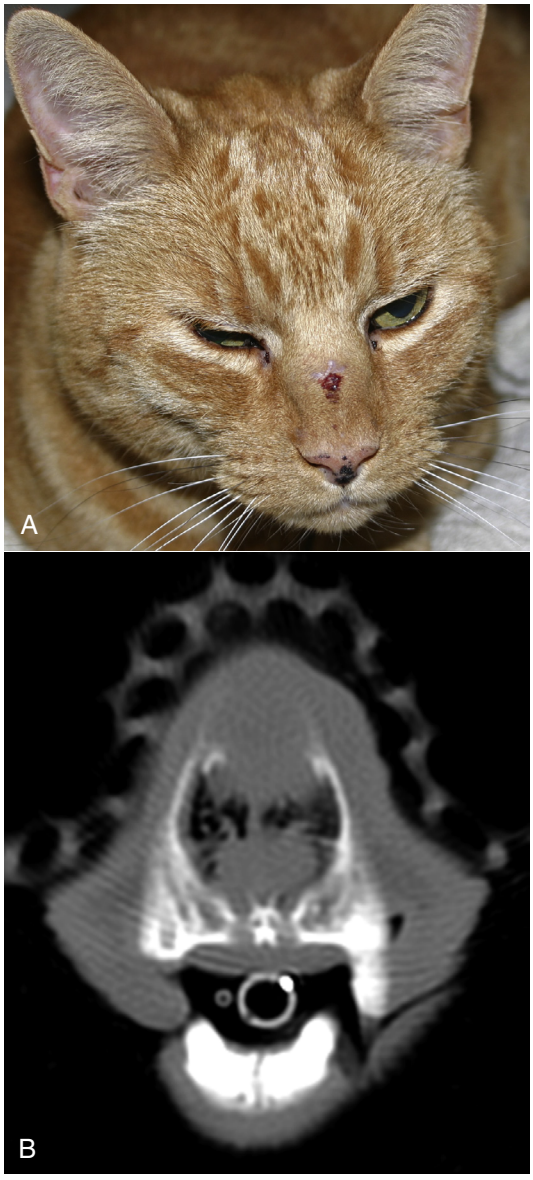

FIGURE 64-3 Nasal sporotrichosis with communication to the overlying skin in a 14-year-old male neutered domestic shorthair. **A,** The cat had a 1-year history of sneezing and a 2-month history of a mass on the bridge of the nose. **B,** Computed tomography revealed a nasal cavity mass with nasal bone destruction and involvement of the subcutaneous tissues.

Laboratory Abnormalities

Complete Blood Count

In many dogs and cats with sporotrichosis, the CBC is unremarkable. The most common abnormalities are mild anemia and leukocytosis due to a neutrophilia, sometimes with a mild left shift.[10,24] Monocytosis, eosinophilia, lymphocytosis, or lymphopenia may also be present. Approximately 50% of dogs in the Brazilian outbreak were anemic, and around 20% had eosinophilia or neutrophilia.[16]

Serum Biochemical Tests

The most frequent serum biochemistry findings in cats and dogs with sporotrichosis are hyperglobulinemia and hypoalbuminemia.[10,16] Rarely, increased liver enzyme activities are present in affected dogs.[16]

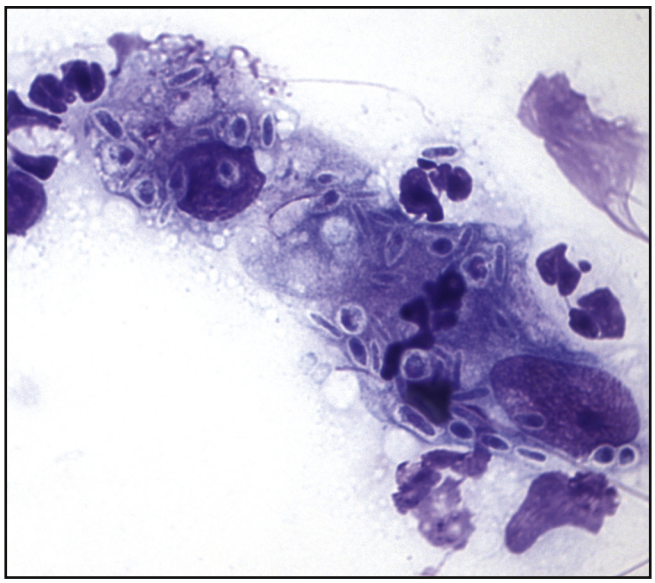

FIGURE 64-4 Cytology of an impression smear from a skin lesion of the cat in Figure 64-1, *A*. There are large numbers of extracellular and intracellular pleomorphic yeasts, with morphology consistent with *Sporothrix* spp.

Urinalysis

Urinalysis in animals with sporotrichosis usually reveals no clinically significant abnormalities.

Diagnostic Imaging

Plain Radiography

Findings on plain thoracic radiographs in cats with pulmonary sporotrichosis have not been described in detail. An interstitial infiltrate was described in one affected cat.[20] Thoracic radiographs were performed on one dog and five cats seen at the author's teaching hospital, but no radiographic abnormalities were present. Radiographs of bones that underlie skin lesions typically reveal only soft tissue swelling; rarely is underlying osteomyelitis detected.

Advanced Imaging

In the author's hospital, computed tomography (CT) of the nasal cavity in a cat with a lesion on the bridge of the nose revealed an irregular rim-enhancing mass within the nasal cavity that invaded through the nasal bones to involve the subcutaneous tissues (Figure 64-3). Severely thickened turbinate mucosa, an intranasal soft tissue density mass, and focal osteolysis were reported on nasal CT in a dog with signs of nasal cavity disease due to sporotrichosis.[25]

Microbiologic Tests

Cytologic Examination

Cytologic examination of impression smears or aspirates of skin lesions typically reveals pyogranulomatous inflammation. In cats, large numbers of round to cigar-shaped yeasts can be found intracellularly within neutrophils or macrophages and extracellularly (Figure 64-4). The yeasts are 4 to 6 µm in diameter and can exhibit a single bud with a narrow base. The sensitivity of cytologic examination of impression smears from skin lesions of 806 cats with sporotrichosis from Brazil was 79%.[26] Yeasts are usually not found in bronchoalveolar lavage fluid from cats with respiratory signs.[19] In general, dogs have very low numbers of

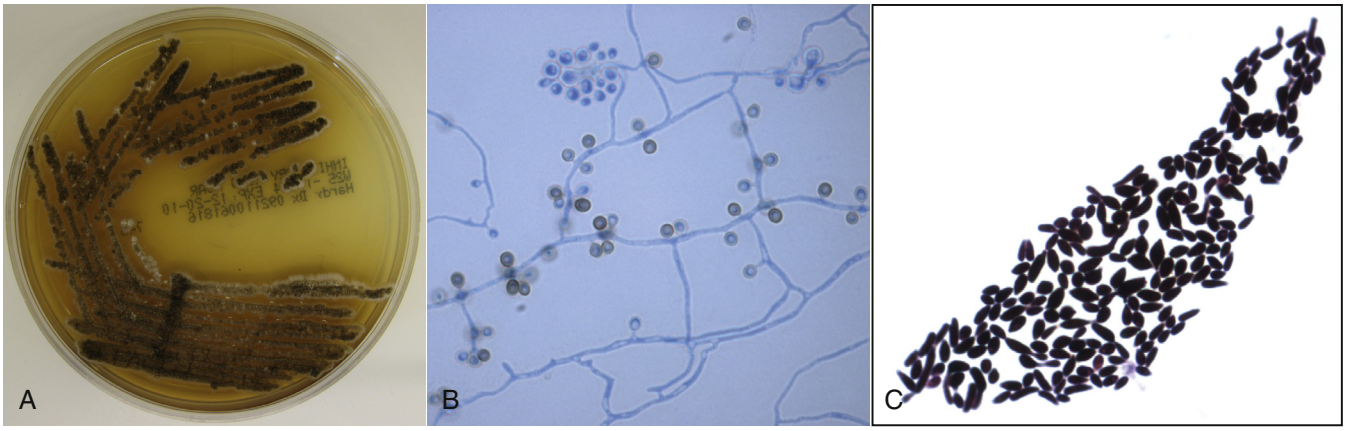

FIGURE 64-5 *Sporothrix schenckii* growing on laboratory media. **A,** The fungus grows on fungal isolation media as a white mold at 30°C with production of pigmented conidia. **B,** Using light microscopy, the mold form is characterized by the production of conidia in a flower-like arrangement. Lactophenol cotton blue stain, 1000× oil magnification. **C,** At 37°C, the organism converts to the yeast form. Gram stain, 1000× oil magnification.

organisms in skin lesions, which leads to a high proportion of false-negative results.[12,16] *Sporothrix* spp. may be confused with *Histoplasma capsulatum*, *Cryptococcus* spp., *Candida* spp., *Leishmania infantum*, and potentially other protozoan parasites such as *Toxoplasma gondii* and *Neospora caninum*.

Fungal Culture

Definitive diagnosis of sporotrichosis can be made by isolation and identification of the organism from clinical specimens (such as skin biopsies, blood, nasal swabs, or respiratory lavage specimens), preferably in both mycelial and yeast forms. The sensitivity of isolation from skin biopsies exceeds 75% in both dogs and cats.[10,13,16] The chance of successful culture is reduced if swab specimens of exudate instead of biopsies are submitted. The organism grows in culture as a white mold, which becomes brown to black as a result of production of pigmented conidia, which are arranged in florets on a stem (conidiophore) (Figure 64-5). Although growth can occur in 5 to 7 days, sometimes several weeks of incubation may be required.[9] When the organism is incubated on rich media such as brain-heart infusion at 37°C, it converts to oval to cigar-shaped yeasts. The organism can then be identified based on light microscopic appearance of the mold and yeast forms (see Figure 64-5, *B* and *C*). Determination of the *Sporothrix* species present requires subsequent molecular analysis by specialized laboratories.[27] Antifungal susceptibility testing can be performed, but established breakpoints are not available. Nevertheless, it may be of help for treatment of refractory cases (see Case Example).

Serologic Diagnosis

ELISA assays that detect antibody to *Sporothrix* cell wall antigens have been developed for diagnosis of human and feline sporotrichosis.[28,29] These assays are not widely available for diagnosis of sporotrichosis in cats or dogs. Currently, no antigen assays are available, but cross-reactivity with the *H. capsulatum* antigen assay occurs in human patients.[30]

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays have been described for detection of *Sporothrix* spp. in lesions.[31,32] These have not been widely applied to the diagnosis of sporotrichosis in cats or dogs.

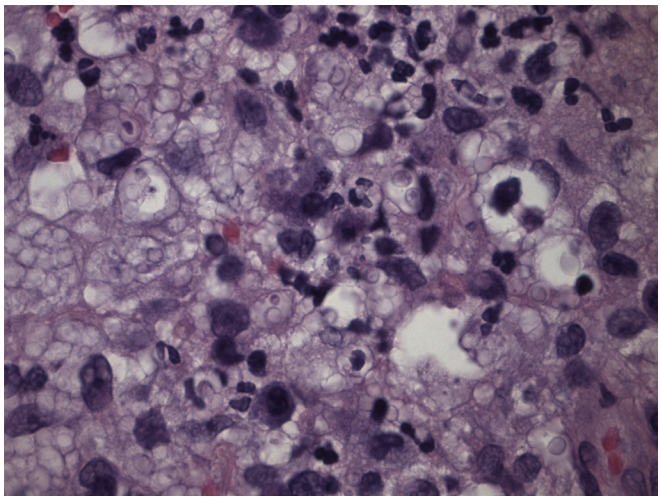

FIGURE 64-6 Histopathology of a biopsy from the skin of an 11-year-old female spayed domestic shorthair cat. Granulomatous inflammation is present with abundant intracytoplasmic fungal organisms consistent with *Sporothrix* spp.

Pathologic Findings

Gross pathologic findings at necropsy in cats with generalized sporotrichosis include multifocal, pinpoint (1 mm) white nodular lesions within the lungs and lymphadenomegaly.[20] Histopathology of lesions from cats usually reveals pyogranulomatous inflammation with a variable number of neutrophils, histiocytes, multinucleated giant cells, and lymphocytes, with fewer plasma cells, eosinophils, and mast cells (Figure 64-6).[12,13] Organized granuloma formation, with focal accumulations of macrophages and sometimes an outer layer of plasma cells, is found in a minority (<15%) of skin biopsies from affected cats[10] and in more than 30% of skin biopsies from affected dogs.[16,33] Intracellular and extracellular yeasts are seen on histopathology in more than 60% of skin biopsies from affected cats.[10,13] In contrast, organisms were found in biopsy specimens from fewer than 20% of dogs with sporotrichosis.[16,33] The presence of the Splendore-Hoeppli phenomenon ("asteroid bodies") around yeasts is commonly described in human infections, but this is not typically observed in dogs or cats.[9] Application of stains such as periodic acid–Schiff (PAS) and especially Gomori's

VetBooks.ir

methenamine silver (GMS) increase the chance that organisms are detected.[12,34] However, despite the use of such stains, diagnosis of canine sporotrichosis can be frustrating because of the scarcity of organisms in tissues. The use of immunohistochemistry (IHC) to aid histologic diagnosis has been reported, although this is not readily available.[34] In one study, the sensitivity of PAS, GMS, and IHC for detection of *Sporothrix* spp. in dogs with sporotrichosis was 20%, 44%, and 66%, respectively.[34] The use of the stains in combination increased the sensitivity to over 80%.

Treatment and Prognosis

Antimicrobial Treatment

The treatment of choice for sporotrichosis in dogs, cats, and humans is itraconazole (see Chapter 9 for recommended doses). In human patients, use of itraconazole results in cure rates for cutaneous sporotrichosis that exceed 90%.[35] Itraconazole resistance has been documented in some *Sporothrix* isolates from animals.[8] Fluconazole is considered less active than itraconazole for treatment of human sporotrichosis but was used successfully to treat disseminated disease in a cat.[12] Treatment of human, canine, and feline sporotrichosis with ketoconazole is more likely to result in relapses, and development of drug toxicity may limit therapy.[10,12,22] In affected cats from Brazil, clinical cure was 1.3 times more likely in cats treated with itraconazole than in cats treated with ketoconazole.[11]

Alternative antifungal drugs for animals with refractory disease include supersaturated potassium or sodium iodide, terbinafine, or amphotericin B. Oral administration of supersaturated potassium iodide (SSKI) for 30 days beyond complete resolution of clinical signs was used to treat sporotrichosis in cats, dogs, or humans before the widespread availability of itraconazole. However, treatment failures and toxic side effects that include anorexia, vomiting, diarrhea, and lethargy are common (41% of cats in one recent report).[10,22,36,37] It has been recommended that the use of SSKI be reserved for fixed cutaneous, lymphocutaneous, or mucosal forms of the disease in human patients. Because of its extremely bitter taste, potassium iodide (KI) capsules have also been used to treat affected cats, with a cure rate of 48% after 4 to 5 months.[23] Inappetence occurred in 52% of cats, and a smaller percentage of cats developed weight loss, diarrhea, or vomiting. Increased liver enzyme activities can also occur. The dose range used was 2.5 to 20 mg/kg PO q24h (median, 15 mg/kg). The dose was increased in 2.5 mg/kg increments every 5 days from an initial dose of 5 mg/kg PO q24h. Alterations in thyroid function can be an adverse effect of KI treatment in humans.[35] Treatment with terbinafine was successful in a human with nasal sporotrichosis that failed treatment with KI and itraconazole.[38]

Although amphotericin B is effective, nephrotoxicity and the need for parenteral administration have limited its use. The primary indication for amphotericin B is for treatment of sporotrichosis that is refractory to itraconazole. Intralesional amphotericin B administration in combination with itraconazole was used successfully to treat fixed or multifocal cutaneous lesions in cats that were refractory to itraconazole alone.[39] The solution was prepared by addition of 5 mL of 2% lidocaine and 5 mL of distilled water to a 50 mg vial of amphotericin B (final concentration, 5 mg/mL). A total of 0.5 to 1.5 mL (median 0.7 mL) was administered intralesionally once a week to once every other week, and 73% of the cats were cured. The number of treatments administered ranged from 1 to 5 (median, 2 treatments per cat). Sterile abscess formation at the site of administration occurred in 15% of cats.

Lastly, localized hyperthermia has been used as a safe and inexpensive method to treat fixed cutaneous and lymphocutaneous sporotrichosis in human patients and was used as the sole treatment in a cat with localized cutaneous disease.[40] In that case, a thermal bag that reached a temperature of 40°C to 42°C was applied twice daily for 15 minutes. When used alone, this method is not likely to be effective in animals with disseminated disease. Surgery or cryotherapy are other alternatives suggested for treatment of localized sporotrichosis in human patients.[35]

Prognosis

Treatment durations of 4 to 6 months are usually required for successful treatment of sporotrichosis. A median time to clinical cure of 26 weeks (range, 8 to 131 weeks) was reported for 175 cats treated with itraconazole.[11] Treatment should be continued for a month after lesions resolve. Some cats may require more than a year of antifungal drug treatment.[10] In general, the prognosis for cure of sporotrichosis is good, with more than 70% of cats in some studies cured of the disease, regardless of the number of skin lesions present.[10,12] Lower cure rates of 38% for itraconazole and 29% for ketoconazole were reported in another study.[11] Co-infection with FIV does not seem to alter the likelihood of treatment success,[10] but the presence of respiratory signs was associated with a twofold increase in death rate.[11] Relapse (or re-infection) may occur between 3 and 18 months after discontinuation of antifungal drug therapy. Spontaneous regression of a persistent cutaneous lesion was also described in a cat.[10] Euthanasia may result from expense related to antifungal drug therapy or concerns for zoonotic transmission.

Spontaneous regression of cutaneous lesions has been described in 15% of 33 dogs.[16] Nearly 80% of dogs were cured after itraconazole or ketoconazole treatment for 2 to 15 months (median, 2.5 months for itraconazole and 3.5 months for ketoconazole).

Immunity and Vaccination

Immunity imparted by T cells appears to be important in limiting the extent of sporotrichosis.[9,41] There is no vaccine.

Prevention

Indoor housing and neutering may reduce sporotrichosis in cats. Isolation of affected cats from other cats and dogs while they are properly treated may also reduce transmission.

Public Health Aspects

Many human sporotrichosis cases result from cutaneous inoculation of organisms in soil or on plant material. Activities associated with human sporotrichosis include rose gardening, topiary production, armadillo hunting, mining, carpentry, forestry work, Christmas tree farming, and hay baling, and outbreaks have been reported after common exposure of multiple individuals to a source of contaminated plant material. Laboratory-acquired infections have also been described.[42,43] Zoonotic transmission has followed bites or scratches from squirrels, horses, dogs, pigs, mules, insects, and especially cats.

In one study from Malaysia, slightly more human sporotrichosis cases resulted from cat bites or scratches than from exposure to plant foreign bodies.[44] Direct transmission can occur from infected cats to humans without an apparent break in the skin. In the epidemic in Rio de Janeiro, disease in cats preceded that in humans and dogs. Nearly 85% of affected humans reported contact with sick cats, and more than half of these individuals reported a history of a scratch or a bite. Women were more likely than men to be affected, especially those involved in domestic activities and animal care.[45] Five percent of the cases were veterinarians or veterinary technicians. Of cats with sporotrichosis from 225 residences in this outbreak, 91 people who had contact with infected cats acquired the infection.[10] In contrast, no human cases were associated with a series of 23 veterinary cases from northern California.[12] Generalized extracutaneous sporotrichosis with involvement of multiple organs has been described in immunocompromised humans, such as those with AIDS.[46,47]

In contrast to feline sporotrichosis, canine sporotrichosis is of minimal zoonotic importance. As occurs in humans, dogs have a paucity of organisms within tissues. There were no reports of transmission to humans as a result of contact with affected dogs in the Rio de Janeiro outbreak.[16]

Owners of dogs and cats with sporotrichosis should be told to minimize contact with affected animals. If contact is necessary, gloves should be worn and proper hand washing performed. Owners should also be informed of the potential for exposure to organisms in the environment.[6]

CASE EXAMPLE

Signalment: "Bingo," a 2-year-old male neutered domestic longhair cat from Fairfield in northern California

History: Bingo was referred to the University of California, Davis, Veterinary Medical Teaching Hospital for evaluation of refractory cryptococcosis. Initially Bingo's owners noted signs of snuffling, sneezing, and nasal discharge, which they attributed to a "cold." One month later a lump appeared on Bingo's nose. Bingo was taken to a local veterinary clinic where cytologic examination of an impression smear of the mass revealed organisms that were suspected to be *Cryptococcus* spp. A CBC showed no abnormalities. The owners declined treatment with itraconazole because of financial limitations, so fluconazole was prescribed (10 mg/kg PO q12h). Despite this treatment, the respiratory signs persisted, nodular skin lesions appeared on the face, and mandibular lymphadenopathy developed. Bingo had been an indoor-outdoor cat but had been housed exclusively indoors for the previous few months. He lived with five other indoor cats and a dog, all of which were well. His appetite and activity level had been normal and he was fed a commercial dry cat food. According to the owners, Bingo had tested negative for FeLV and FIV approximately 1 year previously.

Physical Examination:

Body Weight: 5.7 kg.

General: Bright, alert, responsive, and hydrated. T = 102.2°F (39.0°C), HR = 140 beats/min, RR = 40 breaths/min, CRT 1 s.

Integument, Ears, Eyes, Nose, and Throat: Ulcerated, firm cutaneous nodules (1 cm) were present on the left pinna and first digit of the left thoracic limb (0.25 cm). An ulceration (0.5 cm) was present on the bridge of the nose, which was markedly swollen (Figure 64-7, *A*). There was decreased nasal airflow bilaterally that was more severe on the left side, and mild left-sided mucoid nasal discharge. Marked soft tissue swelling occluded the left nares. There was moderate, left-sided serous ocular discharge. No lesions were detected on fundoscopic examination.

Musculoskeletal: Body condition score was 6/9, ambulatory.

Cardiovascular: No clinically significant abnormalities were detected.

Respiratory: There was a mild increase in respiratory effort with stertor. Thoracic auscultation revealed referred upper airway sounds.

Gastrointestinal and Genitourinary: Abdominal palpation was unremarkable. A small amount of dried feces and a tapeworm proglottid protruded from the anus.

Lymph Nodes: Only the left mandibular lymph node was enlarged (2 cm in diameter).

FIGURE 64-7 Effect of treatment with itraconazole and amphotericin B in a 2-year-old male neutered domestic longhair cat with multifocal cutaneous and mucosal sporotrichosis. **A,** Before institution of treatment. **B,** After itraconazole and eight treatments with amphotericin B. **C,** After an additional 7 months of itraconazole treatment.

VetBooks.ir

Microbiologic Testing: Latex agglutination for *Cryptococcus* antigen: Negative.

Cytologic examination of impression smears from the nares: Erythrocytes, neutrophils, and occasional epithelial cells were present. No fungal elements were identified.

Histopathology of a biopsy from the nasal cavity: Pyogranulomatous inflammation with intralesional fungi with morphology consistent with *Sporothrix* spp.

Diagnosis: Sporotrichosis with nasal and multifocal cutaneous involvement.

Treatment: Bingo was treated with a compounded form of itraconazole (5 mg/kg PO q12h). Clinical improvement did not occur after 2 weeks, so terbinafine was added (30 mg/kg PO q24h). One month later, two nodules appeared on the conjunctiva of the left eye, and the lesions on the left pinna, left thoracic limb, and nasal bridge had enlarged. Mild subcutaneous emphysema of the face was also apparent during respiration. The cat was bright and appetent, but body weight had decreased to 5.1 kg. No abnormalities were detected on the CBC and serum biochemistry panel. Large numbers of *Sporothrix* yeasts were seen on impression smears of the thoracic limb lesion. Fungal culture yielded *S. schenckii* sensu stricto (identified at the University of Texas Health Science Center at San Antonio based on ITS, D1/D2, and calmodulin gene sequencing). Antifungal drug susceptibility testing revealed minimum inhibitory concentrations of 1, 2, 0.06, greater than 64, 1, 1, and 16 µg/mL for amphotericin B, 5-flucytosine, terbinafine, fluconazole, itraconazole, posaconazole, and voriconazole, respectively. A serum itraconazole concentration was less than 0.31 µg/mL. Subsequently the cat was hospitalized and treated with itraconazole (Sporanox) solution (3 mg/kg PO q12h) and deoxycholate amphotericin B (0.25 mg/kg IV). Terbinafine treatment was discontinued. Cutaneous lesions were also treated with local hyperthermia (15 minutes q8h). After eight amphotericin B treatments, the lesions had halved in size (Figure 64-7, *B*). An additional three treatments were administered, after which a mild increase in BUN concentration developed (43 mg/dL, reference range 18-33 mg/dL). Serum creatinine was within the reference range (1.4 mg/dL, reference range 1.1-2.2 mg/dL). The serum itraconazole concentration was 4.03 µg/mL. A new lesion appeared on the right distal thoracic limb, and impression smears of the lesion revealed large numbers of *Sporothrix* yeasts. The itraconazole dose was increased to 5 mg/kg PO q12h, but was reduced by the owner to 5 mg/kg PO q48h after 5 months because Bingo's appetite was slightly decreased. When the cat was reevaluated 7 months after completion of amphotericin treatment, lesions had improved dramatically (Figure 64-7, *C*). The owner was encouraged to increase the dose of itraconazole to 5 mg/kg PO q24h, but the cat was subsequently lost to follow-up.

Comments: This cat had nasal and multifocal cutaneous sporotrichosis that was somewhat refractory to treatment with antifungal drugs. The disease was initially mistaken for cryptococcosis. Limited client financial resources and compliance may have influenced treatment outcome in this case; costs of fungal culture, identification, and antifungal susceptibility testing were not charged to the client. Fluconazole was ineffective, and the antifungal susceptibility panel suggested resistance to this azole. The use of compounded itraconazole resulted in suboptimal serum drug concentrations. However, once treatment with amphotericin B, a brand name itraconazole formulation, and heat compression of lesions was instituted, gradual clinical improvement occurred. The change in itraconazole formulation alone might have been sufficient to cause disease resolution. The owners were told to wear gloves when handling the cat and to wash their hands afterward. No disease was reported in the owners or any other animals in the household.

CHAPTER 65

Aspergillosis

Jane E. Sykes

VetBooks.ir

Overview of Aspergillosis

First Described: Invasive aspergillosis was first described in 1815 in a jackdaw bird (Mayer)[1]

Cause: *Aspergillus* spp. (an ascomycete, teleomorphs *Neosartorya*, *Emericella*, *Eurotium*)

Affected Hosts: Dogs, cats, humans, and a variety of other animal species

Geographic Distribution: Worldwide

Mode of Transmission: Inhalation of conidia from the environment

Major Clinical Signs: Sinonasal aspergillosis: nasal discharge, sneezing, epistaxis, depigmentation of the nares in dogs. Sino-orbital aspergillosis (especially cats): exophthalmos, mass lesions or ulcers in the pterygopalatine fossa. Disseminated aspergillosis: inappetence, weight loss, spinal pain, lameness, pelvic limb paresis or paralysis, cough, vomiting.

Differential Diagnoses: Sinonasal aspergillosis: neoplasia, inflammatory rhinitis, oronasal fistulas, cryptococcosis, nasal mites (dogs), foreign bodies, and polyps (cats). Disseminated aspergillosis: bacterial discospondylitis, bacterial pyelonephritis, and other systemic fungal infections, especially paecilomycosis and penicilliosis.

Human Health Significance: Human *Aspergillus* infections are acquired from the environment. Direct transmission from affected dogs and cats to humans does not occur.

Aspergillosis is the disease caused by pathogenic fungi that belong to the genus *Aspergillus*. *Aspergillus* species are ubiquitous, saprophytic, hyaline molds, the spores of which can be found in soil, water, air, and decaying vegetation. It is estimated that an individual person inhales several hundred *Aspergillus* spores each day.[2] *Aspergillus* species cause a variety of noninvasive, semi-invasive, and invasive forms of disease in dogs and cats that include keratomycosis, fungal otitis externa, sinonasal aspergillosis (SNA), sino-orbital aspergillosis (SOA), bronchopulmonary aspergillosis, and disseminated aspergillosis. *Aspergillus* species that can cause disease in dogs and cats are shown in Table 65-1.[3-14] Teleomorphs (sexual forms) of the fungus have been identified for some *Aspergillus* species. Currently, these are named differently and include fungi that belong to the genera *Neosartorya*, *Emericella*, and *Eurotium*. The name *Aspergillus* may be retained even when teleomorphs are isolated from lesions, to avoid confusion through the use of unfamiliar names.[12] Because accurate identification of *Aspergillus* species (especially rare species) requires advanced molecular techniques, organisms can be misidentified based on their morphology in culture alone. As a result, use of the term "species complex" is recommended when molecular techniques are not used for identification purposes.[15]

Because the etiology, epidemiology, clinical signs, diagnosis, and treatment of upper respiratory tract (URT) aspergillosis, systemic aspergillosis, and keratomycosis/otomycosis differ, they are considered separately in this chapter.

Upper Respiratory Tract Aspergillosis

Etiology and Epidemiology

In dogs, SNA is a subacute to chronic, noninvasive disease of the nasal cavity and sinuses. It is most often caused by *Aspergillus fumigatus*. Rarely, infection by other species, such as *Aspergillus niger* complex organisms (such as *Aspergillus tubingensis*) or *Aspergillus flavus* and the closely related fungus *Penicillium*, occurs. SNA occurs worldwide. Any breed of dog can be affected, but disease is most common in large, nonbrachycephalic breeds, especially German shepherd dogs, Rottweilers, Border collies, Rhodesian ridgebacks, and retrievers. Dogs of any age can be affected (median age around 6 years).[16] No clear sex predisposition exists. SNA is thought to occur when local immune mechanisms fail as a result of uncharacterized genetic or acquired immunodeficiency syndromes, and occasionally as a result of implantation of a foreign body or other preexisting nasal disease, such as nasal neoplasia. Rarely, it occurs in conjunction with other systemic diseases such as hyperadrenocorticism, diabetes mellitus, or systemic autoimmune disorders. However, in most cases, affected dogs are otherwise systemically well and have no evidence of immune compromise. Impaired cell-mediated immune responses have been detected in dogs with SNA, but it is unclear whether this is a cause or consequence of *Aspergillus* infection.[17]

Upper respiratory tract aspergillosis is relatively uncommon in cats, and includes SNA and SOA. Approximately 50 cases of URT aspergillosis have been reported in cats to date.[3] Fungi that belong to the *A. fumigatus* complex and, rarely, other *Aspergillus* species may also be involved (see Table 65-1). A novel organism with a proposed name of *Aspergillus felis* sp. nov. appears to cause SOA in cats,[12] whereas SNA is caused predominantly by *A. fumigatus* sensu stricto.[3] Brachycephalic breeds such as Persians and Himalayan Persians appear to be predisposed to SNA and especially to SOA, but both conditions occur in any breed of cat. Affected cats range in age from 1 to 13 years (median, 5 years). No clear sex predisposition exists.[3] Most cats with URT aspergillosis test negative for retrovirus infection; only one cat with SNA in the

VetBooks.ir

TABLE 65-1

***Aspergillus* Species Associated with Disease in Dogs and Cats[3-14]**

Clinical Form	Host Species	*Aspergillus* species*
Keratomycosis	Cats	*A. fumigatus* *A. flavus*
	Dogs	Not reported
Otomycosis	Cats	*A. fumigatus*
	Dogs (very rare)	*A. ochraceus* *A. versicolor* *A. niger*
Sinonasal aspergillosis	Dogs	*A. fumigatus* *A. niger* *A. nidulans* *A. flavus* *A. tubingensis*
	Cats	*A. fumigatus* *A. niger* *A. udagawae* *A. flavus* *Neosartorya* spp.
Sino-orbital aspergillosis	Cats	*A. felis* sp. nov.
Bronchopulmonary aspergillosis	Dogs and cats	*A. fumigatus* *A. flavus* (dog)
Disseminated aspergillosis	Dogs	*A. terreus* *A. deflectus* *A. fumigatus* *A. niger* *A. flavipes* *A. lentulus* *A. carneus* *A. versicolor* *A. alabamensis* *A. felis* sp. nov.
	Cats	*A. fumigatus*

*Some isolates have not been identified beyond the species complex level (including some *A. flavus*, *A. fumigatus*, and *A. niger*).

literature was co-infected with FeLV.[18] Five of 8 cats with SNA evaluated at the author's teaching hospital had diabetes mellitus.[4]

Clinical Features

Signs and Their Pathogenesis

Aspergillus conidia (or spores), which are 2 to 3 µm in diameter, are inhaled and deposit in the nasal cavity and/or sinuses, where they adhere to epithelial cells. In the absence of adequate immune defenses, the conidia enlarge and germinate to form hyphae. SNA is a noninvasive disease, and the fungus does not extend beyond the mucosal epithelium.[19] Production of toxins by the fungus and a profound host inflammatory response is thought to explain the extensive turbinate and bony destruction that follows fungal colonization. Toxins produced by *A. fumigatus* include aflatoxin, hemolysin, fumagillin, and gliotoxin,[2] but the role that these toxins play in canine SNA has not been determined. Gliotoxin induces

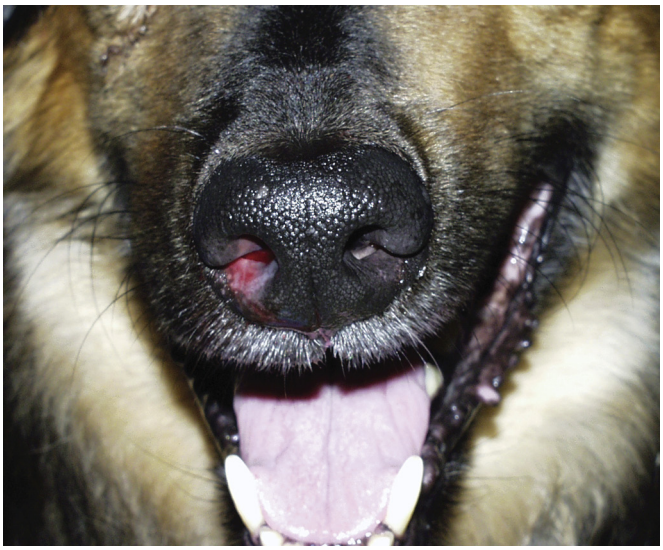

FIGURE 65-1 Unilateral depigmentation and ulceration of the nares of a 7-year-old shepherd mix with sinonasal aspergillosis. (Courtesy Dr. Lynelle Johnson, Small Animal Internal Medicine Service, University of California, Davis.)

ciliostasis and apoptosis and can suppress the host immune response.[2] The fungus also produces proteases and phospholipases. Chemokines such as Il-8 and monocyte chemoattractant protein-1 (MCP-1/CCL2) are secreted by host inflammatory cells in response to the fungus, which may recruit neutrophils and macrophages to the site of infection.[20] Severe disease is associated with destruction of nasal bones, the cribriform plate, and/or the orbit.

Clinical signs of SNA in dogs and cats consist of sneezing, reverse sneezing, serous to mucopurulent nasal discharge, depigmentation of the nasal planum, and, less commonly, epistaxis. Nasal discharge is initially unilateral but can become bilateral as disease progresses. Animals with advanced disease can be lethargic and inappetent and may lose weight. Nasal pain can manifest in dogs as pawing at the face, hiding, or withdrawal when approached. Destruction of the nasolacrimal duct or invasion of the orbit can lead to epiphora. Osteolysis of the cribriform plate is often subclinical, but occasionally leads to meningitis with neurologic signs such as obtundation or seizures.

In cats with SOA, *Aspergillus* invades the submucosal tissue of the nasal cavity and sinus and extends through the orbital bone and into the retrobulbar space. A profound granulomatous inflammatory response to the fungus results in the formation of a retrobulbar mass, with clinical signs that include exophthalmos, protrusion of the third eyelid, mass lesions in or ulceration of the pterygopalatine fossa, and, rarely, blindness due to invasion of the optic nerve or optic chiasm.[3,21-23] Inappetence and dysphagia can also develop.[22] Occasionally, the clinical signs of SOA develop after initial signs of SNA, such as sneezing and nasal discharge.[3,21]

Physical Examination Findings

Physical examination findings in dogs with SNA include unilateral or bilateral serous or mucopurulent nasal discharge, epistaxis, pain on palpation of the face, mild mandibular lymphadenomegaly, and sometimes depigmentation and ulceration of the nares (Figure 65-1).[24,25] Nasal airflow is usually normal or increased because of turbinate lysis. Serous ocular discharge occurs uncommonly as a result of destruction of the bones of the orbit. Rarely, palpation of the nasal bones or the hard palate can reveal defects

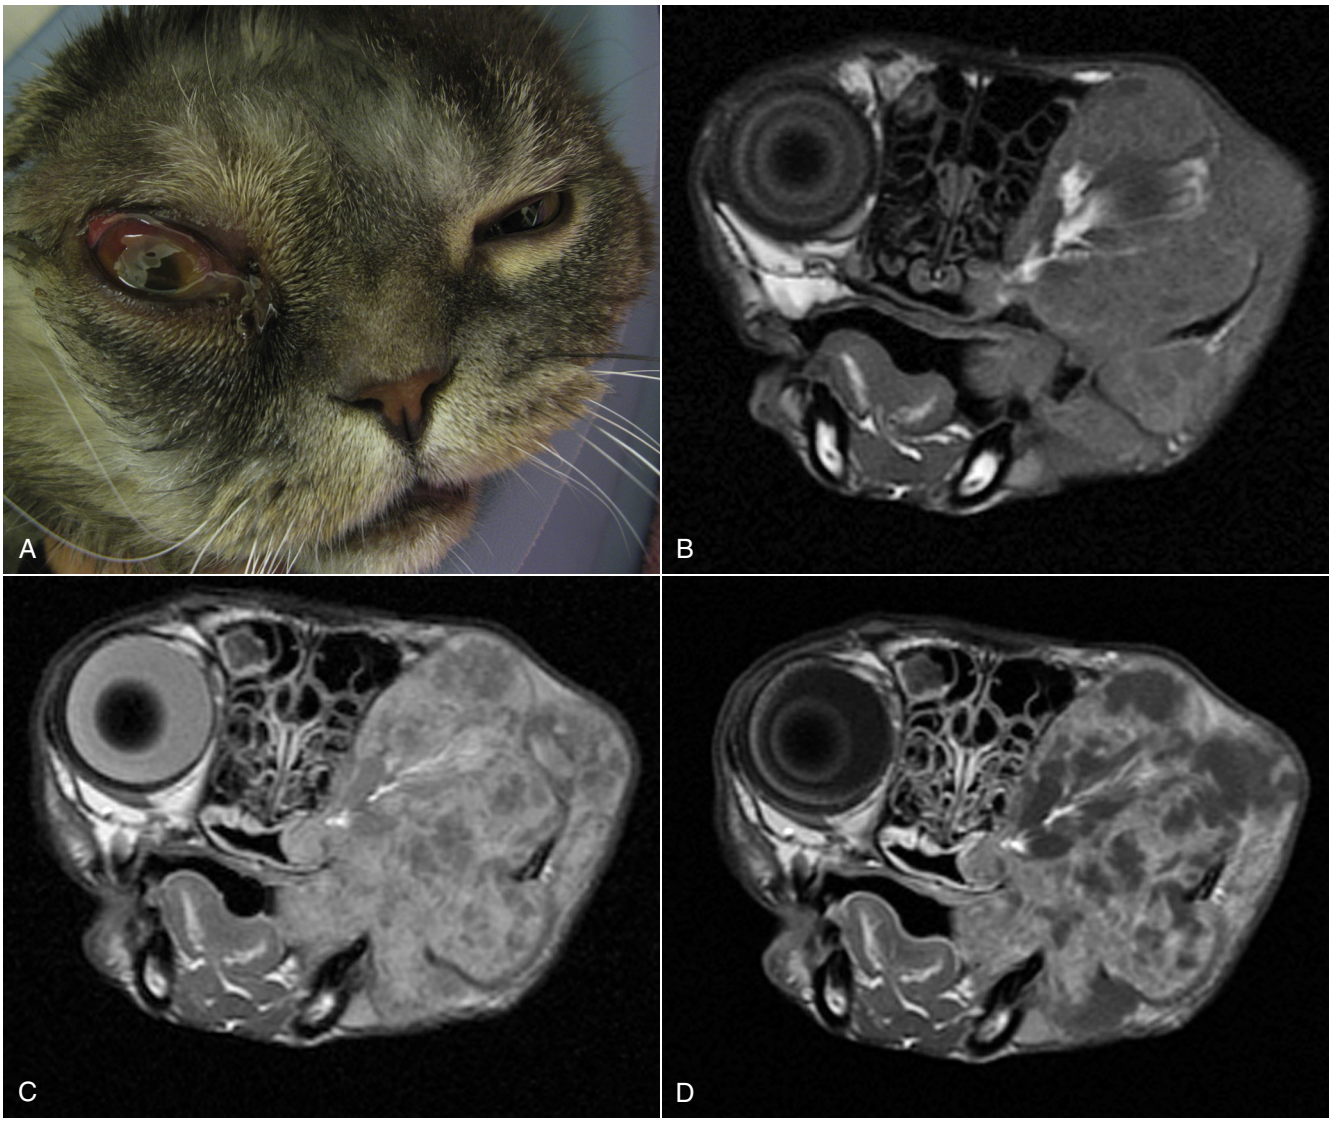

FIGURE 65-2 **A,** Seven-year-old male neutered Scottish fold cat with exophthalmos, conjunctivitis, and blindness of the right eye secondary to sino-orbital aspergillosis. A 1- to 2-cm mass was also identified in the pterygopalatine fossa on oral examination. **B-D,** MRI image of the head of the same cat. The right eye was displaced rostrally by a large retrobulbar mass that is mildly, heterogeneously hyperintense on T1-weighted images **(B)**, hyperintense on T2-weighted images **(C)**, and enhanced with contrast **(D)**. The mass extends medial to the ramus of the mandible and enters the nasopharynx as well as the oropharynx. A small T1-hyperintense structure is noted in the left frontal sinus.

in the underlying bone. Dogs with cribriform plate involvement and meningitis may be obtunded or dehydrated. Dogs with severe epistaxis can have evidence of melena on rectal examination secondary to swallowed blood. Most affected dogs are afebrile.

Physical examination findings in cats with SNA consist of serous or mucopurulent nasal discharge, sneezing, stertor, epistaxis, and, in some cases, facial distortion.[3] Cats with SOA usually have unilateral exophthalmos and deviation of the globe; bilateral involvement has also been described (Figure 65-2).[3,22,23] There may be resistance to ocular retropulsion and protrusion of the third eyelid. Miosis, an absent pupillary light response, and an absent menace response may be present. On examination of the oral cavity, most affected cats also have a mass or ulcer in the pterygopalatine fossa ipsilateral to the affected eye. Other less common findings are exposure keratitis and corneal ulceration, mandibular lymphadenomegaly, pain on opening the mouth, and/or ulceration of the hard palate.[3,22]

Diagnosis

Early diagnosis of URT aspergillosis relies on a high degree of suspicion for the disease and availability of client financial resources, because there is a lack of sensitive, noninvasive diagnostic tests for the disease. Definitive diagnosis requires a combination of imaging, visualization of fungal plaques by rhinoscopy/sinuscopy, and identification of fungal structures on cytology or histopathology. Imaging should be performed before rhinoscopy to avoid the influence of iatrogenic hemorrhage on the results.

Laboratory Abnormalities

Dogs with SNA often have no abnormalities on the CBC, serum chemistry profile, or urinalysis. Occasionally, mild nonregenerative anemia; mild neutrophilia, rarely with a left shift; mild eosinophilia; and/or mild hypoalbuminemia are present.[4] Cats

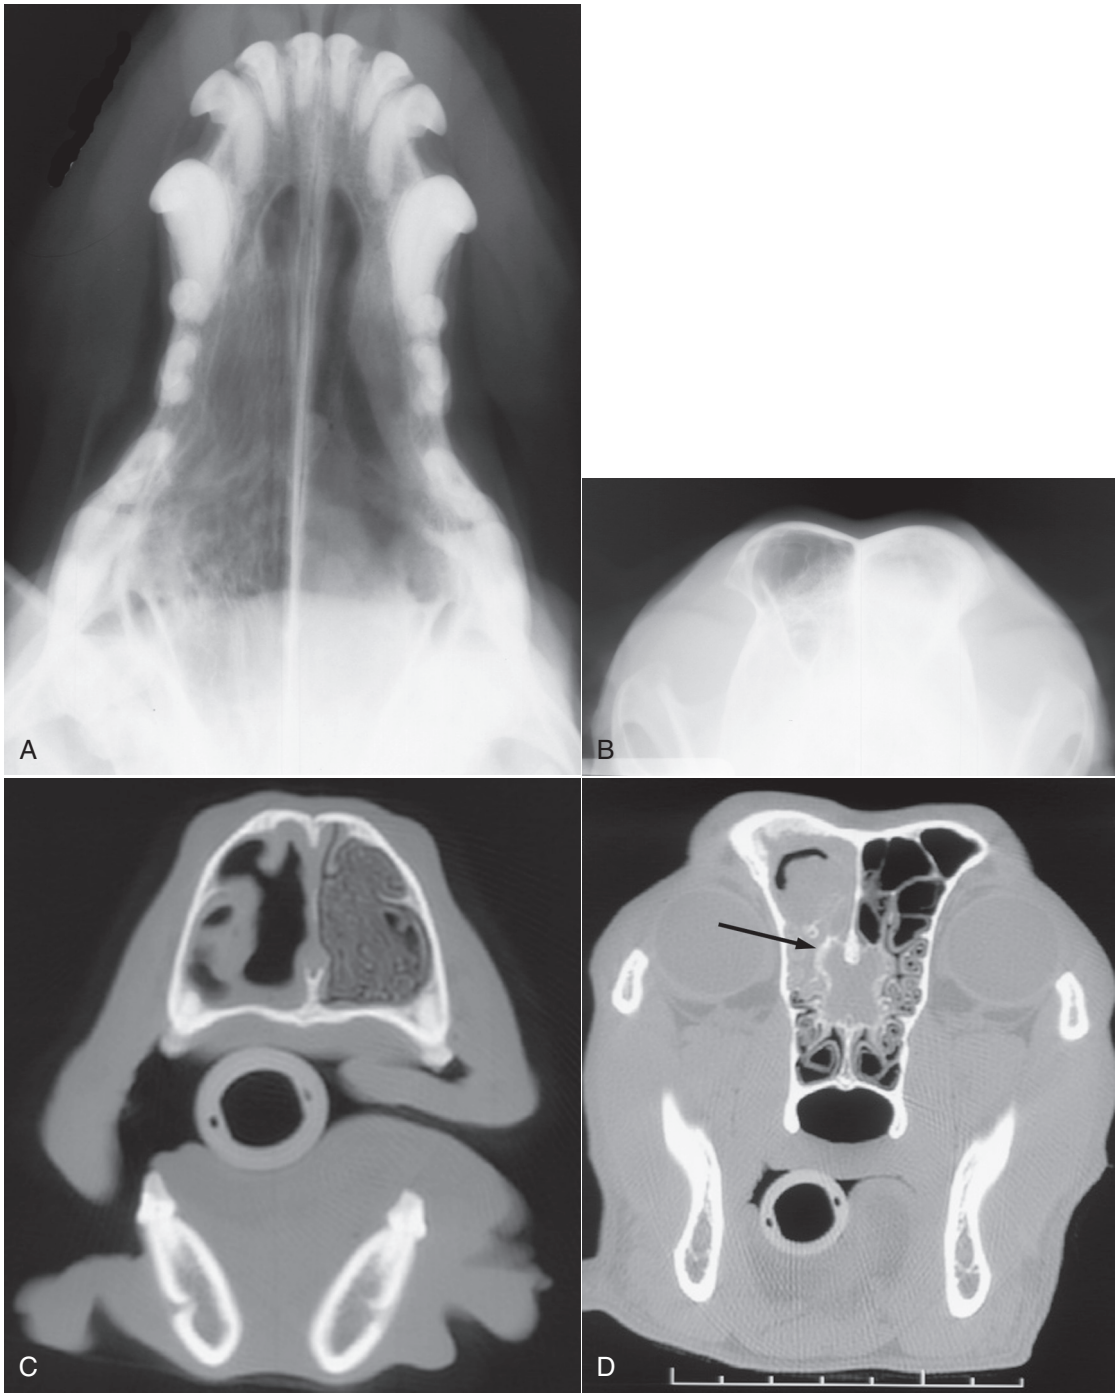

FIGURE 65-3 Plain radiographs (**A** and **B**) and CT scan images (**C** and **D**) of the nasal cavity of a 6-year-old female spayed golden retriever with sinonasal aspergillosis. **A,** Open-mouth view. There is marked loss of detail in the left nasal cavity. **B,** Skyline projection of the frontal sinuses. There is increased opacity in the left frontal sinus. **C,** A transverse image through the nasal cavity shows marked turbinate loss on the left side. **D,** Transverse image through the frontal sinuses and region of the cribriform plate. There is moderate fluid accumulation and irregular soft tissue structures in the left frontal sinus, and the frontal bone that overlies the sinus is thickened and irregular. Bony destruction at the level of the cribriform plate is present (*arrow*).

with SOA may have a mild mature neutrophilia and sometimes mild to severe hyperglobulinemia.[3,21]

Diagnostic Imaging

Advanced Imaging

Whenever possible, computed tomography (CT) or MRI are preferred imaging modalities for the nasal cavity because of their increased sensitivity over plain radiography for evaluation of the nasal cavity, sinuses, and cribriform plate.[26] Bony changes are best appreciated on CT. Findings on CT or MRI in canine and feline SNA include loss of nasal turbinates and defects in the nasal septum; increased soft tissue opacity within the nasal cavity and/or sinuses due to mucosal inflammation, fluid accumulation, or fungal plaques; hyperostosis of the frontal bones; and mandibular or retropharyngeal lymph node enlargement.[3,26-29] Osteolysis of the cribriform plate, orbit, frontal bones, and, rarely, the maxillary or palatine bones may be present (Figure 65-3, *C*). Meningeal enhancement is sometimes evident on contrast

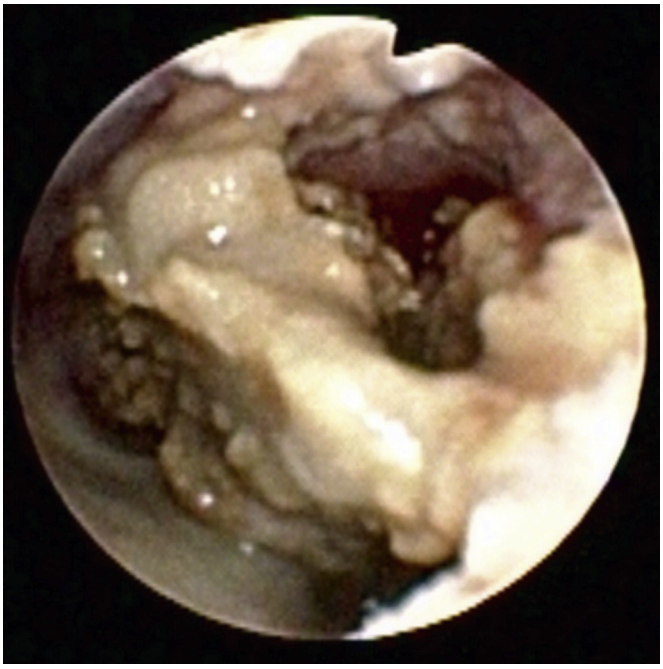

FIGURE 65-4 Rhinoscopic view of a large gray fungal plaque in the nasal cavity of an 8-year-old female pit bull terrier with sinonasal aspergillosis.

administration in dogs with cribriform plate destruction.[25] Fungal plaques and mucosal secretions fail to enhance with contrast and cannot be readily distinguished from each other. In some dogs, lesions are limited to the frontal sinus.[27]

Advanced imaging of the head in cats with SOA reveals a retrobulbar mass that enhances diffusely or heterogeneously with contrast. Displacement of the globe, osteolysis of the orbit, mandibular lymphadenomegaly, and changes consistent with SNA can also be present. With MRI, retrobulbar masses are T2-hyperintense. Invasion of temporal and masseter muscles by the mass may also be apparent on MRI (see Figure 65-2).[30]

Plain Radiography

Plain skull radiographs in dogs with SNA may show unilateral or bilateral loss of turbinate detail, destruction of the nasal septum, and/or increased soft tissue opacity within the nasal cavity. The open-mouth view provides optimum evaluation of the turbinates (see Figure 65-3, *A*). A "skyline" view of the nasal sinuses may show opacification of one or both sinuses and frontal bone hyperostosis (see Figure 65-3, *B*).[26]

Rhinoscopy and Sinuscopy

Visualization of fungal plaques by rhinoscopy and sinuscopy confirms a diagnosis of SNA. Plaques are white, gray, yellow, black, greenish, or a mixture of these colors and are adhered to the nasal mucosa or mucosa of the frontal sinus (Figure 65-4). Caudal rhinoscopy is performed with a flexible endoscope, after which a rigid telescope or flexible endoscope is used to examine the rostral portions of the nasal cavity. In some cases, extensive turbinate destruction allows a flexible endoscope to be passed directly into the frontal sinuses through the nasofrontal opening. If this is not possible, but CT or MRI findings suggest the possibility of frontal sinus lesions, trephination or surgical exploration of the frontal sinuses is necessary to visualize (and treat) this region. After trephination, a rigid endoscope can be used to examine the frontal sinus through the trephination site.

Microbiologic Tests

Cytologic Examination

Cytologic examination of blind or rhinoscopy-directed mucosal swabs, brush specimens of the nasal cavity, or nasal biopsies from dogs or cats with SNA can reveal *Aspergillus* hyphae and sometimes also conidia. Hyphae stain well with Wright's stains. They are septate and branch at 45-degree angles (see Figure 4-3). Large numbers of degenerate neutrophils, ciliated epithelial cells, and/or bacteria are also usually present. In one study, the sensitivity of cytologic examination was 93% when cytology brush specimens were examined and 100% when squash preparations of biopsies were examined, but it was 20% or less when nasal discharge or smears made from blind swab specimens were examined.[31]

Cytologic examination of ultrasound- or CT-guided aspirates of retrobulbar masses from cats with SOA reveals a mixed inflammatory response and sometimes fungal hyphae.

Fungal Culture

Aspergillus fumigatus can be readily grown on routine laboratory media. Colonies of mold generally appear within 96 hours, but occasionally longer incubation times are required.[32] In the absence of supportive rhinoscopic, cytologic, or histopathologic findings, positive cultures from the nasal cavity (or other nonsterile sites) require cautious interpretation because *Aspergillus* may be found within the URT of healthy animals. Nevertheless, in two separate studies, no dogs with nonfungal nasal disorders had positive culture results for *Aspergillus*.[16,32] In one of these studies (which included 21 dogs with SNA and 37 dogs with nonfungal nasal disease), the sensitivity of fungal culture of nasal biopsies for diagnosis of canine SNA was 81%.[16] In the other study, fungal culture of biopsy specimens or plaque specimens collected by rhinoscopic guidance (≥75%) was more sensitive than culture of blindly collected nasal swab specimens (<20%).[32]

Growth of an *A. fumigatus* complex organism from guided aspirates or biopsy specimens collected from a retrobulbar mass in a cat strongly suggests a diagnosis of SOA. In one study, fungal culture of nasal biopsies or aspirates from cats with SOA and SNA had a sensitivity greater than 95%.[3]

Serologic Diagnosis

Both serum antibody and antigen assays have been evaluated for diagnosis of URT aspergillosis. Assays for detection of serum antibodies to *Aspergillus* include ELISA and gel immunodiffusion (ID) assays (see Figure 2-7). Assay types vary in their sensitivity and specificity for diagnosis of SNA, and clinical performance data for some assays used in commercial veterinary diagnostic laboratories may not be available. The sensitivity of one gel ID assay (Meridian Bioscience) for diagnosis of canine SNA was 57% to 77%,[16,25,33] and the specificity was at least 98%.[16,33] The sensitivity and specificity of another gel ID assay (Immuno-Mycologics, OK) was 31% and 97%, respectively.[34] The sensitivity and specificity of an ELISA that detects antibodies against a purified *Aspergillus* antigen extract was 88% and 97%, respectively.[33] Thus, negative results with these antibody assays do not rule out SNA, but positive results strongly suggest the disease is present. The sensitivity and specificity of serum antibody assays for diagnosis of feline URT aspergillosis has not been evaluated in a large number of cats, but both positive and negative assay results have been reported in affected cats.[3,28,35]

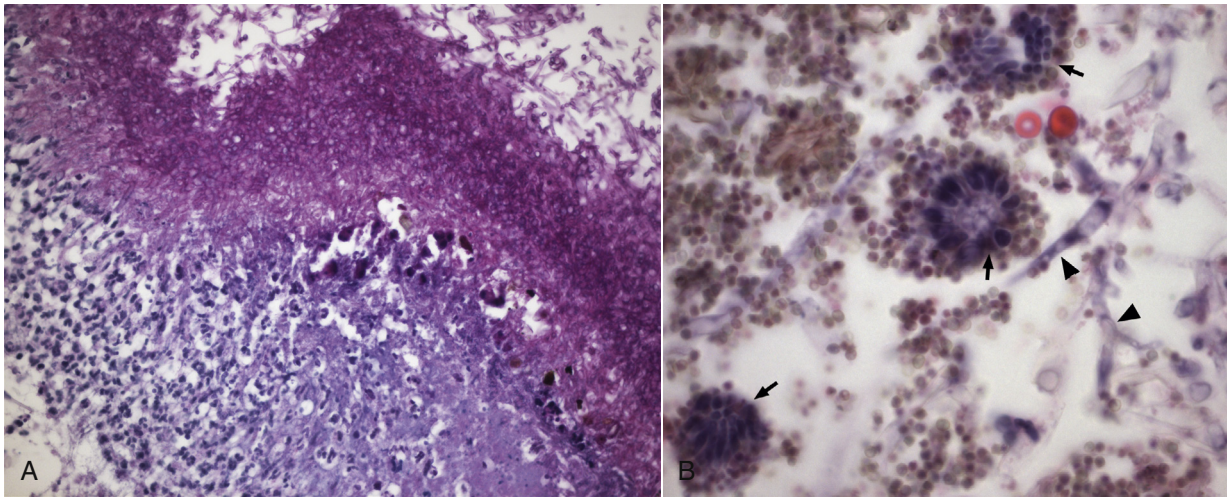

FIGURE 65-5 Histopathology of a nasal biopsy from a 4-year-old intact male Border collie with sinonasal aspergillosis. **A,** There is a profound neutrophilic inflammatory response beneath a thick mat of fungal hyphae, which stain magenta. Periodic acid–Schiff stain, 400× magnification. **B,** *Aspergillus* hyphae *(arrowheads),* conidiophores *(small arrows)* and conidia (spores) can be seen on the surface of the lesion. H&E stain, 1000× oil magnification.

A serum *Aspergillus* galactomannan antigen ELISA assay (Platelia), originally developed for diagnosis of invasive aspergillosis in humans, has been studied for the diagnosis of SNA and SOA in dogs and cats, but its sensitivity and specificity have been low.[5,33,36,37] Only 4 of 17 dogs with SNA were positive in one study, and only weak positive results were obtained (galactomannan indices 0.5-0.8, reference range <0.5).[33] False positive results occurred in 11 of 62 dogs without SNA (galactomannan indices of 0.5-1.5). Only 3 of 13 cats with URT aspergillosis tested positive, and false-positive results were obtained in a number of cats without URT aspergillosis (specificity 78%).[38]

Molecular Detection Using the Polymerase Chain Reaction

The use of real-time PCR assays that detect *Aspergillus* DNA in nasal biopsy specimens has been evaluated for diagnosis of SNA in dogs, but assays evaluated had either unacceptably high rates of false-positive test results (PenAsp assay) or a low sensitivity (*Aspergillus* genus-specific PCR).[34] For both assays, dogs with SNA had higher DNA copy numbers than control dogs or dogs with lymphoplasmacytic rhinitis or neoplasia, but there was considerable overlap in copy numbers between dogs with SNA and those without SNA.

Pathologic Findings

Histopathology of nasal biopsies from dogs with SNA usually reveals branching, septate fungal hyphae in a background of lymphoplasmacytic and neutrophilic inflammation; occasionally the neutrophilic component predominates. Variable numbers of macrophages and eosinophils may also be present, as well as necrotic debris. Other findings include osteolysis, turbinate remodeling, and intralesional bacteria. Occasionally, intralesional plant material is detected. Mats of fungal hyphae may be present if a plaque is submitted for examination. Conidiophores and conidia can be found because the fungus is exposed to air within the nasal cavity (Figure 65-5). The sensitivity of rhinoscopically guided nasal biopsy for diagnosis of canine SNA in one study was 82% (18 of 22 dogs).[25] In that study, three to five biopsy specimens were collected from each side of the nasal cavity.

Histopathology of biopsies of retrobulbar mass lesions in cats with SOA reveals granulomatous inflammation with necrosis and intralesional branching hyphae. A mixed inflammatory reaction (epithelioid macrophages, eosinophils, neutrophils, lymphocytes, and plasma cells) and a peripheral zone of fibrosis surround the granulomas. Inflammatory lesions may efface muscle and bone.

Treatment and Prognosis

Successful treatment of SNA is challenging. Because of the large size of the nasal cavity and sinuses, clinical signs are often not apparent until disease is advanced. Delays in diagnosis can occur because of the costly and invasive nature of diagnosis and treatment and the need for specialized imaging techniques and endoscopic expertise. Owners of adult dogs that develop persistent nasal discharge (e.g., present for at least 1 week) should be encouraged to pursue advanced imaging and rhinoscopy as soon as possible so that the disease can be recognized and treated early. Treatment with antibacterial drugs alone is discouraged, because primary bacterial infections of the nasal cavity in adult dogs are rare.

In general, treatment of SNA requires thorough mechanical debridement of plaques with endoscopic biopsy forceps until no visible fungus remains, which may necessitate extended anesthesia. In some cases, treatment is performed immediately after imaging and rhinoscopy, which further prolongs the period of anesthesia. If plaques within the frontal sinuses cannot be accessed by antegrade rhinoscopy through the nasofrontal opening, frontal sinus trephination and curettage or open surgical debridement of the frontal sinus may be required. Provided the cribriform plate is intact, debridement is followed by repeated lavage with 0.9% saline and suction, followed by topical antifungal drug therapy with clotrimazole or enilconazole. Additional systemic antifungal drug treatment could also be considered, but whether this improves outcome over topical therapy alone is unknown.

Topical Antifungal Drug Treatment

A variety of noninvasive and invasive protocols for topical antifungal drug treatment of canine SNA have been described with varied rates of success. Currently, there is a lack of masked, randomized clinical trials with consistent and long-term follow-up evaluation that indicate clear benefit of one treatment over another. The protocol described here is used at the author's institution. A similar protocol has been used successfully to treat SNA in cats.[38]

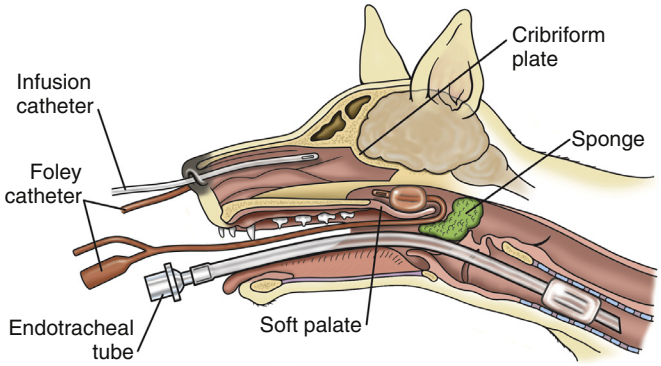

FIGURE 65-6 Diagram illustrating placement of catheters for topical treatment of canine sinonasal aspergillosis with clotrimazole or enilconazole.

A 24F Foley catheter is retroflexed over the soft palate and the balloon inflated until it can be palpated above the soft palate (Figure 65-6). Placement of the catheter is facilitated by insertion of a stiff guidewire into the catheter. The tip of the catheter can then be bent into a U shape and hooked over the soft palate, after which the balloon is inflated. The nasopharynx is packed with moistened laparotomy pads, a gauze pad is placed over the incisive papilla, and the proximal end of the catheter is clamped across the guidewire to prevent leakage of antifungal drug from the nasal cavity. A 10F polypropylene catheter is inserted into each nostril to the level of the medial canthus, or alternatively these two catheters can be placed directly into the frontal sinus with endoscopic guidance.[24,39] The tip of an additional 12F Foley catheter is inserted into each of the nares, the balloon inflated, and the catheters clamped so the nares are occluded. Cotton-tipped swabs can also be inserted into the nares to prevent outflow of antifungal drug. Clotrimazole (1%) or enilconazole (1% or 2%) solution is then administered through the polypropylene catheters. For large-breed dogs, 50 to 60 mL of solution is administered per side, and if frontal sinus trephination was performed, half of the solution can be administered into a catheter placed in the trephination site. The patient is rotated 45 degrees every 15 minutes over an hour to distribute the drug into the nasal cavity and sinuses. The catheters and sponges are then removed with the dog's head tilted downward at an angle of 30 degrees, and the material is allowed to drain from the nasal cavity for 10 minutes. Debridement and a second treatment are then routinely performed 1 month later; sometimes, a third treatment may be necessary. Clotrimazole can be irritating to tissues, and solutions that contain propylene glycol can cause pharyngeal irritation and edema.[40] Enilconazole solutions may be less irritating, but there is no evidence that they are more effective than clotrimazole.

When cribriform plate destruction is present, topical treatment can lead to the development of life-threatening neurologic signs or failure to recover from anesthesia. Nevertheless, treatment has also been performed without complication in some dogs with minor defects in the cribriform plate.[25] Systemic azole antifungal drug therapy could be considered as an alternative in this situation.

Use of topical antifungal creams has been studied in order to improve retention in the sinonasal cavities and reduce procedure time.[24,41] In one study, 1% clotrimazole solution (25 or 60 mL based on patient size) was administered through a catheter placed through a trephination site in each frontal sinus, followed by a 1% clotrimazole cream (10 or 20 g).[41] Debridement was not performed, so the mean treatment time was only 32 minutes. Of 14 dogs treated, 10 had resolution of clinical signs, but outcome was based only on telephone follow-up at 6 to 24 months, and not endoscopic reevaluation. In another study, 15 g of 1% bifonazole cream was administered into the frontal sinus using endoscopic guidance either alone or after topical treatment with enilconazole.[24] Dogs were also treated with ketoconazole or itraconazole. All 12 dogs treated with a combined enilconazole-bifonazole treatment were considered cured after a second treatment, but 2 of 5 dogs treated with bifonazole alone had persistent disease. Bifonazole has limited availability in the United States.

Systemic Antifungal Drug Treatment

Although their efficacy for treatment of SNA has been debated, azole antifungals with activity against molds (i.e., ketoconazole, itraconazole, posaconazole, or voriconazole) have been used either as monotherapy for dogs with cribriform plate involvement or in combination with topical antifungal drugs. Debridement before commencing systemic antifungal drug treatment is recommended if client finances permit, because effective drug concentrations are not likely to be obtained within fungal plaques.

Cats with SOA must be treated with systemic antifungal drugs such as an azole (itraconazole or posaconazole) and/or amphotericin B; the use of terbinafine in combination with these drugs has also been reported.[3] One cat was successfully treated with caspofungin followed by posaconazole monotherapy. More than 50% of treated cats failed treatment in one study.[3] The optimum treatment for SOA requires further study.

Prognosis

The prognosis for SNA depends on the extent of disease at the time of diagnosis. Success rates vary from less than 30% to 100%, but methods to assess treatment success and follow-up times have not been consistent. Serial serologic testing by gel ID is not useful to monitor treatment success.[25] Even if infection is eliminated based on endoscopic reevaluation and biopsy, dogs with extensive turbinate loss are predisposed to recurrent bacterial infections of the nasal cavity, which result in persistent nasal discharge and sneezing. One study showed no difference in the prevalence of sneezing and nasal discharge between dogs that responded to initial treatment and dogs that failed to respond.[25] Recurrence of SNA due to persistent infection or re-infection by *Aspergillus* spp. can also occur. The prognosis for complete remission of SOA in cats is guarded to poor.

Public Health Aspects

There are no reports of transmission of SNA from affected dogs to humans. Whether the handling of affected dogs by immunosuppressed humans poses a risk to their health is unknown, but such individuals should probably minimize contact with affected animals. If contact is necessary, they should be encouraged to discuss the problem with their medical practitioner. At the least, gloves should be worn and proper hand washing practiced.

Systemic Aspergillosis

Etiology and Epidemiology

Systemic aspergillosis may involve the respiratory tract (bronchopulmonary aspergillosis) or may be a disseminated disease of multiple organ systems. Localized bronchopulmonary aspergillosis is rare in dogs and cats, and often follows underlying local

VetBooks.ir

or systemic immunodeficiency.[6,42-44] German shepherds appear to be predisposed to a form of bronchopulmonary aspergillosis characterized by the development of cavitary lung lesions.[6,45-47] Bronchopulmonary aspergillosis is typically associated with infection by *A. fumigatus* complex fungi, whereas disseminated aspergillosis in dogs is most often caused by *Aspergillus terreus* or *Aspergillus deflectus*. Other *Aspergillus* species have also been isolated from dogs with disseminated disease (see Table 65-1).

In dogs, disseminated aspergillosis may occur as a result of an uncharacterized genetic immunodeficiency, because female German shepherds are strongly predisposed to the disease, and immunosuppressive drug treatment is rarely present in the history of affected dogs.[7] Two thirds of affected dogs seen at the author's institution were German shepherds, and German shepherds were 43-fold more likely to develop the disease than other dog breeds.[7] Rhodesian ridgebacks were also predisposed. Females are 3 times as likely to develop disseminated aspergillosis as males, and the median age of affected dogs is 4.5 years (range, 2 to 8 years). Concurrent or sequential infections with other opportunistic pathogens have been described in some dogs.[4,48]

Disseminated and bronchopulmonary aspergillosis are rare in cats.[42,49,50] Affected cats often have recognizable underlying immunosuppressive conditions such as diabetes mellitus, cancer chemotherapy, or severe viral infections. The remainder of this chapter focuses on systemic aspergillosis in dogs.

Clinical Features

Signs and Their Pathogenesis

Pulmonary or disseminated aspergillosis is thought to develop after inhalation of *Aspergillus* conidia, which lodge in the alveoli and adhere to epithelial cells. In the absence of adequate local immune defenses, the conidia enlarge and germinate to form hyphae. Invasion of the bloodstream and dissemination to distant sites may occur as a result of systemic immunosuppression. Fungal virulence factors are also likely to be important, although why *A. terreus* and *A. deflectus* are more likely than *A. fumigatus* to cause disseminated disease in dogs is unclear. Human disseminated aspergillosis is most often caused by *A. fumigatus*–complex fungi.[51]

Anatomic sites of predilection in dogs with disseminated aspergillosis are the vertebral endplates and discs, renal pelvis, spleen, long bones, and lymph nodes. However, any organ may be affected, including the liver, heart, cardiac valves, pancreas, eyes, lungs, brain, bone marrow, meninges, small intestine, skin, spinal cord, thyroid, adrenal glands, prostate, and trachea. Nasal cavity involvement is not generally a feature of the bronchopulmonary or disseminated forms, and dogs with disseminated disease often lack evidence of pulmonary involvement. The median duration of illness before admission in one study was 1 month (range, 2 days to 9 months).[7] The most frequent clinical signs are lethargy, inappetence, pain, lameness, and neurologic signs secondary to discospondylitis (especially ataxia and paresis) (Table 65-2). Other signs include apparent blindness, circling, head tilt, seizures, respiratory distress, and vomiting. Cough, increased respiratory effort, and rarely hemoptysis may occur in dogs with bronchopulmonary aspergillosis.[6,47]

Physical Examination Findings

Physical examination findings in dogs with disseminated aspergillosis are listed in Table 65-3. On physical examination, dogs with disseminated aspergillosis often have muscle wasting and/or a thin body condition. Fever (up to 104.2°F or 40.1°C) is present in one quarter of affected dogs.[7] Musculoskeletal abnormalities include spinal pain, lameness, and, rarely, inability to stand. Neurologic signs include vestibular abnormalities, ataxia, mental dullness, paraparesis, vision impairment, hemiparesis, circling, and seizures. Dogs with respiratory involvement may cough and have harsh lung sounds and/or increased respiratory effort. Peripheral lymphadenomegaly may be detected. Ocular abnormalities include chorioretinitis, hyphema, and panophthalmitis.[7] Rarely, arrhythmias are detected secondary to myocardial involvement, but myocardial involvement is often subclinical.

TABLE 65-2

Historical Signs in 30 Dogs with Disseminated Aspergillosis

TABLE 65-4

Selected Hematologic and Serum Biochemistry Analysis Results in 30 Dogs with Disseminated Aspergillosis

Variable	Median (Range)	No. (%) with Low Values	No. (%) with High Values	Reference Range
Hematocrit (%)	42% (14%-46%)	8 (31%)	0	40%-55%
Neutrophils (cells/μL)	12,643 (7584-28,321)	0	21 (81%)	3000-10,500
Band neutrophils (cells/μL)	0 (0-3051)	0	10 (38%)	Rare
Monocytes (cells/μL)	1608 (499-3760)	0	16 (62%)	150-1200
Lymphocytes (cells/μL)	1566 (115-3998)	4 (15%)	0	1000-4000
Platelets (cells/μL)	262,000 (86,000-400,000)	1 (4%)	0	150,000-400,000
Albumin (g/dL)	2.7 (1.3-3.6)	6 (24%)	0	2.9-4.2
Globulin (g/dL)	4.4 (2.3-5.8)	0	12 (48%)	2.3-4.4
Creatinine (g/dL)	1.1 (0.5-7.8)	0	9 (36%)	0.5-1.6
BUN (mg/dL)	19 (8-196)	0	9 (36%)	8-31
Calcium (mg/dL)	10.8 (9.9-13.9)	0	8 (32%)	9.9-11.4
ALT (IU/L)	37 (19-609)	0	3 (12%)	19-67
ALP (IU/L)	78 (21-1920)	0	3 (12%)	15-127

Diagnosis

Laboratory Abnormalities

Complete Blood Count

Most dogs with disseminated aspergillosis have leukocytosis due to a neutrophilia (Table 65-4).[7] A left shift and toxic neutrophils may also be present. Normocytic, normochromic nonregenerative anemia occurs in approximately one third of affected dogs and may be secondary to inflammatory disease or renal failure.

Serum Biochemical Tests

Common abnormalities in the serum biochemical profiles of dogs with systemic aspergillosis include hyperglobulinemia, azotemia, hypercalcemia, and hypoalbuminemia (see Table 65-4).

Urinalysis

The urine specific gravity of azotemic dogs with disseminated aspergillosis is usually in the isosthenuric range because of renal failure. Hematuria, proteinuria, and pyuria may also be detected. Fungal hyphae were identified in the urine sediment of 2 (8%) of 25 dogs with disseminated aspergillosis in one study.[7]

Cerebrospinal Fluid Analysis

Analysis of the CSF in dogs with neurologic signs or spinal pain due to disseminated aspergillosis can show no abnormalities, or an increased nucleated cell count and CSF protein concentration. The differential cell count reveals mixed or primarily mononuclear or neutrophilic pleocytosis. Abnormalities of the CSF were identified in 8 of 10 dogs with disseminated aspergillosis at the author's teaching hospital.[4]

Diagnostic Imaging

Plain Radiography

Plain thoracic radiographs in dogs with bronchopulmonary aspergillosis may show a bronchial pattern or lung lobe consolidation.[44] Consolidation and cavitary lesions may be seen in the lungs of German shepherd dogs (Figure 65-7).[45-47] Abnormalities in dogs with disseminated aspergillosis include enlarged tracheobronchial and/or sternal lymph nodes, cranial mediastinal masses, pleural effusion, and/or pulmonary alveolar infiltrates.[7]

Spinal radiographs reveals evidence of discospondylitis in approximately half of dogs with disseminated aspergillosis, with a median of 2 sites affected (range, 1 to 9 sites).[7] Productive and destructive bony changes consistent with osteomyelitis may be present in other parts of the skeleton (Figure 65-8). Most dogs

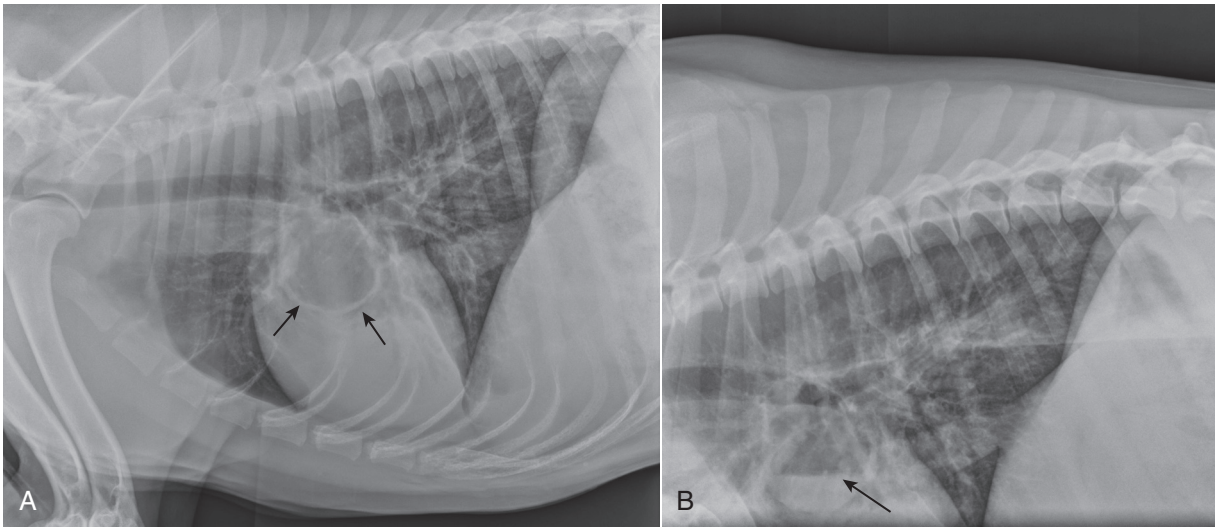

FIGURE 65-7 Lateral thoracic radiograph of a 2-year-old male neutered German shepherd that had a 4-month history of cough and exercise intolerance. **A,** A cavitary lesion *(arrows)* and alveolar infiltrates in the right middle lung lobe are present. **B,** On a horizontal beam projection, a fluid line is present *(arrow)* within the dependent aspect of the lesion.

FIGURE 65-8 Lateral radiograph of the left humerus of a 2-year-old male neutered German shepherd with disseminated aspergillosis. A primarily osteoproductive lesion is present in the mid-diaphysis.

have multiple affected sites, which include the vertebral bodies, sternebrae, ribs, scapula, humerus, and tibia.[7]

Sonographic Findings

Abdominal ultrasound abnormalities in dogs with disseminated aspergillosis are most often in the kidneys, spleen, and

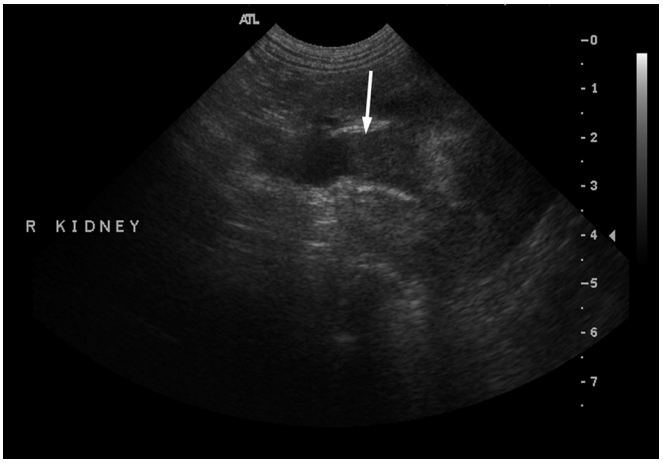

FIGURE 65-9 Ultrasound image of the right kidney of a 6-year-old female spayed German shepherd dog with disseminated aspergillosis. There is dilation of the renal pelvis, which contains echogenic material *(arrow)*.

abdominal lymph nodes.[7] Renal abnormalities include pyelectasia, a distorted and mottled architecture, decreased corticomedullary distinction, echogenic debris within the renal pelvis and proximal ureter, nodules or masses within the renal cortex, and papillary blunting (Figure 65-9). Occasionally, hydronephrosis is detected. Splenic abnormalities include hypoechoic nodules or masses, splenomegaly, changes consistent with infarction, or a mottled echotexture. Abdominal lymph nodes may be enlarged and/or hypoechoic. Other findings include diffuse hepatic or pancreatic hypoechogenicity, ascites, or evidence of venous thrombosis.

Advanced Imaging

MRI of the head in dogs with *Aspergillus* infections that have disseminated to the central nervous system (CNS) may reveal multifocal lesions that are hypo- to isointense and enhance with contrast on T1-weighted images. These lesions are hyperintense or heterogenous on T2-weighted and fluid attenuated inversion recovery (FLAIR) images. Mild or severe meningeal enhancement may also be present.

TABLE 65-5

Diagnostic Assays Available for Aspergillosis in Dogs or Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, body fluids, impression smears of biopsies	Fungal hyphae (with or without conidia in tissues exposed to air)	False negatives can occur when specimen size is small or low numbers of fungi are present. Cytology of brush specimens optimizes sensitivity for dogs with SNA. Identification to species level requires culture and molecular testing.
Fungal culture	Aspirates or biopsies of affected tissues, body fluids	*Aspergillus* species	Sensitivity for diagnosis of canine SNA is at least 75% when endoscopically guided nasal biopsies are cultured. Specificity is >95%. Culture of a typical species (*A. terreus* or *A. deflectus*) from a dog with signs consistent with disseminated disease strongly suggests disseminated aspergillosis. Molecular testing by PCR may be required to identify beyond the species complex level.
Antibody serology (gel ID or ELISA)	Serum	Antibodies to *Aspergillus* species	Assays vary in sensitivity and specificity. In general, positive results support a diagnosis of canine SNA, but negative results do not rule out the disease. Insensitive for diagnosis of disseminated aspergillosis.
Galactomannan antigen assay (ELISA)	Urine, serum	*Aspergillus* spp. galactomannan cell wall antigen	Insensitive for diagnosis of SNA, SOA, and probably bronchopulmonary disease. Very sensitive for diagnosis of disseminated aspergillosis. Cross-reactivity with other fungal pathogens may occur (especially other molds). False positives also occur with Plasmalyte administration.
Real-time PCR assays	Whole blood	*Aspergillus* spp. DNA	Assays studied lack sensitivity or specificity for diagnosis of canine SNA. Usefulness for diagnosis of disseminated aspergillosis requires further study.
Histopathology	Biopsy specimens from affected tissues	Fungal hyphae (with or without conidia in tissues exposed to air)	Sensitivity for diagnosis of canine SNA in rhinoscopically guided biopsies was 82%. Hyphae are usually visualized in biopsies from animals with disseminated aspergillosis, but lesions may be difficult to access for biopsy. Special stains assist organism detection.

Microbiologic Tests

Diagnostic assays available for aspergillosis in dogs or cats are described in Table 65-5.

Cytologic Examination

Hyphae with morphology consistent with *Aspergillus* spp. may be present in aspirates of lymph nodes, kidney, lung tissue, or bone from dogs with systemic aspergillosis (see Figure 4-3).[7] Cytologic examination of pleural effusion, airway lavage specimens, or urine may also reveal hyphae. False-negative results occur when organism numbers are low or specimen size is small. Accurate identification of the organism present requires fungal culture.

Fungal Culture

Aspergillus spp. are readily isolated on routine laboratory media. Isolation of *Aspergillus* spp. (especially *A. terreus* or *A. deflectus*) from normally sterile sites such as urine, blood, or aspirates of lymph node, bone, intervertebral disc, liver, or splenic tissue supports a diagnosis of disseminated aspergillosis. Approximately 50% of dogs with disseminated aspergillosis have positive urine cultures for *Aspergillus* spp., and around one third of dogs have positive blood or CSF cultures.[7] Isolation of *A. fumigatus* from airway washes should be interpreted more cautiously as it may represent contamination. Concurrent cytologic evidence of fungal hyphae is required for definitive diagnosis in this situation.

Once growth of mold occurs in culture, *Aspergillus* species can be identified to the complex level based on conidiophore morphology (Figure 65-10). Accurate identification to the species level requires molecular techniques such as PCR, then sequencing, which are performed by laboratories with special expertise (e.g., the Fungus Testing Laboratory at the University of Texas Health Science Center at San Antonio). Such laboratories can also perform antifungal drug susceptibility testing. However, because clinical breakpoints have not been established for dogs or cats, the relevance of minimum inhibitory concentrations for molds remains unclear.

Serologic Diagnosis

An *Aspergillus* galactomannan antigen ELISA assay (Platelia) has high sensitivity for diagnosis of disseminated aspergillosis in dogs when serum or urine specimens are tested.[36] In the author's hospital, all of 12 dogs with disseminated aspergillosis had positive test results, with galactomannan indices (GMIs) that ranged from 6.4 to 12.2 (reference range, <0.5). Two dogs with localized pulmonary disease had serum GMIs of 0.14 and 0.77, which suggests that, as for SNA, the sensitivity of this assay for diagnosis of bronchopulmonary aspergillosis may be low. High-level

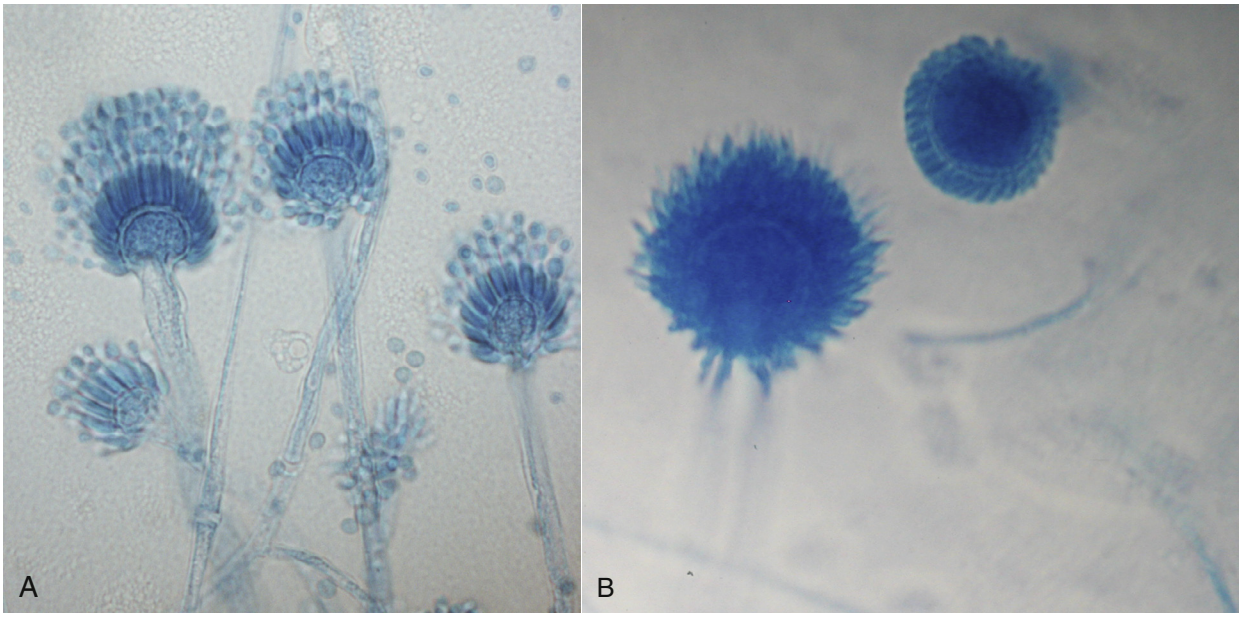

FIGURE 65-10 **A,** Morphology of *Aspergillus fumigatus*. **B,** Morphology of *Aspergillus terreus*, which has an "upswept" appearance. The conidiophore is the specialized hyphal branch that bears the conidia (spores). The vesicle is the dilated top part of the conidiophore. Phialides are flask-shaped projections from the vesicle from which the conidia arise.

false positive test results (GMIs >1.5) appear to only occur in dogs with other fungal infections, especially those caused by *Penicillium* or *Paecilomyces*, and dogs treated with Plasmalyte intravenous fluid therapy. Plasmalyte contains sodium gluconate, which is produced by fermentation in *Aspergillus niger*; carryover of small amounts of galactomannan during production of the fermentation product is thought to occur.[52] Low-level false positives (0.5-1.5) can occur in dogs infected with other fungi (such as *Cryptococcus* spp.), some dogs with nonfungal disease such as neoplasia, or some dogs treated with penicillin derivatives. In summary, a strong positive assay result in a dog with clinical abnormalities consistent with disseminated aspergillosis and no history of Plasmalyte administration within the last 72 hours supports a diagnosis of a mold infection, but fungal culture is required to confirm that *Aspergillus* is the causative agent. A negative result in a dog with disseminated disease suggests that *Aspergillus* is not the cause, but it does not rule out the possibility of infection with another mold species.

Assays that detect antibodies to *Aspergillus* species are insensitive for diagnosis of systemic aspergillosis.[7] This may reflect underlying host immunodeficiency (and hence inability to produce antibodies), or antibodies in affected dogs may not cross-react with the antigens used in the test kits. For example, one widely used gel ID assay (Meridian Bioscience) contains a purified carbohydrate preparation from mycelial phase cultures of *A. fumigatus, A. niger,* and *A. flavus,* but not *A. terreus* or *A. deflectus*.

Molecular Diagnosis Using the Polymerase Chain Reaction

Several real-time PCR assays have been developed and applied for the diagnosis of invasive aspergillosis in humans.[53,54] The sensitivity and specificity of these assays has varied.[54] To date, they have not been widely applied to diagnosis of disseminated aspergillosis in dogs.

Pathologic Findings

Gross pathologic findings in dogs with disseminated aspergillosis include enlarged and/or congested lymph nodes; multifocal, pale, tan to white masses or nodules within a variety of parenchymal organs or the pleura (Figure 65-11, *A*); evidence of discospondylitis and/or osteomyelitis; serosanguineous pleural effusion; and/or mottled and congested lung lobes. Splenic infarction is also a common finding. The renal pelvis may be dilated and contain soft, granular material. Histopathology reveals granulomatous or pyogranulomatous inflammation with abundant intralesional fungal hyphae in a variety of tissues. Some species, such as *A. terreus*, also produce accessory conidia (aleuriospores) in tissues, which may be free or extend from hyphae. Fibrinoid necrosis of blood vessels and associated hemorrhage may be present. Special stains such as Gomori's methenamine silver or periodic acid–Schiff can delineate fungal hyphae in tissues (Figure 65-11, *B*). Immunohistochemistry has also been used to identify *Aspergillus*.[55,56]

Treatment and Prognosis

Many dogs with disseminated aspergillosis have advanced disease at the time of evaluation, sometimes with respiratory distress, pathologic fractures, and vertebral subluxations and cord compression. The prognosis for these dogs is poor. In one study, 57% of 30 dogs were euthanized within a week of examination (median, 3 days).[7] However, dogs that lack severe CNS signs, pain, or respiratory distress may enter remission for months and occasionally years when treated with antifungal drugs. These dogs maintain high antigen titers or persistently positive urine cultures, and they ultimately relapse and die from the disease. Sometimes, euthanasia is performed earlier because continued treatment is unaffordable.

The relative efficacy of different antifungal drug treatment regimens for disseminated aspergillosis in dogs has not been studied prospectively. The most widely used treatments have been itraconazole, voriconazole, posaconazole, and/or amphotericin B. Terbinafine has been used in addition to azole therapy with limited success in the author's experience.[7] *Aspergillus* species are intrinsically resistant to fluconazole, so the use of fluconazole is not recommended. Although expensive, treatment with

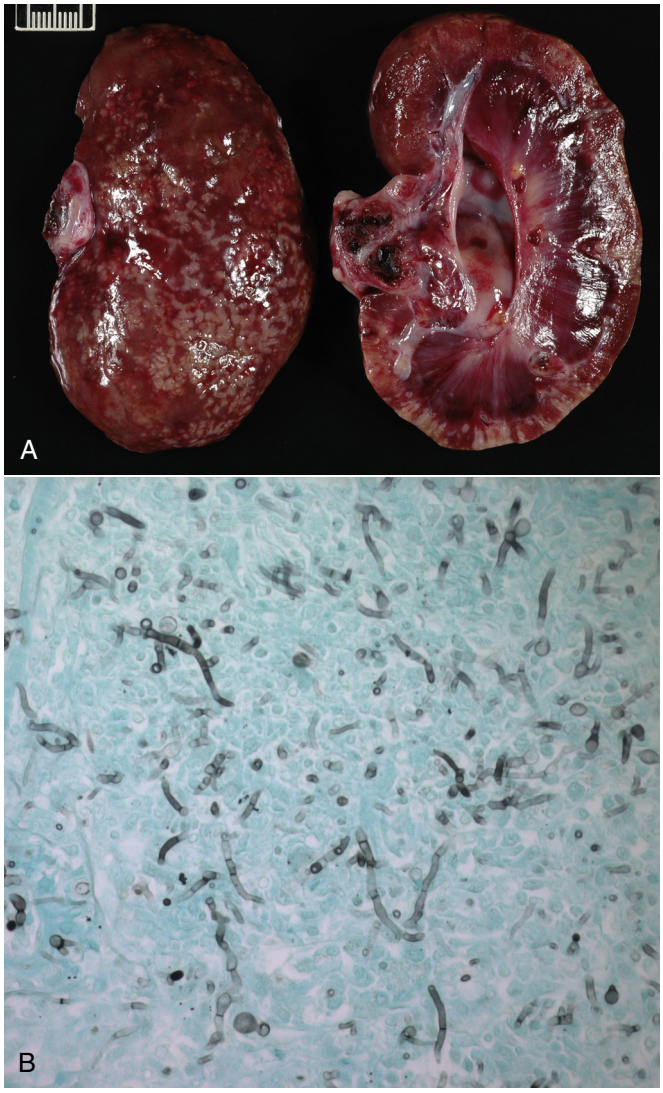

FIGURE 65-11 **A,** Kidney at necropsy from a 5-year-old female English setter with disseminated aspergillosis caused by *Aspergillus terreus*. Numerous small coalescing tan nodules are present throughout the cortex, and the capsular surface is irregular. There is a blood clot adjacent to the renal pelvis. (Image courtesy University of California, Davis, Veterinary Anatomic Pathology Service.) **B,** Histopathology from a 5-year-old male neutered German shepherd dog with disseminated *A. terreus* infection that involved multiple parenchymal organs. Large numbers of septate, branching hyphae are seen. Gomori's methenamine silver stain, 1000× oil magnification.

voriconazole or posaconazole can result in remissions of many months' duration in some dogs.[7,57] Posaconazole in particular has shown promising activity in human patient and mouse models of invasive *A. terreus* infection.[58,59] Many dogs require treatment with multiple antifungal drugs to maintain remission, either in combination or in series. *A. terreus* strains from humans with invasive aspergillosis can become resistant to azoles during treatment.[60] *A. terreus* strains isolated from human patients are also relatively resistant to amphotericin B,[59,61] but clinical improvement can still occur after treatment of infected dogs with amphotericin B (see Chapter 9).[7] Echinocandins (such as caspofungin) are also active against *Aspergillus*, but expense and the need for intravenous administration has limited their use in dogs.

Dogs with localized bronchopulmonary aspergillosis have the best prognosis. These dogs are sometimes cured after treatment with itraconazole alone. Lung lobectomy may be required for successful treatment of German shepherds with cavitary lung lesions.[7,45,46]

FIGURE 65-12 Severe ulcerative keratitis in a 12-year-old female spayed domestic shorthair caused by an *Aspergillus fumigatus* complex organism. The condition was successfully treated using topical voriconazole and a conjunctival island graft. (Courtesy the University of California, Davis, Veterinary Ophthalmology Service.)

Immunity and Vaccination

Immunity to disseminated aspergillosis is critically dependent on the function of neutrophils and dendritic cells, as well as effective T cell function.[62] A vaccine to prevent the disease is not available.

Public Health Aspects

In human patients, invasive aspergillosis primarily occurs in immunosuppressed humans with hematologic malignancy, or after solid organ transplantation or hematopoietic stem cell transplantation.[51] Infections are acquired from the environment. Transmission from affected dogs has not been described. Most cases (>70%) are caused by *A. fumigatus*. Infection with *A. terreus* is rare, and *A. deflectus* is not a recognized human pathogen.

KERATOMYCOSIS AND OTOMYCOSIS CAUSED BY *ASPERGILLUS* SPECIES

Infection of the cornea[8,63] and ear canal[9,10] by *Aspergillus* species occur rarely in dogs and cats (see Table 65-1; Figure 65-12). Diagnosis of these conditions requires visualization of hyphae on cytologic examination or histopathology of biopsy specimens in addition to fungal culture to rule out the possibility of contamination or colonization. One cat with *A. flavus* keratomycosis had a history of feline herpesvirus-1–associated conjunctivitis and keratitis[8] and was successfully treated with 1% topical voriconazole (q2h to q4h). Cats with *Aspergillus* otomycosis often have a history of diabetes mellitus.[4] Dogs with otomycosis may have a history of underlying allergic dermatitis and otitis externa that has been extensively treated with topical and oral antibiotics.[10]

VetBooks.ir

CASE EXAMPLE

Signalment: "Zach," a 2-year-old male neutered German shepherd from Roseville in northern California

History: Zach was evaluated at the University of California, Davis, Veterinary Oncology Service for possible bone cancer. Two months previously, the owners noted that Zach vocalized when he stood up from rest. He was taken to a local veterinary clinic where he was diagnosed with lumbosacral pain and treated with carprofen (1.5 mg/kg PO q12h). Two weeks later, right pelvic limb lameness developed. Pelvic radiographs showed evidence of moderate osteoarthrosis of the left coxofemoral joint. Carprofen treatment was continued. After an additional 2 weeks, lethargy, inappetence, increased thirst and urination, and left thoracic limb lameness developed, and Zach began vomiting once daily. Radiographs of the left thoracic limb revealed an osteoproductive lesion in the mid-diaphysis of the left humerus, which was interpreted as a primary or metastatic bone tumor (see Figure 65-8). Zach was one of two dogs in the household, was normally fed a dry commercial dog food diet, and was up to date on vaccinations, which included those for distemper, adenovirus, parvovirus, rabies, *Borrelia,* and *Bordetella.*

Physical Examination:

Body Weight: 33.5 kg.

General: Quiet, alert, and responsive. T = 103.4°F (39.7°C), HR = 120 beats/min, panting, CRT <2 s, mucous membranes moist and pink.

Eyes, Ears, Nose, and Throat: No clinically significant abnormalities were detected. Fundoscopic examination revealed multiple hyporeflective regions, consistent with chorioretinitis, in the right fundus.

Musculoskeletal: BCS was 4/9, and generalized muscle wasting was present. There was no evidence of lameness or bone pain on orthopedic examination.

Cardiovascular, Respiratory, Gastrointestinal, Genitourinary, and Lymph Nodes: No clinically significant abnormalities were present.

Laboratory Findings:

CBC:

HCT 32.8% (40%-55%)
MCV 65.2 fL (65-75 fL)
MCHC 35.7 g/dL (33-36 g/dL)
WBC 18,530 cells/µL (6000-13,000 cells/µL)
Neutrophils 13,768 cells/µL (3000-10,500 cells/µL)
Lymphocytes 2687 cells/µL (1000-4000 cells/µL)
Monocytes 1334 cells/µL (150-1200 cells/µL)
Eosinophils 741 cells/µL (0-1500 cells/µL)
Platelets 262,000 platelets/µL (150,000-400,000 platelets/µL).

Serum Chemistry Profile:

Sodium 152 mmol/L (145-154 mmol/L)
Potassium 3.8 mmol/L (4.1-5.3 mmol/L)
Chloride 113 mmol/L (105-116 mmol/L)
Bicarbonate 24 mmol/L (16-26 mmol/L)
Phosphorus 5.7 mg/dL (3.0-6.2 mg/dL)
Calcium 11.8 mg/dL (9.9-11.4 mg/dL)
BUN 31 mg/dL (8-21 mg/dL)
Creatinine 1.9 mg/dL (0.5-1.6 mg/dL)
Glucose 107 mg/dL (60-104 mg/dL)
Total protein 6.8 g/dL (5.4-7.4 g/dL)
Albumin 2.8 g/dL (2.9-4.2 g/dL)
Globulin 4.0 g/dL (2.3-4.4 g/dL)
ALT 15 U/L (19-67 U/L)
AST 27 U/L (21-54 U/L)
ALP 28 U/L (15-127 U/L)
GGT 2 U/L (0-6 U/L)
Cholesterol 205 mg/dL (135-345 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.4 mg/dL).

Urinalysis: SGr 1.010; pH 7.0, 1+ protein (SSA), no bilirubin, 3+ hemoprotein, no glucose, 10-15 WBC/HPF, 50-60 RBC/HPF, 0-2 transitional epithelial cells, a few amorphous crystals, and a few budding organisms were seen.

Imaging Findings:

Thoracic Radiographs: The cardiopulmonary structures were unremarkable.

Bone Survey Radiographs: Single lateral radiographs of the distal left antebrachium, distal right antebrachium, and distal left and right pelvic limbs were performed. An additional lateral radiograph of the left humerus was also obtained and compared with referral radiographs taken 1 month previously. This showed progression of a primarily osteoproductive lesion in the mid-diaphysis of the left humerus. An additional site of chronic active periosteal reaction was noted along the distal caudal aspect of the left femur. Patchy increases in medullary density were identified in the distal diaphysis of both humeri.

Abdominal Ultrasound: Hypoechoic mottling of the splenic hilus was identified. There was bilateral renal pyelectasia with echogenic material within the renal pelves bilaterally (see Figure 65-9). There was marked blunting of the renal pelves bilaterally with mild hydroureter.

Microbiologic Findings: Cytologic examination of a fine needle aspirate of lesion in left humerus: Smears were moderately cellular with a dense, proteinaceous background and moderate amounts of cellular debris. Nucleated cells consisted of a population of numerous activated macrophages and variably degenerate neutrophils that were evenly distributed throughout the smear as well as in variably sized aggregates. Numerous multinucleated giant cells were noted. Throughout the specimen were moderate numbers of small, round, yeast organisms as well as numerous fungal hyphae, which were found intracellularly and extracellularly. The fungal hyphae were negative staining, branching, and septate, often with bulging ends.

Fungal culture and susceptibility (left humerus fine needle aspirate, sent to University of Texas for molecular identification): Moderate numbers of *Aspergillus terreus.* MICs for amphotericin B, itraconazole, and voriconazole were 2, 0.125, and 0.25 µg/mL, respectively.

Aerobic urine bacterial culture: Six colonies of *A. terreus*.

Aspergillus antibody serology (gel immunodiffusion, Meridian Bioscience, Ltd.): Negative.

Diagnosis: Disseminated *Aspergillus terreus* infection.

Treatment: Zach was treated with intravenous fluids (lactated Ringer's solution with 20 mEq/L KCl at 75 mL/hr), lipid-complexed amphotericin B (1 mg/kg IV on a Monday-Wednesday-Friday basis for 4 weeks), and itraconazole (5 mg/kg PO q12h). Over the course of amphotericin B treatment, Zach's inappetence, lethargy, and lameness resolved and his serum creatinine and BUN concentrations remained stable with values of 2.1 mg/dL and 49 mg/dL,

VetBooks.ir

respectively, by the end of treatment. At a recheck 2 months after treatment was initiated, fungal culture of the urine revealed a single colony of *A. terreus*, and the creatinine was 1.7 mg/dL. After an additional month, bone survey radiographs showed significant remodeling of the left humeral and left femoral lesions. A serum biochemistry panel showed mildly increased creatinine concentration (1.8 mg/dL) and a serum ALT activity of 364 U/L; the increased serum ALT activity was thought to be secondary to itraconazole administration. Ultrasound of the abdomen showed mild pelvic dilatation, and the echogenic material within the renal pelves had disappeared. Fungal culture of the urine was negative. Four months after treatment was initiated, intermittent vocalization and right pelvic limb lameness developed. Pain was detected only on lumbosacral palpation. Radiographs of this region revealed focal osteolysis of the ventral caudal aspect of the sixth lumbar vertebra. Clinical improvement did not occur after treatment with carprofen and tramadol.

Two weeks later, Zach developed respiratory distress and was seen by the Veterinary Emergency and Critical Care Service. Mild dehydration, pyrexia (105.8°F or 41.0°C), gagging, and ptyalism were detected on physical examination. Thoracic radiographs were unremarkable, but a soft tissue density was seen in the pharyngeal region on cervical radiographs. Blood cultures were negative. Zach was sedated, and on oral examination, multiple large soft tissue masses were observed within the pharynx and around the rim of the epiglottis. Aspiration of the masses revealed suppurative inflammation and possible occasional fungal hyphae. Bronchoscopy was performed, and numerous yellow plaque-like lesions were visualized on the tracheal mucosa. Cytologic examination of biopsies of these lesions revealed fungal hyphae. The owner elected euthanasia. Necropsy findings included severe, locally extensive mural granulomas of the tracheal mucosa with intralesional fungal hyphae and suppurative and eosinophilic pharyngitis with necrosis and edema. There was evidence of healed pyelonephritis and granulomatous nephritis with intralesional fungal hyphae. Granulomatous osteomyelitis with intralesional hyphae was present in the left femur and humerus. There were multiple granulomas in the pancreas and spleen.

Comments: Disseminated aspergillosis in this dog was initially confused with bone neoplasia. An *Aspergillus* antibody titer was negative, which illustrates the lack of sensitivity of this assay for diagnosis of disseminated disease. Galactomannan antigen testing was not performed, but bone lesions were readily accessible for aspiration and culture. The small, round yeast organisms visualized together with the hyphae were likely accessory conidia, which can be found in *A. terreus* infections. Treatment with lipid-complexed amphotericin B and itraconazole was initially associated with clinical remission, but infection was not eliminated. Based on necropsy examination, the cause of the suppurative pharyngeal masses that impaired respiration was not clear. Fungal cultures of the masses were negative.

CHAPTER 66

Rhinosporidiosis

Jane E. Sykes

VetBooks.ir

Overview of Rhinosporidiosis

First Described: In the 1890s, in Argentina (by Malbran and then by Seeber)[1]

Cause: *Rhinosporidium seeberi* (kingdom Protista, class Mesomycetozoea)

Affected Hosts: Dogs, humans, horses, rarely cats and other domestic animals

Geographic Distribution: Worldwide but especially in warm, wet environments such as the south-eastern and south-central United States

Mode of Transmission: Unclear; possibly exposure to contaminated water sources in association with trauma

Major Clinical Signs: Sneezing, epistaxis, mass protruding from nares

Differential Diagnoses: Nasal neoplasia, cryptococcosis, sinonasal aspergillosis, nasal mites *(Pneumonyssoides caninum),* foreign bodies

Human Health Significance: Human infections by *R. seeberi* are likely acquired from the environment, and direct transmission from affected animals to humans has not been described.

Etiology and Epidemiology

Rhinosporidiosis is caused by *Rhinosporidium seeberi*, which causes slow-growing tumor-like masses in the nasal cavity. Although once thought to be a fungus, molecular methods have identified this organism as an aquatic protistan parasite (class Mesomycetozoea). The organism is taxonomically located where animals and fungi diverge and is closely related to pathogens of fish.[2] The organism is difficult or impossible to culture. Rhinosporidiosis has been most widely reported in humans and dogs, but cats, horses, and other mammalian and avian species may also be affected. There is some evidence that host-specific strains of *R. seeberi* exist.[3]

In humans, rhinosporidiosis is most prevalent in southern India, Sri Lanka, and Argentina but also occurs in North America, Africa, Europe, and Asia. In dogs and cats, rhinosporidiosis has been reported from many regions of the United States, Ontario in Canada,[4] Argentina,[5] Italy in continental Europe,[6] and the United Kingdom.[7] Within the United States, the disease is most often reported in dogs and cats from the south-central and southeastern states (Figure 66-1). The overwhelming majority of affected dogs are young-adult to middle-aged (with a range of 1 to 13 years of age), otherwise-healthy, large-breed hunting dogs such as Labrador and golden retrievers, Doberman pinschers, Siberian huskies, German shepherds, and Rhodesian ridgebacks. However, small-breed dogs can also be affected.[7] No clear sex predisposition has been identified, but of cases in the literature, males have outnumbered females. Affected cats have been outdoor cats. One affected cat had concurrent nasal adenocarcinoma,[8] but other cats have had no reported comorbidities.

Although the mode of transmission of *R. seeberi* is not precisely understood, disease often occurs in association with contact with aquatic or marshy environments. It is thought that spores are released into the environment, where they contact susceptible human and animal hosts.[2] Spores may be introduced into tissues after trauma to the mucous membranes, where they form sporangia that produce new spores. Because disease in humans also occurs in arid regions, airborne spore transmission has also been suggested.

Clinical Features

Signs and Their Pathogenesis

In dogs and cats, infection by *R. seeberi* leads to formation of pedunculate or sessile masses within the nasal cavity, usually in the rostral third.[6] The polyps range in size from a few millimeters to several centimeters. Clinical signs consist of subacute (weeks) to chronic (>1 year) sneezing with or without epistaxis, snuffling, and sometimes a serous, mucoid, or serosanguineous unilateral nasal discharge. Sneezing may be frequent and severe and associated with excitement or increased

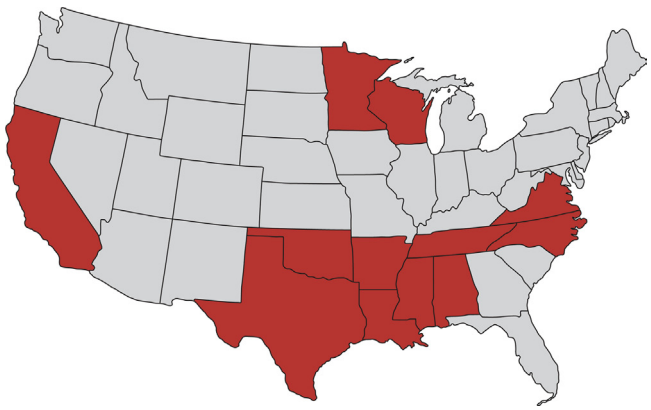

FIGURE 66-1 States within the United States in which rhinosporidiosis has been reported in dogs and cats.

FIGURE 66-2 CT scan of the nasal cavity of a 16-month-old female Labrador retriever with rhinosporidiosis. A soft tissue mass that enhanced with contrast is present in the rostral nasal cavity *(arrow)*.

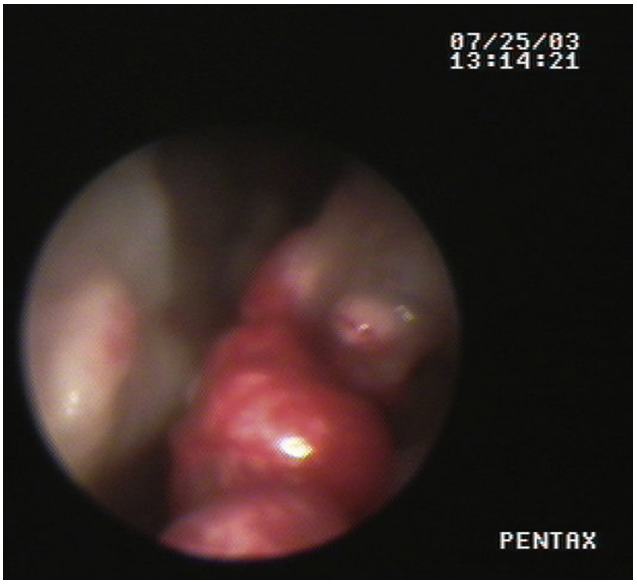

FIGURE 66-3 Rhinoscopic image of a polypoid mass caused by *Rhinosporidium seeberi* in the nasal cavity of a 10-year-old intact female yellow Labrador retriever.

activity. In some dogs, a polypoid pink mass protrudes from the nasal cavity. The masses are often stippled with white-yellowish granules less than 1 mm in diameter, which represent mature sporangia.[6]

Diagnosis

Most animals with rhinosporidiosis have no significant abnormalities on blood work. Plain radiography is insensitive for detection of nasal masses caused by *R. seeberi*.[6] Computed tomography (CT) reveals soft tissue masses in the rostral third of the nasal cavity that can enhance with contrast (Figure 66-2). In some cases evidence of turbinate loss is present. The masses, which can be visualized directly using rostral rhinoscopy, are pink to gray and may be covered with miliary white to yellow foci, but these are not always clearly visible (Figure 66-3).

Definitive diagnosis requires cytology or histopathology of the masses. Cytologic examination of smears from nasal swabs, cytology brush specimens, or impression smears made from biopsies of the polyps reveals suppurative to pyogranulomatous inflammation with dysplastic epithelial cells and numerous immature to mature *R. seeberi* endospores, which occur singly or in clusters.[9] Sometimes sporangia that contain hundreds of endospores are visualized. Mature endospores stain intensely, are round to oval and 10 to 15 µm in diameter, and have a thick cell wall (Figure 66-4). Immature endospores are 2 to 4 µm in diameter and contain a paracentral, light pink-purple structure that may represent nuclear material, as well as one to two smaller, spherical, dark purple structures.[9]

Histopathology reveals abundant sporangia in various stages of development and a mild to severe pyogranulomatous inflammatory response (Figure 66-5). Lymphocytes, plasma cells, and, in some cases, multinucleate giant cells and evidence of turbinate remodeling with activated osteoclasts and osteoblasts may be present. Juvenile sporangia are small (<100 µm in diameter) and have a single nucleus that is surrounded by fibrillar material. Mature sporangia are up to 500 µm in diameter and may

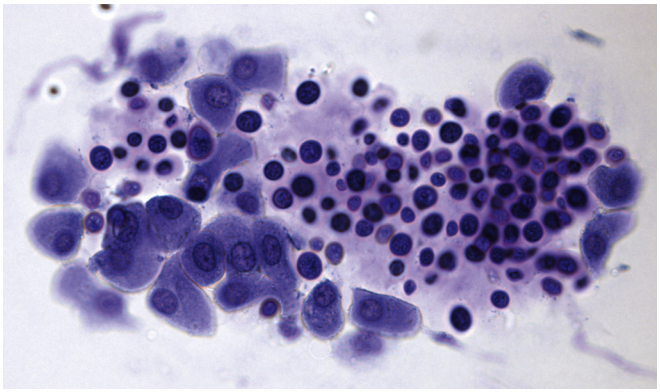

FIGURE 66-4 Impression smear of a biopsy taken from the nasal cavity of a 6-year-old female spayed Labrador retriever with rhinosporidiosis. A large cluster of endospores is present together with several epithelial cells.

be seen releasing endospores at the polyp surface through a pore in the sporangial wall. Although the organisms stain well with special stains such as periodic acid–Schiff, Gomori's methenamine silver, and Mayer's mucicarmine, these stains are usually not required for diagnosis.[6]

Treatment and Prognosis

The treatment of choice for dogs and cats is surgical removal of polyps, which generally requires rhinotomy. Because the polyps are often rostrally located, excisions can often be extended caudally from the nares. Many dogs have no recurrence of clinical signs thereafter, but some dogs develop relapse within months of surgery.[5,10,11] Treatment of these dogs can be frustrating and costly. Povidone-iodine is active against *R. seeberi* in vitro and could be applied in the form of gauze packs topically after surgery in an attempt to minimize the chance of recurrence (see Case Example).[12] In some dogs, apparent transient or long-term responses to treatment with ketoconazole[7,13] or dapsone (1.1 mg/kg PO q8-12h)[11]

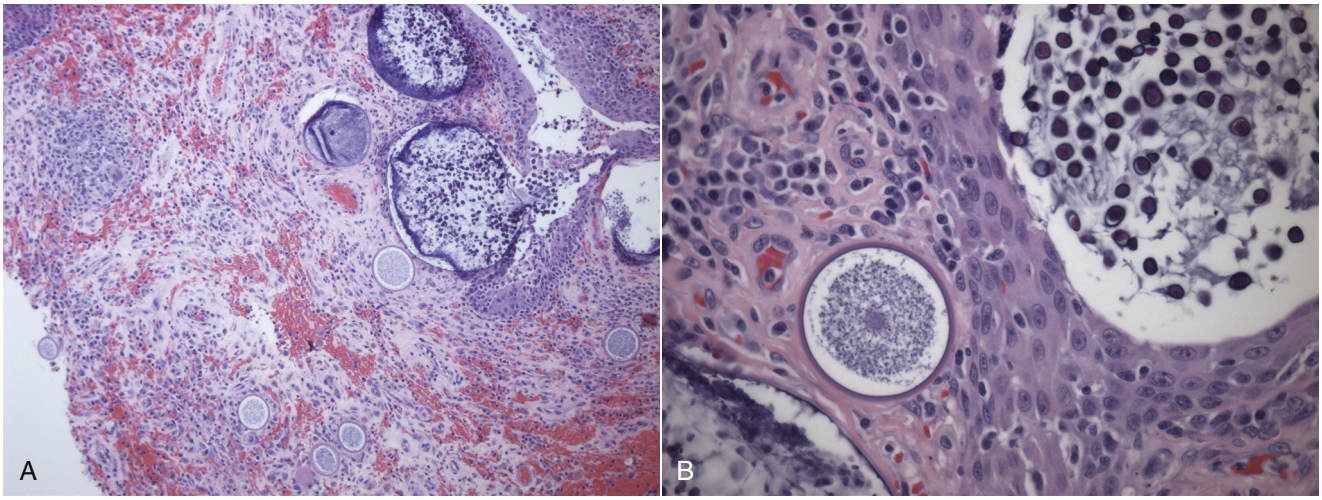

FIGURE 66-5 Histopathology of a polyp caused by *Rhinosporidium seeberi*. **A,** Low-power image that shows sporangia in various stages of development. **B,** High-power image (1000× oil magnification) that shows a juvenile sporangium adjacent to a mature sporangium, which contains endospores *(right)*. H&E stain.

have been described. Responses to dapsone have also been described in human patients. Dapsone could be used to treat dogs with refractory disease, but because both dapsone and ketoconazole can have significant adverse effects, careful monitoring is required. Dapsone is a sulfur drug (diaminophenyl sulfone) that can cause bone marrow suppression in dogs[14] and has the potential to cause hepatotoxicity and cutaneous drug reactions. Treatment of cats with dapsone is not recommended because of a high prevalence of adverse effects in this species, specifically neurotoxicosis and anemia.

Public Health Aspects

In humans, rhinosporidiosis usually involves the nasal cavity or nasopharynx, but involvement of the conjunctiva, genitalia, or skin can occur.[15] Rarely, cutaneous disease is disseminated. Disease is most often reported in males. Infection is likely acquired from the environment, and transmission from animals to humans has not been described. It is possible that strains of *R. seeberi* that infect humans may differ from those that infect dogs.

CASE EXAMPLE

Signalment: "Sarah," a 16-month-old intact female Labrador retriever from the central valley of northern California

History: Sarah was evaluated by her local veterinary clinic for a 1-month history of sneezing, which occurred throughout the day and was more frequent and severe during periods of excitement. The owners had not observed nasal discharge, and they were concerned about the possibility of a foreign body. A limited rhinoscopic examination with an otoscope cone at the local veterinary clinic revealed a large, fleshy, irregular mass in the dorsal meatus near the nares. Histopathology on a biopsy of the mass yielded a diagnosis of rhinosporidiosis, and Sarah was referred to the University of California, Davis, Veterinary Medical Teaching Hospital for further evaluation and treatment.

Sarah had been obtained from a breeder in Oregon as a puppy and since then had been a duck hunting dog in California. During the hunting season, she waded and swam in stagnant and fresh water sources. The owners also had ponds in their backyard. She was otherwise healthy and was fed a dry commercial dog food diet.

Physical Examination:

Body Weight: 32.2 kg.

General: Excited, alert, responsive, and hydrated. T = 101.6°F (38.7°C), HR = 140 beats/min, panting, CRT <2 s, mucous membranes moist and pink.

Eyes, Ears, Nose, and Throat: The dog's face was symmetrical with no pain on palpation, and normal ocular retropulsion. There was no evidence of nasal discharge. Nasal airflow was absent on the right side. Minimal dental calculus was present. There were no other clinically significant findings.

Musculoskeletal: BCS 4/9. Adequate musculature, normal gait.

Cardiovascular, Respiratory, Gastrointestinal, Genitourinary, and Lymph Nodes: No clinically significant abnormalities were detected.

Laboratory Findings: Preanesthetic laboratory assessment: PCV 44%, total solids 6.6 g/dL. Serum urea nitrogen was estimated at 15-26 mg/dL with a reagent strip.

Imaging Findings: Computed tomography of the head: A round, 0.9 × 1.7 × 2.3 cm, soft tissue mass was present in the rostral, dorsal right nasal cavity extending from the level of the incisors to the root of the right maxillary canine tooth. The mass was moderately and heterogeneously contrast enhancing. The superficial soft tissues overlying the mass

Continued

VetBooks.ir

were thickened and contrast enhancing. The remainder of the nasal cavities and sinuses appeared within normal limits. The mandibular and medial retropharyngeal lymph nodes appeared within normal limits.

Diagnosis: Nasal rhinosporidiosis.

Treatment: A rhinotomy was performed using an anterolateral approach, and a single 1.5 cm × 0.5 cm pedunculated mass was identified attached to the mucosal layer of the nasal septum. The mass was resected with sharp dissection and diathermy. A povidone-iodine–soaked gauze pad was placed on the site of resection for 7 minutes, and the nasal vestibule was packed with an iodine-soaked gauze pad for 1 hour after surgical closure. Histopathology of the resected mass confirmed the diagnosis of nasal rhinosporidiosis. The dog was discharged with instructions to administer tramadol (3 mg/kg PO q12h) for pain relief and dapsone (0.8 mg/kg PO q8h for 2 weeks, then 0.8 mg/kg PO q12h for 3 months). At a recheck 2 weeks later, the sneezing had reduced in frequency, but vomiting was reported every 2 days approximately 2 hours after the morning dose of dapsone. A CBC and biochemistry panel were unremarkable. The frequency of dapsone administration was reduced to twice daily. Subsequently Sarah did well with no recurrence of disease or adverse effects of medication.

Comments: In this dog, topical povidone-iodine and dapsone were used after rhinotomy in an attempt to prevent recurrence. The owners were warned about the possibility of reinfection if Sarah continued her hunting activities.

CHAPTER 67

Candidiasis

Jane E. Sykes

VetBooks.ir

Overview of Candidiasis

First Described: The etiology of candidiasis as a fungus was recognized in Stockholm around 1840 (Fredrik Berg),[1] but the disease was described as far back as around 400 BC by Hippocrates.

Cause: *Candida* spp. (an ascomycete)

Affected Hosts: Dogs, cats, humans, and a variety of other animal species

Geographic Distribution: Worldwide

Mode of Transmission: Usually invasion of commensal yeasts secondary to immune suppression

Major Clinical Signs: Local dermatitis; otitis externa; keratitis; lower urinary tract signs; abdominal pain, icterus, and/or ascites due to peritonitis; or severe systemic infections with fever, inappetence, ocular inflammation, lameness due to osteomyelitis, respiratory distress, vomiting

Differential Diagnoses: Other systemic fungal or bacterial infections

Human Health Significance: Human infections by *Candida* species result from invasion by normal flora, but human-to-human transmission of *Candida* strains can also occur. Whether resistant *Candida* species can be transferred from animals to colonize humans or vice versa is not known.

Etiology and Epidemiology

Candida species are yeasts that are typically benign counterparts of the normal gastrointestinal, urogenital, and cutaneous flora but can invade tissues and cause disease as a result of disruption of normal host defenses. *Candida* species can also be isolated from soil, inanimate objects, and hospital environments. The yeasts are small (3 to 6 µm) and ovoid (blastospores) and reproduce by budding. Budding results in the formation of new yeast cells, pseudohyphae (chains of elongated yeast cells), and true septate hyphae. Disease syndromes caused by *Candida* species that occur in dogs and cats are listed in Box 67-1. More than 200 species of *Candida* exist, but only a few species have been identified as pathogens in dogs and cats (Table 67-1[2-10]). The most commonly isolated species is *Candida albicans*, and only *C. albicans* appears to cause disseminated disease in dogs and cats. Local or disseminated infections where *Candida* is present with a mixture of bacterial species can occur. Local infections (such as UTIs) with two different *Candida* species have also been reported.[2,11]

BOX 67-1

Disease Syndromes Caused by *Candida* in Dogs and Cats

Keratitis
Cutaneous candidiasis
Otitis externa and otitis media
Urinary tract infections
Gastrointestinal candidiasis
Peritonitis
Disseminated infections

When compared with human patients, candidiasis is uncommonly described in dogs and cats. Predisposing factors in dogs or cats with local or disseminated candidiasis have included diabetes mellitus,[2,3,12] treatment with immunosuppressive drugs or broad-spectrum antibacterial drugs,[2,13] a history of gastrointestinal surgery,[4,5] parvoviral infections,[14-16] and/or underlying malignancy.[2,17] Often more than one of these factors is in the history. Disseminated candidiasis has most often been described in dogs, but also occurs in cats.[5,18] Although most animals have underlying immunocompromising conditions, disseminated candidiasis has been described in apparently immunocompetent animals,[19,20] which may reflect an unidentified underlying genetic immunodeficiency. Cats with candidiasis usually test negative for FeLV or FIV infection.

Analysis of the author's hospital population suggests that cats are at least as likely as dogs to develop *Candida* UTIs.[11] In other studies, *Candida* species were isolated from the urine of 0.2% of more than 8000 dogs with UTIs[21] and 0.2% of more than 2000 dogs with persistent or recurrent UTIs.[22] Urethrostomy or indwelling cystostomy tube placement may be in the history of some cats and dogs with *Candida* UTIs, respectively.[2,6] Local mucocutaneous infections can occur at the site of long-term placement of feeding tubes.[7]

Clinical Features

Signs and Their Pathogenesis

Disruption of normal barriers is necessary to allow *Candida* spp. to invade the host. Concurrent use of broad-spectrum antibiotics suppresses the normal bacterial flora and allows *Candida* to proliferate, which increases the risk that organisms will be introduced into tissues. *Candida* can adhere to a variety of tissue components such as epithelial and endothelial cells, fibronectin, and

VetBooks.ir

thrombi, as well as other bacteria and inanimate objects such as catheters.[23] The yeasts can also form biofilms on medical devices and produce a huge variety of hydrolytic enzymes. Within tissues, neutrophils are a key defense against *Candida*.[24] *Candida* blastospores are phagocytized and destroyed by neutrophils. Mononuclear cells play a less important role. Reactive oxygen species, hydrolytic enzymes, and antimicrobial peptides contribute to the intracellular destruction of blastospores by neutrophils. Thus, any condition that impairs neutrophil numbers or function, such as neutropenia or diabetes mellitus, predisposes dogs and cats to candidiasis. A large number of other cytokines, complement, dendritic cells, and lymphocytes are also involved in the immune response to *Candida*.[24] The formation of hyphae by *Candida* promotes tissue invasion, which may be followed by life-threatening fungemia and dissemination to multiple organs. This ability of *Candida* to change its morphology ("morphologic dimorphism") is thought to be an important virulence factor.

Lower urinary tract candidiasis may be subclinical or associated with dysuria, stranguria, and/or hematuria. Systemic signs of pyrexia, lethargy, inappetence, and weight loss have also been described in affected dogs and cats,[6] but these signs may result from the presence of other predisposing diseases. Ascending infections may lead to development of *Candida* pyelonephritis.

Cutaneous candidiasis may manifest as erythema, scaling, alopecia, erosions, and crusting, often where disruption of cutaneous or mucocutaneous regions has occurred (such as a previous surgical site or a feeding tube or cystotomy stoma). Persistent disease in the face of systemic or topical treatment with broad-spectrum antibiotics should raise suspicion for candidiasis. Dogs with *Candida* otitis externa often have a history of chronic bacterial otitis externa that has been treated aggressively with systemic or topical antibacterials.

Overgrowth of *Candida* in the gastrointestinal tract may occur in animals that are immunosuppressed or treated with glucocorticoids and/or broad-spectrum antibacterial drugs. In some cases, invasion of the mucosa into the lamina propria or deeper tissues occurs (e.g., intestinal candidiasis). Intestinal candidiasis is occasionally identified at necropsy in puppies that die after treatment for parvoviral enteritis and may be a reason for persistent vomiting, diarrhea, and death despite aggressive fluid and antibacterial drug therapy.[14] *Candida* spp. may also contribute to ulcerative glossitis in puppies with parvovirus infection (Figure 67-1).

TABLE 67-1

***Candida* Species Associated with Disease in Dogs and/or Cats [2-10]**

Species	Clinical Manifestations
Candida albicans	Dermatitis, UTI, otitis externa, keratitis, disseminated infections
Candida glabrata (formerly *Torulopsis glabrata*)	UTI, feeding-tube site infections
Candida krusei	UTI, feeding tube site infections
Candida guilliermondii	UTI, dermatitis
Candida parapsilosis	UTI, otitis, dermatitis
Candida tropicalis	UTI
Candida rugosa	UTI

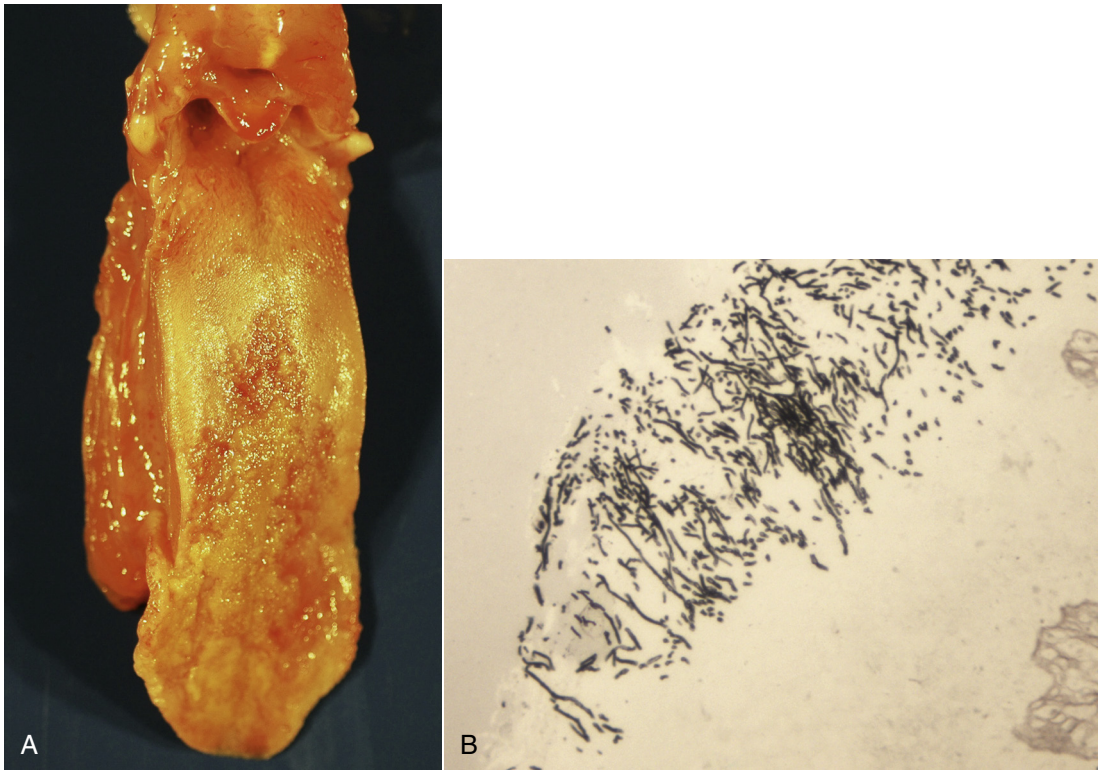

FIGURE 67-1 **A,** Tongue ulcerations at necropsy in a 2-month-old mixed-breed puppy that was euthanized because of canine parvoviral infection. **B,** Histopathology revealed multifocal ulcerative glossitis, pharyngitis, and esophagitis with intralesional yeasts and pseudohyphae. Gomori's methenamine silver stain. (Image courtesy University of California Davis Anatomic Pathology Service.)

Candida peritonitis can follow intestinal surgery, treatment with broad-spectrum antibacterial drugs, and subsequent enterotomy site dehiscence.[4,5] Mixed infections with *Candida* and intestinal flora may develop. Affected dogs are febrile, have abdominal pain, and may have other gastrointestinal signs such as vomiting and diarrhea.

Disseminated candidiasis results from hematogenous spread of *Candida* from intestinal, urinary, or possibly corneal or cutaneous sites.[12,15,25]A diagnosis of disseminated candidiasis should be considered whenever *Candida* infections are identified in the eye, skin, or urinary tract of an animal that has (or subsequently develops) severe systemic illness. Clinical signs of disseminated candidiasis in dogs include fever, inappetence, anorexia, weight loss, and a variety of other clinical signs that reflect underlying immunosuppressive disease processes and specific organs involved. The latter can include the pancreas, liver, mesentery, spleen, kidneys, heart, lungs, lymph nodes, and, less often, the bone, intestinal tract, eyes, meninges, thyroid, and/or prostate gland.[3,12,15,17,20,25-28] Ocular signs in animals with disseminated disease include keratitis and corneal ulceration, uveitis, chorioretinitis, and endophthalmitis.[11,12,28] *Candida* keratitis may also occur as a localized process, sometimes secondary to aggressive treatment of corneal ulceration secondary to other disease processes with topical broad-spectrum antibacterial drugs. Thromboembolic disease may complicate disseminated infections. Pulmonary thromboembolism may result in respiratory distress and death.[3,11]

Diagnosis

Laboratory Abnormalities

Laboratory abnormalities in dogs and cats with candidiasis result from the underlying disease process (such as diabetes mellitus or systemic neoplastic disease) as well as the location and severity of the fungal infection. Laboratory abnormalities in dogs or cats with *Candida* UTIs may be absent, or there may be evidence of renal failure with azotemia and isosthenuria. Grossly, urine may contain flocculent white debris. Urinalysis may reveal proteinuria, pyuria, and, in some cases, hematuria and/or *Candida* fungal elements (see Case Example). Dogs and cats with disseminated candidiasis or *Candida* peritonitis frequently have had nonregenerative anemia and mild to marked neutrophilia with bandemia and toxic neutrophil changes (in contrast to other deep mycoses, where hematologic abnormalities are often mild or absent). Lymphopenia may be present as a result of underlying immunosuppressive illness or drug therapy. Some dogs are thrombocytopenic and have coagulation abnormalities consistent with disseminated intravascular coagulation.[3] Findings on the serum biochemistry panel in dogs with disseminated candidiasis are variable and nonspecific but may include metabolic acidosis, moderate to severe hypoalbuminemia, and increased liver enzyme activities.

Diagnostic Imaging

Plain thoracic radiographs in dogs with disseminated candidiasis may be unremarkable or show increased pulmonary interstitial opacity, thoracic lymphadenomegaly, and/or pleural or pericardial effusion.[13,5,20] Abdominal ultrasound examination in dogs with *Candida* peritonitis or disseminated disease may reveal echogenic ascites fluid, mesenteric hyperechogenicity, changes consistent with pancreatitis, abdominal lymphadenomegaly, or increased echogenicity of the renal cortices or hepatic parenchyma.

Microbiologic Tests

Definitive diagnosis of candidiasis requires visualization of the organism within lesions by cytologic or histopathologic examination and confirmation of its identity using culture.

Cytologic Examination

Candida blastospores, pseudohyphae, and true hyphae can be visualized in swab specimens from the ear canal (ear cytology); tape preparations from the skin; urine sediment or other body fluids (Figure 67-2); or ultrasound-guided aspirates of abdominal lesions.

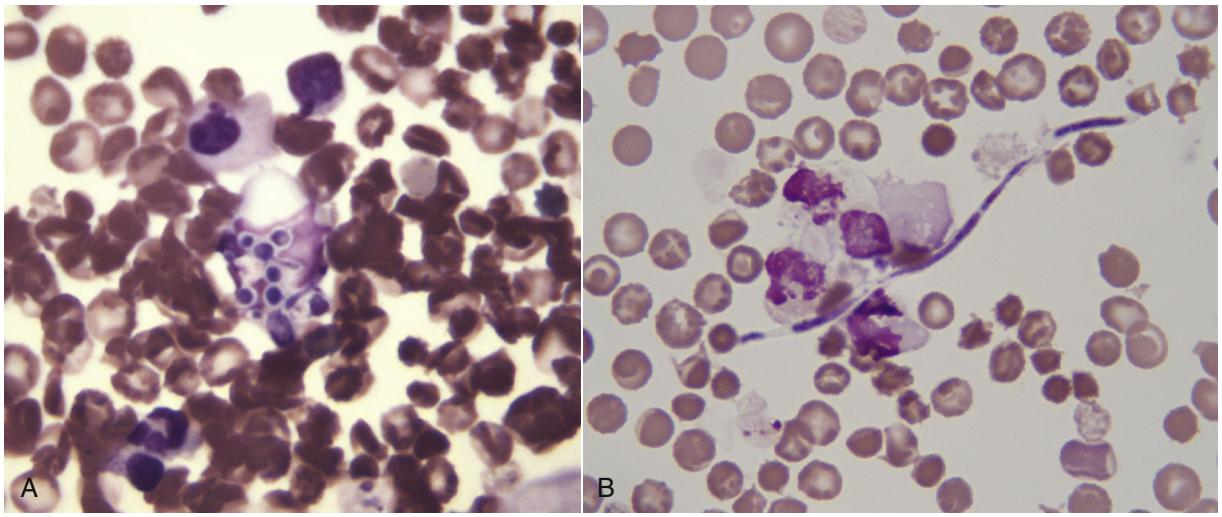

FIGURE 67-2 *Candida albicans* within urine sediment from a 5-year-old female spayed Labrador retriever being treated for multicentric lymphoma and acute-onset hematuria. Both budding **(A)** and filamentous **(B)** fungal elements are visible. (Image courtesy Dr. Barrak Pressler, The Ohio State University. From Bartges J, Polzin D. Nephrology and Urology of Small Animals. John Wiley and Sons, 2011.)

VetBooks.ir

Fungal Culture

Candida grows on routine bacteriologic media as well as fungal media such as Sabouraud dextrose agar. Creamy white colonies appear within 2 to 3 days, and so isolation of the yeast may be reported when it is present in specimens submitted for aerobic bacterial culture, which are typically incubated only for this period of time. If *Candida* is suspected based on the history, fungal culture (rather than bacterial culture alone) should be requested because *Candida* grows best on fungal isolation media. Because *Candida* can be isolated from the skin and mucous membranes of healthy dogs and cats, infection must be confirmed with cytology or histopathology when *Candida* is isolated from these sites.

Identification of *Candida* isolates is based on morphology and biochemical reactions. Preliminary differentiation of *C. albicans* from other *Candida* species can be made based on the ability of *C. albicans* to produce germ tubes when exposed to serum. Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry (see Chapter 3) accurately and rapidly identifies *Candida* species[29] and may replace these methods in the future. Isolation of *Candida* allows not only definitive identification but also antifungal susceptibility testing (see Figure 4-8). This is important for *Candida* because some isolates (especially *C. glabrata* and *C. krusei*) can exhibit antifungal drug resistance.

Pathologic Findings

Gross pathologic findings at necropsy in animals with disseminated candidiasis include peritoneal or pleural effusion, enlarged and edematous lymph nodes, congestion and necrotic whitish foci within affected organs, evidence of tissue thrombosis, and formation of a gray-white or yellow-green fibrinonecrotic layer on affected mucosal surfaces.[3,5,14,15,20,26] Concurrent underlying disease processes are also often identified.

Histopathology of affected tissues reveals yeasts, pseudohyphae, and septate hyphae with an associated inflammatory response that is composed primarily of neutrophils, macrophages, and lymphocytes. Multinucleated giant cells may also be present.[15,20,26] Pseudohyphae and hyphae predominate in invasive infections (see Figure 4-1). Evidence of blood vessel invasion, thrombosing vasculitis, and infarction may be seen, with multifocal mycotic granulomas in affected organs.[15] The organism is most readily visualized with special stains such as periodic acid–Schiff and Gomori's methenamine silver. Immunohistochemistry has also been used to identify *Candida* within lesions.[15,20] When mixed infections with *Candida* and other bacteria are present, tissue gram stains may reveal bacterial rods and/or cocci in addition to gram-positive fungal elements.

Treatment and Prognosis

Treatment of candidiasis should involve management of underlying immunosuppressive disorders, if possible, and specific antifungal drug treatment. Systemic antibacterial drugs should be discontinued if not clearly indicated, or the spectrum of activity should be narrowed as much as possible. Cutaneous and corneal infections are usually treated with a combination of topical antiseptics or antifungal medications and systemic antifungal drugs until lesions resolve.[8]

Dogs and cats with *Candida* UTIs should initially be treated with antifungal drugs that achieve high concentrations in the urine, such as fluconazole with or without 5-flucytosine. Systemic antifungals alone may be adequate to resolve *Candida* UTIs in some animals, although resolution has been reported in some animals in the absence of antifungal drug therapy.[2] Persistent infection may result from drug resistance, adverse effects of treatment that necessitate treatment discontinuation, or inadequate drug penetration into balls of fungus that line the bladder wall (see Case Example). Intravesicular treatment with 1% clotrimazole may be effective in these cases.[30,31] Under anesthesia, the bladder is catheterized with a Foley catheter, emptied, then lavaged with sterile saline. The bladder is then filled with 1% clotrimazole solution (e.g., 30 to 50 mL for a cat). The animal is rotated to promote contact of the solution with the uroepithelium, and after the solution has been in the bladder for an hour, the catheter is removed and the animal is allowed to recover. Treatment is continued weekly until *Candida* can no longer be isolated from the urine. Typically one to four treatments are required.[11,30] Ultrasound-guided administration of clotrimazole via cystocentesis to a dog with *Candida* cystitis was described in one report.[31]

Successful treatment of systemic candidiasis in dogs or cats is rarely described. One dog with *Candida* peritonitis was treated successfully by surgical exploration and lavage of the abdomen, placement of an abdominal drain, and intravenous fluconazole.[4] In addition, aggressive supportive measures were required that included intravenous fluid therapy, fresh frozen plasma, antiemetics, gastroprotectants, total parenteral nutrition, and antibacterial drugs for a suspected catheter-related infection. Antifungal drugs other than fluconazole used to treat invasive candidiasis in human patients include amphotericin B or an echinocandin such as caspofungin,[32] both of which must be administered parenterally.

Prevention

Prevention of candidiasis involves avoidance of excessive immunosuppression as well as discriminate use of antibacterial drugs, which should be tailored to the results of culture and susceptibility whenever possible. Whether *Candida* species carried on the hands of humans can colonize dogs and cats is not known, but routine hand washing and the wearing of gloves when immunosuppressed animals are handled or intravascular devices are placed should minimize the chance of health care–associated infections. Although prophylactic antifungal drug treatment has been used to prevent invasive candidiasis in human high-risk groups, the low incidence of candidiasis in immunosuppressed dogs and cats does not warrant the use of prophylactic antifungal drugs in this group.

Public Health Aspects

Candida species (especially *C. albicans*) are common causes of mucosal disease in humans. Since 2000, *Candida* has also emerged as an extremely important cause of invasive infections owing to the more widespread use of invasive medical devices and immunosuppressive drugs. In hospitalized human patients, *Candida* is reportedly the fourth most common organism isolated from the bloodstream.[33] Although many human infections result from invasion of tissues by commensal yeasts in the face of immune suppression, horizontal transmission of *Candida* and hospital-acquired infections have been described.[34] Whether *Candida* isolates from dogs or cats colonize humans is not known.

CASE EXAMPLE

Signalment: "Lizzie", an 18-year-old female spayed domestic shorthair from the San Francisco Bay area (Figure 67-3, *A*)

History: Lizzie was evaluated by the University of California, Davis, Veterinary Medical Teaching Hospital for a 12-hour history of dysuria and hematuria. The owner described multiple episodes of urination and defecation outside the litter box with stranguria, hematuria, and tenesmus. Lizzie was also observed repeatedly grooming her perineum. The cat had been diagnosed with diabetes mellitus 10 years previously, and more recently with feline bronchial disease, a thoracolumbar (T3 to L3) myelopathy, generalized osteoarthritis, chronic constipation, bilateral cataracts, chronic kidney disease, and recurrent bacterial UTIs (*Streptococcus bovis* group, *Escherichia coli, Enterococcus faecalis,* then *Aerococcus viridans*). She also had a cardiac murmur secondary to dynamic right ventricular outflow tract obstruction. The historical UTIs had been treated with a variety of antimicrobial drugs selected based on the results of aerobic bacterial urine culture and susceptibility (most recently doxycycline, but also amoxicillin-clavulanic acid or marbofloxacin in the past). Her current medications consisted of prozinc insulin (3.5 units SC q12h), lactulose (2 mL PO q12h), a soluble fiber supplement (1 teaspoon with food twice daily), inhaled fluticasone (110-µg puff q12h), theophylline (12 mg/kg PO q24h), and doxycycline (5 mg/kg PO q12h). Her most recent blood work (collected 1 month previously) showed a creatinine of 1.8 mg/dL (reference range, 1.1-2.2 mg/dL) and a BUN of 34 (reference range, 18-33 mg/dL), which were similar to values obtained over the course of the previous 5 years. She was an indoor-only cat and was fed a commercial cat food with occasional turkey meat from the delicatessen. Her appetite was good, there had been no weight loss noted, her water consumption was unchanged, and there had been no vomiting or diarrhea. She had not been vaccinated for the past 4 years but was on regular flea preventative medication (nitenpyram as well as fipronil).

Physical Examination:

Body Weight: 4.1 kg.

General: Quiet, alert and responsive, T = 100.5°F (38.1°C), HR = 170 beats/min, RR = 28 breaths/min, CRT <1 s, pale pink mucous membranes.

Integument: A dull, slightly unkempt haircoat with mild scale was noted.

Eyes, Ears, Nose, and Throat: Immature cataracts were present bilaterally, and all teeth were absent on examination of the oral cavity. No other clinically significant abnormalities were detected.

Musculoskeletal: BCS was 4/9, and there was mild generalized muscle atrophy. The cat was reluctant to ambulate, and appeared painful on manipulation of the elbows, stifles, and coxofemoral joints bilaterally. Crepitus was detected on manipulation of the tarsus.

Cardiovascular and Respiratory Systems: A grade II/VI left parasternal heart murmur was auscultated. Pulses were strong and synchronous. No other abnormalities were detected.

Abdominal Palpation: The abdomen was soft and nonpainful. Both kidneys were small (approximately 2 cm in diameter) and irregular. The urinary bladder was approximately 5 cm in diameter and soft. Severe erythema was noted around the vulva.

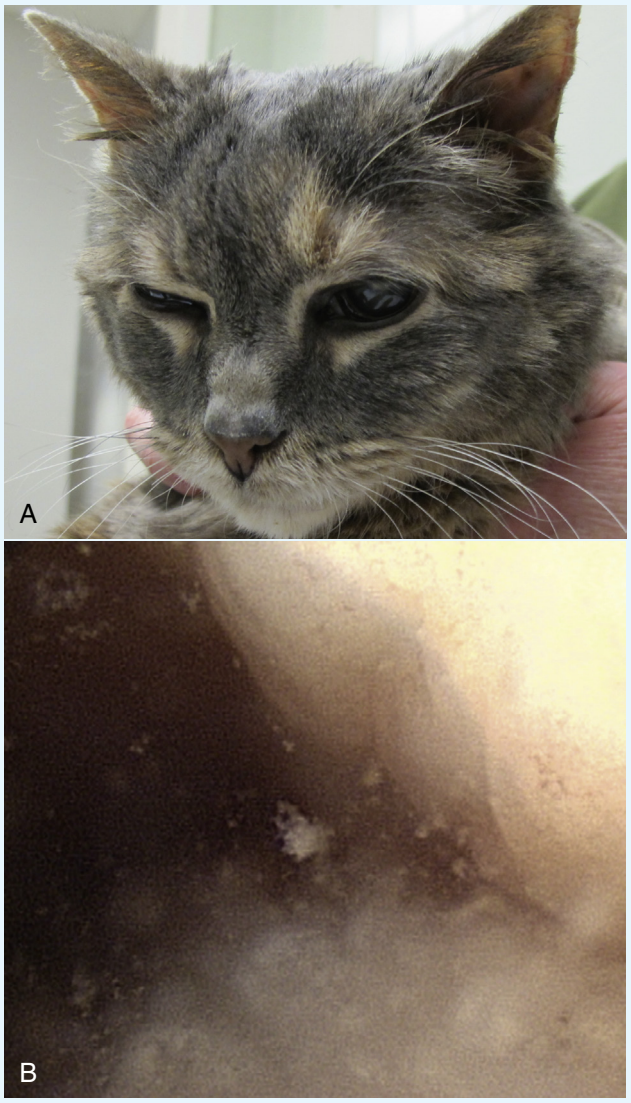

FIGURE 67-3 **A,** 18-year-old female spayed domestic shorthair with a *Candida albicans* urinary tract infection, as well as diabetes mellitus, feline bronchial disease, a myelopathy, and generalized osteoarthritis. **B,** Bladder lumen as viewed by cystoscopy. The urine contains large amounts of fluffy white debris that was loosely adherent to the bladder wall.

Lymph Nodes: All were <1 cm in diameter.

Laboratory Findings: Urinalysis: SGr 1.030; pH 6.0, 75 mg/dL protein, 1000 mg/dL glucose, no ketones or bilirubin, 250 erythrocytes/µL hemoprotein, >100 WBC/HPF, >100 RBC/HPF, few transitional and squamous epithelial cells, many budding yeast organisms

Microbiologic Testing: Aerobic bacterial urine culture: 10^5 organisms/mL *Candida albicans* were cultured.

Yeast antifungal drug susceptibility panel: Susceptible to 5-flucytosine (0.5 µg/mL), caspofungin (0.25 µg/mL), fluconazole (0.25 µg/mL), itraconazole (0.06 µg/mL), voriconazole (0.015 µg/mL). Minimum inhibitory concentrations for amphotericin B and posaconazole were 0.5 µg/mL

Continued

VetBooks.ir

and 0.03 µg/mL, respectively (no interpretative criteria available).

Diagnosis: Susceptible *C. albicans* UTI.

Treatment: Lizzie was treated with fluconazole (50 mg PO q12h). At a recheck examination 10 days later, the owner reported ongoing pollakiuria and incontinence. A fungal urine culture again revealed 10^5 *C. albicans*/mL with a similar susceptibility profile. Addition of flucytosine was recommended (250 mg PO q8h) but was considered unaffordable to the owners. Treatment was continued for another month with little clinical improvement and persistence of infection. A blood glucose curve revealed two-hourly blood glucose concentrations that were "high", 470, 368, 300, 383, and 423 mg/dL, respectively, so the insulin dose was increased to 4 U q12h. Two weeks later the owner described some improvement in the urinary incontinence and reduction in stranguria, but again 10^5 *C. albicans*/mL was cultured from the urine, and persistent urine scalding was noted around the perineum and on the pelvic limbs on physical examination. Body weight was 3.8 kg, and a blood glucose curve revealed two-hourly blood glucose concentrations that were 457, 301, 209, 227, 300, and 296 mg/dL, respectively.

Topical treatment with clotrimazole was elected. Before the procedure was performed, a preanesthetic evaluation was done. A CBC showed a normocytic, normochromic, nonregenerative anemia (HCT 28.3%; RR, 30%-50%), mature neutrophilia (15,206 cells/µL; RR, 2000-9000 cells/µL), lymphopenia (919 cells/µL; 1000-7000 cells/µL), and monocytopenia (33 cells/µL; 50-600 cells/µL). A serum biochemistry profile was unremarkable with the exceptions of a BUN concentration of 49 mg/dL (18-33 mg/dL) and a glucose concentration of 314 mg/dL (63-118 mg/dL). Urinalysis showed a specific gravity of 1.022; pH 6.0, 25 mg/dL protein, 1000 mg/dL glucose, 0-2 WBC/HPF, 0-2 RBC/HPF, and moderate numbers of budding yeast organisms and fungal structures. Thoracic radiographs revealed mild cardiomegaly and a diffuse, static bronchial pattern consistent with the previous diagnosis of feline bronchial disease. Abdominal ultrasound findings included an enlarged and hyperechoic liver, mild diffuse thickening of the gastrointestinal mucosa and submucosa, decreased renal corticomedullary distinction bilaterally with thickening of the renal cortices, a markedly thickened and irregular urinary bladder wall that contained hypoechoic, ill-defined nodules, and thick sediment within the urinary bladder lumen. Cystoscopy revealed a large amount of white, fluffy debris adherent to an edematous bladder wall as well as in the lumen (Figure 67-3, *B*). A 10F Foley catheter was placed over a 0.025-inch guidewire. The bladder was flushed and the majority of the debris removed. A total of 47 mL of 1% clotrimazole solution was infused into the bladder, and the solution was allowed to remain in place for 1 hour. The solution was removed and Lizzie was allowed to recover from anesthesia. Treatment with fluconazole was continued, although the dose was lowered (25 mg PO q12h). At a recheck 2 weeks later, the owners reported that Lizzie was more active and was no longer pollakiuric, although she still urinated outside the litter box and intermittent vomiting had been noted. A CBC, biochemistry panel, and urinalysis revealed nonregenerative anemia (HCT 21.2%); lymphopenia (349 cells/µL); monocytopenia (70 cells/µL); increased activities of serum ALT (1028 U/L; RR, 27-101 U/L), AST (226 U/L; RR, 17-58 U/L), and ALP (223 U/L; RR, 14-17 U/L); hypercholesterolemia (324 U/L; RR, 89-258 U/L); and hyperbilirubinemia (0.7 mg/dL; RR, 0-0.2 mg/dL). Aerobic bacterial urine culture revealed more than 10^5 CFU/mL of hemolytic *E. coli*, and fungal culture of the urine was negative. The fluconazole was discontinued, after which the vomiting ceased and liver enzyme activities returned to reference ranges. Multiple bacterial UTIs were diagnosed over the following 6 months, but *Candida* was never again isolated from the urine.

Comments: In this cat, the *C. albicans* UTI may have occurred secondary to a combination of factors that likely included poorly controlled diabetes mellitus, chronic kidney disease, neurologic disease, and repeated treatment with broad-spectrum antimicrobial drugs. Systemic antifungal drug treatment and improved control of diabetes mellitus were initially used as treatment strategies but failed, probably because of the large mats of fungus that were adherent to the bladder wall. Fortunately, a single topical clotrimazole treatment resulted in resolution of the yeast infection. The hepatopathy that developed was thought to be secondary to fluconazole toxicity, since it resolved when the drug was discontinued.

CHAPTER 68

Miscellaneous Fungal Diseases

Amy M. Grooters

VetBooks.ir

In contrast to the well-recognized fungal pathogens that cause endemic mycoses (such as *Blastomyces*, *Histoplasma*, and *Cryptococcus*), miscellaneous fungal pathogens comprise large groups of fungi with unfamiliar names that traditionally have caused disease only sporadically. These opportunistic fungi have low inherent virulence and typically cause infection only when normal host resistance mechanisms are compromised. Over the past 30 years, these opportunists have become increasingly important in human patients because immunocompromise associated with chemotherapy, organ transplantation, and HIV infection has become more prevalent. Similarly, over the past 5 to 10 years, the frequency with which opportunistic fungal infections are encountered in small animal patients has increased significantly in association with the use of multiagent immunosuppressive therapy (especially with cyclosporine) to treat immune-mediated disease in dogs. Thus, veterinarians are increasingly likely to encounter patients infected by an opportunistic fungal pathogen with which they are unfamiliar.

Unlike the common endemic fungal pathogens (for which a definitive diagnosis can often be made simply by visualizing the unique morphologic features of the organism in cytologic or histologic samples), opportunistic fungi can only be identified to genus and species level by culture or molecular methods. However, they can be assigned to categories based on their morphologic features in tissue, such as pigmentation, hyphal diameter, and frequency of septation. These categories include *phaeohyphomycosis* (pigmented hyphal or yeast forms), *hyalohyphomycosis* (nonpigmented hyphal forms), *eumycotic mycetoma* (fibrosing granuloma with black or white tissue grains consisting of aggregates of pigmented or nonpigmented fungi, respectively), and *zygomycosis* (wide, infrequently septate, nonpigmented hyphae associated with pyogranulomatous and eosinophilic inflammation). Because of its similarities to pythiosis and lagenidiosis, zygomycosis is discussed in Chapter 69. Although identification of a specific pathogen after culture is ideal, classification of opportunistic mycoses based on the categories just listed is usually sufficient to allow the clinician to make a reasonable prediction about clinical course and prognosis and to make appropriate treatment decisions. Because many opportunistic fungi are common contaminants and can normally be found on skin, nasal mucosa, and other nonsterile sites, culture- or PCR-based identification of a potential opportunistic fungal pathogen from a skin specimen, nasal swab, or exudate should not be considered evidence of fungal infection unless there is supportive histologic or cytologic evidence of tissue invasion by a morphologically compatible organism.

Overview of Phaeohyphomycoses

Causes: *Alternaria, Bipolaris, Cladophialophora, Curvularia, Exophiala, Fonsecaea, Moniliella, Phialophora, Ramichloridium, Ulocladium,* and *Scolecobasidium,* among many others

Affected Hosts: A variety of animal hosts that include dogs, cats, horses, and humans

Geographic Distribution: Worldwide

Mode of Transmission: Cutaneous inoculation of organisms from the environment

Major Clinical Signs: Localized cutaneous nodules that may appear pigmented, often on the nose or digits; occasionally meningoencephalitis, with associated neurologic signs

Differential Diagnosis: Neoplasia, cryptococcosis, blastomycosis, sporotrichosis, hyalohyphomycosis, zygomycosis, mycobacterial infections, actinomycosis, nocardiosis

Human Health Significance: Direct transmission from animals to humans has not been described; humans develop infections from environmental sources.

Phaeohyphomycosis

Etiology and Epidemiology

The term "phaeohyphomycosis" refers to cutaneous, subcutaneous, cerebral, or disseminated infections caused by pigmented (also known as dematiaceous) fungi that contain melanin in their cell walls.[1] Infection usually results from cutaneous inoculation. Fungal genera that have been identified as agents of phaeohyphomycosis in veterinary patients include *Alternaria*, *Bipolaris*, *Cladophialophora*, *Curvularia*, *Exophiala*, *Fonsecaea*, *Moniliella*, *Phialophora*, *Ramichloridium*, *Ulocladium*, and *Scolecobasidium*, among others (Table 68-1).

Clinical Features

The most common clinical manifestations of phaeohyphomycosis in immunocompetent small animals are lesions associated with the digits, pinnae, nasal planum, or nasal cavity in cats (Figure 68-1).[2-8] Cutaneous lesions occur less often in dogs.[9] In addition, granulomatous meningoencephalitis caused by pigmented fungi

VetBooks.ir

TABLE 68-1

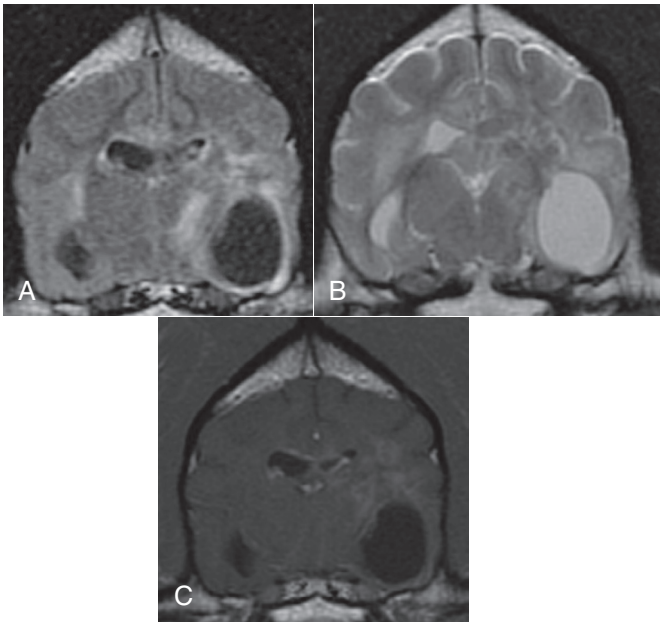
Causative Agents and Histologic/Cytologic Characteristics Associated with Miscellaneous Fungal and Pseudofungal Pathogens

Disease	Causative Agents	Histologic and Cytologic Characteristics
Phaeohyphomycosis	*Alternaria, Bipolaris, Phialophora, Cladophialophora (Cladosporium), Curvularia, Exophiala, Fonsecaea, Moniliella, Ochroconis, Ramichloridium,* others	Pyogranulomatous inflammation associated with pigmented, irregularly septate hyphae or yeast-like cells that may be solitary or may cluster in small groups or chains
Hyalohyphomycosis	*Acremonium, Fusarium, Geotrichum, Geosmithia, Paecilomyces, Phialosimplex, Pseudallescheria, Sagenomella, Scedosporium, Schizophyllum,* others	Pyogranulomatous inflammation associated with hyphal elements that have nonpigmented (transparent, hyaline) walls; *Phialosimplex* may cause yeast-like forms in tissue
Mycetoma (black-grain)	*Curvularia*	Pyogranulomatous inflammation associated with aggregates of pigmented fungal organisms (which appear grossly as pigmented tissue grains)
Mycetoma (white-grain)	*Pseudallescheria boydii*, *Acremonium*	Pyogranulomatous inflammation associated with aggregates of nonpigmented fungal organisms (which appear grossly as nonpigmented tissue grains)
Pythiosis	*Pythium insidiosum*	Pyogranulomatous and eosinophilic inflammation associated with broad (2-7 µm), infrequently septate hyphae (see Chapter 69)
Lagenidiosis	*Lagenidium*	Pyogranulomatous and eosinophilic inflammation associated with broad (4-25 µm), infrequently septate hyphae (see Chapter 69)
Zygomycosis	*Conidiobolus* spp., *Basidiobolus ranarum* in dogs; *Rhizomucor, Mucor,* and *Cokeromyces* in cats	Pyogranulomatous and eosinophilic inflammation associated with broad (5-20 µm), infrequently septate hyphae with thick prominent eosinophilic sleeve (see Chapter 69)
Aspergillosis	*Aspergillus terreus, A. deflectus, A. flavipes, A. fumigatus,* others	Suppurative to granulomatous inflammation associated with multiple, nonpigmented, 3- to 6-µm, septate hyphae with parallel walls and 45-degree angle branching (see Chapter 65)
Candidiasis	*Candida albicans,* other *Candida* spp.	Suppurative inflammation with numerous 2- to 6-µm oval yeasts, pseudohyphae (chains of oval yeast cells), and true hyphae (see Chapter 67)

FIGURE 68-1 Left distal thoracic limb of an 8-year-old male neutered Burmese cat with digital phaeohyphomycosis. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

(especially *Cladophialophora bantiana*) have been described both in dogs and cats.[10-14] In immunocompromised patients, the most common presentation appears to be multifocal cutaneous lesions in dogs treated with multiagent immunosuppressive therapy, especially that which includes cyclosporine.[15-17]

Animals with phaeohyphomycosis typically have cutaneous nodules or a visible nasal mass. Infected tissues may appear grossly pigmented, and thus masses may be confused with melanomas. Phaeohyphomycoses tend to be locally invasive and may extend to involve regional lymph nodes (Figure 68-2). Systemic dissemination more often occurs in animals treated with immunosuppressive drugs, but disseminated infections have also been described in apparently immunocompetent patients.[18,19] Animals with central nervous system (CNS) phaeohyphomycosis may have neurologic signs such as obtundation, seizures, abnormal placing reactions, circling, tremors, ataxia, and abnormal cranial nerve function.



Diagnosis

Laboratory and Imaging Abnormalities

Results of a CBC, biochemistry panel, and urinalysis in animals with cutaneous phaeohyphomycoses are typically unremarkable. Animals with disseminated disease can have abnormalities

FIGURE 68-2 Popliteal lymphadenopathy and abscessation caused by *Curvularia* spp. infection in a 1-year-old female Yorkshire terrier with cutaneous phaeohyphomycosis. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

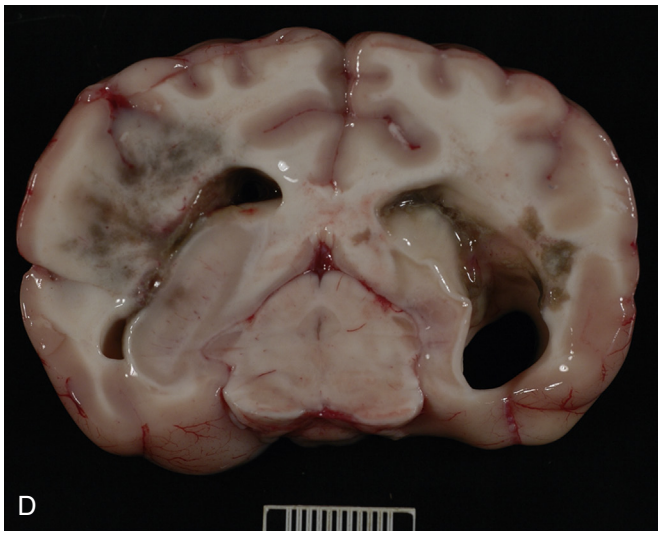


FIGURE 68-3 Axial T1 postcontrast, T2, and FLAIR magnetic resonance images (**A, B,** and **C,** respectively) of the brain of a 6-year-old male neutered Border collie mix that was evaluated for neurologic signs including seizures and progressive obtundation. In the images shown, there is bilateral but asymmetric ventricular dilation that is severe on the right and mild to moderate on the left (asymmetric hydrocephalus). Multifocal regions of contrast enhancement are also present **(A)**. Some of these regions appeared nodular; others had a ring-like appearance. There is also marked contrast enhancement of the ventricular ependymal lining. The regions of contrast enhancement correlate with regions of T2 and FLAIR hyperintensity (**B** and **C**) and were isointense on precontrast T1-weighted sequences (not shown). Meningoencephalitis caused by *Cladophialophora bantiana* and secondary hydrocephalus was diagnosed on brain biopsy and at necropsy **(D)**. Olive-green pigmented masses can be seen on both the left and right sides of the brain. Interestingly, the dog also had cutaneous protothecosis. (Courtesy University of California, Davis, Veterinary Neurology and Anatomic Pathology Services.)

associated with underlying immunosuppressive illness or drug treatment. Imaging with computed tomography (CT) or MRI in animals with CNS involvement may reveal focal or multifocal contrast-enhancing lesions that may be associated with hydrocephalus (Figure 68-3).

Cytologic and Histologic Findings

On histologic or cytologic examination, fungi that cause phaeohyphomycosis appear as dark-walled, irregularly septate hyphae or as yeast-like cells, solitary or in small groups or chains (Figure 68-4). Pigmentation may not always be apparent on cytologic examination (Figure 68-5). The presence of melanin in the walls of lightly-pigmented hyphae can be confirmed by the examination of unstained sections, by lowering the microscope condenser during examination, or by utilization of a Fontana-Masson stain for melanin.

Culture

Organisms that cause phaeohyphomycosis are readily isolated on routine fungal culture of infected tissue biopsies as well as from fine-needle aspirate specimens from infected lymph nodes. Further identification is based on colony and conidial morphology (see also Figure 4-7, *B*) and PCR and sequencing of ribosomal RNA genes. Because pigmented fungi are common laboratory contaminants and can sometimes be isolated from nonsterile sites on healthy animals (such as skin), positive cultures from potentially contaminated sites should only be considered significant if accompanied by cytologic or histologic evidence of fungal infection with a morphologically compatible organism.

Treatment and Prognosis

Pigmented fungi are often poorly responsive to medical therapy, in part because melanin is a virulence factor. Aggressive surgical resection is the treatment of choice for solitary cutaneous phaeohyphomycosis lesions. The surgeon should attempt to obtain wide margins at the time of the initial surgery. Digit amputation is usually indicated for lesions of the distal phalanx. Medical therapy with itraconazole or posaconazole is recommended for 3 to 6 months after surgery, because recurrence of disease at the surgical site is common.

For nonresectable lesions, treatment with itraconazole (10 mg/kg/day) often results in partial or complete resolution of cutaneous lesions, but recurrence is very common, so prolonged courses (6 to 12 months) should be recommended. Voriconazole or posaconazole may be more effective than itraconazole for the treatment of phaeohyphomycosis but are significantly

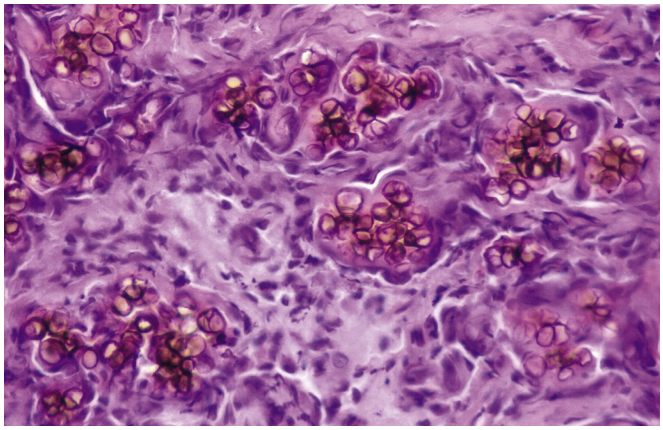

FIGURE 68-4 Histopathology showing small groups of pigmented, yeast-like fungal organisms in tissue from a nasal mass in a cat with phaeohyphomycosis; H&E stain. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

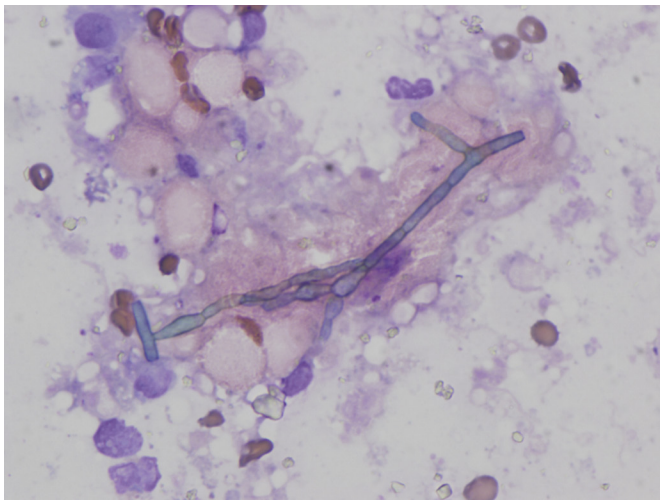

FIGURE 68-5 Impression smear from the brain of the dog in Figure 68-3. Septate, branching hyphae are present, but pigmentation is not clearly apparent. Wright's stain, 1000× magnification. (Courtesy University of California, Davis, Veterinary Pathology Service.)

more expensive. In addition, voriconazole administration is not recommended in cats because of significant adverse effects (see Chapter 9). Recently, long-term voriconazole therapy (7 to 10 mg/kg/day for 10 to 12 months) was used successfully to treat intracranial phaeohyphomycosis in one dog[10] and mycotic peritonitis caused by *Exophiala* in another.[20] Early combination therapy with amphotericin B, flucytosine, and extended-spectrum azoles has been recommended for treatment of human patients with CNS infections,[21] but flucytosine can be prohibitively expensive and is generally not tolerated by dogs (see Chapter 9).

In the author's experience, cutaneous phaeohyphomycosis that occurs in dogs receiving immunosuppressive drug therapy can be resolved in many cases with itraconazole (10 mg/kg/day) administered for at least 6 months if the immunosuppressive drug therapy can be tapered quickly. However, dissemination of disease can also occur, sometimes despite appropriate antifungal therapy. Discontinuation of cyclosporine treatment in these animals appears to be important for achieving a good outcome.

Public Health Aspects

Phaeohyphomycosis in humans clinically resembles that in dogs and cats and may include localized cutaneous lesions in immunocompetent hosts; life-threatening CNS infections in immunocompromised or apparently immunocompetent hosts (especially brain abscesses caused by *C. bantiana*); and, rarely, disseminated phaeohyphomycosis, primarily in immunocompromised hosts.[21] Infections caused by pigmented fungi are acquired from the environment. Although there is no evidence of transmission between mammalian hosts, routine precautions (such as wearing gloves when handling infected tissues or exudate) should be followed. Precautions should also be taken to prevent needlestick injuries if phaeohyphomycosis is suspected.

Overview of Hyalohyphomycoses

Causes: *Acremonium, Fusarium, Geotrichum, Paecilomyces, Pseudallescheria, Sagenomella, Scedosporium,* others

Affected Hosts: A variety of animal hosts that include dogs, cats, and humans

Geographic Distribution: Worldwide

Mode of Transmission: Inhalation or cutaneous inoculation of organisms in the environment

Major Clinical Signs: Keratitis; cutaneous lesions; osteomyelitis; pneumonia; disseminated disease with involvement of lymph nodes, kidneys, liver, spleen, bone, intervertebral discs, and/or CNS

Differential Diagnosis: Neoplasia, aspergillosis, penicilliosis, phaeohyphomycoses, sporotrichosis, cryptococcosis, blastomycosis, candidiasis, endemic mycoses, nocardiosis, actinomycosis, mycobacteriosis, zygomycosis

Human Health Significance: Direct transmission from animals to humans has not been described; humans develop infections from environmental sources.

Hyalohyphomycosis

Etiology and Epidemiology

The term "hyalohyphomycosis" refers to infections caused by fungi that are nonpigmented (hyaline or transparent) in tissue. Genera that have been described as agents of hyalohyphomycosis in veterinary patients include *Fusarium*, *Acremonium*, *Paecilomyces* (especially *Paecilomyces variotii* and *Paecilomyces lilacinus*), *Pseudallescheria boydii* (anamorph *Scedosporium apiospermum*), *Sagenomella*, *Phialosimplex*, *Geosmithia*, and *Geomyces*, among others (see Table 68-1). By convention, infections caused by *Aspergillus* and *Penicillium* species are not included in the term "hyalohyphomycosis," because aspergillosis and penicilliosis can usually be identified as such based on their clinicopathologic features. In general, hyalohyphomycosis occurs more often in dogs than in cats.

Clinical Features

Hyalohyphomycosis ranges from a local disease confined to the skin (Figure 68-6), nasal mucosa, or cornea to osteomyelitis,

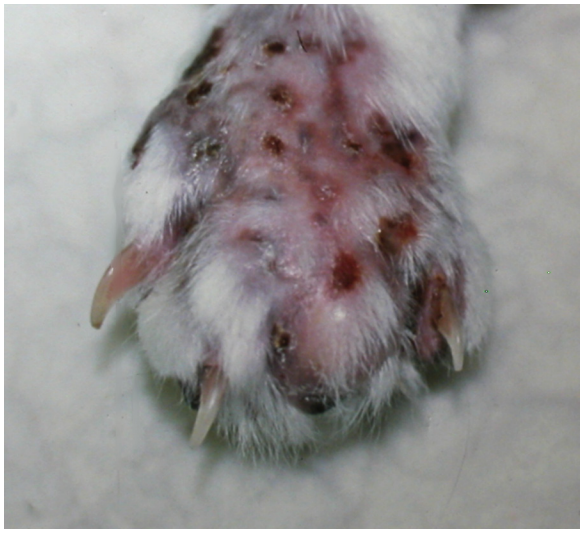

FIGURE 68-6 *Scedosporium prolificans* infection in a domestic shorthair cat. There are multiple draining skin lesions and soft tissue swelling. (Courtesy Spencer Jang, University of California, Davis.)

pneumonia, and disseminated disease that can involve one or more organs including the kidneys, bone marrow, lymph nodes, liver, spleen, bones, intervertebral discs, and CNS, sometimes with associated fungemia.[22-30]

Traditionally, the disseminated and corneal forms of hyalohyphomycosis have been most commonly identified. Therefore, animals with no overt signs of systemic disease that present with cutaneous or bone lesions that contain nonpigmented hyphae should still be evaluated for occult lesions in the chest and abdomen. Like phaeohyphomycosis, hyalohyphomycosis is an increasingly common cause of multifocal skin lesions in dogs receiving multiagent immunosuppressive therapy. These dogs may or may not have accompanying extracutaneous lesions.

Diagnosis

Cytologic and Histologic Findings

Cytologically and histologically, fungi that cause hyalohyphomycosis are nonpigmented, frequently septate, branching hyphae that are often pleomorphic (Figures 68-7 and Figure 4-6). Special stains such as periodic acid–Schiff and Gomori's methenamine silver may be used to identify organisms more readily.

Culture

The fungi that cause hyalohyphomycosis are readily isolated by routine fungal culture methods from infected tissues as well as from fine-needle aspirate specimens from infected lymph nodes, bones, or abdominal organs. Because these fungi are common laboratory contaminants and can sometimes be isolated from the skin or hair of healthy animals, positive cultures from nonsterile sites should be considered significant only if accompanied by cytologic or histologic evidence of fungal infection with a morphologically compatible organism. Species identification is based on conidial morphology (Figure 68-8) and may require PCR and sequencing of ribosomal RNA genes. Species identification may assist in selection of antifungal drug treatments, because some species are predictably less susceptible to conventional antifungal drugs (see Treatment and Prognosis). Proper identification and antifungal drug susceptibility testing are best performed by laboratories that specialize in mycoses (e.g., the

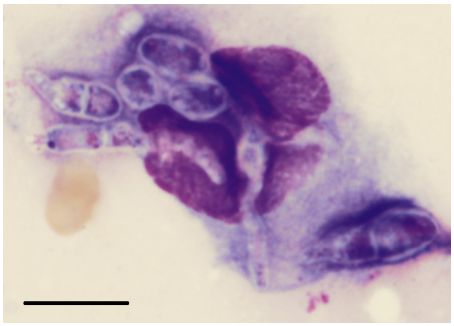

FIGURE 68-7 Fine needle aspirate cytology from a lytic bone lesion in a 4-year-old female spayed mixed breed dog with hyalohyphomycosis. Note the septate, nonpigmented fungal hyphae present within the macrophage; Wright-Giemsa stain, bar = 10 µm. (Courtesy Kaikhushroo Banajee, Louisiana State University, Baton Rouge, LA.)

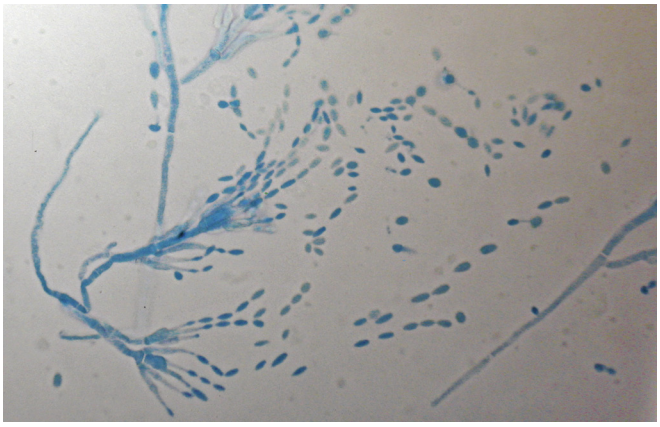

FIGURE 68-8 Cytologic appearance of *Paecilomyces variotii* growing in culture in the laboratory. Lactophenol cotton blue, 1000× magnification. (Courtesy Spencer Jang, University of California, Davis.)

University of Texas Health Science Center at San Antonio) and may be useful for selection of treatments for difficult cases. Nevertheless, evidence that supports a correlation between in vitro susceptibility data and clinical response to treatment is lacking.

Antigen Testing

The Platelia *Aspergillus* galactomannan antigen ELISA assay is positive in some, but not all, animals with hyalohyphomycoses such as paecilomycosis. This results from antigenic cross-reactivity (see Chapter 65).[31] In most dogs with disseminated paecilomycosis that test positive, the magnitude of positive results is somewhat lower than those in dogs with disseminated aspergillosis, but occasionally results are strongly positive (galactomannan indices >6).

Treatment and Prognosis

Treatment of hyalohyphomycosis has traditionally been challenging because many animals have disseminated disease. Drugs used most often to treat hyalohyphomycosis in small animals include itraconazole and amphotericin B, but different fungal species vary in their susceptibility to antifungal drugs, and some species, such as *Pseudallescheria boydii* and *Paecilomyces lilacinus*, are relatively resistant to conventional antifungal drugs in vitro.[32,33] The newer triazoles, voriconazole and posaconazole, and the echinocandins, such as caspofungin, may be more active against these fungi than itraconazole but are significantly

VetBooks.ir

more expensive. In contrast, *Paecilomyces variotii* is usually susceptible to amphotericin B but is less susceptible to voriconazole. Although treatment of disseminated hyalohyphomycosis with antifungal drugs can prolong survival, clinical signs often recur even if signs initially resolve. Therefore, disseminated hyalohyphomycosis generally carries a guarded to poor prognosis.

Cutaneous hyalohyphomycosis that develops in an animal receiving immunosuppressive drug therapy may respond well to oral azole antifungal drugs or may rapidly disseminate. Therefore, fungal skin lesions that develop in immunocompromised patients should be treated aggressively, and a guarded prognosis should be offered. This author most often uses itraconazole (10 mg/kg/day) administered orally for at least 6 months. Other options include amphotericin B, voriconazole, or posaconazole. Combination therapies have been recommended for difficult cases in human patients.[21] Discontinuation of cyclosporine and rapid tapering of other immunosuppressive medications in these patients appears to be important for achievement of a good outcome.

Public Health Aspects

Hyalohyphomycosis in humans is acquired as a result of infection by fungi in the environment. Keratitis and nailbed infections (onychomycosis) can occur in immunocompetent humans. Invasive infections occur in immunocompromised patients such as transplant recipients, patients with AIDS, and leukemic or neutropenic patients. Although there is no evidence to suggest that transmission between mammalian hosts is possible, routine precautions (such as wearing gloves when handling infected tissues or exudate) should be followed. Precautions should especially be taken to prevent needle-stick injuries if hyalohyphomycosis is suspected.

Eumycotic Mycetoma

The term "mycetoma" refers to localized mycotic or actinomycotic infections of the skin, subcutaneous tissue, muscle, or bone that are characterized by the presence of colonies or aggregates of organisms that form "grains" in tissue. Actinomycotic mycetomas are caused by bacteria such as *Actinomyces* spp. or *Nocardia* spp. (see Chapters 42 and 43), dermatophytic mycetomas are caused by dermatophytes (see Chapter 58), and eumycotic mycetomas are caused by nondermatophyte fungi. Lesions result from traumatic implantation of soil organisms into tissue. The grains or granules of eumycotic mycetomas are pigmented (for black-grain mycetoma, caused by dematiaceous fungi) or hyaline (for white-grain mycetoma, caused by nonpigmented fungi), depending on the type of fungal pathogen involved (see Table 68-1).

Black-grain mycetomas are most often caused by *Curvularia* species and typically are associated with chronic nonhealing wounds and cutaneous nodules on the extremities. Lesions often develop weeks to months after a traumatic incident in the same area. Draining tracts are often present, and black grains may be observed in the exudate. White-grain mycetomas, usually caused by *Pseudallescheria boydii* or *Acremonium* spp., most often occur as body-wall and/or intra-abdominal granulomas that develop subsequent to surgical wound contamination or dehiscence. Interestingly, the lesions associated with white-grain mycetoma may not be evident until months or even a year or more after the surgical event. Affected dogs may be evaluated for a draining mass on the body wall or clinical signs of peritonitis.

The treatment of choice for eumycotic mycetoma is aggressive surgical excision of infected tissues, including amputation if clinically indicated. Response to medical therapy is generally poor, but administration of itraconazole, voriconazole, or posaconazole may be considered as adjunctive therapy following surgical excision when wide margins cannot be achieved. Dissemination of eumycotic mycetoma beyond local tissues is rare, but disease within the abdomen or other local tissues may be extensive. The prognosis is guarded if complete surgical resection is not possible.

CASE EXAMPLE

Signalment: "CJ", a 1-year-old male intact boxer dog from central Louisiana

History: CJ was initially evaluated for acute ataxia and abnormal limb placement. Based on results of CSF analysis as well as MRI of the brain and spinal cord, inflammatory central nervous system disease was diagnosed, and treatment with prednisone (1 mg/kg PO q12h) was initiated. Despite a good initial response, neurologic signs recurred 2 weeks later, at which time cytosine arabinoside (50 mg/m^2 SC q12h, for four doses, repeated every 3 weeks) and azathioprine (1.6 mg/kg PO q48h) were added to the treatment protocol. Neurologic signs again improved, but 7 weeks later, the dog was evaluated for ulcerative lesions on the distal extremities that had been present for 1 week and lethargy that had been present for 3 days.

Physical Examination:

Body Weight: 29 kg.

General: Alert and responsive, but painful on ambulation because of ulcerative lesions on all four feet. Vital parameters were within normal limits. Peripheral lymph nodes were palpably normal.

Dermatologic Examination: Pitting edema and multifocal ulcerative lesions were present on all four distal extremities, with sloughing of multiple footpads (Figure 68-9, *A* and *B*). Some of the pad lesions were proliferative and extended into the interdigital area (Figure 68-9, *C*). Multiple light brown colored areas could be visualized within the fibrinonecrotic material that covered the area of the left metacarpal pad (see Figure 68-9, *B*). In addition, a 1-cm ulcerated lesion was present on the left pinna, a crusted lesion was present on the tip of the tail, and a small subcutaneous mass was present in the right saphenous area. Larger (3 cm) ulcerated lesions partially covered with eschar were present on the medial aspect of the right tarsus and the dorsal aspect of the left antebrachium. Major differential diagnoses considered were opportunistic fungal infection and drug eruption.

Cytology and Histology Findings: Cytologic evaluation of the left pinnal lesion, subcutaneous right saphenous mass, and right popliteal lymph node revealed septic neutrophilic to pyogranulomatous inflammation with septate, branching, 3- to 7-µm fungal hyphae, both extracellularly and within neutrophils. Pigmentation of hyphae was not observed.

Continued

FIGURE 68-9 **A-C,** Phaeohyphomycosis of the left thoracic limb that developed after multiagent immunosuppressive therapy in 1-year-old boxer with inflammatory central nervous system disease. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

Histologic evaluation of punch biopsies obtained from cutaneous lesions on the left front foot, right hind foot, and right forelimb revealed severe pyogranulomatous dermatitis with intralesional septate, pigmented hyphae.

Diagnosis: Disseminated cutaneous phaeohyphomycosis extending to regional lymphadenitis.

Treatment and Outcome: Pentoxifylline (30 mg/kg PO q24h) was administered because of suspected vasculitis associated with the cutaneous lesions. Antifungal therapy with itraconazole (10 mg/kg PO q24h) was initiated, but lesion progression was observed over the next several days, so lipid-complexed amphotericin B treatment (2 mg/kg diluted in 5% dextrose, IV, over several hours three times weekly) was initiated. Unfortunately, 2 days later lesions had progressed rapidly with appearance of new draining tracts and abscess formation. Because of the poor prognosis and pain associated with the lesions, the dog was euthanized.

Comments: As was noted here, pigmentation of hyphae may not always be visible on cytologic examination of lesions caused by phaeohyphomycosis, in part because hyphae and the cells that phagocytize them often take up enough color with the Wright-Giemsa stain to mask the pigmentation. Therefore, in this case, evaluation of histologic samples was important for differentiating phaeohyphomycosis from hyalohyphomycosis. Culture would have been ideal for definitive identification of the opportunistic fungal organism that caused the infection in this dog, but was not performed.

CHAPTER 69

Pythiosis, Lagenidiosis, and Zygomycosis

Amy M. Grooters

VetBooks.ir

Pythiosis, lagenidiosis, and zygomycosis are often grouped together because of similarities in their clinical presentations and histologic characteristics (all three cause pyogranulomatous and eosinophilic inflammation associated with large, infrequently septate hyphae with nonparallel walls). Despite their clinicopathologic similarities, however, the pathogens that cause these infections are taxonomically diverse. *Pythium insidiosum* and *Lagenidium* species are water molds in the class Oomycetes and as such are more closely related to red algae and *Prototheca* spp. than to true fungi, including the zygomycetes.[1] Important traits that distinguish oomycetes from fungi include the production of motile, flagellate zoospores that act as infective elements in wet environments, and the fact that the oomycete cell membrane generally lacks ergosterol.[2] In addition, there are clinically relevant differences in prognosis, recommended treatment, and epidemiology that make it important to distinguish among pythiosis, lagenidiosis, and zygomycosis. Although *P. insidiosum* has been recognized as a pathogen in dogs and horses for more than 25 years, *Lagenidium* species have only been recognized as mammalian pathogens since 1999. In comparison to pythiosis and lagenidiosis, infections caused by the zygomycetes are rare.

Overview of Pythiosis

First Described: 1884, India (Smith)[3], in horses

Cause: *Pythium insidiosum* (kingdom Stramenopila, class Oomycota), related to algae and *Prototheca* spp.

Affected Hosts: Horses and dogs; less commonly cats, sheep, cattle, exotic species, and humans

Geographic Distribution: Tropical, subtropical, and some temperate regions worldwide, especially the Gulf Coast region of the United States

Mode of Transmission: Likely penetration of damaged skin or mucosa by motile zoospores, usually after exposure to standing freshwater sources

Major Clinical Signs: Ulcerative, nodular, and mass-like cutaneous lesions with draining tracts (cutaneous form); weight loss, anorexia, vomiting, diarrhea, hematochezia (gastrointestinal form)

Differential Diagnosis: For suspected gastrointestinal pythiosis, differential diagnoses include neoplasia, zygomycosis, histoplasmosis, eosinophilic gastroenteritis, or chronic intestinal foreign bodies; for suspected cutaneous pythiosis, they include lagenidiosis, zygomycosis, mycobacterial infections, actinomycosis, or furunculosis.

Human Health Significance: *P. insidiosum* is a rare cause of disease in human patients; infection is not transmitted directly from affected animals to people.

PYTHIOSIS

Etiology and Epidemiology

Pythium insidiosum is an aquatic oomycete that causes severe, progressive gastrointestinal or cutaneous disease that is often fatal. The infective form of *P. insidiosum* is thought to be the motile flagellate zoospore, which is an asexual reproductive structure produced in wet environments in association with plant material.[4] Zoospores of *P. insidiosum* are attracted to damaged tissue, and likely cause infection by encystation on and invasion of damaged skin or gastrointestinal mucosa.[5] In support of this mechanism of infection, clinical reports have long suggested an association between pythiosis and frequent exposure to warm freshwater habitats. However, some infections occur in dogs with no history of access to lakes or ponds.

Globally, pythiosis occurs in tropical and subtropical climates, including Southeast Asia, eastern coastal Australia, and South America (Figure 69-1). In the United States, the disease occurs most often in the Gulf Coast states, but it has also been recognized throughout the South; along the East Coast as far north as Maryland and New Jersey; in the Midwest including Missouri, Kansas, southern Illinois, and Indiana; and in the West in Arizona and California.[6]

Pythiosis is most common in young, large-breed dogs, especially Labrador retrievers and other outdoor working breeds. Infected dogs are typically evaluated by veterinarians in the fall, winter, and early spring.[7] Pythiosis is uncommon in cats compared to dogs, and specific breed and sex predilections have not been observed in the cases described to date. However, the development of cutaneous pythiosis in very young animals (less than 1 year of age) appears to occur more often in cats than in dogs. For both species, affected animals are typically immunocompetent.

Clinical Features

The clinical signs associated with pythiosis are caused by gastrointestinal or cutaneous lesions, or by extension of disease into regional lymph nodes or adjacent tissues. Generally, gastrointestinal and cutaneous lesions do not occur together in the same animal. Disseminated pythiosis has only been described in one dog.[8]

Gastrointestinal Pythiosis

Gastrointestinal pythiosis in dogs is characterized by severe, segmental, transmural thickening of the stomach wall (Figure 69-2), small intestine, colon, rectum, or, rarely, the

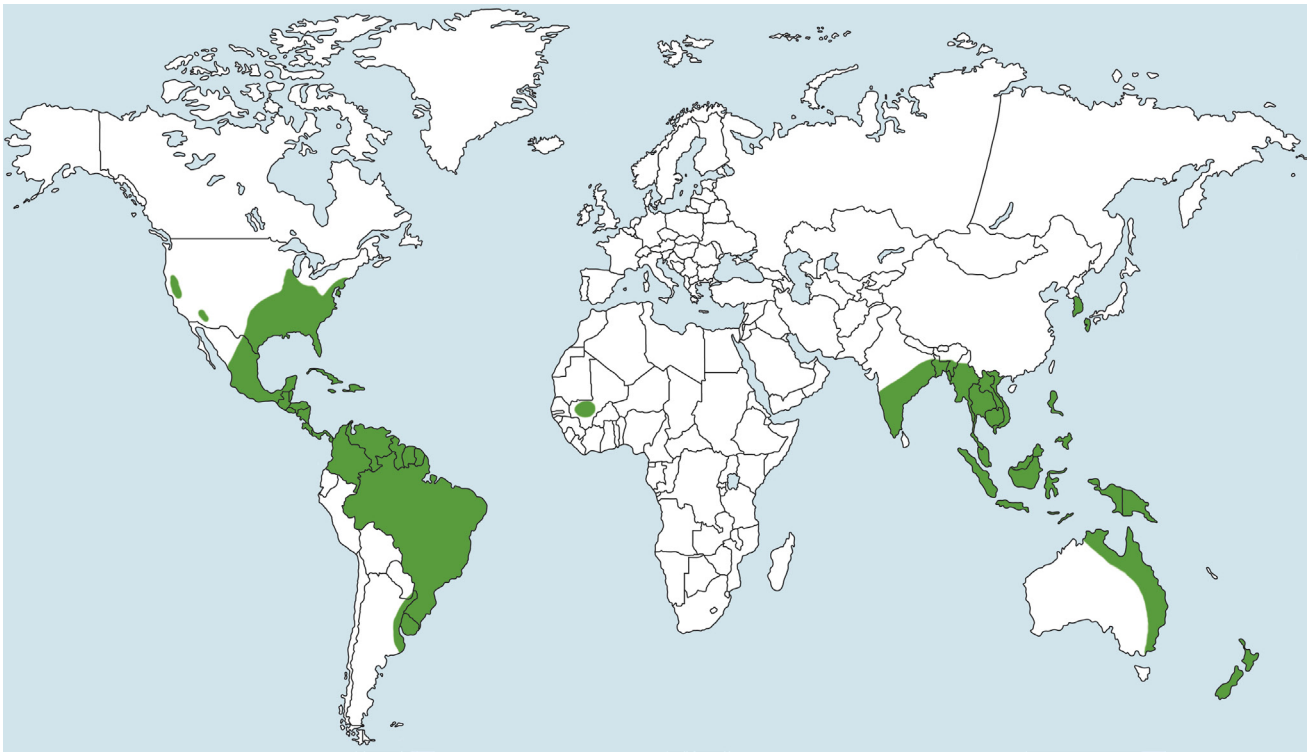

FIGURE 69-1 Worldwide geographic distribution of pythiosis.

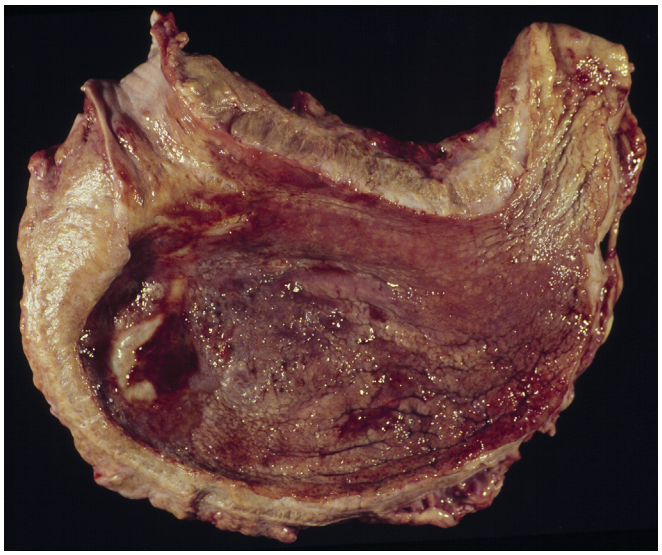

FIGURE 69-2 Gastric pythiosis in a 1-year-old male neutered mixed breed dog. Note extreme thickening of the gastric wall. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

esophagus, and it is not uncommon to find multiple segmental lesions in the same patient.[7,9,10] The most commonly affected regions of the gastrointestinal tract are the gastric outflow area, proximal duodenum, and ileocolic junction. Mesenteric lymphadenopathy is common but is usually caused by reactive hyperplasia rather than infection. Extension of disease into the mesenteric root often causes severe mesenteric lymphadenopathy, with the lymph nodes embedded in a single large, firm mass that is palpable in the cranial to mid abdomen. Invasion of mesenteric vessels may result in bowel ischemia, infarction, perforation, or acute hemoabdomen. In addition, infection may extend into adjacent tissues such as the pancreas or the uterus. Gastrointestinal pythiosis is rare in cats but has been described in two young adult male cats with focal intestinal lesions that were amenable to surgical resection.[11]

Dogs with gastrointestinal pythiosis typically have a history of chronic progressive weight loss, vomiting, diarrhea, anorexia, and sometimes hematochezia, depending on the location of the lesions. Regurgitation may be present in dogs with esophageal involvement. Physical examination usually reveals a poor body condition and sometimes a palpable abdominal mass. Signs of systemic illness such as lethargy or depression are absent unless intestinal obstruction, infarction, or perforation occurs.

Cutaneous Pythiosis

Cutaneous pythiosis in dogs occurs most often at the base of the tail, or on the extremities, ventral neck, or perineum,[8,12] and is characterized by nonhealing wounds and invasive masses that contain ulcerated nodules and draining tracts (Figure 69-3). In contrast to gastrointestinal pythiosis, regional lymphadenopathy associated with cutaneous pythiosis often reflects extension of infection rather than just reactive hyperplasia. Extension of cutaneous disease to tissues other than regional lymph nodes is rare, but the author has observed a single, focal pulmonary lesion caused by *P. insidiosum* in one dog with cutaneous pythiosis on a distal extremity.

In cats, lesions associated with cutaneous pythiosis include cervical, inguinal, or truncal subcutaneous masses; draining nodular lesions or ulcerated plaque-like lesions on the tailhead or extremities[12]; and periorbital and nasopharyngeal lesions.[13]

FIGURE 69-3 Cutaneous pythiosis in a 6-month-old female Labrador retriever. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

Diagnosis

Laboratory Abnormalities

The most common laboratory abnormalities associated with pythiosis are eosinophilia, anemia, hyperglobulinemia, and hypoalbuminemia. Hypercalcemia has been described once.[14]

Imaging Findings

In dogs with gastrointestinal pythiosis, common radiographic findings include poor abdominal detail and the presence of an abdominal mass. Evidence of small bowel obstruction may also be observed. In rare cases of esophageal pythiosis, thoracic radiographs reveals increased soft tissue opacity in the region of the esophagus and deviation of the trachea. Abdominal ultrasonography is the tool of choice for imaging animals suspected to have gastrointestinal pythiosis and usually reveals severe segmental thickening of the gastrointestinal tract and mesenteric lymphadenopathy. In addition, Doppler ultrasonography may identify the presence of vascular pathology (such as an aneurysm) that can result from invasion of mesenteric vessels. In the author's practice, abdominal ultrasonography is a critical tool for determining the location and extent of disease in dogs with gastrointestinal pythiosis to determine the likelihood that surgical resection could be performed successfully and to assess prognosis. In addition, ultrasonography facilitates the acquisition of fine-needle aspirate specimens from affected segments of the gastrointestinal tract and enlarged lymph nodes. In animals with cutaneous pythiosis, computed tomography may provide information about the extent of disease and may assist with surgical planning when lesions are not located on an extremity.[15]

Microbiologic Tests

Diagnostic assays currently available for pythiosis, lagenidiosis, and zygomycosis in dogs and cats are described in Table 69-1.

TABLE 69-1

Diagnostic Assays Currently Available for Pythiosis, Lagenidiosis, and Zygomycosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues	Broad, rarely septate fungal hyphae with tapered, rounded ends	Does not reliably differentiate among pythiosis, lagenidiosis, and zygomycosis.
Culture	Biopsies of affected tissues	*Pythium insidiosum*, *Lagenidium* spp., or zygomycetes	Special tissue handling and expertise required for *P. insidiosum* culture (see text). The use of swab specimens or aspirates may result in false negatives. Species identification requires the use of molecular techniques.
Antibody serology	Serum	Antibodies to *P. insidiosum* or *Lagenidium* spp.	Assays that detect anti-*Pythium* antibodies allow early, noninvasive diagnosis of pythiosis in dogs. Positive test results correlate with active disease, and titers fall with successful treatment. Assays that detect *Lagenidium* antibodies in dogs are less specific and may be positive in animals with other diseases.
Histopathology	Biopsies of affected tissues	Broad, rarely septate fungal hyphae with tapered, rounded ends	Does not reliably differentiate among pythiosis, lagenidiosis, and zygomycosis. Use of special stains may facilitate detection.
PCR assays	Biopsies of affected tissues	*P. insidiosum* DNA	Not widely available.

VetBooks.ir

Cytologic Examination

Cytologically, pythiosis is characterized by pyogranulomatous and eosinophilic inflammation that can be visualized on impression smears made from draining skin lesions or fine-needle aspirates of a thickened gastrointestinal wall or enlarged lymph nodes. Hyphae are observed occasionally in cytologic samples, and their morphologic appearance (broad, rarely septate with tapered, rounded ends) in conjunction with a typical inflammatory response can provide a tentative diagnosis of pythiosis, lagenidiosis, or zygomycosis.[14]

Culture

Isolation of *P. insidiosum* from infected tissues is not difficult but does require specific specimen handling and culture techniques. For best results, unrefrigerated tissue specimens should be wrapped in a saline-moistened gauze sponge and shipped at ambient temperature to arrive within 24 hours at a laboratory that has experience with culture of pathogenic oomycetes. Small pieces of fresh, nonmacerated tissue are placed directly on the surface of vegetable extract agar supplemented with streptomycin and ampicillin (or an alternative selective medium) and incubated at 37°C.[16] Mycelial growth is typically observed within 12 to 24 hours. Isolation of *P. insidiosum* from swabs of exudate collected from draining skin lesions is generally unsuccessful. Because generation of the sexual reproductive structures that are necessary for definitive morphologic classification of pathogenic oomycetes rarely occurs in the laboratory, identification of *P. insidiosum* isolates is based on species-specific PCR amplification[17] or rRNA gene sequencing. Although production of zoospores is an important supporting feature for the identification of pathogenic oomycetes, it is not specific for *P. insidiosum*.

Molecular Diagnosis using the Polymerase Chain Reaction

A species-specific PCR assay has been used to identify *P. insidiosum* DNA in fresh, frozen, or paraffin-embedded tissues, as well as DNA extracted directly from cultured isolates.[18] However, such assays are not widely available on a commercial basis.

Serologic Testing

A highly sensitive and specific ELISA for the detection of anti–*P. insidiosum* antibodies in dogs is currently available through the author's laboratory at Louisiana State University.[19] This assay provides a means for early, noninvasive diagnosis and also allows response to therapy to be monitored. Following complete surgical resection of infected tissues, a dramatic decrease in antibody levels is typically detected within 2 to 3 months. In contrast, antibody levels remain high in animals that go on to develop clinical recurrence following surgical treatment. This same ELISA has been adapted for detection of anti–*P. insidiosum* antibodies in domestic and exotic cats, and although case numbers are too small to generate strong estimates of sensitivity and specificity, in the author's experience they appear to be high.

Pathologic Findings

Histologically, pythiosis is characterized by eosinophilic pyogranulomatous inflammation, with multiple foci of necrosis that are surrounded and infiltrated by neutrophils, eosinophils, and macrophages. In addition, discrete granulomas composed of epithelioid macrophages, plasma cells, multinucleate giant cells, and fewer neutrophils and eosinophils are often observed. Organisms are typically found within areas of necrosis or at the center of granulomas. Vasculitis is occasionally present. In gastrointestinal pythiosis, inflammation centers on the submucosal and muscular layers rather than the mucosa and lamina propria. Therefore, the diagnosis of pythiosis may be missed if endoscopic biopsies that fail to reach deeper tissues are submitted. Similarly, disease in animals with cutaneous pythiosis is typically found in the deep dermis and subcutis, necessitating deep wedge biopsies rather than punch biopsies for optimal evaluation. *Pythium insidiosum* hyphae are not routinely visualized on H&E-stained sections but may be identified as clear spaces surrounded by a narrow band of eosinophilic material. Hyphae are readily visualized in sections stained with Gomori's methenamine silver (GMS) but usually do not stain well with periodic acid–Schiff (PAS). They are wide (mean, 4 µm; range, 2 to 7 µm), have nonparallel walls, are infrequently septate, and occasionally branch at right angles.[7,8]

Treatment and Prognosis

Aggressive surgical resection of all infected tissues with wide margins is the treatment of choice for pythiosis. In animals with cutaneous lesions that are confined to a single distal extremity, amputation should be recommended unless there is evidence of regional lymph node infection. In patients with gastrointestinal pythiosis, segmental lesions should be resected with 5-cm margins whenever possible. Because mesenteric lymph nodes are usually reactive rather than infected, the presence of nonresectable mesenteric lymphadenopathy should not dissuade the surgeon from pursuing resection of a segmental bowel lesion. Enlarged regional lymph nodes should, however, always be biopsied for prognostic information. In animals with cutaneous pythiosis, the surgeon should attempt to obtain skin margins of 5 cm and deep margins of two fascial planes.[15] Enlarged regional lymph nodes in dogs with cutaneous pythiosis are often infected rather than reactive; therefore, they should be evaluated cytologically or histologically before amputation or other aggressive resection is attempted.

Unfortunately, many dogs with pythiosis are not brought to a veterinarian until late in the course of disease, when complete excision is not possible. In addition, the anatomic location of the lesion may prevent complete surgical excision when gastrointestinal pythiosis involves the esophagus, gastric outflow tract, rectum, or mesenteric root, or when cutaneous pythiosis involves the ventral thorax, base of the tail, or trunk. Still, very aggressive surgery such as a partial gastrectomy[14] or massive resection of cutaneous lesions combined with reconstructive techniques[15] can sometimes result in a successful outcome.

Local postoperative recurrence of pythiosis is common (especially when wide surgical margins cannot be achieved) and can occur either at the site of resection or in regional lymph nodes. For this reason, postoperative medical therapy is often recommended when the surgeon is not confident that margins of at least 5 cm were achieved. In the author's practice, dogs with focal midjejunal lesions that are resected with wide margins and dogs without regional lymphadenopathy that undergo amputation for distal extremity lesions are not

VetBooks.ir

routinely treated with postoperative antifungal medication. All other patients with pythiosis typically are treated with itraconazole (10 mg/kg PO q24h) and terbinafine (5 to 10 mg/kg PO q24h) for at least 2 to 3 months after surgical resection. Unfortunately, if resection is incomplete, lesions often progress despite medical therapy, and clinical signs recur within weeks to months.

To monitor for recurrence, ELISA serology should be performed at the time of surgery and 2 to 3 months later. In animals that have had a complete surgical resection and subsequently show no recurrence of disease, serum antibody levels usually drop 50% or more within 3 months. If this occurs, medical therapy can be discontinued. In the author's experience, surgery is curative in a majority of animals with a distal limb lesion treated with amputation, or with a midjejunal lesion that the surgeon believes was completely resected with good margins.

Medical therapy for nonresectable pythiosis is typically unrewarding, likely because ergosterol (the target for most currently available antifungal drugs) is generally lacking in the oomycete cell membrane. Despite this fact, clinical and serologic cures occur in some patients treated with a combination of itraconazole (10 mg/kg PO q24h) and terbinafine (5 to 10 mg/kg PO q24h).[20] Although the percentage of animals that respond to this treatment is still low, the combination protocol anecdotally appears to be superior to itraconazole or amphotericin B alone.

Dogs with nonresectable gastrointestinal pythiosis are often treated with anti-inflammatory doses of glucocorticoids in an effort to palliate clinical signs and to decrease vomiting so that oral antifungal drugs can be administered. Prednisone (1 mg/kg/day) routinely causes improvement in clinical signs in the short term. Surprisingly, the author has observed complete and long-term resolution of gastrointestinal lesions (based on serial ultrasonographic examinations and serologic testing) in a small number of dogs treated with prednisone alone. Although this is certainly not recommended as a primary treatment for animals with resectable lesions, it is a reasonable option in animals with nonresectable gastrointestinal lesions, especially when financial concerns preclude the use of antifungal medication. The author has not observed this effect of prednisone in dogs with cutaneous pythiosis.

An immunotherapy product derived from antigens of *P. insidiosum* has been used successfully to treat pythiosis in horses and people.[21,22] Unfortunately, although controlled trials have not been completed, the efficacy of this product in dogs appears to be poor, and clinical improvement has not been observed in any of the author's patients.

Public Health Aspects

Human infections caused by *P. insidiosum* are rare. Infections are acquired from the environment and have resulted in keratitis, periorbital cellulitis, and arteritis of the lower extremities. Most cases have been reported from Thailand, and almost all patients have thalassemia. Extremely rare reports of the disease exist from humans in North, South, and Central America, Australia, and other parts of Asia, many of whom are apparently healthy. Although there is no evidence to suggest that transmission between mammalian hosts is possible, routine precautions (such as wearing gloves when handling infected tissues or exudate) should be followed.

Overview of Lagenidiosis

First Described: 2003, Louisiana, USA, in dogs (Grooters and others) [23]

Cause: *Lagenidium* spp.

Affected Hosts: Dogs

Geographic Distribution: Southeastern United States

Mode of Transmission: Likely penetration of damaged skin or mucosa by motile zoospores

Major Clinical Signs: Ulcerative, nodular, and mass-like cutaneous lesions with draining tracts (cutaneous form); pelvic limb edema; local, thoracic, or abdominal lymphadenopathy; rupture of infected great vessels in the abdomen may result in hemoabdomen

Differential Diagnosis: Neoplasia, pythiosis, zygomycosis, mycobacterial infections, actinomycosis, snake bite

Human Health Significance: *Lagenidium* spp. infection is acquired from the environment; infection is not transmitted from affected animals to people.

LAGENIDIOSIS

Etiology and Epidemiology

Most species in the genus *Lagenidium* are pathogens of insects, crustaceans, algae, and nematodes. The most well studied species, *Lagenidium giganteum*, is a mosquito larval pathogen that was previously used as a biologic pesticide for control of mosquito populations. Within the past 15 years, two novel oomycetes that appear to belong to the genus *Lagenidium* have been isolated from dogs with cutaneous lesions. The first of these species causes uniformly fatal dermatologic and disseminated disease in dogs in the southeastern United States.[23] The second pathogenic *Lagenidium* species is less common than the first and causes a chronic ulcerative nodular dermatopathy that has a prolonged course and does not appear to extend beyond local tissues. Although strong antigenic and molecular similarities suggest that the first canine pathogen is closely related to *L. giganteum*, differences in their molecular and in vitro growth characteristics suggest that they are likely distinct species. Sporulation and infectivity for these pathogens is thought to be similar to that associated with *P. insidiosum* and *L. giganteum*, causing infection through production of motile aquatic zoospores that adhere to and encyst in damaged tissues.

The epidemiologic features of lagenidiosis are similar in many respects to those associated with cutaneous pythiosis. Affected animals are typically young to middle-aged dogs that live in the southeastern United States. Although most affected dogs have lived in Florida or Louisiana, cases in Texas, Tennessee, Alabama, Georgia, South Carolina, Maryland, Virginia, Indiana, and Illinois have also been identified. A number of infected dogs have had frequent exposure to lakes or ponds. None have had historical evidence of immunocompromise or were treated with immunosuppressive therapy before development of the infection.

Clinical Features

Dogs with *Lagenidium* infection are typically evaluated for progressive, multifocal or focal, cutaneous or subcutaneous lesions

FIGURE 69-4 Tailhead mass caused by lagenidiosis in a 9-year-old female spayed mixed breed dog. Note the extensive tissue necrosis. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

that involve the extremities, mammary region, perineum, or trunk.[23] These lesions may appear as firm dermal or subcutaneous nodules, or as ulcerated, thickened, edematous areas of deep cellulitis with regions of necrosis and numerous draining tracts (Figure 69-4). As with cutaneous pythiosis, skin lesions in dogs with lagenidiosis tend to be progressive, locally invasive, and poorly responsive to medical therapy.

In dogs infected with the more aggressive species of *Lagenidium*, regional lymphadenopathy is often noted and may occur in the absence of obvious cutaneous lesions. Unlike dogs with cutaneous pythiosis, these dogs typically have occult lesions in the thorax or abdomen, which may involve the great vessels, sublumbar and/or inguinal lymph nodes, lung, pulmonary hilus, and cranial mediastinum. Animals with great vessel or sublumbar lymph node involvement usually have cutaneous or subcutaneous lesions on the pelvic limbs and often develop pelvic limb edema. Sudden death caused by great vessel rupture and associated hemoabdomen may occur in these animals.

In dogs infected with the less aggressive species of *Lagenidium*, lesions tend to be locally invasive but rarely extend beyond cutaneous and subcutaneous tissues. Distant lesions in the thorax and abdomen have not been identified, and the clinical course appears to be chronic and slowly progressive; some dogs have lesions that are somewhat stable for several years.

Diagnosis

Because of its clinical, epidemiologic, and histologic similarities to pythiosis, lagenidiosis is often misdiagnosed as pythiosis during routine histologic evaluation. In addition, because many pathologists are more familiar with the zygomycetes than the oomycetes, lagenidiosis may also be misdiagnosed as zygomycosis. Although there are subtle differences in hyphal size, morphology, and distribution among these three infections, histologic lesions associated with lagenidiosis are still often labeled as "suspected pythiosis" or "suspected zygomycosis" during routine evaluation. For this reason, clinicians should always attempt to confirm a suspected histologic diagnosis with serology, culture, or molecular diagnostic assays.

Laboratory Abnormalities

Laboratory abnormalities are often absent in dogs with lagenidiosis; when present, they most often include hyperglobulinemia and eosinophilia. Hypercalcemia has been associated with *Lagenidium* infection in one dog with cutaneous lesions on all four limbs and severe infection and enlargement of popliteal, inguinal, and superficial cervical lymph nodes.

Imaging Findings

Radiographic imaging of the thorax and sonographic imaging of the abdomen are essential parts of the diagnostic evaluation in dogs suspected to have lagenidiosis because of the potential for occult lesions in the thorax or abdomen. These may include solitary pulmonary nodules; sublumbar, inguinal, and medial iliac lymphadenopathy; thickening and invasion of the wall of the aorta or caudal vena cava (sometimes with associated aneurysm); and retroperitoneal or epaxial masses. Thoracic and abdominal lesions have not been observed in dogs infected with the less aggressive *Lagenidium* species.

Microbiologic Tests

Cytologic Examination

Cytologic examination of lymph node aspirates or impression smears made from draining lesions in dogs with lagenidiosis reveal pyogranulomatous to eosinophilic inflammation with or without broad, poorly septate hyphae.

Culture

The diagnosis of lagenidiosis is best made by culture followed by PCR and rRNA gene sequencing, which not only provides a definitive diagnosis but is also the only tool currently available that differentiates between the two pathogenic species. Isolation techniques for *Lagenidium* spp. are similar to those described for *P. insidiosum*, but with peptone-yeast-glucose (PYG) agar. For best results, small pieces of fresh, nonmacerated tissue are placed directly on the surface of the agar and incubated at 37°C. Growth is typically observed within 24 to 48 hours. Because production of the sexual reproductive structures necessary for morphologic classification has not yet been possible, definitive identification of *Lagenidium* species is currently based on rRNA gene sequencing. Although genus-specific PCR assays have been used to identify *Lagenidium* DNA extracted from cultured isolates or from infected tissue specimens,[18] the clinical importance of differentiating between the two pathogenic species in regard to prognosis and treatment makes culture and rRNA gene sequencing the preferred technique.

Serologic Testing

In dogs with supportive clinical signs and histologic findings, immunoblot serology for the detection of anti-*Lagenidium* antibodies in canine serum can suggest lagenidiosis but must be interpreted in conjunction with results of serologic testing for *P. insidiosum* infection because of the potential for cross-reactivity in serum from dogs with pythiosis. In addition, the author has observed nonspecific anti-*Lagenidium* seroreactivity in dogs with other fungal or nonfungal infections. Therefore, based on currently available data, serology alone should not be used as a basis for the diagnosis of lagenidiosis. Serology is not helpful for differentiating between infection by the two canine pathogenic species of *Lagenidium*.

Pathologic Findings

Histologically, lagenidiosis shares many characteristics with pythiosis and zygomycosis, including pyogranulomatous and

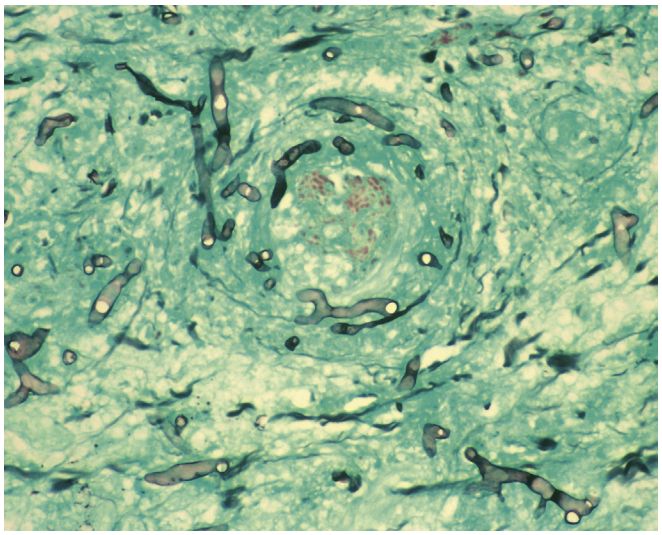

FIGURE 69-5 Broad, thick-walled infrequently septate hyphae associated with granulomatous vasculitis in a lymph node from a dog infected with the more aggressive species of *Lagenidium*. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

eosinophilic inflammation associated with broad, irregularly branching, infrequently septate hyphae with nonparallel walls. Multinucleated giant cells and plasma cells are commonly present. In contrast to *P. insidiosum*, *Lagenidium* spp. hyphae are often visible on H&E-stained sections. On GMS-stained sections, numerous broad, thick-walled, irregularly septate hyphae are easily recognized (Figure 69-5). *Lagenidium* hyphae typically demonstrate a great deal of variability in size, but in general are larger than *P. insidiosum* hyphae, ranging from 7 to 25 µm in diameter, with an average of 12 µm for the more aggressive pathogen and 7.5 µm for the less aggressive pathogen. In some sections, hyphae appear as round or bulbous structures, and right-angle branching is occasionally observed. A scant to thin eosinophilic sleeve may be noted around the hyphae.

Treatment and Prognosis

As with pythiosis, aggressive surgical resection of infected tissues is the treatment of choice for lagenidiosis when disease is confined to a resectable cutaneous lesion. Unfortunately, the vast majority of dogs infected with the more common (and more aggressive) *Lagenidium* pathogen have nonresectable disease in the thorax, abdomen, or regional lymph nodes by the time the initial diagnosis is made, and in the author's experience, the disease is routinely fatal. In dogs infected with the less aggressive species, surgery that achieves 3- to 5-cm margins is often curative. Because the species of *Lagenidium* present is often not known early in the course of diagnostic evaluation, any dog suspected of having lagenidiosis should be evaluated with thoracic radiography and abdominal ultrasonography before surgical resection of cutaneous lesions is attempted. As with pythiosis, medical therapy for lagenidiosis is usually ineffective. However, treatment with a combination of itraconazole (10 mg/kg PO q24h) and terbinafine (5 to 10 mg/kg PO q24h) along with repeated aggressive surgical resection was curative in one dog with recurrent multifocal cutaneous lesions caused by the less aggressive pathogen.

Public Health Aspects

Infections caused by *Lagenidium* species are acquired from the environment. Although there is no evidence to suggest that transmission between mammalian hosts is possible, routine precautions (such as wearing gloves when handling infected tissues or exudate) should be followed.

Overview of Zygomycosis (Entomophthoramycosis and Mucormycosis)

First Described: Reports of zygomycosis in humans date back to the 1800s.

Causes: *Basidiobolus* and *Conidiobolus* spp. (kingdom Fungi, order Entomophthorales); *Rhizopus, Absidia, Mucor* spp., and others (kingdom Fungi, order Mucorales)

Affected Hosts: Dogs, cats, humans, horses, sheep, other mammalian species

Geographic Distribution: Worldwide

Mode of Transmission: Inhalation, ingestion, or cutaneous exposure to organisms in soil and decaying organic matter

Major Clinical Signs: Entomophthoramycoses are associated with chronic, slowly progressive subcutaneous, retrobulbar, or nasal infections in immunocompetent animals; mucormycoses are associated with systemic (respiratory or gastrointestinal) or cutaneous-subcutaneous infections in immunocompromised animals.

Differential Diagnosis: Neoplasia, pythiosis, lagenidiosis, other deep mycoses (especially blastomycosis), mycobacterial infections, actinomycosis

Human Health Significance: Disease in humans results from exposure to organisms in the environment, and direct transmission between animals has not been reported.

ZYGOMYCOSIS

Etiology and Epidemiology

The term "zygomycosis" refers to infections caused by fungi in the class Zygomycetes, which includes pathogenic fungi of the genera *Basidiobolus* and *Conidiobolus* (order *Entomophthorales*) and the genera *Rhizopus*, *Absidia*, *Mucor*, and others (order *Mucorales*). In human and veterinary patients, the *Entomophthorales* typically cause chronic localized infections in subcutaneous tissue or nasal submucosa of immunocompetent patients that usually reside in tropical or subtropical locations (entomophthoramycoses), whereas the *Mucorales* tend to cause acute, rapidly progressive disease in debilitated or immunocompromised individuals worldwide (mucormycoses). *Basidiobolus* spp. and *Conidiobolus* spp. cause cutaneous lesions in dogs that are grossly and histologically similar to those caused by *P. insidiosum* and *Lagenidium* spp. Culture-confirmed infections caused by pathogens in the order *Mucorales* have not been well documented in dogs but have been described in a small number of cats. Unfortunately, clinical and pathologic information about zygomycosis in small

FIGURE 69-6 **A,** Nasopharyngeal *Conidiobolus* spp. infection in a 4-year-old male neutered German shepherd dog. **B,** Note the severe swelling of the nose and muzzle and ulceration of the nasal planum. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

animal patients is lacking because disease is uncommon to rare, and establishment of a definitive diagnosis has historically required tissue biopsy and culture. As a result, small animal patients with zygomycosis often go undifferentiated from those with pythiosis.

Basidiobolus and *Conidiobolus* species are saprophytes commonly found in soil and decaying plant matter. Cutaneous infection with *Basidiobolus* or *Conidiobolus* likely occurs by percutaneous inoculation of spores via minor trauma or insect bites. Infection may also result from inhalation or ingestion of spores.

Clinical Features

In dogs, humans, horses, sheep, and other mammalian species, conidiobolomycosis occurs most often as a nasopharyngeal infection with or without local dissemination into tissues of the face, retropharyngeal region, and retrobulbar space. Manifestations of infection in dogs may include nasal or facial swelling or deformity, nasal discharge, ulceration of the nasal planum or hard palate, exophthalmos, chemosis, ocular discharge, and sometimes skin lesions near the eye (Figure 69-6). In animals with retrobulbar disease that extends into the brain, neurologic signs may occur. *Conidiobolus* infection has been described in a single dog as a cause of multifocal nodular draining subcutaneous lesions and regional lymphadenopathy[24] and as a cause of pneumonia in a dog that was receiving chemotherapy.[25] Basidiobolomycosis is a rare cause of ulcerative skin lesions in dogs and has also been reported as a cause of respiratory disease in a dog.[26] Disseminated *Basidiobolus* infection involving the gastrointestinal tract and other abdominal organs has been described in two dogs.[7,27]

In cats, culture-confirmed cases of zygomycosis are sparse and have been limited to single reports of cats infected with fungi in the order *Mucorales*. *Rhizomucor* was identified as the cause of duodenal perforation in a 7-month-old cat,[28] and *Cokeromyces recurvatus* was isolated from abdominal fluid in a 16-year-old cat following jejunal perforation caused by lymphosarcoma.[29] In addition, a subcutaneous mass caused by a *Mucor* species on the dorsum of the nose of a 14-year-old cat was treated successfully with posaconazole.[30]

Diagnosis

Because of their histologic similarities, zygomycosis is often confused with pythiosis (which is much more common) when tissue biopsies are evaluated. Unfortunately, there are no serologic, immunohistochemical, or molecular techniques that are routinely available for the diagnosis of zygomycosis, making identification of infected animals reliant on fungal culture of fresh tissues. As a result, a definitive diagnosis of zygomycosis is often elusive.

Laboratory and Imaging Abnormalities

Laboratory abnormalities are not well described in animals with zygomycosis. Diagnostic imaging in the form of computed tomography often provides important information about the location and extent of disease in animals with nasopharyngeal and retrobulbar lesions caused by *Conidiobolus* spp. In addition, ocular ultrasonography may help to characterize the extent of disease in dogs with retrobulbar lesions.

Cytologic and Histologic Findings

The cytologic and histologic features of zygomycosis are similar to those associated with pythiosis and lagenidiosis. On

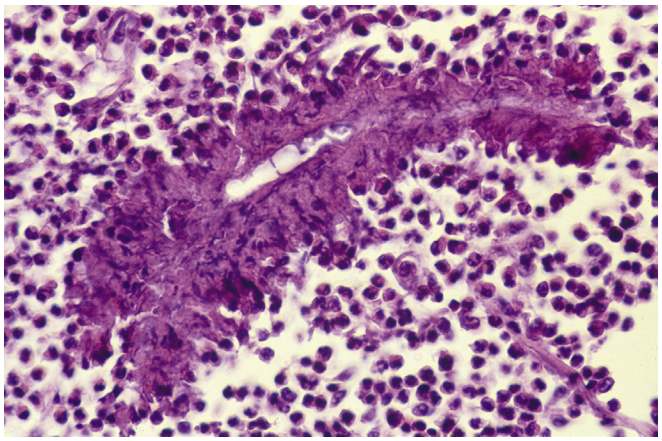

FIGURE 69-7 *Conidiobolus* spp. hyphae in a tissue biopsy from an ulcerated palate lesion in a 3-year-old female boxer. Note the large amount of amorphous eosinophilic material (sleeve) surrounding the hyphal segment; H&E stain. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

GMS-stained sections, hyphae are broad, thin-walled, and occasionally septate. The histologic hallmark of zygomycosis is the presence of a wide (2.5 to 25 µm) eosinophilic sleeve that surrounds the hyphae and makes them easily located on H&E-stained sections (Figure 69-7). This finding helps to differentiate zygomycosis from pythiosis and lagenidiosis, in which eosinophilic sleeves tend to be thin or absent. The hyphal diameter is also significantly larger for *Basidiobolus* spp. (mean 9 µm; range, 5-20 µm) and *Conidiobolus* spp. (mean 8 µm; range, 5-13 µm) than for *P. insidiosum* (mean, 4 µm; range, 2-7 µm).[31]

Treatment and Prognosis

Recommendations for the treatment of zygomycosis are not straightforward because attempted therapy has only been described in a few patients with culture-confirmed diagnoses. Although anecdotal information as well as a small number of cases in the literature suggest that cutaneous zygomycosis may be less aggressive than cutaneous pythiosis or lagenidiosis, progression of lesions and sometimes even dissemination despite treatment have also been observed in zygomycete-infected dogs. The author's current recommendation for dogs with nasopharyngeal conidiobolomycosis is treatment with itraconazole (10 mg/kg PO q24h) for at least 6 months. Recurrence is common after medication is discontinued, so a prolonged course is usually prescribed. Newer oral azoles such as posaconazole would also be reasonable choices but are significantly more expensive. Cutaneous zygomycosis in small animal patients should be treated with aggressive surgical resection of infected tissues whenever possible, followed by itraconazole therapy for 2 to 3 months. If resection is not possible, treatment with itraconazole, posaconazole, or lipid-complexed amphotericin B should be recommended.

Public Health Aspects

Zygomycosis in human patients is rare. Infections are acquired from the environment. Although there is no evidence to suggest that transmission between mammalian hosts occurs, routine precautions (such as wearing gloves when handling infected tissues or exudate) should be followed.

CASE EXAMPLE

Signalment: "Jasper," an 18-month-old intact male Labrador retriever from central Louisiana

History: Jasper was evaluated for a 1-month history of frequent vomiting and persistent diarrhea and a 2-week history of intermittent anorexia. In addition, the owner reported that the dog had lost approximately 6 kg. The diarrhea was watery and yellowish-brown and was produced in large quantity; hematochezia had not been noted. A fecal flotation and heartworm antigen test performed by the referring veterinarian 1 week before the dog was evaluated at the author's institution had been negative. Treatment with metronidazole (17 mg/kg PO q12h) and a change to an easily digestible prescription diet had failed to improve the vomiting and diarrhea. The patient was a field trial dog used for duck and dove hunting in central Louisiana. He frequently worked in rice fields and occasionally in bodies of fresh water and was generally housed in an outdoor kennel.

Physical Examination:

Body Weight: 30 kg.

General: Bright, alert, and responsive. Body temperature = 102.7°F (39.2°C), HR = 110 beats/min, RR = 20 breaths/min, mucous membranes pink, CRT ~ 2 s.

Eyes, ears, nose, and throat: No significant abnormalities were noted.

Musculoskeletal: The dog was underweight with a body condition score of 3/9.

Cardiovascular and Respiratory: Strong femoral pulses. No murmurs or arrhythmias were auscultated. Respiratory rate and effort were normal.

Gastrointestinal and Genitourinary: The patient showed signs of discomfort during abdominal palpation; a large, firm, tubular mass was palpated in the midabdomen. Mild prostatomegaly was detected on rectal examination.

Lymph nodes: All palpable peripheral lymph nodes were normal in size and shape.

Laboratory Findings:

CBC:

HCT 33.7% (37%-55%)
MCV 61.7 fL (62-77 fL)
MCHC 20.8 g/dL (32-37 g/dL)
WBC 10,600 cells/µL (8000-14,500 cells/µL)
Neutrophils 6200 cells/µL (3000-11,500 cells/µL)
Lymphocytes 1700 cells/µL (1000-4800 cells/µL)
Monocytes 1100 cells/µL (100-1400 cells/µL)
Platelets 254,000/µL (220,000-600,000 platelets/µL).

Serum Chemistry Profile:

Sodium 142 mmol/L (140-153 mmol/L)
Potassium 4.4 mmol/L (3.8-5.5 mmol/L)
Chloride 110 mmol/L (107-115 mmol/L)
Bicarbonate 20 mmol/L (17-27 mmol/L)
Phosphorus 4.6 mg/dL (3.4-6.3 mg/dL)
Calcium 9.1 mg/dL (9.4-11.4 mg/dL)

VetBooks.ir

BUN 11 mg/dL (8-22 mg/dL)
Creatinine 0.7 mg/dL (0.5-1.7 mg/dL)
Glucose 96 mg/dL (80-115 mg/dL)
Total protein 5.7 g/dL (5.8-7.5 g/dL)
Albumin 2.0 g/dL (2.6-4.2 g/dL)
Globulin 3.7 g/dL (2.5-4.0 g/dL)
ALT 34 U/L (0-60 U/L)
AST 22 U/L (0-50 U/L)
ALP 13 U/L (0-100 U/L)
Creatine kinase 134 U/L (0-200 U/L)
Cholesterol 158 mg/dL (150-240 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.4 mg/dL).

Urinalysis: SGr 1.041, pH 7.5, 3+ protein, 3+ bilirubin, negative hemoglobin, negative glucose, negative ketones, 0-5 WBC/HPF, 0 RBC/HPF, many lipid droplets.

Imaging Findings:

Plain Abdominal Radiographs: There was a generalized loss of serosal detail in the abdomen. Gas was present in the gastrointestinal tract, but there was no evidence of abnormal intestinal tract dilation.

Abdominal Ultrasound: A severely thickened segment of small bowel could be visualized extending from the cranial to the caudal abdomen. The wall of this bowel segment measured 1.1 cm in thickness and lacked normal layering (Figure 69-8, *A*). Mesenteric lymph nodes were enlarged and heterogenous (Figure 69-8, *B*). There was a small amount of free abdominal fluid.

Cytology Findings: Cytologic evaluation of ultrasound-guided mesenteric lymph node aspirates revealed reactive lymphoid hyperplasia. Examination of ultrasound-guided aspirates of the thickened segment of bowel showed that the cellularity was too low for cytologic evaluation.

Serology Findings: ELISA serology for anti–*Pythium insidiosum* antibodies: Positive at 69%. Results of this assay are expressed as percent positivity in comparison with a strong positive control sample, with values > 40% positivity having been shown to be 100% specific for pythiosis in dogs. Values in healthy dogs range from 3% to 15%.[19]

Diagnosis: Jejunal pythiosis.

Treatment: Abdominal exploratory revealed a 50-cm segment of the mid-jejunum that was severely thickened and firm. This segment was resected with 5-cm margins. After an uneventful postoperative recovery, the dog's vomiting, diarrhea, and anorexia resolved quickly. He was treated with itraconazole (10 mg/kg PO q24h) and terbinafine (8.3 mg/kg PO q24h) for 2 months in an effort to decrease the chance of recurrence of disease at the site of resection. Liver enzyme activities and serum bilirubin concentration were monitored during this time and remained within reference intervals.

Histopathologic Findings: Both the resected segment of jejunum as well as jejunal and ileocolic lymph nodes were submitted for histologic examination. Results revealed severe transmural eosinophilic pyogranulomatous enteritis and lymphoid hyperplasia. In the jejunal lesion, wide (3- to 8-µm), poorly septate hyphae with nonparallel walls were visualized on GMS-stained sections. No organisms were observed in the lymph node sections.

Follow-up: At reevaluation 2 months after resection of the jejunal lesion, the dog remained free of clinical signs and had gained 3 kg body weight. Reevaluation of anti–*Pythium insidiosum* antibody serology at that time yielded a percent positivity of 20%. Because the rapid decrease in antibody levels from 69% to 20% was strongly suggestive of a surgical cure of gastrointestinal pythiosis, oral antifungal medications were discontinued. Reevaluation of anti–*Pythium insidiosum* antibody serology 2 years later yielded results within the range observed in healthy dogs (6%).

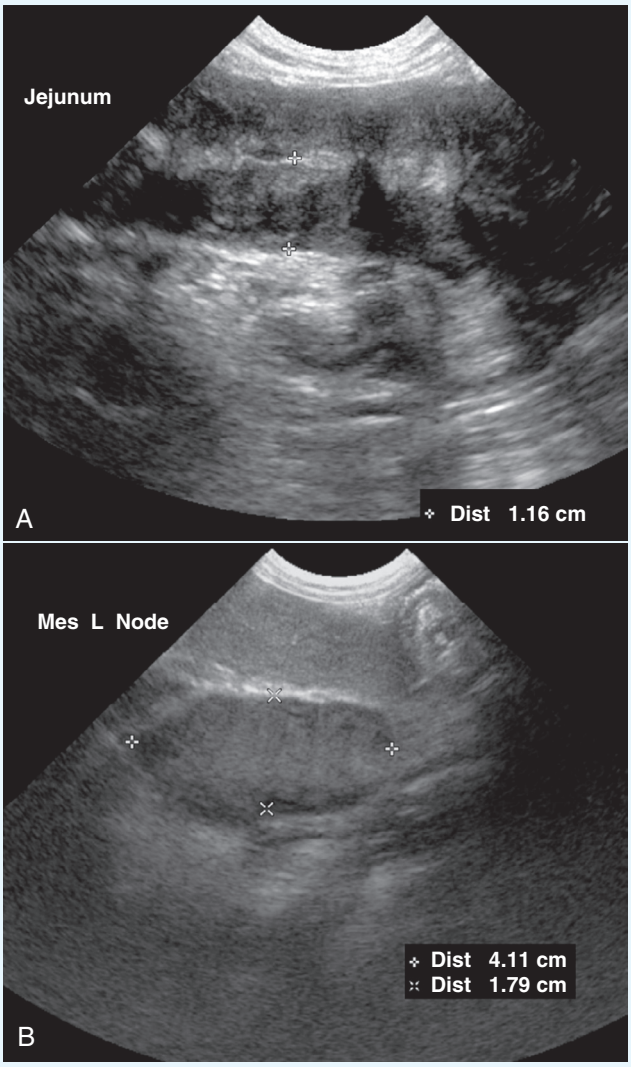

FIGURE 69-8 Sonographic images of the abdomen of the dog described in the case example. Note the severe thickening and loss of layering in the wall of the jejunum **(A)** and the enlarged, heterogenous appearance of the mesenteric lymph node **(B)**.

Comments: Although most dogs with gastrointestinal pythiosis have nonresectable lesions, those with mid-jejunal lesions can often be surgically cured. Preoperative abdominal ultrasound is essential since it helps to determine whether or not a gastrointestinal lesion might be surgically resectable. Because medical therapy alone is often unsuccessful for the treatment of gastrointestinal pythiosis, surgery should be pursued unless there is clear evidence that lesions are nonresectable. Postoperative medical therapy was probably not necessary in the case described

Continued

here, since the postoperative clinical course and follow-up serology results strongly supported a surgical cure. In the author's experience, most dogs with a midjejunal lesion are surgically cured when the surgeon is confident that greater than 5-cm margins of healthy tissue were obtained with the resection and lymph node histology shows hyperplasia rather than infection. In such cases, medical treatment with itraconazole and terbinafine can be offered as optional but likely unnecessary therapy for 2 months until follow-up serology is performed.

CHAPTER 70

Protothecosis

Jane E. Sykes

VetBooks.ir

Overview of Protothecosis

First Described: *Prototheca* spp. was first isolated from tree slime in the 1880s. Naturally occurring protothecosis was not described until 1952, in cattle (mastitis). Canine disease was reported in 1969, 5 years after the first description of human protothecosis (Van Kruiningen and othes).[1]

Cause: *Prototheca* spp. (lower algae, Chlorophyceae)

Affected Hosts: Dogs, cats, cattle, humans, other domestic and wild animal species

Geographic Distribution: Worldwide except Antarctica, but especially in warm, humid climates and where there is organic matter with a high water content

Mode of Transmission: Cutaneous inoculation of organisms into tissues, or possibly systemic invasion in the face of immunosuppression by organisms that have been ingested or colonize the intestinal tract

Major Clinical Signs: Cutaneous nodules or masses or systemic illness with weight loss, blindness due to ocular involvement, polyuria and polydipsia, hematochezia, vomiting, lameness, neurologic signs

Differential Diagnoses: Chlorellosis (a rare algal disease), a variety of fungal diseases (e.g., histoplasmosis, cryptococcosis, sporotrichosis), intestinal pythiosis, neoplasia (especially round cell neoplasia), toxoplasmosis, neosporosis, granulomatous colitis of boxer dogs, inflammatory bowel disease

Human Health Significance: Human infections occur as a result of exposure to organisms in the environment and are often associated with underlying immune compromise.

Etiology and Epidemiology

Protothecosis is an uncommon cutaneous or systemic disease caused by *Prototheca* species, which are unicellular algae. *Prototheca* spp. lack chlorophyll, and as a result they are dependent on a saprophytic lifestyle. Although ubiquitous in nature, they are especially prevalent in warm, humid climates (e.g., southern and southeastern United States, northeastern Australia, southern continental Europe, Japan) in aqueous environments where decaying organic matter is present. They have been isolated from tree slime, sewage, fresh and saltwater sources, fish tanks, soil, animal excrement, and foodstuffs. Routine water chlorination may not inactivate *Prototheca*.[2] *Prototheca* spp. also colonize the skin and gastrointestinal and respiratory tracts of humans.[3]

The algae are round to oval, 5 to 30 µm in diameter, have a thick cell wall, and reproduce asexually by endosporulation (internal division), which results in a sporangium that contains up to multiple sporangiospores. Rupture of the sporangium releases sporangia into tissues, and the cycle continues. Although the classification of *Prototheca* species is still in flux, six species are currently recognized: *Prototheca zopfii, Prototheca wickerhamii, Prototheca blaschkeae, Prototheca stagnora, Prototheca ulmea,* and *Prototheca cutis* (Table 70-1).[4] Only *P. zopfii* and *P. wickerhamii* have been identified as causes of disease in dogs and cats. Two genotypes of *P. zopfii* are recognized. *P. zopfii* genotype 1 is a weakly pathogenic variant and has been isolated from a minority of protothecal mastitis cases in dairy cows.[4,5] In contrast, *P. zopfii* genotype 2 may be the most virulent *Prototheca* variant. It causes the vast majority of bovine *Prototheca* mastitis cases worldwide and most protothecosis in dogs.[4] *P. wickerhamii* is often associated with cutaneous disease and has to date been isolated from all affected cats, some dogs, and almost all human patients (see Table 70-1). In dogs, disease caused by *P. wickerhamii* may follow a less aggressive clinical course than that caused by *P. zopfii* genotype 2.[6]

Protothecosis is an uncommon and sporadic disease of dogs and is rare in cats. In dogs, protothecosis is usually a serious

TABLE 70-1

Major Species (and Genotypes) of *Prototheca* and Their Clinical Relevance

Species	Host Species Infected	Clinical Manifestations
P. zopfii genotype 1	Cattle	Mastitis (low pathogenicity)
P. zopfii genotype 2	Dogs, humans, cattle, other	Mastitis (cattle), disseminated infections (dogs)
P. wickerhamii	Dogs, cats	Cutaneous disease
P. blaschkeae	Cattle, humans	Mastitis (cattle), cutaneous disease (humans)
P. stagnora	Nonpathogenic	NA
P. ulmea	Nonpathogenic	NA
P. cutis	Humans	Cutaneous disease

NA, Not applicable.

VetBooks.ir

disseminated disease, but localized cutaneous disease occurs occasionally. Most affected dogs do not have a history of immunosuppressive drug therapy or illness. Boxer dogs and collies may be predisposed,[6] possibly secondary to an underlying genetic immunodeficiency, although a variety of other small- and large-breed dogs also can be affected. Occasionally protothecosis occurs in dogs in conjunction with infection by other opportunistic pathogens such as *Neospora*,[7] which supports the likelihood that underlying immune deficiency is present. At the author's hospital, disseminated protothecosis was diagnosed in a canine renal transplant recipient that was treated with cyclosporine, and lymphocutaneous *P. wickerhamii* infection was diagnosed in a dog treated with chemotherapy for lymphoma.[7] The median age of affected dogs in one series of 17 dogs was 4 years (range, 18 months to 11 years), and approximately 70% of the affected dogs were female.[6] Cats with protothecosis have single or multiple nodular skin lesions; disseminated disease has not been reported. Affected cats are typically FIV and FeLV negative, are otherwise in good health, and have ranged in age from 3 to 16 years.[8-13]

Clinical Features

Signs and Their Pathogenesis

The pathogenesis of protothecosis is not fully understood. Infection may occur secondary to cutaneous inoculation of organisms, which may be followed by development of localized cutaneous nodules or dissemination through lymphatic or hematogenous spread. It is also possible that systemic invasion by organisms that are ingested or colonize the gastrointestinal tract occurs. An incubation period of 10 days to several weeks has been suggested for human protothecosis, based on recollection of penetrating injuries before onset of disease.[2]

In dogs, *Prototheca* can disseminate to a variety of tissues, but especially the colon, eyes, brain and meninges, kidneys, and long bones. This results in clinical signs of inappetence and weight loss; acute or chronic large bowel diarrhea (often with hematochezia and tenesmus); blindness; neurologic signs such as obtundation, seizures, or ataxia; polyuria and polydipsia; and sometimes lameness due to osteomyelitis.[6,13-16] Deafness is often reported in association with disseminated protothecosis and may occur as a result of central nervous system (CNS) or inner ear involvement.[13,16,17] Ocular lesions include granulomatous chorioretinitis, uveitis, and panophthalmitis. Other affected organs include the liver, skeletal muscle, thyroid gland, lymph nodes, spleen, pancreas, stomach, small intestine, omentum, myocardium, aorta, spinal cord, and/or lungs.[16-19] Involvement of these organs may lead to other signs such as vomiting, small bowel diarrhea, and/or melena. Sudden death has also been reported, possibly secondary to myocardial involvement.[6,20,21]

Physical Examination Findings

Cutaneous lesions in dogs are nodular and may ulcerate. They often involve the footpads or distal limbs and associated draining lymph nodes, but involvement of other sites such as the trunk and planum nasale can also occur. In cats, single or multiple firm and sometimes ulcerated cutaneous nodules may be present. Lesions may be located on the head, footpads, and distal limbs and tailbase[8-10] and can resemble those caused by *Cryptococcus* or *Sporothrix*.

Dogs with disseminated disease may be obtunded and/or dehydrated and can have a thin body condition. Some dogs are febrile, but rectal temperature may also be normal. Ocular involvement may be manifested by blindness or evidence of conjunctivitis, hyphema, uveitis, cataract formation, panophthalmitis, or granulomatous chorioretinitis, often with retinal detachment. Arrhythmias with pulse deficits may be present in dogs with protothecal myocarditis.[7] Neurologic signs include obtundation, blindness, deafness, ataxia, abnormal placing reactions, circling, head tilt, nystagmus, strabismus, and abnormalities of cranial nerve function such as absent or decreased facial sensation, palpebral, menace, or gag reflexes.[6,14,22-25] Dried fecal material or blood may be present around the anus, and rectal examination may reveal the presence of hematochezia, increased fecal mucus, or melena.

Diagnosis

Laboratory Abnormalities

Complete Blood Count and Serum Biochemical Tests

The CBC in dogs with disseminated protothecosis is often normal. Occasionally it reveals nonregenerative anemia and/or leukocytosis due to a neutrophilia and sometimes monocytosis.[15,16,18] Mild bandemia and/or eosinophilia may be present in some dogs. The serum biochemistry panel may also be normal or reveal hyperglobulinemia due to a polyclonal gammopathy. Mild to moderate azotemia may be evident in dogs with renal involvement.[15,18] Hypoalbuminemia and hypocholesterolemia may occur with severe bowel involvement.[6]

Urinalysis

The urinalysis in dogs with disseminated protothecosis may be unremarkable or reveal isosthenuria, hematuria, pyuria, proteinuria, and the presence of *Prototheca* organisms in the sediment.[15] Urinalysis and urine culture should be performed in all dogs suspected to have protothecosis, because more than half of affected dogs shed algae into the urine.

Cerebrospinal Fluid Cytology

CSF analysis in dogs with CNS protothecosis may be normal or reveal markedly increased total nucleated cell count (sometimes >1000 cells/μL) and increased CSF protein concentration (often >500 mg/dL).[18,22,23] Eosinophilic pleocytosis has been described in some dogs,[22,25] but eosinophils are not always present.[23] *Prototheca* algae may also be found in the CSF.[22,23]

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with disseminated protothecosis are usually unremarkable.[15,18,19,21] Radiographs of affected long bones may reveal periosteal proliferative and/or osteolytic lesions due to osteomyelitis.[6]

Sonographic Findings

Findings on abdominal ultrasound examination in dogs with disseminated protothecosis include hyperechogenicity of the renal cortices,[15] a thickened colonic wall with loss of normal bowel wall layering,[6] and abdominal lymphadenopathy. Some dogs have no abdominal sonographic abnormalities despite the presence of disseminated disease with colonic and renal involvement.[7]

Other Imaging

Colonoscopy in dogs with protothecosis that has disseminated to the large intestine may reveal a hyperemic, friable, thickened, irregular, and ulcerated mucosa.[6]

Magnetic resonance imaging of the brain of one dog with CNS involvement revealed mild to moderate ventriculomegaly, mild protrusion of the cerebellar vermis through the foramen magnum, syringomyelia, meningeal contrast enhancement, and a focus of increased signal intensity in the brain on T2-weighted and fluid attenuated inversion recovery (FLAIR) sequences.[23] As it enlarged, the focus developed contrast enhancement and caused deformation of a lateral ventricle.

Microbiologic Tests

Specific diagnostic assays for protothecosis are described in Table 70-2.

Cytologic Examination

Prototheca organisms may be seen using cytologic examination of rectal scrapings; fine-needle aspirates of lymph nodes or bone or skin lesions; CSF or vitreal or aqueous humor; and urine sediment. The organisms are spheroid, ovoid, bean-shaped or elliptical, and range in diameter from 1.5 to 30 µm (*P. zopfii*) or up to 10 µm (*P. wickerhamii*). They have a thick, hyaline cell wall that does not take up stain, and a basophilic, granular cytoplasm. Multiple daughter cells (2 to usually <10) may be seen inside the cell (Figure 70-1). In the case of *P. wickerhamii*, the endospores are arranged symmetrically like a daisy or soccer ball, whereas the endospores of *P. zopfii* are

TABLE 70-2

Diagnostic Assays Available for Protothecosis

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, urine sediment, vitreous or aqueous humor, CSF	*Prototheca* algae	Usually large numbers of organisms are present, so sensitivity is high, but false negatives can still occur (such as when urine sediment or CSF are examined). Organisms may be confused with other fungi or *Chlorella* species, so confirmation of the diagnosis requires culture.
Culture	Urine, blood, CSF, vitreous or aqueous humor, aspirates or biopsies of affected tissues	*Prototheca* species	*Prototheca* spp. grow rapidly (usually within 3 days) on routine media such as blood agar and Sabouraud dextrose agar. Allows species identification and subsequent genotyping.
Histopathology	Skin or colonic biopsies, enucleated eyes, tissues collected at necropsy	*Prototheca* algae	Usually large numbers of organisms are present, so sensitivity is high. Organisms are highlighted with PAS or silver stains. Organisms may be confused with other fungi or *Chlorella* species, so confirmation of protothecosis requires culture.

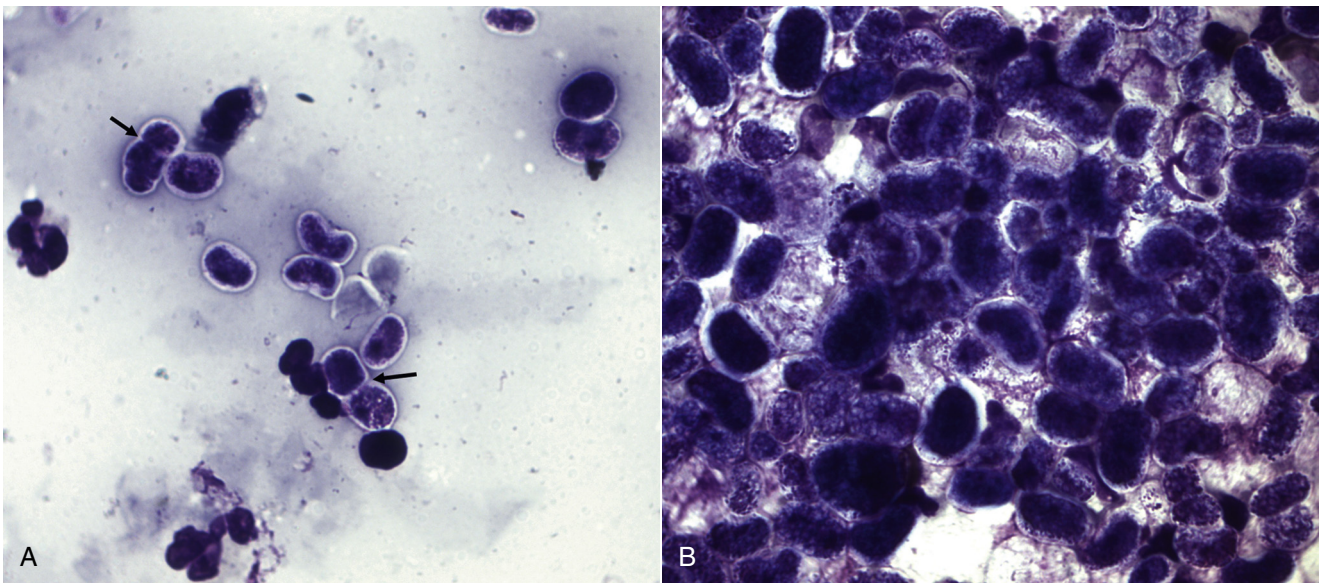

FIGURE 70-1 **A,** Cytology of a subretinal aspirate from an 8-year-old intact male mixed breed dog with panophthalmitis due to *Prototheca* spp. infection. Moderate numbers of oval to bean-shaped organisms are present in a proteinaceous background that contained variably degenerate and ruptured neutrophils. The organisms have a thin clear capsule with deep purple cytoplasmic granulation. Sometimes endosporulation is evident *(arrows)*. Wright's stain, 1000× oil magnification. **B,** Cytology of a bone aspirate from a 2-year-old female mixed breed dog that developed acute vision loss. Physical examination revealed bilateral retinal detachment and a nonpainful swelling of the right distal medial humerus. Abundant numbers of *Prototheca* algae are present. (Courtesy Dr. Emily Pieczarka.)

distributed randomly.[2] The algae may be mistaken for fungi such as *Blastomyces, Coccidioides,* or *Cryptococcus*. Because large numbers of organisms are typically present, the sensitivity of cytologic examination for diagnosis of algal infection is high. However, failure to find organisms does not rule out protothecosis.

Culture

Prototheca species can be readily cultured in the microbiology laboratory on standard media (such as blood agar and Sabouraud dextrose agar), and yeast-like colonies are usually visible within 7 days. Suitable specimens for culture include aspirates or biopsies of affected tissue and body fluids such as urine, CSF, and vitreous or aqueous humor. *Prototheca zopfii* was also cultured from the blood of a dog with disseminated disease.[21] Biochemical testing of isolates allows identification of the *Prototheca* species present and excludes other possible causes such as the green alga *Chlorella,* a very rare cause of disseminated disease in dogs that can closely resemble *Prototheca* in its microscopic appearance.[2,26] Differentiation of *P. zopfii* genotypes requires PCR and ribosomal RNA gene sequencing. Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry offers promise for rapid identification to the species and genotype level in the clinical microbiology laboratory in the future.[4,27]

Antifungal susceptibility testing has been performed for *Prototheca* but has not been standardized, and the clinical relevance of the results is not clear.[2]

Molecular Diagnosis Using the Polymerase Chain Reaction

Real-time PCR assays have been developed that detect and differentiate *Prototheca* species,[28] but these are not available on a commercial basis for diagnosis of protothecosis in animals.

Pathologic Findings

Gross pathologic findings in dogs with disseminated protothecosis include enlarged lymph nodes and gray, tan, or white nodular lesions or streaks in affected organs.[13,16,18,25] The colonic wall may be thickened and contain bloody fluid. Malacic foci may be present in the brain, or the brain may appear normal grossly, even when meningoencephalitis is present.[7,24] Histopathologic examination of affected tissues typically reveals large numbers of sporulating and nonsporulating algae accompanied by a mixed inflammatory response and foci of necrosis (Figure 70-2, *A*). In some tissues the inflammatory response can be minimal to absent.[16,18] Organisms may be seen free and

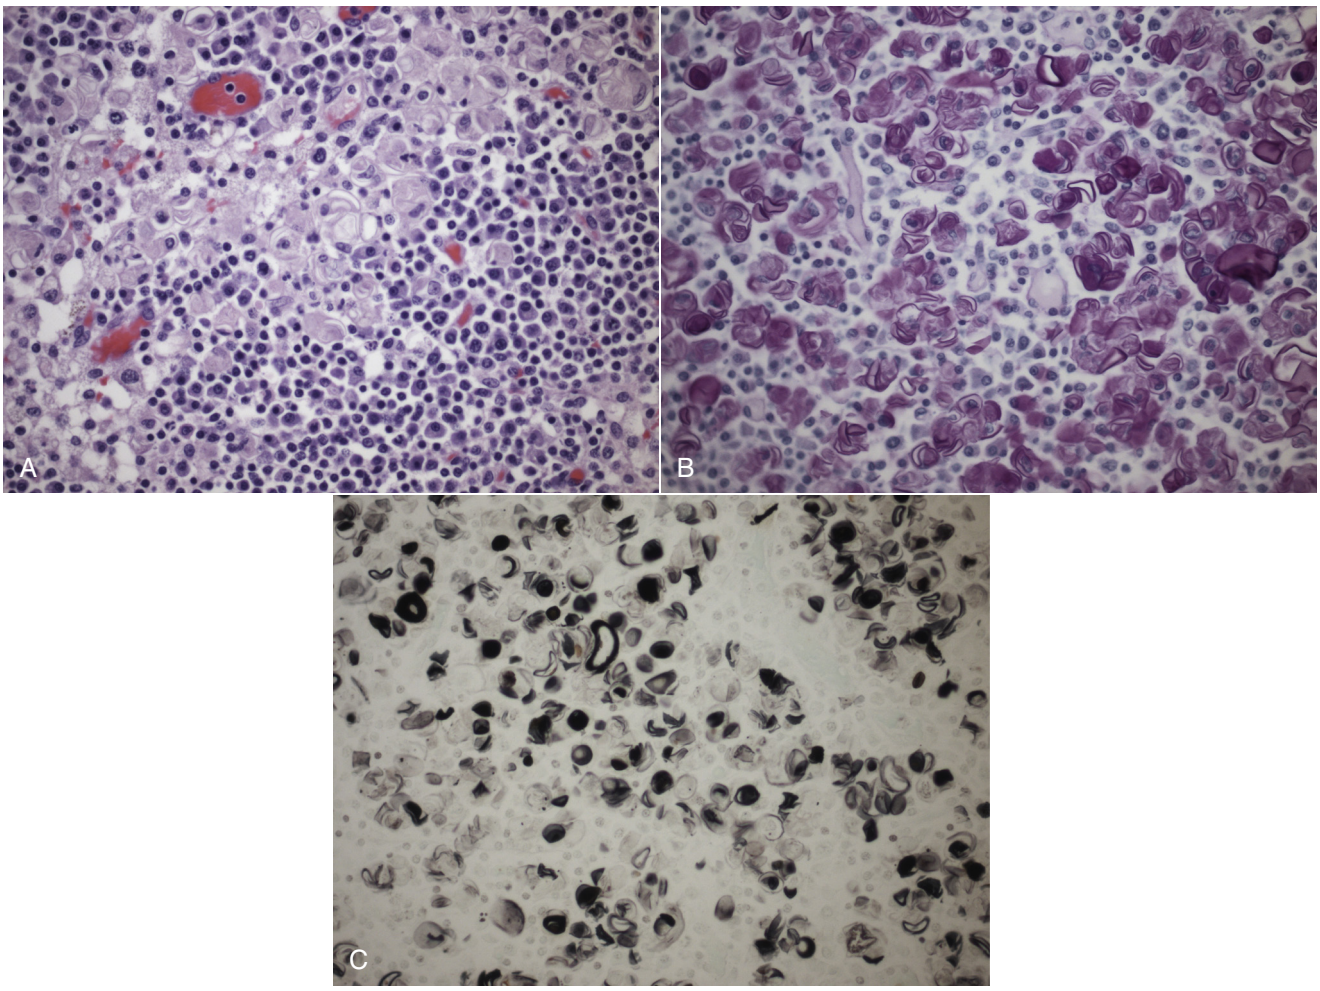

FIGURE 70-2 Histopathology of the renal lymph node of a 6-year-old spayed female shih tzu with protothecosis that was being treated with cyclosporine after renal transplantation. Numerous *Prototheca* organisms are present. The organisms range in diameter from 5 to 15 µm and have several morphologic forms. Sporulating forms are up to 15 µm in diameter and contain two to four wedge-shaped endospores (daughter cells). Many of the organisms present as clear, refractile, oval to polyhedral bodies composed of a thick wall and devoid of cytoplasm and nuclei. **A,** H&E stain. **B,** Periodic acid–Schiff stain. **C,** Gomori's methenamine silver.

within macrophages. The cell wall stains well with Gomori's methenamine silver and periodic acid–Schiff (PAS) stain, but in contrast to *Chlorella*, cytoplasmic granules of *Prototheca* are PAS negative. Cutaneous lesions in cats have been associated with a granulomatous inflammatory response with multinucleated giant cells and, in some cases, necrosis and neutrophilic inflammation.[9,11]

Treatment and Prognosis

Surgical excision can be curative for localized cutaneous protothecosis and should be performed whenever possible.[9] Medical treatment of protothecosis is challenging. In human patients, treatment is generally with amphotericin B, which in some cases results in complete cure. Addition of a tetracycline has also been recommended.[2] Outcomes with azole antifungals alone are often poor, although clinical responses occur in some dogs with itraconazole alone.[7] In one human patient, a combination of amikacin and tetracycline led to cure.[29] Treatment of canine disseminated protothecosis with amphotericin B leads to remission in some cases, but relapse typically occurs when the drug is discontinued, or dogs fail to respond to treatment and ultimately die or are euthanized as a result of the disease.[6,21] One dog with protothecal meningoencephalitis appeared to improve clinically after treatment with oral itraconazole and intrathecal amphotericin B, but was euthanized 4 weeks later because of progressive disease.[23]

Other treatments that may be required for protothecosis include intravenous fluid therapy, antiemetics, topical prednisolone acetate ophthalmic drops for uveitis, or ocular enucleation to control pain and/or remove a focus of infection that fails to respond to chemotherapy (see Case Example). Other treatments such as metronidazole, sulfasalazine, or dietary manipulation may help to control signs of protothecal colitis.

Public Health Aspects

Protothecosis is an uncommon disease of humans and most often caused by *P. wickerhamii*. Infection is acquired from environmental sources, and direct transmission of other animals or humans does not appear to be important. Mortality is low (<5%), and two thirds of infections are chronic and localized to the skin.[2] Joint infections and tendonitis have been described after surgical or accidental wounds; some have been traced back to cleaning an aquarium.[30] Disseminated infections and a syndrome called olecranon bursitis (which follows elbow trauma) account for the remaining third of cases. Underlying local or systemic immune defects can be identified in many patients; topical, local, or systemic glucocorticoid treatment is the most frequently identified risk factor. Other immunosuppressive disorders that may predispose humans to protothecosis include diabetes mellitus and malignancy. Severe disseminated disease has been described in bone marrow and kidney transplant recipients,[31,32] in those with long-standing indwelling catheters or endotracheal tubes, and rarely in AIDS patients.[30,33]

CASE EXAMPLE

Signalment: "Merlot," a 3-year-old female spayed Siberian husky dog from San Francisco, CA

History: Merlot was evaluated at the University of California, Davis, Veterinary Medical Teaching Hospital for a 1-month history of hemorrhagic diarrhea, inappetence, and weight loss. Initially the diarrhea contained fresh blood and mucus but more recently contained only blood. The diarrhea occurred frequently and in small quantities. The owner reported that Merlot had lost approximately 5 kg over the past month and had increased thirst and urination. There had been no history of vomiting, and Merlot's activity level was normal. Her diet consisted of a commercial dry dog food.

At a local veterinary clinic, multiple fecal flotations had been negative, and Merlot had been treated with metronidazole, aminopentamide, bismuth subsalicylate, enrofloxacin, loperamide, tetracycline, metoclopramide, and a highly digestible diet without clinical response. A barium series had recently been performed, and findings were consistent with gastroenteritis.

Merlot had moved to San Francisco from Massachusetts 4 months before the clinical signs began. On the way over the owner stopped in Texas, where Merlot became lost in a field for 30 minutes. The owner reported that Merlot was taken to a dog park in San Francisco several times a week. No other history of illness existed.

Physical Examination:

Body Weight: 18.2 kg.

General: Bright, alert, responsive, and hydrated. T = 102.3°F (39.1°C), HR = 80 beats/min, panting, mucous membranes pink, CRT = 1 s.

Integument, Eyes, Ears, Nose, and Throat: Dried barium was present on the dog's lips, and there were no other clinically significant findings. Fundoscopic examination revealed a region of retinal separation in the left ocular fundus that was adjacent to, dorsomedial to, and approximately the size of the optic disc. The lesion appeared to contain yellowish fluid.

Musculoskeletal: Thin but well-muscled. Body condition score was 3/9.

Cardiorespiratory: No clinically significant findings.

Gastrointestinal/Genitourinary: No masses were palpated in the abdomen. The dog vocalized and appeared painful on caudal abdominal palpation. Frank blood was present on the glove after rectal examination.

Peripheral Lymph Nodes: All peripheral lymph nodes were normal in size.

Laboratory Findings:

CBC:

HCT 48.6% (40%-55%)
MCV 70.9 fL (65-75 fL)
MCHC 34.6 g/dL (33-36 g/dL)
WBC 12,100 cells/µL (6000-13,000 cells/µL)
Neutrophils 9438 cells/µL (3000-10,500 cells/µL)
Lymphocytes 2057 cells/µL (1000-4000 cells/µL)

VetBooks.ir

Monocytes 363 cells/µL (150-1200 cells/µL)
Eosinophils 242 cells/µL (0-1500 cells/µL)
Platelets 259,000/µL (150,000-400,000 platelets/µL).

Serum Chemistry Profile:
Sodium 150 mmol/L (145-154 mmol/L)
Potassium 4.3 mmol/L (3.6-5.3 mmol/L)
Chloride 114 mmol/L (108-118 mmol/L)
Bicarbonate 28 mmol/L (16-26 mmol/L)
Phosphorus 4.2 mg/dL (3.0-6.2 mg/dL)
Calcium 9.8 mg/dL (9.7-11.5 mg/dl)
BUN 21 mg/dL (5-21 mg/dL)
Creatinine 1.2 mg/dL (0.3-1.2 mg/dL)
Glucose 99 mg/dL (64-123 mg/dL)
Total protein 6.4 g/dL (5.4-7.6 g/dL)
Albumin 2.9 g/dL (3.0-4.4 g/dL)
Globulin 3.5 g/dL (1.8-3.9 g/dL)
ALT 61 U/L (19-67 U/L)
AST 42 U/L (19-42 U/L)
ALP 126 U/L (21-170 U/L)
Cholesterol 145 mg/dL (135-361 mg/dL)
Total bilirubin 0 mg/dL (0-0.2 mg/dL).

Urinalysis: SGr 1.005; pH 6.0; no protein (SSA), bilirubin, hemoprotein, or glucose; 0-1 WBC/HPF, rare RBC/HPF, rare transitional epithelial cells; no crystals, casts or bacteria. Moderate numbers of encapsulated organisms were present that measured 10 × 17 µm.

Imaging Findings: Abdominal ultrasound examination: No abnormalities were identified.

Microbiologic Testing: Centrifugal zinc sulfate fecal flotation: Negative, but yeast-like bodies were observed.

Giardia and *Cryptosporidium* fluorescent antibody testing (fecal specimen): Negative.

Cytologic examination of rectal scrapings: Moderate numbers of neutrophils, small numbers of gram-positive coccobacilli, and small numbers of what appeared to be algae were present.

Aerobic bacterial urine culture: Small numbers of *Prototheca zopfii*.

Algal susceptibility testing: MICs for amphotericin B, fluconazole, and itraconazole were 0.5 µg/mL, >64 µg/mL, and 1 µg/mL, respectively.

Histopathology (rectal biopsy obtained by proctoscopy): erosive and hemorrhagic colitis, eosinophilic and lymphoplasmacytic, moderate, with marked expansion of the lamina propria by intralesional spherical organisms (protothecal colitis).

Aerobic bacterial and fungal culture of a rectal biopsy: Small numbers of mixed enteric species and *P. zopfii*.

Diagnosis: Disseminated *P. zopfii* infection with ocular and colonic involvement.

Treatment: Merlot was initially treated with lipid-complexed amphotericin B (3 mg/kg IV) on a Monday, Wednesday, and Friday basis for five doses, after which increased serum creatinine concentration was noted (1.7 mg/dL). She was also treated with oxytetracycline (21 mg/kg PO q8h). She was discharged after 11 days with instructions to administer itraconazole (5 mg/kg PO q12h) and lufenuron (5 mg/kg PO q24h). At a recheck examination 2 weeks later, the owners reported Merlot's appetite had improved slightly and that she was defecating once to twice a day. Each bowel movement was followed by a small amount of diarrhea at the end of defecation, with bloody mucoid material occasionally present. In the 2 weeks since her previous visit, a foxtail had been removed from her right pelvic limb and she had been sprayed in the face by a skunk. Physical examination revealed a body weight of 19.2 kg (1 kg weight gain), but aqueous flare and multifocal retinal separations were present in both eyes. Urinalysis was unremarkable, and rectal scrapings showed no evidence of algal organisms. A biochemistry panel showed normalization of the creatinine and mildly increased activity of ALT, likely secondary to itraconazole administration. Topical prednisolone acetate ophthalmic drops and two additional amphotericin B treatments were administered, but bilateral retinal detachment, blindness, then bilateral hyphema and apparent ocular pain developed despite this treatment. Bilateral enucleation was performed. Histopathology of the globes showed bilateral granulomatous uveitis and retinitis with intralesional *Prototheca* organisms. In the left eye, posterior synechiae, intraocular hemorrhage, and cataract formation were identified.

At a recheck examination 3 months after enucleation, Merlot was eating well and had no signs of large bowel diarrhea. Her body weight was stable and physical examination, a CBC, a biochemistry panel, and cytologic examination of a rectal scraping were unremarkable. Itraconazole treatment was continued at a lower dose (5 mg/kg PO q24h), and the lufenuron was discontinued. Two months later, and shortly after a new puppy was introduced, Merlot developed vomiting and diarrhea with small amounts of hematochezia, and her body weight dropped to 17.5 kg. A serum biochemistry panel showed mild hypoalbuminemia (2.6 g/dL). Cytologic examination of a rectal scraping again revealed *Prototheca* organisms, and a fecal flotation was negative. Merlot was treated with fenbendazole and the dose of itraconazole was increased to 7.5 mg/kg PO daily, after which diarrhea resolved. Four months later (14 months after initial diagnosis), the dog remained in remission but was subsequently lost to follow-up.

Comments: Diagnosis of protothecosis in this dog was straightforward and initially based on routine urine sediment examination. Culture was then used to identify the causative agent as *P. zopfii*. Colonic involvement was confirmed using proctoscopy and biopsy. The most likely place that *Prototheca* infection was acquired was in Texas, but it is possible that infection was acquired elsewhere. Partial clinical remission was observed after treatment with lipid-complexed amphotericin B and itraconazole, but enucleation was required to control pain. Remission was prolonged (>1 year) even though only seven amphotericin B treatments were administered in the first 2 months after diagnosis. Lufenuron is a chitin synthetase inhibitor. Chitin is present in the cell walls of some algae (including *Chlorella*), but whether *Prototheca* possess chitin in their cell walls is not clear.

CHAPTER 71

Pneumocystosis

Remo Lobetti

VetBooks.ir

Overview of Pneumocystosis

First Described: *Pneumocystis* was first discovered in Brazil in 1909 (Chagas), when it was initially mistaken for a trypanosome.[1] It was first reported in dogs in the 1950s.[2]

Causes: *Pneumocystis* spp. (an ascomycete)

Affected Hosts: Dogs, humans, pigs, horses, goats, nonhuman primates; *Pneumocystis* species appear to have host specificity.

Geographic Distribution: Worldwide

Mode of Transmission: Opportunistic invasion of immunosuppressed hosts after transmission by aerosol

Major Clinical Signs: Weight loss, respiratory distress, exercise intolerance, variable cough

Differential Diagnoses: Canine distemper virus infection, bacterial pneumonia, mycobacterial infections, other fungal causes of pneumonia, pulmonary neoplasia (especially lymphoma), parasitic lung disease, acute respiratory distress syndrome, pulmonary fibrosis

Human Health Significance: Severely immunocompromised humans are at risk for pneumocystosis, but only *P. jirovecii* infects humans. Whether humans can become colonized with *Pneumocystis* strains that infect dogs is not known.

Etiologic Agent and Epidemiology

Pneumocystis is a saprophyte of low virulence with a worldwide distribution. Its primary habitat is the mammalian lung, where it causes opportunistic pneumonia. *Pneumocystis* pneumonia has been reported in dogs, pigs, horses, goats, primates, and humans. Subclinical or latent infections are common in rats, mice, guinea pigs, rabbits, cats, sheep, and various wildlife species. Most reports of pneumonia due to *Pneumocystis* spp. infection are linked with documented or suspected immunodeficiency syndromes in the host.[3]

The taxonomy of *Pneumocystis* is uncertain. Previously it was classified as a unicellular protozoan in the phylum Sarcomastigophora. However, ultrastructurally the reproductive behavior of *Pneumocystis* is similar to the ascospore formation by yeasts, and its organelles and staining properties by light microscopy resemble those of pathogenic fungi. Phylogenetic classification based on 16S-like rRNA sequences indicates that *Pneumocystis* is most closely related to the fungi of the class Ascomycetes, especially *Saccharomyces cerevisiae*, and so it has been reclassified as fungus, "albeit an odd one."[4] Biologically, it behaves similarly to a protozoan, because it is susceptible to drugs used to treat protozoal infections but resistant to most antifungal drugs. The morphology of *Pneumocystis* organisms and the histopathology of the lesions they produce in humans and animals throughout the world are similar. Although controversial, five species of *Pneumocystis* have been described, which appear to be highly host specific: two species that infect rats, *Pneumocystis carinii* and *Pneumocystis wakefieldiae*; one species that infects mice, *Pneumocystis murina*; a species that infects rabbits, *Pneumocystis oryctolagi*; and *Pneumocystis jirovecii* (pronounced "yee row vet zee"), which infects humans.[5-7] Species designations for the organisms isolated from dogs and other animals require further genetic and biologic study, although DNA analysis of *Pneumocystis* that infected a Cavalier King Charles spaniel suggested that dogs are infected with a unique species, with the proposed name of *Pneumocystis canis*.[8] Biologic differences between isolates from different hosts are supported by the relative difficulty of experimental cross-host species transmission. Because historically *P. carinii* was thought to cause *Pneumocystis* pneumonia in humans, *Pneumocystis* pneumonia has long been referred to as "PCP." Despite the name change to *P. jirovecii* in the 1970s, the term PCP has been retained for convenience. For purposes of this chapter, the organism will be referred to simply as *Pneumocystis*. Strain differences may also exist within species of *Pneumocystis*.

Pneumocystis appears to be maintained in nature by transmission from infected to susceptible hosts. The primary mode of spread is thought to be airborne droplet transmission.[9] Sporadic disease may occur as a result of activation of latent infection by stress, crowding, and immunosuppressive therapy during hospitalization. Clinical disease can also be experimentally activated by treatment with glucocorticoids or cytotoxic chemotherapy. A higher prevalence of infection was found in dogs with distemper compared with a corresponding control population.[10] Genetic analysis of isolates from humans suggests that recent acquisition of infection from another person, rather than reactivation of infection, may be responsible for clinical illness.[11,12]

Most affected dogs have been young miniature dachshunds (less than 1 year of age) or Cavalier King Charles spaniels.[8,13-17] Affected miniature dachshunds and Cavalier King Charles spaniels may possess an underlying primary immune deficiency.[17,18]

Clinical Features

Signs and Their Pathogenesis

Pneumocystis is inhaled and can colonize the lower respiratory tracts of clinically healthy mammals; however, it rarely multiplies to large numbers in the lungs of healthy hosts. Transmission of infection to neonates can occur via aspiration of contaminated amniotic fluid when the placenta is infected. When impaired

host resistance (especially reduced CD4 T-lymphocyte counts) or preexisting pulmonary disease is present, rapid proliferation of organisms can occur.[19] The entire life cycle of *Pneumocystis* is completed within alveolar spaces (Figure 71-1). In this location, two main forms, the trophozoite (1 to 4 µm in diameter) and cyst (8 µm), are found. Trophozoites adhere closely to alveolar epithelial cells and are thought to undergo sexual reproduction by conjugation, with formation of a diploid zygote. The zygote becomes a sporocyte (or precyst) and undergoes meiosis followed by mitosis. This leads to formation of a mature, thick-walled cyst or spore case, which contains eight haploid ascospores. The cyst ruptures, and the spores transform into trophozoites, which replicate asexually to form more trophozoites, or sexually to form more cyst forms. The transmissible form has not been identified.[7]

The overgrowth and clustering of *Pneumocystis* within alveolar spaces leads to blockage of capillaries and decreased gas exchange. Intra-alveolar organisms are often accompanied by thickening of alveolar septa, but they seldom invade the pulmonary interstitium and are rarely phagocytosed by alveolar macrophages. With an adequate immune response, the body eliminates the infection, but the removal of large numbers of organisms and cellular debris may take up to 8 weeks. Both the presence of the organisms and the mild inflammatory response they provoke contribute to pulmonary damage.

Although *Pneumocystis* infections are usually confined to the lungs, organisms are rarely reported in extrapulmonary sites. In humans, extrapulmonary pneumocystosis occurs primarily when there is overwhelming pulmonary infection, profound underlying immunodeficiency, and after long-term use of aerosolized pentamidine for prophylaxis against *P. jirovecii* pneumonia in HIV-infected patients.[20] Sites of extrapulmonary infection include lymph nodes, spleen, liver, bone marrow, gastrointestinal tract, eyes, thyroid gland, adrenal glands, kidneys, heart, pancreas, and external auditory canal. Extrapulmonary pneumocystosis has been described in one dog.

The typical clinical history in dogs with pneumocystosis is that of gradual weight loss and respiratory difficulty that progresses over 1 to 4 weeks. The weight loss, which occurs in spite of a good appetite in most dogs, may be associated with diarrhea and occasional vomiting. Cough is not always reported, but reduced exercise tolerance is uniform. Infected animals often show a minimal or temporary response to antibiotic and glucocorticoid therapy.

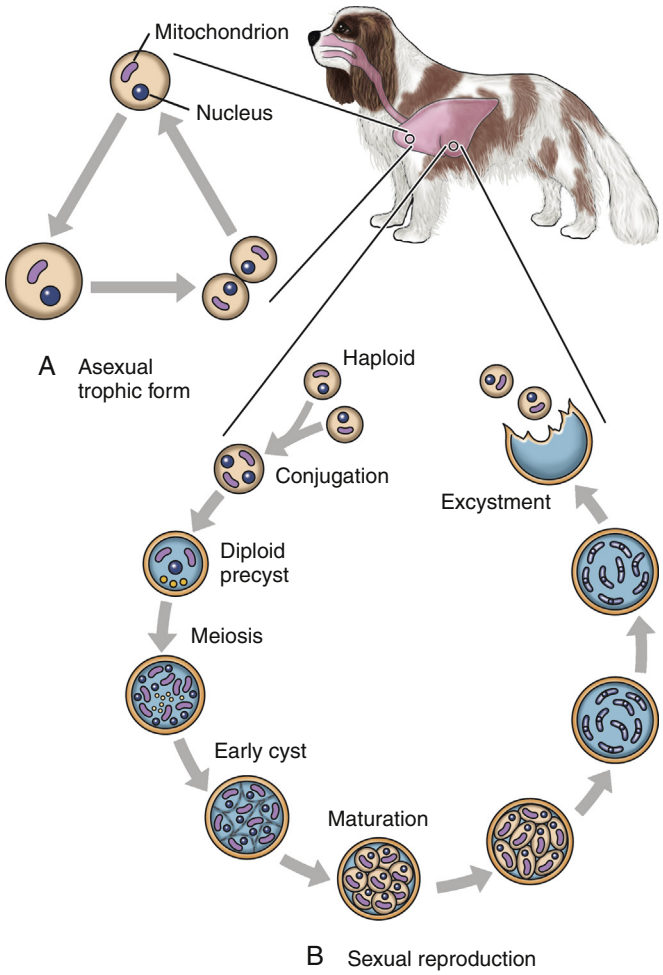

FIGURE 71-1 Life cycle of *Pneumocystis* species. Trophozoites adhere to alveolar epithelial cells in the lungs and undergo both asexual **(A)** and sexual **(B)** reproduction. Sexual reproduction is initiated by conjugation, which results in formation of a zygote. Meiosis occurs followed by mitosis, which leads to the formation of 8 ascospores within a mature cyst. The cyst ruptures, releasing spores that become trophozoites. (Modified from Walzer PD, Smulian AG. Pneumocystis species. In: Mandell GL, Bennett JE, Dolin R, eds. Principles and Practice of Infectious Diseases, 7 ed. Philadelphia, PA: Elsevier; 2010:3377-3390.)

Physical Examination Findings

Abnormalities on physical examination of dogs with pneumocystosis include dyspnea, tachycardia, and increased dry respiratory sounds on thoracic auscultation. Animals are often in poor condition and cachectic and can show dermatologic changes, such as superficial bacterial pyoderma and demodicosis (Figure 71-2). Although the mucous membranes are generally of normal color, they may be cyanotic in severely affected animals. Affected dogs remain relatively alert and afebrile, although mild pyrexia may be present.

FIGURE 71-2 One-year-old dachshund with pneumocystosis. Note the thin body condition and alopecia secondary to generalized demodectic mange.

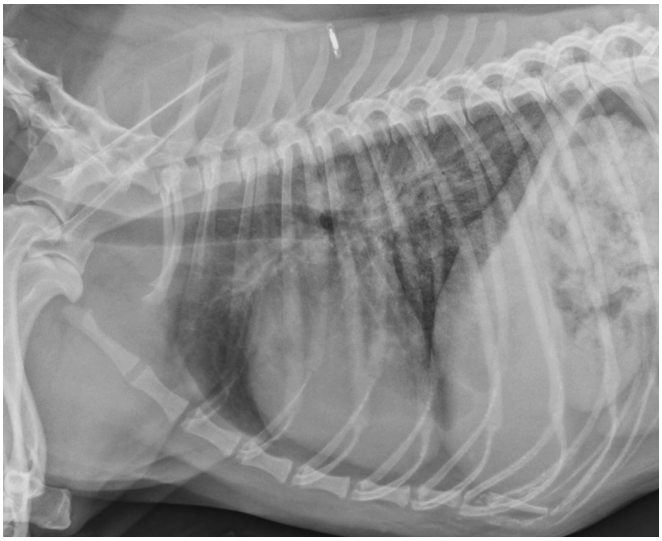

FIGURE 71-3 Lateral thoracic radiographs from a 1-year-old male neutered Cavalier King Charles spaniel with pneumocystosis. A diffuse marked interstitial pattern is present. Mild right-sided cardiomegaly was also identified.

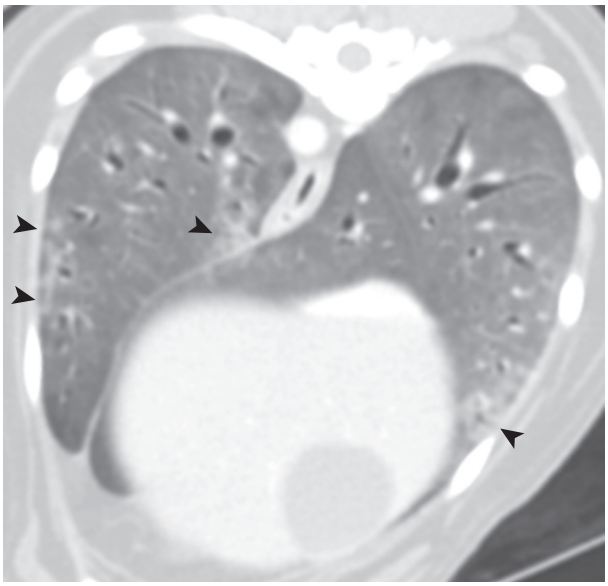

FIGURE 71-4 Thoracic CT scan from a 4-year-old female spayed Cavalier King Charles spaniel with pneumocystosis that was evaluated for lethargy, inappetence, and respiratory distress. There is a diffuse interstitial pattern and focal peripheral alveolar infiltrates *(arrowheads)*.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

Hematologic abnormalities in dogs with pneumocystosis are nonspecific. Neutrophilic leukocytosis is the most consistent finding. Less frequently, eosinophilia or monocytosis are found. Lymphocyte counts can be elevated, normal, or low. Polycythemia may occur secondary to arterial hypoxemia from impaired gaseous exchange. Thrombocytosis is often present in miniature dachshunds. Artifactual thrombocytopenia and megathrombocytosis have been observed in Cavalier King Charles spaniels, which may have a hereditary basis that is likely unrelated to the suspected immunodeficiency.

Serum Chemistry Profile

Total serum proteins are usually within reference limits in dogs with pneumocystosis, with a low to borderline-low globulin level, which correlates with low γ-globulin levels on serum protein electrophoresis.[17] In some dogs, mild hyperglobulinemia is present.[21] Mild hypoalbuminemia may also be detected. Arterial hypoxemia, hypocapnia, and increased arterial blood pH indicate an uncompensated respiratory alkalosis. The arterial pO_2 is often lower than expected based on the clinical signs and thoracic radiographs.

Diagnostic Imaging

Findings on thoracic radiography include diffuse, bilaterally symmetric, miliary-interstitial to alveolar lung disease, with compensatory emphysema in severely infected animals.[22] Interstitial patterns are most common (Figure 71-3). Solitary lesions, unilateral involvement, cavitary lesions, spontaneous pneumothorax, and lobar infiltrates have also been described. Tracheal elevation, right-sided heart enlargement, and pulmonary arterial enlargement reflect cor pulmonale secondary to diffuse pulmonary disease. Computed tomography (CT) scans may show diffuse pulmonary interstitial infiltrates and small focal regions of increased opacity (Figure 71-4), but CT findings in dogs with pneumocystosis have not been extensively described.

Microbiologic Tests

Diagnostic assays available for pneumocystosis in dogs or cats are described in Table 71-1. Identification of pneumonia in a Cavalier King Charles spaniel or miniature dachshund should always raise suspicion for pneumocystosis.

Cytologic Diagnosis

The diagnosis of pneumocystosis requires direct demonstration of *Pneumocystis* cysts in biopsy specimens, respiratory fluids, or occasional extrapulmonary sites. Transtracheal, endotracheal, or bronchoalveolar lavage specimens, lung aspirates, and oropharyngeal secretions may contain organisms. Transtracheal lavage specimens have been useful for detection of organisms in dogs.[17] No cytologic technique is as reliable or as definitive as histopathologic examination of lung biopsy specimens for documentation of active *Pneumocystis* infection. However, lung biopsy is more invasive, has potential complications of hemorrhage or pneumothorax, and is associated with additional costs and hospitalization. *Pneumocystis* organisms are difficult to detect in respiratory secretions or lavage specimens, and success in finding them usually depends on the experience of the examiner and the collection and processing of specimens. Polychrome stains, such as Wright's, Giemsa, and methylene blue, will demonstrate nuclei of trophozoites and intracystic sporozoites in cytologic specimens, but the walls of cysts and trophozoites will not be apparent (Figure 71-5). Diff Quik stain may be useful to rapidly identify organisms.[23]

Serologic Diagnosis

Serologic assays are available for detection of human infections with *P. jirovecii*; however, their diagnostic value is uncertain, since many immunodeficient humans who develop pneumocystosis fail to produce antibody titers, and healthy individuals frequently have high titers. Increased antibody titers to *Pneumocystis* persist for long periods, offering a valuable

VetBooks.ir

TABLE 71-1

Diagnostic Assays Available for Pneumocystosis in Dogs or Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Lung aspirates; transtracheal, endotracheal, or bronchoalveolar lavage specimens	*Pneumocystis* trophozoites and cysts	False negatives can occur when specimen size is small or low numbers of organisms are present. Identification to the genus level requires immunostaining or PCR assay.
PCR assays	Lung aspirates; transtracheal, endotracheal, or bronchoalveolar lavage specimens	*Pneumocystis* spp. DNA	The sensitivity and specificity of assays may vary depending on assay design. Assays designed to detect *P. jirovecii* may not detect organisms that infect dogs. In the absence of cytologic evidence of *Pneumocystis* infection, the significance of a positive PCR result must be interpreted in light of clinical findings, because of the potential for subclinical colonization.
Histopathology	Lung biopsy or necropsy specimens	*Pneumocystis* trophozoites and cysts	Large numbers of organisms are usually found filling alveolar spaces. Cyst forms are best demonstrated with silver stains or periodic acid–Schiff. The identity of the organisms can be confirmed with immunohistochemistry or PCR assay.

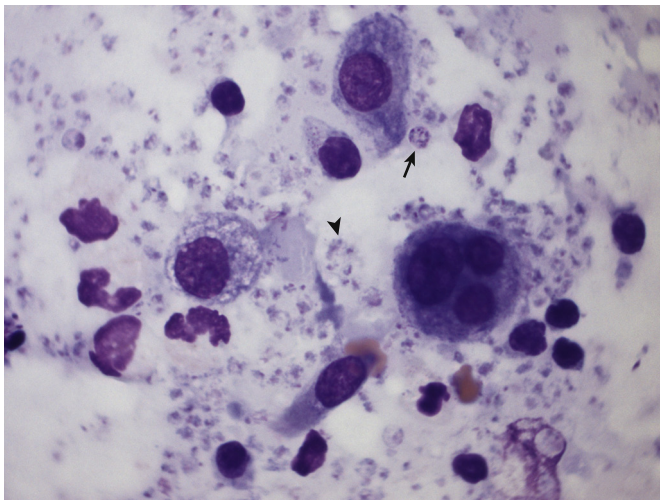

FIGURE 71-5 Impression smear of lung tissue from a 1-year-old male neutered Cavalier King Charles spaniel with pneumocystosis. Large foamy and activated macrophages are present, as well as fewer neutrophils and lymphocytes. Abundant trophozoites are present and range in size from 1 to 2 µm *(arrowhead)*. Organisms can also be seen within a cyst *(arrow)*. Wright's stain.

index of infection in epidemiologic studies. However, they are of limited use for an immediate diagnosis.[24] Circulating *Pneumocystis* antigen has been detected in human serum by counter-immunoelectrophoresis and ELISA methods. However, antigenemia also is found in up to 15% of clinically healthy humans. Direct fluorescent antibody assays can specifically detect organisms in sputum, tracheal aspirates, or pulmonary tissue.[25] Immunoperoxidase techniques also can be used to identify *Pneumocystis* in impression smears or formalin-fixed, paraffin-embedded lung sections.[26]

Fungal Culture

Pneumocystis cannot be cultured in the laboratory from clinical specimens.

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays have been used to detect *Pneumocystis* in bronchoalveolar lavage specimens from humans[12,27-29] and in lung tissue from dogs.[16,30] The sensitivity of PCR assays on bronchoalveolar lavage fluids from infected humans is greater than that of conventional staining.[31] DNA analysis of PCR products has been used to type isolates from humans and animals.[8] Some PCR assays (especially specific real-time PCR assays) that detect *P. jirovecii* may not detect *Pneumocystis* organisms that infect dogs because of sequence differences.

Immunologic Findings

The majority of the immunologic studies of pneumocystosis in dogs have been done in the miniature dachshund.[17,32] Lymphocyte stimulation assay results, using phytohemagglutinin and pokeweed mitogen, show severe immunosuppression, especially when compared to controls, even though a normal lymphocyte count can be present. Immunoglobulin fraction quantification consistently reveals deficiencies of IgA, IgM, and IgG. Low globulin levels, immunoglobulin deficiencies, and decreased lymphocyte function have been reported in the Cavalier King Charles spaniel.[18,30] The absence of immunoglobulins in the presence of pathologic changes is a significant finding, since affected dogs have chronic infections, which should result in an immunoglobulin response. Immunoglobulin deficiencies are still present after the *Pneumocystis* and skin infections have resolved, which supports the presence of a primary defect. Lymphocyte transformation studies and the results of immunoglobulin quantification suggest that both T- and B-cell abnormalities exist in affected dogs. Serum complement activity in affected miniature dachshunds has been normal. CD3 and CD79a lymphocyte staining of lymph nodes and spleen shows marked absence of B cells with the presence of T cells. Immunologic abnormalities in the miniature dachshund are similar to those described in human patients that have common variable immunodeficiency syndrome (also known as acquired or adult-onset hypogammaglobulinemia). Common variable immunodeficiency syndrome is a primary immunodeficiency

VetBooks.ir

disease characterized by little or no antibody production by B lymphocytes, normal or decreased numbers of B lymphocytes, and abnormal T-lymphocyte function.[33]

Pathologic Findings

Gross Pathologic Findings

Pathologic findings in pneumocystosis are primarily confined to the lungs, although dissemination to regional lymph nodes, spleen, liver, bone marrow, and other organs has been reported. On gross examination, the lungs are firm, consolidated, and pale brown or gray. They do not collapse when the chest cavity is opened. Unlike many pneumonic processes, fluid is not expressed from cut surfaces of the lung. The pulmonary and mediastinal lymph nodes are often enlarged. Small amounts of fluid may be found in the pleural cavity. Cardiac enlargement, when present, has been right sided in all cases.

Histopathologic Findings

On histologic examination, alveolar spaces are filled with aggregates of amorphous, foamy, eosinophilic material that has a frothy, honeycomb-like pattern (Figure 71-6). A few macrophages and detached alveolar lining cells may be present, but polymorphonuclear leukocytes are absent. Special stains are needed to identify cyst forms. Little or no phagocytosis of intact *Pneumocystis* organisms is present. However, nonviable organisms (such as those seen after treatment) are often phagocytosed, and macrophages may contain Gomori's methenamine silver (GMS)-positive granular material that represents the residuum of cyst wall degradation. In some instances, alveolar septa are markedly thickened by dense accumulations of plasma cells, lymphocytes, and macrophages (lymphoplasmacytic pneumonia). The septa may be widened by fibrosis in chronic infections. With GMS stain, cyst forms are spherical, ovoid, or crescent-shaped structures that range from 4 to 7 µm in diameter and have dot-like, argyrophilic (stain with silver), focal cyst wall thickenings. Cyst walls also can be demonstrated with other stains such as toluidine blue, and they fluoresce when stained with orange G of a Papanicolaou stain. The internal structure of trophozoites in tissue sections and smears are best demonstrated with Giemsa stain. On ultrastructural examination, intact alveoli are filled with compact aggregates of trophozoite and cyst forms. Trophozoites commonly line alveoli.

Appropriate histologic staining is essential to ensure detection of *Pneumocystis* organisms. Routine hematoxylin and eosin stain does not readily demonstrate the developmental forms of *Pneumocystis*. Only the nuclei of intracystic sporozoites and trophozoites are stained. Various modifications of methenamine silver staining can be employed to stain the cyst walls brownish-black; trophozoites will not be detected. The cyst wall also stains with periodic acid–Schiff stain (see Figure 71-6).

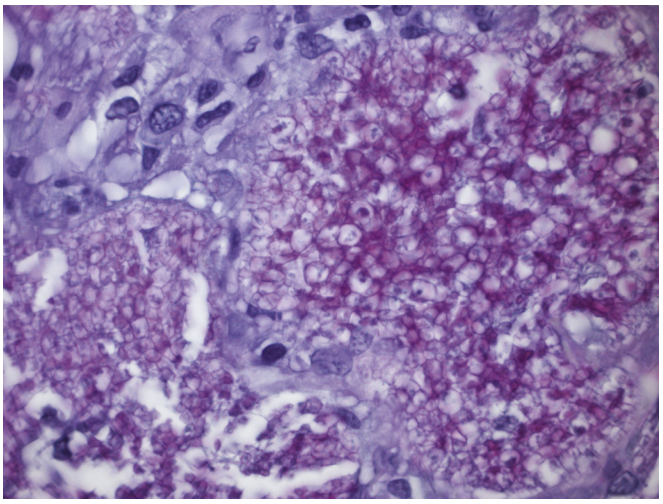

FIGURE 71-6 Histopathology of the lung of an 18-month-old male neutered Cavalier King Charles spaniel with pneumocystosis. Foamy, honeycomb-like material fills the alveoli. Periodic acid–Schiff stain.

Treatment and Prognosis

Specific antimicrobial chemotherapy is most beneficial when pneumocystosis is suspected (usually based on the affected dog breed) or diagnosed during its early stages. The treatment of choice is trimethoprim and a sulfonamide (TMS). Pentamidine isethionate (an aromatic diamidine) has also been effective in humans, but TMS is more effective and less toxic. TMS has also been used as prophylaxis in immunodeficient humans.

Treatment with TMS has been reported in 8 dogs;[16,17,22] 4 were dachshunds that subsequently recovered.[22] A TMS dose of 15 mg/kg, every 8 hours, or 30 mg/kg, every 12 hours, for 3 weeks was used; the longest reported follow-up in these studies was for 4 months. Folic acid supplementation should be given if adverse effects such as leukopenia and anemia are observed or if long-term therapy is required. In human infections, resistance to sulfonamides has been noted among some strains of *P. jirovecii*.[34]

Other treatment options include atovaquone, clindamycin and primaquine, and dapsone-trimethoprim combinations. Atovaquone is licensed for the treatment of human pneumocystosis.[35] This drug, which also has been used to treat canine babesiosis (see Chapter 10), is not as effective against *Pneumocystis* infections in humans as pentamidine or TMS but has lower toxicity. In humans, pentamidine or atovaquone has also been administered by aerosol, but this is less effective than oral administration and is not recommended.[36,37]

Combination therapy with clindamycin and primaquine is now the preferred alternative to treatment with TMS in humans (e.g., for patients intolerant of TMS)[37] but has not been reported for treatment of dogs. Dapsone and trimethoprim or pyrimethamine, in combination, have been effective in experimental animals and in clinical trials in immunosuppressed humans with pneumocystosis.[38] *Pneumocystis* is resistant to azole antifungal drugs and amphotericin B (because it lacks ergosterol in its cell wall), but the anthelmintics benzimidazole and albendazole have been effective in experimental infections.[39,40]

Nonspecific immunostimulants such as cimetidine and levamisole have been given adjunctively to treat affected miniature dachshunds,[41] without much success. Supportive care is essential for any patient with *Pneumocystis* pneumonia because of disturbed alveolar gaseous exchange. Supplemental oxygen therapy may be needed, and ventilatory assistance may also be required. Immunosuppressive agents should be discontinued if possible. Antimicrobial chemotherapy of pulmonary pneumocystosis results in a decline in arterial oxygen related to the inflammatory reaction to dying organisms. Administration of anti-inflammatory doses of glucocorticoids during specific treatment for *P. jirovecii* infection improves pulmonary function and survival in humans.[37,42-44]

Public Health Aspects

Pneumocystis organisms are ubiquitous in the environment. However, molecular and epidemiologic evidence suggests that spread may occur between humans because of localized outbreaks. Humans and animals are exposed to the same environmental sources of *Pneumocystis*. *Pneumocystis* species that infect dogs are likely different from those that infect humans, but further studies are required to verify this. The primary risk factor for clinical pneumocystosis in humans is immunodeficiency (especially HIV infection, hematologic malignancies and solid tumors, transplant recipients, and collagen vascular disorders).[37] Thus, the greatest risk for acquisition of infection from a pet would be if the animal was clinically ill from *Pneumocystis* pneumonia and the person in close contact was immunocompromised.

CASE EXAMPLE

Signalment: "Tessa", a 1-year-old intact female miniature dachshund (see Figure 71-2)

History: Tessa was evaluated for a history of chronic tachypnea and weight loss. The clinical signs had been nonresponsive to various treatments that had included multiple antibiotics, bronchodilators, mucolytics, multivitamins, and glucocorticoids. From 2 months of age, she had a history of recurrent infections including otitis externa, hemorrhagic enteritis, tonsillitis, folliculitis, and pyogranulomatous dermatitis. These conditions had responded each time to supportive care.

Physical Examination:

Body Weight: 4.5 kg.

General: Quiet, alert, and responsive. Ambulatory on all four limbs. Rectal temperature = 101.8°F (38.8°C), HR = 138 beats/min, RR = 129 breaths/min, mucous membranes pink, CRT = 1 s.

Integument: A poor coat was present with focal alopecia on the head and back.

Musculoskeletal: Body condition score was 3/9 with diffuse and symmetrical muscle atrophy.

Respiratory: An increased respiratory rate with increased abdominal effort was noted; tracheal palpation elicited a dry cough.

All Other Systems: No clinically significant abnormalities were noted.

Laboratory Findings:

CBC:

HCT 54% (40-55%)
MCV 68 fL (65-75 fL)
MCHC 35.7 g/dL (33-36 g/dL)
WBC 34,600 cells/µL (6000-15,000 cells/µL)
Neutrophils 23,200 cells/µL (3000-11,000 cells/µL)
Band neutrophils 700 cells/µL (0-300 cells/µL)
Lymphocytes 5500 cells/µL (1000-4800 cells/µL)
Monocytes 4800 cells/µL (100-2000 cells/µL)
Basophils 350 cells/µL (100 cells/µL)
Platelets 730,000 platelets/µL (200,000-500,000 platelets/µL).

Serum Chemistry Profile:

Sodium 147 mmol/L (145-154 mmol/L)
Potassium 4.6 mmol/L (3.6-5.3 mmol/L)
Phosphorus 4.8 mg/dL (3.0-6.2 mg/dL)
Calcium 10.9 mg/dL (9.7-11.5 mg/dL)
BUN 17 mg/dL (5-21 mg/dL)
Creatinine 0.5 mg/dL (0.3-1.2 mg/dL)
Glucose 132 mg/dL (64-123 mg/dL)
Total protein 5.1 g/dL (5.3-7.5 g/dL)
Albumin 3.5 g/dL (2.3-3.5 g/dL)
Globulin 1.6 g/dL (2-3.7 g/dL)
ALT 65 U/L (10-60 U/L)
ALP 210 U/L (100-250 U/L)
Cholesterol 196 mg/dL (135-361 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL)
α-globulins 0.8 g/dL (0.8-1.6 g/dL)
β-globulins 0.6 g/dL (0.7-1.3 g/dL)
γ-globulins 0.3 g/dL (0.4-1.1 g/dL).

Urinalysis: SGr 1.045; pH 6.0, negative for protein, bilirubin, blood, and glucose. Inactive sediment.

Imaging Findings: On thoracic radiographs the cardiovascular structures appeared within normal limits. A diffuse interstitial pulmonary pattern was present.

Cytology Findings: Transtracheal wash cytology demonstrated active, blastic alveolar macrophages with phagocytic vacuolization, large numbers of neutrophils, and many free and phagocytosed *Pneumocystis* organisms.

Aerobic Bacterial Culture: Culture of the transtracheal wash fluid yielded no growth after 48 hours' incubation.

Fecal Examination: Fecal flotation: Negative for parasites.

Diagnosis: *Pneumocystis* spp. pneumonia.

Treatment: The dog was treated with a potentiated sulfonamide at 15 mg/kg PO q8h for 3 weeks, which resulted in a complete recovery.

Comments: This dog was diagnosed with pneumocystosis as a result of a primary immune deficiency disease, most likely common variable immunodeficiency syndrome. The latter would also explain the history of chronic skin infections and gastroenteritis. CD3 and CD79a lymphocyte staining of a peripheral lymph node biopsy showed a marked absence of B cells.

CHAPTER 72

Toxoplasmosis

Michael R. Lappin

Overview of Toxoplasmosis

First Described: The organism that was ultimately named *Toxoplasma gondii* was first described in France in 1908 (Nicolle and Manceaux)[1]

Cause: *Toxoplasma gondii,* a coccidial protozoan parasite (phylum Apicomplexa)

Affected Host Species: Cats are the definitive host and are the only species known to complete the sexual phase of *T. gondii* culminating in the passage of oocysts in feces. Cats and most other vertebrates can serve as intermediate hosts; invertebrates can serve as transport hosts by mechanical carriage of *T. gondii* oocysts.

Geographic Distribution: *T. gondii* has a worldwide distribution except in the absence of cats

Major Clinical Signs: Fever, ocular inflammation, ataxia, seizures, muscle pain, and respiratory distress are the most common clinical signs in cats; dogs have similar signs but develop illness less frequently than cats.

Differential Diagnoses: In the dog, *Neospora caninum* induces the most similar clinical signs; many other chronic intracellular bacterial infections and fungal infections in dogs and cats need to be considered a differential diagnoses for many of the clinical and laboratory abnormities induced by *T. gondii*.

Human Health Significance: There is significant risk to the fetus after transplacental infection and to any immunocompromised person.

Etiologic Agent and Epidemiology

Toxoplasma gondii is a coccidian that is one of the most prevalent parasites infecting warm-blooded vertebrates around the world.[2-4] Only cats complete the sexual phase in the gastrointestinal tract (also known as the enteroepithelial cycle) and pass environmentally resistant oocysts in feces (Figure 72-1). Sporozoites develop within shed oocysts after 1 to 5 days of exposure to oxygen and appropriate environmental temperature and humidity (Figure 72-2). This process is known as sporulation. After oocyst ingestion, released sporozoites can penetrate the intestinal tracts of cats or intermediate hosts and disseminate in blood or lymph as tachyzoites during active infection. *T. gondii* can penetrate most mammalian cells and replicates asexually within infected cells until the cell is destroyed. If an appropriate immune response occurs, replication of tachyzoites is attenuated and slowly dividing bradyzoites develop that persist within cysts in extraintestinal tissues. These tissue cysts form readily in the central nervous system (CNS), muscles, and visceral organs. Live bradyzoites may persist in tissue cysts for the life of the host.

It is likely that most *T. gondii*–infected cats and dogs harbor tissue cysts for life. Thus, the presence of serum antibodies is likely to indicate current infection. *T. gondii* seroprevalence rates vary by the lifestyle of the cat or dog. In general, increased seroprevalence correlates with increased age as a result of increased risk of exposure over time. It also correlates with outdoor exposure, since animals with access to the outdoors are most likely to contact infected intermediate hosts. In a recent study of clinically ill cats, *T. gondii* antibodies were detected in 31.6% of the 12,628 cats tested.[5] The seroprevalence was lowest in regions with low humidity (Figure 72-3). In another study of feral cats in Florida, *T. gondii* antibodies were detected in 12.1% of the cats.[6] Although *T. gondii* infection is common among cats, the oocyst shedding period is generally less than 21 days. Thus, detection of *T. gondii* oocysts in feline feces is uncommon. For example, in two studies in the United States, *T. gondii* oocysts were detected in feces of fewer than 1% of cats.[7,8]

Dogs do not produce *T. gondii* oocysts, but they can mechanically transmit oocysts after they ingest feline feces.[9] The tissue phases of *T. gondii* infection occur in dogs and may be associated with clinical disease. Approximately 20% of dogs in the United States are seropositive for *T. gondii* antibodies.[10] Before 1988, many dogs diagnosed with toxoplasmosis based

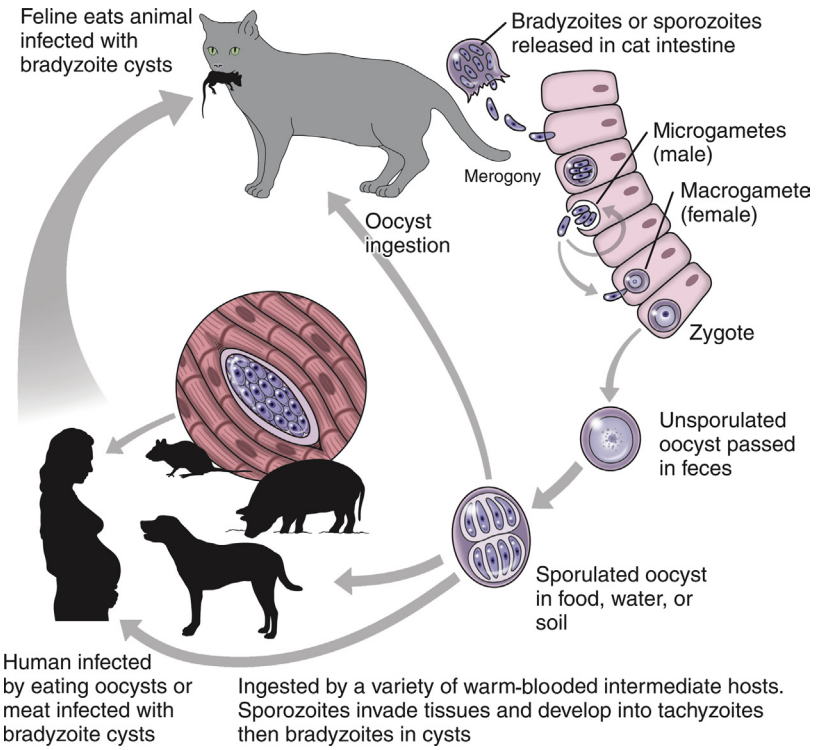

FIGURE 72-1 Life cycle of *Toxoplasma gondii*. Cats are most often infected when they ingest bradyzoite cysts in tissues of prey. The bradyzoites transform into merozoites and undergo repeated cycles of schizogony in the cat's intestinal tract. The merozoites then transform into microgametes (male) and macrogametes (female). When a microgamete penetrates a macrogamete, a zygote forms. The zygote is shed as an unsporulated oocyst in the feces, which is not infectious. Sporulation occurs after 1 to 5 days. The extraintestinal cycle occurs in cats or other intermediate hosts after they ingest sporulated oocysts or tissue cysts. Sporozoites penetrate intestinal cells and transform into tachyzoites, which rapidly multiply in nucleated cells throughout the body in the face of immunosuppression. This can result in severe disease in the developing fetus. Ultimately organisms are contained by the immune system within bradyzoite cysts in muscle, brain, and visceral organs (latent infection).

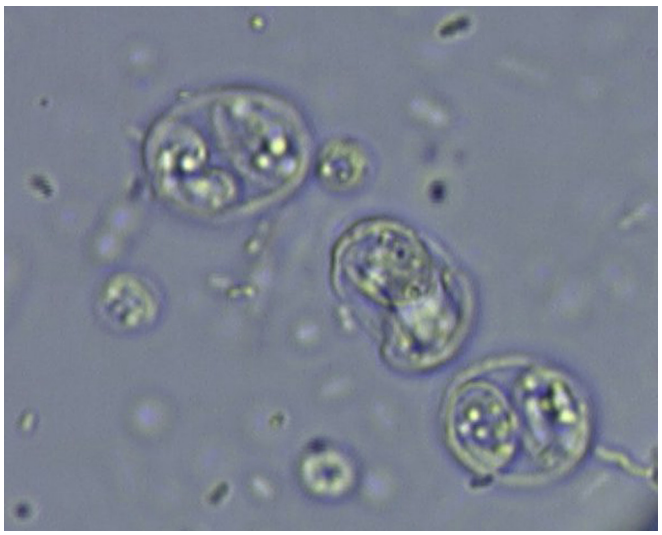

FIGURE 72-2 Sporulated oocysts of *Toxoplasma gondii*. The oocysts are 10 × 12 µm in diameter.

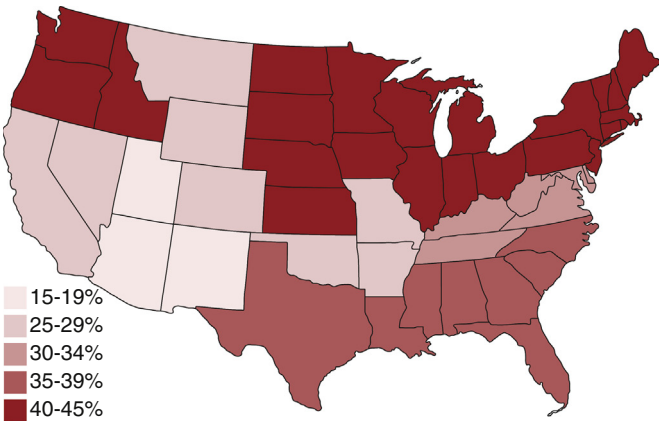

FIGURE 72-3 Continental United States regional seroprevalence in clinically ill cats. Results were based on the presence of *Toxoplasma gondii*-specific IgG or IgM in serum. Information was available from 3,640 serum specimens. (From Vollaire MR, Radecki SV, Lappin MR. Seroprevalence of *Toxoplasma gondii* antibodies in clinically ill cats in the United States. Am J Vet Res 2005;66:874-877.)

on histologic evaluation were in fact infected with *Neospora caninum* (see Chapter 73).

Clinical Features

Signs and Their Pathogenesis

Infection of warm-blooded vertebrates occurs after ingestion of any of the three life stages of *T. gondii* (sporozoite, tachyzoites, bradyzoites) or it can occur by transplacental transmission. Cats can also be infected through the transmammary route.[11] In dogs, evidence for venereal transmission also exists, and repeated transplacental infection has been documented.[12,13]

Most cats are not coprophagic, so most are infected when they ingest *T. gondii* bradyzoites in tissue cysts during carnivorous feeding. After ingestion, the bradyzoites transform into merozoites, which replicate in the epithelial cells of the intestinal tract, then transform into microgametes and macrogametes.

VetBooks.ir

When a microgamete penetrates a macrogamete, a zygote forms. The zygote then transforms into an unsporulated oocyst, which is shed in feces for 3 to 21 days. After sporulation (formation of sporozoites within the oocyst), oocysts can survive in the environment for months to years and are resistant to most disinfectants. The *T. gondii* oocyst shedding prepatent period is stage dependent (ingestion of bradyzoites has a shorter prepatent period than ingestion of sporozoites) but is not dose dependent.[14] In addition, transmission of *T. gondii* is most efficient when cats consume tissue cysts (carnivorism) and when intermediate hosts consume oocysts (fecal-oral transmission). Infection of rodents with *T. gondii* leads to clinical signs of altered behavior, so that the rodent becomes less fearful of cats.[15] This may increase the likelihood that the definitive host (cat) will become infected and potentiate the sexual phase of the organism.

Whether clinical toxoplasmosis develops is dependent on both host and parasite effects. Some strains of *T. gondii* may be more pathogenic than others, and some strains may have specific tissue affinities, such as a tendency to cause ocular disease in cats.[16,17] If a poor immune response is mounted after primary infection, overwhelming tachyzoite replication that results in tissue necrosis is the major cause of disease.[2-4] This mechanism is also likely in cats or dogs with chronic (latent) toxoplasmosis that then become immune suppressed. One example is activation of *T. gondii* infection in cats or dogs after administration of immunosuppressive drugs such as cyclosporine.[18-21] Other immunosuppressive conditions such as FIV infection can also result in activation of toxoplasmosis.[22] The mechanisms for chronic clinical toxoplasmosis have not been fully determined.[2] *T. gondii* antigens and antigen-containing immune complexes have been documented in the serum of affected cats. Persistent infection was not associated with chronic kidney failure in cats of one study.[23-25]

The large majority of cats infected with *T. gondii* never develop detectable clinical abnormalities. In general, the enteroepithelial cycle in the cat rarely leads to clinical signs. Only 10% to 20% of experimentally inoculated cats develop self-limiting, small bowel diarrhea for 1 to 2 weeks following primary oral inoculation with *T. gondii* tissue cysts; this is presumed to be from the enteroepithelial replication of the organism. *T. gondii* enteroepithelial stages were found in intestinal tissues from two cats with inflammatory bowel disease that had positive response to administration of anti-*Toxoplasma* drugs.[26] Eosinophilic fibrosing gastritis was recently described in a *T. gondii*–infected cat.[27]

Fatal extraintestinal toxoplasmosis in cats can develop from overwhelming intracellular replication of tachyzoites following primary infection; hepatic, pulmonary, CNS, and pancreatic tissues are commonly involved.[2-4,28-30] Kittens infected by the transplacental or transmammary routes develop the most severe signs of extraintestinal toxoplasmosis and generally die of pulmonary or hepatic disease. Common clinical signs in cats with disseminated toxoplasmosis include lethargy, anorexia, and respiratory distress. Disseminated toxoplasmosis has been documented in cats concurrently infected with FeLV, FIV, or feline infectious peritonitis virus, as well as following cyclosporine administration for allergic dermatitis, immune-mediated disorders, or after renal transplantation.[18,19,31]

Chronic toxoplasmosis occurs in some cats and should be on the differential diagnosis list for cats with uveitis, chorioretinitis (Figure 72-4), cutaneous lesions, fever, muscle hyperesthesia, myocarditis with arrhythmias, weight loss, anorexia, seizures, ataxia, icterus, diarrhea, respiratory distress, or pancreatitis.[2-4,32-42] Toxoplasmosis appears to be a common infectious cause of uveitis in cats; anterior uveitis or posterior uveitis can occur, and the manifestations can be either unilateral or bilateral.[2,41,42] Kittens infected transplacentally or through the transmammary route commonly develop ocular disease.[16]

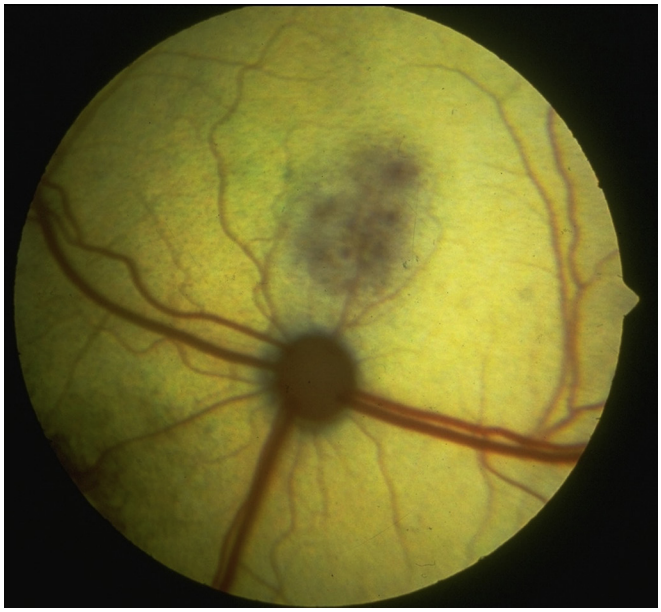

FIGURE 72-4 *Toxoplasma gondii*–associated chorioretinitis in an experimentally inoculated cat.

In dogs, respiratory, gastrointestinal, or neuromuscular infection with associated signs of fever, vomiting, diarrhea, respiratory distress, ataxia, seizures, and icterus occurs most commonly with generalized toxoplasmosis.[2,43-50] Generalized toxoplasmosis is most common in immunosuppressed dogs, such as those with canine distemper virus infection or those treated with cyclosporine to prevent renal transplant rejection. Neurologic signs depend on the location of the primary lesions and include ataxia, seizures, tremors, cranial nerve deficits, paresis, and paralysis. Dogs with myositis present with weakness, stiff gait, or muscle atrophy. Rapid progression to tetraparesis and paralysis with lower motor neuron dysfunction can occur. One study associated *T. gondii* antibodies with polyradiculoneuritis in dogs.[49] Some dogs with suspected neuromuscular toxoplasmosis probably have neosporosis. Myocardial infection with ventricular arrhythmias occurs in some infected dogs. Retinitis, anterior uveitis, iridocyclitis, nodular conjunctivitis, and optic neuritis occur in some dogs with toxoplasmosis, but they are less common than in cats.[50] Cutaneous disease also has been reported, which can manifest as pustules, pruritus, subcutaneous nodules, and/or alopecia.[21,51]

Diagnosis

Diagnosis of toxoplasmosis requires interpretation of specific microbiologic tests (Table 72-1) in light of the presence of consistent clinical abnormalities. No clinical abnormalities are specific for the disease.[2-4]

Laboratory Abnormalities

Complete Blood Count

T. gondii should be on the differential diagnosis list for cats or dogs with appropriate clinical findings and nonregenerative anemia, neutrophilic leukocytosis or neutropenia, lymphocytosis or lymphopenia, monocytosis, and/or eosinophilia.

TABLE 72-1

Microbiologic Assays for Diagnosis of *Toxoplasma gondii* Infection

Assay	Specimen Type	Assay Target	Comments
Fecal flotation	Feces	*T. gondii* oocysts	The negative predictive value of this assay is poor for clinical toxoplasmosis, since most cats cease shedding by the time illness occurs.
Fecal PCR assay	Feces	*T. gondii* DNA	As for fecal flotation.
Cytologic examination	Effusions, skin lesions, tissue aspirates	*T. gondii* tachyzoites and occasionally bradyzoites	Confirms current infection and is generally associated with disease. Organisms cannot be readily distinguished from *Neospora caninum*.
Histopathology	Multiple tissues	*T. gondii* tachyzoites and bradyzoites	If the organisms are detected in the presence of inflammation and necrosis, clinical toxoplasmosis is likely. Can be difficult to differentiate *T. gondii* from tissue protozoans such as *N. caninum* in dogs. Immunohistochemistry can be used to differentiate the two species.
PCR assay	Effusions, blood, multiple tissues	*T. gondii* DNA	*T. gondii* DNA can be amplified from the blood of normal dogs and cats and so PCR on blood has a low positive predictive value. Amplification of specific DNA confirms infection, and if appropriate clinical signs and inflammation are present, positive results document clinical toxoplasmosis.
Serology for *T. gondii* IgM	Serum	*T. gondii* IgM antibodies	Most consistent with recent infection but can be induced during reinfection and by other immune drugs such as glucocorticoids. Positive results do not correlate with active disease.*
T. gondii IgG	Serum	*T. gondii* IgG antibodies	Most consistent with infection of > 10 days duration. Positive results do not correlate with active disease.*
Agglutination assays	Serum	*T. gondii* antibodies	Hypothetically detects all antibody classes but can be falsely negative in animals that only possess anti-*Toxoplasma* IgM antibody. Positive results do not correlate with active disease.*

*Results of serum antibody assays are combined with clinical findings to aid in making a diagnosis of clinical toxoplasmosis.

Serum Chemistry Profile

Depending on the organ system involved, cats with clinical toxoplasmosis may have increases in serum protein and bilirubin concentrations, as well as increased activities of creatine kinase, ALT, ALP, and lipase.[2-4] Findings are similar for dogs; dogs with chronic toxoplasmosis may develop hyperglobulinemia that is generally polyclonal.[52]

Urinalysis

Proteinuria and bilirubinuria have been detected in some dogs or cats with clinical toxoplasmosis.

Cerebrospinal Fluid Analysis

CSF protein concentrations and cell counts are often higher than normal, with the predominant white blood cells in CSF being small mononuclear cells. However, increased neutrophils also are commonly found in cats with acute CNS toxoplasmosis. Increased CSF protein concentrations and mixed inflammatory cell infiltrates occur in dogs with CNS toxoplasmosis.

Diagnostic Imaging

Radiographs

Pulmonary toxoplasmosis most commonly causes diffuse interstitial to alveolar patterns (Figure 72-5); pleural effusion has rarely been documented as well.

Sonography

Ultrasound findings consistent with pancreatitis or diffuse hepatitis could be noted in dogs or cats with involvement of these tissues due to *T. gondii* infection. Intra-abdominal lymphadenomegaly may be noted in dogs or cats with polysystemic disease.

Advanced Imaging

MRI findings in dogs and cats with toxoplasmosis may be unremarkable, or focal or mass lesions may be identified in the brain and/or spinal cord. On MRI, lesions are often isointense on T1-weighted imaging and hyperintense on T2-weighted imaging, and they may enhance peripherally or uniformly with contrast (Figure 72-6).[53-55]

Microbiologic Testing

Cytologic Diagnosis

Using cytologic examination, *T. gondii* bradyzoites or tachyzoites can be detected in tissues, effusions, bronchoalveolar lavage fluids, aqueous humor, or CSF (Figure 72-7).[32,35,36,38] A definitive antemortem diagnosis of toxoplasmosis can be made if the organism is identified; however, this is uncommon, particularly in association with sublethal disease. In the dog, *N. caninum* tachyzoites cannot be distinguished from those of *T. gondii* on cytologic examination, and so further diagnostics are needed to make a definitive diagnosis.[2]

VetBooks.ir

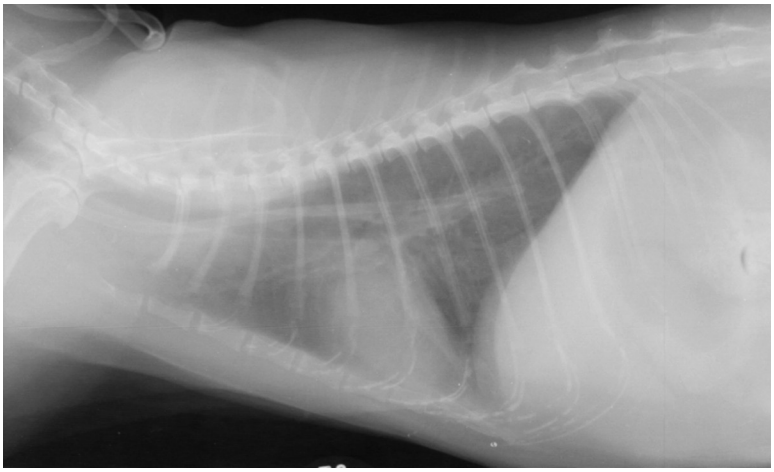

FIGURE 72-5 Thoracic radiographs of a 7-year-old female spayed domestic shorthair cat with pulmonic toxoplasmosis that developed one month after renal transplantation. There is a diffuse interstitial pattern. The cat subsequently developed respiratory arrest and tachyzoites were seen in fluid that was suctioned from the endotracheal tube used for resuscitation. Necropsy revealed severe, diffuse, necrotizing pneumonia with intralesional tachyzoites. Histiocytic, lymphoplasmacytic, and necrotizing lesions with intralesional tachyzoites were also seen in the renal allograft, ureter, bladder, liver, pancreas, peritoneum, muscularis mucosa of the stomach, and myocardium. Tachyzoites were not seen in the brain, but there was perivascular inflammation that suggested the possibility of infection. Immunohistochemistry confirmed that the tachyzoites were *T. gondii*.

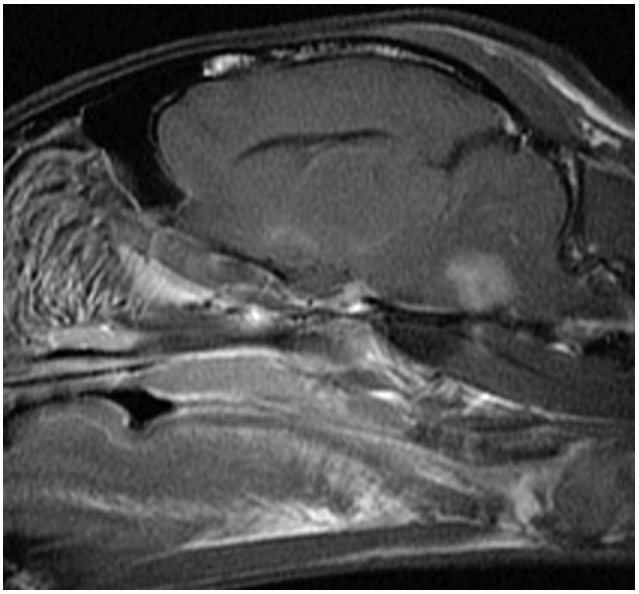

FIGURE 72-6 T1-weighted postcontrast sagittal magnetic resonance image from an 11-year-old female spayed domestic longhair that was evaluated for a 5-day history of inappetence, ataxia, abnormal vocalization, and circling. The cat was FIV and FeLV negative and had no other immunosuppressive conditions. A contrast-enhancing lesion is present in the right brainstem. CSF analysis revealed a mixed monocytic (primarily lymphocytic) pleocytosis with a total nuclear cell count of 36 cells/μL and a total protein concentration of 78 mg/dL. Meningoencephalitis secondary to *T. gondii* infection was confirmed at necropsy.

Fecal Flotation

T. gondii oocysts measure 10 × 12 μm. When identified in feces of cats with diarrhea, this suggests infection by *T. gondii*.[2-4,56] However, *Besnoitia* and *Hammondia* infections of cats produce morphologically similar oocysts. If oocysts of this size are detected in feces of dogs, *N. caninum* infection is most likely if clinical disease is present.[2] However, *T. gondii* oocysts can be present if the dog has ingested infected feline feces. PCR assays are available to differentiate *T. gondii* and *N. caninum*. Alternately, serum antibody responses can be followed sequentially to attempt to determine the infecting genus. Overall, detection of oocysts in cats has a poor negative predictive value for clinical toxoplasmosis, because most clinical toxoplasmosis results from disseminated infections that occur after oocyst shedding has been completed.

Serologic Diagnosis in Cats

Detection of *T. gondii* antibodies in serum is used most frequently for the diagnosis of clinical toxoplasmosis. A multitude of different techniques have been assessed, including ELISA, immunofluorescent antibody (IFA), Western blot immunoassay, and a variety of agglutination tests.[57-67] A latex agglutination assay and an indirect hemagglutination assay are available commercially. These assays can be applied to serum from either dogs or cats and theoretically detect all classes of immunoglobulin directed against *T. gondii*. However, they rarely detect antibody in feline serum samples when only IgM is present.[60] ELISA, IFA, and Western blot immunoassays have been adapted to detect IgM, IgG, and IgA antibody responses by using heavy-chain–specific secondary antibodies.[57,63,64] *T. gondii*–specific serum IgA antibody responses are similar to IgG antibody responses, and this antibody class is usually measured only in research studies. Several commercial laboratories in the United States offer *T. gondii* IgM and IgG testing by ELISA.[68] The following are common findings concerning *T. gondii* IgM and IgG antibody test results in cats.

Toxoplasma gondii IgM antibody titers.

- Using ELISA, approximately 80% of healthy, experimentally infected cats have detectable *T. gondii*–specific IgM in serum within 2 to 4 weeks after inoculation with *T. gondii*; these titers generally are negative within 16 weeks after infection.[57,58]
- As occurs in some healthy women, persistent IgM titers (>16 weeks) have been documented commonly in cats co-infected with FIV and in cats with ocular toxoplasmosis.[41,65] Because of these findings and the fact that some cats never have a detectable IgM response, IgM titers cannot accurately be used to predict when a cat is shedding oocysts. If a clinician is concerned that an individual cat is shedding *T. gondii* oocysts, fecal flotation or a fecal PCR assay should be performed.

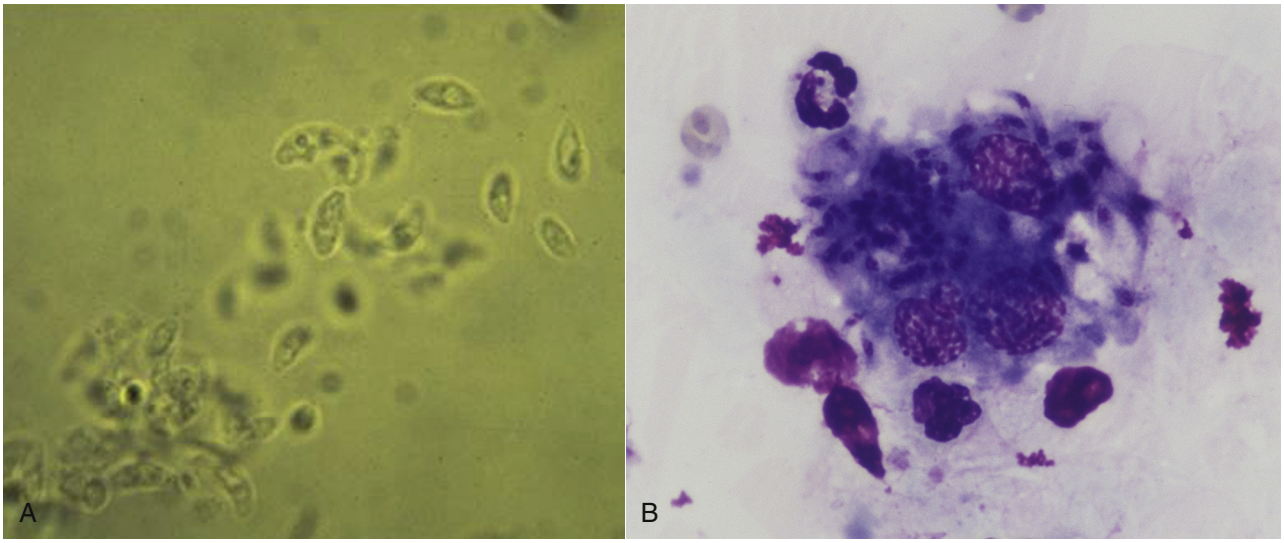

FIGURE 72-7 **A,** Tachyzoites of *Toxoplasma gondii* from the peritoneal cavity of a cat with fulminant toxoplasmosis. Unstained specimen. **B,** Cluster of tachyzoites in a tracheobronchial lavage specimen from a 12-year-old male neutered cat that developed respiratory distress 3 weeks after renal transplantation. Wright's stain, 1000× oil magnification.

- In one study of cats with clinical toxoplasmosis, *T. gondii* IgM titers were detected in the serum of 93% of the cats, whereas *T. gondii* IgG titers were detected in only 60% of the cats. Thus, IgM antibodies have a higher positive predictive value than IgG for clinical feline toxoplasmosis.[57,65]
- Some cats with chronic *T. gondii* infections that are initially IgM positive, but then become IgM negative, again became IgM positive after repeat inoculation with *T. gondii* and immunosuppression through inoculation with FIV and administration of glucocorticoids.[57,67] However, clinical signs of toxoplasmosis do not develop in these cats. Thus, presence of IgM antibodies in feline serum does not always mean that clinical toxoplasmosis is present.

***Toxoplasma gondii* IgG titers.**

- *T. gondii*–specific IgG can be detected by ELISA in serum in the majority of healthy experimentally inoculated cats within 3 to 4 weeks after infection.[57,58]
- By the time IgG antibodies are detected, the oocyst shedding period has usually been completed. Thus, IgG-seropositive cats are of minimal public health risk.
- *T. gondii* IgG antibody titers can be detected for at least 6 years after infection in experimentally inoculated cats; because the organism probably persists in tissues for life, IgG antibodies probably do as well.[62]
- Single, high IgG titers do not necessarily suggest recent or active *T. gondii* infection; healthy cats can have titers that exceed 1:10,000 as long as 6 years after experimental induction of toxoplasmosis.[62]
- Some cats with low *T. gondii* antibody titers can become seronegative based on the cutoff value used in an individual assay even though *T. gondii* is still within tissues. Based on an approximate 10% interassay variation in the ELISA technique, some cats with low positive IgG titers (1:64) can be positive for IgG antibodies on one analysis and negative on a subsequent analysis or vice versa.
- An increasing *T. gondii* IgG titer documents recent or active infection, but in experimentally infected cats, the time span from the first detectable positive IgG titer to the maximal IgG titer is approximately 2 to 3 weeks. Thus, some cats with clinical toxoplasmosis will have reached their maximal IgG titer by the time they are evaluated serologically.
- Rising *T. gondii* IgG antibody titers occur in healthy infected cats as well as cats with clinical toxoplasmosis and so, when assessed alone, do not prove clinical toxoplasmosis.
- In humans and cats that reactivate chronic *T. gondii* infection after immune suppression, IgG titers only rarely increase.

In dogs, assays that detect IgM and IgG titers are available in some commercial laboratories.[68] There have been very few research studies that assess canine serologic responses to *T. gondii* in different situations. However, most of the findings documented in cats appear to be true in dogs, based on the author's clinical experience.

For the reasons just discussed, antibody test results alone cannot be used to make a diagnosis of feline or canine toxoplasmosis. However, the following combination can be used to make a presumptive antemortem diagnosis:

- Demonstration of antibodies in serum that suggest exposure to *T. gondii*
- Demonstration of an IgM titer higher than 1:64, or a fourfold or greater rise in IgG titer, which suggests recent or active infection
- Clinical signs of disease consistent with toxoplasmosis
- Exclusion of other common causes of the clinical syndrome
- Positive response to appropriate treatment

Because *T. gondii* infection cannot be eliminated, most cats and dogs will be antibody positive for life, so there is little reason to repeat serum antibody titers after the clinical disease has resolved or to administer drugs with *T. gondii* activity to cats or dogs without clinical signs of toxoplasmosis.

Other serologic assays. Assays that measure *T. gondii* antigens or immune complexes have been evaluated in some cats. However, as for antibody tests, antigen or immune complexes can be detected in cats with or without clinical illness. These assays are not offered commercially.[23,24,57]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Recently, PCR assays have been used to document *T. gondii* DNA in feces and can be used to differentiate *T. gondii* from other organisms.[56] *T. gondii* DNA can be amplified from the blood of

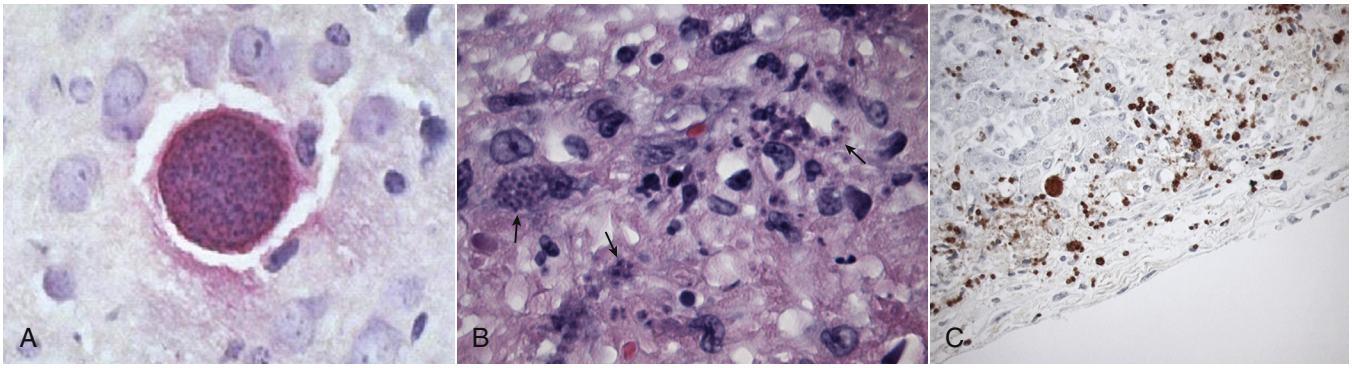

FIGURE 72-8 Histopathologic findings in *Toxoplasma gondii* infections. **A,** A tissue cyst filled with *Toxoplasma gondii* bradyzoites in the brain tissues of an experimentally infected mouse. **B,** Pancreas of the cat in Figure 72-5. TABLE 72-2

Antimicrobial Drugs That May Be Used to Treat Clinical Toxoplasmosis in Dogs and Cats

Drug	Dose	Route	Interval	Duration
Azithromycin	10 mg/kg	PO	q24h	4 weeks
Clindamycin	10-12 mg/kg	PO	q12h	4 weeks
Ponazuril	20 mg/kg	PO	q24h	4 weeks
Trimethoprim-sulfa	15 mg/kg	PO	q12h	4 weeks

If a positive response to treatment is achieved by week 4 but the animal is still improving slowly, continue treatment for 1 week past clinical resolution or when maximal response is recognized.

healthy cats and dogs, and so positive PCR assay results do not correlate with clinical disease.[69,70] Thus, PCR assays are used most frequently with cytologic examination or histopathology to document that the organisms seen were *T. gondii*, or to detect *T. gondii* in aqueous humor or CSF in conjunction with serology.[42,44-46,70]

The combination of detection of *T. gondii*–specific antibody in serum, blood, aqueous humor, or CSF and amplification of *T. gondii* DNA by PCR assay is the most accurate way to diagnose ocular or CNS toxoplasmosis. Whereas *T. gondii*–specific IgA, IgG, and DNA can be detected in aqueous humor and CSF of both normal and clinically ill cats, *T. gondii*–specific IgM has only been detected in the aqueous humor or CSF of clinically ill cats and so may be the best indicator of clinical disease. Whether this is true for dogs has not been assessed to date.

Pathologic Findings

Gross Pathologic Findings

T. gondii infection generally induces pyogranulomatous reactions and necrosis. The pyogranulomas may be visualized grossly depending on the organ involved. Effusions that are characteristic of modified transudates or exudates may be found on necropsy.

Histopathologic Findings

Histopathology in animals with toxoplasmosis usually reveals pyogranulomatous inflammation with necrosis. *T. gondii* tachyzoites or bradyzoites are commonly detected (Figure 72-8, *A* and *B*). However, if necrosis is severe, the organism may be obscured. In these cases, DNA can often be amplified from the tissues, or the agent can be visualized after immunohistochemical staining (Figure 72-8, C). Because *T. gondii* and *N. caninum* induce similar syndromes in dogs, performance of PCR assays for both organisms in dogs is indicated in order to differentiate between them.

Treatment and Prognosis

Cats or dogs with suspected clinical toxoplasmosis should be administered supportive care as needed. Clindamycin hydrochloride or a trimethoprim-sulfonamide combination has been prescribed most frequently for the specific treatment of clinical toxoplasmosis (Table 72-2).[2-4,66] One of the drugs should be prescribed for 1 week, since most clinical signs of toxoplasmosis will begin to resolve within that time period. If a positive response is recognized, treatment should be continued for a total of 4 weeks if possible. If there is a poor response to therapy after the first 7 days, an alternative drug should be considered. Recurrence of clinical signs may be more common in cats or dogs treated for less than 4 weeks.[72]

Azithromycin has been used successfully in a limited number of cats, but the optimal duration of therapy is unknown. Pyrimethamine combined with sulfa drugs is effective for the treatment of human toxoplasmosis but commonly results in toxicity in cats. Pyrimethamine has been administered successfully with other drugs for the treatment of neosporosis in dogs and so may be effective for treatment of clinical toxoplasmosis in this species. Ponazuril has been used experimentally in *T. gondii*–infected rodents and should be studied for the treatment of feline toxoplasmosis.[71,73] Currently, an optimal treatment regimen for the use of this drug for this purpose in

VetBooks.ir

cats is unknown. However, ponazuril (20 mg/kg PO q24h for 28 days) was apparently successful in the treatment of a dog with suppurative keratitis and necrotizing conjunctivitis due to *T. gondii* infection.[50] Addition of fluconazole to pyrimethamine and trimethoprim was also effective in rodent models of toxoplasmosis and requires further study.[74] Cats or dogs with suspected *Toxoplasma* uveitis should be treated with anti-*Toxoplasma* drugs in combination with topical or systemic glucocorticoids to avoid secondary lens luxations and glaucoma. Enucleation may be required if lens luxations and glaucoma develop from persistent uveitis.

The prognosis is poor for cats or dogs with hepatic, CNS, or pulmonary disease caused by tachyzoite replication, particularly in those that are immunocompromised by anti-inflammatory drugs or retrovirus co-infection. If they survive, cats or dogs with CNS involvement may not experience complete resolution of neurologic signs after treatment.

Immunity and Vaccination

There is no evidence to suggest that any drug can eliminate *T. gondii* infection in dogs or cats. Thus, recurrence of disease is always possible, and infected dogs and cats often remain seropositive. In cats, if repeat oocyst shedding occurs, the number of oocysts shed is small and shedding is of short duration. Systemic reactivation of *T. gondii* infection after administration of immunosuppressive drugs can occur in both dogs and cats.

Several types of vaccines have been studied to block oocyst shedding in cats, but there is no vaccine for prevention of clinical toxoplasmosis in dogs or cats.

Prevention

To avoid exposure to *T. gondii,* cats and dogs should not be allowed to hunt or be fed undercooked meats. Care should be taken to control transport hosts such as cockroaches that have been shown to carry *T. gondii* oocysts.

Public Health Aspects

Primary *T. gondii* infection in immunocompetent humans results in self-limiting fever, malaise, and lymphadenopathy that may not be recognized or is misdiagnosed. Primary infection of mothers by *T. gondii* during gestation can lead to clinical toxoplasmosis in the fetus; stillbirth, CNS disease, and ocular disease are common clinical manifestations (Figure 72-9). As T-helper cell counts decline, approximately 10% of people with AIDS develop toxoplasmic encephalitis from reactivation of bradyzoites in tissue cysts.

People most commonly acquire toxoplasmosis by ingestion of sporulated oocysts or tissue cysts, or transplacentally. To prevent toxoplasmosis, humans should avoid consumption of undercooked meats or ingestion of sporulated oocysts. In a study of 6282 meat samples from 698 retail meat stores, using a feline bioassay, *T. gondii* was detected in none of the beef or chicken specimens tested and only a small number of pork specimens.[75] However, *T. gondii* has been detected in the tissues of free-ranging chickens.[76] Although exposure to cats is epidemiologically associated with acquiring toxoplasmosis in some

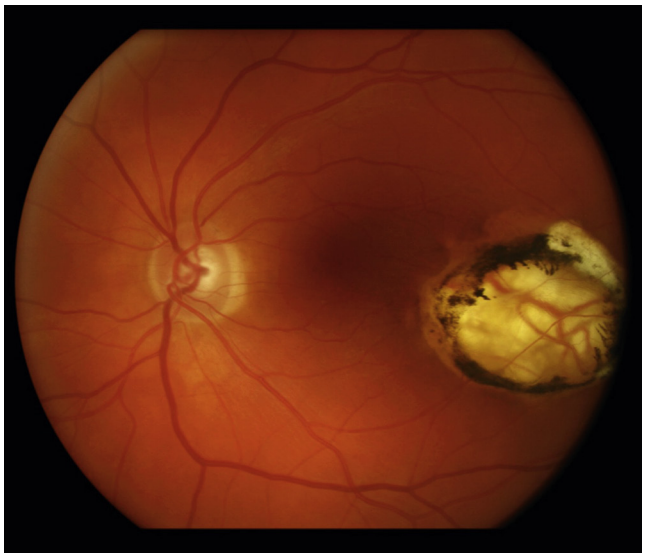

FIGURE 72-9 Healed chorioretinitis in a 60-year-old woman who had recovered from congenital toxoplasmosis. The infection resulted in a permanent visual deficit. (Image courtesy Mrs. Susan Sykes.)

studies, touching individual cats is probably not a common way to acquire toxoplasmosis for the following reasons[2-4,77-81]:

- Cats generally only shed oocysts for days to several weeks after primary inoculation.
- Repeat oocyst shedding is rare, even in cats receiving glucocorticoids or cyclosporine, or in those infected with FIV or FeLV.
- Cats inoculated with tissue cysts 16 months after primary inoculation do not shed oocysts.
- Cats are very fastidious and usually do not allow feces to remain on their skin for time periods long enough to lead to oocyst sporulation; the organism was not isolated from the fur of cats that had been shedding millions of oocysts 7 days previously.

However, because some cats will repeat oocyst shedding when exposed a second time, cat feces should always be handled carefully. If a fecal specimen from a cat contains oocysts that measure 10 × 12 µm, it should be assumed that the organism present is *T. gondii.* The feces should be collected and removed daily until the oocyst shedding period is complete; administration of clindamycin (20 mg/kg PO daily) may shorten the oocyst shedding period if started after infection is documented.[2,82]

Because humans are not commonly infected with *T. gondii* through contact with individual cats, testing healthy cats for evidence of *T. gondii* infection is not recommended.[79] Fecal examination is an adequate procedure to determine when cats are actively shedding oocysts but cannot indicate when a cat has shed oocysts in the past. There is no serologic assay that accurately indicates this, and most cats that are shedding oocysts are seronegative. Most seropositive cats have completed the oocyst shedding period and are unlikely to repeat shedding; most seronegative cats would shed the organism if infected. If owners are concerned that they may have toxoplasmosis, they should see their physicians for testing.

Dogs do not complete the enteroepithelial phase of *T. gondii* but can mechanically transmit oocysts after ingesting feline feces.[9]

CASE EXAMPLE

Signalment: "Fluffy," a 3-year-old male neutered Siamese mix from Evans in northern Colorado

History: Fluffy was referred after being treated for anterior uveitis and recurrent fever at another clinic. The clinical signs had been noted for approximately 1 month. Fluffy was entirely indoors in a suburban environment, but adopted from a humane society at around 6 months of age. His last vaccines (rabies, feline herpesvirus-1, feline calicivirus, and panleukopenia virus) were administered 6 months before the uveitis was first noted. He was fed a commercial processed food. There were no other animals at the house. He was treated with selamectin monthly but had not received his dose this month because of the fever. The fever seemed intermittent, and when normal, Fluffy had normal appetite and attitude. The uveitis persisted in spite of treatment with amoxicillin-clavulanic acid administered daily for 10 days and topical 1% prednisolone acetate applied three times daily.

Physical Examination:

Body Weight: 4.2 kg

General: Quiet, alert, and responsive. Ambulatory on all four limbs. T = 104.3°F (40.2°C), HR = 180 beats/min, RR = 30 breaths/min, mucous membranes pink, CRT = 1 s.

Integument: A dull haircoat was present. There was no evidence of ectoparasites.

Eyes: Bilateral anterior uveitis was present; fundoscopic examination was difficult due to aqueous flare.

Musculoskeletal: Body condition score was 4/9; possible discomfort was detected on muscle palpation.

Gastrointestinal: The cranial abdomen was tense with abdominal splinting noted on palpation.

All Other Systems: No significant abnormalities were noted.

Laboratory Findings:

Complete Blood Count: All values were within reference ranges.

Serum Biochemistry Profile: All values were within reference ranges except for the activity of serum AST (190 U/L; reference range, 19-42 U/L) and the activity of serum CK (2000 U/L; reference range, 50-125 U/L).

Urinalysis: No significant abnormalities; SGr = 1.041.

Imaging Findings: Thoracic and abdominal radiographs and abdominal ultrasound were offered but declined by the owner.

Microbiologic Testing: Serologic testing: FeLV antigen negative; FIV antibody negative; serum *Bartonella* IgG negative; *Bartonella* PCR assay negative on whole blood; *T. gondii* serum IgM 1:256; *T. gondii* serum IgG 1:1024.

Diagnosis: Suspected chronic, and possibly recurrent, toxoplasmosis.

Treatment: Clindamycin (12 mg/kg PO q12h) was administered for 28 days; fever resolved on day 3 of treatment. Prednisolone acetate was continued every 6 hours topically bilaterally for the first 14 days and was discontinued after anterior uveitis resolved. Subsequently, chorioretinal scars were noted on fundoscopic examination.

Comments: The findings were suggestive of chronic recurrent toxoplasmosis, which does not respond to treatment with β-lactam antibiotics. Myositis or pancreatitis may have contributed to some of the clinical and laboratory findings. These tissues commonly contain tissue cysts with *T. gondii* bradyzoites that can repeatedly replicate as tachyzoites, which in turn results in acute disease. *T. gondii* IgM can be detected in some cats with recurrent disease. Fluffy may have been infected with *T. gondii* when he was a stray and had an exacerbation or alternatively may have been infected more recently in the home environment by ingestion of a transport host (cockroach, etc.) or intermediate host (rodent).

CHAPTER 73

Neosporosis

Jane E. Sykes

VetBooks.ir

Overview of Neosporosis

First Described: 1984, in boxer dogs in Norway (Bjerkas and others)[1]

Cause: *Neospora caninum,* a coccidial protozoan parasite (phylum Apicomplexa)

Affected Hosts: Dogs are the definitive hosts and are the only species known to complete the sexual phase of *N. caninum* replication with passage of oocysts in the feces. Clinical illness primarily occurs in dogs and cattle, but sheep, deer, and water buffalo may also act as intermediate hosts.

Geographic Distribution: Worldwide

Mode of Transmission: Dogs can be infected transplacentally or through the transmammary route. Postnatally, dogs may be infected after they ingest infected tissues of intermediate hosts or bovine fetal membranes

Major Clinical Signs: Ascending paralysis, muscle atrophy, neurologic (especially cerebellar) signs, nodular dermatitis, respiratory distress

Differential Diagnoses: Toxoplasmosis, sarcocystosis, hepatozoonosis, deep mycoses, protothecosis, rabies, canine distemper virus infection, West Nile virus infection, canine monocytic ehrlichiosis, migrating ascarid infections, neuronal storage diseases, granulomatous meningoencephalitis, immune-mediated neuromuscular disease, primary or metastatic neoplasia

Human Health Significance: There is no clear evidence that *N. caninum* infects humans.

Etiology and Epidemiology

Neospora caninum is an obligately intracellular protozoan pathogen that closely resembles *Toxoplasma gondii*; before its description in 1984, it was misidentified as *T. gondii*. In contrast to *T. gondii*, domestic dogs and wild canids (coyotes, dingos, and probably wolves), and not cats, act as definitive hosts of *N. caninum* and shed oocysts after ingestion of *N. caninum* tissue cysts (enteroepithelial cycle) (Figure 73-1). Clinical neosporosis results from systemic replication of *N. caninum* tachyzoites (which divide by a process known as endodyogeny) and has been described in dogs and certain domestic and wild herbivores such as cattle, sheep, goats, deer, and marsupials. A related parasite, *Neospora hughesi*, sporadically causes myeloencephalitis in horses.[2] This organism has an unknown definitive host that is unlikely to be the dog, based on experimental infection studies.[3]

N. caninum is one of the most important causes of infertility, abortion, and neonatal mortality in cattle worldwide. Sheep can also develop reproductive and neonatal disease, but the economic importance of *N. caninum* in sheep is less clear when compared with cattle.[4] Herbivores likely become infected when they ingest oocysts shed in canine feces or through subclinical transplacental transmission. Oocysts sporulate and become infective 24 to 72 hours after they are shed in canine feces and can survive in the environment for prolonged periods. After oocysts are ingested, sporozoites are released in the intestinal tract and penetrate intestinal epithelial cells. Organisms can then disseminate to a variety of tissues, where they ultimately encyst as bradyzoite cysts. In dogs, pregnancy is associated with reactivation of bradyzoite cysts, with replication of tachyzoites and subsequent abortion or transplacental transmission. In breeding dogs, repeated reactivation of *N. caninum* replication occurs in late gestation with successive pregnancies, so that multiple litters of puppies can be affected. Transmission may also occur via the transmammary route. Infection of immunologically naïve cattle late in pregnancy is most likely to lead to transplacental spread with abortion (also known as *exogenous* transplacental transmission).[5] However, transplacental transmission as a result of reactivation of latent infection during pregnancy (*endogenous* transplacental transmission) can also occur.[6] The pregnant cow typically shows no other overt clinical signs of infection. Although antibodies to *N. caninum* have been found in cats and humans, naturally occurring neosporosis has not been described in these species.

Aside from transplacental transmission, dogs can become infected and shed oocysts when they ingest bovine placental material as well as other bovine tissues, such as muscle, liver, brain, and heart muscle.[7] This horizontal transmission is important and is thought to maintain infection in the dog population.[8] The DNA of *N. caninum* has been found in birds, small rodents, and lagomorphs, but whether predation of these species leads to oocyst shedding by dogs is not clear.[4] Experimental evidence suggests that ingestion of infected chicken eggs by dogs may lead to oocyst shedding.[9] However, ingestion of *oocysts* by dogs does not lead to oocyst shedding or development of tissue cysts.[10] When dogs do shed oocysts, the shedding begins 5 to 13 days after infection, and only low numbers of oocysts are shed for a short period (several days); seroconversion does not always occur. Rarely, protracted oocyst shedding (several months) by dogs has been described.[11] Puppies shed more oocysts than adult dogs,[12] and the number of oocysts shed decreases with repeated exposures to bradyzoite cysts.

In dogs, seroprevalence increases with age (because of an increased likelihood of exposure through horizontal transmission over time) and is higher in free-roaming dogs than in pet

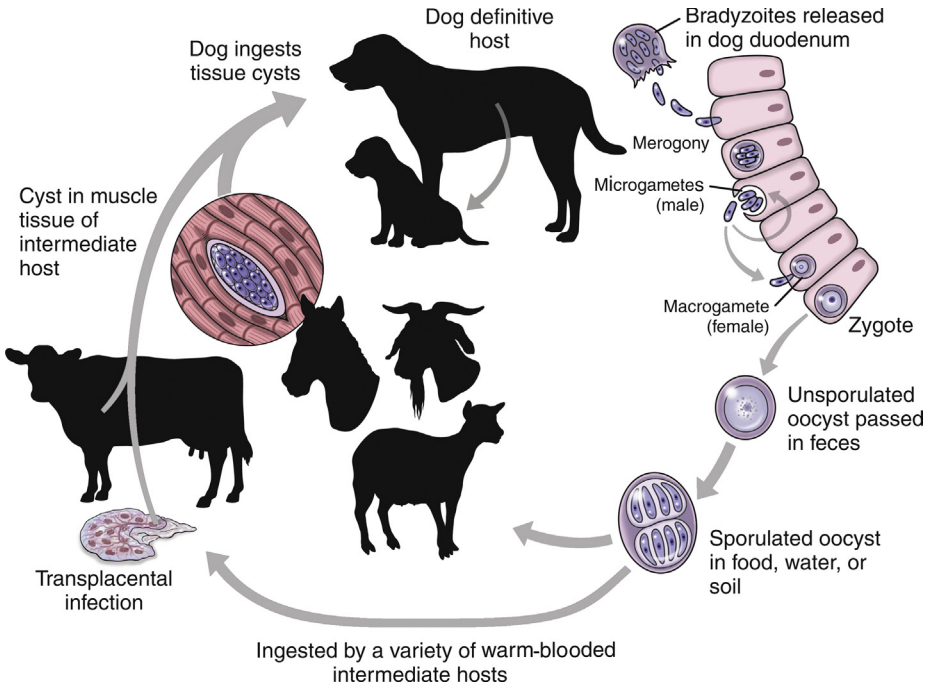

FIGURE 73-1 Life cycle of *Neospora caninum*. Dogs become infected when they ingest tissue cysts in bovine placental material and other bovine tissues. Bradyzoites are released in the intestine and transform into merozoites, where they undergo merogony. A zygote forms and is shed in the feces as an unsporulated oocyst. In addition, organisms can penetrate the dog's intestinal tract and form tissue cysts. Reactivation of these cysts in pregnancy can result in repeated transplacental transmission to the fetus. Herbivores are infected when they ingest sporulated oocysts. Infection of cattle can lead to transplacental spread of tachyzoites and abortion.

dogs. Dogs that reside on cattle farms or dogs in rural areas are also more likely to be seropositive than dogs that reside in urban areas.[13-16] Introduction of infected dogs to a farm can lead to outbreaks of abortion in cattle on the farm,[17] and the more dogs present on a farm, the greater the chance that cattle will be exposed. Although mixed breed dogs are more likely to be seropositive (exposed) than purebred dogs, purebred dogs often develop clinical neosporosis,[18] possibly because of genetic defects in cell-mediated immune function. Commonly affected breeds in the literature and/or in the author's practice include boxers, Rhodesian ridgebacks, bull mastiffs, greyhounds, basset hounds, Labrador retrievers, Rottweilers, and West Highland white terriers.

Clinical Features

Signs and Their Pathogenesis

Although exposure to *N. caninum* is common, clinical disease is uncommon in dogs. The development of clinical neosporosis, the signs that develop, and their rate of progression may depend on the virulence of the infecting *N. caninum* strain and the age and immunocompetence of the host.[4,19] Many affected dogs are infected transplacentally, after which clinical signs usually become apparent from 4 weeks to 6 months of age. Up to 50% of puppies in a litter can be infected, but not all puppies develop signs simultaneously, and sometimes only one puppy in the litter develops clinical illness.[20] Stillbirths and neonatal deaths may also be reported.[18] Reactivation of subclinical infection can occur in older dogs after treatment with immunosuppressive drugs or chemotherapy.[21-23] Horizontal acquisition of infection by adult dogs may occur through consumption of raw meat; one dog that developed neosporosis had a history of being fed raw elk meat.[22]

Transplacental infection of puppies usually leads to myositis and polyradiculoneuritis that initially involves the lumbosacral spinal nerve roots. This is manifested as ascending paralysis, muscle atrophy, and fibrous muscle contracture with arthrogryposis (joint contracture), hyperextension of the pelvic limbs, and loss of patellar reflexes.[18] Early signs of disease include exercise intolerance, ataxia, a high-stepping gait, splaying of the pelvic limbs, a "bunny hopping" gait, urinary incontinence, and/or muscle pain.[18,24-26] Clinical signs progress in some dogs to lethargy, tetraplegia, inability to fully open the mouth, dysphagia, and respiratory difficulty. Involvement of esophageal muscle may lead to megaesophagus.[27,28] Mandibular paralysis, vomiting, and lethargy were described as the only clinical signs in one affected dog.[28] Although ocular lesions are not a major clinical feature of neosporosis, focal chorioretinitis has been reported in some puppies.[29] Less often, young dogs develop signs of hepatitis; pneumonia; meningoencephalomyelitis; or myocarditis with arrhythmias, acute onset of respiratory distress, or sudden death.[26,27,30,31] Puppies with neuromuscular signs may have subclinical infection of other organ systems.[27]

In contrast to puppies, adult dogs typically develop polymyositis and/or meningoencephalomyelitis, with a variety of neurologic signs.[19,27,32] Although lesions can occur throughout the central nervous system (CNS),[27] *N. caninum* has a predilection for the cerebellum.[19] Some dogs can develop cerebellar atrophy.[19,33] Disseminated infections that involve the myocardium, liver, pancreas, lungs, skin, and/or eyes can also occur in adult dogs but are less common than encephalitis. In one unusual case, *N. caninum* tachyzoites were found in the peritoneal fluid of a dog with bacterial peritonitis.[34]

Physical Examination Findings

Physical examination findings in puppies with polyradiculoneuritis-myositis vary from mild ataxia and muscle atrophy to

VetBooks.ir

TABLE 73-1

Diagnostic Assays Available for Neosporosis in Dogs

Assay	Specimen Type	Target	Performance
Fecal flotation	Feces	*N. caninum* oocysts	Dogs with clinical neosporosis typically do not shed oocysts so this has a very low sensitivity and is not used routinely for diagnosis. Oocysts cannot be readily distinguished from those of *Hammondia heydorni*.
Fecal PCR assay	Feces	*N. caninum* DNA	As for fecal flotation.
Cytologic examination	CSF, aspirates of skin lesions, rarely specimens from the respiratory tract	*N. caninum* tachyzoites	Insensitive except in the case of skin lesions. Confirms active infection and is generally associated with disease. Organisms cannot be readily distinguished from *Toxoplasma gondii*.
Serology (IFA or ELISA)	Serum or CSF	Antibodies to *N. caninum*	Assays can vary in performance between laboratories. A fourfold increase in titer is associated with recent infection. Dogs with chronic neosporosis may not show a rise in titer, but titers >1:800 in conjunction with consistent clinical signs suggest neosporosis.
Histopathology	Muscle biopsies, multiple tissues collected at necropsy	*N. caninum* bradyzoites and tachyzoites	If organisms are detected in the presence of inflammation and necrosis, clinical neosporosis is likely. May be difficult to differentiate *N. caninum* and *T. gondii*. Immunohistochemistry can aid in the differentiation of the two species.
PCR assay	Muscle or skin biopsies, body fluids (especially CSF), tissues collected at necropsy	*N. caninum* DNA	Assay performance may vary between laboratories. Because positive PCR results can occur in healthy dogs, they must be interpreted in light of clinical signs and other findings in the specimens tested.

tetraparesis with rigid extension of one or both pelvic limbs and arthrogryposis. Reduced patellar and sometimes other segmental reflexes (including the perianal reflex) are often present.[18,24,35,36] Severely affected dogs may be lethargic and exhibit respiratory difficulty, and it may only be possible to open the mouth a few centimeters. Fever is rare.[18]

Adult dogs with *N. caninum* meningoencephalitis may be obtunded and exhibit signs that include ataxia, circling, head tilt, nystagmus, hypermetria, head tremors, delayed placing reactions, abnormal cranial nerve function, anisocoria, depressed segmental reflexes, tetraparesis, cervical hyperesthesia, and seizures.

Dogs with myocardial involvement may develop acute onset of respiratory difficulty and cyanosis.[18,27] Cutaneous involvement is manifested as dermatitis with single or multifocal firm nodules, crusting, and/or ulceration, which can appear at additional sites over time and may or may not be accompanied by other systemic signs of infection.[21,37-40] Rarely, dogs with pulmonary involvement are evaluated for cough or respiratory difficulty.[41]

Diagnosis

Neosporosis should be suspected in young dogs (<1 year of age) that develop ascending paralysis and muscle atrophy. It should also be suspected in dogs that develop neurologic (and especially cerebellar) signs or nodular dermatitis, especially in predisposed breeds or dogs treated with immunosuppressive drugs. Diagnosis most often relies on serology or detection of protozoal organisms in body fluids, aspirates, or tissues using light microscopy and/or PCR assays (Table 73-1). Often, antemortem diagnosis is based only on serologic testing because organisms are not easily found.

Laboratory Abnormalities

Complete Blood Count, Serum Biochemistry Panel, and Urinalysis

As for toxoplasmosis, there are no specific hematologic or biochemical abnormalities that suggest neosporosis. The CBC is often normal, but occasionally mild nonregenerative anemia, mild eosinophilia, or monocytosis is evident.[18,32] The serum biochemistry panel reveals increased creatine kinase activity in dogs with myositis.[19,23,24,26] Occasionally, increased activity of serum ALT (due to hepatitis or severe myositis) or hyperglobulinemia is evident.[23,32] The urinalysis is generally unremarkable.

Cerebrospinal Fluid Analysis

The CSF of dogs with *N. caninum* meningoencephalitis may be normal or show mild to markedly increased total nuclear cell count (TNCC) (sometimes >1000 cells/μL) and mild to markedly increased CSF protein concentration.[19,32] Usually,

a mononuclear pleocytosis is present, but occasionally the response is mixed or primarily composed of neutrophils or eosinophils.[19,24,32,35] *N. caninum* tachyzoites are rarely seen in CSF.[22,32]

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with neosporosis are usually unremarkable but may show a diffuse interstitial pattern in dogs with pneumonia, or evidence of megaesophagus in dogs with neuromuscular signs.[18]

Sonographic Findings

Abnormalities are rarely detected on abdominal ultrasound examination of dogs with neosporosis.

Advanced Imaging

MRI of adult dogs with cerebellar signs associated with *N. caninum* infection may show moderate to marked bilateral cerebellar atrophy.[19] Meningeal contrast enhancement may be present.[19,32] Single or multifocal T2-weighted and FLAIR hyperintensities that enhance with contrast on T1-weighted images may be present within the cerebellum or other parts of the brain (Figure 73-2). Mild to moderate heterogenous T2-weighted and FLAIR hyperintensities can also be seen in the masseter and temporalis muscles, which may appear atrophied.

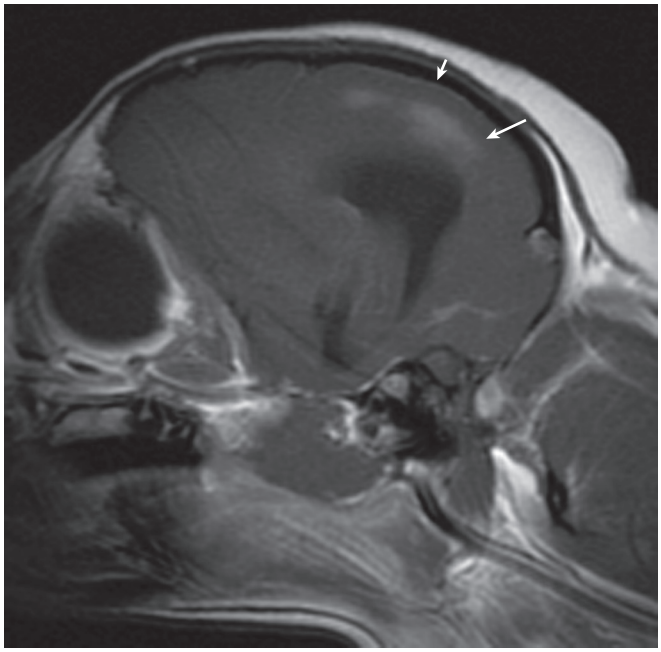

FIGURE 73-2 Sagittal T1-weighted postcontrast MRI image from a 4-year-old female spayed Chihuahua with suspected *Neospora caninum* meningoencephalitis. Multiple poorly defined regions of contrast enhancement were identified in the cerebral cortices *(large arrow)*, and mild meningeal enhancement was evident *(small arrow)*. CSF analysis revealed a mononuclear pleocytosis, and *Neospora* DNA was detected using PCR in the cerebrospinal fluid.

Electrodiagnostic Testing

Electromyography in dogs with neosporosis may reveal spontaneous fibrillation potentials, positive sharp waves, and repetitive discharges.[24,26] In some dogs, nerve conduction studies have revealed reduced conduction velocities and compound muscle action potentials.[24]

Microbiologic Tests

Cytologic Examination

The tachyzoites of *N. caninum* may be visualized within aspirates of skin lesions (which often contain many organisms) and rarely in CSF or other body fluids. They are approximately 6 × 1 µm and oval to crescent-shaped.[22,32,34,37] They may be seen singly, in pairs, or in larger groups, extracellularly and intracellularly, and are often associated with a pyogranulomatous inflammatory response (Figure 73-3). In the dog, *N. caninum* tachyzoites cannot be distinguished from those of *T. gondii* on cytologic examination. Because some cross-reactivity between *N. caninum* and *T. gondii* can occur with immunocytochemistry depending on the antibodies used, the use of PCR assays is recommended to definitively identify organisms as *N. caninum*. For unknown reasons, such cross-reactivity may be most likely to occur in dermal neosporosis.[8]

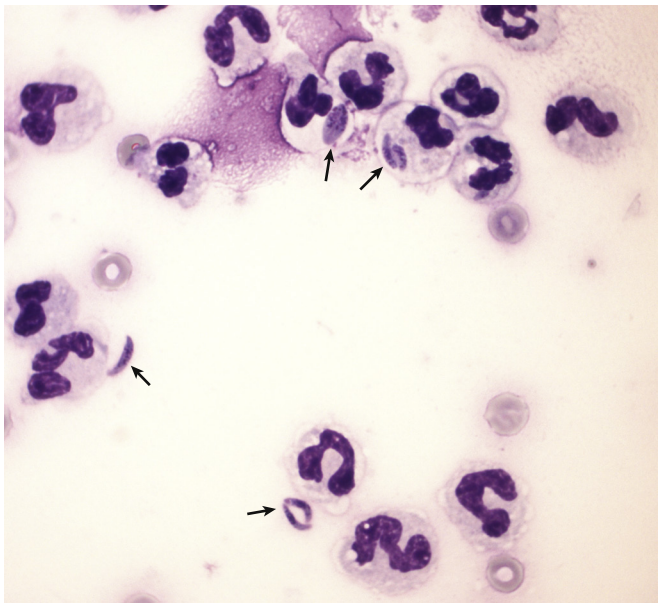

FIGURE 73-3 Cytology of abdominal fluid sediment in a 7-year old male neutered Rhodesian ridgeback showing intracellular and extracellular *Neospora caninum* tachyzoites *(arrows)*. Nucleated cells are predominantly nondegenerate to mildly degenerate neutrophils.

Fecal Flotation

Fecal flotation with sugar or zinc sulfate solutions can be used to detect the oocysts of *N. caninum* in feces. However, clinically affected dogs do not typically shed oocysts. When oocysts are seen, they are indistinguishable from those of *Hammondia heydorni* or *Toxoplasma gondii*.

Serologic Diagnosis

Serologic assays are available commercially that detect antibody to *N. caninum* in serum and/or in CSF. Titers are often higher in serum than in the CSF of affected dogs. Indirect IFA assays are widely used, but ELISA assays have also been developed and may be used to detect IgM and IgG antibody. Seroconversion usually occurs within 2 to 3 weeks of infection, and a rising serum titer can be identified in acutely infected dogs.[26] This rise may not occur in chronically infected dogs, so in this case a single high titer in a dog with consistent clinical signs is suggestive of the diagnosis. Some dogs with neosporosis have extremely

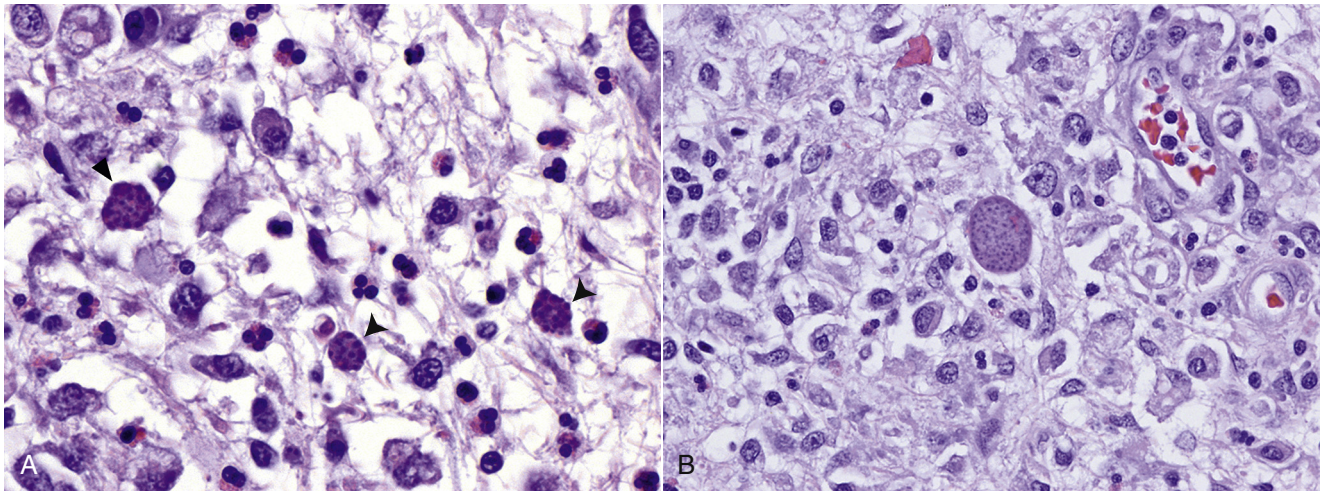

FIGURE 73-4 Histopathology of the cerebellum from a 6-year-old intact male Rhodesian ridgeback with neosporosis. **A,** Large areas of malacia were present admixed with a marked granulomatous inflammatory infiltrate and abundant protozoal cysts *(arrowheads)*. **B,** The protozoal cysts had a thick wall and stained positive with anti-*Neospora* antibodies (not shown). (Courtesy Dr. Robert Higgins, University of California, Davis Veterinary Anatomic Pathology Service.)

high serum titers (e.g., in the tens of thousands), but others have only low antibody titers. The latter situation might reflect the presence of underlying immunodeficiency and inability to produce antibodies. Because interassay variation may cause results to differ between laboratories,[42] the same laboratory should always be used when paired titers are performed or when titers are monitored over time.

Some weak serologic cross-reactivity may occur between the antigens of *T. gondii* and *N. caninum*, so low titers to *T. gondii* may be present in dogs infected with *N. caninum*. Cross-reactivity appears to be less common when IFA assays are used.[42] Serologic cross-reactivity can also occur to *N. hughesi,* again at a slightly lower titer,[43] but the extent to which this organism infects dogs is not clear.

Molecular Diagnosis Using the Polymerase Chain Reaction

Both conventional and real-time PCR assays have been developed for diagnosis of neosporosis.[44-46] Some are available for diagnosis on a commercial basis from veterinary diagnostic laboratories. Suitable specimens for testing include CSF, tissue biopsies (e.g., muscle), or tissues collected at necropsy. The sensitivity and specificity of these assays has the potential to vary considerably between laboratories, and more information is required on how these assays perform for antemortem diagnosis of clinical neosporosis in dogs. Because *N. caninum* DNA can be detected in tissues from healthy dogs, PCR results must always be interpreted in light of the clinicopathologic findings and serologic test results. In one study, *N. caninum* DNA was detected in the liver and/or spleen of one third of shelter dogs that had been euthanized, and PCR assay results did not always correlate with the results of serology.[44] PCR assays can be used to confirm that organisms seen in tissues or body fluids are truly *N. caninum* and not another protozoan parasite such as *Sarcocystis* or *T. gondii*.[23]

Pathologic Findings

Gross pathologic findings may be absent in dogs with neosporosis, or foci of discoloration may be present in the brain and spinal cord, and/or there may be evidence of meningitis (e.g., meningeal thickening or adherence of the meninges to the brain or cranial vault). White streaks within muscle may be found in affected puppies.[24] Histopathology in these puppies reveals polyradiculoneuritis with myelin loss and axonal degeneration, and there may be evidence of muscle fiber degeneration and fibrosis.

Examination of the brain and spinal cord of dogs with CNS involvement usually reveals multifocal nonsuppurative meningoencephalitis and/or myelitis with neuronal degeneration and necrosis, perivascular cuffing, and gliosis. Both gray and white matter can be affected, and the cerebellum may be primarily involved. A mixed inflammatory response with myonecrosis and sometimes dystrophic mineralization may be seen in affected skeletal or cardiac muscle. Bradyzoite cysts and/or tachyzoites may be evident (Figure 73-4). Bradyzoite cysts are up to 100 µm in diameter and have a wall that is 4 µm in diameter, which is thicker than that for *T. gondii*. Skin biopsies from dogs with dermal neosporosis contain tachyzoites and pyogranulomatous inflammation. Occasionally (such as in acute, fulminant infections in immunosuppressed dogs), tachyzoites are found in other tissues, including the peripheral nerves, the eye, reproductive tissues, adrenal glands, lung, liver, kidney, spleen, and esophageal muscle.[27] If intralesional protozoa are identified, immunohistochemistry and PCR assays can be used to distinguish *N. caninum* from other protozoal species.[40] Although serologic cross-reactivity between *N. caninum* and *T. gondii* is uncommon, it can occur with some antibodies, so immunohistochemistry is best performed with a panel of antibodies to each protozoan parasite.

In healthy dogs or dogs that die of other diseases, rare bradyzoite cysts in the absence of an inflammatory response may be found at necropsy in skeletal muscle and the CNS.

Treatment and Prognosis

The primary antimicrobial drug that has been used to treat neosporosis in dogs is clindamycin (Table 73-2). Treatment is usually only temporarily, partially, or completely ineffective, and long periods (>8 weeks) of treatment may be required.[18,19,39] Bradyzoite cysts persist despite treatment with clindamycin.[47] Treatment appears to be most effective for cutaneous neosporosis, although one dog developed neurologic signs when treatment was discontinued, such that reinstitution of long-term treatment was needed.[39] Other treatments that have been successful (or partially successful)

VetBooks.ir

TABLE 73-2

Antimicrobials Used to Treat Neosporosis in Dogs

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Clindamycin	10-12 mg/kg	PO	q8h	At least 4 weeks
Trimethoprim-sulfa	15 mg/kg	PO	q12h	At least 4 weeks
Pyrimethamine	1 mg/kg	PO	q24h	At least 4 weeks
Ponazuril	20 mg/kg	PO	q24h	At least 4 weeks

are trimethoprim-sulfadiazine-pyrimethamine, combinations of clindamycin and trimethoprim-sulfadiazine, or combinations of clindamycin and pyrimethamine. The efficacy of ponazuril for treatment of canine neosporosis requires further study but shows promise based on studies in mice and cattle.[8] Treatment should be continued so long as clinical improvement is occurring. The prognosis for puppies once muscle contracture has developed is poor. It has been suggested that once neosporosis has been diagnosed in a puppy, all dogs in a litter should be treated, because the later treatment is initiated after the onset of clinical signs, the worse the prognosis.[48] At the minimum, puppies whose littermates have succumbed to neosporosis should have their serum antibody titer to *N. caninum* checked, and treatment should be considered for those with positive titers. The use of immunosuppressive drugs should be avoided in seropositive puppies.

A low dose of glucocorticoids (e.g., prednisone, 0.5 mg/kg PO q12h) in addition to antiprotozoals is often used to treat *N. caninum* meningoencephalomyelitis, but no prospective controlled trials have been performed to determine if this alters outcome. Very high doses of methylprednisolone acetate reactivate experimental *N. caninum* infections in dogs.[49] Physiotherapy may also be beneficial for young dogs with polyradiculoneuritis-myositis.

Immunity and Vaccination

Immunity to *N. caninum* is dependent on cell mediated immune responses. No vaccines for canine neosporosis exist.

Prevention

Neosporosis on farms can be prevented by not allowing dogs to access bovine placental materials, dead calves, or raw or undercooked meat and by preventing dogs from defecating around livestock. Predation should also be discouraged. The use of a muzzle for dogs that work on farms has been suggested to prevent *Neospora* abortions in cattle.[8] It may be necessary to stop the breeding of bitches that have puppies that develop neosporosis, and the owners of puppies that are diagnosed with neosporosis should be advised to inform the breeder of the diagnosis. No drugs are known to prevent transplacental transmission. Where possible, avoidance of excessive pharmacologic immunosuppression (e.g., with glucocorticoids, cyclosporine, azathioprine, or other immunosuppressive drugs) may help to prevent the disease in adult dogs. However, the relative rarity of reactivated neosporosis in adult dogs does not justify routine serologic screening of dogs for infection before commencing immunosuppressive drug treatment.

Public Health Aspects

Although antibodies to *N. caninum* have been detected in the serum of humans, the DNA of *N. caninum* has never been found in humans, and currently *N. caninum* is not thought to be a zoonotic risk.

CASE EXAMPLE

Signalment: "Lenny," a 6-year-old intact male Rhodesian ridgeback from coastal northern California

History: Lenny was evaluated on a referral basis for a 1-week history of an abnormal gait. The owner first noticed that Lenny was not paying attention during an obedience show. Over the next few days Lenny was observed to stumble on stairs, and he also fell from a bed. For the 3 days before evaluation the owner had noted that Lenny appeared uncoordinated and off balance. There had been no changes in his mentation and no evidence of inappetence, vomiting, diarrhea, or changes in thirst or urination. A soft, intermittent nonproductive cough had been noted since the onset of the other clinical signs. Bloodwork at a local veterinary clinic showed a normal CBC, increased activity of serum creatine kinase (2922 U/L, reference range [RR] 10-200 U/L), ALT (155 U/L, RR 5-60 U/L), and AST (135 U/L, RR 5-55 U/L). Serum thyroxine concentration was within the reference range. A urinalysis was unremarkable and aerobic bacterial urine culture was negative. Serology for antibodies to *Borrelia burgdorferi*, *Anaplasma* spp., *Ehrlichia canis*, and antigen of *Dirofilaria immitis* (4Dx SNAP test, IDEXX Laboratories) was negative. A *T. gondii* titer was pending. Lenny was treated with clindamycin (7.5 mg/kg PO q12h) and doxycycline (5 mg/kg PO q12h) with no signs of improvement.

Lenny had traveled extensively to Iowa, Colorado, and Kentucky but had no history of toxin exposure or trauma. He was fed a raw diet that consisted of turkey necks, chicken meat, lamb, and vegetables. He was up to date on routine vaccinations (distemper, adenovirus, parvovirus, and rabies) and on heartworm prophylaxis, but did not receive flea or tick prophylaxis and had been exposed to ticks in the past. He had been bred once and only one of three puppies survived. There was no other significant medical history.

VetBooks.ir

Physical Examination:

Body Weight: 40.2 kg.

General: Bright and alert, hydrated. T = 100.5°F (38.1°C), HR = 80 beats/min, panting, mucous membranes pink and moist, CRT 1 s.

Musculoskeletal: Body condition score was 4/9. Truncal ataxia was present with a wide-based stance (see Neurologic Examination). There was no evidence of lameness or muscle atrophy.

All Other Systems: With the exception of the neurologic examination, no other clinically significant abnormalities were detected.

Neurologic Examination: The dog was alert and responsive. Truncal ataxia was present with hypermetria that was most pronounced on the left side. Head tremors were also noted. A slight left-sided head tilt was present, together with a decreased to absent menace response on the left side. There was normal physiologic nystagmus and no evidence of spontaneous nystagmus. Delayed placing reactions were detected in all four limbs but were most pronounced on the right side. Spinal reflexes were within normal limits. Neuroanatomic location: cerebellar/vestibular disease.

Laboratory Findings: Muscle biochemistry panel: AST 85 U/L (21-54 U/L), creatine kinase 1683 U/L (46-320 U/L).

Imaging Findings:

Thoracic Radiographs and Abdominal Ultrasound Examination: No abnormalities were detected.

Magnetic Resonance Imaging (Brain): On T2-weighted images, there was increased intensity of the vermis and left cerebellar hemisphere. The cerebellum appeared normal on T1-weighted images. Subtle regions of contrast enhancement were suspected in the left cerebellum on sagittal T1-weighted postcontrast images.

Other Testing: CSF analysis: Total nucleated cell count was 62 cells/μL (normal <2 cells/μL); total protein was 75 mg/dL (normal <25 mg/dL). There were 86% eosinophils, 8% small mononuclear cells, 5% large mononuclear cells, and 1% nondegenerate neutrophils. The large mononuclear cells were mostly of unremarkable morphology but occasionally had mildly increased cytoplasmic vacuolation. No infectious agents were seen.

Microbiologic Testing: Serologic testing (IFA): *Neospora caninum* serum antibody titer positive at 1:20,480; the CSF titer was 1:640.

Zinc sulfate fecal flotation: Negative for parasite ova.

Fecal Baermann examination: Negative for parasite larvae.

Treatment: Before the *Neospora* titers were available, a diagnosis of eosinophilic meningoencephalitis was made, and the dog was treated with prednisone (0.5 mg/kg PO q12h) but showed no clinical improvement over the subsequent 3 days. A second CSF specimen collected at that time had a cell count of 37 cells/μL and a total protein concentration of 59 mg/dL, with no change in the differential cell count. Lenny was discharged from the hospital, and once the *N. caninum* serology results became available (1 week later), treatment with trimethoprim-sulfamethoxazole (15 mg/kg PO q12h) and ponazuril (10 mg/kg, or 2.5 mL of 15% ponazuril paste PO q24h) was added. A baseline Schirmer tear test (performed to monitor for keratoconjunctivitis sicca secondary to sulfamethoxazole) was negative. At a recheck examination 3 weeks later, all neurologic signs were persistent but mildly improved. A CBC showed mild, nonregenerative anemia (34.9%) and mild bandemia (198 cells/μL). Serum CK activity was 88 U/L. CSF analysis showed a total protein concentration of 33 mg/dL and a TNCC of 2 cells/μL, with 0% eosinophils, 51% small mononuclear cells, and 49% mildly reactive large mononuclear cells. The serum and CSF antibody titers to *N. caninum* were both 1:5120. A Schirmer tear test was normal. Two weeks later, the trimethoprim-sulfamethoxazole was discontinued. Neurologic signs persisted but continued to show mild but slow improvement over the next 3 weeks. The ponazuril was discontinued, but after an additional 3 weeks, the head tremors worsened slightly. Blood work was unchanged, CSF analysis (cisternal and lumbar) was within normal limits, and serum and CSF *N. caninum* antibody titers were 1:1280 and 1:640, respectively. The prednisone was also discontinued. Two months later (4 months after initial diagnosis), severe ataxia and falling returned over a 2-week period. The owner declined reinstitution of antiprotozoal treatment and elected euthanasia. A complete necropsy revealed severe, locally extensive, necrotizing granulomatous encephalitis that was localized to the cerebellum. Abundant protozoal cysts were present within the cerebellar lesions, which were identified using immunohistochemical stains as *N. caninum*. Protozoa were not visualized in any other tissues.

Diagnosis: Granulomatous cerebellitis secondary to *N. caninum* infection.

Comments: Neosporosis in this dog resulted from cerebellar encephalitis, which illustrated the suggested predilection of *N. caninum* for the cerebellum. Development of encephalitis rather than polyradiculoneuritis-myositis is typical of neosporosis in adult dogs. It is possible this dog contracted neosporosis as a result of consumption of a raw food diet; tissue cysts have been identified in CNS tissues of a lamb,[50] and chickens are suspected as intermediate hosts based on seropositivity and positive PCR assay results on brain tissue.[51] The inflammatory response in the CSF was profoundly eosinophilic, as previously reported in other dogs with neosporosis. Fecal flotation was negative for *N. caninum* oocysts, which is expected given the life cycle of the parasite and the short shedding period with low numbers of oocysts shed. The fecal examinations were performed to evaluate for the possibility of visceral larva migrans, given the CSF eosinophilia. Although treatment with trimethoprim-sulfamethoxazole and then ponazuril led to resolution of CSF abnormalities, clinical signs showed only mild improvement. Treatment of neosporosis with glucocorticoids remains controversial, but attempts to reduce the prednisone dose were associated with worsening of clinical signs. Ultimately, all treatment was discontinued because of minimal improvement in clinical signs but resolution of laboratory abnormalities. Relapse subsequently ensued, and the diagnosis was confirmed at necropsy.

CHAPTER 74

Leishmaniosis

Jane E. Sykes, Gad Baneth, and Christine A. Petersen

VetBooks.ir

Overview of Leishmaniosis

First Described: The cause of visceral leishmaniosis was first described in India in 1903 (separately by William Leishman and Charles Donovan)[1]

Causes: Canine and feline visceral leishmaniosis is caused by *Leishmania infantum* (syn. *L. chagasi*) (phylum Euglenozoa, class Kinetoplasta, family Trypanosomatidae). Other species such as *L. braziliensis* cause localized cutaneous lesions in South America (American tegumentary leishmaniosis).

Affected Hosts: Dogs and less commonly cats; also humans, rodents, wild canids, and marsupial species

Geographic Distribution: Primarily southern Europe and the Middle East, central and South America; also some parts of the United States. Travel-related disease can occur in non-endemic regions worldwide.

Mode of Transmission: *Phlebotomus* and *Lutzomyia* sandflies. Transmission through blood transfusion as well as vertical transmission can occur.

Major Clinical Signs: Weight loss, inappetence, scaling and/or ulcerative cutaneous lesions, onychogryphosis, fever, keratoconjunctivitis, uveitis, lymphadenopathy, hepatosplenomegaly, pallor, lameness, signs of renal failure

Differential Diagnoses: Differential diagnoses in dogs with visceral disease include canine monocytic ehrlichiosis, babesiosis, histoplasmosis, brucellosis, hemic neoplasia, and primary autoimmune diseases such as systemic lupus erythematosus. Differential diagnoses for cutaneous lesions in dogs include demodectic or sarcoptic mange, pyoderma, *Malassezia* dermatitis, cutaneous vasculitis, and pemphigus foliaceus. Differential diagnoses for cutaneous lesions in cats include squamous cell carcinoma, cutaneous vasculitis, herpesviral dermatitis, and dermatophytosis. The primary differential for American tegumentary leishmaniasis is sporotrichosis.

Human Health Significance: Human infections are primarily transmitted by sandflies and involve a large number of different *Leishmania* species. Dogs are considered the major reservoir for *L. infantum* infections. Precautions should be taken when handling potentially infected tissue and blood specimens.

CANINE LEISHMANIOSIS

Etiology and Epidemiology

The leishmaniases are a group of zoonotic vector-borne diseases caused by various species of the protozoa *Leishmania*, which are primarily transmitted by sandflies. Around 30 species of *Leishmania* exist worldwide, and at least 20 species cause disease in humans, although the taxonomy of *Leishmania* spp. has been highly debated.[2,3] There are two subgenera of *Leishmania*, *Leishmania* and *Vianna*, which develop in the foregut or the hindgut/midgut of the sandfly vector, respectively. Human and animal disease due to *Leishmania* spp. is distributed across five continents (Africa, Asia, Europe, and the Americas) and nearly 100 countries (Figure 74-1). Disease syndromes in humans are divided into cutaneous leishmaniasis (CL), mucosal leishmaniasis (ML), and visceral leishmaniasis (VL). Disease syndromes in dogs are divided into visceral leishmaniosis and American tegumentary leishmaniosis, a localized cutaneous form that occurs in parts of South America. The term 'leishmaniosis' as opposed to 'leishmaniasis' is preferred to distinguish the disease in animals from that in humans.

Leishmania species are transmitted by female sandflies of the genus *Phlebotomus* in the Old World (Africa, Asia, and Europe) and *Lutzomyia* in the New World (i.e., the Americas). The regional prevalence of leishmaniasis, and the type of disease syndrome that develops, varies with the infecting *Leishmania* species present, sandfly species in the region, and host responses to infection. Some sandfly species transmit certain *Leishmania* species primarily to humans (anthroponotic leishmaniasis), whereas other sandfly species transmit *Leishmania* species to mammalian host species, such as dogs, cats, and rodents. Dogs and rodents are important reservoirs for *Leishmania* infection of humans (zoonotic leishmaniasis). Thus, the major mammalian reservoirs for the disease in a region depend on the *Leishmania* species and the sandfly species present.

The life cycle of *Leishmania* alternates between two major forms: the *promastigote* and the *amastigote* (Figure 74-2). The promastigote resides in the gut of the sandfly vector and is an elongated, flagellated form. Promastigotes are inoculated into tissues when the sandfly feeds, where they are phagocytized by macrophages in the dermis and transform into intracellular, nonmotile, ovoid, or round amastigotes. The amastigotes survive and replicate within macrophage phagolysosomes, and eventually the infected macrophages rupture. Released amastigotes then infect other macrophages that have been attracted to the site of infection. If the infected host fails to control the infection, amastigotes disseminate via regional lymphatics and the blood to infect the entire reticuloendothelial system. Intracellular amastigotes that are ingested by a female sandfly during

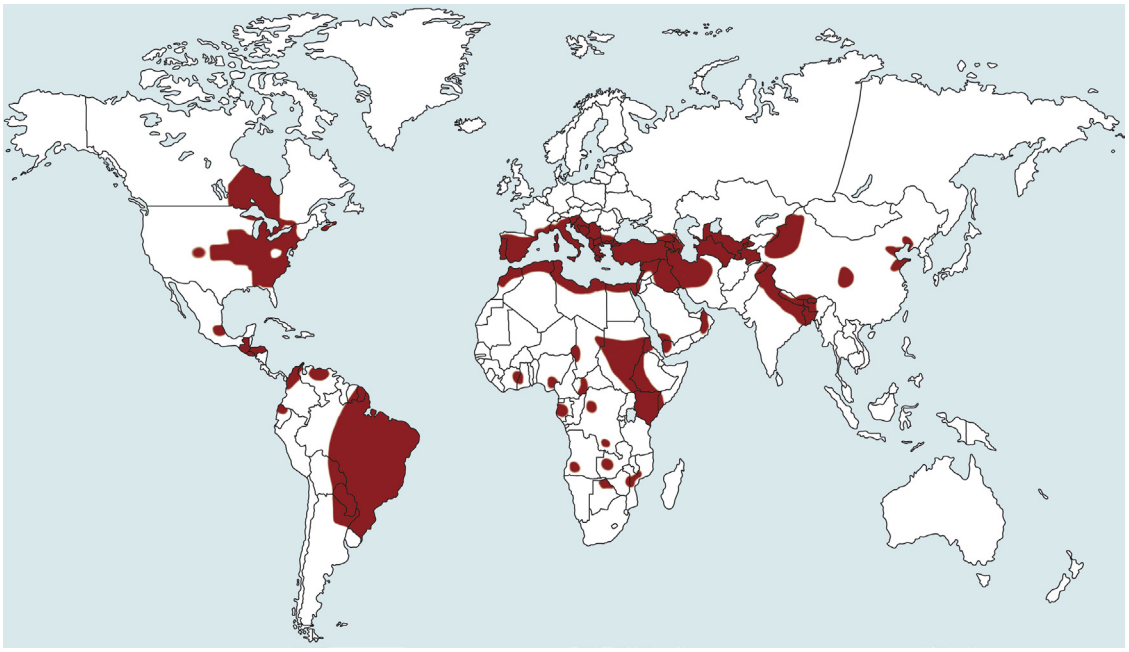

FIGURE 74-1 Geographic distribution of visceral leishmaniases in humans and dogs.

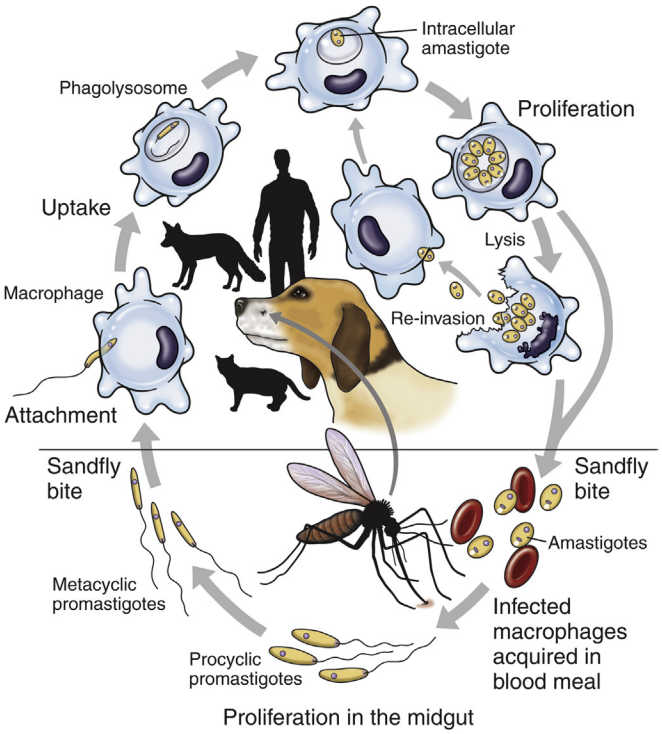

FIGURE 74-2 Life cycle of *Leishmania infantum*. Dogs, cats, and humans become infected when they are bitten by a sandfly. Promastigotes are inoculated into the dermis and penetrate macrophages. Within the macrophage, they transform into amastigotes and replicate within a phagolysosome. The macrophage ruptures and new macrophages are infected. If the host fails to control the infection in the skin, amastigotes disseminate via regional lymphatics and the blood to infect the entire reticuloendothelial system. Amastigotes that are ingested by a female sandfly during feeding convert back into promastigotes, and replication of promastigotes within the sandfly completes the life cycle.

feeding convert back into promastigotes over a period of about 1 week, and replication of promastigotes within the sandfly completes the life cycle. Sandflies breed in cracks in the walls of dwellings, rubble, and in rodent burrows, feed primarily at night, and fly a maximum of 2.5 km from their breeding sites. As a result, the prevalence of infection in dogs can vary considerably between adjacent regions. Lesser modes of transmission of *Leishmania* spp. include vertical transmission from bitches to puppies, venereal transmission, and blood transfusion.[4-7] These modes of transmission become more obvious in regions where suitable sandfly vectors do not exist. Aggressive interactions between dogs also have the potential to transmit infection, but this route has not been proven.

Canine visceral leishmaniosis in dogs and cats is caused by *Leishmania infantum* (also referred to as *Leishmania chagasi* in Central and South America). *L. infantum* is endemic in the Mediterranean basin, the Middle East, and Asia and may have been introduced to Latin America by early explorers and their domestic dogs.[8] Because leishmaniosis has a long incubation period and prolonged disease course, travel-related leishmaniosis in dogs and cats is diagnosed sporadically in regions where sandfly transmission does not occur, such as parts of Scandinavia, Switzerland, Japan, the United Kingdom, and the western United States (most often in dogs imported from southern Europe).[9-13] In highly endemic regions of the Mediterranean and Brazil, infection rates among dogs vary widely but may reach 80%.[14-17] At least 2.5 million dogs are infected in southwestern Europe alone.[14] The disease may be spreading northward in Europe, and has recently appeared in nontraveled dogs in countries such as Germany and Hungary.[5,18,19] Spread of *Leishmania* spp. into new areas can occur when humans bring infected dogs into regions where competent insect vectors exist, or when sandfly populations expand as a result of factors such as climate change.

Risk factors for infection in dogs include age at least 2 years, prolonged exposure to the outdoors, lack of topical insecticide use, and, in some studies, a short haircoat.[20-23] Some authors have described a bimodal age distribution that peaks at 3 years and at

VetBooks.ir

greater than 8 years of age.[24] Sex is not an important risk factor for infection. Factors that promote proliferation of sandfly populations, such as poor sanitation and limited garbage collection, as well as the occurrence of stray dogs around homes, also put dogs at risk of infection.[25] In Europe, German shepherd dogs, boxers, Rottweilers, cocker spaniels, and Dobermans may be at increased risk for leishmaniosis; the Ibizan hound in Spain appears to be resistant to clinical disease.[24,26-29] Concurrent diseases are common in dogs with leishmaniosis in endemic regions and include transmissible venereal tumor,[30] demodicosis,[31] sarcoptic mange,[32] and a variety of other vector-borne diseases such as canine monocytic ehrlichiosis, babesiosis, hepatozoonosis, and dirofilariasis.[32-36] Concurrent lymphoma has also been described.[32]

Uncommonly, dogs worldwide are infected by other species of *Leishmania*, which include *Leishmania donovani, Leishmania tropica, Leishmania braziliensis, Leishmania peruviana, Leishmania mexicana, Leishmania panamensis, Leishmania guyanensis, Leishmania amazonensis,* and other as-yet-uncharacterized species.[37-45] *L. braziliensis*, *L. guyanensis*, and *L. panamensis* have been isolated from dogs with American tegumentary leishmaniosis. Outbreaks of American tegumentary leishmaniosis have occurred in humans and dogs.[43]

Canine Leishmaniosis in North America

Most sporadic cases of visceral leishmaniosis in dogs in North America are diagnosed in dogs with a travel history to other continents. Infected dogs continue to be introduced every year as a result of travel from endemic regions in Europe and Latin America. In addition, over the past 30 years, visceral disease has been described in dogs in the United States that have had no apparent travel history. These have included a basenji dog from a kennel in Texas and dogs of foxhound breed from Ohio, Oklahoma, and Colorado.[46-49] Involvement of multiple dogs in a foxhound kennel was reported in Oklahoma,[47] and outbreaks in foxhounds have also been described in New York, Alabama, and Michigan.[50] Spread to other dogs has occurred as a result of transplacental transmission and, in rare cases, transfusion of infected blood.[4,6] A competent arthropod vector for *Leishmania* spp. has not yet been identified in the United States, and infection has not been detected in surveys of non-foxhound dogs in the United States.[51]

Clinical Features

Signs and Their Pathogenesis

The outcome of *Leishmania* spp. infection is variable. Some dogs completely eliminate the infection, and a small percentage of dogs develop severe, life-threatening disease. Some dogs remain persistently but subclinically infected, with the possibility of reactivation later in life with immunosuppression; these dogs also act as reservoir hosts and can infect sandflies.[52] In general, dogs that mount strong T-cell–mediated immune responses eliminate the infection, whereas those that mount weak cell-mediated immune responses and marked, nonprotective humoral (IgG) immune responses develop clinical disease.[53] Host genetic factors are important in determining progression to clinical disease, and several candidate genes have been identified in dogs that may influence susceptibility.[28,54-56] When clinical disease appears, it occurs after a long incubation period (up to 7 years) and varies from mild papular or exfoliative dermatitis to severe disseminated disease due to massive proliferation of histiocytes, B lymphocytes, and plasma cells in reticuloendothelial tissues and immune-mediated consequences of chronic, persistent infection.

FIGURE 74-3 Periocular alopecia and crusting in an 8-year-old male neutered husky mix with visceral leishmaniosis. The dog was evaluated in northern California but had a travel history to Spain. Lesions are also present on the muzzle and the pinnae.

Cutaneous lesions most commonly manifest as alopecia, scaling, and/or ulceration but can be nodular or papular (Figure 74-3). They are often noticed before signs of systemic infection develop, despite the fact that they occur as a consequence of parasite dissemination. Many dogs also develop onychogryphosis (abnormally long or brittle claws).

Systemic signs of visceral leishmaniosis include fever, weight loss, muscle atrophy, inappetence, and lethargy; oral ulceration; progressive splenomegaly and lymphadenomegaly; mucosal pallor due to anemia; and rarely, hepatomegaly (Table 74-1). Development of autoantibodies and circulating immune complexes is thought to lead to immune-mediated thrombocytopenia and/or thrombocytopathia and signs such as epistaxis or melena, lameness and joint swelling due to immune-mediated polyarthritis, myositis, uveitis, vasculitis, and glomerulonephritis.[57-62] Positive antinuclear antibody tests are found in up to 50% of dogs tested.[32,61,63] Many dogs also have positive Coombs' tests.[32,63]

Glomerular injury ultimately culminates in nephrotic syndrome and/or failure of tubular function for many dogs, with polyuria and polydipsia, vomiting, diarrhea, and dehydration. Renal failure may occur in the absence of other lesions.[32] Anemia may be due to a combination of factors that include blood loss, inflammation, renal failure, immune-mediated destruction, and marrow aplasia or hypoplasia. In addition to uveitis, other ocular lesions include blepharitis, conjunctivitis, panophthalmitis, and keratoconjunctivitis. Keratoconjunctivitis results from direct infection of the lacrimal gland by *Leishmania*.[64]

Atypical presentations of canine visceral leishmaniosis have also been reported. Almost any organ can be affected, with reports of *Leishmania* prostatitis and infertility[65]; nodular lesions

TABLE 74-1

Clinical Signs in Dogs with Visceral Leishmaniosis

Clinical Sign	Prevalence (%)
Lymphadenomegaly	65-90
Cutaneous lesions	51-89
Weight loss	25-64
Lethargy	11-60
Pallor	58
Splenomegaly	10-53
Polydipsia	4-40
Abnormal locomotion or polyarthritis	3-38
Pyrexia	4-36
Onychodystrophy	20-31
Diarrhea	30
Vomiting	26
Ocular lesions (keratoconjunctivitis, uveitis, panophthalmitis, blepharitis)	7-24
Inappetence	17
Polyphagia	15
Epistaxis	6-15
Melena	13

Data from Ciaramella P, Oliva G, Luna RD, et al. A retrospective clinical study of canine leishmaniasis in 150 dogs naturally infected by *Leishmania infantum*. Claw histopathology and parasitic load in natural cases of canine leishmaniosis associated with *Leishmania infantum*. Vet Dermatol 2010;21:572-577.

of the tongue and other mucosal surfaces[66,67]; pancreatitis[68]; gastrointestinal tract, myocardial, or pulmonary involvement[69-71]; osteomyelitis[72,73]; meningitis[74]; and granuloma formation within the spinal cord.[75]

American Tegumentary Leishmaniosis

American tegumentary leishmaniosis in dogs is characterized by development of a nodular skin lesion at the site of a sandfly bite that enlarges and eventually may ulcerate. Lesions most often occur on regions of the body that have less hair, such as the nose, perineal region, scrotum, and pinnae.[43,76]

Physical Examination Findings

Physical examination findings in dogs with visceral disease include lethargy, muscle atrophy or cachexia, variable and typically low-grade fever, focal or generalized peripheral lymphadenomegaly, and hepatosplenomegaly on abdominal palpation (Figure 74-4). Lymphadenomegaly can be severe and be suggestive of lymphoma. Although not always detected, skin lesions consist of scaling and crusting, hyperkeratosis, alopecia, erythema, and cutaneous ulceration and may be nonpruritic or pruritic. They most often occur on the limbs, pinnae, muzzle, and periocular regions. Mucocutaneous lesions can also occur. Ocular involvement may be associated with mucopurulent ocular discharge, blepharitis, and anterior uveitis.

FIGURE 74-4 Poor body condition of 8-year-old male intact foxhound that was seropositive and PCR positive for *Leishmania infantum*. (Courtesy Dr. Christine Petersen, Iowa State University.)

Onychogryphosis may be present. Lameness or reluctance to move may be associated with joint swelling, crepitus, and pain.[72] Epistaxis may also be noted.

Diagnosis

Diagnosis of leishmaniosis may be straightforward, such as when organisms are seen cytologically in impression smears of typical skin lesions, or it may require assessment of the results of a combination of diagnostic assays in light of clinicopathologic findings (Table 74-2). Specific diagnostic assays include cytologic or histopathologic examination of affected tissues, serology, culture of the organism, or the results of PCR assays on affected tissues or blood. In endemic areas, diagnosis may be challenging (1) because dogs may be infected with the parasite for long periods of time in the absence of clinical signs, so the significance of positive test results may be unclear, and (2) because co-infections with other vector-borne pathogens may complicate the clinical picture and cause signs that resemble those of leishmaniosis.

Laboratory Abnormalities

Complete Blood Count

The most common CBC abnormality in dogs with leishmaniosis is a mild to moderate, normocytic, normochromic, nonregenerative anemia. Mild thrombocytopenia is present in up to 50% of affected dogs.[32,63,77] Total leukocyte, neutrophil, lymphocyte, monocyte, and eosinophil counts may be decreased, within the reference range, or increased. Pancytopenia may be present. Although most dogs are lymphopenic, some have moderate to severe lymphocytosis.[77]

Serum Biochemical Tests

Changes on serum biochemistry analysis in dogs with leishmaniosis include hyperglobulinemia, hypoalbuminemia, and

VetBooks.ir

TABLE 74-2

Diagnostic Assays Currently Available for Leishmaniosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of lymph nodes, spleen, or bone marrow; impression smears of skin lesions; rarely blood smears or buffy-coat preparations	*Leishmania infantum* amastigotes within mononuclear phagocytes	In the absence of experience, organisms may be confused with fungi such as *Histoplasma capsulatum* or *Sporothrix schenckii*. Organisms may be few in number and in some cases are absent.
Leishmania culture	Aspirates or biopsies of affected tissues	*L. infantum*	Sensitive and specific but requires special techniques and expertise that are not widely available.
Antibody serology (IFA or ELISA)	Serum	Antibodies to *L. infantum*	Most infected dogs test positive (sensitivity > 90%), but positive test results occur in healthy animals, so results must be interpreted in light of clinical signs. Sensitivity may be lower in cats. False positives can occur in dogs exposed to *Trypanosoma* spp. (IFA) and dogs vaccinated with *Leishmania* vaccines.
Real-time PCR assays	Conjunctival swabs, aspirates of affected tissues, lymph node, bone marrow, whole blood, skin biopsies	*L. infantum* DNA	May be useful in dogs with suggestive lesions in which organisms cannot be found cytologically. Sensitivity and specificity depends on assay design. Quantitative PCR may be useful for evaluation of treatment efficacy.
Histopathology	Biopsy specimens from affected tissues (e.g., skin lesions)	*L. infantum* amastigotes	Use of immunohistochemistry may increase sensitivity and can be used to confirm the presence of *Leishmania* spp. in tissues.

IFA, Immunofluorescent antibody.

mild to moderate azotemia.[32,63,77] Hyperglobulinemia and hypoalbuminemia are present in more than 75% of affected dogs. Serum globulin concentration ranges from mild to severe (up to 8 g/dL) and reflects a polyclonal gammopathy; monoclonal gammopathy is rare.[78] Azotemia has been reported in 16% to 38% of dogs. Some studies have shown mild to moderate increases in liver enzyme activities.

Urinalysis

Dogs with leishmaniosis may have proteinuria or isosthenuria, secondary to glomerular and tubulointerstitial renal function impairment, respectively. Cylindruria may be detected.

Synovial Fluid Examination

Cytologic examination of synovial fluid from dogs with *Leishmania* polyarthritis reveals increased numbers of neutrophils and/or lymphocytes.[72] In some cases, *Leishmania* amastigotes are visible within macrophages in the synovial fluid.

Bone Marrow Examination

Bone marrow cytologic alterations described in canine leishmaniosis include erythrophagocytosis, erythroid hypoplasia and dysplasia, eosinophilic hypoplasia, granulocytic hyperplasia, and increased numbers of lymphocytes and plasma cells.[79,80] Amastigotes may also be visible.

Diagnostic Imaging

Abdominal radiography or ultrasonography in dogs or cats with visceral leishmaniosis can reveal abdominal lymphadenomegaly, splenomegaly, and hepatomegaly. Radiographic lesions of long bones in dogs with bone involvement consist of soft periosteal proliferation, increased or decreased intramedullary opacity, and/or cortical and medullary destruction.[63,72] Lesions tend to be bilateral and symmetrical. Joint radiographs in dogs with signs of arthritis may reveal erosive changes, or arthritis may be non-erosive.

Microbiologic Tests

Cytologic Examination

Identification of *Leishmania* spp. amastigotes in lesions with cytology is diagnostic for leishmaniosis (Figure 74-5). Organism densities are particularly high in skin lesions, bone marrow, and the spleen, but specimens collected from other tissues, such as lymph node and hepatic aspirates, may also contain organisms. Organisms are not found in some lesions, and inexperienced microscopists may fail to identify organisms when present or confuse them with other parasites, such as *Trypanosoma*,

Histoplasma, or *Sporothrix schenckii*. Rarely, organisms are seen in circulating white blood cells.[81]

Serologic Diagnosis

Serologic assays based on immunofluorescent antibody (IFA), ELISA, Western immunoblot, and agglutination techniques have all been used for serodiagnosis of canine leishmaniosis, or for screening apparently healthy dogs in endemic areas for evidence of infection. IFA is commonly used by veterinary practitioners in Europe[82] and has a diagnostic sensitivity that ranges from 90% to 100% and a specificity of 80% to 100% in dogs that have not received a *Leishmania* vaccine. Dogs with *Trypanosoma* spp. infections may have false-positive test results due to serologic cross-reactivity between *Trypanosoma* and *Leishmania* antigens. ELISA assays based on recombinant antigens often have higher specificity and are technically less difficult to perform than IFA.[42,83] A rapid lateral flow assay is available commercially (SNAP Canine *Leishmania* Antibody Test Kit, IDEXX Laboratories) that had an overall sensitivity of 95% and a specificity of 91% in one study of 400 dogs from Brazil.[83] Other immunochromatographic assays are available that vary in their sensitivity.

Negative serologic test results may reflect delayed seroconversion in some animals, which can take several months to occur. However, many dogs with clinical signs have already seroconverted because of the long incubation period. Importantly, in endemic areas, positive serologic test results do not imply that disease is due to *Leishmania* spp. infection, because subclinical infections are widespread. Thus, for diagnosis of clinical leishmaniosis, results must be interpreted in conjunction with clinical findings and cytologic and histopathologic evaluation of affected tissues. Because seroconversion occurs in dogs that have received the *Leishmania* vaccine, current serologic assays cannot be used to efficiently differentiate between infected and vaccinated animals.[84]

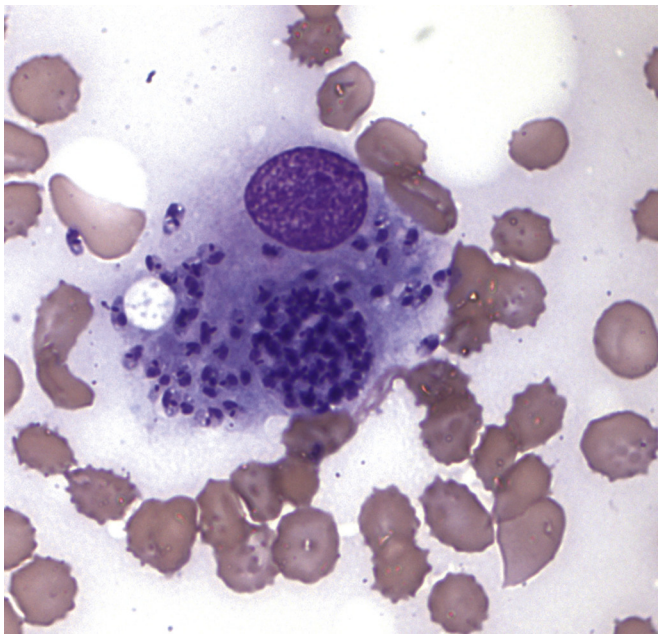

FIGURE 74-5 Bone marrow aspirate cytology findings in a dog with visceral leishmaniosis. Numerous *Leishmania* amastigotes can be seen within a histiocyte. (Courtesy Dr. Sheri Ross, University of California, Davis – San Diego.)

Molecular Diagnosis Using the Polymerase Chain Reaction

Several different conventional and real-time PCR assays have been developed and evaluated for detection of *Leishmania* spp. in dogs and cats. Real-time PCR assays that detect *Leishmania* spp. are now offered on a commercial basis by some veterinary diagnostic laboratories worldwide. Suitable specimens for testing include splenic, hepatic, lymph node, or bone marrow aspirates; whole blood; skin biopsies; conjunctival swabs; and even oral swabs. Conjunctival swabs; aspirates of spleen, bone marrow, or lymph nodes; and skin biopsies are most likely to yield positive results.[85,86] Positive PCR assay results in endemic areas do not confirm that disease is caused by *Leishmania* spp., because dogs without clinical signs can test positive.[87] However, in one study, clinical disease subsequently appeared in 71% of ELISA-positive dogs that lacked clinical signs but had medium to high parasite loads (more than 10 parasites/mL of blood) as determined with a quantitative PCR assay.[86] PCR assays may also be useful in order to monitor the efficacy of treatment.

Culture

Leishmania spp. can be isolated in culture from specimens such as lymph nodes, skin biopsies, spleen, or bone marrow, although special media and expertise are required, and incubation times of up to 30 days may be needed.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with visceral leishmaniosis include cachexia; generalized enlargement of the spleen, lymph nodes, and sometimes the liver; focal pale nodular lesions in a variety of organs; bone and joint lesions; and gastrointestinal ulcerations.

Histopathologic Findings

Histopathology of most affected tissues in dogs with leishmaniosis typically reveals granulomatous to pyogranulomatous and lymphoplasmacytic inflammation, with variable numbers of intrahistiocytic amastigotes (Figure 74-6). Skin lesions are accompanied by orthokeratotic to parakeratotic

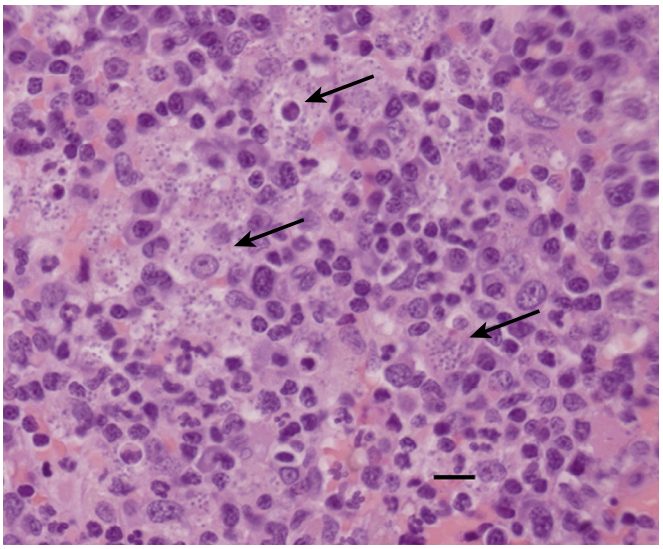

FIGURE 74-6 Histopathology of the spleen in a dog with visceral leishmaniosis. Multiple amastigotes (which have a granular appearance, *arrows*) are present within macrophages. H&E stain; bar = 20 µm. (Courtesy Dr. Christine Petersen, Iowa State University.)

hyperkeratosis, acanthosis, and ulceration. Claw histopathology in dogs with onychogryphosis reveals lichenoid mononuclear cell infiltration, with or without basal keratinocyte vacuolation and dermo-epidermal clefting; organisms are generally not visible.[88] Renal lesions consist of membranoproliferative glomerulonephritis, lymphoplasmacytic tubulointerstitial nephritis, and rarely amyloidosis (Figure 74-7).[46,89-91] Immunohistochemistry can be used to unambiguously detect *Leishmania* amastigotes in tissue sections. Immunohistochemistry may permit detection of *Leishmania* spp. when organisms are not seen with routine histopathology.[70,92] In situ hybridization has also been used to identify *Leishmania* amastigotes in paraffin-embedded specimens.[92]

Treatment and Prognosis

Antiprotozoal Therapy

Drugs with activity against *Leishmania* spp. include the pentavalent antimonials meglumine antimoniate (Glucantime) and sodium stibogluconate; allopurinol; amphotericin B; and miltefosine (Table 74-3). Ketoconazole has also been used. Unfortunately, regardless of the treatment used, complete parasitologic cure is rare, and relapses are frequent.[93,94] In endemic areas, reinfections occur and contribute to apparent treatment failures. Staging systems and consensus treatment guidelines have been published (Table 74-4).[29,95]

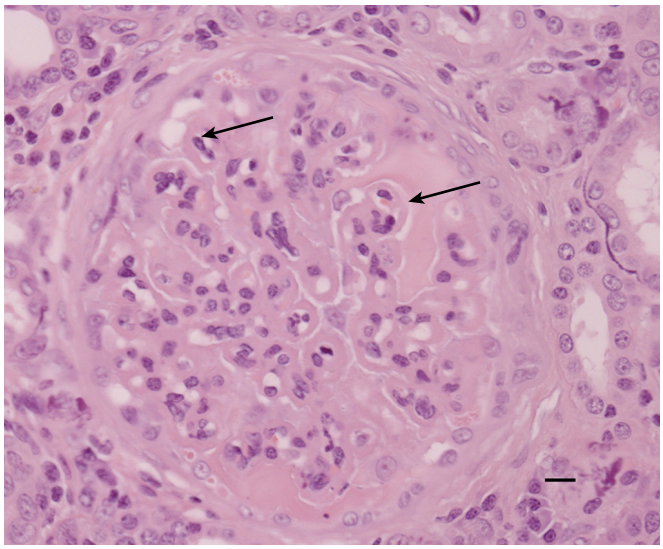

FIGURE 74-7 Histopathology of the kidney in a dog with visceral leishmaniosis. There is marked thickening of glomerular capillary loops *(arrows)* indicative of glomerulonephritis. H&E stain. Bar = 50 µm. (Courtesy Dr. Christine Petersen, Iowa State University.)

Pentavalent antimonials are thought to inhibit protozoal enzymes and damage protozoal DNA, whereas allopurinol interferes with protein synthesis by *Leishmania* spp. (see Chapter 10 for more information on these drugs). In general, a combination of meglumine antimoniate (100 mg/kg SC q24h for 4 weeks) and allopurinol (10 mg/kg PO q12h until clinical signs have resolved and quantitative serology becomes negative) is the treatment of choice for dogs with leishmaniosis.[96] Clinical improvement generally occurs within 1 to 2 months of treatment initiation if no overt renal disease is present. Complete or near-complete clinical remission rates of 65% to 100% have been reported with combination therapy, with relapse rates of around 10%.[93,97] Dogs that relapse can be retreated with one or more cycles of meglumine. Relapses can occur years after treatment is initiated, even in the face of allopurinol treatment. Rarely, xanthine urolithiasis complicates long-term allopurinol treatment.[97] A liposomal form of meglumine antimoniate (LMA) (6.5 mg/kg of stibogluconate every 4 days), when used together with allopurinol (20 mg/kg PO q24h) and administered for 140 days, significantly reduced clinical signs and parasite load and blocked transmission of the parasite to sandflies, but was associated with apparent cure in only 50% of treated dogs.[98] Unfortunately, resistance to antimonials has emerged among some *Leishmania* isolates in highly endemic areas such as southern Europe. Antimonials are also not readily available for treatment of dogs in the United States.

Miltefosine activates proteases in *Leishmania* spp. and causes apoptotic death of the parasite (see Chapter 10). Miltefosine can be used as an alternative to meglumine antimoniate in conjunction with allopurinol for 1 month, after which monotherapy with allopurinol is continued.[99] Unfortunately this combination protocol does not result in parasitologic cure, and relapse is common. Even a second cycle of miltefosine treatment failed to eliminate the parasite in one study.[99]

TABLE 74-3

Suggested Drug Doses for Treatment of Canine Visceral Leishmaniosis

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration and Comments
Allopurinol	10	PO	12	At least 6 to 12 months or until both clinical signs disappear and quantitative serology becomes negative
Meglumine antimoniate	75-100 50	SC	24 12	30 days. Use with allopurinol. Meglumine antimoniate is the first-line treatment where available.
Miltefosine	2	PO	24	28 days. Use with allopurinol where miltefosine is available.
Lipid-complexed amphotericin B	3	IV	Every 48 hours on Monday, Wednesday, and Friday	Dilute to 1 mg/mL in D5W and administer over 1 to 2 hours until a cumulative dose of 21 mg/kg is reached. Monitor kidney values (see Chapter 9). Optimal dosing schedule for dogs is unknown.

VetBooks.ir

TABLE 74-4

Clinical Staging of Canine Visceral Leishmaniosis Based on Serologic Status, Clinical Signs, Laboratory Findings, Type of Treatment, and Prognosis for Each Stage

Clinical Stage	Antibody Titer	Clinical Signs	Laboratory Findings	Therapy	Prognosis
Stage I	Negative or low positive (<3- to 4-fold increase above the laboratory cutoff)	Mild signs such as peripheral lymphadenopathy or papular dermatitis	Usually none, creatinine <1.4 mg/dL, UPC <0.5	None, allopurinol monotherapy, or combination therapy	Good
Stage II	Positive (low or high)	Diffuse or symmetrical cutaneous lesions, ulcerations, anorexia, weight loss, fever, and/or epistaxis	Anemia, hyperglobulinemia, and/or hypoalbuminemia present. Substage a: nonazotemic, nonproteinuric Substage b: nonazotemic, UPC 0.5-1	Combination therapy	Good to guarded
Stage III	Medium to high	Stage II abnormalities plus signs of immune-complex disease (vasculitis, arthritis, glomerulonephritis)	Stage II abnormalities plus IRIS* stage I with UPC >1, or IRIS stage II	Combination therapy	Guarded to poor
Stage IV	Medium to high	Stage III abnormalities plus nephrotic syndrome, pulmonary thromboembolism, or end-stage renal disease	Stage II abnormalities plus IRIS stage III or IV; marked proteinuria (UPC >5)	Consider monotherapy with allopurinol. Follow IRIS guidelines for treatment of chronic kidney disease.	Poor

Data from Solano-Gallego L, Koutinas A, Miro G, et al. Directions for the diagnosis, clinical staging, treatment and prevention of canine leishmaniosis. Vet Parasitol 2009;165:1-18.
*International Renal Interest Society, http://www.iris-kidney.com/guidelines/en

Lipid-complexed amphotericin B is the treatment of choice for human visceral leishmaniasis. Limited reports of the use of both deoxycholate and lipid-complexed forms of amphotericin B to treat dogs with leishmaniosis exist.[100,101] The need for intravenous administration of amphotericin B and its nephrotoxicity has limited its use for treatment of disease in dogs. In one study, use of liposomal amphotericin B (Ambisome) to treat canine leishmaniosis was associated with rapid resolution of clinical signs, but cytologic evidence of parasites persisted in lymph node aspirates.[100] However, treatment was administered for less than 2 weeks (and for some groups of dogs in the study, only 3 days). The FDA-approved regimen for liposomal amphotericin B treatment of immunocompetent human patients consists of seven infusions over 21 days (days 1 through 5, 10, and 21), for a total dose of 21 mg/kg.[102]

Because of the likelihood of relapse in dogs after treatment, the World Health Organization does not advocate treatment of pet dogs with anti-*Leishmania* chemotherapy protocols used to treat humans and instead suggests monotherapy with allopurinol.[103]

Supportive Care

Dogs with renal failure secondary to *Leishmania* infection may require supplemental fluid therapy and medications that address complications of uremia and/or protein-losing nephropathy, such as antacids, antiemetics, phosphate binders, low-protein diets, and antihypertensive drugs.

Immunity and Vaccination

Although immunity to leishmaniosis is complex and not well understood, it is clear that it is strongly dependent on the development of a robust Th1-cell–mediated immune response. Production of cytokines such as IFN-γ and TNF-α activates macrophages to destroy amastigotes, which occurs through nitric oxide–mediated mechanisms. Dogs that resist leishmaniosis exhibit strong delayed type hypersensitivity responses to leishmanial antigen when it is administered intradermally. A balance between Th1 and Th2 immune responses appears to be important in determining the clinical outcome of infection.

Several vaccines against leishmaniosis have been evaluated in dogs under field conditions. One of these vaccines, Leishmune, became licensed for prevention of leishmaniasis in dogs in Brazil in 2011.[53] Leishmune is composed of a promastigote antigen (fucose-mannose ligand) and the adjuvant saponin.[104,105] The vaccine has not been approved in Europe because of adverse effects induced by the saponin adjuvant. Efficacy in initial field trials was approximately 80% and has correlated with a

VetBooks.ir

reduction in human leishmaniasis in the area.[53] The vaccine is also licensed in Brazil for immunotherapy, and reduces clinical signs in infected dogs,[106] but when used without antiprotozoal drugs did not reduce 4.5-year mortality when compared with infected control dogs.[107] Another vaccine (CaniLeish, Virbac) composed of purified excreted-secreted proteins of *Leishmania infantum* (LiESP) is licensed in Europe for prevention of canine leishmaniosis. This vaccine stimulates a Th1-dominated anti–*L. infantum* response within 3 weeks of administration.[108]

Prevention

In addition to vaccination, use of ectoparasiticides such as deltamethrin-impregnated dog collars or spot-on repellants that contain permethrin can prevent canine leishmaniosis.[111-114] Indoor housing or use of fine-mesh netting around dogs and humans when sandflies feed at night (from dusk to dawn) is also recommended. Because of transplacental transmission, neutering may also reduce the spread of *Leishmania*.[6] Potential blood donors should be screened with serology and PCR assays and should only be used if both assays are negative.[29]

A dopamine-based oral suspension Leisguard is available in some parts of Europe for prevention of leishmaniosis in dogs that travel to regions where the disease is endemic. This contains the dopamine D2 receptor antagonist domperidone, which activates phagocytic cells and enhances intracellular killing of the parasite.[109] A prospective, randomized controlled trial showed that Leisguard prevented transmission of leishmaniosis to naïve dogs in a kennel.[115] The drug was administered q24h for two 30-day periods at the estimated beginning and end of the vector activity period. Leisguard may also hasten recovery when used for treatment of affected dogs in combination with meglumine antimoniate and allopurinol,[110] but additional studies are required.

Public Health Aspects

An estimated 12 million people worldwide have leishmaniasis, and at least 350 million people are estimated to be at risk. Approximately 0.2 to 0.4 million new cases of VL and 0.7 to 1.2 million cases of CL are believed to occur in humans annually, and it has been estimated that 20,000 to 40,000 leishmaniasis deaths occur per year.[116]

VL in humans is also known as kala-azar. It is caused mostly by *L. donovani* and *L. infantum* (referred to as *L. chagasi* in Central and South America), but also by *L. tropica*. More than 90% of VL cases globally occur in India, Bangladesh, Sudan, South Sudan, Brazil, and Ethiopia. Many cases are due to *L. donovani*, for which humans are the primary reservoir.[116] *L. infantum* causes VL in central Asia, China, the Mediterranean basin, the Middle East, and Latin America. Most disease associated with *L. infantum* infection occurs in children (infantile leishmaniasis) and immunocompromised adults, such as those with AIDS. *L. infantum* is also responsible for some CL in humans. Dogs are considered the primary reservoirs for *L. infantum,* and control of disease in dogs has been associated with reduction in human cases in the area. Nevertheless, other canine species, such as foxes, may also play a role as reservoirs.

Human CL occurs in the Americas, the Mediterranean basin, and western Asia from the Middle East to Central Asia, and especially in Afghanistan, Algeria, Colombia, Brazil, Iran, Syria, Ethiopia, North Sudan, Costa Rica, and Peru. In Africa and western Asia, CL is caused by *L. major, L. tropica,* and *L. aethiopica,* whereas in the Americas, the most common causes are *L. mexicana* and *L. braziliensis*. Mucocutaneous disease occurs primarily in South America and is caused by *L. braziliensis*, for which rodents and other small mammals are the primary reservoirs.[117]

Recommendations of the World Health organization for the control of leishmaniasis in humans consist of treatment of human disease; culling of wild and feral seropositive dogs; and insecticidal treatment of human homes, such as with pyrethroid sprays.[103] The effectiveness of the culling of seropositive or infected dogs is controversial.[42,118] At present this is only undertaken systematically in Brazil. Concerns raised include the ethics of destruction of pet dogs, delays between detection of seropositive dogs and culling, and the persistence of other subclinically or clinically infected canine and wildlife reservoirs. Vaccination of dogs may be more effective than the culling of seropositive dogs and could overcome the ethical concerns that relate to culling.[53]

FELINE LEISHMANIOSIS

Cats are relatively resistant to leishmaniosis, but cases have been described from southern Europe, the Middle East, Latin America, and Texas.[119,120] The cat from Texas was infected with *L. mexicana*. *L. infantum* and a variety of other *Leishmania* species such as *L. braziliensis* and *L. venezuelensis* have also been isolated from cats. Serologic studies of cats in endemic areas have generally revealed seroprevalences of less than 10%, although 34 (36%) of 95 stray cats from the Yucatán peninsula in Mexico had antibodies to *L. infantum, L. braziliensis,* or *L. mexicana*.[119] Disease in cats may be associated with concurrent FIV infection.[121,122] The extent to which cats are a reservoir for infection of humans is unclear.

Clinical signs of leishmaniosis in cats include cutaneous lesions, weight loss, lymphadenopathy, oral ulceration, mucopurulent ocular and nasal discharge, keratitis, altered mentation, diarrhea, and/or tachypnea. Cutaneous lesions consist of nodules, scaling and crusting, erythema, ulceration, and alopecia. Cutaneous lesions can occur anywhere and may be localized or generalized, but are often on the pinnae, bridge of the nose, limbs, or dorsal trunk. In one study, 50% of cats with skin lesions had evidence of visceral spread.[121]

Diagnosis of leishmaniosis in cats is similar to that in dogs, although cats often have low antibody titers.[121] Limited information exists in regard to treatment of feline leishmaniosis. Treatment with allopurinol monotherapy may result in clinical improvement or disease resolution in some cats.[123] Surgery may be curative for localized cutaneous lesions.[12]

VetBooks.ir

CASE EXAMPLE

Signalment: "Fausto," an 8-year-old male neutered husky mix from northern California

History: Fausto was referred to the University of California, Davis, Veterinary Medical Teaching Hospital (VMTH) for evaluation of suspected autoimmune disease. The dog had a 6-month history of progressive skin lesions that began as crusting and ulceration around the elbow and stifle joints. This was followed by development of similar lesions above both eyes and on the dog's ears and dorsal muzzle. Three months after the skin lesions appeared, Fausto became stiff and lethargic and was lame and reluctant to walk. At that time, Fausto was taken to a local veterinary clinic where an injection of triamcinolone acetonide (Vetalog) was administered, and he was prescribed carprofen and trimethoprim-sulfamethoxazole. There was no improvement in the clinical signs. The day before he was brought to the VMTH, the owner had taken Fausto to a local emergency clinic because he was reluctant to move. Blood work and arthrocentesis (left and right tarsal joints) were performed. The blood work showed a normocytic, normochromic nonregenerative anemia (HCT 31%); mild hypoalbuminemia (2.4 g/dL); and moderate hyperglobulinemia (7.7 g/dL). Cytologic examination of the synovial fluid revealed large numbers of nondegenerate neutrophils, which was considered consistent with immune-mediated polyarthritis. Cephalexin and carprofen were prescribed, and the dog was referred for further evaluation.

The owner had not noticed any coughing, sneezing, vomiting, diarrhea, or changes in thirst or urination. Fausto was fed 3 cups of a commercial dry chicken and rice–based dog food once a day, and his appetite was good. He was fully vaccinated for rabies, canine distemper virus, canine adenovirus, and canine parvovirus. The dog did not receive heartworm prophylaxis medication but was treated with fipronil once a month for flea control. There was one other healthy dog in the household. The owner and his dogs had moved to California from Barcelona, Spain, a few weeks earlier, around the time that the skin lesions appeared. In Spain, Fausto had worn a collar to prevent insect bites.

Physical Examination:

Body Weight: 34.4 kg.

General: Quiet, alert, and responsive, but reluctant to ambulate. T = 102.7°F (39.3°C), HR = 132 beats/min, panting but eupneic, mucous membranes moist and pink.

Integument: Multiple focal regions of crusting, erythema, hyperpigmentation, thickening, and sometimes ulceration were present over the elbows and stifles, prepuce, ventral aspect of the mandible, above both eyes, and on both pinnae. Moderate pruritis was present.

Musculoskeletal: BCS 5/9. The dog was able to walk but had a shifting lameness. Pain was detected on extension of the joints, but there was no palpable effusion present.

Abdominal Palpation: Splenomegaly was detected.

Lymph Nodes: Superficial cervical and popliteal lymph nodes were all enlarged (approximately 3 cm in diameter).

All Other Systems: No significant abnormalities were detected.

Laboratory Findings:

CBC:

HCT 32.4% (40%-55%)
MCV 62.7 fL (65-75 fL)
MCHC 35.2 g/dL (33-36 g/dL)
Reticulocyte count 54,500 cells/µL
WBC 9300 cells/µL (6000-13,000 cells/µL)
Neutrophils 7533 cells/µL (3000-10,500 cells/µL)
Lymphocytes 930 cells/µL (1000-4000 cells/µL)
Monocytes 651 cells/µL (150-1200 cells/µL)
Eosinophils 186 cells/µL (0-1500 cells/µL)
Platelets 338,000 platelets/µL (150,000-400,000 platelets/µL).

Serum Chemistry Profile:

Sodium 140 mmol/L (145-154 mmol/L)
Potassium 4.4 mmol/L (4.1-5.3 mmol/L)
Chloride 107 mmol/L (105-116 mmol/L)
Bicarbonate 15 mmol/L (16-26 mmol/L)
Phosphorus 3.8 mg/dL (3.0-6.2 mg/dL)
Calcium 10.4 mg/dL (9.9-11.4 mg/dL)
BUN 16 mg/dL (8-31 mg/dL)
Creatinine 0.9 mg/dL (0.3-1.2 mg/dL)
Glucose 109 mg/dL (70-118 mg/dL)
Total protein 10.7 g/dL (5.4-7.4 g/dL)
Albumin 2.1 g/dL (2.9-4.2 g/dL)
Globulin 8.6 g/dL (2.3-4.4 g/dL)
ALT 12 U/L (19-67 U/L)
AST 39 U/L (21-54 U/L)
ALP 43 U/L (15-127 U/L)
GGT 3 U/L (0-6 U/L)
Cholesterol 191 mg/dL (135-345 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.4 mg/dL).

Serum Protein Electrophoresis: There was a marked increase in gamma-globulin with mild hypoalbuminemia. The gammopathy was polyclonal.

Urinalysis (Cystocentesis): SGr 1.037; pH 7.0, 4+ protein, 1+ bilirubin, 1+ hemoprotein, no glucose or ketones, rare WBC/HPF, 1-3 RBC/HPF, rare hyaline casts, few lipid droplets.

Urine Protein-to-Creatinine Ratio: 2.99 (normal, <0.5).

Microbiologic Testing: IFA serology for antibodies for *Ehrlichia* spp., *Anaplasma* spp., *Rickettsia* spp., *Bartonella clarridgeiae, Bartonella vinsonii* subsp. *berkhoffii,* and *Bartonella henselae*: Negative.

Western immunoblot for antibodies to *Borrelia burgdorferi*: Negative.

Knott's and ELISA antigen test for *Dirofilaria immitis* infection: Negative.

Aerobic bacterial, anaerobic bacterial, and *Mycoplasma* culture of synovial fluid: Negative.

Aspiration cytology (right and left superficial cervical and popliteal lymph nodes): A heterogeneous population of lymphocytes was present, which consisted primarily of small mature lymphocytes and slightly increased numbers of intermediate-sized lymphocytes and lymphoblasts. Large numbers of plasma cells were noted. A few macrophages, nondegenerate neutrophils, and eosinophils were scattered throughout the specimen.

Bone marrow aspiration cytology: Many unit particles were present. Unit particles were normocellular, and a small amount of storage iron was noted. There were normal numbers of

VetBooks.ir

megakaryocytes. The myeloid-to-erythroid ratio was mildly increased; both series were synchronous and complete. Increased numbers of plasma cells were noted throughout the specimen, with few small lymphocytes. Macrophages occasionally contained intracytoplasmic organisms consistent with *Leishmania* spp. amastigotes. Interpretation: Mild erythroid hypoplasia, *Leishmania* spp., and mild plasma cell hyperplasia.

Skin biopsy: There was a thick band of inflammatory cells that extended from the superficial to the mid-dermis. The inflammatory infiltrate was composed of dense sheets of large foamy macrophages admixed with smaller numbers of lymphocytes and plasma cells and few neutrophils. Many of the large macrophages contained multiple, round to oval, intracytoplasmic basophilic organisms that were 1 to 2 µm in diameter. The epidermis was hyperplastic and hyperkeratotic and was covered by exudate admixed with keratin, degenerate neutrophils, and cellular debris.

Diagnosis: Canine visceral leishmaniosis.

Treatment and Outcome: Fausto was initially treated with a combination of allopurinol (10 mg/kg PO q8h), ketoconazole (9 mg/kg PO q12h), cephalexin (30 mg/kg PO q12h for 4 weeks, for secondary bacterial pyoderma), and carprofen (4.4 mg/kg PO q24h). At a recheck examination 2 weeks later, the dog's owner reported that 1 or 2 days after treatment was started, Fausto became intensely pruritic. Fausto's appetite also decreased and he developed increased thirst and urination, but the lameness resolved. Physical examination showed severe crusting and ulceration of the face, with an associated foul odor. This extended from the dorsal nasal planum to the temporal and supraocular regions, as well as the inner aspect and tips of the pinnae. The lesions on the limbs were static or slightly improved from the last visit. A CBC was unchanged, and a serum chemistry profile showed worsened hyperglobulinemia (9.3 g/dL) and hypoalbuminemia (1.9 g/dL). A drug reaction was suspected, and the cephalexin was replaced with clavulanic acid–amoxicillin. Over the next month, the skin lesions improved. The owner subsequently obtained meglumine antimoniate from Spain, and treatment was changed to allopurinol (10 mg/kg PO q12h) and meglumine antimoniate (88 mg/kg SC q24h for 1 month). However, 6 days later, the dog developed prolapsed third eyelids and was unable to catch treats when they were thrown to him. Physical examination showed healing skin lesions with evidence of hair regrowth, prolapsed third eyelids, risus sardonicus, and erect ears. A presumptive diagnosis of localized tetanus was made. A serum chemistry panel showed an albumin of 2.5 g/dL and a globulin of 6.4 g/dL. The urine protein-to-creatinine ratio was 0.2. Fausto was treated with metronidazole (10 mg/kg PO q8h for 14 days) and tetanus antitoxin (20,000 U in 250 mL saline over 1 hour, IV, once). Clinical signs of tetanus had almost resolved 11 days later when the owner was contacted by telephone. The dog was subsequently lost to follow-up.

Comments: This case is an interesting example of travel-related canine visceral leishmaniosis that was ultimately complicated by what appeared to be a cutaneous drug reaction to cephalexin and then localized tetanus. The diagnosis of leishmaniosis was suspected based on the clinical signs together with the travel history from southern Europe. The bone marrow aspirate and skin biopsies were obtained simultaneously for the sole purpose of diagnosis of leishmaniosis; impression smears of the skin lesions failed to yield organisms, and the lymph node aspirates were also negative. The owner and his dog traveled back to Spain in order to obtain the meglumine antimoniate, which could not be obtained in the United States. The development of tetanus may have followed wound contamination or use of contaminated needles by the owner for subcutaneous injection of the meglumine.

CHAPTER 75

Babesiosis

Adam J. Birkenheuer

VetBooks.ir

Overview of Babesiosis in Dogs and Cats

First Described: Early descriptions of intraerythrocytic parasites in dogs with signs of babesiosis were made in Africa in 1893 (Hutcheon).[1] The first documented case of canine babesiosis in the United States was in 1934 (Eaton).[2]

Cause: *Babesia canis, Babesia gibsoni, Babesia conradae* (dogs); *Babesia felis, Babesia cati* (cats), several other unnamed species (phylum Apicomplexa)

Affected Hosts: Domestic dogs and cats

Geographic Distribution: Worldwide, but different *Babesia* species vary in their geographic distribution

Mode of Transmission: A variety of tick vector species; fighting or biting interactions; vertical transmission; blood transfusion

Major Clinical Signs: Lethargy, pallor, splenomegaly. Dogs with severe babesiosis caused by *B. canis rossi* may show neurologic signs, anuria, tachypnea, and poor perfusion parameters.

Differential Diagnoses: Hemoplasmosis, primary immune-mediated hemolytic anemia and/or thrombocytopenia, other causes of hemolysis such as oxidative toxins or microangiopathic hemolysis (e.g., with splenic hemangiosarcoma). Canine monocytic ehrlichiosis, Rocky Mountain Spotted Fever, and bacterial endocarditis should also be considered.

Human Health Significance: *Babesia* species that infect dogs and cats are not known to infect humans.

Etiology and Epidemiology

Babesiosis, caused by infection with organisms from the genus *Babesia*, is characterized by hemolytic anemia, fever, and splenomegaly. *Babesia* infections can also be subclinical or cause severe life-threatening illness. *Babesia* spp. are intraerythrocytic protozoan parasites of the phylum Apicomplexa. Altogether, more than 100 species of *Babesia* have been described, and with the advent of molecular techniques such as PCR assays, new species and genotypes are identified each year. Historically, species have been named and identified based on the vertebrate host and the size of the parasite (large or small *Babesia* species). Large *Babesia* spp. are 3 to 7 µm in length, whereas small *Babesia* spp. are 1 to 3 µm in length. In most parts of the world, tick vectors are the most important means of transmission of *Babesia* species. However, for some *Babesia* species, such as *Babesia gibsoni* in North America and Europe, direct transmission between dogs, through fighting (and exchange of blood), or congenital transplacental transmission, is believed to be the most common route of transmission when competent tick vectors are absent.[3-5]

When ticks are involved in transmission, sporozoites are released from the tick salivary glands as the tick feeds and they enter the bloodstream of the vertebrate host (Figure 75-1). They then attach to, and are endocytosed by, erythrocytes. Within erythrocytes, they undergo asexual reproduction (merogony), and the daughter cells infect new erythrocytes. A naïve tick then ingests infected erythrocytes. It is unclear whether transformation from merozoite to gametocyte begins in the vertebrate host or in the tick. In the tick midgut, the sexual phase of reproduction occurs when the gametocytes fuse to form a zygote. The zygote invades epithelial cells of the tick gut. The resultant forms, ookinetes, leave the epithelial cell and invade either the salivary gland or the ovary, where they participate in transstadial and transovarial transmission, respectively. Prior to transmission, another asexual form of reproduction occurs in the salivary gland, sporogony.

Babesiosis in Dogs

Canine babesiosis is a disease of worldwide importance. Initially, two species of *Babesia* were recognized in dogs (*Babesia canis* and *B. gibsoni*); however, now at least nine genetically distinct canine piroplasms have been described. *Babesia* species that infect dogs vary in their geographic distribution, which in turn has been subject to change due to movement of infected animals, movement of tick vectors, and reclassification with improved diagnostic techniques. As new species have been recognized, it has become more important for the clinician to understand the differences in diagnosis, prognosis, and treatment for infection with each species.

Babesia canis

Babesia canis is the most common large *Babesia* species and has three distinct subspecies: *B. canis vogeli, B. canis canis,* and *B. canis rossi*. It has been proposed that these are in fact three distinct species (*B. vogeli, B. canis,* and *B. rossi*).[6] *B. canis vogeli* is transmitted by the brown dog tick *(Rhipicephalus sanguineus)*. Infection is most commonly diagnosed in warm, humid regions of the world, and the disease occurs throughout the year in endemic regions. *B. canis vogeli* can be found in Africa, Asia, Australia, Europe, and the Americas. In the United States, disease is most often diagnosed in the southern regions. *B. canis vogeli* reported seroprevalence in dogs has ranged from 3.8% to 59%.[7] The prevalence of seroreactivity is higher in adult dogs than in dogs younger than 1 year.[8] In an antibody serosurvey of dogs in Florida, 46% of 393 greyhounds were seroreactive.[7] The prevalence of seroreactive dogs within these kennels ranged from 17% to 100%; the lower prevalence was noted in kennels

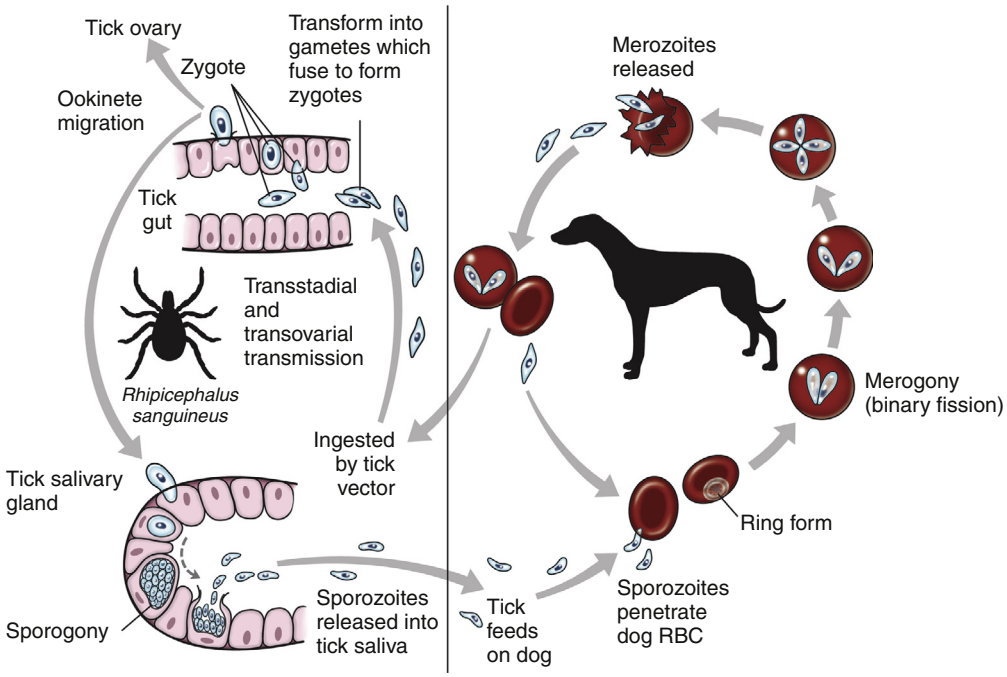

FIGURE 75-1 Life cycle of *Babesia canis*.

with more intensive tick control. None of 50 non-greyhound, individually housed adult pet dogs within the same geographic area were seroreactive, which implicated environment and breed susceptibility as possible risk factors in endemic areas.[7] Transplacental transmission of *B. canis vogeli* infections is strongly suspected but unproven in an experimental setting.[9]

B. canis canis is found in Europe and Africa. It is transmitted by the ornate cow tick, *Dermacentor reticulatus,* but *R. sanguineus* may also be a vector.[10] The incidence of infection is highest in the fall and spring. Higher prevalence rates are most commonly found in rural or suburban areas that are adjacent to prairies or woodlands that provide suitable habitat for *D. reticulatus*.[11] *B. canis canis* infection is most often diagnosed in France. Infections are being reported more frequently from other European countries such as Croatia, Poland, and Germany, possibly due to changes in the distribution of *D. reticulatus*.[12] Outbreaks of disease due to *B. canis canis* infection in Polish sled dogs share many similarities with those due to *B. canis vogeli* infection in North American greyhounds.[13]

B. canis rossi is transmitted by the yellow dog tick, *Haemaphysalis elliptica* (formerly *Haemaphysalis leachi*).[14] Reports of *B. canis rossi* infection have been limited to Africa, with the vast majority of reports coming from South Africa, where more than 10% of the dogs evaluated in some veterinary hospitals may be affected.[15,16] The incidence of infection is highest during the summer months. Breed predispositions for infection have not been well studied, but the traditional fighting breeds (American pit bull terriers, Staffordshire bull terriers, and bull terriers) are more likely to die when they are diagnosed with severe babesiosis.[17]

Unnamed Large *Babesia* Species

A large *Babesia* sp. has been isolated from dogs in North America that had been splenectomized or were undergoing chemotherapy for cancer. Infected dogs have been identified in North Carolina, New Jersey, New York, and Texas.[18-20] A tick vector has not been identified. A different novel large *Babesia* sp. was reported in a dog from Great Britain that never traveled outside of that country.[21] The dog died as a result of infection.

Babesia gibsoni

Infections with *B. gibsoni* occur throughout the world, and the insidious nature of this infection has allowed the inadvertent transport of infected dogs from Asia to other areas. *B. gibsoni* can be found in Africa, Asia, Australia, North and South America, and Europe. Depending on the availability of suitable vectors, two distinct epidemiologic scenarios exist for *B. gibsoni*: tick transmission and direct transmission between dogs.[22,23] *B. gibsoni* is transmitted primarily by the tick vectors *Haemaphysalis bispinosa* and *Haemaphysalis longicornis,* and possibly by *R. sanguineus*.[24-28] In its original endemic area of Asia, the geographic range of *B. gibsoni* correlates with that of *H. bispinosa,* and tick infestation is a risk factor for infection in nonfighting breeds. In the United States where competent tick vectors are not endemic, *B. gibsoni* infections occur in dogs engaged in fighting activities.[23,29] Most dogs with *B. gibsoni* infection in the United States have been American pit bull terriers.[29,30] However, an increased prevalence of infection has even been noted in fighting breeds in areas such as Japan, where *Haemaphysalis* spp. are endemic. In fighting breeds, transmission has been associated with a fight or bite by an infected dog or having been born to an infected bitch. Perinatal transmission is believed to occur.[3-5]

Babesia conradae

B. conradae (previously referred to as "the California isolate" and the "western piroplasm" and historically misidentified as *B. gibsoni*)[31] has been detected primarily in dogs from southern California.[31,32] Tick vectors have not been identified. Transmission studies that attempted to prove vector competence for *R. sanguineus* and *Dermacentor variabilis* were unsuccessful or inconclusive.[33] The author has identified *R. sanguineus* as well as soft-bodied ticks, *Ornithodoros coriaceus,* on *B. conradae*–infected dogs. A high prevalence of *B. conradae* infection was

noted in a kennel of greyhound mixed-breed dogs that were used to hunt coyotes.[34] A history of coyote fights was a risk factor for infection. *B. conradae* DNA was detected in the spleen of 1 of 50 coyotes, so fighting may be one mode of transmission for this *Babesia* species.

Babesia microti–Like Organism

A *B. microti*–like parasite (also referred to as *Babesia annae* or *Theileria annae*) has been identified in dogs, the majority of which have lived in, or traveled to, northwestern Spain.[35-38] A single American pit bull terrier confiscated from a suspected dog-fighting operation in North America was also infected.[39] A high percentage of European and North American foxes are infected with a genetically identical parasite.[40,41] A tick vector has not been definitively identified, but in Spain an association between *Ixodes hexagonus* infestation and *B. microti*–like infection has been observed.[42]

Feline Babesiosis

Feline babesiosis has not been studied as extensively as canine babesiosis. Several small *Babesia* species have been identified in cats, which include *Babesia felis, Babesia cati,* and *Babesia leo*. *Babesia felis* is a highly pathogenic *Babesia* species that infects domestic cats in southern Africa and the Sudan.[43] Infection of domestic cats has primarily been identified along the coast of South Africa.[44,45] Affected cats are usually younger than 3 years, and there is no recognized breed or sex predilection. *Babesia cati* is less pathogenic and found primarily in India. *Babesia leo* has been detected in lions *(Panthera leo)* in Kruger National Park, as well as a single domestic cat in a molecular survey.[46] A small piroplasm was visualized in blood smears from feral cats in Rio de Janeiro, Brazil, but no molecular data were available to confirm the identity of these organisms.[47]

Large *Babesia* species also appear to infect cats. DNA sequences, most similar to those of *B. canis canis* and a *B. microti*–like parasite, have been amplified from the blood of three cats with retroviral infections from Spain and Portugal, but no organisms were visualized.[48] *B. canis presentii* was identified in two cats in Israel.[49] Another *B. canis*–like parasite has been identified in a naturally infected cat from Poland.[50] Feline babesiosis has not been reported in the United States.

Clinical Features

Clinical Signs and Their Pathogenesis

Canine Babesiosis

The pathogenicity of *Babesia* organisms is determined primarily by the species and strain involved. Host factors, such as the age of the host and the immunologic response generated against the parasite or vector tick, are also important. Although most often subclinically infected, dogs infected with "avirulent" species such as *B. canis vogeli* may have severe clinical disease. Similarly, dogs infected with "virulent" species such as *B. canis rossi* may be subclinically infected without overt clinical or laboratory findings. However, features that should raise clinical suspicion for babesiosis include fever, thrombocytopenia, hemolytic anemia, and splenomegaly. Dogs often have nonspecific signs such as lethargy, anorexia, and weakness (Box 75-1). Occasionally owners note jaundice, mucosal pallor, or discoloration of the urine caused by bilirubinuria or hemoglobinuria. Dogs infected with *B. canis vogeli* may have fever of unknown origin only without overt hematologic abnormalities.[51] Co-infections with other tick- or bloodborne pathogens may also influence the clinical signs of disease.

Box 75-1

Clinical Findings in Dogs with Babesiosis

Prevalence	Duration
Common signs	**Hyperacute signs (primarily *B. canis rossi*)**
Anorexia	Hypothermia
Lethargy	Shock
Weakness	Coma
Pyrexia	Disseminated intravascular coagulation
Weight loss	Metabolic acidosis
Uncommon/atypical signs (predominantly *B. canis rossi*)	Death
Ascites	**Acute signs**
Edema	Hemolytic anemia
Constipation	Icterus
Diarrhea	Splenomegaly
Ulcerative stomatitis	Lymphadenopathy
Hemorrhage	Vomiting
Congested mucous membranes	**Chronic signs**
Polycythemia	Intermittent pyrexia
Ocular and nasal discharge	Partial anorexia
Respiratory distress	Loss of body condition
Masticatory myositis	Lymphadenomegaly
Temporomandibular joint pain	Splenomegaly
Back pain	No signs
Central nervous system signs (seizures, ataxia, paresis)	

Parasite antigens are incorporated on the erythrocyte surface and induce host-opsonizing antibodies, which in turn leads to removal of infected erythrocytes by the mononuclear-phagocyte system. Soluble parasite antigens can also adhere to the surface of noninfected erythrocytes and platelets. This may lead to their opsonization by antibodies, with or without complement, and account for hemolytic anemia and thrombocytopenia that is often not correlated with the level of parasitemia. Parasitemia and anemia are more severe in splenectomized dogs, and splenectomy may precipitate disease in dogs with chronic subclinical infections. Mechanisms other than immune-mediated destruction that contribute to erythrocyte damage include increased erythrocyte osmotic fragility, direct injury of erythrocytes by *Babesia* parasites, accumulation of cyclic nucleotides, and oxidative injury.[52-56] Lipid peroxidation increases erythrocyte rigidity and slows the passage of erythrocytes through capillary beds. Soluble parasite proteases activate the kallikrein system and induce fibrinogen-like protein formation. These proteins make erythrocytes more "sticky," and they sludge in capillary beds, which contributes to anemia and many of the other potential clinical signs. The most severe sludging occurs in the central nervous system (CNS) and muscles.

Thrombocytopenia may result from immune-mediated or coagulatory consumption of platelets. Despite severely decreased platelet counts, bleeding is rarely observed in dogs infected with most *Babesia* strains, and other abnormal coagulation test results are uncommon (with the exceptions of *B. conradae* and also *B. canis rossi*). Dogs with *B. conradae*

VetBooks.ir

infection have experienced life-threatening hemorrhages, the pathogenesis of which requires further study.[57]

Other possible complications include membranoproliferative glomerulonephritis, which may have an immune-mediated pathogenesis.[58-60] Renal failure occurs in up to 40% of dogs infected with *B. microti*–like parasites, and their presence has been associated with increased mortality.[35,36,38,61,62] Nonregenerative anemia, azotemia, and proteinuria with high urine protein/creatinine ratios were found in these dogs.[35]

Severe Babesiosis

Virulent *B. canis canis* and especially *B. canis rossi* strains induce a profound systemic inflammatory response, which can result in a severe sepsis-like syndrome with multiple organ dysfunction (see Chapter 86). The majority of dogs infected with *B. canis rossi* have uncomplicated babesiosis and can be treated as outpatients. However, up to 31% of the dogs examined at a university clinic required hospitalization, and 10% of hospitalized dogs did not survive.[17] Severe clinical illness in dogs infected with *B. canis rossi* results from hypotension, acute renal failure (ARF), neurologic complications, disseminated intravascular coagulation (DIC), a hepatopathy, and acute respiratory distress syndrome (ARDS). Tissue hypoxia results from anemia, shock, vascular stasis, excessive endogenous production of carbon monoxide, parasitic damage to hemoglobin, and decreased ability of hemoglobin to off-load oxygen.[53,63] Lactic acid generation from tissue hypoxia can result in severe metabolic acidosis.[64]

"Red biliary syndrome" is a paradoxical phenomenon of severe intravascular hemolysis (manifested as hemoglobinemia and hemoglobinuria) in combination with hemoconcentration (high-reference-range or elevated hematocrit).[63] The hemoconcentration is thought to occur when plasma shifts from the vascular to the extravascular compartment as a result of increased capillary permeability, with a resultant decrease in blood volume. Hemoconcentration has been associated with cerebral babesiosis, DIC, ARF, and ARDS.

Neurologic complications result from sludging of parasitized erythrocytes in CNS capillary beds, with congestion and macroscopic and microscopic hemorrhages. Severe hypoglycemia can also result in neurologic signs. Other complications of severe babesiosis include pancreatitis, rhabdomyolysis, ocular involvement, upper respiratory signs, cardiac arrhythmias, necrosis of the extremities, and fluid accumulation. Pulmonary, CNS, and renal complications are associated with a higher rate of mortality. Persistent lactate concentrations above 40 mg/dL are a poor prognostic indicator for survival.[65]

Feline Babesiosis

Cats with babesiosis from southern Africa generally show lethargy, anorexia, weakness, an unkempt haircoat, and/or diarrhea.[45] Fever and icterus are less common. Anemia can be severe and is the underlying reason for the clinical signs. The disease is chronic, and signs may not be apparent until a later stage of illness. Cats usually adapt to the anemia and may have only mild clinical signs until they are stressed by handling. Complications of the hemolytic anemia have included hepatopathy, pulmonary edema, renal failure, CNS signs, and concurrent infections.

Physical Examination Findings

Physical examination abnormalities in most dogs with babesiosis consist of fever, mucosal pallor, lethargy, splenomegaly, and bounding pulses. Fever is not consistently identified, because it often waxes and wanes. Tachycardia and tachypnea may be present in severely anemic dogs. Mucosal hemorrhages and/or epistaxis may be present in dogs with *B. conradae* infection (Figure 75-2), and excessive bleeding from venipuncture sites may be noted.

FIGURE 75-2 Greyhound infected with *Babesia conradae*. Mucosal hemorrhages are apparent. These resolved after treatment with atovaquone and azithromycin. (Courtesy Dr. Jane Sykes, University of California, Davis.)

Dogs with severe babesiosis may show CNS signs such as incoordination, pelvic limb paresis, muscle tremors, nystagmus, anisocoria, intermittent loss of consciousness, seizures, stupor, coma, aggression, or vocalization.[63] Dogs with red biliary syndrome may have congested mucous membranes or icterus. Other clinical abnormalities in dogs with severe babesiosis include tachypnea, increased lung sounds, and cardiac arrhythmias.

Affected cats may be lethargic, pale, tachycardic, and tachypneic, and in some cases, icteric.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

In dogs with babesiosis, the primary hematologic abnormalities are anemia and thrombocytopenia. Thrombocytopenia is often present, even when anemia is absent. A mild, normocytic, normochromic anemia is generally noted in the first few days after infection, which becomes macrocytic, hypochromic, and regenerative as the disease progresses. Uncommonly with *B. canis rossi* infections, a relative polycythemia may be noted.[63] Leukocyte abnormalities are inconsistently observed but may include leukocytosis (with or without a left shift), leukopenia, neutrophilia, neutropenia, lymphocytosis, and/or eosinophilia.[34,66-68] Leukopenia or a low-normal leukocyte count due to relative neutropenia has been frequently observed in dogs from Europe with *B. canis* infections and dogs from the United States with *B. conradae* infections.[34,68] Autoagglutination, positive direct antiglobulin (Coombs') tests, and spherocytosis may also be present.

TABLE 75-1

Diagnostic Assays Available for Babesiosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cell culture	Whole blood	*Babesia* spp.	Not widely offered or utilized for routine diagnostic purposes. Requires several weeks' incubation.
Cytology	Whole blood, buffy-coat smears (the area just below the buffy coat), tissue aspirates	*Babesia* spp.	Rapid and specific (i.e., when merozoites are identified by experienced cytologists, the sample is likely to be infected with *Babesia* spp.; however, *Babesia* spp. cannot be accurately differentiated based on morphology alone). Less sensitive than PCR.
Immunofluorescent antibody serology	Serum	Antibodies to *Babesia* spp.	Acute and convalescent serology may be required for diagnosis of acute infection, because initial results may be negative in dogs with acute disease and positive results may reflect previous exposure rather than active infection. Cross-reactivity can occur between *Babesia* spp. Some dogs do not develop detectable antibody titers despite chronic infection.
PCR	Whole blood, splenic aspirates	*Babesia spp.* DNA	Confirms active infection. Sensitivity and specificity varies depending on assay design and specimen type. Both false-positive and false-negative results are possible; PCR results must be interpreted in light of the clinical signs. Serial sampling (i.e., two or more tests on specimens obtained 2-4 weeks apart) will increase sensitivity, especially in chronically infected animals.

In cats, anemia associated with *B. felis* infection is typically macrocytic, hypochromic, and regenerative.[69] Thrombocytopenia is an inconsistent finding.

Serum Chemistry Profile

There are no pathognomonic biochemical findings in dogs with babesiosis. Common findings in North American dogs include hyperglobulinemia (which may be present in the absence of other laboratory abnormalities), mildly increased liver enzyme activities, and, less commonly, hyperbilirubinemia. A study of dual infections with *B. canis* and *Ehrlichia canis* showed that the prevalence of hyperglobulinemia was higher in dogs with dual infections than in dogs with a single infection caused by either organism.[70] Hyperbilirubinemia is a consistent finding during acute disease caused by *B. canis canis* and *B. canis rossi* but not by *B. gibsoni* or *B. conradae*.[34,67] Dogs with severe *B. canis rossi* infections may have hemoglobinemia, moderately increased liver enzyme activities, increased BUN and serum creatinine concentrations, hypoalbuminemia, hypoglycemia, and metabolic acidosis.

Cats infected with *B. felis* typically have elevated serum ALT activity and total bilirubin concentrations. Serum protein values are usually within reference limits, but hyperglobulinemia can occur. Renal parameters are unaffected.[69]

Urinalysis

Urinalysis abnormalities in dogs with babesiosis are variable but include bilirubinuria, hemoglobinuria, proteinuria, and, in rare cases, granular casts. Some dogs have pigmenturia consisting most commonly of bilirubin, and occasionally hemoglobin.

Coagulation Testing

The most consistent hemostatic abnormality in complicated and uncomplicated babesiosis is thrombocytopenia. DIC has been reported; however, complete confirmation of DIC in animals with babesiosis may be difficult because of the nature of the underlying disease process and the reported unreliability of the human fibrin degradation product test for evaluating canine specimens. Dogs with *B. conradae* infection appear to have altered platelet function tests.[57]

Microbiologic Testing

There are three basic methods available for specific diagnosis of *Babesia* infections: microscopic identification, serologic testing, and nucleic acid–based detection methods (Table 75-1). The true clinical sensitivity and specificity of most of the available tests is unknown, but all modalities can have either false-positive or false-negative results. Therefore, there is no "perfect" test for *Babesia* infection, and in some cases, multiple diagnostic tests are indicated.

Cytologic Diagnosis

Light microscopic examination is highly specific for the identification of *Babesia* organisms, but because of its limit of detection (0.001% parasitemia), it has relatively poor sensitivity and is not a suitable screening test. Several species/genotypes are virtually indistinguishable by light microscopy, making accurate

identification to the species level impossible. However, when cytologic detection is used in combination with the history, signalment, physical examination, clinicopathologic data, and geographic location, the clinician may be able to predict the most likely species present.

Babesia canis are large, pyriform organisms and usually exist singly or in pairs (Figure 75-3, *A*). Smaller single intracellular organisms are likely to be *B. gibsoni* or *B. conradae* (see Figure 75-3, *B* and *C*). However, when the parasites are rapidly replicating, the classic intraerythrocytic forms may not predominate and some more atypical irregular, amoeboid parasite forms with a wide range of sizes can be detected. During these phases of infection, some small *Babesia* spp. have large forms and some large *Babesia* spp. have small forms. In chronic infection, the level of parasitemia is often low, especially in *B. canis*–infected dogs, and thorough examination of thin blood smears is necessary. Evaluation of stained slides requires experience and a significant time commitment on the part of the laboratory technician. For *B. canis* infections, blood collected from the peripheral capillary beds of the ear tip or nailbed may yield higher numbers of parasitized cells.[71] Rarely, phagocytized organisms and erythrocyte fragments are seen in neutrophils. Methods that concentrate and stain buffy-coat specimens may improve the sensitivity of parasite detection.[72,73]

Serologic Diagnosis

Because *Babesia* parasites are difficult to detect, especially in chronic carriers, immunodiagnostics may be used to screen for exposure. Immunofluorescent antibody (IFA) assays are used most commonly to detect antibodies to *Babesia* species. Laboratory methods differ, and each laboratory should be consulted for cutoff antibody titers. As a general guideline, titers to *B. canis* or *B. gibsoni* of 1:64 or greater on a single specimen are supportive of exposure. Serologic assays for *B. conradae* are not widely available at the time of writing.

Titers to multiple *Babesia* species must be measured if antibody testing is performed in geographic areas where more than one species of *Babesia* exists. Cross-reactivity between *Babesia* spp. makes parasite identification by PCR necessary to definitively identify a given species. There are also many documented instances in which parasites or parasite DNA have been detected but anti-*Babesia* antibodies could not be detected. Very young dogs or dogs tested early in the disease course may have negative antibody test results, so convalescent serology is required in some cases. Antibodies were not detected in 36% of dogs with *B. canis* parasitemia in one study.[8] ELISAs that target several different antigens have been developed for use in antibody or antigen detection tests and offer promise for serodiagnosis of canine babesiosis in the future. However, there are no

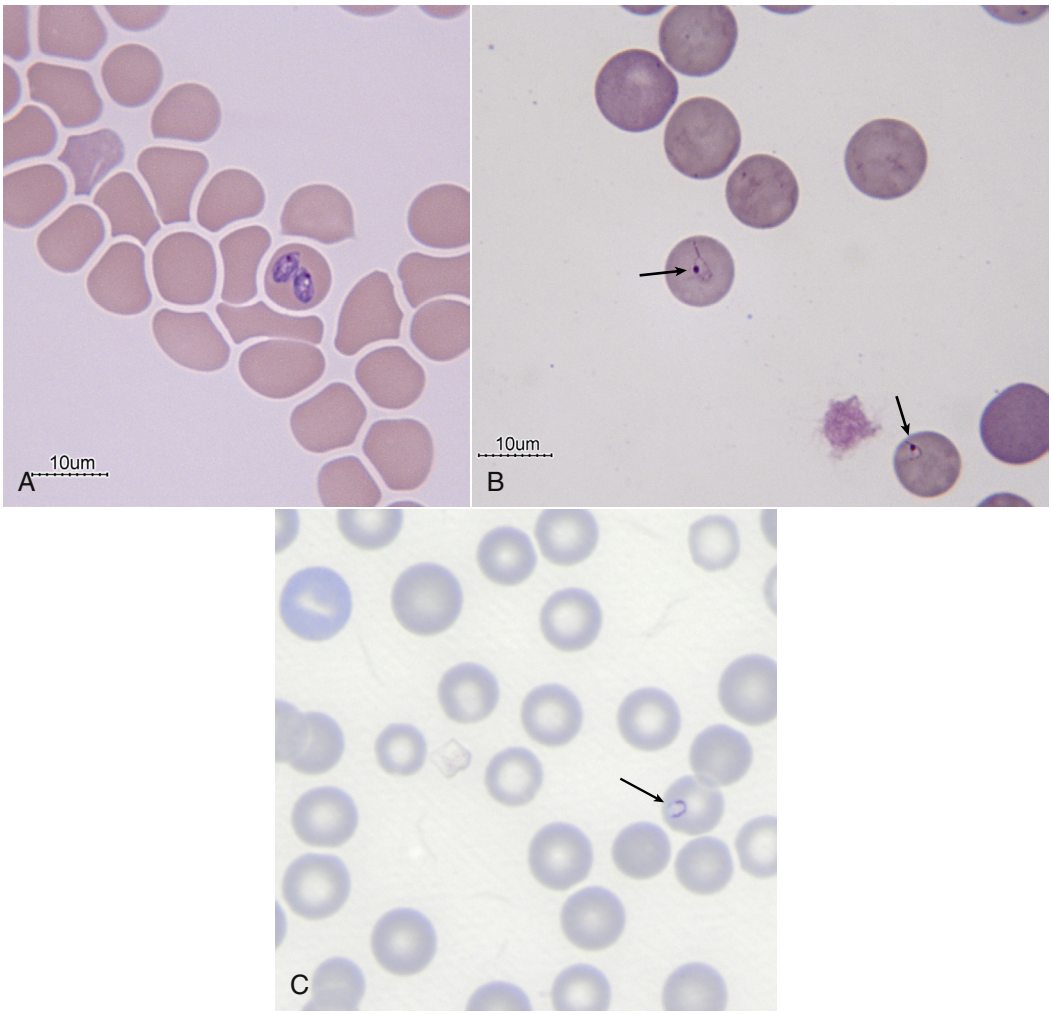

FIGURE 75-3 Blood smears from dog with babesiosis. **A,** Large unnamed *Babesia* piroplasm originally identified in dogs in North Carolina. A pair of large, piriform-shape merozoites are present within an erythrocyte. **B,** Individual merozoites of *Babesia gibsoni* in erythrocytes *(arrows)*. **C,** *Babesia conradae* merozoite within an erythrocyte *(arrow)*. Polychromasia and anisocytosis are also present. Although considered a small *Babesia* species, in this image, the organism is relatively large. Wright's stain, 1000×.

commercially available ELISA assays for the detection of anti-*Babesia* antibodies in the United States.

Molecular Diagnosis Using the Polymerase Chain Reaction

Genetic methods such as PCR assays are the most sensitive and specific means of detecting active infection with *Babesia*. Some assays have a lower limit of detection that is more than 1300-fold more sensitive than the level (0.001% parasitized erythrocytes) of light microscopy.[74] Many different PCR assays have been published for the identification and differentiation of *Babesia* infections, and several commercial diagnostic laboratories offer real-time PCR assays for detection of *Babesia* infection. Species identification can then be accomplished by DNA sequencing or by the use of species-specific PCR assays. PCR assays that are designed to detect multiple *Babesia* spp. (i.e., a broad-range *Babesia* PCR) can facilitate screening. A well-designed species-specific assay will only detect one species, and a negative test may lead clinicians to falsely conclude that the patient is not infected with *Babesia* because the wrong species was targeted for testing. In addition, broad-range PCR assays have been helpful for identification of novel *Babesia* species.

Pathologic Findings

The most striking pathologic findings occur in dogs that die from severe babesiosis (usually associated with *B. canis rossi*). These include staining of tissues with hemoglobin or bilirubin, hepatosplenomegaly, lymphadenomegaly, and kidneys that are a dark-reddish color. Edema and hemorrhage, which may indicate vascular injury and poor tissue oxygenation in severely affected dogs, are often most severe in the lungs. Nonparasitized cells often line the endothelial surface with parasitized cells sludged in the lumen. Pathologic changes in the brain of these dogs include congestion, macroscopic and microscopic hemorrhages, sequestration of parasitized erythrocytes in capillary beds, and pavementing of parasitized cells against the endothelium. Cardiac histologic changes include hemorrhage, necrosis, inflammatory infiltrate, and fibrosis. Microthrombi of many tissues may be evident in animals exhibiting signs of DIC. Impression smears of the spleen may substantiate the diagnosis of babesiosis at necropsy. Nonspecific findings in dogs with all forms of babesiosis include erythroid hyperplasia in the bone marrow, extramedullary hematopoiesis of the liver and spleen, mononuclear phagocyte system hyperplasia, and centrilobular necrosis of the liver. Vasculitis has been observed in *B. conradae* infections and is associated with hepatitis and lymphadenitis with multifocal deposits of IgM in inflamed arteries and renal glomeruli.[60] In chronic canine babesiosis and feline babesiosis, the only gross finding may be splenomegaly.

Treatment and Prognosis

Antiprotozoal Treatment

Dogs

Dogs generally show clinical improvement within 24 to 72 hours of treatment with antibabesial drugs, but some animals take as long as 7 days to respond (Table 75-2). Imidocarb

TABLE 75-2

Selected Antibabesial Compounds Used in the Treatment of Dogs and Cats

Generic Name*	Dose (mg/kg)	Route	Interval (hours)	Duration (days)	Organism			
					Babesia canis	*Babesia gibsoni*	*Babesia conradae*	*Babesia felis*
Imidocarb dipropionate[†]	5-6.6 7.5	IM IM	Once Once	Repeat in 14 NA	+++	+	+	—
Diminazene aceturate	3.5-5	IM	Once[‡]	NA	+++	++	?	+
Azithromycin[§] *and* Atovaquone[§]	10 13.3	PO PO	24 8	10 10	+++	+++	+++	?
Clindamycin[‖] *and* Doxycycline *and* Metronidazole	25 5 15	PO PO PO	12 12 12	90 90 90	+	+	?	?
Primaquine phosphate	0.5 1 mg *per cat*[#]	PO IM	24 36	1-3 6	? —	— —	? ?	+++ +++

+++, Very good; ++, good; +, fair to poor; —, not effective; *?*, unknown.

*For specific information on each drug, see Chapter 10.

[†]For combination therapy, a dose of 3.5 mg/kg diminazene has been followed by a dose of 6.0 mg/kg imidocarb.

[‡]Not available in the United States, except by compassionate use. For *B. canis*, this dose is sufficient; for *B. gibsoni*, repeat dose in 24 hours. Total dosages of 7 mg/kg or higher are associated with an increased risk of neural and parasympathomimetic toxicity.

[§]These two drugs should be used in combination. Atovaquone must be given with a fatty meal to facilitate absorption. The suspension causes minimal gastrointestinal side effects.

[‖]Anecdotal evidence for activity against *B. canis*. Not effective in clearing the infection. Not recommended as sole therapy because of the potential to develop resistance. Further documentation needed to establish efficacy of this combination (see text).

[#]Note that 1 mg/kg is a lethal dose.

VetBooks.ir

dipropionate is active against *B. canis*.[75] Imidocarb can eliminate *B. canis*, eliminates infection in ticks that engorge on treated animals for up to 4 weeks after treatment, and prevents infection for up to 6 weeks after a single injection.[76] A single dose of 7.5 mg/kg or a single dose of 6 mg/kg given the day after a dose of diminazene (3.5 mg/kg) also clears infection.[77] In areas where reinfection is likely, some practitioners use a lower dose, 2 mg/kg SC once, that does completely clear infection. This approach is an attempt to induce a state of premunition. Premunition is the immunity of existing infection in which chronic subclinically affected carriers may be resistant to reinfection or at least have reduced morbidity with new infections. In contrast, animals that have been cleared of infection are more susceptible to reinfection with recurrent clinical disease. The risk of this approach is that clinical babesiosis may relapse in some chronic carriers. Therefore, this approach is not recommended for the treatment of canine babesiosis in many parts of the United States, where vector transmission and risk for reinfection are thought to be low. Imidocarb does not clear *B. gibsoni* infections, but reduces morbidity and mortality. Therefore, this is a reasonable alternative treatment for *B. gibsoni* if the owner cannot immediately afford more effective treatments. The same may be true for *B. conradae* infections. Pretreatment with atropine (0.5 mg/kg SC 30 minutes before injection) reduces the adverse effects of imidocarb (see Chapter 10).

Other related aromatic diamidines include diminazene aceturate, phenamidine isethionate, and pentamidine isethionate (see Chapter 10). Although these are not available for treatment of dogs in the United States, the first two of these drugs have been used in many other countries and are highly active against *B. canis*. They do not clear *B. gibsoni* infections, but can reduce morbidity and mortality.

Atovaquone and azithromycin combination therapy is the most effective treatment for *B. gibsoni* and *B. conradae* infections (see Table 75-2).[78,79] Atovaquone and azithromycin are given for 10 days. Atovaquone must be administered with a fatty meal to maximize drug absorption. The treatment appeared to sterilize *B. gibsoni* infections or reduce the parasitemia below detectable limits in approximately 80% of dogs in a randomized double-blind placebo-controlled trial.[79] However, in another study, this combination only eliminated *B. gibsoni* infection (or reduced parasitemia below detectable limits of PCR assay), in 2 of 7 dogs.[80] It also did not clear experimental infection with two Australian isolates of *B. gibsoni*.[81] When atovaquone is used alone to treat *B. gibsoni* infection, recrudescence of infection develops more than 30 days after treatment.[81] Drug resistance has been identified in vitro, so atovaquone should always be used in combination with other drugs. Mutations in the genes that encode the putative molecular target of atovaquone have been identified in *B. gibsoni* isolated from dogs that failed to clear infection after atovaquone treatment.[80,82]

In this author's experience, dogs that fail to clear *B. gibsoni* infections after initial treatment with atovaquone and azithromycin will not clear their infection after a follow-up treatment with the same drugs, although clinical disease may resolve. There are also two commercially available formulations of atovaquone: a single-drug liquid suspension that is very well tolerated, and a combination tablet product (atovaquone and proguanil hydrochloride). Although the combination product is less expensive, it causes severe vomiting in some patients. Because drug absorption is critical and resistance to atovaquone can develop or be selected, this author recommends *only* use of the suspension. Dogs that have been splenectomized before treatment do not appear to clear infections with treatment.[83] Likewise, immunosuppressive therapy may reduce the ability of antibabesial treatment to clear dogs of *B. gibsoni* infection. The recommended follow-up after treatment with atovaquone and azithromycin is a minimum of two PCR tests approximately 60 and 90 days after completing treatment.

An alternative treatment strategy can be used to treat *B. gibsoni* infections that fail to respond to atovaquone and azithromycin.[84] This regimen involves a combination of clindamycin, metronidazole, and doxycycline for a minimum of 3 months (see Table 75-2). In an uncontrolled study, 3 of 4 experimentally infected dogs had negative PCR assay results after treatment, whereas 1 dog remained persistently infected and experienced clinical relapses during treatment.[84] Clearance of the infection as determined by PCR was not detected until 30 and 72 days after completing a 90-day treatment course in 2 dogs. The PCR test result became negative in the third dog 12 days into treatment. Three of the dogs were initially treated with three doses of diminazene aceturate. In another study, 3 naturally infected dogs that had clinical relapse after or during atovaquone and azithromycin treatment had clinical recoveries after treatment with the clindamycin, metronidazole, and doxycycline combination.[80] The small number of cases reported and the high degree of variability in the PCR results after treatment make the efficacy of this combination uncertain. However, as with the atovaquone-azithromycin combination, PCR testing should be performed 60 and 90 days after completing therapy.

Aggressive supportive care and monotherapy with clindamycin (25 mg/kg PO q12h for 7 to 21 days) has been recommended if specific antibabesial drugs are not available. At this dosage, clinical abnormalities resolve even if organism clearance does not occur. This author *does not* recommend this practice for *B. gibsoni*–infected dogs, because it has the potential to select for macrolide resistance and interfere with subsequent atovaquone and azithromycin treatment.

Other treatments that have been used to treat *B. canis* infections are quinuronium sulfate and 1% trypan blue solution. Trypan blue does not clear infections and results in bluish discoloration of tissues and plasma.

Cats

Treatment of feline babesiosis has not been as critically evaluated, but most antibabesial drugs appear ineffective. Primaquine phosphate, an antimalarial compound, administered orally or as an intramuscular injection, is currently the drug of choice (see Table 75-2). However, the effective dose, 0.5 mg/kg, is very close to the lethal dose (1 mg/kg). In experimental studies, rifampin and trimethoprim-sulfadiazine were not as effective as primaquine.[85]

Supportive Care

Other supportive care measures that may be required to treat animals with babesiosis are packed red blood cell transfusions and intravenous crystalloid fluid therapy. The administration of the plasma component of whole blood is unnecessary in the majority of dogs with babesiosis and can place the patient at risk of volume overload. If rehydration is required, crystalloid replacement solutions are preferable. Whether glucocorticoids are indicated to counteract the immune-mediated complications of babesiosis is controversial. In one study, 21% of

VetBooks.ir

134 dogs with *B. canis rossi* infection had hemolytic anemias that did not respond to antibabesial therapy alone.[63] This seems less common with *B. canis vogeli* or *B. gibsoni* infections, because these often respond completely to antibabesial treatment alone. In most dogs that require glucocorticoids, the glucocorticoid dosage can be tapered and discontinued within a 2- to 3-week period. Continued glucocorticoid therapy may predispose the animals to other infections and has the potential to induce babesial relapse.[86]

Immunity and Vaccination

The duration of protective immunity against *B. canis* infection is limited. Antibody titers may gradually decline between 3 and 5 months after infection.[76] Recovered dogs are protected against homologous infection within 5 to 8 months after infection.[76] Cross-protection between strains does not occur, and seropositivity does not guarantee protection against heterologous challenge.

A vaccine produced from cell-culture–derived exoantigens of *B. canis canis* is available in Europe.[87] An efficacy of 70% to 100% has been reported, with the disease occasionally seen in the vaccinates generally being mild. Other field studies have been less impressive. Vaccination does not prevent infection but appears to block initiation of many of the pathologic processes involved in disease pathogenesis.[88,89] Vaccines may limit parasitemia and reduce development of anemia and splenomegaly. A bivalent vaccine derived from soluble parasite antigens from *B. canis canis* and *B. canis rossi* (Nobivac Piro, MSD Animal Health South Africa) reduces clinical signs after challenge with both species.[90,91] Differences in strain antigenicity limit the usefulness of the commercial vaccine in other areas. Because *B. canis* vaccines do not cross protect against all *B. canis* subspecies, they are highly unlikely to protect against other *Babesia* species.

Prevention

Treatment of babesiosis is expensive and may be ineffective, so prevention is of paramount importance. Preventive measures alone may be sufficient to control *B. canis* outbreaks in kennels in the southeastern United States. The primary means of prevention is tick control (see Prevention section in Chapter 28). Early tick identification and removal is important because it likely takes a minimum of 2 to 3 days of feeding for transmission of the parasite to occur. Dogs should be tested, treated if necessary, and quarantined before being introduced into a colony. The use of amitraz-impregnated collars significantly reduced new infections in a *B. canis rossi*–endemic area. In this study none of 20 dogs treated with the collars acquired infections, compared to 27% of 30 control dogs that received no tick prevention.[92] Prevention of aggressive interactions with other dogs (especially fighting breeds such as American pit bull terriers) may also prevent infection. All prospective canine blood donors should be tested for babesiosis with serology and PCR assays, and animals positive by either or both methods should not be used for blood donation.

Of 16,000 greyhounds adopted through rescue leagues in 1995, 20% to 60% were seropositive for *B. canis*. Much of this screening was done before the availability of PCR assays, and serologic testing results likely overestimate the true prevalence of infection. The likelihood that an adopted greyhound will develop clinical babesiosis or directly transmit infection to other dogs is low. However, the risk to other dogs is great if the infected animal is placed in a breeding kennel in which dogs are housed together and tick control is not adequate, or if the animal is used as a blood donor. Treatment with imidocarb dipropionate may eliminate the *B. canis* carrier status. This approach should be considered in situations in which risk of spread is likely. In other situations, the owner should be made aware of the seropositive status so that should clinical signs consistent with babesiosis arise, the attending veterinarian can be alerted to the possibility of the disease. Splenectomy should be avoided if possible in these dogs should it become indicated.

Public Health Aspects

Canine and feline *Babesia* spp. do not appear to pose a zoonotic risk to immunocompetent humans. Their risks to immunocompromised individuals are unknown, but as with many infectious diseases, people who are undergoing chemotherapy, are infected with HIV, or have been splenectomized should exercise special caution when handling blood samples from dogs. Babesiosis is a rare tick-borne zoonosis of people in Europe and in the United States, and isolated uncharacterized *Babesia* infections have been reported in Africa and Mexico.[93] The majority of infections are mild or asymptomatic; however, some result in severe illness and death. Splenectomized people or those older than 55 years are especially at risk.[94,95] No *Babesia* species has been identified that is host specific for people. Sylvan cycles with wild animal reservoirs occur in nature. People serve as accidental hosts for *Babesia* of animals when they are bitten by infected ticks. Transmission through blood transfusion has also been described. *B. microti* is the primary parasite that infects people in the northeast and upper Midwest of the United States. The vector tick is *Ixodes scapularis*, which can co-transmit anaplasmosis and Lyme borreliosis. The hemolytic disease with flu-like symptoms is usually mild and self-limiting or easily treated with clindamycin and quinine. Both asymptomatic infections and clinical babesiosis with severe anemia have been reported in people in California and Washington and is caused by the more recently described parasite *Babesia duncani*.[96-98]

Babesia divergens causes a severe form of human babesiosis in Europe, which usually occurs in people who have had a splenectomy and is often fatal. Babesiosis was also identified in splenectomized people from Italy and Austria with a new strain (EU1) that was more closely related to *Babesia odocoilei*.[98] Identical isolates of *Babesia* have been found in *Ixodes ricinus* ticks from Slovenia, suggesting a more widespread distribution of this organism in Europe.

CASE EXAMPLE

Signalment: "Dora," a 4-year-old female spayed American Staffordshire terrier from North Carolina

History: Dora was evaluated for a 3- to 4-day history of anorexia and lethargy. Before referral, an ELISA that detects heartworm antigen and antibodies to *E. canis* or *B. burgdorferi* antigens was performed and the results were negative. The dog had mild anemia (HCT 28.4%) and moderate thrombocytopenia (59,000 platelets/µL) on an automated hematology analyzer. Amoxicillin–clavulanic acid, doxycycline, and famotidine were prescribed. The patient began showing signs of increased energy and appetite as well as an increase in the HCT (38%) and platelet count (147,000 platelets/µL) after 4 weeks of treatment. However, because the values did not return to within reference range, the case was referred.

Physical Examination:

Body Weight: 24.2 kg.

General: Bright, alert, responsive, hydrated. T = 101.6°C (38.7°F), HR = 100 beats/min, RR = 24 breaths/min, mucous membranes pink, CRT <2 s. Physical examination was otherwise unremarkable.

Selected Laboratory Findings:

	Pretreatment	Posttreatment	Reference Range
PCV (%)	41	52	39-58
Platelet count (× 10^3/µL)	80	361	190-468
TP (g/dL)	6.3	6.5	5.2-7.3
Albumin (g/dL)	2.7	3.8	3-3.9
Globulin (g/dL)	3.5	2.7	1.7-3.8
Albumin/globulin ratio	0.78	1.38	0.9-1.8
Visualization of *Babesia* on microscopic examination of blood smear	Negative	Negative	
Babesia canis IFA	1:256	ND	
Ehrlichia canis IFA	<1:16	ND	
Bartonella vinsonii IFA	<1:16	ND	
Bartonella henselae IFA	<1:16	ND	
Rickettsia rickettsii IFA	1:64	ND	
SNAP 4Dx ELISA	Negative for all agents	ND	
Babesia spp. PCR	Positive (*B. gibsoni*)	Negative	

Diagnosis: *Babesia gibsoni* infection.

Treatment: Atovaquone and azithromycin.

Comments: Dogs with babesiosis often have a positive clinical response to doxycycline, which leads clinicians to suspect rickettsial infection. Although fever is considered a classic sign of babesiosis, most dogs are afebrile during initial examination, and waxing and waning fever is often documented with serial rectal temperatures. Thrombocytopenia is often a more prominent hematologic finding than anemia and may be the only finding in some cases. Babesiosis may be associated with changes in both albumin and globulin concentrations. Hypoalbuminemia can be secondary to proteinuria (not documented in this case). Globulins are often increased, although they may not be above the high end of the reference range. Organisms are frequently not observed on routine examination of stained blood smears, and PCR assay is required to document infection. Panels that detect antibodies to tick-borne pathogens typically either do not include *Babesia* spp. at all or only detect antibodies against *B. canis*. Serologic cross-reactivity between species can occur, leading to inappropriate diagnosis and treatment recommendations. The positive titer to *Rickettsia* spp. was interesting, but in this geographic location, approximately 20% to 25% of healthy dogs are seropositive to *Rickettsia* spp., so its significance was unclear. Although acute phase serology for *B. gibsoni* was not done, a convalescent titer to *B. gibsoni* at a follow up examination was 1:64.

CHAPTER 76

Cytauxzoonosis

Leah A. Cohn

VetBooks.ir

Overview of Cytauxzoonosis

First Described: *Cytauxzoon felis* was first described in domestic cats from Missouri in 1976[1]

Cause: *Cytauxzoon felis,* a hemoprotozoan parasite (phylum Apicomplexa)

Affected Hosts: Any felid; bobcats are the major reservoir host.

Mode of Transmission: *Amblyomma americanum* (Lone Star tick), possibly *Dermacentor variabilis* (American dog tick)

Geographic Distribution: South central, southeastern, and mid-Atlantic United States, and South America

Major Clinical Signs: Lethargy, anorexia, dyspnea, fever, icterus, anemia

Differential Diagnosis: Hemotropic mycoplasmosis, tularemia, cholangiohepatitis, sepsis, primary immune-mediated hemolytic anemia, oxidative toxicities, toxoplasmosis, feline infectious peritonitis

Human Health Significance: *Cytauxzoon felis* is not known to infect humans.

Etiology and Epidemiology

Cytauxzoonosis, a life-threatening acute febrile illness of cats, is caused by the hemoprotozoan parasite *Cytauxzoon felis*, an apicomplexan parasite within the order Piroplasmida and family Theileriidae.[2] The parasite infects both domestic and wild Felidae, but not other mammals.[3] Both *Amblyomma americanum* (Lone Star ticks) and *Dermacentor variabilis* (American dog ticks) harbor the pathogen and are competent transmission vectors, although it is likely that *Amblyomma* ticks are the more important natural disease vectors.[4-6]

As for other apicomplexan parasites, the parasite life cycle involves sexual reproduction in the vector tick and asexual reproduction in the mammalian host. The parasite is inoculated into the host as a sporozoite when an infected tick vector feeds. As for other members of the *Theileriidae* family, the pathogen exists within the mammalian host in both a non-erythrocytic (schizont) and an erythrocytic (piroplasm) form. Approximately 2 weeks after inoculation, schizogony occurs, whereby mononuclear cells become distended with parasites.[7,8] When these cells rupture, merozoites are released and endocytosed by RBCs, where they are known as piroplasms.[8] The piroplasms are ingested by naïve ticks during feeding (Figure 76-1). The acute illness, known as cytauxzoonosis, occurs during the schizogenous phase of infection, whereas piroplasms can be found both during illness and in healthy carrier cats.

There is no breed, sex, or age predisposition for infection, and retroviral infection has not been proven to predispose cats to infection or disease.[9] Often, infected cats are young adults and previously quite healthy. They are typically outdoor or indoor/outdoor cats from wooded suburban or rural areas, where they are more likely to encounter a tick that has recently fed on an infected bobcat *(Lynx rufus),* the predominant reservoir host.[9,10] Often, multiple cats in a neighborhood are affected nearly simultaneously, which likely reflects the presence of infected ticks. Infection occurs most commonly in spring and summer when the tick vector is most active.[9] Originally identified in only the south-central United States, the geographic range of *C. felis* has expanded simultaneously with expansion in the range of the vector Lone Star ticks. Infections in domestic cats are now recognized throughout the south-central, southeastern, and mid-Atlantic states, and the pathogen has been identified in bobcats as far north as Pennsylvania and North Dakota (Figure 76-2).[10,11]

Clinical Features

Signs and Their Pathogenesis

Owners of cats with cytauxzoonosis usually notice an acute onset of profound lethargy and anorexia in a previously healthy cat. Less consistently, owners report vocalization, elevation of the nictitans, tachypnea and/or dyspnea, or icterus, or that the cat feels warm to the touch.[12] The vast majority of the considerable pathologic damage that occurs during acute illness is due to the schizogenous phase of parasitemia.[8] The degree of schizogony appears to be correlated with severity of disease; bobcats (the natural host) undergo a brief and milder schizogenous phase as compared to domestic cats, and correspondingly illness is less pronounced in bobcats than in domestic cats.[13] Schizont-distended mononuclear cells occlude small veins and capillaries, most notably in the liver, lung, spleen, and lymph nodes.[8,14] Obstruction fuels hypoxic tissue damage and release of inflammatory cytokines, which can lead to systemic inflammatory response syndrome, sepsis, disseminated intravascular coagulation (DIC), and multisystem organ failure. The presence of piroplasms may trigger hemolysis in the later stages of the acute illness; however, hemolysis abates in surviving cats, and hemolytic anemia has not been noted in chronic carriers.[15-18]

Physical Examination Findings

Physical examination findings associated with acute cytauxzoonosis are nonspecific.[8,12,19] The most consistent single finding is fever. Although temperatures greater than 104°F (40°C) are

VetBooks.ir

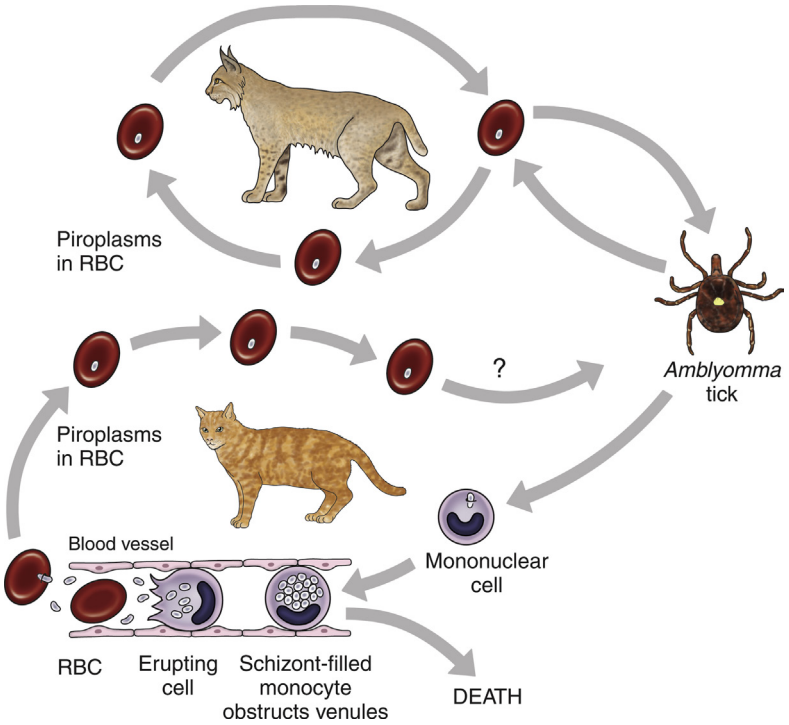

FIGURE 76-1 Life cycle of *Cytauxzoon felis*. The parasite is maintained in bobcats (top) which are subclinically infected. The sexual cycle of the organism occurs in *Amblyomma americanum* hard ticks, which then transmit sporozoites to domestic cats. Sporozoites invade mononuclear cells, where they undergo schizogony. Schizont-filled monocytes obstruct venules and capillaries and cause multiorgan failure and death. In cats that survive the schizogony phase, the organism infects erythrocytes and forms piroplasms. The importance of domestic cats as a reservoir for infection of ticks is unknown. The schizogony stage in the bobcat is relatively mild and brief.

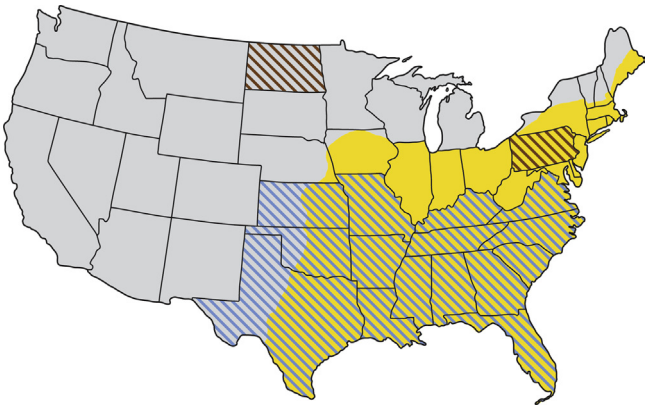

FIGURE 76-2 Geographic distribution of *Cytauxzoon felis* infections. Shaded areas show confirmed cases in either domestic cats *(blue),* or bobcats only (ND and PA). The yellow region represents the distribution of *Amblyomma americanum* ticks.

common, body temperature drops in moribund animals, and many cats are hypothermic for several hours before death.[8,12] Cats are almost always lethargic. Icterus and pallor are common findings but may not be present initially. The nictitating membrane is commonly elevated (Figure 76-3). Both tachycardia and tachypnea, with or without increased respiratory effort, are also common. Cardiac murmurs are sometimes auscultated, especially in anemic cats. Splenomegaly, hepatomegaly, and lymphadenomegaly may be appreciable. Cats may have seizures or become obtunded shortly before death. Because the onset of illness occurs as long as 2 weeks after the cat is bitten by a tick, ectoparasites are not consistently found on examination.

FIGURE 76-3 Cat with *Cytauxzoon felis* infection. There is elevation and hyperemia of the nictitating membranes.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

Abnormalities on the CBC in cats with cytauxzoonosis commonly include pancytopenia or bicytopenia and characteristic signet ring

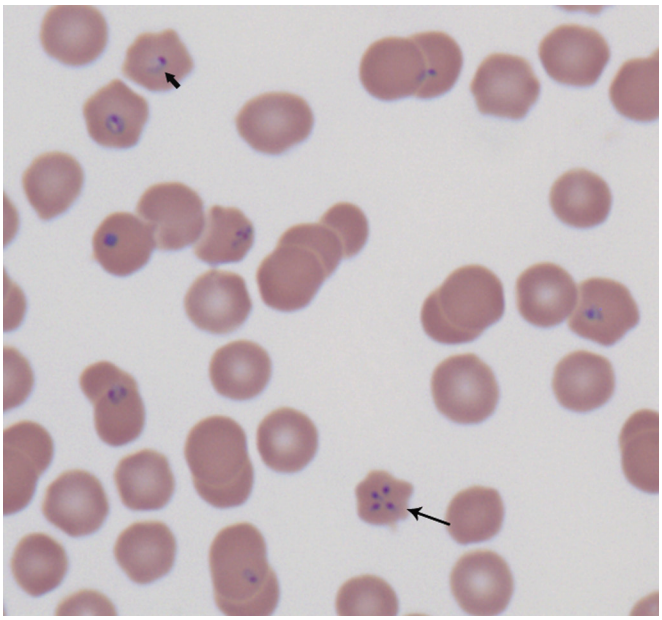

FIGURE 76-4 Wright-Giemsa–stained peripheral blood smear from a cat with cytauxzoonosis at 1000× magnification. Multiple RBC contain signet ring–shaped piroplasms *(short arrow);* a single RBC demonstrates a tetrad form *(long arrow).* (Courtesy Dr. Marlyn Whitney, University of Missouri Veterinary Medical Diagnostic Laboratory.)

intraerythrocytic inclusions (see Cytologic Examination) (Figure 76-4). Various combinations of neutropenia, lymphopenia, thrombocytopenia, and nonregenerative anemia are observed.[12,19,20] Occasionally, neutrophilia or bandemia are observed. Although thrombocytopenia is usually identified and may be related to DIC or vasculitis, platelet clumping is common even in healthy cats and can result in false thrombocytopenia. Anemia may be absent at the onset of illness but usually develops about the same time piroplasms become identifiable. Because of the acute nature of the disease, anemia is initially nonregenerative. In recovered carrier cats, cell counts rebound to values within reference ranges, and chronic anemia is not a feature of the carrier state.[15,17,18,21]

Serum Chemistry Profile

Although there are no specific findings on serum chemistry analysis, a number of abnormalities are commonly identified in cats with cytauxzoonosis. Hyperbilirubinemia is common and may result from hepatic vascular occlusion and/or hemolysis. The activities of serum ALP and ALT increase in a minority of sick cats, and increases are usually mild to moderate.[12] Mild to moderate hyperglycemia is common in stressed, sick cats. Mild hypoproteinemia, hypocalcemia, hyponatremia, and hypokalemia can occur during acute illness.[12,19] No consistent abnormalities have been reported on serum chemistry analysis for recovered carrier cats.[17,21]

Urinalysis

Urinalysis results are rarely reported for cats with cytauxzoonosis.[19] Certainly, hyperbilirubinemia may be reflected by bilirubinuria, and hyperglycemia that surpasses the renal threshold may cause mild glucosuria. In the author's experience, the urinalysis is otherwise unremarkable.

Clotting Function

Acute cytauxzoonosis is a form of sepsis and, as such, is expected to be associated with altered coagulability. Thrombocytopenia is common in affected cats, but because platelet clumping occurs readily in cats, the frequency of true thrombocytopenia may be overestimated.[12,19,20] Although not often assayed, prolongation of APTT and PT in several affected cats suggests that DIC is a common complication.[22,23]

Diagnostic Imaging

Imaging studies do not contribute directly to the diagnosis of cytauxzoonosis, and results are seldom reported in the literature. Splenomegaly, hepatomegaly, or both may be identified either on plain radiographs or on abdominal ultrasound examination. Although thoracic radiographic findings are seldom documented in the literature, the author has commonly identified diffuse interstitial pulmonary patterns on radiographs from cats with respiratory signs. Less commonly, alveolar lung patterns or pleural effusion are recognized.

Microbiologic Testing

Diagnostic assays currently available for cytauxzoonosis in cats are described in Table 76-1.

Cytologic Examination of Aspirates or Blood Smears

Careful microscopic examination for intracellular parasites is the most commonly used method for diagnosis of infection. A well-made thin blood smear stained with Wright's stain or Diff Quik should be carefully scanned for either RBC piroplasms or schizont-laden mononuclear cells. Schizont-distended mononuclear cells are sometimes, but not usually, found on careful examination of the entire feathered edge of the blood smear during acute illness (Figure 76-5). If these cells are identified, a diagnosis of acute cytauxzoonosis is confirmed. More commonly, microscopic review allows identification of piroplasms within RBCs. Unfortunately, because illness is most associated with schizogenous replication, illness precedes development of piroplasms in up to half of cats examined. When cytauxzoonosis is suspected but piroplasms are not identified, reexamination of another blood smear the following day may yield positive results. Piroplasms are most often 1 to 1.5 µm, signet ring–shaped inclusions, but tetrad, "safety pin," and coccoid organisms are seen on occasion (see Figures 76-4 and 76-5).[8] Stain precipitate, Howell-Jolly bodies, or other RBC pathogens such as *Mycoplasma haemofelis* have features that distinguish them from *C. felis* piroplasms, but a less experienced microscopist may misidentify them as *C. felis*. Importantly, recovered cats may harbor piroplasms for months to years after initial infection. It is important to realize that piroplasms might be discovered incidentally in chronic carrier cats that survived infection in the distant past. Thus, although identification of piroplasms confirms infection, piroplasms alone (especially in low numbers) cannot confirm that current illness is due to cytauxzoonosis.

When compared with peripheral blood, mononuclear cells distended with merozoites are more commonly identified on fine-needle aspiration (FNA) from spleen, liver, lymph nodes, or lungs of affected cats. Because schizogony precedes piroplasm development, FNA of these organs can rapidly confirm a diagnosis when piroplasms are absent (Figure 76-6).

Molecular Diagnosis using the Polymerase Chain Reaction

PCR assays are the most sensitive diagnostic test for cytauxzoonosis.[18,24] Several commercial veterinary diagnostic laboratories that perform molecular diagnostics offer PCR analysis of whole blood samples for *Cytauxzoon felis* DNA. As with any PCR test, only

VetBooks.ir

TABLE 76-1

Diagnostic Assays Currently Available for Cytauxzoonosis in Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Whole blood smears, aspirates of lymph nodes, spleen, liver, lung	*Cytauxzoon felis* piroplasms in erythrocytes, or merozoites/schizonts in mononuclear cells or reticuloendothelial tissues	Piroplasms may initially not be visible in acutely ill cats or may be confused with other erythrocyte inclusions such as hemoplasmas or Howell-Jolly bodies. Schizonts may be found in fine-needle aspirates of reticuloendothelial tissues before piroplasms are found on blood smear examination in some cats.
PCR assays	Whole blood	*C. felis* DNA	Sensitivity and specificity may vary depending on assay design, but PCR assays may be more sensitive than cytology for detection of piroplasms, especially in chronic carrier cats.

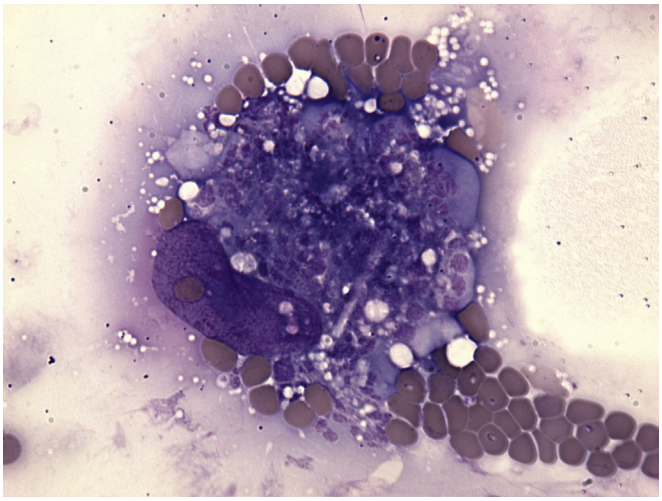

FIGURE 76-5 Wright-Giemsa–stained peripheral blood smear from a cat with cytauxzoonosis at 1000× magnification. A mononuclear cell massively distended with a schizont is surrounded by multiple RBCs, a few of which contain *Cytauxzoon felis* piroplasms.

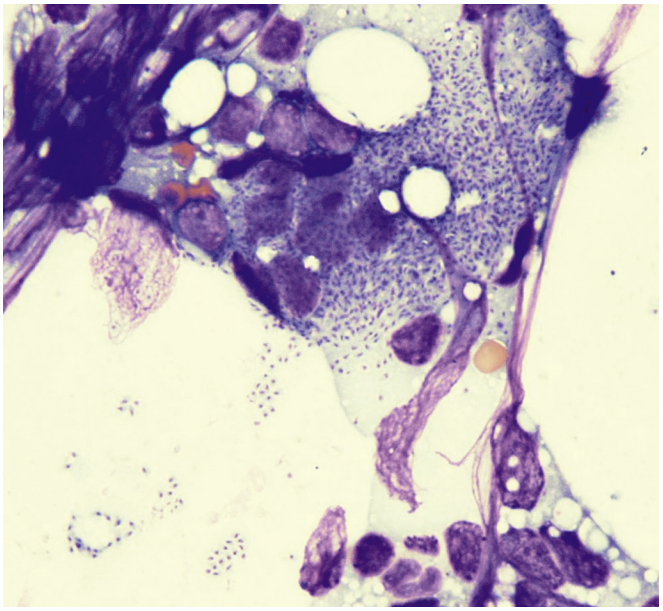

FIGURE 76-6 Fine-needle aspirate of a lymph node from a cat with cytauxzoonosis. Large numbers of merozoites (which have a granular appearance) erupt from a mononuclear cell.

reputable laboratories should be used; quality control is crucial. Because of the delay inherent in any mail-out PCR test, presumptive disease treatment needs to precede the results of PCR testing.

Healthy, chronic carrier cats have been identified by PCR assays applied to peripheral blood samples.[18,25,26] Although the importance of such carrier cats in propagation of infection is not known, they are competent hosts for transmission of infection to other cats via the bite of a tick vector.[27] Some cat owners may request screening of healthy cats that reside in the same neighborhood as a cat with cytauxzoonosis; such screening is best accomplished with PCR assays. Unfortunately, no method has been confirmed to completely eliminate parasitemia from chronic carrier cats.[21,28,29]

Other Diagnostic Assays

To date, *C. felis* has not been successfully cultured in vitro. Although serologic tests have been developed for detection of antibodies to *C. felis*, they are not practical for disease diagnosis, because illness likely precedes antibody formation.[30]

Pathologic Findings

Gross Pathologic Findings

Icterus and pallor are common gross pathologic findings in cats that die from cytauxzoonosis.[8,19,31] The spleen and liver are often enlarged, and mesenteric lymph nodes may be enlarged and edematous.[8,19,31] The lungs are often wet and fail to collapse. Pleural effusion is sometimes identified, as is pericardial effusion.[32] Petechial hemorrhages are occasionally found on the serosal surface of organs.[8,33]

Although histopathology is not a commonly performed antemortem diagnostic test, a diagnosis of cytauxzoonosis is easily confirmed at necropsy by histopathology.[19,31,33] Numerous venules and capillaries, especially in the spleen, liver, and lungs, are occluded with markedly enlarged merozoite-distended mononuclear cells (Figure 76-7).[19,33,34] The germinal centers of

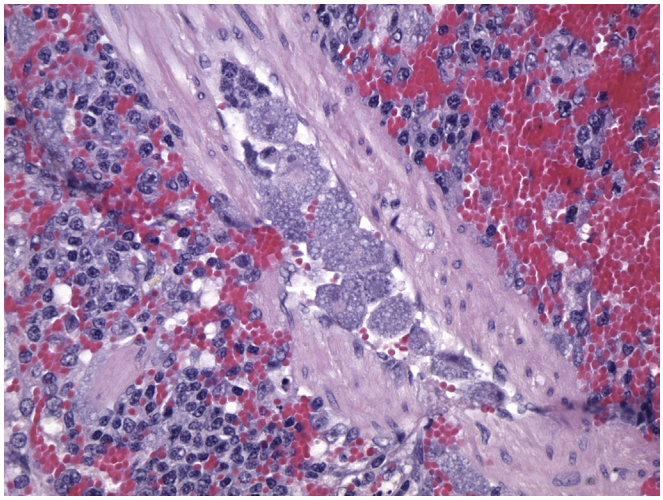

FIGURE 76-7 Histopathologic image of a section of spleen from a cat that died of cytauxzoonosis. Schizont-distended mononuclear cells obstruct blood vessels. H&E stain, 400× magnification. (Courtesy Dr. Linda Berent, University of Missouri Veterinary Medical Diagnostic Laboratory.)

lymphoid tissues contain many parasitized mononuclear cells as well, but organisms are not found in lymphocytes themselves.[8] Pulmonary lesions, which are common, are typified by moderate to severe vascular occlusion of medium-caliber vessels and interstitial pneumonia with edema and neutrophil accumulation.[35]

Treatment and Prognosis

Antiprotozoal Drugs

Currently, the treatment of choice for feline cytauxzoonosis is a combination of atovaquone suspension (Mepron, GlaxoSmithKline, Research Triangle Park, NC) and azithromycin (see also Chapter 10) (Table 76-2). Both drugs are administered orally for 10 days.[12] Although atovaquone is expensive, a single bottle will treat many cats. Compounding pharmacies may supply reasonably priced atovaquone in smaller quantities. In recovered carrier cats, the combination of atovaquone and azithromycin does not consistently eliminate parasitemia, but in most treated cats, pathogen burden drops to levels below PCR detection and piroplasms are no longer visible on peripheral blood smears.[19]

Other antiprotozoal therapies have been investigated for the treatment of cytauxzoonosis. Parvaquone and buparvaquone, both used to treat related *Theileria* infections, were ineffective for treatment of experimental cytauxzoonosis.[36] Imidocarb dipropionate has not proved to be an effective treatment for cytauxzoonosis; only 25% of cats treated with the drug survived.[12] Additionally, imidocarb does not reduce the parasite burden in carrier cats.[29] Diminazene aceturate is a drug used extensively in Africa, South America, and the far East for treatment of protozoal diseases. In a retrospective report, 5 of 6 cats treated with diminazene aceturate at 2 mg/kg IM, plus supportive care, survived acute cytauxzoonosis.[22] The author has used diminazene to treat four additional cats with cytauxzoonosis, and only one survived. Studies in naturally infected cats are difficult to conduct because this drug is not approved for use in the United States. As with imidocarb, diminazene aceturate was unable to eliminate or reduce parasitemia from healthy carrier cats.[21,30]

TABLE 76-2

Antimicrobial Drugs Indicated for Treatment of Feline Cytauxzoonosis

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Atovaquone/azithromycin combination:				
Atovaquone *and*	15	PO	8	10
Azithromycin	10	PO	24	10

Supportive Care

Cats with cytauxzoonosis are critically ill and require supportive care. Crystalloid fluids address dehydration, correct prerenal azotemia, and may improve organ perfusion but should be used judiciously in cats with evidence of pulmonary damage or pleural effusion. Whole blood or packed RBC transfusion is often necessary during the hemolytic stage of acute illness. Plasma administration may be useful in cats with DIC, and although the recommendation is controversial, some clinicians advocate treatment with heparin at 200 units/kg SC q8h.[12] Because affected cats may be severely febrile and apparently in pain, antipyretic, anti-inflammatory, and analgesic drugs are often used. Unfortunately, no controlled studies have examined whether these therapies improve or worsen clinical outcome. The author does not usually administer either glucocorticoids or nonsteroidal anti-inflammatory drugs but has treated cats with buprenorphine as an analgesic. There are numerous reports of antibacterial drugs used in the therapy of cats with cytauxzoonosis, but the drugs utilized (enrofloxacin, doxycycline, and/or sodium ampicillin) seem unlikely to have contributed substantially to any improved outcome.[19,37] Cats typically have a poor appetite during recovery from cytauxzoonosis. Early placement of a nasoesophageal or esophagostomy feeding tube not only allows for provision of enteral nutrition and hydration, but facilitates administration of oral medications (i.e., atovaquone and azithromycin) with minimal stress to the patient.

Prognosis

In the early history of the disease, treatment options for cytauxzoonosis were considered ineffective and the disease was regarded as uniformly fatal. However, it is now recognized that some cats become infected without recognized clinical illness, and others survive illness with supportive or specific medical care.[12,15,18,26,38] Either differences in the individual cat's immune response to infection or reduced pathogenicity of the infecting organism are possible explanations for chronic infection in cats with no history of prior illness. The latter theory is supported by finding many cats with chronic infection but no history of illness in a limited geographic region around northwestern Arkansas.[15,27,39]

Despite occasional recognition of subclinically infected cats, most infected cats become extremely ill and die in the absence of aggressive treatment.[19,39] Even when treated with atovaquone and azithromycin, only 60% of infected cats survive.[12] Because most cats that die despite therapy do so within a day of presentation, even the most active antiprotozoal compound may not prevent death in a proportion of infected cats once clinical illness is recognized.

Immunity and Vaccination

Cats that survive experimentally induced schizogenous infection appear to be immune to illness on re-infection, although experimental inoculation with piroplasms alone does not provide protection.[36,40,41] Resistance to re-infection with *C. felis* offers hope that successful vaccine development may be possible, but safe and effective vaccines against apicomplexan parasites are notoriously difficult to develop.[42] Inoculation of cats with a less pathogenic *Cytauxzoon* species *(C. manul)* failed to reduce mortality associated with *C. felis* challenge.[43] Many veterinarians in endemic regions have observed clinical illness indistinguishable from cytauxzoonosis in cats known to have survived cytauxzoonosis in previous years. Because no attempt has been made to look for schizonts in the cats experiencing a second illness, it is unclear if these cats have recrudescent cytauxzoonosis, re-infection, or some other illness altogether.

Prevention

For now, prevention relies on avoidance of tick exposure. Given the sensitivity of domestic cats to many commonly used ectoparasiticides, the arsenal of acaricides available for cats is limited to flumethrin-impregnated collars, fipronil, and possibly selamectin, although the latter does not make a label claim of efficacy against ticks in cats.[44,45] Given their potent activity against ticks and their safety in cats, flumethrin-impregnated collars offer the greatest potential for prevention of cytauxzoonosis in cats that reside in endemic areas. However, no ectoparasiticide prevents tick bites entirely.[12,46] Where possible, cats in endemic areas should be kept indoors to minimize tick exposure.

Recovered cats may remain carriers, and may serve as reservoirs for infection of naïve ticks.[6] For this reason, recovered cats should also be kept indoors and ectoparasite control practices instituted in order to minimize the risk of transmission to other cats via tick bite. Treatment of recovered cats with imidocarb dipropionate or diminazene aceturate does not reduce piroplasm parasitemia, but treatment with atovaquone and azithromycin may reduce the parasite burden and potentially reduce the risk of transmission to feeding ticks.[29,30]

Public Health Aspects

Cytauxzoon felis is not known to infect humans. However, infected cats have the potential to be infected with other vector-borne pathogens, so precautions should be taken to avoid needlestick injuries or direct skin contact with blood from infected cats.

CASE EXAMPLE

Signalment and History: "Ginger," a 2-year-old female spayed domestic longhaired cat that lived near Springfield, Missouri, was evaluated for a 1-day history of anorexia and lethargy in April of the year. The cat was an indoor/outdoor cat with no known history of tick exposure. There were no other cats in the household.

Physical Examination: On examination, the cat's rectal temperature was 105.6°F (40.9°C), with a heart rate of 200 beats/min and a respiratory rate of 28 breaths/min. The spleen was prominent on abdominal palpation and the nictitans was elevated (see Figure 76-3), but examination was otherwise unremarkable.

Laboratory Findings: Blood was obtained for a CBC and retrovirus testing. The cat tested negative for FeLV antigen and FIV antibody. The cat had a mild, nonregenerative anemia (PCV 27%) and leukopenia (4200 cells/µL, reference range 5500-19,500 cells/µL). Although the platelet count was low, platelet clumps were present. Plasma in the spun hematocrit tube was icteric. No parasites were observed on microscopic slide review.

Because of a high degree of suspicion for cytauxzoonosis, a fine-needle aspirate was obtained from the spleen. Multiple markedly enlarged mononuclear cells containing numerous merozoites were observed.

Diagnosis: Cytauxzoonosis.

Treatment and Outcome: A nasoesophageal tube was placed to facilitate administration of atovaquone suspension (15 mg/kg PO q8h) and azithromycin (10 mg/kg PO q24h). A cephalic vein catheter was placed and intravenous crystalloid fluids administered at a maintenance rate. Heparin (200 units/kg SC q8h) and buprenorphine (0.01 mg/kg SC q8h) were administered.

The following day, the cat's PCV was 20% and icterus was evident on physical examination. Additionally, many piroplasms were visible on cytologic analysis of a smear of peripheral blood. A serum chemistry profile confirmed hyperbilirubinemia and a mild increase in the activity of serum ALT but was otherwise unremarkable.

By day 3, the PCV was 12%, and both respiratory and heart rate were increased. The cat was administered a single unit of whole blood, after which the PCV increased to 19%. Nutritional support was administered via the nasoesophageal tube, but otherwise treatment remained unchanged.

On day 5, the PCV dropped to 11%, which necessitated another whole blood transfusion. The cat remained tachypneic after transfusion. Thoracic radiographs revealed pleural effusion and a marked diffuse interstitial lung pattern. The cat was treated with supplemental oxygen, and 25 mL of a clear, yellow, modified transudate was removed using thoracocentesis.

By day 7, the cat no longer required supplemental oxygen to maintain respiratory function, and the anemia was regenerative. The cat was discharged from the hospital on day 8 with continued administration of atovaquone and azithromycin at home, but all other treatments were discontinued.

On recheck examination 1 week later, the cat was seemingly normal to the owners, and no abnormalities were detected on physical examination. The PCV was 29%, platelet and WBC counts had normalized, and a single piroplasm was observed on careful review of the entire feathered edge of the blood smear. The cat's owners were advised to keep the cat entirely indoors and to use an ectoparasiticide regularly to minimize any risk that the cat could serve as a reservoir for infection of ticks. The cat remained healthy 1 year later.

CHAPTER 77

Canine and Feline Hepatozoonosis

Nancy Vincent-Johnson

VetBooks.ir

Overview of Canine Hepatozoonosis

First Described: *Hepatozoon canis,* India, 1905 (James)[1]; *Hepatozoon americanum,* USA, 1978 (Craig and others)[2]

Cause: *Hepatozoon canis, Hepatozoon americanum* (phylum Apicomplexa)

Affected Hosts: Domestic dogs, possibly some wild carnivores

Geographic Distribution: *H. americanum,* southeastern and south-central United States; *H. canis,* Asia, Africa, southern Europe, the Middle East, the Americas.

Mode of Transmission: Primarily by ingestion of tick vectors. For *H. americanum,* the vector is *Amblyomma maculatum;* for *H. canis,* the vector is *Rhipicephalus sanguineus*. Other tick species (*Amblyomma, Rhipicephalus,* and *Haemaphysalis* spp.) may also be involved.

Major Clinical Signs: Dogs with *H. americanum* infections most often show lethargy, fever, weight loss, locomotory abnormalities, hyperesthesia, mucopurulent ocular discharge, signs related to protein-losing nephropathy such as polyuria and polydipsia. Dogs with severe *H. canis* infections may show fever and lethargy.

Differential Diagnoses: Sterile or infectious meningitis, bacterial discospondylitis, Lyme borreliosis, canine monocytic ehrlichiosis, toxoplasmosis, sarcocystosis, systemic immune-mediated diseases such as systemic lupus erythematosus

Human Health Significance: Canine *Hepatozoon* species are not known to infect humans.

Etiology and Epidemiology

Apicomplexan protozoal parasites from the genus *Hepatozoon* include more than 300 species that infect a wide variety of amphibians, reptiles, birds, and mammals.[3] Despite its name, canine hepatozoonosis is not a zoonotic disease and rarely affects the liver. Canine hepatozoonosis is caused by one of two species of *Hepatozoon* currently known to cause disease in dogs, *Hepatozoon canis* and *Hepatozoon americanum* (compared in Table 77-1). First described in India in 1905, *H. canis* has long been known as the agent that infects dogs in many regions of the Old World, including Asia, Africa, southern Europe, and the Middle East, and more recently has been identified in the New World in both North and South America (Figure 77-1).[1,3-20] *Hepatozoon americanum* causes American canine hepatozoonosis, which occurs in dogs primarily in the southeastern and south-central United States. It was first confused with *H. canis* in 1978 in dogs from the Gulf Coast region of Texas and has subsequently been detected in dogs from Louisiana, Oklahoma, Alabama, Georgia, Florida, and Tennessee.[2,21-25] In 1997, it was identified as a distinct species, *H. americanum*.[26,27] Occasional cases have been identified in diverse locations across the United States, including Washington, California, Nebraska, Vermont, and Virginia.[17] Because infection is chronic, the infection may be diagnosed in dogs with a history of travel to endemic areas. The DNA of a *Hepatozoon felis*–like organism was detected in a dog from southern California, but the clinical significance and epidemiology of this organism are unknown.[28]

Recent reports indicate that *H. canis* also exists in the United States, although infection with *H. americanum* is diagnosed much more frequently. *H. canis* has been identified in dogs from Mississippi, Louisiana, Alabama, Georgia, Oklahoma, and Virginia and in a dog that lived in New Jersey but was born in a Texas shelter.[16,17,29] A few dogs have mixed infections with both *H. americanum* and *H. canis*. Domestic cats can also be infected by *Hepatozoon* spp., which include *H. felis* and possibly *H. canis* or closely related species (see later section on feline infections and Table 77-1).[30,31]

Because dogs or other vertebrates serve as intermediate hosts, a vector is needed to complete the sexual phase of the life cycle of *Hepatozoon* species. In the case of *H. americanum*, the definitive host is the Gulf Coast tick, *Amblyomma maculatum,* whereas the definitive host of *H. canis* is the brown dog tick, *Rhipicephalus sanguineus*.[32,33] In Japan, *Haemaphysalis* spp. ticks have been implicated as vectors of *H. canis*, and in Brazil, *Amblyomma ovale* and *Rhipicephalus (Boophilus) microplus* are suspected vectors.[34-36]

As it feeds on an infected dog, the nymphal tick ingests circulating leukocytes that contain gamonts. Within the tick's gut, the gamonts are freed from the cells and undergo further development before fertilization occurs. The resulting zygote divides through sporogony and develops into an oocyst within the hemocoel of the tick (Figure 77-2). Oocysts mature while the tick molts to the adult stage. In the case of *H. americanum,* the larval stage of the tick can also become infected, resulting in a nymph that contains viable oocysts capable of transmitting the disease.[37] Each mature oocyst contains hundreds of sporocysts, with each sporocyst containing 10 to 26 infective sporozoites. Unlike most tick-borne diseases, hepatozoonosis is not transmitted through the bite of an infected tick but rather by *ingestion* of an infected tick. This typically occurs when the dog grooms itself but can also occur if the dog feeds on tick-infested prey. Once ingested, exposure to bile in the dog's intestinal tract results in release of the sporozoites, which penetrate the intestinal epithelial wall and are transported to the target organs and tissues, likely within mononuclear cells.

TABLE 77-1

Comparison of *Hepatozoon canis* Infection, American Canine Hepatozoonosis, and Feline Hepatozoonosis

	H. canis Infection	American Canine Hepatozoonosis	Feline Hepatozoonosis
First described	India, 1905	Texas Gulf Coast, 1978	India, 1908
Etiologic agent	*Hepatozoon canis*	*Hepatozoon americanum*	Multiple poorly defined *Hepatozoon* sp.
Primary vector	*Rhipicephalus sanguineus* (brown dog tick)	*Amblyomma maculatum* (Gulf Coast tick)	Unknown
Route of transmission	Ingestion of tick (not a tick bite)	Ingestion of tick (not a tick bite)	Probably ingestion of tick (not a tick bite)
Additional routes of transmission	Transplacental from dam to puppy	Ingestion of cystozoites in transport hosts; transplacental is likely	Unknown
Affected mammalian hosts	Dogs, foxes, jackals, hyenas, other carnivores	Dogs, coyotes, possibly bobcats, ocelots, and other wildlife	Domestic cats, wild felids
Geographic distribution	Africa, Middle East, Asia, southern Europe, South America, United States	Primarily southern and southeastern United States	India, Africa, Israel, Brazil, Spain, France, Thailand, United States (Hawaii)
Severity of disease	Subclinical to mild; occasionally severe, esp. if immunosuppressed	Usually severe, even in absence of immunosuppression	Typically subclinical unless immunosuppressed
Major clinical signs	Lethargy, fever, weight loss	Fever, pain, lameness, ocular discharge	Nonspecific
Common laboratory abnormalities	Anemia Extreme leukocytosis is rare but may occur with high parasitemia	Marked leukocytosis (20,000-200,000 cells/μL), anemia, elevated ALP activity, low glucose concentration	Elevated CK activity
Radiographic lesions	Nonspecific; rare periostitis	Common; periosteal bone proliferation	Not reported
Histopathology findings	No muscle lesions "wheel-spoked" meronts in spleen, bone marrow, lymph nodes	Myositis, onion-skin cysts, pyogranulomas, and meronts in skeletal muscle	Meronts in myocardium and skeletal muscle
Blood smear findings	Gamonts common; parasitemia of 1%-5% is typical; rarely see parasitemia of 5%-100%	Rarely observed gamonts; parasitemia is usually <0.1%	Parasitemia is rare; when present usually <1% of neutrophils
Human health significance	None known	None known	None known

In *H. americanum* infections, infected cells preferentially travel to skeletal muscle, where each organism develops within its host cell, which becomes lodged between myocytes (Figure 77-3). Concentric layers of mucopolysaccharide are laid down by the host cell to form an "onion-skin cyst," which may protect the organism from the immune response (Figure 77-4). Merogony occurs within the cyst, and on maturation of the meront, the cyst ruptures, and merozoites are released. This elicits a severe inflammatory response, with recruitment of neutrophils and monocytes to the area. A pyogranuloma develops in the space where the cyst existed (Figure 77-5). Many of these inflammatory cells become infected with a single zoite. Angiogenesis within the pyogranuloma results in a highly vascular structure from which the infected cells can reenter circulation. The intracellular parasites can travel to other target sites, where they continue the asexual reproductive cycle, or they may become gamonts. The gamonts are then ingested by feeding ticks, which completes the life cycle. Some of the onion-skin cysts lie dormant for varying lengths of time; their activation is responsible for the waxing and waning nature of the disease as well as the relapse of clinical signs that can occur months after perceived clinical cure.

In *H. canis* infections, infected cells are carried by lymph or blood to the spleen, bone marrow, lymph nodes, and other organs such as the liver, kidney, and lungs where the organisms divide asexually through merogony (Figure 77-6). Two types of meronts form: the "wheel spoke" meront, which contains 20 to 30 micromerozoites which form around a central round structure (Figure 77-7), and a meront that contains up to four macromerozoites.[38] Once released from the mature meront, micromerozoites invade neutrophils and monocytes and become

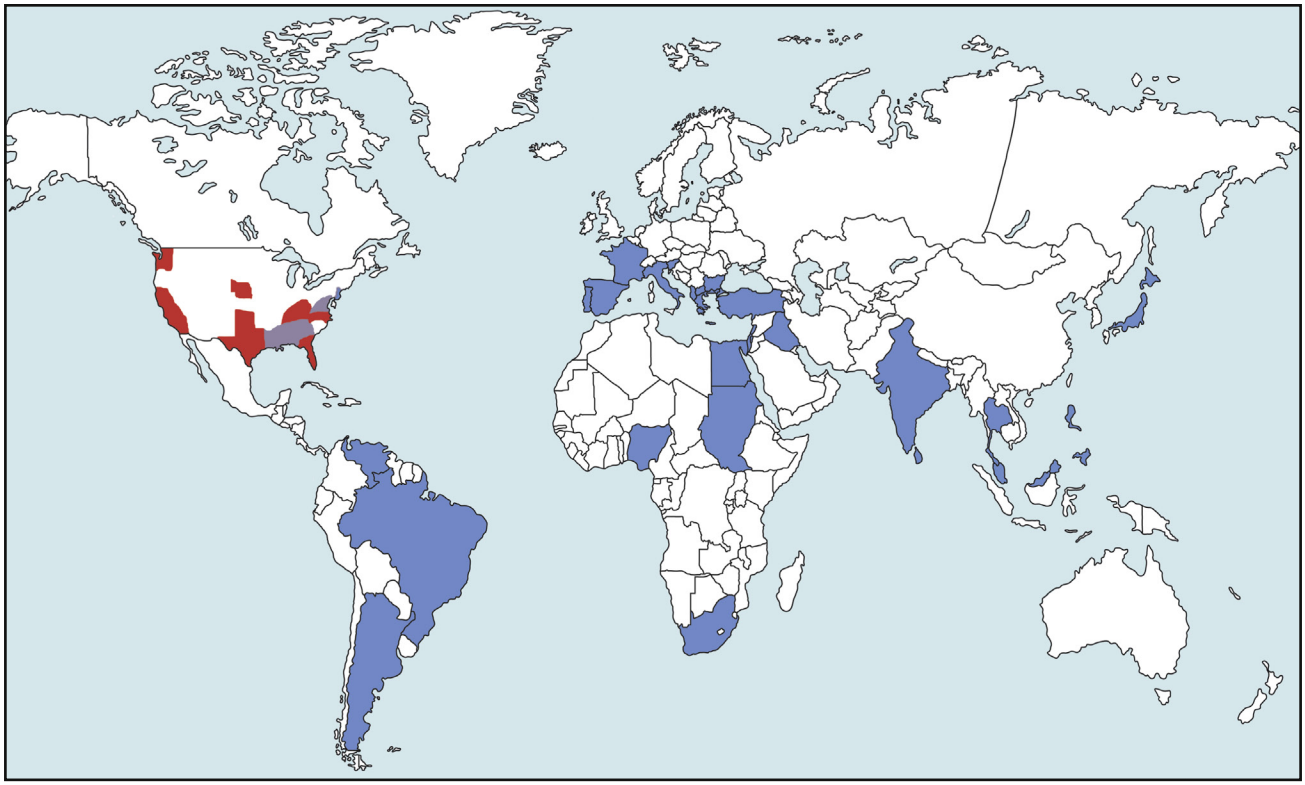

FIGURE 77-1 Geographic distribution of reported *Hepatozoon canis* and *Hepatozoon americanum* infections. Both species exist in the United States. (Blue, *Hepatozoon canis;* red, *Hepatozoon americanum;* purple both species.)

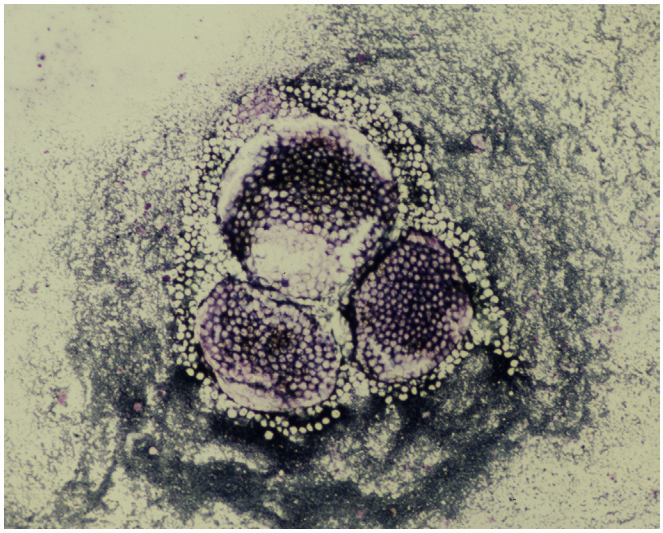

FIGURE 77-2 *Hepatozoon americanum* oocysts from the hemocoel of an *Amblyomma maculatum* tick. Hundreds of small, round sporocysts are present within each oocyst. Each sporocyst contains 10 to 26 infective sporozoites.

gamonts, which can then be ingested by feeding ticks (Figure 77-8). The larger macromerozoites are believed to be responsible for the production of secondary meronts in the target tissues, which continue the asexual cycle of merogony. Another tissue stage found in dogs with *H. canis* but not *H. americanum* infections is a small monozoic cyst that resembles the cystozoite found in transport hosts of other *Hepatozoon* species.[39]

Other modes of transmission also occur in hepatozoonosis. Transplacental transmission from dam to puppies has been documented for *H. canis* infections and likely occurs in *H. americanum* infections as well.[40] Ingestion of tissue from wild animals or prey may transmit *H. americanum*.[41-43] Laboratory rodents fed *H. americanum* oocysts developed cystozoites, but they did not develop gamonts or meronts or become ill. Cystozoite-laden rodent tissue fed to naïve dogs resulted in *H. americanum* infection along with its classical clinical signs. Investigation of a natural outbreak in a pack of hunting beagles revealed that clinical signs of American canine hepatozoonosis arose 4 to 6 weeks after some of the dogs were allowed to consume a wild rabbit carcass, whereas dogs not allowed to consume the rabbit did not develop clinical signs. The predation route of transmission has not yet been proven to occur with *H. canis*.

The geographic distribution of American canine hepatozoonosis aligns closely with the range of the Gulf Coast tick. Although this tick is endemic in the states that surround the Gulf of Mexico, its range is expanding and it has been found as far north as Kansas and Kentucky.[44] Larval and nymphal stages of *A. maculatum* preferentially feed on birds and small rodents. Surveys of wildlife have revealed the presence of *Hepatozoon* spp. that are related but not identical to *H. americanum* in small rodents and rabbits.[45] Although a reservoir species has not yet been identified, dogs are likely an aberrant, rather than natural, host of *H. americanum*. *H. americanum* or closely related species have been identified in coyotes, bobcats, and ocelots.[46-49] Because these wild animals were in good physical condition at the time of capture, they may represent a reservoir host in nature. In contrast to adult animals, coyote puppies developed classic signs of *H. americanum* infection after experimental transmission.[50]

VetBooks.ir

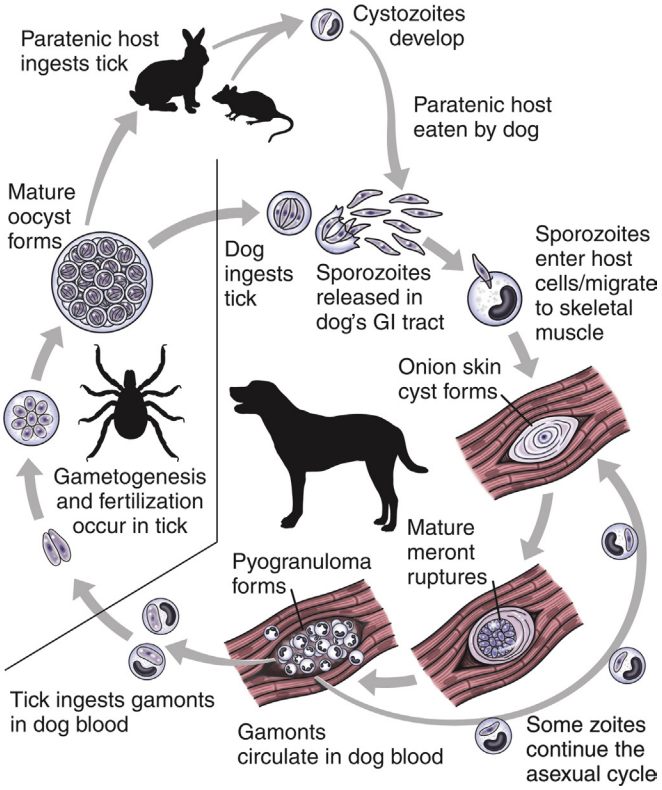

FIGURE 77-3 Life cycle of *Hepatozoon americanum*.

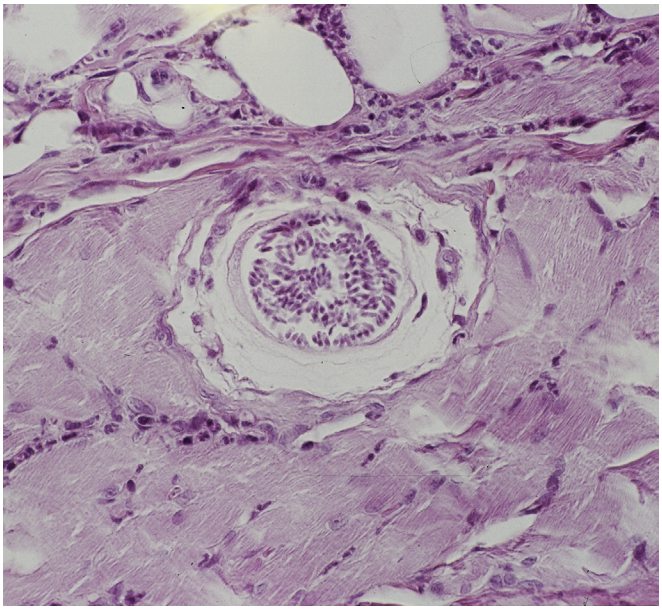

FIGURE 77-4 Skeletal muscle containing a developing meront of *H. americanum*. The mucopolysaccharide layers produced by the host cell protect the developing organisms from the host's immune system.

Dogs are believed to be the natural host reservoir of *H. canis*. The brown dog tick, which serves as the definitive host of *H. canis,* is found worldwide, and all three stages preferentially feed on dogs. Life stages of *H. canis* or morphologically indistinguishable *Hepatozoon* spp. have been reported in numerous carnivore species around the world, including several species of fox, jackal, African wild dog, hyena, palm civet, cheetah, leopard, lion, and Pallas cat.[30]

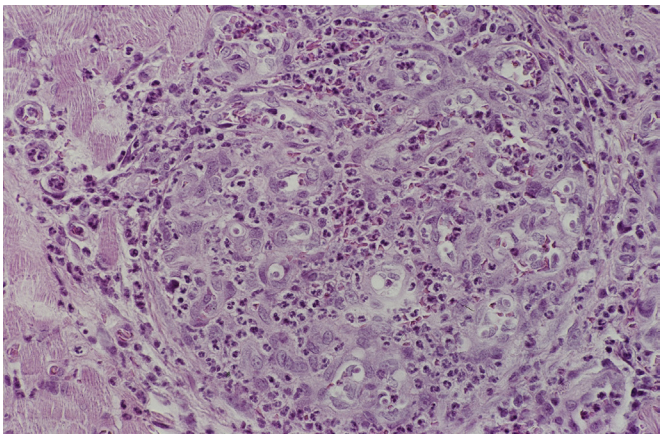

FIGURE 77-5 Pyogranuloma in skeletal muscle of a dog infected with *Hepatozoon americanum*. Zoites displace the nucleus in several of the inflammatory cells.

There is no sex or breed predilection for hepatozoonosis, but hunting dogs, rural dogs, and dogs allowed to roam are most at risk.

Clinical Features

Signs and Their Pathogenesis

Dogs with *H. americanum* infection exhibit a moderate to severe illness, whereas most dogs infected with *H. canis* have no or only mild signs of illness. Immunosuppression or concurrent disease is an important factor in expression of illness in *H. canis* but not in *H. americanum* infections. Co-infections with other pathogens such as *Ehrlichia, Babesia, Anaplasma, Leishmania,* parvovirus, or canine distemper virus can allow establishment of a new *H. canis* infection as well as progression or reactivation of an existing infection.

Clinical signs of *H. americanum* infection are associated with the strong inflammatory response that occurs when meronts rupture, leukocytes are recruited, and pyogranulomas form in skeletal muscle. The earliest lesions occur 3 weeks after infection.[51] As the organisms multiply, the infection disseminates, which results in more severe inflammation that waxes and wanes over time. The inflammation causes fever and myositis, which is associated with locomotor abnormalities and hyperesthesia (Table 77-2). The clinical signs can mimic those of meningitis or discospondylitis. Many affected dogs also develop bone lesions that are evident radiographically and resemble lesions seen in hypertrophic osteopathy, except they are proximal rather than distal in distribution (Figure 77-9). It is unknown whether the bone lesions result from nearby localized muscle inflammation or from humoral factors. Dogs usually have a mucopurulent ocular discharge that may be caused by pyogranulomatous inflammation of the extraocular muscles or of the lacrimal gland (Figure 77-10). Return of ocular discharge is frequently the first indication of a relapse following treatment. Dogs with American canine hepatozoonosis frequently maintain a fairly normal appetite; however, weight loss, cachexia, and muscle atrophy occur over time. There may be a history of polyuria and polydipsia that is due to glomerulonephritis or amyloidosis, which can occur secondary to long-standing inflammation. Nephrotic syndrome and thromboembolic complications may ensue. Less common clinical signs include

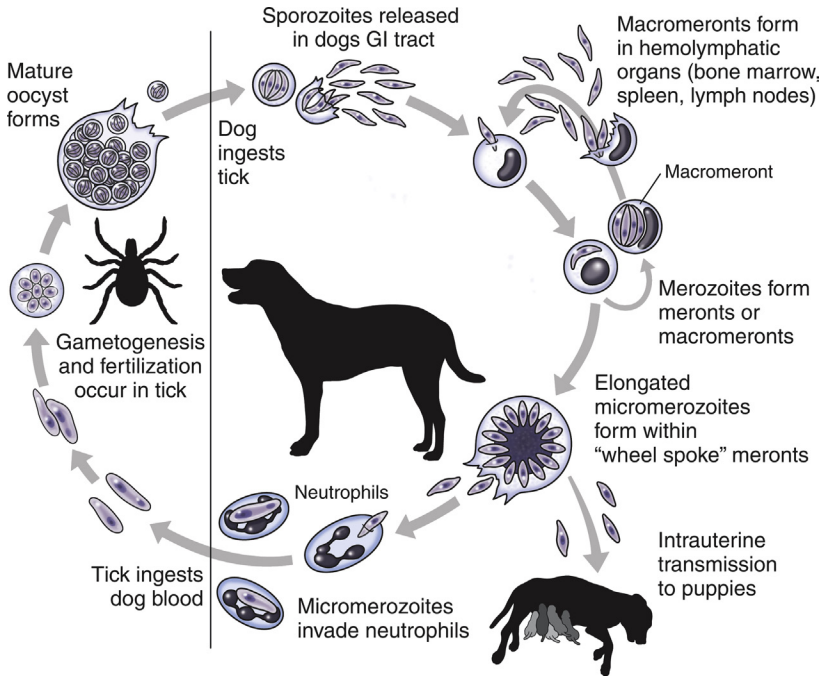

FIGURE 77-6 Life cycle of *Hepatozoon canis.*

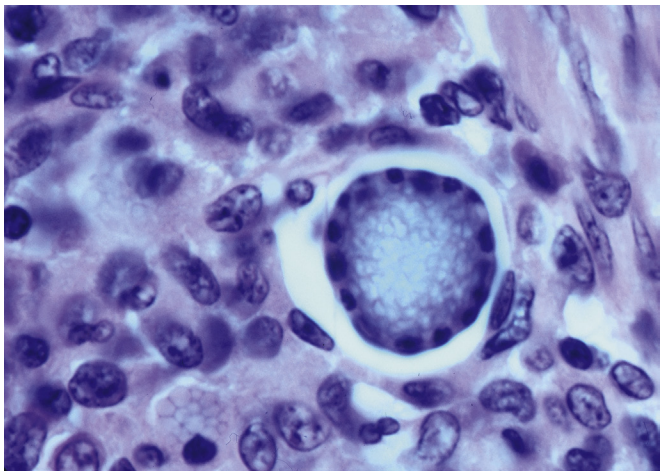

FIGURE 77-7 *Hepatozoon canis* meront in splenic tissue of a dog from Israel demonstrating the typical "wheel spoke" pattern. (Courtesy of Dr. Gad Baneth, Koret School of Veterinary Medicine, Israel.)

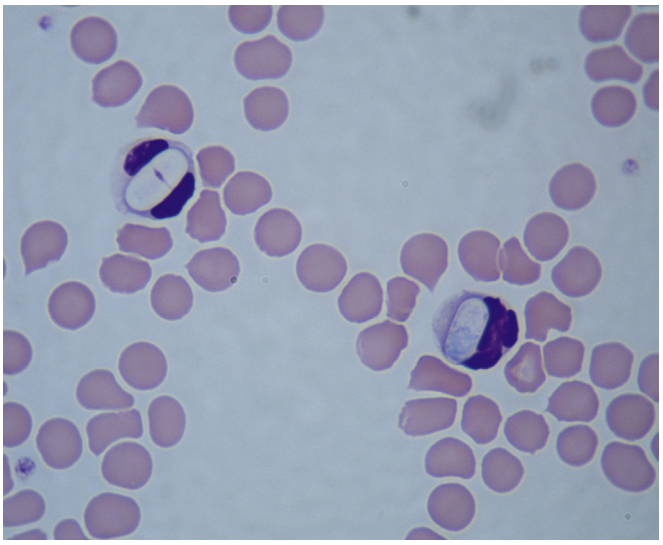

FIGURE 77-8 Two *Hepatozoon canis* gamonts in neutrophils on a blood smear. The gamonts of *Hepatozoon americanum* are nearly identical in appearance to those of *H. canis,* although they are rarely seen. 1000x magnification. (Courtesy of Dr. Gad Baneth, Koret School of Veterinary Medicine, Israel.)

diarrhea, mucosal pallor, cough, abnormal lung sounds, and lymphadenomegaly.

Most dogs infected with *H. canis* have a low level of parasitemia, with less than 5% of circulating leukocytes infected with gamonts.[52] These dogs have a limited inflammatory reaction. About 15% of parasitemic dogs have a high level of parasitemia (>800 gamonts/μL). The degree of parasitemia correlates with the severity of clinical signs; the sickest dogs have a level of parasitemia that approaches 100% of infected circulating leukocytes. These dogs may have hepatitis, glomerulonephritis, or pneumonitis in addition to severe anemia, fever, and cachexia.

Physical Examination Findings

With *H. americanum* infection, fever (up to 105.6°F or 40.9°C) is common, although because of the waxing and waning nature of the disease, body temperature may be normal at any given time.[23] Because of the myositis, dogs are typically evaluated for gait abnormalities, which range from lameness or stiffness to recumbency and an inability to rise. Hyperesthesia is common and may appear as cervical, back, joint, or generalized pain. Lethargy is common, and cachexia and generalized muscle atrophy may be apparent. Mucopurulent ocular discharge is often present. Other ocular lesions seen on occasion include focal retinal scars or hyper-reflectivity, increased retinal pigmentation, papilledema, and uveitis with active inflammatory fundic lesions. Mucosal pallor and lymphadenomegaly may also be present.

VetBooks.ir

TABLE 77-2

Frequency of Clinical Signs in 22 Dogs with American Canine Hepatozoonosis

Clinical Sign	Number of Dogs (%)
Fever	19 (86)
Weight loss	18 (82)
Mucopurulent ocular discharge	17 (77)
Low tear production	8 (36)
Muscle atrophy	14 (64)
Pain (all types)	14 (64)
Joints	2 (9)
Lumbar	4 (18)
Cervical	5 (23)
Generalized	3 (14)
Stiffness	12 (55)
Generalized weakness	9 (41)
Pelvic limb paresis and ataxia	5 (23)
Inability to rise	5 (23)
Anorexia	5 (23)

From Vincent-Johnson NA. American canine hepatozoonosis. Vet Clin North Am Small Anim Pract. 2003;33:905-920. Data from Macintire DK, Vincent-Johnson N, Dillon AR, et al. Hepatozoonosis in dogs: 22 cases (1989-1994). J Am Vet Med Assoc. 1997;210:916-922.

Dogs with mild *H. canis* infections may have pale mucous membranes and lethargy. Dogs with high parasitemia often exhibit fever, lethargy, and severe weight loss or cachexia, even if they maintain a good appetite. Splenomegaly and lymphadenomegaly may be detected. Dogs often have physical examination abnormalities that relate to the presence of co-infections or other comorbidities.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

The most common laboratory abnormality in *H. americanum* infection is leukocytosis, which is often extreme (Table 77-3). White cell counts are typically 20,000 to 200,000 cells/μL, with reported means of 76,807 and 85,700 cells/μL.[23,53] The leukocytosis is due to a mature neutrophilia, although sometimes there is a mild to moderate left shift. A mild normocytic, normochromic nonregenerative anemia is typical. Platelets are usually normal to increased, sometimes with thrombocytosis up to 916,000 platelets/μL. When thrombocytopenia is evident, concurrent tick-borne diseases such as ehrlichiosis should be considered.

The most common laboratory finding in *H. canis* infection is anemia, which is usually normocytic, normochromic, and occasionally regenerative.[52] Platelets are decreased about one third of the time, but this may be due to concurrent infection with *Ehrlichia canis* or other disease. The white blood cell count is typically normal in cases with low parasitemia but is elevated in dogs with high parasitemia. Some dogs have neutrophil counts of 50,000 to 150,000/μL with close to 100% of these cells containing gamonts.

FIGURE 77-9 Radiograph of the pelvic limb of a dog with *Hepatozoon americanum* infection. There is smooth periosteal proliferation on the cranial aspect of the femur. (From Vincent-Johnson NA. American canine hepatozoonosis. Vet Clin North Am Small Anim Pract. 2003;33:905-920.)

FIGURE 77-10 Rottweiler with *Hepatozoon americanum* infection. Note the hunched appearance, muscle atrophy, and mucopurulent ocular discharge.

Serum Chemistry Profile

In *H. americanum* infection, a mild elevation in the activity of ALP is typical, possibly due to periosteal new bone formation. Serum glucose concentration is often decreased (40 to 60 mg/dL) and occasionally as low as 5 mg/dL. This is not a true hypoglycemia, but rather a laboratory artifact due to

VetBooks.ir

TABLE 77-3

Frequency of Laboratory and Radiographic Findings in 22 Dogs with American Canine Hepatozoonosis

Finding	Number of Dogs (%)
Moderate to marked leukocytosis*	22 (100)
Mature neutrophilia	15 (68)
Mild left shift	7 (31)
Elevated ALP activity	22 (100)
Hypoglycemia	20 (91)
Hypoalbuminemia	19 (86)
Periosteal proliferation on radiography	18 (82)
Anemia (nonregenerative)	14 (64)
Hypocalcemia	14 (64)
Normal platelet count	11 (50)
Thrombocytosis	9 (41)
Hyperphosphatemia	7 (32)
Low BUN concentration	7 (32)
Hyperglobulinemia	4 (11)
Hypercalcemia	2 (9)
Elevated CK activity	1 (5)

From Vincent-Johnson NA. American canine hepatozoonosis. Vet Clin North Am Small Anim Pract. 2003;33:905-920. Data from Macintire DK, Vincent-Johnson N, Dillon AR, et al. Hepatozoonosis in dogs: 22 cases (1989-1994). J Am Vet Med Assoc. 1997;210:916-922.
*Minimum white cell count was 27,800 cells/μL.

utilization of glucose in the specimen by the high number of white blood cells. Hypoalbuminemia is common and may be due to chronic inflammation, decreased protein intake, or renal loss from secondary glomerulonephritis or amyloidosis. Except in dogs with significant renal damage, BUN concentration is often low. The combination of increased activity of serum ALP and low glucose, BUN, and albumin concentrations may mislead the clinician to suspect liver disease. Serum bile acid concentrations are normal or only slightly elevated. Surprisingly, the activity of serum CK is consistently within the normal range even though *H. americanum* infection causes severe myositis.

Common serum chemistry findings in *H. canis* infection include hyperproteinemia, hyperglobulinemia, and hypoalbuminemia. The hyperglobulinemia is due to a polyclonal gammopathy.[52,54] Increases in the activities of ALP and CK are usually present.

Diagnostic Imaging

Plain Radiography

Many dogs with *H. americanum* infection show radiographic abnormalities of the skeletal system; therefore, radiographs of the pelvis or long bones can be useful to support a clinical diagnosis of American canine hepatozoonosis. Young dogs are more likely than older dogs to show bone lesions. In experimental infections, bone lesions are recognizable histologically within 5 weeks postexposure.[55] Disseminated, symmetric periosteal new bone formation occurs most frequently and severely on the diaphysis of long bones but occurs to a lesser degree on flat and irregular bones. The radiographic appearance can vary from subtle irregular periosteal exostoses to thick parallel pseudocortices. *H. americanum* infection typically affects the more proximal bones while sparing the distal bones.[56]

In *H. canis* infections, radiographic bone lesions are rare. Periostitis has only been described in three reports from Japan, India, and Italy, and in an experimental infection in Israel.[4,57]

Microbiologic Testing

Diagnostic assays currently available for hepatozoonosis in dogs are described in Table 77-4.

Cytologic Diagnosis

The sexual stage of *H. americanum* and *H. canis*, the gamont, appears as a light blue to clear oblong structure with a faintly staining nucleus within the cytoplasm of neutrophils or monocytes stained with Diff Quik or Giemsa. The gamonts of the two species look nearly identical, although there is a slight difference in size: *H. canis* gamonts measure approximately 11.0 × 4.3 μm while *H. americanum* gamonts are slightly smaller at 8.8 × 3.9 μm.[26]

In dogs with *H. americanum* infection, gamonts are rarely found within monocytes or neutrophils on peripheral blood smears. When present, infected cells rarely exceed 0.1% of the circulating leukocytes; several thousand cells may have to be examined before an infected cell is found. The chance that gamonts are detected can be increased by examination of buffy-coat smears. Neither bone marrow nor lymph node aspirates are of much value in making a definitive diagnosis of *H. americanum* infection; organisms are not usually seen in these specimens.

In most dogs with *H. canis* infections, gamonts are found on blood smear examination in 0.5% to 5% of neutrophils and monocytes. Parasitemia may approach 100% in heavy infections. Gamonts may also be identified in dogs that are apparently healthy.

Serologic Diagnosis

An ELISA assay for detection of antibodies to *H. americanum* has been developed at Oklahoma State University for research purposes, but this assay is not available commercially to veterinary practitioners.[58] Both an indirect immunofluorescent antibody (IFA) assay and ELISA assays for *H. canis* antibodies have been developed and used for epidemiologic studies in countries outside of the United States.[59-62] Positive serologic test results indicate exposure but do not prove active infection or correlate with clinical disease. Thus, serologic testing is mostly of use for epidemiologic studies and for screening blood donor animals.

Molecular Diagnosis Using the Polymerase Chain Reaction

A real-time PCR assay that detects *Hepatozoon* spp. is available commercially to veterinary practitioners through the Auburn University Molecular Diagnostics Laboratory.[63] Other commercial veterinary diagnostic laboratories also offer real-time PCR assays for detection of *Hepatozoon* species. The assay performed at Auburn University detects as few as seven genomic copies of *Hepatozoon* spp. per mL of blood, and it distinguishes between infection with *H. canis* and *H. americanum*.[16,17] Although highly sensitive and specific, false negatives can occur early in the course of infection or in dogs with chronic disease where the numbers of circulating gamonts are extremely low or absent. Muscle biopsy should be performed in dogs suspected

VetBooks.ir

TABLE 77-4

Diagnostic Assays Currently Available for Hepatozoonosis in Dogs

Assay	Specimen Type	Target	Performance
Cytologic examination	Whole blood smears	*Hepatozoon* spp. gamonts in leukocytes	False negatives are common because of low circulating numbers of gamonts, especially in clinical *H. americanum* infections.
Antibody serology (ELISA or immunofluorescent antibody)	Serum	Antibodies to *H. canis*	Positive test results indicate exposure but do not indicate the presence of the organism in circulating leukocytes and do not correlate with clinical disease.
Real-time PCR assays	Whole blood	*H. americanum* or *H. canis* DNA	Sensitivity and specificity may vary depending on assay design, but in general PCR assays are more sensitive than cytology. False-negative results may occur when organism levels are very low, such as early in disease or in very chronic infections.
Histopathology	Muscle biopsy specimens	*H. americanum* cysts, meronts, and pyogranulomas	Most reliable method of diagnosis of *H. americanum* infection, but requires anesthesia.

to have *H. americanum* infection but that have negative PCR assay results.

Pathologic Findings

Gross Pathologic Findings

In dogs with *H. americanum* infection, muscle atrophy and cachexia are consistent findings on gross necropsy examination. Pyogranulomas may appear as multiple 1- to 2-mm–diameter white-tan foci.[23] These are scattered diffusely throughout skeletal and cardiac muscle but may also be observed in other tissues. Roughening and thickening of bony surfaces are often present. Less common findings include lymphadenomegaly, congestion of the gastric mucosa, splenic coagulative necrosis, and pulmonary congestion.

In dogs with *H. canis* infection, the spectrum of gross pathologic lesions depends on the severity of the infection. In heavy infections, splenomegaly and hepatomegaly are common findings and these organs often exhibit diffuse white necrotic foci that are 1 to 2 mm in diameter.[14] The necrotic areas may be larger and nodular and can also be found in other tissues, such as pancreas and pleura. Lymphadenomegaly is common, and pneumonia may be present.

Histopathologic Findings

For *H. americanum* infections, muscle biopsy has long been considered the most reliable method for diagnosis. Small pieces of muscle (approximately 2 cm × 2 cm) are obtained from the biceps femoris or semitendinosus muscles under general anesthesia.[25] Submission of multiple specimens increases sensitivity, especially in low-level infections. Muscle lesions consist of large onion-skin cysts, pyogranulomas, and myositis. The cysts are round to oval and have mean cross-section dimensions of 186 × 150 µm.[26] At the center of the cyst is a host cell nucleus and protozoa, but depending on the plane of the cut surface, these may or may not be visible. Surrounding the center of the cyst are concentric layers of mucopolysaccharide. Occasionally meronts in various stages of development are observed within these cystic structures. The highly vascular pyogranulomas are packed with neutrophils and macrophages, many of which contain a single zoite. Myositis is characterized by muscle necrosis and atrophy with infiltration of neutrophils, macrophages, and occasional lymphocytes between muscle fibers. Although consistently identified in skeletal and cardiac muscle, *H. americanum* cysts, meronts, and pyogranulomas can sporadically be found in adipose tissue, intestinal smooth muscle, pancreas, liver, lymph node, spleen, skin, salivary gland, lung, and kidney.[64] Renal damage is common and manifests as focal pyogranulomatous inflammation with mild glomerulonephritis, lymphoplasmacytic interstitial nephritis, mesangioproliferative glomerulonephritis, or occasionally amyloidosis. Amyloid deposits have also been found in the spleen, lymph nodes, small intestines, and liver of affected dogs. Various organs can show vascular changes, which include fibrinoid degeneration of vessel walls, mineralization and proliferation of the vascular intima, and pyogranulomatous vasculitis.

In *H. canis* infections, "wheel-spoked" meronts are present in varying numbers and stages of development throughout hemolymphatic target organs, such as bone marrow, spleen, and lymph nodes. The meronts are approximately 30 µm in diameter and on central cross-section appear as a circle of micromerozoite nuclei surrounding a central core. Meronts can be found in small numbers as an incidental finding in dogs from endemic areas.[65] Inflammation associated with meronts can range from none to very severe. In heavy infections, microscopic lesions may include hepatitis with Kupffer's cell hyperplasia and inflammatory infiltrates, interstitial pneumonia and thickening of alveolar septae with inflammatory infiltrates, glomerulonephritis or interstitial nephritis with multifocal necrosis, and focal splenic necrosis.

Treatment and Prognosis

Although no treatment effectively eliminates the tissue stages of *H. americanum*, remission of clinical signs can be achieved using a combination of a trimethoprim-sulfa, clindamycin, and pyrimethamine for 14 days (Table 77-5).[66] Response to therapy is usually dramatic, with resolution of clinical abnormalities within 48 to 72 hours of initiating therapy. Ponazuril

TABLE 77-5

Antimicrobial Drugs Indicated for Treatment of American Canine Hepatozoonosis

Drug	Dose* (mg/kg)	Route	Interval (hours)	Duration (days)
TCP combination:				
Trimethoprim-sulfonamide *and*	15	PO	12	14
Clindamycin *and*	10	PO	8	14
Pyrimethamine *and*	0.25	PO	24	14
Decoquinate†	10-20	PO	12	730

Adapted from Baneth G, Macintire DK, Vincent-Johnson N, et al. Hepatozoonosis. In Greene CE, ed. Infectious Diseases of the Dog and Cat, 3 ed. St. Louis, MO: Saunders; 2006:698-711.

TCP, Trimethoprim-sulfadiazine, clindamycin, and pyrimethamine; *PO*, by mouth.

*Dose per administration at specified interval.

†Use the decoquinate 6% (27.2 g/lb) powder, Deccox (Alpharma Inc., Fort Lee, NJ). One teaspoonful is equivalent to approximately 180 mg decoquinate. Administer at a rate of 1 teaspoon per 10 kg of body weight and feed q12h mixed into moist dog food.

(10 mg/kg PO q12h for 14 days) is an alternative therapeutic option.[67] Either of these protocols must be followed by long-term administration of decoquinate in order to prevent relapse. Without the addition of decoquinate, relapse occurs in most dogs 2 to 6 months following treatment. Although these dogs generally respond well to another round of combination therapy, subsequent relapses occur more frequently, and eventually disease becomes refractory to treatment. Persistent infections and multiple relapses lead to complications such as glomerulonephropathy, amyloidosis, vasculitis, and cachexia, which carry a guarded to poor prognosis. Decoquinate, a livestock anticoccidial agent, apparently breaks the asexual recycling of infection by arresting development of the merozoites after their release from meronts. Two years of daily decoquinate therapy is recommended.[66] Alternatively, a PCR assay can be performed every 3 to 6 months, and when the PCR becomes negative, treatment can be discontinued. Mild relapses can occur even during treatment with decoquinate. If clinical signs are severe, another course of combination therapy is indicated. Long-term administration of decoquinate results in extended survival times and excellent quality of life with a good prognosis. During the initial few days of treatment with either antiprotozoal regimen, administration of a nonsteroidal anti-inflammatory drug at standard dosages can provide relief from fever and pain.

Hepatozoon canis infections are treated with imidocarb dipropionate (5 to 6 mg/kg SC or IM every 14 days) until gamonts are no longer seen on blood smear examination.[52] Although some dogs require only one or two treatments, at least 8 weeks of treatment may be required for dogs with heavy infections. Doxycycline (10 mg/kg/day PO for 21 to 28 days) is frequently given in conjunction with imidocarb dipropionate. It has been recommended that all dogs, even those with only mild disease, be treated, because parasitemia may increase over time. A recent study showed that despite negative blood smears, dogs remained positive by PCR or buffy-coat examination even when treated repeatedly over 8 months.[68] This study also found that buffy-coat examination was twice as sensitive as blood smear examination in detecting gamonts, and PCR was even more sensitive for detection of persistent infection. Addition of toltrazuril does not seem to provide any additional benefit to imidocarb therapy.[69] Despite lack of a parasitologic cure, clinical cure is achieved in many dogs. Dogs with low parasitemia generally have a good long-term prognosis for survival, whereas those with high parasitemia have a guarded prognosis.

Immunity and Vaccination

Current treatments do not cure *H. americanum* or *H. canis* infections, so dogs remain susceptible to relapse of disease, especially if immunosuppressed. In experimental *H. canis* infections, treatment with an immunosuppressive dose of glucocorticoids was followed by the appearance of parasitemia.[33] Vaccines for *H. americanum* or *H. canis* infections are not available.

Prevention

Since both *H. canis* and *H. americanum* are transmitted by ingestion of ticks, the use of topical acaricides, environmental parasiticides, and immediate removal of ticks from dogs are the most important means of prevention. Because *H. americanum*, and possibly *H. canis*, can also be transmitted through ingestion of cystozoites in muscle from other animals, dogs should not be allowed to roam, scavenge, or engage in predatory behavior. Dogs should not be fed uncooked or undercooked game meat. Although *Hepatozoon* spp. have not been shown to be transmitted through blood transfusion, it seems logical that dogs infected with *Hepatozoon* species be avoided as blood donor dogs. To prevent congenital infections of puppies, infected females either should not be bred or should receive treatment before breeding.

Public Health Aspects

Only one case of human infection with a *Hepatozoon* spp. has been reported. Gamonts were identified on blood smears of an adult man from the Philippines who suffered from anemia and icterus, but no parasites were found in liver or bone marrow biopsies.[70] Because hepatozoonosis is transmitted by tick ingestion rather than a tick bite, tick ingestion is an unlikely route of transmission for humans. However, caution should be used when removing ticks from dogs or when handling tick-infested dogs or blood from infected dogs because of the

unknown zoonotic potential of organisms that cause canine disease and the possibility that known human pathogens may also be present.

Hepatozoonosis in Domestic Cats

Feline hepatozoonosis occurs primarily in areas where canine hepatozoonosis exists, and it has been reported in a number of countries, including India, South Africa, Nigeria, Brazil, Israel, Spain, France, and Thailand.[30,31] In the United States, there is one report of hepatozoonosis in a domestic cat from Hawaii.[71] A survey of blood specimens from stray cats in Bangkok, Thailand, showed that 32.3% were positive by PCR for a *Hepatozoon* sp. most closely related to *H. canis*, whereas only 0.7% of the cats had gamonts observed on blood smears.[7] In Israel, *Hepatozoon* DNA was amplified from the blood of 36% of 152 cats, and infected cats were significantly more likely to have access to the outdoors.[31] The vast majority of cats were infected with an organism that resembled *H. felis*, although 2 cats were infected with an organism that resembled *H. canis*. Most infections were subclinical. Meronts have also been found in the myocardium and skeletal muscles of cats with no signs of illness. Cats with clinical hepatozoonosis are commonly immunosuppressed because of infection with FIV or FeLV. A range of clinical signs has been reported, including weakness, intermittent anorexia, weight loss, fever, lymphadenomegaly, ulcerative glossitis, hypersalivation, anemia, serous ocular discharge, and icterus. Treatment success has been reported with oral doxycycline at 5 mg/kg PO once a day for 10 days.[72]

CASE EXAMPLE

Signalment: "Pepper," a 1.5-year-old male miniature schnauzer from Opelika, AL (Figure 77-11)

History: Pepper was seen for a 1-month duration of illness characterized by intermittent fever (104.0°F to 105.0°F [40.0°C to 40.6°C]), lethargy, and ocular discharge. His owner reported that Pepper had also been stiff and reluctant to move. Despite a fairly good appetite, he had lost weight and muscle mass. The fever and other clinical signs had been nonresponsive to antibiotics, which included enrofloxacin and doxycycline, prescribed at the onset of illness. Pepper was a house dog but spent time outdoors in a rural environment. No vomiting, coughing, or sneezing had been reported, but he had had mild diarrhea at the onset of illness that resolved after a week. He had also had a mild increase in thirst and urination. He was fed a high-quality commercial dry dog food, received monthly heartworm preventive, and was current on all vaccinations, including canine distemper, hepatitis, parvovirus, and rabies vaccines. He had not traveled outside of the local area. The owner mentioned that she had had another dog that died about 1 year earlier after exhibiting similar clinical signs, but a diagnosis was not made.

Current medications: Aspirin 11 mg/kg PO q12h for pain.

Physical Examination:

Body Weight: 7.6 kg.

General: Quiet, slightly lethargic, but responsive. Reluctant to walk or stand; appeared painful. T = 103.8°F (39.9°C), HR = 96 beats/min, RR = 32 breaths/min, mucous membranes pink, CRT = 1.5 s.

Integument: The skin and haircoat appeared normal with no evidence of ectoparasites.

Eyes, Ears, Nose, and Mouth: A moderate amount of mucopurulent ocular discharge was present bilaterally. No other abnormalities were identified.

Musculoskeletal: Body condition score was 3/9 with moderate generalized muscle atrophy. The dog exhibited hyperesthesia during palpation of trunk, head, neck, and limb muscles. The dog's gait was very stiff and slow.

All Other Systems: Apart from abdominal splinting on palpation of the abdomen, no clinically significant abnormalities were present.

FIGURE 77-11 "Pepper," a 1.5-year-old male miniature schnauzer with *H. americanum* infection.

Ophthalmic Exam: Pupillary light reflex (direct and consensual): Normal.

Conjunctiva: injected bilaterally, mucopurulent discharge bilaterally.

Cornea and lens: Normal.

Schirmer Tear Test: Right eye = 18 mm; left eye = 16 mm (normal > 15 mm).

Fluorescein stain: Negative.

Tonometry: Normal.

Fundoscopic examination: A small grayish, slightly raised focal lesion was identified in the right fundus.

Laboratory Findings:

CBC:

PCV 38.7% (37%-55%)
MCV 68.7 fL (60-77 fL)
MCHC 35.4 g/dL (32-36 g/dL)
WBC 39,200 cells/µL (6000-17,000 cells/µL)
Neutrophils 35,672 cells/µL (3000-11,400 cells/µL)
Lymphocytes 1176 cells/µL (1000-4000 cells/µL)
Monocytes 2352 cells/µL (150-1200 cells/µL)
Eosinophils 0 (100-750 cells/µL)
Platelets 607,000 platelets/µL (200,000-400,000 platelets/µL).
The clinical pathologist's blood smear review showed no evidence of microorganisms.

VetBooks.ir

Serum Chemistry Profile:
BUN 8 mg/dL (10-25 mg/dL)
Creatinine 0.6 mg/dL (0.3-1.0 mg/dL)
ALP 142 U/L (19-50 U/L)
ALT 37 U/L (17-66 U/L)
Creatine kinase 148 U/L (92-357 U/L)
Total bilirubin 0.3 mg/dL (0.1-0.3 mg/dL)
Glucose 52 mg/dL (80-100 mg/dL)
Sodium 153 mmol/L (146-160 mmol/L)
Potassium 4.7 mmol/L (3.5-5.9 mmol/L)
Chloride 118 mmol/L (108-125 mmol/L)
Calcium 10.3 mg/dL (9.5-11.8 mg/dL)
Phosphorus 3.9 mg/dL (3.3-5.8 mg/dL)
Total protein 6.4 g/dL (5.1-7.3 g/dL)
Albumin 2.7 g/dL (2.6-3.5 g/dL)
Globulin 3.7 g/dL (3.6-5.0 g/dL)
Total CO_2 21.8 mmol/L (13.9-31.5 mmol/L).

Urinalysis: SGr 1.035; pH 8.0, protein 1+, bilirubin negative, hemoprotein negative, glucose negative, 0 WBC/HPF, 0 RBC/HPF, no crystals, moderate lipid droplets.

Imaging Findings:

Pelvic Radiographs: Bilateral smooth periosteal bone formation was present on the ilium and femurs.

Abdominal Ultrasound Examination: No abnormalities were detected.

Bone Marrow Aspirate: The bone marrow smears were highly cellular with many particles. Megakaryocytes were adequate. In a 500-cell count, the M:E ratio was 1.7 (reference range 1.3-2.1) with normal maturation sequences in both red and white series. Multiple smears examined showed no evidence of microorganisms.

Muscle Biopsy: Histopathology showed infiltration of neutrophils and monocytes between muscle fibers. There were rare onion-skin cysts and one focal pyogranuloma. Many of the monocytes and neutrophils within the granuloma contained a single zoite. Findings were consistent with *Hepatozoon americanum* infection.

Cytology Findings: Although negative at the initial evaluation, blood smears and buffy-coat smears performed a few days later showed oblong "jellybean" inclusions in the cytoplasm of <0.1% of the leukocytes. These were characteristic of *Hepatozoon* gamonts.

Diagnosis: American canine hepatozoonosis (*Hepatozoon americanum* infection).

Treatment: Triple combination therapy consisting of (1) pyrimethamine 0.5 mg/kg PO q24h for 14 days; (2) sulfadiazine/trimethoprim 15 mg/kg PO q12h for 14 days; and (3) clindamycin 10 mg/kg PO q8h for 14 days. This was associated with resolution of fever within 24 hours. According to his owner, Pepper was back to normal within 7 days. After the 14-day course of triple combination therapy was completed, Pepper was started on decoquinate 15 mg/kg PO q12h with food. At day 74, the owners ran out of decoquinate and Pepper missed 2 days of treatment before a refill was obtained. Eight days later, the owners called to say that Pepper was doing poorly, could not get up, and his eyes were matted shut with a yellow-green discharge. Physical exam and CBC findings were similar to initial findings. Another 14-day course of triple combination therapy with pyrimethamine, sulfadiazine/trimethoprim, and clindamycin was prescribed. Once again, Pepper's clinical signs resolved within a few days. Pepper has continued on the decoquinate twice daily with no further breaks in doses and no more relapses.

Comments: American canine hepatozoonosis was suspected in this dog because of the geographic location in an endemic area of the southeastern United States, a waxing and waning fever, muscle pain, ocular discharge, leukocytosis, and other laboratory findings. As initially occurred in this case, organisms often cannot be seen on blood smear or buffy-coat exam. Muscle biopsy has been considered the most reliable way to diagnose infection, although PCR is also a very sensitive and specific diagnostic tool. This case illustrates the typical relapsing nature of the disease and the need for continuous long-term decoquinate therapy. After missing only a few doses of decoquinate, this dog suffered a relapse days later. He made a quick recovery with a second round of triple combination therapy. Effective treatment requires daily decoquinate therapy with no breaks for at least 2 years or until PCR of whole blood becomes negative.

CHAPTER 78

Trypanosomiasis

Stephen C. Barr, Ashley B. Saunders, and Jane E. Sykes

VetBooks.ir

Overview of American Trypanosomiasis

First Described: Chagas' disease (American trypanosomiasis) was first described in humans in 1909 (Carlos Chagas).[1]

Cause: *Trypanosoma cruzi,* a protozoan parasite (phylum Sarcomastigophora, family Trypanosomatidae)

Affected Hosts: Dogs, humans, and more than 150 other domestic or wildlife mammalian species

Geographic Distribution: Central and South America; to a lesser extent southern United States (especially southeastern Texas)

Mode of Transmission: A bite from, or ingestion of, reduviid (kissing bug) vectors, primarily *Triatoma* species. Transmission through blood transfusion and vertical transmission can occur.

Major Clinical Signs: American trypanosomiasis in puppies manifests as lethargy, inappetence, mucosal pallor, lymphadenopathy, splenomegaly, arrhythmias, or sudden death. Neurologic signs such as pelvic limb ataxia and exaggerated spinal reflexes may also occur. Adult dogs may show lethargy, arrhythmias, signs of right- or left-sided congestive heart failure, or sudden death.

Differential Diagnoses: The differential diagnoses for suspected Chagas' myocarditis include dilated cardiomyopathy of large-breed dogs, parvoviral myocarditis in puppies, canine monocytic ehrlichiosis, babesiosis, and leishmaniosis. The primary differential diagnoses for suspected Chagas' meningoencephalitis in puppies are canine distemper virus infection and neosporosis, but other infectious and inflammatory causes of meningoencephalitis should also be considered.

Human Health Significance: Transmission to humans has the potential to occur after needle-stick injuries; caution is advised when handling tissues or clinical specimens from dogs with suspected trypanosomiasis.

AMERICAN TRYPANOSOMIASIS

Etiology and Epidemiology

Chagas' disease, or American trypanosomiasis, is caused by the flagellated protozoan *Trypanosoma cruzi*. In North America, disease in dogs usually manifests as cardiac disease typified by arrhythmias or myocarditis (acute or chronic), and, rarely, neurologic disease.[2-7] However, many infected dogs are subclinically infected for life. Cats can become infected, but disease in cats has not been recognized. *Trypanosoma cruzi* is an important vector-borne zoonosis in the Americas, particularly South and parts of Central America, and is the leading cause of dilated cardiomyopathy in humans.[8] Within the United States, most cases in dogs occur in Texas and especially involve working dogs that reside in southeastern Texas (Figure 78-1).[9-11] A few affected dogs have been reported from other southern states,[5,6,12-14] and as far north as Missouri.[15] The seroprevalence in dogs from Louisiana and Texas has generally been in the range of 12% to 22%, with seroprevalences of <10% in other states where canine disease has been identified.[16] Canine Chagas' disease is of importance to veterinary practitioners because it can be difficult to diagnose, is a potential zoonosis, and there is a lack of therapeutic options.

Trypanosoma cruzi exists in three morphologic forms. The form that circulates freely in the host's peripheral blood is the *trypomastigote*. This form is 15 to 20 µm long, with a flattened spindle-shaped body and a centrally placed vesicular nucleus. A single flagellum originates near a large, subterminal kinetoplast (situated posterior to the nucleus) and passes along the body to project anteriorly (Figure 78-2). The host intracellular or *amastigote* form is approximately 1.5 to 4.0 µm in diameter, is roughly spheroid, and contains both a nucleus and a rod-like kinetoplast. A small flagellum is present, but this is rarely obvious under light microscopy. The third morphologic form, the *epimastigote*, is found in the arthropod vector, a reduviid or "kissing bug" (subfamily Triatomae). Epimastigotes are flagellated and spindle shaped with the kinetoplast situated anterior to the nucleus. When a vector is involved in transmission, infection occurs when trypomastigotes are deposited in the triatomine's feces at the insect bite site. This is the main mode of transmission to humans in South America.

Transmission of *T. cruzi* in endemic countries depends on the confluence of vectors, reservoirs, parasites, and hosts (both people and animals) in a single habitat. Only three Triatomae species (*Triatoma infestans* [the main vector in South America], *Triatoma dimidiata,* and *Rhodnius prolixus*) that feed on man in endemic regions in South America display the appropriate behavior that enables them to transmit *T. cruzi* effectively. These species feed on blood from both people and domestic reservoir mammals (dog, cat, guinea pigs), reproduce prolifically while cohabiting close to people, and defecate soon after taking a blood meal, meaning that they are usually still on the host near the bite wound when they defecate.[17] Infection rates in these vectors can be as high as 100% south of the equator. By contrast, domestic transmission cycles probably do not occur in the United States, except in areas of southeastern

FIGURE 78-1 **A,** Approximate distribution of Chagas' disease in humans in the Americas. Insect-transmitted human Chagas' disease has also been rarely reported in Tennessee, California and Louisiana. **B,** States within the United States where Chagas' disease is most prevalent in dogs. Disease in Texas primarily occurs in the southeast. Occasional cases have been reported in other southern states and as far north as Virginia and Missouri.

Texas where there is evidence to suggest that the dog can be involved in domestic transmission cycles involving vectors and man.[18] Generally, though, the two principal vectors in the United States (*Triatoma protracta* and *Triatoma sanguisuga*) have low infection rates (20%), display different feeding habits, and defecate about 20 minutes after feeding, often when they have long fled the host.[19] As a result, it is more likely that dogs in North America become infected when they eat infected triatomines or their excreta. Certainly, opossums[20] and armadillos[21] become infected by this route, and outbreaks have occurred in humans following ingestion of contaminated food

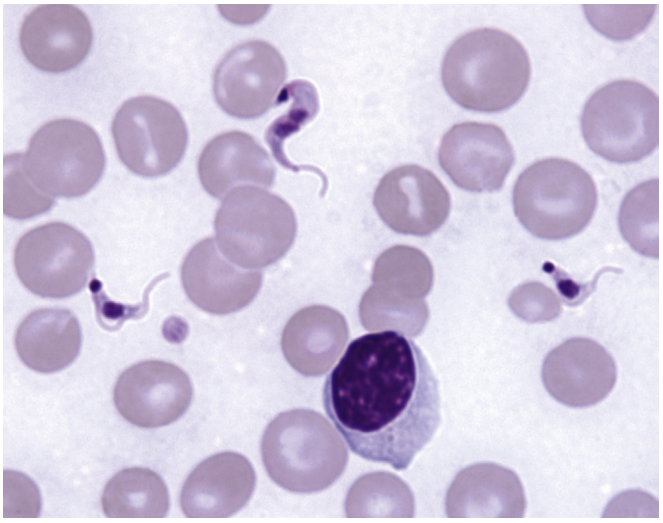

FIGURE 78-2 Trypomastigotes of *Trypanosoma cruzi* in a blood smear of a dog. Wright-Giemsa stain, 1000× oil magnification. (From Barr SC. Canine Chagas' disease (American trypanosomiasis) in North America. Vet Clin North Am. 2009;39:1055-1064.)

or drinks.[22] Blood transfusion and transplacental transmission can also occur, and infection after ingestion of infected milk from lactating bitches has been proposed.[6] Whether ingestion of reservoir hosts leads to transmission is unclear.

Within the United States, the principal wildlife reservoir hosts of *T. cruzi* in the eastern seaboard states south from Maryland and in most other southern states (Texas, Louisiana, and Oklahoma, to name a few) are opossums and raccoons. Armadillos can also be infected.[23] Various mouse, squirrel, and rat species are the main reservoir hosts in New Mexico and California.[24] Isolates of *T. cruzi* from vectors and animal reservoirs in North America are less pathogenic in mice than South American isolates.[23,25] Experimental inoculation of *T. cruzi* isolates from opossums and armadillos into dogs produces a disease consistent with naturally acquired acute and chronic canine trypanosomiasis, so it is likely that dogs in nature are infected with the same isolates as these wildlife hosts.[2-6] Six genotypes of *T. cruzi* have been identified (TcI through TcVI, also known as *discrete typing units* or *DTUs*), which appear to differ in their vector preferences and the extent to which they cause disease.[26]

After infection, trypomastigotes enter macrophages, transform into amastigotes, and multiply by binary fission (Figure 78-3). Alternatively, they spread hematogenously from the site of infection, infect myocardiocytes, transform into amastigotes, multiply, and transform back into trypomastigotes. The host cell then ruptures and trypomastigotes are released back into circulation. Parasitemia in dogs appears as early as 3 days postinfection (DPI), peaks at 17 DPI, and is cytologically undetectable *(subpatent infection)* by 30 DPI.[2] Clinical signs of acute myocarditis, should they occur, develop about 14 DPI with recovery occurring around 28 DPI.[2] Rapid intracellular multiplication ensures a rapid rise in parasitemia before effective immunity develops. Parasitemia steadily rises as more and more intracellular multiplication cycles add to the number of circulating trypomastigotes. The vector becomes infected when it ingests circulating trypomastigotes, which transform into epimastigotes and multiply by binary fission. Transformation of the epimastigotes back into trypomastigotes occurs in the vector's hindgut before the trypomastigotes are passed in the feces.

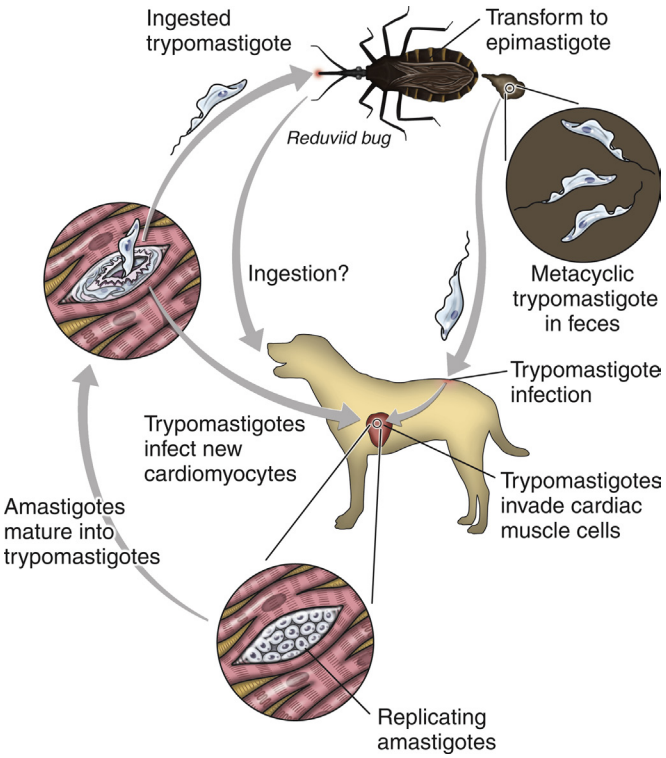

FIGURE 78-3 Life cycle of *Trypanosoma cruzi*. Dogs are infected when a triatome (reduviid bug) defecates at its bite site, and possibly when dogs ingest infected triatomes. Other routes of transmission may also predominate in the United States (see text). Trypomastigotes infect cardiomyocytes (as well as other tissues) and form amastigotes, which replicate locally, leading to myocarditis.

Clinical Features

Signs and Their Pathogenesis

As in humans, there are three phases of Chagas' myocarditis in dogs: acute, indeterminate (or latent), and chronic.[2-6] Acute myocarditis results from cell damage and inflammation as trypomastigotes rupture from myocardiocytes. Lethargy, fever, inappetence, generalized lymphadenopathy, slow capillary refill time with pale mucus membranes, and, in some cases, splenomegaly and hepatomegaly are the main signs in puppies. Diarrhea can also occur. In dogs over 6 months of age, parasitemia develops more slowly and clinical signs are often much less severe or not apparent at all. Sudden death, presumably from cardiac muscle failure or conduction system failures leading to malignant arrhythmias, is not a common occurrence. Although less common than signs referable to cardiac abnormalities, neurologic signs referable to meningoencephalitis (as a direct result of parasitic invasion of the neurologic system) may also occur and include weakness, pelvic limb ataxia, and exaggerated spinal reflexes suggestive of distemper. Humans with Chagas' disease can also develop severe megaesophagus or megacolon due to parasympathetic denervation,[22] but these have not been described in dogs.

Dogs that survive the acute phase enter a prolonged indeterminate phase typified by a lack of clinical signs. Parasitemia becomes cytologically undetectable at about 30 DPI, although it can still be demonstrated by blood culture. The ECG is usually normal during this phase, although ventricular arrhythmias can be induced by exercise.[3] Although not all dogs progress to develop chronic disease, some develop chronic myocarditis with cardiac dilatation over the subsequent 8 to 36 months.[2,3] ECG abnormalities become more prevalent in these dogs and may even result in sudden death. Clinical signs referable to right-sided and eventually, in some, left-sided heart failure occur and can include exercise intolerance, pulse deficits, ascites, pleural effusion, hepatomegaly, and jugular venous congestion.[2] Chronic Chagas' myocarditis is clinically indistinguishable from dilated cardiomyopathy of large breed dogs.[4-6] The pathogenesis of the cardiomyopathy is unknown, but proposed mechanisms include damage to myocardiocytes or the autonomic nervous system by immune-mediated mechanisms or toxic parasitic products, and/or microvascular disease coupled with platelet dysfunction.[27,28] Cardiac dilatation occurs when fibrosis no longer permits efficient compensatory hypertrophy.[27,29] Some *T. cruzi* isolates that infect dogs in the United States are not pathogenic but produce a marked serologic response and a low-level parasitemia following immunosuppression.[2,30] Reactivation of infection with immunosuppression can occur in human patients.[22]

Physical Examination Findings

The most common physical examination findings in puppies with Chagas' disease are lethargy, generalized lymphadenomegaly, splenomegaly, pallor, and arrhythmias. Generalized subcutaneous edema has also been reported.[31] Dogs with chronic Chagas' disease may show signs of right- and/or left-sided congestive heart failure, with tachypnea, ascites, or jugular pulses. Cardiac murmurs and/or arrhythmias may be detected on auscultation of the heart.

Diagnosis

The key to diagnosis of Chagas' disease is a high degree of clinical suspicion. Chagas' disease should be considered in any dog with signs of myocarditis or cardiomyopathy, particularly if it lives or has lived at any time—even years before evaluation—in an endemic region.

Laboratory Abnormalities

Complete Blood Count

During the acute *T. cruzi* infection, the CBC of some dogs may reveal anemia, leukocytosis due to a neutrophilia, eosinophilia, monocytosis, and lymphocytosis.[32,33] Thrombocytopenia, leukopenia, and/or lymphopenia have also been documented.[16] Dogs in the chronic phase of infection may have no hematologic abnormalities.

Serum Biochemical Tests

Serum ALT activity, AST activity, and creatinine and urea nitrogen concentrations can be elevated in dogs with *T. cruzi* infection, especially those that are at risk of death from severe acute myocarditis. Rarely, moderate to severe hypoalbuminemia with or without hyperglobulinemia occurs in acutely affected dogs.[16,31] Serum troponin I levels rise slowly in infected dogs and peak at around 10 to 30 mg/mL by 21 DPI. Serum troponin I levels are elevated in dogs infected after 6 months of age but usually not to such high levels.

Urinalysis

There are no specific findings reported on urinalysis in dogs with Chagas' disease.

Electrocardiography

The ECG of dogs with severe Chagas' myocarditis may show sinus tachycardia, decreased R-wave amplitude, axis shifts, T-wave

VetBooks.ir

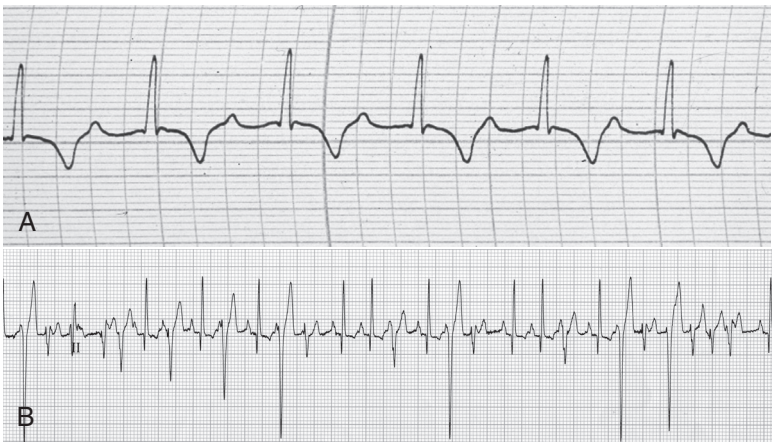

FIGURE 78-4 Electrocardiographic findings in dogs with Chagas' disease. **A,** Second-degree heart block and depressed QRS complexes. (From Barr SC. Canine Chagas' disease (American trypanosomiasis) in North America. Vet Clin North Am. 2009;39:1055-1064.)**B,** Multiform ventricular premature complexes in an 11-year-old, neutered male Labrador retriever presenting for collapse. Recording speed 25 mm/s, sensitivity 10 mm/mV.

inversion, ventricular arrhythmias, and conduction abnormalities, including first-, second-, and third-degree atrioventricular block and right bundle branch block (Figure 78-4).

Diagnostic Imaging

Plain Radiography

Plain thoracic radiographs in dogs with chronic Chagas' myocarditis may reveal cardiomegaly or evidence of congestive heart failure (pulmonary edema or pleural effusion) (Figure 78-5).

Sonographic Findings

Echocardiograms of puppies with acute myocarditis are usually within normal limits. Echocardiographic abnormalities in dogs with chronic Chagas' myocarditis include right ventricular dilation with progression to include a loss of left ventricular function with decreased fractional shortening, reduced ejection fraction, reduced left ventricular free wall thickness, and increased end-systolic volume (Figure 78-6).

Microbiologic Tests

Diagnostic assays for trypanosomiasis in dogs and cats are described in Table 78-1.

Cytologic Examination

During acute disease, trypomastigotes may be detected on blood smear examination (see Figure 78-2). However, only a few parasites may be present on the entire slide, demanding diligent examination, or some form of concentration technique may be used. High-power (400×) examination of the buffy-coat layer from a centrifuged microhematocrit tube may reveal the motile parasites. Examination of a thick-film buffy-coat smear stained with either Wright or Giemsa stains is more sensitive than examination of a blood smear. A highly effective concentration technique involves pelleting trypomastigotes from plasma (obtained by centrifugation of 10 to 50 mL of heparinized blood at 800 × *g* for 10 minutes) by further centrifugation (8000 × *g* for 15 minutes). The pellet from the final centrifugation may be examined microscopically after staining or be submitted for PCR analysis or culture. The larger the volume of the blood specimen collected, the greater the likelihood that organisms will be detected. Trypomastigotes may also be found on cytologic examination of lymph node aspirates and in abdominal effusions. Amastigotes were described in the lymph node of one affected dog that were cytologically indistinguishable from those of *Leishmania*.[31]

Culture

Trypanosoma cruzi can be cultured from blood in liver infusion tryptose (LIT) growth medium. However, several weeks are required before epimastigotes grow in this medium, which is too long to be helpful for making treatment decisions. Although culture is more sensitive than blood smear examination, false-negative results can still occur; in humans the sensitivity of blood culture is estimated to be only 50%.[22] Culture of trypanosomes is a specialized procedure that is not routinely available in veterinary diagnostic laboratories.

Serologic Diagnosis

Serology is extremely useful for the diagnosis of Chagas' disease, especially during the indeterminate and chronic phases when trypomastigotes are very difficult to detect.[34] Indirect fluorescent antibody, ELISA, and radioimmunoprecipitation assays are most commonly used. A rapid immunochromatographic dipstick test has also been developed.[35] Serologic tests confirm the presence of antibodies to *T. cruzi,* but most cross-react with antibodies to *Leishmania.* Further, in rare situations in dogs, the clinical signs of Chagas' disease and leishmaniasis overlap sufficiently that it is necessary to go to considerable lengths to establish a diagnosis.[31] Therefore a detailed history of the likelihood of exposure to *Leishmania* must be known in order to accurately interpret serologic results. A higher antibody titer to *Trypanosoma* than to *Leishmania* may support a diagnosis of trypanosomiasis. Positive serology in association with consistent clinical signs is the most common means of diagnosis of Chagas' disease in dogs. If possible, two different serologic assays should be used to confirm a positive titer, especially in regions of low prevalence. The serum titer usually becomes positive by 21 DPI, when parasitemia is declining, and persists for the life of the animal irrespective of whether clinical signs develop.[30]

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays, which detect DNA of *T. cruzi* in various clinical specimens (blood, plasma pellets, lymph node aspirates, or ascites fluid), can be highly specific for *T. cruzi* but can have

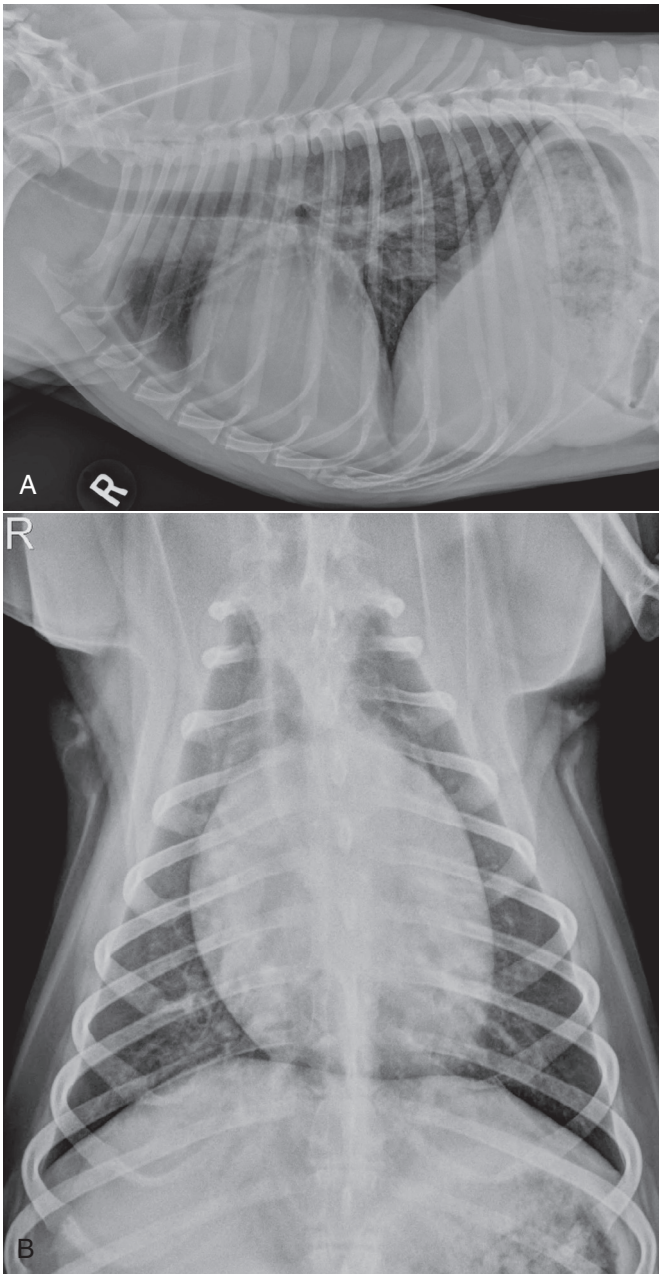

FIGURE 78-5 Right lateral **(A)** and dorsoventral **(B)** thoracic radiographic images of a dog with trypanosomiasis and mild generalized cardiomegaly. The pulmonary veins are slightly larger than the corresponding artery, and a slight interstitial pattern was present throughout the lungs.

variable and sometimes low sensitivity for diagnosis of chronic infections unless multiple specimens are tested.[34] Real-time PCR assays have been developed for diagnosis of human Chagas' disease that detect repetitive sequences found in very high copy number within *T. cruzi*.[36] Because each parasite may have more than 100,000 copies of the sequence, the sensitivity of the assay is increased.[22] The sensitivity of PCR assays varies depending on the *T. cruzi* strain involved.[36,37] PCR may be useful to confirm infection when organisms are not seen on blood smears. Currently, PCR assays for *T. cruzi* are not widely available from veterinary diagnostic laboratories on a commercial basis, but have been used for diagnosis of canine Chagas' disease.[31]

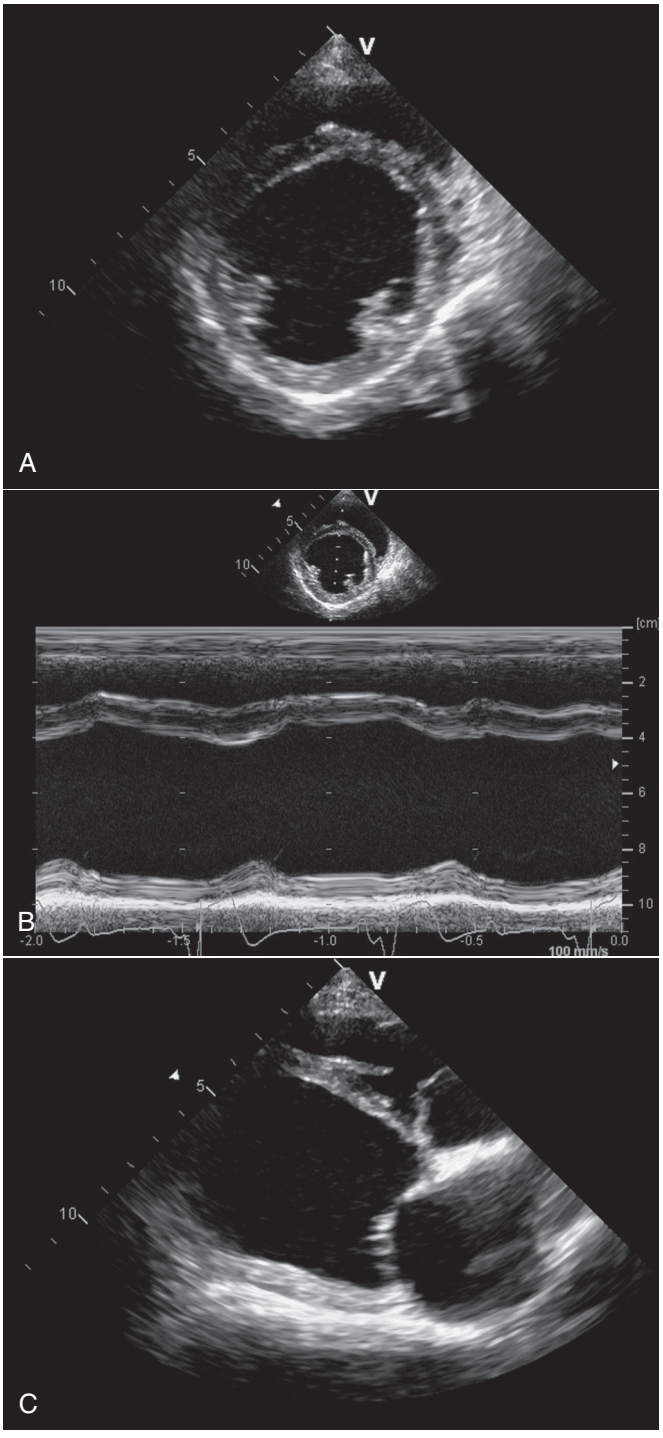

FIGURE 78-6 Two dimensional **(A)** and M-mode **(B)** transthoracic echocardiogram images obtained in a right parasternal short-axis view and long-axis view **(C)** from a dog with Chagas' disease documenting significant left ventricular enlargement and mild right ventricular enlargement.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with Chagas' disease include lymphadenopathy, evidence of congestive heart failure (ascites, pleural effusion, or congestion of viscera), and biventricular cardiac enlargement with thinning of the ventricular wall. Often the right side of the heart is more enlarged than the left. Hemorrhages and pale foci may be identified in the myocardium.

TABLE 78-1

Diagnostic Assays Currently Available for Trypanosomiasis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of lymph nodes, spleen, bone marrow, blood smears, or buffy-coat preparations	*Trypanosoma* trypomastigotes or, less commonly, amastigotes	Organisms may be few in number and in chronic trypanosomiasis are often not found.
Trypanosoma culture	Blood or buffy-coat preparations, bone marrow	*Trypanosoma* spp.	Requires special techniques and expertise that are not widely available. Sensitivity may be low in chronic infections.
Antibody serology (immunofluorescent antibody or ELISA)	Serum	Antibodies to *Trypanosoma* spp.	Most infected dogs test positive, but positive test results occur in healthy animals, so results must be interpreted in light of clinical signs. False positives can occur in dogs exposed to *Leishmania* or those vaccinated with *Leishmania* vaccines.
Real-time PCR assays	Whole blood, buffy coats, splenic or lymph node aspirates, CSF	*Trypanosoma* DNA	May be useful in dogs with suggestive clinical signs in which organisms cannot be found cytologically. Sensitivity and specificity depend on assay design. Quantitative PCR may be useful for evaluation of treatment efficacy. Limited availability.

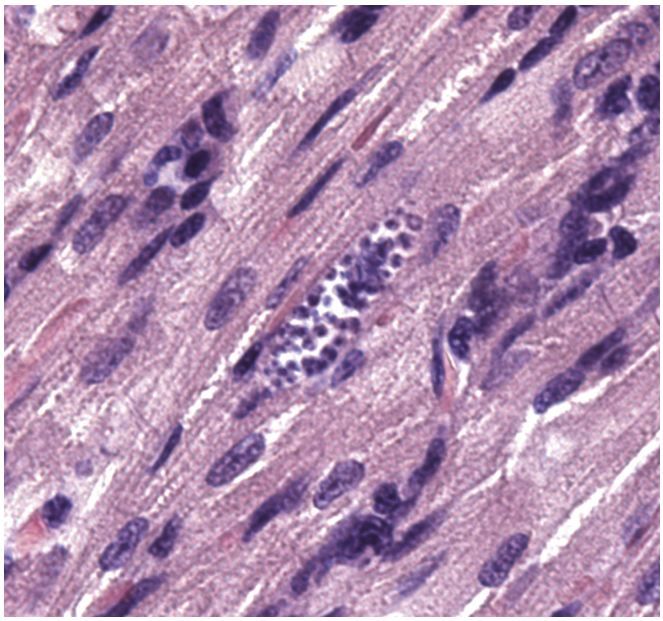

FIGURE 78-7 Pseudocyst of *Trypanosoma cruzi* within a myocardiocyte of an infected dog. H&E stain, 1000× magnification. (From Barr SC. Canine Chagas' disease (American trypanosomiasis) in North America. Vet Clin North Am. 2009;39:1055-1064.)

Histopathologic Findings

Histopathologic findings in Chagas' disease include a severe diffuse granulomatous myocarditis, large numbers of parasitic pseudocysts (intracellular collections of amastigotes), and minimal fibrosis (Figure 78-7). Immunohistochemistry does not distinguish *Leishmania* from *Trypanosoma* amastigotes, because of serologic cross-reactivity.[31] Histopathology of the myocardium in chronic Chagas' myocarditis is characterized by multifocal lymphocytic infiltrates, perivasculitis, and marked fibrosis, and rare, if any, parasitic pseudocysts.[4,27]

TABLE 78-2

Antimicrobials Used to Treat Acute Chagas' Disease in Dogs

Drug*	Dose (mg/kg)	Route	Interval (hours)	Duration (months)
Benznidazole	5-10	PO	24	2
Nifurtimox	2-7	PO	6	3-5
Prednisone	0.5	PO	12	1

*Both benznidazole and nifurtimox are available from the Centers for Disease Control and Prevention, Atlanta, GA.

Treatment and Prognosis

Antimicrobial Treatment

Treatment of dogs with naturally occurring acute Chagas' myocarditis is poorly documented, since this phase is seldom recognized. The use of nifurtimox (usually in association with glucocorticoids)[38] or benznidazole[39] has been reported in the dog (Table 78-2). However, the severe adverse effects of nifurtimox preclude its use, so benznidazole is the drug of choice (see Chapter 10). Benznidazole is available from the Centers for Disease Control and Prevention, Atlanta, GA. After treatment with benznidazole, serum antibody titers usually remain elevated, although they are reported to decline in people. Treatment of experimentally infected dogs with *acute* Chagas' disease with benznidazole reduced or prevented subsequent fibrosis and arrhythmias, even if parasites were not completely eliminated.[40] Benznidazole-resistant strains of *T. cruzi* have been described. Ketoconazole, gossypol, allopurinol, and verapamil have shown promise in other species but are ineffective for the treatment of Chagas' disease in dogs. Ravuconazole and posaconazole also reduce parasite load,[41,42] but to date azole

VetBooks.ir

drugs have not been adopted for treatment of humans because they lack significant benefit over benznidazole or nifurtimox.[22] However, the combination of the antiarrhythmic amiodarone and an azole (itraconazole or posaconazole) has synergistic antiprotozoal activity against *T. cruzi* and shows promise as an effective treatment for chronic Chagas' disease in humans.[43,44]

Most dogs are diagnosed with Chagas' disease during the chronic stage. Unfortunately, treatments directed against the parasite at this stage do not significantly alter the outcome of disease.[45] Treatment should be directed toward the myocardial failure and ventricular arrhythmias, although the latter are often refractory to drug therapy. Pacemaker implantation may be required for some dogs with bradyarrhythmias such as third-degree atrioventricular block. In humans with indeterminate and chronic symptomatic Chagas' disease, the benefit of treatment remains controversial and is still under investigation by means of a large, prospective clinical trial (the Benznidazole Evaluation for Interrupting Trypanosomiasis [BENEFIT] trial).[36]

Prognosis

The prognosis for dogs that develop Chagas' disease is poor because of the lack of effective treatments. Dogs diagnosed at an older age (mean of 9 years) survive longer (30 to 60 months) than dogs diagnosed at a younger age (mean of 4.5 years), which survive only up to 5 months postdiagnosis.[11]

Immunity and Vaccination

Recovery from *T. cruzi* infection is not associated with protective immunity. No vaccine is available.

Prevention

The risk of infection by *T. cruzi* can be reduced by limiting contact between dogs and vectors and possible reservoir hosts (raccoons, opossums, armadillos, and skunks). Dogs should not be fed meat from reservoir hosts. Kennels and surrounding structures (chicken houses, wood piles) in endemic areas should be sprayed monthly with a residual insecticide. Dog housing should be upgraded to remove vector nesting sites. Applications of fipronil on the coats of dogs do not appear to prevent infections in dogs or reduce the feeding of vectors,[46] but deltamethrin-treated collars do reduce feeding by *Triatoma infestans*.[47,48] Blood donor dogs should be serologically screened to determine previous exposure to *T. cruzi*. In highly endemic regions (southern Texas), bitches should be screened serologically, and positive animals should not be bred.

Public Health Aspects

American trypanosomiasis is a major human health problem in South and Central America and is increasingly recognized in Mexico.[8,49] It is primarily a problem in impoverished regions where humans live in rural areas. Dogs are considered a reservoir for human infection in these regions because they maintain high levels of parasitemia and are a preferred host for triatomine insects. Cats may also act as a reservoir for human infection in South America.[50] Fewer than one third of infected humans ultimately develop Chagas' disease.[22]

To date, fewer than 10 human cases of Chagas' disease involving transmission by vectors have been reported in the United States (4 in Texas, and 1 each in California, Tennessee, and Louisiana). By far the largest number of people infected with *T. cruzi* in the United States (estimated at approximately 100,000 people) have emigrated from endemic regions such as Mexico and Central America. Consequently, reports of cases associated with transmission by blood transfusion continue to rise.[51,52] Imported cases in tourists who return to the United States have not been described. There are probably several reasons why only a handful of naturally acquired cases have been reported in the United States. First, North American vector species are poorly adapted to living in houses and do not defecate on the host after a blood meal. Higher standards of housing in North America than in parts of Central and South America may also prevent vectors from nesting in human dwellings. Third, some human cases of Chagas' disease in North America may be overlooked because of a low level of suspicion.

Although the risk of a human acquiring infection from an infected dog is extremely low, the severity and difficulty of treating disease in humans makes this disease of considerable public health significance. Veterinarians should be careful when handling blood samples from infected dogs and warn laboratory staff of the potential infectivity of the samples. Accidental needle-stick injuries when administering therapy to or collecting specimens from infected dogs should be reported immediately to the CDC.

Overview of African Trypanosomiasis in Dogs

First Described: Reports of African trypanosomiasis date back to Egyptian times. Trypanosomes were identified as the cause in 1895, when they were detected in cattle by a Scottish microbiologist, David Bruce (after whom *Brucella* was named).[53]

Cause: *Trypanosoma brucei rhodesiense, Trypanosoma congolense, Trypanosoma evansi* (protozoan parasites, family Trypanosomatidae)

Affected Hosts: Dogs and a variety of other mammalian host species. Humans are infected with *T. brucei gambiense* and *T. brucei rhodesiense.*

Geographic Distribution: Central Africa *(T. brucei, T. congolense); T. evansi* is found in Africa as well as in Asia, Latin America, and the Canary Islands in Spain.

Mode of Transmission: A bite from the tsetse fly *(T. brucei or T. congolense)* or mechanical transmission by hematophagous flies *(T. evansi)*

Major Clinical Signs: Lethargy, inappetence, weight loss, pallor, peripheral edema, ascites, hematemesis, hemorrhagic diarrhea, uveitis, corneal edema, neurologic signs due to meningoencephalitis

Differential Diagnoses: These include canine monocytic ehrlichiosis, babesiosis, leishmaniosis, and systemic immune-mediated diseases. Canine distemper virus infection and neosporosis are important differential diagnoses in dogs with meningoencephalitis.

Human Health Significance: Although most *Trypanosoma* species that cause African trypanosomiasis in dogs do not infect humans, *T. brucei rhodesiense* does, so caution is advised when handling tissues or clinical specimens from dogs or cats with suspected trypanosomiasis.

AFRICAN TRYPANOSOMIASIS

African trypanosomiasis is caused by *Trypanosoma brucei* and *Trypanosoma congolense.* These organisms are transmitted by tsetse flies (*Glossina* species), which are only found in Africa. *Trypanosoma brucei* includes *Trypanosoma brucei brucei, T. brucei gambiense,* and *T. brucei rhodesiense,* which are indistinguishable morphologically and are referred to as "*T. brucei* complex" organisms. *T. evansi* also belongs to this group (see later). The epidemiology, host range, and clinical features of disease caused by these *T. brucei* complex organisms differ. *Trypanosoma brucei gambiense* and *T. brucei rhodesiense* cause "sleeping sickness" in humans from Africa (West African and East African trypanosomiasis, respectively) (Figure 78-8). A variety of animal reservoirs of *T. brucei rhodesiense* have been identified, but an animal reservoir for *T. brucei gambiense* has not.[54] Along these lines, only naturally occurring infections with *T. brucei rhodesiense* , and not *T. brucei gambiense*, have been reported in dogs.[55] *Trypanosoma brucei brucei* and *T. congolense* cause trypanosomiasis in a variety of domestic animal species ("nagana") but do not infect humans. Dogs are especially susceptible to *T. congolense* infection. Four types of *T. congolense* have been identified—savannah, forest, Tsavo, and Kilifi—which may vary in pathogenicity. There are several reports of travel-related infections with *T. congolense* in dogs,[56-58] sometimes in association with a long period of latency.[57] It has been suggested that African dogs may exhibit a degree of "trypanotolerance," whereas dogs imported into Africa may be more susceptible to infection and disease.[59]

African trypanosomes exist only as a trypomastigote in the blood of the mammalian host; in contrast to Chagas' disease, there is no amastigote phase. Epimastigotes develop in the salivary glands of the tsetse fly, and the organism is transmitted in saliva when it feeds on the mammalian host. Transmission to the mammalian host results in hemolymphatic spread of the organism over weeks to months with signs that relate to proliferation of mononuclear phagocytes and increased vascular permeability. *T. brucei* complex organisms are well known for their ability to evade the host immune response through extensive variation of their outer surface glycoproteins (known as *variant antigen types,* or *VATs*). The hemolymphatic phase may be followed by the development of meningoencephalitis in some animals. In humans, meningoencephalitis is most apparent with *T. brucei gambiense* infections and results in tremors and progressive daytime somnolescence (hence the term "sleeping sickness"). Pancarditis with arrhythmias and congestive heart failure is a more typical outcome of *T. brucei rhodesiense* infection in humans.

The clinical signs of African trypanosomiasis in dogs include persistent fever, lethargy, anorexia, weight loss, pallor, mucopurulent oculonasal discharge, lymphadenopathy, hepatosplenomegaly, variable peripheral edema, abdominal distention due to ascites, petechial hemorrhages, signs of pancarditis, and ocular signs such as unilateral or bilateral uveitis, corneal edema, and/or keratitis (which can mimic "blue eye" due to canine adenovirus-1). Hemorrhagic vomiting and diarrhea can occur in dogs infected with *T. congolense.*[58,60] Neurologic signs (seizures, tremors, opisthotonos, and hyperreflexia) due to meningoencephalitis have also been described in dogs infected with *T. congolense*.[58]

Laboratory abnormalities in dogs with African trypanosomiasis have been most well described for *T. congolense* infections. The most common findings are regenerative or nonregenerative anemia, leukocytosis or leukopenia, and thrombocytopenia.[57,58,60] Serum biochemistry findings include increased serum liver

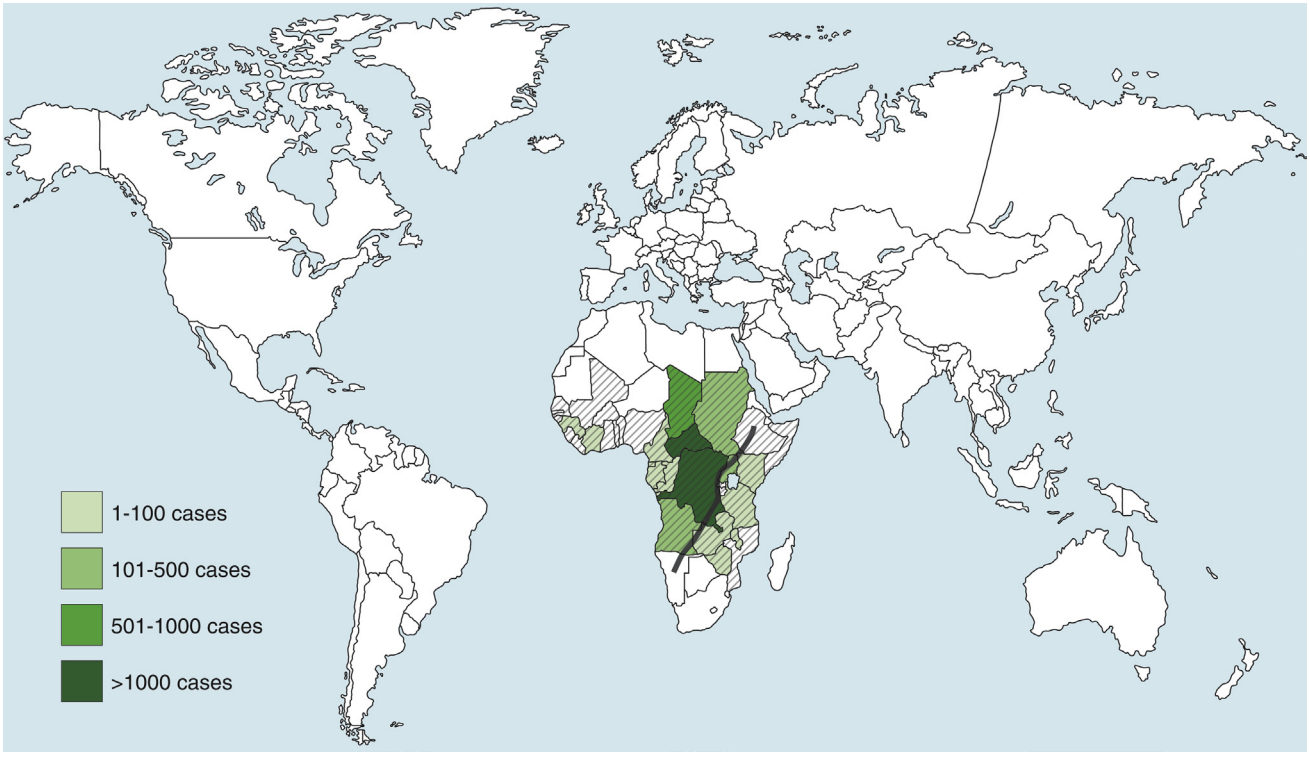

FIGURE 78-8 Map showing geographic distribution of human African trypanosomiasis (green countries) and the number of cases reported in natives in the year 2009. *Trypanosoma brucei gambiense* is found in western Africa and *Trypanosoma brucei rhodesiense* is found in eastern Africa. The line divides the geographic distribution of the two forms of disease. *T. brucei brucei,* which infects dogs, occurs throughout both regions. The hashed lines indicate the countries in which tsetse flies are found. (Modified from Brun R and Blum J. Human African Trypanosomiasis. Inf Dis Clin North Am. 2012;26:261-273.)

VetBooks.ir

enzyme activities, azotemia, hyperglobulinemia, and hypoalbuminemia,[57,58] but one dog had no significant abnormal serum biochemistry findings.[56]

The primary means of diagnosis is cytologic detection of the organism in aspirates, body fluids, or blood smears. Identification of the infecting species requires PCR and sequencing. The treatment of choice for dogs is diminazene aceturate, but this may not always be effective or available. Treatment of the hemolymphatic disease in humans is with pentamidine isethionate *(gambiense)* or suramin *(rhodesiense)*, whereas disease of the central nervous system is treated with the arsenical melarsoprol, but these drugs can have significant adverse effects. Pentamidine was used with apparent success to treat one dog with African trypanosomiasis.[61] Prevention is through the use of insect repellants and indoor housing.

OTHER *TRYPANOSOMA* INFECTIONS

Other *Trypanosoma* species that can infect dogs (and to a lesser extent, cats) include *Trypanosoma evansi* and *Trypanosoma caninum*.

T. evansi causes surra (= "rotten") and is endemic in large parts of Asia, Africa, Latin America, and the Canary Islands of Spain. It causes disease in a variety of mammalian host species that include horses, cattle, dogs, and cats, but not humans. *T. evansi* is very closely related to *T. brucei* and may have derived from *T. brucei* as a result of partial or complete loss of kinetoplast DNA, which stops it from developing within the insect vector. Instead, the organism is transmitted mechanically by biting flies. Ingestion of infected meat may also lead to infection. Because populations of biting flies are greatest during the rainy season, a seasonal incidence of disease has been observed in dogs.[62] Travel-related disease has been described.[63,64] The disease has an acute course; clinical signs and laboratory abnormalities resemble those of African trypanosomiasis, with lethargy, fever, anorexia, weight loss, pallor, lymphadenopathy, vomiting, conjunctivitis, uveitis, corneal edema, and peripheral edema, as well as leukopenia, thrombocytopenia, and anemia on the CBC.[62-65] Hyperglobulinemia and proteinuria have also been reported.[64] Some dogs develop neurologic signs late in the course of disease due to nonsuppurative meningoencephalitis.[64] Definitive diagnosis of infection is based on cytologic examination of blood smears and/or PCR assay. Treatment is usually with diminazene aceturate or suramin, although diminazene aceturate is considered less effective against *T. evansi* than *T. congolense* infection.[64] Untreated infection is usually fatal in dogs.

Trypanosoma caninum is a recently discovered *Trypanosoma* species that has only been identified in dogs from South America, many of which have been apparently healthy.[66,67] The pathogenicity of this organism requires further study. Importantly, infection with *T. caninum* leads to false-positive serologic test results for *Leishmania*, which can confound control methods that rely on culling of dogs that are seropositive for *Leishmania* (see Chapter 74).

CASE EXAMPLE

Signalment: "Duke," a 5-year-old male beagle mix dog from San Antonio, TX

History: Duke's owner reported a 7-day history of inappetence, lethargy, and decreased exercise tolerance. Two months earlier, the dog had been diagnosed with dirofilariasis and was treated with melarsomine dihydrochloride using a split protocol. He had not traveled out of his local area. He was up to date on vaccinations, which included vaccines for distemper, hepatitis, parvovirus, and rabies.

Current medications: Monthly oral ivermectin/pyrantel heartworm preventative.

Physical Examination:

Body weight: 19.9 kg.

General: Lethargic. T = 101.7°F (38.7°C), HR = 142 beats/min, RR = 48 breaths/min, mucous membranes pink, CRT = 1 s.

Integument, Eyes, Ears, Nose, and Throat: Full, shiny haircoat. No evidence of ectoparasites was detected. No other significant abnormalities were noted.

Musculoskeletal: Body condition score was 6/9.

Cardiovascular: An irregular rhythm and a grade 3/6 systolic left apical murmur were detected on thoracic auscultation. Strong femoral pulses were palpated bilaterally.

Respiratory: Mild tachypnea was identified with normal breath sounds and normal respiratory effort.

Gastrointestinal, Genitourinary, and Lymph Nodes: No abnormalities were detected.

Laboratory Findings:

CBC:

PCV 48.3% (31%-56%)
MCV 66.4 fL (60-77 fL)
MCHC 35 g/dL (32-36 g/dL)
WBC 13,100 cells/μL (6000-17,000 cells/μL)
Neutrophils 8777 cells/μL (3000-11,500 cells/μL)
Lymphocytes 2096 cells/μL (1000-4800 cells/μL)
Monocytes 1179 cells/μL (150-1250 cells/μL)
Platelets 238,000 platelets/μL (200,000-500,000 platelets/μL)

Serum Chemistry Profile:

Sodium 144 mmol/L (139-147 mmol/L)
Potassium 3.9 mmol/L (3.3-4.6 mmol/L)
Chloride 118 mmol/L (107-118 mmol/L)
Bicarbonate 22 mmol/L (20-28 mmol/L)
Phosphorus 3.6 mg/dL (2.9-6.2 mg/dL)
Calcium 9.8 mg/dL (9.3-11.8 mg/dL)
BUN 19 mg/dL (5-29 mg/dL)
Creatinine 1.27 mg/dL (0.3-2.0 mg/dL)
Glucose 108 mg/dL (60-135 mg/dL)
Total protein 5.5 g/dL (5.7-7.8 g/dL)
Albumin 2.6 g/dL (2.4-3.6 g/dL)
Globulin 2.9 g/dL (1.7-3.8 g/dL)
ALT 136 U/L (10-130 U/L)
ALP 103 U/L (21-147 U/L)
GGT 11 U/L (0-25 U/L)
Cholesterol 199 mg/dL (120-247 mg/dL)
Total bilirubin 0.2 mg/dL (0-0.8 mg/dL)
Magnesium 2.1 mg/dL (1.7-2.1 mg/dL)

Urinalysis: SGr 1.012; pH 7.5, trace protein (SSA), no bilirubin, no glucose, no WBC/HPF, 0-1 RBC/HPF.

Heartworm Antigen Test: Negative.

Cardiac Troponin I: 0.69 ng/mL (<0.2 ng/mL).

Chagas Immunofluorescent Antibody Titer: Positive at 1:160.

VetBooks.ir

Imaging Findings:

Thoracic Radiographs: The cardiac silhouette was mildly, generally enlarged. The pulmonary veins were mildly larger than the corresponding artery. A mild pulmonary interstitial pattern was present.

Echocardiogram: The left ventricular internal dimensions were enlarged, and systolic function was reduced (fractional shortening 16.1%, area shortening 26.9%; normal is >25% and >50%, respectively). Moderate mitral regurgitation was documented, and the left atrium was enlarged. The right ventricle was mildly dilated. Pulmonic and aortic velocities were within normal limits. No heartworms were visualized.

Additional Testing: Electrocardiogram: Sinus rhythm with frequent, multiform ventricular premature complexes.

Blood pressure: Systolic blood pressure was 115 mm Hg.

Diagnosis: American trypanosomiasis (Chagas' disease).

Treatment: Medication to address cardiac enlargement, dysfunction, and arrhythmias included pimobendan (0.25 mg/kg PO q12h), enalapril (0.5 mg/kg PO q12h), and sotalol (1 mg/kg PO q12h). This was associated with improvement in clinical signs within 1 week of starting treatment.

Comments: This dog was diagnosed with trypanosomiasis based on an index of suspicion in the presence of ventricular enlargement and dysfunction in combination with multiform ventricular arrhythmias. Infection by *Leishmania* could also have caused the positive serologic test result, but this was considered unlikely based on the geographic location and clinical signs. PCR assays or *Trypanosoma* blood culture could have been performed to confirm the diagnosis, but these are not widely available and have low sensitivity when used in chronic infections. Antiprotozoal drugs were not used to treat this dog because they do not appear to alter outcome in chronic Chagas' disease. The dog did very well clinically while being managed with cardiac medications including antiarrhythmics along with routine evaluation. After 2.5 years, ventricular arrhythmias increased in severity and were more difficult to control with antiarrhythmic therapy. He died suddenly at home 5 days after reevaluation.

CHAPTER 79

Giardiasis

Michael R. Lappin

VetBooks.ir

Overview of Giardiasis

First Described: Trophozoites that were likely *Giardia* spp. were first described in 1681 by Antonie van Leeuwenhoek (who found the parasite in his own stools[1]) and the genus was established in the early 1900s. Infections of dogs and cats were first described in the 1960s.[2]

Cause: *Giardia duodenalis* (multiple genetic assemblages); a flagellate protozoan (phylum Sarcomastigophora)

Transmission: Fecal-oral

Affected Host Species: Dogs and cats are the definitive hosts for several different *Giardia* assemblages and pass either trophozoites (diarrhea) or cysts (diarrhea or normal stool) in feces.

Intermediate Hosts: Although there are no intermediate hosts, there are multiple potential transport hosts that may carry *Giardia* spp. cysts and indirectly infect dogs or cats.

Geographic Distribution: Worldwide

Major Clinical Signs: Most dogs and cats harbor subclinical infections. Acute watery diarrhea that can contain mucus can occur. Steatorrhea can be observed. Chronic or intermittent diarrhea and weight loss may be noted in animals with concurrent infections or immunocompromise.

Differential Diagnoses: All causes of small bowel diarrhea including *Isospora* spp., *Cryptosporidium* spp., bacterial infections such as salmonellosis, nematode infections, dietary intolerance, exocrine pancreatic insufficiency, and inflammatory bowel disease

Human Health Significance: *Giardia* assemblages that infect dogs (assemblage C and D) or cats (assemblage F) are usually not associated with clinical disease in humans but can be detected in the feces of immunocompromised people. Human assemblages A and B can be found in feces of dogs and cats when animals share human environmental features (such as contaminated water). However, it is unlikely that new human infections with *Giardia* assemblage A or B infections are acquired from the feces of dogs or cats.

Etiologic Agent and Epidemiology

Giardia spp. are protozoans in the flagellate group that have been recognized in the feces of animals and man for many years.[3] *Giardia* spp. occurs in two forms, the trophozoite and the cyst (Figure 79-1). The trophozoite is the active, motile form; it is approximately 15 µm long and 8 µm wide and has a teardrop shape and a ventral adhesive disk (Figure 79-2). Trophozoites are almost never found in normal feces and are susceptible to many environmental conditions; thus, they usually are not associated with transmission among animals. The 12-µm long and 7-µm wide cyst is the environmentally resistant stage primarily responsible for transmission. The cyst contains two incompletely separated but formed trophozoites, the axoneme, fragments of the ventral disks, and as many as four nuclei (Figure 79-3). The cyst can survive several months outside the host in wet and cool conditions but is susceptible to desiccation in dry and hot conditions.

Giardia spp. are transmitted by the direct ingestion of fecal cysts or by indirect ingestion of contaminated water, food, transport hosts, infected prey species, or fomites. The prepatent period (time between ingestion and appearance of cysts in the feces) in cats ranges from 5 to 16 days (mean around 10 days) and in dogs ranges from 4 to 12 days (mean around 8 days). Shedding of *Giardia* cysts by cats may fluctuate from undetectable to concentrations of more than 1 million cysts/g of feces over periods as short as 2 to 7 days.[4] Young dogs shed an average of 2000 cysts per gram of feces; the mean cyst count per gram of feces for all infected dogs (regardless of age) was 706.[5] Most infections are self-limited with cessation of cyst shedding in 27 to 35 days in dogs and cats. However, some infected animals shed cysts for several months.

Although there are many *Giardia* spp., *G. duodenalis* (syn. *G. intestinalis* or *G. lamblia*) is the species that infects people, dogs, and cats.[6] Based on genetic analyses, there are at least seven distinct assemblages (A-G) within *G. duodenalis*. Assemblage A has been amplified from feces of infected humans, dogs, and cats as well as many other mammals. Assemblage B is most commonly amplified from human feces but is occasionally amplified from dog feces. Overall, most dogs are infected with the species-specific assemblages C and D, and cats are infected with assemblage F.[6] It has been proposed that these assemblages be recategorized as separate species of *Giardia* (Table 79-1), but this has not yet been unanimously accepted.[7]

Giardia infections in cats and dogs have been reported in many prevalence studies, case reports, and treatment studies from around the world. Infection rates vary with the assay used and whether or not diarrhea is occurring. However, in general they are approximately 5% to 20% in dogs and cats.[3] In most studies there is no association between the presence of *Giardia* in the feces and clinical signs, because of the high prevalence of subclinical infections.[3,8] Younger or immunosuppressed animals and those living in crowded environments are at the highest risk of showing clinical signs of disease.

*The *Giardia* assemblages listed currently fall within the single species *Giardia duodenalis*

Clinical Features

Signs and Their Pathogenesis

After *Giardia* spp. cysts are ingested by a susceptible host, gastric acid and pancreatic enzyme exposure in the duodenum induces release of the two trophozoites, which mature quickly and attach to the brush border of the villous epithelium by means of their ventral adhesive disk and a number of parasitic

surface molecules, including the giardins (alpha, beta, delta, and gamma giardins) and a network of contractile proteins. In dogs, trophozoites are found from the duodenum to the ileum; in cats, they predominate in the jejunum and ileum. Trophozoites multiply by binary fission and then encyst by an unknown mechanism. Contamination of fomites, which can include arthropods and the coats of animals, or food and especially water sources by *Giardia* cysts is an important mode of transmission, because cysts remain viable for days to weeks in the environment when conditions are cool and moist.

Although the pathogenesis of *Giardia* is not completely understood, in vitro and in vivo studies suggest it is multifactorial with a combination of intestinal malabsorption and hypersecretion as the primary mechanisms associated with development of diarrhea. The host-parasite interaction leads to the upregulation of genes involved in the apoptotic cascade and in the formation of reactive oxygen species.[9] The induction of apoptosis increases gastrointestinal permeability, allowing luminal antigens to activate host immune-dependent pathologic pathways. *Giardia* also alters epithelial claudin proteins that are components of tight junctions.[9] However, *Giardia* can cause clinical signs in the absence of villous atrophy or other signs of mucosal injury.[9] *Giardia* infection stimulates chloride secretion and results in a diffuse loss of brush border microvillus length, which causes epithelial maldigestion and malabsorption of glucose, sodium, and water and reduced disaccharidase activity. Mild to moderate infiltrates of intraepithelial lymphocytes can be recognized and may be associated with the sodium and glucose malabsorption. Loss of epithelial barrier function may have the potential to lead to chronic intestinal disorders, but the mechanisms remain unclear.[9] Mast cell hyperplasia may also contribute to the loss of epithelial barrier function. It is unknown why some people and animals maintain chronic, subclinical infections, but this is likely related to both host and parasite factors.

Although most cats and dogs that shed *Giardia* do not show clinical signs of disease, *Giardia* infection can induce illness in some animals. The primary clinical signs of giardiasis include chronic diarrhea and weight loss. The diarrhea is usually mucoid, pale, and soft and has a strong odor; steatorrhea may be present as well.[3] The presence of blood in the stool is uncommon unless co-infections with other agents such as *Ancylostoma* spp., *Isospora* spp., *Tritrichomonas foetus,* or *Clostridium perfringens* occur. Fever or vomiting is almost never recognized in dogs or cats with giardiasis. Co-infections with other agents such as *Cryptosporidium* spp. or *T. foetus* may potentiate diarrhea in dogs or cats.[10,11] It is currently unknown whether the different assemblages induce different clinical signs in cats and dogs or if there are strains within a given assemblage that are more pathogenic than others.

Diagnosis

Laboratory Abnormalities

Giardia spp. infection alone is rarely associated with CBC or serum biochemical panel abnormalities.

Diagnostic Imaging

Abdominal radiographic abnormalities are uncommon and nonspecific and, when present, are suggestive of diffuse enteritis.

Microbiologic Testing

Because of the small size of *Giardia* cysts and the high subclinical infection rate, giardiasis is commonly misdiagnosed, underdiagnosed, or overdiagnosed.[3,12] Yeasts are easily mistaken for *Giardia*, which leads to false-positive fecal flotation results. *Giardia* cysts are shed intermittently, and repeated fecal analysis may be needed to detect cysts. In addition, cysts can deteriorate in fecal flotation solutions, leading to false-negative results.[12] A variety of different *Giardia* assays have been evaluated for use in cats and dogs (Table 79-2). There is no one test that can be performed on a single fecal specimen that has 100% sensitivity. The following is a discussion of the currently available diagnostic methods.

Cytologic Examination

Feces can be evaluated for the presence of *Giardia* trophozoites by wet mount examination. Approximately 2 mm × 2 mm of fresh diarrheic feces or mucus is mixed with a drop of normal saline solution (warmed to body temperature) on a microscope slide and a coverslip placed. At 100× magnification, trophozoites are recognized by their "falling leaf" motion. Evaluation for structural characteristics is then performed at 400× magnification. Because trophozoites may be associated with mucus, the only visible motility may be the flagella. Although *Giardia* trophozoites can be confused with tritrichomonads that are similar in size, they can be differentiated from tritrichomonads based on their motility and morphology. In contrast to *Giardia* spp., tritrichomonads have an undulating membrane and a rolling form of motility, lack a concave surface, and have only a single nucleus (see Chapter 80).[3] Further testing of feces for *Giardia* antigen, *Giardia* DNA by PCR assay, or fecal culture or PCR assay for *Tritrichomonas foetus* can be used to differentiate the organisms if cytology is inconclusive. Once *Giardia* is detected in a direct smear or wet mount based on motility, further cytologic examination with staining should be performed on a fresh specimen. The application of Lugol's solution, methylene blue, or acid methyl green to the wet mount helps in the visualization of the internal structures of the trophozoites. Trophozoites are rarely found in solid feces.

Concentration Techniques

Giardia cysts are more likely to be detected after fecal concentration techniques. Sheather's sugar centrifugation and zinc sulfate centrifugation are commonly used. In addition to the identification of *Giardia* cysts, ova of other common parasites can easily be identified. *Giardia* cysts can be confused with yeast because of similar size, but *Giardia* cysts have a distinct structure (see Figure 79-3). Because of the intermittent pattern of shedding, at least three specimens should be examined over a period of about 1 week before ruling out *Giardia* spp. infection as a cause of diarrhea. If fecal specimens cannot be examined immediately, storage at 4°C for several days is acceptable, but specimens should not be frozen.

Duodenal Aspirates

Endoscopic sampling of duodenal secretions and then examination of the sediment for trophozoites was once considered the most sensitive technique for detection of *Giardia* spp. infection in dogs, but with the advent of immunologic and molecular techniques, duodenal aspirates are no longer performed. In cats, because of the location of the parasite in the mid to distal small bowel, this technique is unlikely to yield positive results.

Direct Immunofluorescence

A monoclonal antibody–based immunofluorescent antibody (IFA) assay (Merifluor *Cryptosporidium/Giardia,* Meridian

VetBooks.ir

TABLE 79-2

Diagnostic Assays Available for Giardiasis in Dogs or Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Feces	*Giardia* trophozoites and cysts	False negatives are common and occur when specimen size is small or low numbers of organisms are present, or because of intermittent shedding. False positives can occur when cysts are confused with yeasts.
Centrifugal fecal flotation (concentration techniques)	Feces	*Giardia* cysts	Because of the intermittent pattern of shedding, at least three specimens should be examined over a period of about 1 week before concluding that *Giardia* spp. infection is an unlikely cause of diarrhea. False positives can occur when cysts are confused with yeasts.
Direct immunofluorescence	Feces	*Giardia* cysts	May be more sensitive and specific than centrifugal fecal flotation, but sensitivity for detection of assemblages that infect dogs and cats is not well understood. Sensitivity appears to be similar to that of *Giardia* antigen ELISA assays.
Giardia antigen ELISA assays	Feces	*Giardia* cyst antigen	When used in combination with centrifugal fecal flotation, sensitivity can approach 98%. However, performance varies with the assay used, and the sensitivity of ELISA assays for detection of assemblages from dogs and cats is not well understood. It has been recommended that this assay be used in addition to fecal flotation only during evaluation of dogs and cats with diarrhea and not healthy pets (see text).
PCR assays	Feces	*Giardia* spp. DNA	The sensitivity and specificity of assays may vary depending on assay design. False negatives can occur as a result of PCR inhibitors in feces. The significance of a positive PCR result must be interpreted in light of clinical findings because of subclinical infections.

Diagnostics, Cincinnati, OH) used to detect *Giardia* spp. cysts and *Cryptosporidium* spp. oocysts in human feces has been applied to feces from dogs and cats in multiple studies.[3,13,14] It is believed that *Giardia* cysts from assemblages C, D, and F are detected by this assay, but this hypothesis has not been rigorously assessed using genotyped specimens. The assay gives both immunologic confirmation (fluorescence) and morphologic evaluation (size and shape) to confirm the presence of *Giardia* in feces. In one study, the assay was more sensitive and specific than zinc sulfate flotation but comparable to an antigen-detection technique when used on fecal specimens from shelter dogs.[13] Because *Cryptosporidium* spp. are also associated with small bowel diarrhea, can exist as co-infections with *Giardia,* and are difficult to detect with other techniques, the IFA assay is used frequently by some clinicians (see Chapter 81). A fluorescence microscope is needed to read the IFA slides; therefore, this assay is usually only performed in diagnostic laboratories. If the specimens cannot be examined immediately, they can be stored at 4°C for a maximum of several days but should not be frozen.

Fecal Antigen Detection by Enzyme-Linked Immunosorbent Assays

Several ELISAs are available for detection of *Giardia* antigen in human feces. A veterinary assay is labeled for use with dog and cat feces (SNAP *Giardia,* IDEXX Laboratories, Portland, ME). Results vary with the ELISA assay used, and inconsistent results have been reported with some *Giardia* antigen tests when compared to other techniques. In a study of cats, the SNAP *Giardia* antigen assay had similar sensitivity and specificity when compared to fecal flotation, and when the results of the two techniques were combined, the overall sensitivity was 97.8%.[14] Little information is available as to whether currently available fecal antigen assays detect *Giardia* assemblages C, D, or F (i.e., the canine- and feline-associated assemblages). In one study of 4 assemblage C isolates and 13 assemblage D isolates (which infect dogs), all were positive by the SNAP *Giardia* antigen assay.[15] The Companion Animal Parasite Council currently recommends that fecal antigen tests be used as an addition to fecal flotation only during the evaluation of dogs and cats with diarrhea and not healthy pets, because the clinical and zoonotic impact of an antigen-positive, cyst-negative healthy pet is unknown.[16] It is also unknown how long *Giardia* antigen assays remain positive after resolution of diarrhea. Therefore, if a veterinarian chooses to assess the success of the treatment for giardiasis in cats and dogs, only fecal flotation is recommended for the follow-up evaluation.

Molecular Diagnosis Using the Polymerase Chain Reaction

Giardia spp. DNA can be amplified from feces by PCR assay, and such molecular methods can be used to determine the *Giardia* assemblage present through sequence analysis of the PCR product. However, the assignment of isolates to specific *G. duodenalis* assemblages using PCR assays is not always

consistent because different results occur depending on the target sequence amplified.[5,17] Thus, some dog or cat isolates can be genotyped as "potentially zoonotic" using one target gene but as "host specific" with another. It is currently recommended that if the assemblage is to be determined, three genes should be assessed (the assessment of multiple genes using PCR and sequencing is also known as multilocus sequence typing). *Giardia* PCR assays can also be falsely negative because of the presence of PCR inhibitors in feces and so should not be used as the sole *Giardia* spp. assay.

Pathologic Findings

Gross Pathologic Findings

Giardia spp. infection may cause mild intestinal thickening. Because the agent is not enteroinvasive, blood is generally not present within the intestinal lumen unless co-infections are recognized. Animals with chronic clinical signs of disease may be emaciated. Other parasites such as roundworms or hookworms may be found.

Histopathologic Findings

In clinically affected animals with *Giardia* infection, a diffuse loss of brush border microvillus length may be noted on histopathology of the small intestine. Increased numbers of intraepithelial lymphocytes and mast cell hyperplasia may also be present. However, diarrhea has been associated with giardiasis in dogs, cats, and people with normal intestinal biopsy results.

Treatment and Prognosis

Giardia spp. have specific antimicrobial susceptibility patterns, and so it is currently impossible to predict which anti-*Giardia* drug will be effective in individual dogs or cats. Because *Giardia* spp. of dogs and cats can be difficult to culture in the laboratory, there is little in vitro susceptibility test result information available. Although a variety of drugs have been used to treat giardiasis in dogs and cats, there are few studies that have evaluated the efficacy of drugs and varied drug doses in experimentally infected animals. In most studies, fecal specimens were evaluated for only short periods of time after treatment, and immune suppression was not induced to evaluate whether infection was eliminated or merely suppressed. Infection with *Giardia* does not appear to cause permanent immunity, and so re-infection can occur, a finding that also hampers assessment of treatment studies.

Treatment options that are currently available or used historically for dogs or cats with confirmed or suspected giardiasis include albendazole, febantel/pyrantel/praziquantel, fenbendazole, furazolidone, ipronidazole, metronidazole, quinacrine, and tinidazole (Table 79-3). Newer drugs being studied or those with minimal information available for dogs and cats include azithromycin, nitazoxanide, paromomycin, and secnidazole.

Administration of metronidazole is indicated if concurrent infection with *Clostridium* spp. is suspected (see Chapter 48). In cats, metronidazole benzoate is preferred to metronidazole USP because it is better tolerated by most cats.[18] However, metronidazole should not be administered orally for longer than 7 days sequentially or at a total daily dose greater than 50 mg/kg because of the risk for neurotoxicity.[19,20] Ipronidazole, ronidazole, secnidazole, and tinidazole are other drugs with this class that have been used to treat giardiasis in dogs or cats (see Table 79-3). Ipronidazole added to the drinking water could be considered if a large number of dogs are clinically affected.[21] Ronidazole was used with hygiene management to control giardiasis in a dog kennel, but the author recommends reserving this drug for the treatment of *T. foetus* infections because of the potential for neurotoxicity and emerging ronidazole-resistant *T. foetus* strains.[22-24] Tinidazole should be considered as a secondary *Giardia* spp. treatment for dogs and cats if metronidazole is not tolerated, but optimal dosing protocols are not known. Secnidazole was evaluated in a small study of cats with minimal recognized toxicity (elevated liver enzyme activity in one cat) and apparent efficacy after one dose.[25] Further research is needed before routine use of this drug can be recommended.

If concurrent nematode infestation is suspected, albendazole, febantel/pyrantel/praziquantel, or fenbendazole may be most effective anti-*Giardia* drugs.[26-35] Albendazole has been associated with bone marrow suppression in some dogs and cats, so some clinicians avoid use of this drug.[35] Febantel/pyrantel/praziquantel is licensed in some countries for treatment of *Giardia* spp. infection in dogs and can be effective when administered daily for 3 days.[26] This combination has also been studied in small numbers of experimentally infected cats.[33] Data from an experimental model suggest that the combination of febantel with pyrantel is synergistic.[34] Many clinicians currently prescribe fenbendazole once daily for 5 days as initial therapy for dogs or cats with diarrhea and *Giardia* infection because of minimal expense and wide safety margin.

If the first drug fails to clear the infection (cyst shedding) or resolve the diarrhea, antimicrobial drug resistance may be present, so a second drug from an alternative class is indicated. Some clinicians currently recommend the concurrent administration of metronidazole and fenbendazole. Other clinicians resort to combination therapy only if there is evidence of a persistent infection that has not been cleared by monotherapy.

Azithromycin was used successfully in the management of giardiasis in one dog.[36] Paromomycin has anti-*Giardia* properties but has been absorbed across the gastrointestinal epithelium and associated with reversible acute renal failure in cats. Nitazoxanide is labeled for the treatment of giardiasis and cryptosporidiosis in humans in some countries and has been studied

TABLE 79-3

Drugs Used for the Treatment of *Giardia* spp. Infections

Drug	Species	Dose
Febantel, pyrantel, praziquantel	D	Label dose for 3 days
	C	56 mg/kg (based on the febantel component) PO q24h for 5 days
Fenbendazole	D, C	50 mg/kg PO daily for 3-5 days
Ipronidazole	D	126 mg/liter of water PO ad libitum for 7 days
Metronidazole	D, C	15-25 mg/kg PO q12-24h for 5-7 days
Tinidazole	D	44 mg/kg PO q24hr for 3 days
	C	30 mg/kg PO q24hr for 3 days

C, Cat; D, dog.

VetBooks.ir

VetBooks.ir

in some dogs and cats, but optimal protocols for the treatment of giardiasis are unknown. In addition, nitazoxanide is commonly associated with vomiting in dogs and cats.[31] The author currently administers nitazoxanide at 10 mg/kg PO q12h with food for 7 days for the treatment of dogs or cats with small bowel diarrhea and co-infections with *Giardia* spp. and *Cryptosporidium* spp. A longer duration of treatment appears to be required for some dogs and cats, and so treatment should be continued if an initial positive response is noted but clinical resolution is not achieved after the first 7 days.

The addition of fiber to the diet may help control clinical signs of giardiasis in some animals through reduction of bacterial overgrowth or by inhibiting organism attachment to microvilli. Feeding a fat-restricted diet may also be effective. In one study, administration of the probiotic *Enterococcus faecium* SF68 (FortiFlora, Nestle Purina PetCare) lessened *Giardia* spp. shedding in mice when fed before infection and enhanced *Giardia* immune responses.[37] In contrast, administration of this probiotic to dogs with chronic subclinical giardiasis had no measurable effect on cyst shedding.[38] In another study, dogs with acute diarrhea that were housed in shelters responded more rapidly to treatment if the probiotic was administered with metronidazole than if metronidazole was administered alone; many of these dogs were infected with *Giardia* spp.[39]

Bathing all dogs during medical treatment may lessen re-infection rates. In dogs and cats with persistent diarrhea and *Giardia* spp. infection, a more extensive work-up to attempt to diagnose other underlying diseases is indicated if several therapeutic trials fail to control the diarrhea. Potential underlying disorders that should be considered include cryptosporidiosis, tritrichomoniasis (primarily in cats), inflammatory bowel disease, gastrointestinal lymphoma, bacterial overgrowth, exocrine pancreatic insufficiency, and immunodeficiencies.

The primary goal of *Giardia* treatment is to resolve clinical signs of diarrhea. It is controversial whether to treat healthy dogs and cats with *Giardia* spp. cysts in feces, because healthy pets are generally not considered significant human health risks by the Centers for Disease Control and Prevention.[40] This is because infection can recur rapidly or not be cleared, and because all drugs have adverse effects. For example, in one small study of naturally infected dogs, approximately 50% of dogs had adverse events associated with treatment, and more than 60% of treated dogs were still *Giardia* infected when rechecked 34 days after treatment.[31] However, because clinical signs induced by *Giardia* spp. can be intermittent and since some *Giardia* spp. may be of zoonotic concern (especially to the immunocompromised), treatment of healthy infected animals should be discussed with each owner. If treatment is deemed indicated by the clinician and owner, many clinicians currently recommend that a 5-day course of fenbendazole be administered to apparently healthy dogs and cats that test positive for *Giardia* spp. cysts in feces. After treatment, if the animal is healthy and negative for cysts, retesting is not indicated again until the next scheduled wellness examination and fecal flotation. *Giardia*–infected dogs or cats should not be tested for *Giardia* antigen or DNA in feces since it is unknown how long positive assay results persist after treatment.

A common question is how to manage dogs or cats that have normal stool and are *Giardia* antigen positive but *Giardia* cyst negative. These animals may have a low-grade infection, or a low percentage of animals (approximately 2% to 5%) have false-positive antigen test results. To further evaluate for cyst shedding, the veterinarian can perform an IFA test or two additional fecal flotations (three negative centrifugal flotation assays run within 5 days is considered adequate to rule out a *Giardia* infection in both animals and humans). If these other test results are negative, the antigen test was likely falsely positive. If cysts are still identified after fecal centrifugal flotation performed 2 weeks after appropriate administration of a drug with anti-*Giardia* activity, a second course of therapy may be indicated using a drug from a different class. It is recommended that apparently well animals *not* be treated beyond two courses of therapy.[40] No further diagnostics are indicated unless gastrointestinal signs occur or the animal is again due for routine fecal screening (once to twice annually as a minimum for all dogs and cats).

Immunity and Vaccination

Sterilizing immunity to *Giardia* spp. does not occur, and so repeated shedding, clinical signs, and infection may occur. Reinfection occurs even in vaccinated dogs or cats, and so the previously available *Giardia* vaccines have been discontinued.

Prevention

Prevention of *Giardia* infection involves boiling or filtering of water collected from the environment before drinking and disinfection of premises contaminated with infected feces with steam cleaning or quaternary ammonium compounds (1 minute contact time). Transport hosts should be controlled, and treatment and bathing of all animals in the environment could be considered if intermittent diarrhea occurs. Feces from infected animals should be removed from the environment promptly.

Public Health Aspects

In humans, infection with *Giardia* can be asymptomatic or result in acute or chronic gastrointestinal illness. Acute giardiasis is characterized by watery diarrhea, epigastric pain, nausea, vomiting, decreased appetite, and weight loss; these signs occur 6 to 15 days after infection. Young children and immunodeficient individuals are most likely to show clinical signs; chronic infections are also more likely to occur in the immunocompromised. Recent studies suggest that functional gastrointestinal disorders such as irritable bowel syndrome can be associated with a previous *Giardia duodenalis* infection.[41]

Infection with the *Giardia* assemblages of dogs (assemblage C and D) or cats (assemblage F) is usually not associated with clinical disease in humans, but can be detected in the feces of immunocompromised people.[1] Human assemblages A and B can be found in feces of dogs and cats when animals share human environmental features (i.e., contaminated water). However, it is unlikely that new human infections by *Giardia* assemblages A or B are acquired from dogs or cats.[3] Thus, healthy animals that test positive for *Giardia* are probably not significant human health risks if the family members are also healthy. Greater risk is likely to exist for immunocompromised people, and so the potential for contact with infected feces should be minimized.

VetBooks.ir

CASE EXAMPLE

Signalment: "Duke," a 12-week-old intact male Golden retriever from Fort Collins, CO

History: Duke was adopted from a backyard breeder. The puppy was eating well and was in good body condition. Small bowel diarrhea was the only historical complaint. The stool character varied from soft to watery with occasional streaks of white material that was interpreted as mucus. The diarrhea began just after adoption (a week before evaluation). This was also the time that a new commercial puppy food designed for large-breed dogs was introduced by the owner. The puppy's first two vaccines (attenuated live distemper, adenovirus, parvovirus, parainfluenza virus) had been administered at 7 and 10 weeks of age, at which times he also was administered pyrantel pamoate orally for strategic deworming. It was unknown whether or not other littermates had diarrhea or parasitic infections. The resident adult collie was considered normal by the owner, and the adult dog's feces were normal the previous day.

Physical Examination: The dog was bright, alert, and responsive and weighed 11.2 kg. T = 101.3°F (38.5°C), HR = 120 beats/min, RR = 24 breaths/min, mucous membranes pink, and CRT = 1 s. Body condition score was 4/9. The dog's haircoat was normal and there was no evidence of ectoparasites. No clinically significant abnormalities were noted on physical examination.

Results of Microbiologic Testing: Fecal wet mount examination: No motile flagellates were noted.

Zinc sulfate centrifugal fecal flotation: cysts consistent with *Giardia* spp. were noted.

Fecal cytology: no inflammatory cells, spore-forming rods, or spirochetes were detected.

Diagnosis: *Giardia* spp. infection.

Treatment: Fenbendazole (50 mg/kg PO q24h) for 3 days was prescribed together with a commercially available intestinal diet and probiotic (daily for 1 month). The adult housemate was not treated. The feces were normal 2 days later, after which the puppy food was reinstituted by feeding a progressively increasing percentage over 5 days. Clinical signs of diarrhea never developed in the adult dog. A second vaccine was administered at the recheck 1 week later and again with a rabies vaccine at 16 weeks of age, at which time a fecal flotation was negative. The puppy was still clinically healthy at the 16-week vaccine visit.

Comments: The findings were characteristic of *Giardia* spp.–associated diarrhea; however, because *Giardia* spp. cysts are common in both healthy puppies and puppies with diarrhea, it is impossible to definitively make a diagnosis of giardiasis. Since the puppy needed an additional strategic deworming, fenbendazole was chosen rather than metronidazole. Febantel/praziquantel/pyrantel would also have been an appropriate choice. Because the history was also consistent with stress-associated diarrhea (diet change, housing change), the probiotic and diet change were initiated. Both of these adjunct treatments also may aid in the treatment of giardiasis. *Giardia* antigen testing was not performed, because cysts were clearly identified on fecal flotation. *Giardia* assemblage determination was not performed, but could have been considered if immunosuppressed family members lived in the household. If recheck fecal examination is to be performed, only fecal flotation is indicated, not fecal antigen tests or PCR assays. Whether to test or treat in-contact healthy adult dogs is controversial; however, 5% to 10% of healthy dogs are already infected with *Giardia* in most studies, re-infection is common, and drugs are expensive and can be toxic. Thus, many clinicians just treat the animal with clinical signs of disease during the first episode of diarrhea, with the potential to escalate therapies should the problem persist.

CHAPTER 80

Trichomoniasis

Michael R. Lappin

VetBooks.ir

Overview of Trichomoniasis

First Described: Trophozoites that were likely to be *Tritrichomonas foetus* have been recognized in cat feces for many years, but *T. foetus* was not definitely recognized as the primary cause of trichomonal diarrhea until 2003 (Levy).[1]

Cause: *Tritrichomonas foetus*; flagellate protozoan (phylum Sarcomastigophora, order Trichomonadida)

Affected Host Species: Cats are infected more commonly than dogs. Clinical signs of disease are most common in purebred, young animals that are housed in crowded environments.

Mode of Transmission: Fecal-oral. There are no proven intermediate hosts, but *T. foetus* can survive outside the host for several hours as well as survive transit through slugs, and so transport hosts are possible.

Geographic Distribution: Although infections have not been documented in all countries, *T. foetus* infection of cats is thought to have a worldwide distribution.

Major Clinical Signs: Subclinical infections are common in high-risk cats. Continuous or intermittent large bowel diarrhea is most common in kittens with clinical infections. Swelling of the anus and fecal incontinence can occur.

Differential Diagnoses: All causes of large bowel diarrhea, including *Isospora* spp., *Clostridium perfringens*, dietary intolerance, and inflammatory bowel disease. If motile trophozoites are noted on wet mount examination of feces, *Giardia* spp. and *Pentatrichomonas hominis* are differential diagnoses.

Human Health Significance: There are no known significant human health risks associated with *T. foetus* infections of cats. Nevertheless, cat feces should always be handled as if the possibility of zoonosis exists.

Etiologic Agent and Epidemiology

Members of the order Trichomonadida are flagellates that reproduce by binary fission and do not form cysts (Figure 80-1).[2,3] The trophozoite of *Tritrichomonas foetus* is 10 to 26 µm long and 3 to 5 µm wide and has three anterior flagella (Figure 80-2). In vertebrates, trichomonads are parasites of the gastrointestinal system, the reproductive system, and the upper portions of the respiratory tract. *Tritrichomonas foetus* infects the reproductive tract of both cows and bulls and can cause abortion and other reproductive abnormalities. The organism parasitizes the gastrointestinal system of the cat and can be associated with diarrhea. Genetic characterization of bovine and feline isolates of *T. foetus* has been performed, and minor differences exist.[4-6] Feline isolates of *T. foetus* remained in the reproductive tract of heifers but did not cause the same pathologic changes as a bovine isolate in one study.[7] Similarly, bovine isolates of *T. foetus* may not cause diarrhea in cats as successfully as feline isolates.[8]

T. foetus is transmitted by the direct fecal-oral route. The organism can survive in the environment for hours to days in very moist conditions. Shared litter boxes and mutual grooming likely contribute to transmission from one cat to another.

Cats that harbor *T. foetus* infection have now been documented in multiple countries.[9-27] Cats in crowded environments and purebred catteries are commonly colonized; the organism is uncommon in feral cats. In one of the first large prevalence studies in the United States, 31% of 117 cats owned by 89 different breeders at an international cat show were colonized.[14] In the United Kingdom, 16 (14.4%) of 111 diarrhea specimens were positive for *T. foetus* by PCR assay.[15] *T. foetus*–associated diarrhea is most common in kittens and young cats, but adult cats can also be affected.[14,15] Catteries with a recent history of refractory diarrhea, adult cats with *Isospora* spp. infections, and cats living in a facility with a small number of square feet per cat were

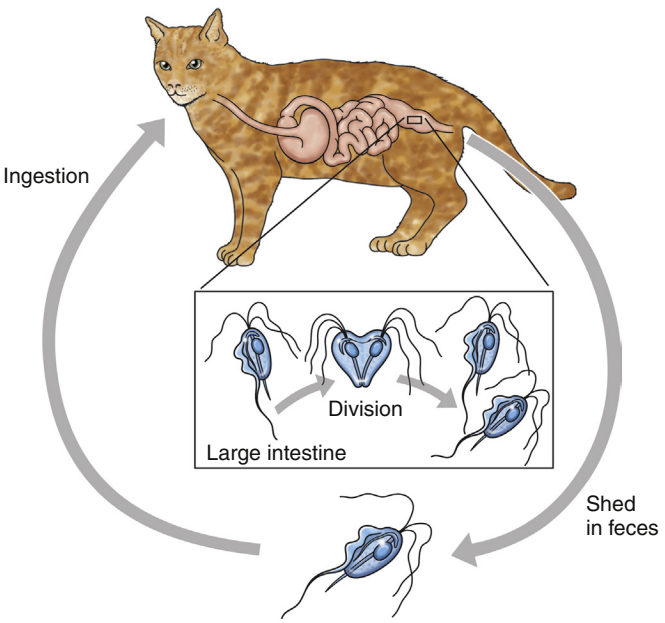

FIGURE 80-1 Life cycle of *Tritrichomonas foetus*. The organism has a direct life cycle, and the parasite replicates by binary fission.

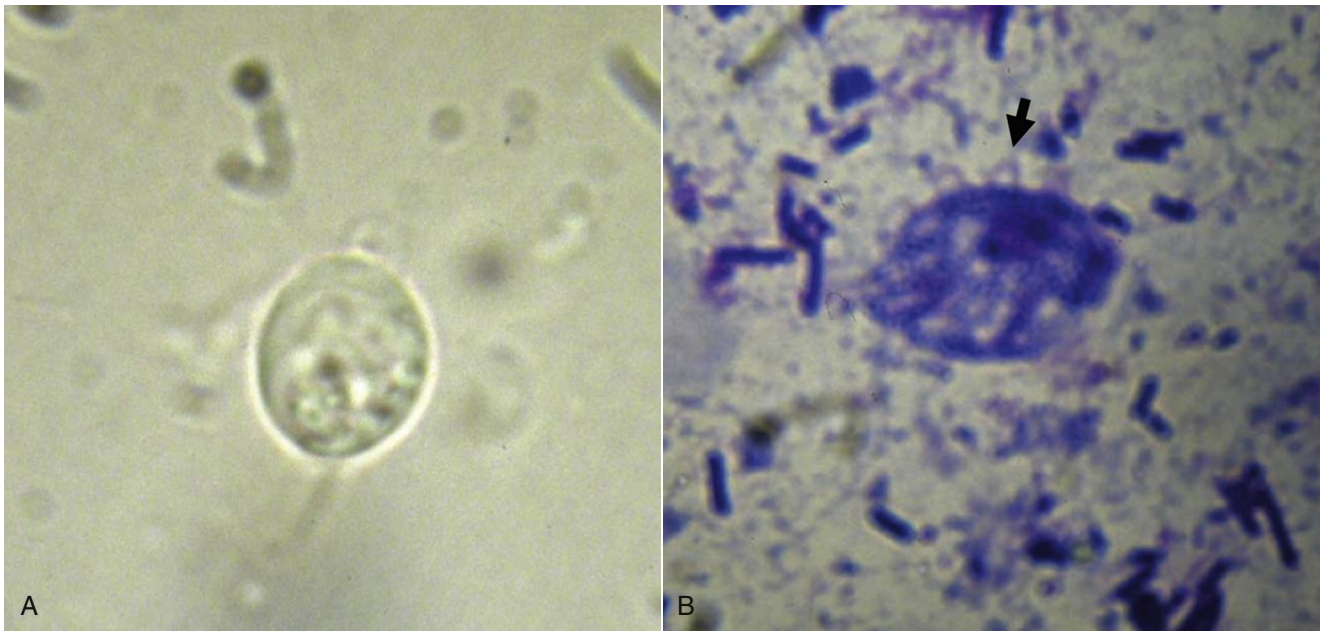

FIGURE 80-2 **A,** *Tritrichomonas foetus* trophozoite seen on a saline wet mount of a fecal specimen. The organism can be recognized by its progressive forward, rolling motility. **B,** Diff Quik stain. The undulating membrane can be clearly visualized coursing along the lateral aspect of the trophozoite *(arrow)*.

more likely to be infected with *T. foetus* in some studies.[14,15] Other co-infections, such as those with *Giardia* spp. and *Cryptosporidium felis*, may also increase the potential for disease.

Clinical Features

Signs and Their Pathogenesis

Tritrichomonas foetus is an obligate parasite that depends on endogenous bacteria and host secretion for nutrients. However, the organism can survive for short periods of time in contaminated water, urine, feces, and cat litter.[28,29] In one study, the organism was shown to survive 30 minutes on dry cat food, several hours in moist cat food, and hours to days in cat feces.[29] The organism also survived transit through the gastrointestinal tract of two types of slugs.[30]

In experimentally infected cats, the location of *T. foetus* is restricted to the ileum, cecum, and colon.[31,32] Fluctuations in the colonic microflora or other factors are necessary to produce the clinical signs of *T. foetus* infection. The organism can persist in cats without diarrhea, and diarrhea can worsen without a change in the organisms present, suggesting that the underlying mechanisms that lead to diarrhea are multifactorial.[31] The organism adheres to the intestinal epithelium and incites a lymphoplasmacytic and neutrophilic inflammatory response.[33] An increased number of *T. foetus* organisms and increased severity of diarrhea was associated with co-infection with *Cryptosporidium* spp. in one study.[31] However, co-infections are not always associated with the presence of *T. foetus*–associated diarrhea.[23] There is little information available as to whether immunosuppression predisposes to chronic infection with *T. foetus*. Administration of prednisolone did not change the fecal consistency or the frequency of positive results on direct fecal exams in one study.[31]

The clinical signs of trichomoniasis are variable and range from subclinical infection to chronic intractable diarrhea. The signs often are intermittent and can resolve with antimicrobial drug treatment, only to recur after treatment is discontinued. The diarrhea is mainly a large bowel diarrhea characterized by increased frequency of defecation and passage of semiformed to liquid, often foul-smelling feces that sometimes are associated with fresh blood and mucus. When the diarrhea is severe, the anus may become edematous and fecal incontinence may develop (Figure 80-3). Although diarrhea may persist, most affected cats maintain a good appetite and body condition score.

VetBooks.ir

TABLE 80-1

Diagnostic Assays Available for Tritrichomoniasis in Dogs or Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Feces	*Tritrichomonas* trophozoites	False negatives are common and occur when specimen size is small or low numbers of organisms are present, or because of intermittent shedding. The sensitivity of this method is <20%.
Culture (InPouch test)	Feces	*T. foetus*	Considered the gold standard for diagnosis. May take days for the organism to grow. The sensitivity of this method is approximately 55%. False negatives can occur if feces are dried out, because of intermittent shedding or recent treatment with antiprotozoal drugs, or if the pouch is overgrown by intestinal bacteria.
PCR assays	Feces	*T. foetus* DNA	The sensitivity and specificity of assays may vary depending on assay design. Well designed assays have the highest sensitivity of all diagnostic test methods, but false negatives can occur if specimen size is small or as a result of PCR inhibitors in feces.

Tritrichomonas foetus was detected in the uterine contents of a cat with endometritis and pyometra.[32] However, the organism was not associated with infection or disease of the reproductive tract in a separate study of cats with *T. foetus* infection that were housed in catteries.[34]

Diagnosis

Laboratory Abnormalities

Tritrichomonas foetus infections only rarely lead to systemic laboratory abnormalities. However, if the diarrhea is severe, decreases in potassium, sodium, and chloride concentrations may be present from gastrointestinal losses.

Diagnostic Imaging

Abdominal radiographic or ultrasonographic abnormalities are uncommon, are nonspecific, and, when present, are suggestive of diffuse colitis.

Microbiologic Testing

A direct fecal smear should be performed for all cats with large bowel diarrhea to evaluate for the presence of *T. foetus* trophozoites (Table 80-1), using the technique described for *Giardia* (see Chapter 79). *Tritrichomonas foetus* is similar in size to *Giardia* but can be differentiated by the presence of an undulating membrane, a rapid forward motion, the lack of a concave surface, and a single nucleus. Video clips that demonstrate the classic motility can be found online (http://www.cvm.ncsu.edu/docs/personnel/gookin_jody.html). The trophozoite and its undulating membrane may also be identified on fecal smears stained with Diff Quik stain. The sensitivity of a direct smear using specimens from naturally infected cats was only 14% in one study, so false negatives are common with this method.[31] The sensitivity can be improved by analyzing multiple fecal smears. If *T. foetus* infection is still suspected after the initial work-up, culture can be performed using a commercially available culture system (InPouch TF, BioMed Diagnostics, White City, OR). In this system, a tiny amount of feces is inoculated into the pouch, which can be incubated in the clinic at room temperature and examined daily by microscopy for evidence of protozoal growth. The medium used does not support the growth of *Giardia* spp. or *Pentatrichomonas hominis*, and positive test results suggest infection by *T. foetus*.[35] This assay is considered the gold standard for diagnosis of infection. However, it takes days for positive test results to develop in some cases. Thus, PCR assays are also used by clinicians to document current infection. Several PCR-based assays that are specific for *T. foetus* are also commercially available, and these assays are recommended for assessment of fecal specimens that were found negative by microscopy and fecal culture and to confirm that microscopically observed or cultivated organisms are *T. foetus*.[36] PCR assays are available that are specific for *T. foetus* and do not amplify *Giardia* or *P. hominis* DNA.[37] The DNA of *P. hominis* has been amplified from the feces of cats co-infected with *T. foetus*, but whether this potentiates *T. foetus*–associated clinical disease is currently unknown.[37]

Pathologic Findings

Gross Pathologic Findings

The gross findings associated with *T. foetus* infection in cats are nonspecific and associated primarily with the colon. The colon may be normal or appear mildly thickened with or without hyperemia.

Histopathologic Findings

Lesions associated with *T. foetus* infection in cats are confined to the colon. The organisms are noted in most experimentally infected cats, but not in all sections.[38] Thus, if colonoscopy is performed, multiple specimens should be collected for histopathologic evaluation. The organisms are usually close to the mucosal surface and are associated with mild-to-moderate lymphoplasmacytic and neutrophilic infiltrates; crypt epithelial cell hypertrophy, hyperplasia, and increased mitotic activity; loss of goblet cells; crypt microabscesses; and attenuation of the superficial colonic mucosa.[38] In some cats, *T. foetus* may be detected in the lumen of colonic crypts and can invade the lamina propria. In situ hybridization techniques can be used to identify *T. foetus* and *P. hominis* in biopsy specimens.[39,40]

Treatment and Prognosis

The treatment of choice for *T. foetus* infections is the nitroimidazole drug ronidazole (Table 80-2). Before ronidazole was discovered as an effective treatment, multiple other treatment

VetBooks.ir

TABLE 80-2

Drugs Commonly Used for Treatment of *Tritrichomonas foetus* Infection in Cats

Drug	Dose	Route	Interval (hr)	Minimum duration (days)
Ronidazole	30 mg/kg	PO	24	14
Tinidazole	30 mg/kg	PO	24	14

regimens had been attempted in cats with *T. foetus* infections with generally poor responses.[12,25,41] In some cases, temporary improvement was noted with a variety of drugs, but relapse was invariable. Some of the apparent clinical improvement may have been due to secondary effects of drugs on the intestinal bacterial flora, although treatment may also prolong trophozoite shedding.

A number of drugs have also been tested in vitro to determine *T. foetus* susceptibility patterns.[42] Ronidazole has been the most effective drug used clinically to date and is currently recommended at a dose of 30 mg/kg PO q24h for 14 days.[43] Clinical signs can relapse after administration of ronidazole, but generally resolve again after the treatment regimen is repeated. The pharmacokinetics have been determined for ronidazole in cats.[44,45] Higher doses of ronidazole and twice-daily dose regimens can result in neurologic signs.[46] This likely relates to the high oral bioavailability and slow elimination of the drug by cats.[44] To date, all reported cases of ronidazole-related neurotoxicity have been reversible, but irreversible neurotoxicity can occur in some cats. Not all cats treated with high doses of ronidazole develop toxicity. In one study, a dose of 50 mg/kg PO q12h was used in research cats with no reported adverse effects.[47] Ronidazole is teratogenic and should not be used to treat pregnant or lactating queens or very young kittens. A delayed-release (guar gum) formulation offers promise for targeted delivery of ronidazole to the colon and reduced likelihood of systemic adverse effects in cats.[45]

Some strains of *T. foetus* are resistant to ronidazole.[48] Poor compounding can be another reason for failure of treatment in some situations. Ronidazole also has activity against *Giardia*.[49] However, to lessen potential for selection of resistant strains, ronidazole should be reserved for use for *T. foetus* infections, because multiple other drugs are effective for treatment of giardiasis.

Tinidazole, administered at 30 mg/kg for 14 days, suppressed *T. foetus* shedding to undetectable levels in two of four cats during a 33-week period posttreatment.[50] However, this drug is currently considered inferior to ronidazole because infection was not eliminated in all cats.

Immunity and Vaccination

Immunity to reinfection by *T. foetus* does not occur in the short term after recovery. However, although intestinal infection can be prolonged, the development of effective immune responses as kittens mature is followed by resolution of clinical disease. Vaccines for prevention of *T. foetus* infection in cats are not currently available.

Prevention

Kittens in crowded environments are more susceptible to infection due to stress or immunologic immaturity. Thus, minimizing stress and reduction of population-dense housing conditions will likely reduce the chances of exposure to *T. foetus*. Protocols for eliminating infections or lessening signs of *T. foetus* infection in catteries are available and involve testing, isolation or removal of cats that test positive, and retesting.[51] Treatment with ronidazole does not guarantee cure even if repeated PCR assays are negative, and relapse of infection (or reinfection) can occur months after discontinuation of treatment. For this reason, reintroduction of treated cats to a cattery is not recommended.

Public Health Aspects

Only a single case of an immunosuppressed human infected with *T. foetus* has been reported.[52] The parasite was isolated from a bronchoalveolar lavage specimen in a patient with *Pneumocystis* pneumonia. The authors did not rule out the possibility of a human host-adapted strain of *T. foetus*. However, because of the apparent poor host specificity of *T. foetus* and the close contact between cats and humans, zoonotic transmission should be considered and infected kittens with diarrhea should be handled with care. In addition, the possible presence of other zoonotic pathogens should always be considered in cats with diarrhea.

CASE EXAMPLE

Signalment: "Belle," a 14-week-old, intact female Pixie-bob cat from Seattle, WA

History: Belle was considered a pet quality Pixie-bob and so was sold into a private home at 14 weeks of age. The cattery had three queens and one tom and had bred at least six litters over the previous 2 years. No significant health problems were reported to the adoptive owner, and the cattery was retrovirus free. Belle appeared healthy the day the adoption was completed and was also pronounced healthy by the new attending veterinarian. The breeder had administered one dose of a vaccine for prevention of feline herpesvirus-1, feline calicivirus, and feline panleukopenia virus (FVRCP) and a dose of pyrantel pamoate at 7 and 10 weeks of age. The veterinarian administered an attenuated live FVRCP vaccine subcutaneously, gave one dose of pyrantel pamoate, discharged Belle with selamectin to be applied monthly, and scheduled a recheck at 16 weeks of age for rabies vaccination. Belle was taken to her new home by car for 4 hours and then housed in her private room while attempting to socialize to the two black Labrador retrievers living at the new home. The kitten was not allowed to see the dogs the first 2 days, but the dogs were allowed to sniff under the door of the room Belle was housed in and occasionally barked. On day 3, Belle

began having diarrhea that the owner reported to be "pea soup" consistency, with white strands and fresh blood. Tenesmus was also noted.

Physical Examination:

Body Weight: 2.1 kg.

General: Quiet, alert, and responsive. Ambulatory on all four limbs. Body weight was 2.1 kg and body condition score was 4/9. T = 101.3°F (38.5°C), HR = 180 beats/min, RR = 24 breaths/min, mucous membranes pink, CRT = 1 s. The only abnormality detected on physical examination was that the cat postured to defecate, and passed a small volume of diarrhea with streaks of blood and mucus when the caudal abdomen was palpated. Intestinal palpation was unremarkable.

Microbiologic Testing: Fecal wet mount examination: Motile flagellates noted with morphology and motility consistent with that of *Tritrichomonas foetus.*

In-house *Giardia* ELISA assay (SNAP *Giardia*, IDEXX Laboratories): Negative.

Zinc sulfate centrifugal fecal flotation: Negative.

Diagnosis: *Tritrichomonas foetus* infection.

Treatment: FortiFlora (Nestle Purina PetCare) for 1 month and ronidazole at 30 mg/kg PO daily for 14 days were prescribed. The stool normalized 3 days later, and ultimately, Belle learned to tolerate Labrador retrievers. She was clinically healthy at the visit 2 weeks later for rabies vaccination. The breeder was informed of the findings, and it was recommended that the breeder discuss management of this agent in the cattery with a veterinarian.

Comments: The findings were characteristic of a stress-activated *T. foetus* infection associated with moving to the new home and first contact with dogs. Many cats in catteries maintain subclinical infections that may be followed by clinical signs of large bowel diarrhea when the infected cats are subjected to stress. While *T. foetus* can be amplified by PCR assay or grown from feces of dogs, it is unlikely that healthy adult dogs will become clinically ill, and so no tests or treatments were performed on the family dog. In this cat, the clinical scenario was characteristic, so PCR assay or culture were not performed. However, if there had been any doubt that the organisms seen were *T. foetus*, these assays could also have been performed.

CHAPTER 81

Cryptosporidiosis

Michael R. Lappin

VetBooks.ir

Overview of Cryptosporidiosis

First Described: *Cryptosporidium* was first described in mice in 1907 (Tyzzer).[1] Although *Cryptosporidium* spp. oocysts were reported in feces of cats and dogs in earlier reports, genetic evidence for the existence of host-adapted species was reported in 1998 (cats) and 2000 (dogs).[2,3]

Cause: *Cryptosporidium felis* (cats), *Cryptosporidium canis* (dogs), which are coccidian protozoan parasites (phylum Apicomplexa)

Mode of Transmission: Fecal-oral

Affected Host Species: Dogs and cats are the definitive hosts for the species-adapted *C. canis* or *C. felis*, respectively. Other *Cryptosporidium* spp. such as *Cryptosporidium parvum* may be detected in dog or cat feces, but the potential for disease causation is unclear.

Intermediate Hosts: Although there are no intermediate hosts, there are multiple potential transport hosts that may carry *Cryptosporidium* spp. oocysts and indirectly infect dogs or cats.

Geographic Distribution: Worldwide

Major Clinical Signs: Most dogs and cats harbor subclinical infections. Acute watery diarrhea or chronic or intermittent diarrhea and weight loss may be noted in animals with concurrent infections such as *Giardia* spp. or *Tritrichomonas foetus*, immunocompromise, or coexistent conditions such as inflammatory bowel disease.

Differential Diagnoses: All causes of small bowel diarrhea including *Isospora* spp. infection, *Giardia* spp. infection, dietary intolerance, and inflammatory bowel disease

Human Health Significance: *Cryptosporidium parvum* and *C. hominis* are the species most commonly associated with disease in people; neither of these organisms is common in dogs and cats. Although DNA of *C. felis* and *C. canis* has been amplified from human feces, the disease-inducing potential in humans appears to be minimal. However, immunocompromised people should take extra care to avoid accidental ingestion of dog or cat feces, particularly if diarrhea is present.

Etiologic Agent and Epidemiology

Cryptosporidium spp. are coccidians that reside in the small intestines and are occasionally associated with disease in some infected hosts. There are now 16 accepted species of *Cryptosporidium*, and approximately 50 *Cryptosporidium* genotypes have been described.[4] In the past, most mammalian cryptosporidiosis was attributed to *Cryptosporidium parvum*. However, molecular studies have demonstrated that cats are usually infected with the host-specific *Cryptosporidium felis* and dogs are usually infected with *Cryptosporidium canis*.[4-16] Occasionally, dogs or cats are infected with *C. parvum*.[17] A mixed infection with *Cryptosporidium muris* and *C. felis* was reported in one cat.[18] *Cryptosporidium hominis* is the most common human host–adapted strain and has not been associated with infection in dogs and cats.

Cryptosporidium spp. infections of dogs and cats can be quite common, with prevalence rates generally being 2% to 12% in dogs or cats with or without diarrhea, depending on the method of diagnostic testing.[19-30] In one study of specimens collected from around the United States, *Cryptosporidium* spp. DNA was amplified by PCR assay from feces of 29.4% of cats and 15.1% of dogs with diarrhea.[24] In a study of cats in shelters in upstate New York, fecal flotation identified oocysts in 3.8% of the cats tested.[21]

Clinical Features

Signs and Their Pathogenesis

Cryptosporidium felis and *C. canis* are transmitted among dogs and cats by the ingestion of oocysts in feces from mutual grooming, shared litter boxes, ingestion of contaminated food or water, and possibly ingestion of infected prey species. The oocysts are passed in the feces already sporulated and so are immediately infectious (Figure 81-1). In a study of cats inoculated with *C. parvum*, oocysts were detected by day 7 and *C. parvum* DNA was detected by day 2 after inoculation.[31] In contrast, *C. felis* oocysts are first shed in the feces 3 to 6 days after infection. Approximately 20% of the oocysts produced in the intestine are "thin-walled" oocysts that fail to form an oocyst wall. These oocysts rupture within the intestines, and when the sporozoites are released, auto-infection occurs, which allows for rapid amplification of infection. Thick-walled oocysts are passed in the feces, are environmentally resistant, and are the likely source of new infections. Between 1 and 1000 oocysts of pathogenic species such as *C. parvum* are enough to cause infection in humans.[4]

Although infection of dogs and cats with *Cryptosporidium* spp. is common, most infected animals are clinically normal. In prevalence studies, only rarely is there an association between positive *Cryptosporidium* spp. assay results and the presence of diarrhea.[28] Diarrhea is generally more common in young animals.[32-46] When diarrhea occurs, it is usually watery, without mucus, blood, melena, or straining, and so is classified as small bowel diarrhea (Figure 81-2). Weight loss may also

VetBooks.ir

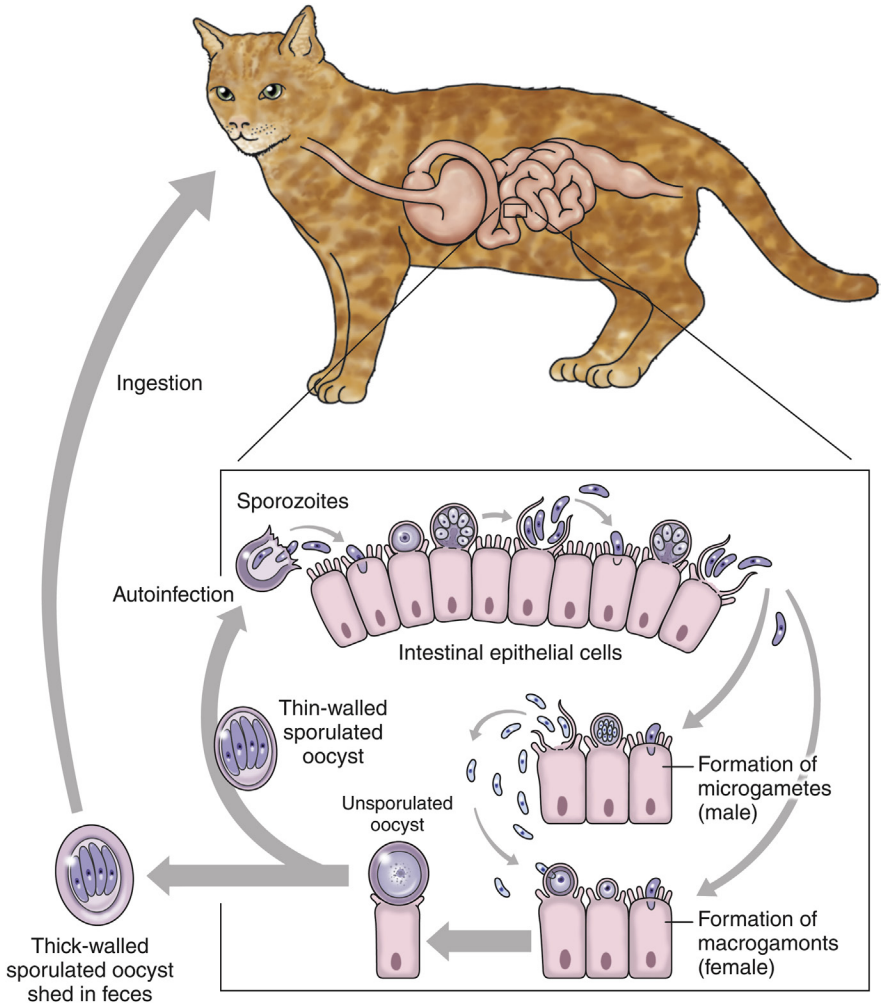

FIGURE 81-1 Life cycle of *Cryptosporidium* spp. Gametogony generates both thin-walled oocysts, which are immediately infective, and thick-walled oocysts, which are shed in the feces already sporulated.

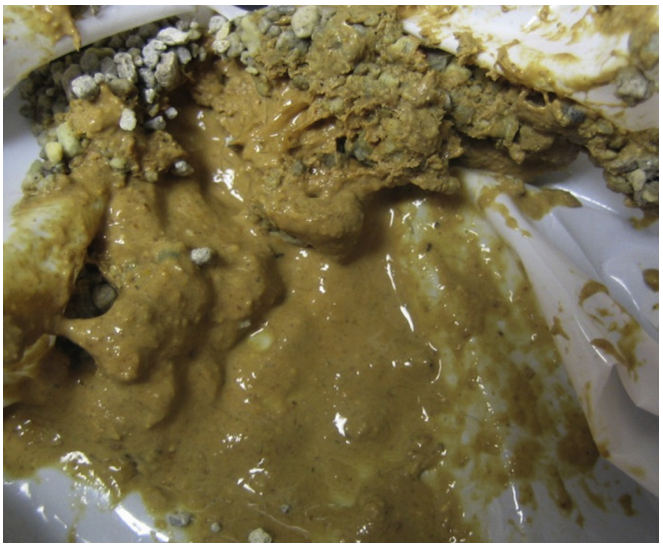

FIGURE 81-2 Characteristic appearance of diarrhea induced by *Cryptosporidium felis* and *Giardia* spp. co-infection. The image is from the case example described at the end of this chapter.

occur. Co-infection with other protozoans such as *Giardia* spp. (dogs and cats) or *Tritrichomonas foetus* (cats) may be associated with more significant illness than infection with just one of the parasites.[47,48] The presence of immunosuppressive diseases such as lymphoma, FeLV infection, canine distemper virus infection, or canine parvovirus infection also can potentiate the development of clinical signs of disease. Clinical signs appear to be more likely in cats infected with *C. felis* than in dogs infected with *C. canis*. In the cat with a mixed *C. muris* and *C. felis* infection, both vomiting and diarrhea were present, and *C. muris* was identified in the stomach in the presence of inflammation.[18]

Little information is available in regard to the pathogenesis of *Cryptosporidium* spp. in cats and dogs; most information is from what is known in humans and mice after infection by *C. parvum*.[49] After ingestion, *Cryptosporidium* spp. sporozoites attach to the intestinal epithelium via interactions among multiple parasite ligands and host receptors. The organism resides between the cell membrane and the cell cytoplasm, which may partially explain its resistance to antiprotozoal chemotherapy. The intestinal epithelial cells act as a physical barrier and produce a variety of cytokines and chemokines in response to the pathogen. Mucosal infiltration with neutrophils, macrophages, and lymphocytes in the lamina propria can result. There is upregulation of both proinflammatory and antiinflammatory

VetBooks.ir

TABLE 81-1

Diagnostic Assays Available for Cryptosporidiosis in Dogs or Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Feces	*Cryptosporidium* oocysts	Modified acid-fast staining has a sensitivity of approximately 70% and so false negatives are common. However, the technique is more sensitive than fecal flotation.
Fecal flotation	Feces	*Cryptosporidium* oocysts	The small size of the oocysts and small numbers shed by dogs and cats makes this an inadequate screening procedure. The sensitivity is unknown but may be as low as 10%.
Immunofluorescent antibody assay	Feces	*Cryptosporidium* oocysts	IFA assays are available that detect both *Cryptosporidium* spp. oocysts and *Giardia* cysts. Morphology can be evaluated as well as fluorescence, and so this assay is considered by most to be the gold standard. The assay appears to detect *C. felis* and *C. canis*. The sensitivity of the assay is >70%, but false negatives can occur because oocyst numbers fluctuate.
PCR assays	Feces	*Cryptosporidium* DNA	The sensitivity and specificity of assays may vary depending on assay design. Well-designed assays have the highest sensitivity of all diagnostic test methods, but false negatives can occur if low numbers of oocysts are shed, the specimen size is small, or as a result of PCR inhibitors in feces. Use of PCR as a screening assay will result in detection of many subclinical infections.

cytokines, and the ratio of these cytokines likely determines whether diarrhea develops. Cellular immunity mediated by CD4+ and CD8+α/β T cells is an important component for the resolution of *C. parvum* infection. When it occurs, *Cryptosporidium* spp. diarrhea is associated with impaired intestinal absorption and enhanced secretion.[49] It is possible that susceptibility to cryptosporidiosis in animals could have a genetic basis as suggested for humans.[50,51]

Physical Examination Findings

Most dogs or cats colonized with *Cryptosporidium* spp. have a normal physical examination. On abdominal palpation, small intestines may feel slightly thickened. Because some dogs or cats with *Cryptosporidium* spp. infection and diarrhea have had underlying diseases such as inflammatory bowel disease, lymphoma, or infections (especially *T. foetus*, FeLV, canine distemper virus, or canine parvovirus), physical examination findings may reflect the presence of these conditions.

Diagnosis

Laboratory Abnormalities

Cryptosporidium spp. infection alone is rarely associated with CBC or serum biochemistry panel abnormalities. Electrolyte and acid-base changes may be present if diarrhea is severe. If concurrent immunosuppressive conditions such as FeLV infection or FIV infection exist, test results consistent with those conditions may be present.

Diagnostic Imaging

Abdominal radiographic and ultrasonographic abnormalities in dogs and cats with *Cryptosporidium* infection are uncommon, are nonspecific, and, when present, are suggestive of diffuse enteritis.

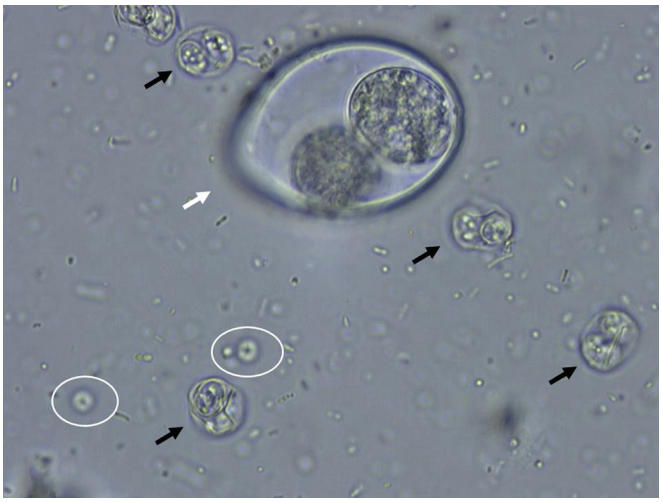

FIGURE 81-3 Fecal flotation from a cat that was co-infected with *Toxoplasma gondii, Isospora felis,* and *Cryptosporidium felis.* The image is magnified approximately 2,000×. The black arrows are sporulated *T. gondii oocysts;* the white arrow shows *Isospora felis;* the white circles surround *Cryptosporidium felis* oocysts.

Microbiologic Testing

Specific diagnostic assays for cryptosporidiosis are shown in Table 81-1.

Cytologic Examination

Cryptosporidium felis and *C. canis* oocysts are similar in size; *C. felis* oocysts are 5 µm by 4.5 µm and *C. canis* oocysts are 4.95 µm by 4.71 µm (Figure 81-3). However, their small size means that the oocysts are easy to overlook. Modified acid-fast staining of a thin fecal smear can be performed in the small animal practice to aid in the detection of the organisms

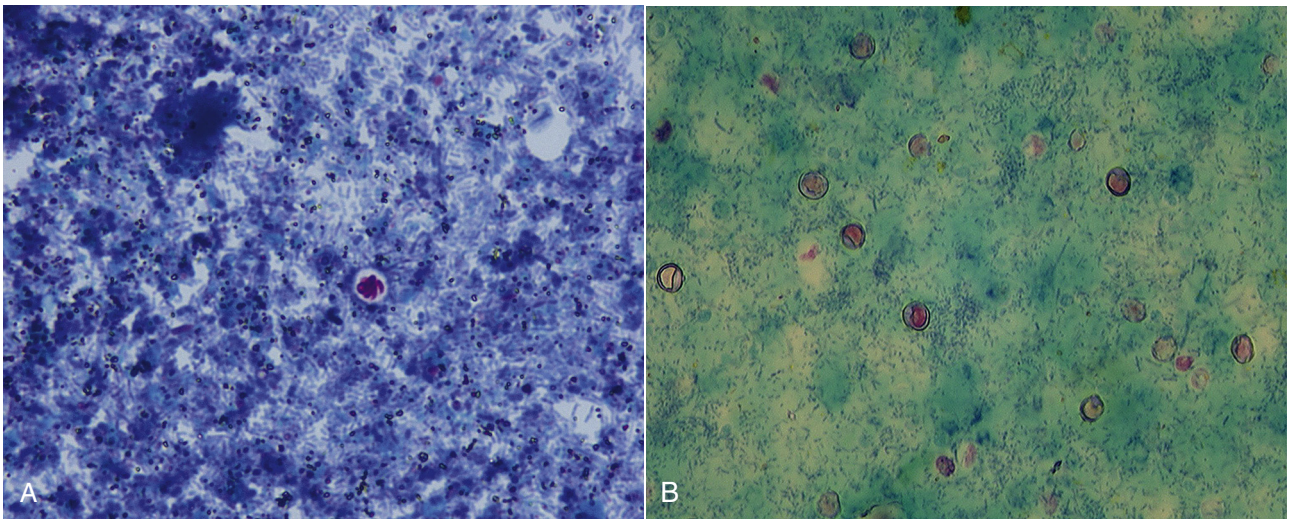

FIGURE 81-4 Acid-fast (Ziehl-Neelsen) stained fecal smears showing *Cryptosporidium felis*. **A,** Smear from a cat with diarrhea that shows a single oocyst of *C. felis.* (From: Marks SL, Willard MD. Diarrhea in kittens. In: August JR, ed. Consultations in Feline Internal Medicine. 5th ed. St. Louis: Saunders; 2006.) **B,** Multiple oocysts of *C. felis* that have a more crinkled appearance. The oocysts are approximately 5 µm in diameter and stain pink to red. (From Ettinger SJ, Feldman EC. Textbook of Veterinary Internal Medicine. 7th ed. St. Louis: Saunders; 2011.)

(Figure 81-4).[23,52] *Cryptosporidium* spp. are generally the only enteric organism of the size just specified that stain pink to red with acid-fast stain. However, in one study, acid-fast staining detected only approximately 70% of *Cryptosporidium* spp.–infected kittens when a single specimen was tested.[52]

Concentration Techniques

Centrifugal fecal flotation is usually performed as part of the initial diagnostic work-up of dogs or cats with small bowel diarrhea.[53] *Cryptosporidium* spp. oocysts are frequently missed because of their small size, and only low numbers of oocysts are passed in infected dog or cat feces (often <500 oocysts/gram of feces).

Direct Immunofluorescent Antibody Testing

A fluorescein-labeled monoclonal antibody system is available that contains monoclonal antibodies that react with *Cryptosporidium* spp. oocysts and *Giardia* spp. cysts (Merifluor IFA, Meridian Biosciences, Cincinnati, OH). In limited studies, this assay appears to detect both *Giardia* spp. and *Cryptosporidium* spp. isolates from dogs and cats.[12,24,31,52] The IFA provides both a morphologic assessment of the oocysts and immunologic identification, which makes false-positive results unlikely.

Fecal Antigen Detection by Enzyme-Linked Immunosorbent Assays

Fecal ELISA antigen tests for *Cryptosporidium* spp. are available for use with human feces, but results of these assays have been variable when applied to feces from infected animals.[12,52,54] The assays use antibodies against *C. parvum* in their design, and so the high false-negative rate in animals may reflect antigenic differences among *C. parvum, C. felis,* and *C. canis*.

Molecular Genetic Techniques

PCR assays are currently available to amplify *Cryptosporidium* spp. DNA from canine or feline feces. These assays appear to be more sensitive than IFA when used with cat feces.[24,31,55] Real-time PCR assays are available commercially through some veterinary diagnostic laboratories. Specific PCR assays are available for each host-adapted species, or PCR products generated with genus-specific assays can be sequenced to identify the *Cryptosporidium* species present. Because *Cryptosporidium* oocysts or DNA can be detected in apparently healthy dogs and cats, positive test results do not prove a disease association.

Pathologic Findings

Gross Pathologic Findings

Cryptosporidium spp. infection can cause mild intestinal thickening. Because the agent is not enteroinvasive, blood is generally not noted in the intestinal lumen unless co-infections are present. Animals with chronic cryptosporidiosis may be emaciated. The concurrent presence of other parasites such as roundworms or hookworms may be noted.

Histopathologic Findings

On histopathology of the gastrointestinal tract, infected cats can exhibit loss of microvilli, degeneration of host epithelial cells, and atrophy of villi and can have lymphocytic-plasmacytic infiltrates.[4,42] Histopathologic findings in infected dogs include severe crypt damage with hyperplasia, dilation, marked villous atrophy, and loss of glands from the mucosa. The lamina propria is generally infiltrated with lymphocytes, plasma cells, and neutrophils.[32,34,35,37] *Cryptosporidium* organisms may be seen in association with the apical membrane of enterocytes. In one puppy with gastrointestinal cryptosporidiosis, *C. canis* were most abundant within the gastric region.[34] This finding was similar to those reported for the cat with *C. felis* and *C. muris* co-infection, whereby *C. muris* was identified in the stomach.

Treatment and Prognosis

There have been no controlled treatment studies in dogs or cats for cryptosporidiosis, and so all protocols discussed should be considered empirical. Because most small animals likely have self-limited disease, feeding highly digestible diets used for small bowel diarrhea may be all that is needed. In addition, administration of probiotics may also have a nonspecific beneficial effect.[56]

More than 100 compounds have been used in an attempt to treat *Cryptosporidium* spp. infections in mammals, and no

TABLE 81-2

Antiprotozoal Drugs Used for the Treatment of Cryptosporidiosis in Cats and Dogs

Drug	Dose	Route	Interval (hours)	Minimum Duration (days)
Azithromycin	10 mg/kg	PO	24	5-7
Nitazoxanide	10-25 mg/kg	PO	12	7
Tylosin	10-15 mg/kg	PO	12	14

compound is consistently effective.[57-60] Paromomycin was initially believed to be effective for treatment of human cryptosporidiosis and was used to treat a cat in one case report.[61] However, this orally administered aminoglycoside can be absorbed across a damaged intestinal epithelium and cause renal and otic toxicity.[62] In addition, in people with AIDS and cryptosporidiosis, the drug has been ineffective.[63] Thus, use of paromomycin in dogs and cats cannot be recommended.

Diarrhea in dogs or cats infected with *Cryptosporidium* spp. sometimes resolves after administration of tylosin (Table 81-2). It is unlikely that tylosin has anti-*Cryptosporidium* effects, and so apparent clinical responses may relate to antibacterial or antiinflammatory effects of the drug. In the one published case report suggesting a tylosin response, clindamycin had been administered before tylosin.[41] However, apparent responses to tylosin have been noted in other cases.[48] Tylosin is very difficult to administer to cats because of its bitter taste and so is usually prescribed in capsules.

Several studies have suggested a beneficial effect of azithromycin for the treatment of cryptosporidiosis in cattle or people.[64,65] Azithromycin (10 mg/kg PO q24h) has been used by the author to treat some cats with suspected cryptosporidiosis, but controlled data are lacking. Vomiting and diarrhea in the cat that was co-infected with *C. felis* and *C. muris* reduced in severity after treatment with azithromycin for 2 weeks. Biopsies were obtained a year later and documented oocysts consistent with *C. muris* in gastric biopsies; *C. felis* was not detected. Azithromycin is believed to have antiinflammatory properties and has effects against other gastrointestinal agents such as *Campylobacter* species. Thus, apparent treatment responses may relate to other drug effects.

Nitazoxanide is labeled for the treatment of cryptosporidiosis in people in some countries and is one of the most widely studied anticryptosporidial drugs.[47,66,67] Nitazoxanide is active against many gastrointestinal pathogens and so may be effective for some co-infections. In a study of research cats infected with both *Tritrichomonas foetus* and *C. felis*, administration of nitazoxanide resulted in temporary resolution of fecal shedding of both organisms and resolution of diarrhea.[47] However, *T. foetus* shedding and diarrhea recurred. The author has administered nitazoxanide (10-25 mg/kg PO q12-24h) in unpublished research studies and to client-owned animals with cryptosporidiosis. The drug is a gastrointestinal irritant and can cause vomiting (see Chapter 10). Thus, it is often administered at 10 mg/kg PO q12h, initially with food. There is no longer a veterinary formulation of nitazoxanide, and so the human product is used (Alinia, Romark Laboratories, Tampa, FL). Because the suspension for children has a low drug concentration, formulation of 500-mg tablets may result in increased ease of administration.

If an apparent clinical response to the first 7 days of therapy with tylosin, azithromycin, or nitazoxanide occurs and toxicity has not been noted, treatment of affected dogs or cats should be continued for 1 week past clinical resolution of diarrhea. Some cats with *Cryptosporidium* spp. infection with or without *Giardia* co-infection have required several weeks of treatment before diarrhea resolves. Whether use of fiber, silymarin, or probiotics in addition to antimicrobial therapy is of benefit is unknown. Some of the cats and dogs with apparently resistant cryptosporidiosis have underlying diseases (i.e., inflammatory bowel disease, *Tritrichomonas foetus*, immunodeficiency syndromes), and so the diagnostic work-up should be continued if therapeutic failures occur. No drug treatment has been shown to consistently eliminate *Cryptosporidium* spp. infections. Thus, the primary goal for the treatment of dogs or cats with cryptosporidiosis is to resolve diarrhea. Since infection is unlikely to be eliminated, following results of *Cryptosporidium* spp. diagnostic tests in normal animals seems to have little clinical utility.

Immunity and Vaccination

Sterilizing immunity to *Cryptosporidium* spp. does not occur, and so repeated shedding, clinical signs, and infection may occur. There are currently no vaccines available for *Cryptosporidium* spp. infection in dogs or cats.

Prevention

Avoidance of contaminated food and water or potential transport hosts is the primary means of prevention. *Cryptosporidium* DNA can be amplified from some raw meat diets.[67] Housing dogs or cats indoors and feeding commercially processed foods may also lessen the chances for exposure. *Cryptosporidium* spp. oocysts are resistant to most frequently used disinfectants, including commercial bleach. Formal saline (10% solution; a formaldehyde solution) and ammonia (5% solution) destroy the viability of the oocysts, but the required contact time is 18 hours. Concentrated ammonia solutions (50%) can inactivate *Cryptosporidium* oocysts after 30 minutes. Moist heat (steam or pasteurization [over 55°C]), freezing and thawing, or thorough drying are more practical means of disinfection. Swimming pools can be disinfected by using high-chlorine concentrations for long periods (3 mg/L of water for 53 hours or 8 mg/L for 20 hours). Exceptional sanitation and use of boiling water for the cleaning of water and food bowls should decrease the possibility of contamination within crowded environments. When a person is infected with cryptosporidiosis, it is advisable to exclude the infected person from the work place, school, or other institutional settings until 48 hours after the last diarrhea episode. This last preventive measure might also be prudent for infected cats or dogs being housed in animal day care environments.

Public Health Aspects

Cryptosporidium is an important cause of water- and foodborne gastrointestinal illness in humans.[68] The organism resists salt water and chlorination and is not readily filtered from water supplies. This, combined with the low dose of organisms required to cause disease has led to significant

outbreaks of disease in association with recreational activities that involve water. Young children in day care centers and humans with AIDS are particularly susceptible to disease. Infection may be subclinical or lead to fever, severe abdominal pain, nausea, decreased appetite, weight loss, vomiting, and voluminous watery diarrhea. Life-threatening disseminated infections that involve the respiratory tract, gallbladder, liver, and pancreas in addition to the gastrointestinal tract have been reported in humans with AIDS. The most beneficial treatment for these individuals has been reversal of underlying immunosuppression with highly active antiretroviral therapy (HAART).

The DNA of *C. felis* or *C. canis* have been amplified from the feces of some immunosuppressed people, suggesting that zoonotic transfer of these agents can occur.[69-72] However, *C. felis* or *C. canis* represent the minority of *Cryptosporidium* isolates from people. For example, in one study of 14,469 isolates from humans, 38 were *C. felis* and one was *C. canis*.[70] Overall, it appears unlikely that healthy or immunocompromised people acquire *Cryptosporidium* spp. infection from healthy cats or dogs.[72,73] Thus, the Centers for Disease Control and Prevention does not consider healthy pets to be significant human health risks for HIV-infected people.[74] However, if a dog or cat is known to shed *Cryptosporidium* spp., the family should be informed, and families with immunocompromised individuals or very young children should take particular care to avoid contact with the animal's feces and to practice good hygiene.

CASE EXAMPLE

Signalment: "Ben," a 24-week-old, male neutered, domestic shorthair cat from Denver, CO.

History: Ben and his littermate were adopted into a private home from a large open-admission animal shelter at approximately 18 weeks of age. When adopted, both kittens had diarrhea (see Figure 81-2). The diarrhea had the consistency of toothpaste with no blood or mucus and the kittens were eating well without vomiting. An attenuated live vaccine (feline herpesvirus-1, feline calicivirus, and feline panleukopenia virus) and one dose of pyrantel pamoate had been administered at the shelter on admission. The kittens were taken to a veterinarian immediately after adoption for a general health examination, fecal flotation, FeLV antigen assay, and FIV antibody assay. The kittens were fed a commercial processed food.

Physical Examination: Bright, alert, and responsive. Ambulatory on all four limbs. Body weight was 3.5 kg and body condition score was 4/9. T = 100.3°F (37.9°C), HR = 180 beats/min, RR = 24 breaths/min, mucous membranes pink, CRT = 1 s. No clinically significant abnormalities were noted on the physical examination.

Microbiologic Testing: Centrifugal fecal flotation: *Giardia* spp. cysts were present.

Fecal wet mount examination: No motile flagellates noted.

ELISA assay for FeLV antigen and FIV antibody: Negative.

Initial Diagnosis: *Giardia* spp. infection.

Treatment: Metronidazole benzoate in tuna suspension was administered to both kittens at 20 mg/kg PO twice daily for 7 days. A commercially available intestinal diet was administered to both cats.

Follow-up: The findings were characteristic of *Giardia* spp. infection. However, there was no improvement in stool character after administration of metronidazole and in the week that followed. The rDVM then prescribed a veterinary probiotic to be administered once daily and fenbendazole (50 mg/kg PO q24h) for 5 days with no improvement in stool character. One week after finishing the fenbendazole treatment, the stool character of both cats remained abnormal. At a recheck examination, the physical examination was still normal. A CBC, serum biochemical panel, and abdominal radiographs were normal. Serum B_{12} concentration, folate concentration, feline trypsin-like immunoreactivity, and a commercially available fluorescent antibody assay that detects *Giardia* spp. cysts and *Cryptosporidium* spp. oocysts were performed. The presence of both *Giardia* spp. cysts and *Cryptosporidium* spp. oocysts were the only abnormalities detected. Both cats were treated with nitazoxanide (10 mg/kg PO q12h) for 7 days and the stool consistency improved but was not normal. Treatment was continued for an additional 10 days, and the stool consistency normalized 5 days into treatment.

Comments: Cats with mixed *Giardia* spp. and *Cryptosporidium* spp. infection will fail to respond to drugs with activity against *Giardia* spp. alone. The small size of *Cryptosporidium* spp. oocysts can result in false-negative fecal flotation results, and so the fluorescent antibody assay that detects *Giardia* spp. cysts and *Cryptosporidium* spp. oocysts is indicated for cats with small bowel diarrhea, in particular if there is failure to respond to anti-*Giardia* drugs. Most *Giardia* spp. and *Cryptosporidium* spp. of cats are the host-adapted feline genotypes which are of minimal risk to healthy humans. Genotyping could have been performed if the owner was concerned about zoonotic transfer of infection.

CHAPTER 82

Isosporiasis

Michael R. Lappin

VetBooks.ir

Overview of Isosporiasis

First Described: Coccidian parasites were first described in dogs and cats in the 1800s; the organisms were placed in the genus *Isospora* spp. in 1906.[1]

Cause: *Isospora* spp., a coccidial protozoal parasite (phylum Apicomplexa)

Mode of Transmission: Fecal-oral; ingestion of intermediate hosts

Affected Host Species: Dogs and cats are the definitive host of different *Isospora* spp. The sexual phase of the organism is completed in the gastrointestinal tract, which culminates in the passage of oocysts in feces.

Intermediate Hosts: Most other vertebrates can serve as intermediate hosts; invertebrates can serve as transport hosts by carrying *Isospora* spp. oocysts.

Geographic Distribution: Worldwide

Major Clinical Signs: Most dogs and cats harbor subclinical infections. Watery diarrhea that can contain blood occasionally occurs in puppies and kittens.

Differential Diagnoses: These include other enteropathogenic bacterial (e.g., *Clostridium perfringens, Campylobacter*) and protozoal infections (e.g., *Giardia, Tritrichomonas foetus*), as well as nematode infestations.

Human Health Significance: *Isospora* spp. of dogs and cats do not infect humans.

Etiologic Agent and Epidemiology

Isospora spp. are protozoan coccidian parasites that have been recognized for years as potential pathogens in dogs and cats.[2-4] The sexual phase of reproduction occurs in the gastrointestinal tracts of dogs and cats and culminates in the passage of oocysts in feces. Cats are the definitive hosts for *Isospora felis* and *Isospora rivolta*, and dogs are the definitive hosts for *Isospora canis*, *Isospora ohioensis*, *Isospora neorivolta*, and *Isospora burrowsi*.[2] The oocysts vary in microscopic appearance; this can be used to determine which species is present (Table 82-1).[3,4]

Isospora spp. are host specific, have worldwide distribution, and infections are very common, particularly in young animals. In the United States, the Companion Animal Parasite Council reports that prevalence rates for *Isospora* spp. infection in dogs and cats vary from 3% to more than 30%.[5] In a study of more than one million fecal specimens from dogs in the United States, 4.4% contained *Isospora* spp. oocysts.[6] In a study of 1355 cats in the United Kingdom, *I. felis* oocysts were detected in 3%.[7] Gender and breed do not usually influence the *Isospora* spp. shedding rates, but young animals are usually more likely to be shedding oocysts than adults. For example, in one Austrian study, 8.7% of dogs less than 2 years of age were infected; 78% of the positive specimens were in puppies less than 4 months of age.[8] In the study from the United Kingdom, *I. felis* was found in the feces of 9% of cats less than 6 months of age.[7]

Clinical Features

Signs and Their Pathogenesis

Infection by *Isospora* spp. in dogs or cats is initiated by ingestion of sporulated oocysts in the environment or by ingestion of tissues of other infected vertebrate "transport" hosts (Figure 82-1).[9,10] Infection can also occur if the dog or cat ingests sporulated oocysts carried mechanically by flies, cockroaches, or dung beetles.[10] The enteroepithelial phase occurs in the small intestine of infected animals and culminates in the passage of unsporulated oocysts in feces. The prepatent period (time between infection and appearance of oocysts in the feces) and patent period (time that the organism can be detected in the body) vary slightly by the species. In one study of dogs experimentally infected with *I. canis*, the mean prepatent period was 9.8 days (range, 9 to 11 days, n = 22 dogs), the patent period was 8.9 days (range, 7 to 18 days, n = 20 dogs), and all of the puppies developed diarrhea.[9] In contrast, the prepatent period for *I. ohioensis* in one study was 6 to 7 days, and diarrhea was variable.[8] The number of oocysts shed by infected animals can vary dramatically.[8,9] Depending on the environmental conditions, sporulation can occur in as little as 12 hours. Clinical disease is most common in young, debilitated, and immunocompromised animals. All the different *Isospora* spp. replicate in the small intestine, but the regions with the heaviest infection vary by species.

Isospora spp. infections are generally only associated with disease in puppies and kittens. Clinically ill puppies and kittens can exhibit vomiting, abdominal discomfort, inappetence, and watery diarrhea that sometimes contains blood. Depending on the age of the animal and the parasite burden, severe dehydration and death can occur. Puppies and kittens with subclinical infection can repeat shedding and clinical signs of disease during periods of stress.

Diagnosis

Laboratory Abnormalities

Isospora spp. infections only rarely lead to systemic laboratory abnormalities. A regenerative anemia can develop from blood

loss in puppies or kittens with heavy parasite loads. Other CBC abnormalities are uncommon. Decreases in serum total protein, albumin, and globulin concentrations can occur concurrently with blood loss. If diarrhea is severe, potassium, sodium, and chloride concentrations may decrease as a result of gastrointestinal losses.

TABLE 82-1

***Isospora* spp. Oocyst Characteristics after Detection by Centrifugal Fecal Flotation**

	Oocyst Dimensions
Cats	
Isospora felis	30 × 40 µm
Isospora rivolta	20 × 25 µm
Dogs	
Isospora burrowsi	17 × 20 µm
Isospora canis	30 × 38 µm
Isospora neorivolta	11 × 13 µm
Isospora ohioensis	19 × 23 µm

Diagnostic Imaging

Abdominal radiographic abnormalities in puppies and kittens with isosporiasis are uncommon and nonspecific and, when present, are suggestive of diffuse enteritis.

Microbiological Testing

The definitive diagnosis of coccidiosis is made by demonstrating oocysts in fecal specimens from affected animals. *Isospora* spp. oocysts are large and often numerous and so are generally easy to identify on microscopic examination of feces after centrifugal fecal flotation (Figure 82-2). However, nondiarrheic animals also can pass *Isospora* spp. oocysts, and so positive test results do not prove a disease association. False-negative fecal flotation results are uncommon in clinically infected animals, but occasionally clinical signs precede oocyst shedding, and so a second fecal flotation may be needed to prove infection in some cases.

Pathologic Findings

Clinically affected puppies and kittens are often emaciated. Other parasites such as roundworms or hookworms may be noted. The small intestines of clinically ill puppies and kittens may be thickened. Microscopic lesions observed in some infected animals include villous atrophy, dilation of lacteals, and hyperplasia of lymph nodes in Peyer's patches.

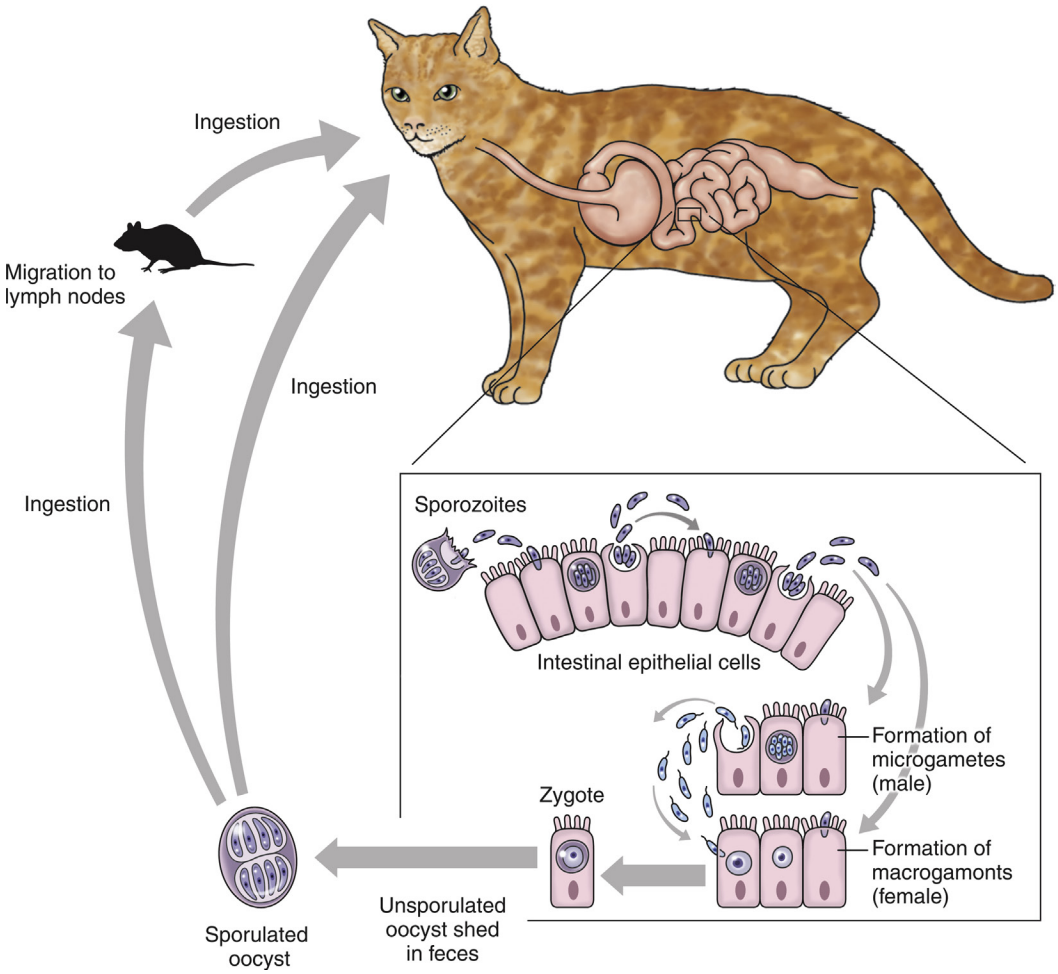

FIGURE 82-1 Life cycle of *Isospora* spp. The host species (in this case, cats) can be infected by ingestion of sporulated oocysts or ingestion of prey that have organisms encysted in their mesenteric lymph nodes. Oocysts shed in the feces can sporulate in as little as 12 hours under optimal environmental conditions.

Treatment and Prognosis

Coccidiosis is generally self-limited, and clinical signs in most puppies and kittens resolve without therapy. However, treatment can speed resolution of clinical disease and may lessen environmental contamination and the potential for infecting other, in-contact animals (Table 82-2). The only approved treatment for coccidiosis in the United States is sulfadimethoxine. Other drug regimens have been used with some success, and these include trimethoprim-sulfa (30 to 60 mg/kg of trimethoprim daily for 6 days in animals >4 kg; or 15 to 30 mg/kg trimethoprim daily for 6 days in animals <4 kg) and a variety of protocols using amprolium alone or in combination with sulfadimethoxine.

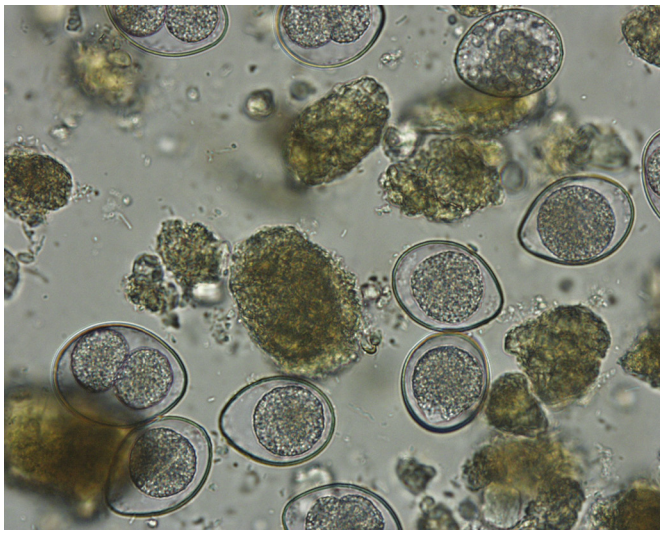

FIGURE 82-2 Oocysts of *Isospora felis* from a kitten with diarrhea (1000× magnification). (From Marks SL, Willard MD. Diarrhea in kittens. In: August JR, ed. Consultations in Feline internal Medicine. 5th ed. St Louis: Saunders Elsevier: 2006; 138.)

Amprolium can cause anorexia, diarrhea, lethargy, and central nervous system disease due to induction of thiamine deficiency.

The use of ponazuril and toltrazuril for the treatment of small animal coccidiosis has recently been studied (see Chapter 10). These drugs are coccidiocidal and so may be superior to other drugs for the treatment for coccidiosis.[11,12] The equine drug ponazuril has been used most frequently in the United States. This drug can be administered off-label at 20 mg/kg PO twice 1 to 7 days apart or at 50 mg/kg PO once, although its efficacy is unclear. Many compounding pharmacies in the United States will appropriately formulate the drug by prescription. In Europe, toltrazuril is available in combination with the anthelmintic emodepside (Procox Oral Suspension for Dogs, Bayer Animal Health) for treatment of isosporiasis and roundworm infections in puppies over 2 weeks of age (see Chapter 10 for additional information). A single 9 mg/kg dose is recommended. Use of prebiotics (food ingredients that stimulate the growth or activity of beneficial bacteria), or probiotics and/or dietary manipulation may speed resolution of diarrhea, but controlled data are lacking.

Most *Isospora* spp.–infected puppies and kittens survive infection, and so the prognosis is considered good to excellent.

Immunity and Vaccination

Immunity to *Isospora* spp. reinfection does not occur, so repeated shedding, clinical signs, and infection may occur. However, although intestinal infection can be prolonged, immune responses usually block the development of clinical disease as puppies and kittens grow older. Vaccines for *Isospora* spp. that infect dogs and cats are not currently available.

Prevention

Isospora spp. oocysts are very resistant to environmental conditions and disinfectants. The key to control is to provide good sanitation, including prompt removal of feces before oocyst sporulation. Steam cleaning can be used to destroy oocysts that

TABLE 82-2

Drugs Used for the Treatment of *Isospora* spp. Infections*

Drug	Species	Dose	Route	Interval and Duration
Amprolium	C D	60-100 mg total 300-400 mg total	PO	q24h for 5 days
Furazolidone	C, D	8-20 mg/kg	PO	q12-24h for 5 days
Ponazuril	C, D	20 mg/kg 50 mg/kg	PO	Twice, 1 to 7 days apart Once
Toltrazuril†	C, D	9 mg/kg	PO	Once
Sulfadimethoxine	C, D	50-60 mg/kg	PO	q24h for 5 to 20 days
Trimethoprim-sulfonamide	C, D	15-30 mg/kg	PO	q12-24h for 5 days
Amprolium-sulfadimethoxine	D	150 mg amprolium and 25 mg/kg sulfadimethoxine	PO	q24h for 14 days

C, Cats; D, dogs.

*Sulfadimethoxine is the only approved drug for the treatment of coccidiosis in the United States. Sulfonamides or trimethoprim-sulfonamide combinations can cause macrocytic anemia, keratoconjunctivitis sicca, type III hypersensitivity reactions (primarily Doberman pinschers), and acute hepatic necrosis. See also Chapter 8.

†In Europe, toltrazuril is available in combination with emodepside (Procox Oral Suspension for Dogs, Bayer Animal Health) for treatment of isosporiasis and roundworm infections in puppies over 2 weeks of age. The suspension contains 18 mg/mL of toltrazuril.

contaminate surfaces. Treatment of dams and queens with anticoccidial agents before parturition can lessen the occurrence of coccidiosis in young animals. In environments with heavy infections, treatment of all in-contact animals, particularly puppies and kittens, could be considered. Ponazuril administered to all at-risk puppies and kittens on intake to shelters may aid in the control of coccidiosis.[12]

Public Health Aspects

Isospora spp. of dogs and cats do not infect people. However, some infected animals are co-infected with other parasites with potential for zoonotic transfer to people, such as *Cryptosporidium* spp. and *Giardia* spp. Thus, a complete diagnostic work-up should be completed for animals with diarrhea.

CASE EXAMPLE

Signalment: "No-name," an 8-week-old, intact male, domestic shorthair cat from a pet store in Fort Collins, CO

History: No-name was housed in a pet store. The kitten appeared small for his age and weighed 25% less than the littermates also housed at the pet store. Although he was eating well, he was thin. Small bowel diarrhea was the other historical complaint, and stool character varied from soft to watery with occasional flecks of what appeared to be fresh blood but no mucus. The source of the kitten was not disclosed. His first vaccine (an attenuated live vaccine for prevention of feline herpesvirus-1, feline calicivirus, and feline panleukopenia virus infections) had been administered subcutaneously 2 weeks previously. He had been fed a commercial processed food followed by a bland diet with no improvement noted in body weight or diarrhea. The other littermates were normal according to the pet store owner. The kitten was administered pyrantel pamoate once on entry to the pet store; no other treatments had been administered.

Physical Examination: Quiet, alert, and responsive. Ambulatory on all four limbs. Body weight was 1.1 kg and body condition score was 3/9. T = 101.3°F (38.5°C), HR = 180 beats/min, RR = 24 breaths/min, mucous membranes pink, CRT = 1 s. The cat's haircoat was dull but there was no evidence of ectoparasites. Abdominal palpation revealed mild diffuse thickening of the small intestinal loops. No other significant abnormalities were detected.

Results of Microbiologic Testing: FeLV antigen ELISA assay: Negative.

FIV antibody ELISA assay: Negative.

Fecal wet mount examination: No motile flagellates were noted.

Fecal flotation: Oocysts that were morphologically consistent with *I. felis* were noted.

Diagnosis: *Isospora felis* infection.

Treatment: Ponazuril at 20 mg/kg PO q24h for 2 days; the littermates were treated as well. A commercially available intestinal diet was administered until the stool normalized 5 days later.

Comments: The findings were characteristic of *Isospora* spp. infection. Although the littermates were clinically normal, ponazuril was administered to try to lessen oocysts shedding into the pet store environment and lessen the potential for reinfection.

VetBooks.ir

MISCELLANEOUS SYSTEMIC PROTOZOAL INFECTIONS

Besides the systemic protozoal infections described in Chapters 72 to 78, other systemic protozoal infections of dogs and cats include sarcocystosis, amebiasis, rangeliosis, and theileriosis. These are uncommon causes of disease when compared with the other protozoal infections described in this book and are briefly reviewed here. Some have been recognized relatively recently and the life cycle and pathogenesis of these pathogens are not fully understood.

Sarcocystosis

Sarcocystosis is caused by *Sarcocystis* species, which are coccidian parasites that resemble *Toxoplasma* and *Neospora* and have a life cycle that involves intermediate and definitive host species. After ingestion of oocysts, organisms replicate in the intermediate host, forming schizonts, usually in endothelial cells. Merozoites are released from the schizonts and ultimately encyst in tissues as a sarcocyst which contains bradyzoites. On ingestion of tissues from the intermediate host by the definitive host, bradyzoites are released from sarcocysts and replicate in the small intestine, with formation of oocysts. The oocysts are then excreted in feces. Dogs are definitive hosts for numerous species of *Sarcocystis*, but the life cycles of these *Sarcocystis* species are incompletely understood.[1] *Sarcocystis canis* can cause hepatitis, encephalitis, dermatitis, and pneumonia in dogs, with most reports involving puppies.[2-6] *Sarcocystis neurona* is an unusual species with opossums as definitive hosts and several other animal species as intermediate or aberrant hosts, including dogs, cats, marine mammals, and horses.[7,8] There are rare reports of severe *S. neurona*–like infections in dogs and cats, usually with central nervous system signs associated with the schizont stage.[9,10] An unnamed *Sarcocystis* species has been identified as a cause of systemic illness and myositis in dogs.[11] Dogs infected with this *Sarcocystis* species have shown signs of fever, lethargy, anorexia, thrombocytopenia, and increased liver enzyme activities, followed by development of generalized muscle stiffness, muscle atrophy, and increased CK activity. These clinical signs can resemble a systemic immune-mediated disease. Large numbers of sarcocysts are found in muscle biopsies, with an associated inflammatory and necrotizing myopathy (Figure 83-1). Treatment of one dog with decoquinate led to resolution of signs of myositis.

Rangeliosis and Theileriosis

Rangelia vitalii and *Theileria* species are piroplasms that resemble *Babesia* species and are probably transmitted by ticks. *Rangelia vitalii* has been identified only in dogs from southern Brazil. It causes a disease characterized by fever, anemia, thrombocytopenia, icterus, weight loss, lymphadenopathy, hepatosplenomegaly, and cutaneous and mucosal hemorrhages with hematemesis and bloody diarrhea.[12,13] Locally the disease has been referred to as "nambiuvú" ("bloody ear") because of extensive bleeding that can develop on the outer surface of the pinnae.[12] *Rangelia vitalii* replicates in erythrocytes, monocytes, neutrophils, and capillary endothelial cells and can be found in aspirates of reticuloendothelial tissues. Treatment with a single dose of diminazine was effective in the early stages of disease in experimentally infected dogs,[13] but several naturally infected dogs died despite this treatment.[12] Treatment with a combination of doxycycline, imidocarb dipropionate, and prednisone was effective in other studies.[14] A *Babesia microti*–like small piroplasm (also known as the "Spanish isolate" or *Theileria annae*) has been identified in dogs in Europe,[15,16] and a *Theileria* species has also been detected in dogs in South Africa.[17] The extent to which *Theileria* parasites cause clinical disease in dogs and cats requires further study.

Vet Pathol. 2004;41:506-510.)

Systemic Amebiasis

Acanthamoeba spp. and *Balamuthia mandrillaris* are amoebae that can rarely cause granulomatous meningoencephalitis, nephritis, and/or pneumonia in dogs[18-25] as well as humans.[26] Other organs may also be affected, such as the heart, pancreas, and lymph nodes.[21] Affected dogs are febrile and show a variety of neurologic signs, with CSF pleocytosis. Diagnosis is usually based on finding amoebae in tissues with cytology or histopathology (Figure 83-2). Specific PCR assays have been described that can specifically identify the amoeba species involved. Treatment is difficult but in humans is usually with a combination of antiprotozoal and antifungal drugs.

MISCELLANEOUS GASTROINTESTINAL PROTOZOAL INFECTIONS

Several protozoal species can infect the gastrointestinal tracts of dogs and cats in the absence of clinical signs. These include the coccidian species *Hammondia, Besnoitia,* and *Sarcocystis* spp. Cats are definitive hosts for *Hammondia hammondi, Besnoitia* spp., and *Sarcocystis* spp. Dogs are the definitive hosts for *Hammondia heydorni.* In recent years, *H. heydorni* has been associated with diarrhea in puppies that are kept in overcrowded environments.

Amoeba species that can infect the colon include *Balantidium coli* and *Entamoeba histolytica*. Balantidiasis has been reported very rarely in dogs but not in cats. Affected dogs showed signs of large bowel diarrhea with hematochezia and tenesmus, although co-infections with *Trichuris* have been reported.[27,28] *Entamoeba histolytica* infection occurs worldwide and is an important cause of disease in humans and nonhuman primates (Figure 83-3). Infection can occur in both dogs and cats. Most infections are subclinical, but large bowel diarrhea and anorexia can also occur.[29,30] Dogs and cats may acquire infection from humans in the household, so the owners of pets diagnosed with *E. histolytica* infection should be referred to their physicians for medical advice.

SECTION 5

Infections of Selected Organ Systems

Jane E. Sykes, Terry M. Nagle, and Stephen D. White

CHAPTER 84

Pyoderma, Otitis Externa, and Otitis Media

Jane E. Sykes, Terry M. Nagle, and Stephen D. White

Overview of Pyoderma

Cause: *Staphylococcus pseudintermedius*; less commonly *Staphylococcus schleiferi* and *Staphylococcus aureus*. Gram-negative bacteria may be involved in dogs with deep pyoderma.

Affected Hosts: Dogs, less commonly cats

Geographic Distribution: Worldwide

Major Clinical Signs: Cutaneous epidermal collarettes, pruritus, erythema, papules, pustules, alopecia. Deep pyoderma is characterized by deep nodules and fistulous tracts. Local lymphadenopathy may be present. Hyperpigmentation and lichenification occur with chronicity.

Differential Diagnoses: Pemphigus foliaceus, dermatophytosis, demodicosis, allergic dermatitis, drug eruptions, erythema multiforme, *Malassezia* dermatitis. For deep pyoderma, sterile pyogranulomatous dermatitis, juvenile cellulitis, neoplasia, foreign body reactions, and deep cutaneous mycoses and pythiosis must be considered.

Human Health Significance: *S. pseudintermedius* prefers not to colonize humans, but zoonotic transmission has been reported. *S. aureus* infections in dogs most likely represent reverse zoonotic transmission from humans to dogs. *S. schleiferi* has also been reported to infect humans.

PYODERMA

Etiology and Epidemiology

Pyoderma is a cutaneous infection with pyogenic (pus-forming) bacteria. Although the term *pyoderma* literally means "pus in the skin," the pus may not always be visible to the naked eye. Pyoderma is the one of the most common disorders of canine skin. It results from impaired local defense mechanisms, which permit secondary bacterial invasion of the skin. The most common underlying skin diseases are allergic dermatitis and endocrine diseases, but a variety of other skin diseases can also predispose to pyoderma. In cats, pyoderma is uncommon to rare, although feline acne can be classified as a pyoderma. Three broad classifications of pyoderma exist, based on the depth of skin and follicle involvement: *surface pyoderma*, *superficial pyoderma*, and *deep pyoderma*.

Surface pyoderma occurs when bacteria proliferate on the surface of the skin and incite an inflammatory response, without invading the skin. Surface pyodermas include the "fold" pyodermas (also known as *intertrigo*), "hot spots" (also known as *pyotraumatic dermatitis*), and mucocutaneous pyoderma, which commonly affects German shepherd dogs.[1] The last probably has an immunologic as well as a bacterial etiology. Mucocutaneous pyoderma is histologically identical to intertrigo, and differentiation between the two entities must be made clinically.[2] Microbial overgrowth has also been categorized as a surface pyoderma when it involves bacteria (as opposed to just *Malassezia* spp.).

In superficial pyoderma, bacteria infect the superficial epidermal layers that lie immediately under the stratum corneum (the outermost layer of the skin) and the portion of the hair follicle above the sebaceous duct (the infundibulum) (Figure 84-1). This is the most common type of pyoderma. It includes superficial bacterial folliculitis, superficial spreading pyoderma, and "puppy pyoderma" (also known as *impetigo* or *juvenile pustular dermatitis*).

Deep pyoderma is defined by infection deep within the hair follicle, with or without follicular rupture *(furunculosis)* (Figure 84-2) German shepherd dogs seem prone to a more severe and extensive form of deep pyoderma.[3] Other examples include pedal folliculitis and furunculosis, pressure-point pyoderma, pyotraumatic folliculitis and furunculosis, and muzzle folliculitis and furunculosis ("canine acne").

VetBooks.ir

The most common cause of pyoderma in dogs is the coagulase-positive *Staphylococcus pseudintermedius* (previously misidentified as *Staphylococcus intermedius*) (see Chapter 35 for more information on staphylococci).[4] *S. pseudintermedius* is a normal resident of mucosal sites such as the anus and nares and is thought to colonize the skin transiently following grooming and excessive licking in dogs with pruritus.[5] In contrast, the resident flora of the canine skin includes coagulase-negative staphylococci, *Micrococcus* spp., α-hemolytic streptococci, aerobic coryneforms, *Acinetobacter* spp., and some anaerobes. Other organisms implicated in canine pyoderma are *Staphylococcus schleiferi* and, uncommonly, *Staphylococcus aureus*.[6-8] Gram-negative bacteria such as *Pseudomonas aeruginosa, Proteus* spp., and *Escherichia coli* may be isolated from dogs with deep pyoderma.[9,10] These organisms are thought to invade secondary to alteration of local environmental conditions by *S. pseudintermedius*. Complete genome sequencing of *S. pseudintermedius* isolated from a dog with pyoderma has shown that *S. pseudintermedius* possesses a number of virulence factors that resemble those produced by *S. aureus*.[11]

Over the past 5 years, clonal spread of methicillin-resistant *S. pseudintermedius* has occurred across Europe and North America.[12] Methicillin resistance has also been described among *S. schleiferi* and *S. aureus* isolates from dogs with pyoderma.[8] These organisms encode an altered penicillin binding protein that incurs resistance to all β-lactam antimicrobials, and many also demonstrate resistance to fluoroquinolone antimicrobials.

FIGURE 84-1 Superficial bacterial folliculitis manifested by severe erythema, epidermal collarettes, pustules, papules, and plaques in a 10-year-old female spayed pit bull terrier cross dog with underlying atopic dermatitis. Cytologic examination showed numerous cocci and neutrophils. Culture and susceptibility grew a methicillin-susceptible, β-lactamase–producing *Staphylococcus pseudintermedius* that was treated successfully with cephalexin together with management of the underlying atopic skin disease.

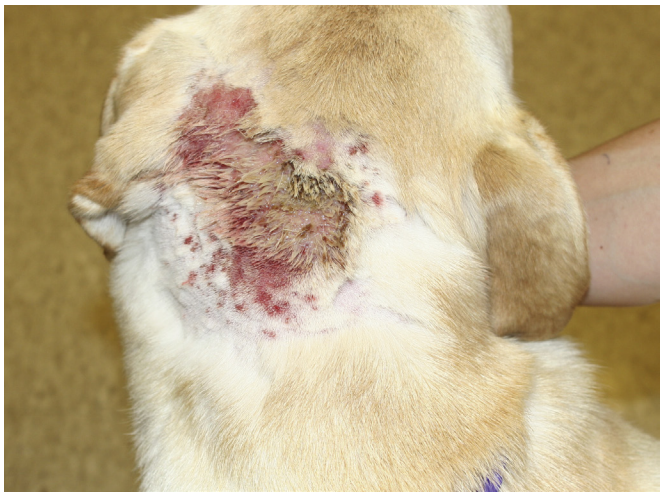

FIGURE 84-2 Deep pyoderma in a 2-year-old male neutered Labrador retriever. Cytology showed numerous cocci and neutrophils. No mites were detected in a skin scraping.

Clinical Features

Signs and Their Pathogenesis

Surface Pyoderma

Surface pyoderma is usually caused by superficial skin trauma, such as the rubbing together of lip, facial, vulvar, and tail folds in dogs with skinfold pyoderma. "Hot spots" occur secondary to self-trauma, such as that secondary to flea allergy dermatitis, and are commonly found in the lumbosacral area. Clinical signs include erythema, variable pruritus, alopecia, moist exudation, and a foul odor. Chronic lesions may be characterized by lichenification and hyperpigmentation. The exact causes of mucocutaneous pyoderma and surface microbial overgrowth have not yet been elucidated. Mucocutaneous pyoderma is characterized by erosions and ulcerations with or without crusting, which involve the lips, nasal planum, nares, perioral skin, and sometimes the anus, vulva, prepuce, and eyelids. It has also been reported in the axillary and inguinal region.[1] Microbial overgrowth syndrome usually involves the ventral aspect of the body and is characterized by erythema, pruritus, a foul odor, erythema, alopecia, hyperpigmentation, lichenification, and excoriations, but no evidence of papules, pustules, epidermal collarettes or crusts.[13]

Superficial Pyoderma

Early lesions of superficial pyoderma are erythematous follicular papules (papules from which a hair shaft protrudes). As pus accumulates within the epidermis and hair follicles, these lesions become pustules. Papules and pustules are *primary skin lesions*. When pustules rupture, crusted papules result. Epidermal collarettes are circles of epidermal scale with a free edge facing toward the center of the circle (see Figure 84-1), and may be remnants of ruptured papules. In thick-coated or shaggy dogs, the scale may become trapped throughout the haircoat as epidermal collarettes exfoliate. Hair fragments are shed from damaged follicles, which results in alopecia. Crusted papules, epidermal collarettes, and alopecia are *secondary lesions*.

Impetigo generally occurs in dogs less than a year of age. In impetigo, pustules are confined to the epidermis, without follicular involvement, and are most commonly found in the poorly haired (glabrous) areas on the ventral abdomen and inguinal region and around the chin. Superficial bacterial folliculitis usually occurs secondary to underlying allergic or atopic dermatitis or endocrinopathies such as hyperadrenocorticism or hypothyroidism. Pruritus is less common in dogs with underlying endocrinopathies. Other conditions that predispose to pyoderma include cornification disorders, genetic skin disorders, and ectoparasitism. In dogs with atopic dermatitis, invasion of the skin by staphylococci can in turn lead to a hypersensitivity response to staphylococcal antigens, which exacerbates the pyoderma.[14]

VetBooks.ir

Deep Pyoderma

Follicular rupture in dogs with deep pyoderma leads to a granulomatous foreign body inflammatory response within the dermis. Deep nodules with fistulation can be seen grossly.

Physical Examination Findings

Because the lesions of bacterial pyoderma are directly visible, in many cases, diagnosis can be made based on a thorough physical examination. Use of a hand lens may be helpful. In some cases, clipping of small areas of the haircoat may be required. This can help to identify epidermal collarettes in dogs with dry scale. Careful attention should be paid to the presence of follicular papules, pustules, crusted papules, epidermal collarettes, alopecia, nodules, fistulous tracts, and the presence or absence of pruritus (Box 84-1). The distribution of lesions should be noted because it can be a clue to underlying disease, such as demodicosis. In dogs with deep pyoderma, the skin may feel warm to the touch, and peripheral lymphadenomegaly may be detected.

BOX 84-1

Physical Examination Findings in Dogs with Pyoderma

Erythema	Epidermal collarettes
Pruritus	Hyperpigmentation
Papules	Hypopigmentation
Crusted papules	Alopecia
Pustules	Peripheral lymphadenopathy

Diagnosis

The diagnostic approach to pyoderma should involve confirmation of the presence of pyoderma and a thorough search for possible underlying causes. The differential diagnosis includes many diseases that predispose to pyoderma, such as demodicosis, dermatophytosis, and pemphigus foliaceus (see Overview). When crusting is present, cornification disorders should be considered, although crusting may also result from self-trauma. The presence or absence of *Malassezia* spp. must also be determined (Chapter 59).

In addition to a thorough physical examination, diagnostic procedures that may be necessary include skin scrapings, cytologic examination, aerobic bacterial culture and susceptibility, and skin biopsy (Table 84-1). Dermatophyte culture is indicated when underlying dermatophytosis is suspected (see Chapter 58). Identification and subsequent treatment of underlying allergic skin disease may require additional testing such as intradermal skin testing, for which referral to a veterinary dermatologist should be considered.

Microbiologic Testing

Skin Scrapings

Skin scrapings should be performed in any dog suspected to have pyoderma to assess for underlying demodicosis. Pustules or papules that are associated with hair follicles should be targeted, because *Demodex* mites have a predilection for this site.

Cytologic Examination

Cytology can be performed on tape preparations of the skin or smears made after swabbing pustules or draining tracts. Cytologic examination is essential in order to identify concurrent

TABLE 84-1

Diagnostic Assays Available for Pyoderma, Otitis Externa, and Otitis Media in Dogs

Assay	Specimen Type	Target	Performance
Cytology	Pyoderma: Swabs or tape preparations of pustules or draining tracts Otitis externa: Swabs from the horizontal ear canal Otitis media: Swabs of the material obtained from the tympanic bulla after myringotomy	Assessment for inflammatory cells, cocci, or rod-shaped bacteria and *Malassezia* spp.	Five to 10 oil immersion fields should be examined. Results of cytology do not address the underlying cause of disease. Neutrophils may be absent in dogs with underlying immunosuppression. Pyoderma: Degenerate neutrophils and intracellular cocci suggest infection. Otitis externa: Any bacteria found with leukocytes are abnormal. In healthy animals, cocci may be found at counts ≤5 (dogs) and ≤4 (cats)/400× magnification.
Histopathology	Pyoderma: Biopsy specimens Otitis externa: Biopsy specimens after total ear canal ablation with bulla osteotomy	Classifies extent and type of pyoderma and aids in identification of other conditions	Useful for refractory pyoderma, deep pyoderma, and when underlying cause not apparent. Occasionally assists diagnosis of underlying cause of otitis externa (such as demodicosis or neoplasia).
Culture	Superficial pyoderma: Swabs from pustules or epidermal collarettes Deep pyoderma: Skin biopsy specimens Otitis externa: Swabs from the horizontal ear canal Otitis media: Swabs or aspirates from the tympanic bulla	Pathogenic bacteria	Allows susceptibility testing in chronic, refractory, or recurrent cases or when gram-negative bacteria are present. Always interpret in light of cytologic findings because of the presence of commensal bacteria and mixed populations of bacteria. False negatives may occur in the face of antimicrobial treatment.

infection with *Malassezia pachydermatis*. Slides should be air-dried and stained with a modified Wright's stain such as Diff Quik. The presence of cocci suggests *S. pseudintermedius* infection (Figure 84-3). Infection is supported by the presence of degenerate neutrophils and intracellular cocci. Inflammatory cells may be absent in dogs with underlying immunosuppressive disorders or those receiving glucocorticoid treatment.

Culture and Susceptibility Testing

Given the rapidly increasing prevalence of methicillin-resistant staphylococci worldwide, aerobic bacterial culture and susceptibility testing is playing a more important role in diagnosis of canine pyoderma. Although probably not necessary for dogs with a first-time diagnosis of pyoderma, culture and susceptibility testing is never contraindicated and should always be offered in dogs with recurrent or refractory pyoderma, or in dogs that have a history of recent treatment with systemic antimicrobial drugs. Refractory pyoderma is pyoderma that fails to respond to treatment within a 3- to 4-week treatment period. Culture also can definitively identify the staphylococcal species involved, which may have public health implications (see Public Health Aspects, later). The results of culture and susceptibility testing must always be interpreted in light of the clinical signs present and any history of antimicrobial drug treatment.

The best lesions for culture in dogs with superficial pyoderma are pustules. A thorough search for pustules is recommended. If pustules cannot be detected, culture can be performed on swab specimens collected from the skin that lies beneath crusts or from epidermal collarettes. No surface antisepsis should be performed. Any hair should be clipped from the lesion using sterile scissors, and crusts should be lifted with sterile forceps. Pustules can be ruptured using a sterile needle, and a swab used to obtain purulent material. Papules can be biopsied using local anesthesia and submitted for culture. In this case, surface antisepsis with a single 70% alcohol wipe is indicated before collection of the biopsy. Culture of biopsy specimens from nodules and furuncles is best for dogs with deep pyoderma. After collection of the biopsy, the epidermis can be removed using a sterile blade and the deeper tissues submitted for macerated tissue culture.

Pathologic Findings

Histopathologic Findings

Findings on histopathology in dogs with uncomplicated pyoderma include a neutrophilic infiltrate and abundant bacterial organisms. Histopathologic evaluation of skin biopsy specimens allows classification of the extent and type of pyoderma and identification of other conditions such as allergic dermatitis, demodicosis, dermatophytosis, pemphigus foliaceus, neoplasia, deep mycoses, and vasculitides. Biopsy should be considered in recurrent or refractory cases, in dogs with deep pyoderma, or when the underlying cause is not apparent. Biopsies can be performed under local anesthesia using a 6-mm punch biopsy. An attempt should be made to include both affected and adjacent healthy tissue when identifying sites for biopsy collection. The biopsy site should be sutured after the specimen has been collected.

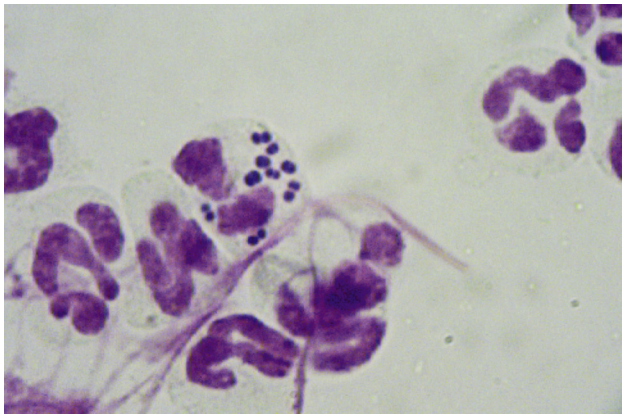

FIGURE 84-3 Cytology showing intracellular cocci *(Staphylococcus pseudintermedius)* and leukocytes in a tape preparation from a dog with pyoderma. Wright's stain, 1000× magnification.

Treatment and Prognosis

Factors to consider when treating dogs for pyoderma include the underlying disease present, the severity and extent of lesions, and the local prevalence of staphylococcal resistance. Veterinarians' reliance on systemic antimicrobial drug treatment has been challenged by the increasing prevalence of multidrug-resistant staphylococci. Topical treatments that help to restore skin structure and function, as well as topical antimicrobial therapy, should be considered as alternatives.[15] In dogs with mild disease, treatment aimed at the underlying disorder may be sufficient to resolve infection (see Prevention).

Topical Treatments

Antibacterial shampoos may be effective alone in some dogs with surface or mild superficial pyoderma and should be used as adjunctive therapy in dogs with deep pyoderma. They aid in debridement, reduce surface bacterial numbers, and decrease pain and pruritus. Options include shampoos that contain benzoyl peroxide, ethyl lactate, chlorhexidine, or triclosan. Initially, they should be used at least twice weekly with a 10-minute contact time. Benzoyl peroxide shampoos can be drying and so are best reserved for dogs with greasy dermatitides. Daily shampooing may be required for dogs with deep pyoderma. If available, treatment with daily whirlpool baths containing chlorhexidine may also be helpful for these dogs.

Topical antimicrobial drugs and antiseptics result in high concentrations of drug at the skin surface that can overwhelm bacterial drug resistance mechanisms, and can be useful when pyoderma is limited to small areas of skin. Aside from having the potential to be messy, these drugs have minimal side effects and result in minimal exposure of bystander organisms (such as gut flora) to antimicrobial drugs. Examples of topical drugs with excellent activity against staphylococci include neomycin, gentamicin, polymyxin B, bacitracin, hydroxyl acids (such as acetic acid), novobiocin, and silver sulfadiazine. Mupirocin and fusidic acid are additional topical antimicrobial drug preparations that may also be useful for treatment of pyoderma that is restricted to small areas. Unfortunately, resistance to mupirocin and fusidic acid has been documented in methicillin-resistant *S. aureus* isolates from humans.[16,17]

Systemic Antimicrobial Drug Therapy

When pyoderma is severe, treatment with systemic antimicrobial drugs may be required. The drug selected for empiric treatment should be based on the local prevalence of resistance, and narrow-spectrum drugs that target staphylococci are preferable. Clindamycin, first-generation cephalosporins (such as cephalexin), and amoxicillin-clavulanic acid are reasonable first choices (Table 84-2). Other acceptable alternatives when the

VetBooks.ir

TABLE 84-2

Suitable First-Tier Drugs for Treatment of Superficial Pyoderma in Dogs

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Cephalexin	22 to 30	PO	12	28, and at least 7 days after clinical resolution
Clindamycin	10	PO	12	28
Amoxicillin-clavulanic acid	12.5 to 25	PO	12	28
Lincomycin	15 to 25	PO	12	28
Doxycycline	5	PO	12	28
Trimethoprim-sulfamethoxazole*	15 to 30	PO	12	28

*Concerns exist regarding idiosyncratic and immune-mediated adverse effects in some patients with sulfa drugs, especially with prolonged therapy. Baseline Schirmer's tear testing is recommended, with periodic re-evaluation and owner monitoring for ocular discharge. Avoid in dogs that may be sensitive to potential adverse effects such as keratoconjunctivitis sicca (KCS), hepatopathy, hypersensitivity, and skin eruptions. See also Chapter 8.

local regional susceptibility of *S. pseudintermedius* is known include doxycycline, trimethoprim- or ormetoprim-potentiated sulfonamides, lincomycin, and erythromycin. The use of third-generation cephalosporins for empiric therapy is controversial because their use in particular has been associated with selection for methicillin-resistant staphylococci in humans and they have the potential to select for resistant populations of gram-negative bacteria in the gastrointestinal tract.[18] More research is required to determine whether this is also true in dogs and for all third-generation cephalosporins. When pyoderma is severe, and only when culture and susceptibility indicate the presence of multidrug-resistant staphylococci, the use of chloramphenicol, minocycline, doxycycline, third-generation cephalosporins, rifampin, clarithromycin, azithromycin, amikacin, or fluoroquinolones (such as enrofloxacin, marbofloxacin, orbifloxacin, pradofloxacin, or ciprofloxacin) could be considered as indicated based on culture and susceptibility results. The use of fluoroquinolones in humans and dogs is a risk factor for selection of methicillin-resistant *S. pseudintermedius* and also has the potential for selection of resistant populations of gram-negative bacteria in the gastrointestinal tract.

Treatment should be for a minimum of 4 weeks for superficial pyoderma and 8 weeks for deep pyoderma. A small percentage of dogs with superficial pyoderma require 6 weeks of treatment. For superficial pyodermas, treatment should be continued for at least 7 days beyond clinical resolution of lesions, because inflammation subsides before infection is completely resolved. For deep or recurrent superficial pyoderma, treatment should be continued for 14 days beyond clinical resolution.

Although intermittent administration of antimicrobials on a regular basis ("pulse therapy") has been used to treat some dogs with recurrent pyodermas, there is concern for induction of resistance using these protocols. If this appears to be necessary, referral to a veterinary dermatologist is recommended.

Prevention

Prevention of pyoderma relies on addressing the underlying cause or causes whenever possible. This could include treatment with antihistamines and essential fatty acids, intradermal skin testing and hyposensitization injections, frequent bathing to restore skin condition, dietary management for dogs with food allergies, or breeding practices that aim to select against atopy and dogs with abundant skin folds. Specific prevention of methicillin-resistant staphylococcal infections relies on handwashing and disinfection practices and judicious use of antimicrobial drugs, as outlined earlier, although more data are required in regard to risk factors for development of resistant pyodermas in dogs.

When treatment of the underlying cause or use of topical therapy is unsuccessful in preventing recurrence of pyoderma, subcutaneous administration of autogenous bacterins or commercial bacterial antigens (such as Staphage Lysate, Delmont Laboratories, USA) may be beneficial in some dogs.[19,20] These are generally given once or twice weekly (see Chapter 7).

Public Health Aspects

Although *S. pseudintermedius* prefers not to colonize humans, human infection has been reported occasionally, including among veterinarians.[21-23] A methicillin-susceptible *S. pseudintermedius* was detected as a cause of endocarditis in a human patient,[23] and methicillin-resistant *S. pseudintermedius* has been isolated from human patients with sinusitis.[21] In all cases, pet dog contact was reported and suggested to be the source of infection. In one case, an isolate from the dog matched that isolated from the human as determined using pulsed field gel electrophoresis.

In contrast, contact with human hospitals and children may be risk factors for acquisition of methicillin-resistant *S. aureus* infections by dogs, and *S. aureus* infections appear to be a reverse zoonosis. Colonization is generally transient in dogs and cats, so specific treatment to decolonize dogs and cats is not necessary.[24]

Two subspecies of *S. schleiferi* have been described: *S. schleiferi* subsp. *coagulans*, which is coagulase positive, and *S. schleiferi* subsp. *schleiferi*, which is coagulase negative. Although it may be carried elsewhere on the body, *S. schleiferi* subsp. *coagulans* has been isolated primarily from dogs with otitis externa and was reported as a cause of endocarditis in an immunocompromised human.[25] Coagulase-negative *S. schleiferi* are thought to be a commensal of the skin of both humans and dogs, and although they are common contaminants, they can cause disease in both species.[8,26]

Frequent and *proper* hand washing using soap and water and disinfectant foams or gels is the number one practice that limits spread of these infections in human hospitals. Hands should be washed before and after handling each patient. Clean clothing should be worn and laboratory coats changed regularly. Attention must be paid to regular disinfection of other fomites such as stethoscopes, cell phones, rectal thermometers, computer keyboards and mice, calculators, and bandage scissors. Disinfectant

wipes that contain alcohol or accelerated hydrogen peroxide can be used to clean these surfaces.

Overview of Otitis Externa and Otitis Media

Cause: *Staphylococcus pseudintermedius* and *Pseudomonas aeruginosa*; less commonly *S. schleiferi, S. aureus, Proteus mirabilis, Escherichia coli, Corynebacterium* spp., *Klebsiella* spp., enterococci, and β-hemolytic streptococci

Affected Hosts: Dogs, less commonly cats

Geographic Distribution: Worldwide

Major Clinical Signs: Otic erythema, pruritus, head shaking, purulent discharge, swelling, malodor, and pain. Proliferative changes and ulceration occur with chronicity. Vestibular signs, deafness, Horner's syndrome, and facial paralysis occur with middle ear involvement.

Differential Diagnoses: Underlying causes include allergic dermatitis, foreign bodies, neoplasia, hypothyroidism, cornification disorders, pemphigus foliaceus, otoacariasis, dermatophytosis, demodicosis, and drug eruptions. *Malassezia* otitis externa must also be considered.

Human Health Significance: *S. pseudintermedius* prefers not to colonize humans, but zoonotic transmission has been reported.[21] Frequent hand washing is recommended for dogs that are known or suspected to have drug-resistant *Pseudomonas aeruginosa* otitis externa.

OTITIS EXTERNA AND OTITIS MEDIA

Etiology and Epidemiology

Otitis externa, or inflammation of the ear canal, although relatively uncommon in the cat, is one of the most common diseases of dogs, accounting for 10% to 20% of all accessions seen in general veterinary practice.[27] Bacterial and fungal infections of the ear canal are virtually always secondary to an underlying condition, and recognition of the underlying cause or causes of otitis externa is *critical* for effective treatment. Repeated treatment with antimicrobial drugs without regard for the underlying cause leads only to the selection of resistant bacterial populations and treatment failure.

The causative factors for otitis externa have been grouped into predisposing, primary, and perpetuating factors (Box 84-2). Predisposing factors include ear canal conformation, obstructive processes such as tumors within the ear canal, and increased moisture within the ear. Primary causes of otitis externa in dogs are allergic dermatitis, which accounts for as many as 90% of cases,[28] and less commonly endocrinopathies (especially hypothyroidism), foreign bodies, ear mite infestation *(Otodectes cynotis)*, and cornification disorders (such as seborrhea in cocker spaniels). More than 80% of dogs with atopy have otitis externa, and otitis externa may be the only sign of allergic dermatitis.[10] Seasonal occurrence of otitis externa can be a clue to underlying atopic dermatitis. In cats, ear mite infestation accounts for at least 50% of cases, with young cats being predisposed.[29] These factors increase inflammation within the ear, which intensifies bacterial and yeast infections. Chronic inflammation then leads to progressive pathology within the ear canal, tympanic membrane, and middle ear, which prevents resolution of otitis externa. Predisposed breeds include cocker and Brittany spaniels, poodles, and Labrador retrievers.

A variety of bacteria and occasionally yeasts can be isolated from the ear canals of healthy dogs, including *S. pseudintermedius, S. schleiferi, Streptococcus* spp., and *Malassezia pachydermatis*. Gram-negative rods are rarely isolated from normal ears. In dogs with otitis externa, overgrowth of yeast and bacterial organisms occurs within the ear canal. *S. pseudintermedius* is the most common bacterial pathogen isolated from dogs with otitis externa. *Pseudomonas aeruginosa* is frequently isolated from dogs with chronic otitis externa, and this may be challenging to treat effectively because of the development of antimicrobial resistance. Less commonly, *S. schleiferi, S. aureus, Proteus mirabilis, E. coli, Corynebacterium* spp., *Klebsiella* spp., enterococci, and β-hemolytic streptococci are isolated.

Malassezia pachydermatis is the most common fungal cause of otitis externa. In one study, it was isolated from more than 60% of otitic ears.[30] Fungi such as *Candida* spp., *Aspergillus* spp., and dermatophytes are less commonly reported causes. In dogs with bilateral otitis externa, the organisms

BOX 84-2

Major Factors That Predispose to, Cause, and Perpetuate Otitis Externa

Predisposing Factors
Stenotic canals (e.g., shar-pei)
Pendulous pinnae
Excessive moisture (swimming, humidity)
Excessive cerumen production
Trauma from cotton applicators
Topical treatments that irritate the canal
Ear canal neoplasia, polyps, cholesteatomas, or foreign bodies
Immunosuppression

Primary Causes
Parasites, such as *Otodectes cynotis, Demodex canis*, and *Otobius megnini*
Dermatophytosis
Allergic dermatitis (atopy, food and contact hypersensitivities)
Primary idiopathic seborrhea
Hypothyroidism
Foreign bodies (grass awns, sand, inspissated medications)
Cerumen gland hyperplasia

Perpetuating Factors
Aerobic bacterial infection
Malassezia pachydermatis infection
Hyperkeratosis
Hyperplasia
Dermal edema
Fibrosis
Stenosis
Mineralization
Osteomyelitis

present in each ear frequently differ.[31] Unilateral otitis externa may suggest the presence of an underlying foreign body or neoplasia, although bilateral involvement with these causes is possible, and unilateral involvement can occur with symmetric disorders such as allergic dermatitis and ceruminous gland hyperplasia.

Otitis media is inflammation of the middle ear. More than half of dogs with chronic otitis externa have otitis media, although the bacteria present in the external ear canal often differ from those present in the middle ear.[32] The tympanic membrane can rupture and reseal, so it frequently appears intact on examination of the external ear canal. Less commonly, otitis media results from extension of infection from the nasopharynx or hematogenous spread. Evidence of otitis media is sometimes detected during computed tomography (CT) of the skull of cats or dogs with chronic rhinosinusitis.

Clinical Features

Signs and Their Pathogenesis

Early clinical signs of otitis externa are erythema of the pinnae, external meatus, and lining of the ear canal. Progression of disease with proliferation of bacteria and yeasts leads to signs of pruritus, head shaking, ceruminous or purulent discharge from the ear canal, swelling, malodor, lesions resulting from self-trauma (including aural hematomas), and/or pain when the ear is touched or palpated (Figure 84-4). With chronicity, proliferative changes occur that lead to stenosis and occlusion of the ear canal, and the tympanic membrane may rupture. Subsequently, there is fibrosis and mineralization of the ear canal, which uncommonly (but especially with *P. aeruginosa* infections) is accompanied by ulcerations of the canal, sometimes with ongoing pain and debilitation.[28]

Physical, Dermatologic, and Otoscopic Examination Findings

A thorough physical and dermatologic examination may provide clues to the underlying cause of otitis externa. In addition to lesions of the external ear canal (see Signs and their Pathogenesis), examination may reveal signs consistent with underlying endocrine disease, or skin lesions suggestive of underlying allergic dermatitis (atopic, food, or contact dermatitides), parasitic infections, or keratinization disorders.

A complete otoscopic examination of both ears should be performed, starting with the least affected ear. Sedation may be required in animals that are painful or uncooperative, or the animal may need to be reexamined at a later date for otoscopy after treatment has been initiated to reduce pain and inflammation. Usually cytologic examination with or without culture is still possible in these animals.

Either a handheld otoscope or video otoscope can be used for otoscopic examination. Video otoscopy allows a higher degree of magnification and intense illumination of the ear canal (Figure 84-5). The ear canal should be examined for the presence and characteristics of foreign bodies, exudate, erythema, stenosis, proliferation, ulceration, and mass lesions. The tympanic membrane may be visualized in some cases and inspected for rupture, distortion, or discoloration that suggests the presence of hemorrhage or pus within the middle ear. In dogs with chronic otitis externa, ear flushing under general anesthesia may be required in order to properly visualize the tympanic membrane. Proper assessment of the integrity of the tympanum may still not be possible in some dogs. In dogs with severe stenosis or ear canal ulceration, treatment with topical and oral glucocorticoids may be necessary for 4 to 7 days before proper otoscopic examination can be performed. Clients should always be educated regarding the complications of ear canal flushing such as Horner's syndrome, facial nerve paralysis, vestibular signs, and deafness.

Diagnosis

Diagnosis is based on the physical, dermatologic, and otoscopic examination; cytology of the ear canal; culture; and in some cases, advanced imaging. Each ear should be considered as a separate unit, because organisms present in one ear canal may differ from those present in the other.[31]

FIGURE 84-4 Chronic, multidrug-resistant *Pseudomonas aeruginosa* otitis externa in a 4-year-old intact male Old English sheepdog showing erythema and multifocal ulcerative lesions on the pinna.

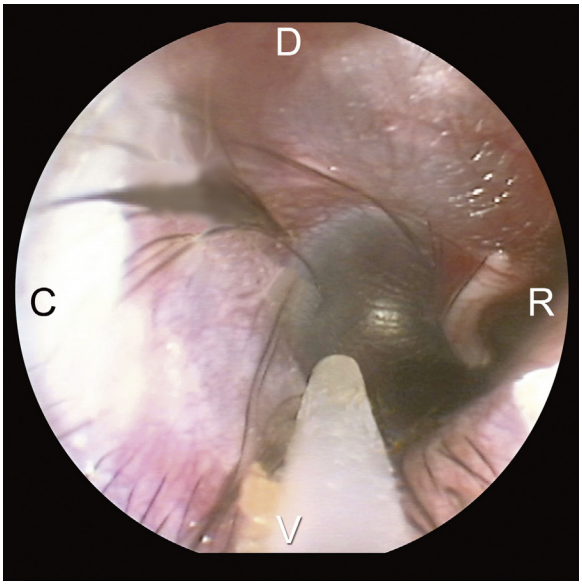

FIGURE 84-5 Proper site for myringotomy, right tympanic membrane. The caudoventral quadrant of the pars tensa is approached with a tomcat catheter. *C,* caudal; *D,* dorsal; *R,* rostral; *V,* ventral. (From Cole LK. Otoscopic evaluation of the ear canal. Vet Clin North Am Small Anim Pract. 2004;34[2]:397-410.)

Microbiologic Testing

Cytologic Examination

Cytologic examination of the ear canal should *always* be performed in dogs and cats seen for otitis externa. The results of otic cytology support culture and susceptibility data, guide initial treatment decisions, and allow the response to treatment to be monitored. In some situations (such as when mites or foreign bodies are found), otoscopy permits diagnosis of the underlying cause. Specimens are collected from the external ear canal with a cotton-tipped applicator before any cleaning or treatment administration. The tip of the swab is directed at the junction of the horizontal and vertical ear canal, being cautious to avoid trauma to the tympanic membrane. For dogs and cats suspected to have otitis media, specimens for cytology and culture should be collected from the middle ear following myringotomy, which is performed in an anesthetized animal by perforating the ventrocaudal quadrant of the tympanum with a small sterile swab, catheter, or spinal needle (see Figure 84-5).

Slides should be labeled according to the ear they are from and briefly heat fixed, because the high lipid content of cerumen causes material to be washed from the slide during staining. After staining with a modified Wright's stain, 10 to 15 oil immersion fields of each slide should be examined for the presence of cocci, rods, fungi (most commonly *Malassezia* spp.), and leukocytes, and the type and number of each should be recorded for each ear. Any bacteria associated with leukocytes are abnormal. Bacterial counts considered abnormal are at least 25/400× magnification (40× objective) for dogs and 15 or more for cats.[33] Normal dogs and cats have 5 or fewer and 4 or fewer organisms/400× magnification, respectively, and intermediate counts represent a gray zone.[33] Rod-shaped bacteria or large numbers of leukocytes are also rarely found in normal ear canals. The presence of leukocytes suggests a true bacterial infection; rarely they can indicate other underlying disease processes, such as pemphigus foliaceus or otocariasis. *Malassezia* spp. are found in the ear canals of healthy dogs and dogs with otitis externa. An inflammatory response is typically not present, even when *Malassezia* spp. are contributing to disease progression. Estimation of yeast counts may be helpful to determine the role of *Malassezia* in otitis. It has been suggested that a mean count of 5 or more yeasts/400× magnification (40× objective) is abnormal in dogs, and 12 or more yeasts/400× magnification is abnormal in cats. Normal dogs and cats have 2 or fewer yeasts/400× magnification.[33] If the presence of mites is suspected, a mineral oil preparation is made on a separate slide, and the slide is examined using low-power magnification.

Bacterial Isolation

Culture allows identification of the species of bacteria present and subsequent documentation of antimicrobial susceptibility. Culture is indicated (1) when bacterial rods (as opposed to cocci) or degenerate neutrophils are present on cytology; (2) when otitis externa is recurrent (within 6 months), or is chronic and refractory to initial treatment; or (3) when otitis media is present. Because culture of the external ear canal does not distinguish among commensal bacteria, overgrowth, and true infection, it must *always* be interpreted in light of cytologic examination findings. As for cytologic examination, each ear canal should be considered as a separate unit. When otitis media is present, the external ear canal and middle ear should be cultured separately.[32]

Diagnostic Imaging

Diagnostic imaging under general anesthesia is indicated for dogs with recurrent otitis externa, those with evidence of chronic disease (such as infection with *P. aeruginosa*), or animals with suspected middle ear involvement. Imaging can be performed using plain radiography or CT. MRI abnormalities in dogs with otitis externa and media have been described, but MRI is less sensitive than CT for evaluation of cartilage and bony detail. MRI is useful for evaluation of the central nervous system (CNS) of dogs and cats that have neurologic signs in conjunction with otitis media and assists in the differentiation between central and peripheral vestibular lesions.

Plain radiography of the tympanic bulla should include lateral, dorsoventral, latero-20 degree ventral-laterodorsal oblique, and rostro-30 degree ventral-caudodorsal open-mouth oblique radiographs. An additional 10-degree ventrodorsal view may assist visualization of the tympanic bulla in cats.[34] Advanced imaging can often be performed more quickly than plain radiography because advanced imaging does not require multiple views and precise positioning. CT also offers advantages of increased sensitivity for detection of changes to the bulla and external ear canal, although false negatives can still occur when otitis media is mild.[35]

Changes found on plain radiography and CT of the ear in dogs and cats with otitis externa include increased soft tissue opacity in association with the lumen or wall of the ear canal, and/or stenosis or mineralization of the wall of the ear canal. In animals with otitis media, increased soft tissue opacity within the tympanic bulla, thickening of the bulla wall, or bony proliferation of the wall of the bulla may be evident (Figure 84-6). Lysis of the bulla may be evident in animals with severe otitis media.

Using MRI, changes suggestive of otitis media include medium-signal intensity material in the bulla on T1-weighted images, with hyperintensity of this material on T2-weighted images.[34,36] After contrast agent administration, meningeal

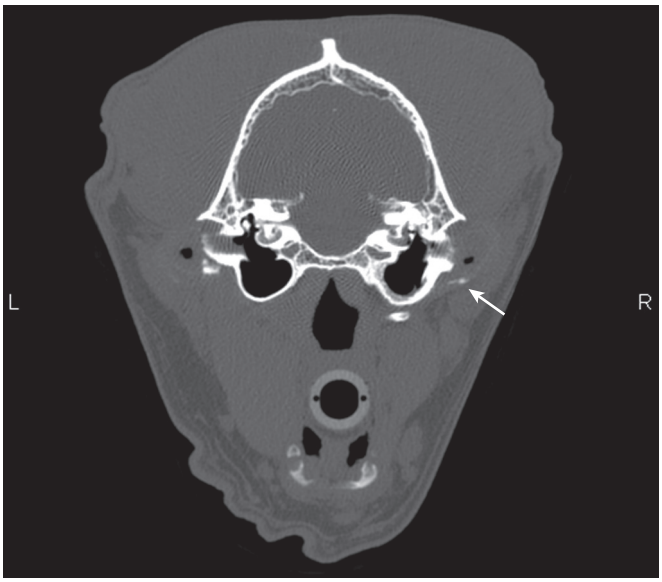

FIGURE 84-6 CT scan showing mineralization of the external ear canals (arrow) and thickening and debris within the right tympanic bulla in a 5-year-old male neutered German shepherd dog with chronic, multidrug-resistant *Pseudomonas aeruginosa* otitis externa and severe, chronic otitis media.

enhancement may be appreciated in animals with otitis interna, or changes suggestive of brain abscessation, such as mass lesions with ring enhancement, may be present (Figure 84-7).[36]

Treatment and Prognosis

Otitis Externa

The decision to treat otitis externa and the specific treatments used depend on assessment of the history, clinical signs, cytologic findings, and, if performed, consideration of culture results as they relate to the most common pathogens present. A plethora of different treatments have been used, because no single treatment is effective for all cases, and many veterinarians and veterinary dermatologists base their choice(s) on familiarity. Regardless of the treatment used to control secondary bacterial infections, attention to identification and treatment of the underlying cause (foreign bodies, allergic dermatitis) is critical for successful long-term resolution of otitis externa. For dogs with chronic or recurrent otitis externa, the importance of regular rechecks at monthly intervals should be emphasized to ensure compliance with medications and an appropriate response to treatment. Clients should be offered referral to a veterinary dermatologist for dogs with recurrent, refractory, or chronic otitis externa, and when *P. aeruginosa* or highly resistant bacterial infections are present.

Treatments for otitis externa may be topical or systemic. The treatment of otitis externa presents challenges because of the difficulty in obtaining adequate drug concentrations in the bacterial exudate that accumulates within the ear canal; difficulties in obtaining owner compliance, especially in dogs that have otic pain; and the potential for ototoxicity with ear cleaners and other topical treatments. Ototoxicity occurs rarely but is unpredictable and may be manifested by vestibular signs, Horner's syndrome, facial paralysis, or deafness. Neurologic signs following ear flushing are especially apt to occur in cats. Usually these signs are transient but occasionally can be permanent. Clients should be taught how to properly lavage the ear canal, administer topical medications, and monitor for and treat ototoxicity. The prognosis for resolution of otitis externa depends strongly on owner compliance in regard to medications and rechecks and the ability to address the underlying cause. Treatment is generally continued until cytologic examination, performed at 2- to 3-week intervals, shows no evidence of bacteria or neutrophils. Infections with *P. aeruginosa* should be treated until *P. aeruginosa* is no longer cultured from the ear canal.

Ear Cleaning

Gentle ear cleaning and flushing removes secretions and some foreign bodies and allows better penetration and activity of antimicrobial drugs. It is essential for resolution of otitis media, provided the tympanic membrane remains open. Some ear cleansers also have antimicrobial properties.[37] Ear cleaners should be warmed to body temperature before use. Ear cleaning in the home may not be possible until several days of oral analgesics and topical antimicrobials have been administered, to counteract pain resulting from infection and inflammation. Once tolerated, cleaning is generally performed on a 12- or 24-hour basis for the first 5 to 7 days, and then every second or third day until clinical signs resolve. Subsequently, weekly maintenance cleaning may be needed to reduce the risk of recurrence while managing the underlying cause of otitis externa. If the tympanum is intact, a routine ear cleanser and dryer can be used. If the integrity of the tympanum is unknown, ceruminolytic agents (such as those containing squalene, dioctyl sodium sulfosuccinate, carbamide peroxide, or triethanolamine polypeptide locate-condensate) should be avoided. Isotonic saline or a tromethamine-ethylenediaminetetraacetate (Tris EDTA) solution can be used twice daily, either before

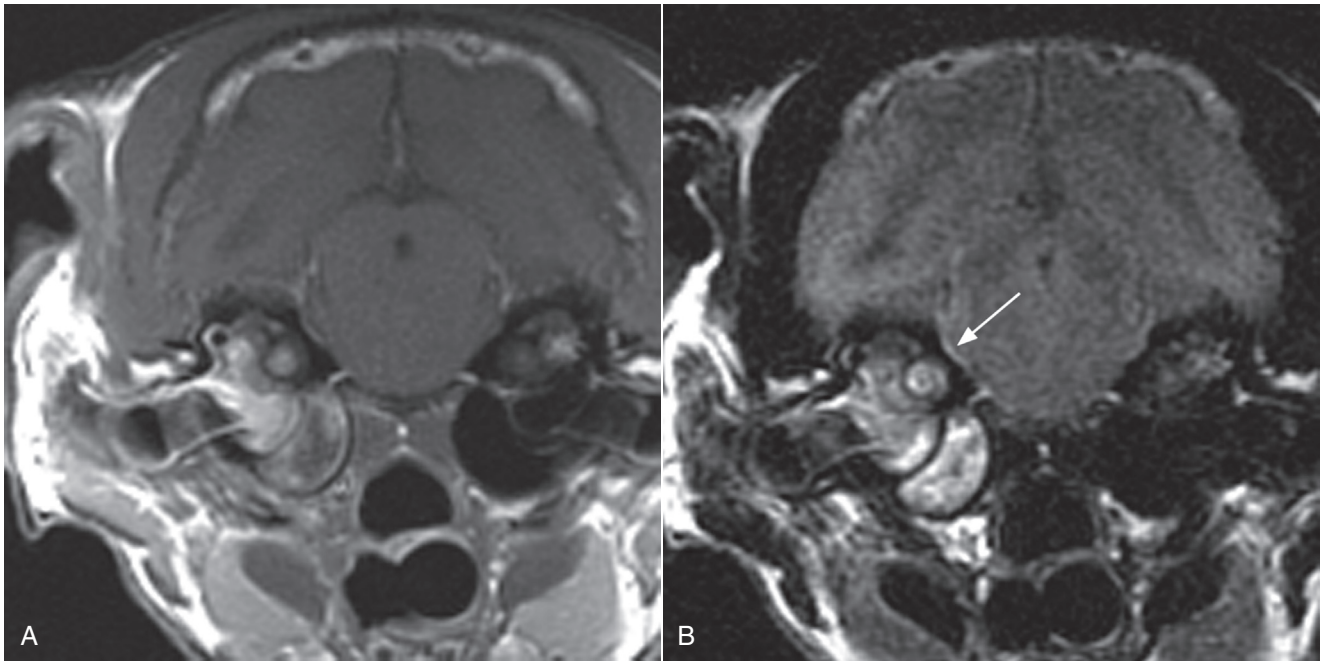

FIGURE 84-7 Post-contrast T1-weighted image **(A)** and FLAIR image **(B)** from an MRI scan of the brain of a 15-year-old female spayed domestic shorthair cat. Precontrast images showed diffuse hyperintensity within the left tympanic bulla. The postcontrast images showed moderate contrast enhancement of the lining of the tympanic bulla and mild enhancement of the lateral meninges of the left cerebellar hemisphere adjacent to the bulla (see arrow on FLAIR image). These findings were consistent with otitis media and edema of the left cerebellar meninges.

topical antimicrobials are instilled or as a solution that contains antimicrobials. Tris EDTA destabilizes the bacterial cell wall and potentiates the effect of topical antimicrobials.[38] Several proprietary solutions are available in the United States (Table 84-3). Preparations that contain acetic or boric acid can also be used once daily, although the potential for these preparations to cause adverse effects in dogs with ruptured tympanums is unknown. If owner-administered treatment fails to remove exudates and otitis persists, flushing and examination of the ear canal and tympanic membrane with warm isotonic saline under anesthesia may be indicated. This may also be necessary for resolution of *P. aeruginosa* infections and for dogs with otitis media.

Glucocorticoids

Systemic and/or topical glucocorticoid treatment may be indicated for dogs with otitis externa if it is accompanied by severe inflammation or proliferative changes in the ear canal, including those with *P. aeruginosa* infections. Treatment with oral prednisolone for 1 to 2 weeks, with subsequent tapering over an additional 4-week period, helps to reduce or resolve inflammation, pain, and proliferative changes (Table 84-4). Treatment with prednisolone is discontinued when these abnormalities have significantly reduced or resolved. Many topical otic preparations also contain glucocorticoids (see next section). These have the disadvantage of making the ear appear healthy to the client, who may then discontinue treatment before bacterial infection has resolved, so client education is important. Dogs with severe proliferative changes may benefit from topical administration of the potent combination of fluocinolone and DMSO. Intralesional triamcinolone acetonide injections have also been used to treat severe proliferative otitis externa,[39] usually with reduction in the dose of concurrently administered systemic glucocorticoids. Referral to a dermatologist is recommended for these cases.

Topical Glucocorticoid/Antibiotic/Antifungal Drugs

Topical preparations that contain glucocorticoids and antimicrobial drugs allow delivery of high concentrations of antimicrobials to the ear canal, with or without local anti-inflammatory effect

TABLE 84-3

Drug Preparations Administered Topically That May Be Used to Treat Canine Otitis Externa

Drug	Dose*	Interval (hours)	Duration	Goal
1:2 solution of enrofloxacin injectable (22.7 mg/mL): dexamethasone sodium phosphate (4 mg/mL)† *or* a 1:2 solution of enrofloxacin:Tris EDTA‡	Fill ear and massage in	12	Until cytologic resolution, 2 to 4 weeks	Antibiotic, anti-inflammatory
Gentamicin/betamethasone/clotrimazole ointment§	4 to 8 drops	12	Until cytologic resolution, 2 to 4 weeks	Antibiotic/anti-inflammatory/antifungal
Gentamicin/mometasone/clotrimazole ointment‖	4 to 8 drops	24	Until cytologic resolution, 2 to 4 weeks	Antibiotic/anti-inflammatory/antifungal
Polymyxin B/prednisolone acetate/miconazole ointment¶	4 to 8 drops	12	Until cytologic resolution, 2 to 4 weeks	Antibiotic/anti-inflammatory/antifungal
Orbifloxacin/mometasone/posaconazole ointment#	4 to 8 drops	24	Until cytologic resolution, 2 to 4 weeks	Antibiotic/anti-inflammatory/antifungal
Enrofloxacin/silver sulfadiazine ointment**	4 to 8 drops	12	Until cytologic resolution, 2 to 4 weeks	Antibiotic with some antifungal properties, promotes reepithelialization. Effect may be potentiated after Tris EDTA flush.
Fluocinolone and DMSO solution††	4 to 8 drops depending on dog size	12	Until significant reduction of pain and inflammation	Anti-inflammatory, antipruritic, and analgesic

*Some clinicians suggest that ointment volumes of up to 1 mL should be used depending on body weight; use a syringe for accurate dosing has been recommended.
†Add 1% miconazole lotion in a 1 (enrofloxacin):1 (dexamethasone sodium phosphate):2 (miconazole) ratio when *Malassezia* spp. is present. If bacteria are absent, a 1:1 solution of miconazole:dexamethasone should be used.
‡Such as TrizEDTA (Dechra Veterinary Products), T8 or T8 Keto (DVM Pharmaceuticals).

TABLE 84-4

Drug Preparations Administered Orally That May Be Required to Treat Dogs with Otitis Externa

Drug	Dose (mg/kg)	Interval (hours)	Duration	Effect
Tramadol	1 to 4	12	Days to weeks	Analgesic
Prednisolone	0.5	12-24, then taper and discontinue	Days to weeks, until proliferative changes have reduced or resolved	Anti-inflammatory, antipruritic, and analgesic
Cephalexin	30	12	3 to 8 weeks	Antibiotic (initial choice when cocci are seen)
Marbofloxacin	4 to 5.5	24	3 to 8 weeks	Antibiotic (initial choice pending culture when rods are seen)
Ketoconazole, fluconazole, or itraconazole	5	24	Until cytologic resolution	Antifungal (when *Malassezia* spp. are present)

(see Table 84-3). Most acute, first occurrences of otitis externa will respond to topical treatments alone, without the need for systemic treatment. Culture and susceptibility results may not predict the response to treatment with topical antimicrobials, because of the high concentrations that can be achieved safely in the ear canal using such treatments. The choice of topical treatment should be based on the results of cytologic examination and, if possible, an assessment of the integrity of the tympanic membrane. If the integrity of the tympanic membrane is unknown, owners should be warned regarding the potential for ototoxicity, although ototoxicity has the potential to occur with any topical treatment. If the tympanum is intact, all options are acceptable. If the integrity of the tympanum is unknown, and increased numbers of bacteria are present, enrofloxacin solutions appear to be well tolerated. A solution of enrofloxacin and dexamethasone sodium phosphate can be used, or enrofloxacin can be diluted in Tris EDTA (see Table 84-3). Serial cytologic examinations should be used to monitor treatment efficacy and complications such as *Malassezia* overgrowth, which can occur following the use of topical antibiotics alone.

If bacterial rods predominate on cytologic examination, aerobic bacterial culture and susceptibility are indicated; a solution containing an aminoglycoside, polymyxin B, or ticarcillin-clavulanate is a good first empirical choice, although all have the potential to cause ototoxicity. Ototoxicity following topical aminoglycoside administration in dogs appears to be very uncommon,[40] but the risk of ototoxicity may outweigh the benefits of these treatments in service or performance dogs, and proper examination of the tympanum under anesthesia before initiating these treatments is recommended. A variety of other topical treatments have been used by veterinary dermatologists, including those containing antibacterials such as fusidic acid and silver sulfadiazine.[40] Silver sulfadiazine may also promote reepithelialization of ulcerated ears. The presence of *P. aeruginosa* is commonly associated with recurrent otitis externa, poor compliance, and primary causes that have not been addressed. The use of a more potent or expensive topical antimicrobial alone is rarely effective in successfully managing these cases, even in the short term.

Systemic Antimicrobial Drugs

Systemic antimicrobial treatment is not always necessary, even in *P. aeruginosa* otitis. General indications for systemic antibiotic treatment include (1) chronic and recurrent otitis externa; (2) the presence of ulceration; (3) the presence of otitis media; or (4) owner inability to effectively administer topical antimicrobial drugs. The antimicrobial is chosen on the basis of cytologic findings initially, while the results of culture and susceptibility testing are pending. A change in antimicrobial drug may be indicated if the results of susceptibility testing suggest resistance to the initial drug selected. Appropriate initial choices include cephalexin for otitis associated with the presence of cocci, and a fluoroquinolone for otitis associated with the presence of rods (see Table 84-4). Susceptibility panels should include enrofloxacin, marbofloxacin, ciprofloxacin, ticarcillin-clavulanate, and ceftazidime, in addition to those antibiotics routinely tested. Systemic azole antifungal treatment may be required when *Malassezia* spp. are present (see Chapter 59). Treatment is for a minimum of 6 to 8 weeks for dogs with otitis media and should be continued until there is normalization of the ear canals with no evidence of microorganisms on cytologic examination. The tympanic membrane may or may not regenerate. For dogs with highly resistant bacterial infections of the external or middle ear, daily lavage in conjunction with aggressive topical treatment alone may be successful.[40]

Surgery

Surgical treatments are salvage options that are reserved primarily for dogs with irreversible ear canal disease that is not responsive to medical treatment, and include total ear canal ablation (TECA) or total ear canal ablation with bulla osteotomy (TECA-BO). Indications for surgery in dogs with otitis externa include severe proliferative changes that occlude the ear canal, collapse or stenosis of the horizontal canal, or severely calcified periauricular tissues. Lateral wall resections achieve poor control of the disease and are not generally recommended. Addition of the bulla osteotomy to a TECA can help to prevent recurrence of disease due to persistent otitis media, manifested as recurrent infection with draining tracts. Severe intraoperative hemorrhage, postoperative wound infections, recurrent otitis media with draining tract formation, pinna necrosis, permanent or transient facial nerve damage, peripheral vestibular signs, and deafness are potential complications of the procedure, but the overall prognosis for resolution of disease is good. Resected tissue and bulla epithelium should be submitted for histopathology (see Table 84-1), since

a previously undiagnosed underlying cause is occasionally detected. Cultures are obtained from the external and middle ear during surgery, and antimicrobials are administered perioperatively and for 4 to 8 weeks postoperatively (depending on the extent of middle ear involvement). Referral to a specialist surgeon is encouraged.

Public Health Aspects

The public health aspects outlined for pyoderma also apply to otitis externa. Hand hygiene should particularly be emphasized to owners of dogs with otitis externa associated with multidrug-resistant gram-negative bacteria, especially *P. aeruginosa*.

CASE EXAMPLE

Signalment: "Carla," a 3-year-old FS cocker spaniel dog from northern California (Figure 84-8)

History: Carla was brought to a veterinary dermatologist for a 1-year history of chronic skin problems that began on her back and progressed to involve her ventral abdomen, paws, lips, and neck. The owner reported she had been licking, scratching, biting, and rubbing the affected areas, and on a scale of 1 to 10 for pruritus, the owner believed she was an 8. She had also been lethargic and her appetite had been decreased. The condition had responded twice to antimicrobial drug treatment in the past (amoxicillin–clavulanic acid, then clindamycin) but returned when they were discontinued, and the third, most recent episode failed to respond to treatment with cephalexin and diphenhydramine. She was obtained as a puppy at 14 weeks of age and had no skin problems for her first 2 years of life. She was treated monthly with spinosad for flea prevention. There was one other healthy dog in the house.

Current medications: Diphenhydramine 2.5 mg/kg PO q12h

Physical Examination:

Body Weight: 10 kg.

General: Quiet, alert, hydrated, responsive. T = 102.5°F (39.2°C), HR = 120 beats/min, eupneic, CRT = 2 s.

Eyes, Ears, Nose, and Throat: Both eyes showed moderate scleral injection, moderate hyperemia with mild chemosis of third eyelid, and moderate tear staining. Both inner pinnae felt greasy with moderate yellow debris in the left ear canal, but no odor was detected. Mild to moderate dental calculus was present.

Integument: There was a full, soft, clean haircoat with moderate scaling but no evidence of ectoparasites. Generalized crusts with erythematous borders were noted. The crusts ranged from small (4-5 mm) round crusts randomly distributed on the dorsum to larger, irregularly shaped consolidated yellow crusts along the ventrum and left cervical region. Marked erythema of the inguinal region was present. There was bilateral erythema and diffuse thickening of the lower lip. Marked bilateral periocular alopecia with marked periocular scaling and crusting and moderate edema and swelling of the lower eyelids was noted. There was also marked erythema and moist skin interdigitally on both palmar and dorsal surfaces of both thoracic limbs, and yellow discoloration was present interdigitally on the dorsal surfaces. Mild to moderate erythema and moist skin was present interdigitally on both plantar and dorsal surfaces of both pelvic limbs.

Musculoskeletal: Body condition score was 8/9, ambulatory.

Genitourinary: There was mild perivulvar alopecia with mild erythema, mild yellow dried vulval discharge.

Other Systems: All other systems examined were within normal limits. All peripheral lymph nodes were <1 cm in diameter.

Cytology Findings:

Tape Preparations: Inguinal skin and dorsal feet: Degenerate neutrophils, cocci (too numerous to count).

Perianal skin: Degenerate neutrophils and 3 to 5 yeasts/oil immersion field.

Interdigital region: Degenerate neutrophils and 1 to 2 yeasts/oil immersion field.

Ear Swab Cytology: Right ear: Degenerate neutrophils and 15 to 20 cocci/oil immersion field.

Left ear: Degenerate neutrophils and cocci (too numerous to count).

Aerobic Bacterial Culture and Susceptibility: Moderate numbers of *Staphylococcus pseudintermedius* and a few *Pseudomonas aeruginosa* were isolated from the skin beneath crusts in the inguinal region.

	Bacteria Isolated	
Drug	***S. pseudintermedius***	***P. aeruginosa***
Amikacin	S ≤ 4.00	S ≤ 4.00
Amoxicillin–clavulanic acid	R	R > 32.00
Ampicillin	R	—

*No Int P, no interpretative criteria (breakpoint) available.

VetBooks.ir

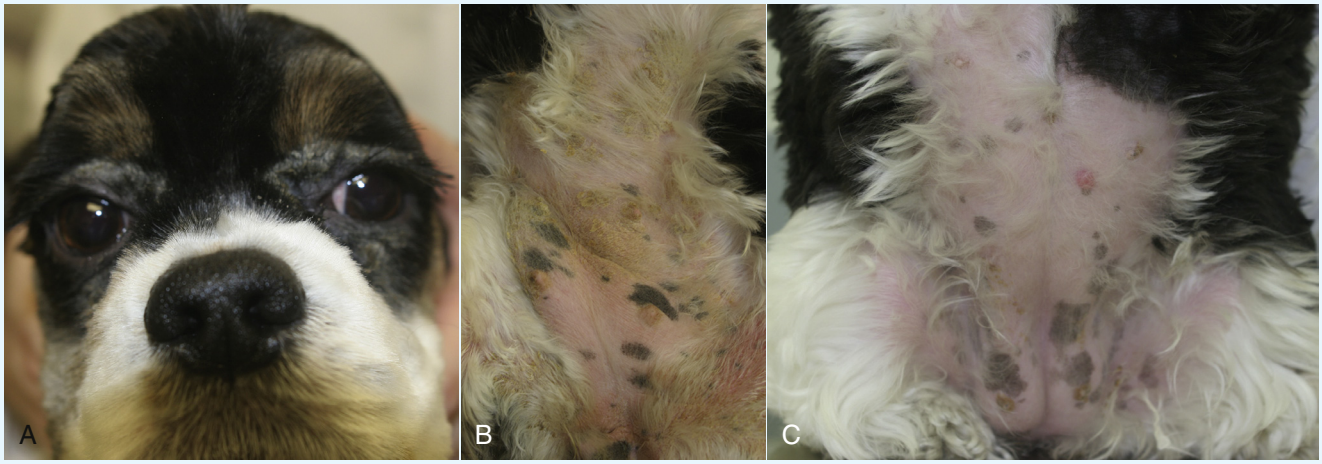

FIGURE 84-8 A 3-year-old FS Cocker spaniel with generalized superficial pyoderma, *Malassezia* spp. dermatitis, and bacterial otitis externa. **A,** Note periocular alopecia, scaling, and crusting. **B,** Consolidated yellow crusting and erythema are present on the ventral abdomen. **C,** Ventral abdomen of the same dog at a recheck 2 months after initiation of treatment.

Diagnosis: Generalized superficial pyoderma (methicillin-resistant *S. pseudintermedius*), *Malassezia* spp. dermatitis, bacterial otitis externa; suspect underlying allergic dermatitis or primary seborrhea of cocker spaniels.

Treatment: Fluconazole, 5 mg/kg PO q24h; prednisolone/trimeprazine 10 mg/4 mg (2 tablets) PO q12h for 2 days, then 10 mg PO q24h for 5 days, 10 mg q48h for 7 days, then one tablet twice weekly; routine ear cleaning twice daily followed 10 minutes later by topical gentamicin/betamethasone/clotrimazole ointment. Treatment with chloramphenicol was also initiated once culture and susceptibility results became available, but because of gastrointestinal adverse effects this was changed to doxycycline, 5 mg/kg PO q12h for 4 weeks. Suspected primary seborrhea was treated with every other day bathing with antiseborrheic shampoo and a spot-on antiseborrhea treatment (Duoxo, Sogeval). At a recheck 6 weeks after the initial visit, lesions and cytologic findings were greatly improved (see Figure 84-8, *C*). Subsequent management of Carla's skin condition required monthly rechecks with adjustment of treatments based on dermatologic examination and cytologic findings, routine ear cleansing with an antiseborrheic micellar ear solution (Duoxo, Sogeval), and a novel single-source protein diet for a suspected underlying food allergy.

Comments: This dog was diagnosed with superficial pyoderma and otitis externa on the basis of the dermatologic examination, cytologic findings, and culture. The *P. aeruginosa* was considered a likely contaminant based on the low numbers of organisms isolated and lack of cytologic evidence of bacterial rods. Failure to identify and address the underlying causes of this dog's pyoderma and otitis externa resulted in inadequate control of the disease, with development of a resistant bacterial infection. Culture and susceptibility testing of a pustule found 7 months after discontinuation of systemic antimicrobial treatment showed an *S. pseudintermedius* isolate with the same susceptibility pattern as the previous isolate, except now with intermediate susceptibility to tetracyclines. Although Carla's skin is much improved, inadequate owner compliance with bathing and medications has been partly responsible for the failure to eliminate the infection.

CHAPTER 85

Osteomyelitis, Discospondylitis, and Infectious Arthritis

Jane E. Sykes and Amy S. Kapatkin

VetBooks.ir

Overview of Musculoskeletal System Infections

Causes: The most common cause of osteomyelitis and infectious monoarthritis in dogs is *Staphylococcus* spp., but streptococci, other gram-negative bacteria, anaerobes, and fungi may be involved. *Bartonella, Nocardia,* and *Mycobacterium* can also cause osteomyelitis. *Brucella* can cause osteomyelitis and discospondylitis. Polyarthritis may be caused by a wide range of gram-positive and gram-negative bacteria; vector-borne bacterial pathogens *(Rickettsia rickettsii, Ehrlichia canis, Anaplasma phagocytophilum, Ehrlichia ewingii, Borrelia burgdorferi);* protozoa *(Leishmania);* and fungi.

Geographic Distribution: Worldwide, although the prevalence of brucellosis and vector-borne and fungal causes varies geographically

Major Clinical Signs: Pain, lameness, fever, inappetence, lethargy, draining skin lesions, and soft tissue swelling may occur with osteomyelitis. Spinal pain, fever, lethargy, inappetence, and pelvic limb paresis or paralysis can occur with discospondylitis. A stiff gait, reluctance to move, lameness, fever, inappetence, lethargy, and swollen joints may occur with polyarthritis.

Differential Diagnoses: Differential diagnoses for suspected osteomyelitis, monoarthritis, and discospondylitis include bone neoplasia, sterile foreign body reactions, and degenerative osteoarthritis. Primary immune-mediated polyarthritis is the major differential diagnosis for suspected infectious polyarthritis.

Human Health Significance: When draining wounds are present, resistant bacteria such as methicillin-resistant *Staphylococcus aureus* associated with osteomyelitis and arthritis in dogs and cats may have the potential to colonize human patients. Discospondylitis and polyarthritis caused by *Brucella* spp. can be transmitted to humans through contact with infected urine. Because vector-borne pathogens and fungi of importance to human health can cause polyarthritis, hospital staff should take special care to avoid sharps injuries when working with animals with polyarthritis.

Infectious osteomyelitis is defined as infection of the cortical bone, periosteum, and myeloid cavity and the associated inflammatory response. The axial and/or appendicular skeleton may be involved. *Discospondylitis* refers to inflammation of the intervertebral discs and adjacent cartilaginous endplates, and almost always results from infection by bacteria or fungi. *Infectious arthritis* refers to inflammation of the synovium, synovial fluid, and associated cartilage secondary to infectious causes.

Osteomyelitis, discospondylitis, and arthritis can result from (1) hematogenous spread of bacteria or fungi to these sites, or (2) from direct introduction of bacteria as a result of penetrating wounds or surgery. When fungi are involved, molds such as *Aspergillus* spp. or *Paecilomyces* spp. are more likely than yeasts to cause discospondylitis; *Candida* has rarely been associated with discospondylitis in dogs.[1] In contrast, osteomyelitis can be caused by opportunistic molds or dimorphic fungi, especially *Coccidioides* spp. or *Blastomyces dermatitidis*. Fungal arthritis is uncommon but has been associated with infection by *Coccidioides* spp., *B. dermatitidis*, and *Cryptococcus* spp.

OSTEOMYELITIS

Etiology, Pathogenesis, and Epidemiology

Bacterial osteomyelitis most often results from direct introduction of bacteria into wounds adjacent to bone. Bacteria can be introduced into the bone as a result of penetrating foreign bodies, surgical wounds (especially orthopedic surgeries with implant placement), traumatic wounds, bite wounds, or extension of soft tissue infections. Tibial plateau leveling osteotomy (TPLO) surgery for cranial cruciate rupture, one of the most common orthopedic surgical procedures performed, has a postoperative infection rate that ranges from 0% to 7%.[2-5] For unknown reasons, the infection rate after TPLO appears to be higher than that after routine "clean" orthopedic surgeries that involve osteotomy (as opposed to fracture repair). In a report that was published before the TPLO procedure was described, the overall infection rate after any orthopedic surgery procedure was 3 of 502 surgeries (<1%).[6] In contrast, radiographically detectable osteomyelitis was reported in 14 (7.3%) of 193 dogs that underwent TPLO surgery and was the single most common complication of the procedure.[3] In another study, the infection rate after fracture repair was 9 (8%) of 110 surgeries.[7] In this study, 20% of the fractures were open. Open fractures were 4 times more likely to be contaminated with bacteria at the time of surgery than the closed fractures, and contaminated wounds were 5 times more likely to develop complications (seroma, drainage, and dehiscence) than those without contamination. Distal radius/ulna and tibial fractures were 10.5 times and 7.5 times more likely to be contaminated than femoral fractures, respectively. Animals with a normal postoperative temperature and a clean surgical wound did not develop postoperative complications.

Although gram-positive aerobes such as staphylococci and, to a lesser extent, streptococci predominate as a cause of osteomyelitis in dogs and cats, the organisms present and the bone(s)

	Propionibacterium acnes	1 (2)	NA	ND

Mixed infections with 2 or 3 bacterial species or strains were present in 7 (23%) of the dogs (total 41 isolates).
NA, Not applicable; ND, not done.
*Resistant to three or more classes of antimicrobial drugs.
†One of 2 *E. coli* and the *Proteus* isolate did not undergo susceptibility testing because isolation was performed at necropsy.

affected generally reflect the underlying type of injury that led to infection. For example, osteomyelitis that follows surgical site infection is often caused by *Staphylococcus pseudintermedius*, a common commensal of canine skin (Table 85-1). *Staphylococcus aureus* and gram-negative bacterial infections can also cause orthopedic surgical site infections.[5] In contrast, anaerobes and aerobic gram-positive bacteria (staphylococci, enterococci, streptococci) or gram-negative bacteria *(Pseudomonas, E. coli, Klebsiella pneumoniae, Proteus, Pasteurella)* predominate in osteomyelitis that results from bite wound infections, tooth root abscesses, or penetrating foreign bodies.[8,9] Such mixed bacterial infections are also common in dogs with digital osteomyelitis.

Osteomyelitis secondary to bacteremia, also known as *hematogenous osteomyelitis,* is very rare and usually affects young animals. The metaphyseal regions are often involved, sometimes with extension to the epiphyses and joints (Figure 85-1). The pathogenesis remains obscure. It has been suggested that discontinuous endothelium in the primary spongiosa may predispose to extravasation of erythrocytes and bacteria in this region.[10] In humans, blunt trauma appears to contribute to development of focal childhood osteomyelitis, and it has been hypothesized that the periosteum, rather than the metaphysis, may initially be involved.[11] Sternal and vertebral osteomyelitis can also result from hematogenous spread of bacteria. Osteomyelitis occasionally also results from hematogenous spread of fastidious bacteria such as *Brucella, Bartonella, Mycobacterium,* and *Nocardia* spp.

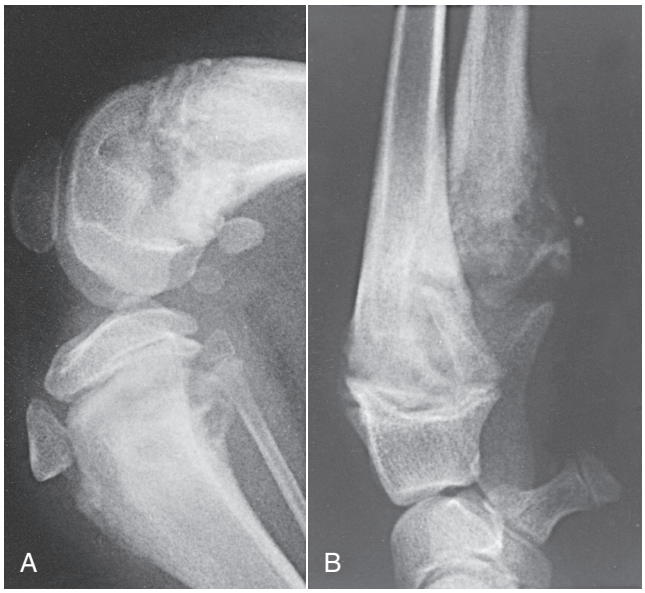

FIGURE 85-1 Polyostotic metaphyseal osteomyelitis in a Border collie puppy that had persistent neutropenia. **A,** Disruption of metaphyseal architecture of distal femur and proximal tibia, with irregular areas of radiolucency and sclerosis and some adjacent periosteal new bone. **B,** Similar changes are evident in the distal radius and ulna. (From Ettinger SJ, Feldman EC, eds. Textbook of Veterinary Internal Medicine. 7th ed. St. Louis, MO: Saunders; 2010.)

Clinical Features

Signs and Their Pathogenesis

The development of bacterial osteomyelitis requires the presence not only of bacteria, but also of compromised bone. Bone necrosis can result from trauma (i.e., fracture), surgery, or underlying bone neoplasia. Bacteria adhere to fibronectin, a connective tissue glycoprotein, through the use of a variety of adhesins. The presence of foreign material promotes persistence of infection in the form of biofilm (Figure 85-2). Within biofilm, bacteria evade opsonization and phagocytosis and are protected from the effects of antimicrobial drugs. Bone sequestra can also

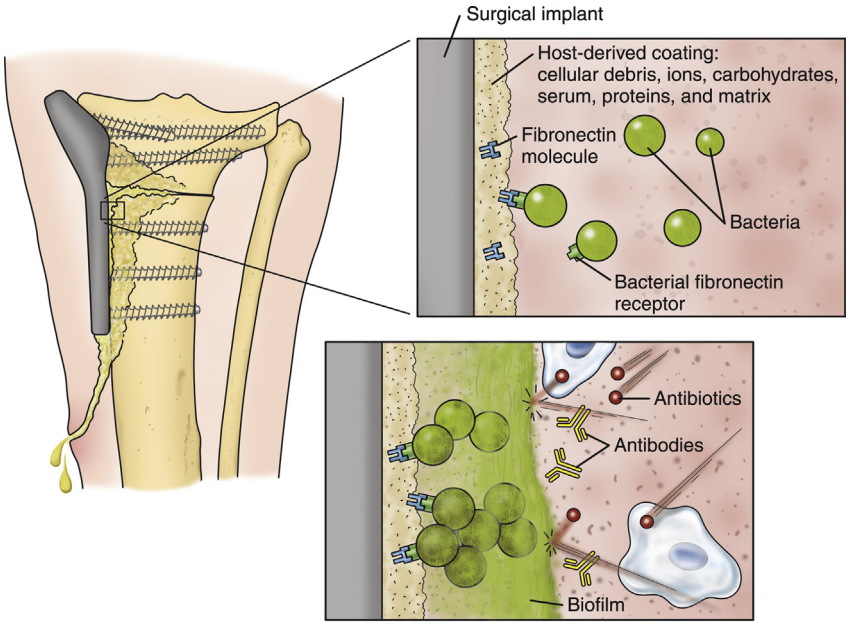

FIGURE 85-2 Pathogenesis of osteomyelitis. Necrotic bone is colonized by bacteria, which adhere to fibronectin and in the presence of foreign material (in this case, an implant) can form biofilm. Biofilm consists of bacterial aggregates embedded in a matrix of exopolysaccharide (bacterial slime). The biofilm protects the bacteria from antibodies, phagocytosis, and antimicrobial drugs.

become colonized by bacteria, which evade host defenses in the absence of adequate blood supply. Loose implants and fracture instability contribute to bone resorption, compromised blood supply, and persistent infection.[10] Some implant types are more apt to be colonized by bacteria. In one study, Slocum TPLO plates were more likely to be removed than other types of TPLO plates because of local bacterial infection and clinical signs of inflammation.[12]

Inflammatory cells recruited to the site of infection release enzymes that cause additional bone necrosis, with destruction of cancellous and cortical bone and abscessation of associated soft tissue. The end result is focal swelling, pain, draining skin lesions, and lameness. Small draining skin lesions often represent the "tip of the iceberg", with extensive bone involvement hidden beneath the skin (Figure 85-2). The presence of anaerobes can be associated with a foul odor or gas production. Fever, inappetence, lethargy, and leukocytosis are occasionally present in animals with acute osteomyelitis but are often absent in chronic osteomyelitis. Occasionally, infection reactivates in dogs years after surgery and implant placement. In human patients, latent periods between infection and development of osteomyelitis can last many decades.[13]

Physical Examination Findings

Physical examination findings in dogs and cats with osteomyelitis include lameness, localized pain, soft tissue swelling, muscle atrophy, and the presence of draining tracts. Fever and lethargy can also be identified in some animals.

Diagnosis

In most cases, osteomyelitis is diagnosed on the basis of history, physical examination, and radiographic findings. Aerobic and anaerobic bacterial culture of affected bone or any implants present is required for definitive diagnosis.

Laboratory Abnormalities

The CBC of animals with osteomyelitis may be unremarkable or reveal mild anemia, neutrophilia with bandemia, and monocytosis. The serum biochemistry panel and urinalysis are usually unremarkable, unless bacteremia or other systemic disease is also present.

Diagnostic Imaging

Radiographic changes in dogs and cats with osteomyelitis vary considerably in extent and character. In some dogs and cats, only soft tissue swelling may be evident. Plain radiography is insensitive and can be poorly specific for diagnosis of osteomyelitis, and interpretation can vary from one board-certified radiologist to another. In one study, plain radiographic findings were interpreted as osteomyelitis by two radiologists in only 5 of 8 dogs with experimentally induced osteomyelitis.[14] One radiologist diagnosed osteomyelitis in only 3 of the 8 dogs, but that radiologist was less likely than the other radiologists to diagnose osteomyelitis when infection was absent.

When radiographic bony changes are evident, they consist of periosteal proliferation, which may be smooth or speculated; focal osteopenia with cortical resorption or thinning; loss of trabecular markings; lucency around implants such as plates or screws; and sequestration (Figure 85-3). Pathologic fractures may be evident in dogs with fungal osteomyelitis. Scintigraphy with technetium-99m ciprofloxacin has also been investigated for diagnosis of osteomyelitis in a rabbit model.[15] False negatives and false positives were common early (4 weeks) in the course of healing, but sensitivity increased to 75% to 100% later in the course of healing, with specificities that approached 100%. Ultrasound imaging, contrast computed tomography (CT), and MRI may be useful for identification of sequestra, foreign material, and abscess formation. Intravenous administration of ultraparamagnetic iron oxide nanoparticles during MRI, which are taken up by macrophages, has shown promise for early detection of vertebral osteomyelitis and differentiation of osteomyelitis from aseptic inflammation.[16]

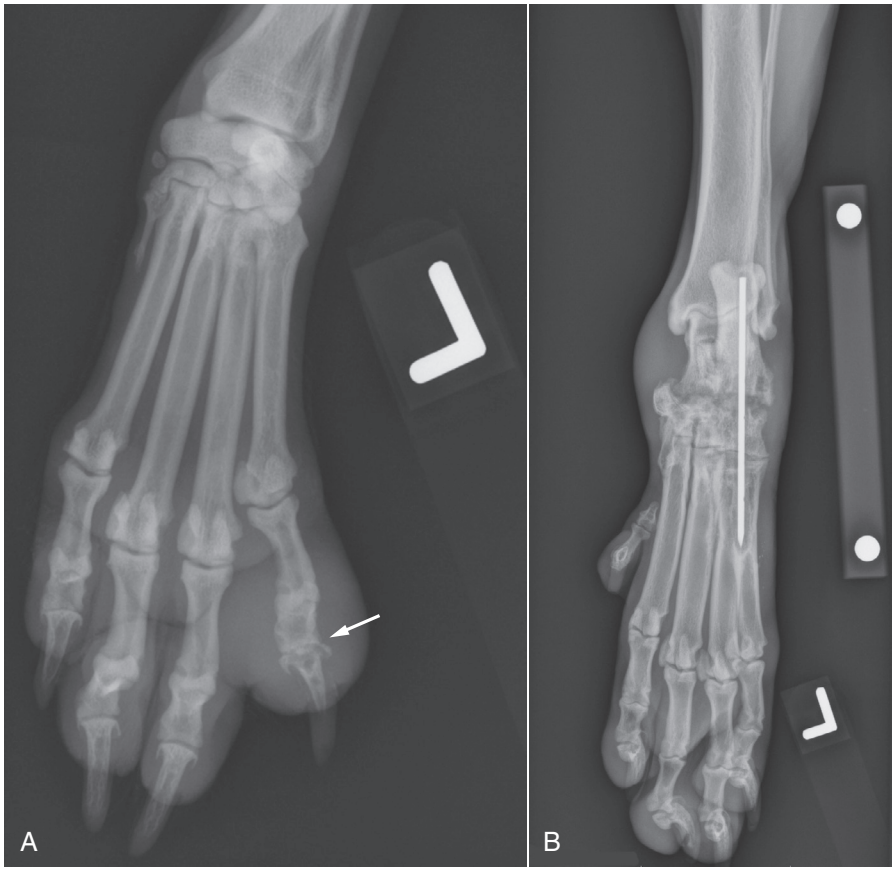

FIGURE 85-3 Radiographic changes in bacterial osteomyelitis. **A,** Osteomyelitis of the third phalanx of the fifth digit in a 7-year-old female spayed fox terrier with systemic lupus erythematosus that had been treated with prednisone and cyclosporine. There is severe soft tissue swelling, moderate lysis of the distal aspect of the third phalanx, and an irregular cortical margin with loss of the normal P2-P3 joint space *(arrow)*. A *Nocardia* sp. was isolated from the draining lymph node. **B,** Radiographs of the left tarsus of a 5-year-old male neutered pit bull terrier with implant-associated osteomyelitis. A partial left tarsal arthrodesis had been performed a year previously after the dog suffered a traumatic injury. Draining tracts then developed in association with the screw heads, and treatment with cephalexin was unsuccessful. There is severe irregular bone lysis on both sides of the proximal intertarsal joint. A surgical pin extends from the proximal calcaneus through the tarsal joint to the level of the mid-diaphysis of the 5th metatarsal bone. There is a region of lucency that surrounds the tip of the surgical pin within the 5th metatarsal bone. The cortex of the 4th metatarsal bone adjacent to the pin is thickened with a slightly irregular periosteal reaction. The first phalanx of the first digit is incomplete (likely congenital). There is marked soft tissue swelling associated with the tarsus. A methicillin-susceptible *Staphylococcus aureus* was cultured from the implant at surgery to remove the pin. Tobramycin-impregnated calcium sulfate beads were used to fill the pin tract.

Microbiologic Tests

Isolation and Identification

Aerobic and anaerobic bacterial culture and susceptibility should be performed on aspirates of pus, bone biopsies, or removed implants from dogs and cats with osteomyelitis. Aspirates should be collected in a sterile manner from the focus of infection to avoid contamination with surface bacteria (e.g., via aspiration of lesions through healthy skin after skin antisepsis, or through collection of biopsies or implants during surgical exploration). Negative culture results may reflect an insufficient specimen size, or the presence of fastidious bacteria such as anaerobes, *Bartonella*, *Brucella*, *Nocardia*, or *Mycobacterium* spp. Blood cultures should be performed if hematogenous osteomyelitis is suspected based on the history and clinical findings (young animal, multiple sites affected, sternal or vertebral involvement, other systemic illness or immunosuppression).

Pathologic Findings

Pathologic findings in osteomyelitis depend on the causative agent and chronicity of infection. Inflammatory cell infiltrates may range from suppurative (acute osteomyelitis) to pyogranulomatous or lymphoplasmacytic. The neutrophilic infiltrate in dogs with acute osteomyelitis may be accompanied by the presence of fibrin, free red blood cells, and necrotic debris. There may be evidence of bone resorption with multinucleated osteoclasts and new bone and fibrous tissue formation. In some cases, intralesional bacteria or fragments of foreign material (such as plant material) are observed (Figure 85-4).

Treatment and Prognosis

Treatment recommendations for focal osteomyelitis secondary to trauma, surgery, or foreign body penetration depends on the severity and chronicity of disease, the location of osteomyelitis, the presence or absence of foreign material, and the extent of blood supply to the bone. In animals with fractures, early detection and treatment of osteomyelitis is critical to prevent extensive bone necrosis and nonunion. Antimicrobial drug treatment alone is usually not sufficient to resolve chronic bacterial osteomyelitis, because sequestra and biofilm are avascular and are not effectively penetrated by antimicrobial drugs. In general, treatment requires debridement, removal of sequestra and foreign material (such as implants), dead space removal, extensive lavage with sterile saline, rigid fracture stabilization,

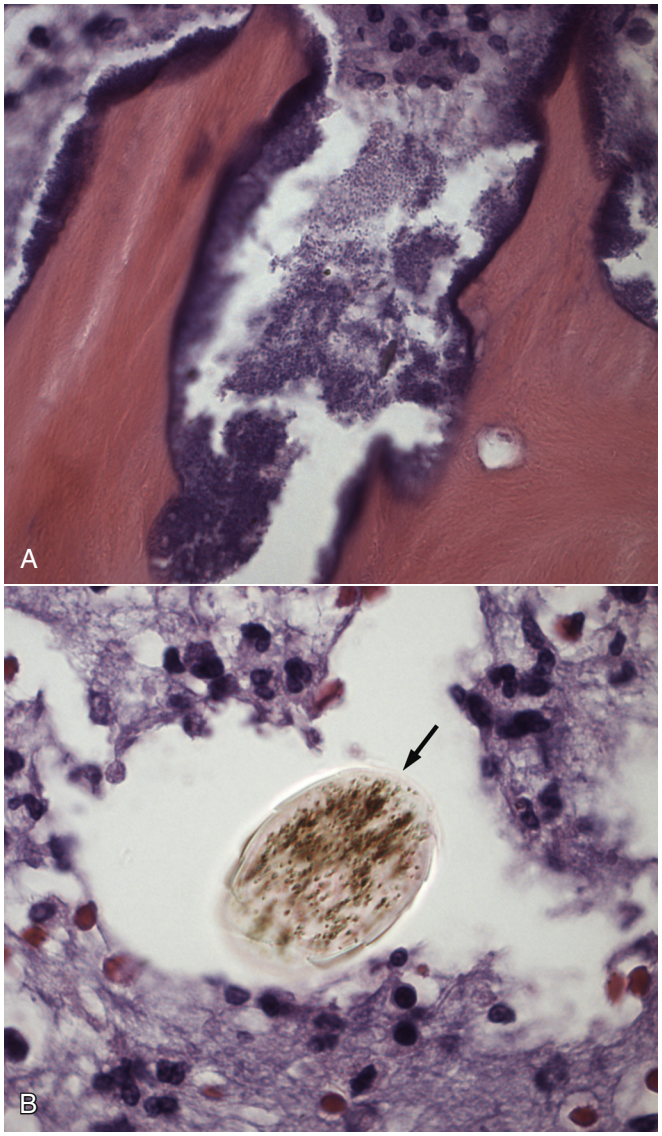

FIGURE 85-4 Histopathology from the right pelvic fourth digit of a 3-year-old intact male Labrador retriever with an open articular fracture and chronic suppurative bacterial osteomyelitis. **A,** Large numbers of bacteria are adhered to bone fragments (eosinophilic material) with an associated neutrophilic inflammatory response. **B,** In other fields, intralesional plant material was visible *(arrow)*.

systemic +/- local administration of appropriate antimicrobial drugs, and grafting of bone deficits. Because implants must ultimately be removed to resolve infection, fractures may need stabilization through alternative means, such as external skeletal fixation. If implants are rigidly stable, they should be left in place until bone healing is complete and then they should be removed in a second surgical procedure. Systemic antimicrobial drug therapy (and often regional antibiotic therapy in the form of antimicrobial drug–impregnated beads) is required while the bone heals. In some cases, foci of osteomyelitis may be removed en bloc without the need for further graft placement or stabilization (e.g., digital osteomyelitis). Resected bone should be submitted for histopathology (to confirm the presence of osteomyelitis and identify other processes such as fungal infection or neoplasia) as well as culture and susceptibility. Wounds are left open after debridement if continued debridement is needed via wet-to-dry bandaging. If all nonviable tissue has been removed, closed irrigation systems or vascularized tissue flaps may be used to manage dead space. A sterile dressing should be used to cover the wounds, with daily bandage changes until exudation resolves. If needed, autogenous cancellous bone graft placement is delayed until infection has been controlled and granulation tissue has begun to fill the wound (usually 1 to 2 weeks after initiation of antimicrobial drug treatment).[17] When graft placement or fracture stabilization is not possible because of financial concerns or uncontrollable infection, amputation may be necessary.

The choice of antimicrobial drugs should be based on the results of aerobic and anaerobic bacterial culture and susceptibility. If the animal is stable, treatment should be withheld until results are available, and medications to manage pain should be administered. If earlier antimicrobial treatment is deemed necessary pending the results of culture and susceptibility, the drug chosen should be based on the history (e.g., postsurgical infection versus bite wound infection) and local prevalence data for the practice (Table 85-2). Clindamycin is a reasonable initial choice for infections that could include susceptible staphylococci and/or anaerobic bacteria and was effective in experimental models of *S. aureus* osteomyelitis in dogs,[18] but a significant proportion of methicillin-resistant staphylococci exhibit clindamycin resistance or inducible clindamycin resistance (see Chapter 35). If gram-negative bacteria or methicillin-resistant staphylococci are suspected, the addition of an aminoglycoside may be necessary if treatment must be instituted before the results of culture and susceptibility become available. However, aminoglycosides penetrate poorly into purulent material, so adequate debridement is essential. Combinations of antibiotics are sometimes required in animals with polymicrobial infections. Systemic antibiotic treatment should be continued for at least 4 to 6 weeks. Longer periods of treatment may be required in some dogs and cats. Antimicrobial drugs should be given parenterally in the hospital for at least the first 3 to 5 days, and for longer if possible.

In addition to systemic treatment, antibiotic-impregnated beads can be used to treat chronic osteomyelitis and septic arthritis in dogs.[19-21] These are prepared in the operating room by mixing an antimicrobial drug with commercially available cement and setting the cement into beads on a suture through the use of a plastic mold or by hand. The beads are counted and strings of beads are placed at the site of infection, where they deliver high concentrations of drug to the site (e.g., initially 500-fold that of normal serum concentrations with systemic treatment), sometimes for several weeks, without systemic adverse effects.[22] The antimicrobial drugs used are generally heat stable, hydrophilic, and have activity against methicillin-resistant staphylococci, such aminoglycosides (gentamicin or tobramycin) or vancomycin. Clindamycin has also been used. Once the antimicrobial drug has diffused from the bead, nonbiodegradable beads such as those composed of polymethylmethacrylate (PMMA) may act as foreign bodies and a nidus for infection, and so a second surgery is usually required for bead removal. Biodegradable materials are also available, and include antibiotic-impregnated collagen, bone graft substitutes such as calcium phosphate or calcium sulfate (plaster of Paris, e.g., Osteoset) beads (Figure 85-5), and a variety of synthetic polymers such as polylactic acid, polylactide-co-glycolides, and cross-linked polydimethylsiloxane.[22] Tobramycin-impregnated calcium phosphate beads have been used successfully to treat osteomyelitis in dogs.[20] Polymers can be engineered to control the duration and concentration of antibiotic treatment at the site.

TABLE 85-2

Suggested Initial Antimicrobial Drug Doses for Stable Animals with Bacterial Orthopedic Infections Pending Culture and Susceptibility Results

Disease	Drug	Dose (mg/kg)	Route	Interval (hours)
Osteomyelitis or monoarthritis	Clindamycin hydrochloride, clindamycin phosphate	11-33 (dogs) 11 (cats) 10	PO PO IV,* IM	12 (dogs) 24 (cats) 12
	Enrofloxacin†	5-20 (dogs)	IV, IM, PO	24
	Gentamicin sulfate‡	14 (dogs) 8 (cats)	IV, IM, SC	24
	Amikacin‡	15-30 (dogs) 10-14 (cats)	IV, IM, SC	24
Discospondylitis	Ampicillin sodium	20	IV	6
	Ampicillin-sulbactam§	20	IV	8
	Amoxicillin–clavulanic acid	20-25	PO	12
	Cefazolin sodium	20-35	IV, IM	8
	Cephalexin	20-30	PO	6-8

See Chapter 86, Table 86-8, for suggestions for severe sepsis.
*For IV administration, dilute 1:10 in 0.9% saline and administer over 30-60 minutes.
†Addition of fluoroquinolones to clindamycin or a β-lactam is indicated if gram-negative bacteria may be present and methicillin resistance among staphylococci is not prevalent in the region. In cats, other fluoroquinolones such as pradofloxacin or marbofloxacin are preferred because of the risk of retinopathy (see Chapter 8 for doses and contraindications). Use of pradofloxacin has been associated with bone marrow suppression in dogs, especially at high doses.
‡Addition of aminoglycosides to clindamycin or a β-lactam is indicated if gram-negative bacteria and/or methicillin-resistant staphylococci may be present. See Chapter 8 for contraindications.
§Dose based on ampicillin component

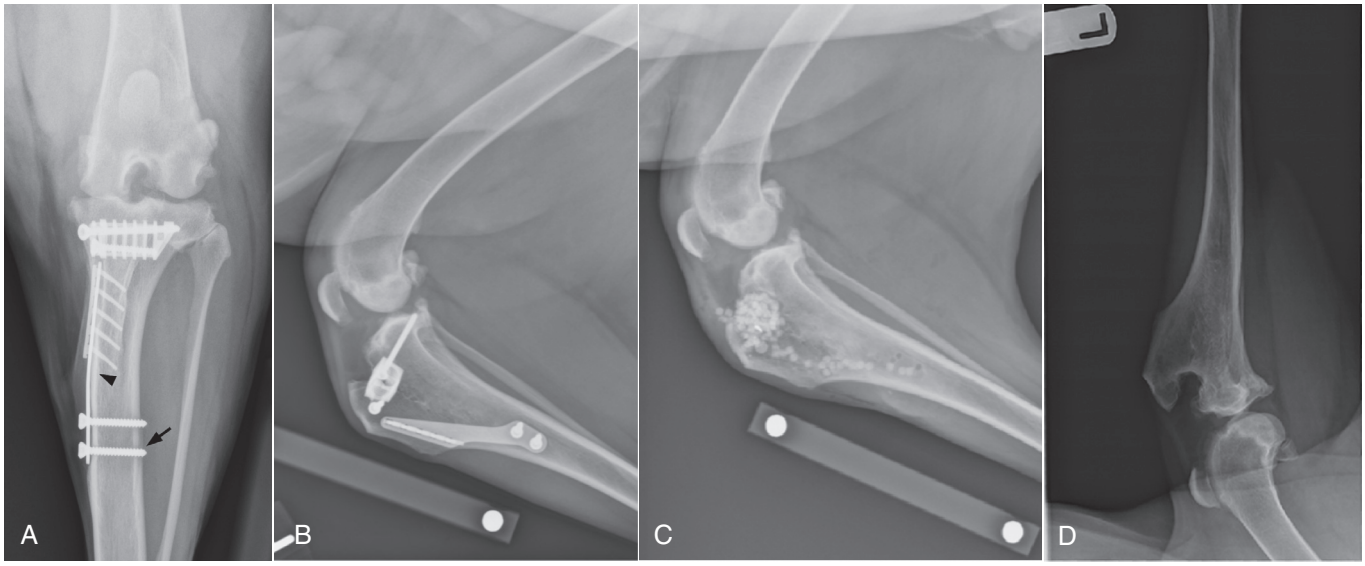

FIGURE 85-5 Lateral radiographs of the left stifle from a 10-year-old female spayed greyhound–pit bull terrier mix that developed osteomyelitis at the site of a left tibial tuberosity advancement surgery (see Case Example). Anteropalmar **(A)** and lateral **(B)** radiographs of the left stifle 13 months after the surgery. The osteotomy site has filled with bone to some extent, but the site is still visible as a result of incomplete union. There was also lucency in the region of the most distal screw *(arrow)* and thinning of the cortical bone adjacent to the plate *(arrowhead)*. **C,** The cage was removed by drilling around it, and calcium sulfate (Osteoset) beads were used to fill the defect. **D,** Radiograph taken 13 months postoperatively showing resolution of osteomyelitis and degradation of the calcium sulfate beads.

Prevention

Although not a substitute for sterile surgical technique and strict hospital infection control measures (see Chapter 11), preoperative antimicrobial drug treatment is an accepted aid for prevention of soft tissue surgical infections and osteomyelitis, especially when orthopedic implants are anticipated. Guidelines published for human medicine state that adequate prophylaxis requires (1) antimicrobial agents with activity against organisms likely to be encountered in the surgical field; (2) timely preoperative antimicrobial drug administration (within 60 minutes of incision); (3) bactericidal concentrations of drug in the serum and tissues

during the time that the wound is open; and (4) a duration of 24 hours after surgery.[23] Additional intraoperative doses should be given if the procedure lasts longer than two half-lives of the drug being administered (usually at least 2 hours). In practices where the prevalence of postoperative infections with methicillin-resistant staphylococci is low, preoperative treatment with cefazolin may be effective. Where the regional prevalence of skin colonization with methicillin-resistant staphylococci is high (e.g., >10%), preoperative treatment with cefazolin and an aminoglycoside such as amikacin could be used. Prophylactic treatment should never be continued for longer than 24 hours after surgery because it can select for drug-resistant bacterial infections. In human patients, antibiotic-impregnated implants have been used to prevent attachment of bacteria to their surface.[22] Minimization of surgery time, careful surgical technique, and use of plate types that are associated with a lower risk of postoperative infection (i.e., non–Slocum-type TPLO plates) may also prevent postsurgical osteomyelitis.[12] Metals used in implants should be of the same type (e.g., plate and screws) to minimize the chance of galvanic corrosion. Galvanic corrosion occurs when metals of different electrochemical properties are placed in close proximity in an electrolytic environment. This can predispose to implant loosening, local infection, or sarcoma formation.[24] Currently, it is considered acceptable to leave implants in place after healing unless the animal is very young, there is persistent pain associated with the implant, or radiographic evidence of osteomyelitis or osteopenia is present. This is because the process of implant removal itself can be costly and may be followed by osteomyelitis or fracture. However, owners of pets with implants should be advised that although rare, possible long-term complications of implant placement include reactivation of infection in the future or development of malignancy at the implant site.

Public Health Aspects

Dogs and cats with bacterial osteomyelitis can shed antibiotic-resistant gram-positive and gram-negative bacteria that have the potential to colonize humans and later be a source of human infection. Infections acquired after orthopedic surgeries, especially TPLOs, are problematic. Most dogs are infected with *S. pseudintermedius*, but a smaller percentage of dogs are infected with *S. aureus*, which is more likely to colonize humans (see Table 85-1). However, in some cases, the human in the household may have been the source of *S. aureus* infection. Some hospitals experience a high prevalence (>10%) of postoperative wound infections with methicillin-resistant staphylococci. In a case-control study that included dogs with methicillin-resistant *S. aureus* infection (cases) and dogs with methicillin-susceptible *S. aureus* infection (controls), surgical implant placement was associated with a 33-fold increased risk of methicillin-resistant *S. aureus* infection ($P = 0.001$).[25] Infected osteomyelitis wounds should be covered with a suitable dressing at all times, and owners should be advised to wear gloves when handling their pets (especially if the wound is infected) and to wash their hands properly afterwards. In the hospital, animals with draining orthopedic surgical wound infections due to methicillin-resistant or multi-drug resistant bacteria should be handled by a limited number of individuals who wear gloves, a gown, and dedicated equipment, and signage should be posted. Hand washing should be performed after protective wear is removed, and all equipment used should be disinfected properly (see Chapter 11).

DISCOSPONDYLITIS

Etiology, Pathogenesis, and Epidemiology

Discospondylitis most often follows hematogenous spread of bacteria or fungi to the cartilaginous vertebral endplates, with extension to the intervertebral discs. Bacteria or fungi are thought to lodge in the endplates because blood flow slows in this region. In most cases, the source of infection cannot be identified, but infection can originate from the urogenital tract, abscesses, skin wounds, respiratory tract infections, or the oral cavity. Occasionally discospondylitis follows extension of infection from an adjacent site, such as following vertebral column surgical site infections, complications of epidural anesthesia, bite wounds, or migrating grass awns.

Risk factors for discospondylitis in dogs include male sex, older age, and breed.[1] Predisposed breeds include great Danes, boxers, Rottweilers, English bulldogs, German shepherd dogs, and Doberman pinschers. German shepherds and Rhodesian ridgebacks are predisposed to systemic mold infections that can target the intervertebral discs.[26] Although discospondylitis is frequently diagnosed in Labrador and golden retrievers, these dogs are popular breeds and were not found to be at risk.[1] Discospondylitis is extremely rare in cats and usually follows trauma such as cat bites, with associated meningomyelitis.[27-31] Concurrent disorders identified in dogs include genitourinary tract infections (prostatitis, orchitis, metritis, and/or urinary tract infection), pyoderma and otitis, immunosuppressive drug treatment, heartworm disease, recent vertebral column surgery, respiratory tract infection, bite wounds and other traumatic injuries, recent nonvertebral surgery, septic arthritis, severe intestinal parasitism, and infective endocarditis.

The incidence of discospondylitis in dogs and prevalence of different causative infectious agents varies geographically. In one study, the incidence of discospondylitis in the southern U.S. states was higher than in northern states.[1] In 123 dogs with discospondylitis from the southern United States, the most common pathogen isolated was *Staphylococcus* (41% of 63 isolates), followed by *Streptococcus* (12%), and *E. coli* (11%).[1] Other bacteria included *Klebsiella*, *Brucella, Pseudomonas, Proteus,* and *Actinomyces* spp. (<10% each). When the results of *Brucella* serology and culture were combined, 13 of the dogs were diagnosed with brucellosis. Only 2 dogs were infected with fungal organisms, one with *Candida tropicalis* and the other with an unidentified fungal agent. Mixed infections were detected in 11 (9%) of dogs. In 23 dogs with discospondylitis from the Pacific northwest of the United States, 10 of 18 isolates were staphylococci, 3 were streptococci, and 3 were *E. coli; Brucella* infection was not reported and a filamentous fungal species (*Phialemonium* or *Paecilomyces*) was isolated from 2 dogs.[32] In contrast, filamentous fungal species were isolated from nearly one third of dogs diagnosed with discospondylitis at the University of California, Davis (Table 85-3). The most common bacterial isolate was methicillin-susceptible *S. pseudintermedius;* methicillin-resistant staphylococci were not detected. In more than half of dogs with discospondylitis, the causative agent is not identified. Lumbar discospondylitis caused by *Actinomyces* spp. and anaerobic bacteria may occur as a result of migration of inhaled grass awns, which lodge in the retroperitoneal space. Sexually intact male dogs and dogs from the southeastern states are at increased risk for *Brucella canis* discospondylitis,[33] but it can occur in any region and in dogs of any sex.

TABLE 85-3

Infectious Agents Isolated from 31 Dogs with Culture-Positive Discospondylitis Seen at the University of California, Davis, Veterinary Medical Teaching Hospital*

Organism Type	Infectious Agent	Number of Isolates (%)
Gram-positive aerobes (n = 15, 42%)	*Staphylococcus pseudintermedius* (methicillin-susceptible)	12 (33)
	Coagulase-negative staphylococci	2 (6)
	Streptococcus equisimilis	1 (3)
Gram-negative aerobes (n = 5, 14%)	*Klebsiella pneumoniae*	2 (6)
	Escherichia coli	2 (6)
	Brucella canis	1 (3)
Anaerobes (n = 4, 11%)	*Actinomyces* spp., *Prevotella*, *Fusobacterium*, *Porphyromonas*	4 (11)
Fungi (n = 11, 31%)	*Aspergillus* spp.	6 (17)
	Paecilomyces spp.	3 (8)
	Other molds	2 (3)

*Based on culture of blood and/or disc material (26 dogs) or urine only (5 dogs; 3 with mold infections, 1 with *E. coli*, and 1 with *K. pneumoniae* infections)

Clinical Features

Signs and Their Pathogenesis

Clinical signs of discospondylitis include fever, lethargy, inappetence, spinal pain, a hunched stance, lameness, reluctance to move, and/or reluctance to jump or climb stairs. The duration of signs is extremely variable, but are usually present for less than one month.[32] Spinal cord compression as a result of vertebral subluxation, abscess formation, disc protrusion or extrusion, and soft tissue proliferation can lead to neurologic deficits such as delayed or absent placing reactions, paresis with ataxia or paralysis, and loss of deep pain sensation. Neurologic deficits were detected in 59 (48%) of 123 dogs in one study,[1]; in another study, paresis or paralysis was detected in 20 of 23 dogs (87%) and 8 of these dogs were nonambulatory.[32] The neurologic signs reflect the severity and location of discospondylitis lesions; in one study the severity of neurologic signs was correlated with the number of compressive lesions and the percentage of spinal cord or cauda equina compression.[32] The majority (50% to 60%) of dogs have lesions in the thoracolumbar spine (especially the lumbosacral junction); cervical lesions are present in fewer than 20% of dogs.[1,32,34,35] Around 30% to 40% of dogs have multiple lesions. Thus, tetraparesis (which reflects the presence of compressive cervical lesions) is less common (<5% of dogs) than pelvic limb paresis or paralysis (33% of dogs). The location of discospondylitis lesions (e.g., L7 to S1 versus C5 to C6) does not seem to affect the likelihood of cord compression.[34]

Physical Examination Findings

Dogs with discospondylitis may have fever (although it is often absent), lethargy, weakness, and pain on palpation or manipulation of the spine. In some dogs, pain is difficult to localize or manifests as apparent abdominal pain when the abdomen is palpated, especially if upward pressure is placed on the spine. Dogs with neurologic deficits can be tetraparetic or have pelvic limb paresis or paralysis. Loss of deep pain sensation can occur in dogs with severe compression lesions. Neurologic examination may reveal delayed or absent placing reactions and exaggerated or reduced segmental reflexes. Evaluation for abnormalities that reflect the presence of concurrent disorders (such as cardiac murmurs in dogs with endocarditis or swollen joints in dogs with polyarthritis) should be carefully performed. Occasionally, discospondylitis is an incidental finding on plain radiography (performed to evaluate concurrent disease such as fever of unknown origin), and clinical signs that suggest discospondylitis are absent.

Diagnosis

Diagnosis of discospondylitis is based on physical examination findings; imaging (plain radiography, CT/MRI); culture of blood, CSF, or aspirates of disc material; and serologic testing for *Brucella* spp. (antibody tests) or fungi (antigen tests). The reader is referred to Chapters 53 (Canine Brucellosis) and Chapter 65 (Aspergillosis) for information on serologic testing for these diseases. Serologic testing for *Aspergillus* galactomannan antigen is inexpensive, and positive results (galactomannan indices >1.5) correlate strongly with an underlying mold infection.[36] Rarely, mixed infections with bacteria and fungi occur, and bacterial contaminants can complicate interpretation of blood and disc aspirates. Thus, all dogs with discospondylitis should ideally be tested for *Aspergillus* antigen before antibiotic treatment is initiated. It is especially important to test predisposed breeds such as German shepherds and Rhodesian ridgebacks. Affected dogs should be evaluated for evidence of disease at other anatomic sites. If possible, this should consist of thoracic radiographs and abdominal ultrasound, echocardiography (for infective endocarditis), and aerobic bacterial culture of the urine.

Laboratory Abnormalities

Often the CBC and biochemistry panel are surprisingly unremarkable in dogs with discospondylitis. There may be mild to moderate neutrophilia with bandemia and/or lymphopenia on the CBC. Mild hypoalbuminemia and mild to moderate hyperglobulinemia are the most common abnormalities on the biochemistry panel. Dogs with fungal discospondylitis may be azotemic

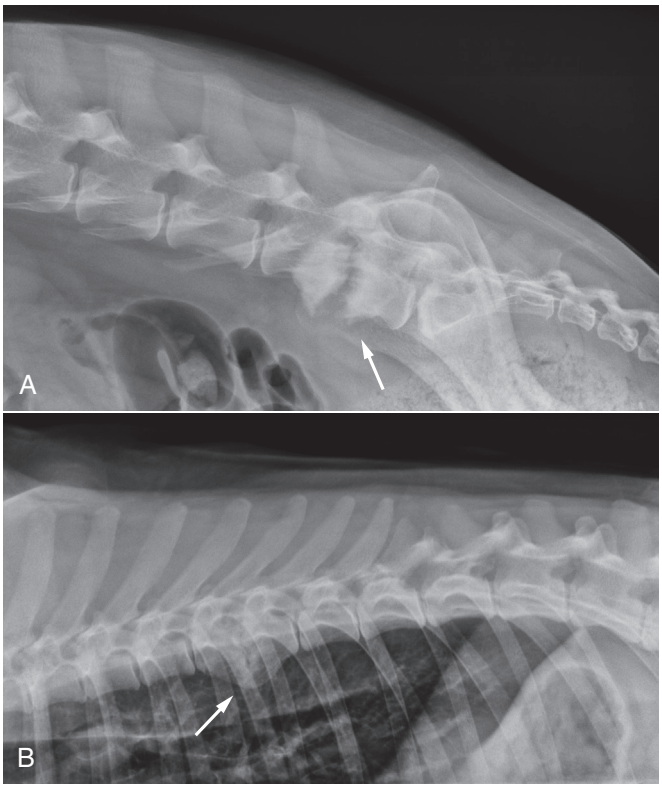

FIGURE 85-6 Radiographic changes in discospondylitis. **A,** Lateral radiograph of the lumbosacral region of a 3-year-old female spayed German shepherd with *Aspergillus* spp. discospondylitis. There is severe destruction of the endplates at L6-L7 *(arrow)* with sclerosis and ventral periosteal proliferation. **B,** Lateral radiograph of the thoracic spine of a 1-year-old female malamute. Resolving discospondylitis is present at T8-T9 *(arrow)*. There is lysis and irregularity to the endplates of these vertebrae. There is bridging spondylosis ventrally.

because of concurrent fungal pyelonephritis.[26] Urinalysis may show pyuria, bacteriuria, funguria, proteinuria, and/or cylindruria in dogs with concurrent urinary tract infections. Analysis of the CSF often reveals mild to markedly increased CSF protein concentration and rarely increased total nucleated cell count.[32]

Diagnostic Imaging

Plain Radiography

Radiographic changes in dogs (and cats) with discospondylitis include narrowing or widening of the intervertebral space, irregularity or lysis of the vertebral body endplates, endplate lucency, sclerosis at the margins of bone loss, proliferative lesions within adjacent vertebral bones and bridging spondylosis, and, in some cases, vertebral subluxation or fracture (Figure 85-6). Because multiple disc spaces are frequently affected, radiographs of the entire spine should be performed to properly assess the extent and severity of disease. Radiographic changes may lag behind clinical signs for as long as 6 weeks in dogs with discospondylitis, so radiographs should be repeated every 1 to 2 weeks if discospondylitis is suspected and plain radiographs are initially normal. Alternatively, advanced imaging with CT or MRI may reveal lesions not seen on plain radiographs. Plain radiography does not allow visualization of the degree of spinal cord compression, so myelography or advanced imaging is required to further evaluate dogs with neurologic signs. Ultrasonography may be useful for detection of retroperitoneal grass awns in dogs with localized lumbar discospondylitis on plain radiography.

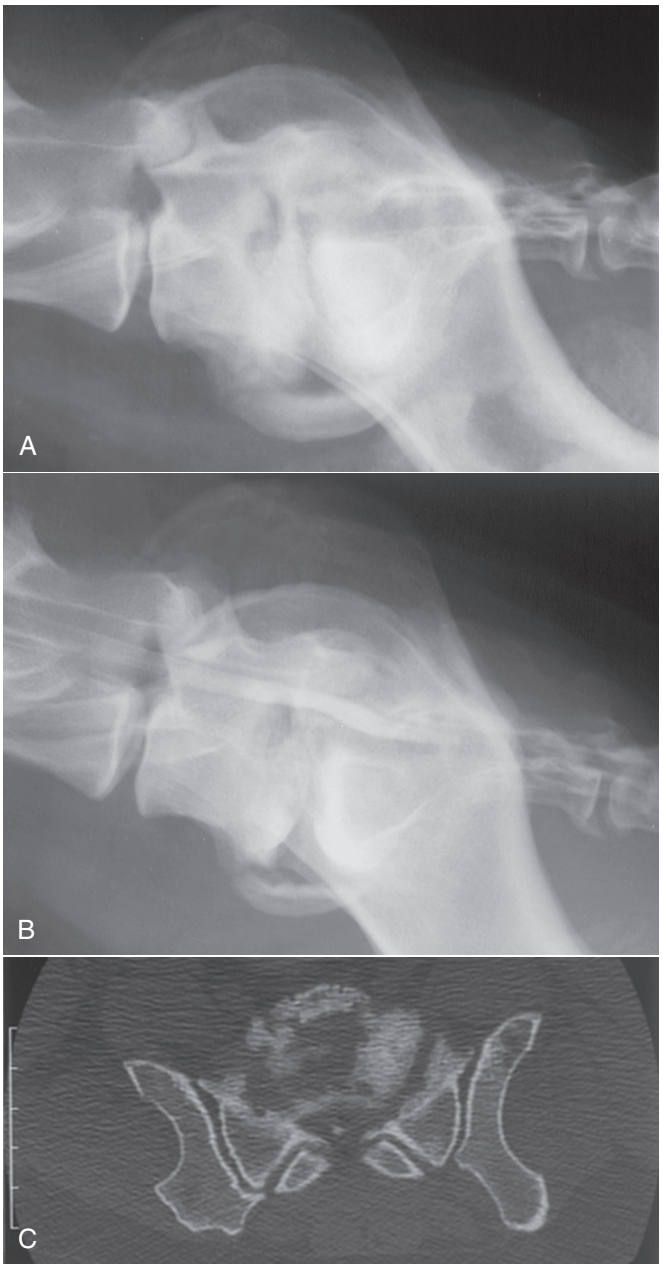

FIGURE 85-7 Images from a 9-year-old intact male Rottweiler with a 3-day history of difficulty standing and decreased appetite. Findings on neurologic examination included lumbosacral spinal pain, left pelvic limb paresis, and right pelvic limb paralysis. Blood and synovial fluid cultures yielded a methicillin-susceptible *Staphylococcus pseudintermedius*. Radiographic findings were consistent with chronic discospondylitis at the lumbosacral disc space and secondary compression of the spinal cord. **A,** Plain lateral radiograph of the pelvis. The lumbosacral joint space is narrowed and there is significant bridging spondylitis, with endplate osteolysis. **B,** Myelogram. Dorsal elevation of the conus is present at the lumbosacral junction. **C,** Contrast tomography of the lumbosacral junction. There is substantial endplate osteolysis. (All images courtesy the University of California, Davis, Veterinary Neurology/Neurosurgery Service.)

Contrast Radiography

Myelography can identify the site(s), type (vertebral subluxation or soft tissue proliferation), and extent of spinal cord compression in dogs with discospondylitis and allow planning for decompressive surgery (Figure 85-7).[34] However, MRI is less

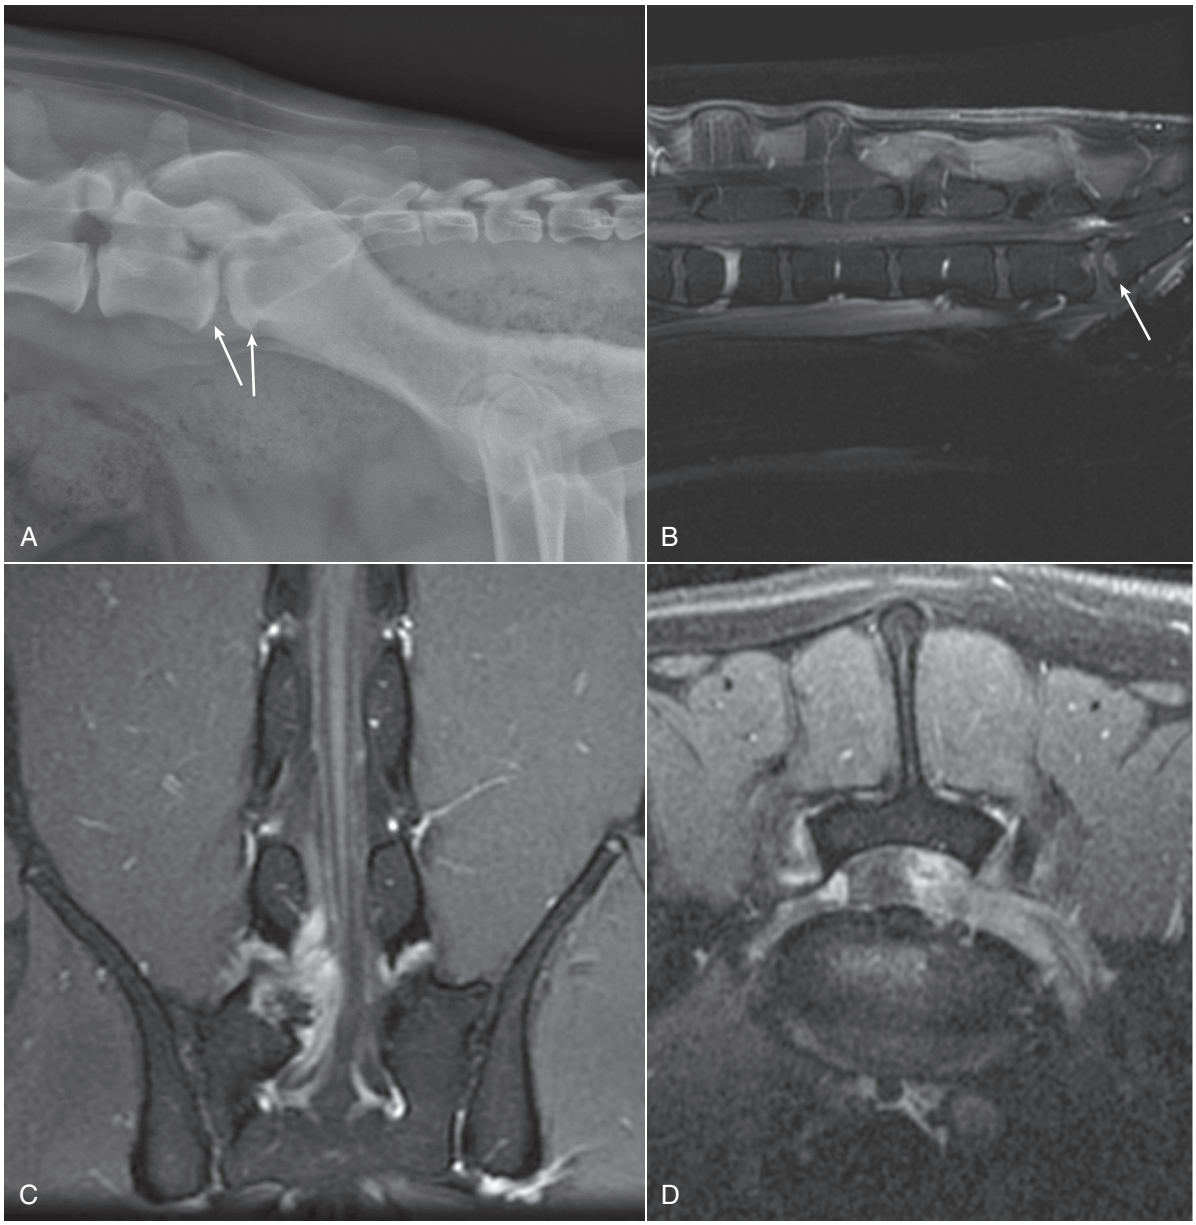

FIGURE 85-8 Images from a 5-year-old intact male German shepherd dog with a history of progressive reluctance to jump over the previous 18 months. Neurologic examination revealed decreased pelvic limb placing reactions and lumbosacral pain. Blood cultures were negative. Clinical signs and radiographic lesions improved dramatically with cephalexin treatment. **A,** Plain right lateral radiograph of the pelvis. The lumbosacral disc space is narrowed and there is vertebral endplate sclerosis *(arrows)*. There is also bony proliferation of the endplates at the level of the vertebral canal. **B,** Sagittal T1-postcontrast MRI with fat saturation, caudal lumbar and lumbosacral vertebral column. There is strong contrast enhancement in the endplates of L7 and S1 *(white arrow)* on either side of the disc space. **C,** Dorsal view. There is diffuse contrast enhancement of the tissues around the 7th lumbar nerve root with displacement of neural structures. **D,** Transverse view. There is marked enlargement and strong uniform enhancement of the right 7th lumbar spinal nerve. The primary differential based on radiologic findings was chronic lumbosacral discospondylitis with regional soft tissue inflammation on the right, and severe neuritis of the right 7th lumbar nerve. The impingement of the right 7th lumbar nerve by contrast-enhancing material was thought to result from granulation tissue formation. (All images courtesy the University of California, Davis, Veterinary Neurology/Neurosurgery Service.)

invasive and is now the preferred method for diagnosis of cord compression due to discospondylitis.

Advanced Imaging

CT and MRI may have increased sensitivity for diagnosis of discospondylitis when compared with plain radiography. MRI is the gold standard for diagnosis of discospondylitis in human patients and is increasingly used for diagnosis and characterization of discospondylitis in dogs.[32,35,37] Affected vertebral bodies are classically hypointense on T1-weighted images and may be hypointense, isointense, or hyperintense on T2-weighted images when compared with normal surrounding structures.[32,35] Hyperintensity of the vertebral bodies in dogs is more commonly observed in short tau inversion recovery (STIR) images, which suppress the signal from fat. Two adjacent vertebrae are consistently involved. Intervertebral discs are hyperintense on T2-weighted and STIR images when discospondylitis is present. Marked uniform or heterogenous contrast enhancement is usually apparent in vertebral endplates, within the disc, and in surrounding soft tissue (Figure 85-8). Paravertebral soft tissues

VetBooks.ir

may also be hyperintense on T2-weighted and especially STIR images.[32] With more chronic infection, there is loss of definition and cortical continuity and destruction of cortical margins in T1-weighted images. Distortion and narrowing of the disc space is also apparent, and subluxation and disc protrusion with associated spinal cord compression can be easily identified.

Microbiologic Tests

Isolation and Identification

The optimal specimens for identification of the causative agent of discospondylitis are blood or disc aspirates (or biopsies performed during decompressive surgery), because organisms isolated from these specimens are most likely to reflect those involved in disc destruction. Blood cultures are indicated in all dogs with discospondylitis (see Chapter 3 for blood culture technique and interpretation). Because anaerobes are uncommonly isolated from dogs with discospondylitis and they have predictable susceptibilities, the decision to perform anaerobic blood culture should be considered in light of any underlying disease processes and client financial constraints. Negative blood cultures occur in more than half of dogs with discospondylitis and may reflect low-level bacteremia or fungemia, the presence of fastidious or unculturable organisms such as *Brucella* or anaerobes, or recent antimicrobial drug treatment. Urine cultures may reveal the causative organism when blood cultures are negative, but not uncommonly bacterial species present in the urine differ from the organism present in affected discs. However, isolation of a mold species from the urine suggests a disseminated mycosis. Serologic testing for *Aspergillus* antigen and *Brucella* antibody should be performed in dogs with culture-negative discospondylitis. *Aspergillus* serology should also be considered for dogs that have blood culture-positive discospondylitis, because mixed infections with fungi and bacteria can rarely occur. Dogs with *Paecilomyces* discospondylitis can have positive *Aspergillus* serum and urine antigen tests due to serologic cross-reactions between these fungi.[36]

When blood cultures are negative, disc aspirates can be obtained under anesthesia with fluoroscopic (or other advanced imaging such as CT) guidance after preparation of the skin in a sterile manner.[38] Aspiration is performed with a 22-G, 1.5- to 2.5-inch spinal needle into a syringe that contains a small amount of sterile saline. In one study, 0.3 to 0.5 mL of sterile saline was injected and immediately reaspirated,[38] but dry aspiration can also be performed into the needle. The saline in the syringe can then be used to flush the contents of the needle into a plain sterile tube, which is submitted for bacterial and fungal culture. Only 3 of 11 aspirates or biopsies were positive in one study.[1] However, in another study, positive bacterial cultures were obtained in 9 of 12 disc aspirates.[38] Other specimens that may yield growth include CSF, aspirates of cellulitis or abscesses adjacent to sites of discospondylitis, or synovial fluid. When disease is present at other sites, every effort should be made to perform culture for aerobic and anaerobic bacteria and fungi from these sites in order to identify an infectious etiology.

Pathologic Findings

Gross pathologic findings in dogs with discospondylitis include the presence of pus and necrotic debris in the intervertebral disc spaces, irregularity and collapse of the disc spaces, and discoloration and friability of the vertebral endplates (Figure 85-9). Protrusion of disc material and compression of the spinal cord may be apparent. There may also be evidence of bony callus material (ankylosing spondylosis). The nature of the inflammatory infiltrates on histopathology varies with the chronicity of the lesions and the underlying cause. For example, fungal discospondylitis may be associated with granulomatous or pyogranulomatous inflammation and intralesional fungal hyphae, whereas chronic bacterial discospondylitis may be associated with neutrophilic and lymphoplasmacytic infiltrates, with perilesional fibrosis and granulation tissue. Osteonecrosis may be present, as well as necrosis of compressed spinal tissue.

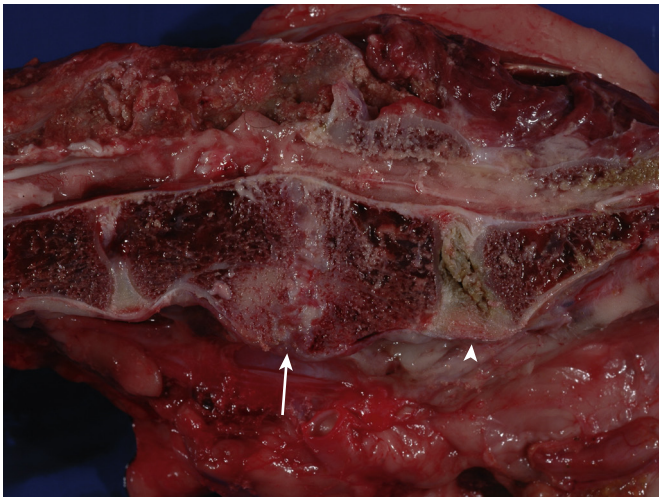

FIGURE 85-9 Vertebral column of a 4-year-old female spayed German shepherd at necropsy that had multifocal discospondylitis caused by *Aspergillus* spp. The L6-L7 disc space *(arrow)* is collapsed with degenerate disc material, sclerotic endplates, and marked ventral proliferation of bone. The lumbosacral disc space *(arrowhead)* has an irregular annulus with friable, pale tan nuclear material that protrudes ventrally. (Courtesy of the University of California, Davis, Veterinary Anatomic Pathology Service.)

Treatment and Prognosis

Treatment of discospondylitis involves prolonged antimicrobial drug treatment and strict restriction of movement for several weeks to prevent herniation of disc material or subluxation, with a gradual increase in movement once lesions have healed. It is important to stress to owners of dogs with discospondylitis that it is a serious, life-threatening condition. Analgesics such as tramadol or fentanyl patches can also be administered provided they do not encourage excessive movement. Non-steroidal anti-inflammatory drugs may also be beneficial.

The antibiotic chosen to treat discospondylitis should ideally be based on the results of culture and susceptibility. Treatment recommendations for dogs with *Brucella* discospondylitis are described in Chapter 53. Dogs with fungal discospondylitis should be treated with antifungal drugs that have activity against molds, such as voriconazole (if finances allow) or itraconazole (*not* fluconazole) with or without amphotericin B; prognosis is guarded, and lifelong treatment may be required (see Chapter 65). Dogs with culture-negative discospondylitis that have negative serum or urine *Aspergillus* galactomannan antigen tests should be treated with high doses of a drug with activity against susceptible staphylococci and *E. coli*, such as amoxicillin-clavulanic acid or cephalexin (see Table 85-2). Amoxicillin-clavulanic acid also has activity against penicillinase-producing anaerobes. However,

VetBooks.ir

occasionally gram-negative organisms such as *Klebsiella pneumoniae* cause discospondylitis, and these may not respond to treatment with β-lactam drugs. Addition of a fluoroquinolone or an aminoglycoside should be considered if there is no improvement after 1 week of treatment with a β-lactam drug. For dogs that are systemically unwell or that have neurologic abnormalities, antimicrobials should be administered parenterally in the hospital for as long as possible (ideally at least 10 days) before changing to oral administration. Antimicrobial drugs should be administered for at least 6 to 8 weeks; in some cases treatment may need to be extended for many months. In one study, the mean ± standard deviation for duration of antimicrobial treatment in dogs that were cured of discospondylitis was 54 ± 45 weeks; for dogs with staphylococcal infections, it was 74 ± 62 weeks.[1] Dogs with fungal discospondylitis may require lifelong treatment with antifungal drugs (see Chapter 65). Dogs should be reevaluated clinically and radiographically every 3 to 4 weeks. Improvement is characterized by resolution of bone lysis, sclerosis of bone, and vertebral fusion. Antimicrobial drug treatment should be continued until lysis resolves completely. MRI may be the most sensitive imaging technique to confirm resolution of active infection. Imaging should also be performed 1 to 2 months after antimicrobial drugs are discontinued. If clinical deterioration occurs during treatment, additional imaging (ideally with MRI) should be offered to evaluate for development of new lesions, abscessation, subluxation, fracture, or disc protrusion.

Dogs with severe neurologic deficits (such as paralysis) may require decompressive surgery, debridement of abscesses or vertebral osteomyelitis, and stabilization of the vertebral column. However, return of neurologic function can sometimes occur with antimicrobial drug treatment alone, provided deep pain is present. Decompressive surgery should be performed within 24 hours if deep pain is absent. Referral to a specialist surgeon is recommended in this situation. In one study, 9 of 27 dogs with discospondylitis received some form of decompressive surgery.[34] Physical therapy may also be beneficial in these animals.

Public Health Aspects

The most important public health consideration in dogs with discospondylitis is the possibility of *Brucella* infection. Human disease has occurred as a result of contact with dogs with *Brucella canis* discospondylitis and is typically an influenza-like illness. The possibility of *B. canis* infection should be considered in all dogs with discospondylitis, and precautions such as routine hand washing, minimization of exposure to urine, and the wearing of gloves should be taken until appropriate diagnostic testing has ruled out *Brucella* as a cause.

ARTHRITIS

Etiology, Pathogenesis, and Epidemiology

Infectious arthritis may be classified as *monoarthritis* or *polyarthritis*. Bacterial monoarthritis can follow orthopedic surgeries that involve the joint (such as TPLOs, arthroscopies, or joint arthrodesis), spread from soft tissue or bone infection at adjacent sites, or result from trauma or bite wound infections. Less commonly, monoarthritis follows systemic spread of bacteria to a single joint. Bacterial causes of monoarthritis are similar to those involved in osteomyelitis; the most common cause is *Staphylococcus* spp., especially *S. pseudintermedius* but also *S. aureus* and coagulase-negative staphylococci. Other reported causes are *Streptococcus canis* and *Streptococcus equi* subsp. *zooepidemicus, E. coli,* and *P. aeruginosa*.[39,40]

Systemic spread of bacteria to the joints more often results in polyarthritis. Infection with a variety of bacteria, protozoa, fungi, and, rarely, viruses (West Nile virus) have been associated with polyarthritis in dogs and cats. In areas where tick-borne infections are endemic, the most common bacterial causes are *Anaplasma phagocytophilum, Ehrlichia ewingii, Ehrlichia canis, Borrelia burgdorferi,* and *Rickettsia rickettsii,* but non–vector-borne bacteria such as *Streptococcus canis, Staphylococcus aureus, Erysipelothrix, Salmonella, Brucella,* and mycoplasmas (see Chapter 40) can also be involved. Although its importance as a cause of polyarthritis remains unclear, *Bartonella* should also be considered. Endocarditis is frequently (if not almost always) present in dogs with polyarthritis caused by facultative aerobic gram-positive and gram-negative bacteria, and among dogs with endocarditis, *Streptococcus canis* infections are most likely to be associated with polyarthritis. Worldwide, the most important cause of protozoal polyarthritis in dogs is *Leishmania*. Fungal polyarthritis is uncommon but can result from infection by dimorphic fungi and, rarely, molds such as *Aspergillus*. Infectious polyarthritis is an important differential diagnosis for primary (idiopathic) immune-mediated polyarthritis (IMPA) in dogs. Although infectious polyarthritis is less common than primary IMPA, failure to identify an underlying infection can have disastrous consequences when treatment with immunosuppressive drugs is initiated.

Clinical Features

Clinical signs of monoarthritis may be acute or chronic in onset and include variable fever, lethargy, inappetence, lameness that involves a single limb, and a swollen joint that may be erythematous, warm to the touch, and occasionally drain purulent or blood-tinged fluid (Figure 85-10). The draining lymph node may be enlarged and firm. The most common joints affected in one study were the stifle and elbow joints, followed by the tarsi and coxofemoral joints, and signs developed within 2 to over 8 weeks after articular or periarticular surgery.[40] In polyarthritis, multiple peripheral joints are affected, and dogs (and less commonly cats) show signs of recumbency, reluctance to move, generalized peripheral lymphadenopathy, a stiff gait, and/or shifting leg lameness; drainage of fluid is not usually apparent. Dogs with bacterial polyarthritis can also show signs of severe sepsis (see Chapter 86 as well as the Case Example in Chapter 45).

Diagnosis

Diagnosis of infectious arthritis is based on the history, clinical signs, and cytology and culture of joint fluid; serologic assays for *Brucella canis* and fungal pathogens; and/or molecular diagnostic and/or serologic testing for vector-borne pathogens in endemic regions. Blood cultures may also allow identification of the underlying etiology in dogs with bacterial polyarthritis. As for discospondylitis, dogs with bacterial polyarthritis should ideally be evaluated for evidence of disease at other sites with thoracic

VetBooks.ir

FIGURE 85-10 Surgical site of a 5-year-old male neutered mastiff dog with non–weight-bearing lameness and a draining skin lesion that developed along the incision site approximately 1 month after a tibial plateau leveling operation. The right stifle was swollen and warm. Synovial fluid aspirated from the joint was red and turbid and contained 161,550 nucleated cells/μL (98% nondegenerate neutrophils) and 90,000 red blood cells/μL. Aerobic and anaerobic cultures of the fluid yielded a methicillin-resistant, multidrug-resistant *Staphylococcus pseudintermedius* that was resistant to all β-lactams, macrolides, and clindamycin, fluoroquinolones, and trimethoprim-sulfamethoxazole. The infection was treated successfully with joint exploration, lavage, and oral chloramphenicol for 8 weeks.

radiographs, spinal radiographs (for concurrent discospondylitis) and abdominal ultrasound, echocardiography (for endocarditis), and aerobic bacterial culture of the urine.

Laboratory Abnormalities

Routine laboratory testing in animals with bacterial arthritis typically shows leukocytosis due to a neutrophilia, which can be accompanied by bandemia. Thrombocytopenia may be present in dogs with bacteremia or vector-borne bacterial infections and should prompt diagnostic evaluation for vector-borne infections with PCR assays and serology. Urinalysis may be normal or show pyuria, bacteriuria, proteinuria, and/or cylindruria in dogs with concurrent aerobic bacterial urinary tract infections.

Synovial fluid from affected joints is often yellow or blood-tinged (normal synovial fluid is clear), cloudy, increased in volume, and thin or watery in consistency. Cytologic examination of synovial fluid reveals increased numbers of leukocytes (>5000 cells/μL), with a predominance of nondegenerate and/or degenerate neutrophils. Importantly, in the majority of dogs with septic arthritis, degenerate neutrophils are not visualized,[39,40] so the presence of only nondegenerate neutrophils does not rule out an underlying bacterial infection. Rarely, bacteria or fungal organisms are visualized extracellularly or within leukocytes. Morulae are occasionally seen within neutrophils in synovial fluid of dogs infected with *A. phagocytophilum* or *E. ewingii* (see Figure 29-3C).

Diagnostic Imaging

Radiographs of the joints in dogs and cats with infectious arthritis most often reveal soft tissue swelling and joint effusion. In severe and chronic bacterial monoarthritis, associated osteomyelitis may be present, with subchondral bone lysis, articular erosion, and periarticular new bone formation.

Microbiologic Tests

Isolation and Identification

Confirmation of bacterial arthritis requires culture of synovial fluid or of the synovium itself. Synovial fluid from dogs with neutrophilic polyarthritis should be submitted for aerobic bacterial culture and susceptibility, and anaerobic, fungal, or *Mycoplasma* culture should at least be considered if the history is suggestive. Situations in which anaerobic culture may be indicated include a history of foreign body (such as plant awn) exposure or bite wounds. Although rare, the possibility of *Mycoplasma* arthritis should be considered in cats and dogs with a history of immune compromise, surgery, or bite wounds, and when treatment with β-lactam drugs fails (see Chapter 40). Dogs with fungal polyarthritis may have lesions elsewhere (e.g., chorioretinitis, pulmonary disease) that support a diagnosis of disseminated fungal disease. However, anaerobic and *Mycoplasma* culture may be insensitive (especially when there are delays in specimen transport to the laboratory); *Mycoplasma* and fungal cultures require prolonged incubation; and anaerobes, fungi, and mycoplasmas tend to have predictable susceptibilities. Aerobic blood cultures may assist in identification of bacteria involved in polyarthritis.

If arthroscopy or arthrotomy is performed as part of evaluation and treatment of bacterial monoarthritis, a biopsy of the synovium could also be submitted for culture and susceptibility and may yield growth when synovial fluid culture is negative.[39] In most cases, synovial fluid culture alone is sufficient for diagnosis of bacterial arthritis.

Treatment and Prognosis

Treatment of infectious arthritis depends on whether one joint is involved or whether polyarthritis is present, as well as on the identity of the causative agent. Infectious monoarthritis may require surgical exploration, lavage and drainage, and treatment with appropriate antimicrobial drugs based on the results of culture and susceptibility. Monoarthritis is considered a surgical emergency, and lavage should be performed immediately after diagnosis, either via an ingress-egress approach or with open surgery. For ingress-egress lavage, large-bore (14- to 16-G) needles are inserted percutaneously into two to three fluid pockets around the joint while the animal is heavily sedated or anesthetized. Several liters of sterile saline is then administered through one portal under pressure and allowed to drain from the other portal(s). The sites of ingress and egress are switched until the fluid becomes clear. Arthroscopy can also be used. Arthrotomy may be necessary if there are large accumulations of fibrin or inspissated purulent debris that cannot be effectively flushed from the joint. If implants are present, they should be removed when healing has occurred or if stabilization has failed. If the implant is stable but the bone has not healed, lavage is performed and the implant left in place, because bone can heal

VetBooks.ir

if rigidly stable despite infection. Ultimately, the implant must be removed to resolve the infection; removal should be done as soon as possible after healing. Antimicrobial drugs should initially be given parenterally if possible. Treatment should continue until implants can be removed if left in place. Once implants are removed, treatment may need to be continued for another 2 to 4 weeks. If local antibiotic therapy is used in associated osteomyelitis lesions (i.e., impregnated beads), systemic antimicrobial drug treatment should also be used. The prognosis depends on the degree of cartilage and bone destruction, the degree to which progressive osteoarthritis occurs, and the joint affected. Unfortunately, evidence-based clinical studies that document long-term prognosis or prognostic indicators for infectious monoarthritis are not available. In one retrospective study, dogs that fully recovered tended to have a shorter duration of lameness before treatment (median, 11 days compared with 26 days) and lower synovial fluid cell counts (median, 54×10^9 cells/mL compared with 100×10^9 cells/mL) than dogs that never fully recovered, and had significantly lower body weights (median, 29 kg compared with 44 kg).[40]

Polyarthritis caused by vector-borne bacteria usually responds to treatment with doxycycline within 24 to 48 hours. Antimicrobials for treatment of polyarthritis caused by other bacteria should be selected based on the results of cytologic examination of synovial fluid (cocci versus rods) and culture and susceptibility of blood or synovial fluid. Because streptococci, staphylococci, and *Erysipelothrix* are usually involved, a β-lactam drug such as amoxicillin-clavulanic acid (or amoxicillin if streptococci are more likely) could be used. Because bacterial polyarthritis is frequently associated with endocarditis or discospondylitis, the duration of treatment should be based on resolution of these lesions. The reader is referred to Chapter 86 for additional information on treatment of bacteremia and sepsis.

Public Health Aspects

Polyarthritis can be caused by organisms of public health significance, such as *Salmonella*, *Brucella*, *S. aureus*, pathogenic fungi, *Leishmania*, and vector-borne bacterial pathogens of importance to human health. This should be kept in mind when handling dogs with polyarthritis. Care should be taken to avoid needle-stick injuries during venipuncture, arthrocentesis, and aspiration of other tissues such as lymph nodes. Deep sedation or anesthesia is recommended for arthrocentesis.

CASE EXAMPLE

Signalment: "Tilly," a 10-year-old female spayed greyhound/pit bull terrier mix from Davis, CA (Figure 85-11).

History: Tilly was brought to the University of California, Davis, VMTH Orthopedic Surgery service for evaluation of a draining tract on her left medial proximal tibia that developed after a tibial tubercle advancement (TTA) surgery for left cranial cruciate ligament tear. The ligament tear had been diagnosed at the VMTH 15 months previously after an acute onset of lameness, and the surgery was performed 2 months after diagnosis at another veterinary hospital after there had been no improvement with conservative management (activity restriction and anti-inflammatory drugs). Immediately after the surgery, the dog was placed on a 10-day course of doxycycline. The tract was first observed 2 weeks after the doxycycline course had finished, and the owner (a veterinary student) noted that the tract subsequently healed over, then drained again. When the wound initially appeared, treatment with doxycycline was reinstituted for a month, with no improvement. A radiograph of the limb was performed at the end of the course of treatment at the VMTH. Soft tissue swelling was identified at the medial aspect of the stifle, but there was no radiographic evidence of implant infection or motion. Regional osteopenia of the left tibial tuberosity and proximal tibia was present, and there was progressive left stifle osteoarthrosis. Culture of the wound yielded very small numbers of *Streptococcus canis* and a coagulase-negative *Staphylococcus*. The wound subsequently closed over again and antibiotic treatment was not initiated, but 11 months later the tract reappeared. Since the surgery, the incision had appeared healthy. Tilly had been bearing progressively more weight on the limb, although some lameness persisted. Other treatments had included activity restriction and carprofen (2 mg/kg PO q12h) for pain relief. Tilly had no other significant medical history apart from multiple lipomas that had been evaluated with fine-needle aspiration cytology, which had not changed in size.

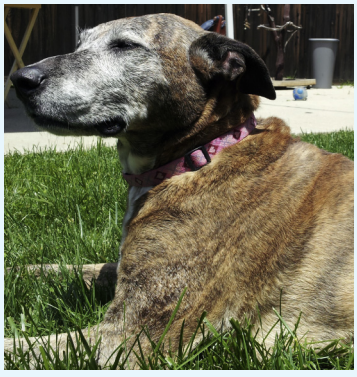

FIGURE 85-11 Tilly, 10-year old female spayed greyhound – pit bull terrier mix that developed osteomyelitis at the site of a left tibial tuberosity advancement surgery.

Physical Examination:

Body Weight: 37.2 kg.

General: Bright, alert, responsive. T = 101.0°F (38.3°C), HR = 80 beats/min, panting.

Eyes, Ears, Nose, and Throat: No abnormalities were identified apart from moderate periodontal disease.

Musculoskeletal: Left pelvic limb lameness was present, but there was intermittent right pelvic limb lameness and muscle atrophy of both pelvic limbs. There was pain on extension of both coxofemoral joints. Examination of the left pelvic limb

VetBooks.ir

revealed a 1-cm, open round wound on the medial aspect of the proximal left tibia, which oozed serosanguineous fluid. A positive cranial drawer sign and tibial thrust were present.

All Other Systems: No clinically significant abnormalities were detected.

Imaging Findings:

Plain Radiographs (Pelvis): Bilaterally there was poor coverage of the femoral heads by the acetabulae. The femoral heads and necks were thickened and irregularly margined. There was periarticular osteophytosis of the acetabulae. Atrophy of the pelvic musculature was appreciated bilaterally although somewhat worse on the left than the right. Findings were consistent with bilateral hip dysplasia with severe degenerative change.

Plain Radiographs (Left Stifle): The implants associated with the TTA procedure were in place and intact (see Figure 85-5, *A* and *B*). The osteotomy site had filled in with bone to some extent, although the site was still visible nearly its entire length, and bridging bone was absent at the proximal aspect of the osteotomy and around the basket implant. There was thinning of the cortical bone adjacent to the plate that was associated with the tibial tuberosity and proximal tibial diaphysis, and mild lucency surrounded the medial aspect of the distalmost screw, which suggested implant-associated osteomyelitis. A gap was present between the bone plate and the tibia. Distal to the bone plates, there was smooth periosteal proliferation. The patella was displaced distally. There was moderate intracapsular soft tissue swelling of the stifle. There was also persistent, moderate periarticular osteophytosis of the distal femur and proximal tibia.

Diagnosis: TTA implant-associated osteomyelitis with incomplete union of osteotomy; severe canine hip dysplasia.

Treatment: Surgical exploration of the left stifle joint was performed. The draining tract was followed to the plate and screws. The TTA plate and screws were removed. The cage was removed by drilling around it, which left a 2-cm round defect in the tibia. During the procedure, it was discovered that a titanium plate had been used together with 316L steel screws, which led to concerns that osteomyelitis may have developed secondary to a galvanic reaction. The area was extensively flushed, and the defect was filled with calcium sulfate beads. Beads were also placed in the area previously occupied by the plate (see Figure 85-5, *C*). The fascia, subcutaneous tissue, and skin were closed, and a modified Robert-Jones bandage was placed. Aerobic and anaerobic bacterial cultures of the implant yielded small numbers of methicillin-susceptible *Staphylococcus pseudintermedius*. The organism was resistant to ampicillin, penicillin, ticarcillin, and doxycycline. Tilly was therefore treated with amoxicillin-clavulanic acid (10 mg/kg PO q12h). At the time of suture removal 2 weeks later, Tilly was weight bearing on the left pelvic limb, and the draining tract had resolved. A small draining tract reappeared 2 weeks later, and a swab from the tract again grew *S. pseudintermedius* with the same antibiogram, but only from the enrichment broth. Treatment was continued for an additional month, all lesions resolved, and lameness was reduced. A year later (at the time of writing) the dog was doing well and there had been no recurrence of draining tracts (see Figure 85-5, *D*).

Comments: Diagnosis and treatment of osteomyelitis in this case was delayed because of the lag in radiographic changes and the appearance and disappearance of the draining tract. This illustrates the difficulties associated with diagnosis of osteomyelitis. Although unconfirmed, use of two different metals may have contributed to development of osteomyelitis in this dog, which required costly and difficult surgical intervention with implant removal. The defects were closed with biodegradable beads and infection resolved after 2 months of systemic antimicrobial drug treatment, based on the results of culture and susceptibility.

CHAPTER 86

Infections of the Cardiovascular System

Jane E. Sykes and Steven Epstein

VetBooks.ir

Overview of Cardiovascular System Infections

Causes: Most often staphylococci, streptococci, and *Escherichia coli* are involved. Gram-negative bacterial etiologies predominate in cats. Culture-negative infections of the bloodstream may be caused by *Bartonella* spp. or other fastidious bacteria. Anaerobes and mycobacteria are less commonly involved. *Rickettsia rickettsii* can cause vasculitis and myocarditis. Viruses (e.g., parvoviruses), fungi, and protozoal organisms can also infect the bloodstream and myocardium.

Geographic Distribution: Worldwide

Major Clinical Signs: Highly variable. Fever, inappetence, lethargy, and tachycardia are common. Vomiting and/or diarrhea can also occur. Additional findings in infective endocarditis include cardiac murmurs, arrhythmias, lameness, and neurologic signs due to thromboembolic disease. Spinal pain, paresis, or paralysis may occur when discospondylitis complicates bacteremia or fungemia.

Differential Diagnoses: Noninfectious conditions that can mimic sepsis include pancreatitis, trauma, hypoadrenocorticism, heat stroke, anaphylaxis, pulmonary thromboembolism, hemorrhage, cardiac tamponade, and some toxicities. Dogs with primary immune-mediated disorders may show clinical signs that resemble those of chronic bacteremia and infective endocarditis. For suspected infectious pericarditis, the major differential diagnoses are idiopathic or benign pericardial effusion and neoplastic disorders.

Human Health Significance: Dogs and cats with cardiovascular infections may be infected with pathogens that have the potential to cause disease in humans, such as *Salmonella, Bartonella,* and *Brucella* spp.

Etiologic Agents, Epidemiology, and Clinical Features

Bacterial infections of the cardiovascular system include bacteremia, infective endocarditis, myocarditis, and infectious pericarditis. These infections are frequently associated with *sepsis*, or the host systemic inflammatory response to infection. When sepsis is associated with hypotension and distant organ dysfunction, the terms *septic shock* and *severe sepsis* are used, respectively. These terms have been clearly defined in human medicine[1] and adapted for use in small animals (Table 86-1). *Septicemia* is a term that has been used interchangeably with bacteremia by veterinary medical and medical professionals, but it is incompletely defined, and as a result, the use of this term is no longer recommended.

Bacteremia

Bacteremia can be divided into *uncomplicated* and *complicated bacteremia* (see Table 86-1). Transient, low-level (≤10 CFU/mL) subclinical bacteremia follows a variety of procedures such as dental prophylaxis, endoscopy, gastrointestinal surgery, and catheter placement. This is typically cleared rapidly (within 15 to 30 minutes) by a functional mononuclear phagocyte system. However, persistent release of large numbers of bacteria into the bloodstream can overwhelm the host immune response and culminate in clinically significant bacteremia. Overwhelming bacteremia can occur with disorders such as pyelonephritis, pyothorax, severe pyoderma, bacterial peritonitis, pyometra, pneumonia, pancreatitis, a variety of gastrointestinal disorders, bite wounds, orthopedic infections, or catheter-related infections. Underlying immune system dysfunction (such as occurs with diabetes mellitus, malignancy, and neutropenia) also predisposes to clinically significant bacteremia, because bacteria multiply unhindered in the bloodstream.

The most common organisms isolated from the blood of sick, bacteremic dogs are *Staphylococcus* spp., *Streptococcus* spp. (especially *Streptococcus canis*), and *Escherichia coli* (Table 86-2).[2] Less than 10% of bacteremic dogs in the author's hospital are infected with anaerobes, but in a study of critically ill dogs and cats from Colorado, anaerobes were isolated from 31% of 39 dogs and 40% of 10 cats.[3] With the exception of *Bartonella* and hemoplasmas, bacteremia is less commonly recognized in cats than in dogs and usually results from infection with gram-negative bacterial pathogens.[2] Polymicrobial infections of the blood are common and typically occur in 10% to 20% of dogs and cats with positive blood culture results. Mixed infections with two or more different strains of a single bacterial species can also occur. Polymicrobial infections often occur when anaerobes are involved or when bacteremia develops secondary to compromise of the gastrointestinal tract.

In addition to sepsis and septic shock, bacteremia may be followed by the development of infective endocarditis (IE), discospondylitis, and metastatic abscess formation in a variety of tissues. Chronic bacteremia may trigger secondary immune-mediated disorders, especially immune-mediated polyarthritis or glomerulonephritis, and rarely immune-mediated hemolytic anemia. This can result in erroneous diagnosis of a primary immune-mediated disorder and inappropriate treatment with immunosuppressive drugs, sometimes with a fatal outcome.

VetBooks.ir

TABLE 86-1

Definitions That Apply to Cardiovascular Infections in Dogs and Cats

Term	Definition
Bacteremia	The presence of viable or cultivable bacteria in the bloodstream
Uncomplicated bacteremia	Positive blood culture results and exclusion of endocarditis; no implants; negative follow-up cultures 2-4 days after the initial set; defervescence within 72 hours of initiation of effective treatment; and no evidence of metastatic sites of infection
Complicated bacteremia	Animals with positive blood culture results that do not meet the criteria for uncomplicated bacteremia
Fungemia	The presence of viable fungi in the bloodstream
Systemic inflammatory response syndrome (SIRS)	The clinical manifestation of systemic inflammation due to both noninfectious and infectious etiologies. Criteria for dogs and cats have been adapted from those in human medicine, but these have varied slightly in the cutoff values used. A single definition for dogs or cats has not been widely accepted. SIRS criteria are nonspecific and must be interpreted in light of an underlying disease. Dogs: 2 of 4 of temperature <100°F or >103.0°F (hypothermia or fever), HR > 140 beats/min, nonpanting RR > 30 breaths/min or PCO_2 < 32 mm Hg (venous or arterial), WBC <6000 or > 16,000 cells/μL, or >3% band neutrophils Cats: 3 of 4 of temperature <100°F or >103.5°F, HR < 140 or >225 bpm, RR > 40 breaths/min, WBC > 19,500 or <5000 cells/μL, or >5% band neutrophils
Sepsis	SIRS due to a proven or clinically suspected infection
Severe sepsis	Sepsis that is accompanied by dysfunction of organs remote from the site of infection, or sepsis-induced tissue hypoperfusion
Sepsis-induced tissue hypoperfusion	Sepsis that is accompanied with hypotension, an elevated lactate concentration, or oliguria either before or after adequate fluid loading
Septic shock	Sepsis that is accompanied by hypotension (systolic blood pressure < 90 mm Hg or mean arterial pressure < 70 mm Hg) that does not resolve with fluid resuscitation alone (i.e., vasopressor therapy is required)
Multiple organ dysfunction syndrome (MODS)	Dysfunction of two or more organ systems (distant to site of infection) in an animal with SIRS/sepsis
Infective endocarditis	Infection of one or more endocardial surfaces of the heart; almost always involves a cardiac valve

Sepsis

Bacteremia does not need to be present for sepsis to occur, but the clinical signs of bacteremia reflect the presence of sepsis (i.e., the host inflammatory response to infection). An understanding of the pathogenesis of sepsis has been critical for the development of drugs to improve survival, but it is complex and not fully understood. In summary, sepsis occurs when components of microbes (known as *pathogen-associated molecular pattern molecules*, or PAMPs) activate a host inflammatory response when they bind to pattern-recognition receptors (PRRs) such as Toll-like receptors (TLRs) and nucleotide-binding domain, leucine-rich repeat containing proteins (NLRs).[3a] The lipid A portion of bacterial lipopolysaccharide (LPS) is especially well known for its ability to stimulate this response (see Chapter 36), but other molecules, such as peptidoglycan, flagellin, DNA, and viral double-stranded RNA, may also be involved. Superantigens of gram-positive bacteria induce a cytokine cascade through simultaneous activation of large numbers of T cells (see Chapter 34). Bacterial LPS binds to an acute phase reactant protein called *LPS binding protein*, which transfers the LPS to CD14, a receptor on the surface of phagocytes.[4] CD14 then transfers the LPS to TLR4, which transmits the signal to the cell interior. This leads to activation of NF-κB and the secretion of cytokines such as TNF-α and Il-1β. The released cytokines induce fever (which may serve to limit bacterial growth), and cause further lymphocyte activation and release of proinflammatory cytokines. Damaged host cells also release molecules (*damage-associated molecular pattern molecules*, or DAMPs) that bind to TLRs and stimulate cytokine release. Important DAMPs recognized in humans include a chromatin-associated protein known as *high mobility group box-1* (HMGB1) and cellular DNA. The cascade of cytokines that is produced in response to DAMPs and PAMPs in turn induces the release and activation of a huge variety of mediators, such as complement, colony stimulating factors, prostacyclin, thromboxane, platelet-activating factor, coagulation factors, histamine, serotonin, nitric oxide, angiotensin II, and endothelin-1. Many of these mediators serve to recruit large numbers of immune cells and trigger fibrin deposition in order to localize, control, and ultimately eliminate the infection. Other molecules, such as cortisol and epinephrine, act to control the inflammatory response. Endothelial cell damage results in increased exposure of tissue factor (which activates the extrinsic coagulation pathway) as well as von Willebrand's factor. Endothelial cell damage also results in decreased expression of thrombomodulin, an important anticoagulant that normally binds thrombin and prevents it from cleaving fibrinogen.

VetBooks.ir

TABLE 86-2

Organisms That May Be Cultured Using Routine Blood Culture Methods from the Bloodstream of Dogs and Cats with Bacteremia*

	Dogs	Cats
Common (>10% of isolates)	• *Staphylococcus* spp., including *S. pseudintermedius*, *S. aureus*, and coagulase-negative staphylococci • *Streptococcus* spp., especially *S. canis*, but also *S. bovis* complex organisms and rarely other streptococci • *Escherichia coli*	• *Escherichia coli* • Other Enterobacteriaceae (*Klebsiella pneumoniae*, *Citrobacter freundii*, *Enterobacter cloacae*) • Anaerobes
Uncommon (1% to 10% of isolates)	• *Enterococcus* spp. • *Klebsiella pneumoniae*, *Serratia* spp., *Enterobacter cloacae* • *Pasteurella canis* and *Pasteurella dagmatis* • *Pseudomonas aeruginosa* • Anaerobes (*Clostridium perfringens*, *Prevotella* spp., *Bacteroides* spp., *Fusobacterium* spp., *Actinomyces* spp., *Peptostreptococcus* spp.)	• *Salmonella* spp. • Non-Enterobacteriaceae gram-negative bacteria (*Pasteurella multocida*, *Pseudomonas aeruginosa*, *Acinetobacter baumannii*) • Staphylococci • Streptococci
Rare (≤1% of isolates)	• *Erysipelothrix* spp. • *Brucella* spp. • *Citrobacter freundii* • *Acinetobacter* spp. • *Salmonella* spp. • *Mycobacterium* spp. • *Campylobacter* spp. • Other nosocomial pathogens, e.g., *Ralstonia pickettii*, *Burkholderia cepacia*	• *Enterococcus* spp.

*Not including fastidious organisms such as *Bartonella* spp.

The thrombomodulin-thrombin complex also activates protein C, which binds to protein S; the activated protein C–protein S complex degrades activated coagulation factors Va and VIIIa and prevents coagulation. Recombinant activated protein C has been the subject of much attention and controversy as a specific treatment for sepsis in human patients (see Treatment).

When the inflammatory response to infection is not effectively controlled or localized, the end result is systemic hypotension, tachycardia, increased vascular permeability, leukocytosis, activation of the coagulation cascade, and disordered tissue perfusion as a result of microcirculatory disturbances, volume depletion, and depressed myocardial function. This leads to further damage to host cells, lactic acidosis, and multiple organ dysfunction. Impaired perfusion, tissue hypoxia, and endothelial cell damage may have a wide range of effects on organ function (Table 86-3). Cats may be particularly susceptible to acute lung injury in sepsis, whereas gastrointestinal and/or hepatic dysfunction is often observed in dogs. Clinical signs of severe sepsis in dogs often include fever, obtundation, tachycardia, bounding or weak pulses, bright red mucous membranes, shortened capillary refill time, icterus, and tachypnea. However, many dogs with sepsis are evaluated when in the hypodynamic phase, with tachycardia, poor pulse quality, prolonged capillary refill time, and cold extremities. Cats may show obtundation, pale mucous membranes or icterus, abdominal pain, poor pulse quality, bradycardia, and/or tachypnea and may either be febrile or hypothermic.[5]

Infective Endocarditis

The reported incidence of canine IE has ranged from fewer than 0.1% of cases seen at veterinary teaching hospitals to approximately 1% of cases presenting to veterinary cardiologists.[6-9] IE is uncommonly diagnosed in cats. Dogs with IE are typically middle aged to older, large-breed dogs such as German shepherds, golden and Labrador retrievers, Weimaraners, mastiffs, and Rottweilers. For unclear reasons, male dogs are affected approximately twice as often as females. Factors that predispose to IE are similar to those that predispose to continuous bacteremia. However, virulence factors possessed by bacteria subsequently affect whether IE develops, which explains why some bacterial species (especially gram-positive bacteria) are more likely to produce IE than others (gram-negative bacteria). Although valvular heart defects, especially congenital defects such as subaortic stenosis, may predispose young dogs to development of IE, the vast majority of dogs with subaortic stenosis never develop IE, and more than 80% of dogs with IE have no identifiable underlying cardiac abnormality.[8,10] Furthermore, IE is rarely diagnosed in small-breed dogs, which are predisposed to myxomatous mitral valve degeneration. One study also found no association between periodontal disease and IE in dogs.[10]

The most commonly reported etiologic agents in canine IE are streptococci, staphylococci, and, to a lesser extent, gram-negative rods, enterococci, and *Bartonella* spp. (Table 86-4).[7,10-13] Organisms that are less commonly incriminated include fungi, gram-positive rods, mycobacteria, and anaerobes. In dogs, the mitral and/or the aortic valves are most commonly affected (Figure 86-1). The larger, septal leaflet of the mitral valve is more commonly affected than the mural leaflet.[8] The tricuspid valve and ventricular wall are rarely involved. This distribution correlates with the degree of pressure that rests on each closed valve. Classically, vegetative lesions develop along the line of valve closure.

VetBooks.ir

TABLE 86-3

Potential Effects of Sepsis on Organ Function

Organ	Clinical Abnormalities
Neurologic system	Obtundation, rarely focal signs and seizures; autonomic dysfunction
Heart	Heart rate variability, arrhythmias (ventricular or supraventricular), decreased contractility
Vasculature	Hypotension despite adequate fluid loading
Lungs	Acute lung injury or acute respiratory distress syndrome
Kidneys	Azotemia, oliguria, anuria
Gastrointestinal tract	Impaired barrier function and bacterial translocation, gastrointestinal ulceration, diarrhea, vomiting
Pancreas	Pancreatitis
Endocrine system	Adrenal insufficiency, hypoglycemia
Liver	Cholestatic jaundice
Immune system	Immunosuppression
Coagulation	Disseminated intravascular coagulation with or without hemorrhage

TABLE 86-4

Causes of Infective Endocarditis in Dogs

Microorganism	Prevalence[11]
Streptococci (primarily *S. canis* but also *S. bovis* group organisms)	29%
Bartonella spp.	20%
Staphylococci (*S. pseudintermedius*, *S. aureus*, and coagulase-negative staphylococci)	15%
Gram-negative rods (most commonly *E. coli*, but also *Pseudomonas aeruginosa*, *Salmonella* spp., *Citrobacter freundii*, *Klebsiella pneumoniae*, *Proteus* spp., *Pasteurella* spp., *Brucella* spp.)	15% (7% *E. coli*; <5% other species)
Other gram-positive bacteria (*Erysipelothrix* spp., *Granulicatella adiacens*, *Actinomyces* spp., *Corynebacterium* spp., *Mycobacterium* spp.)	7% (<5% each species)
Enterococcus spp.	5%
Fungi (e.g., *Aspergillus* spp.)	<5%

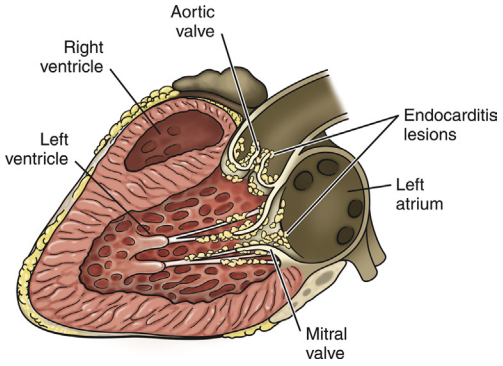

FIGURE 86-1 Infective endocarditis. Vegetations are attached to the mitral and aortic valves and may be mobile or sessile.

The development of IE begins with colonization of a heart valve by bacteria and deposition of fibrin, platelets, leukocytes, and erythrocytes. Colonization may be facilitated by changes in the valve surface as a result of turbulent blood flow, which results in the deposition of platelets, fibrin, and fibronectin; the end result is a sterile vegetation, or *nonbacterial thrombotic endocarditis*. Bacteria then adhere to this matrix, induce inflammatory cytokine and tissue factor release, and become covered with additional layers of platelets and fibrin, which promote bacterial growth to extremely high densities in an environment that is protected from the immune system. Properties of bacteria known to promote valve colonization include adhesins such as *fimA* in streptococci and clumping factor and fibronectin-binding proteins in staphylococci,[14,15] as well as factors that cause platelet aggregation. Portions of the vegetation can then dislodge and embolize in a variety of different tissues, especially the kidneys, spleen, brain, joints, and muscles, with an enormous spectrum of associated clinical manifestations. Thromboembolic complications are more likely to occur in dogs with mitral valve involvement than in those with aortic valve IE.[8] Regardless of the valve affected, valvular dysfunction can lead to impaired cardiac output and congestive heart failure (CHF).

As in humans, IE in dogs may be best classified on the basis of the etiologic agent involved, because the etiologic agent often determines the clinical course of disease, disease manifestations, prognosis, and the most appropriate antimicrobial drugs for treatment. For example, *Bartonella* IE is more likely to involve the aortic valve than the mitral valve, often occurs in the absence of fever, has a high prevalence of CHF when compared with IE caused by other bacterial pathogens, and is negatively correlated with survival (see Figure 52-3). In contrast, *Streptococcus canis* IE usually involves the mitral valve and is often associated with secondary polyarthritis. Dogs with gram-negative IE may be less likely to develop CHF than those with IE caused by other pathogens.[11]

The clinical signs and physical examination abnormalities that occur with IE are extremely variable and depend not only on the causative organism, but also on the valve affected, the presence or absence of thromboembolic complications, and the sites and extent of thromboembolism. Common historical findings include lethargy; inappetence; locomotory problems such as lameness, shifting lameness, joint pain, stiffness, reluctance to move, and inability to walk; and vomiting, weight loss, respiratory difficulty, and/or cough. Locomotory abnormalities can result from peripheral arterial thromboembolism, embolic or immune-mediated polyarthritis, neurologic abnormalities, and rarely, hypertrophic osteopathy.

TABLE 86-5

Physical Examination Findings in 70 Dogs with Infective Endocarditis Seen at the University of California, Davis, Veterinary Medical Teaching Hospital

Physical Examination Finding	Number Affected (%)
Cardiac murmur	41 (59)
Tachycardia	34 (50)
Fever	26 (38)
Tachypnea	24 (35)
Abnormal lung sounds	24 (34)
Recumbency	21 (30)
Mental dullness	19 (27)
Neurologic signs (ataxia, delayed or absent placing reactions, strabismus, nystagmus, head tilt, obtundation)	16 (23)
Swollen joints	15 (21)
Stiffness or lameness	13 (19)
Arrhythmias	14 (19)
Dehydration	11 (16)
Bounding pulses	10 (14)
Muscle atrophy	10 (14)
Thin body condition	9 (13)
Weak pulses	8 (11)
Reluctance to stand	8 (11)
Peripheral edema	7 (10)
Spinal pain	7 (10)
Abdominal pain, mucosal pallor, red mucous membranes, muscle pain, weakness, cyanosis, cool or cold limbs, oral ulceration, abdominal enlargement, hepatomegaly, icterus, uveitis, petechial or ecchymotic hemorrhages, cutaneous ulceration	6 or fewer (<10)

Modified from Sykes JE, Kittleson MD, Chomel BB, et al. Clinicopathologic findings and outcome in dogs with infective endocarditis: 71 cases (1992-2005). J Am Vet Med Assoc. 2006;228:1735-1747.

The most common initial physical examination findings are fever, tachycardia, and a cardiac murmur (Table 86-5).[8] In one study of dogs with IE, fever was present in the history or serial physical examinations of only 41 (60%) of 68 dogs with IE, and a cardiac murmur in only 53 (76%) of 70 dogs with IE, so an absence of fever or cardiac murmur does not rule out IE.[8] Although diastolic murmurs are suggestive of IE, more than 90% of dogs with murmurs due to IE have systolic murmurs.

Infectious Myocarditis

Infectious myocarditis in dogs and cats usually results from hematogenous spread of microorganisms to the myocardium or extension of endocarditis lesions to the myocardium. Viruses, bacteria, protozoa, or fungi may be involved. Some organisms have a particular tropism for the myocardium (Table 86-6). Infectious myocarditis is rare in cats.

TABLE 86-6

Infectious Causes of Myocarditis in Dogs and Cats

Pathogen Type	Examples	Affected Host Species
Viruses	West Nile virus	D
	Canine parvovirus 2 variants	D
	Feline panleukopenia virus	C
	Pseudorabies virus	D
Bacteria	Gram-negative and gram-positive bacteria (e.g., extension of endocarditis)	D, C
	Bartonella spp.	D, C
	Borrelia burgdorferi	D
	Rickettsia rickettsii	D
Fungi	*Blastomyces dermatitidis*	D
	Candida albicans	D
	Cryptococcus neoformans	D
	Aspergillus spp.	D
	Paecilomyces variotii	D
Algae	*Prototheca* spp.	D
Protozoa	*Trypanosoma cruzi*	D
	Sarcocystis felis	C
	Leishmania	D
	Neospora caninum	D
	Hepatozoon americanum	D
	Toxoplasma gondii	D, C

C, Cat; D, dog.

Myocarditis may be subclinical or result in arrhythmias, CHF, or sudden death. Simultaneous infection of a variety of other organs is frequent for most pathogens that cause myocarditis, so clinical signs of systemic infection (fever, lethargy) and other organ dysfunction are often present.

Infectious Pericarditis

Infectious pericarditis may result from direct inoculation of organisms into the pericardium (such as occurs with penetrating wounds), extension of infection from adjacent organs such as the pleural space or lungs, or hematogenous dissemination of viral, bacterial, or fungal pathogens to the pericardium. Bite wounds or grass awn migration usually result in mixed aerobic-anaerobic infections that involve organisms such as *Actinomyces* spp. (see Chapter 42). Infectious pericarditis as a result of hematogenous spread of pathogens is rare; idiopathic pericardial effusion and heart-base neoplasia are the most common causes of inflammatory or hemorrhagic pericardial effusion in dogs. Pathogens with particular tropism for the pericardial sac include feline infectious peritonitis virus and *Coccidioides* spp. (see Chapters 20 and 63). Pericarditis results in diastolic cardiac dysfunction with subsequent development of right-sided heart failure, which is manifested as weak pulses, tachycardia, jugular venous distention, ascites, and pleural effusion. Muffled heart sounds may be detected on cardiac auscultation as a result of pericardial and/or pleural effusion.

VetBooks.ir

BOX 86-1

Reasons to Consider Blood Culture in Dogs and Cats

Fever (especially when viral infection is not likely or underlying immunosuppression or barrier disruption is present)
Unexplained peripheral edema in dogs
Evidence of thromboembolism in dogs (e.g., organ infarction, cold limbs)
Neutrophilic polyarthritis in dogs
Discospondylitis in dogs
Echocardiographic evidence of infective endocarditis or new heart murmur
Neutrophilic lymphadenitis
Severe pneumonia or pyothorax
Peritonitis
Development of leukopenia, bandemia, or leukocytosis in association with immunosuppression, catheters, or other devices
Thrombophlebitis in association with an indwelling catheter
Sepsis in a patient in which a culture cannot be obtained from the suspected source (e.g., pneumonia in a severely hypoxemic patient, gastrointestinal bacterial translocation)
Immune-mediated hemolytic anemia or thrombocytopenia

TABLE 86-7

Modified Duke Criteria Used for Diagnosis of Infective Endocarditis in Dogs and Cats[8,20]

Major Criteria	Minor Criteria
Identification of a typical organism using blood culture • *Streptococcus* spp. • *Staphylococcus* spp. • *Escherichia coli*	Predisposing heart condition (congenital valvular malformation)
All 3, or most of 4, separate blood cultures positive, with first and last specimens drawn at least 1 hour apart	New or worsening heart murmur
Two positive blood cultures for any microorganism, when blood cultures are drawn more than 12 hours apart	Fever (≥103°F [39.4°C])
Findings on echocardiogram positive for infective endocarditis	Presence of vascular/embolic phenomena
	Immunologic phenomena: nondegenerate neutrophilic polyarthritis, glomerulonephritis, immune-mediated hemolytic anemia
	Microbiologic phenomena: positive blood culture not meeting major criteria, *or* serologic evidence of infection with a typical organism, *or* detection of a typical organism using PCR technology

Definite endocarditis: 2 major criteria, or histopathologic confirmation of endocarditis.
Possible endocarditis: Positive echocardiographic findings and 1 minor criterion, or 1 major and 3 minor criteria, or 5 minor criteria. In recent human guidelines, 1 major and 3 minor criteria, or 5 minor criteria, are considered sufficient evidence for diagnosis of definitive endocarditis.[19]

Diagnosis

Antemortem diagnosis of bacteremia is based on culture of bacteria from the bloodstream. Reasons to consider blood culture are shown in Box 86-1. The diagnosis of sepsis is based on the presence of the systemic inflammatory response syndrome (SIRS) together with suspected or proven infection (see Table 86-1). A number of biomarkers have been investigated for discrimination of sepsis from SIRS in dogs,[16-18] but as yet, highly sensitive and specific biomarkers for sepsis have not been identified. The diagnosis of IE is based on a set of criteria modified from the Duke criteria used for diagnosis of IE in human patients, which consider the results of blood culture and echocardiography as major criteria, and other clinical manifestations of IE as minor criteria (Table 86-7).[8,19,20] Diagnosis of infective pericarditis relies on echocardiography and the results of cytologic examination and culture of pericardial fluid, or alternatively, histopathologic examination and culture of pericardial biopsies obtained during thoracotomy or thoracoscopy. In dogs and cats, infectious myocarditis is usually a necropsy diagnosis because myocardial biopsy is rarely performed. However, bacterial myocarditis may be suspected based on echocardiographic abnormalities, the presence of arrhythmias, and positive blood cultures.

Laboratory Abnormalities

Complete Blood Count

Common CBC findings in dogs and cats with bloodstream infections are mild nonregenerative anemia, neutrophilia with a left shift and neutrophil toxicity, lymphopenia, and/or monocytosis. Degenerative left shifts may be present, and dogs and cats with disseminated intravascular coagulation (DIC) may be thrombocytopenic or have evidence of schistocytosis. Rarely, bacteria are seen within circulating leukocytes on blood smear examination.

Serum Biochemical Tests

The serum chemistry profile in dogs and cats with bloodstream infection may show evidence of organ dysfunction as a result of severe sepsis or bacterial embolization and infarction. Abnormalities include azotemia, increased activities of liver enzymes, mild to moderate hyperbilirubinemia (usually <5 mg/dL), and electrolyte and acid-base abnormalities (such as a high anion gap metabolic acidosis due to azotemia or lactic acidosis). Hyperglycemia may be present early in septic shock. Hypoglycemia can also be present as a result of decreased hepatic gluconeogenesis or upregulation of non–insulin dependent glucose transporters. Hypoalbuminemia occurs in most dogs with IE, ranges from mild to severe, and may result from decreased hepatic production, from increased vascular permeability, or as part of the inflammatory response (albumin is a negative acute-phase reactant protein). Dogs with thromboemboli to skeletal muscle may have markedly increased activity of serum creatine kinase.

Urinalysis

Urinalysis findings in dogs and cats with bacteremia or IE include proteinuria, pyuria, cylindruria, microscopic hematuria, and/or bacteriuria. Severe proteinuria (urine protein:creatinine

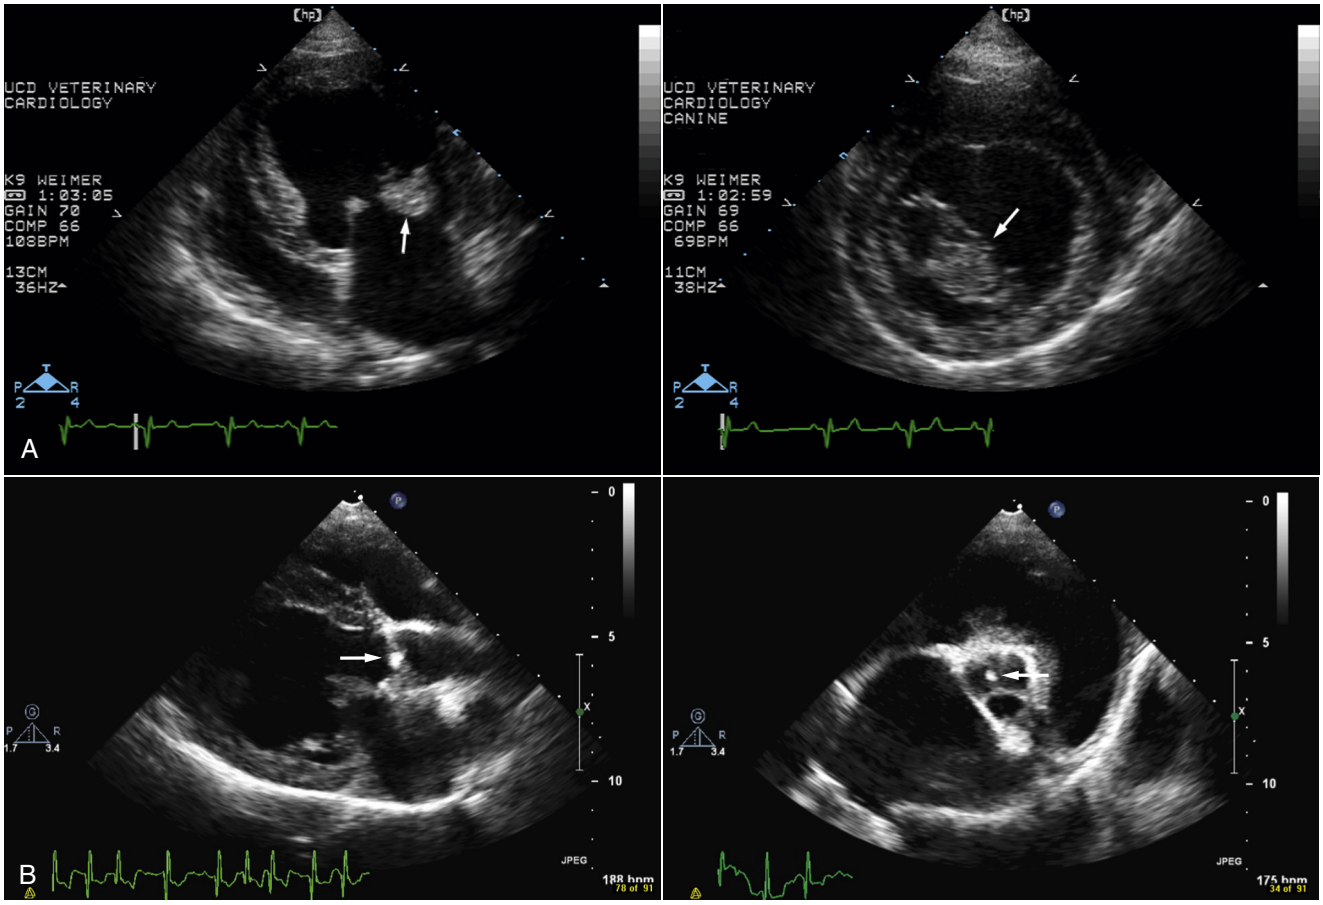

FIGURE 86-2 **A,** Parasternal *(left)* and short-axis *(right)* views of the mitral valve of a 7-year-old male neutered Weimaraner with *Enterococcus faecium* endocarditis that was diagnosed after a perineal urethrostomy procedure. There is a large vegetative lesion attached to the mitral valve *(arrow)*. A smaller lesion is attached to the septal leaflet of the valve. **B,** Parasternal *(left)* and short-axis *(right)* views of the aortic valve of a 4-year-old intact male Doberman with culture-negative endocarditis. The aortic valve cusps are thickened and a hyperechoic nodule is evident *(arrow)*. (Images courtesy University of California, Davis Veterinary Cardiology Service.)

ratio >5) may occur as a result of glomerular damage in dogs with IE.

Coagulation Profile

Dogs and cats with sepsis and DIC may have prolonged APTT and PT, increased concentrations of fibrin degradation products or D-dimers, and/or decreased concentrations of plasma fibrinogen and antithrombin. If thromboelastography is used, either hyper- or hypocoagulability may be documented in dogs.[21] In dogs with IE, PT is often shortened, and fibrinogen concentration is often increased.[8]

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with IE often show no detectable abnormalities. When present, abnormal findings include pulmonary infiltrates as a result of pneumonia, acute respiratory distress syndrome (ARDS), or CHF; generalized cardiomegaly; left atrial enlargement; pulmonary venous distention; mild pleural effusion; and, occasionally, even microcardia or vascular attenuation (see Figure 52-4). Infectious pericarditis may be associated with radiographic evidence of pleural effusion or cardiomegaly. Changes to the intervertebral disc spaces that suggest discospondylitis may also be detected in dogs with bacteremia or IE (see Chapter 85).

Echocardiography

Echocardiography is indicated when infective endocarditis, myocarditis, or pericarditis is suspected based on the history and physical examination findings (such as fever, arrhythmias, a new murmur, or signs of left- or right-sided CHF). It is also indicated for all dogs and cats with bacteremia, even in the absence of a cardiac murmur or arrhythmia; for dogs with neutrophilic polyarthritis; and for dogs and cats with evidence of systemic thromboembolic disease. Echocardiographic findings in IE can include valvular hyperechogenicity, thickening and irregularity of the valves, and valvular vegetations, which may be nodular, discrete, or have a shaggy or moth-eaten appearance (Figure 86-2 and see Figure 52-5). Large vegetations can oscillate or vibrate, and follow-up echocardiography sometimes reveals sudden disappearance of a vegetative lesion in association with thromboembolism. Mild or severe valvular regurgitation or insufficiency may be present in association with the lesions. Other echocardiographic findings include left ventricular eccentric hypertrophy, chamber dilation, mural hyperechogenicity, ruptured chordae tendineae, acquired defects in the valves or myocardium, and mild pericardial effusion. Echocardiography is a sensitive tool for diagnosis of IE (in one study, its sensitivity was 88% when necropsy was used as the gold standard),[8] but negative results do not completely rule out the

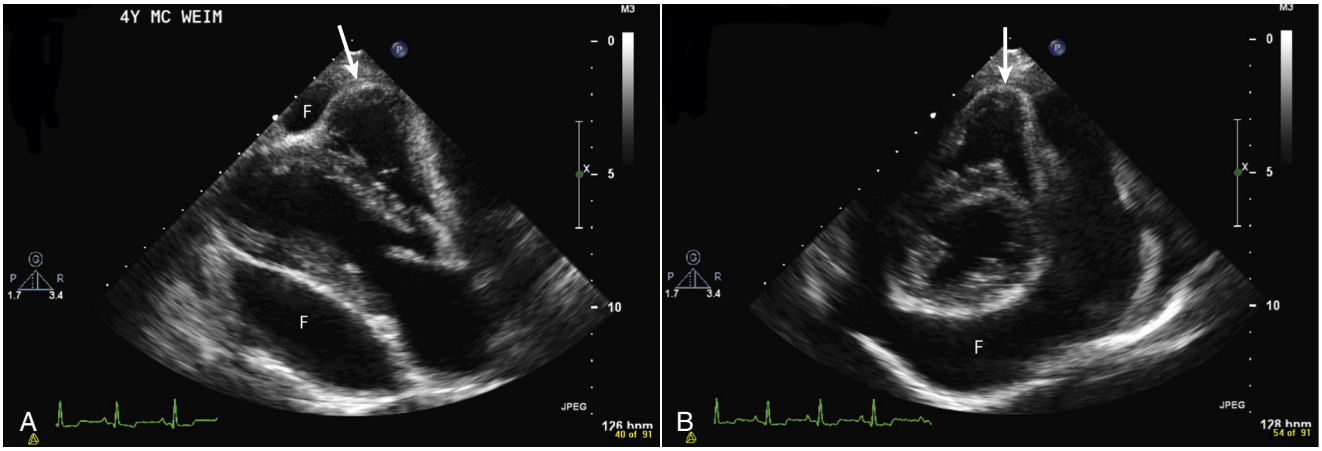

FIGURE 86-3 Long-axis **(A)** and short-axis **(B)** echocardiographic images that show pericarditis in a 4-year-old male neutered Weimaraner with disseminated coccidioidomycosis. The epicardium is adhered to the pericardium *(arrow)*, and a moderate quantity of anechoic pericardial fluid *(F)* can be appreciated. The cardiac chambers are distorted. (Images courtesy University of California, Davis Veterinary Cardiology Service.)

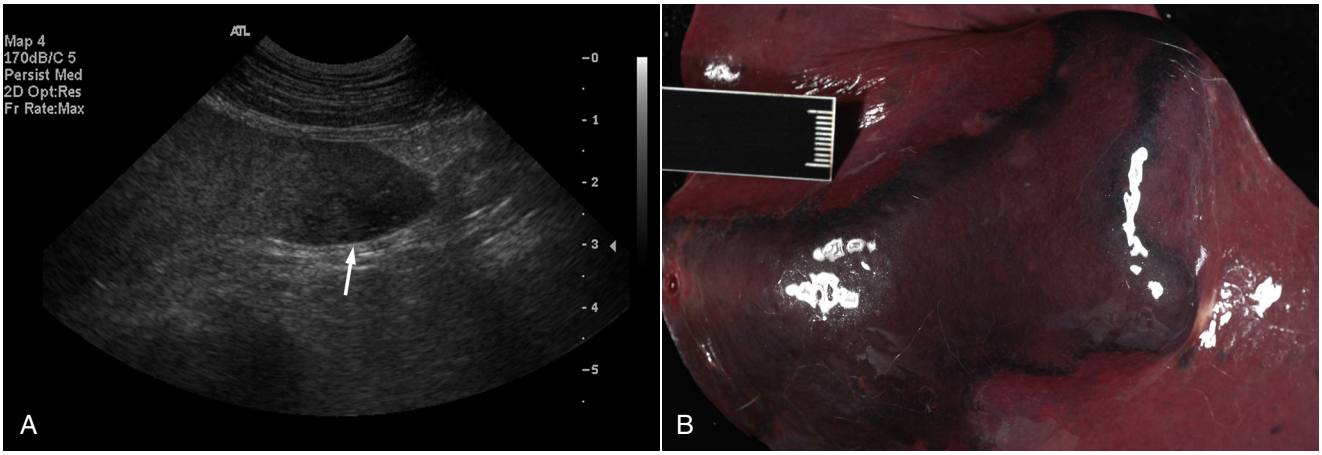

FIGURE 86-4 **A,** Abdominal ultrasound image that shows a splenic infarct *(arrow)* in a 6-year-old female spayed bouvier des Flandres with *Staphylococcus aureus* infective endocarditis. **B,** Splenic infarct at necropsy. (Image courtesy University of California, Davis Veterinary Anatomic Pathology Service.)

possibility of IE. Echocardiography is also useful for monitoring treatment of IE.

Echocardiographic findings in infectious pericarditis include pericardial effusion, adhesions of the pericardium to the epicardium, and sometimes focal or diffuse pericardial thickening and hyperechogenicity (Figure 86-3). Restrictive disease is characterized by impairment of diastole, with decreased left ventricular internal dimensions during diastole, and variation of blood flow velocity across the mitral valve with the respiratory cycle (increased with expiration and decreased with inspiration). In addition, deviation of the interventricular septum into the left ventricle can occur during inspiration and into the right ventricle during expiration.

Abdominal Sonographic Findings

Sonographic abnormalities can be present in a variety of organs in dogs with IE and may reflect underlying disease processes (such as neoplasia or bacterial peritonitis) or septic thromboembolism. Infarction and hemorrhage secondary to thromboembolism can result in focal cavitary or hypoechoic lesions in the spleen (Figure 86-4) or focal hyperechoic or hypoechoic lesions in the kidney. Thrombi may be found in the iliac arteries or aorta.

Microbiologic Tests

Culture

Routine blood cultures assist in identification of infecting pathogens and permit susceptibility testing. Ideally, at least three blood cultures should be obtained from separate sites within a 24-hour period. A suggested protocol for blood cultures is outlined in Chapter 3 (see Box 3-2). The use of separate venipuncture sites has been suggested but is not considered essential for diagnosis of human IE, although collection of specimens from indwelling catheters should be avoided.[19] If a catheter-related bloodstream infection is suspected, collection of paired specimens has been recommended in humans, with one specimen collected from the catheter before removal and the other collected from a peripheral site.[22] The skin should be prepared in the same manner used for surgery, and utmost care should be taken to avoid contamination with commensal bacteria. Because IE is generally associated with continuous bacteremia, positive results in only one of multiple bottles should be interpreted with caution. Positive results for *Bacillus* spp. or coagulase-negative staphylococci in a single bottle generally reflect contamination.

The decision to perform anaerobic blood culture should be considered in light of the animal's underlying disease process and client financial constraints. For example, anaerobic culture

VetBooks.ir

may not be cost effective in dogs with IE, given the rare involvement of anaerobes in this condition. Anaerobes are more likely to be present in dogs with histories that suggest involvement of plant awn foreign bodies, bite wounds, or gastrointestinal compromise.

False-negative blood cultures may occur as a result of low-level bacteremia or fungemia, the presence of fastidious or unculturable organisms such as *Bartonella* or anaerobes, insufficient specimen size, suboptimal specimen transport conditions, or recent antimicrobial treatment. Nevertheless, blood culture is still indicated in animals with a history of antimicrobial treatment, especially if antimicrobials have only been administered for 2 to 3 days. If an animal with IE is in stable condition, discontinuation of existing antibiotic treatment for several days (ideally 7 to 10 days) could be considered before blood cultures are obtained. Specific culture and serology for *Bartonella* is also indicated in dogs and cats with IE or suspected myocarditis (see Chapter 52). This should be considered even if routine blood cultures are positive, because polymicrobial infections that include *Bartonella* spp. and other bacteria can occur.[11] Special media used to isolate *Bartonella* spp. (*Bartonella* α-Proteobacteria growth medium [BAPGM]) may also yield other fastidious bacteria such as *Sphingomonas* spp., the clinical significance of which requires further study.[23] Serologic testing for *Aspergillus* antigen and *Brucella* antibody could also be considered for dogs with culture-negative IE (see Chapters 53 and 65).

Attempts should also be made to isolate causative organism(s) from other sites that are suspected to be a source of infection based on the history and clinical findings. Appropriate specimens could include transtracheal or bronchoalveolar lavage specimens, urine, ascites fluid, wounds, or pleural effusion. Urinary tract infections may reflect ascending pyelonephritis or spread of bacteria from the blood into the urine. However, bacteria cultured from the urine do not always reflect those present in the bloodstream,[11] so blood cultures should always be performed even when urine cultures are positive. Isolation of the same organism from the blood as well as an additional site facilitates interpretation of the significance of a single positive blood culture and aids decisions regarding appropriate antimicrobial drug treatment.

Molecular Diagnosis Using the Polymerase Chain Reaction

PCR assays have been used to rapidly detect bacterial DNA within whole blood and especially valvular tissue (obtained at necropsy) of animals with IE and are especially useful for detection of fastidious bacteria such as *Bartonella* spp. within heart valves (see Chapter 52). These assays use broad-range primers that target bacterial 16S ribosomal subunit DNA, and the identity of the organism is determined by sequence analysis of resulting PCR products.

In one prospective study that examined the performance of a conventional broad-range bacterial PCR assay on whole blood for diagnosis of the etiology of IE in 18 dogs, there was no difference in the overall sensitivity of the PCR assay and culture, but the combined use of the PCR assay and blood culture was more sensitive than the use of either assay alone.[20] This was because the PCR assay detected several fastidious organisms, which included *Bartonella vinsonii, Brucella,* and *Granulicatella adiacens*, but appeared less sensitive than culture for detection of less fastidious organisms such as streptococci. Studies that include larger numbers of dogs and cats and that examine the performance of other PCR assays such as real-time PCR assays are required before broad-range bacterial PCR can be recommended for routine diagnosis of bacteremia and IE in dogs and cats, but PCR assays show promise when used in conjunction with blood cultures. Of major concern is the possibility of false positives with highly sensitive PCR assays due to detection of contaminating bacteria. Even in human medicine, evidence is considered insufficient to recommend the routine use of whole blood or serum real-time PCR assays for the diagnosis of culture-negative IE.[19]

Pathologic Findings

There are no specific pathologic findings in sepsis or bacteremia, but underlying causes such as pneumonia, pyometra, or peritonitis may be apparent. Microabscesses may be present in multiple tissues. Isolation of the same bacterial species from multiple different tissues supports a diagnosis of bacteremia. Pathologic findings in IE include valvular vegetations; avulsion or perforation of valvular structures; and gross and histopathologic evidence of infarction, widespread thrombosis, and CHF (Figure 86-5). The inflammatory process may be chronic, with lymphoplasmacytic and histiocytic cell infiltrates and fibrosis; or acute, suppurative, and fibrinous, with or without microscopically visible intralesional bacteria (see Figure 34-6). *Bartonella* IE is characterized by chronic inflammation and may be associated with valvular mineralization (Figure 52-6), whereas IE due to other microorganisms may be acute or chronic and is rarely associated with mineralization.[11] Use of tissue gram stains and silver stains can reveal organisms within valvular vegetations. Necrotizing vasculitis may also be present in the lungs, myocardium, kidney, spleen, liver, and/or brain. Erythrophagocytosis has been described in reticuloendothelial tissues of dogs with IE due to gram-positive cocci. Membranoproliferative, membranous, or necrosuppurative glomerulonephritis may also be identified.[8]

Gross examination of the heart in animals with myocarditis may reveal focal or multifocal areas of myocardial pallor and/or friability. The pericardium of dogs and cats with pericarditis may be thickened and discolored, and pericardial effusion may be present. Histopathology reveals acute or chronic inflammatory infiltrates, depending on the underlying cause, sometimes with intralesional bacteria, protozoa, or fungi.

Treatment and Prognosis

The mainstay of treatment of bacteremia, IE, sepsis, and bacterial myocarditis or pericarditis is early antimicrobial drug treatment. The initial choice of antimicrobial drugs should be based on knowledge of the prevalent bacterial species and their antimicrobial drug susceptibilities for each hospital and/or geographic region, as well as the likely source of infection (which can provide information about the likely bacterial species involved) (Tables 86-8 and 86-9). The presence or absence of IE and/or severe sepsis also affects treatment recommendations.

In addition to antimicrobial drug therapy, the underlying cause of infection or chronic bacteremia should be identified and removed if possible. All catheters or devices should be removed and replaced at new sites if they are still needed. An attempt should be made to locate foreign bodies such as grass awns with imaging techniques and surgically remove them. Surgery may be required to resolve gastrointestinal compromise, such as occurs with foreign bodies, intestinal neoplasia, or torsion. Underlying immunosuppressive disease such as neoplasia or diabetes mellitus should be identified and treated if possible.

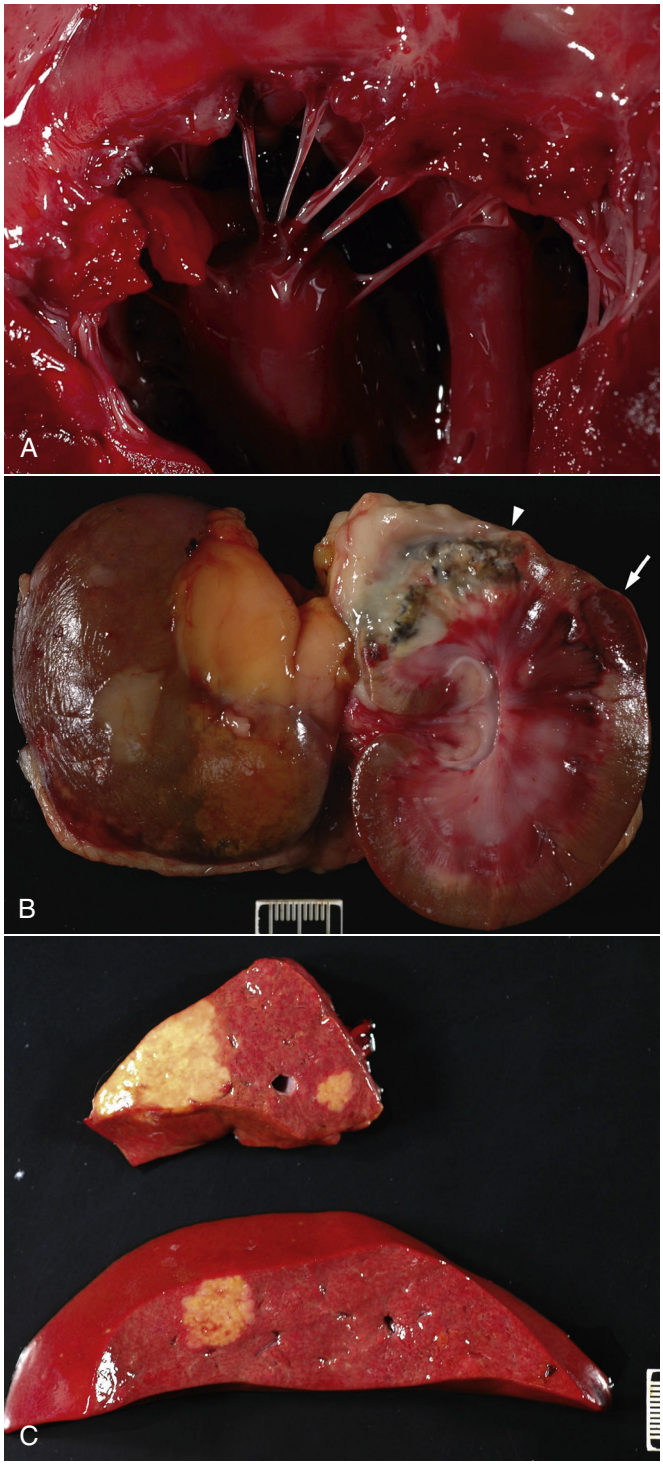

FIGURE 86-5 Gross pathology findings in a 12-year-old male neutered Irish water spaniel with *Enterococcus durans* infective endocarditis and widespread thromboembolic disease. **A,** Mitral valve. The leaflets are thickened and nodular. **B,** Left kidney. Multiple, variably sized, well-demarcated red foci with dark red rims and numerous well-demarcated tan slightly depressed foci are present. On cut surface, these foci extend to and beyond the corticomedullary junction as wedge-shaped lesions *(white arrow)*. On one pole there is a 2.0 cm × 1.5 cm × 1.4 cm tan to brown-green abscess *(white arrowhead)*. **C,** Spleen. Several well-demarcated lesions that measured 0.3 to 0.5 cm in diameter are present. (Courtesy the University of California, Davis, Veterinary Anatomic Pathology Service.)

Maintenance of optimal oxygen delivery to tissues and adequate tissue perfusion is essential for effective treatment of severe sepsis and septic shock. The use of goal-directed therapy for the management of severe sepsis/septic shock in the emergency room during the first 6 hours of hospitalization reduces mortality in humans.[24] The first priority is to rapidly correct blood volume deficits. Liberal administration of IV crystalloids is a critical treatment for dogs and cats with sepsis. Colloids could also be used, but studies of human patients with septic shock have shown either no additional benefit of synthetic colloids such as hetastarch and the possibility of increased mortality[25] or increased risk of development of acute kidney injury.[26] Because hypoalbuminemia is common and affected animals often have increased vascular endothelial permeability, fresh frozen plasma may be needed to maintain appropriate intravascular volume. Excessive fluid administration may be associated with increased mortality, so careful monitoring of central venous pressure (CVP) is optimal. The endpoints of fluid resuscitation should be mean arterial pressure (MAP) of at least 65 mm Hg, adequate perfusion on physical examination, and a lactate clearance of at least 10% or a plasma lactate concentration less than 2 mmol/L.[27] Fluid support is provided until a maximal target CVP of 8 to 12 mm Hg is reached or the listed goals are met.

Tight glycemic control (targeting a blood glucose of <150 mg/dL) has been shown to increase the risk of serious adverse effects in humans and is not recommended at this time.[26] However, blood glucose concentrations must be monitored and hypoglycemia avoided by the addition of supplemental dextrose to IV fluids. Bicarbonate therapy is not recommended to treat metabolic acidosis associated with tissue hypoperfusion because acidosis may be protective. Animals that develop acute lung injury (ALI) or ARDS (bilateral pulmonary interstitial to alveolar infiltrates that are not due to left-sided congestive heart failure with a P_aO_2/F_iO_2 ratio less than 300 [ALI] or less than 200 [ARDS]) may benefit from mechanical ventilation. For less severely affected animals, supplemental oxygen to maintain a SpO_2 of at least 95% or P_aO_2 of at least 80 mm Hg is indicated.

Arterial blood pressure must be monitored either by direct (arterial catheter) or indirect (oscillometric) means and maintained through treatment at or above 65 mm Hg. If hypotension persists despite adequate fluid loading as described previously, a diagnosis of septic shock is made and treatment with vasopressors such as dopamine, norepinephrine, or vasopressin may be indicated. The decision to use inotropes (such as dobutamine) first is based on echocardiographic evidence of impaired myocardial contractility (decreased fractional shortening on echocardiogram, or direct measurement of cardiac output via pulmonary artery catheter or other techniques). If inotropes are not indicated, then vasopressors should be prescribed to achieve an adequate blood pressure. Often treatment with dopamine (5-15 µg/kg/min) is attempted first. If an adequate MAP cannot be obtained, then norepinephrine (0.1-1 µg/kg/min), or vasopressin (0.5-4 mU/kg/min) can be added; additional vasopressors are always added and not substituted. If MAP cannot be maintained with norepinephrine, then vasopressin is added (or vice versa).

Treatment of severe sepsis and septic shock with hydrocortisone has been controversial in human medicine. High doses of hydrocortisone increase mortality and should not be used.[28,29] Relative adrenal insufficiency has been identified in dogs and cats[30] with an apparent reversal of signs of shock

VetBooks.ir

TABLE 86-8

Suggested Empiric Antimicrobial Drug Choices for IV Use in Dogs and Cats with Severe Sepsis or Septic Shock Pending the Results of Blood Culture and Susceptibility*

Antimicrobial Drug	Spectrum	Suspected Source of Infection	Comments
Ampicillin or clindamycin *and* an aminoglycoside†	Activity against most gram-negative bacteria, methicillin-resistant staphylococci, streptococci, enterococci, and most anaerobes	Urinary tract, abdomen	Good first choice for most infections, except when the respiratory tract is involved. Consider use of ampicillin-sulbactam instead of ampicillin or addition of metronidazole if infection with penicillinase-producing anaerobes is possible (e.g., gastrointestinal compromise or plant foreign body, IE absent).
Ampicillin or clindamycin *and* a fluoroquinolone	Active against most anaerobes, streptococci, susceptible staphylococci, and aerobic gram-negative rods. Not active against some methicillin-resistant staphylococci, enterococci, and MDR gram-negative bacteria.	Lung, urinary tract, abdomen, pyothorax	Consider when MDR gram-negative bacteria, enterococci, or methicillin-resistant staphylococci are *unlikely* based on local resistance patterns and aminoglycosides are contraindicated because of toxicity or concerns related to drug penetration. Consider use of ampicillin-sulbactam instead of ampicillin or addition of metronidazole if infection with penicillinase-producing anaerobes is likely.
A carbapenem *or* piperacillin-tazobactam *or* ticarcillin-clavulanate	Active against aerobic gram-negative rods including *Pseudomonas*, anaerobes, streptococci. Not active against methicillin-resistant staphylococci and some enterococci.	Abdomen, aspiration pneumonia	Use when infection with MDR gram-negative bacteria and anaerobes is likely but *aminoglycosides are contraindicated because of toxicity or concerns related to drug penetration* (e.g., airway involvement). Consultation with a veterinary clinical specialist with a focused interest in infectious disease or antimicrobial pharmacology recommended before use.
Vancomycin *and* a carbapenem	Active against methicillin-resistant staphylococci, streptococci, MDR aerobic gram-negative bacilli, and anaerobes.	Skin/soft tissue, urinary tract, abdomen	Last line for treatment of life-threatening mixed infection with MDR gram-negative bacteria, MDR enterococci, anaerobes, and methicillin-resistant staphylococci *when aminoglycosides are contraindicated because of toxicity or concerns related to inadequate drug penetration.* Consultation with a veterinary clinical specialist with a focused interest in infectious disease or antimicrobial pharmacology recommended before use.

Dosages for IV administration (normal renal function). See Chapter 8 for precautions.
- Amikacin, 15 mg/kg q24h (dogs), 10 mg/kg q24h (cats)
- Ampicillin sodium, 20 mg/kg q6h
- Ampicillin-sulbactam, 20 mg/kg q6-8h (dose based on ampicillin component)
- Clindamycin phosphate, 10 mg/kg q12h (dilute 1:10 in sterile saline and give slowly over 30 min)
- Gentamicin sulfate, 14 mg/kg q24h (dogs), 8 mg/kg q24h (cats)
- Ciprofloxacin hydrochloride, 10 mg/kg q24h
- Enrofloxacin, 5-20 mg/kg q24h (dogs); avoid in cats and never exceed 5 mg/kg, see important cautionary notes in Chapter 8
- Imipenem-cilastatin, 5 mg/kg q6h (dilute in 100 mL sterile saline and give slowly over 30 min)
- Meropenem, 25 mg/kg q8h
- Piperacillin-tazobactam, 40 mg/kg q6h
- Ticarcillin-clavulanate, 50 mg/kg q6h
- Vancomycin, 15 mg/kg q8h (dilute in sterile saline and give slowly over 30 min)

MDR, Multidrug-resistant.

*Spectrum should be reduced once culture and susceptibility results become available.

†In human patients, amikacin is less nephrotoxic than gentamicin and may be preferable for treatment of dogs and cats with severe sepsis or septic shock.

VetBooks.ir

TABLE 86-9

Suggested Empiric Antimicrobial Drug Treatment for IV Use in Dogs and Cats with Infective Endocarditis Pending the Results of Blood Culture and Susceptibility*

Antimicrobial Drug	Spectrum	Comments
Ampicillin *and* gentamicin	Streptococci, *Bartonella*, methicillin-resistant staphylococci, enterococci, aerobic gram-negative rods	Covers all major causes of IE including most MDR gram-negative rods. Consider substitution of gentamicin with a fluoroquinolone if impairment of renal function is present.
Vancomycin *and* a carbapenem	Methicillin-resistant staphylococci, enterococci, gram-negative aerobes	Use only when infection with methicillin-resistant staphylococci is likely, local susceptibility patterns preclude use of other antimicrobials, *and aminoglycosides are contraindicated because of toxicity* (e.g., refractory pyoderma; history of orthopedic surgery, antimicrobial treatment, or hospitalization in the last year; or contact with other animals or humans known to have methicillin-resistant staphylococcal infections). Consultation with a veterinary clinical specialist with a focused interest in infectious disease or antimicrobial pharmacology recommended before use.

For drug doses, see bottom of Table 86-8.
*Spectrum should be reduced once culture and susceptibility results become available.

with the treatment of hydrocortisone in one reported case.[31] Current recommendations for human patients are to consider hydrocortisone therapy when hypotension responds poorly to adequate fluid resuscitation and vasopressors. Hydrocortisone is preferred to dexamethasone and dosed at 1 mg/kg IV q6h.

Other supportive treatments could include the H2 blocker famotidine or proton pump inhibitors to manage gastrointestinal ulceration. The use of red blood cell transfusions to maintain a hemoglobin concentration above 7.0 g/dL may be beneficial. Recombinant activated protein C (drotrecogin alfa) was the only approved drug specifically indicated to treat severe sepsis in human patients, but was withdrawn from the market after a worldwide trial showed that it failed to improve outcome for severe sepsis and septic shock.[32] An anti-TLR4 receptor compound, eritoran tetrasodium, also failed to improve outcome. Human intravenous immunoglobulin has been used to treat humans with sepsis, with improved survival. Whether this also translates to dogs and cats is not known.[33,34]

Bacteremia and Septic Shock

It is well established in human patients that the earlier appropriate antimicrobial drug treatment is initiated in sepsis, the lower the mortality. With every hour that antimicrobial drug therapy is delayed after documented hypotension, mortality in affected people increases by 8%.[35] Because of the urgent need to initiate antimicrobial drug treatment, initial treatment should be intravenous, bacteriocidal and broad spectrum, and should occur within an hour of diagnosis of severe sepsis and septic shock, pending the results of culture and susceptibility. Reasonable initial choices for septic shock in dogs and cats are outlined in Table 86-8. *In order to avoid overuse of antimicrobial drugs reserved for treatment of resistant bacterial infections, the drug spectrum should be reduced according to the results of culture and susceptibility as soon as those results are available.* Treatment should be continued for at least 2 weeks, although the optimum duration of treatment may vary depending on the underlying cause. Repeat blood cultures could be considered if fever or clinical abnormalities that suggest ongoing infection persist after 7 days of treatment, but the need for and timing of follow-up blood cultures in animals that are responding adequately to treatment requires further study.

Infective Endocarditis

Guidelines for the treatment of IE in humans have been published and updated.[19,36] However, many factors considered for treatment of human patients do not apply to dogs and cats, including the availability of valve replacement; penicillin allergy in some patients; the higher incidence of infections with methicillin-resistant staphylococci and vancomycin-resistant enterococci; evidence that supports use of specific antimicrobial drugs or drug combinations; and the possibility of long hospitalization times for parenteral antimicrobial drug therapy. Indications for cardiac surgery in humans include severe acute regurgitation or valve obstruction with refractory pulmonary edema; uncontrolled infection with enlarging vegetations; persistent fever and positive blood culture for at least 10 days after appropriate antimicrobial drug treatment is commenced; infection caused by fungi or multidrug-resistant bacteria; large vegetations (>10 mm) in association with embolic episodes or other complications; and isolated large vegetations (>15 mm).[19]

For dogs and cats, valve replacement is not generally possible, so treatment must rely on antimicrobial drugs and resolution of any predisposing factors. Where the local prevalence of multiresistant gram-negative bacteria and methicillin-resistant staphylococci is low, a combination of ampicillin and an aminoglycoside is a good choice for empiric treatment of IE pending the results of culture and susceptibility. Where bloodstream infections with multiresistant gram-negative bacteria and methicillin-resistant staphylococci are locally prevalent, empiric recommendations made for human patients could be considered for dogs and cats pending the results of culture and susceptibility, provided there is a chance of treatment success in the absence of valve replacement. When severe sepsis is absent and IE follows an indolent

VetBooks.ir

TABLE 86-10

Suggested Antimicrobial Drugs for Treatment of Major Causes of Infective Endocarditis in Dogs and Cats Once Cause is Known*

Cause	Preferred Treatment	Oral Equivalent
Methicillin-susceptible *Staphylococcus* spp.	Ampicillin IV Flucloxacillin IV (β-lactamase producer) Ampicillin-sulbactam IV (β-lactamase producer)	Amoxicillin PO Flucloxacillin PO Clavulanic acid–amoxicillin PO
Methicillin-resistant but rifampin-susceptible *Staphylococcus* spp.	Gentamicin IV and rifampin PO *or* Vancomycin IV* and rifampin; IV trimethoprim-sulfas, chloramphenicol or doxycycline with or without rifampin could also be considered if tolerated and the organism is susceptible.	None
Streptococcus spp.	Benzylpenicillin IV Ampicillin IV	Amoxicillin PO
Penicillin-susceptible enterococci	Ampicillin IV	Amoxicillin PO
Penicillin-resistant enterococci	Vancomycin IV* and gentamicin IV. If possible, consider other options based on culture and susceptibility.	None. Linezolid could be considered as an oral alternative.*
Aerobic gram-negative rods	Ampicillin IV and gentamicin IV Ampicillin IV and fluoroquinolone IV Imipenem-cilastatin or meropenem IV* Or base on susceptibility (other options, such as injectable cephalosporines, piperacillin-tazobactam, or ticarcillin-clavulanate may be effective)	Base on susceptibility
Bartonella spp.	Ampicillin IV and gentamicin IV Doxycycline IV and rifampin PO	Doxycycline PO and rifampin PO
Aspergillus spp.	Voriconazole or posaconazole	Voriconazole or posaconazole

*In part based on recommendations for treatment of human IE. The reader is referred to the text for precautionary statements on the use of vancomycin, linezolid, and carbapenems such as meropenem in animals.

course, it is recommended in human patients that antimicrobial treatment be withheld pending the results of culture and susceptibility, or a combination of penicillin with or without low-dose gentamicin (1 mg/kg IV q12h) be administered until results are available. Aminoglycosides are used at this low dose, twice daily for their synergistic activity with penicillin against enterococci and viridans streptococci, which are uncommon causes of IE in dogs. Empiric treatment protocols that have activity against drug-resistant bacteria are used in human patients pending results of culture and susceptibility when severe sepsis is present, such as vancomycin and low-dose gentamicin (no risk factors present for gram-negative bacterial infection), or vancomycin and meropenem (risk factors present for multiresistant Enterobacteriaceae and *Pseudomonas* infection). However, the use of vancomycin and meropenem in dogs and cats has been controversial and may not be permitted or feasible in some geographic locations.

Recommendations for treatment of IE in dogs once the microbial etiology is known are shown in Table 86-10. Intravenous antimicrobial drugs should be continued in the hospital for as long as possible (ideally at least 7 to 10 days). A switch to oral medications is not recommended for human IE patients because of poor activity when compared with intravenous medications.[19] However, oral antibiotic treatment has been used with success to treat some dogs with IE and may be the only viable option. At-home treatment with intravenous drugs through peripheral indwelling catheters, vascular access ports, or subcutaneous injections may be possible for some dogs, but dog, owner, and drug factors should be considered very carefully and proper client education is critical. If oral antimicrobial drugs are used, bacteriocidal drugs with good and reliable oral bioavailability are preferable.

Medical treatment should be continued for at least 4 to 6 weeks, until the underlying disease process has resolved and valvular lesions have also resolved based on echocardiographic examinations. Echocardiography should be repeated after 4 weeks, or earlier if there is evidence of complications (CHF, embolic disease) or inadequate treatment response. Successful resolution of IE is associated with reduction in size and consolidation of valvular vegetations and increase in valvular echogenicity. With unsuccessful treatment, lesions enlarge or remain unchanged, and/or new lesions may appear on other valves.[8]

Infective Pericarditis

In addition to specific antimicrobial drug treatment, surgery may be required in dogs with infective pericarditis in order to debride the pericardium and restore cardiac diastolic function. This carries a significant risk of mortality; if feasible, referral to an experienced cardiac surgeon is recommended.

Prognosis

The prognosis for dogs and cats that develop septic shock, severe sepsis, IE, myocarditis, or pericarditis is guarded, and depends

on underlying disease processes, the severity of organ damage, and the etiologic agent or agents. In a study of 114 dogs seen at a veterinary teaching hospital with sepsis secondary to gastrointestinal tract leakage, overall mortality rate was 47.4%.[37] The mortality rate was 40/57 (70%) for dogs with MODS and 14/57 (25%) for dogs without MODS; 50% of the dogs in the study had MODS. In another study, mortality rate in dogs due to IE was at least 40/71 (56%), and median survival time was only 54 days.[8] Factors strongly associated with negative outcome in dogs with IE were thrombocytopenia, increased serum creatinine concentration, renal complications, thromboembolic complications, and *Bartonella* infection.

Prevention

Methods to prevent bloodstream infections and sepsis include limiting the use of invasive devices and catheters unless absolutely necessary and attention to routine hygiene in the hospital to minimize nosocomial infections. Other measures include management of immunosuppressive disorders such as diabetes mellitus, minimizing use of immunosuppressive drugs such as glucocorticoids, and prompt attention to wounds or other underlying infections that have the potential to spread to the bloodstream.

The role of prophylactic antimicrobial drugs to prevent bacteremia and sepsis has been controversial. Beneficial outcomes have been reported when antimicrobials are used to prevent infection after chemotherapy. In one study, the use of a 14-day course of trimethoprim-sulfadiazine reduced morbidity in dogs with osteosarcoma or lymphoma during the first 14 days after treatment with doxorubicin.[38] In human patients a 7-day course of a fluoroquinolone during the expected neutropenic period after chemotherapy for solid tumors and lymphomas reduced the incidence of fever, probable infection, and hospitalization.[39] Prophylactic treatment with antimicrobial drugs could be considered for animals with severe neutropenia (<500 cells/μL), although more studies are required that examine the prevalence of bacteremia in neutropenic animals and the benefits of prophylactic antimicrobial drug treatment. Finally, prophylactic antimicrobial drug treatment has been suggested for dogs and cats with congenital heart defects that undergo dental procedures, but evidence to support the need for this practice is lacking.

Public Health Aspects

Dogs with bloodstream infections may harbor bacteria such as methicillin-resistant *Staphylococcus aureus* that have the potential to colonize humans; these bacteria may not only be present in the bloodstream, but also at other anatomic sites of colonization such as the gastrointestinal tract or nasal cavity. Therefore, routine precautions should be taken when these dogs are handled, with special attention to hand hygiene and fomite disinfection. Dogs and cats with signs of cardiovascular infection may also be infected with important human pathogens such as *Salmonella* spp., *Bartonella* spp., *Brucella* spp., and *Rickettsia rickettsii*, so caution should be taken when handling blood from animals with cardiovascular infections, and needle-stick injuries should be avoided.

CASE EXAMPLE

Signalment: "Betsy," a 6-year-old female spayed bouvier des Flandres from Fallon, NV

History: Betsy was seen at the UC, Davis, VMTH emergency service for treatment of possible sepsis. One week before she was evaluated she had been lethargic and reluctant to stand while on a camping trip. Over the next 2 days she lost interest in food and water and seemed disoriented and unable to see, then developed dark, liquid diarrhea. She was taken to the local veterinary clinic 3 days later where her temperature was 106.3°F (41.3°C), she was unable to stand, and blood work showed moderate thrombocytopenia and hypoglycemia. An injection of ceftiofur (unknown dose), cephalexin (15.4 mg/kg PO q8h), and cimetidine (4.5 mg/kg PO q12h) were prescribed and she was referred for further evaluation. Betsy was up to date on vaccinations for distemper, canine adenovirus, parvovirus, and rabies.

Physical Examination:

Body Weight: 64 kg.

General: Obtunded, laterally recumbent, T = 106.2°F (41.2°C), HR = 170 beats/min, RR = 50 breaths/min, mucous membranes dark red, CRT <1 s.

Eyes, Ears, Nose, and Throat: Hypopyon and conjunctivitis were present in both eyes, and there was marked mucopurulent ocular discharge bilaterally. Serous nasal discharge was present bilaterally. There was moderate dental calculus and gingivitis. Several small gingival ulcerations were present.

Integument: Generalized cutaneous petechiation was noted.

Musculoskeletal: The dog was nonambulatory and unable to stand. Body condition score was 7/9.

Cardiovascular: No arrhythmias or murmurs were auscultated. Very strong, synchronous femoral pulses were palpated bilaterally.

Respiratory: Increased bronchovesicular sounds were present in all fields.

Abdominal Palpation: Moderate abdominal distention was noted. Palpation was difficult because of recumbency and the large size of the patient.

All Other Systems: No abnormalities detected.

Laboratory Findings:

Venous Blood Gas: pH 7.351, pCO_2 31 mm Hg, pO_2 41.4 mm Hg, base deficit 7.8 mmol/L, ionized calcium 1.14 mmol/L, bicarbonate 16.3 mmol/L, lactate 4.2 mmol/L, glucose 59 mg/dL.

CBC:

HCT 47.8% (40%-55%)
MCV 68.5 fL (65-75 fL)
MCHC 36.2 g/dL (33-36 g/dL)
WBC 25,250 cells/μL (6000-13,000 cells/μL)
Neutrophils 17,675 cells/μL (3000-10,500 cells/μL)
Band neutrophils 3030 cells/μL
Lymphocytes 505 cells/μL (1000-4000 cells/μL)

VetBooks.ir

Monocytes 3788 cells/μL (150-1200 cells/μL)
Platelets 23,000 platelets/μL (150,000-400,000 platelets/μL)
Marked neutrophil toxicity was evident.

Serum Chemistry Profile:
Anion gap 25 mmol/L (10-24 mmol/L)
Sodium 146 mmol/L (145-154 mmol/L)
Potassium 3.8 mmol/L (3.6-5.3 mmol/L)
Chloride 113 mmol/L (108-118 mmol/L)
Bicarbonate 12 mmol/L (16-26 mmol/L)
Phosphorus 2.9 mg/dL (3.0-6.2 mg/dL)
Calcium 10.3 mg/dL (9.7-11.5 mg/dL)
BUN 34 mg/dL (5-21 mg/dL)
Creatinine 1.6 mg/dL (0.3-1.2 mg/dL)
Glucose 59 mg/dL (64-123 mg/dL)
Total protein 5.9 g/dL (5.4-7.6 g/dL)
Albumin 3.0 g/dL (3.0-4.4 g/dL)
Globulin 2.9 g/dL (1.8-3.9 g/dL)
ALT 58 U/L (19-67 U/L)
AST 130 U/L (19-42 U/L)
ALP 356 U/L (21-170 U/L)
Cholesterol 377 mg/dL (135-361 mg/dL)
Total bilirubin 0.7 mg/dL (0-0.2 mg/dL)

Urinalysis: SGr 1.028; pH 8.0, 3+ protein (SSA), 1+ bilirubin, 2+ hemoprotein, no glucose or ketones, 1-3 WBC/HPF, 4-10 RBC/HPF, 0-2 granular casts, few triple phosphate crystals, no bacteria seen.

Coagulation Panel: PT 8.3 s (7.5-10.5 s), PTT 19.3 s (9.0-12.0 s), fibrinogen 506 mg/dL (90-255 mg/dL), D-dimer >2.0 μg/mL (0-0.25 μg/mL).

Arterial Blood Gas (Post–Fluid Bolus)(FiO_2 65%): pH 7.278, pCO_2 40 mm Hg, pO_2 62.7 mm Hg, oxygen saturation 82.3%, ionized calcium 1.36 mmol/L, bicarbonate 17.6 mmol/L, base deficit 7.5 mmol/L, lactate 2.8 mmol/L.

Imaging Findings:

Abdominal Ultrasound: The liver was hypoechoic and enlarged. The gallbladder wall was edematous. Bright mesentery surrounded the left limb of the pancreas. There was a dilated, fluid-filled duodenum. Multiple splenic infarcts were identified, some of which were anechoic, consistent with the presence of fluid (see Figure 86-4). The spleen was enlarged, and a splenic venous thrombus was present.

Echocardiography: The left ventricle and atrium were normal in size. There was laminar flow through the pulmonary artery and aorta. The right heart chambers were subjectively normal in size. There was no tricuspid regurgitation. There was a hyperechoic, oscillating vegetative lesion associated with the anterior mitral valve leaflet and possibly with the aortic valve. A small jet of mitral regurgitation was observed. No aortic insufficiency was observed.

Microbiologic Testing: Aerobic urine culture (cystocentesis specimen): No growth.

Aerobic and anaerobic blood culture (3 specimens): Large numbers of *Staphylococcus aureus* from the first 2 of 3 bottles. The isolate was susceptible to all antimicrobials tested.

Treatment and Outcome: Before the results of diagnostic tests were available, treatment was initiated with shock doses of IV fluids (6 liters of lactated Ringer's solution IV as a bolus over 1 hour). Ticarcillin-clavulanate (50 mg/kg IV q6h), enrofloxacin (10 mg/kg IV q24h), famotidine (0.5 mg/kg IV q12h), prednisolone acetate ophthalmic suspension (1 drop in each eye [OU] q6h), and atropine ophthalmic solution (1 drop OU q12h) were administered. Temperature, respiratory rate, and perfusion parameters were monitored by physical examination after each liter of fluid was administered. Systolic blood pressure was 180 mm Hg throughout the resuscitation period. Lactated Ringer's solution with 30 mEq KCl/L and 2.5% dextrose was then continued at 4.7 mL/kg/hr, with monitoring of arterial blood pressure and urine output. Three units of fresh frozen plasma were administered because total plasma protein dropped to 4.2 g/dL, colloid osmotic pressure was 11.6 mm Hg, and further volume resuscitation was indicated. When severe hypoxemia in the face of maximal supplemental oxygen administration (P_aO_2/FiO_2 ratio = 65) was identified on arterial blood gas analysis, the dog was anesthetized and mechanical ventilation commenced. Mean arterial pressure (measured via an arterial catheter) dropped to 45 mm Hg, so a dopamine constant rate infusion was administered to maintain arterial blood pressure >65 mm Hg; a diagnosis of septic shock was made. Subsequently, diagnoses of DIC, hypoglycemia, ARDS, and MODS became apparent. The dog developed melena, and hemorrhagic fluid with a PCV of 15% appeared in the endotracheal tube. Despite additional colloid support with fresh frozen plasma and hetastarch, colloid osmotic pressure remained low and pitting edema of the distal limbs developed. Creatinine increased to 2.6 mg/dL, albumin dropped to 1.4 mg/dL, globulin to 1.3 g/dL, PCV to 22%, and liver enzyme activities increased (ALT 299 U/L, AST 408 U/L, ALP 617 U/L, total bilirubin 5.4 mg/dL). Ultimately, the dog became oliguric (urine output 0.35 mL/kg/hr). Furosemide and mannitol constant rate infusions had no effect to increase urine output. Because of the poor prognosis, euthanasia was elected.

Necropsy Findings: Gross necropsy findings included mucosal petechiations throughout the oral cavity, hemorrhagic nasal discharge, generalized icterus, subcutaneous edema, and 2 liters of cloudy, dark red fluid with floating fibrin strands within the abdomen. The spleen was enlarged and contained a large infarct (see Figure 86-4). A large infarct was also identified in one kidney, and there were multiple foci up to 5 mm in diameter throughout both kidneys. Multiple, slightly depressed, and nodular foci up to 1 cm in diameter were present on the surface of the liver and extended into the parenchyma. The mitral valve leaflets were thickened and rough, with thick fibrin clots adhering to their surfaces. Ecchymoses were present on the left ventricular wall. The lungs were diffusely wet, firm, and red and failed to collapse when the thorax was opened. They also contained multiple 2- to 4-mm tan foci. Histopathology revealed moderate chronic, active neutrophilic mitral valve endocarditis with a few gram-positive intralesional cocci; acute multifocal neutrophilic and necrotizing myocarditis; acute multifocal neutrophilic and necrotizing pneumonia with hemorrhage; acute diffuse alveolar septal necrosis with hemorrhage, fibrin, and hyaline membrane formation (ARDS); multifocal acute necrotizing and neutrophilic hepatitis, tubulointerstitial nephritis, and splenitis with thrombi and infarcts; hepatic congestion and bile stasis; and severe neutrophilic endophthalmitis with hypopyon. *Enterococcus* spp. and

Continued

VetBooks.ir

Acinetobacter spp. were cultured in enrichment broth from the heart valve.

Diagnosis: *Staphylococcus aureus* IE with septic shock.

Comments: This dog had mitral valve IE and widespread thromboembolic complications as a result of overwhelming *S. aureus* infection. Notably, a heart murmur was absent; echocardiography was performed when infarction was recognized on abdominal sonography. MODS with septic shock was present based on the diagnosis of sepsis (endocarditis with positive blood cultures and 4 of 4 SIRS criteria met) and dysfunction of the coagulation, hepatic, cardiovascular, and pulmonary systems. Aggressive treatment with broad-spectrum antimicrobial drugs, fluids, colloids, pressors, and mechanical ventilation was not successful despite the in vitro susceptibility of the *S. aureus* isolated. The significance of the *Enterococcus* spp. and *Acinetobacter* spp. isolated from the valve at necropsy is unclear; they may have represented contaminants or may have been present as part of a polymicrobial infection. The source of bacteremia and endocarditis was not apparent. The blood culture results became available the day the dog was euthanized.

CHAPTER 87

Bacterial Bronchopneumonia and Pyothorax

Jane E. Sykes

VetBooks.ir

Overview of Bacterial Tracheobronchitis and Bronchopneumonia Secondary to Invasion by Resident Bacteria

Causes: Frequently isolated secondary bacterial invaders in respiratory tract infections are *Escherichia coli, Pasteurella* spp., *Mycoplasma* spp., and anaerobes. *Pseudomonas* spp., *Staphylococcus* spp., and *Streptococcus* spp. may also be isolated.

Geographic Distribution: Worldwide

Mode of Transmission: Aspiration of gastrointestinal or oropharyngeal bacteria, opportunistic invasion of commensals as a result of impaired bronchopulmonary immune defenses

Major Clinical Signs: Lethargy, fever, cough, nasal discharge, tachypnea, respiratory distress, cyanosis, increased lung sounds (pneumonia)

Differential Diagnoses: Viral, protozoal, fungal, algal, or parasitic pneumonia; pneumonia caused by primary bacterial pathogens such as *Bordetella, Mycobacterium, Leptospira, Nocardia,* or *Yersinia;* aspiration pneumonitis (chemical injury); toxicity (e.g., paraquat); inflammatory lung diseases (e.g., eosinophilic bronchopneumopathy); pulmonary hemorrhage or edema; foreign body pneumonia; neoplasia

Human Health Significance: Multidrug-resistant bacteria that infect the lungs of dogs and cats may have the potential to colonize human patients, but this requires further study. Some primary bacterial causes of pneumonia in dogs and cats are directly zoonotic.

BACTERIAL TRACHEOBRONCHITIS AND BRONCHOPNEUMONIA

Etiology, Epidemiology, and Pathogenesis

Bacterial tracheobronchitis or bronchopneumonia may be acute or chronic and varies considerably in severity from subclinical through to fulminant and immediately life threatening. Infection of the airways and pulmonary parenchyma can occur secondary to (1) aspiration of gastrointestinal or oropharyngeal bacteria; (2) opportunistic invasion of commensal bacteria as a result of impaired bronchopulmonary immune defenses; (3) hematogenous spread of bacteria to the bronchopulmonary tree from extrapulmonary sites; or (4) aerosol or oronasal transmission of primary respiratory pathogens. Bronchitis and bronchopneumonia that result from invasion by commensal bacteria are the focus of this section. Organisms maintained in the environment (and/or in reservoir hosts) such as *Nocardia, Mycobacterium, Leptospira, Rickettsia rickettsii,* and *Yersinia* can also cause pneumonia in dogs or cats. The reader is referred to Chapters 30, 43, 44, 50 and 55 in Section 2 for more information on these infections. Information on *Bordetella, Mycoplasma,* and *Streptococcus* infections (as part of Canine Infectious Respiratory Disease Complex) is provided in Chapters 34, 38 and 40 in Section 2. *Bordetella, Mycoplasma* and some *Streptococcus* strains have the potential to be contagious pathogens that most often cause disease in young (or young adult) dogs and cats and those housed in overcrowded environments.

Many aerobic and anaerobic commensal bacterial species have been isolated from dogs and cats with opportunistic tracheobronchitis and bronchopneumonia (Figure 87-1 and Box 87-1).[1-13] The relative prevalence of each bacterial species may be affected by the underlying condition(s) that predisposes to bacterial invasion, the population of animals studied (see Figure 87-1), and the methods used to collect and culture specimens from the respiratory tract.

Aspiration Pneumonia

Secondary bacterial infection after aspiration of gastrointestinal or oropharyngeal contents is a common underlying reason for bacterial bronchopneumonia in adult dogs, but is rare in cats. Chemical damage to the lungs results from inhalation of acidic gastric fluid and particulate matter ("aspiration pneumonitis"). In some cases this is followed by development of bacterial bronchopneumonia. Conditions that predispose dogs to aspiration pneumonitis include brachycephalic obstructive syndrome; laryngeal paralysis, laryngeal surgery, or laryngeal foreign bodies; esophageal disorders such as megaesophagus, decreased esophageal motility, or esophageal foreign bodies; hiatal hernia; decreased mentation, seizures, or recumbency secondary to neurologic disease, sedation, or anesthesia; tracheostomy tube placement; vomiting; and swallowing disorders such as cricopharyngeal achalasia.[11,13-15] More than 30% of dogs in one study had more than one abnormality that predisposed to aspiration; the combination of esophageal and neurologic disease was most common.[11] In cats, most bacterial pneumonia follows viral infections or hematogenous spread of bacteria to the respiratory tract; aspiration pneumonia is rarely reported.[4,6,12] Aspiration pneumonia has been described rarely in association with dysautonomia[16] and arytenoid lateralization for treatment of laryngeal paralysis.[17] Systemic immune compromise can predispose to life-threatening bacterial infection after aspiration in both dogs and cats.

In a study of 47 dogs with aspiration that had airway lavage specimens cultured (primarily by transtracheal wash), 77% of specimens yielded bacterial organisms.[13] The most prevalent species was *Escherichia coli*. Other frequently isolated

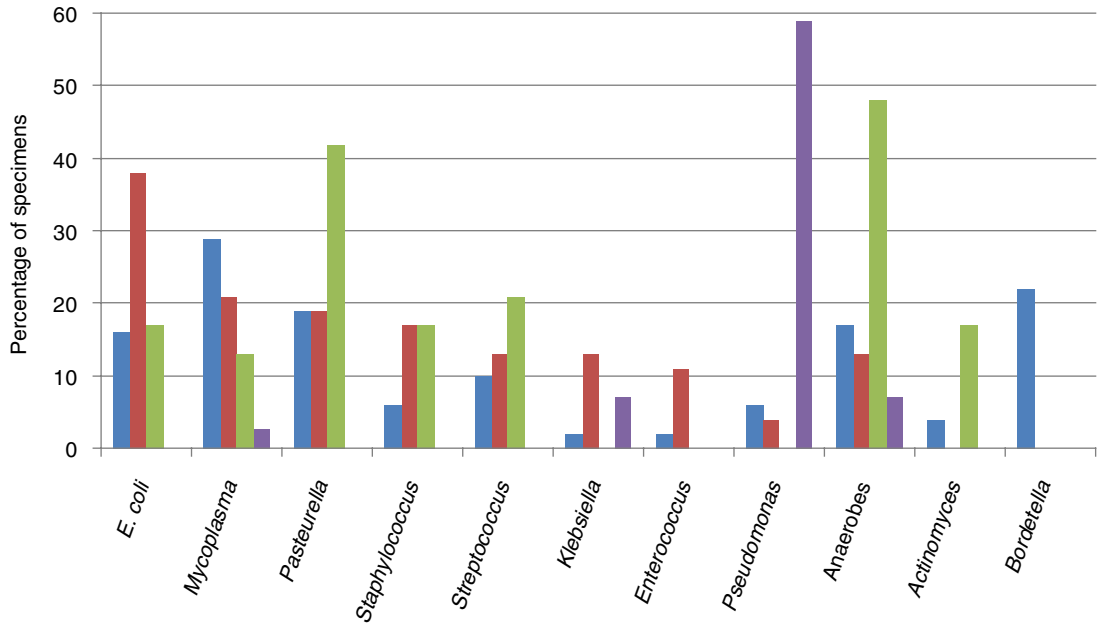

FIGURE 87-1 Prevalence of bacterial species isolated from respiratory lavage specimens from dogs with lower respiratory infection (BAL, blue), aspiration (transtracheal lavage or BAL, red), foreign body pneumonia (BAL, green), and dogs with bronchoscopically diagnosed tracheal collapse (BAL, purple). (Compiled from references 7, 9, 10, and 13.)

BOX 87-1

Bacteria That May Be Isolated from Cats with Lower Respiratory Tract Infection[1,3,4,12,37]

Mycoplasma spp.
Pasteurella spp.
Escherichia coli
Streptococcus spp. (especially *S. canis*)
Enterobacter spp.
Anaerobes (e.g., *Fusobacterium, Peptostreptococcus, Porphyromonas*)
Other gram-positive bacteria (e.g., *Staphylococcus* spp., *Enterococcus, Corynebacterium*)
Other gram-negative bacteria (e.g., *Pseudomonas, Acinetobacter, Klebsiella, Proteus, Bordetella bronchiseptica, Moraxella, Alcaligenes, Neisseria* spp.)

organisms from dogs with aspiration pneumonia were *Mycoplasma* spp., *Pasteurella* spp., *Staphylococcus* spp., *Klebsiella* spp., and *Enterococcus* spp.[13] Overall, gram-negative aerobes are more likely to be present than gram-positive aerobes in dogs with aspiration pneumonia. Anaerobes are also frequently isolated, and many dogs have mixed bacterial infections. Infections with *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, and *Corynebacterium* species such as *Corynebacterium ulcerans* have also been described.[13,18] Some of these infections may be acquired from the hospital environment.

Tracheobronchitis and Bronchopneumonia Secondary to Impaired Local Airway Defenses

Conditions that impair local airway defenses predispose to opportunistic invasion of the tracheobronchial tree and pulmonary parenchyma by commensal bacteria. These conditions include ciliary dyskinesia, viral infections (especially persistent viral infections such as canine distemper virus or feline calicivirus infection), tracheobronchial collapse, tracheal stent placement, eosinophilic bronchopneumopathy, airway foreign bodies or neoplasia, chronic bronchitis, and bronchiectasis.[5,7,9,12,18-21] Chronic bronchitis and bronchiectasis either may be sterile inflammatory processes that predispose to opportunistic bacterial invasion, or alternatively they occur secondary to chronic bacterial infections of the airways (e.g., as a result of chronic low-grade aspiration secondary to laryngeal paralysis). However, in many dogs with disorders such as tracheobronchial collapse, eosinophilic bronchopneumopathy, or chronic bronchitis, concurrent bacterial infection is not present.

In one study of dogs with tracheal collapse that underwent bronchoscopy and bronchoalveolar lavage (BAL), *Pseudomonas* was the most prevalent opportunistic bacterial species isolated (see Figure 87-1).[9] In contrast, *Pseudomonas* is an uncommon isolate from dogs with opportunistic lower respiratory infection.[10] In dogs with airway foreign bodies (usually grass awns), anaerobes, *Pasteurella*, gram-positive cocci, and *Actinomyces* predominate.[7]

Clinical Features

Signs and Physical Examination Findings

Dogs with bacterial bronchitis may have no clinical signs, or cough may be present. Other systemic signs such as fever, lethargy, or inappetence are usually absent. Involvement of the pulmonary parenchyma may be associated with more severe signs such as fever (as high as 107°F [41.6°C]), anorexia, lethargy, dehydration, weakness, weight loss, a moist and/or productive cough, serous to mucopurulent nasal discharge, tachypnea, tachycardia, respiratory distress, increased or harsh lung sounds on thoracic auscultation, crackles, wheezes, reduced lung sounds (due to lung consolidation), and/or cyanosis.[13,22] Some animals with pneumonia show no signs or only a few of these signs. Uncommonly, hemoptysis is reported.[23] Clinical signs of the underlying illness (such as

VetBooks.ir

vomiting, regurgitation, neurologic signs, or septic shock) may also be identified.[13]

Cats with bacterial bronchopneumonia may show only fever, lethargy, and/or inappetence. Respiratory signs, and especially cough, are often absent.[12]

Diagnosis

Bacterial bronchitis or bronchopneumonia is usually suspected based on a history of underlying predisposing conditions, clinical signs, and radiographic findings. Antemortem diagnosis of *infection* is most often based on cytologic examination in conjunction with culture and susceptibility of airway lavage specimens. Procedures for collection of airway lavage specimens include transtracheal wash, endotracheal wash, or BAL. Fine-needle aspiration of consolidated lung tissue may also be useful to rule out other disorders such as neoplasia or fungal pneumonia but carries some risk of iatrogenic pneumothorax.[4,24,25] The risk of pneumothorax may be reduced if ultrasound guidance is used. Assessment of laryngeal function (with doxapram stimulation) should be considered in any dog anesthetized for bronchoscopy and airway lavage. In some instances, the diagnosis of bacterial bronchopneumonia is made by histopathology and culture of a lung biopsy specimen collected during surgery or tissue specimens collected at necropsy.

Laboratory Abnormalities

Complete Blood Count, Serum Biochemistry Profile, and Urinalysis

Most dogs and cats with bacterial bronchopneumonia have leukocytosis due to a neutrophilia, often with bandemia and toxic neutrophil changes.[4,5,12,13,22] Leukopenia may also occur, but some animals have a normal leukogram. Anemia of inflammatory disease may also be present. The serum biochemistry profile and urinalysis can be unremarkable or may have changes that reflect the presence of concurrent systemic disease.

Arterial Blood Gas Analysis

Arterial blood gas analysis provides the most accurate assessment of oxygenation status in animals with bronchopneumonia. Hypoxemia (PaO_2 ≤80 mm Hg at sea level) can be detected in around 75% of dogs with aspiration pneumonia,[13,22] with a mean PaO_2 of 69 to 77 mm Hg.[5,13,22] Hypocapnia may also be present. The alveolar-arterial (A-a) oxygen gradient may be increased (up to 83 mm Hg with a median around 41 mm Hg; for room air, values >15 mm Hg indicate lung dysfunction).[13,22]

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with bacterial bronchitis may reveal a diffuse bronchial pattern and there may be evidence of underlying airway disease, such as tracheobronchial collapse or bronchiectasis. Plain thoracic radiographs are insensitive for diagnosis of bacterial bronchitis, and dogs with severe bronchitis can have normal findings.

Dogs with aspiration bronchopneumonia may have bronchointerstitial to alveolar changes in one or more lung lobes. Most often an alveolar pattern is present (Figure 87-2).[13,22] The most commonly affected lung lobe is the right middle lung lobe, and so a left lateral projection as well as right lateral and ventrodorsal projections in full inspiration are important to identify changes in this lobe. The left and right cranial lung lobes are also frequently affected.[13,22] Radiographic changes can lag behind the aspiration event for up to 24 hours. Clues to underlying causes of bronchopneumonia, such as megaesophagus or situs inversus (ciliary dyskinesia), may also be evident.

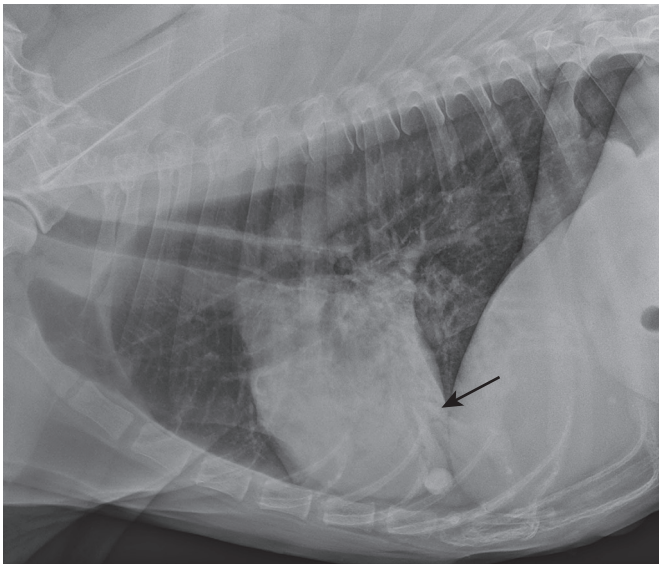

FIGURE 87-2 Left lateral thoracic radiograph from a 12-year-old male neutered German shepherd dog with a history of regurgitation, cough, and pyrexia. Air bronchograms (*arrow*) can be seen overlying the cardiac silhouette, which were less apparent on the right lateral view. The presence of an alveolar pattern in the ventral portions of the left and right cranial lung lobes in this dog was consistent with a diagnosis of aspiration pneumonia. Air is also visible in the esophagus.

Dogs and cats with plant awn pneumonia may have a focal interstitial to alveolar pattern that tends to involve the caudal and accessory lung lobes, and to a lesser extent the right middle and left and right cranial lung lobes.[26] Less often, pneumothorax, consolidation of affected lung lobes, and/or pleural effusion (see Pyothorax) are identified.

Advanced Imaging

Because of increased sensitivity over plain radiography, computed tomography (CT) may be useful to evaluate the airways and pulmonary parenchyma when thoracic radiographs are unremarkable or underlying plant awn pneumonia is suspected. Airway thickening and bronchiectasis may be evident in dogs with bronchitis. Focal interstitial to alveolar pulmonary opacities and pleural thickening are the most common finding in animals with migrating plant foreign bodies; other findings include pneumothorax and/or pneumomediastinum, mild enlargement and contrast enhancement of thoracic lymph nodes, lung lobe opacification, mediastinal or thoracic wall masses, and/or pleural effusion (Figure 87-3).[26] CT may be useful to guide subsequent bronchoscopy and BAL fluid collection for animals with focal bronchopneumonia.

Bronchoscopy

On bronchoscopic examination, dogs and cats with bacterial bronchitis or bronchopneumonia may have edematous and hyperemic airways, accumulation of mucus or mucopurulent secretions, and/or mucosal irregularity.[5,6] Other findings include airway collapse, airway stenosis, and bronchiectasis. Foreign bodies such as plant awns may be identified and removed (see Figure 87-3, *B*);[7] if not, identification and localization of a focal accumulation of pus in an airway may direct subsequent surgical removal of a lobe affected by a migrating plant awn.

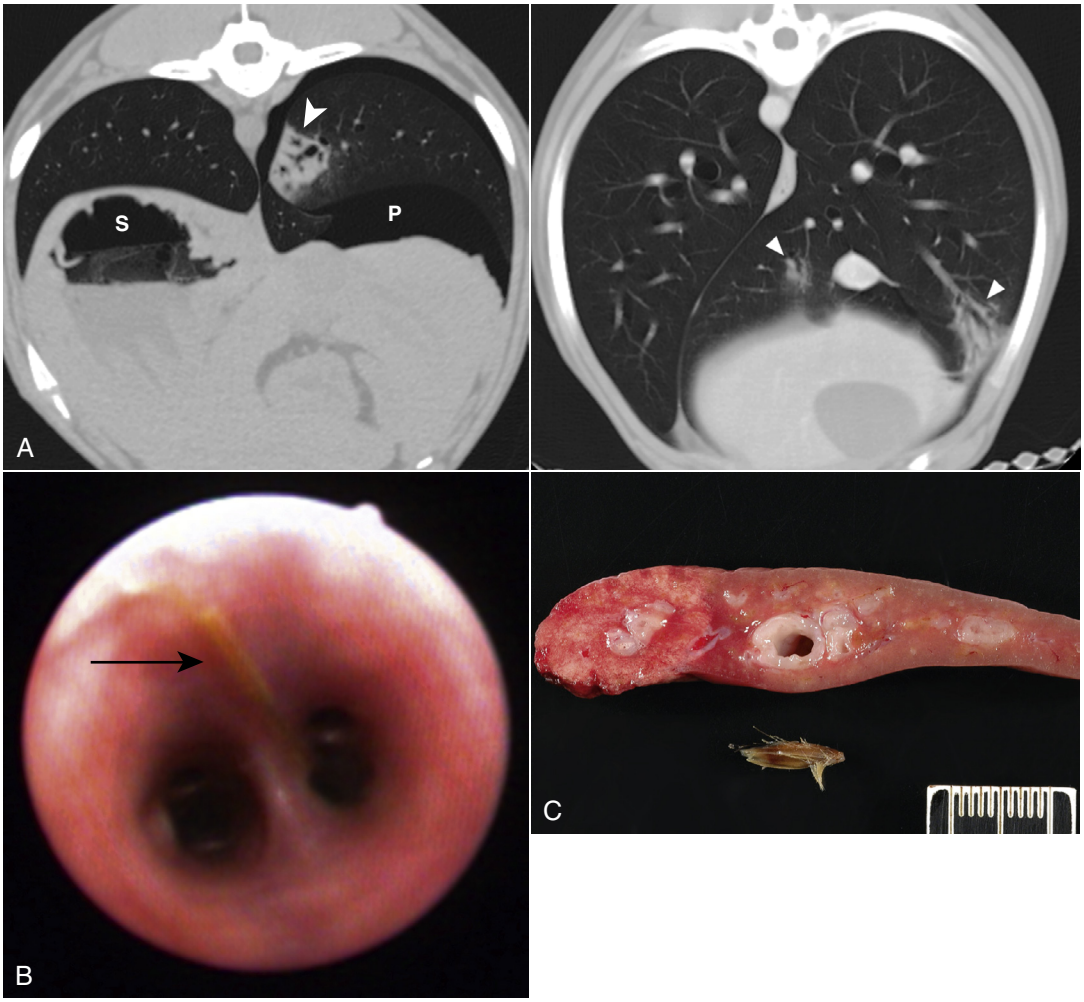

FIGURE 87-3 Migrating plant awn foreign bodies. **A,** CT scan images from a 1-year-old female spayed German shorthaired pointer dog. Pneumothorax (*left*, *P*) and multifocal pulmonary opacities (*white arrowheads*) are present (*S* = stomach). **B,** Bronchoscopic image showing a plant awn in a bronchus of a 2-year-old male neutered Belgian Malinois. **C,** Portion of the right middle lung lobe of a 2-year-old female spayed Labrador retriever, which was removed during thoracotomy. A 1-cm plant awn was removed from a pocket of mucoid material within a bronchus. (**C,** Image courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

Microbiologic Tests

Cytologic Examination

Cytologic examination of airway lavage specimens or fine-needle aspirates of the lung in dogs and cats with bacterial bronchopneumonia usually reveals a mixed inflammatory response with a predominance of neutrophils. The presence of degenerate neutrophils should increase suspicion for bacterial infection. In some animals, one or more bacterial populations may be seen intracellularly and extracellularly, but culture is considerably more sensitive than cytologic examination for detection of bacteria in airway lavage specimens.

Culture

Ideally, airway lavage specimens should be collected and submitted for aerobic, anaerobic, and *Mycoplasma* cultures before treatment with antimicrobial drugs is commenced, although this may not be feasible if severe respiratory compromise is present. The need for anaerobic cultures is controversial because anaerobes are difficult to isolate and tend to have predictable susceptibilities. Anaerobes are most likely to be present in dogs with aspiration pneumonia or grass awn foreign bodies. *Mycoplasma* species may also be difficult to isolate (see Chapter 40). False-negative culture results can also occur if low numbers of bacteria are present, if the specimen is small, fastidious organisms are present, or if antimicrobial drugs have recently been administered.

Because a variety of gram-positive and gram-negative bacteria as well as *Mycoplasma* spp. can be found in low numbers in the lower respiratory tracts of healthy dogs and cats,[3,27-29] a positive culture on a respiratory lavage specimen alone is not diagnostic for bacterial bronchitis or bronchopneumonia. However, a positive culture in conjunction with cytologic evidence of leukocytosis with intracellular bacteria supports the presence of infection. When quantitative bacterial cultures on BAL fluid can be performed, it has been suggested that growth greater than 1.7×10^3 CFU/mL is likely to be clinically significant.[5] BAL is more likely to identify clinically significant bacteria, but collection of specimens by transtracheal wash is sufficient if diffuse disease is present and bronchoscopy is not available or not affordable.[30] Care should be taken not to overinterpret the significance of few organisms, or minimally pathogenic organisms (e.g., *Bacillus* spp. or coagulase-negative staphylococci) that may represent airway contaminants.

Some animals with bacterial pneumonia may have positive blood cultures. If airway lavage is not possible because of severe respiratory compromise, blood cultures should be considered in

order to obtain information about the identity and susceptibility of bacteria involved. Further study is required to determine the sensitivity and specificity of blood culture for diagnosis of bacterial pneumonia in dogs or cats.

Pathologic Findings

The lung lobes of animals with bacterial bronchopneumonia may be diffusely mottled red or dark pink, firm, and ooze fluid on cut section. The airway mucosa also may be diffusely reddened, with evidence of mucus accumulation. Intraluminal food accumulation may be present in animals with acute aspiration pneumonia. Evidence of predisposing causes such as neoplasia, plant material, or bronchiectasis may be present. Histopathology most often reveals focal, multifocal, or diffuse suppurative and necrotizing inflammation, sometimes with intralesional bacteria. In chronic infections, histiocytic infiltrates may be present.

Treatment and Prognosis

Antimicrobial Drugs

Selection of antimicrobial drugs for treatment of secondary bacterial tracheobronchitis and bronchopneumonia in dogs and cats should ideally be based on the results of culture and susceptibility testing. For dogs with secondary bacterial tracheobronchitis, treatment should be withheld until the results are available, or empiric treatment with doxycycline (first choice) or amoxicillin–clavulanic acid (second choice) is suggested (Table 87-1). Amoxicillin–clavulanic acid is not active against *Mycoplasma*, so if *Mycoplasma* infection is suspected, doxycycline is a more appropriate choice. The optimal duration of treatment is unknown, but if a clinical response to treatment occurs in the first 7 to 10 days, treatment could be continued for a week beyond resolution of clinical signs.[30]

Animals with severe bronchopneumonia may require hospitalization and parenteral treatment with broad-spectrum antimicrobial drugs such as a combination of a fluoroquinolone and a β-lactam (ampicillin, ampicillin-sulbactam) or clindamycin (Table 87-2). Clindamycin may be a good choice if lung consolidation is present and/or anaerobes are suspected, because of its good tissue penetration, although some anaerobes and *Pasteurella* are resistant to clindamycin. If fluoroquinolone resistance is likely based on the regional prevalence of bacterial resistance, drugs other than a fluoroquinolone with activity against gram-negative bacteria may be indicated based on culture and susceptibility test results or the regional prevalence of bacterial resistance. Examples include aminoglycosides, third-generation cephalosporines, carbapenems such as meropenem, or ticarcillin–clavulanic acid. The spectrum of antimicrobial activity should be narrowed once the results of culture and susceptibility are available.

The optimum duration of treatment requires further study. Traditionally, at least 4 weeks of treatment have been recommended for lower respiratory infections, or for at least 1 week after radiographic resolution of pulmonary lesions. Shorter periods of treatment are used in human patients and may also be effective in dogs and cats.

Surgery

In some cases, surgery is required to remove abscessed lung lobes that fail to improve with medical therapy, or plant awn foreign bodies that cannot be retrieved using bronchoscopy.[7]

TABLE 87-1

Antimicrobial Drugs That May Be Useful to Treat Secondary Bacterial Tracheobronchitis in Dogs

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Doxycycline	5	PO	12	1 week beyond resolution of signs
Amoxicillin-clavulanic acid	22	PO	12	1 week beyond resolution of signs

TABLE 87-2

Suggested Empiric Antimicrobial Drug Choices for IV Use in Dogs or Cats with Bacterial Bronchopneumonia Pending the Results of Culture and Susceptibility*

Drug	Dose (mg/kg)	Route	Interval (hours)
Ampicillin *or*	20	IV	6
Ampicillin-sulbactam† *or*	20	IV	8
Clindamycin phosphate *and*	10	IV	12*
Enrofloxacin‡	5-10 (dogs)	IV	24

*Spectrum should be reduced once the results of culture and susceptibility are available.
†Dose based on ampicillin component.
‡Other fluoroquinolones such as pradofloxacin (which also has activity against anaerobes) should be considered for treatment of cats because of the risk for retinal toxicity in this species, although parenteral formulations are not available. Other drugs with activity against gram-negative bacteria (e.g., meropenem, third-generation cephalosporines, aminoglycosides) could also be considered for parenteral treatment of cats or if the regional prevalence of fluoroquinolone resistance is high. See also Chapter 86.

The development of pneumothorax in association with migrating foreign bodies may also be an indication for surgical intervention.

Supportive Care

Other supportive treatments that may be needed for dogs and cats with severe bronchopneumonia include supplemental humidified oxygen, intravenous fluid therapy, nebulization, and coupage to aid in the mobilization of secretions. Animals that are hypoventilating or that fail to respond to supplemental oxygen therapy may require mechanical ventilation.

Prognosis

The survival rate to discharge for aspiration pneumonia in one study was 77%,[11] with a mean duration of hospitalization of 5 days

VetBooks.ir

(range, 1 to 23 days). In one study of dogs with aspiration pneumonia, dogs with two or more affected lung lobes had a worse outcome than dogs with single lung lobe involvement.[13] However, in another study, there was no correlation between radiographic findings and survival.[11] No correlation has been found between survival and the identity of bacterial species present, the number of bacterial species present, the underlying cause of aspiration, or the presence of multiple underlying causes of aspiration.[11,13] Identification and management of the underlying cause, when possible, is critical to prevent recurrence.

Prevention

Prevention of bacterial bronchitis and bronchopneumonia relies on identification and management of underlying causes. Aspiration pneumonia can be prevented by fasting before sedation or anesthesia and proper use of cuffed endotracheal tubes for anesthesia. Upright feeding may be used in an attempt to prevent recurrent aspiration for dogs with laryngeal and esophageal disorders, but the extent to which upright feeding prevents aspiration in these conditions is not known. Antiemetics should be administered to control vomiting in patients that are vomiting secondary to underlying disorders such as pancreatitis or uremia. If a feeding tube is in place, care should be taken to minimize the chance of vomiting and aspiration by slow, frequent feeding of small amounts of food that do not overwhelm gastric capacity. Prophylactic antimicrobial drugs are not recommended because they may predispose dogs to infection by drug-resistant bacteria.

Public Health Aspects

Multidrug-resistant bacteria can be isolated from the airways of some dogs with opportunistic bronchitis and bronchopneumonia.[18] Whether these organisms can colonize humans has not been clearly established. Some causes of pneumonia in dogs or cats, such as *Pasteurella* species, *B. bronchiseptica, Streptococcus equi* subsp. *zooepidemicus, Mycobacterium tuberculosis,* and *Capnocytophaga* and *Yersinia* species are potentially zoonotic pathogens, and immunocompromised humans may be at higher risk for development of infection or serious illness. As for every patient, routine precautions such as hand washing should be used before and after handling dogs and cats with suspected bacterial bronchopneumonia. Dogs with bronchopneumonia should not be allowed to lick in-contact humans.

PYOTHORAX

Etiology, Epidemiology, and Pathogenesis

Pyothorax is defined as the presence of pus within the pleural space. Multiple underlying conditions lead to pyothorax in dogs and cats. These include penetrating injuries to the thoracic wall (such as bite wounds or migrating plant awns), esophageal perforation, or spread of infection from the lungs to the pleural space secondary to rupture of lung abscesses or necrotic pulmonary neoplasia. Rarely, pyothorax occurs secondary to aspiration pneumonia.[31,32] Pathogens may also spread hematogenously to the pleural space as part of a disseminated infection. In many animals with pyothorax, the underlying cause or route of bacterial entry is not clear.

Overview of Bacterial Pyothorax

Causes: Primarily anaerobic bacteria and *Pasteurella* species in cats; anaerobes, aerobic gram-negative enteric bacteria, and *Pasteurella* in dogs. Other bacterial species are involved less commonly.

Geographic Distribution: Worldwide

Mode of Transmission: Traumatic inoculation of bacteria into the pleural space (e.g., bite wounds, foreign bodies), spread from sites of pneumonia (e.g., rupture of lung abscesses), hematogenous spread

Major Clinical Signs: Lethargy, fever, inappetence, tachypnea, rapid and shallow respiratory pattern, decreased lung and heart sounds. Hypothermia, bradycardia, and hypersalivation may be identified in cats.

Differential Diagnoses: Chylothorax, hemothorax, neoplasia, fungal pyothorax (e.g., *Aspergillus, Candida, Cryptococcus*), feline infectious peritonitis (cats), congestive heart failure

Human Health Significance: Bacteria that cause pyothorax are typically commensal organisms found in the oral cavities of healthy cats and dogs.

Pyothorax in Cats

Pyothorax is a common cause of pleural effusion in cats.[33] Cats with pyothorax are usually FeLV and FIV negative and tend to be young to middle-aged adults with outdoor exposure, although cats of any age may be affected.[31,33-35] There is no sex or breed predisposition,[31,35] but residence in a multicat household may increase the risk for pyothorax.[35] In some cats, pyothorax develops after puncture or bite wounds to the thorax or when plant foreign bodies are inhaled or penetrate the thorax.[31,35] However, other cats that develop pyothorax are housed indoors and have no history of exposure to other cats. Ruptured lung abscesses have been identified in some cats.[33,35,36] Occasionally, migrating parasites (*Cuterebra, Aelurostrongylus, Toxocara*) are detected in the lungs of affected cats.[31,35] Other cats have a history of upper respiratory tract infection.[1,3,4,12,37] It has been suggested that pyothorax in these cats occurs secondary to bronchopneumonia.[31]

Oropharyngeal bacterial species, primarily a mixture of anaerobic bacterial species and/or *Pasteurella*, are most often isolated from pleural fluid (Table 87-3).[33-35,38,39] A mixture of anaerobic and facultative bacteria is isolated from over 40% of affected cats.[38]

Pyothorax in Dogs

In dogs, bacterial pyothorax develops secondary to penetrating thoracic wall trauma, migrating grass awn foreign bodies, esophageal perforation, or bite wounds. Young adult, medium to large-breed dogs (especially spaniels, pointers, retrievers, and Border collies) with outdoor exposure are most often affected, but the disease can occur in dogs of any age or breed.[32,34,38,40,41] In some studies, male dogs slightly outnumber female dogs. Obligate anaerobes and gram-negative enterics such as *E. coli* and *Klebsiella pneumoniae* are often isolated, with mixed anaerobic-aerobic infections in at least one third of affected dogs.[32,38,41] Other frequently isolated bacteria include *Actinomyces, Streptococcus canis, Pasteurella,* and *Nocardia*.[32,34,38,37] Less often, other bacterial species are isolated (see Table 87-3).[32,34,38,41,42] Obligate

VetBooks.ir

TABLE 87-3

Bacterial Causes of Pyothorax in Dogs and Cats

Prevalence*	Cats	Dogs
Common (>75% of cases)	*Pasteurella multocida* Obligate anaerobes (*Peptostreptococcus*, *Bacteroides*, *Fusobacterium*, *Porphyromonas*, *Prevotella*, *Filifactor villosus*, and *Clostridium*)	Obligate anaerobes Enterobacteriaceae (especially *E. coli*, *Klebsiella pneumoniae*)
Occasional (25%-75% of cases)	*Actinomyces* spp. *Streptococcus* spp. *Mycoplasma* spp.	*Pasteurella* spp. *Actinomyces* spp. *Streptococcus canis* *Nocardia* spp.
Uncommon to rare (<25% of cases)	*Staphylococcus* spp. Gram-negative bacteria other than *Pasteurella* *Nocardia* spp. *Rhodococcus equi*	*Mycoplasma* spp. *Staphylococcus* spp. *Enterococcus* spp. *Corynebacterium* spp. *Bacillus* spp. *Enterobacter* spp. *Arcanobacterium pyogenes* *Acinetobacter* spp. *Capnocytophaga* spp. *Kluyvera* spp. *Stenotrophomonas maltophilia* *Aeromonas hydrophila* *Achromobacter xylosoxidans* *Serratia marcescens* *Pseudomonas* spp. *Listeria monocytogenes*

*Percentages are approximate, because prevalences of bacteria listed in the occasional and uncommon groups vary between studies.

anaerobes, *Actinomyces* spp., and *Streptococcus canis* infections may be more prevalent where grass awn exposure is common.

Clinical Features

The severity and duration of clinical signs in cats and dogs with pyothorax are extremely variable. Illness durations of months to up to a year can occur, with a median duration of 14 days.[34] Cats can be found dead within 24 hours of having a normal appetite and activity level.[43] Systemic signs of illness are common and include fever, lethargy, weakness, inappetence, weight loss, and/or dehydration.[31,32,34,35,41,42] Clinical signs referable to the respiratory tract include tachypnea with a rapid and shallow respiratory pattern and orthopnea. Physical examination may also reveal decreased lung sounds on auscultation of the ventral thorax, and muffled heart sounds.[31,34,42] Less often, cough or hemoptysis occurs.[33,34] Vomiting and diarrhea occur in a minority of affected dogs,[41] and vomiting, hypersalivation, halitosis, and/or oculonasal discharge may be present in cats.[31,35,39] Cats with severe sepsis may have mucosal pallor and be obtunded, bradycardic, and hypothermic with poor pulse quality.[35,36]

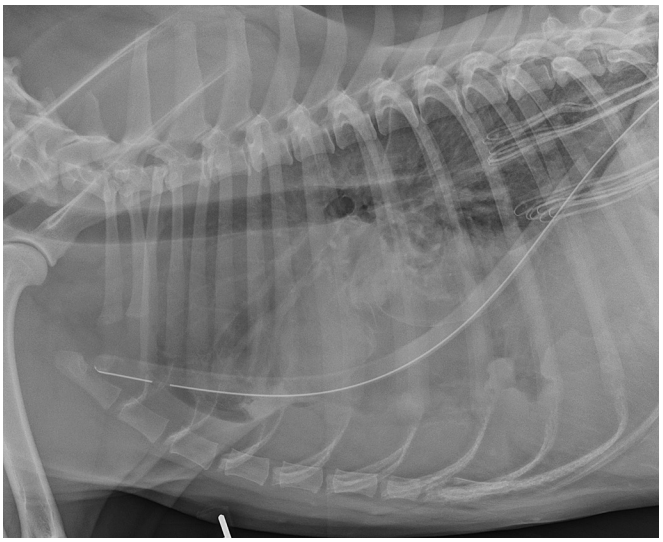

FIGURE 87-4 Lateral thoracic radiograph from a 3-year-old female spayed Labrador retriever mix with pyothorax. A right-sided thoracostomy tube had been placed on an emergency basis. The cardiac silhouette is obscured by the presence of exudate. Cytology of the fluid revealed a mixed bacterial population.

Diagnosis

Diagnosis of pyothorax is based on radiographic findings and gross and cytologic examination of pleural fluid. Imaging may be useful to identify underlying causes such as lung abscessation or esophageal perforation. Culture and susceptibility of the pleural fluid permits identification of the bacteria involved and can guide antimicrobial drug treatment.

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, Urinalysis

Most dogs and cats with pyothorax have mild to marked leukocytosis with increased numbers of toxic band neutrophils and sometimes a degenerative left shift or metamyelocytes on the CBC.[31,34,35,37,42] The CBC may also be unremarkable. Nonregenerative anemia may be present,[31,34] and animals with severe sepsis and disseminated intravascular coagulation may be thrombocytopenic. The serum biochemistry panel may reveal electrolyte abnormalities such as hyponatremia or hypochloremia, as well as hypoalbuminemia and/or hyperglobulinemia. Mild hyperbilirubinemia can be present in cats.[35] Serum creatine kinase activity may be increased if pyothorax is secondary to trauma to the thoracic wall.

Diagnostic Imaging

Plain Radiography

Findings on plain thoracic radiography in dogs and cats with pyothorax include mild to severe pleural effusion and mass lesions in the pleural space or pulmonary parenchyma (Figure 87-4). Most (>75%) of affected cats and dogs have bilateral effusion, but unilateral effusions also occur.[31,32,34,35,41] Sternal or tracheobronchial lymphadenomegaly may also be evident. In dogs, tracheobronchial lymphadenomegaly may be severe when *Actinomyces*, *Nocardia*, or filamentous fungi such as *Aspergillus* spp. are present.

VetBooks.ir

Sonographic Findings

Thoracic ultrasound of dogs and cats with pyothorax can reveal the presence of echogenic pleural fluid, fibrinous tags adhered to pleural surfaces, pericardial thickening and effusion, consolidated lung lobes, and lung lobe abscessation.[35,41] Occasionally, plant awn foreign bodies are identified in the thoracic wall.[26,44]

Advanced Imaging

CT may be more sensitive than plain radiography for identification of pulmonary mass lesions and esophageal disease and can raise suspicion for the presence of plant awn foreign bodies,[26] and so can assist in surgical decision making. Findings in dogs and cats with pyothorax include unilateral or bilateral pleural effusion, gas within the pleural space secondary to thoracocentesis or foreign body migration, pleural thickening, and focal, single, or multiple soft tissue opacities within the pulmonary parenchyma.[40,43] Mediastinal lymphadenomegaly may also be identified (Figure 87-5). The presence of foreign material may be suspected based on the results of CT, although CT is insensitive for detection of plant foreign bodies. Findings on CT in dogs with pyothorax correlate well with surgical findings, although CT is probably more sensitive for detection of abnormalities within the lung parenchyma.[40]

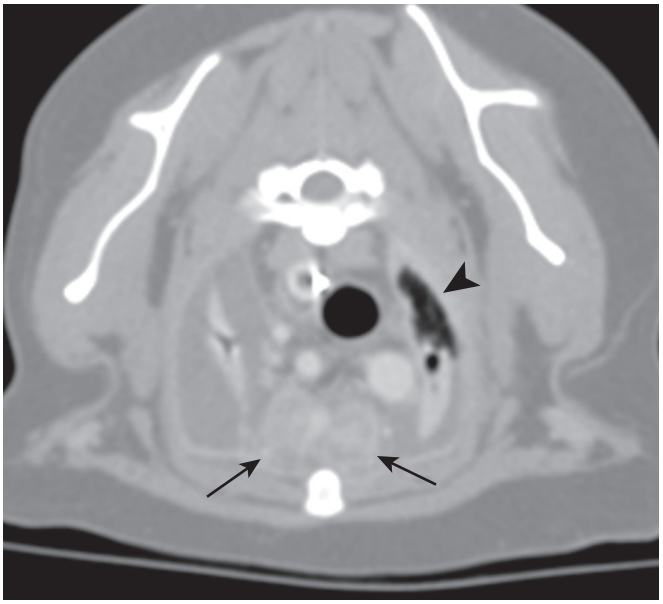

FIGURE 87-5 Thoracic post contrast CT scan image from a 5-year-old male neutered, indoor-outdoor domestic shorthair cat that was evaluated for pyothorax. The cat was hypoventilating after placement of a thoracostomy tube, and mechanical ventilation was required. Culture revealed clindamycin-resistant *Pasteurella multocida*, small numbers of coagulase-negative staphylococci, an *Actinomyces*-like organism, and abundant mixed anaerobic growth that included *Fusobacterium* and β-lactamase–producing *Bacteroides/Prevotella*. Serial thoracic radiographs showed progressive lung lobe consolidation and persistent pleural effusion. The CT scan showed persistent pleural effusion and collapse of the cranial and caudal portion of the left cranial lung lobe, right middle lung lobe, and accessory lung lobe. Three large nodules were present in the ventrocranial thorax that enhanced heterogeneously with contrast; these were interpreted to be enlarged lymph nodes. Two of the nodules are shown (*arrows*), and a small portion of the right cranial lung lobe is aerated (*arrowhead*). Two long plant awns were removed from the mediastinum during exploratory thoracotomy. The thorax was debrided and lavaged and the severely consolidated caudal portion of the left lung lobe was resected. The cat recovered fully.

Microbiologic Tests

Cytologic Examination

Thoracocentesis typically yields fluid that is purulent, flocculent, and/or hemorrhagic; it may also have a fetid odor due to the presence of anaerobes. Sulfur granules may be grossly visible within the fluid if *Actinomyces* or *Nocardia* are present. Cytologic examination of the fluid shows large numbers of leukocytes, most often with a predominance of degenerate neutrophils.[34] Erythrocytes and histiocytes may also be present. Bacteria are visualized in approximately 80% of pleural fluid specimens, either as a mixture of rods, cocci, and filamentous organisms or as a monomorphic bacterial population (Figure 87-6; see also Figure 37-6).[31,34]

Culture

Pleural fluid should be submitted for Gram staining and aerobic and anaerobic bacterial culture and susceptibility. Because *Mycoplasma* spp. can be isolated from dogs and cats with pyothorax, specific culture for *Mycoplasma* spp. could also be considered. Although the sensitivity of effusion culture in dogs and cats with pyothorax is generally high (>69%),[32,34,35] false negatives can occur as a result of recent antibiotic treatment or the presence of fastidious bacteria such as anaerobes and *Mycoplasma*. Because isolation of *Nocardia* and *Actinomyces* can require prolonged incubation and specialized growth conditions, the laboratory should be alerted that these organisms may be present.

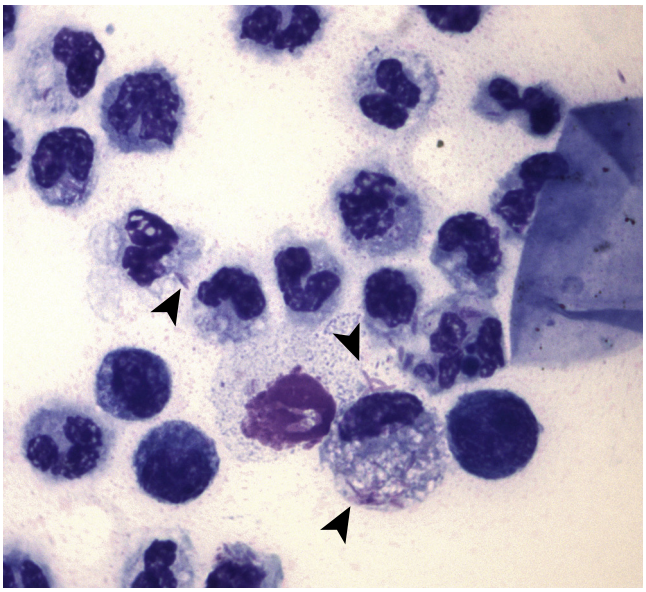

FIGURE 87-6 Cytology of pleural effusion from a 3-year-old male neutered domestic shorthair with pyothorax. There are many variably karyolytic neutrophils. Many contain bacterial rods, which can also be seen extracellularly (*arrowheads*). Anaerobic bacterial culture yielded *Fusobacterium russii*. Aerobic culture was negative.

Pathologic Findings

Gross findings in dogs and cats with pyothorax consist of variable quantities of hemorrhagic to purulent fluid within the thoracic cavity, enlarged thoracic lymph nodes, pleural thickening and irregularity, and mottled and consolidated lung lobes. Plant foreign bodies or lung abscesses may be found. The pleural fluid may contain sulfur granules or fibrinous material (Figure 87-7). Histopathology reveals a fibrinonecrotic to pyogranulomatous inflammatory response in the pleura and sometimes also the mediastinum, pericardium, and/or lungs. Intralesional bacteria may be seen.

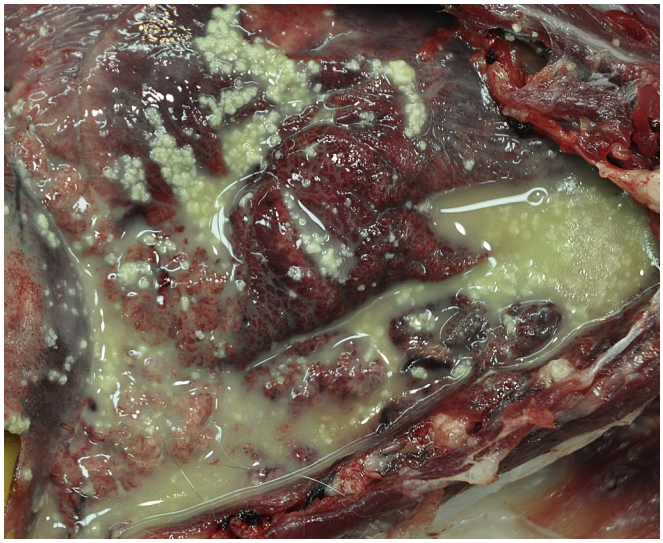

FIGURE 87-7 Thoracic contents of a 5-year-old male neutered domestic shorthair with pyothorax at necropsy. The cat had a 5-day history of progressive inappetence, weakness, and vomiting and on physical examination was stuporous, hypothermic, and in respiratory distress. Creamy white to yellow fluid was present in the thoracic cavity that contains gritty white flecks of material (sulfur granules). The fluid was malodorous. Culture of the fluid yielded *Bacteroides fragilis*, an anaerobic gram-positive rod, and an *Actinomyces* species. (Image courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

Treatment and Prognosis

Treatment of pyothorax involves a combination of drainage of pus from the thoracic cavity (with or without lavage), combined with targeted antimicrobial drug therapy and supportive care.

Drainage and Lavage

Treatment of pyothorax with antimicrobial drugs alone is generally ineffective, and drainage is required to facilitate drug penetration. This is most often accomplished by unilateral or bilateral placement of indwelling thoracostomy tubes followed by continuous or intermittent suction. Suction is generally continued until cytologic and microbiologic evidence of infection resolves in the pleural fluid. This may take from days to up to 3 weeks, with a median duration of approximately 5 to 7 days.[31,32,34,35] While the thoracostomy tubes are in place, lavage may be performed through the tubes with warm isotonic saline (e.g., 10 to 20 mL/kg administered over 5 to 10 min). The frequency of intrapleural lavage has ranged from q5h to q24h.[31,32,34] Currently, there is no clear evidence that lavage influences outcome in animals with pyothorax, or that instillation of heparin or antimicrobial drugs into the pleural space influences outcome. Ultrasound-guided drainage via a single, unilateral thoracocentesis without lavage has been successful when the pleural effusion is not excessively thick or granular.[37] Exploratory thoracotomy and resection of affected tissues may be required after initial stabilization if there is extensive fibrous tissue formation, pulmonary parenchymal abscessation, known or suspected presence of a foreign body, esophageal perforation, large accumulations of inspissated purulent material that obstructs drainage, or failure to respond to medical therapy.[34,41] Surgical treatment in both dogs and cats has been associated with improved outcomes when compared with medical treatment alone.[35,41] However, thoracotomy is associated with increased cost and length of hospital stay, pain, and anesthetic risk, so it is generally reserved for those animals in which medical management with thoracostomy tube drainage is failing or likely to fail.

Antimicrobial Drug Therapy

Parenteral administration of antimicrobial drugs with activity against *Pasteurella*, *Actinomyces*, and anaerobes is indicated. Ampicillin-sulbactam may be sufficient in most cats. Addition of a fluoroquinolone could be considered in dogs (where gram-negative enteric species such as *E. coli* are more likely to be present), or when the possibility of *Mycoplasma* spp. infection exists. Ampicillin alone or clindamycin may be effective, but some anaerobes are resistant to ampicillin and clindamycin and some *Pasteurella* isolates are clindamycin resistant. Antibiotic choice should then be tailored to the organism(s) present based on culture and susceptibility. If combination therapy was initiated and the bacterial isolates are susceptible to both drugs, the fluoroquinolone should be discontinued. If organisms are grown that are resistant to one of the drugs, that antimicrobial should be discontinued. Drugs that are inactivated by purulent material, such as trimethoprim-sulfamethoxazole, should be avoided. Oral antimicrobial therapy is continued after the animal leaves the hospital.

The optimal duration of treatment for pyothorax is not known and may depend on the severity and chronicity of the disease. Most animals are treated for a minimum of 3 weeks. Serial thoracic radiographs may be useful to determine whether antimicrobial drug treatment should be continued, but whether persistent radiographic abnormalities correlate with the need for additional antimicrobial drug treatment requires further study. If the pyothorax persists or reoccurs after cessation of antibiotic treatment, pleural fluid should again be submitted for culture and susceptibility testing, because the organism(s) involved may change.

Supportive Care

Intravenous fluid therapy and oxygen supplementation is frequently required in the initial stages of management of pyothorax. Early placement of a feeding tube should also be considered if inappetence is present. Rarely, mechanical ventilation is required.

Prognosis

The first 48 hours of hospitalization is the most critical period for dogs and cats with pyothorax.[34,35] Thereafter, prognosis improves considerably.

In general, the prognosis for recovery in dogs with pyothorax is fair to good. Short-term (survival to discharge) and long-term survival rates of 74% and 63% have been reported.[32] Death usually results from complications related to respiratory function or septic shock. The bacterial species present and volume of pleural effusion do not seem to affect survival.[32] In a minority of dogs (≤20%), recurrence of pyothorax occurs for up to 5 years, but most often, months after discharge from the hospital.

The survival rate for cats with pyothorax in one study was 48%; 18% of cats died and 34% were euthanized.[35] The presence of hypersalivation or bradycardia were negative prognostic signs.[35] Serum cholesterol concentration and total white cell counts were significantly lower in cats that died. In another study, 78% of cats were treated successfully, although long-term follow-up was not available.[31]

Prevention

Housing cats indoors and restricting access of dogs and cats to areas where plant awns are abundant may help to prevent pyothorax.

VetBooks.ir

CASE EXAMPLE

Signalment: "Frank", a 3-year-old male neutered domestic shorthair cat from Woodland, CA, was presented for acute onset of respiratory distress of approximately 30 minutes duration. Frank was a barn cat and was outdoors with more than 20 other barn cats. Also on the property were five dogs, horses, and cattle. Other cats in the barn had previously been attacked by "wild animals" and had been diagnosed with a variety of injuries that included abscesses and septic peritonitis. There was no previous medical history and Frank was up to date on routine feline vaccinations (feline herpesvirus-1, calicivirus, panleukopenia virus, rabies and FeLV).

Physical Examination:

Body Weight: 5.6 kg.

General: Obtunded, but ambulatory, dehydrated. T = 103.7°F (39.8°C), HR = 140 beats/min, panting. Mucous membranes were pale pink, CRT = 2 s.

Integument: Some flea excrement was present.

Eyes, Ears, Nose, and Throat: Mild gingivitis was present with halitosis and hypersalivation. No other clinically significant abnormalities were detected.

Musculoskeletal: Body condition score was 4/9.

Cardiovascular: No murmurs or arrhythmias were detected, and pulses were strong and synchronous.

Respiratory: Respiratory difficulty with open mouth breathing was noted. Lung sounds were dull ventrally on auscultation of both sides of the thorax.

All Other Systems: No clinically significant abnormalities.

Laboratory Findings:

Venous Blood Gas: pH 7.273, pCO_2 37.9 mm Hg, pO_2 40.9 mm Hg, base deficit/base excess −8.6 mmol/L, bicarbonate 16.8 mm Hg, ionized calcium 1.3 mmol/L, lactate 4.4 mmol/L, PCV 26%, total plasma protein 6.7 g/dL.

CBC:

HCT 29.8% (30%-50%)
MCV 43.4 fL (42-53 fL)
MCHC 32.2 g/dL (30-33.5 g/dL)
Reticulocytes 15,200 cells/µL
WBC 16,650 cells/µL (4500-14,000 cells/µL)
Neutrophils 4995 cells/µL (2000-9000 cells/µL)
Band neutrophils 7992 cells/µL
Lymphocytes 3497 cells/µL (1000-7000 cells/µL)
Monocytes 167 cells/µL (50-600 cells/µL)
Eosinophils 0 cells/µL (150-1100 cells/µL)
Platelets 345,000/µL (180,000-500,000 platelets/µL)

Serum Chemistry Profile:

Sodium 153 mmol/L (151-158 mmol/L)
Potassium 4.4 mmol/L (3.6-4.9 mmol/L)
Chloride 123 mmol/L (117-126 mmol/L)
Bicarbonate 18 mmol/L (15-21 mmol/L)
Phosphorus 5.7 mg/dL (3.2-6.3 mg/dL)
Calcium 8.3 mg/dL (9.0-10.9 mg/dL)
BUN 18 mg/dL (18-33 mg/dL)
Creatinine 0.8 mg/dL (1.1-2.2 mg/dL)
Glucose 81 mg/dL (63-118 mg/dL)
Total protein 4.9 g/dL (6.6-8.4 g/dL)
Albumin 1.9 g/dL (2.2-4.6 g/dL)
Globulin 3.0 g/dL (2.8-5.4 g/dL)
ALT 29 U/L (27-101 U/L)
AST 86 U/L (17-58 U/L)
ALP 3 U/L (14-71 U/L)
GGT < 3 U/L (0-4 U/L)
Cholesterol 99 mg/dL (89-258 mg/dL)
Total bilirubin 1.9 mg/dL (0-0.2 mg/dL)
Creatine kinase 1532 U/L (73-260 U/L)

In-Clinic FeLV Antigen and FIV Antibody Serology: Negative.

Initial Treatment: Supplemental oxygen was administered. A brief thoracic ultrasound examination confirmed the presence of large amounts of pleural effusion. Thoracocentesis yielded 170 mL of opaque red fluid. Cytologic examination of the fluid in the emergency room revealed numerous degenerate neutrophils and macrophages with filamentous bacterial rods. The fluid was submitted for further analysis and culture. Treatment with intravenous fluids (150 mL bolus of lactated Ringer's solution, then 50 mL/hr of lactated Ringer's solution with 20 mEq/L KCl), enrofloxacin (5 mg/kg IV q24h), and ampicillin (22 mg/kg IV q8h) was initiated. Packed red blood cells were administered because the PCV dropped to 21%. Frank was anesthetized and a 12F chest tube placed on the left side of the thorax.

Thoracic Radiography: Moderate bilateral pleural effusion and irregular scalloping of the ventral lung margins were present. On the lateral projection, several rounded gas lucencies were superimposed over the ventral thorax and apex of the heart. On the ventrodorsal (VD) projection, there was increased opacity to the left of the cardiac silhouette superimposed over the pulmonary parenchyma. A chest tube was present extending into the left cranial hemithorax. Impressions: Moderate bilateral pleural effusion with irregular lung margination, findings consistent with the clinical diagnosis of pyothorax. The increased opacity superimposed over the left lung on the VD projection was thought to represent focal pulmonary infiltrates or pocketing effusion. Slight pneumothorax, likely iatrogenic.

Microbiologic Testing:

Cytologic Examination (Pleural Fluid): Total protein 3.5 g/dL; RBC 240,000 cells/µL; total nucleated cells 206,160 cells/µL with 66% neutrophils, 11% small mononuclear cells, and 23% large mononuclear cells. The neutrophils were variably karyolytic, and many contained intracellular bacteria. The bacterial population was a monomorphic population of long, thin, and linear rods (see Figure 87-6). These bacteria were noted extracellularly and intracellularly.

Aerobic and Anaerobic Bacterial Culture (Pleural Fluid): Small numbers of *Fusobacterium russii* (identified by DNA sequencing), negative for β-lactamase production.

Mycoplasma Culture (Pleural Fluid): Negative.

Diagnosis: Anaerobic bacterial pyothorax.

Outcome: Over the course of day 1, 70 mL/kg of fluid was removed from the thoracostomy tube. Treatment with antimicrobial drugs, intravenous fluids, mechanical intermittent (q4h) suction through the thoracostomy tube, and opioid analgesia was continued. On day 2, fluid production from the tube dropped to 1 mL/kg/hr, yet thoracic radiographs showed persistent pleural effusion. Intrapleural lavage with 60 mL of warm saline was performed.

VetBooks.ir

On day 3, Frank became progressively more obtunded with increased respiratory rate (60 breaths/min) and effort. Cytologic examination of the pleural fluid showed persistent bacterial infection. An exploratory thoracotomy by median sternotomy was performed. Entry into the mediastinum was followed by escape of a large amount of mucopurulent material that contained caseous material and fibrin clots. The mediastinal, pericardial, and sterno-pericardial fat were necrotic and were easily stripped from the pericardium and other mediastinal structures. There was no evidence of communication with the trachea or esophagus and no evidence of plant awn foreign bodies. The right middle and accessory lung lobes were atelectatic. Fibrinous material coated the pleural surfaces. Additional mucopurulent material was present in both pleural cavities. Following mediastinectomy, the pus was suctioned from the thoracic cavity and vigorous lavage and suction applied. Mechanical debridement was performed using moist gauze sponges. Gentle decortication of the right middle lung lobe was performed, resulting in partial re-inflation, and 16F thoracic drains were placed bilaterally.

The following day Frank was more alert and began to eat. Intermittent suction (q6h) and thoracic lavage were performed through the thoracostomy tubes (30 mL warm saline each side q12h). A CBC revealed 79,520 WBC/μL, 16,699 band neutrophils/μL, and 54,074 neutrophils/μL, with moderate neutrophil toxicity. The antibiotic treatment was changed to amoxicillin-clavulanic acid (20 mg/kg PO q8h). After an additional 48h, the thoracostomy tubes yielded only small amounts of mildly hemorrhagic fluid, and so they were removed. Frank was discharged on day 7 of hospitalization, when he was alert and eating well. Antibiotic treatment was continued for 6 weeks. He continued to improve at home and was followed for an additional 2 years with no evidence of recurrence.

Comments: This cat had severe pyothorax likely secondary to thoracic wall trauma (e.g., a bite wound) that was fortunately discovered and treated rapidly. The cat was bradycardic and had ptyalism and low-normal serum cholesterol concentration, all negative prognostic indicators in one study.[35] A thoracotomy was needed because of inspissated pus within the thorax that failed to drain effectively with medical management. The spectrum of antimicrobials used may have been excessive based on the results of culture and susceptibility testing (amoxicillin alone should have been active), but it is possible that other anaerobes may also have been present that failed to grow. Note that the use of parenteral enrofloxacin is off-label for cats and has the potential to cause blindness.

CHAPTER 88

Intra-abdominal Infections

Jane E. Sykes

VetBooks.ir

Overview of Bacterial Intra-abdominal and Hepatobiliary Infections

Causes: Most commonly *Escherichia coli, Enterococcus* spp., and anaerobes; less often other gram-negative aerobes, *Streptococcus,* and *Staphylococcus* spp.

Mode of Transmission: Opportunistic invasion by commensal bacteria of the gastrointestinal and urogenital tracts

Major Clinical Signs: Inappetence, fever, vomiting, diarrhea, abdominal pain

Differential Diagnoses: Nonbacterial causes of pancreatitis, peritoneal effusion, hepatitis, or extrahepatic biliary tract obstruction (especially neoplasia and inflammatory disorders but also viral, protozoal, or fungal infections)

Human Health Significance: Enteric bacteria involved may be multidrug-resistant organisms that have the potential to colonize humans.

INFECTIOUS GASTROENTERITIS

Gastroenteritis in dogs and cats may be caused by an enormous array of microorganisms that include viral, bacterial, fungal, and protozoal pathogens (Table 88-1[1-5]). Other parasites (such as nematodes) should also be considered on the differential diagnosis list. Enteropathogenic bacteria cause diarrhea by adhesion to or destruction of enterocytes, secretion of a variety of potent enterotoxins, and stimulation of the host inflammatory response. Many of these microbes can be detected in the feces of apparently healthy animals as well as the feces of those with clinical signs of diarrhea. Therefore, it may be difficult to ascertain the role that these organisms play in disease in a single patient. Clinical signs of diarrhea may be more likely to occur when multiple organisms are present simultaneously ("polyparasitism"). In addition, other host factors (such as nutritional status or age) and bacterial virulence factors influence whether clinical signs develop. When outbreaks occur in dog and cat populations, collection of specimens from multiple affected and in-contact animals may be useful to determine the significance of one or more organisms involved. Use of antibiotics to treat bacterial diarrhea should be reserved for animals with systemic signs of illness such as fever, lethargy, and leukocytosis on the CBC.[6] Other infections are self-limiting, and the mainstay of treatment is proper fluid therapy and supportive care.

The reader is referred to other chapters in this book for detailed information on pathogenesis, clinical signs, diagnosis, and treatment for the organisms that are most commonly involved. References are also provided in Table 88-1 for information on pathogens that are uncommon or rarely identified or that have uncertain pathogenicity.

BACTERIAL PERITONITIS

Etiology and Epidemiology

Peritonitis may be focal or diffuse and can also be classified as *primary* or *secondary peritonitis*. Primary peritonitis is peritonitis that has no identifiable underlying cause. In secondary peritonitis, a reason for bacterial leakage into the abdomen can be identified.

In humans, primary peritonitis has also been referred to as *spontaneous bacterial peritonitis* and most often complicates development of ascites (e.g., secondary to cirrhosis, hepatitis, or congestive heart failure).[7,8] In contrast, conditions that predispose to ascites are rarely present in the history of dogs and cats with primary peritonitis. Some primary peritonitis in dogs or cats may result from hematogenous spread of bacteria to the peritoneum or bacterial translocation from the gastrointestinal tract.[7]

Secondary peritonitis is the most common form of peritonitis in dogs and cats and occurs when bacteria are introduced into the peritoneal space as a result of gastrointestinal perforation, penetration of the abdominal wall, rupture of the genitourinary tract, rupture of intra-abdominal abscesses, gallbladder rupture, or ascending infection of the umbilicus in neonates (Table 88-2).[7,9-15] In dogs, low preoperative total protein or serum albumin concentrations are risk factors for development of bacterial peritonitis after gastrointestinal surgery.[16]

The bacterial species involved in peritonitis reflect the normal flora of the gastrointestinal tract. Mixed aerobic-anaerobic infections, with up to four different bacterial species, occur in more than 50% of affected dogs and cats.[7,10] *Escherichia coli* is the most common isolate from both dogs and cats, followed by *Enterococcus* and *Clostridium* spp.[7,10,11,14,15,17,18] Other isolates include staphylococci, streptococci, *Pseudomonas aeruginosa* or *Acinetobacter* spp., a variety of anaerobes, gram-negative Enterobacteriaceae (*Proteus, Citrobacter, Serratia, Klebsiella,* or *Enterobacter*), *Actinomyces,* or in cats, *Pasteurella multocida*. In one study, a greater proportion of dogs with primary peritonitis had gram-positive bacterial infections than dogs with secondary peritonitis.[7] Uncommonly, *Candida albicans* can be involved, especially if there is a history of antibiotic treatment (see Chapter 67).

The mean age of dogs with peritonitis is around 5 to 7 years, and the mean age of cats is 7 to 10 years, although dogs and cats of any age can be affected.[9,12,19] Age was not found

TABLE 88-2

Underlying Causes of Secondary Peritonitis in Dogs

Organ System Affected	Disease Process
Gastrointestinal system	Gastrointestinal surgical site dehiscence (e.g., resection and anastomosis) Penetrating abdominal trauma Nonsteroidal or steroidal anti-inflammatory drug toxicity Foreign bodies Gastrointestinal neoplasia Eosinophilic gastroenteritis Torsion Intussusception
Genitourinary tract	Ruptured pyometra Surgical site dehiscence (e.g., ovariohysterectomy) Ruptured prostatic abscess Necrotizing bacterial cystitis
Hepatobiliary system	Gallbladder rupture (especially animals with necrotizing bacterial cholecystitis) Hepatic abscess rupture
Other abdominal organs	Abscess rupture
Umbilicus	Ascending infection in neonates

to relate to development of primary versus secondary peritonitis in dogs or cats.[7] There is no known breed or sex predisposition. In one study, three quarters of affected cats were indoor-only.[10]

Clinical Features

The most common historical signs in dogs and cats with bacterial peritonitis are lethargy, anorexia, vomiting, and diarrhea.[7,10,15] Weakness and collapse can also occur.[14] Diarrhea and vomiting may result from intestinal hypermotility or ileus or may be secondary to underlying intestinal disease.

Physical examination findings include dull mentation, fever (up to 108°F or 42°C), dehydration, mucosal pallor, abdominal pain, thin body condition, and/or abdominal enlargement and a palpable fluid wave due to ascites.[7,10,14] Tachypnea or tachycardia may be present as a result of abdominal pain. However, some affected animals, and especially cats, show none of these signs. More than one third of cats lack any evidence of abdominal pain.[10,15] Signs of septic shock may be present, such as tachycardia, tachypnea, weak pulses, and injected mucous membranes in dogs, or hypothermia and bradycardia in cats (see Chapter 86).[10,15]

Diagnosis

Diagnosis of bacterial peritonitis is based on abdominal imaging findings, cytologic examination of peritoneal fluid, and aerobic and anaerobic bacterial culture of the fluid.

Laboratory Abnormalities

Complete Blood Count and Serum Biochemical Tests

Frequent findings on the CBC in dogs and cats with bacterial peritonitis are leukocytosis due to neutrophilia, a mild to severe bandemia, and monocytosis.[7,10,12] Neutrophil toxicity is often present. Some animals are leukopenic (as low as 270 cells/μL in cats and 1000 cells/μL in dogs).[7,10,15] Anemia of inflammatory disease may be identified. Thrombocytopenia may be present in animals with septic shock and DIC. The serum biochemistry panel often shows electrolyte and acid-base abnormalities and/or hypoalbuminemia due to inflammation or third-space losses. Mild to moderate increases in liver enzyme activities, hypoglycemia, or hyperglycemia may be detected; hyperbilirubinemia can be present in cats.[7,10] Assessment of acid-base status in both dogs and cats most often reveals acidemia; hyperlactatemia is present in at least 50% of affected animals.[7,10,15]

Coagulation Profile

Dogs and cats that develop DIC may have prolongations of PT or APTT, increased plasma D-dimer or fibrin degradation product concentrations, and/or decreased plasma antithrombin concentration.

Diagnostic Imaging

Plain Radiography

Abdominal radiographs in dogs and cats with peritonitis may show a focal or diffuse loss of abdominal detail due to variable amounts of peritoneal effusion. In some animals, pneumoperitoneum is identified secondary to rupture of an abdominal viscus or penetrating abdominal trauma. Evidence of gastrointestinal obstruction or intestinal mass lesions may also be present.[10,14] In tachypneic animals, thoracic radiographs should be considered to determine whether a pulmonary problem (such as acute respiratory distress syndrome or pulmonary thromboembolism) is contributing to respiratory distress.

Sonographic Findings

Findings on abdominal ultrasound examination include focal or diffuse hyperechogenicity of the mesentery and the presence of ascites fluid (Figure 88-1). The latter may have an echogenic appearance if it is an exudate. Evidence of underlying disease may be present, such as intestinal mass lesions or foreign bodies. The presence of pneumoperitoneum; dilated, air-filled bowel loops; or severe abdominal pain may interfere with complete ultrasound examination of some patients. CT examination is preferred to ultrasound for evaluation of human patients with bacterial peritonitis,[7,8] but its usefulness for diagnosis and treatment of peritonitis in dogs and cats requires further investigation.

Microbiologic Tests

Cytologic Examination

Specimens for cytologic examination from animals with peritonitis may be collected by blind or ultrasound-guided abdominocentesis or diagnostic peritoneal lavage (DPL). With the increased availability and sensitivity of ultrasound to detect and guide collection of small quantities of undiluted intra-abdominal fluid, DPL is now uncommonly performed in the author's practice. Peritoneal fluid from dogs and cats with bacterial peritonitis is typically a modified transudate or exudate, although fluid from dogs with primary peritonitis may be more likely to be a modified transudate or transudate.[7] Fluid analysis from most animals with peritonitis reveals a high protein concentration and an increased erythrocyte and total nucleated cell count (usually >500 cells/μL and up to 160,000 cells/μL). There is typically a predominance of neutrophils that may have a degenerate appearance, and foreign material and/or intracellular and extracellular bacteria may be seen. The presence of intracellular bacteria is generally considered diagnostic for bacterial peritonitis. Because an absence of bacteria does not rule out bacterial peritonitis, submission of fluid for culture is essential.[10,14] A blood-to-fluid glucose difference greater than 20 mg/dL was 100% sensitive and 100% specific for a diagnosis of bacterial peritonitis in one study of dogs and cats.[18]

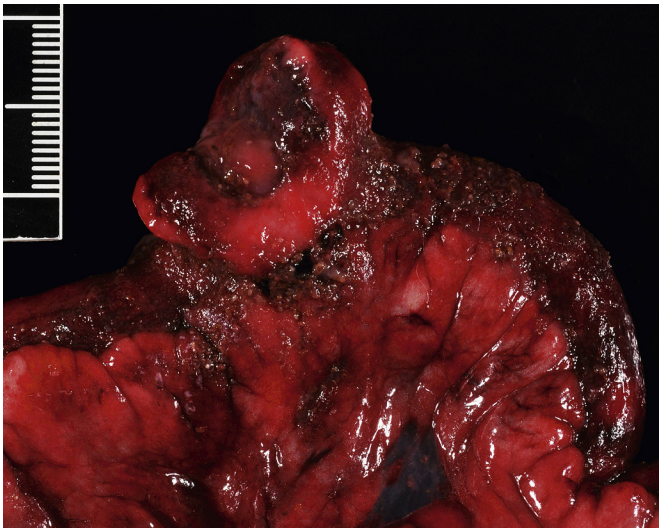

FIGURE 88-1 Necropsy image from a 7-year-old terrier mix with severe bacterial peritonitis secondary to perforated intestinal lymphoma. The dog had acute onset of diarrhea and collapse before being brought to the veterinary clinic in cardiorespiratory arrest. On ultrasound examination there was a large volume of echogenic peritoneal effusion and the mesentery was severely hyperechoic. The stomach, small intestine, and colon were fluid distended, hypomotile, and had thickened, corrugated walls with diminished blood flow. At necropsy, the omentum was discolored dark red to purple, and a segment of jejunum had an intramural mass with a central depression that communicated with the intestinal lumen. (Courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

Culture

If bacterial peritonitis is suspected, abdominal fluid specimens should be submitted for aerobic and anaerobic bacterial culture and susceptibility testing. Inoculation of blood culture bottles with ascites fluid could be considered if there is to be any delay in transport of the specimen to the laboratory.

Treatment and Prognosis

Treatment of peritonitis involves a combination of antibiotic treatment, supportive care, and surgery. The goal of surgery is to identify and correct the source of leakage and to lavage and drain the abdomen. The latter is critical for effective antibiotic penetration. Cytologic evidence of inflammation with intracellular bacteria in peritoneal fluid specimens and/or the identification of free air within the abdomen (in the absence of a history of surgery or abdominocentesis) are indications for surgical exploration.

VetBooks.ir

TABLE 88-3

Suggested Empiric Antimicrobial Drug Choices for IV Use in Dogs and Cats with Bacterial Peritonitis Pending the Results of Culture and Susceptibility*

Antimicrobial Drug	Spectrum	Comments
Ampicillin-sulbactam *and* a fluoroquinolone (e.g., enrofloxacin, marbofloxacin)	Activity against gram-negative bacteria, some methicillin-resistant staphylococci, streptococci, enterococci, and most anaerobes	Replace the fluoroquinolone with an aminoglycoside (amikacin or gentamicin) if the regional prevalence of fluoroquinolone resistance is high.
Metronidazole *and* a fluoroquinolone	Activity against susceptible gram-negative and gram-positive bacteria and anaerobes	Replace the fluoroquinolone with an aminoglycoside (amikacin or gentamicin) or a third-generation cephalosporine if the regional prevalence of fluoroquinolone resistance is high.
Ticarcillin–clavulanic acid	Activity against susceptible gram-positive and gram-negative aerobes (including *Pseudomonas aeruginosa*) and some anaerobes	Not active against methicillin-resistant staphylococci
Carbapenem (meropenem or imipenem-cilastatin)	Activity against susceptible gram-positive and gram-negative aerobes and anaerobes	Not active against methicillin-resistant staphylococci. Reserve use for when multidrug-resistant gram-negative bacterial infection is suspected.
Piperacillin-tazobactam	Activity against susceptible gram-positive and gram-negative aerobes, including *Pseudomonas aeruginosa,* and some anaerobes	Not active against methicillin-resistant staphylococci. Reserve use for when multidrug-resistant gram-negative bacterial infection is suspected.

*If appropriate, reduce spectrum once the results of culture and susceptibility are available.
Dosages for IV administration (normal renal function). See Chapter 8 for precautions.
Amikacin 15-30 mg/kg q24h (dogs), 10-14 mg/kg q24h (cats)
Ampicillin-sulbactam, 20 mg/kg q6-8h (dose based on ampicillin component)
Gentamicin sulfate, 14 mg/kg q24h (dogs), 8 mg/kg q24h (cats)
Ciprofloxacin hydrochloride, 10 mg/kg q24h
Enrofloxacin, 5-20 mg/kg q24h (dogs); avoid in cats and never exceed 5 mg/kg, see important cautionary notes in Chapter 8
Imipenem-cilastatin, 5 mg/kg q6h (dilute in 100 mL sterile saline and give slowly over 30 min)
Meropenem, 25 mg/kg q8h
Piperacillin-tazobactam, 40 mg/kg q6h
Ticarcillin-clavulanate 50 mg/kg q6h

Antimicrobial Treatment

Parenteral antimicrobial drug treatment should be initiated as soon as possible after diagnosis of peritonitis, because delayed antimicrobial drug treatment in severe sepsis and septic shock may increase mortality (see Chapter 86). The initial choice of antimicrobial drugs in dogs and cats with bacterial peritonitis should include a broad-spectrum combination of antimicrobials with activity against both obligate anaerobes and facultative anaerobes (especially *E. coli* and *Enterococcus*) (Table 88-3). Subsequently, treatment should be adjusted on the basis of cytology and culture and susceptibility results. Because obligate anaerobes may not grow reliably in the laboratory and are commonly involved, continued use of an antibiotic that provides activity against anaerobes is recommended even when anaerobic cultures are negative.

Surgical Treatment

Careful surgical exploration for a site of bacterial leakage is indicated after initial stabilization with fluids, vasopressors, and antimicrobial drug treatment. The underlying cause must be surgically corrected (e.g., intestinal resection and anastomosis), and the peritoneum should be debrided and lavaged thoroughly with warm isotonic saline. The need for subsequent drainage is controversial. Drainage is generally selected when debridement and lavage cannot adequately reduce contamination. Methods of drainage include primary closure with closed suction drains, open peritoneal drainage, and, most recently, vacuum-assisted peritoneal drainage.[10,12,17,20-22] In retrospective studies, no significant differences in survival have been identified among methods, but prospective studies are required. Complications of drainage are ascending nosocomial infection, obstruction of closed suction drains by omentum, and hypoproteinemia. Evisceration and bowel desiccation have the potential to occur with open peritoneal drainage, and fluid production cannot be quantified. Dogs and cats that undergo open drainage are also more likely to require plasma or blood transfusions and may have longer hospitalization times.[17] Frequent sedation or anesthesia for bandage changes is also required.

Supportive Care

Supportive care for cats and dogs with bacterial peritonitis generally includes intensive crystalloid and colloid fluid therapy, administration of vasopressors, and enteral or parenteral nutritional support. Blood transfusions may also be required. Dogs that received early nutritional support had significantly shorter hospitalization times than those for which nutritional support was delayed.[13]

Prognosis

Survival rates of 32% to 67% have been reported in dogs with secondary peritonitis.[7,9,11,12,16,21,22] Survival rates of 44% to

VetBooks.ir

70% after surgery have been reported for cats.[7,10,15] Typically hospitalization is required for 3 to 16 days (median around 5 to 6 days). When death occurs, it usually results from septic shock, DIC, or multiple organ dysfunction. Negative prognostic indicators identified in dogs with bacterial peritonitis include a diagnosis of primary as opposed to secondary peritonitis[7]; preoperative anemia, leukocytosis, or hypoproteinemia[16]; and postoperative administration of glucocorticoids.[16] Low preoperative systolic blood pressure was a negative prognostic factor in a study that included both dogs and cats.[14] Low preoperative median serum ALT activity (56 U/L for surviving cats compared with 179 U/L for non-survivors) was the only positive prognostic indicator in one study of cats with peritonitis.[10] Age, preoperative heart rate, rectal temperature, the results of other laboratory parameters, or the presence of polymicrobial infection did not affect survival. In another study, a high plasma lactate concentration was a negative prognostic indicator in cats with bacterial peritonitis.[15]

HEPATOBILIARY INFECTIONS

Etiology and Epidemiology

Hepatobiliary infections include hepatic abscesses; a variety of viral, bacterial, protozoal, or fungal infections that have spread hematogenously to the liver as part of a systemic infection; ascending infections of the biliary tree; and possibly bacterial translocation from the portal circulation. The focus of this section is bacterial infections of the biliary tree; hepatic abscesses are considered in a separate section that follows.

Bacterial infections of the hepatobiliary system occur occasionally in cats and are rare in dogs. The main mechanism thought to be involved is ascending infections of the biliary tree, although hematogenous spread and bacterial translocation from the portal system are other proposed mechanisms.[23] They have been associated with suppurative cholangitis/cholangiohepatitis, cholecystitis, choledochitis, and cholelithiasis.[24-31] *Cholangitis* is inflammation of intrahepatic bile ducts, whereas *cholangiohepatitis* is inflammation of the bile ducts that has spread to the adjacent liver parenchyma. The use of the term "cholangitis" (rather than "cholangiohepatitis") has been recommended by the WSAVA Liver Diseases and Pathology Standardization Group, because of the variable existence of hepatic involvement, so this term will be used from this point onward. In cats, cholangitis has been classified histologically as *neutrophilic cholangitis, lymphocytic cholangitis,* or *chronic cholangitis associated with liver fluke infestation.* Neutrophilic cholangitis can be further subclassified as acute or chronic depending on the presence of fibrosis, fibroplasia, or bile duct proliferation.[32] Neutrophilic cholangitis is thought to develop as a result of ascending bacterial infection from the gastrointestinal tract, which may occur secondary to inflammatory bowel disease (IBD) and/or pancreatitis (Figure 88-2). It is hypothesized that the common entry of the pancreatic and common bile ducts into the intestine in cats may predispose them to concurrent intestinal, pancreatic, and biliary disease due to pancreatic and hepatobiliary reflux in the face of IBD ("triaditis"). However, not all cats with cholangitis have histologic evidence of associated pancreatitis or IBD. Cats with acute neutrophilic cholangitis tend to be younger than those with chronic neutrophilic cholangitis.[32,33] Retrovirus infection does not appear to be a predisposing factor. The cause of lymphocytic cholangitis is unclear; currently it is thought to be an immune-mediated condition.[34] Chronic cholangitis associated with liver fluke infestation is rare and is primarily reported from regions with subtropical climates such as the southeastern United States and Hawaii, but disease can occur in non-endemic areas in traveled cats. Several different fluke species may be involved, but the most prevalent appears to be *Platynosomum concinnum*.[35]

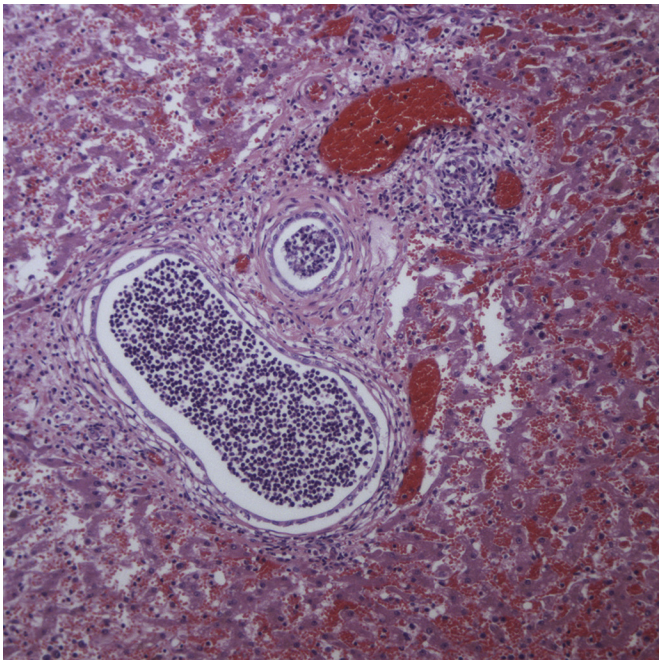

FIGURE 88-2 Histopathology showing severe, acute neutrophilic cholangitis in a 20-year-old female spayed domestic shorthair. Bile ducts are expanded by neutrophils. *Escherichia coli* was isolated from the liver in large numbers at necropsy. Concurrent diseases found at necropsy were pulmonary adenocarcinoma and moderate multifocal glomerulonephritis.

Choledochitis is inflammation of the common bile duct. *Cholecystitis* is inflammation of the gallbladder and may or may not be associated with cholangitis or choledochitis. In some instances, necrotizing and/or emphysematous cholecystitis can develop, which may lead to perforation of the gallbladder wall and septic bile peritonitis. *Cholelithiasis* is stone formation within the biliary tree. In some instances, cholelithiasis or neoplasia of the biliary tree may predispose to cholangitis and necrotizing cholecystitis.[28,29] Alternatively, it has been suggested that bacterial cholecystitis predisposes to stone formation through bacterial deconjugation of soluble bilirubin glucuronide to insoluble unconjugated bilirubin and glucuronic acid.[27] Smaller breed (dachshunds, poodles, miniature schnauzers) female dogs were predisposed to cholelithiasis in one study.[27]

Biliary cultures are more likely to be positive than hepatic cultures in both dogs and cats with hepatobiliary disease. In one large study, approximately 30% of biliary cultures were positive in dogs and cats, whereas hepatic cultures were positive in 14% of cats and 5% of dogs.[31] In cats, more than 80% of biliary cultures yielded a single bacterial species, whereas multiple bacterial species were isolated from approximately 50% of dogs. Bacterial species isolated from cats include obligate anaerobes, a variety of Enterobacteriaceae, *Enterococcus*, *Streptococcus*, or *Staphylococcus* species.[24,31,32] Dogs are most commonly infected with mixtures of *E. coli*, *Enterococcus* spp., and anaerobes, primarily *Bacteroides* and *Clostridium* species.[25-29,31]

VetBooks.ir

Staphylococcus spp., other gram-negative aerobes (*Klebsiella, Enterobacter, Citrobacter,* and *Pseudomonas aeruginosa*), and *Streptococcus* spp. may also be isolated from dogs. *Salmonella* in cats and *Campylobacter* in dogs have also been associated with cholecystitis. Although rare, emphysematous cholecystitis in dogs and cats is usually associated with *Clostridium* spp. and/or *E. coli* infection.[36]

Clinical Features

Clinical Signs and Physical Examination Abnormalities

The most common clinical signs of hepatobiliary infection in both dogs and cats are lethargy, inappetence, vomiting, weight loss, and diarrhea.[24,25,30,32,33] These signs may be chronic, acute, and rarely peracute.[25,37] Peracute disease can occur with necrotizing cholecystitis and rupture of the gallbladder wall and may be associated with clinical signs of septic shock. Hypersalivation may be evident in cats with neutrophilic cholangitis.[24] Physical examination may reveal fever, lethargy, dehydration, icterus, thin body condition, and/or pain on palpation of the abdomen. Hepatomegaly may also be identified.[32] Some animals are tachycardic or tachypneic.

Diagnosis

Laboratory Abnormalities

Complete Blood Count

The CBC in dogs and cats with hepatobiliary infections may show leukocytosis due to a neutrophilia, bandemia, and sometimes monocytosis.[24-26,30,32,33,37] Some cats with cholangitis are leukopenic.[24,32] Lymphopenia and/or anemia may also be present.

Serum Biochemical Tests

Dogs with cholangitis or cholecystitis typically have increased activities of serum ALT, ALP, and GGT and hyperbilirubinemia. At least 50% of cats with cholangitis have mild to moderate increases in the activity of ALT and/or ALP (usually <1000 U/L). Increased activity of GGT may also be present. However, some cats with cholangitis have normal serum ALT, ALP, and GGT activities.[32] Hyperbilirubinemia is present in approximately two thirds of cats. Electrolyte abnormalities may be present secondary to gastrointestinal losses in animals with vomiting or diarrhea.[24,33] Hypocholesterolemia, hyperglobulinemia, and hypoalbuminemia are uncommonly identified. Hypercholesterolemia may be present in dogs with cholestasis or bile duct obstruction but is uncommonly present in cats.[26,28,30]

Urinalysis

Urinalysis in animals with hepatobiliary infections may be unremarkable or show evidence of bilirubinuria.[24,26,38]

Coagulation Profile

Coagulation abnormalities such as prolongations of PT and PTT may be present in dogs and cats with hepatobiliary infections, either secondary to impaired absorption of vitamin K secondary to biliary obstruction, or potentially as a result of liver dysfunction.[25,33]

Diagnostic Imaging

Plain Radiography

The most common finding on abdominal radiography in dogs and cats with cholecystitis and cholangitis is hepatomegaly, which is variable.[30,33] Uncommonly, single or multiple radiopaque choleliths are visible (Figure 88-3), although choleliths may also be radiolucent.[26-28] In some animals, no abnormalities are detected. Emphysematous cholecystitis is characterized by the presence of gas in the liver in the region of the gallbladder. Loss of abdominal detail may be present if gallbladder rupture and septic bile peritonitis have occurred.[25]

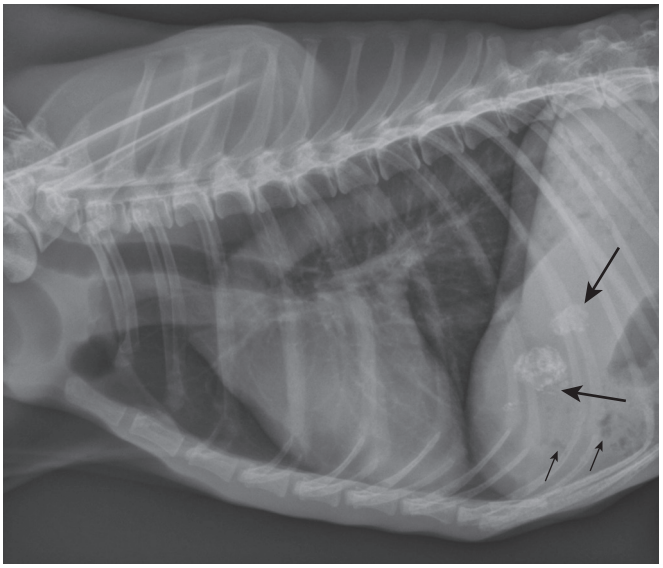

FIGURE 88-3 Lateral thoracic radiograph from a 4-year-old male neutered Chihuahua with a 3-month history of vomiting, lethargy, weight loss, and progressive icterus. Within the viewable abdomen, multiple irregular mineral opacities are present in the region of the gallbladder (*large arrows*). In this region, there are also multiple small irregular gas opacities (*small arrows*). A diagnosis of necrotizing cholecystitis and secondary bile peritonitis was made based on ultrasound and abdominal fluid analysis. Exploratory laparotomy revealed multiple choleliths, and a cholecystectomy was performed. Histopathology revealed severe, subacute to chronic, transmural suppurative and necrotizing cholecystitis.

Sonographic Findings

Abdominal ultrasound findings in dogs and cats with cholangitis are similar and include hepatomegaly, normal or abnormal hepatic echotexture with a homogenous or heterogenous increase in echogenicity, prominent portal vasculature, a thickened and hyperechogenic gallbladder wall, and sediment within the gallbladder.[24-26,30,32,39,40] The gallbladder wall may also appear irregular and contain polypoid mass lesions. Abdominal pain in the right cranial quadrant may be evident during the procedure. Choleliths are occasionally identified within the biliary tract as hyperechoic masses that shadow. Distention of the biliary tract may be evident, sometimes with tortuosity of the cystic and common bile ducts.[24,25,39] Evidence of concurrent pancreatic and/or intestinal wall disease may be present in cats.[32] Gas may be identified in the gallbladder wall of animals with emphysematous cholecystitis (Figure 88-4).

Microbiologic Tests

Cytologic Examination

Cytologic examination of bile collected by percutaneous ultrasound-guided cholecystocentesis (or intraoperative cholecystocentesis) in animals with hepatobiliary infection may reveal increased numbers of degenerate neutrophils, small and/or large mononuclear cells, and in some cases, a mixed or monomorphic bacterial population.[24] Cholecystocentesis carries some risk of

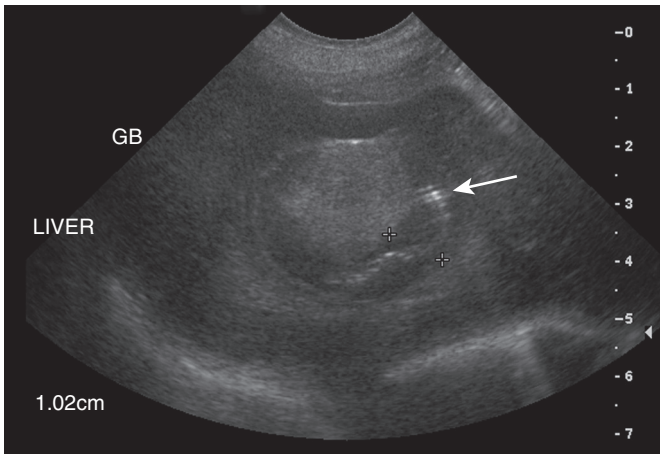

FIGURE 88-4 Abdominal ultrasound image of the gallbladder of a 6-year-old female spayed American Eskimo dog with emphysematous cholecystitis. The gallbladder wall is markedly thickened (1 cm), is diffusely hypoechoic, and the gallbladder contains homogenous sludge. Multiple hyperechoic foci were identified tracking throughout the wall *(arrow)*. The hepatic parenchyma immediately adjacent to the gallbladder was poorly characterized because of a large amount of markedly hyperechoic inflamed mesentery within the cranial abdominal region.

gallbladder leakage or rupture and should be avoided if there is evidence of gas in the gallbladder wall. As much bile should be removed as possible to minimize the chance of leakage. It is possible that percutaneous drainage of infected bile may have a therapeutic benefit, although this requires further study.

Culture

Aerobic and anaerobic bacterial culture can be performed on bile collected by ultrasound-guided or intraoperative cholecystocentesis or liver biopsies. Culture of bile is more likely to yield positive results than culture of liver biopsies. Although it is generally accepted that bile is sterile in healthy dogs and cats,[23,41] transient cytologic and microbiologic evidence of bactibilia has been identified in healthy dogs.[42] Liver tissue from healthy dogs can also harbor a variety of enteric bacterial species.[43] Thus, the results of bile culture must be interpreted in light of clinical and cytologic findings. Antimicrobial drug resistance among bacteria isolated from the bile of dogs and cats with cholecystitis and cholangitis has been described in several studies, and so culture and susceptibility testing should be performed whenever possible. When cholecystocentesis is undesirable because of concerns for gallbladder rupture (see Cytologic Examination), blood cultures may be useful, although the utility of blood culture in dogs and cats with cholecystitis has not been studied. In human patients, bile cultures are positive in 50% to 95% of patients with acute cholecystitis, and blood cultures are positive in 30% to 40% of patients.[44]

Pathologic Findings

On histopathology, neutrophilic cholangitis in cats varies in severity, chronicity, and the extent of associated hepatic parenchymal involvement.[32,38] Concurrent hepatic lipidosis may also be present. In a small percentage of affected cats, complete or partial biliary obstruction is identified as a result of inflammation, neoplasia, or cholelithiasis. Other findings in affected cats include acute or chronic pancreatitis (65% of cats in one study), inflammatory bowel disease and/or intestinal lymphoma (46% of cats). Histopathology of the gallbladder wall in both dogs and cats with cholecystitis may reveal mucosal and glandular hyperplasia and thickening and neutrophilic or lymphoplasmacytic inflammation of the gallbladder wall.[26,30,32]

Choleliths in cats are most often composed of calcium carbonate, although they also may be a mixture of cholesterol, calcium bilirubinate, and calcium carbonate.[26,28] In dogs they are often composed of calcium bilirubinate, bilirubin, or a mixture of bilirubin and cholesterol.

Treatment and Prognosis

Treatment of cholangitis and cholecystitis is usually with supportive care and antimicrobial drug administration. Dogs and cats with necrotizing or emphysematous cholecystitis require cholecystectomy. Cholecystectomy could also be considered to prevent recurrence of cholelithiasis in animals with chronic cholecystitis. Cholecystectomy, biliary stenting procedures, and/or biliary diversion surgery may be required for animals with obstructive processes such as cholelithiasis, biliary neoplasia, or obstructive cholangitis.[27,28] Because cholecystotomy or biliary diversion surgery often results in dehiscence and septic bile peritonitis if bacterial cholecystitis or choledochitis is present, cholecystectomy has been recommended for dogs with cholelithiasis as opposed to cholecystotomy.[27] When compared with other surgical biliary procedures, cholecystectomy has been associated with good clinical outcomes in dogs and cats, but any condition that requires biliary surgery carries a guarded prognosis.

Antimicrobial Drug Treatment and Supportive Care

Empirically used antibiotics should target gram-negative enteric bacterial species and anaerobes and be concentrated in bile. Suitable antibiotics include ampicillin-sulbactam or amoxicillin-clavulanic acid, or a fluoroquinolone with metronidazole, although resistance to amoxicillin-clavulanic acid or enrofloxacin has been documented among biliary isolates from dogs and cats.[30] Pradofloxacin also has a favorable spectrum of activity, because of its activity against anaerobes (see Chapter 8). In human patients, specific treatment of *Enterococcus* biliary infections when they are combined with other bacterial infections may not be necessary, since they tend to resolve when the other infections are treated.[44] Supportive treatments that could be considered include intravenous crystalloid fluids with or without colloids, nutritional support by parenteral or enteral means (with a restricted fat diet), ursodiol, *S*-adenylmethionine, antiemetics, antacids, and parenteral vitamin K supplementation.

Prognosis

The prognosis for cats with neutrophilic cholangitis is fair to good, with mean survival times longer than 1 year.[24,33] Poor outcomes may be related to the presence of underlying disease that contributes to mortality such as neoplasia.[28,33] The presence of septic bile peritonitis was associated with mortality in one study of dogs that underwent extrahepatic biliary surgery; more than half of dogs with septic bile peritonitis died.[29] In another study, 9 of 23 dogs with necrotizing cholecystitis died.[25]

HEPATIC ABSCESSES

Hepatic abscesses are uncommon in dogs and very rare in cats.[45,46] They may be associated with ascending bacterial infection of the biliary tree, translocation of portal bacteria, or hematogenous spread of bacteria to the liver, although the source of

bacteremia in some animals is unclear. Because bacteria can be found in the liver of healthy dogs, abscessation may also develop when these bacteria proliferate secondary to compromise of normal defenses (such as hepatic necrosis).[43] Affected animals are typically middle aged to older;[45,46] the mean age of affected dogs or cats is 10 years. The abscesses may be acute or chronic, single or multiple, and macroabscesses or microabscesses may form. Pancreatitis, diabetes mellitus, other hepatobiliary disease, neoplasia, colonic surgery, cholelithiasis, or chronic phenobarbital or glucocorticoid administration have been in the histories of affected dogs.[46-48] Migrating plant awn foreign bodies may also be an underlying cause.[48] Concurrent conditions in affected cats have included IBD, pancreatitis, hepatobiliary neoplasia, chronic cholecystitis, colonic surgery, or congestive heart failure.[45] Many cats have concurrent bacterial urinary tract infections.

The most common bacterial species isolated from hepatic abscesses in both dogs and cats is *E. coli*. In dogs, other species have included *K. pneumoniae, Staphylococcus,* and *Clostridium* spp. In cats, *Bacteroides, Enterococcus,* and *Streptococcus* spp. have been isolated, often in mixed infections with *E. coli*. Blood cultures are also often positive.[45,46] Clinical signs and laboratory abnormalities are similar to those for other hepatobiliary infections, except that severe illness and signs of septic shock are often present. Evidence of bleeding diatheses may be present. Marked neutrophilia or neutropenia, bandemia, toxic neutrophils, anemia, lymphopenia, and thrombocytopenia may be present on the CBC. Hypoalbuminemia and coagulation abnormalities are common.[45,46] Abdominal radiographs may be unremarkable, or they may show hepatomegaly or a hepatic mass effect, poor abdominal detail, and/or pneumoperitoneum if abscess rupture has occurred (Figure 88-5). Thoracic radiography often reveals interstitial, bronchiolar, or alveolar lung infiltrates,[44,46] which may result from associated embolic or aspiration pneumonia. Ultrasonographic examination of the abdomen reveals one or more hypoechoic, anechoic, or heteroechoic hepatic masses, with or without peritoneal effusion. In some cases, gas is evident within the masses.

Antemortem diagnosis of hepatic abscesses usually relies on cytologic examination of ultrasound-guided fine-needle aspirates of the masses, which reveals large numbers of degenerate neutrophils. Abscesses may also be discovered during exploratory laparotomy (e.g., in dogs and cats with bacterial peritonitis). Culture and susceptibility of aspirates of the liver abscesses, free peritoneal fluid, and/or blood should be performed. Effective treatment of solitary abscesses relies on appropriate antimicrobial drug treatment together with complete or partial liver lobectomy, or abscess drainage and omentalization. With the exception of microabscesses, antimicrobial drug therapy alone is often ineffective. Aggressive supportive care in an intensive care unit may be required. Initial antimicrobial drug treatment should be broad

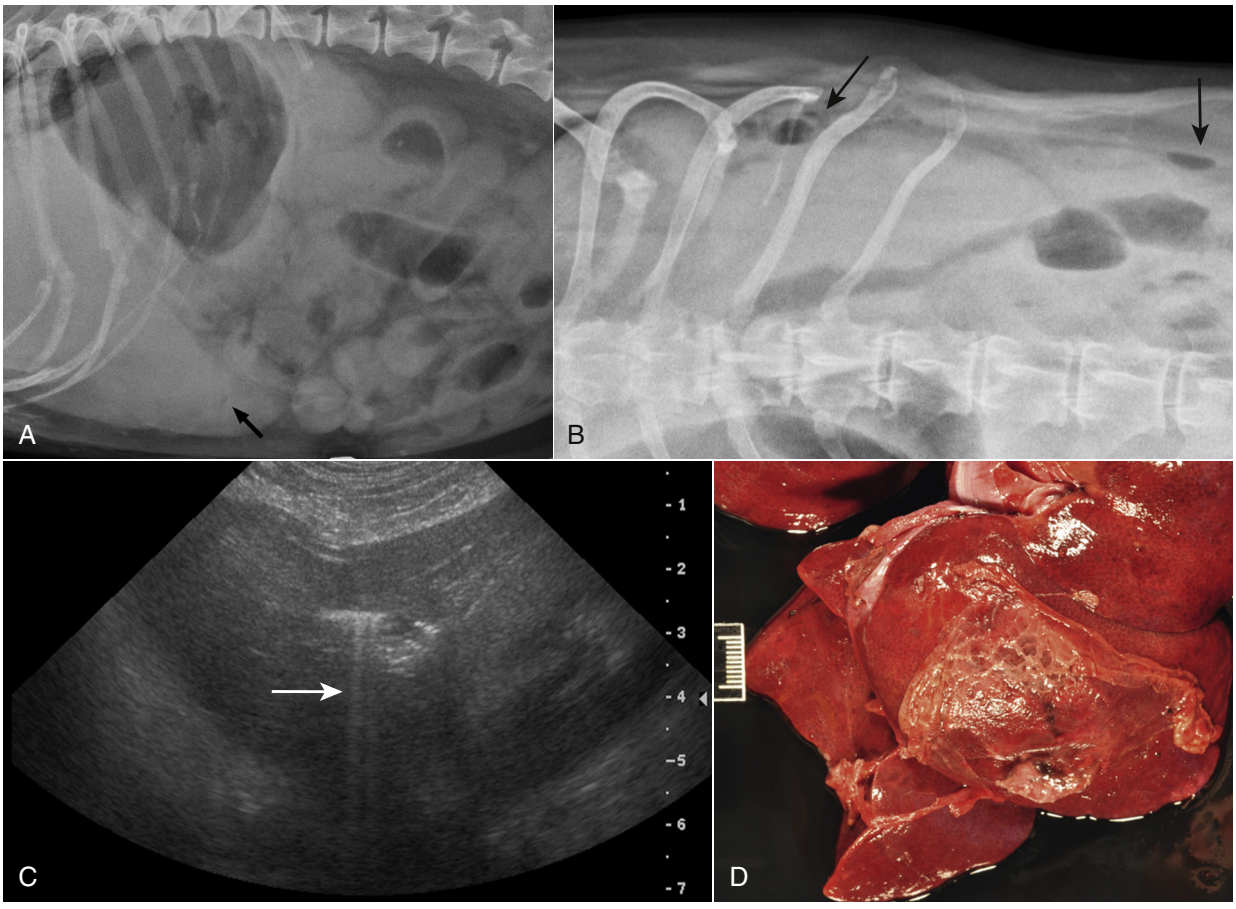

FIGURE 88-5 Ruptured hepatic abscess. **A,** Right lateral abdominal radiograph from a 15-year-old male neutered dachshund with acute onset of vomiting and diarrhea secondary to a ruptured hepatic abscess. There is a diffuse loss of serosal detail as well free peritoneal gas present throughout the abdomen. The liver is enlarged. There are multiple small rounded gas opacities present over the ventral and right aspects of the liver *(arrow).* Multiple small intestinal loops contain gas and fluid, some of which measure at the upper limits or over the upper limit of normal. **B,** Free peritoneal air can be seen clearly *(arrows)* using a horizontal beam view. **C,** Comet-tail artifact *(arrow)* due to the presence of gas within the liver on ultrasound examination. **D,** Hepatic abscess from the same dog at necropsy.

spectrum, after which it should be adjusted based on the results of culture and susceptibility. Mortality rates of 50% and 79% have been reported for dogs and cats, respectively.[45] The prognosis is especially poor when multiple abscesses are present.[45,46]

Pancreatitis and Pancreatic Abscesses

In dogs and cats, pancreatitis and pancreatic abscess formation most often appears to be a sterile process that results from tissue destruction and necrosis by pancreatic enzymes. Experimentally, necrotizing pancreatitis can be complicated by secondary bacterial invasion due to ascending infection from the duodenum or bacterial translocation,[49,50] although the extent to which this occurs in dogs and cats with naturally-occurring pancreatitis remains unclear. Occasionally, pancreatitis results from hematogenous spread of bacteria to the pancreas, usually in addition to other organs (see Table 86-2). Other microorganisms known to cause pancreatitis as a result of systemic infection include *Leptospira* species, *Toxoplasma gondii*, and fungi such as *Cryptococcus neoformans*. In cats, pancreatitis can also result from invasion by flukes *(Eurytrema procyonis)*.[51] When a primary infectious cause of pancreatitis cannot clearly be identified, the use of antimicrobial drugs to treat pancreatitis in dogs and cats is controversial. If used, the primary goal of antimicrobial treatment is to prevent or treat secondary ascending bacterial infection or bacterial translocation; treatment should target enteric bacteria. However, no evidence currently exists that use of antimicrobials alters outcome in dogs and cats with naturally occurring pancreatitis, and it has the potential to select for infection by multidrug-resistant enteric pathogens. In addition, many widely used antimicrobial drugs in veterinary medicine (such as β-lactams and aminoglycosides) penetrate inflamed pancreatic tissue poorly. Suitable choices include fluoroquinolones (for gram-negative aerobes), third-generation cephalosporines, and metronidazole (for anaerobes).

CASE EXAMPLE

Signalment: "George," a 16-year-old male neutered domestic shorthair from northern California

History: George was evaluated for a 2-day history of vomiting and progressive lethargy and inappetence. The owners reported that the vomiting occurred six times at the onset of illness and was associated with apparent abdominal pain but had since ceased. The day he became ill, he was seen at an emergency clinic where a CBC showed only a mild left shift (479 band neutrophils), a chemistry panel showed mild hypokalemia (3.1 mmol/L, reference range 3.6-4.9 mmol/L), and a total serum T4 concentration was increased (10.2 µg/dL, reference range, 1.1-3.3 µg/dL). Pancreatitis was suspected and George was initially treated with subcutaneous lactated Ringer's solution (200 mL SC q24h), mucosal buprenorphine (0.02 mg/kg PO q8h to q12h), and ondansetron (0.2 mg/kg PO q12h) pending the results of laboratory testing. However, because George became inappetent and lethargic, he was returned for reevaluation the following day.

Other medical history: George had been diagnosed with pancreatitis 8 months previously. He was also diagnosed with a biliary cystadenoma at that time. He had been hospitalized for 9 days and treated with jejunostomy tube feeding. Since then, he had been well until this recent onset of illness.

Physical Examination:

Body Weight: 6.1 kg.

General: Quiet, alert, hydrated. T = 103.8°F (39.9°C), HR = 240 beats/min, RR = 32, mucous membranes pink and moist, CRT = 1 s.

Eyes, Ears, Nose, and Throat: Palpable thyroid nodule.

Musculoskeletal: Body condition score was 5/9. The cat was ambulatory with normal gait.

Cardiovascular: A gallop rhythm was present. No murmurs or arrhythmias were auscultated. Femoral pulses were strong and synchronous.

Genitourinary/Gastrointestinal: Soft, mildly painful abdomen. The urinary bladder was small.

Other Systems, Including Peripheral Lymph Nodes: No clinically significant findings.

Imaging Findings:

Abdominal Ultrasound: The margins of the kidneys were irregular, and there was decreased corticomedullary distinction. In the region of the left limb of the pancreas, the mesentery was markedly hyperechoic and hyperattenuating. There was diffuse thickening of the muscularis of the small bowel. There was no evidence of mesenteric lymphadenomegaly. There was a small amount of free anechoic peritoneal fluid.

Thoracic Radiographs: The cardiac silhouette appeared mildly enlarged. There was a mild bronchointerstitial pattern throughout the thorax. There was poor serosal detail within the viewable cranial abdomen.

Outcome: George was treated supportively for pancreatitis with intravenous fluids (lactated Ringer's solution with 20 mEq/L KCl at 15 mL/hr), buprenorphine (0.01 mg/kg IV q6h), famotidine (0.5 mg/kg IV q12h), and ondansetron (0.5 mg/kg IV q12h). His temperature normalized, but he showed no interest in food or his surroundings. Cytologic examination of an ultrasound-guided liver aspirate on day 2 of hospitalization showed moderate hepatic lipidosis and mild mixed inflammation. Laboratory testing was reevaluated and an echocardiogram was performed on the third day of hospitalization in preparation for anesthesia and placement of an esophageal feeding tube. The echocardiogram was unremarkable; the gallop rhythm was suspected to result from a systolic click. New findings on the CBC were mild, nonregenerative anemia (HCT 29.9%, RR 30%-50%), with a WBC of 11,580 cells/µL (4500-14,000 cells/µL), 4053 neutrophils/µL (2000-9000 cells/µL), bandemia (3242 cells/µL), and circulating metamyelocytes (232 cells/µL). Findings on the serum biochemistry panel included a bicarbonate of 24 mmol/L (15-21 mmol/L), calcium of 8.3 mg/dL (9.0-10.9 mg/dL), BUN of 20 mg/dL (18-33 mg/dL), creatinine of 0.8 mg/dL (1.1-2.2 mg/dL), glucose of 114 mg/dL (63-118 mg/dL), total protein of 5.3 g/dL (6.6-8.4 g/dL), albumin of 2.0 g/dL (2.2-4.6 g/dL), globulin of 3.3 g/dL (2.8-5.4 g/dL), ALT of 57 U/L (27-101 U/L), AST

VetBooks.ir

of 46 U/L (17-58 U/L), ALP of 26 U/L (14-71 U/L), GGT of <3 U/L (0-4 U/L), cholesterol of 109 mg/dL (89-258 mg/dL), and total bilirubin of 0.4 mg/dL (0-0.2 mg/dL). Urinalysis showed a specific gravity of 1.015; pH 7.0, protein 25 mg/dL, no bilirubin, 25 erythrocytes/µL hemoprotein, 1-3 WBC/HPF, 1-6 RBC/HPF, and many lipid droplets. Serum vitamin B_{12} and folate concentrations were 383 ng/L (279-1254 ng/L) and 7.5 ng/mL (10.4-20.7 ng/mL), respectively.

Because of the severely left-shifted neutrophil count and mild hyperbilirubinemia, bacterial cholecystitis was suspected. Findings on abdominal ultrasonography were unchanged from the previous examination. Ultrasound-guided cholecystocentesis was performed while George was under anesthesia for esophagostomy tube placement, and a small volume of the scant peritoneal fluid present was also collected.

Microbiologic Testing:

Cytologic Examination (Bile): Smears had light blue backgrounds and contained a moderate amount of unidentified material. Nucleated cells were not found, but many short, plump coccobacilli were seen. Most of the bacteria were in large clusters, but a few groups were in chains.

Peritoneal Fluid Analysis: Grossly the fluid was pink and cloudy, and it had a yellow, clear supernatant. The total protein concentration was 2.8 g/dL and there were 100,000 RBC/µL. There were 5380 nucleated cells/µL, with 70% nondegenerate neutrophils, 6% small and well-differentiated lymphocytes, 7% foamy macrophages, and 17% eosinophils. No infectious agents were identified.

Aerobic and Anaerobic Bacterial Culture (Bile): Large numbers of *Enterococcus faecium*. No anaerobes were cultured. The isolate was susceptible to amoxicillin-clavulanic acid (≤4 µg/mL), ampicillin (≤0.25 µg/mL), penicillin (0.12 µg/mL), chloramphenicol (≤4 µg/mL), doxycycline (≤2 µg/mL), imipenem (≤1 µg/mL); had intermediate susceptibility to erythromycin (1 µg/mL); and was resistant to rifampin (>2 µg/mL).

Aerobic and Anaerobic Bacterial Culture (Peritoneal Fluid): Very small numbers of *Enterococcus faecium*. The antibiogram was identical to the isolate from the bile.

Diagnosis: Peritonitis and suspected bacterial cholecystitis caused by *E. faecium*; pancreatitis and secondary hepatic lipidosis.

Treatment: Medical treatment with ampicillin-sulbactam (20 mg/kg [ampicillin component] IV q8h) and enrofloxacin (5 mg/kg slow IV q24h) was commenced on day 3 of hospitalization, before the results of culture and susceptibility were available. Treatment was also continued with intravenous fluids, buprenorphine, famotidine, ondansetron, and nutrition through the esophageal feeding tube with a slurry of a commercially available gastroenteric diet (Purina EN Feline Formula, q4h). Surgery was considered, but because George was stable and the amount of free peritoneal fluid was scant, a decision was made to continue medical treatment with close observation and serial CBC and abdominal ultrasound examinations. Within 12 hours of antibiotic treatment, George was brighter. A repeat abdominal ultrasound showed no changes except that mildly enlarged and hypoechoic mesenteric lymph nodes were identified. The CBC showed persistent nonregenerative anemia (HCT of 26.4%), 10,181 neutrophils/µL, 5553 bands/µL, 185 metamyelocytes/µL, and a normal platelet count (305,000/µL) with moderately toxic neutrophils. On day 5 of hospitalization, ultrasonography showed a decrease in the amount of peritoneal fluid. The enrofloxacin was discontinued when the results of culture and susceptibility became available. On day 6, the CBC showed a stable HCT, 9366 neutrophils/µL, 2810 bands/µL, moderately toxic neutrophils, and no metamyelocytes. A serum chemistry panel was unremarkable, and the total bilirubin was 0.1 mg/dL. On day 8, George began eating a small amount of food on his own, and the CBC showed further improvement with 6048 neutrophils/µL, 336 bands/µL, mild monocytosis (896 cells/µL), and no toxic neutrophils. He was discharged from the hospital the following day with instructions to continue tube feeding, ondansetron (0.3 mg/kg PO q24h), famotidine (0.5 mg/kg PO q12h), and amoxicillin–clavulanic acid (15 mg/kg PO q12h). At a recheck 1 week later, the owner reported that George had been doing well at home, although he had vomited three times over the course of the week. Physical examination was unremarkable, apart from the thyroid nodule and mild weight loss (body weight, 5.6 kg compared with 5.9 kg at discharge). A CBC showed a HCT of 30%, 10,592 neutrophils/µL, and 132 bands/µL. A serum chemistry panel was within normal limits, and the total T4 concentration was 8.2 µg/dL. Treatment with methimazole (1.25 mg q12h) was initiated for the hyperthyroidism, but because of continued vomiting, this was discontinued after three doses. George continued to improve. A week later he was eating canned and dry food on his own with no vomiting, a CBC showed no abnormalities, and the antibiotics were discontinued. The esophageal tube was removed 3 weeks later, and methimazole was reinstituted, after which his T4 normalized. Six months later George was still doing well.

Comments: In this cat, bacterial peritonitis and suspected cholecystitis were diagnosed based on cytologic and microbiologic analysis of bile and peritoneal fluid. However, there were no ultrasonographic abnormalities within the biliary tract, and cytologic evidence of inflammation in the bile was absent. Pancreatitis may have predisposed the cat to ascending infection of the biliary tract, and/or infection may have resulted from bacterial translocation. The lack of an inflammatory reaction in the bile was unusual, but it may have resulted from marked neutrophil degeneration in a toxic environment. Isolation of the same organism from both the bile and the peritoneal fluid and the rapid clinical response to antibiotic treatment suggested that *Enterococcus* played a role in disease in this cat, although some of the clinical signs and hematologic abnormalities may also have resulted from severe pancreatitis and hepatic lipidosis. Surgery was postponed with careful monitoring because the peritonitis appeared to be very low grade and there was concern it might exacerbate pancreatitis. Fortunately, the cat made a complete recovery. See Chapter 8 for precautions regarding administration of enrofloxacin to cats.

CHAPTER 89

Bacterial Infections of the Genitourinary Tract

Jane E. Sykes and Jodi L. Westropp

VetBooks.ir

Overview of Bacterial Infections of the Genitourinary Tract

Causes: The most common cause of genitourinary tract infections is *Escherichia coli*, but other gram-negative bacteria, staphylococci, and streptococci may also be involved. Anaerobic bacterial infections are rare causes of genitourinary tract infections but may be involved in pyometra.

Geographic Distribution: Worldwide

Major Clinical Signs: Dysuria, hematuria, or pollakiuria may occur with lower urinary tract infection, although some infections are subclinical. Acute pyelonephritis, prostatitis, and pyometra may be accompanied by fever or abdominal pain. Lethargy, inappetence, vomiting, or diarrhea may occur if sepsis develops. Pyometra may be accompanied by abdominal distention and/or a vaginal discharge. Prostatitis may be accompanied by dysuria, dyschezia, and a purulent or hemorrhagic urethral discharge.

Differential Diagnoses: Differential diagnoses for suspected bacterial cystitis include idiopathic/interstitial cystitis (cats), bladder neoplasia, or cystolithiasis. Differentials for bacterial pyelonephritis include nephrotoxin exposure, leptospirosis, fungal pyelonephritis, or protozoal nephritis. Pregnancy, mucometra, or hydrometra are differentials for pyometra, and benign prostatic hyperplasia, paraprostatic cysts, and prostatic neoplasia are differentials for prostatitis.

Human Health Significance: Multidrug-resistant uropathogens from dogs and cats may have the potential to colonize human patients, but this requires further study.

Bacterial infections of the genitourinary tract include uncomplicated and complicated lower urinary tract infections (UTIs); prostatitis; pyelonephritis; renal abscesses; epididymitis and orchitis; and vaginitis, metritis, and pyometra. Infections of the genitourinary tract usually follow impairment of normal host defenses and invasion by bacteria that are part of the normal flora. Less commonly, infection results from hematogenous spread of bacteria to urogenital organs. Specific pathogens such as *Leptospira* spp. that injure the kidneys secondary to systemic infection are described elsewhere in this book.

In healthy dogs and cats, bacteria are not found in the upper urinary tract, urinary bladder, proximal urethra, and prostate gland. Factors that prevent bacterial colonization of the bladder include the glycosaminoglycan layer that covers bladder transitional epithelium, frequent voiding, the normal urethral microflora, antimicrobial properties of urine, an appropriate host immune response, and a functional urethral sphincter. Commensal bacteria that reside in the distal urethra, prepuce, and vagina invade opportunistically when these mechanisms are disturbed. The most common pathogen involved in all genitourinary tract infections is *Escherichia coli*, which has a particular propensity to adhere to epithelial cells of the genitourinary tract. Others include coagulase-positive and coagulase-negative staphylococci; *Enterococcus* spp.; other aerobic gram-negative bacilli such as *Klebsiella*, *Proteus*, *Enterobacter*, and *Pseudomonas aeruginosa; Corynebacterium* spp.; streptococci; and mycoplasmas. Anaerobic bacteria can also be found in the genital tracts of female dogs and can contribute to pyometra and metritis when host defenses are impaired. In addition to impaired host defenses, a variety of bacterial virulence factors influence the ability of certain bacteria to ultimately invade tissues and cause disease. Virulence factors of uropathogenic *E. coli* are described in more detail in Chapter 36.

LOWER AND UPPER URINARY TRACT INFECTIONS

Etiology and Epidemiology

Bacterial UTIs are commonly diagnosed in dogs. Although mixed bacterial infections can occur, the vast majority of UTIs involve a single bacterial species.[1] The most common uropathogen isolated is *E. coli*, which accounts for approximately 50% of all isolates, followed by *Staphylococcus*, *Proteus*, *Klebsiella*, *Enterococcus*, and *Streptococcus* species. Mycoplasmas have also been isolated from dogs with UTIs, although their clinical significance can be unclear because they are usually isolated from dogs that have other disorders of the lower urinary tract, such as underlying neoplasia or cystolithiasis. Spayed females and older dogs are at increased risk for bacterial UTIs; the mean age at diagnosis is 7 to 8 years of age.[1,2] As a result of breakdown in host defense mechanisms, systemic disorders such as acute or chronic kidney disease, hyperadrenocorticism, diabetes mellitus, and systemic neoplasia also predispose dogs to UTIs (Table 89-1).

In cats, bacterial UTIs are less common than in dogs. The prevalence of bacterial UTI in cats with lower urinary tract signs (i.e., stranguria, hematuria, pollakiuria, or dysuria; hereafter referred to as LUTS) evaluated by referral institutions has ranged from just 1% to 3%,[3-5] although the prevalence was higher (23% of cystocentesis-collected specimens) in a study from Norway.[6] Most young cats with LUTS have disorders such as feline interstitial cystitis, which are not associated with bacterial infection. When UTIs do occur in *young* adult cats, they are generally secondary to catheterization, perineal urethrostomy, or rarely, congenital anatomical defects. In older cats,

VetBooks.ir

TABLE 89-1

Factors That May Predispose (or Contribute) to Development of Urinary Tract Infections in Dogs and Cats

Dogs	Cats
Recessed vulva or excess vulvar folds	Perineal urethrostomy
Diabetes mellitus	Hyperthyroidism
Hyperadrenocorticism	Diabetes mellitus
Renal failure	Renal disease
Urinary catheterization	Micturition abnormalities (urinary incontinence or urinary retention)
Ectopic ureters	Urinary catheterization
Micturition abnormalities (urinary incontinence or urinary retention)	Urolithiasis
Tube cystostomy	Urinary neoplasia (rare)
Glucocorticoid treatment and possibly treatment with other immunosuppressive drugs	Immunosuppressive drug treatment?
Urethrostomy	
Urolithiasis	
Urinary neoplasia	
Proliferative urethritis	
Polypoid cystitis	

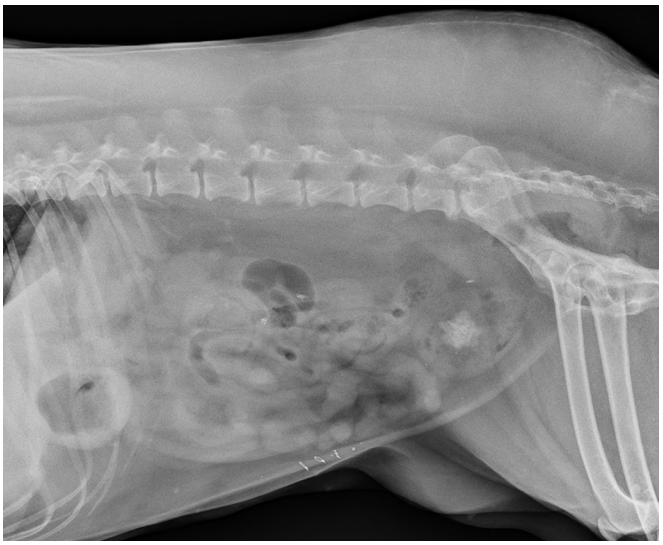

FIGURE 89-1 Lateral abdominal radiograph from a 10-year-old female spayed miniature schnauzer with emphysematous cystitis and a large, irregular cystic calculus. Irregular gas densities can see throughout the urinary bladder wall. *Escherichia coli* was cultured from a urine specimen that was obtained by cystocentesis.

TABLE 89-2

Definitions Applied to Urinary Tract Infections

Term	Definition
Simple uncomplicated UTI	Sporadic bacterial infection of the urinary bladder in an otherwise apparently healthy individual with normal urinary tract anatomy and function
Complicated UTI	UTI that occurs in the presence of an anatomic or functional abnormality or comorbidity that predisposes to persistent UTI, recurrent infection, or treatment failure
Recurrent UTI	Three or more episodes of UTI during a 12-month period
Refractory UTI	Isolation of the same microorganism more than once in the face of treatment, despite in vitro susceptibility to the antimicrobial drug used
Relapsing UTI	Isolation of the same microorganism within 6 months of apparent clearance of the infection with treatment in between positive cultures
Re-infection	Isolation of a different microorganism within 6 months of apparent resolution of a previous infection
Subclinical bacteriuria	Presence of bacteria in the urine as determined by a positive bacterial culture, in the absence of LUTS; differentiation from subclinical UTI may be difficult

UTIs often accompany diabetes mellitus, hyperthyroidism, and/or chronic kidney disease (CKD). The prevalence of UTIs in cats with diabetes mellitus is 11% to 13%.[7,8] At two referral institutions, positive aerobic bacterial urine cultures were found in 17% and 22% of cats with CKD and 22% and 12% of cats with hyperthyroidism.[7,9] Other factors that may predispose cats to UTI are breed (Persians or Abyssinians), female sex, older age, and lower body weight,[5,8,9] although some of these risk factors may also be associated with the comorbidities mentioned earlier. As in dogs, *E. coli* is the most common infecting species in cats. Other potential uropathogens in cats include *Streptococcus* spp., *Staphylococcus* spp., *Enterococcus* spp., *Klebsiella* spp., *Pasteurella* spp., and *Enterobacter* spp.[1,8,9] Mycoplasmas are very rarely isolated from the urine of cats.[9]

Uncommon forms of bacterial UTI in dogs and cats are *encrusting cystitis* and *emphysematous cystitis*. Encrusting cystitis is caused by the gram-positive bacterium *Corynebacterium urealyticum*. Urease production by this organism leads to precipitation of large amounts of struvite and calcium phosphate within the bladder and along the bladder and urethral mucosa, and in some cases within the ureters and renal pelvis as well.[10-12] Most animals with *C. urealyticum* infections have severe LUTS. Emphysematous cystitis is characterized by the production of gas by bacteria within the urinary bladder wall (Figure 89-1). The most common cause is *E. coli*, but *Clostridium* spp. may also be involved.[13,14] Most dogs and cats that develop *E. coli* emphysematous cystitis have glucosuria (usually secondary to diabetes mellitus), and gas production may result from fermentation of glucose to gas products by *E. coli*. In the absence of glucose, proteins such as albumin may be fermented to gas. Emphysematous cystitis caused by *Clostridium perfringens* occurs in the absence of diabetes mellitus.[13,14]

Definitions applied to infections of the urinary and genital tract are shown in Table 89-2. *Simple uncomplicated UTI* is a

VetBooks.ir

sporadic bacterial infection of the bladder in an otherwise apparently healthy individual with normal urinary tract anatomy and function.[15] It has been estimated that uncomplicated UTI occurs in 14% of dogs that visit a veterinarian during their lifetime.[16] However, the actual prevalence of simple uncomplicated UTI may actually be lower, because abnormalities in host defenses probably go unrecognized in many dogs. As noted earlier, uncomplicated UTI is rare in cats. *Complicated UTIs* are associated with concurrent disorders that predispose to recurrent or persistent UTI (see Table 89-1).

Recurrence of UTI may reflect refractory (or persistent) infection, relapsing infection, or re-infection (see Table 89-2). Without the use of molecular techniques (e.g., pulsed field gel electrophoresis), it is not possible to definitively distinguish between relapse of infection and re-infection if the same bacterial species is isolated repeatedly, because different strains may be present. *Enterococcus* spp. and *Pseudomonas* spp. are isolated more commonly from dogs with persistent or recurrent UTIs than from dogs with simple uncomplicated UTIs.[2] *E. coli* can invade and form microcolonies within uroepithelial cells,[17] which may contribute to persistent infection in the face of antimicrobial treatment. Bacteria may also be able to form biofilms in association with the bladder wall ("deep seated" infections), but studies that document this in the dog are lacking.

Subclinical (or asymptomatic) bacteriuria is a term used in human medicine to describe the presence of bacteria in the urine as determined by a positive bacterial culture, in the absence of LUTS. This has generally been referred to as *subclinical UTI* in the veterinary literature. The use of the term *subclinical bacteriuria* in animals and its distinction from *infection* (which implies invasion of host tissues by bacteria and the associated inflammatory response) has been controversial, because subtle signs of infection (such as bladder pain, pollakiuria, or intermittent hematuria) may not always be detected. The term *subclinical UTI* could perhaps be applied to dogs and cats if cytologic evidence of infection (e.g., pyuria or hematuria) is present,[15] but in human patients, the term subclinical bacteriuria is used even when pyuria is present. Subclinical bacteriuria or subclinical UTIs are commonly detected in dogs and cats, especially those with underlying endocrinopathies, renal failure, or neurologic disease, as well as dogs treated with glucocorticoids or cyclosporine.[7,8,18-20] In a study of dogs treated with glucocorticoids for dermatologic disorders, 18% of 127 dogs had bacteriuria in the absence of clinical signs, whereas none of 94 dogs that had not received glucocorticoids had bacteriuria.

Pyelonephritis most often occurs when bacteria ascend into the renal pelvis and parenchyma from the lower urinary tract. Less commonly, hematogenous spread to the kidney occurs. A single bacterial species (most often *E. coli*) is isolated from the urine of approximately three quarters of dogs with pyelonephritis; two species are isolated in fewer than 10% of dogs and three species from fewer than 5% of dogs. Pyelonephritis may be acute or chronic. Strains of *E. coli* that cause pyelonephritis have greater ability to adhere to cells than strains that cause cystitis. Adhesins located on the tip of *E. coli* fimbriae (P fimbriae) adhere to glycolipid residues on tubular, collecting duct, and bladder epithelial cells. In human pyelonephritis, both P and type I fimbriae are important in colonization of the renal pelvis.[21,22] Other *E. coli* virulence factors associated with pyelonephritis include hemolysin, cytotoxic necrotizing factor, the iron scavenger aerobactin, and a serum protease known as Sat. Fimbriae are also important in the pathogenesis of *Proteus* pyelonephritis.[23] The renal medulla is more sensitive to colonization than the cortex, possibly owing to impaired host defenses in a high osmolality, low pH, and low blood flow milieu. Organisms adhere to pelvic, distal, and proximal tubular epithelium and have been observed intracellularly. Considerable renal injury results from the inflammatory response to infection. Aggregation of neutrophils within capillaries and induction of vascular spasm by bacterial toxins and/or cytokines can contribute to renal ischemia.

Clinical Features

Clinical Signs

Clinical signs of lower UTI may be absent, or include signs such as dysuria, hematuria, stranguria, and pollakiuria. Cats may urinate outside the litter box (periuria or inappropriate urination). Rarely, animals with lower UTIs may be lethargic, but fever and inappetence are not present. Acute or acute-on-chronic pyelonephritis may result in inappetence, lethargy, variable fever, hematuria, and clinical signs of uremia, such as vomiting and diarrhea. Polyuria and polydipsia may also be present, or dogs with severe disease may be anuric. Dogs and cats with chronic pyelonephritis may show no signs, or only polyuria and polydipsia.

Physical Examination Findings

Physical examination findings in dogs or cats with lower UTIs may be unremarkable, or urine or urine scalding may be identified around the perineum. A strong ammonia-like odor may be present. Sometimes, pain can be detected on palpation of the urinary bladder of dogs or cats with bacterial cystitis, and abdominal or flank pain may be noted in animals with acute pyelonephritis. The urinary bladder is often small as a result of pollakiuria. A thickened bladder wall may also be palpated. If a large, turgid bladder is present in dogs or cats with a UTI, urethral obstruction due to neoplasia, calculi, proliferative urethritis, or encrusting cystitis should be suspected. Underlying disorders that predispose to lower UTIs may also be apparent (such as vulvar fold dermatitis).

Dogs and cats with severe pyelonephritis may show signs of lethargy, dehydration, variable fever, and evidence of severe sepsis or septic shock (e.g., tachycardia or bradycardia, tachypnea, or prolonged capillary refill time).

Diagnosis

Diagnosis of UTIs is based on the clinical signs present, laboratory abnormalities, imaging findings, and culture of urine. The presence of fever or leukocytosis in addition to a positive bacterial urine culture should increase suspicion for concurrent bacterial pyelonephritis, prostatitis, or pyometra (see relevant sections later in this chapter). Ultrasound examination findings also can support the diagnosis and assist in the identification of underlying disorders such as neoplasia, anatomic abnormalities, or the presence of calculi or foreign material. At a minimum, collection of urine by cystocentesis followed by complete urinalysis (with sediment examination) and quantitative aerobic bacterial urine culture are recommended to properly confirm the presence of bacterial UTI for dogs or cats with signs of lower urinary tract disease.[15] Additional diagnostics

VetBooks.ir

are indicated for animals that have recurrent LUTS or those with systemic signs such as fever, weight loss, or inappetence. The owners of animals diagnosed with what appears to be uncomplicated UTI should be advised that other underlying disease may be present.

Laboratory Abnormalities

Complete Blood Count and Serum Biochemical Tests

Animals with infections confined to the lower urinary tract typically have no hematologic or serum biochemistry abnormalities. Animals with pyelonephritis may have mild anemia, leukocytosis due to a neutrophilia, bandemia, and monocytosis. A degenerative left shift, toxic neutrophils, and thrombocytopenia may also be present. The serum biochemistry panel may show azotemia and sometimes hypoalbuminemia and/or electrolyte abnormalities.

Urinalysis

Findings on the urinalysis in dogs and cats with UTIs include isosthenuria, pyuria, hematuria, proteinuria, and/or bacteriuria. Animals with pyelonephritis may have cylindruria, and small amounts of glucose may be present as a result of altered proximal tubular function. However, the urinalysis can also be normal, even in dogs and cats with pyelonephritis. Infections with urease-producing bacteria such as staphylococci, *Proteus* spp., and *C. urealyticum* can be associated with a high urine pH and struvite crystalluria.

Coagulation Profile

Evidence of coagulation abnormalities may be present in animals with severe pyelonephritis that develop severe sepsis or septic shock (see Chapter 86).

Diagnostic Imaging

Plain Radiography

Dogs or cats with bacterial cystitis generally have no radiographic abnormalities. The urinary bladder may be small if pollakiuria is present. Emphysematous cystitis is characterized by the presence of radiolucencies within the bladder lumen and/or in association with the bladder wall (see Figure 89-1). Radiopaque cystic or renal ("staghorn") calculi may be visible in dogs with struvite calculi secondary to *Staphylococcus* spp. or *Proteus* spp. infections (Figure 89-2).

Renomegaly may be present with acute pyelonephritis, which is typically mild. The kidneys may be small and irregular in dogs or cats with chronic pyelonephritis.

Contrast Radiography

Contrast cystourethrography can be useful for diagnosis of conditions that predispose to recurrent or persistent UTIs, such as anatomic abnormalities, diverticuli, bladder or urethral neoplasia, proliferative urethritis, polypoid cystitis, or nonradiopaque calculi. Intravenous contrast urography has been used to identify pyelectasia and assist in the diagnosis of pyelonephritis, but has largely been replaced by abdominal ultrasound for this purpose, which is less invasive.

Sonographic Findings

Ultrasound examination of the urogenital tract provides information about the extent and severity of disease and underlying causes such as neoplasia, calculi, or foreign bodies. *It does not permit visualization of the entire urethra*, and so urethral abnormalities may be overlooked in some animals if only ultrasound is used to image the lower urinary tract. Ultrasound examination of the urinary bladder may be unremarkable or show a mild to moderately thickened bladder wall in dogs or cats with bacterial cystitis. Echogenicity of the urine may be present. Rarely, the bladder wall is severely thickened (Figure 89-3). Animals with emphysematous cystitis may have a hyperechoic urinary bladder wall with acoustic shadow artifacts. Shadow artifacts also occur when cystic calculi are present.

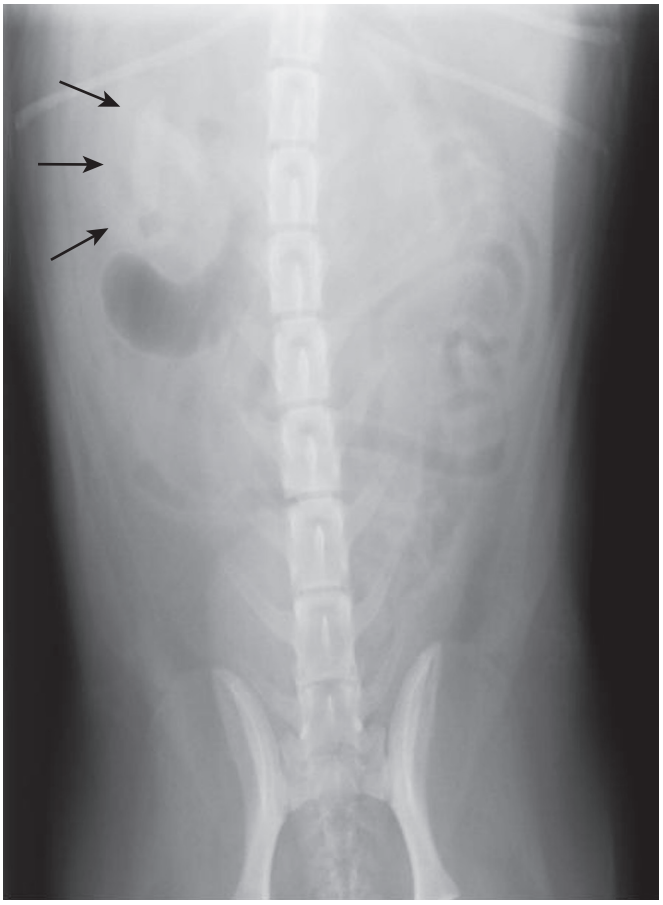

FIGURE 89-2 Dorsoventral radiograph of a 6-year-old female spayed shih tzu mix with a urinary tract infection caused by *Proteus mirabilis* and *Enterococcus faecalis* and nephrolithiasis. An opacity ("staghorn" calculus) occupies the right renal pelvis (*arrows*).

Dogs or cats with pyelonephritis may have a normal abdominal ultrasound examination; or blunting of the renal papilla, pyelectasia, irregularity of the renal contour, and/or hydronephrosis may be seen (Figure 89-4). However, pyelectasia can occur in animals with normal renal function, diuresis, and outflow tract obstruction, and there is considerable overlap in the extent of dilatation between groups.[24] The renal pelvis of dogs and cats with severe pyelonephritis may contain hyperechoic debris.[25] Sometimes the surrounding mesentery is hyperechoic, and perinephric anechoic fluid is present as a result of localized peritonitis. Other nonspecific findings in pyelonephritis include increased renal cortical echogenicity and decreased corticomedullary definition.

Cystoscopy

Cystoscopy can be a useful diagnostic procedure to identify underlying causes of recurrent UTIs in dogs and cats, after

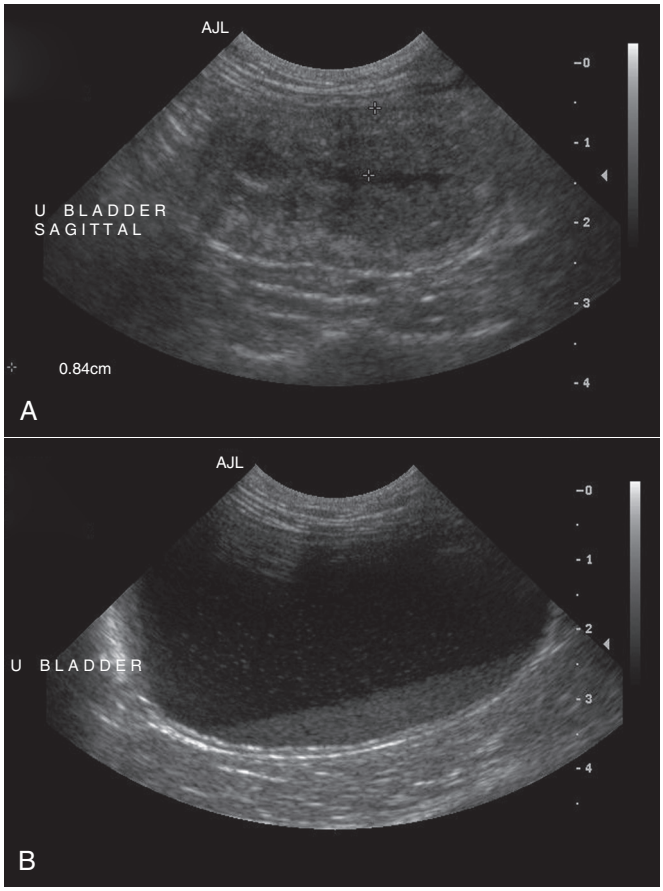

FIGURE 89-3 Ultrasound images of the bladder of an 18-year-old female spayed domestic shorthair cat with diabetes mellitus, generalized osteoarthritis, a cervical myelopathy, and L4-L6 disc space compression and recurrent urinary tract infections. The cat had severe lower urinary tract signs (hematuria, pollakiuria, and stranguria), and a hemolytic *Escherichia coli* was isolated from the urine. **A,** The wall of the urinary bladder is markedly thickened. **B,** Resolution of bladder wall thickening after treatment with marbofloxacin for 3 weeks, which also resolved the clinical signs.

evaluation has been performed first to evaluate for metabolic abnormalities such as renal failure, hyperadrenocorticism, or diabetes mellitus. Cystoscopy or contrast computed tomography are the most sensitive diagnostic tests for identification of ectopic ureters. Cystoscopy can also be used to obtain mucosal uroepithelial biopsies for histopathology and culture.

Microbiologic Tests

Isolation and Identification

Quantitative aerobic bacterial culture and susceptibility is always indicated for dogs or cats with UTIs before starting antimicrobial drugs, because of the possibility of antimicrobial drug resistance, which is well recognized among *E. coli* strains isolated from dogs and cats with UTIs.[26,27] Guidelines for diagnosis of bacterial UTIs in dogs and cats have been published.[15] Ideally, urine should be collected by cystocentesis; if this is not possible, urethral catheterization can be used. Although any pathogens isolated from specimens collected by cystocentesis are likely significant, bacterial contamination from the skin is possible; therefore, the presence of more than 10^3 CFU/mL of bacteria is considered clinically significant. If specimens are collected via catheterization, colony counts that exceed 10^4 CFU/mL for male dogs and 10^5 CFU/mL for female dogs are considered clinically significant.[15] Free-catch (midstream voiding) specimen collection should not be used for dogs or cats because it is highly susceptible to contamination. A positive aerobic bacterial culture of a cystocentesis-collected urine specimen confirms the presence of bacterial infection in animals that have LUTS. Culture can also help to differentiate re-infection from relapse should a UTI return; if the second isolate is a different bacterial species or has a different antibiotic susceptibility pattern (also known as an *antibiogram*), reinfection is likely.[15] Specimens for culture should be refrigerated immediately and submitted to the laboratory as soon as possible. For specimens that reach the laboratory more than 24 hours after collection, culture results should be interpreted with caution, because false-negative and false-positive test results can occur. For dogs and cats with recurrent UTIs that undergo surgery, culture of a bladder wall biopsy or of cystoliths should be considered.

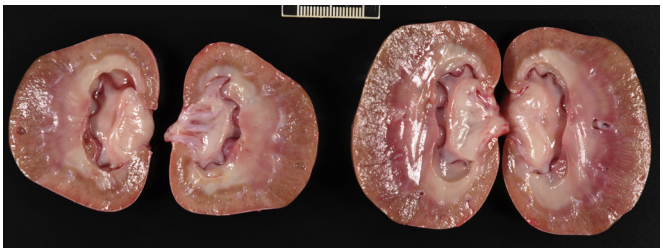

FIGURE 89-4 Kidneys of a 2-year-old male neutered German shepherd with diabetes mellitus and chronic pyelonephritis secondary to *Klebsiella pneumoniae* infection. The kidneys are bilaterally asymmetrical; the right kidney is larger than the left. There are several small, cortical subcapsular cysts, and the kidneys have an irregular conformation with markedly shrunken poles and are fibrotic. The renal parenchyma at the poles is markedly collapsed from the capsule to the pelvis, and the pelvis is uniformly dilated. (Image courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

Inexpensive urine "paddles" are available for in-house veterinary diagnosis of UTIs. One type consists of two different types of agar on either side of a plastic paddle (see also Chapter 3, Figure 3-6). The media are inoculated with urine collected by cystocentesis, and the paddles are then incubated and examined daily for growth. These paddles can be useful screening tools when client finances do not permit submission of specimens to a microbiology laboratory for culture, and they allow identification of significant bacterial growth by comparison of colony numbers to a chart provided by the manufacturer. They also reduce the effect of delays in submission of specimens to a laboratory. However, they may be inaccurate for identification of bacterial species involved, especially when mixed infections are present.[28] Paddles may not yield reliable results if submitted to a laboratory for confirmation and minimum inhibitory concentration (MIC) testing. If used, and growth is detected on the paddle within 24 hours, saved (refrigerated) urine or a freshly collected urine specimen should be submitted to a microbiology laboratory for culture and susceptibility testing. Another type of in-house culture system provides limited information on bacterial antibiotic susceptibility (Flexicut Vet, Atlantic Diagnostics), but requires further study. In-house bacterial cultures should only be performed in clinics with appropriate laboratory facilities, proper biosafety level containment and waste management, and adequately trained personnel.[15] Accurate susceptibility testing is difficult to perform and interpret, and whenever possible, submission to a veterinary diagnostic laboratory that adheres to Clinical and Laboratory Standards Institute (CLSI) guidelines is recommended.

For animals with indwelling urinary catheters, some bacteriuria is expected due to compromise of host immune defenses. Culture is indicated if clinical signs of infection are present

VetBooks.ir

(e.g., gross hematuria, pyuria, or suspected bacteremia).[15] Optimally, the catheter should be removed and cystocentesis performed after the bladder is allowed to fill with urine. Alternatively, the catheter could be removed, replaced with a new catheter, and a urine specimen collected through the catheter after several milliliters of urine are removed to clear the catheter. Urine culture should never be submitted from specimens collected from the urine bag, and there is no indication to culture the catheter tip.

When pyelonephritis is present, bacteria cultured from the urine are usually those present in the upper tract. A negative urine culture does not rule out bacterial pyelonephritis. In some cases, cytology and culture of ultrasound-guided aspirates of the renal pelvis (pyelocentesis) may assist in the diagnosis of pyelonephritis. Blood cultures could also be considered in animals with acute pyelonephritis, especially when signs of sepsis are present.

Laboratories that perform and report susceptibility testing for uropathogens should adhere to local regulatory guidelines (such as the CLSI). Breakpoints for systemic infections also apply to UTIs (see Chapter 3 for a discussion of breakpoints). However, many antimicrobials achieve much higher concentrations in the urine than they do in the serum. Therefore, if routine serum susceptibility testing is performed for a dog or cat with a lower UTI and normal renal function, some antimicrobials may eradicate the UTI, despite in vitro resistance. This is especially true for treatment of staphylococcal UTIs with penicillins and cephalosporines. Urinary breakpoints are available for ampicillin or amoxicillin in dogs (≤8 µg/mL), amoxicillin-clavulanate in dogs and cats (<8/4 µg/mL), and nitrofurantoin. Urinary breakpoints (reported as urine MICs by the laboratory) should be used only when infection is confined to the lower urinary tract.

Pathologic Findings

Pathologic findings in dogs with bacterial cystitis and pyelonephritis depend on the chronicity of the infection, the underlying cause, and the uropathogens present. Acute infections are associated with a dense neutrophilic infiltrate in tissues on histopathology and intralesional bacteria may be identified. Chronic infections may be associated with histiocytic or lymphoplasmacytic infiltrates.

Treatment and Prognosis

Treatment of UTIs consists of removal or management of the underlying cause(s) of infection, followed by antimicrobial drug treatment. Antimicrobial drug treatment alone without attention to an underlying cause frequently leads to recurrent infection and selection for resistant bacteria. Because of the increasing prevalence of multidrug-resistant (MDR) *E. coli* and staphylococci in dogs and cats with UTIs, consideration should be given to delaying antimicrobial drug treatment until the results of culture and susceptibility are available, provided the patient is stable and sepsis is absent. This is especially true for dogs and cats with recurrent UTIs that have a history of antimicrobial drug treatment. Empiric treatment while awaiting the results of culture and susceptibility could be considered to relieve discomfort, if present; however, some dogs respond well to analgesic therapy (e.g., tramadol) pending susceptibility test results. When sepsis is present, initial treatment should be broad-spectrum and cover MDR gram-negative bacteria (see Chapter 86).

Uncomplicated UTIs

In most situations, rational choices for initial treatment of uncomplicated UTIs include amoxicillin or trimethoprim-sulfonamide (TMS) (Table 89-3), although TMS has the potential to cause significant adverse effects in dogs. Amoxicillin–clavulanic acid could be considered if practice/regional susceptibility trends suggest a high (>10%) prevalence of β-lactamase production by uropathogens isolated (i.e., >10% of bacteria isolated in a practice show susceptibility to amoxicillin–clavulanic acid but not amoxicillin).[15] However, amoxicillin–clavulanic acid may need to be given q8h to ensure significant concentrations of clavulanic acid in the urine. Once culture and susceptibility results are available, the chosen antimicrobial drug should either be continued (if a clinical response has occurred) or switched to an alternative drug with activity against the pathogen that enters urine in high concentrations. A treatment duration of 7 days has been suggested.[15] One study showed that treatment of dogs that had uncomplicated UTIs with high-dose enrofloxacin (20 mg/kg) for 3 days was not inferior to treatment with amoxicillin–clavulanic acid for 14 days.[29] Additional studies of dogs with naturally occurring UTI that evaluate short durations of treatment with other antimicrobial drugs such as amoxicillin or TMS are needed. Studies are also needed to evaluate the need for posttreatment cultures to determine whether resolution of infection has occurred.[15]

Complicated UTIs

Investigation to identify an underlying cause is strongly recommended for animals with complicated UTIs. Referral should be considered for advanced imaging and diagnostic tests to evaluate the patient for predisposing factors. The choice of antimicrobial drug should be based on culture and susceptibility test

TABLE 89-3

Suggested Initial Treatment for Stable Dogs or Cats with Genitourinary Tract Infections Pending Culture and Susceptibility Results

Disease	Drug	Dose (mg/kg)	Route	Interval (hours)
Bacterial cystitis or pyometra	Amoxicillin *or*	11-15	PO	8
	Trimethoprim-sulfadiazine *or*	15*	PO	12
	Amoxicillin–clavulanic acid	12.5-25	PO	8
Pyelonephritis, prostatitis	Enrofloxacin *or*	10-20 (dogs)	PO	24
	Marbofloxacin *or*	2.7-5.5	PO	24
	Orbifloxacin	7.5	PO	24

See Table 86-8 for options for severe sepsis.
*Based on trimethoprim plus sulfadiazine concentration.

VetBooks.ir

results, and preference should be given to drugs that are excreted in the urine in active form. If excreted in the urine, drugs with intermediate susceptibility could be used to treat UTIs that are resistant to other appropriate drug choices; however, a higher dose (for concentration-dependent antimicrobials) or dosing frequency (for time-dependent antimicrobials) should be considered in these circumstances. Use of nitrofurantoin could be considered for lower UTIs that are resistant to other oral antimicrobial drugs that are excreted in the urine. When mixed infections are present, ideally antimicrobial drug treatment should be directed at all organisms present. In mixed infections that involve *Enterococcus* spp., anecdotal evidence suggests that the *Enterococcus* spp. infection will resolve when the other organisms are successfully treated.[15] Typically, 4 weeks of treatment is recommended for complicated UTIs, but shorter courses may be effective. Urine culture could be considered 5 to 7 days after initiating treatment to ensure the infection is not persistent and is recommended 7 days after treatment has been discontinued. If follow-up cultures are positive, further investigation to identify an underlying cause may be required. If no clinical signs are present, management should be as for subclinical bacteriuria (see later discussion).

There is no evidence that direct instillation of antimicrobials, antiseptics, glycosaminoglycans, or dimethyl sulfoxide (DMSO) directly into the bladder via a urinary catheter is effective for treatment of recurrent UTIs in dogs. These compounds are rapidly eliminated from the bladder when the animal urinates and may be locally irritating, which may predispose further to infection with drug-resistant bacteria. Approaches used in an attempt to prevent recurrence are detailed in the Prevention section.

Subclinical Bacteriuria

Treatment may not be required for dogs or cats that lack LUTS, but could be considered for dogs or cats that have underlying immunosuppressive disorders or are receiving glucocorticoids or chemotherapeutics (which may predispose them to ascending or systemic infection). However, some animals with disorders that predispose to bacterial colonization of the bladder are continuously bacteriuric, and treatment with antimicrobial drugs only selects for colonization by resistant organisms. More evidence that supports the need for diagnosis and treatment of subclinical bacteriuria when accompanied by specific disorders such as hyperadrenocorticism, diabetes mellitus, or chronic glucocorticoid treatment is required. Bacterial virulence factors may determine whether systemic invasion occurs.[30] MDR organisms are often of low virulence and may be replaced by susceptible bacteria when antimicrobial drug pressure is removed. After that, treatment may be possible if clinical signs develop or if there is concern for ascending infection. In human patients, treatment of asymptomatic bacteriuria associated with *Enterococcus* spp. infection is not recommended.[31] Whether this is also an appropriate recommendation in dogs and cats is unclear.

Pyelonephritis

Treatment of dogs with acute pyelonephritis should be initiated immediately, without waiting for culture and susceptibility test results. Cytologic examination of stained urine sediment may assist in initial selection of an antimicrobial drug (i.e., based on the presence of rods versus cocci). The use of a fluoroquinolone that is excreted in the urine in active form (i.e., not difloxacin) is recommended for gram-negative bacterial pyelonephritis, provided regional susceptibility data do not show widespread resistance to fluoroquinolones.[15] The dosage used may need to be reduced if severe renal impairment is present. If combination treatment is initiated and antimicrobial susceptibility test results show susceptibility to only one drug, the other drug should be discontinued. Treatment for 4 to 6 weeks is recommended, although shorter periods of treatment may be effective and require further study. Dogs with acute pyelonephritis may need hospitalization and treatment with intravenous fluids and other medications for acute renal failure or sepsis. Urinalysis and culture should ideally be performed after 7 days of treatment and again 7 days after treatment has been discontinued, to ensure that infection has been eliminated. If the same organism is isolated again, then an additional antimicrobial drug with in vitro activity against the organism could be added. Struvite nephrolithiasis (such as "staghorn" calculi) or struvite cystoliths may dissolve with antimicrobial treatment, although dietary intervention may also be needed in some cases. When stones are present, antimicrobial treatment should be continued until there is no radiographic or ultrasonographic evidence of calculi and the urine is sterile. Other calculi such as calcium oxalate, urate and cystine can predispose animals to recurrent bacterial infections and, if possible, should be removed. While dissolution protocols are described for urate and cystine, they often are not as rewarding as struvite. Calcium oxalate stones are not amenable to dissolution with dietary or antimicrobial therapy.

Prevention

Prevention of lower UTIs involves identification and reversal of underlying causes of infection, such as vulvar fold dermatitis or congenital abnormalities such as ectopic ureter. Urinary catheterization should be used only when necessary and should be performed in a manner that maintains sterility as much as possible. Intermittent catheterization is preferred to placement of an indwelling catheter. If indwelling catheterization is required, a closed sterile collection system should always be used, and the catheter should be removed as soon as it is no longer required, because the risk of ascending infection increases with every day the catheter is left in place. Treatment of catheterized animals with antimicrobial drugs may increase the risk for infection[32] and so should be done only when necessary; antimicrobial drugs should not be used in an attempt to prevent urinary catheter infection. Routine antimicrobial treatment after catheter removal is not indicated unless clinical signs of UTI develop, because colonization that follows catheterization is cleared once the catheter is removed and host defenses are restored.

Many treatments for prevention of UTIs in dogs and cats with a history of recurrent disease have been considered. Currently there is no evidence that urinary antiseptics (such as methenamine) or nutritional supplements (such as cranberry juice extract) are effective in dogs or cats. Some studies of the use of cranberry extract in human patients have shown no effect.[33,34] Evidence that intermittent (pulse) therapy or chronic, low-dose antimicrobial treatment prevent recurrent UTIs is anecdotal; because it may select for resistant organisms, it is not generally recommended.

Public Health Aspects

Dogs and cats with UTIs have a potential to act as a source of MDR bacteria for humans. Similarities between uropathogenic *E. coli* isolates from dogs and those from humans have been identified,[35,36] but differences also exist.[37] Owners of pets with MDR UTIs should always wash their hands after handling their pets

and wear gloves when medications are administered, and pets should be taken to urinate away from other people and animals.

ORCHITIS, EPIDIDYMITIS, AND PROSTATITIS

Etiology and Epidemiology

Orchitis and epididymitis may occur in association with bacterial UTIs or penetrating foreign bodies (e.g., plant awns) in intact male dogs, but this is rare. Infection with *Brucella canis* should always be suspected in dogs with epididymitis (see Chapter 53).

E. coli accounts for most cases of bacterial prostatitis in dogs. Occasionally other gram-negative or gram-positive bacteria, including atypical organisms such as *Mycoplasma* spp. and *Brucella* spp., cause prostatitis. Bacterial prostatitis is extremely rare in cats.[38]

Clinical Features

Signs and Their Pathogenesis

Bacterial prostatitis in dogs may be acute or chronic. It can occur secondary to benign prostatic hyperplasia or prostatic neoplasia, most likely as a result of ascending infection secondary to altered urinary defense mechanisms. Bacterial prostatitis should be suspected in any intact male dog that develops a UTI. Dogs with bacterial prostatitis may show infertility, fever, lethargy, inappetence, weight loss, LUTS, purulent or hemorrhagic urethral discharge, abdominal pain, and sometimes a stiff gait. Tenesmus, vomiting, and diarrhea also occur in some dogs. Acute bacterial prostatitis can be accompanied by severe sepsis or septic shock (see Chapter 86). Formation of prostatic abscesses may be followed by abscess rupture and peritonitis. Dogs with chronic prostatitis may be lethargic or have no clinical signs of illness.

Physical Examination Findings

Dogs with acute bacterial prostatitis may exhibit pain on palpation of the prostate during physical examination. The prostate may be normal in size and shape, or enlarged or irregularly shaped. Fluctuant regions may be palpated if abscesses are present. Palpation should always be performed cautiously when acute bacterial prostatitis is suspected to avoid rupture of prostatic abscesses. Hemorrhagic or purulent discharge may be seen at the urethral orifice. Dogs with severe acute prostatitis may be dehydrated, febrile, obtunded, and show other signs of severe sepsis or septic shock (e.g., tachycardia or bradycardia, tachypnea, prolonged capillary refill time). Intact male dogs with bacterial orchitis or epididymitis may have testicular enlargement, hyperemia, and pain on palpation of the testicles. These findings may be present in association with prostatitis.

Diagnosis

Diagnosis of bacterial prostatitis is based on clinical signs, laboratory abnormalities, imaging findings, and culture of urine or prostatic secretions.

Laboratory Abnormalities

Dogs with acute prostatitis may have mild anemia and leukocytosis due to a neutrophilia, bandemia, and monocytosis. A degenerative left shift, toxic neutrophils, and thrombocytopenia may be present in severely affected dogs. Hypoalbuminemia and electrolyte abnormalities may be present, or there be evidence of organ dysfunction in dogs with septic shock. Hyperglobulinemia can be present in dogs with chronic prostatitis. The urinalysis may reveal abnormalities consistent with UTI.

Diagnostic Imaging

Plain and Contrast Radiography

Plain radiography is of limited value for diagnosis of bacterial prostatitis. Dogs with prostatic abscesses may have prostatomegaly (a prostate diameter >70% of the distance between the pubis and the sacral promontory), with ventral and cranial displacement of the urinary bladder.[39] Prostatic mineralization rarely accompanies chronic bacterial prostatitis in intact dogs, but when present in a neutered dog, mineralization strongly supports the presence of prostatic neoplasia.[40] Extravasation of contrast material into the prostate during retrograde contrast cystourethrography supports a diagnosis of prostatitis or prostatic neoplasia.

Sonographic Findings

Sonographic abnormalities in dogs with prostatitis include prostatic irregularity, mixed echogenicity, and focal accumulations of anechoic or hypoechoic fluid, with distance enhancement (prostatic cysts or abscessation) (Figure 89-5).[41]

Microbiologic Tests

Isolation and Identification

Many dogs with prostatitis shed bacteria into the urine, and therefore bacteria cultured from the urine are usually those involved in prostatitis. However, a negative urine culture does not rule out bacterial prostatitis, and occasionally the organisms isolated from the urine differ from those isolated from the prostate.

Collection of prostatic fluid via ejaculation, prostatic wash, or aspiration of the prostate or prostatic cysts may also be helpful

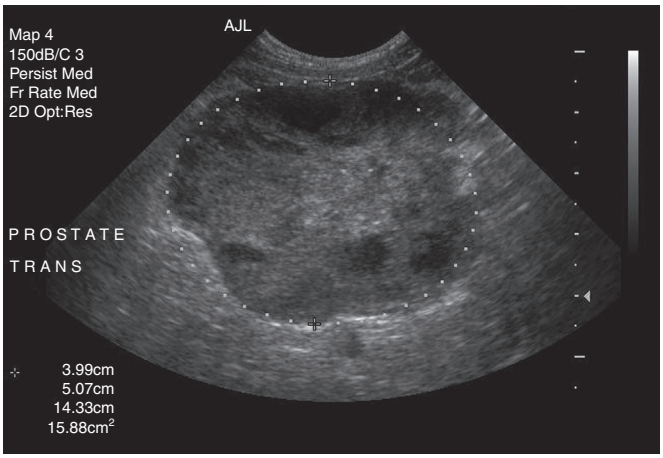

FIGURE 89-5 Ultrasound image of the prostate of a 12-year-old intact male beagle dog that had acute prostatitis due to *Escherichia coli* and associated bacterial peritonitis. The dog was seen for acute onset of anorexia and vomiting. Bloodwork revealed 2254 neutrophils/μL, 1160 band neutrophils/μL, mild hypoalbuminemia (2.4 g/dL; reference range, 2.9-4.2 g/dL), increased serum ALP activity (1338 U/L; reference range, 15-127 U/L) and increased serum total bilirubin concentration (0.5 mg/dL, reference range, 0-0.4 mg/dL). The prostate was significantly increased in size on sonographic examination and contained multiple hypoechoic nodules. There was a small quantity of ascites, which were localized in the caudal abdomen in the region of the prostate. Hemolytic *E. coli* was isolated from urine and from a prostatic aspirate. The owners elected euthanasia. Acute prostatitis and peritonitis were confirmed at necropsy.

VetBooks.ir

for the diagnosis of bacterial prostatitis. Aspirates of the prostate for culture and cytology (if clinically indicated) can be done in dogs with acute and chronic prostatitis; however, dogs with acute prostatitis may require sedation for patient comfort. The presence of large numbers of bacteria (>10^5 CFU/mL) together with an inflammatory response suggests infection. Cytologic examination and culture of ultrasound-guided aspirates of prostatic abscesses has been used to assist diagnosis, but there is a risk of localized peritonitis when abscessed tissues are aspirated.

Pathologic Findings

Dogs with acute prostatitis may have infiltrates of neutrophils with or without intralesional bacteria in the prostate on histopathology. Chronic infections may be associated with histiocytic or lymphoplasmacytic infiltrates. In some cases, prostatic hyperplasia or abscess formation are identified.

Treatment and Prognosis

Acute prostatitis should be treated with an appropriate antimicrobial drug for 4 weeks. If the dog is septic, parenteral antimicrobial administration may initially be required. If inflammation is severe, any drug appropriate for treatment of UTIs may still penetrate the prostate in the acute phase.

Drug penetration is impaired in dogs with chronic prostatitis because of the blood–prostatic fluid barrier. Drugs that effectively cross the prostatic barrier of dogs include enrofloxacin, ofloxacin, marbofloxacin, trimethoprim, and chloramphenicol. Because trimethoprim-sulfamethoxazole and chloramphenicol are more likely to be associated with adverse effects when administered for prolonged periods, a fluoroquinolone such as enrofloxacin is the drug of choice for initial treatment of gram-negative bacterial prostatitis. If the MIC of the organism is between 0.5 and 1.0 µg/mL, the highest dose of enrofloxacin is recommended (20 mg/kg q24h). Clindamycin may be a reasonable choice for dogs with gram-positive bacterial prostatitis, although this is uncommon. Treatment of dogs with chronic prostatitis should continue for at least 6 weeks. Organisms may persist within the prostate of dogs with chronic prostatitis despite appropriate antimicrobial drug treatment. Cure may not be possible without castration.

Surgical castration is recommended for dogs with prostatitis and should be performed as soon as the dog is stable to undergo anesthesia and surgery. The efficacy of drugs that cause prostatic involution, such as finasteride, is not clear, but finasteride enhanced resolution of infection in a rat model of chronic prostatitis when administered with a fluoroquinolone.[42] Prostatic abscesses also must be treated surgically, although ultrasound-guided drainage together with antimicrobial drug treatment can be effective for small (e.g., <2.5 cm) abscesses. Castration and antimicrobial drug treatment alone do not effectively resolve prostatic abscesses; surgical drainage is required. Long-term, once-daily treatment with antimicrobial drugs that enter the prostate has been suggested for dogs that fail to respond to medical and surgical treatment of chronic prostatitis, as used to treat humans.[43]

Follow-up should consist of a recheck 7 to 10 days after initiating treatment. Aerobic bacterial urine culture should be considered at this time if a positive urine culture was initially present. A recheck should also be performed 1 week after discontinuation of treatment, at which time physical examination, urinalysis, urine culture, and prostatic fluid cytology and culture should be performed. Where available, prostatic ultrasound may also provide useful information at these follow-up times and, if possible, should be performed 1 week after discontinuation of antimicrobial drugs.

Prevention

Routine castration reduces the risk of prostatitis, but prostatitis can still occur in neutered animals.

VAGINITIS, METRITIS, AND PYOMETRA

Etiology and Epidemiology

Bacterial vaginitis in adult bitches is usually secondary to an underlying disorder such as neoplasia, foreign bodies (e.g., grass awn), UTI, or anatomic abnormalities such as strictures. Puppy vaginitis is thought to be a consequence of immaturity rather than bacterial infection.

Metritis results from ascending infection of the uterus. It usually occurs shortly after parturition (e.g., within a week) or after obstetrical procedures. It may be associated with clinical signs of lethargy, fever, decreased appetite, and purulent vaginal discharge.

Pyometra is an accumulation of pus within the uterus (Figure 89-6). The pathogenesis of pyometra is incompletely understood. However, in contrast to metritis, pyometra most often seems to occur as a result of increased serum progesterone concentrations, which cause cystic endometrial hyperplasia (CEH), impaired immune function, and decreased uterine contractility. The end result for some dogs and cats is opportunistic bacterial invasion, most often by *E. coli* strains that have virulence factors typical of uropathogenic isolates.[35,44] Other bacterial species that cause pyometra are similar to those that cause UTIs, with the exception that anaerobes are more often involved in pyometra, usually in mixed infections with other bacteria. CEH is not an absolute requirement for development of pyometra, and some animals with CEH never develop pyometra. Exogenous administration of estrogen (used to treat mismating) or progesterone has also been associated with pyometra.[45] Rarely, pyometra occurs in conjunction with uterine

FIGURE 89-6 Uterus of an 11-year-old female spayed Pomeranian with pyometra after ovariohysterectomy. The uterine horns were severely dilated and fluid-filled. (Image courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

VetBooks.ir

neoplasia.[46] Emphysematous pyometra has been reported in dogs but is uncommon.[47-49] Etiologic agents in emphysematous pyometra include *C. perfringens*, *Citrobacter diversus*, and *P. aeruginosa*.

In dogs, pyometra usually occurs in diestrus, but it can occur in anestrus. Middle-aged to older (mean age around 9 years), intact female dogs are most often affected, but pyometra has been reported in dogs as young as 8 months of age. Older dogs develop pyometra as a result of chronic, repeated exposure to progesterone with cycling over many years. In contrast, younger dogs tend to develop pyometra as a result of treatment of mismatings with estrogens. Pyometra is prevalent wherever routine ovariohysterectomy of dogs is not widely performed. In a study from Scandinavia, breeds of dogs with increased risk included collies, Rottweilers, Bernese mountain dogs, Cavalier King Charles spaniels, English cocker spaniels, and golden retrievers.[50,51] Nulliparous bitches are at increased risk for development of pyometra when compared with those that have had litters, but false pregnancy does not influence the risk for pyometra in dogs.

In cats, CEH also seems to underlie pyometra. Although cats with pyometra are generally more than 3 years of age (mean, 5 years), pyometra can occur in cats of any age.

Clinical Features

Clinical Signs

Clinical signs of pyometra in dogs usually occur 2 to 10 weeks after estrus or breeding, but occasionally occur as long as 15 weeks after estrus (mean, 7 weeks). In both dogs and cats, clinical signs may be acute or chronic and include lethargy, polyuria and polydipsia, vomiting, weight loss, inappetence, diarrhea, fever, and/or abdominal pain. Some dogs or cats show no signs of illness. Animals with *open-cervix pyometra*, the most common form of pyometra (>60% of dogs), usually have purulent vaginal discharge. The discharge may have a fetid odor and it may be mucopurulent, purulent, or contain blood. Dogs or cats with *closed-cervix pyometra* do not have vaginal discharge, but abdominal distention may be present. Animals with closed pyometra are more likely to have severe signs of systemic illness than those with open pyometra. Concurrent glomerular and tubulointerstitial disease and/or the effects of *E. coli* endotoxin may also contribute to signs of polyuria and polydipsia.[52,53] In some dogs or cats, pyometra is accompanied by severe sepsis or septic shock. When disease is severe the uterus can rupture, which leads to peritonitis.

Stump pyometra is an uncommon form of pyometra. It sometimes occurs after remnants of the ovaries are inadvertently left in place after ovariohysterectomy, but this is not always the case. Stump pyometra occurs most commonly in dogs, but has been reported in the cat.[54] Clinical signs are similar to animals with pyometra. Stump pyometras can also contribute to recurrent lower UTIs.

Physical Examination Findings

Purulent vaginal discharge, sometimes with a putrid odor, may be present in animals with bacterial vaginitis or open pyometra. Fever is most likely to be identified in animals with closed-cervix pyometra. Abdominal pain may be present on palpation of the abdomen. Abdominal palpation should always be performed cautiously when pyometra is suspected so that uterine rupture does not occur. Dogs and cats with severe pyometra may be lethargic, dehydrated, and show signs of severe sepsis or septic shock.

Diagnosis

Diagnosis of vaginitis, metritis, and pyometra is based on signalment, history, clinical signs, laboratory abnormalities, imaging findings, and, in some cases, bacterial culture of the urine or uterine contents obtained during surgery. Blind cystocentesis should never be performed if pyometra is suspected because of the risk of inadvertent puncture and rupture of the uterus. This also has the potential to occur with ultrasound-guided cystocentesis, but the risk is lower.

Laboratory Abnormalities

Acute metritis or pyometra (especially closed-cervix pyometra) may be associated with anemia, leukocytosis due to a neutrophilia, bandemia, a degenerate left shift, toxic neutrophils, and monocytosis. Thrombocytopenia and signs of organ dysfunction (such as azotemia, increased serum ALP activity, and coagulation abnormalities) may be detected in dogs with severe sepsis or septic shock. Azotemia may result from severe dehydration or concurrent pyelonephritis. Hypoalbuminemia and electrolyte abnormalities such as low serum sodium-to-potassium ratios may be present.[55,56] Dogs and cats with chronic pyometra can have few laboratory abnormalities; some animals are hyperglobulinemic. On urinalysis, abnormalities consistent with UTI may be present. Urine protein-to-creatinine ratios may be increased as a result of renal tubular or glomerular injury.[53]

Diagnostic Imaging

Plain Radiography

Abdominal radiographs in dogs with pyometra may reveal the presence of a large coiled or tubular mass in the caudal and mid-abdomen that displaces the small intestine cranially and dorsally. The uterus may not be visible in dogs with open pyometra. Differentiation of pyometra from pregnancy may require ultrasound examination. Localized or generalized loss of abdominal detail may be present in dogs with peritonitis secondary to uterine rupture.

Sonographic Findings

Ultrasound is the imaging technique of choice for diagnosis of pyometra and differentiation of pyometra from pregnancy. However, it may not effectively distinguish pyometra from mucometra or hydrometra. Dogs with pyometra have an enlarged uterus, which is immediately dorsal to the bladder. The uterus may be thin-walled and distended with echogenic intraluminal fluid, or have a thickened wall with anechoic areas due to glandular proliferation and enlargement.[57] Stump pyometra may be recognized as a hypoechoic structure that is located dorsal and caudal to the urinary bladder (Figure 89-7).

Microbiologic Tests

Isolation and Identification

Fine-needle aspiration of the uterus is contraindicated in animals with suspected pyometra because of the risk of uterine rupture. Instead, the bacteria involved in pyometra are initially identified through bacterial culture of the urine, which frequently contains the same bacteria as those involved in the pyometra. However, a negative urine culture does not rule out pyometra, and

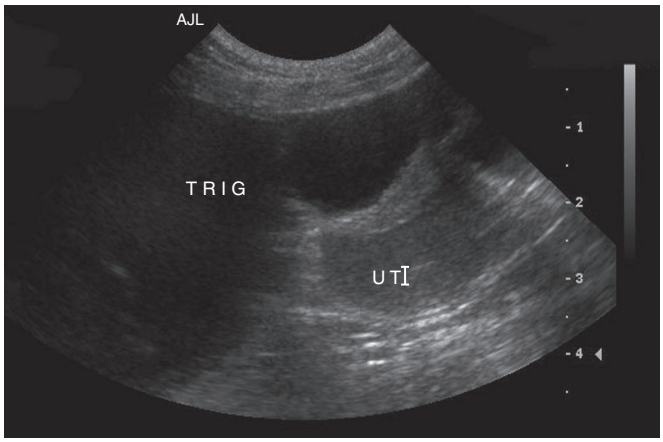

FIGURE 89-7 Ultrasound image of the urinary bladder and uterine stump in a 3-year-old female spayed mixed-breed dog that had vaginal discharge with a putrid odor due to a stump pyometra. An oval structure (*UT*) that contained flocculent material is present within the pelvic inlet caudal to and dorsal to the anechoic urinary bladder (*TRIG*, trigone). A cystic structure was seen in the region of the left ovary that represented a left ovarian remnant (not shown).

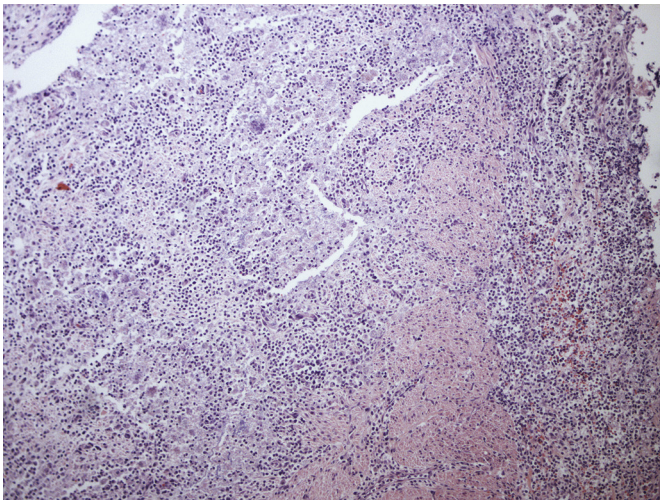

FIGURE 89-8 Histopathology of the uterus from a 7-year-old female poodle with pyometra. The dog was seen for vomiting, inappetence, obtundation, nystagmus, collapse, and abdominal distention. The owner elected euthanasia. Severe, chronic, suppurative metritis with uterine perforation and septic peritonitis was found at necropsy. The myometrium (pink) is almost completely replaced by large numbers of inflammatory cells. Aerobic and anaerobic bacterial culture of the abdominal fluid yielded mixed growth that consisted of *Escherichia coli* and a non-enteric gram-negative aerobic bacterial species, a *Bacteroides levii*–like anaerobe, *Bacteroides fragilis*, *Prevotella heparinolyticus*, *Fusobacterium nucleatum*, and *Peptostreptococcus anaerobius*. H&E stain.

occasionally the organisms isolated from the urine differ from those causing the pyometra. For animals with open pyometra, culture of a swab specimen collected from the cranial vaginal vault could be considered, but the bacteria cultured may or may not be the same as those present within the uterus. Tissues removed surgically can be submitted for culture and susceptibility testing. This should be performed despite administration of broad-spectrum antimicrobial drugs before surgery, because these drugs are unlikely to penetrate pus within the uterus. If possible, both anaerobic and aerobic bacterial cultures should be submitted. Blood cultures could be considered when signs of severe sepsis are present.

Pathologic Findings

As for other urogenital infections, acute pyometra is associated with a dense neutrophilic infiltrate on histopathology (Figure 89-8), and intralesional bacteria may be identified; chronic infections may be associated with histiocytic or lymphoplasmacytic infiltrates. CEH (expansion of the endometrium with hyperplastic and dilated or cystic glands) and corpora lutea may be identified.

Treatment and Prognosis

Sick dogs or cats with metritis or pyometra should be treated aggressively with intravenous fluids and broad-spectrum parenteral antimicrobial drugs that have activity against gram-negative bacteria and anaerobes, such as a combination of clindamycin or metronidazole and a fluoroquinolone. Ovariohysterectomy is strongly recommended for animals with pyometra and may need to be performed on an emergency basis to resolve sepsis or septic shock. Caution is required to avoid rupture of a distended or friable uterus during surgery, because this has been associated with an increase in mortality (from <10% to approximately 50%). Reevaluation should be performed 1 week after discharge from hospital and should include physical examination, a CBC, biochemistry panel, and urinalysis. Usually there is a rapid response to treatment and hematologic and biochemical abnormalities resolve within this time period. The white cell count can increase dramatically after surgery before it returns to normal, because of sudden removal of the leukocyte "sink". Antimicrobial drug treatment should be continued for 7 to 10 days after ovariohysterectomy.

In conjunction with antimicrobial drug treatment, medical treatment with natural or synthetic prostaglandin $F_2\alpha$ ($PGF_2\alpha$) is an alternative option to surgery, especially for dogs with open pyometra that are young (<6 years of age) and otherwise in good health (Table 89-4[58-60]). This treatment causes lysis of the corpora lutea with expulsion of uterine contents. Medical treatment for pyometra without surgery is not recommended for dogs that are systemically unwell, and the possibility of pregnancy must first be ruled out with ultrasound. Medical treatment is less attractive for dogs with closed pyometra because (1) it risks uterine rupture; (2) it is less effective than in dogs with open pyometra; and (3) dogs are often systemically unwell. Nevertheless, it has been used with success in some dogs with closed pyometra. Medical treatment is most

TABLE 89-4

Published Treatment Protocols for Medical Therapy of Pyometra in Dogs and Cats[58-60]

Drug	Dose
Natural $PGF_{2\alpha}$ (Lutalyse)	0.1 mg/kg SC once (day 1), 0.2 mg/kg SC once (day 2), 0.25 mg/kg SC q24h days 3 to 7
Aglepristone	10 mg/kg SC once on days 1, 2, and 7
Aglepristone and cloprostenol	Aglepristone: 10 mg/kg SC once on days 1, 2, and 8 Cloprostenol: 1 µg/kg SC for 5 days on days 3 through 7

VetBooks.ir

likely to be successful in dogs in late diestrus (>5 weeks after the end of estrus). Improvement is generally not evident for at least 48 hours, and adverse reactions to $PGF_2\alpha$ are common and include restlessness, hypersalivation, panting, vocalization, vomiting, diarrhea, mydriasis, fever, and rarely, signs of shock. As a result, treatment should be given in the morning on an empty stomach, hospitalization and observation are recommended for at least 4 hours after the injection (or throughout the treatment period in dogs with closed pyometra), and the dose should be carefully calculated and appropriate for the product used. Walking dogs for 20 to 40 minutes after drug administration (while adverse effects occur) may lessen the adverse effects and promotes close observation.[58] The severity of signs tends to decrease with each injection administered. For dogs with closed pyometra, serial abdominal ultrasound examinations are recommended every 2 days during treatment to evaluate for evidence of peritonitis. $PGF_2\alpha$ can also be used to treat postpartum metritis.

Aglepristone, a progesterone receptor antagonist that is available in Europe, appears to be a safe and effective alternative to $PGF_2\alpha$ for treatment of pyometra in both dogs and cats.[59] Addition of low-dose cloprostenol (a synthetic $PGF_2\alpha$ derivative) to aglepristone in one study increased success rate in dogs with open pyometra from 60% to 84%.[60]

All dogs treated medically should be reevaluated 2 weeks after treatment. If signs of pyometra persist, culture of a swab specimen from the cranial vaginal vault could be performed to determine if resistance to antimicrobials is present, and treatment should be repeated a second time or surgery performed. The measurement of serum progesterone to monitor effective treatment is not necessary, because it does not change treatment recommendations. After successful treatment, the dog or cat should be bred at each subsequent cycle until pregnancy occurs. The chance that subsequent pregnancy will occur is over 80%, and the vast majority of dogs that respond go on to have more than one litter. Once the dog or cat is no longer required as a breeding animal, it should be neutered.

Prevention

Routine ovariohysterectomy reduces the risk of pyometra. Although stump pyometra can still occur in neutered animals, it is relatively rare. There is no known treatment for CEH. Use of estrogens to treat mismatings is not recommended.

CASE EXAMPLE

Signalment: "Molly", a 6-year-old female spayed shih tzu mix from Sacramento, CA

History: Molly was brought to the UC Davis VMTH for evaluation of recently diagnosed nephrolithiasis and hematuria. Three weeks previously, the owners had observed blood in Molly's urine. There had been no stranguria, polyuria, polydipsia, or change in the frequency of urination. They took her to their local veterinary clinic, where blood work was performed; her hematocrit was 56.5% and thrombocytopenia (86,000 platelets/µL) was present. A urine dipstick analysis revealed 2+ protein, a pH of 8, hematuria, and pyuria. Urine specific gravity was 1.014. Abdominal radiographs revealed a 3-cm opacity in the right renal pelvis that was consistent with a nephrolith (see Figure 89-2). The kidneys had a mildly irregular shape but were normal in size. Treatment with amoxicillin was initiated (23 mg/kg PO q12h for 10 days). Twelve days later, the dog was returned for dental prophylaxis. A CBC showed a hematocrit of 50% and persistent thrombocytopenia (51,000 platelets/µL). An abdominal ultrasound showed a 2.9-cm right renal pelvic nephrolith and a 7-mm left renal pelvic nephrolith. The kidneys were normal in size but had a mildly irregular shape. There was moderate thickening of the apical wall of the urinary bladder, with a small (4-mm) apical polyp. Moderate flocculent suspended debris was present within the urine and multiple sand-like calculi were present. All other organs evaluated were within normal limits. The dental procedure was canceled and Molly was referred for further evaluation.

Other Medical History: Molly had traveled frequently to Oregon and Nevada. She was fed a stone dissolution diet (Royal Canin Urinary SO), which had been prescribed 4 years ago when crystals were seen in her urine on urinalysis, as part of a wellness examination. She was also occasionally fed dog treats. She had been vaccinated using a 3-yearly protocol for canine distemper virus, canine adenovirus, canine parvovirus, and rabies; and yearly for *Bordetella bronchiseptica*, canine coronavirus, leptospirosis, and Lyme disease. Her last vaccination was more than 8 months previously. She was treated with imidacloprid and ivermectin for flea and heartworm prophylaxis, respectively, each month.

Physical Examination:

Body Weight: 10.8 kg.

General: Bright and alert, hydrated. T = 101.6°F (38.7°C), HR = 128 beats/min, RR = 32, mucous membranes pink and moist, CRT < 1 s.

Eyes, Ears, Nose, and Throat: Mild epiphora was present bilaterally and there was mild dental calculus and gingivitis. No other clinically significant abnormalities were detected.

Integument: The abdomen was clipped from the previous ultrasound examination with healing clipper wounds. There was a 1-cm ecchymosis on the ventral abdomen.

Musculoskeletal: Body condition score was 7/9. The dog was ambulatory with normal gait.

Genitourinary/Gastrointestinal: The dog had a soft and mildly painful abdomen on palpation. The urinary bladder was moderately sized. Rectal examination was unremarkable. There was no vulvar discharge and no evidence of perivulvar dermatitis. A slightly recessed vulva was present.

All Other Systems: No clinically significant findings.

Laboratory Findings:

CBC:

HCT 49.1% (40%-55%)
MCV 70.3 fL (65-75 fL)
MCHC 35.0 g/dL (33-36 g/dL)
nRBC 1/100 WBC

VetBooks.ir

WBC 10,200 cells/μL (6000-13,000 cells/μL)
Neutrophils 7140 cells/μL (3000-10,500 cells/μL)
Band neutrophils 102 cells/μL
Lymphocytes 1632 cells/μL (1000-4000 cells/μL)
Monocytes 816 cells/μL (150-1200 cells/μL)
Platelets 12,000 platelets/μL (150,000-400,000 platelets/μL)
MPV 21.6 fL (7-13 fL)
Many macroplatelets were reported on smear evaluation.

Serum Chemistry Profile:
Sodium 148 mmol/L (145-154 mmol/L)
Potassium 4.0 mmol/L (3.6-5.3 mmol/L)
Chloride 111 mmol/L (108-118 mmol/L)
Bicarbonate 23 mmol/L (16-26 mmol/L)
Phosphorus 3.6 mg/dL (3.0-6.2 mg/dL)
Calcium 10.1 mg/dL (9.7-11.5 mg/dL)
BUN 12 mg/dL (5-21 mg/dL)
Creatinine 0.9 mg/dL (0.3-1.2 mg/dL)
Glucose 92 mg/dL (64-123 mg/dL)
Total protein 6.1 g/dL (5.4-7.6 g/dL)
Albumin 3.4 g/dL (3.0-4.4 g/dL)
Globulin 2.7 g/dL (1.8-3.9 g/dL)
ALT 42 U/L (19-67 U/L)
AST 16 U/L (19-42 U/L)
ALP 85 U/L (21-170 U/L)
Cholesterol 257 mg/dL (135-361 mg/dL)
Total bilirubin 0.1 mg/dL (0-0.2 mg/dL)

Urinalysis: SGr 1.013; pH 8.0, 2+ protein (SSA), 1+ bilirubin, 4+ hemoprotein, no glucose, no ketones, >100 WBC/HPF, 30-50 RBC/HPF, no crystals or casts, many rods, rafts of atypical transitional cells, many degenerated cells.

Coagulation Panel: PT 9.9 s (7.5-10.5 s), PTT 8.4 s (9.0-12.0 s), fibrinogen 395 mg/dL (90-255 mg/dL).

Microbiologic Testing: Direct smear of urine: Moderate numbers of gram-negative rods and gram-positive cocci were visualized.

Aerobic bacterial urine culture and susceptibility (cystocentesis specimen): 10^5 CFU/mL *Proteus mirabilis*, *Proteus mirabilis* (nonswarming strain), and *Enterococcus faecalis*. Both *Proteus* spp. were resistant to ampicillin (≥256 μg/mL) but susceptible to amoxicillin–clavulanic acid (4 μg/mL), cephalexin (8 μg/mL), chloramphenicol (≤16 μg/mL), enrofloxacin (≤1 μg/mL), tetracycline (64 μg/mL), and trimethoprim-sulfamethoxazole (≤4 μg/mL). The *E. faecalis* was susceptible to ampicillin, amoxicillin–clavulanic acid (≤2 μg/mL), chloramphenicol (≤16 μg/mL), enrofloxacin (≤1 μg/mL), and tetracycline (16 μg/mL).

Diagnosis: *Proteus mirabilis* and *Enterococcus faecalis* cystitis and suspected pyelonephritis with nephrolithiasis, with possible secondary immune-mediated thrombocytopenia.

Treatment: Molly was treated with enrofloxacin (7 mg/kg PO q24h). The following day her platelet count increased to 31,000 platelets/μL, and by day 3 of treatment it was 64,000 platelets/μL. After 7 days of treatment, a CBC showed a neutrophil count of 5700/μL and no band neutrophils, and the platelet count was 79,000 platelets/μL. A urine culture obtained by cystocentesis at this time showed 10^4 CFU/mL of *E. coli* and *E. faecalis*. The *E. coli* was resistant to ampicillin, cephalexin, enrofloxacin, tetracycline, and trimethoprim-sulfamethoxazole, but susceptible to amoxicillin–clavulanic acid (64 μg/mL). The susceptibility of the *E. faecalis* had not changed, with the exception that the MIC for tetracycline was 32 μg/mL. Treatment was changed to amoxicillin–clavulanic acid (23 mg/kg PO q12h). When reevaluated 3 weeks later, Molly had no clinical signs of illness. A CBC showed only mild thrombocytopenia (146,000 platelets/μL, with an MPV of 12.6 fL). However, bacteria and large numbers of white blood cells were still present in the urine sediment, the urine pH was 8.0, and *E. coli* with the same susceptibility pattern was again isolated from the urine. An extended panel showed susceptibility to amikacin (≤4 μg/mL) and imipenem-cilastatin (≤1 μg/mL), but resistance to cefazolin, cefoxitin, cefpodoxime, cephalothin, gentamicin, marbofloxacin, orbifloxacin, and ticarcillin–clavulanic acid. The dosage of clavulanic amoxicillin–clavulanic acid was increased to 23 mg/kg PO q8h. The diet was changed to a commercial urolith dissolution diet (Hill's s/d Canine Dissolution diet). After an additional month, urinalysis findings were unchanged and the same *E. coli* was again isolated from the urine. The platelet count was 244,000 platelets/μL and a biochemistry panel was unremarkable. Abdominal radiographs and ultrasound showed no evidence of nephrolithiasis, but multiple small, rounded mineral opacities were present in the region of the right ureter.

Antimicrobial drug treatment was ultimately changed to amikacin (15 mg/kg SC q24h) 2 weeks later because an *E. coli* was isolated that was resistant to clavulanic acid–amoxicillin. Kidney values were monitored every 2 weeks during amikacin treatment to evaluate for nephrotoxicity. The urine then became sterile, and ultrasound examination showed disappearance of all urinary calculi over a 2-month period, after which antimicrobial drug treatment was discontinued and the diet was changed to a maintenance diet. Because of the recessed vulva and the dog's excess body condition, a weight loss program was discussed with the owner. Molly was diagnosed with a subclinical *Enterobacter aerogenes* UTI 2 months later, which was broadly susceptible to antimicrobial drugs and treated with enrofloxacin. The platelet count was within the reference range. Further evaluation for underlying conditions predisposing to recurrent UTIs (contrast cystourethrography and cystoscopy), followed by vulvoplasty if no other abnormalities were detected, were offered to the owners but they declined further treatment and evaluation. The dog remained alive, untreated, and without clinical signs 4 years later, at which time CBC and biochemistry panel results were unremarkable but MDR *E. coli* was repeatedly isolated from the urine.

Comments: This is an interesting case of bacterial cystitis and pyelonephritis associated with struvite nephrolithiasis, and probable secondary immune-mediated thrombocytopenia. The struvite urolithiasis was likely secondary to the *P. mirabilis* infection, because *P. mirabilis* produces urease. Months of antimicrobial treatment were necessary because of bacterial sequestration within urinary calculi. This may have explained continued isolation of bacteria from the urine in the face of antimicrobial drug treatment, although ultimately resolution of the *E. coli* infection quickly followed the change in antimicrobial drug choice. Meropenem would have been another appropriate choice based on the susceptibility of the organism isolated, but its use in animals is controversial because it is an important

Continued

option for treatment of serious resistant bacterial infections in humans. Fortunately, dissolution of the nephroliths occurred in this case with antimicrobial and dietary therapy, and surgery to remove infected uroliths was not required. Continued UTIs were a likely sequela in this dog in the absence of successful identification and treatment of an underlying cause. Although treatment of the UTI was necessary during nephrolith dissolution, treatment of the subclinical *E. aerogenes* infection may not have been necessary.

Bacterial Meningitis

Craig E. Greene

VetBooks.ir

Overview of Canine and Feline Bacterial Meningitis

Cause: Bacterial meningitis is caused by a variety of pyogenic bacteria that enter the subdural space. Organisms are usually microfloral species or from environmental contamination of penetrating objects.

Affected Hosts: Dogs and cats of all ages are affected.

Geographic Distribution: Worldwide

Mode of Transmission: Bacteria can spread to the meninges from (1) sites of infection in the nasal sinuses, retrobulbar tissues, or middle or inner ear when host immune defenses are compromised; (2) sites of traumatic focal penetration; (3) sites of infection in adjacent venous sinuses or bony structures; or (4) via hematogenous arterial dissemination.

Major Clinical Signs: Fever, reluctance to move, stiff gait, and muscle spasms are the most common clinical signs. Paraspinal hyperesthesia and progressive neurologic dysfunction are progressive features.

Differential Diagnoses: Meningeal inflammation caused by nonbacterial microorganisms and immune-mediated causes should be considered. Myeloid or lymphoid neoplasias that affect the meninges may cause similar diffuse signs of inflammation.

Human Health Significance: None. The organisms that cause bacterial meningitis are indigenous microflora or environmental contaminants. Precautions should always be taken in collecting or handling cerebrospinal fluid potentially laden with microorganisms during diagnostic medical procedures.

Etiology and Epidemiology

Bacterial meningitis involves inflammation of the subdural covering of the brain and spinal cord, including the arachnoid membrane, subarachnoid space, pia mater, and cerebrospinal fluid (CSF), in response to a bacterial infection. The subarachnoid space projects into the nervous tissue alongside penetrating blood vessels. Bacterial infections can spread into the meningeal spaces from natural orifices such as the nasal sinuses, retrobulbar tissues,[1-3] and middle or inner ear.[4] Bacteria that proliferate in middle or inner ear infections can enter the cranial vault and produce cranial meningitis or subdural abscess formation (empyema) and, frequently, central vestibular dysfunction.[5-8] Bacteria can also enter the meningeal spaces through traumatic focal penetration (foreign bodies or bite wounds),[9,10] spread from sites of infection in adjacent venous sinuses or bony structures, or spread via hematogenous arterial dissemination.[11,12] Vascular spread can result in lodgment of bacteria in the endothelial cells of capillaries or the choroid plexus, which results in bacterial invasion of the parenchyma of the central nervous system (CNS) or colonization of the CSF, respectively. In the CSF, bacteria have adequate nutrients and a paucity of phagocytes and immunoglobulin, and they can proliferate, which produces a progressive inflammatory process that can readily spread along CSF pathways.

Bacteria that cause meningitis in dogs or cats are varied and can include aerobic, microaerophilic, and anaerobic species. Staphylococci, streptococci, *Pasteurella* spp., *Actinomyces* spp., *Nocardia* spp., and a variety of anaerobic bacteria have been isolated.[5,13-15]

Clinical Features

Signs and Their Pathogenesis

On entry into the CSF, bacteria can replicate to a moderate degree before they trigger a host protective response, because the immune response in this area is slow. The immune response of the host, rather than virulence of the pathogen, is usually responsible for most of the subsequent pathologic events. Toll-like receptors (TLRs), which are present on astrocytes, neurons, microglia, and oligodendrocytes, initiate innate recognition of the microorganisms. TLR signals initiate the release of a wide variety of proinflammatory mediators including reactive intermediates, cytokines, and chemokines within the CNS tissues and CSF spaces.[16] Within the nervous tissue, inflammatory processes lead to increased expression of TNF-α; thus, higher CSF concentrations of TNF-α have been used to distinguish bacterial from aseptic meningitis in humans.[17,18] Immunologic damage to bacteria leads to the release of breakdown products into the CSF and local CNS tissue. This further stimulates release of cytokines and prostaglandins, which are chemotactic for leukocytes and contribute to meningeal and ependymal inflammation. Subsequent inflammation leads to vascular injury and vascular thrombosis; tissue inflammation, edema, and necrosis; and increased CNS pressure within the confines of the dura mater and bony spaces. Inflammatory processes may also lead to adhesions and obstruction to CSF flow, resulting in obstructive internal or external hydrocephalus.[19]

Hyperesthesia from nerve root irritation is an important clinical sign of meningitis from any cause. Any stretching of extremities or palpation of muscles, especially of the paraspinal region, can lead to hyperesthesia and muscle spasm. The gait of animals with meningitis is often choppy and stiff. With progression, the inflammatory process may penetrate the spinal cord and brain parenchyma, which results in additional neurologic deficits. Manifestations of intracranial deficits include seizures,

VetBooks.ir

FIGURE 90-1 Dog with meningitis that had hyperesthesia on palpation of its spine and extremities. (Courtesy Craig Greene, Copyright 2012, University of Georgia Research Foundation Inc.)

behavioral abnormalities, and progressive decline in mental status until coma occurs.

Physical Examination Findings

Elevated rectal temperature may be found on examination because of fever, as well as excessive muscular exertional activity. Animals walk with a short stiff stride. Often the back of affected dogs is arched and the neck is outstretched with the head pointing in a downward direction. Paraspinal and extremity hyperesthesia is present with limb and spinal manipulation (Figure 90-1). When inflammation is confined to the meninges, postural reactions that involve motor responses are often stilted. As the inflammation progresses into the CNS parenchyma, deficits in sensory and motor responses are observed. Delayed placing reactions, paresis, and ataxia can be observed if cerebrospinal pathways are affected. Cranial nerve deficits are often observed on neurologic examination. Further signs of cerebral dysfunction include signs such as altered mentation (depression, aggression) or seizures. Myotatic and flexor reflexes may be difficult to elicit because of increased muscle tone from the animal's extreme tenderness and unwillingness to relax. Loss of reflex function occurs if spinal nerves become damaged in the inflammatory process.

Diagnosis

Inflammation or compression of muscle, bone, and joints can be initially confused with that of nerve root or peripheral nerve inflammation. The differential diagnosis for bacterial meningitis includes other infectious causes of meningeal irritation including that caused by viral, rickettsial, fungal, protozoal, and algal organisms (Table 90-1).[20] Feline infectious peritonitis is probably the most common cause of meningomyelitis in cats.[21,22] When parenchymal neurologic dysfunction is apparent, such as evidenced by delayed placing reactions, then protozoal meningoencephalomyelitis should also be considered. Frequently, more localized hyperesthesia associated with upper or lower motor neuron deficits can be observed with epidural empyema, discospondylitis, or paraspinal osteomyelitis. Steroid-responsive meningitis-arteritis in dogs can mimic all the signs of bacterial meningitis.[23] Diseases associated with myositis (such as American canine hepatozoonosis and leptospirosis) can also produce clinical signs that resemble those of meningitis.

TABLE 90-1

Examples of Infectious Agents That Can Cause Meningitis in Dogs and Cats*

	Dogs	Cats
Viruses	Canine distemper virus Arboviruses Suid herpesvirus 1 (pseudorabies)	Feline infectious peritonitis virus Borna disease virus Suid herpesvirus 1 (pseudorabies)
Bacteria	*Staphylococcus* spp. *Streptococcus* spp. *Pasteurella multocida* Enterobacteriaceae (including *Salmonella* spp.) *Actinomyces* spp. *Nocardia* spp. *Mycoplasma* spp. Anaerobes *Brucella canis* *Bartonella* spp.? *Borrelia burgdorferi*? *Leptospira* spp.? *Anaplasma phagocytophilum*? *Rickettsia rickettsii* *Neorickettsia helminthoeca* *Ehrlichia canis*	*Streptococcus* spp. *Pasteurella multocida* *Nocardia* spp. *Mycoplasma* spp. Anaerobes
Fungi	*Blastomyces dermatitidis*† *Coccidioides* spp. *Cryptococcus* spp.† *Aspergillus* spp.† *Candida* spp. *Histoplasma* spp. Phaeohyphomycoses Hyalohyphomycoses (e.g., *Paecilomyces* spp.)	*Cryptococcus* spp.†
Protozoa	*Toxoplasma gondii* *Neospora caninum* *Leishmania* spp. *Balamuthia mandrillaris* *Acanthamoeba* spp.	*Toxoplasma gondii*
Algae	*Prototheca* spp.	

*Many of the listed agents also cause encephalitis or encephalomyelitis in association with meningitis.
†Via dissemination or cribriform plate destruction as a result of extension of nasal cavity disease.

Laboratory Abnormalities

Although there are no hematologic or biochemical abnormalities that are specific for bacterial meningitis, the CBC may reveal leukocytosis, often with a left shift, especially if the process that leads to the meningitis resulted from hematogenous spread; however, an absence of neutrophilic leukocytosis is common in dogs or cats with meningitis.[15] Serum chemistry abnormalities are variable and nonspecific and can include increased ALT and ALP activities, hyperglycemia, and variable changes in serum electrolytes.

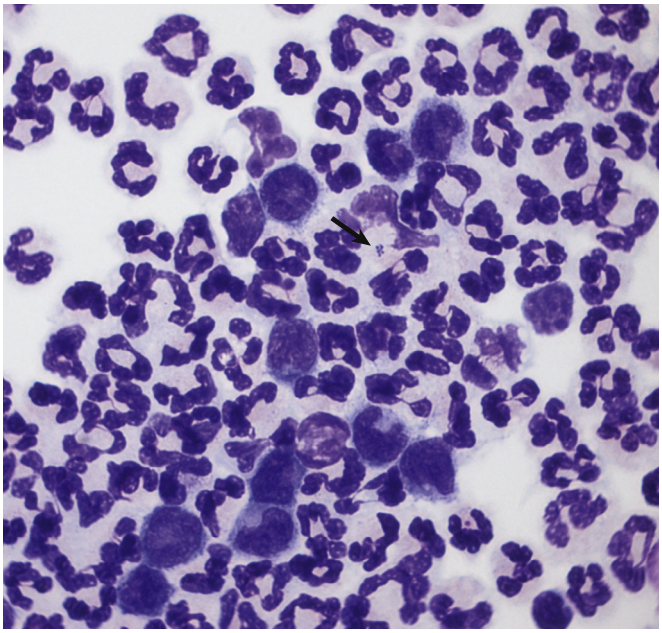

FIGURE 90-2 Cytologic appearance of CSF (cytospin preparation) in a 3-year-old male neutered Labrador retriever with bacterial meningitis. There is a large population of nondegenerate to moderately degenerate neutrophils. Many of the neutrophils contained intracellular cocci to pleomorphic short rod-shaped bacteria found in pairs and small aggregates *(arrow)*. Moderate numbers of foamy macrophages and reactive lymphocytes are also present. CSF analysis revealed a total protein of 402 mg/dL (reference range, <25 mg/dL), 100 red blood cells/μL, and 5200 white cells/μL, 92% of which were neutrophils.

Definitive diagnosis of bacterial meningitis requires evaluation of the CSF. Precautions should be taken not to remove too much fluid if CSF pressures could be increased. If imaging capabilities are available, they should be performed and evaluated before CSF removal, since they may reveal evidence of increased intracranial pressure. However, findings on medical imaging should not be used to eliminate CNS inflammatory disease, because CSF findings have the highest sensitivity for its detection.[24] Abnormalities found on CSF analysis in animals with bacterial meningitis usually consist of marked neutrophilic pleocytosis (Figure 90-2), and CSF protein concentration is increased. CSF protein concentration (often >100 mg/dL) and leukocyte numbers (usually >100 cells/μL) tend to be greatest in suppurative meningitis (especially of infectious origin) as compared to other CNS diseases; however, the electrophoretic patterns of the proteins are not specific for a diagnosis.[25] Neutrophils generally predominate; however, especially in chronicity or with concurrent antimicrobial use, monocytes, lymphocytes, or eosinophils may be observed. In human bacterial meningitis, glucose levels in the CSF are reduced because of inflammatory cell utilization, and lactic acid levels may be increased. Further studies are needed to determine if these can be used in dogs and cats to differentiate bacterial from other causes of meningeal inflammation. Finding organisms in the CSF on cytologic examination is exceedingly rare, and isolation of organisms in culture is also uncommon despite their visible presence on histopathologic examination.

Diagnostic Imaging

Plain Radiography

Plain radiographic findings are unremarkable in dogs or cats with bacterial meningitis unless a bacterial osteomyelitis of paraspinal or cranial bones is a source of infection. Bulla radiography is a valuable procedure for animals with suspected otogenic sources for their CNS infection; however, advanced imaging procedures are preferred when available.

Computed Tomography

Computed tomography of the brain or spinal cord in dogs or cats with bacterial meningitis may reveal contrast-enhancing lesions on the meningeal or ependymal surfaces. Focal areas of enhancement in areas of abscess formation or edema may also be present.

Magnetic Resonance Imaging

Purulent exudates that cover the CNS tissue may be visualized by MRI in animals with meningitis using T2-weighted sequences while suppressing the signal from CSF (high fluid attenuation inversion recovery [FLAIR]) (Figure 90-3, *A*). This method results in enhancement of signal intensity found in the meninges.[26] In more advanced cases, using T2-weighted or postcontrast T1-weighted images, meningeal enhancement (signal hyperintensity) indicates thickening of the meninges and edema of adjacent CNS tissue.[27] Occasionally, plaque-like densities are found that compress nervous tissue, which represent abscesses.

Microbiologic Tests

The main microbiologic assays used for diagnosis of bacterial meningitis in dogs and cats are aerobic bacterial culture and PCR assay of cerebrospinal fluid. False-negative results occur because organism numbers in CSF of dogs and cats are often low. Depending on the sensitivity of the PCR assay used and the viability of the bacteria in the specimen, culture may be positive when PCR results are negative, and vice versa.

Bacterial Culture

Bacteria may be isolated using routine aerobic and anaerobic bacterial culture media and conditions. At least 0.5 mL of CSF should be submitted for aerobic and anaerobic bacterial culture if possible. Organisms are uncommonly cultured from CSF because of their low number and the small amounts of fluid that are typically available; however, when successful, subsequent susceptibility testing assists in appropriate antimicrobial drug selection. Because of the infrequency of positive culture results despite the histopathologic presence of organisms at necropsy,[15] empiric antibacterial therapy should be employed based on a suspected site of origin of infection (see Antimicrobial Treatment, later).

Molecular Diagnosis Using the Polymerase Chain Reaction

Sensitive and specific real-time PCR assays for detection of bacteria in the CSF have been described.[28] However, as with culture methods, their sensitivity is low. The use of PCR to document bacterial infection of the CSF has been implemented in human medicine.[29,30] Although it has been used on a clinical basis on CSF of dogs and cats,[31] further studies are needed to document the sensitivity and specificity of various PCR assays for detection of microorganisms in CSF.

Pathologic Findings

Gross Pathologic Findings

At necropsy, sites of infection in animals with bacterial meningitis may be found in organs outside the CNS, such as the skin or mucous membranes, respiratory tract, internal organs,

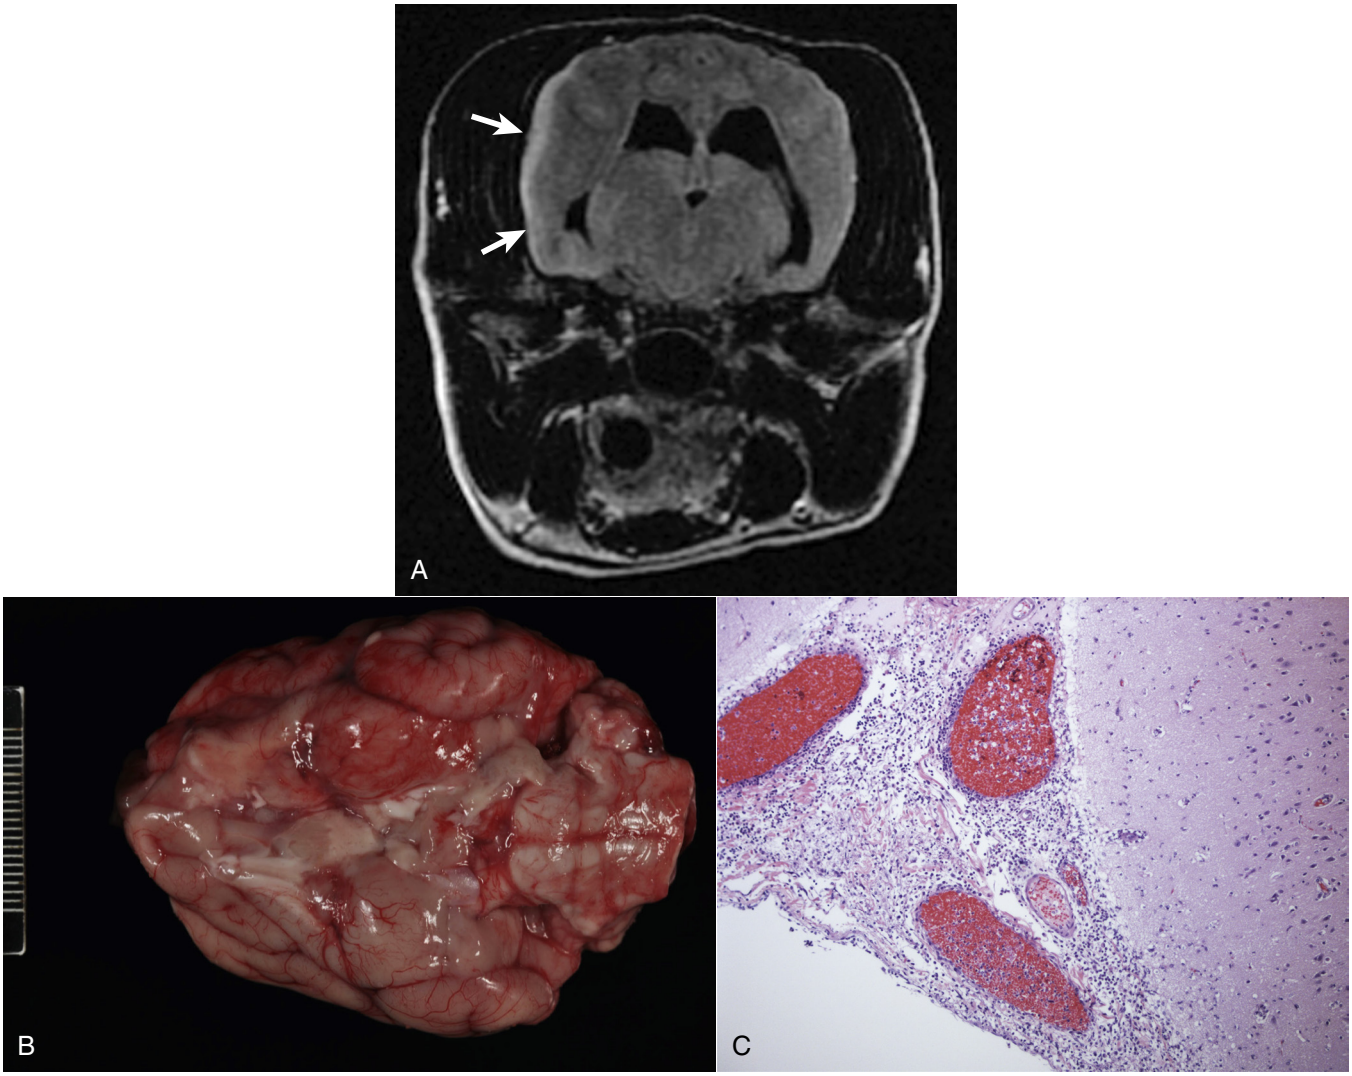

FIGURE 90-3 Clinical images from a 4-year-old female spayed Yorkshire terrier with bacterial meningitis. The dog had a 12-hour history of hypersalivation, generalized seizures, and vomiting. Small numbers of *Corynebacterium* spp. were isolated in culture from the meninges. **A,** MRI (FLAIR image). There is marked hyperintensity of the meninges on the left side *(white arrows)*. **B,** Gross pathologic findings. Ventral aspect of the brain. Purulent material covered the cerebellum and left cerebral cortex and pooled on the floor of the calvarium. The right cerebral vasculature was markedly engorged (shown). Cerebellar herniation was also found (not shown). **C,** Histopathologic appearance of meningitis. The meninges and Virchow-Robin spaces are expanded with inflammatory cells. The diagnosis was chronic, suppurative meningitis. H&E stain, 100× magnification. (Courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

external or middle ear, or ocular tissues. Gross pathologic findings in the CNS are generally minimal in dogs or cats with early inflammatory changes. As the infection progresses in the parenchyma, the meninges may appear congested and nervous tissue parenchyma in the regions adjacent to CSF surfaces may be discolored or opaque (Figure 90-3, *B*). Focal accumulations of pus may occasionally be observed in the meningeal spaces or adjacent nervous tissue. In late stages, ischemic infarction of CNS tissue may occur as a result of severe vascular inflammation and necrosis. Occasionally, obstructive hydrocephalus occurs if the inflammatory process occludes the mesencephalic aqueduct.

Histopathologic Findings

Microscopic findings in bacterial meningitis consist of a suppurative inflammatory response that is prominent in the meningeal spaces and the penetrating sulci that contain blood vessels (Virchow-Robin spaces) (Figure 90-3, *C*). With tissue gram stains, bacteria may be observed within inflammatory cells, blood vessels, or neural tissues, in association with inflammation of the meninges and adjacent neural parenchyma.

Treatment and Prognosis

Antimicrobial Treatment

Because of the low sensitivity of culture and/or PCR assays in bacterial meningitis and the turnaround time involved, treatment must be instituted following the neurologic examination and availability of the results of CSF analysis (Table 90-2). The earlier the drug is administered, the better the chance that parenchymal damage will be minimized. Anti-inflammatory agents have been recommended, with some caution and on a temporary basis, to reduce intracranial pressure. Almost all drugs, either ionic or lipid-soluble, penetrate acutely inflamed meninges. However, as the inflammation subsides, only lipid-soluble drugs are effective. Where parenchymal abscesses are present, antibacterial drugs may not effectively penetrate affected tissue.

VetBooks.ir

TABLE 90-2

Antibacterial Drugs that Penetrate Central Nervous System Tissues and Fluids*

High	Intermediate	Low
Trimethoprim-sulfonamide, chloramphenicol, doxycycline, metronidazole	Third-generation penicillins, third-generation cephalosporines, fluoroquinolones	Penicillin, first-generation cephalosporines, aminoglycosides, clindamycin

*During acute inflammation, penetration is adequate for most drugs; however, as treatment progresses and inflammation subsides, the penetration becomes limited.

In these cases, neurosurgical drainage is required in addition to systemic antibacterial therapy.

Antiinflammatory Therapy

In addition to antimicrobial therapy, control of the immune response and resultant inflammation in CNS tissues is critical when intracranial or intraspinal pressures are elevated. Control of CNS edema is usually achieved with targeted dosages of glucocorticoids; however, therapy must be judicious, since these medications are immunosuppressive and nonspecific in their effect on the host.[32]

Supportive Care and Prognosis

The prognosis for dogs with early acute bacterial meningitis is good, provided that minimal CNS parenchymal tissue is damaged. Dogs with severe hyperesthesia should be treated with muscle relaxants to help reduce the increase in body temperature. Anticonvulsant medications may be needed for animals with signs of cerebrocortical irritation.

Prevention

Bacterial meningitis is a result of exogenous or endogenous factors that allow bacterial organisms to gain access to the subdural spaces. Although these insults cannot be completely prevented, injuries or lesions that occur close to the cranial or paraspinal spaces potentially predispose to CNS infection. Animals with wounds or infections in these areas or with systemic bacteremia should be treated appropriately then monitored closely for CNS signs and placed on judicious antimicrobial therapy if meningitis is highly suspected or documented. Although the signs of bacterial meningitis are confused with those of immune-mediated meningitis, continued use of immunosuppressive drugs may lead to detrimental progression of a bacterial disease process.

Public Health Aspects

There are minimal, if any, public health risks associated with bacterial meningitis in dogs or cats—that is, unless veterinary staff inadvertently inoculate themselves with organisms being collected for culture or PCR assays. *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitidis*, which cause contagious respiratory disease and subsequent complicating hematogenous-origin meningitis in humans, do not readily infect dogs or cats.

CASE EXAMPLE

Signalment: "Jake," a 10-month-old male Weimaraner from North Georgia, USA

History: Jake was evaluated for a 2-week history of reluctance to move, in association with anorexia and fever. He had been treated with oral enrofloxacin and clindamycin for 2 days; however, the signs of discomfort returned 2 days after medication was discontinued. Jake also had a history of external ear inflammation and pruritic skin disease for the previous month. The dog was up to date on routine vaccinations, lived indoors and outdoors, and traveled outdoors locally with the owner.

Physical Examination: The dog was alert, but held his head down with his neck extended. He was reluctant to stand or walk, and appeared painful when his head was elevated or lifted; however, no further discomfort could be elicited by more caudal paraspinal palpation. T = 103.5°F (39.7°C), HR = 110 beats/min, RR = 30 breaths/min, with shallow breathing. Body condition score was 3/9 and body weight was 31 kg. Mild erythema of the external ear canals was present and small amount of yellow-colored exudate was noted in the ear canals bilaterally. With the exception of the neurologic examination, no other abnormalities were detected.

Neurologic Examination: The dog held its neck extended and head down and walked with a short, stiff gait. Placing reactions were present in all limbs, but initiation and follow-through were stilted. In lateral recumbency, the dog did not relax, and myotatic reflexes were difficult to elicit because of excessive muscle tone. Discomfort was elicited by paraspinal palpation and application of traction on the extremities or with deep muscle palpation. No deficits in cranial nerve responses or reflexes were observed.

Imaging Findings: Cervical spinal radiographs without anesthesia showed no detectable abnormalities.

Laboratory Findings: Hematologic and biochemical findings: The only abnormality of the CBC was a low MCV (65.5 fL; reference range 66-77 fL) and mild leukocytosis (13,200 cells/μL; reference range 5100-13,000 cells/μL). Serum alkaline phosphatase activity was increased (267 IU/L; reference range 13-122 IU/L). No abnormalities were found on urinalysis.

Arthrocentesis: Synovial fluid was pink and hazy. Nucleated cell count was slightly increased (3.2×10^3 cells/μL in the stifle joint). Nondegenerate neutrophils predominated; no intracellular inclusions or LE cells observed. Impressions: Mild purulent inflammation.

CSF analysis findings (specimen collected from cisterna magna): Clear, RBC = 26 cells/μL, WBC = 462 cells/μL (reference range, <5 cells/μL), total protein 72.6 mg/dL (reference range, 15-35 mg/dL). Differential cell count: Lymphocytes 4%, macrophages 18%, neutrophils 78%, occasional RBC, no bacteria observed in this specimen. Impressions: Marked purulent inflammation.

VetBooks.ir

Microbiologic Testing: Aerobic bacterial culture (CSF): Negative. Anaerobic culture was not done.

Outcome: The dog was treated with chloramphenicol (35 mg/kg IV q8h) for 5 days and was then discharged on oral therapy for 3 weeks. The dog made a complete recovery from the signs when monitored for over 1 year.

Diagnosis: Meningitis (antibacterial-responsive) caused by suspected unidentified bacterial organisms.

Comments: Bacterial meningitis was suspected in this dog based on the history, clinical signs, laboratory findings, and response to chloramphenicol. Systemic spread of infection from a hematogenous route was suspected based on some of the inflammatory indicators in the hematologic and biochemical profile and evidence of mild suppurative polyarthritis that was found. The original treatment with enrofloxacin and clindamycin may have been subtherapeutic since it was short-lived and may not have penetrated the CNS tissues and fluids as well as chloramphenicol. Furthermore, IV dosing with chloramphenicol for the first days of therapy allowed for very high levels of drug in the CNS. Although an organism was not observed or isolated, bacterial infection was suspected based on the dramatic response to antibacterial therapy alone. In bacterial meningitis of dogs and cats, organisms are not often identified by cytologic or cultural examination of CSF. Response to antibacterial therapy should be considered presumptive evidence of bacterial infection.

APPENDIX

Vaccination Schedules for Dogs and Cats

The schedules provided in this appendix are guidelines for immunization of dogs and cats against major viral and bacterial agents. These assume the availability of (1) client resources and (2) suitable products for immunization. The schedules are based on guidelines written by the WSAVA, AAHA, AAFP, and ABCD[1-11] and on information available at the time of writing. These are *general guidelines*, because the vaccine types recommended and the frequency of immunization vary depending on the lifestyle of the pet being immunized—that is, indoor versus outdoor pets, shelter animals, travel plans, kennel/boarding plans, and underlying disease conditions such as immune-mediated diseases or preexisting infections such as FIV infection. Because these factors may change over time, the vaccination plan for individual pet animals should be decided by the owner at routine annual examinations, after a discussion between the veterinarian and the client regarding the animal's lifestyle in the year ahead and the advantages and disadvantages of vaccination. This discussion should be documented in the medical record. A previous history of vaccine reactions in an individual pet will also affect recommendations for immunization. Considerable research is still required to generate optimal recommendations for vaccination of dogs and cats.

Guidelines for Vaccination of Individual Pet Dogs and Cats

Guidelines for vaccination of individual pet dogs and cats are summarized in Tables A-1 and A-2, respectively.

TABLE A-1

Guidelines for Vaccination of Individual Pet Dogs

Vaccine	Initial Vaccination: Age ≤ 16 Weeks	Initial Vaccination: Age > 16 Weeks	Booster Schedule	Comments
CPV-2 (A, SC)	6-8 weeks of age, then every 3-4 weeks until no sooner than 14-16 weeks (16-20 weeks in breeding kennels)	Two doses 3-4 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter	***Core.*** Protection after the 12-month booster may be lifelong. Administer with vaccines for CDV and CAV-2.
CPV-2 (I, SC)				Not recommended when attenuated vaccines are available and indicated
CDV (A, SC)	6-8 weeks of age, then every 3-4 weeks until no sooner than 14-16 weeks (16-20 weeks in breeding kennels)	Two doses 3-4 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter	***Core.*** Protection after the 12-month booster may be lifelong. Administer with CPV and CAV-2 vaccines.
CDV (Recombinant, SC)	6-8 weeks of age, then every 3-4 weeks until no sooner than 14-16 weeks (16-20 weeks in breeding kennels)	Two doses 3-4 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter	***Core.*** Can be interchanged with the attenuated live vaccine. May immunize in the face of maternal antibody. Administer with CAV2 and CPV vaccines.
CAV-2 (A, SC)	6-8 weeks of age, then every 3-4 weeks until no sooner than 14-16 weeks	Two doses 3-4 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter	***Core.*** Administer with CDV and CPV vaccines.

TABLE A-1

Guidelines for Vaccination of Individual Pet Dogs—cont'd

Vaccine	Initial Vaccination		Booster Schedule	Comments
	Age ≤ 16 Weeks	Age > 16 Weeks		
CAV-2 (A, IN)	One dose as early as 3 weeks of age	Single dose	Annual	Parenteral CAV-2 vaccines preferred for protection against CAV-1. Administered with IN CPiV and *B. bronchiseptica* vaccines
CAV-1 (A and I, SC)				Not recommended when CAV2 available because of adverse effects
Rabies (I, SC)	One dose as early as 3 months of age depending on local regulations	Single dose	1 year, then every 3 years thereafter with an approved product for 3-yearly immunization. Local regulations may dictate alternate protocols.	***Core.*** In endemic areas or where required by local regulations
CPiV (A, SC)	6-8 weeks of age, then every 3-4 weeks until no sooner than 14-16 weeks	Single dose	Annual or within 6 months of boarding, and at least 1 week before boarding	***Noncore.*** Use as a monovalent product or in combination with other noncore vaccines for annual boosters
CPiV (A, IN)	One dose as early as 3 weeks of age; consider second dose 2-4 weeks later if initial immunization occurs at < 6 weeks of age	One dose	Annual or within 6 months of boarding, and at least 1 week before boarding	***Noncore.*** Potential to provide improved local mucosal immunity over SC products. Available in combination with IN *B. bronchiseptica*.
Bordetella bronchiseptica (I, SC)	Two doses 3-4 weeks apart as early as 6 weeks of age	Two doses, 3-4 weeks apart	Annual or within 6 months of boarding, and at least 1 week before boarding	***Noncore***
B. bronchiseptica (cell wall antigen extract, SC)	Two doses 3-4 weeks apart starting at 8 weeks of age	Two doses, 4 weeks apart	Annual or within 6 months of boarding, and at least 1 week before boarding	***Noncore***
B. bronchiseptica (Avirulent live, IN)	One dose as early as 3 weeks of age	One dose	Annual or within 6 months of boarding, and at least 1 week before boarding	***Noncore.*** Potential to provide improved local mucosal immunity over SC products. Never administer SC, as may cause fatal hepatic necrosis.
Borrelia burgdorferi (I, SC or recombinant OspA, SC)	Two doses 3-4 weeks apart starting at 12 weeks of age	Two doses, 3-4 weeks apart	Annual. Revaccinate 1 month before the onset of the local *Ixodes* tick season	***Noncore***
Canine influenza (I, SC)	Two doses 3-4 weeks apart starting at 6 weeks of age	Two doses, 3-4 weeks apart	Annual	***Noncore.*** For dogs at risk of exposure such as co-housed dogs, or before import to certain countries as dictated by regulations.

VetBooks.ir

TABLE A-1

Guidelines for Vaccination of Individual Pet Dogs—cont'd

Vaccine	Initial Vaccination: Age ≤ 16 Weeks	Initial Vaccination: Age > 16 Weeks	Booster Schedule	Comments
Leptospira (I, SC)	Two doses 3-4 weeks apart starting at 12 weeks of age	Two doses, 3-4 weeks apart	Annual. Revaccinate 1 month before the onset of the season if disease occurs seasonally.	***Noncore.*** For dogs at risk of exposure. If available, a 4-serovar vaccine is preferred because protection is serovar-specific
Canine coronavirus (I and A, SC)				Not recommended because disease is mild and immunization of unproven benefit

A, Attenuated live; I, inactivated whole organism; IN, intranasal; SC, subcutaneous.

TABLE A-2

Guidelines for Vaccination of Individual Pet Cats

Vaccine	Initial Vaccination: Age ≤ 16 Weeks	Initial Vaccination: Age > 16 Weeks	Booster Schedule	Comments
FPV (A, SC; I, SC; A, IN)	6-8 weeks of age, then every 3-4 weeks until no sooner than 16 weeks (16-20 weeks in breeding catteries)[4]	Two doses, 3-4 weeks apart	1 year, then every 3 years thereafter	***Core.*** Protection after the 12-month booster is strong and may be lifelong. Provides cross-protection to CPV2.[12] Do not give attenuated live vaccines to pregnant cats. Inactivated vaccines are for pregnant cats (if absolutely necessary) and cats with retrovirus infection. Inactivated and intranasal FPV vaccines should be avoided for routine vaccination in heavily contaminated environments such as shelters.
FHV-1 (A, SC; I, SC; A, IN)	6-8 weeks of age, then every 3-4 weeks until no sooner than 14-16 weeks	Two doses, 3-4 weeks apart	1 year, then every 3 years thereafter. Annual revaccination may be indicated in heavily contaminated environments.	***Core.*** Does not provide complete protection. Attenuated live vaccines preferred if available and indicated. Inactivated vaccines are for pregnant queens (if absolutely necessary) and in retrovirus-infected cats. Intranasal vaccines may be associated with transient upper respiratory signs. One dose of IN vaccine may be sufficient to reduce clinical signs due to FHV-1 infection.
FCV (A, SC; I, SC; A, IN)	6-8 weeks of age, then every 3-4 weeks until no sooner than 14-16 weeks	Two doses, 3-4 weeks apart	1 year, then every 3 years thereafter. Annual revaccination may be indicated in heavily contaminated environments.	***Core.*** Does not provide complete protection. Attenuated live vaccines preferred if available and indicated. Inactivated vaccines are for pregnant queens (if absolutely necessary) and in retrovirus-infected cats. Intranasal vaccines may be associated with transient upper respiratory signs. One dose of IN vaccine may be sufficient to reduce clinical signs due to FCV.

TABLE A-2

Guidelines for Vaccination of Individual Pet Cats—cont'd

Vaccine	Initial Vaccination: Age ≤ 16 Weeks	Initial Vaccination: Age > 16 Weeks	Booster Schedule	Comments
Hypervirulent FCV (I, SC)	Two doses, 3-4 weeks apart starting at 8 weeks of age	Two doses, 3-4 weeks apart	Annual	Not generally recommended. Hypervirulent strains have differed for every outbreak, and outbreaks are effectively halted after institution of disinfection and quarantine programs.
Rabies (I, SC)	One dose as early as 3 months of age depending on local regulations	Single dose	1 year, then every 3 years thereafter with an approved product for 3-yearly immunization. Local regulations may dictate alternate protocols.	Core in endemic areas or where required by local regulations. Provides strong protection. Vaccine-associated sarcoma task force recommended immunization as distal as possible in the right pelvic limb.
Rabies (recombinant canarypox, SC)	Single dose as early as 8 weeks of age depending on local regulations	Single dose	Annual	Core in endemic areas or where required by local regulations. Provides strong protection. Vaccine-associated sarcoma task force recommended administration as distal as possible in the right pelvic limb
FeLV (I, SC)	Two doses 3-4 weeks apart starting at 8 weeks of age	Two doses, 3-4 weeks apart	1 year, then every 3 years thereafter when risk is ongoing. Beyond 1 year of age, age-related resistance may provide protection.	***Noncore.*** *Only for FeLV-negative cats. FeLV testing before administration mandatory before first administering the vaccine to kittens and if exposure was likely before, booster immunization is required. Can provide strong protection.[13] Vaccine-associated sarcoma task force recommended administration as distal as possible in the left pelvic limb
FeLV (recombinant canarypox, SC)	Two doses 3-4 weeks apart starting at 8 weeks of age	Two doses, 3-4 weeks apart	Annual when risk is ongoing.† Beyond 1 year of age, age-related resistance may provide protection.	***Noncore.*** *Only for FeLV-negative cats (see FeLV (I, SC)). More data are required on relative efficacy and whether these are associated with a reduced risk of injection-site sarcomas. Vaccine-associated sarcoma task force recommended administration as distal as possible in the left pelvic limb.
FeLV (subunit, SC)	Two doses, 3 weeks apart, starting at 8 weeks of age	Two doses, 3 weeks apart	Annual when risk is ongoing.† Beyond 1 year of age, age-related resistance may provide additional protection.	Inactivated whole virus vaccines may provide superior protection.[13] See above.
FIV (I, SC)	Three doses, 3 weeks apart, starting at 8 weeks of age	Three doses, 3 weeks apart	Annual	Not generally recommended. Immunization does not provide complete protection and interferes with interpretation of antibody test results, and PCR is insufficiently sensitive for accurate diagnosis. The first dose should only be given to FIV-negative cats. Antibodies may also be passed to kittens in colostrum and interfere with testing up to 12 weeks of age.

VetBooks.ir

TABLE A-2

Guidelines for Vaccination of Individual Pet Cats—cont'd

Vaccine	Initial Vaccination: Age ≤ 16 Weeks	Initial Vaccination: Age > 16 Weeks	Booster Schedule	Comments
FIP (A, IN)	Two doses, 3-4 weeks apart, starting at 16 weeks of age	Two doses, 3-4 weeks apart	Annual	Not generally recommended. Only seronegative cats have the potential to be protected. Benefit and risks currently unclear
Chlamydia felis (I and A, SC)	Two doses, 3-4 weeks apart, starting at 9 weeks of age	Two doses, 3-4 weeks apart	Annual	***Noncore.*** Provides incomplete protection. Could be used as part of a control program in multiple cat households where infection is confirmed using appropriate diagnostic tests as endemic. Vaccination may be associated with adverse effects.
B. bronchiseptica (A, IN)	One dose as early as 8 weeks of age	One dose	Annual, but young cats are most at risk	***Noncore.*** Provides incomplete protection. Use as part of a control program in multiple-cat households where infection is confirmed using appropriate diagnostic tests as endemic. Never administer parenterally.

A, attenuated live; I, inactivated whole organism; IN, intranasal; SC, subcutaneous.
*The AAFP highly recommends immunization of all kittens for FeLV.[2]
†Annual vaccination of adult cats for FeLV is controversial. The ABCD and WSAVA suggest boosters every 2 to 3 years in view of the significant lower susceptibility of older cats, even with recombinant and subunit vaccines.

Guidelines for Immunization of Dogs and Cats in Shelter Environments

For shelter animals, attenuated live core vaccines apart from rabies should be given before or immediately on entry to the shelter. Optimally, immunization for CPV and CDV should occur at least 3 days before entry to a shelter environment, but immunization even hours before entry has the potential to make a difference. When outbreaks of known parvovirus disease or canine distemper are present, vaccines can be administered as early as 4 to 5 weeks of age, but they should not be administered earlier than this because of the possibility of vaccine-induced disease and immunosuppression. In the absence of an outbreak situation, immunization for these pathogens should be performed no earlier than 6 weeks of age. In a shelter situation, the benefits and risks of vaccination of individual pregnant animals with attenuated live vaccines must be carefully assessed. Immunization with an inactivated vaccine is probably better than no vaccine for pregnant animals that enter a shelter, but inactivated vaccines should not be administered to other animals in the shelter environment, because the onset of immunity is slower than with attenuated live vaccines. Attenuated live vaccines should be administered if ovariohysterectomy is to be performed during pregnancy. If pregnant animals are not immunized, they should be strictly isolated from the rest of the shelter animal population. The use of rapid in-house serologic tests that determine the immune status of pregnant animals may be helpful in this situation (see Chapter 12).

Revaccination should be performed no more frequently than at intervals of 2 to 3 weeks, because vaccine administration that occurs within 3 to 14 days of another immunization attempt with attenuated live vaccines can interfere with development of immune responses. Further study is required to determine optimum revaccination intervals in shelter environments. Revaccination is most important for pups and kittens younger than 16 weeks of age and is performed to maximize the chance of immunization as soon as possible after the disappearance of maternal antibody interference. Puppies and kittens should also be physically separated from the rest of the shelter animal population and handled with strict attention to quarantine protocols.

Intranasal vaccines are preferred for management of upper respiratory tract disease in shelter environments because of the potential for improved local immunity, the possibility of administration to very young animals, more rapid onset of protection, and improved protection in the face of maternal antibody. However, they also have been associated with vaccine-induced upper respiratory disease, which may be more severe in debilitated animals and can be difficult to distinguish from natural infection. In addition, field studies have yet not shown benefit of intranasal over parenteral vaccines for prevention of respiratory disease.[14] Intranasal *Bordetella bronchiseptica* vaccines should never be given parenterally. This is an emergency situation that requires immediate treatment. See Chapter 12 for specific instructions for how to manage accidental parenteral administration of these vaccines.

In endemic areas, if possible, a rabies vaccine could be administered at the time of discharge from the facility.[1] Administration

VetBooks.ir

of a 3-year product is preferred, but regardless of the product used, booster immunization must be performed no later than 1 year after the initial immunization. Rabies immunization must be properly documented, and a veterinarian must usually be present at the time of immunization. Otherwise, the number of vaccines should be limited to those that can assist control of disease that is confirmed to exist within the shelter. This will avoid excessive immune suppression that may worsen the severity of illness due to other pathogens in the shelter for which vaccines are nonexistent.

TABLE A-3

Guidelines for Vaccination of Dogs in Shelter Environments

Vaccine	Initial Vaccination		Recommendations for Booster at Exit	Comments
	Age ≤ 16 Weeks	Age > 16 Weeks		
CPV-2 (A, SC)	On entry no earlier than 6 weeks of age,* then every 2-3 weeks until no sooner than 16 weeks (and up to 20 weeks if outbreaks occur)	Two doses 2-3 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter.	***Core.*** Potential to provide strong protection. Do not use in pregnancy. Administer with vaccines for CDV and CAV-2.
CDV (A, SC)	On entry no earlier than 6 weeks of age,* then every 2-3 weeks until no sooner than 16 weeks (up to 20 weeks when outbreaks occur)	Two doses 2-3 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter	***Core.*** Potential to provide strong protection. Do not use in pregnancy. Administer with CPV and CAV-2 vaccines.
CDV (recombinant, SC)	On entry no earlier than 6 weeks of age,* then every 2-3 weeks until no sooner than 16 weeks (up to 20 weeks when outbreaks occur)	Two doses 2-3 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter	***Core.*** Administer with CPV and CAV-2. Potential to provide strong protection and immunize pups in the face of maternal antibody. More studies needed that compare the relative efficacy of recombinant and live attenuated CDV vaccines in dogs of all ages in shelter environments.
CAV-2 (A, SC)	On entry no earlier than 6 weeks of age,* then every 2-3 weeks until no sooner than 16 weeks	Two doses 2-3 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter.	***Core.*** Administer with CDV and CPV vaccines. Do not use in pregnancy.
Rabies (I, SC)	If at all, one dose on exit from the shelter as early as 3 months depending on local regulations	If at all, one dose on exit from the shelter	1 year, then every 3 years thereafter with an approved product for 3-yearly immunization. Local regulations may dictate alternate protocols.	Use in endemic areas. Local regulations can dictate the need for rabies immunization.
CPiV (A, SC)	On entry no earlier than 6 weeks of age,* then every 2-3 weeks until no sooner than 16 weeks	Two doses 2-3 weeks apart recommended, but one dose is considered protective	Annual or within 6 months of boarding, and at least 1 week before boarding with monovalent SC or IN respiratory disease vaccines	If the SC vaccine is used, it can be administered in shelters in combination with CDV, CPV, and CAV-2. Administer with a vaccine for *B. bronchiseptica*.

VetBooks.ir

TABLE A-3

Guidelines for Vaccination of Dogs in Shelter Environments—cont'd

Vaccine	Initial Vaccination		Recommendations for Booster at Exit	Comments
	Age ≤ 16 Weeks	Age > 16 Weeks		
CPiV (A, IN)	Two doses 2-3 weeks apart starting as early as 3 weeks, although one dose may be sufficient	Two doses 2-3 weeks apart, although one dose may be sufficient	Annual or within 6 months of boarding, and at least 1 week before boarding	Potential to provide improved local mucosal immunity over SC products, but further study required. Available in combination with IN *B. bronchiseptica*
B. bronchiseptica (A, IN)	Two doses 2-3 weeks apart starting as early as 3 weeks, although one dose may be sufficient	Two doses 2-3 weeks apart, although one dose may be sufficient	Annual or within 6 months of boarding, and at least 1 week before boarding	Potential to provide improved local mucosal immunity over SC products, but further study required. Provides more rapid immunization than SC products and improved likelihood of immunization in the face of maternal antibody compared with SC products available at the time of writing. Never administer SC. Available in combination with CPiV
Canine influenza (I, SC)	On entry, two doses 3 weeks apart starting at 6 weeks of age	Two doses, 3 weeks apart	Annual if risk is ongoing	For dogs at risk of exposure in shelters in endemic regions of the United States. Maximal protection does not occur until approximately one week after the second vaccine.

A, attenuated live; I, inactivated whole organism; IN, intranasal; SC, subcutaneous.
*Immunization can be performed as early as 4-5 weeks in the face of an outbreak.

TABLE A-4

Guidelines for Vaccination of Cats in Shelter Environments

Vaccine	Initial Vaccination		Recommendations for Booster at Exit	Comments
	Age ≤ 16 Weeks	Age > 16 Weeks		
FPV (A, SC)	On entry and no earlier than 4-6 weeks of age, then every 2-3 weeks until no sooner than 16 weeks (up to 20 weeks when outbreaks occur)[4]	Two doses 3 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter.	Potential to provide strong protection against FPV and CPV-2.[12] Administer alone or with SC vaccines for FHV-1 and FCV. Do not use in pregnant queens. The use of IN FPV vaccines is not recommended in shelters.
FHV-1 (A, SC; A, IN)	On entry and no earlier than 4-6 weeks of age, then every 2-3 weeks until no sooner than 14-16 weeks	Two doses 3 weeks apart recommended, but one dose is considered protective	1 year, then every 3 years thereafter. Annual revaccination may be indicated in contaminated environments.	Does not provide complete protection. Avoid use in pregnancy. Intranasal vaccines may be associated with transient upper respiratory signs. Administer with FCV. One dose of the IN vaccine may be sufficient.

Abdominal infections. *See* Intra-abdominal infections.
Actinomycosis, 399–408
  case example, 405b–407b
  clinical features, 399–401
    physical examination findings, 401
    signs and their pathogenesis, 399–401, 400f–401f
  diagnosis, 402–404
    diagnostic imaging, 402–403
    laboratory abnormalities, 402
    microbiologic tests, 403–404, 403t
    pathologic findings, 404, 404f
  etiology and epidemiology, 399, 399b
  imaging, diagnostic, 402–403
    imaging, advanced, 403
    radiography, plain, 402–403, 402f
    sonographic findings, 403
  laboratory abnormalities, 402
    complete blood count (CBC), serum biochemical tests, and urinalysis, 402
    cytologic examination of body fluids, 402
  microbiologic tests, 403–404, 403t
    isolation and identification, 403
    polymerase chain reaction (PCR), molecular diagnosis using, 404
  prevention, 405
  public health aspects, 405–407
  treatment and prognosis, 404–405, 405f, 405t
Aerobic and anaerobic bacteria, isolation and identification of, 17–28
  antimicrobial susceptibility testing, 23
    importance of, 23
    methods, 23
  bacterial culture results, interpretation of, 23
    specimens that test negative, 23
    specimens that test positive, 23
  bacterial identification, 22–23, 23f–24f
  diagnostic methods, 18–23
    airway specimens, 21–22
    bacterial culture, 19–20, 19t, 20f
Aerobic and anaerobic *(Continued)*
    body fluids, 21
    catheters, blood and intravascular, 20–21, 21b
    feces, 22
    organisms, fastidious and and unculturable, 22
    skin, 21
    smears, microscopic examination of, 18–22, 19b, 19f
    tissue specimens, 21
    urine, 22, 22f
  diffusion methods, 26–28, 26f
    bacteriocidal concentration, minimum and serum, 27–28
    breakpoints, definition of, 26–27, 27b, 27f
    mutant prevention concentration (MPC), 28
  dilution methods, 23–26, 25f
  specimen collection and transportation, 17, 18f, 18t
Aerobic bacterial infections. *See* Anaerobic bacterial infections.
African trypanosomiasis, 766–768, 767f
Amebiasis, systemic, 798, 798f
American trypanosomiasis, 760
Anaerobic bacteria, isolation and identification of aerobic and, 17–28
Anaerobic bacterial infections, 364–371
  case example, 369b–370b, 370f
  clinical features, 364–366
    bacteremia, 366
    periodontal disease, 365, 365f
    peritonitis, 366
    pneumonia and pyothorax, 366, 366f
    retrobulbar abscesses, 365–366, 366f
    signs and their pathogenesis, 364–365, 365f
    skin and soft tissue infections, 365–366
  diagnosis, 367–368, 367b, 367f
    laboratory abnormalities, 367
    microbiologic tests, 367–368
  etiology and epidemiology, 364, 364b
  laboratory abnormalities, 367
    complete blood count (CBC), biochemistry, and urinalysis findings, 367
    cytologic analysis, 367, 367f
Anaerobic bacterial *(Continued)*
  prevention, 368
  public health aspects, 368–370
  treatment and prognosis, 368, 368t
Anaplasma phagocytophilum infection, 290
  clinical features, 291–292
    physical examination findings, 292
    signs and their pathogenesis, 291–292, 291f, 292t
  diagnosis, 292–295
    diagnostic imaging, 294
    laboratory abnormalities, 293–294
    microbiologic tests, 294–295, 294t
    pathologic findings, 295
  etiology and epidemiology, 290–291, 291f
  imaging, diagnostic, 294
    radiography, plain, 294
    sonographic findings, 294
  immunity and vaccination, 295
  laboratory abnormalities, 293–294
    complete blood count (CBC), 293, 293f
    serum biochemical tests, 293, 293t
    synovial fluid analysis, 294
    urinalysis, 293–294
  microbiologic tests, 294–295, 294t
    culture, 295
    polymerase chain reaction (PCR), molecular diagnosis using, 294–295
    serologic diagnosis, 294
  prevention, 295
  public health aspects, 295
  treatment and prognosis, 295
Anaplasma platys infection, 295
  clinical features, 296
    physical examination findings, 296
    signs and their pathogenesis, 296
  diagnosis, 296
    laboratory abnormalities, 296
    microbiologic tests, 296
    pathologic findings, 296
  etiologic agent and epidemiology, 295–296
  microbiologic tests, 296
    fluorescent antibody, direct, 296
    polymerase chain reaction (PCR), molecular diagnosis using, 296
Anaplasma platys (Continued)
    serologic diagnosis, 296
  prevention, 297
  public health aspects, 297–298
  treatment and prognosis, 296–297
Anaplasmosis, 290–299
  anaplasma phagocytophilum infection, 290
  anaplasma platys infection, 295
  case example, 297b–298b
Antibacterial drugs, 66–86
Antifungal drugs, 87–96
Antiherpesviral drugs, 54–57
Antiinfective therapy, principles of, 46–53
  administration, route of, 50–51
  antimicrobial drug combinations, 52–53, 52f
  antimicrobial drugs
    classification of, 47, 48f, 48t
    pharmacodynamics of, 47–49, 49f
  antimicrobial resistance, 51–52, 51f
  antimicrobial resistance, mechanisms of, 51–52
    antimicrobial inactivation, 51–52
    efflux pump induction, 52
    membrane alteration, 52
    novel approaches, 52
    target modification, 52
  host factors, miscellaneous, 49–50
  infecting organism, identification of, 46–47
  infection, site of, 49, 50b
  treatment, monitoring response to, 53
Antiinfluenza viral drugs, 58–59
Antiprotozoal drugs, 97–104
Antiretroviral drugs, 57–58
Antiviral drugs, 54–59
  antiinfluenza viral drugs, 58–59
  antiretroviral drugs, 57–58
  miscellaneous, 59
Arthritis, 825
  clinical features, 825
  diagnosis, 826
    imaging, diagnostic, 826
    laboratory abnormalities, 826
    microbiologic tests, 826
  etiology, pathogenesis and epidemiology, 825
  public health aspects, 827–828
  treatment and prognosis, 826–827
Arthritis, infectious, 814–829
Aspergillosis, 633–648, 634t
  case example, 646b–647b

Page numbers followed by *f* indicate figures, *t* tables, and *b* boxes.

Aspergillosis, systemic, 639
clinical features, 640
physical examination findings, 640, 640t
signs and their pathogenesis, 640, 640t
diagnosis, 641–644
imaging, diagnostic, 641–642
laboratory abnormalities, 641
microbiologic tests, 643–644, 643t
pathologic findings, 644, 645f
etiology and epidemiology, 639–640
imaging, diagnostic, 641–642
imaging, advanced, 642
radiography, plain, 641–642, 642f
sonographic findings, 642, 642f
immunity and vaccination, 645
laboratory abnormalities, 641
cerebrospinal fluid (CSF) analysis, 641
complete blood count (CBC), 641, 641t
serum biochemical tests, 641
urinalysis, 641
microbiologic tests, 643–644, 643t
cytologic examination, 643
fungal culture, 643, 644f
polymerase chain reaction, molecular diagnosis using, 644
serologic diagnosis, 643–644
public health aspects, 645
treatment and prognosis, 644–645
Aspergillosis, upper respiratory tract, 633
clinical features, 634–635
physical examination findings, 634–635, 634f–635f
signs and their pathogenesis, 634
diagnosis, 635–638
diagnostic imaging, 636–637
laboratory abnormalities, 635–636
microbiologic tests, 637–638
pathologic findings, 638, 638f
etiology and epidemiology, 633–634
imaging, diagnostic, 636–637
imaging, advanced, 636–637, 636f
radiography, plain, 637
rhinoscopy and sinuscopy, 637, 637f
microbiologic tests, 637–638
cytologic examination, 637
fungal culture, 637
polymerase chain reaction (PCR), molecular detection using, 638
serologic diagnosis, 637–638
public health aspects, 639
treatment and prognosis, 638–639
Aspergillosis *(Continued)*
drug treatment, systemic antifungal, 639
drug treatment, topical antifungal, 638–639, 639f
prognosis, 639
Aspergillus species, keratomycosis and otomycosis caused by, 645–647, 645f
Assays. *See* immunoassays

B

Babesiosis, 727–738
antiprotozoal treatment, 733–735
cats, 733t, 734
dogs, 733–734, 733t
supportive care, 734–735
case example, 736b
clinical features, 729–730
clinical signs and their pathogenesis, 729–730
physical examination findings, 730, 730f
clinical signs and their pathogenesis, 729–730
canine babesiosis, 729–730, 729b
feline babesiosis, 730
severe babesiosis, 730
diagnosis, 730–733
laboratory abnormalities, 730–731
microbiologic testing, 731, 731t
pathologic findings, 733
in dogs, 727–729
babesia canis, 727–728
babesia conradae, 728–729
babesia gibsoni, 728
babesia microti-like organism, 729
babesia species, unnamed large, 728
etiology and epidemiology, 727–729, 728f
feline, 729–730
immunity and vaccination, 735
laboratory abnormalities, 730–731
coagulation testing, 731
complete blood count (CBC), 730–731
serum chemistry profile, 731
urinalysis, 731
microbiologic testing, 731, 731t
cytologic diagnosis, 731–732, 732f
polymerase chain reaction (PCR), molecular diagnosis using, 733
serologic diagnosis, 732–733
prevention, 735
public health aspects, 735–736
treatment and prognosis, 733–735
antiprotozoal treatment, 733–735
Bacteria, isolation and identification of aerobic and anaerobic, 17–28
Bacterial bite wound infections, 546b
Bacterial bronchopneumonia and pyothorax, 847–858
Bacterial infections
cell wall-deficient, 380–381
gram-negative, 355–363
Bacterial meningitis, 886–892
Bacterial peritonitis, 859
Bartonellosis, 498–511
case example, 507b–509b
clinical features, 499–502
cats, clinical manifestations in, 499t, 500–501, 501f–502f
dogs, clinical manifestations in, 500b, 501–502, 502f
physical examination findings, 502
signs and their pathogenesis, 499–500
diagnosis, 502–505, 503t
imaging, diagnostic, 503–504
laboratory abnormalities, 503
microbiologic tests, 504–505
pathologic findings, 505, 505f
etiology and epidemiology, 498–499, 499t
imaging, diagnostic, 503–504
abdominal ultrasound, 503
echocardiography, 504, 504f
radiography, plain, 503, 504f
immunity and vaccination, 506
microbiologic tests, 504–505
culture, 504–505
polymerase chain reaction (PCR), molecular diagnosis using, 505
serologic diagnosis, 505
prevention, 506
public health aspects, 506–509, 507b
treatment and prognosis, 505–506, 506t
Bite and scratch wound infections, 546–557
antimicrobial treatment, 552
rabies prophylaxis, 552
wounds, contaminated, 552
wounds, infected, 552, 552t
case example, 555b–556b
clinical features, 547–550
cats, 549f–550f
dogs, 548f
clinical features - cats, 549–550
clinical features - dogs, 547–549
diagnosis, 550–551
cytologic examination, 551
diagnostic imaging, 551
laboratory abnormalities, 550–551
microbiologic tests, 551
diagnostic imaging, 551
imaging, advanced, 551
radiology, plain, 551
sonographic findings, 551
epidemiology of dog and cat bite wounds, 553–557
cat bite infections, 553, 554t
clinical manifestations, 553, 555f
dog bite infections, 553, 554t
prevention, 555–557
etiology and epidemiology, 546–547, 547t
microbiologic tests, 551
Bite and scratch *(Continued)*
isolation and identification: cats, 551
isolation and identification: dogs, 551
prevention, 553
public health aspects, 553–557
epidemiology of dog and cat bite wounds, 553–557
treatment and prognosis, 551–552
antimicrobial treatment, 552
prognosis, 552
surgical management: cats, 552
surgical management: dogs, 551
Blastomycosis, 574–586
case example, 583b–584b
clinical features, 575–577
physical examination findings, 576–577, 576f–577f
signs and their pathogenesis, 575–576, 575t
diagnosis, 577–581, 578t
imaging, diagnostic, 578–579
laboratory abnormalities, 578
microbiologic tests, 579–580
pathologic findings, 580–581, 581f
etiology and epidemiology, 574–575, 574f–575f
imaging, diagnostic, 578–579
imaging, advanced, 579
radiography, plain, 578–579, 579f–580f
immunity and vaccination, 582
laboratory abnormalities, 578
cerebrospinal fluid (CSF) analysis, 578
complete blood count (CBC), 578
serum biochemical tests, 578
urinalysis, 578
microbiologic tests, 579–580
cytologic examination, 579, 580f
fungal culture, 579–580
polymerase chain reaction (PCR), molecular diagnosis using, 580
serologic diagnosis, 579
prevention, 582
public health aspects, 582–584
treatment and prognosis, 581–582
antimicrobial treatment, 581
prognosis, 581–582, 582f
supportive care, 581
Bordetellosis, 372–379
case example, 377b
clinical features, 373–374
physical examination findings, 374, 374f
signs and their pathogenesis, 373–374
diagnosis, 374–375
imaging, diagnostic, 374
laboratory abnormalities, 374, 374f
microbiologic tests, 374–375, 375t
pathologic findings, 375

Enteric *Escherichia coli* infections, 445–451
Enterococcal infections, streptococcal and, 334–346
Epididymitis, 878
Escherichia coli infections, enteric, 445–451
case example, 449b–450b, 449f
clinical features, 445–447
physical examination findings, 447
signs and their pathogenesis, 445–447, 446f
diagnosis, 447–448
endoscopic findings, 447, 447f
imaging, diagnostic, 447
laboratory abnormalities, 447
microbiologic testing, 447–448
pathologic findings, 448
etiology and epidemiology, 445, 446t
immunity and vaccination, 448
laboratory abnormalities, 447
complete blood count (CBC), 447
serum chemistry panel and urinalysis, 447
microbiologic testing, 447–448
bacterial isolation and typing, 447–448
virulence assays, 448
pathologic findings, 448
AIEC, 448, 448f
EHEC, 448
prevention, 448
public health aspects, 448–450
treatment and prognosis, 448
Eumycotic mycetoma, 665–666

F

Feline coronavirus (FCoV) infection, 195–208
case example, 205b–207b
clinical features, 196–197
physical examination findings, 197, 197f
signs and their pathogenesis, 196–197, 197f
diagnosis, 198–203
diagnostic imaging, 200–201
laboratory abnormalities, 198–200
microbiologic tests, 201–202
pathologic findings, 202–203
Feline coronavirus *(Continued)*
diagnostic imaging, 200–201
magnetic resonance imaging (MRI) of central nervous system, 201
radiography, plain, 200, 201f
sonographic findings, 200, 201f
etiology and epidemiology, 195–196, 196f
immunity and vaccination, 204–205
laboratory abnormalities, 198–200
cerebrospinal fluid (CSF) analysis, 200, 200t
coagulation profile, 200
complete blood count, 198, 198t
effusion fluid, analysis of, 200, 200t
serum biochemical tests, 198–199, 199f, 199t
urinalysis, 200
microbiologic tests, 201–202
immunostaining of FCoV antigen, 201–202, 202f, 203t
polymerase chain reaction (PCR), molecular diagnosis using, 201
serologic diagnosis, 201
pathologic findings, 202–203
gross pathologic findings, 202, 204f
histopathologic findings, 203, 204f
prevention, 205
public health aspects, 205
treatment and prognosis, 203–204, 204t
Feline immunodeficiency virus (FIV) infection, 209–223
case example, 219b–220b, 220t
clinical features, 210–214
physical examination findings, 213–214
signs and their pathogenesis, 210–213, 212f–213f, 213t
diagnosis, 214–216, 214b, 214t
laboratory abnormalities, 215
microbiologic tests, 215–216
pathologic findings, 216, 216f
etiology and epidemiology, 209–210, 210f–211f, 211t–212t
immunity and vaccination, 218
laboratory abnormalities, 215
bone marrow, cytologic evaluation of, 215
coagulation testing, 215
complete blood count (CBC), 215
serum biochemical tests, 215
urinalysis, 215
microbiologic tests, 215–216
polymerase chain reaction (PCR), molecular diagnoses using, 215–216
serologic diagnosis, 215
virus isolation, 216

Feline immunodeficiency *(Continued)*
pathologic findings, 216, 216f
prevention, 218
public health aspects, 218–220
treatment and prognosis, 216–218
antiviral and immunomodulator drugs, 217
FIV-infected cats, management of, 217–218
prognosis, 218
supportive care, 216–217, 217t
Feline leishmaniosis, 721–723
Feline leukemia virus (FeLV) infection, 224–238
case example, 234b–235b
clinical features, 225–229
physical examination findings, 229
signs and their pathogenesis, 225–229
diagnosis, 229–232
diagnostic imaging, 230, 230f
laboratory abnormalities, 229–230
microbiologic tests, 230–232, 230t
pathologic findings, 232
etiology and epidemiology, 224–225, 224f, 225t
immunity and vaccination, 233–234
laboratory abnormalities, 229–230
bone marrow cytology and histopathology, 229–230
complete blood count (CBC), 229
serum biochemical tests and urinalysis, 229
microbiologic tests, 230–232, 230t
antibody assays, 232
antigen assays, 230–231
immunofluorescent antibody or immunoperoxidase staining, 231
polymerase chain reaction (PCR), molecular diagnosis using, 231–232, 232f
virus isolation, 232
prevention, 234
public health aspects, 234–235
signs and their pathogenesis, 225–229, 226b, 226f
anemia and bone marrow disorders, 227–228, 227b, 228f
gastrointestinal disease, 228, 229f
immune-mediated disorders, 228
neoplasia, 227
neurologic disorders, 228
opportunistic infections, 226, 226f
reproductive disorders, 229
treatment and prognosis, 232–233, 233t
Feline panleukopenia virus (FPV) infection and other viral enteritides, 187–194
case example, 192b
clinical features, 187–188
physical examination findings, 188
signs and their pathogenesis, 187–188, 188f, 189b
diagnosis, 188–191
imaging, diagnostic, 189
laboratory abnormalities, 188–189
microbiologic tests, 189–190, 189t
pathologic findings, 190–191
etiology and epidemiology, 187
imaging, diagnostic, 189
MRI findings, 189
radiography, plain, 189
immunity and vaccination, 191–192
laboratory abnormalities, 188–189
complete blood count (CBC), 188–189
serum biochemical tests, 189
microbiologic tests, 189–190, 189t
antigen detection enzyme linked immunosorbent assay (ELISA), 190
fecal electron microscopy, 190
polymerase chain reaction (PCR), molecular diagnosis using, 190
serologic diagnosis, 189–190
virus isolation, 190
pathologic findings, 190–191
gross pathologic findings, 190, 190f
histopathologic findings, 190–191, 191f
prevention, 192
public health aspects, 192–193
treatment and prognosis, 191
antimicrobial treatment and supportive care, 191
prognosis, 191
Feline poxvirus infections, 252–256
Feline respiratory viral infections, 239–251
Fungal diseases, miscellaneous, 660–667
eumycotic mycetoma, 665–666
hyalohyphomycosis, 663
phaeohyphomycosis, 660
Fungi, isolation and identification of, 29–36
antifungal susceptibility testing, 34–35, 35f
definitions, introduction and, 29, 29f
diagnostic methods, 30–33
fungal culture, 30–33, 33t, 34f
fungal identification, 33, 34t
smears, microscopic examination of direct, 30, 31t, 32f–33f
fungal culture results, interpretation of, 33–34
Fungi, isolation *(Continued)*
specimens that test negative, 33–34
specimens the test positive, 34
specimen collection and transport, 29–30

G

Gastric *Helicobacter*-like infections, 465–473
Gastroenteritis, infectious, 859, 860t
Gastrointestinal protozoal infections, miscellaneous, 798
Genitourinary tract, bacterial infections of, 871–885
case example, 882b–884b
orchitis, epididymitis, and prostatitis, 878
urinary tract infections (UTIs), lower and upper, 871
vaginitis, metritis, and pyometra, 879
Giardiasis, 771–778
case example, 777b
clinical features, 772–773
diagnosis, 773–775
imaging, diagnostic, 773
laboratory abnormalities, 773
microbiologic testing, 773–775, 774t
pathologic findings, 775
etiologic agent and epidemiology, 771, 772f, 772t
immunity and vaccination, 776
microbiologic testing, 773–775, 774t
concentration techniques, 773
cytologic examination, 773
duodenal aspirates, 773
fecal antigen detection by enzyme-linked immunosorbent assays (ELISAs), 774
immunofluorescence, direct, 773–774
polymerase chain reaction (PCR), molecular diagnosis using, 774–775
pathologic findings, 775
gross pathologic findings, 775
histopathologic findings, 775
prevention, 776
public health aspects, 776–777
treatment and prognosis, 775–776, 775t
Gram-negative bacterial infections, 355–363
case example, 361b–362b, 362f
diagnosis, 359–360
laboratory abnormalities, 359
microbiologic tests, 360
Enterobacteriaceae, 355–358
Citrobacter, 358
Enterobacter, 357–358
Escherichia coli, 356
Klebsiella, 356–357, 357f
Proteus, 356
Serratia marcescens, 357
Gram-negative *(Continued)*
etiology, epidemiology and clinical features, 355–359, 356f–357f
Enterobacteriaceae, 355–358
non-Enterobacteriaceae, 358–359
laboratory abnormalities, 359
coagulation profile, 359
complete blood count (CBC), biochemistry, and urinalysis findings, 359
cytologic abnormalities, 359
non-Enterobacteriaceae, 358–359
Acinetobacter, 359
Pasteurella, 358
Pseudomonas aeruginosa, 358–359, 358f
prevention, 360
public health aspects, 360–362
treatment and prognosis, 360, 360t

H

Helicobacter-like infections, gastric, 465–473
case example, 470f, 471b
clinical features, 466
diagnosis, 466–468
microbiologic testing, 466–468, 467t
pathologic findings, 468
etiology and epidemiology, 465, 466f, 466t
immunity and vaccination, 470
microbiologic testing, 466–468, 467t
bacterial isolation, 467
cytology and histopathology, diagnosis using, 466–467, 468f–469f
Helicobacter DNA, detection of, 467
serology, 468
stool antigen assays, 468
urea breath and blood testing, 468
urease testing, rapid, 467
public health aspects, 470–472
treatment and prognosis, 468–470, 470t
Hemoplasma infections, 390–398
case example, 393f, 396b–397b
clinical features, 392–393
physical examination findings, 393
signs and their pathogenesis, 392–393, 392f
diagnosis, 393–394
imaging, diagnostic, 393, 393f
laboratory abnormalities, 393
microbiologic tests, 393–394, 394t
pathologic findings, 394
etiology and epidemiology, 390–392, 390f–392f, 391b
immunity and vaccination, 395
laboratory abnormalities, 393
complete blood count (CBC), 393

Hemoplasma infections *(Continued)*
serum biochemical tests, 393
urinalysis, 393
microbiologic tests, 393–394, 394t
culture, 394
cytologic examination of blood smears, 393–394
polymerase chain reaction (PCR), molecular diagnosis using, 394
serologic diagnosis, 394
prevention, 395
public health aspects, 395–397
treatment and prognosis, 394–395, 395t
Hepatic abscesses, 865–867, 866f
Hepatitis. *See* Infectious canine hepatitis (ICH)
Hepatobiliary infections, 863
clinical features, 864
diagnosis, 864–865
diagnostic imaging, 864
laboratory abnormalities, 864
microbiologic tests, 864–865
pathologic findings, 865
diagnostic imaging, 864
radiography, plain, 864
sonographic findings, 864, 864f–865f
etiology and epidemiology, 863–864, 863f
laboratory abnormalities, 864
coagulation profile, 864
complete blood count (CBC), 864
serum biochemical tests, 864
urinalysis, 864
microbiologic tests, 864–865
culture, 865
cytologic examination, 864–865
overview of, 859b
treatment and prognosis, 865
antimicrobial drug treatment and supportive care, 865
prognosis, 865
Hepatozoonosis, canine, 747–759
case example, 756b–757b, 756f
clinical features, 750–752
physical examination findings, 751–752
signs and their pathogenesis, 750–751, 752f, 752t
diagnosis, 752–754
diagnostic imaging, 753
laboratory abnormalities, 752–753
microbiologic testing, 753–754, 754t
pathologic findings, 754
etiology and epidemiology, 747–750, 748t, 749f–751f
immunity and vaccination, 755
laboratory abnormalities, 752–753
complete blood count (CBC), 752, 753t
serum chemistry profile, 752–753
microbiologic testing, 753–754, 754t
cytologic diagnosis, 753
Hepatozoonosis *(Continued)*
polymerase chain reaction (PCR), molecular diagnosis using, 753–754
serologic diagnosis, 753
overview of, 747b
pathologic findings, 754
gross pathologic findings, 754
histopathologic findings, 754
prevention, 755
public health aspects, 755–756
treatment and prognosis, 754–755, 755t
Hepatozoonosis, feline, 756–757
Herpesvirus infection. *See* Canine herpesvirus (CHV-1) infection
Histoplasmosis, 587–598
case example - canine, 594b–595b
case example - feline, 596b–597b
clinical features, 587–590
physical examination findings, 589–590, 589f
signs and their pathogenesis, 587–589, 588f
diagnosis, 590–592
diagnostic imaging, 591
laboratory abnormalities, 590–591
microbiologic tests, 591–592, 592t
pathologic findings, 592, 593f
etiology and epidemiology, 587, 588f
imaging, diagnostic, 591
endoscopy, 591, 591f
radiography, plain, 590f, 591
sonographic findings, 591
immunity and vaccination, 593
laboratory abnormalities, 590–591
coagulation testing, 591
complete blood count (CBC), 590
serum biochemical tests, 590
urinalysis, 591
microbiologic tests, 591–592, 592t
cytologic examination, 591, 593f
fungal culture, 592
polymerase chain reaction (PCR), molecular diagnosis using, 592
serologic testing, 591–592
prevention, 594
public health aspects, 594–597
treatment and prognosis, 592–593
antimicrobial treatment, 592–593
supportive treatment, 593
Hyalohyphomycosis, 663
clinical features, 663–664, 664f
diagnosis, 664
antigen testing, 664
culture, 664, 664f
cytologic and histologic findings, 664, 664f
etiology and epidemiology, 663
Hyalohyphomycosis *(Continued)*
public health aspects, 665
treatment and prognosis, 664–665

I

Immunization, 119–130
immune responses
components of, 121–122
measurements of, 122–123, 123t
immunogenicity, determinants of, 122, 122b, 123f
vaccine composition and types of vaccines, 119–120, 120t, 121f
vaccine selection, 128
vaccine storage, handling, and administration, 120–121
vaccines, adverse reactions to, 124–128
cutaneous reactions, local, 126–127, 126f–127f
diagnostic test results, interference with, 127–128
organism-induced disease, vaccine, 126
reactions, immune-mediated vaccine, 124–126, 124f–125f
sarcomas, injection-site, 126–127, 126f–127f
Immunoassays, 10–16, 11f
diagnostic methods, 11–14
agar gel immunodiffusion (AGID), 14, 14f
agglutination testing, 13–14
complement fixation (CF) testing, 14
enzyme linked immunosorbent assays (ELISAs), 12, 12f–13f
immunofluorescent and immunoperoxidase antibody assays, 11–12, 11f
Western immunoblotting, 12–13, 13f
results, interpretation of, 14–16, 15t–16t
antibody detection, negative results for, 16
antibody detection, positive results for, 16
antigen detection, negative results for, 16
antigen detection, positive results for, 16
specimen collection and transport, 10–11
Immunodeficiency virus infection, feline. *See* Feline immunodeficiency virus (FIV) infection
Immunomodulators, 59–63, 60t
antimicrobial drugs with immunomodulatory properties, 63
glucocorticoids, 62–63
interferons, 61–62
lactoferrin, 62
mammalian proteins, naturally occurring, 59–62
microbial products, 59

influenza virus infections, 247
keratitis and ulcerative facial dermatitis, 246–247
upper respiratory disease, acute, 246
Rhinosporidiosis, 649–652
case example, 651b
clinical features, 649–650
diagnosis, 650, 650f–651f
etiology and epidemiology, 649, 649f
public health aspects, 651–652
treatment and prognosis, 650–651
Rocky Mountain spotted fever (RMSF), 300–310
case example, 307b–308b
clinical features, 303–304
physical examination findings, 303–304, 304f
signs and their pathogenesis, 303
diagnosis, 304–306, 304f
imaging, diagnostic, 305
laboratory abnormalities, 304–305
microbiological tests, 305–306, 305t
pathologic findings, 306
epidemiology, 301–303
hosts, life cycle, and transmission, 301–302, 301f–302f
incidence and geographic distribution, 302–303, 302f
etiologic agent, 300–301
immunity and vaccination, 307
laboratory abnormalities, 304–305
body fluid cytology, 304–305
coagulation profile, 304
complete blood count (CBC), 304
serum biochemical tests, 304
urinalysis, 304
microbiological tests, 305–306, 305t
culture, 305
polymerase chain reaction (PCR), molecular diagnosis using, 306
serologic diagnosis, 305
pathologic findings, 306
gross pathologic findings, 306
histopathologic findings, 306
prevention, 307
public health aspects, 307–309
treatment, 306–307
antimicrobial treatment, 306, 306t
prognosis, 306–307
supportive care, 306

S
Salmon poisoning disease (SPD), 311–319
case example, 317b–318b, 318f

Salmon poisoning *(Continued)*
clinical features, 312
physical examination findings, 312
signs and their pathogenesis, 312, 313b
diagnosis, 312–316
imaging, diagnostic, 313–314
laboratory abnormalities, 312–313
microbiologic tests, 314–316
pathologic findings, 316
etiologic agent and epidemiology, 311–312, 311f
imaging, diagnostic, 313–314
radiography, plain, 313
sonographic findings, 313–314, 314f
immunity and vaccination, 317
laboratory abnormalities, 312–313
clotting function, 313
complete blood count (CBC), 312–313, 314t
serum chemistry profile, 313, 314t
urinalysis, 313
microbiologic tests, 314–316
cytologic diagnosis, 315, 315f
diagnosis using fecal examination, 314–315
polymerase chain reaction (PCR), molecular diagnosis using, 316
serologic diagnosis, 315
pathologic findings, 316
gross pathologic findings, 316, 316f
histopathologic findings, 316
prevention, 317
public health aspects, 317–319
treatment and prognosis, 315t, 316–317, 317t
Salmonellosis, 437–444
case example, 441b–442b, 441f–442f
clinical features, 438
signs and their pathogenesis, 438, 438f
diagnosis, 439–440, 439t
imaging, diagnostic, 439
laboratory abnormalities, 439
microbiologic testing, 439–440
pathologic findings, 440
enteric bacterial infections, prevention of, 440
etiology and epidemiology, 437–438, 437t
imaging, diagnostic, 439
radiography, plain, 439
sonographic findings, 439
immunity and vaccination, 440
laboratory abnormalities, 439
clotting function, 439
complete blood count (CBC), 439
serum chemistry profile, 439
urinalysis, 439
Salmonellosis *(Continued)*
microbiologic testing, 439–440
bacterial isolation, 439
polymerase chain reaction (PCR), molecular diagnosis using, 439–440
pathologic findings, 440
gross pathologic findings, 440
histopathologic findings, 440, 440f
public health aspects, 440–443
treatment and prognosis, 440
Sarcocystosis, 797, 797f
Scratch wound infections, bite and, 546–557
Sporotrichosis, 624–632
case example, 630b–631b, 630f
clinical features, 624–626
physical examination findings, 626
signs and their pathogenesis, 624–626, 625f–626f, 625t
diagnosis, 626–629, 626t
diagnostic testing, 627
laboratory abnormalities, 626–629
microbiologic tests, 627–628
pathologic findings, 628–629, 628f
diagnostic testing, 627
imaging, advanced, 627, 627f
radiography, plain, 627
etiology and epidemiology, 624
immunity and vaccination, 629
laboratory abnormalities, 626–629
complete blood count (CBC), 627
serum biochemical tests, 627
urinalysis, 627
microbiologic tests, 627–628
cytologic examination, 627–628, 627f
fungal culture, 628, 628f
polymerase chain reaction (PCR), 628
serologic diagnosis, 628
prevention, 629
public health aspects, 629–631
treatment and prognosis, 629
antimicrobial treatment, 629
prognosis, 629
Staphylococcus infections, 347–354
case example, 352b–353b, 353f
clinical features, 349
diagnosis, 349–350
laboratory abnormalities, 349
microbiologic tests, 349–350
etiology and epidemiology, 347–349, 348f
Staphylococcus aureus, 348–349
Staphylococcus pseudintermedius, 347–348
Staphylococcus schleiferi, 349
laboratory abnormalities, 349
Staphylococcus (Continued)
complete blood count (CBC), biochemistry, and urinalysis findings, 349
cytologic abnormalities, 349
microbiologic tests, 349–350
isolation and identification, 349–350
polymerase chain reaction (PCR), molecular diagnosis using, 350
prevention, 351
public health aspects, 351–354
treatment and prognosis, 350–351, 350t, 351f
Streptococcal and enterococcal infections, 334–346
diagnosis, 339–340
laboratory abnormalities, 339
microbiologic tests, 339
pathologic findings, 339–340, 340f
etiology, epidemiology, and clinical features, 334–339, 334f–335f, 335t
Enterococcus spp., 338–339, 338b
physical examination findings, 339
streptococcal species, miscellaneous, 337
Streptococcus bovis group, 337–338
Streptococcus canis, 335–337, 336b, 336f
Streptococcus equi subsp.*zooepidemicus*, 337, 337f
laboratory abnormalities, 339
clotting function, 339
complete blood count (CBC), biochemistry, and urinalysis findings, 339
cytologic abnormalities, 339
prevention, 342
public health aspects, 342–344
treatment and prognosis, 340–342, 341t
bacteremia and endocarditis, 341
enterococcal infections, 341–342, 341t
meningitis/meningoencephalitis, 340–341
necrotizing fasciitis, myositis, and toxic shock syndrome, 340
Streptococcus canis infection, case example, 342b–344b

T

Tetanus and botulism, 520–530
clinical features, 520–524
examination findings, physical and neurological, 521–524, 524f
signs and their pathogenesis, 520–521, 521f–523f
diagnosis, 520–524, 524t
diagnostic imaging, 525, 525f
Tetanus and botulism *(Continued)*
electrodiagnostic tests, 525, 526t
laboratory abnormalities, 524
microbiologic tests, 525
pathologic findings, 525
etiology and epidemiology, 520
immunity and vaccination, 527
microbiologic tests, 525
isolation and identification, 525
serologic diagnosis, 525
toxin detection, 525
prevention, 527
public health aspects, 527–529
treatment and prognosis, 525–527
prognosis, 527, 527t
specific treatment, 525–526, 526t
supportive care, 526–527
Theileriosis, 797
Toxoplasmosis, 693–703
case example, 701b
clinical features, 694–695
signs and their pathogenesis, 694–695, 695f
diagnosis, 695–699, 696t
diagnostic imaging, 696
laboratory abnormalities, 695–696
microbiologic testing, 696–699
nucleic acid-based testing, molecular diagnosis using, 698–699
pathologic findings, 699
serologic diagnosis in cats, 697–698
etiologic agent and epidemiology, 693–694, 694f
imaging, diagnostic, 696
imaging, advanced, 696, 697f
radiographs, 696, 697f
sonography, 696
immunity and vaccination, 700
laboratory abnormalities, 695–696
cerebrospinal fluid (CSF) analysis, 696
complete blood count (CBC), 695
serum chemistry profile, 696
urinalysis, 696
microbiologic testing, 696–699
cytologic diagnosis, 696, 698f
fecal flotation, 697
pathologic findings, 699
gross pathologic findings, 699
histopathologic findings, 699, 699f
prevention, 700
public health aspects, 700–701, 700f
treatment and prognosis, 699–700, 699t

Carbon dioxide content	mEq/L	mmol/L	1.00	1.00
Cholesterol	mg/dL	mmol/L	0.026	38.7
Chloride	mEq/L	mmol/L	1.00	1.00
Creatinine	mg/dL	µmol/L	88.40	0.011
Glucose	mg/dL	mmol/L	0.056	18.0
Magnesium	mg/dL	mmol/L	0.411	2.43
Phosphorus	mg/dL	nmol/L	0.323	3.10
Potassium	mEq/L	mmol/L	1.00	1.00
Protein, total	g/dL	g/L	10.0	0.100
Sodium	mEq/L	mmol/L	1.00	1.00
Urea nitrogen	mg/dL	mmol/L	0.357	2.8

*Factor to multiply by to convert from one unit to the other
