List of Contributors x
Uncle Mikey's Maxims xiii

Section I: General Approach

CHAPTER 1: Client Communication 3
Bobbi J. Conner

CHAPTER 2: Common Clinical Problems 12
2.1 Abdominal Distension (*Steven Holloway*) .. 12
2.2 Cough (*Elizabeth Rozanski*) 17
2.3 Diarrhea (*Frédéric Gaschen*) 20
2.4 Dyspnea (*Claire R. Sharp*) 27
2.5 Dysuria (*Isabelle Cattin*) 33
2.6 Epistaxis (*Samantha Wigglesworth and Amber Vitalo*) 38
2.7 Fever of Unknown Origin (*Robert Armentano*) 41
2.8 Icterus (*Julien R.S. Dandrieux*) 48
2.9 Pallor (*Elisa M. Mazzaferro*) 53
2.10 Peripheral Edema (*Stuart Walton*) 56
2.11 Pigmenturia (*Leonel Londoño and Michael Schaer*) 60
2.12 Polydipsia and Polyuria (*Michael Schaer*) 65
2.13 Proteinuria (*Laura Rayhel and Mark J. Acierno*) 70
2.14 Regurgitation (*Roman Husnik*) 75
2.15 Seizures (*Gabriel A. Garcia*) 80
2.16 Syncope, Episodic Weakness, and Collapse (*Boyd R. Jones*) 86
2.17 Vomiting (*Frédéric Gaschen*) 90

Section II: Diagnostic Techniques

CHAPTER 3: Approach to Thoracic Radiographs 97
L. Abbigail Granger

CHAPTER 4: Approach to Abdominal Radiographs 131
L. Abbigail Granger

Section III: Diseases of Specific Organ Systems

CHAPTER 5: Diseases of the Oral Cavity and Teeth 163
Erin P. Ribka and Brook A. Niemiec

CHAPTER 6: Respiratory Disorders 188
Cécile Clercx

CHAPTER 7: Diseases of the Pleural Space 220
J. Brad Case

CHAPTER 8: Cardiovascular Disorders 237
Romain Pariaut and Carley Saelinger

CHAPTER 9: Digestive Diseases 289
Frédéric Gaschen

CHAPTER 10: Hepatobiliary Disease 360
Andrea N. Johnston

CHAPTER 11: Exocrine Pancreatic Disorders 378
Frédéric Gaschen

CHAPTER 12: Endocrine Disorders 395
Michael E. Herrtage

CHAPTER 13: Nephrology/Urology 452
Mark J. Acierno

CHAPTER 14: Disorders of the Nervous System and Muscle 504
Simon R. Platt

CHAPTER 15: Musculoskeletal Disorders and Injuries 603
Matthew D. Johnson, Mitchell S. Gillick, and Steven M. Fox

CHAPTER 16: Hematologic Disorders 647
Katie M. Boes, Claire M. Cannon, and Julien R.S. Dandrieux

CHAPTER 17: Disorders of Hemostasis 717
Alex Lynch

CHAPTER 18: Dermatologic Disorders 736
Domenico Santoro and Amelia White

CHAPTER 19: Ocular Manifestations of Systemic Diseases 789
Ralph Hamor

Section IV: Multisystemic Disorders

CHAPTER 20: Clinical Toxicology 845
Tina Wismer

CHAPTER 21: Infectious Diseases 873
21.1 Dogs (*Stuart Walton*) 873
21.2 Cats (*Sophie Keyte and Séverine Tasker*) 914

CHAPTER 22: Immunologic Disorders 962
Michael J. Day

Section V: Elements of Therapy

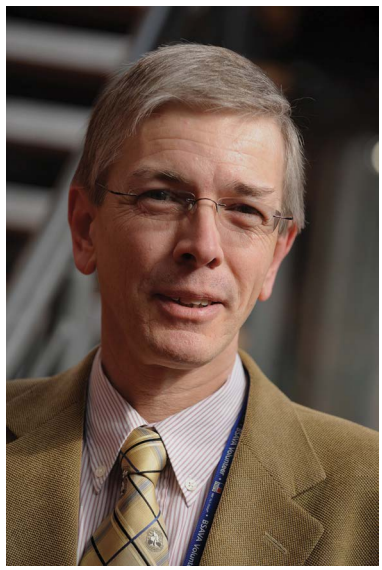
CHAPTER 23: Fluid Therapy 987
Leonel Londoño

CHAPTER 24: Pain Management 997
Beatriz P. Monteiro and Bradley T. Simon

CHAPTER 25: Nutrition of the Critically Ill Dog and Cat 1019
Justin Shmalberg

CHAPTER 26: Management of the Obese Dog or Cat 1037
Alexander J. German

Index 1051



Preface to the Fourth Edition

Before the first edition of *Clinical Medicine of the Dog and Cat* was published, no other comprehensive small animal veterinary medicine textbook was available with a comparable amount and quality of relevant illustrated materials. The information in the first, second, and third editions was carefully selected so that it would be a one-stop resource offering clinically applicable information for the veterinary student, the small animal intern, and the general practitioner. It complemented our belief that clinical observation and the cognitive sense of the clinician are essential professional qualities that contribute to our clinical acumen. In the previous edition, Editors Michael Schaer and Frédéric Gaschen carefully selected experienced specialists from North America, Europe, and Australasia with the distinctive objective of providing the book with quality material that would have a truly international appeal. For this fourth edition, they welcome Stuart Walton to the editorial team. Dr. Walton received his veterinary degree and initial residency training in Australia. He then completed a second small animal internal residency at Louisiana State University. Dr. Walton is an ACVIM Diplomate in Small Animal Internal Medicine and is currently a faculty member at the University of Florida College of Veterinary Medicine. This new team of editors has brought forth fresh ideas, which include new chapter topics, a new five-part organization, and several new outstanding authors.

Like the third edition, this new textbook is composed of two main sections. The first elaborates on the medical approach to solving common medical problems. These additional short topics, written by experts, include medical history taking, polydipsia and polyuria, pigmenturia, vomiting, diarrhea, dyspnea, cough, fever of unknown origin, epistaxis, and pallor, with brand new sections on abdominal distension, peripheral edema, proteinuria, regurgitation, and seizures. The practical application of the information in these sections is presented with text, tables, and algorithms. The objective of this clinical problems section is to emphasize the logical clinical approach to the selected clinical signs.

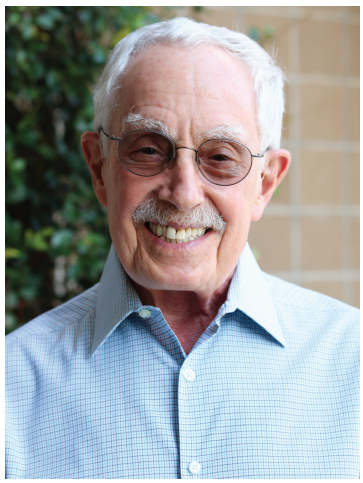
The second section contains detailed medical information covering most organ systems, with selected clinical case material integrated throughout, applying some of the principles of medicine discussed. A number of new authors who are experienced specialists in their fields have contributed to this fourth edition: Steven Holloway, Claire Sharp, Samantha Wigglesworth, Amber Vitalo, Leonel Londoño, Laura Rayhel, Roman Husnik, Gabriel Garcia, Andrea Johnston, Matthew Johnson, Mitchell Gillick, Claire Cannon, Alex Lynch, Domenico Santoro, Amelia White, Ralph Hamor, Tina Wismer, Sophie Keyte, Severine Tasker, Beatriz Monteiro, Brad Simon, and, of course, Stuart Walton, whose biography you can find on page IX. In several instances, they provide a completely rewritten approach to chapters included in previous editions of the book. We would like to take this opportunity to thank our previous authors for their contributions to this textbook. Other chapters from the third edition have been revised by their authors with the inclusion of additional text and images (exception, the obesity chapter has no additions from the third edition). Chapters on thoracic and abdominal radiographs are now included in a new part on Diagnostic Techniques, for ease of reference.

In May 2020, during the writing of this update, the Editors received the devastating news that author Emeritus Professor Michael J. Day had passed away after a battle with cancer. His excellent chapter in Section IV on Immunologic Disorders is preserved from the third edition as a tribute to his immense contribution to the field. Professor Day championed a One Health approach and was awarded the WSAVA's prestigious Award for Global Meritorious Service. He was also renowned for his ability to teach immunology to veterinary undergraduates and postgraduates by making the complex seem accessible. Not just a highly respected colleague, Michael Day was a much-loved friend to many of us in the global veterinary community. We are honored to include his chapter in the fourth edition.

In this update, the Editors adhered to the original organizational plan of *Clinical Medicine of the Dog and Cat*, which was to cover the primary disorders of all organ systems as well as the associated subspecialties of veterinary internal medicine. However, in order to make this a practical text for our projected audience,

we omitted certain valuable topics such as genetics, preventive medicine, and coverage of the reproductive system. These areas, in addition to oncology, are instead included as a part of the organ systems chapters where indicated. Ophthalmology and dermatology certainly have enough information to fill books in their own right. Therefore, the Editors requested that the information provided be restricted to what would most likely impact on internal medicine.

As in the first three editions, each chapter of this text is arranged to provide the definition of each disorder, its clinical features, the differential diagnoses, the diagnostic methodology, and the treatment and prognosis. The aim remains to achieve brevity and clarity in order to provide the practicing veterinarian with a readily available resource of important clinical information. The numerous illustrations fulfill the main philosophy of this textbook, namely that "a picture is worth a thousand words," which is especially useful in the practice of veterinary medicine. Each author was requested to restrict his or her content to the more commonly seen clinical disorders but was allowed to exercise as much freedom of choice as possible. A limited list of recommended references is offered in this latest edition. The Editors elected to be flexible with the number of references included by the authors. With today's readily available access to literature search engines, we feel that the reader can easily find unlimited information for further detailed reading.



We would like to take this opportunity to thank our publisher's project leader Ms. Alice Oven and her editorial assistant Ms. Shikha Garg for their expertise in assembling all the information provided in this valuable learning tool. We would have never been able to complete this project without their patience and guidance. We are also grateful to Ms. Kalie Koscielak and Ms. Linda Leggio for their work on the copyediting, typesetting, and proofreading of the book, a heroic endeavour given they had almost 1000 pages to work with! Thirdly, we would like to thank Mr. Jim Wilson, who is a local wildlife artist in Gainesville, Florida, and whose artwork appears on the front cover.

The Editors are most appreciative to all our authors for taking time out of their very busy days to provide their valuable contributions. We thank you very much.

Lastly, but not least, we thank our families and our work colleagues for tolerating our frustrating moments brought about by long work hours, personal sacrifices, and all the other obstacles that confront editors who assume a major project such as this.

We hope that you, the readers, will truly enjoy using this textbook and that the information provided will be of assistance in your day-to-day practice of veterinary medicine.

Editor Biographies

Dr. Michael Schaer received his DVM degree from the University of Illinois in 1970. He then went to the Animal Medical Center (AMC) in New York City where he served as an intern and then as a medicine resident between 1970 and 1973. After the residency, he remained at the AMC as a staff member in the department of medicine until 1977. He then joined a private small animal practice in New Jersey until late 1978 at which time he joined the faculty at the University of Florida, College of Veterinary Medicine where he has remained until the present time. He has published numerous papers and book chapters, and he has lectured nationally and internationally. Dr. Schaer is also the author of five textbooks: *Clinical Medicine of the Dog and Cat* first, second, and third editions and *Clinical Signs in Small Animal Medicine* first and second editions. At the University of Florida, Dr. Schaer functions mainly as a clinician and a teacher. His previous UF professional duties included: Professor and Associate Chairman-Department of Small Animal Clinical Sciences, Associate Chief of Staff-Small Animal Hospital, and Service Chief—Small Animal Medicine. Dr. Schaer served as Interim Chair, Department of Comparative, Diagnostic, and Population Medicine from February 2017 until September 2018. He is currently Professor Emeritus and Adjunct Professor in Emergency and Critical Care Medicine, while still doing active teaching in the classroom and in the critical care unit. Dr. Schaer is board certified in internal medicine (ACVIM) and emergency and critical care (ACVECC), and is on the board of directors for the North American Society of Toxinology. He is also an Associate Member of the American College of Physicians.

Dr. Frédéric Gaschen is a graduate of the University of Bern, Switzerland. After a few years in mixed practice, he trained as a veterinary internist in North America (Ontario Veterinary College, Canada, and University of Florida, United States). He is a specialist in small animal internal medicine and a diplomate of both the American and the European Colleges of Veterinary Internal Medicine (ACVIM and ECVIM-CA). After teaching for 15 years at his alma mater, he joined the Louisiana State University (LSU) School of Veterinary Medicine 16 years ago where he is currently a professor of small animal medicine. Dr. Gaschen has a passion for canine and feline gastroenterology and recently became a Fellow of the American Gastroenterology Association. He has directed and published research on chronic enteropathies, digestive motility, and the impact of antibiotics on the gut microbiota in dogs and cats and has authored numerous book chapters on small animal gastroenterology topics. Dr. Gaschen loves to share his passion with his students, interns, and residents at LSU and with colleagues at congresses worldwide. He has been actively involved in professional associations for many years and is currently co-chair of the scientific committee of the World Small Animal Veterinary Association (WSAVA). He has been a member of the editorial team of *Clinical Medicine of the Dog and Cat* since the third edition.

Dr. Stuart Walton is a graduate of the University of Queensland, Australia. Dr. Walton initially worked in mixed practice for several years before transitioning into emergency medicine and critical care. He trained as a veterinary internist initially in Brisbane, Australia (Veterinary Specialist Services) before traveling to North America where he completed his residency training in small animal internal medicine at Louisiana State University (LSU) in Baton Rouge, Louisiana. He is a specialist in small animal internal medicine and a diplomate of the American College of Veterinary Internal Medicine (ACVIM). After his residency, Dr. Walton joined the University of Florida (UF) College of Veterinary Medicine where he is currently a clinical assistant professor of small animal medicine. He has a broad range of interests, including infectious and inflammatory diseases, immune-mediated disease, respiratory disease, and extracorporeal blood purification techniques. He has directed and published research on therapeutic plasma exchange, oomycete infections, and pancreatitis. He is passionate about the profession and is very involved in the education of students, interns, and residents at UF. Dr. Walton is the newest addition to the editorial team of *Clinical Medicine of the Dog and Cat*.

Uncle Mikey's Maxims

A guiding philosophical path through the challenges of emergency medicine and critical care medicine.
—Michael Schaer, DVM

1. Treat for the treatable.
2. Assumptions lead to trouble; therefore, don't assume.
3. Always interpret clinical information within the context of the patient's presentation.
4. Avoid tunnel vision.
5. Treat your patient, not just his/her disease.
6. Avoid overmedicating.
7. Be honest with yourself.
8. Don't postpone today's urgencies until tomorrow.
9. Think that common things occur commonly.
10. Look closely at your patient; he/she will usually tell you what's wrong.
11. Never let your patient die without the benefit of the silver bullet.
12. When you hear hoofbeats, look for horses but don't forget about the zebras.
13. Never sell the basics short—they are still the best buy in town.
14. If you don't think it, you won't find it.
15. Never let a biological specimen go to waste.
16. Disaster lurks whenever a patient's problem is routine.
17. If he/she is not getting worse, give him/her a chance to get better.
18. Don't stray too far from the patient; the diagnosis will appear eventually.
19. Don't give your patient a disease he/she doesn't deserve to have.
20. Don't let technology make you decerebrate.
21. The necropsy is the clinician's trial by jury.
22. The wisdom of experience should never be ignored.
23. The diagnostician should always ask him/herself these two questions: Where am I with this patient and where am I going?
24. If the patient isn't going where you expect him/her to be going, then go back to square one.
25. In order to successfully treat a cat, you must think like a cat.
26. Avoid the pitfalls of the red herring.
27. If they can't afford a Caddy, then offer them a Chevy.
28. Know thy patient.
29. Nobody wants to pay for a big bill and a dead animal.
30. What matters is not so much what you say to a concerned client but how they perceive what you said.
31. Diagnostic cloudiness will soon be replaced by clear skies.
32. Better that the dying patient expire in the hospital than during the car ride home.
33. You must have cognition to be a competent diagnostician.
34. To prognose you must first be able to diagnose.
35. The toaster effect will occur when your patient reaches the turning point toward recovery.
36. To cut is to see; to see is to do; to do is to cure.

CHAPTER 1

Client Communication

Bobbi J. Conner

Introduction 3
Diversity, Equity, and Inclusion 3
Types of Medical Communication Styles 4
The Client Encounter 5
Summary 11
Recommended Further Readings 11

INTRODUCTION

Effective communication is one of the most important aspects of providing veterinary care. No matter how good a veterinarian's clinical skills may be, if they cannot establish trust and a good working relationship with their clients, those skills may very well be wasted. The past few decades have seen a huge increase in awareness around the importance of developing good communication skills in both human and veterinary medicine. As such, there are many ways to approach client communication, and no one way will likely work for everyone in all situations. Indeed, veterinarians with excellent communication skills are often able to comfortably transition between different approaches to accommodate the diverse needs of their clientele. Though there are exceptions, nearly all patients a veterinarian will treat in their career will be attached to a human client; it is reasonable to occasionally remind oneself that the Veterinarian's Oath includes, in addition to the protection of animal health and welfare, the "promotion of public health," and part of public health necessarily includes human emotional and mental well-being. We as veterinary health professionals will be able to better achieve our goals of preventing and relieving animal suffering if we form a partnership with our patients' families and engage them as active participants in the health care of their pets. Finally, it is important to recognize that communication is a skill, and like all skills, it requires training and practice to develop, improve, and maintain skills. The following is an overview of some of the major components that should be considered when developing communication skills. There are also many excellent training programs, books, articles, podcasts, webinars, and more to help veterinary professionals continue the lifelong work of improving their communication.

DIVERSITY, EQUITY, AND INCLUSION

Although it has been rightly pointed out that veterinary medicine is among the least diverse of all the professions in the United States for which data is available, the clientele of veterinarians will be made up of a richly diverse group of people with respect to race, ethnicity, age, class, gender, sexual identity, religion, health, physical and mental ability, education, and a myriad of other differences. The common denominator of virtually any veterinary encounter is the shared responsibility of caring for an animal. In order to maximize the success of the veterinary–patient–client relationship, veterinary health professionals must be able to develop relationships with people from all backgrounds. This means actively trying to create an inclusive environment where all people (staff and clients alike) feel safe and welcome. Acknowledging the inequities that exist in our society and actively working to ameliorate the effect those inequities have on our clients' abilities to care for their pets may be one small way that veterinarians can have a positive impact on society.

Implicit Bias

Implicit bias refers to our unconscious attitudes and stereotypes that we hold that affect our decisions and actions – without us being aware of them. Implicit biases are deeply held biases that start to develop at a very early age and are influenced by many factors, including family, local environment, the media, and our collective experiences. Of particular importance are the implicit biases we hold that are in direct conflict with our declared beliefs. Also important is understanding that our biases are not set in stone. We can work to change our biases. We can work to identify these biases and work to reduce the impact they have on our behavior.

DOI: 10.1201/9781003254591-2

Implicit bias can cause a veterinarian to behave differently with one client versus another. The way a client dresses for an appointment may impact the options given to a client because of subconscious beliefs about the clients' financial means. The effects of implicit bias on the inequities in human medicine are well documented. It is fair to assume that similar biases exist in veterinary medicine and may very well impact the care that pets are given. Although our implicit biases often develop to favor a group to which we belong, this is not always the case. There are many resources available to help individuals identify and understand their own implicit biases. When we acknowledge the biases we hold, we can begin to recognize when they might influence our behaviors and can actively work to reject the unfair biases we hold. Readers are encouraged to learn more about implicit bias. One excellent resource is *Biased: Uncovering the Hidden Prejudice That Shapes What We See, Think, and Do* by Jennifer L. Eberhardt, PhD. Readers might also consider exploring the website implicit.harvard.edu for information about implicit biases as well as a test you can take to help identify some of your own specific biases.

Acknowledging the presence of our implicit biases (even if we don't know what they are) is necessary to addressing any impact our biases may have on our ability to communicate with clients. Additional references to strategies aimed at reducing the effect of implicit bias will be referenced throughout this chapter.

TYPES OF MEDICAL COMMUNICATION STYLES

There are many ways to describe or categorize various approaches to medical communication. For this chapter, we will focus on the following three: Veterinarian (doctor)-centered, client (patient)-centered, and relationship-centered (see Table 1.1). In 1994, the Pew-Fetzer Task Force published a report describing the relationship-centered approach to medical care, adding to the previously dichotomous description of doctor-centered versus patient-centered. We will explore what each of these approaches means and some of the advantages and disadvantages of each approach.

Veterinarian-Centered Communication

This style of communication puts the evidence first. The emphasis is on evidence-based medicine, and, in general, the doctor approaches cases in a rational way, and provides information to the client about the best medical recommendations they have for the patient. Veterinarians who primarily use this approach will focus on getting as much information about the patient's clinical signs and pertinent history as possible. They also focus on the conveyance of facts and data to the client to help explain their pet's condition. The veterinarian makes recommendations based on what is best for the patient.

Client-Centered Communication

Client-centered communication prioritizes the client's feelings and concerns when making recommendations for the patient's care. How a pet's condition affects the client's well-being would be explored in a client-centered approach. Veterinarians who use a client-centered communication style will typically ask how a pet's condition is affecting the clients. When discussing care for the patient, the veterinarian will often present options, leaving the treatment decision up to the client, based on their specific situation and needs.

Relationship-Centered Communication

For this style of communication, the veterinarian and the client form a partnership. Both parties are stakeholders and take responsibility for the pet's care. In a relationship-centered approach, the veterinarian still provides information regarding options for the patient and will also clearly indicate their opinions for the best care; however, the veterinarian will also actively seek to understand the specific needs, concerns, and preferences of the client, and together the client and the veterinarian will determine a plan of action for the patient.

TABLE 1.1 Communication styles – Summary

	Veterinarian-centered	Client-centered	Relationship-centered
Options provided	Veterinarian provides only options which are considered appropriate by veterinarian	Veterinarian provides all options without providing preferences or weight to each option	Veterinarian provides all options and includes recommendations; client preferences also discussed
Decision-making	Primarily veterinarian	Primarily client	Shared responsibility between veterinarian and client
Pros	Theoretically, best medical care is provided; indecision by client avoided	Client's needs are considered, and responsibility for outcome falls with client	Client and veterinarian share responsibility for outcome of care; all parties opinions are considered
Cons	Client does not share responsibility for outcomes; may not be able to follow-through with care plan	Veterinarian may be upset when "best" treatment option not selected; patient care may be compromised	Small additional investment of time; not all clients will engage in this approach

Although relationship-centered communication is generally considered the ideal approach, some clients and some situations may call for different approaches. Some clients become paralyzed at the thought of making a decision for their pet's care; it is not uncommon for clients to say, "please do whatever you think is best." Keep in mind that cultural differences between the veterinarian and the client may necessitate adjusting one's "typical" communication style to accommodate the needs of the other person. In most cases, though, it is advisable to query the client about their particular situation and their ability to perform certain tasks or adhere to treatment plans. For example, sling-walking a lame 50 kg Saint Bernard may not be realistic for the single client who lives on a third-floor apartment. Thrice daily levetiracetam administration for a dog with idiopathic epilepsy may not be realistic for the firefighter who works 18-hour shifts at the fire station. Clients and veterinarians will often be more satisfied with the patient care if time is taken to get the full picture from the client at the outset.

THE CLIENT ENCOUNTER

Building Trust

A prerequisite for a successful veterinary–client relationship is establishing trust. You might think, "I can't *make* my clients trust me, especially if I've only just met them!" But you're likely benefitting from a general sense of trust in the veterinary profession; that is, your clients will likely give you the benefit of the doubt initially, and there are ways that you can enhance your ability to build trust with your clients. Two of the biggest things you can do to build trust are having an awareness of your nonverbal communication and expressing empathy.

Nonverbal Communication

You are likely aware that the majority of communication between two people is actually through nonverbal communication or your body language. We have likely evolved to pick up on one another's physical cues because they may be more reflective of our true thoughts than our words. By some estimates, the actual words we say make up as little as 7% of what we communicate. The remainder of our verbal communication is the character of our voice (tone, pace, inflection, etc.). Of particular importance is when our words don't match the other 93% of what we are trying to communicate. Most of us have some experience with our words being misinterpreted. A classic example is when our written words don't effectively convey the subtext that our voice and body language are so adept at. If you've ever sent or received an email or text message that was badly misinterpreted, you've experienced this.

Maintaining and awareness of what your body language and voice tone are communicating can be incredibly important when building trust with clients. Certain body positions can convey openness, such as keeping your arms uncrossed and your body angled slightly toward the client. Making eye contact with the client, particularly when important or potentially upsetting information is being delivered, is important for establishing trust. Looking away can be interpreted as a sign of dishonesty or a lack of confidence, causing a client to second-guess you. Avoid creating a power dynamic. It is often best to mirror the client's position. If they are seated, you should also take a seat or squat nearby, if possible. Try to remove any physical barriers between you and the client, such as an exam table. While it might be reasonable to take notes during a discussion, if you are only looking at the screen or pad of paper, you may lose the opportunity to make a connection with the client. Ensure you are looking up and making eye contact regularly or make use of a voice recorder or assistant to take notes.

It is also important to be aware of distractors that may seep into your body language without your awareness. If you are stressed about the full surgery schedule you have that day, you may inadvertently display to the client that you are in a rush, leaving them to wonder if you care about their concerns. Before entering the conversation, try to attend to urgent tasks (or delegate them to other staff) so that the focus can be on the client and their concerns.

Paying attention to the client's nonverbal communication cues is also important for building trust in the relationship. If you notice the client becoming anxious (tapping their feet, clenching and unclenching their fists), perhaps take a moment to check in with them to see how they are handling the information you're providing.

Expressing Empathy

The ability to understand and share the feelings of others is empathy. As people, we have an innate capacity for empathy; however, it can and should be developed. Here, we will discuss ways to express empathy as a method for building trust with your clients. A good "trick" for finding your empathy is to think of every client as a loved one or a close friend. How would you want your mother/sister/son/grandfather, etc., treated in this situation? Try looking for opportunities to express empathy either in real life or simulated client encounters. This can help improve your ability to express empathy naturally.

Opportunities to express empathy are frequent – "it must be exciting and also a lot of work to have a new puppy at home" or "I can see how much it terrified you to see Jasper breathing like that." Sometimes clients will share a personal situation they are going through, and these can be great opportunities to express empathy and build trust. For example, if a client is running late for an appointment (which can then seem to disrupt your whole day!), saying something like "It seems like you've got a lot on your plate right now" might be a good, nonjudgmental way to acknowledge the client's circumstances. Expressions of empathy don't tell the client how to feel, and they are often expressions of our assumptions or interpretations of the situation.

Many expressions of empathy start with phrases such as: "It seems like…" "I'm sensing that…" "It sounds like…" Leaving a pause after an expression of empathy is also important to convey the feeling behind your words. Even though the statement may not have been a question, empathic statements frequently invite the client to share more about how they are feeling: "We are definitely having fun with this new puppy, but he's a ball of energy, and we are all exhausted!" or "I didn't get any sleep at all last night because I was so worried about Jasper."

Remember that expressing empathy isn't about solving a problem. It's about acknowledging the situation, and it gives us an opportunity to bond over shared human experiences – the good and the bad ones. It's also not a good idea to tell the client that you understand exactly how they feel. Although you can start an empathic statement with the words "I understand…" I find it's often better to avoid those words altogether, lest we fall into the trap of minimizing the client's experiences.

Having a few phrases that you're comfortable with is a good place to start if you find expressing empathy to be a challenge. We want to ensure we are genuine when we empathize with clients, so taking a moment to really think about what the client must be going through is paramount to expressing empathy. Simple phrases like, "This must be really difficult for you" or "This must be really exciting for you" might be good starting points to incorporate more empathy into your client communication.

Getting a History

Establishing trust with a client occurs throughout all phases of the client encounter, so being aware of your nonverbal communication and finding opportunities to express empathy are often part of the history-taking portion a client visit. Getting an accurate medical history about the patient is crucial for diagnostic accuracy.

A more specific approach to take is the 4Es method: Engage, empathize, educate, and enlist (Figure 1.1). These can parallel the 2Fs for the biomedical tasks: Find it and fix it. Engaging and empathizing with the client can help us find the problem, while educating and enlisting the client in the fixing it process can help enhance the veterinarian–client relationship. Getting the medical history is the first, and arguably most important, part of the finding the problem – engage and empathize with the client to ensure you get the whole story.

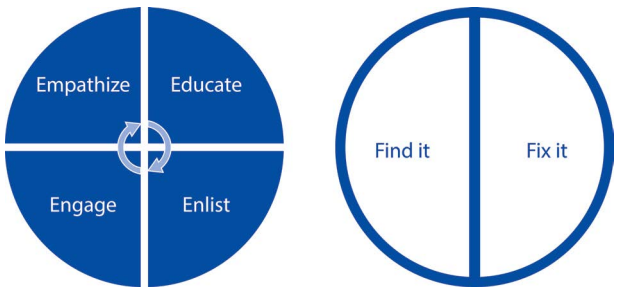

FIGURE 1.1 The 4Es of client communication versus the 2Fs representing the medical tasks for a patient's care.

Engaging the client is part of making a connection with them. At its most basic, it often starts with the introduction. Use the client's name during the introduction. It can be tempting to default to the pet's name ("You must be Scruffy's mom"); however, making an effort to engage with the client will help build the relationship, and ultimately, you depend on the client to provide care for the patient. Veterinarians may find the introduction challenging if the client's name is difficult to pronounce or they have different cultural norms. Making an effort to pronounce someone's name, without making a joke about it, can be a great icebreaker. "Did I pronounce your name correctly? I want to make sure I get it right" can be a sign of respect, or, "Could you say your name for me? I don't want to mispronounce it." If you suspect your offer to shake hands made the client uncomfortable, you could ask them if they prefer a different type of greeting: "I typically shake hands when I meet new people. Is there another greeting that you use?"

Telling the client your name and role is also important for engaging the client. Your title and anticipated role in their pet's care are helpful for creating realistic expectations for the client:

> I'm Patricia and I'm a veterinary technician here. I'm going to start by getting some information from you before Dr. Gonzales comes in to do her examination. Later, I'll be part of helping to collect any samples we need from Baxter and will help make sure you know what you need to do for him at home.

Remember to be aware of your nonverbal communication – smile, meet the client at their level (e.g., sit if they are sitting). Remember to use your expressions of empathy during this phase.

Organization of the History

Using a funneling technique (Figure 1.2) when gathering the history can help ensure that both the client's and veterinary team's needs are met. The client gets to

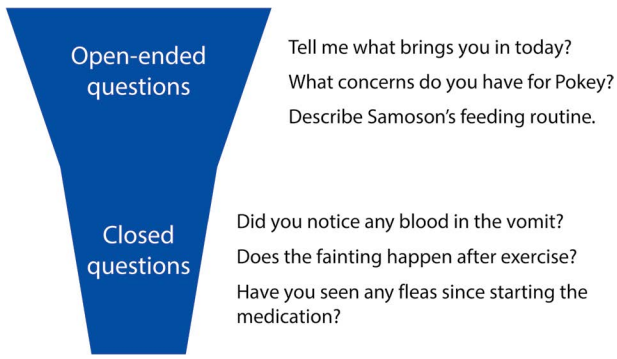

FIGURE 1.2 When getting a history from the client, start with open-ended questions and then funnel the conversation by asking follow-up, directed, and closed questions to get more detail as needed.

TABLE 1.2 Closed versus open-ended questions

Examples of closed questions and how to make them open-ended		
Information sought	**Closed question example**	**Open-ended example**
Vaccination status	Is your pet vaccinated?	Tell me about your pet's vaccination history.
Exercise routine	How often do you walk your dog?	What's a normal day like for your dog?
Indoor/outdoor status	Is your cat primarily indoor or outdoor?	Tell me about your cat's weekly routine.
Medication history	Is your cat on any medications?	What medications or treatments are you giving your cat?

tell their story, and the veterinary team gets the needed information to create a problem list and differentials.

Funneling is about starting with open-ended questions and then following up with directed, closed questions to address anything not covered by the open-ended questions. Some veterinary professionals like to use a checklist to ensure important questions don't get missed. Checklists can be helpful if used *in conjunction with*, not in place of, open-ended questions. Some options for getting the conversation going are: "Tell me what brings you in with Rufus today" or "What are your goals for today's appointment?" Examples of closed questions and how they can be converted to open-ended questions is provided in Table 1.2. A good guideline to help you is that it is difficult to start a closed question with the word "What."

Specific Elements of the History

It can be helpful to have some themes in mind when taking a history to ensure all necessary information is obtained. Much of the information may be covered during the open-ended portion of the conversation when the client is sharing their story. The veterinarian or other veterinary health care team member may take some notes as a reminder to follow up for any areas that need further exploration or anything that wasn't covered during the initial story. Depending on the chief complaint of the client and the physical examination findings, the veterinarian may need to spend more or less time on each of the areas discussed later. Remember, too, that any information that is forgotten or missed during the first chat is generally available with a follow-up conversation.

1. *Chief complaint:* Ensuring you understand the client's chief complaint or their most pressing concern is important. Sometimes their top concern will mirror your own, but at other times, the major medical issue for the pet may not be what the client is most concerned about. For example, if a client brings their pet in for "bloody urine," and the veterinarian identifies severe thrombocytopenia, the veterinarian will rightly focus on the platelets as a primary concern. The client, on the other hand, may not understand why the veterinarian doesn't seem to care about the urine problems and may feel that their concerns are being dismissed. Asking the client to identify their top concerns can help ensure that the right information can be relayed to address their needs. Taking a moment to explain the likely link between the platelets and the discolored urine may be all that is needed for the client to feel assured the pet's problems are being addressed.
2. *Diet and appetite:* In all pet encounters, it is important to elicit information about the pet's current appetite and any recent changes in the pet's eating habits. Increases or decreases in appetite are important to note and necessitate further exploration. What the pet is being offered (and what they are consuming) are also important details to obtain from the history. Recent changes to the diet being offered to the pet (and what prompted the change) should be documented in the history. As with the history overall, starting with open-ended questions ("Tell me about George's eating habits."), followed by specific, directed questions ("How much of the dry kibble are you giving George each day?") can help the veterinarian gather all the relevant information.
3. *Thirst and eliminations:* Drinking habits, urination, and defecation are all important details from the history and can be part of the chief complaint or may provide useful information in other diseases. If the client can quantify or estimate how much (or how little) a pet is drinking, that may provide insight into overall health or clue the veterinarian in to certain disease states. Thirst is a powerful stimulus in pets that become dehydrated or hypovolemic. Pets that have stopped drinking may be quite sick, and this should warrant investigation, although it may not indicate a specific condition. Polydipsia, on the other hand, can be a sign of many different diseases or syndromes. Excessive drinking is often accompanied by polyuria. Clients may not readily recognize the difference between polyuria (increased urine production) and pollakiuria (increased frequency to void urine), so asking specific questions about an animal that is reportedly urinating more can help. If the client has observed the pet urinating, ask if the pet appears to be straining or if it is urinating frequently but only small amounts rather than simply asking to go outside or using the litterbox more often than usual. Asking about the pet's bowel movements is also necessary for a complete history. Whether the stools appear normal in color or consistency or if the pet has any changes to their defecation habits (straining, increased frequency) will all be helpful details to sort out.
4. *Travel history:* It may not always be immediately obvious whether and how recent travel history will become important during a case investigation, and, therefore, it's a good idea to include questions about the pet's geographic history into the routine conversation. Differences in exposure to infectious diseases by region can greatly impact how differential diagnoses are prioritized. Further, asking about a pet's

exposure to other environments (even locally) can divulge important information about other exposures. Has the pet been around other domestic animals, wild animals, or people that it usually isn't around? Was the pet purchased from a breeder in another county, state, or country?

5. *Local environment:* Similar to travel history, a thorough understanding of the pet's local environment can reveal information that is crucial to making an accurate list of differential diagnoses; however, mundane facts may seem irrelevant to the client. Starting with a general question: "Tell me what Sasha's normal environment is like" and following up with more directed, specific questions can help the veterinarian determine what the routine exposures are and risks the pet may have.
6. *Progression of the condition:* It can be difficult at times for clients to keep track of what's been going on with their pet. Worry about the pet's condition can affect memory and distort what the client recalls. It can be helpful to direct the client by asking questions such as "When was the last time you remember that Sassy was completely normal?" Summarizing your understanding of the chronology for the client is also a great opportunity to reflect back to them, confirm you are both on the same page, and creates an opportunity for the client to fill in any gaps they've forgotten.
7. *Treatments attempted and responses to therapy:* In many cases when signs come on gradually, clients may forget things they've tried at home (switching the food for a pet with a reduced appetite, trying an over-the-counter pain medication). It can be important to avoid judgment when asking the client about treatments they have tried, and if the client feels like they may have done something wrong, they might avoid divulging important information. One approach could be, "You must have been worried about how Beanie was doing at home. What things have you tried so far to help her feel better?" Following up with questions about specific treatments they might have tried but didn't consider a treatment could be useful, too. For each treatment the client tried, clarify whether they perceived any response. Whether the pet improved with certain approaches can help narrow or prioritize the differential diagnoses and might even help guide the treatment plan.
8. *Current or recent medications and vaccination history:* Asking the client, "What other medications has Joey been getting?" rather than, "Is Joey taking any other medications?" will for some clients challenge them to really think about what other medications they have forgotten. In the former question, you are assuming there are other medications, and the client will often try to think what they could be. The latter closed question is more easily dismissed with a simple, "no." Also, asking "What is Joey vaccinated for?" might provide more information than simply asking if the pet is up to date. Admittedly, many clients won't remember the details, but for many, they will be able to recall at least some information about their pet's vaccination status. Again, funneling to more narrow questions after the initial query can help you gather the necessary detail.

When you think you've got all the information you need, it's a good idea to check back in with the client to ensure all their needs have been addressed. Rather than asking, "Do you have any other concerns?" you could switch it up to "What other concerns do you have for Boomer that we haven't yet covered?" Although a relatively slight change in the wording of the question, the second phrasing suggests that you have time for more discussion, rather than implying the end of the conversation. If the client was holding anything back, this might be their chance to bring up one more concern. Veterinarians might be rightly concerned that this could extend the time spent during the history-taking portion of the client visit; however, remember you could be saving time by addressing any concerns about the pet sooner rather than later, and that could lead to an improved outcome for the pet, which is everyone's ultimate goal!

Making a Plan

Once the veterinarian has a prioritized list of differential diagnoses, a diagnostic and preliminary therapeutic plan is created. In most situations, there are a variety of options available that can range from the gold standard or best recommendations to the most conservative plan. This is where employing a relationship-centered communication approach can be helpful.

In order for the client to be an equal partner in the decision-making process, as the veterinary professional, you'll likely need to educate them on their pet's condition or the diagnostic approach you would like to take. It's tempting to want to give the client a lot of information about the disease you've diagnosed or are suspecting. After all, the goal is for the client to be able to make an informed decision, right? Keep in mind, veterinarians have a minimum of 4 years of veterinary school plus experience gained before and since. It's not practical to expect the client to become an expert during the span of a single visit. It might be helpful to start by asking the client what they think might be going on with their pet, or, if you've made a diagnosis, what do they already know about the disease. This is a great opportunity for you to build them up, "Wow, I'm impressed with how knowledgeable you are about pancreatitis" or identify areas of confusion. "I can understand why you'd be confused about the signs of kidney disease versus a bladder infection. Let me see if I can clarify the differences."

When educating the client about their pet's condition, pay extra attention to the words you are using. It can be easy to fall into the trap of using medical jargon ("stifle" instead of "knee" or "radiographs" instead of "X-rays"). In human healthcare visits, physicians use an average of four un-clarified technical terms *per visit*. Veterinarians likely do this too without realizing it. If you let the client tell you what they know about the disease first, you can mirror the language they have used to avoid this situation. It's also useful to follow up with, "Have I used any technical language that was unclear to you?" or, more broadly, "I know you're planning to discuss this with your family. Could you summarize your understanding of the options so that we can ensure we're all on the same page?"

Once the education phase is complete (for now), it's time to enlist the client. Enlisting means you're inviting the client to share in the decision-making process. By collaborating with the client, you are validating their specific needs and preferences. This can be particularly important when we are trying to avoid making assumptions and different recommendations because of our implicit biases. By actively and intentionally involving the client from the beginning, you can reduce the likelihood that you are making (or withholding) recommendations based on the client's age, ability, race, ethnicity, gender, or other differences. Enlisting clients to be part of their pet's healthcare team can lead to reduced confusion, reduced anxiety, increased motivation and adherence to treatment plans, and greater satisfaction for both the client and the veterinary team.

It would be helpful to be clear that you want to form a partnership with the client in order to create the best plan moving forward for them and their pet. You could make your goals explicit by saying something like, "I certainly have my own opinions about what might be best for Charlie, and I want to hear from you about what your priorities and expectations for his care might be. Together, we can create a plan that works for you and Charlie."

The Medical Discharge

In human medicine, physicians tend to overestimate their patients' understanding of their discharge instructions and ongoing treatment plan. This has been recognized for decades without clear guidance on a resolution to the problem. There is some evidence that standardized verbal or written instructions can improve patient recall of important discharge information, though there is not clear evidence if verbal or written is superior. Both methods can be adversely affected by the client's comfort in the language communicated in and their overall literacy (for written), and veterinary health professionals must also take steps to minimize the effect their own biases may have on the communication that occurs at the end of a patient visit. Keeping in mind accessibility as an important barrier to overcome when considering client information is crucial. Multiple options to provide the same information is ideal. A variety of media may be a helpful way to provide clients with multiple options to obtain necessary information.

Having standardized handouts or pamphlets, trusted websites with informational videos, or even a phone number or two for them to call if they have questions (remind them of your clinic's contact information and, if appropriate, the nearest trusted emergency clinic's contact information). Consider having handouts in multiple languages, depending on the demographics in your region. Websites with videos should be closed-captioned for clients with hearing difficulties. Remember, too, that not all clients will have easy access to the internet, a reliable phone, or know who to call if your clinic is closed. Having this information (if not the method of delivery) standardized will also help ensure that all clients are given the same information about resources – don't assume the client wearing scrubs already knows what to do – and avoids the perception of judgment or criticism if you provide clients with standardized verbal, written, or a combination of instructions.

Remember, too, that all client instructions and information should be free of unclarified medical jargon. It generally should also be relatively brief and concise but may provide additional resources for the client who wants more information from trusted sources. The most important components of discharge instructions for clients typically includes three key components: (1) Medication instructions, (2) signs of improvement, and (3) worrisome signs/indications to seek medical advice.

At discharge, clients should be encouraged to ask questions about their instructions. A staff member knowledgeable about the patient should be available to spend time with the client to try to ensure they understand and are comfortable with the plan. Asking, "What questions do you have about Mickey's home care?" will likely yield more questions than the typical, "Do you have any questions?" It's also reasonable to ask the client to reiterate the instructions back to you before leaving: "Ms. Green, I've just gone over a lot of information about Bailey. Could you summarize for me your understanding of her at-home care to make sure we don't have a misunderstanding?"

Discharge instructions of any format should also be flexible to account for the back-and-forth that occurs during the discussion of at-home care that is unique to each case. Written instructions may have a space for annotation that is specific to the client's situation or questions. An audio or audiovisual recording of the discharge discussion might be a relatively easy way (with the ubiquity of smart phones or other recording devices) to provide documentation of the discharge instructions that both the client and the veterinary team can keep for reference.

Discussing Euthanasia and Making End-of-Life Decisions

One of the most important and impactful things a veterinarian will do in their career is to help clients through the difficult scenario surrounding the end of a pet's life. Although it is always difficult, it can actually help bring closure and a sense of well-being to both the client and the veterinarian when it is approached with compassion, patience, and understanding. Generally, the same concepts that have been discussed throughout this chapter apply to the discussion of end-of-life care and euthanasia, and we'll reinforce those concepts through this section.

Because end-of-life scenarios are necessarily fraught with intense emotions in many cases, conflict can arise under even the best of veterinarian–client relationships. Both clients and veterinarians bring their personal beliefs and wishes to these discussions, and veterinarians must acknowledge both the clients' and their own needs during these challenging scenarios. End-of-life communication, like all communication, involves a set of skills that can be learned, practiced, and reinforced. It can sometimes be helpful to break the topic up into separate components. There are numerous ways to do this, and the approach discussed here is simply one option of many.

Delivering Bad News

Veterinarians frequently must share difficult information about a client's pet to them, and the resultant reaction by the client can be emotionally jarring for both the client and the veterinarian. Clients may respond with anger, guilt, frustration, disbelief, sadness, or they may appear stoic or unaffected. Veterinarians should prepare for the unpredictability of a client's emotions, and there are techniques that can make the process easier for everyone involved.

One of the first things to do before delivering bad news to a client is to prepare. Ensure there is appropriate space, privacy, and time to have this conversation. Avoid situations that will make it difficult for the client to focus on what you need to share with them. If they are at work, can they take a break? If they have young children, can arrangements be made for someone to keep an eye on the kids for a while? If the news can be delivered in person, which might be preferred, if possible, having a designated comfort room at your clinic is ideal.

Depending on what has been discussed previously and recently about the pet's condition, it may be helpful in some situations to gather information from the client about how their pet is doing. This way, you can get a sense for how shocking this news will be for the client, and you can adjust your conversation accordingly. "Tell me what you're thinking about Buster's condition." You might learn the client is already anticipating the bad news, or you might learn they have no idea what's coming. You want to then ensure that the client is prepared to have this conversation. It's a great idea to ask permission: "I have new information about Buster's condition; is now a good time for you discuss things?" or "Would it be okay for me to share with you what we've learned about Buster?" If the owner isn't able to talk, arrange a better time to have the conversation.

If the client agrees to have the conversation, it's best to give them a warning about the content of the conversation: "Unfortunately, I don't have good news to share with you about Buster" or "As you suspected, Buster's condition is quite poor," or, if they weren't expecting the news: "This may come as a shock; however, I have some difficult information to share with you about Buster."

After the initial warning, it may be tempting to provide a lot of medical information about the case in an effort to explain the situation logically. Clients that are hearing bad news about their pet may be unable to process much information at a time. Try to be kind and empathetic and avoid using euphemisms that can be confusing. A direct approach is often most effective: "Buster's kidney values have continued to worsen and are causing him to feel so poorly. This progression will continue and eventually cause Buster's death." Some clients will have questions and want to know more. Others will need time to process what you've told them. You can ask, "I can tell how difficult this is for you. Would you like to know more about Buster's condition, or would you prefer to talk more later? Perhaps it would be helpful to have your partner here for the discussion." In this way, you can show you empathize with the client and that you can be flexible depending on their needs. Remember, too, that periods of silence might be needed. It can be difficult to let the silence linger, but your nonverbal communication may be more powerful and more appropriate in many cases.

Humane Euthanasia

Euthanasia, or good death, is a commonly performed medical procedure in veterinary medicine. As such, many veterinarians are relatively comfortable with humane euthanasia. That comfort often does not extend to the families of a pet that is terminally ill and may be suffering. Using some of the guidance described previously for delivering bad news also applies to initiating discussions about euthanasia. Depending on the communication style that has been used prior to this discussion, the veterinarian may choose to continue with the same approach or may need to switch up their communication style to be more appropriate. Again, as before, a relationship-centered approach may be best and lead to better outcomes for the client and the veterinarian. Sharing responsibility and reaching a consensus can help ensure that everyone's voice and perspective was considered.

Bringing up humane euthanasia for the first time can be difficult for the veterinarian. It is important to note that the majority of clients believe it is the veterinarian's responsibility to first broach the subject, so even if you mention it first, the client may have already been considering it for their pet. Bringing up euthanasia gives the client permission to start considering it if they haven't yet, and it validates their own concerns if they were wondering about it already. "We've been discussing the various treatment options for Jack, and another option we should consider is humane euthanasia" or "Given the severity of Jack's condition, would you be open to discussing humane euthanasia and whether and when it might be the right choice for you and Jack?" Avoid using euphemisms that can lead to miscommunication. Phrases like "putting to sleep" or "ending suffering" can mean different things to different people. Suggesting a plan for a "peaceful passing" could suggest to the client you mean hospice care. The pain caused by a misunderstanding would be far worse than the unavoidable pain caused when a beloved pet is declining.

Remember that clients will have different feelings about euthanasia, and for some, they may not consider it to ever be an option. Although this can be challenging for veterinarians in some cases, trying to explore the client's needs and wishes can help you continue to work together to ease the suffering of the pet: "If I'm understanding you correctly, electing humane euthanasia wouldn't be right for you and Jack. Would it be okay if we discuss options, including palliative care and hospice?" For veterinarians who have little experience or comfort with hospice care for pets, there may be resources in your area to refer pets for in-home or in-hospital hospice or palliative care. The International Association for Animal Hospice and Palliative Care (community.iaahpc.org) is a good resource to start with. Some areas have dedicated clinics where terminally ill pets can be referred for hospice

care. Having this information ready before you need it can reduce stress and anxiety for both the client and the veterinary healthcare team.

Once the decision to humanely euthanize a pet has been made, the veterinarian or other veterinary professional will need to discuss what will happen next. "If it's okay with you, I'd like to talk you through the process of humane euthanasia that we do here." Discussing the procedure, care of remains, and finances all should happen before the euthanasia is performed, whenever possible, so that the client can immediately continue the grieving process afterward. You can also discuss options for memorializing the pet, such as with a special urn for pets that will be cremated, or a clay paw impression. Make sure that clients understand not all decisions need to be made immediately. Allow them the opportunity to think about it or discuss options with family and friends if needed.

Once the client is ready, if the situation allows, it can be best to perform the euthanasia in a quiet, comfortable room that is free of distractions and, if possible, has a separate exit from the building. Check with the client to see if they want to spend some time with the pet. Let them know you'll check on them frequently but not to feel rushed. Sometimes it's helpful to ask the client if they've been through euthanasia for a pet before. Regardless of their previous experience, it's a good idea to remind them of the process:

> We are first going to place an IV catheter in Sassy's arm, which is how we'll deliver the medication. We will give her an overdose of an anesthetic drug, so at first, she'll go to sleep, as if she were having a procedure. As we continue to give the medication, her heart and brain function will stop. The procedure is painless, however you may notice some twitching or even some agonal or gasping-like breaths, which can occur even after death. I'll be right here with you the whole time if you have any questions or concerns, and you just need to hold Sassy and remind her how much you love her. The entire process takes between 30 and 90 seconds. Although it will be difficult for you, it will be painless for Sassy.

Offer the client an opportunity to ask questions, if needed, or to see if that process seems appropriate. If they comment that it seems quick or might be disturbing, discuss alternatives with them. Intraperitoneal sodium pentobarbital is an excellent alternative for clients who wish privacy during their pet's passing or don't want the death to be quite as quick as with intravenous administration. It's also a good alternative in situations where IV access has proven difficult. The sodium pentobarbital can be administered away from the client, and the pet can then be brought to the client to visit while the medication takes effect, generally after 10–20 minutes. If a client is uncomfortable being present for the euthanasia, ensure them that their pet will not be alone and will be made as comfortable as possible.

Once the pet has been euthanized, again expressing empathy is helpful: "I can see that this was difficult for you. I know how much you loved Gus and that you made this decision out of love for him. If you'd like, I'll give you some time with him, and I'll be back to check on you shortly." Having resources at the ready to give to clients to aid them with the grieving process can also be helpful. There are a number of potential resources, including hotlines, websites, or, if you're lucky, you might have access to a veterinary counselor or veterinary social worker to refer clients to.

Client communication doesn't end after the pet has died or been euthanized. Calling a client after a few days to check in to see how they are coping, if they have any questions, or if they need help with anything is a powerful way to show the client you care about them and to maintain the relationship. Sending a sympathy card with a handwritten message can also be very meaningful for clients. Expressing sympathy for their grief and maybe sharing a special memory of their pet can also help. Again, empathizing with the client's loss is important. Becoming adept at end-of-life discussions is an attainable and important goal for veterinarians to achieve. We are responsible for promoting the well-being of animals and to prevent their suffering. In doing so, we can also promote the well-being of our clients and ourselves.

SUMMARY

Communication is an integral part of a veterinarian's professional career, and fortunately, it is a skill that everyone can and should continually work to improve. Being able to communicate effectively with clients in all types of situations and from all kinds of backgrounds can help ensure that the veterinarian provides the best possible outcomes for the animals under our care and will also help ensure the mental health and well-being of veterinarians as well. Ensuring effective communication can increase adherence to medical advice, improve client satisfaction, and reduce complaints. Veterinarians can be leaders in their practice when it comes to seeking opportunities to practice and model effective communication, prioritize communication-based continuing education for themselves and their staff, and being open to feedback on their own communication.

CHAPTER 2

Common Clinical Problems
CHAPTER 2.1 Abdominal Distension

Steven Holloway

Introduction 12
Clinical Approach to Abdominal Distension 12
Differential Diagnosis 14
Recommended Further Readings 16

INTRODUCTION

Abdominal distension is a frequently encountered problem in small animal patients. Several potential etiologies exist for this common presentation. A thorough history and clinical examination are the first steps toward making a diagnosis and instituting treatment.

CLINICAL APPROACH TO ABDOMINAL DISTENSION

History, Signalment

The importance of a good history cannot be overemphasized in investigating abdominal distension. The presentation of an animal with an acute history versus chronic history together with physical examination findings can assist in determining if abdominal distension is something that can be determined easily and methodically or something that that may present as a catastrophe requiring immediate treatment (Figure 2.1.1). Diet, previous illness, reproductive status, age and breed, and duration of clinical signs are important to ascertain prior to examination.

The "6 Fs" and Clinical Examination

This "6 Fs" acronym has been used for many years to guide the clinician with a simple but effective way to examine the patient, formulate a differential diagnosis, and interpret clinical findings.

The "6 Fs" are categories of diseases that cause abdominal distension.

1. Flatus

Flatus is gaseous distension of the abdomen secondary to gastric dilation, bowel obstruction, ileus, or pneumoperitoneum (Figure 2.1.2).

FIGURE 2.1.1 Abdominal enlargement in a dog with ascites. A fluid wave was present on abdominal ballottement. Note there is some loss of muscle along the spine and the normal taper of the abdomen caudally is lost. This dog was diagnosed with a pericardial effusion as the cause of ascites.

A generalized taught feeling or drum-like ping on auscultation occurs on palpation and percussion. Abdominal distension may be more on one side than the other.

2. Fluid

Intraperitoneal fluid collection is associated with symmetrical abdominal enlargement (Figure 2.1.3). A fluid wave may be palpable on ballottement with an accompanying dullness to percussion.

3. Feces

Accumulation of feces in the colon can produce abdominal and gaseous distension of more proximal bowel. Feces is generally recognized as firm to hard lumps usually in the caudal-dorsal abdomen. The segments of

DOI: 10.1201/9781003254591-3

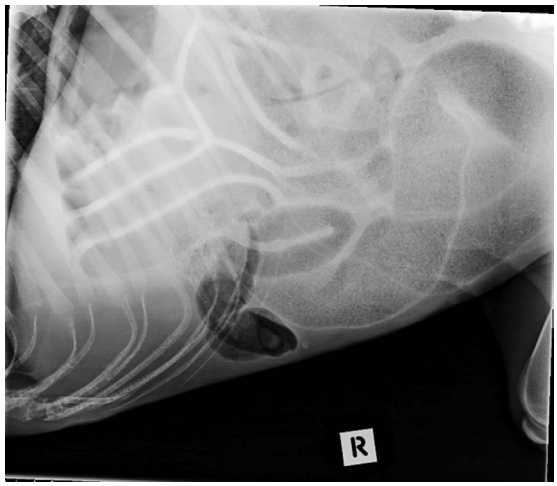

FIGURE 2.1.2 Radiography of a dog presented for vomiting with abdominal enlargement. The dog has severe tympany on abdominal percussion. There is marked generalized intestinal gas distension evident on radiograph. Ultrasound examination of the abdomen showed a mass located at ileocecal valve as the cause of the obstruction and accompanying distension. Cytology of the mass confirmed lymphoma.

colon overlying the brim of the pelvis may be felt on caudal abdominal palpation.

4. Fetus

Pregnancy and the associated enlarged uterus produce a form of organomegaly. The swelling is confined to the lower abdomen. Feti are usually identifiable on abdominal palpation in the second half of gestation.

5. Fat

Within the abdomen, fat commonly produces abdominal distension (Figure 2.1.4). It does not have characteristic features on clinical examination. Obesity related to endocrine disorders, such as hyperadrenocorticism and hypothyroidism, may be associated with characteristic skin changes and other clinical examination findings. Hepatomegaly is a prominent feature of hyperadrenocorticism.

FIGURE 2.1.3 Ascites fluid removed from a dog's abdomen. Note the fluid is serosanguineous. Analysis of the fluid was consistent with a modified transudate. The dog was investigated for right-side heart failure and diagnosed with cor pulmonale secondary to chronic heartworm disease.

FIGURE 2.1.4 This dog presented for abdominal enlargement. The physical examination revealed hepatomegaly, thin skin, and alopecia. Additionally, loss of muscle mass and increased abdominal fat are evident. Examination using abdominal ultrasonography showed the abdominal enlargement was due to hepatomegaly which added to the effect of abdominal myasthenia. Investigation revealed pituitary hyperadrenocorticism as the cause of hepatomegaly.

6. "Fantastically" Big Organs

Organomegaly is a frequent cause of abdominal enlargement (Figure 2.1.5).

Careful palpation may elucidate the origin of the organomegaly. Hepatomegaly is associated with palpation of the liver beyond the ventral rib margin. Splenomegaly may palpate as an elongated firm mass within the mid to midventral abdomen.

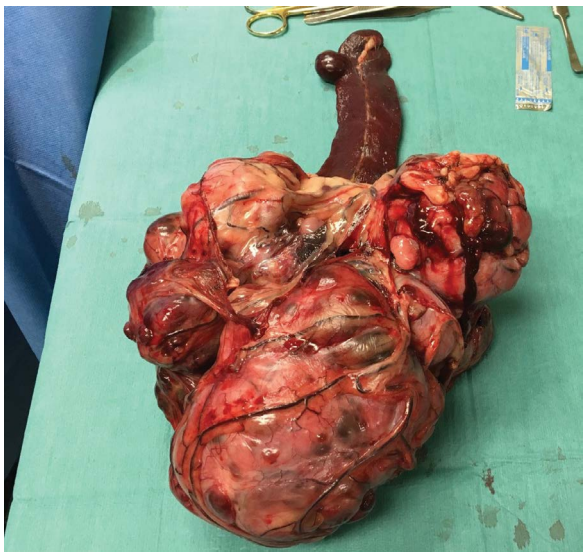

FIGURE 2.1.5 Image of a massively enlarged spleen following splenectomy. This dog was presented for abdominal enlargement. The abdomen was noted to be extremely enlarged and firm to palpate over all areas. Investigation using radiography and ultrasonography identified a large splenic mass that occupied 80% of the abdominal cavity. Surgical removal was required for definitive diagnosis. Histopathology diagnosed it as benign splenic hematoma.

Additionally, very large splenic masses may present as firm hard masses too large to palpate completely. Similarly, distension of the urinary bladder may reach extremes in animals with bladder emptying disorders and may be difficult to differentiate from ascites fluid. Prostatic masses are typically located in the caudal-dorsal abdomen and are firm to palpation. Large paraprostatic cysts may be located more cranially within the caudal to midabdomen. The sublumbar lymph nodes when enlarged may also present as firm masses in the caudal dorsal abdomen. Rectal palpation in such cases may assist with interpretation. Renomegaly may be unilateral or bilateral. This is more easily detected in the cat where the kidneys are more mobile and are located midabdomen. In the dog, renomegaly is palpated within the craniodorsal quadrant.

Initial Categorization Following Clinical Examination

Following physical examination, abdominal imaging may be helpful in establishing a diagnosis. Radiographic examination is most often used to confirm which category of "F" is the cause of abdominal enlargement. Alternatively, ultrasound examination of the abdomen may be used. It is best suited for detection of fluid or organomegaly. However, it is less useful for identifying the cause of gaseous distension. Following this initial characterization, careful investigation of differential diagnoses is instigated.

DIFFERENTIAL DIAGNOSIS

1. Flatus

Gastric Dilatation-Volvulus

Gastric aerophagia (seen with upper respiratory tract diseases, cats with cryptococcosis, asthma).

Ileus (paralytic, dysautonomia, or due to intestinal wall infiltrative disease (leiomyositis/pseudo-obstruction)).

Pneumoperitoneum

This most commonly occurs with perforating injuries to the abdomen wall or internal organs such as the stomach, intestine, or urinary bladder. It may be seen, for example, with rupture of a gastric dilatation-volvulus. It is identified on radiographs as free air in the abdomen associated with increased serosal detail.

2. Fluid (Ascites)

Radiographically, fluid is identified by a loss of abdominal detail. Ultrasound can reliably detect small volumes of fluid and is a useful first-line imaging modality for clinical triage. It is useful for guidance of abdominocentesis for fluid analysis (see algorithm). Fluid may accumulate due to different pathomechanisms (Figure 2.1.6). These include transudation due to alteration in osmotic effects and Starling forces, exudation (the movement of cells and fluid, septic or nonseptic), and modified

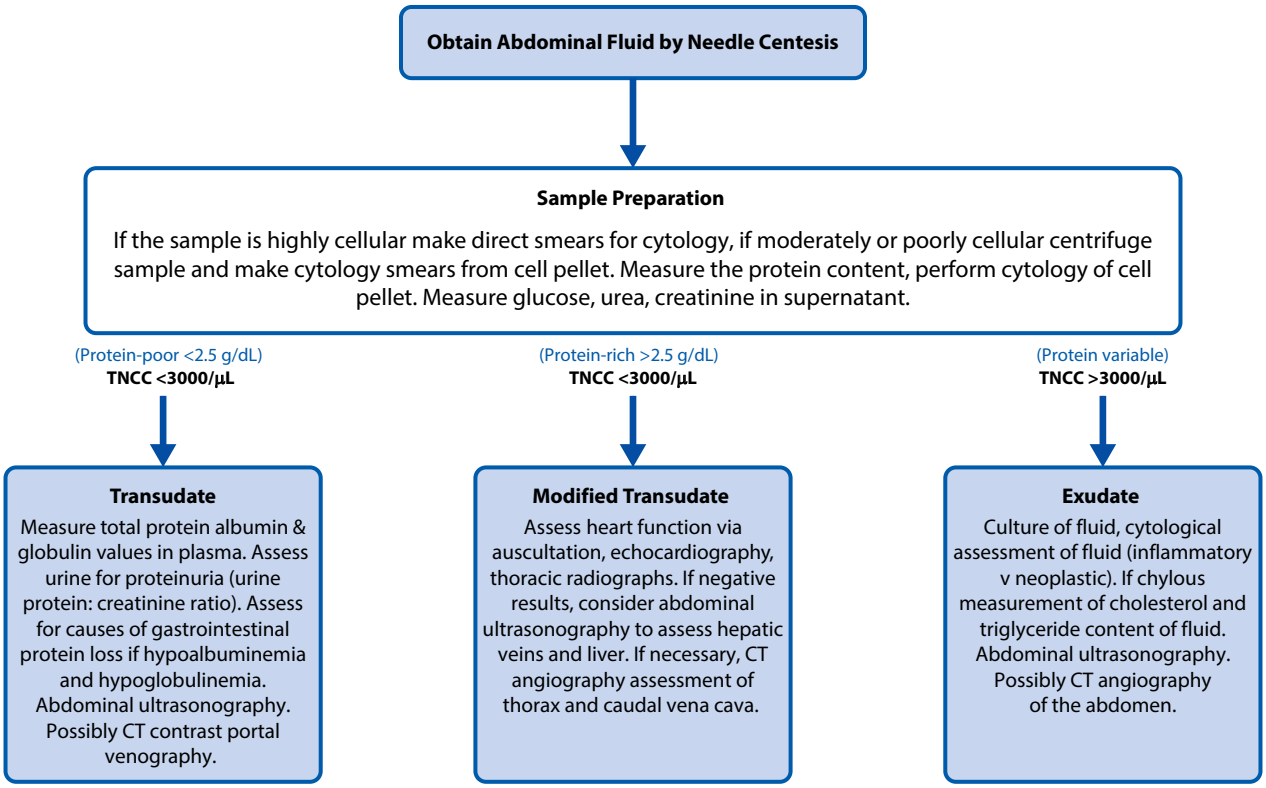

FIGURE 2.1.6 Characterization of abdominal fluid types.

transudates (cells and fluids).[1–3] When detected, recovered fluid should undergo analysis, which should include measurement of specific gravity, protein content, and microscopic examination. Bacterial culture, glucose, and lactate concentrations of effusions are performed in suspected septic exudates. Fluid analysis should be interpreted in light of clinical examination, complete blood count, biochemical testing, and urinalysis. Additional testing may be required in some cases such as pancreatitis (canine pancreatic lipase immunoreactivity or cPLi) or FIP (immunohistochemistry). The classification of fluid type and associated etiologies is seen in Table 2.1.1.[2–3]

3. Feces

The accumulation of feces may be due to dietary factors such as ingestion of bone material or water imbalance/dehydration such that stools are too hard or painful to pass. Distal intestinal obstruction etiologies include neoplasia, anal/rectal stricture, pelvic fracture, and intrapelvic masses. Failure to defecate may also occur with damage to the pelvic nerve or intramural nerve/muscular elements.

4. Fetus

Abdominal enlargement associated with pregnancy may be unexpected when animal's reproductive history is unknown. This is particularly common in cats. Radiography and ultrasonography can assist with differentiating pregnancy from pyometra or other uterine abnormalities.

5. Fat

Obesity may be multifactorial in origin. Investigation requires consideration of dietary factors (caloric intake) and exercise levels/inactivity assessment. A genetic propensity has been identified in Labradors and likely exists in other breeds of dogs. Obesity may also occur secondary to underlying endocrine disorders such as hypothyroidism or hyperadrenocorticism. Specific laboratory testing should be considered where history and physical examination is supportive.

6. "Fantastically" Big Abdominal Organ

It is important to recognize that any abdominal organ may become enlarged. Etiologies vary, with neoplasia, abscesses, and cystic structures predominating, although multiple other causes are identified (Table 2.1.2). The clinician must be aware that the prognosis is not linked to the size of the organ and that accurate diagnosis is essential. Accurate diagnosis is usually accomplished by diagnostic imaging and/or tissue biopsy methods

TABLE 2.1.1 Etiopathology, characteristics, and analysis of ascites fluid

Effusion type	Etiopathology
Transudate (protein-poor <2.5 g/dL) TNCC <3000/μL	Hypoalbuminemia (GI loss, renal loss, starvation)
	Liver failure with presinusoidal portal hypertension (may have hypoalbuminemia also), e.g., cirrhosis
	Prehepatic portal hypertension, portal vein hypoplasia, post-portosystemic shunt ligation
	Splenic vein thrombosis
Modified transudate (protein-rich >2.5 g/dL)	Right-sided congestive heart failure with its associated postsinusoidal hypertension
TNCC <3000/μL	Pericardial disease
	Post-sinusoidal hepatic portal hypertension
	Caudal vena cava thrombosis (Budd-Chiari syndrome)
	Liver disease with sinusoidal hypertension such as chronic hepatitis
Exudate (cell-rich and protein-rich >2.5 g/dL)	
TNCC >3000/μL	
Septic (bacteria identified, culture positive)	GIT leakage
	Penetrating wounds
	Migrating foreign bodies
	Urogenital tract rupture
	Hematogenous spread or primary bacterial peritonitis
Nonseptic (bacteria not identified culture negative)	Inflammatory (pancreatitis)
	Hemorrhagic
	Chylous
	Bile
	Neoplasia associated exfoliation (lymphoma, mesothelioma, other)
	Inflammatory (FIP in cats)
	Sclerosing encapsulating peritonitis

FIP, feline infectious peritonitis; GIT, gastrointestinal tract; TNCC, total number of cells counted.

TABLE 2.1.2 Differential diagnosis for organomegaly

Organomegaly	Common differential diagnosis
Liver	– Neoplasia (primary carcinoma, adenoma) metastatic neoplasia, abscess, hepatitis – Metabolic diseases, including hyperadrenocorticism (amyloidosis cats), lipidosis, glycogen storage diseases
Spleen	– Neoplasia (hemangiosarcoma, lymphoma, mast cell tumor, plasma cell/myeloma, histiocytic sarcoma, metastatic neoplasia, other) – Large splenic hematoma – Torsion, portal hypertension, lymphoid hyperplasia – Splenitis (infection or inflammation-associated) – Sedation, splenic vein thrombosis
Kidneys	– Hydronephrosis and pyonephrosis, abscess, cysts (single or polycystic) – Neoplasia (carcinoma, lymphoma)
Adrenal glands	– Neoplasia (adenoma, adenocarcinoma, pheochromocytoma, lymphoma) – Note: Severe retroperitoneal hemorrhage may be associated with adrenal masses causing abdominal enlargement and pain
Uterus	– Neoplasia, pregnancy, and pyometra
Prostate	– Adenocarcinoma, paraprostatic cyst(s), prostatic abscess, hyperplasia
Ovary/Retained testis	– Neoplasia (ovarian carcinoma, testicular Sertoli cell, Leydig cell tumor and seminoma) – Ovarian cysts
Urinary bladder	– Urethral obstruction (tissue, calculi), neurogenic paralysis of bladder
Stomach	– Neoplasia (carcinoma, leiomyoma/sarcoma), gastric outflow obstruction (pyloric antral hypertrophy) – Gastric pythiosis
Pancreas	– Rarely large enough to cause abdominal distension, except for cystic adenocarcinoma in cats
Intestine	– Rarely large enough to cause abdominal distension – However, distal obstructions (neoplastic or anatomical) may cause feces to accumulate to extraordinary amounts – Megacolon, for example

Not all differentials may cause organomegaly; however, "fantastically big" organomegaly may cause clinically apparent abdominal distension.

(cytology of fine-needle aspirates and/or tissue biopsy and histopathology). Abdominal radiography (3 orthogonal views) has the advantage of giving a "global" view of the abdomen. Ultrasound examination may provide information on structure, blood supply, and fluid content and is useful for assisting rapid diagnosis in the emergency patient.[5] Ultrasound guidance is also used for obtaining samples for cytology, culture, and histopathology. Where surgical removal of a large mass is contemplated, contrast CT scanning may be useful for delineating margins and identifying vasculature.

CHAPTER 2

Common Clinical Problems

CHAPTER 2.2 Cough

Elizabeth Rozanski

History 17
Physical Examination 17
Diagnostic Imaging 18
Sampling 18
Management 19
Recommended Further Readings 19

Cough is a common presenting complaint for dogs and, to a lesser extent, cats. Cough is a sign of an underlying disorder and not a primary diagnosis. Therefore, the cause of the cough should be identified and treated, if possible. In some cases, the cause of cough may be simple to identify and easy to correct, such as kennel cough. In other cases, the cough may be multifactorial or relatively resistant to therapy.

Cough is defined as a sudden expiratory effort producing a noisy expulsion of air from the lungs. A cough usually signals an effort to clear the lungs of real or imagined foreign material. Cough can be productive or dry, although this may be at times hard for the owners to determine if the cough is productive, as animals rarely expectorate and tend to swallow any mucus that is produced. Cough can be classified as acute or chronic. A cough is considered chronic if it lasts for 2 months or longer.

Most coughing in animals is presumed to be an involuntary response. The cough reflex is the primary defense mechanism to prevent aspiration of large particles or debris.

Stimuli to cough include pressure on the outside of the airway, presence of foreign material or perception of foreign matter, excessive secretions, or recurrent aspiration. Cough plays an important function both by aiding in the clearance of foreign debris and by enhancing the actions of the mucociliary elevator.

HISTORY

Historical information and a description of the cough may help to pinpoint the etiology. Cough may also be classified as to a specific time of day (e.g., night, morning) or coupled with an event such as drinking, eating, running, or pulling on a leash. Coughing at nighttime may result in more complaints due to interference with the owner's own sleep, especially for owners that are away during the daytime. In cats, cough may be confused with retching or attempts to vomit hairballs. Kennel cough or canine infectious respiratory disease complex (CIRD) is common in dogs, and even brief exposure to other apparently healthy dogs can result in infection. As always, questions about prior therapy and any apparent benefit or lack of benefit may help improve the diagnostic and therapeutic option.

PHYSICAL EXAMINATION

Pets that are presented for evaluation of cough should be immediately assessed as "stable" or "unstable." Congestive heart failure most commonly presents as tachypnea and/or respiratory distress, but occasionally, signs are misinterpreted to be only cough, particularly when large volumes of pulmonary edema are present. Tracheal collapse may result in severe respiratory distress due to airflow obstruction, although affected dogs may have cough occasionally as well. Other unstable causes of cough include pneumonias and pleural space disease, such as spontaneous pneumothorax or chronic pleural effusion. Unstable pets should be rapidly administered supplemental oxygen, and diagnostic testing should be pursued promptly.

In stable patients, a complete physical examination of the cardiopulmonary system is warranted, including examination of the oral cavity, palpation of the neck for masses or lymphadenopathy, auscultation of the upper and lower airways and heart, and abdominal palpation. Dogs with a visible expiratory "push" commonly have obstructive lower airway disease, while a dog with a palpably dorsoventrally flattened trachea is more commonly affected with obstructive tracheal disease in the cervical or thoracic inlet regions. Pets should be evaluated for weight loss or loss of muscle mass, which may accompany primary or metastatic neoplasia,

DOI: 10.1201/9781003254591-4

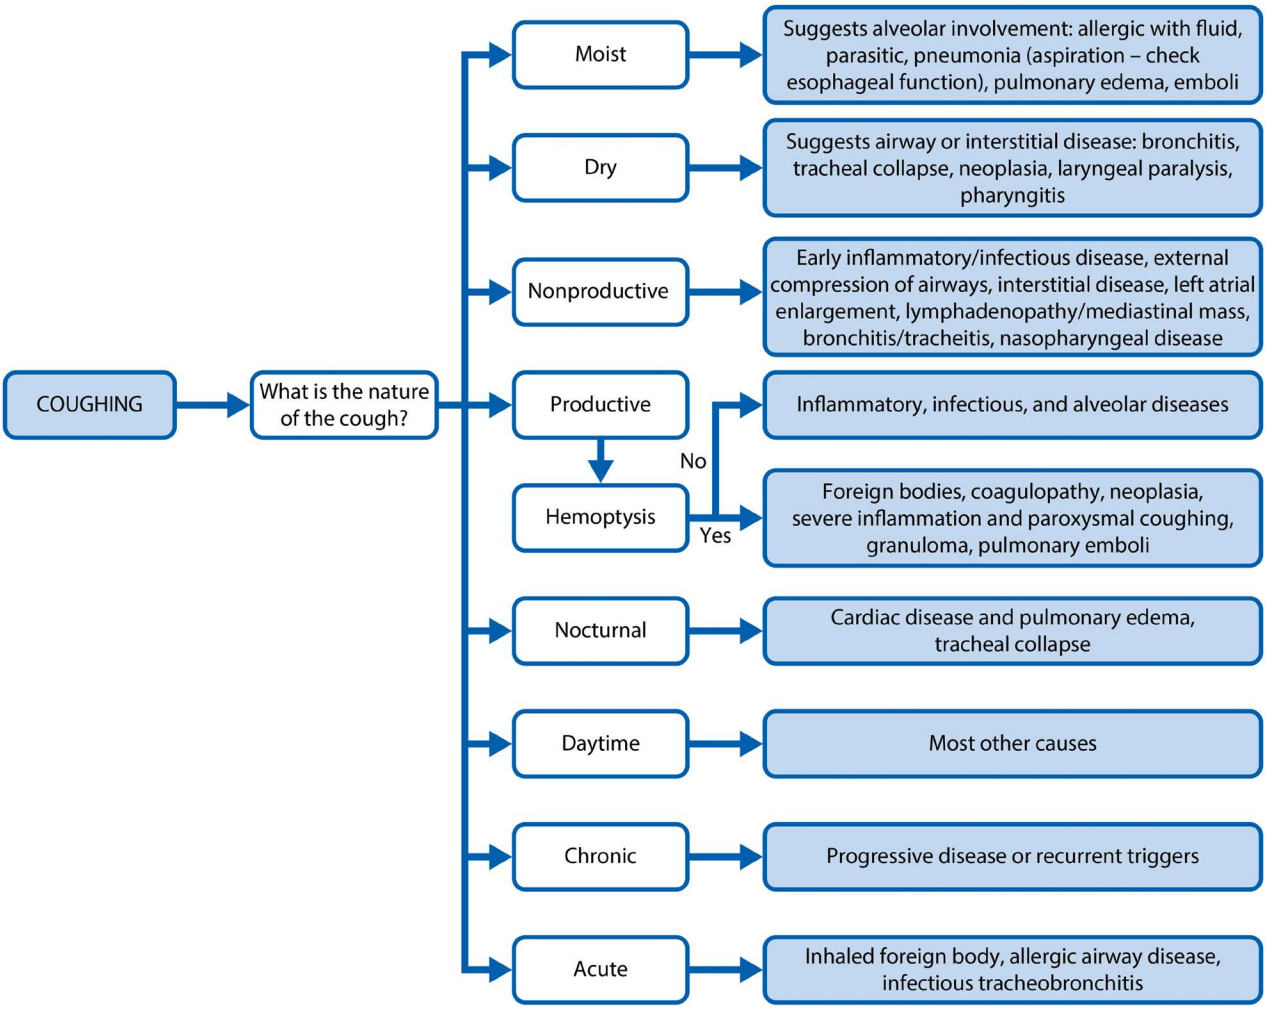

FIGURE 2.2.1 An algorithm showing the various characteristics and causes of different types of coughs.

heart disease, or severe obstructive pulmonary disease. Esophageal (megaesophagus) and laryngeal dysfunction may lead to recurrent pneumonias due to aspiration. Recent work has supported an increasing role of aerodigestive disorders in causing cough (see algorithm, Figure 2.2.1).

DIAGNOSTIC IMAGING

Thoracic imaging is recommended for evaluation of the patient with cough. Thoracic radiographs enable evaluation of lung parenchyma, large airways, as well cardiac size and pleural space. Computed tomography (CT) may be used as well for pulmonary diagnostics and may provide additional information about airway and lung parenchyma.

At a minimum, dogs and cats with a cough should have thoracic radiographs performed to not only try and identify an underlying cause but also to direct appropriate therapeutics. Point-of-care ultrasound has been gaining in popularity for evaluating evidence of pulmonary infiltrates, as assessed by the presence of B-lines or other pulmonary pathology. In dogs undergoing bronchoscopy to assess airway structure, an initial laryngeal examination should be performed, especially in animals with concurrent stridor. Bronchoscopy is considered the "gold standard" for evaluating airway structure and should be combined with focused bronchoalveolar lavage (BAL) sampling.

SAMPLING

Sampling of the airways for cytology, aerobic culture and sensitivity testing, and/or polymerase chain reaction (PCR) testing should be considered in dogs and cats without a clear diagnosis from history, physical examination, and thoracic radiographs. Any anticoagulant medication precludes a transthorasic fine needle aspiration. Airway cytology is useful to document infection, inflammation, or eosinophilic infiltrates. Cultures should be interpreted in light of the cytological findings as normal airways may not be sterile. Parasites are occasionally identified in airway washes.

MANAGEMENT

Treatment of cough is varied depending on the identified underlying cause. Specific therapy is more likely to be useful than simple supportive care. If no specifically treatable cause is found, supportive care should be used.

The most common cause of chronic cough in dogs and cats is chronic bronchitis and feline lower airway disease/asthma, respectively. Lifestyle changes are important and may help significantly to reduce both the frequency and severity of the cough. Changes include:

1. Switching from a collar to a harness
2. Avoiding excessive excitement (and accompanying barking)
3. Avoiding indoor air pollutants (e.g., cigarette smoke and perfumes)
4. Weight loss to reduce the cough and exercise intolerance

Additionally, avoiding contact with dogs that may have infectious respiratory disease, such as kennel cough complex, is beneficial. Vaccination against the kennel cough complex may be helpful. Using mobile groomers may also help to limit exposure.

Controlling inflammation is helpful in dogs with chronic bronchitis and cats with lower airway disease and is most often achieved through oral or aerosolized glucocorticoids. Glucocorticoids decrease airway inflammation, which subsequently decreases cough. Glucocorticoids are usually extremely effective against cough but may have side effects, such as weight gain, panting, polyphagia, and polydipsia, which preclude long-term high-dose use. Oral glucocorticoids may be tapered to the lowest dose that controls signs. Inhaled glucocorticoids (e.g., fluticasone) are gaining in popularity for treatment of airway disease and may be very useful for long-term control. Most patients can be trained to accept the inhaler.

While chronic bronchitis is not primarily an infectious disease, treatment with antibiotics may be warranted during exacerbation of coughing episodes. In people with chronic obstructive pulmonary disease (COPD), treatment with macrolides, such as azithromycin, reduce hospitalizations. Fluoroquinolones and doxycycline are also useful as long-term antimicrobials. Owners should be advised that in patients with chronic bronchitis, an acute exacerbation of a cough may represent an antibiotic "deficiency" as secondary infections may develop, magnifying the cough. Deworming (e.g., fenbendazole) is appropriate, although the likelihood of parasites in adult dogs and cats is relatively low.

Cough suppressants are also used for the treatment of chronic bronchitis. In general, the cough reflex is essential to help clear secretions or trapped foreign particles. Chronic cough may be very tiring for both the dog and the family. Antitussives may be divided into central and local-acting substances. Centrally acting drugs act by depressing the cough center within the brain to the various stimuli. Opioids are effective central-acting antitussives. Opioids may have additional properties, such as sedation, impaired micturition, or constipation. In some animals, one opioid may be clearly more effective than another. Thus, if significant coughing is still occurring, it may be useful to try another medication or to increase the dose, as tolerance may develop after prolonged usage. It is particularly helpful to give sedative cough suppressants to the dog before bedtime to help both the pet owner and the pet sleep through the night.

Central-acting cough suppressants used in veterinary medicine include codeine, butorphanol, and hydrocodone. Dextromethorphan is available over the counter in many human cough medications and is occasionally effective in dogs. It is available in combination with guaifenesin as "cough tabs."

In some cases, concurrent pulmonary hypertension may develop, associated with chronic pulmonary disease. If this can be documented, treatment with sildenafil may be beneficial.

Maropitant, gabapentin, and tricyclic antidepressants have been proposed for chronic cough. In humans, gabapentin has been effective in chronic cough but has not been formally studied in dogs. One small clinical trial of maropitant in dogs with chronic bronchitis showed a moderate benefit.

CHAPTER 2

Common Clinical Problems

CHAPTER 2.3 Diarrhea

Frédéric Gaschen

Introduction 20
Pathophysiology 21
Differential Diagnoses 22
Clinical Approach 24
Recommended Further Readings 26

INTRODUCTION

Diarrhea is characterized by decreased fecal consistency, increased fecal volume, and/or increased defecation frequency.

All cats and dogs with diarrhea have intestinal dysfunction due to primary intestinal disease or secondary intestinal involvement associated with disorders originating outside the intestine. The clinical signs vary depending on whether the disease primarily originates in the small intestine or in the colon (Table 2.3.1 and Figures 2.3.1–2.3.6). However, not all animals with intestinal disease experience diarrhea. For instance, cats with inflammatory bowel disease (IBD) or small-cell intestinal lymphoma may present with weight loss, hyporexia, lethargy, and/or vomiting without diarrhea in spite of significant involvement of their intestinal mucosa. Also, dogs with protein-losing enteropathy (PLE) may show significant protein loss in the absence of diarrhea.

TABLE 2.3.1 Clinical signs associated with small and large bowel diarrhea

Clinical sign	Small intestinal disease	Large intestinal disease
Frequency of defecation	Normal or only slightly increased	Moderately to severely increased
Fecal volume per defecation	Normal to large	Small
Presence of mucus	No	Common
Presence of blood	Melena (digested blood) and possibly hematemesis if lesion in the duodenum or above Hematochezia if lesion in the jejunum or ileum	Hematochezia (fresh blood)
Steatorrhea	Possible	No
Tenesmus	No	Common
Urgency	No	Common
Dyschezia	No	Common
Flatulence, borborygmi	Possible	Uncommon
General condition	May be decreased (lethargy)	Usually unchanged
Appetite	Hyporexia common	Usually unchanged
Abdominal discomfort	Possible	Possible
Vomiting	Relatively common (especially in cats)	Possible but occasional
Weight loss	Common (if chronic)	Uncommon

Commonly, the disease process may involve both the small and large intestine, and affected animals present with a mixture of clinical signs indicating small and large bowel diarrhea.

DOI: 10.1201/9781003254591-5

FIGURE 2.3.1 A 4-year-old male neutered Weimaraner with dietary indiscretion and bloody diarrhea.

Secondary signs that may occur in diarrheic animals include dehydration, lethargy, dysorexia, abdominal pain, borborygmi, flatulence, hematochezia, melena, and anal/perianal irritation. Animals with chronic small intestinal diarrhea may present with weight loss (including loss of muscle mass) and possibly ascites in case of significant intestinal protein loss.

FIGURE 2.3.2 Liquid diarrhea of small bowel origin in a cat with inflammatory bowel disease.

FIGURE 2.3.3 Hematochezia with soft stool in a dog with diet-responsive chronic enteropathy.

FIGURE 2.3.4 Melena and diarrhea in a Boxer with GI bleeding secondary to duodenal adenocarcinoma. (*Courtesy of M. Schaer.*)

PATHOPHYSIOLOGY

The following mechanisms are commonly involved in the pathogenesis of diarrhea. In many instances, several mechanisms contribute concurrently to the onset of diarrhea in intestinal diseases.

FIGURE 2.3.5 Cow-pat-like feces from a 9-month-old Mastiff with exocrine pancreatic insufficiency.

FIGURE 2.3.6 Mucoid feces from a dog with chronic idiopathic colitis.

Osmotic Diarrhea

Osmotic diarrhea occurs in the presence of large, poorly absorbable, osmotically active molecules such as undigested carbohydrates, solutes that may additionally undergo fermentation by intestinal microbiota. These molecules ultimately result in a lack of water absorption and loss of water and nutrients in the feces. Osmotic diarrhea may occur following dietary indiscretion and with maldigestion secondary to exocrine pancreatic insufficiency or severe intestinal mucosal inflammation. Unlike most other forms of diarrhea, it typically resolves after the affected animal is fasted.

Secretory Diarrhea

Secretory diarrhea is the result of activation of cellular pathways leading to the secretion of electrolytes and water by the enterocytes. Inflammatory cytokines, fatty acids, bile acids, and bacterial endotoxins may trigger this pathway. IBD and enteropathogenic *E. coli* may elicit diarrhea through this pathway.

Increased Mucosal Permeability

This results from a loss of integrity of the intestinal mucosal barrier, which may occur through loss of enterocytes or compromise of paracellular structures such as the tight junctions connecting the enterocytes. Examples of diseases include parvovirus infection, IBD, intestinal lymphoma, and PLE.

Abnormal Intestinal Motility

This develops in the presence of mucosal inflammation. Giant aboral contractions (small intestine) and giant migrating contractions (colon) are common and may severely shorten intestinal transit times.

DIFFERENTIAL DIAGNOSES

There is a myriad of possible causes for diarrhea in dogs and cats. Therefore, it is meaningful to differentiate acute from chronic diarrhea and young from adult animals when preparing a list of differential diagnoses. In addition, the environment plays an important role: Dogs and cats in group housing are more susceptible to developing infectious diseases (animal shelters, boarding facilities, and breeding facilities). Common differential diagnoses for dogs and cats with acute and chronic diarrhea are summarized in Tables 2.3.2 and 2.3.3.

Acute Diarrhea

In young dogs and cats, acute diarrhea is often caused by enteric infections, and parvovirus infection is an obligate initial rule out in puppies/kittens presenting with acute-onset vomiting and bloody diarrhea. Additionally, parasitic infestations with nematodes (e.g., roundworms, hookworms, whipworms) or protozoa (e.g., various coccidia, *Giardia*) are very frequent causes of acute diarrhea. Alternatively, diarrhea may also be dietary in origin (dietary overload, dietary indiscretion, abrupt change in diet).

In adult dogs and cats, parasitic and dietary causes of diarrhea are also very common and need to be ruled out early in the diagnostic process. Acute flare-ups of chronic recurring diarrhea should be differentiated from truly acute disease. Acute hemorrhagic diarrhea syndrome (AHDS) is a disease of unknown etiology that typically but not exclusively affects middle-aged dogs of small and toy breeds (Figure 2.3.7). Severe cases may have a fatal outcome without aggressive treatment.

With the exception of shelters, boarding and breeding facilities, or dogs with acute hemorrhagic diarrhea

TABLE 2.3.2 Common causes of acute diarrhea in dogs and cats

	Dog	Cat
	Infectious	
Viral	Parvovirus*, coronavirus*	Parvovirus*, FeLV, FIV
Bacterial	*Campylobacter* spp., *Clostridium perfringens, Clostridium difficile, E. coli, Salmonella* spp., *Neorickettsia helminthoeca*†	*Campylobacter* spp., *E. coli, Salmonella* spp., *Clostridium perfringens, Clostridium difficile*
Parasitic	Nematodes (roundworms, hookworms, and whipworms)	Nematodes (roundworms and hookworms)
	Protozoa: Coccidia (*Isospora* spp.*, *Cryptosporidium* spp.), *Giardia* spp.	Protozoa: Coccidia, (*Isospora* spp.*, *Cryptosporidium* spp.), *Giardia* spp., *Tritrichomonas fetus*‡
Diet	Dietary indiscretion, abrupt diet change	Abrupt diet change, dietary indiscretion
Toxins, drugs	Numerous plants, drugs (e.g., antibiotics, chemotherapy drugs), chemicals	Same as dog
Idiopathic	Acute hemorrhagic diarrhea syndrome	
Diseases originating outside the intestine	Pancreatitis, liver disease, kidney disease, toxemia, sepsis	Same as dog

* Puppies and kittens;
† in endemic areas;
‡ young cats, multi-cat housing.

	Dog	Cat
Bacterial	*Campylobacter* spp., *Clostridium perfringens, Clostridium difficile, E. coli, Salmonella* spp., *Neorickettsia helminthoeca*‡	*Campylobacter* spp., *E. coli, Salmonella* spp., *Clostridium perfringens, Clostridium difficile*
Fungal, oomycetes, algal	*Histoplasma capsulatum*‡, *Pythium insidiosum*‡, *Prototheca* spp.‡	*Histoplasma capsulatum*‡
Parasitic	Nematodes (round, hook, and whipworms), *Heterobilharzia americana*‡	Nematodes (round and hookworms)
	Protozoa: Coccidia (*Isospora* spp.*, *Cryptosporidium* spp.), *Giardia* spp.	Protozoa: Coccidia, (*Isospora* spp.*, *Cryptosporidium* spp.), *Giardia* spp., *Tritrichomonas fetus*†
Diet	Diet-responsive diarrhea	Diet-responsive diarrhea
Dysbiosis	Present in most chronic inflammatory and neoplastic intestinal diseases	Present in most chronic inflammatory and neoplastic intestinal diseases
Chronic inflammation	Inflammatory bowel disease, granulomatous colitis!	Inflammatory bowel disease
Neoplasia	T-cell intestinal lymphoma	Small-cell intestinal lymphoma (T-cells)
Idiopathic diseases	Idiopathic intestinal lymphangiectasia	
Diseases originating outside the intestine	Atypical hypoadrenocorticism, exocrine pancreatic insufficiency, chronic pancreatitis, liver disease, kidney disease	Hyperthyroidism, exocrine pancreatic insufficiency, chronic pancreatitis, liver disease, kidney disease

* Puppies and kittens;
† young cats, multi-cat housing;
‡ in endemic areas;
! Boxers and Bulldogs.

syndrome, the role of bacterial enteropathogens is probably peripheral, since these bacteria and their toxins have been detected with similar frequency in the feces of healthy and diarrheic animals.

Chronic Diarrhea

As is the case with acute diarrhea, parasites (nematodes and protozoa) are also very frequently involved.

Chronic enteropathies (CE) are associated with intestinal mucosal inflammation. A complex relationship exists between the intestinal microbiota and the gut immune system, which is disrupted in chronic intestinal diseases. Additional factors such as dietary antigens may also contribute to the inflammation. Considerable and long-lasting changes in the composition of the microbiota have been documented in dogs and cats with CE. The differential diagnoses of canine CE include diet-responsive diarrhea, idiopathic intestinal dysbiosis (most common in young, large breed dogs such as German Shepherd Dogs), IBD, and T-cell intestinal lymphoma. Diet-responsive disease and IBD are also very common causes of feline CE and must be differentiated from small-cell intestinal lymphoma (T-cells), which may show similar clinical signs.

FIGURE 2.3.7 Liquid bloody diarrhea from a mixed-breed dog with acute hemorrhagic diarrhea syndrome.

CLINICAL APPROACH

A thorough history should be obtained that includes a description of the onset and duration of diarrhea, appearance of the feces, description of defecation, including frequency, and clinical course of the disease. Acute and new problems should be differentiated from recurrent or chronic issues. Additionally, the presence of factors that may trigger the development of diarrhea, such as dietary changes or administration of drugs such as antibiotics or nonsteroidal anti-inflammatory drugs (NSAIDs), should be discussed. Anthelmintic treatment and vaccination history should be obtained. The owner should also be asked if other animals in the household have the same signs and if the diarrheic dog/cat also shows additional signs such as hyporexia, vomiting, weight loss, polydipsia, and polyuria.

Acute Diarrhea

At the time of initial presentation, puppies and kittens that could have highly contagious parvovirus infection should be identified on the basis of clinical signs and absent/incomplete vaccination status. They should be immediately triaged and screened for the presence of viral antigen in the feces. Cage-side fecal tests have excellent specificity, and positive animals should be isolated from the rest of the hospital population while they receive treatment. However, fecal antigen test sensitivity is good but not perfect, and a negative result does not rule out the presence of virus. Consequently, in unvaccinated or incompletely vaccinated animals, suggestive clinical signs are sufficient to justify isolation.

In adult animals, acute diarrhea is often self-limiting, particularly if the underlying problem (parasites, diet) can be eliminated. Feces should be collected for parasitological testing (e.g., direct smear, zinc sulfate flotation, fecal *Giardia* antigen test). Alternatively, a broad-spectrum anthelmintic drug such as fenbendazole can be administered empirically (50 mg/kg orally [PO] q.24h. for 3 days). Further diagnostic tests such as screening for additional infectious diseases may be indicated in kennel, cattery, or shelter situations.

Treatment is supportive and focused on fluid therapy to address dehydration, the most common complication of acute diarrhea. Dogs and cats with limited systemic repercussions of diarrhea and mild dehydration may benefit from oral and subcutaneous (SC) fluids; however, lethargic, anorexic, and moderately to severely dehydrated animals require intravenous (IV) fluid therapy designed to rapidly and efficiently correct existing fluid and electrolyte deficits.

All animals with acute diarrhea generally benefit from a 12-hour fasting period followed by frequent small meals consisting of easily digestible food (commercial intestinal diet or home-prepared boiled skinless chicken breast and rice) for 3–5 days before being progressively reintroduced to their regular diet. Importantly, young puppies and kittens should not be systematically fasted as they may become hypoglycemic if not fed regularly. Antidiarrheal drugs are rarely necessary in small animals with acute diarrhea. Antimicrobials are generally not recommended in the treatment of acute diarrhea, except in the presence of severely compromised mucosal barrier and evidence of severe systemic repercussions such as severe depression, marked leukocytosis, or leukopenia, or in shelter animals. In a few clinical studies, probiotics have been documented to shorten the time to passage of normal feces and the time to discharge. A 2- to 4-week treatment extending well beyond expected clinical recovery is generally recommended.

Chronic Diarrhea

Dogs and cats with small or large bowel diarrhea and absent or minimal systemic repercussions (e.g., lethargy, dysorexia, weight loss) benefit from a sequential approach using various empirical treatment trials (**Box 2.3.1**). First and foremost, intestinal parasites must be eliminated using a broad-spectrum anthelmintic drug such as fenbendazole. Then, a dietary trial using either a novel protein or a hydrolyzed peptide commercial diet should be implemented. Clinical studies have shown that 50%–65% of dogs and cats with chronic diarrhea respond to such a dietary trial within 1–2 weeks. The proportion of responders is even higher among young, large breed dogs with mostly large bowel diarrhea. Dogs that do not respond to the elimination trial could benefit from a second elimination trial with a different

diet. Alternately, addition of a highly concentrated multistrain probiotic or use of antibiotics could be beneficial to address changes in the intestinal microbiota (dysbiosis), as outlined in Box 2.3.1. Finally, if empirical treatment is not successful, a full workup is indicated.

In sick dogs and cats with chronic diarrhea and dysorexia, lethargy, weight loss, or ascites, a more aggressive approach is recommended. This includes a minimal database with CBC, biochemical profile, and urinalysis, as well as abdominal ultrasound, if available. Depending on the severity of disease, these tests may reveal an inflammatory leukogram, panhypoproteinemia (hypoalbuminemia and hypoglobulinemia), and increased liver enzymes. Abdominal ultrasound may document intestinal wall lesions in all or select segments of the intestine. In parallel to the diagnostic plan, correction of fluid and electrolyte deficits may be required. Ultimately, intestinal mucosal biopsies may need to be collected endoscopically or surgically and evaluated histologically. In severely debilitated patients that are poor anesthetic risks or in cases with financial limitations, a carefully designed treatment trial for the most likely cause of the chronic diarrhea can be initiated if indicated (for further details, see Chapter 9, Digestive Diseases).

The recommended approach to chronic large bowel diarrhea is illustrated in the algorithm (Figure 2.3.8).

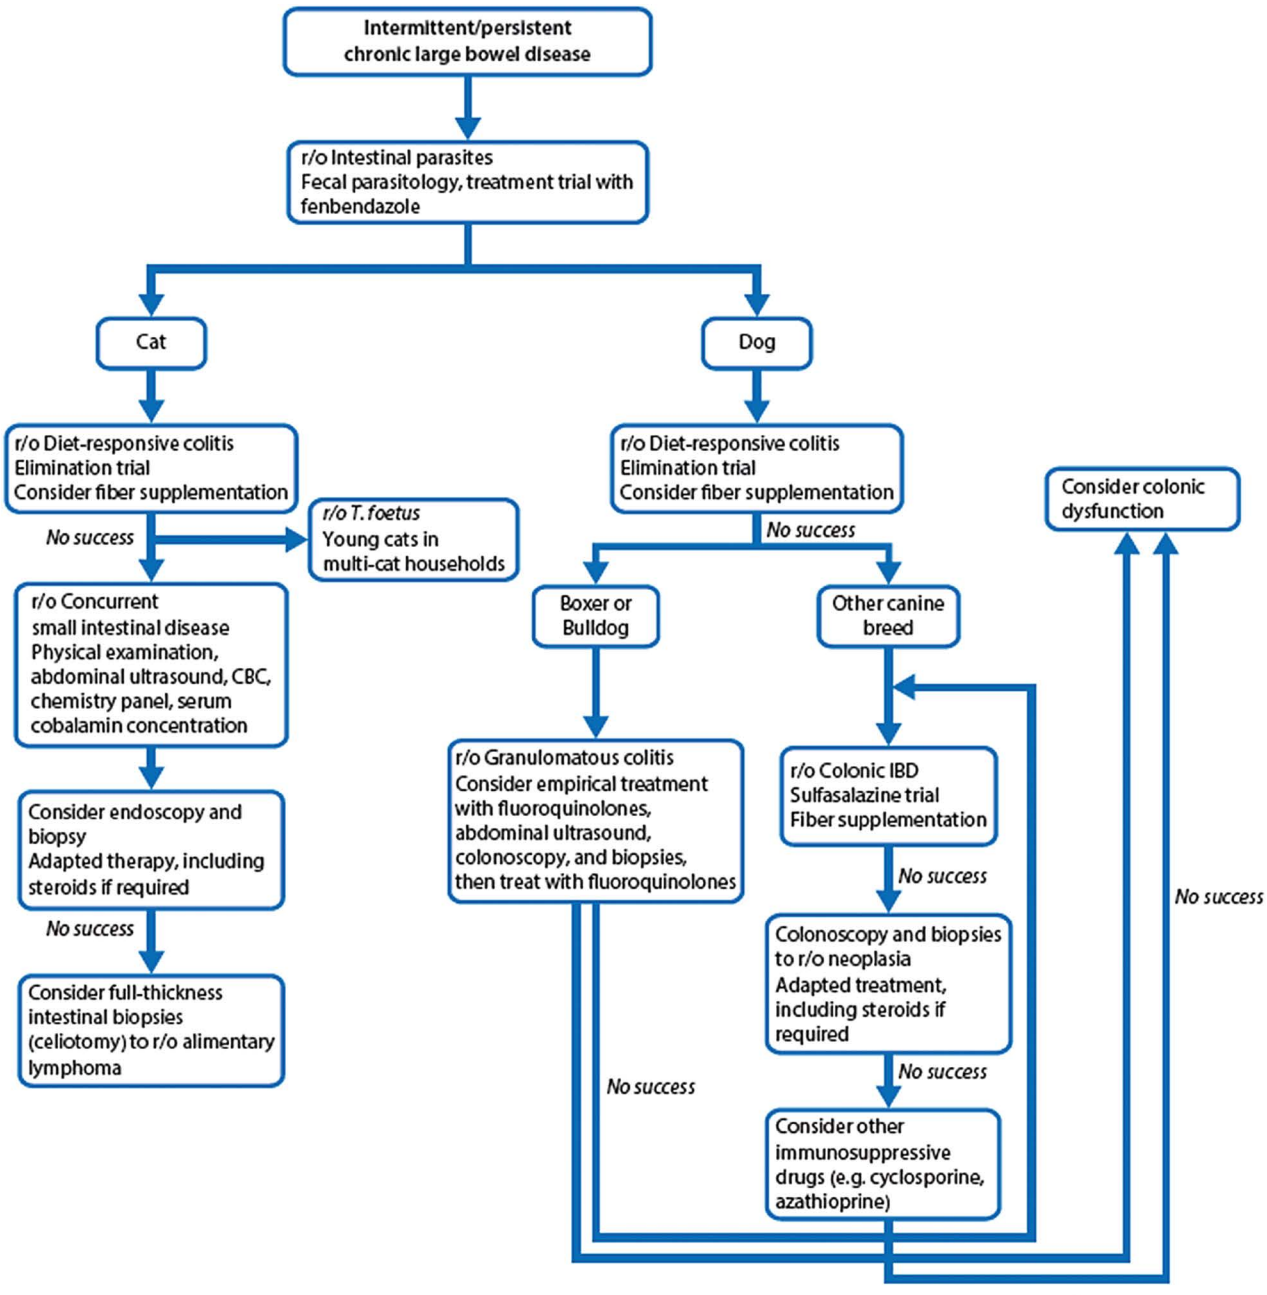

FIGURE 2.3.8 Clinical approach in cats and dogs with intermittent or persistent chronic large bowel diarrhea. r/o, rule out.

BOX 2.3.1 Approach to chronic diarrhea in dogs with minimal or absent systemic signs. While a sequential application of the following steps is theoretically preferable, they can also be combined (e.g., parasiticide and diet initiated at the same time).

- **Rule out intestinal parasites**
  Repeated parasite screenings and/or treatment with broad-spectrum anthelmintic drug (e.g., fenbendazole 50 mg/kg q.24h. for 3 days).

- **Rule out diet-responsive enteropathy**
  Elimination trial with hypoallergenic diet; a response should be seen within 2 weeks. In case of failure, some cases may benefit from a second trial with a different diet:
  - Novel protein diet (based on patient's dietary history)
  or
  - Hydrolyzed peptide diet

- **Rule out persistent intestinal dysbiosis**
  Administer a highly concentrated multistrain probiotic (e.g., 100–400 billion colony-forming units [CFU] per dog per day). Alternately, antibiotics such as tylosin (10–20 mg/kg p.o. q.12h.), or metronidazole (10–15 mg/kg p.o. q.12h.) have been used as well; a response should be seen within 2 weeks. If successful, treatment with probiotics or antibiotics should be pursued for an additional 2 or more weeks following improvement of clinical signs.

- If none of the above approaches works, obtain a minimal database with complete blood count (CBC), biochemistry panel, urinalysis, and abdominal ultrasound. Finally, endoscopy and intestinal biopsy or full-thickness surgically obtained intestinal biopsies might be required for a histopathologic diagnosis.

CHAPTER 2

Common Clinical Problems
CHAPTER 2.4 Dyspnea

Claire R. Sharp

Clinical Approach to the Dyspneic Patient 27
Upper Airway Obstruction 27
Lower Airway(s) Obstruction 30
Pulmonary Parenchymal Disease 31
Pleural Space Disease 32
Recommended Further Readings 32

Dyspnea represents a true emergency in dogs and cats, and rapid attention is warranted to limit the sensation of difficulty breathing, and institute appropriate diagnostic and therapeutic interventions. Some authors prefer to avoid the term dyspnea, as it defines a sensation of breathlessness in people, which dogs and cats are unable to describe. As such, the terms respiratory distress, shortness of breath, or abnormal breathing pattern may be used interchangeably.

CLINICAL APPROACH TO THE DYSPNEIC PATIENT

Supplemental oxygen should be immediately provided to a dog or cat in respiratory distress, by flow-by or mask if patient handling is required, or in an oxygen cage in a "hands-off" approach. A hands-off approach is particularly appropriate for cats, since additional handling when they are already in distress may precipitate decompensation and respiratory arrest. Table 2.4.1 outlines the various methods for providing supplemental oxygen.

Sedation may also provide therapeutic relief (Table 2.4.2). An (intravenous) IV catheter should be placed when feasible and initial blood samples collected. Point-of-care blood tests indicated on all patients in respiratory distress include packed cell volume, total solids, and venous blood gas. Additionally, the clinician must be prepared to intubate and provide positive pressure ventilation to patients with extreme respiratory distress.

Localization of the problem causing dyspnea is vital to guide diagnostic and therapeutic choices. The four most common anatomical causes of respiratory distress are upper airway obstruction, lower airway obstruction, pulmonary parenchymal disease, and pleural space disease. Respiratory lesions can generally be localized to one of these four sites by a combination of physical examination and thoracic auscultation (Figure 2.4.1). Other less common causes of respiratory distress include chest wall disease, pulmonary thromboembolism, abdominal distention, and look-alike diseases.

Physical examination of the respiratory system should start with an assessment of the breathing pattern and thoracic auscultation. Is their effort increased on inspiration, expiration, or both? Do they have stridor, signs of trauma, or abdominal distention? Are their lung sounds increased or decreased on auscultation?

UPPER AIRWAY OBSTRUCTION

See also Chapter 6, Respiratory Disorders.

Upper airway obstruction is classically associated with inspiratory difficulty and an externally audible noise termed stridor. Stridor is a continuous sound heard during inspiration. Hyperthermia is often present as these patients are unable to dissipate heat. An upper respiratory tract (URT) obstruction occurs due to mechanical or functional obstruction of the large airways and may occur at the level of the pharynx, larynx, or extrathoracic trachea (Table 2.4.3). The most common causes of URT obstruction are laryngeal paralysis (particularly in large breed, older dogs), tracheal collapse (particularly in small breed dogs), and brachycephalic obstructive airway syndrome (BOAS). Aspiration pneumonia may complicate cases of URT obstruction.

Initial treatment of URT obstruction includes sedation, cooling if hyperthermic, and oxygen supplementation. Various sedative drugs can be considered (Table 2.4.2). Depending on the nature and severity of the obstruction, the airway may need to be cleared and/or secured via orotracheal intubation or, rarely, an emergency tracheostomy. An anti-inflammatory dose of glucocorticoids (e.g., 0.1–0.15 mg/kg dexamethasone SC, IM, or IV) may also be considered to reduce URT

DOI: 10.1201/9781003254591-6

TABLE 2.4.1 Comparison of the fraction of inspired oxygen achieved by different methods of oxygen supplementation, their advantages and disadvantages

Method	Fraction of inspired oxygen (FiO_2) achieved	Advantages	Disadvantages
Flow-by	Generally low 25%–40% with a flow rate of 2–3 L/min versus 30%–90% if 5 L/min and held within a few centimeters of nostrils	– Noninvasive – Well tolerated – Easy access to patient – Useful during triage	– Wasteful of oxygen – Short term only – Labor intensive – requires someone to hold in front of patient
Face mask	5–12 L/min FiO_2 up to 50%–60% versus 80%–90% if tight-fitting	– Noninvasive – Relatively high FiO_2 – Easily administered – Easy access to patient	– Rebreathing of CO_2 and hyperthermia can occur if tight-fitting mask – May not be tolerated in awake and coherent patients – Labor intensive
Oxygen hood (e.g., Elizabethan collar with plastic wrap over the top)	0.5–1.0 L/min flow rate can achieve FiO_2 of 30%–40% High flows may achieve close to 100% FiO_2 Must have an outflow	– Noninvasive – Generally well tolerated – Economical – Minimal equipment	– CO_2 accumulation and hyperthermia if not adequately vented – Condensation interferes with visualization
Oxygen cage	Up to 60+%	– Noninvasive – Minimal patient stress – Tight control of FiO_2 – Temperature and humidity controlled if using a commercially available cage	– CO_2 accumulation if no soda lime – Expensive – Use large volumes of oxygen – Opening cage results in loss of high FiO_2 – No direct patient access
Traditional nasal prongs / catheters	Flow rates of 50–150 mL/kg per minute achieve 30%–60% FiO_2	– Minimally invasive – Generally well tolerated – Allow patient access	– Can be irritating → sneezing, epistaxis – Not tolerated by all animals – May require sedation to place – May require local anesthetic to reduce local irritation
High-flow nasal cannulae	Up to 100% depending on the flow rate	– Minimally invasive – Can provide continuous positive airway pressure (CPAP)	– Require specialized equipment – Pneumothorax, pneumomediastinum, and SC emphysema have been reported in humans
Transtracheal oxygen (rarely indicated)	~70% depending on flow rate	– Higher FiO_2 – A degree of CPAP – Bypass URT obstruction – Useful during tracheobronchoscopy – Easy to maintain once in, if immobile patient – Allows patient access	– Invasive unless via existing tracheostomy – More labor intensive – Often require sedation for percutaneous placement or anesthesia for surgical approach – Easy to dislodge or kink – Potential for SC emphysema – Contraindicated in coagulopathy
Intubation (and ventilation)	Up to 100%	– Indicated if hypoxemia (PaO_2 < 60 mmHg, SpO_2 < 90% despite oxygen supplementation), hypercapnia (PCO_2 > 60 mmHg), or respiratory fatigue – Fine control of FiO_2, PEEP, and all aspects of ventilation	– Invasive – Requires anesthesia – Mechanical ventilation – Expensive

CPAP, continuous positive airway pressure; CO_2, carbon dioxide; FiO_2, fraction of inspired oxygen; PCO_2, partial pressure of carbon dioxide; SC, subcutaneous; URT, upper respiratory tract.

TABLE 2.4.2 Drugs commonly used for the emergency treatment of dyspneic dogs and/or cats depending on lesion localization

Drug name and rationale	Drug class	Dosing guide	Considerations
Sedatives/anxiolytics			
Butorphanol	Opioid analgesic	0.1–0.3 mg/kg IM or IV	First-line sedative for respiratory distress Minimal cardiovascular depression
Acepromazine	Phenothiazine sedative, premedicant	0.005–0.03 mg/kg IM or IV	Dose-dependent hypotension Long duration of action
Medetomidine	α2-adrenergic agonists with sedative, premedicant, and analgesic properties	2–5 mcg/kg IV 5–10 mcg/kg IM	Induce vasoconstriction and bradycardia Reversible with atipamezole
Dexmedetomidine		1–5 mcg/kg IV 3–10 mcg/kg IM	
Trazodone	Serotonin (5-HT) antagonist/reuptake inhibitor antidepressant	Starting dose 1–6 mg/kg p.o. q.8–12h.	Avoid in patients receiving other serotonergic drugs (due to risk of serotonin syndrome)
Bronchodilators			
Terbutaline	Short-acting β2-adrenergic agonist bronchodilator	0.01 mg/kg IM or SQ once	Indicated for rescue treatment of asthma in cats and chronic bronchitis in dogs
Albuterol / Salbutamol		1 puff (90 mcg) via metered-dose inhaler, spacer, and mask; may repeat q.30 minutes	
Epinephrine / Adrenaline	Potent, nonselective adrenergic agonist	0.01 mg/kg IM	Indicated for anaphylaxis only
Diuretics			
Furosemide	Loop diuretic	2–4 mg/kg IV or IM initially, repeating q.2-8h. depending on severity	CRI may be more effective for refractory pulmonary edema
Vasodilators / Afterload reducers			
Pimobendan	Inodilator; positive inotrope and vasodilator via selective inhibition of phosphodiesterase 3 and calcium sensitization	0.15 mg/kg IV or 0.25 mg/kg p.o. q.8–12h.	Indicated for dogs in congestive heart failure (CHF)
Nitroprusside	Parenteral arterial and venous vasodilator (via nitric oxide release)	1 mcg/kg/min CRI starting dose, titrate up or down as needed	Dose dependent hypotension Indicated for dogs with severe CHF
2% nitroglycerin paste	Transdermally administered arterial and venous vasodilator	Paste applied inside pinna or to skin in axilla, groin, or flank q.6–12h. – 1/8–1/4 inch cats – 1/4–1/2 inch small dogs – 1/2–1 inch medium dogs – 1–2 inches large dogs	Wear gloves to avoid transdermal absorption

swelling. Cooling can involve administration of room temperature IV fluids, wetting the fur coat with water, and application of a fan.

The diagnostic approach to an URT obstruction starts with a sedated upper airway examination by laryngoscopy and/or tracheoscopy. Cervical radiographs, thoracic radiographs, and/or fluoroscopy may also be indicated. Ongoing treatment will then be determined by the definitive diagnosis and may be medical or surgical.

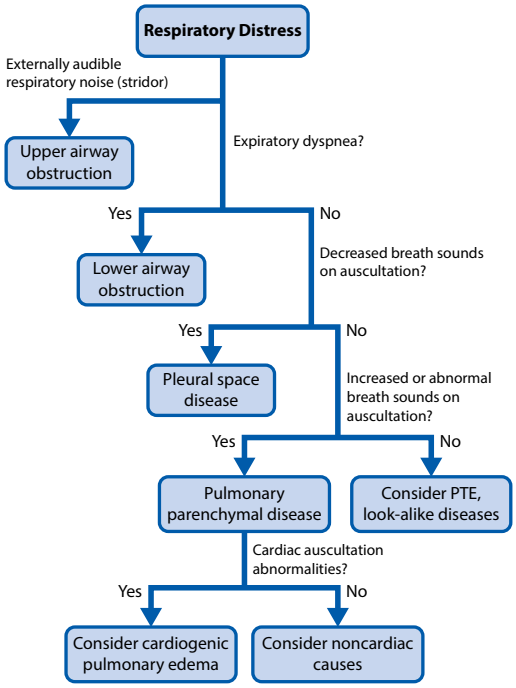

FIGURE 2.4.1 Localizing the cause of respiratory distress based on the abnormal breathing pattern and findings on thoracic auscultation.

LOWER AIRWAY(S) OBSTRUCTION

See also Chapter 6, Respiratory Disorders.

A lower airway obstruction is classically associated with expiratory difficulty and wheeze. Wheezes refer to continuous musical sounds heard on expiration during thoracic auscultation with a stethoscope. Severe cases may even have an expiratory grunt. Lower respiratory tract (LRT) obstruction occurs due to narrowing of the intrathoracic trachea or bronchi, which can occur secondary to bronchospasm, diffuse bronchomalacia, intrathoracic tracheal collapse, accumulation of mucus, and/or bronchial wall edema (Table 2.4.3).

History and signalment can be useful in cases of LRT obstruction. For example, cough is often present in cats for many months or years before they present with respiratory distress due to asthma. Asthma also tends to affect young to middle-aged cats. Similarly, a history of a harsh or honking cough in an older small breed dog increases the index of suspicion for chronic bronchitis, intrathoracic tracheal collapse, and/or bronchomalacia.

In addition to oxygen supplementation, a bronchodilator trial is indicated as part of treatment, particularly for cats with LRT obstruction (Table 2.4.2). Once the patient has stabilized, diagnostics should include thoracic

TABLE 2.4.3 Differential diagnoses for respiratory distress in dogs and cats based on anatomic localization

Localization of respiratory disease	Differential diagnoses
Upper respiratory tract obstruction	– *Pharynx:* Polyp, mass, foreign body, elongated soft palate, hematoma (especially with coagulopathy or trauma) – *Larynx:* Laryngeal paralysis, collapse, neoplasia – *Extrathoracic trachea:* Collapse, foreign body, stenosis, stricture, mass (intra- or extraluminal) – *Brachycephalic obstructive airway syndrome:* Combination of primary and secondary abnormalities, including stenotic nares, macroglossia, elongated soft palate, everted laryngeal saccules, enlarged tonsils, hypoplastic trachea
Lower respiratory tract obstruction	– *Intrathoracic trachea:* Collapse, foreign body, stenosis, stricture, mass (intra- or extraluminal) – *Bronchospasm:* Feline asthma, lungworm, heartworm-associated respiratory disease – *Diffuse bronchomalacia:* Severe (end-stage) chronic bronchitis – *Accumulation of mucus or other exudate:* Particularly in asthma and chronic bronchitis – *Bronchial wall edema:* Anaphylaxis
Pulmonary parenchymal disease	– *Pneumonia:* Primary infectious etiology versus aspiration – *Pulmonary edema:* Cardiogenic versus noncardiogenic – *Interstitial lung disease:* Interstitial fibrosis, eosinophilic bronchopneumopathy – *Pulmonary neoplasia:* Primary versus metastatic pulmonary contusions, hemorrhage – Lung lobe torsion
Pleural space disease, and/or chest wall disease	– *Pleural effusion:* Transudate or modified transudate, pyothorax, chylothorax, hemothorax – *Pneumothorax:* Traumatic (blunt or penetrating trauma) or spontaneous (latter due to ruptured blebs or bullae) – *Space occupying lesion:* Large chest wall mass – Diaphragmatic hernia – Flail chest (traumatic) causes visually obvious focal flail segment – Respiratory compromise is usually due to concurrent pulmonary contusions and/or pneumothorax, pain
Pulmonary thromboembolism	– Predisposing conditions include anything that predisposes to thrombosis (e.g., immune-mediated hemolytic anemia, protein-losing nephropathy, protein-losing enteropathy, neoplasia, acute necrotizing pancreatitis, etc.)
Abdominal distention	– Impedes thoracic expansion during inspiration, but respiratory condition is not usually dire (e.g., gastric dilatation and volvulus, marked hepatomegaly, abdominal masses, late-stage pregnancy)
Look-alike syndromes	– Apparent difficulty breathing (increased respiratory rate and/or effort) caused by nonrespiratory conditions – Considerations include pain, severe metabolic acidosis (e.g., diabetic ketoacidosis), severe anemia, hyperthermia

radiographs and potentially tracheobronchoscopy and/or bronchoalveolar lavage cytology. Heartworm and lungworm testing may also be indicated. Following a definitive diagnosis, chronic treatment may involve corticosteroids, bronchodilators, and/or antiparasitic drugs.

PULMONARY PARENCHYMAL DISEASE

Pulmonary parenchymal disease may result in both inspiratory and expiratory difficulty or rapid shallow breathing. Breath sounds will usually be increased on auscultation, and crackles may be present. Crackles are discontinuous popping sounds heard on thoracic auscultation.

Pulmonary parenchymal disease includes diseases of the terminal and respiratory bronchioles, interstitium, and alveoli. Differential diagnoses include pneumonia, pulmonary edema (cardiogenic versus noncardiogenic), interstitial lung disease, pulmonary neoplasia, and pulmonary contusions (Table 2.4.3). Auscultable cardiac abnormalities and tachycardia increase the index of suspicion for cardiogenic pulmonary edema, as does jugular venous distention. In these cases, empirical furosemide can be considered. In contrast, a low heart rate and/or respiratory sinus arrhythmia is suggestive of primary respiratory disease. The distribution of abnormal lung sounds may also be helpful in ranking differential diagnoses and mirrors that of diagnostic imaging abnormalities (Table 2.4.4). Patients with cardiogenic pulmonary edema may be hypothermic, while those with pneumonia or infectious respiratory disease may have a fever.

TABLE 2.4.4 Diagnostic investigations indicated for patients with respiratory distress depending on lesion localization

Diagnostic test	Abnormalities identified in different diseases
Pulse oximetry	SpO_2 < 95% = hypoxemia and indicates the need for supplemental oxygen SpO_2 < 90 mmHg = severe hypoxemia
Arterial blood gases	PaO_2 < 80 mmHg = hypoxemia and indicates the need for supplemental oxygen PaO_2 < 60 mmHg = severe hypoxemia
NT-proBNP	Increased in dogs and cats with left atrial enlargement; high NT-proBNP in patient with respiratory distress suggestive of heart failure
Point-of-care thoracic ultrasound	Pleural effusion Absence of a glide sign = pneumothorax Increased B-lines / lung rockets = pulmonary parenchymal disease Increased left atrial:Aortic ratio (LA:Ao) suggestive of congestive heart failure
Upper airway examination and laryngoscopy (under sedation and/or anesthesia)	Will usually identify the cause of upper respiratory tract obstruction
Tracheobronchoscopy	Facilitates visualization of tracheal and bronchial collapse, as well as obstruction due to an intraluminal foreign body or mass lesion
Fluoroscopy	Useful to identify dynamic airway collapse (e.g., tracheal and/or main stem bronchial collapse)
Thoracic radiographs *Further information can be found in Chapter 3*	Feline lower airway disease (asthma) characterized by a generalized bronchointerstitial pattern, bronchial thickening ("doughnuts" and "tramlines"), and diaphragmatic flattening associated with hyperinflation Cardiogenic pulmonary edema in dogs associated with cardiomegaly, left atrial enlargement, pulmonary venous engorgement, and an increased opacity (interstitial to alveolar) in the perihilar region Noncardiogenic pulmonary edema classically associated with interstitial to alveolar pattern in caudodorsal lung fields with normal cardiac silhouette Aspiration pneumonia characterized by alveolar pattern in right middle lung lobe and/or ventral lung fields Nodular pattern commonly associated with pulmonary neoplasia or infectious causes (especially systemic mycoses) Pleural effusion associated with scalloped lung lobes (retracted from chest wall) and border effacement of the cardiac silhouette and diaphragm
Thoracic CT scan	With angiography is the diagnostic modality of choice for PTE given inconsistent abnormalities on radiographs Also imaging modality of choice for interstitial lung disease and identifying pulmonary metastases
Airway sampling (transtracheal wash, endotracheal wash or bronchoalveolar lavage)	Fluid analysis, cytology, culture and susceptibility will aid in determining cause of inflammatory or infectious pulmonary parenchymal diseases
Lung biopsy	Often required for a definitive diagnosis of interstitial lung disease and pulmonary neoplasia

LA:Ao, left atrial: aortic ratio; NT-proBNP, N-terminal pro brain natriuretic peptide; PaO_2, partial pressure of oxygen; PTE, pulmonary thromboembolism; SpO_2, oxygen saturation.

Diagnostics including point-of-care ultrasound (POCUS), thoracic radiographs, lower airway cytology, echocardiography, thoracic CT, and even lung biopsy may be indicated. Ongoing therapy depends entirely on the diagnosis.

PLEURAL SPACE DISEASE

See also Chapter 7, Diseases of the Pleural Space.

Pleural space disease can result in inspiratory difficulty (without stridor), paradoxical breathing, or rapid shallow breathing. Normally, the chest and abdomen move together, out on inspiration and in on expiration. In a paradoxical breathing pattern, the abdomen moves inward during inspiration and outward during expiration (i.e., inverse to thoracic motions). Pleural space disease will also result in decreased lung sounds on thoracic auscultation.

Pleural space disease occurs due to abnormal accumulations within the pleural space. This may be fluid (i.e., pleural effusion), air (i.e., pneumothorax), a space occupying/mass lesion, or abdominal organs, as in the case of diaphragmatic hernia (**Table 2.4.3**).

While supplemental oxygen may provide slight relief to a patient with pleural space disease, urgent thoracocentesis is indicated in cases with pleural effusion or pneumothorax. Pleural effusion will be identified by the presence of fluid deep to the chest wall on POCUS, while pneumothorax is identified by the absence of a glide sign.

Thoracocentesis can be both diagnostic and therapeutic in cases with pleural effusion or pneumothorax. If coagulopathy is a differential diagnosis for pleural effusion, clotting times should be checked, and the coagulopathy corrected prior to thoracocentesis. Fluid analysis should be performed to differentiate the major types of pleural effusion and narrow the differential diagnoses.

The prognosis for dogs and cats with dyspnea depends on the ability of the clinician to stabilize the patient and the underlying cause.

CHAPTER 2

Common Clinical Problems

CHAPTER 2.5 Dysuria

Isabelle Cattin

Introduction 33
Evaluation of the Patient with Dysuria 33
Etiology 33
Further Investigations 35
Summary 36
Recommended Further Readings 37

INTRODUCTION

Dysuria is defined as difficulty urinating. It can be combined with pain during urination, pollakiuria (frequent urination), stranguria (extreme difficulty in passing urine (Figure 2.5.1), and hematuria (blood in the urine). A timely evaluation of the patient is essential, as inability to urinate can lead to potentially life-threatening complications.

EVALUATION OF THE PATIENT WITH DYSURIA

The initial evaluation of a patient presenting with dysuria should include signalment, history, and a physical examination (Figure 2.5.2). A detailed signalment can be helpful as some conditions associated with dysuria might be seen more readily at a certain age or in specific breeds. Typically, cystitis occurs commonly in both adult and young animals, whereas neoplastic processes can be seen in geriatric patients. A complete history, including duration of clinical signs, general health, and description of the urination pattern along with the appearance of the urine is necessary. Pigmenturia (bilirubinuria or hemoglobinuria) can signal other disorders in the body. Evaluation of the urination pattern includes voiding frequency, urine volume, ability to pass urine, pain, urination in inappropriate places, and passing discolored/bloody urine. The presence of systemic signs may reveal the existence of an underlying disease. Especially with feline patients, one should try to differentiate straining to defecate from straining to urinate to avoid missing a urinary obstruction. Palpation of the urinary bladder informs about size, shape, and tonicity of the bladder wall. A large, tonic, painful bladder in a cat suggests acute urethral blockage, whereas a large, flaccid (easy to express) bladder might point toward a neurologic problem. Passing a urinary catheter in male dogs can help confirm the presence of a urethral obstruction.

FIGURE 2.5.1 Cat with stranguria and hematuria associated with urethral obstruction and cystitis. (*Courtesy of M. Schaer.*)

ETIOLOGY

Causes of dysuria can be variable: Inflammatory/infectious, obstructive, neurogenic, and traumatic. The first two are the most prevalent in dogs and cats.

Inflammatory/Infectious Causes

Bacterial or less commonly fungal urinary tract infections are seen in both cats and dogs and can result in dysuria. Urinalysis and a urine culture are necessary to confirm the presence of infection. In intact male dogs, prostatic infections (prostatitis, prostatic abscess) should be ruled out. Less commonly, congenital malformations (e.g., remnant urachus) can cause urinary infections. Noninfectious, inflammatory conditions can occur in various locations of the urinary tract. "Idiopathic" (noninfectious) cystitis is very common in

DOI: 10.1201/9781003254591-7

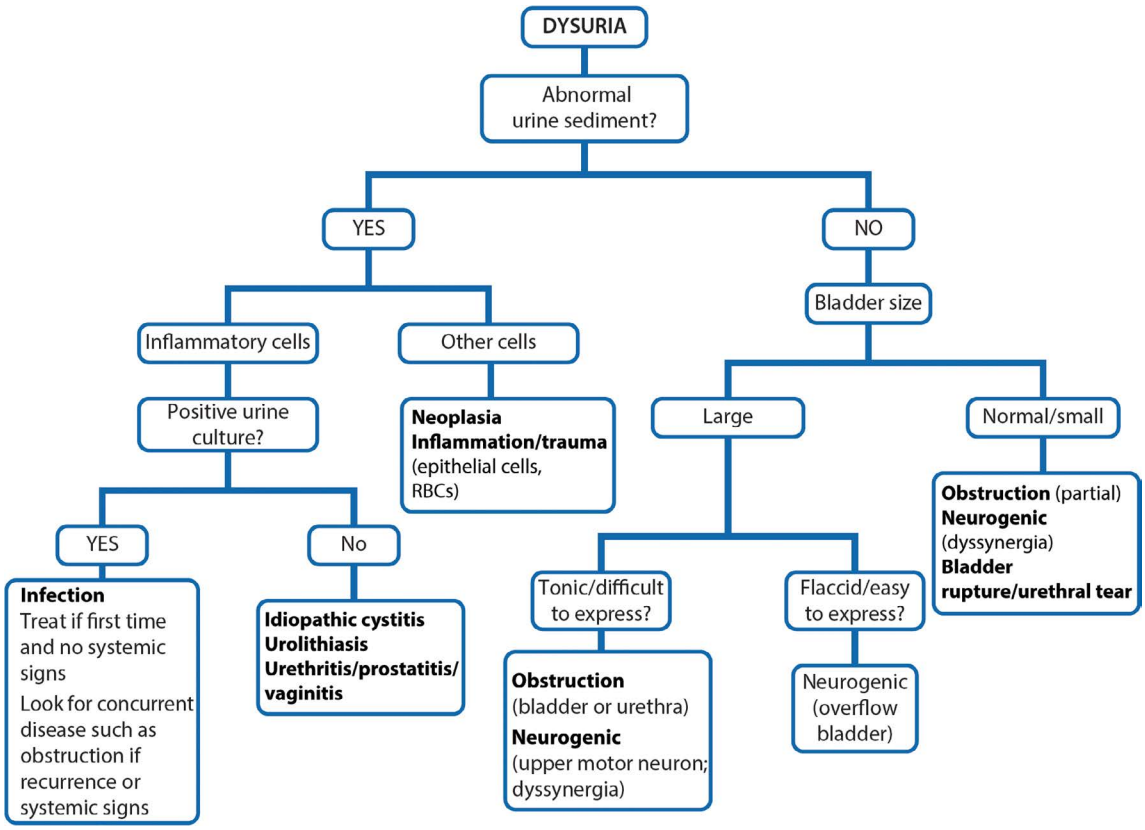

FIGURE 2.5.2 Algorithm for the clinical approach to dysuric dogs and cats.

cats and has a multifactorial origin. Behavioral issues play an important role here, thus showing the importance of taking a thorough history to differentiate between anatomical urinary tract pathology and behavioral issues. Granulomatous urethritis is a proliferative condition seen mostly in female dogs.

Obstructive Causes

Obstruction of the lower urinary tract can result in urination problems. Intraluminal obstructions can be caused by urolithiasis, urethral blood/mucus plugs, urethral strictures, or neoplastic processes. Discomfort associated with bladder wall inflammation can cause dysuria, but urethral obstruction should always be ruled out because it requires immediate care. In cats, blood clots or mucus plugs are a frequent cause of urethral obstruction. Urethral strictures can occur with severe urethritis or secondary to local trauma (stones, traumatic catheterization, surgery). Neoplastic processes in the urinary bladder or the urethra can cause inflammation or partial/complete obstruction. Extraluminal urethral obstructions can be seen with prostatomegaly due to prostatitis, prostatic abscess (Figure 2.5.3a, b), cyst or neoplasia.

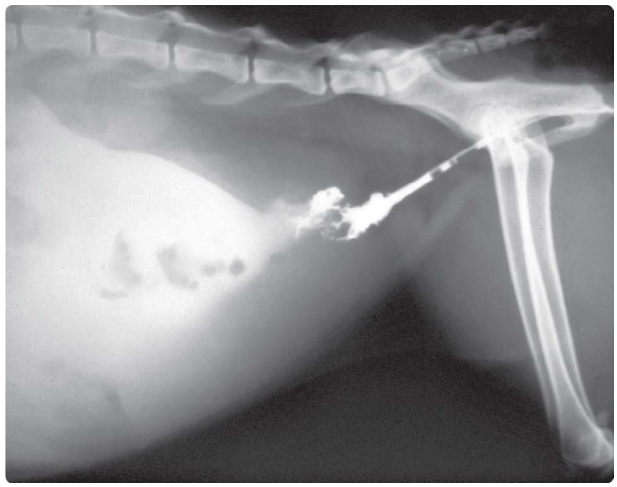

FIGURE 2.5.5 Cystogram showing a ruptured urinary bladder caused by excessive palpation. (*Courtesy of M. Schaer.*)

Neurogenic Causes

Upper or lower motor neuron diseases can cause either decreased ability to contract the bladder or increased spasticity of the external urethral sphincter, causing difficulty in urinating. A full neurologic examination and palpation of the urinary bladder are important steps in these cases. Increased urethral sphincter tone can cause a dynamic obstruction, while a decreased bladder tone can result in pollakiuria or incontinence ("overflow bladder"). In animals experiencing prolonged difficulty in emptying the bladder (as in urethral obstruction), the chronically distended urinary bladder can cause neurogenic dysuria (Figure 2.5.4). The problem should be promptly recognized and resolved, as the damage to the muscles and nerves of the urinary bladder can be irreversible. Reflex dyssynergia is seen in large breed dogs: Inadequate coordination between the bladder detrusor muscle and the urethral sphincter musculature leads to difficulty urinating, as the urethral muscle fails to relax when the bladder contracts.

Traumatic Causes

Trauma can lead to lesions of the urinary bladder or urethra. Causes include road traffic accidents, gunshots, blunt abdominal trauma, iatrogenic rupture (palpation or instrumentation) (Figure 2.5.5), or urinary calculi.

FURTHER INVESTIGATIONS

These include routine tests and sometimes more specialized methods (endoscopy or cystometry/urethral pressure profile) that require referral to a specialist.

Laboratory Testing

Urinalysis should include urine specific gravity (SG) and a sediment analysis. Cystocentesis is the preferred method to sample urine. Catheter samples are adequate, while voided samples may be contaminated by cells and bacteria from the lower genital tract. Sediment analysis may reveal the presence of red and/or white blood cells, crystals, organisms, parasite ova (*Capillaria* [*Pearsonema*] spp., *Schistosoma* spp.), and neoplastic cells. The absence of crystals does not rule out the presence of uroliths.

Urine culture will document an infection and assist in the choice of appropriate antibiotic treatment. In immunosuppressed animals, urine sediment may not show any signs of inflammation despite an ongoing infection. Blood chemistry and complete blood count (CBC) can help detect underlying conditions or, for example, life-threatening electrolyte imbalances. In dogs, cytologic analysis of an ultrasound-guided fine-needle aspiration of the prostate can help document any prostatic changes.

Imaging

Radiography and ultrasonography are useful to diagnose causes of dysuria.

Radiography can show the size and position of the urinary bladder and document the presence of uroliths, although not all types of uroliths are radiopaque. Extraurinary structures can be assessed (prostate, sublumbar lymph nodes, bony structures). Evidence of vertebral abnormalities might represent a neurologic cause of the dysuria (discospondylitis, lumbosacral stenosis (Figure 2.5.4), intervertebral discs, or spinal neoplasia). Radiographic contrast studies (double contrast cystogram, retrograde urethrogram) can help identify causes of urinary obstruction that cannot be seen on plain radiographs, such as radiolucent stones, narrowing of the urethral lumen (urethral strictures or spasms), or mucosal inflammation in the urinary bladder or urethra (Figure 2.5.6). Urinary leakage can also be diagnosed with this method.

Ultrasonography is helpful to evaluate the urinary bladder (mucosa, stones, or masses), the prostate, and the surrounding organs (kidneys, lymph nodes).

FIGURE 2.5.6 A double contrast cystogram in a cat with a transitional cell carcinoma in the urinary bladder that caused a radiographic filling defect. (*Courtesy of M. Schaer.*)

Evaluation of the complete urethra is more difficult due to the intrapelvic location and limited visibility (Figure 2.5.7).

Other Diagnostic Methods

Endoscopy is a useful diagnostic tool for confirming urethral strictures and mucosal abnormalities. Mucosal biopsies can be collected to differentiate inflammatory from neoplastic processes. Furthermore, endoscopic removal of bladder stones using lithotripsy has been reported.

Cystometry and urethral pressure profilometry are specialized techniques used to assess the function of the urinary bladder and urethral muscles in cases of suspected neurogenic dysuria (like reflex dyssynergia). A review of the indications for the different diagnostic tests used in dysuria is shown in Table 2.5.1.

FIGURE 2.5.7 Ultrasound image of a dog with prostatic carcinoma showing urethral pathology caused by tumor invasion. (*Courtesy of M. Schaer.*)

SUMMARY

A systematic stepwise approach to dysuria cases is necessary to localize the problem and to assess if urgent care is needed. Dysuria potentially leads to serious complications; thus, those patients need prompt evaluation.

TABLE 2.5.1 Clinical usefulness of various tests in dysuric cats and dogs

Test	Indication/suspected process	Advantages	Disadvantages
Urinalysis	Any case of dysuria	Fast and cheap Can be helpful to document infection, crystalluria, possibly neoplasia	Nonspecific Some causes can be missed (neoplasia, urolithiasis)
Urine culture (usually aerobic)	Abnormal urinalysis Recurrent signs Underlying disease with risk of silent infection Evaluation of treatment success	Readily available Reasonable cost Allows targeted treatment	Delayed results (48–72 hours) Does not always preclude further testing (an infection can be secondary to other causes)
Radiography (plain)	Urolithiasis Extraurinary diseases Posterior abdominal extraluminal masses	Readily available Easily performed Evaluation of extraurinary/bony structures	Radiolucent uroliths not seen Mucosal abnormalities rarely visible
Radiography (with contrast)	Mucosal abnormalities Urolithiasis Urethral disease	Minimally invasive Allows evaluation of urethral content/mucosa	Requires technical skills Sedation or anesthesia usually necessary
Ultrasound	Urolithiasis Bladder wall abnormalities Extraurinary diseases Diseases of the proximal urethra	Frequently available Excellent image of bladder mucosa Allows sampling Can show all types of uroliths	Requires technical skills Urethra cannot be fully viewed
Endoscopy	Urethral disease Urolithiasis Bladder wall abnormalities	Allows direct visualization of mucosa Allows sampling Therapeutic in some cases (urolithiasis, polyps)	Only available in limited facilities Needs experienced operator Anesthesia necessary Increased cost

History taking and complete physical examination are essential, and knowledge of the different diseases and their clinical expression helps in choosing further diagnostic steps. Treatment recommendations for the different conditions mentioned in this chapter are discussed in Chapter 13, Nephrology/Urology.

CHAPTER 2

Common Clinical Problems

CHAPTER 2.6 Epistaxis

Samantha Wigglesworth and Amber Vitalo

Pathophysiology 38
Clinical Signs/Physical Exam 38
Diagnosis 39
Treatment 39
Prognosis 40
Recommended Further Readings 40

PATHOPHYSIOLOGY

Epistaxis is defined as hemorrhage coming from the nasal cavity. The nasal cavity begins at the nostrils and extends caudally to end at the choanae as the cavity opens up into the pharynx. It is composed of the nasal planum, paired nasal cavities, and three paranasal sinuses. Within the nasal cavities are turbinates that are lined by thin epithelium. This epithelium contains a large blood supply which originates from the maxillary branch of the external carotid artery. Due to the presence of this complex network of blood vessels, even a small amount of damage can lead to significant bleeding.

Epistaxis is a common disorder that can have local (intranasal) or systemic (extranasal) origin. Local causes include nasal neoplasia, trauma, idiopathic rhinitis, foreign bodies, and infectious disease (i.e., aspergillosis). Systemic causes, such as coagulation disorders or hypertension, are less common but still need to be considered in patients presenting for nasal hemorrhage. The intranasal and extranasal causes of epistaxis are provided in Table 2.6.1.

CLINICAL SIGNS/PHYSICAL EXAM

Epistaxis is typically the primary complaint for patients presenting with nasal hemorrhage. Signalment may help in distinguishing certain disease processes such as a young Dobermann with von Willebrand's disease or young cats with nasopharyngeal polyps. The owner should be questioned regarding chronicity, duration (constant versus intermittent), and description of the nasal discharge (color, odor, single nostril versus both) may also aid in prioritizing differentials. Additionally, obtaining a detailed history from the owner about vaccination status, environment, travel history, medications,

TABLE 2.6.1 Common local and peripheral signs of epistaxis associated with intra- and extranasal etiologies

Intranasal	Extranasal
Trauma Neoplasia – Adenocarcinoma, carcinoma, osteosarcoma, melanoma, lymphoma, etc. Infection – Fungal – aspergillosis, pythiosis, cryptococcus – Viral – calicivirus, feline viral rhinotracheitis – Bacterial – often secondary – Parasitic – nasal mites Inflammatory – Lymphoplasmacytic rhinitis, allergic rhinitis Dental – Tooth root abscess, oronasal fistula Foreign body Vascular malformation	Thrombocytopenia – Infectious, drugs, neoplasia, bone marrow aplasia, immune-mediated, microangiopathy, sequestration Thrombocytopathia – von Willebrand disease (VWD), drugs, uremia, polycythemia vera Coagulation factor deficiency – Hemophilia A (FVIII) and B (FIX), anticoagulant rodenticide, liver failure, disseminated intravascular coagulation (DIC) Hypertension – Primary or secondary (renal failure, Cushing's disease, hyperthyroidism, cardiomyopathy, pheochromocytoma) Hyperviscosity – Hyperviscosity syndrome (Waldenström macroglobulinemia), leukemias Systemic infection – Tick-borne disease, FeLV/FIV, Rocky Mountain spotted fever, hepatozoonosis, septicemia, endotoxemia

DOI: 10.1201/9781003254591-8

TABLE 2.6.2 Clinical signs associated with intranasal and extranasal causes of epistaxis

Intranasal signs	Extranasal signs
– Unilateral nasal discharge – Ocular discharge (same side as nasal discharge) – Decreased retropulsion of the globe (same side as nasal discharge) – Facial discomfort (pawing, rubbing, painful on palpation) – Other nasal discharge (purulent, serous) – Sneezing – Depigmentation of the nasal planum – Deformities of the oral cavity/palate	– Bilateral nasal discharge – Signs of platelet dysfunction (ecchymosis, petechiation, melena, hematuria) – Coagulopathy (joint swelling, cavitary bleeding, anemia) – Signs of hypertension (retinal hemorrhage and/or detachment, organ dysfunction – brain, kidneys) – Systemic signs (inappetence, lethargy, elevated rectal temperature)

and any additional clinical signs (i.e., sneezing or coughing) at home is very important and may help to repositioning of certain differentials. Knowing if the epistaxis is unilateral or bilateral can also be helpful in distinguishing intra-versus extranasal disease processes.

While it is often a readily visible exam finding, a thorough physical examination is essential in prioritizing possible underlying causes (Table 2.6.2). This should begin with assessing the patient for any facial deformities or discomfort by palpating the face and the muzzle and performing gentle retropulsion of the eyes. Determining the presence of nasal airflow in both nostrils with a glass slide or tuft of cotton can also aid in disease localization. The nasal planum should be examined for ulceration, depigmentation, or obvious masses obstructing airflow. The oral cavity and surrounding lymph nodes should be inspected for any palate deformity, masses, oronasal fistulas, severe periodontal disease, and regional peripheral lymphadenopathy. A complete evaluation of the skin and mucous membranes should be performed to look for evidence of petechiae or ecchymoses that are indicative of hemostatic disorders. Lastly, a rectal exam is recommended to assess for melena, possibly indicative of swallowed blood or hemostatic disorders such as thrombocytopenia or coagulation disorders.

DIAGNOSIS

Epistaxis is a clinical sign, not a diagnosis in itself; therefore, a diagnostic workup is often necessary to determine the underlying cause (Figure 2.6.1). The differential diagnoses for epistaxis can be divided into local (intranasal) and systemic (extranasal) causes for organizational purposes. Typically, systemic disease and coagulopathies are investigated first due to the ease of this preliminary testing. First, a blood pressure should be obtained on presentation to rule out hypertension as the underlying cause of the epistaxis. Initial diagnostic testing should include a minimum database to screen for anemia, thrombocytopenia, and/or liver disease that can lead to hemostatic disorders. Investigating coagulopathies by evaluating platelet counts, a buccal mucosal bleeding time for von Willebrand factor, and clotting factor status with prothrombin time (PT) and partial thromboplastin time (PTT) or viscoelastic testing, such as thromboelastography (TEG), viscoelastic coagulation monitor (VCM), or thromboelastometry (TEM) is recommended to rule out hemostatic disorders as the primary cause. In cats, testing for feline leukemia virus/feline immunodeficiency virus (FeLV/FIV) is recommended, if the status is unknown. Serology for tick-borne disease, heartworm, and cryptococcus can also be performed if exam findings are concerning for these disease processes. Thoracic radiographs are often obtained to screen for metastatic disease indicative of local or systemic neoplasia.

Local disorders are the most common causes of epistaxis and include trauma, neoplasia, infection, inflammation, periodontal disease, and foreign body. Systemic causes include hemostatic disorders, hypertension, and systemic infection.

If initial testing is not indicative of a cause for the epistaxis, then more invasive additional testing is recommended. This includes CT scan of the head to screen for large masses or foreign material followed by rhinoscopy with biopsy of any abnormal tissue. Biopsy samples are submitted for histopathology and may also be submitted for bacterial and fungal cultures. In most cases of epistaxis, a cause can be identified when a thorough history, physical exam, and diagnostic workup are done.

TREATMENT

The goal for treatment is to control the epistaxis until a definitive diagnosis can be obtained. Often epistaxis does not require treatment itself; however, patients with significant and uncontrollable hemorrhage may require local control. Initially, intranasal application of vasoconstrictive drugs such as phenylephrine or epinephrine should be trialed. The use of sedatives can be helpful to relieve anxiety and blood pressure and reduce the amount of hemorrhage present. Patients with severe bleeding may require blood products to replace red blood cells and clotting factors. If these treatment options are ineffective, the patient will need to be sedated and intubated to either apply direct pressure in the nasal cavity or tie off the maxillary artery/vein to control the source of the bleeding.

Once a definitive diagnosis is obtained, therapy should be aimed at the treating the underlying cause. Patients identified to have hypertension should be started on antihypertensive therapy with close monitoring of blood pressure. Most trauma patients will only need monitoring with supportive care. Foreign bodies can often be removed at the time of imaging or rhinoscopy. Nasal tumors may require surgery for debulking followed by radiation and/or chemotherapy. Fungal infections can be treated locally with antifungal infusions as well as systemic antifungal medications. Immune-mediated disease (i.e., immune thrombocytopenia)

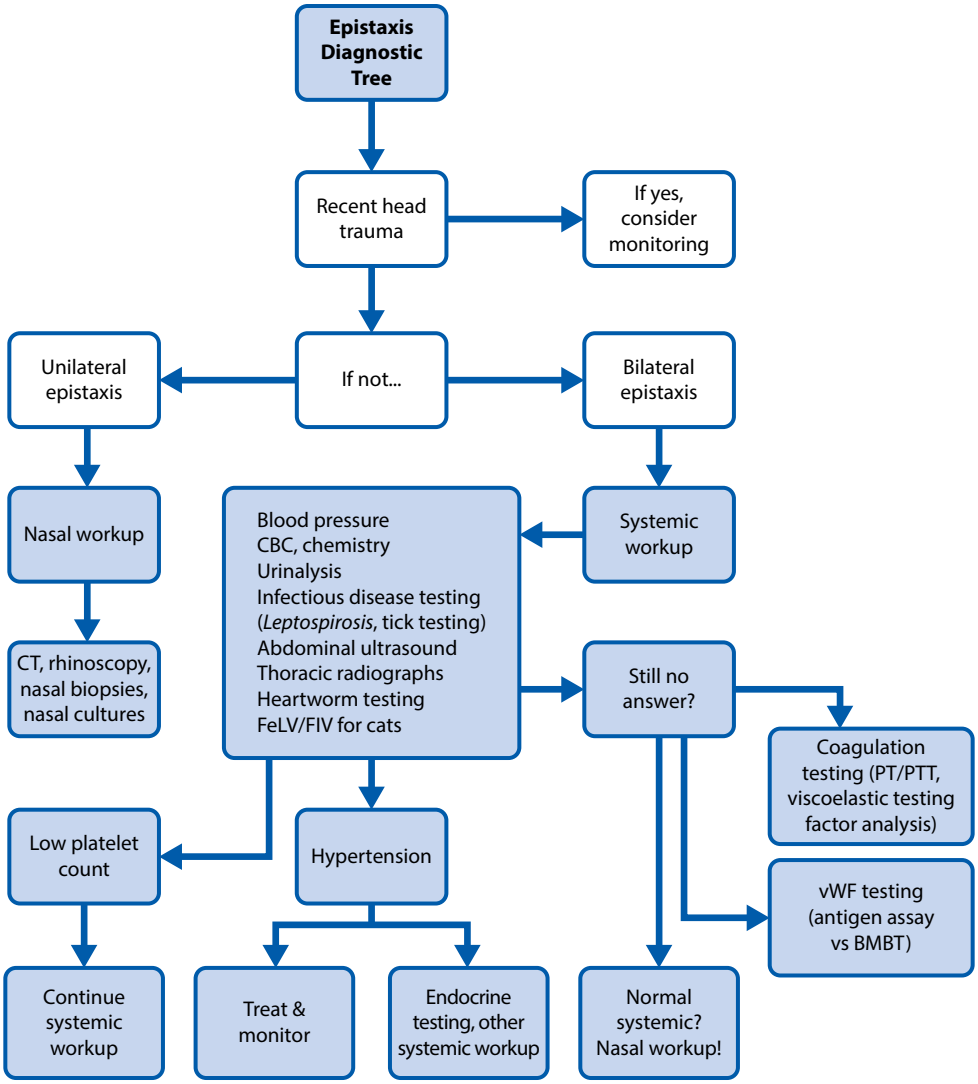

FIGURE 2.6.1 Algorithm for diagnostic workup of epistaxis. BMBT, buccal mucosal bleeding time; CBC, complete blood count; CT, computed tomography; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; PT, prothrombin time; PTT, partial thromboplastin time; VWF, von Willebrand factor.

should be treated with immunosuppressive doses of glucocorticoids and/or other immunosuppressive medications, which will hopefully allow the platelet count to rebound. In cats, nasopharyngeal polyps should be removed. Supportive therapies for any additional clinical signs present secondary to the underlying disease process should also be initiated.

PROGNOSIS

The long-term prognosis for patients with epistaxis is dependent on the underlying cause. For patients with neoplasia, long-term survival will be much less than those diagnosed with systemic hypertension. As with any disease process, response to therapy is crucial in determining prognosis.

CHAPTER 2

Common Clinical Problems
CHAPTER 2.7 Fever of Unknown Origin

Robert Armentano

Introduction 41
Pathophysiology 41
Etiology 41
Diagnosis 42
Treatment 45
Recommended Further Readings 47

INTRODUCTION

The classic definition of "fever of unknown origin" (FUO) provided for humans involves an illness of at least 3 weeks' duration, fever (continuous or fluctuating temperature of >104°F [40°C]), and no established diagnosis after at least 1 week of hospital investigation. There is no accepted definition of this term in veterinary medicine, except that the term FUO is used to define any febrile animal patient for which there is no obvious cause after "routine" diagnostic tests have been done. What constitutes routine will vary among different authors. The main diagnostic categories for FUO include infections (local and systemic), neoplasms, and immune-mediated diseases. Other less common causes include granulomatous diseases; noninfectious, inflammatory diseases such as pancreatitis, steatitis, and tissue necrosis and drugs. It is only after a search for the above causes that the clinician is left with the diagnosis of FUO.

PATHOPHYSIOLOGY

Normal body temperature is regulated within a fairly narrow range and is a balance between heat-producing and heat-dissipating mechanisms of the body. Fever is an increase of body temperature as a result of a change in the hypothalamic thermoregulatory center. Substances that cause fever are called endogenous or exogenous pyrogens. The majority of exogenous pyrogens are microorganisms, their products, or toxins. Exogenous pyrogens can act directly on the brain to cause fever but also act by inducing the formation of endogenous products, which stimulate the host's monocytes and macrophages. These endogenous pyrogen-producing substances mainly include antigen–antibody complexes with complement and cytokines.

The major pyrogenic cytokines include IL-1ß, IL-1α, tumor necrosis factor (TNF)-α, TNF-ß, interferon α, and IL-6. These cytokines circulate to the anterior hypothalamus where prostaglandin E2 and other arachidonic acid metabolites are produced. These in turn induce the formation of secondary messengers such as cyclic adenosine monophosphate that cause the rise in the thermoregulating set point leading to fever.

ETIOLOGY

The true incidence of FUO is unknown. A study by Feldman (1980)[4] noted the incidence of FUO in dogs as 40% infectious, 20% neoplastic, 20% immune-mediated disease, 10% miscellaneous disease, and 10% of a true FUO. A true FUO is diagnosed as a fever in which the underlying etiology is never discovered and that either spontaneously resolves or responds to a combination of antibiotics and/or steroids.

There are few retrospective papers documenting FUO in dogs (**Table 2.7.1**). There are no large, published studies in cats, but anecdotally, infectious etiologies are much more common than neoplastic and immune-mediated diseases. The conclusions from three recent retrospective reviews in dogs were that immune-mediated was the most commonly diagnosed category of disease, with immune-mediated polyarthritis as well as steroid-responsive meningitis-arteritis being the most common diagnoses (**Table 2.7.1** and **Figure 2.7.1**). These studies also concluded that imaging (radiographs and ultrasound) and cytology had the highest diagnostic yield (**Figure 2.7.2**).

Infections should always be considered first in the search for the etiology of FUO. See algorithms and **Table 2.7.2** for a complete list of localized and systemic

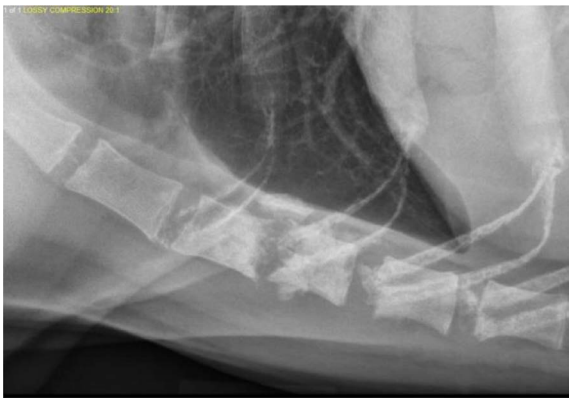

FIGURE 2.7.2 Lytic sternal lesion, consistent with discospondylitis.

infections that should be included as a differential for an FUO.

Neoplasia is a fairly common cause of fever. Feline leukemia virus (FeLV)-related cancers (e.g., lymphoma or myeloproliferative disease) in cats are the most common cause of fever in this class. The fever can be a paraneoplastic syndrome associated with the tumor itself, or it can be due to secondary infections. Solid tumors can also cause fever as the result of the host's immune response to the tumor or tumor necrosis.

Noninfectious inflammatory disease, including immune-mediated diseases, are not so rare. Some immunologic diseases, such as immune-mediated hemolytic anemia (IMHA), pemphigus, and systemic lupus erythematosus, can be readily identified. Others such as the polyarthropathies, sterile meningitis, and polymyositis are other examples of immune-mediated inflammatory disease.

There are many other causes of noninfectious inflammatory fevers. Examples of these include noninfectious inflammatory diseases such as amyloidosis (Figure 2.7.3); drug-associated fever as commonly reported with tetracycline and not so commonly with others, including sulfonamides, penicillins, nitrofurantoin, amphotericin B, barbiturates, atropine, cimetidine, salicylates, antihistamines, buprenorphine, and procainamide; and metabolic and endocrine diseases. This information is summarized in Table 2.7.2.

DIAGNOSIS

The key to obtaining a diagnosis includes a systematic approach for the medical evaluation for FUO. The most important steps prior to implementing a diagnostic plan include obtaining a thorough history and doing a complete physical examination that should include orthopedic, neurologic, funduscopic, and

AUS, abdominal ultrasound; AXR, abdominal radiographs; BAPGM, Bartonella alpha-Proteobacteria growth medium; CT, computed tomography; FIV, feline leukemia virus; IFA, immunofluorescent antibody; PARR, PCR for antigenic rearrangement; PCR, polymerase chain reaction; TXR, thoracic radiographs.

FIGURE 2.7.3 Shar Pei with swollen, edematous hocks consistent with Shar Pei fever (amyloidosis).

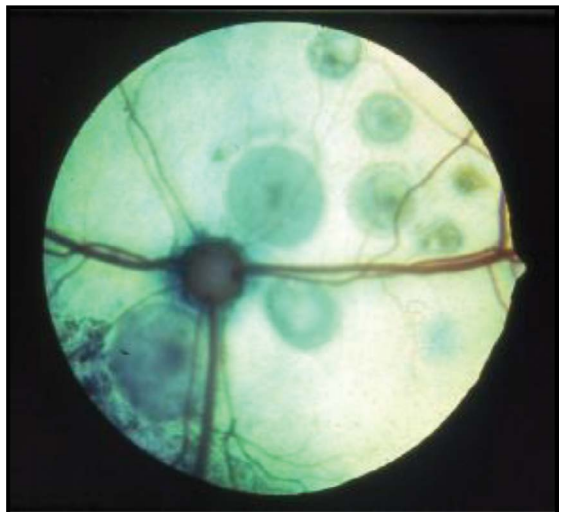

FIGURE 2.7.4 Funduscopic exam of a cat with *Cryptococcus* spp. infection.

FIGURE 2.7.5 Blood culture vials. To maximize culture utility large sample volume is recommended (16–20 mL in large dogs, 5 mL in small dogs and cats), as well as using vials with antibiotic binding beads, and aerobic and anaerobic culture media. Sterile collection is required, ideally at two venous (+/– one arterial) sites.

rectal examinations (Figures 2.7.4 and 2.7.6). A staged diagnostic approach should be implemented in patients with vague clinical signs and no definitive lesion identified (Table 2.7.2 and Figure 2.7.7).

Stage one testing includes the history and physical examination as well as screening laboratory testing. The routine tests should include a serum chemistry panel, CBC with pathologist review, and a complete urinalysis. Screening infectious disease testing such as a 4DX/Accuplex in dogs (heartworm, Lyme, Anaplasma, and Ehrlichia enzyme-linked immunosorbent assay [ELISA] test) and FeLV/FIV testing in cats should also be done. If the physical examination findings indicate a body cavity lesion, such as lung crackles, or long bone pain, radiographs should be included in stage one testing. Occasionally, there is enough diagnostic information from stage one to start treatment as indicated below.

Stage two testing would consist of additional imaging tests and further diagnostic sampling (Table 2.7.2 and Figure 2.7.7). Cytology samples will often have the highest diagnostic yield if a lesion is identified.

Infectious disease testing is a key component to the diagnostic workup. Specific tests should be selected based on the clinician's differential diagnoses, patient signalment, duration of clinical signs, and geographic locale. Bacterial culture and sensitivity testing should be done on urine, specific abnormal tissues, and blood if sepsis is suspected. Blood cultures, if indicated, should be performed early in the diagnostic phase, since it often takes days for results to become available, which can lead to potentially detrimental delays in prescribing the correct antimicrobial treatment (Figure 2.7.5).

Stage three diagnostic testing includes advanced imaging or more invasive tissue sampling techniques. (Table 2.7.2 and Figures 2.7.6 and 2.7.7) These tests include arthrocentesis and echocardiography, even if a lesion is not identified (no apparent murmur, no joint effusion), as disorders in these locations can remain sequestered and asymptomatic early in the disease process.

TREATMENT

Medications used for empiric treatment of the febrile patient often include antibiotics and/or antipyretics. Broad-spectrum antimicrobials are targeted against a multitude of different bacterial agents or more specifically toward vector-borne disease. Doxycycline or azithromycin are often used in cases of the latter etiology. Antipyretics should not be used in the acute phase of disease unless temperatures exceed 106°F (41.1°C). Anti-inflammatory medications will often mask the underlying disease and can compromise the patient. Nonsteroidal anti-inflammatory drugs (NSAIDs) side effects such as GI ulceration, as well as hepatic and renal damage, must be considered when prescribing these medications in debilitated and dehydrated patients. If the patient's body temperature exceeds 106°F (41.1°C), intravenous (IV) fluid therapy should be administered to replace any increased water losses caused by peripheral vasodilatation. NSAID therapy may be considered if the risks of adverse reactions appear to be minimal. External cooling using fans is not recommended, as this will only combat the thermoregulatory mechanisms, causing compensatory shivering to maintain the hypothalamic set point. Depending on the status of the patient, it is often appropriate to forego an empiric medication trial and pursue staged diagnostic testing as noted in order to identify the underlying etiology. Steroids and other immunosuppressive medications are used if an autoimmune disease is diagnosed and/or infectious disease has been deemed highly unlikely. The prognosis for FUO is dependent on the underlying etiology and the ability to implement an early and appropriate treatment plan.

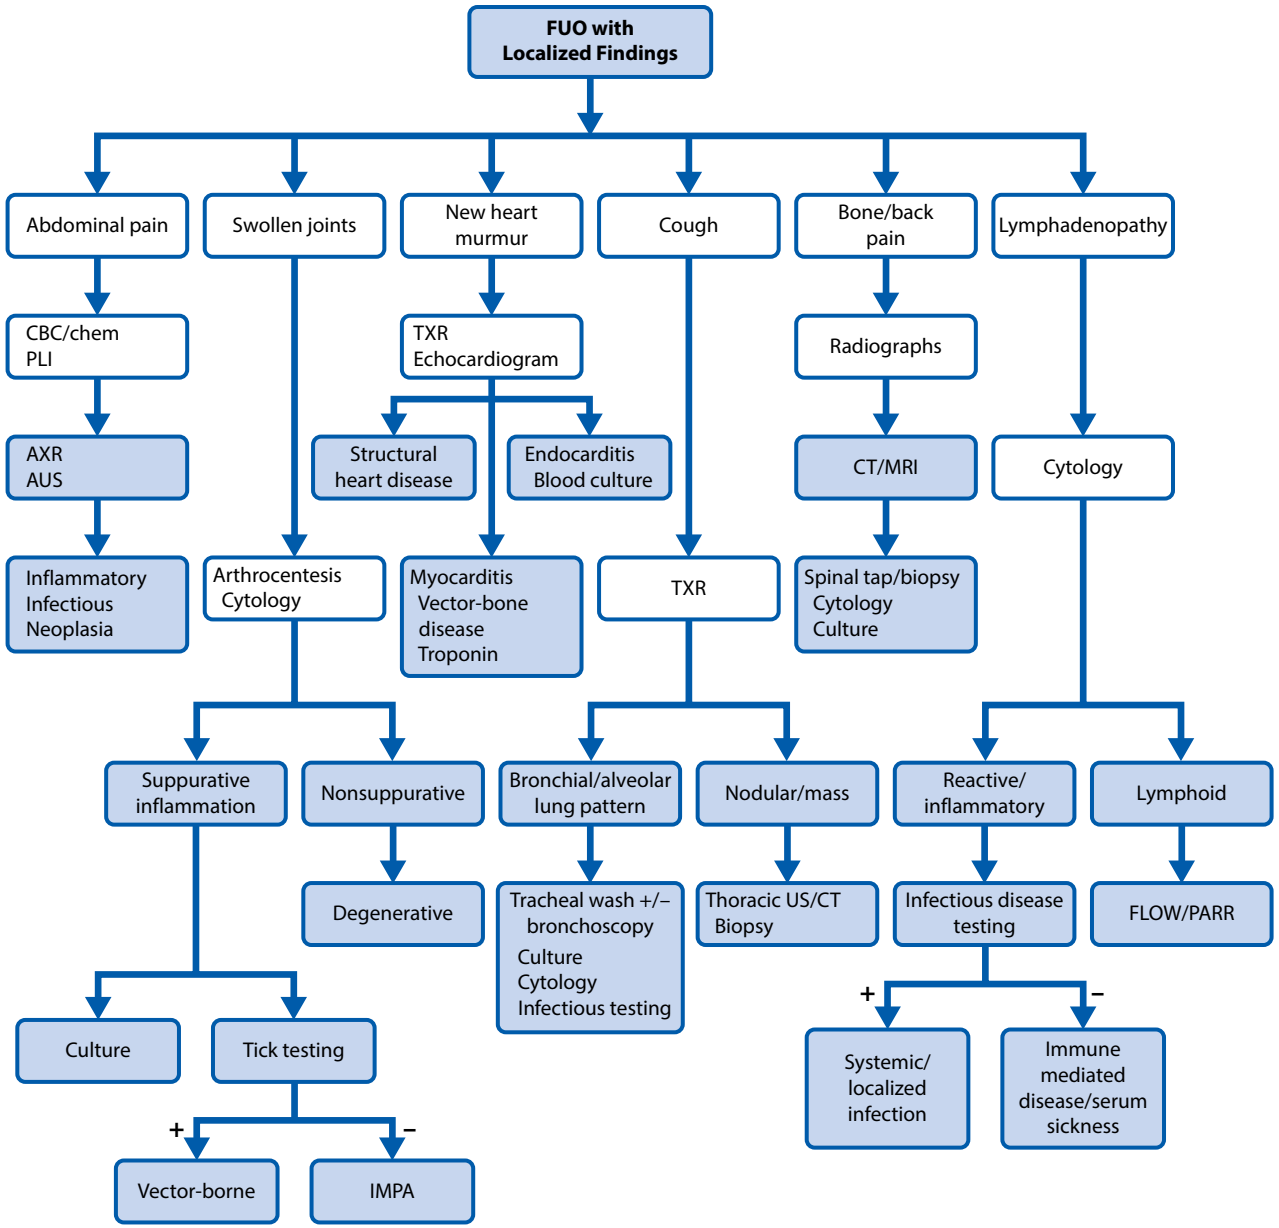

FIGURE 2.7.6 Strategic diagnostic workup for FUO with common localized exam findings. TXR, thoracic radiographs; AUS, abdominal ultrasound; IMPA, immune mediated polyarthritis; PARR, PCR for antigenic receptor rearrangement.

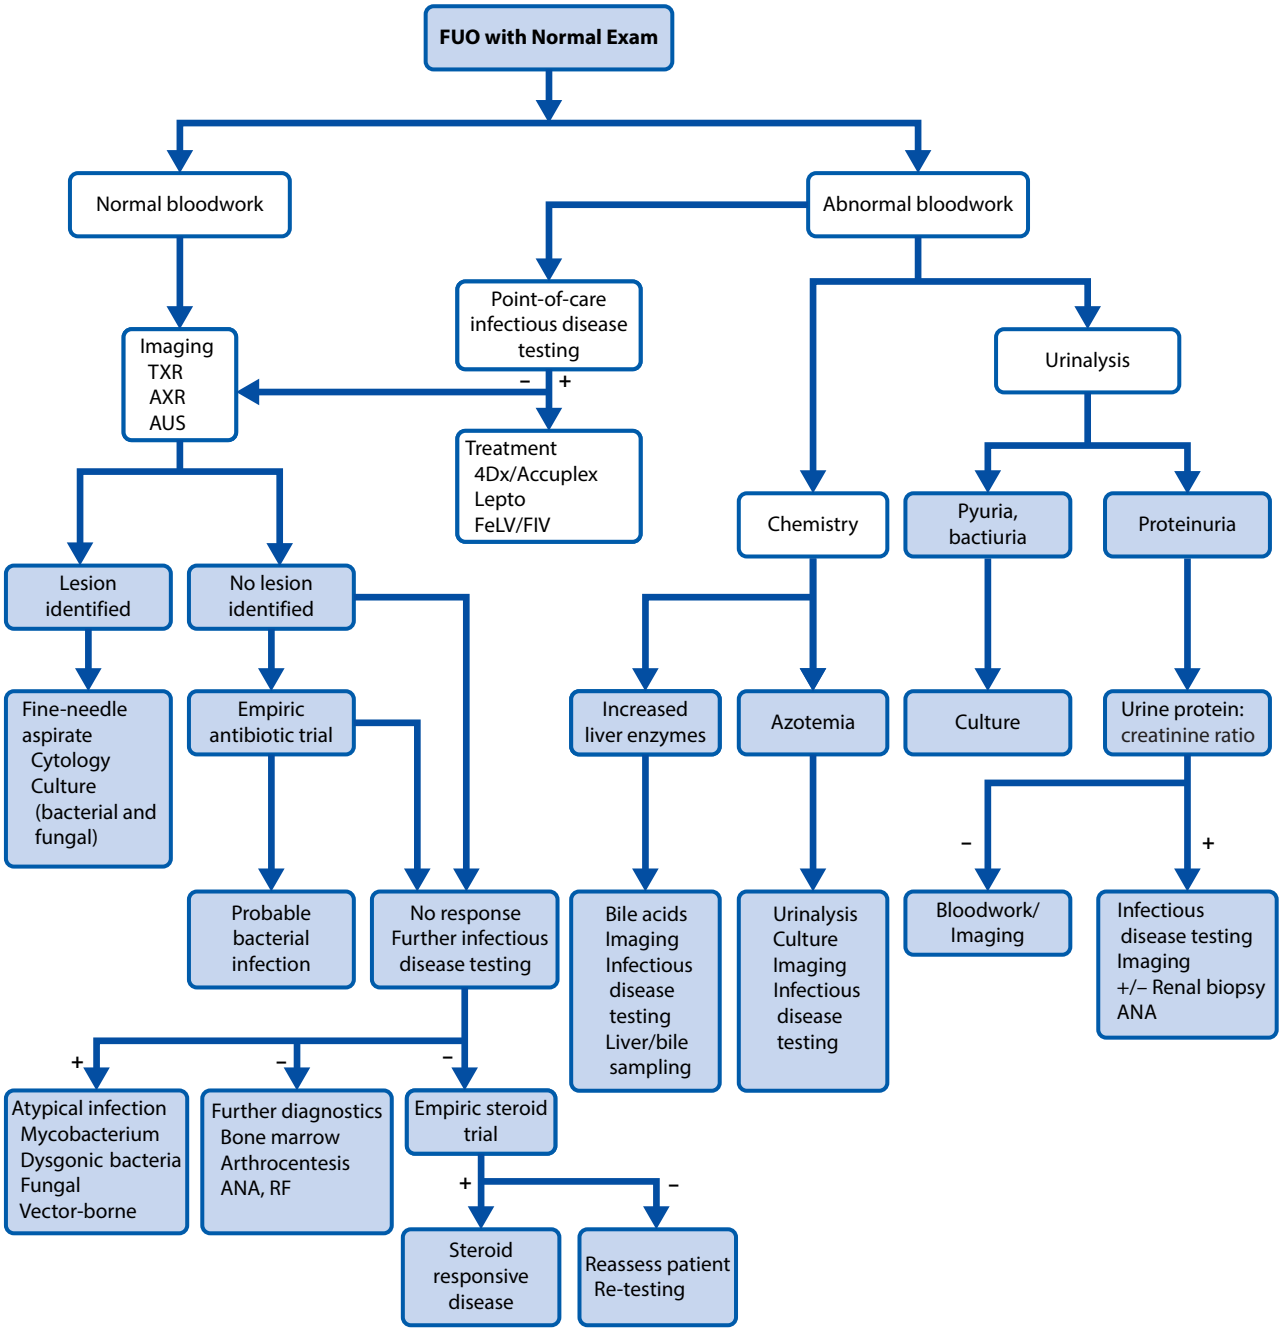

FIGURE 2.7.7 Strategic diagnostic workup for FUO with normal exam findings. TXR, thoracic radiographs; AXR, abdominal radiographs; AUS, abdominal ultrasound; ANA, antinuclear antibody; RF, rheumatoid factor.

CHAPTER 2

Common Clinical Problems
CHAPTER 2.8 Icterus

Julien R.S. Dandrieux

Introduction 48
Etiology 48
Clinical Approach 49
Recommended Further Readings 52

INTRODUCTION

Icterus (or jaundice) is a clinical finding that is characterized by the yellow discoloration of tissues (sclerae, mucous membranes, and skin) and body fluids (plasma and urine) secondary to hyperbilirubinemia and bile pigment deposition. This chapter outlines the diagnostic approach to the icteric animal. The reader is referred to the chapters discussing anemia and liver and biliary diseases for an in-depth discussion of the different diseases or their treatment.

In the normal physiologic state, bilirubin is constantly produced from the degradation of heme (contained principally in hemoglobin but also in other hemoproteins) by phagocytes in the liver, spleen, and bone marrow. Hydrophobic unconjugated bilirubin (UB) is produced and transported in the plasma noncovalently bound to albumin. Bilirubin is processed by the hepatocytes to conjugated bilirubin (CB), a hydrophilic form, which is then excreted through the biliary system into the intestinal lumen (rate-limiting step). CB is further metabolized by intestinal bacteria and is the origin of the normal color of feces (stercobilin). Acholic (pale to white) feces are sometimes seen in animals with lack of CB secretion in the intestine due to complete extrahepatic bile duct obstruction (EBDO).

If CB cannot be excreted into the biliary system, it will backflow in the blood and be excreted in the urine. Renal tubular resorption of bilirubin in dogs is very limited, which explains why bilirubinuria can precede hyperbilirubinemia. Furthermore, dogs (male more than female) have the capacity to process heme in the renal tubules to UB and then CB. For this reason, mild bilirubinuria is often detected in healthy dogs with a urine specific gravity (SG) of 1.025–1.040 (1+) or moderate levels with an SG higher than 1.040 (up to 2+). Cats have a higher capacity for tubular resorption and are not able to process bilirubin in their kidneys. For these reasons, bilirubinuria is always considered pathologic in this species.

Bilirubin can also be covalently bound to albumin (albB, also called delta-bilirubin or biliprotein). This form occurs spontaneously in disease but not in healthy animals. The half-life of albB is the same as albumin (about 8 days in dogs) and can explain persistence of jaundice in some animals after resolution of the cause. It needs to be considered in an animal that is clinically improving despite persistent icterus.

Urobilinogen is a colorless compound formed from the degradation of bilirubin in the intestine and passively absorbed by the small bowel mucosa. The fraction that is not removed from the portal blood by hepatocytes enters the blood and is excreted in the urine. Urobilinogen is detected in the urine with a dip stick reagent but is not commonly tested because of its nonspecific interpretation.

In summary, bilirubin in a healthy animal predominantly consists of UB with negligible concentrations of CB and albB.

ETIOLOGY

Hyperbilirubinemia can occur either when the rate of UB production exceeds the rate of UB uptake in the hepatocytes (hemolysis), when UB is not converted to CB or transported into the biliary tract (hepatic insufficiency), or when CB cannot be excreted through the biliary tract (biliary tract disease). Hence, the main causes for icterus are as follows:

- *Prehepatic icterus:* Increase in red blood cell destruction
- *Hepatic icterus:* Liver insufficiency
- *Posthepatic icterus:* Obstruction at the level of the biliary system (intra- or extrahepatic) or rupture of the biliary tree
- *Others:* Sepsis (cholestasis induced by tumor necrosis factor alpha and endotoxin), resorption of large hematomas (rare)

FIGURE 2.8.1 Icteric sclera in a dog with immune-mediated hemolytic anemia secondary to lymphoma. Note the bright yellow color of the sclera.

TABLE 2.8.1 Interpretation of bilirubinuria and plasma thresholds for detection of icterus

Where	Concentration/Degree of bilirubinuria or bilirubinemia*
Urine	Cat: Any degree is abnormal Dog: Up to 2+ bilirubin with SG >1.040 can be normal; bilirubinuria can precede hyperbilirubinemia
Serum or plasma	>0.9 mg/dL (15 µmol/L)
Sclera	>1.5 mg/dL (25 µmol/L)
Mucous membrane (nonpigmented)	>2.6 mg/dL (45 µmol/L)

* These are not absolute values, and the threshold for visual detection of icterus varies between individuals.

CLINICAL APPROACH

The icteric animal can be identified on physical examination (Figure 2.8.1) or by the color of its plasma or serum. Concentrations at which jaundice becomes visible in different locations are summarized in Table 2.8.1.

The first step after detection of icterus is to inquire about possible toxic or infectious causes with a thorough history, including vaccination status and travel history (common causes are listed in Table 2.8.2).

The second step is to determine whether other abnormalities are present on physical examination. A good body condition score is suggestive of an acute disease (e.g., acute cholangiohepatitis, hemolytic anemia, hepatotoxic insult) whereas a poor body condition score suggests chronic disease (e.g., chronic cholangiohepatitis, neoplastic process, end-stage liver disease). Generalized peripheral lymphadenomegaly is suggestive of infectious disease or lymphoma, and cytologic evaluation can help in reaching a diagnosis. If ascites is present, fluid sampling for analysis should be done. Findings such as septic peritonitis or bile peritonitis (biliary tree rupture) are strong indications for exploratory laparotomy.

TABLE 2.8.2 Common causes of icterus in dogs (D) and cats (C)

Type	Toxin	Infection	Others
Prehepatic → hemolysis	Copper; drugs (acetaminophen/ paracetamol [C, HB]; fenbendazole); onions (HB); zinc (HB)	*Dirofilaria* (caval syndrome [D]); *Cytauxzoon felis* (C)	DIC; erythrocyte congenital defect (e.g., PFK); hypophosphatemia (C>D); neoplasia (e.g., hemangiosarcoma)
Prehepatic → immune-mediated hemolysis	Drugs (cephalosporin, penicillin, potentiated sulfonamides)	*Babesia* (D); *Ehrlichia* (D); FeLV (C); hemotropic *Mycoplasma* spp. (C)	Blood transfusion; idiopathic IMHA (D>C); neoplasia (e.g., lymphoma); inflammation (e.g., pancreatitis, prostatitis)
Hepatic	Aflatoxins; mushrooms (*Amanita* spp.); blue–green algae; copper accumulation; drugs (acetaminophen/ paracetamol [C>D], diazepam [C], ketoconazole, itraconazole, lomustine, methimazole [C], NSAIDs [D], phenobarbital, trimethoprim/sulfonamide); sago palm; xylitol (D)	Virulent calicivirus (C); coronavirus (C); canine adenovirus (D); *Histoplasma capsulatum; Leishmania* (D); *Leptospira* (D); *Toxoplasma* (C>D); Hepatozoon (D); Cytauxzoon (F)	End-stage chronic liver disease; heat stroke; hepatic lipidosis (C); hepatitis/ cholangiohepatitis; neoplasia (carcinoma, lymphoma)
Posthepatic		Liver flukes (C) *Platynosomum* liver fluke (C)	Cholecystitis; cholelithiasis; gallbladder rupture; gallbladder mucocele (D); neoplasia (biliary adenocarcinoma); pancreatitis

DIC, disseminated intravascular coagulation; FeLV, feline leukemia virus; HB, formation of Heinz bodies; IMHA, immune-mediated hemolytic anemia; PFK, phosphofructokinase deficiency.

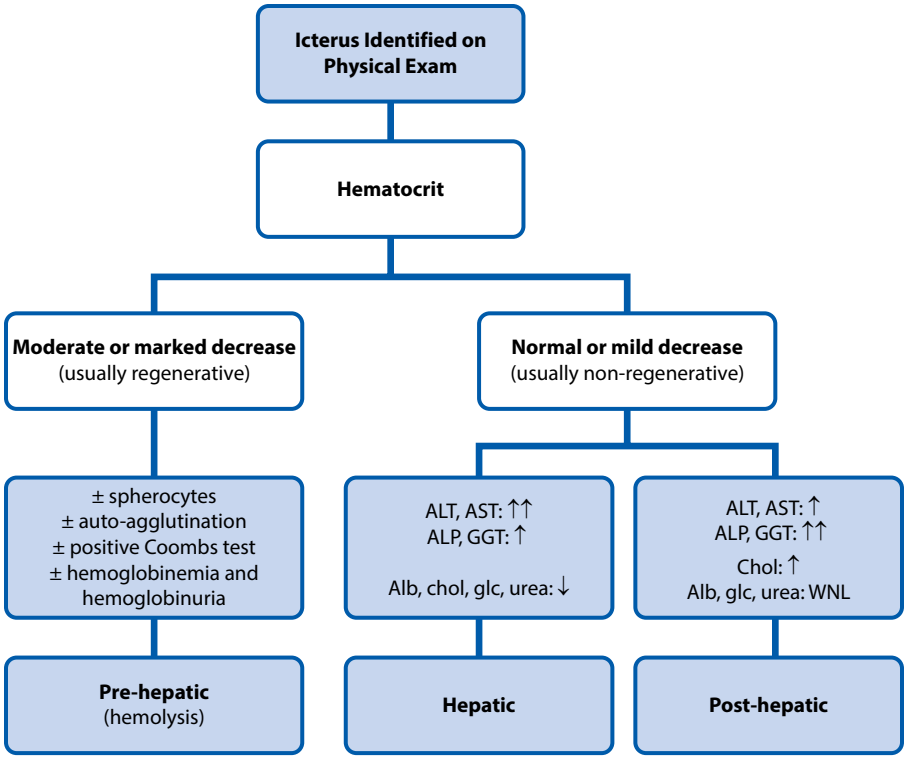

FIGURE 2.8.2 Flow chart showing the findings on laboratory blood work that can help determine the origin of icterus. Alb, albumin; ALP, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; Chol, cholesterol; GGT, gamma-glutamyl transferase; Glc, glucose; WNL, within normal limits; ↑, relative increase; ↓, relative decrease. See text for limitations in the interpretation. Further workup is then needed to determine the disease process.

Splenomegaly and hepatomegaly are common findings with prehepatic icterus secondary to extramedullary hematopoiesis, which can accompany immune-mediated diseases, but it can also be seen with neoplastic or infectious diseases.

Laboratory testing, including hematology, biochemistry, and urinalysis, is the next step to determine the cause of the icterus, and typical findings are outlined in Figure 2.8.2. A packed cell volume is very useful as a first step, as moderate-to-marked anemia is expected with prehepatic icterus and should become regenerative within 3–5 days, whereas anemia is usually mild and non-regenerative with other causes. In an animal with icterus of hepatic origin, hepatocellular enzymes such as alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are expected to be increased to a higher magnitude than biliary epithelium enzymes such as alkaline phosphatase (ALP) and gamma-glutamyl transferase (GGT), whereas the opposite is expected with a posthepatic icterus. Liver functional parameters (albumin, urea, cholesterol, and glucose) might also be decreased with significant loss of liver function. These parameters are expected to be normal with posthepatic obstruction, except for the increased cholesterol (cholestatic disease). Although these changes can help determine the origin of the icterus, they have many limitations. For example, prehepatic icterus often causes hepatic hypoxia with increases in ALT and AST. The serum activity of these two enzymes might normalize in end-stage liver disease because of the decrease in functional tissue. Additionally, hepatocytes will often be affected by processes causing posthepatic icterus over time, resulting in increases in ALT and AST. Therefore, all abnormal test results must be interpreted within the context of the animal and its stage of disease. If liver disease or complete EBDO is suspected, a coagulation profile, including fibrinogen concentration, is recommended prior to taking biopsies, as coagulopathies may develop secondary to these conditions.

If prehepatic icterus is suspected, the next diagnostic step is to determine its origin. Immune-mediated hemolytic anemia (IMHA) is a common cause of hemolysis. Dogs are more prone to primary (idiopathic) IMHA and cats to secondary IMHA from a variety of primary diseases. Imaging and testing for different infectious diseases, depending on the travel history and geographic location of the animal, is indicated.

Imaging modalities, particularly abdominal ultrasound, are very useful for differentiating hepatic from posthepatic icterus (Figures 2.8.3 and 2.8.4). Abdominal ultrasound can help confirm the location of the problem and suggest possible causes such as microhepatica in end-stage liver disease, changes in liver echogenicity or outline with infiltrative disease (Figure 2.8.5), or dilation of the common bile duct with long-standing post-hepatic obstruction (Figure 2.8.4). Abdominal ultrasound is also useful for collecting samples for cytology, histology, and culture, as indicated, to obtain a final diagnosis (Figure 2.8.6), although in some cases, surgical biopsies are

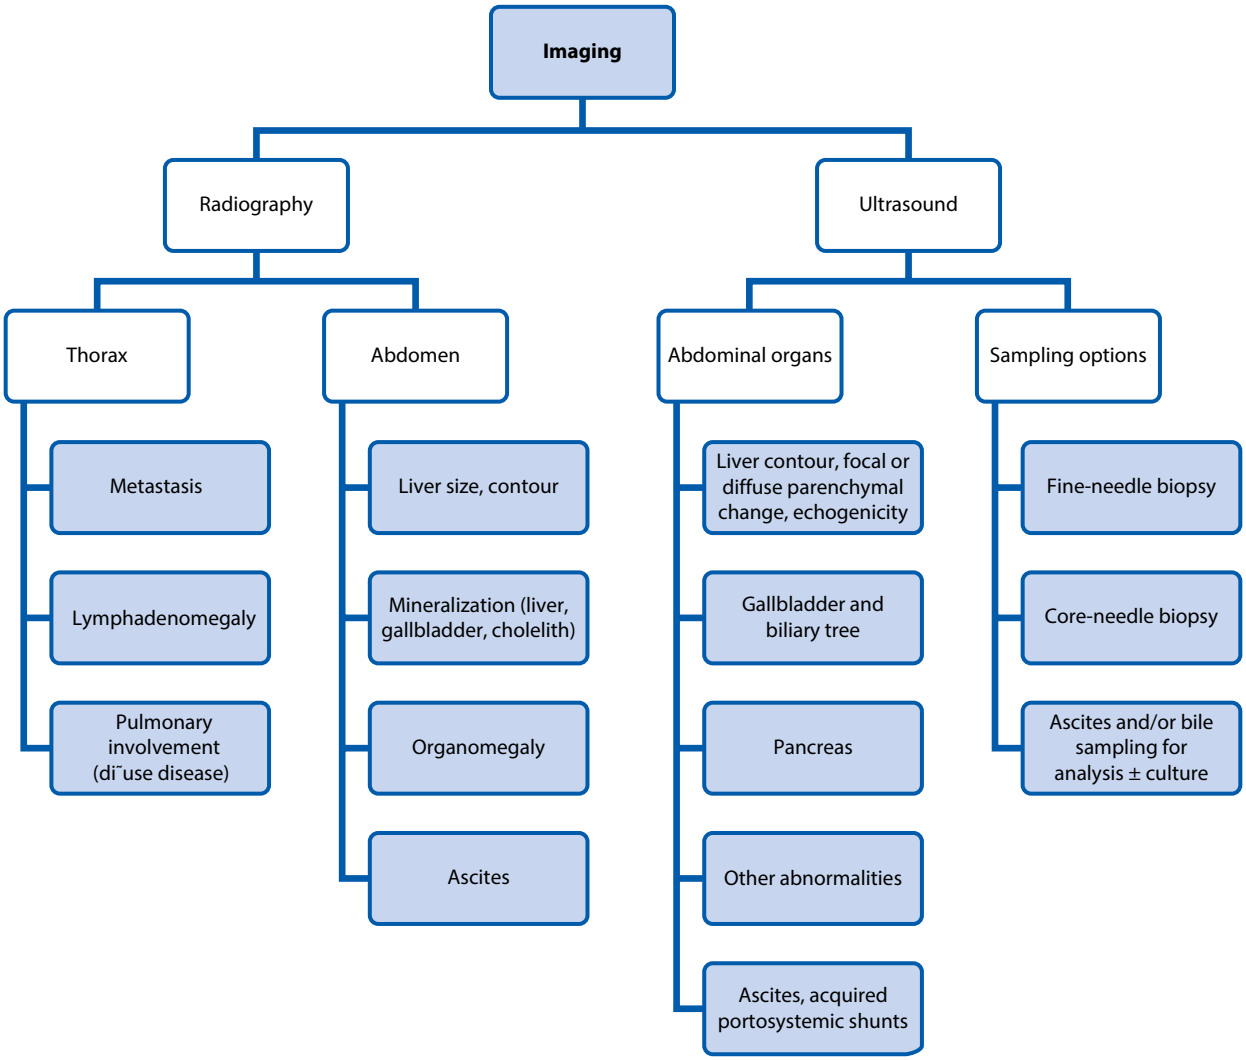

FIGURE 2.8.3 Flowchart showing the imaging modalities for the workup of the icteric patient. Radiographs are an adequate first step to get an overview of the abdominal organs and the chest if a systemic disease is suspected. Ultrasound can be very helpful, but yields are dependent on machine quality and operator. It allows targeted sampling.

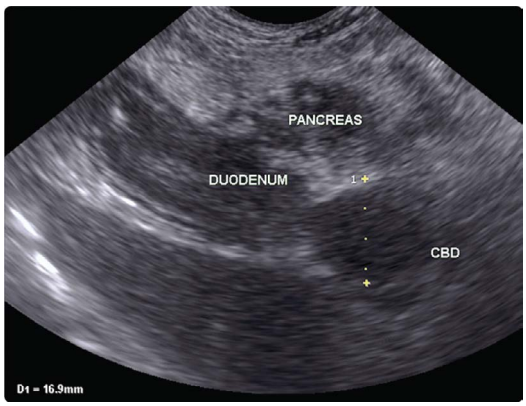

FIGURE 2.8.4 Ultrasound image of the common bile duct in an icteric cat. Anatomically, the duodenum, pancreas, and common bile duct (CBD) are in close contact with each other, as can be appreciated on this ultrasound picture. This explains how a severe pancreatitis can lead to development of icterus. Note in this patient that the CBD is markedly enlarged (16.9 mm; normal is less than 3 mm). (*Courtesy of C. Beck*.)

FIGURE 2.8.5 Ultra sonographic appearance of the liver in a dog presented with icterus. The parenchyma is heterogeneous with hyper- and hypoechoic nodules. Fine-needle aspirates were taken, and the cytology is depicted in **Figure 2.8.6**. (*Courtesy of D. Tyrell*.)

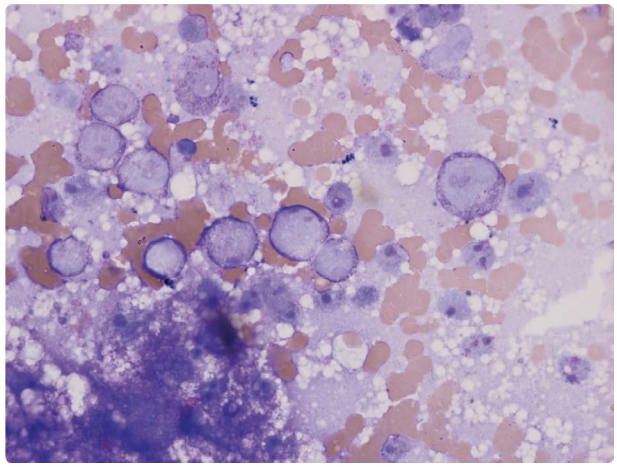

FIGURE 2.8.6 Cytologic slide from a fine-needle liver aspirate in an icteric dog (from the dog in **Figure 2.8.5**). Hepatocytes can be seen in the bottom left corner displaying marked vacuolation. A population of large atypical round cells with round nuclei containing fine chromatin and a thin rim of cytoplasm is also present. These cells are consistent with lymphoma. (*Courtesy of C. Connolly*.)

preferred. If available, other modalities such as CT and MRI may be helpful in complex cases.

If neoplasia is high on the list of differentials, chest radiographs or CT should be considered to screen for metastasis.

CHAPTER 2

Common Clinical Problems

CHAPTER 2.9 Pallor

Elisa M. Mazzaferro

Introduction 53
Etiology/Pathophysiology 53
Clinical Appearance 54
Diagnosis 54
Recommended Further Readings 55

INTRODUCTION

Pallor is defined as an extreme or unnatural paleness of the skin. Pallor can be caused by anemia, peripheral vasoconstriction, hemorrhage, stress, or death. In humans, pallor is most readily observed in the skin and mucous membranes. In animals with fur and pigmented mucous membranes, pallor may be less easily identified. In general, pallor is a subjective visual index of tissue perfusion and oxygen delivery to the skin and mucous membranes, including the conjunctiva.

ETIOLOGY/PATHOPHYSIOLOGY

A clinician's index of suspicion as to the cause of a clinical problem, including pallor, starts with a thorough patient signalment and history. Some of these key questions are found in Table 2.9.1.

Oxygen delivery is a function of cardiac output, peripheral vascular resistance, and arterial oxygen content (Figure 2.9.1). Cardiac output is a function of the heart rate and the stroke volume. The latter involves the cardiac preload (the amount of blood that is delivered to the heart), cardiac afterload (the force against which the heart must contract), and myocardial contractility. Hemorrhage and hypovolemia, including that caused by severe dehydration, in addition to obstructive causes such as pericardial effusion/tamponade and/or gastric dilatation-volvulus (GDV) or large masses within the abdominal cavity, can result in impaired cardiac preload. Hypothermia as well as the release of catecholamines to promote vasoconstriction as an adaptive mechanism to maintain perfusion during states of hypovolemia can increase cardiac afterload. Finally, primary cardiac disease such as dilated cardiomyopathy, end-stage mitral insufficiency, as well as impaired contractility due to circulating inflammatory cytokines with sepsis can all result in impaired myocardial function and decreased cardiac output.

TABLE 2.9.1 Key historical questions for diagnosing pallor

– Could an animal have ingested any toxins, including a vitamin K antagonist rodenticide or zinc-containing objects, including U.S. pennies minted after 1982?
– Is there a potential history of trauma?
– Is there a travel history outside of the patient's normal location?
– Have there been recent vaccinations or medications, including over-the-counter or homeopathic remedies?
– Has there been a change in appetite, vomiting, diarrhea, weight loss, or apparent weight gain? Has there been a change in the color of the feces or the urine?
– Has there been any coughing, hemoptysis, or gingival or other bleeding?
– Do the clients use flea and tick preventatives?

Note: A clinician's index of suspicion as to the cause of a clinical problem, including pallor, starts with a thorough patient signalment and history.

A second important contributor to pallor or lack thereof is red blood cell mass and saturation of hemoglobin. Conditions associated with blood loss, such as hemorrhage, body cavity effusions/bleeding, GI ulceration, and immune-mediated destruction of red blood cells, can result in regenerative anemia. Inadequate erythropoiesis, as observed with end-stage renal disease, or inadequate production at the level of the bone marrow, as observed with myelophthisis or bone marrow aplasia, can also result in inadequate production of red blood cells. Iron deficiency can result in inadequate production of hemoglobin and a microcytic, hypochromic

DOI: 10.1201/9781003254591-11

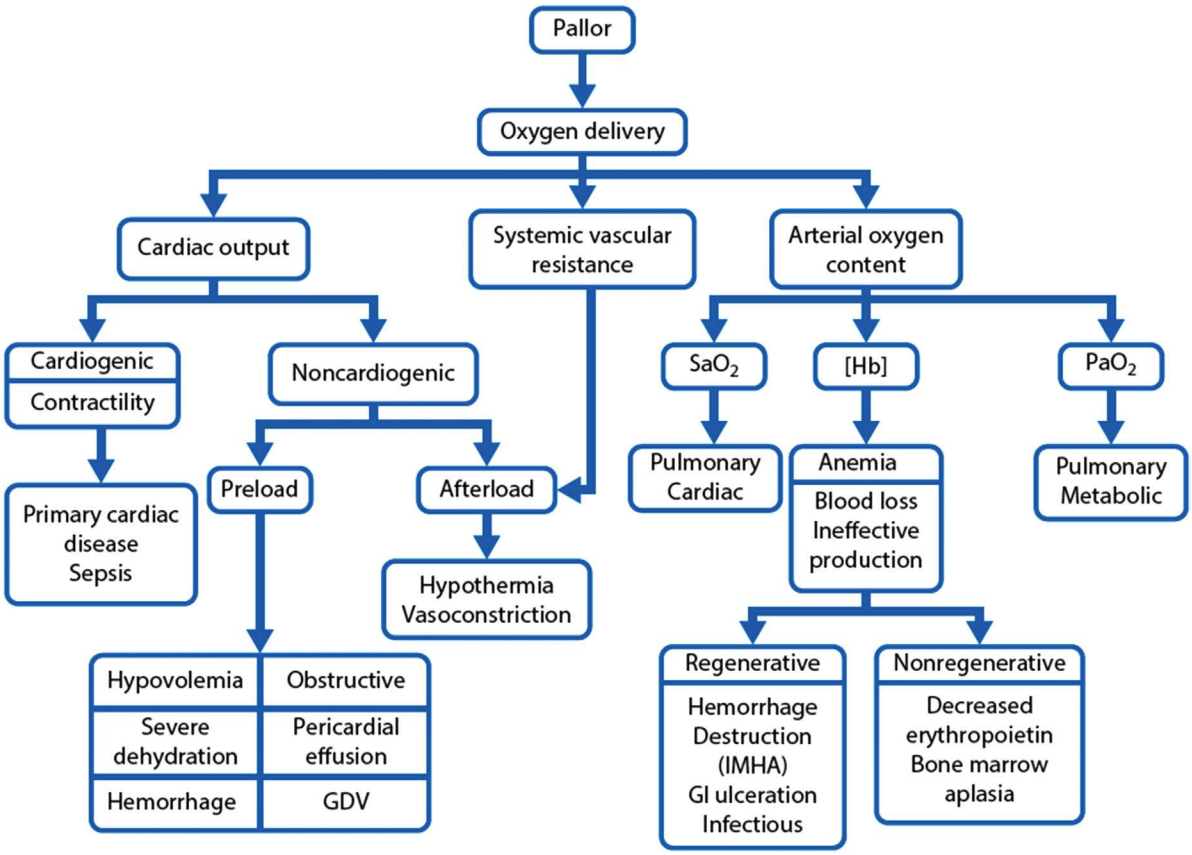

FIGURE 2.9.1 Algorithm for the pathophysiology of pallor.

anemia. Finally, lack of adequate saturation of hemoglobin with oxygen due to primary or secondary pulmonary disease can also result in clinical signs of pallor.

CLINICAL APPEARANCE

Once a thorough history is obtained, the physical examination should be performed, with careful attention paid to perfusion parameters: Heart rate, capillary refill time (CRT), pulse rate, synchrony and quality, body temperature, and peripheral extremity warmth. The CRT normally should be 1–1.5 seconds in a small animal patient. A brisk CRT (<1 second) may be observed with compensatory shock or sepsis, whereas a prolonged CRT (>2 seconds) is observed in decompensatory shock or hypothermia. Extreme tachycardia (>160 beats per minute [bpm] in dogs, >220 bpm in cats) or cardiac dysrhythmias may be observed with compensatory hypovolemic shock, anemia or due to primary cardiac disease or other conditions such as GDV. In addition, extremely low bradyarrhythmias such as that observed with sick sinus syndrome, third-degree AV block, or end-stage decompensatory shock can also result in the clinical signs of pallor. Although perfusion parameters are very different than hydration parameters, marked eye retraction within the globe, dry mucous membranes, and extreme skin turgor are also physical examination signs of severe dehydration, which can result in hypovolemia. Careful attention should be paid to auscultation of the heart and the lungs. Muffled heart sounds may be present with pericardial tamponade, severe hypovolemia, or pleural effusion. The presence of both muffled heart and muffled lung sounds should lead the clinician to consider pleural space disease such as pleural effusion or pneumothorax. Harsh lung sounds may be present with pulmonary contusions, pneumonia, or hemorrhage, for example.

DIAGNOSIS

At the time a physical examination is being performed, the patient's blood pressure should be measured and ECG performed to rule out systemic hypo- or hypertension and cardiac dysrhythmias (Table 2.9.2). Pulse oximetry should be considered to determine whether the patient is hypoxemic. Initial diagnostic blood work should include a packed cell volume (PCV) and total solids (TS), as well as a complete blood count (CBC). If a patient is anemic (low PCV) with a concomitant low TS, a source of whole blood loss should be considered. If, however, the PCV is low with a normal TS, destruction of red blood cells or lack of production should be considered. That is where the CBC with a reticulocyte count is important to determine if the anemia is regenerative or non-regenerative. If an automated CBC is not possible, performing a saline agglutination test and a

TABLE 2.9.2 Differential diagnosis for pallor

Anemia
Regenerative
- Blood loss
  - Hemorrhage
    - Trauma
    - Neoplasia
    - Toxin (vitamin K antagonist rodenticide)
  - GI ulceration
  - Body cavity effusion
  - Destruction
    - Immune mediated
    - Infectious
    - Toxin (zinc, *Allium* spp.)

Non-regenerative
- Decreased erythropoietin – renal disease
- Bone marrow aplasia
- Anemia of chronic disease

Decreased oxygen delivery
Decreased cardiac output
- Decreased preload
  - Hemorrhage/hypovolemia
  - Abdominal mass/effusion/GDV
  - Pericardial mass or effusion/tamponade
  - Pleural effusion
  - Pneumothorax/tension pneumothorax
- Increased afterload
  - Peripheral vasoconstriction
    - Compensatory from cardiogenic or hypovolemic shock
    - Increased catecholamines (pheochromocytoma)
    - Hypothermia

Depressed myocardial contractility
- Primary cardiac disease
  - Dilated cardiomyopathy
  - End-stage mitral insufficiency
  - HCM/HCOM/RCM/unclassified
- Secondary to circulating myocardial depressant cytokines
  - Sepsis
  - Systemic inflammatory response

Decreased saturated hemoglobin
Pulmonary disease
- Pulmonary hemorrhage
- Pulmonary contusions/trauma
- Pulmonary edema
- Pneumonia
- Neoplasia
- Pulmonary hypertension

Pleural space disease
- Pleural effusion
- Pneumothorax

Metabolic/toxic
- Methemoglobinemia

GDV, gastric dilatation volvulus; HCM, hypertrophic cardiomyopathy; HOCM, hypertrophic obstructive cardiomyopathy; RCM, restrictive cardiomyopathy.

peripheral blood smear to evaluate for the presence of spherocytes, red blood cell parasites, anisocytosis, red blood cell pallor, and thrombocytopenia can be useful in an emergency situation. Tests of coagulation, particularly the prothrombin time, can be useful as a screening test for vitamin K antagonist rodenticide intoxication. A simple whole blood clotting time can be used when other coagulation tests cannot be run where the failure of blood to clot in a serum tube after 10 minutes is strongly suspicious. Thoracic and abdominal radiographs may be useful to investigate for dilated cardiomyopathy, pericardial effusion, pulmonary parenchymal disease, pneumothorax, pleural effusion, abdominal effusion and masses, metallic foreign material, GDV, or peritoneal effusion. Finally, a focused assessment using sonography of the abdomen and thorax may prove to be useful in scanning for pericardial, pleural, or peritoneal effusions or pneumothorax.

CHAPTER 2

Common Clinical Problems

CHAPTER 2.10 Peripheral Edema

Stuart Walton

Diagnostic Approach 56
Treatment 59
Recommended Further Readings 59

Peripheral edema is a pathologic expansion of interstitial fluid volume in tissue resulting from either increased net filtration of fluid from the vascular space or impaired return of fluid by lymphatics. Peripheral edema can affect any part of the body and is characterized as either generalized, regional, or local. Moderate-to-severe increases (≈30%) in interstitial fluid volume are evident on visual examination as a result of the physical changes in the tissue.

Under normal circumstances, interstitial fluid volume is kept within tight boundaries so that peripheral edema does not result. Typically, there is a dynamic flow of fluid (water and small solute molecules) from the intravascular space in the capillaries and venules to the interstitial space bathing cell. This is described according to the revised Starling's forces equation.

$$J_v = L_p S\left[\left(P_c - P_i\right) - O'\left(\pi_{esl} - \pi_b\right)\right]$$

J_v is the net fluid movement from the intravascular space to interstitial space
L_P is the hydraulic permeability coefficient
S is the surface area
P_c and P_i are the capillary hydrostatic and interstitial hydrostatic pressures, respectively
O' is the reflection coefficient for protein
π_{esl} and π_b are the oncotic pressure in the endothelial glycocalyx layer and the subglycocalyx, respectively

This net fluid movement is important not only for cellular nutrition but also for the removal of metabolic waste products. Factors that control interstitial fluid flow include hydrostatic pressure, oncotic pressure, endothelial integrity, and the lymphatic system. Under normal circumstances, the net hydrostatic pressure difference is greater than the net colloid osmotic pressure difference, favoring filtration of fluid from the intravascular to interstitial space. Excess plasma filtrate within the interstitium is then removed via the lymphatic system and returned to the systemic venous circulation via the cranial thoracic duct.

Several safety factors help to regulate interstitial fluid volume and resist the tendency of fluid to accumulate in the interstitium. These include:

a. Reduced tissue compliance, which limits the volume of fluid that can accumulate (i.e., increased interstitial fluid pressure from reduced tissue compliance opposes/limits further filtration).
b. Automatic readjustment of a similar magnitude of interstitial oncotic pressure in response to either increases in capillary filtration or interstitial hydrostatic pressure.
c. Increased lymphatic flow due to increased interstitial volume and pressure.

Excessive accumulation of interstitial fluid is detrimental to tissue function due to compromised cellular metabolism, both in the effective delivery and removal of oxygen/nutrients and toxic cellular metabolism by-products, respectively. This simultaneous reduction of plasma volume and increase of extracellular fluid space results from:

1. Increased capillary hydrostatic pressure, from either increased arteriole or venous pressures, or by a decreased arteriolar resistance.
2. Decreased plasma or increased interstitial oncotic pressure.
3. Depressed endothelial lymphatic function.

DIAGNOSTIC APPROACH

The diagnostic approach to peripheral edema is provided in Figure 2.10.1. The common challenge and frustration for clinicians is to determine the underlying cause (Table 2.10.1) and find an effective treatment for peripheral edema when an underlying cause remains

DOI: 10.1201/9781003254591-12

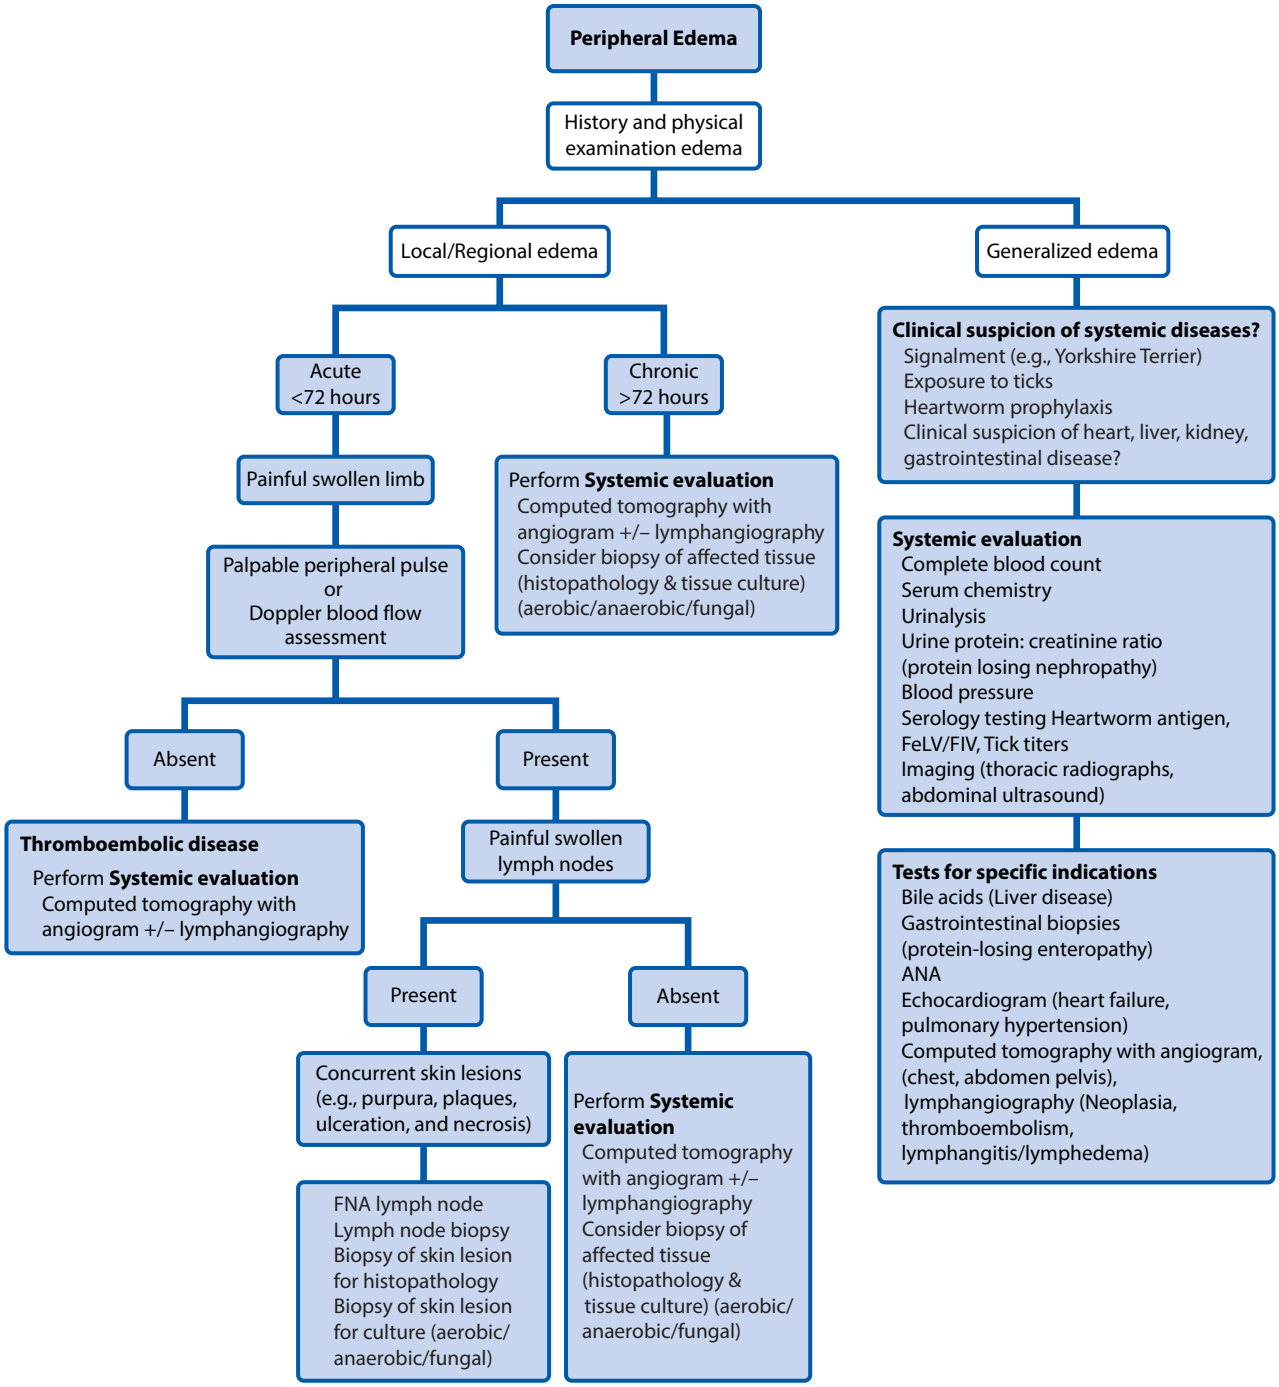

FIGURE 2.10.1 The clinical approach to assessing edema.

elusive despite extensive investigation. A complete history and thorough physical examination may aid in determining the cause of edema. Signalment may help clinicians to prioritize differentials and diagnostic testing (e.g., Yorkshire Terrier and protein-losing enteropathy [PLE], Abyssinian cat with renal amyloidosis).
Owners should be questioned regarding:

1. Chronicity and duration of the clinical signs (i.e., acute versus chronic, localized versus generalized, static versus progressive disease)
2. Does the patient seem painful (i.e., non-weight-bearing lameness, pain when touching the affected limb)?
3. Is there any improvement of the peripheral edema throughout the day?
4. Recent vaccination history
5. Environment (outdoor only, indoor only, indoor/outdoor)
6. Exposure to ticks
7. Heartworm prophylaxis
8. Travel history
9. Current medications (patient and owner)

10. Recent trauma
11. Any currently treated illnesses
12. Additional clinical signs (e.g., vomiting, diarrhea, weight loss, abdominal distension, increased water consumption, or urination)

It is also important to define the type of edema (i.e., local versus generalized). In general, localized edema is confined to a single limb and is due to vascular obstruction (i.e., thrombosis), infection, inflammation, or neoplasia. Generalized peripheral edema may be due to a local cause or systemic disease such as protein-losing enteropathies or nephropathies, among others (Figure 2.10.2).

The affected limb(s) should be palpated for warmth and peripheral pulses. Assessment for pain in the affected limb is important as pain may be consistent with vascular obstruction, inflammation, or infection. Lymphedema is rarely associated with pain. Peripheral regional lymph nodes should be examined for size, consistency, lobulation, adhesions, response to palpation/manipulation, and temperature of overlying skin. Fever, warm swelling, and enlarged, painful lymph nodes may be associated with inflammatory, infectious, or neoplastic etiologies. It is important that the infected limb(s) initially be inspected for concurrent skin lesions (e.g., purpura, plaques, ulceration, and necrosis of affected skin).

Care should be taken by clinicians to not only focus on the affected limb(s), as patients presenting with peripheral edema may have concurrent systemic clinical signs unrelated to peripheral edema. Attention should be paid to auscultation, palpation, and ballottement, looking for new murmurs, pulse character changes, and fluid waves, respectively.

The category of edema (i.e., localized versus generalized) and other pertinent findings discovered on physical examination will determine the next diagnostic steps. Local or regional peripheral edema is most commonly associated with one of the following three mechanisms of formation:

1. Disease of local lymph nodes/lymphatics resulting in poor lymphatic drainage
2. Infection/inflammation of the local tissues
3. Obstruction of local venous drainage

Diagnostics selected should include, but not be limited to, Doppler assessment of the affected limb(s) for blood

TABLE 2.10.1 Causes of peripheral edema

Increased capillary hydrostatic pressure
– Functional or structural obstruction to blood flow
– Congestive heart failure
– Venous obstruction (e.g., thrombosis)
– Compression of a vessel by a mass lesion
– Arteriovenous fistula
Decreased colloid oncotic pressure (hypoalbuminemia)
– Protein-losing enteropathies
– Protein-losing nephropathies
– Decreased hepatic synthesis
– Decreased dietary intake (e.g., malnutrition)
– Chronic hemorrhage
– Exudative lesion with large surface (e.g., burns, peritonitis)
Permeability changes
– Chronic inflammatory disease
– Infectious disease (Figure 2.10.2)
– Rickettsial (e.g., Rocky Mountain spotted fever and ehrlichiosis)
– Bacterial (e.g., bacterial endocarditis, septicemia, mycobacterial disseminated vasotropic)
– Viral (e.g., feline infectious peritonitis, canine coronavirus, and canine circovirus, herpesvirus, feline immunodeficiency virus, feline leukemia virus)
– Fungal (opportunistic)
– Parasitic (e.g., *Dirofilaria immitis*, *Angiostrongylus vasorum*, *Leishmania* spp., *Babesia gibsoni*, trypanosomiasis)
– Protozoan (e.g., Toxoplasma)
– Noninfectious (e.g., drugs, food additives, endogenous antigen, neoplasia, idiopathic)
– Vascular trauma (mechanical versus chemical injury)
– Vasculitis (infectious, iatrogenic, idiopathic)
Decreased lymphatic drainage (lymphedema)
– Primary lymphedema (autosomal dominant) – Bulldogs, poodles, whippets
– Secondary lymphedema
– Infectious (e.g., *Brugia pahangi*, lymphatic filarial infection, Southeast Asia)
– Granulomatous disease
– Neoplastic (e.g., lymphoma, lymphangiosarcoma)
– Traumatic injury (e.g., radiation therapy, thoracic duct ligation)
– Compression of lymphatics
Increased interstitial gel matrix
– Myxedema coma (hypothyroidism) – rare

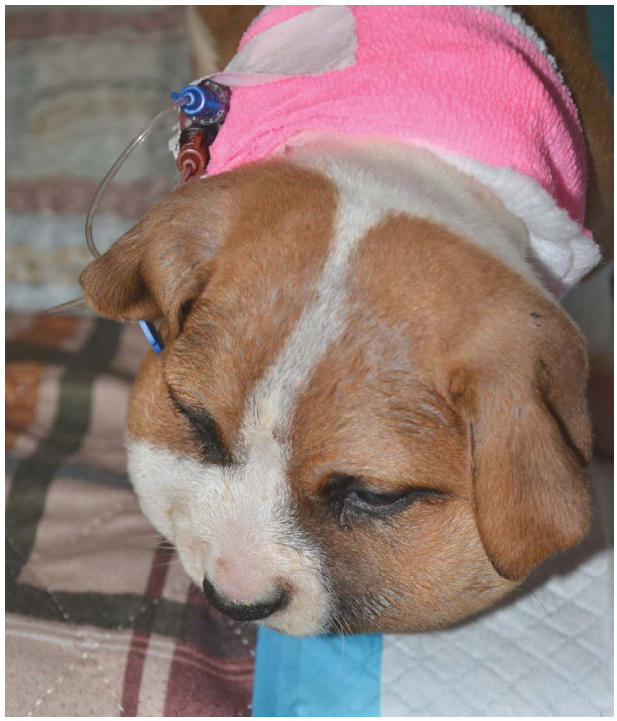

FIGURE 2.10.2 A 4-month-old female Terrier presenting with parvovirus enteritis. During hospitalization, the patient developed significant hypoalbuminemia, hypotension, and both forelimb and facial edema. (*Courtesy of M. Schaer.*)

flow; B-mode ultrasonography to assess venous patency, character, and blood flow; advanced imaging (plain radiographs, computed tomography with angiogram, lymphangiography) as well as biopsy of affected tissue with subsequent histopathology and aerobic/anaerobic bacterial/fungal cultures.

Generalized edema results from the simultaneous reduction of plasma volume with an increase of the extracellular fluid space from either reduced oncotic pressure, increased hydrostatic pressure, or changes in vessel permeability. A reduction in plasma volume results in decreased renal excretion of sodium, presumably by hormonal mechanisms. Sodium retention may further promote extracellular fluid accumulation and can exacerbate edema formation. Reduced oncotic pressure due primarily to hypoproteinemia and hypoalbuminemia usually does not become evident until the serum albumin concentration falls below 1.5 g/dL.

The diagnostic investigation should begin with routine clinical pathology (complete blood count, serum biochemistry, urinalysis, and urine protein-to-creatinine ratio), serology (e.g., heartworm antigen, retroviral testing [FeLV, FIV]), and evaluation of systolic blood pressure. Advanced imaging (thoracic/abdominal radiographs and/or abdominal ultrasound) can be performed to assess thoracic and abdominal organs, including the heart, gastric and intestinal wall, kidneys, and liver, and assess for any masses. Serology should be performed if there are concurrent clinical signs suggestive of viral or rickettsial-induced vasculitis. Specialized laboratory tests (e.g., bile acids, antinuclear antibody [ANA] titer) may be considered based on the information obtained from initial diagnostics in order to identify the primary problem. Contrast radiography with concurrent angiograms or lymphangiograms are indicated to confirm an obstructive lesion or the presence of an arteriovenous fistula.

If sepsis is suspected, then tissue, blood, and urine cultures should be performed. For patients with ulcerative skin lesions, skin biopsies from the active edges of developing lesions should be performed to confirm vasculitis. It is important to recognize that these may not reveal an underlying cause.

TREATMENT

Therapy should be based upon the identification of the underlying cause and mechanism(s) for edema formation. Patients with moderate to severe clinical signs due to reduced plasma oncotic pressure and hypoalbuminemia may require a plasma transfusion and either enteral/parenteral nutrition to prevent further edema formation while treating the primary disease. Additional therapies should be directed toward maximizing patient comfort (e.g., soft/cushioned bedding) while attempting to restore homeostasis.

CHAPTER 2

Common Clinical Problems

CHAPTER 2.11 Pigmenturia

Leonel Londoño and Michael Schaer

Introduction 60
Hemoglobinuria 60
Myoglobin 61
Bilirubinuria 62
Exogenous Causes of Pigmenturia 62
Clinical Approach to Pigmenturia 63
Recommended Further Readings 64

INTRODUCTION

Pigmenturia is a pathological condition that describes the accumulation of an endogenous or exogenous substance that imparts a different color to the urine. Under normal circumstances, the color of the urine ranges from clear, pale yellow to dark yellow or amber depending on the concentration of two pigments: Urochrome (a sulfur-containing substance) and urobilin (an oxidation product of urobilinogen). Concentrated urine (high specific gravity) may appear darker yellow or amber, and diluted urine (low specific gravity) may appear more clear or pale yellow, but there is no direct relationship between urine specific gravity and color. In small animals, hematuria is a common finding associated with red discoloration of the urine (Figure 2.11.1). Hematuria is not associated with an accumulation of a specific pigment or molecule, but once the concentration of red blood cells in the urine sediment reaches >50 RBCs per high-power field (hpf), then red discoloration of the urine can be observed. The three main endogenous causes of discolored urine secondary to pigment accumulation besides macroscopic hematuria are described in Table 2.11.1.

FIGURE 2.11.1 Severe hematuria in a 4-year-old spayed female dog secondary to immune-mediated thrombocytopenia, leading to urinary tract hemorrhage.

HEMOGLOBINURIA

Intravascular hemolysis is the most common cause of hemoglobinuria in small animals. Accumulation of heme protein can cause oxidative stress and systemic signs of toxicity. Three main mechanisms protect the body from the pathologic or nonpathologic accumulation of heme protein in circulation: Binding by haptoglobins and degradation by the reticuloendothelial system, oxidation of ferrous heme to ferric heme, and oxidation of hemoglobin to soluble methemoglobin by nitrous oxide. Once these mechanisms are saturated with severe hemolysis, hemoglobinuria and its pathological consequences are observed. One of the clinical consequences of hemoglobinuria is pigment-induced acute kidney injury (AKI). Although rarely reported in dogs or cats, it is known to cause significant tubulotoxicity. The exact mechanism of hemoglobin-induced AKI

DOI: 10.1201/9781003254591-13

TABLE 2.11.1 Classification, clinical description, and most common differentials of endogenous and exogenous causes of pigmenturia

	Hematuria	Hemoglobinuria	Myoglobinuria	Bilirubinuria
Pigment name	N/A	Hemoglobin	Myoglobin	Bilirubin/urobilin
Urine gross color	Red, blood tinged	Pink to dark red	Brown (tea-colored) to port-wine color	Orange
Supernatant urine color	Clear	Pink to dark red	Reddish brown	Orange
Pathophysiology	Upper (kidneys, ureter) or lower urinary tract (bladder, urethra) hemorrhage; vaginal or preputial hemorrhage	Red blood cell lysis, most likely intravascular, allowing for the release of heme protein	Trauma, necrosis, or muscle exertion leads to leakage of striated muscle cell contents, including myoglobin	Any prehepatic, hepatic, or posthepatic causes of hyperbilirubinemia
Differential diagnoses	– Primary or secondary coagulopathies – Neoplasia (TCC, renal carcinoma) – Renal cysts – Urolithiasis – Urinary tract infections – Feline lower urinary tract disease (FLUTD) – Abdominal/pelvic trauma – Preputial/vaginal trauma, foreign bodies or neoplasia – Drugs (cyclophosphamide)	– Immune-mediated hemolytic anemia (IMHA) – Infectious causes in dogs (*Babesia* spp.) and cats (*Mycoplasma haemofelis*, *Cytauxzoon felis*) – Coral snake envenomation – Dirofilariasis – Drug reactions – Blood transfusion reactions – Neonatal isoerythrolysis	– Severe trauma – Seizures, tremors – Strenuous exercise (working dogs) – Heat stroke – Pyomyositis (*Streptococcus* spp., *Staphylococcus* spp., *Clostridium* spp.) – Pitviper envenomation – Sepsis – Hereditary myopathies – Severe hypokalemic rhabdomyolysis	– See Chapter 2.8, Icterus

FLUTD, feline lower urinary tract disease; IMHA, immune-mediated hemolytic anemia; TCC, transitional cell carcinoma.

is unknown, but heme proteins may cause direct cytotoxicity to the tubular epithelium and lead to formation of intratubular casts. Evaluation of urine sediment reveals lack or low numbers of red blood cells, and after centrifugation of a urine sample in a hematocrit tube, the supernatant color is pink to dark red depending on the severity of hemoglobinuria (Figure 2.11.2).

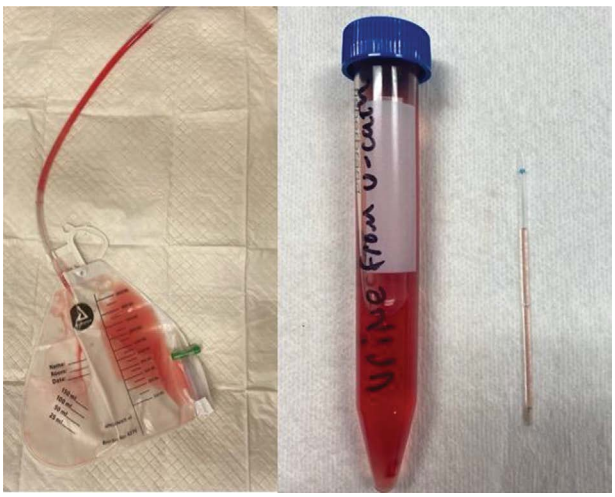

FIGURE 2.11.2 Hemoglobinuria in a 2-year-old male dog with caval syndrome secondary to dirofilariasis and evidence of hemolysis and hemoglobinuria. Note the pink-colored supernatant in the capillary tube representing hemoglobin in the plasma.

MYOGLOBIN

Rhabdomyolysis is a main cause of myoglobinuria and refers to the disintegration of striated muscle, resulting in the accumulation of muscle protein (myoglobin) in circulation. Trauma and crushing injuries are the most common cause of rhabdomyolysis in small animals. Other pathologies that cause depletion of adenosine triphosphate (ATP) and impaired function of ATP-dependent calcium pumps lead to accumulation of sarcoplasmic calcium and activation of proteases and lipases that ultimately disintegrate the myocyte. Pathologic accumulation of myoglobin leads to dark brown to port-wine discoloration of the urine (Figure 2.11.3a, b). Evaluation of urine sediment reveals lack of red blood cells, and after centrifugation of a urine sample in a hematocrit tube, the supernatant color is brown or dark red depending on the severity of myoglobinuria. To differentiate between hemoglobinuria and myoglobinuria, a venous sample is centrifuged in a hematocrit tube, and in cases of hemoglobinuria, plasma color is pink to dark red consistent with intravascular hemolysis, while in cases of myoglobinuria, the plasma color is clear. Similar to hemoglobin-induced AKI, myoglobin can also cause pigment-induced nephropathy secondary to intrarenal vasoconstriction, direct toxicity to proximal epithelial tubular cells, and formation of intratubular casts that obstruct the distal tubular lumen. Once myoglobin is filtered into the renal tubules, it

FIGURE 2.11.3 Myoglobinuria in a 7-year-old spayed female dog with severe bite-wound trauma to all four limbs and extensive crushing injuries. This dog developed AKI with oliguria (urine output 0.6 mL/kg per hour) and serum creatinine of 3.5 mg/dL. Note in the hematocrit tubes filled with **(a)** urine and **(b)** whole blood after centrifugation, the urine remains with dark red supernatant while the plasma color is clear.

precipitates with the Tamm–Horsfall protein, a process that is facilitated by acidic urine.

BILIRUBINURIA

The pathophysiology and causes of icterus are further described in Chapter 2.8. Bilirubin accumulation in the urine is in the form of conjugated bilirubin, while unconjugated bilirubin is bound to plasma proteins in systemic circulation. Canine renal epithelial cells can convert hemoglobin to conjugated bilirubin while the feline renal cells cannot perform this conversion. Dogs have a low renal threshold for clearance of bilirubin. Mild bilirubinuria (1–2+) is not always associated with pathology in this species. Bilirubin causes a neon yellow to orange discoloration of the urine (**Figure 2.11.4**). Bile cast nephropathy has been linked to the pathophysiology of hepatorenal syndrome in people with severe jaundice, but this has not been described in small animals.

EXOGENOUS CAUSES OF PIGMENTURIA

Other causes of pigmenturia in small animals, although rare, may be secondary to administration of medications or accidental ingestion of toxins or certain foods that can lead to discolored urine. Various drugs that can cause pigmenturia in humans are listed in **Table 2.11.2**. An example of drug-associated pigmenturia is shown in **Figure 2.11.5a, b**, which depict methylene blue-induced discoloration of the oral mucosa and blue-green pigmenturia in a cat.

TABLE 2.11.2 Some drugs that can cause pigmenturia in humans, dogs, and cats

Drug	Urine color
Deferoxamine	Red
Rifampin	Red
Hydroxycobalamine	Red
Methylene blue	Blue, green

FIGURE 2.11.4 Bilirubinuria in a 10-year-old spayed female Domestic Shorthair cat with severe hepatic lipidosis (total bilirubin 11.5 mg/dL) and marked bilirubinuria.

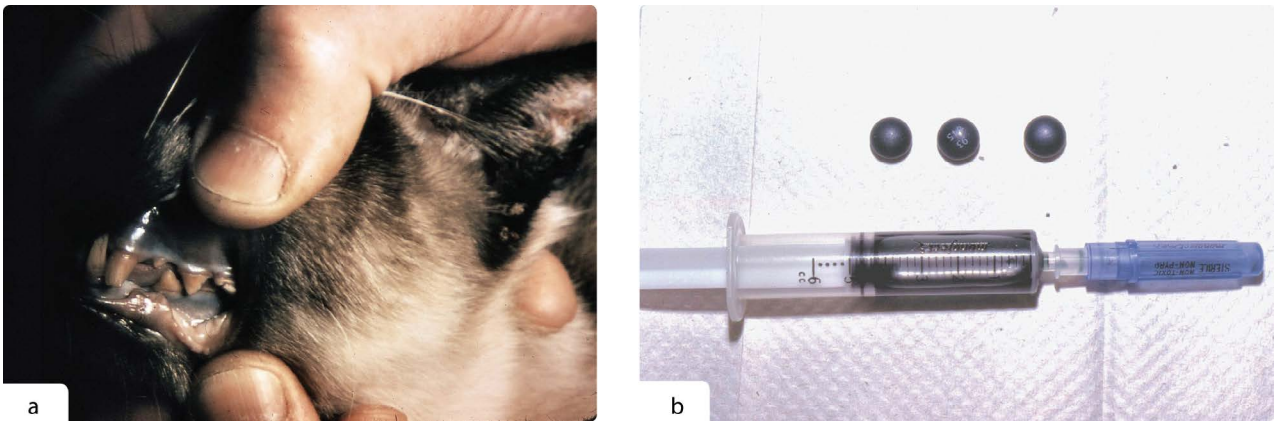

FIGURE 2.11.5 This cat's oral mucous membranes were discolored from the methylene blue contained in its medication for urinary tract disease **(a)**. The cat's urine sample was a blue-green color **(b)**. This product is no longer used in cats because of the associated Heinz body hemolytic anemia that it can cause.

CLINICAL APPROACH TO PIGMENTURIA

Identification of discolored urine should alert the clinician to identify the possible underlying cause of hematuria or pigmenturia. The algorithm in Figure 2.11.6 shows the differential features of pigmenturia. Although AKI in the dog and cat is a rare complication identified with pathological pigment accumulation in the urine, the recognition of AKI is limited to functional markers of renal function (creatinine, symmetric dimethylarginine [SDMA], urine output), which have major limitations in the ability to detect cellular injury and

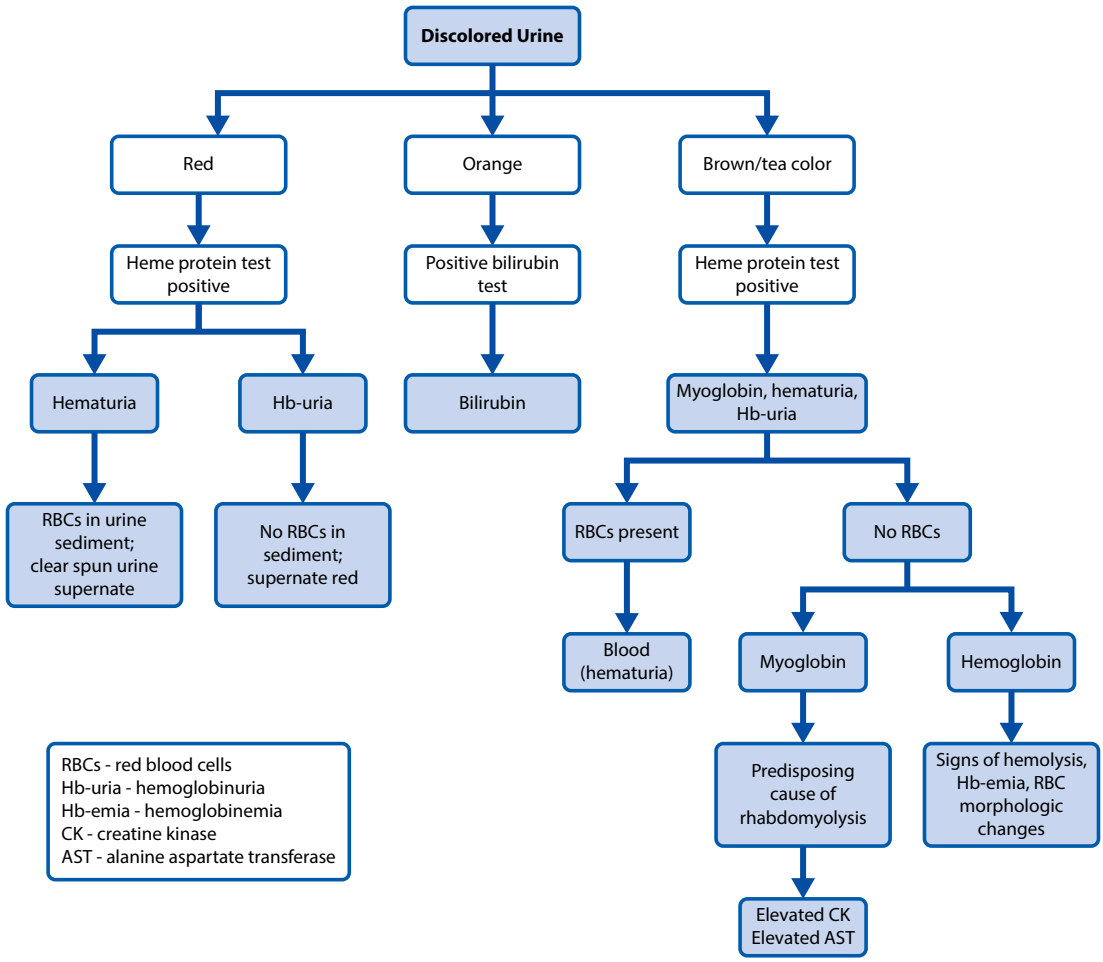

FIGURE 2.11.6 Algorithm showing the differential features of endogenous pigmenturia.

only increase once renal function has declined by more than 40%–75% depending on the functional marker used. Urine microscopy, specifically the detection of tubular casts, may have better sensitivity in recognizing AKI. Tubular casts accumulate in urinary sediment as a result of direct epithelial cellular injury by pigment, although by the time the casts appear, damage has already transpired. The damage associated with myoglobin and hemoglobin-induced AKI is maximized by coexisting metabolic acidosis and acidic urine. Therefore, in order to prevent or minimize the damage to the renal tubular epithelium, rapid restoration of effective circulating volumes and hydration deficits with balanced electrolyte solutions (lactated Ringer's solution [LRS], Normosol-R, or Plasma-Lyte 148) is recommended to not only improve renal perfusion but also to correct blood and urine pH abnormalities. It is recommended that chloride-rich fluids and synthetic colloids be avoided, as these will worsen systemic acidosis and are considered nephrotoxic. In certain cases, the use of sodium bicarbonate is recommended in patients where serum pH cannot be corrected by fluid therapy alone, and urine pH remains acidic.

CHAPTER 2

Common Clinical Problems

CHAPTER 2.12 Polydipsia and Polyuria

Michael Schaer

Introduction 65
Etiology 65
Pathophysiology 65
Clinical Signs 66
Treatment and Prognosis 69
Recommended Further Readings 69

INTRODUCTION

Polydipsia is defined as increased thirst. Normal water consumption in dogs should not exceed 90 mL/kg per day (Figure 2.12.1), while normal water intake in a cat should not exceed 45 mL/kg per day (Figure 2.12.2). Any water intake that exceeds these amounts is described as polydipsia. Normal urine production in the dog and cat ranges from 20–45 mL/kg per day, and an amount that exceeds this range is described as polyuria.

ETIOLOGY

The two main causes of polydipsia and polyuria (PD/PU) syndromes include primary disorders of excess water intake and those that involve excess urine production.

FIGURE 2.12.1 This polydipsic dog was diagnosed with psychogenic polydipsia. He was able to concentrate his urine to 1.025 with the water deprivation test.

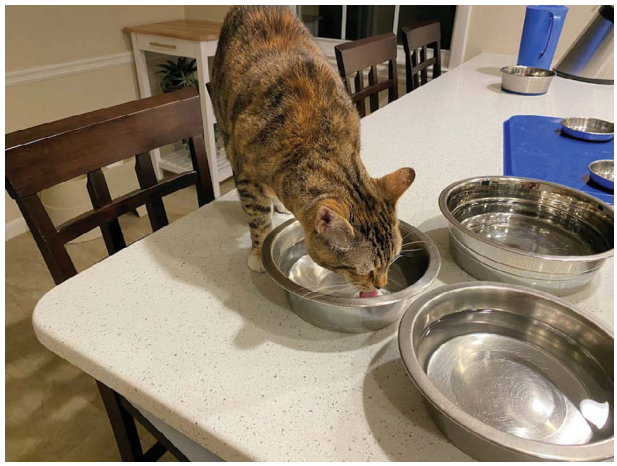

FIGURE 2.12.2 This cat's increased thirst continued for several minutes' duration.

There are approximately 14 endogenous causes of PD/PU and three exogenous causes. These and their main mechanisms are shown in Table 2.12.1. Many of the endogenous causes of PD/PU are accompanied by several other clinical features that characterize the specific disorder (Table 2.12.2). Also, there are certain conditions that can characteristically progress to eventually make the patient overtly ill when dehydration and any associated toxin accumulation occurs (Table 2.12.3).

PATHOPHYSIOLOGY

The pathophysiology underlying each PD/PU disorder varies and depends on the particular syndrome at hand (see Table 2.12.1). Any animal that is able to concentrate its urine >1.025 will usually not qualify as having a PD/PU syndrome unless the increased thirst and urination are periodic, which might characterize

DOI: 10.1201/9781003254591-14

TABLE 2.12.1 The causes and mechanisms of polydipsia and polyuria

Disease	Mechanism of polydipsia/polyuria
Endogenous causes	
Diabetes mellitus	Osmotic diuresis, hyperosmotic stimulation of the hypothalamic thirst center
Chronic renal disease	Decreased nephron mass, dysfunctional renal medullary countercurrent multiplier
Hypoadrenocorticism	Renal sodium loss and impaired renal countercurrent multiplier
Hyperthyroidism	Hyperdynamic renal blood flow causing increased renal water filtration and impaired medullary concentrating ability Other factors: Aquaporin downregulation and decreased renal filtration fraction
Hyperadrenocorticism	Increase renal plasma blood flow, central thirst stimulation, distal renal tubular resistance to ADH
Hypercalcemia	Nephrocalcinosis, renal distal tubular resistance to ADH
Pyometra	Uterine *E. coli* bacterial endotoxins impairing distal renal tubular response to ADH In some cases, antigen–antibody deposits along with impaired renal perfusion causing acute kidney injury
Diabetes insipidus	Decreased ADH release from posterior pituitary or absent distal renal tubular and collecting duct response to ADH due to various pathologies affecting the distal renal segment
Chronic liver disease	Decreased urea synthesis impairing function of renal medullary countercurrent multiplier, central thirst stimulation
Postobstructive (and postoliguric renal injury) diuresis	Solvent drag associated with the accumulated osmols in the blood subsequently being able to filter through the kidney Polydipsia due to the excessive water loss stimulating the hypothalamic osmoreceptors and the thirst mechanism
Hypokalemia	Primary stimulation of thirst, diminished urine concentrating ability due to diminished renal tubule response to ADH The reason for the latter might be due to decreased expression of aquaporin 2
Psychogenic polydipsia	Psychologically induced disturbance involving the hypothalamic thirst center
Renal glycosuria	Polyuria at high glucose concentrations, asymptomatic at low concentration
Exogenous causes	
Diuretics	Various mechanisms affecting the absorption of electrolytes and water at specific points along the nephron, depending on particular drug
Hyperosmotic solution infusions	Increased renal perfusion and accompanying solvent drag as seen with mannitol Hypertonic saline can increase the plasma osmolality and stimulate the thirst center in the hypothalamus
Excessive parenteral fluid administration	Increased renal blood flow and filtration causing water diuresis Decreased stimulation for ADH secretion
Glucocorticoid drugs	Increased renal plasma flow causing increased glomerular filtration rate, antagonizes ADH at the distal renal tubular segments
Increased sodium chloride ingestion	Increases plasma space tonicity, increased thirst, and increased urination

ADH, antidiuretic hormone.

psychogenic or primary polydipsia (Figures 2.12.3 and 2.12.4). A patient that shows no evidence of any major underlying disease and no response to the water deprivation test should be suspect for having diabetes insipidus (Figure 2.12.5).

CLINICAL SIGNS

Several disorders will not characteristically result in a clinically ill patient so long as water is available and the animal can successfully imbibe and retain the water, as seen in the syndromes of psychogenic polydipsia, diabetes insipidus, and early-stage hyperadrenocorticism. Other conditions that will eventually worsen to cause a clinically ill patient include chronic renal failure, diabetic ketoacidosis, pyometra, hypercalcemia, hypoadrenocorticism, late-stage hyperadrenocorticism, and chronic liver disease. All of these conditions can worsen to involve multiple organ systems, which can cause the patient's eventual demise. One of these is illustrated with diabetic ketoacidosis being accompanied by acute kidney injury (AKI) and sepsis.

Primary polydipsia (psychogenic polydipsia) occurs because of a defect involving the thirst center in the hypothalamus. In humans, there can be underlying diseases such as mental disorders or diseases such as sarcoidosis that can impair hypothalamic function and disrupt the thirst center. Most of these patients, including dogs, are

TABLE 2.12.2 Typical clinical features of the polydipsia/polyuria syndromes

Disease	Classic clinical features (not all signs necessarily present depending on stage of disease)
Diabetes mellitus	PD/PU, eventually dehydration, weight loss, and vomiting, variable hypertension, varying urine SG, hyperglycemia, glycosuria, +/– hyperketonemia/hyperketonuria, other serum chemistry abnormalities (hypokalemia, hyponatremia, hypophosphatemia, lipid abnormalities), metabolic acidosis, azotemia
Chronic renal disease	PD/PU with hypertension, weight loss, and dehydration at moderate and late stages, vomiting, urine SG isosthenuric (1.008–1.012), azotemia, hyperphosphatemia, other electrolyte abnormalities (hyper-, eu-, or hypokalemia, hyper- or hypocalcemia), nonresponsive anemia
Hypoadrenocorticism	Progressive weakness and poor appetite, vomiting, diarrhea, weight loss, dehydration, decreased vitality, hypovolemic shock in late stages, varying urine SG, hyperkalemia and hyponatremia in typical form, hypochloremia, mild anemia, hypoproteinemia, hypocholesterolemia, hypocortisolemia, ACTH stimulation test cortisol <1.0 µg/dL, ECG abnormalities associated with hyperkalemia, small adrenal gland size on ultrasound in some
Hyperthyroidism	Progressive weight loss despite increased appetite, +/– hypertension, heart rate normal or increased, palpable goiters, increased serum thyroxin, decreased TSH, sometimes mild increased liver enzymes, sometimes mild anemia
Hyperadrenocorticism	PD/PU, panting, hypertension, dermatologic changes, abdominal distension, elevated liver enzymes (especially serum alkaline phosphatase in dogs), lipid abnormalities, increased serum cortisol-to-creatinine ratio, increased response to ACTH stimulation, impaired response to dexamethasone suppression, increased plasma ACTH levels with pituitary origin and low ACTH concentration with functional adrenal tumor origin, often adrenomegaly on abdominal ultrasound
Hypercalcemia	PD/PU, lethargy, weakness, dehydration, vomiting, vague abdominal discomfort, urinary calculi, hyper (with nephrocalcinosis) or hypophosphatemia, increased or normal serum PTH, enlarged parathyroid gland on cervical ultrasound examination with primary hyperparathyroidism, low serum PTH with hypercalcemia of malignancy, eventually azotemia and hyposthenuria or isosthenuria regardless of cause
Pyometra	PD/PU, dehydration, decreased appetite, purulent vaginal discharge with open pyometra, uterine enlargement, leukocytosis, sometimes renal dysfunction overt sepsis and septic shock
DI	Marked PD/PU, sometimes decreased appetite, hyposthenuria (urine SG < 1.008), no response to water deprivation, central DI will respond to ADH (**Figure 2.12.4**), nephrogenic form has no response to ADH
Chronic fibrosing liver disease	Decreased appetite and weight loss, encephalopathy (late stage), variable increases in serum liver enzyme tests, hyperammonemia, decreased liver size, increased bile acids, coagulopathy (late stage), anemia, sometimes icterus
Hypokalemia	Low serum potassium (<3.5 mEq/L; 3.5 mmol/L), skeletal and smooth muscle weakness, ECG changes, features of underlying disease (diabetes mellitus, hyperaldosteronism, metabolic alkalosis and its cause [gastric outflow obstruction], chronic renal disease)
Postobstructive and postoliguric renal injury	Features of the underlying urinary tract disease, marked PD/PU
Psychogenic polydipsia	PD/PU, no other signs of organic disease, perhaps a psychological trigger historically, able to concentrate urine with water deprivation test

Note: See specific chapters for details. Note that exact clinical signs are subject to individual patient variation.

ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; DI, diabetes insipidus; PTH, parathyroid hormone.

TABLE 2.12.3 PD/PU disorders that can rapidly progress to cause severe clinical illness*

Chronic renal disease
Diabetes mellitus
Hypoadrenocorticism
Pyometra
Hypercalcemia
Chronic liver disease
Extreme hypokalemia (serum K^+ < 2.5)

* These disorders can progress to cause sick, dehydrated, anorectic animals compared with other PD/PU disorders such as diabetes insipidus, psychogenic polydipsia, and hyperadrenocorticism, which do not typically show such progression. Hypokalemia causes marked skeletal muscle weakness and impaired ventilation (in severe cases).

FIGURE 2.12.3 These two urine samples show urine concentration ability after an 8-hour water deprivation test. The diagnosis was psychogenic polydipsia. It is important to realize that actual measurements of urine specific gravity (SG) or osmolality are the only ways to lend credence to this empirical visual impression.

FIGURE 2.12.4 This series of urine-filled tubes show the results of a positive antidiuretic hormone (ADH) response test in a dog with central diabetes insipidus. The palest colored urine sample was the most dilute, while the progressively darker colored urine was more concentrated when measured with a reflectometer.

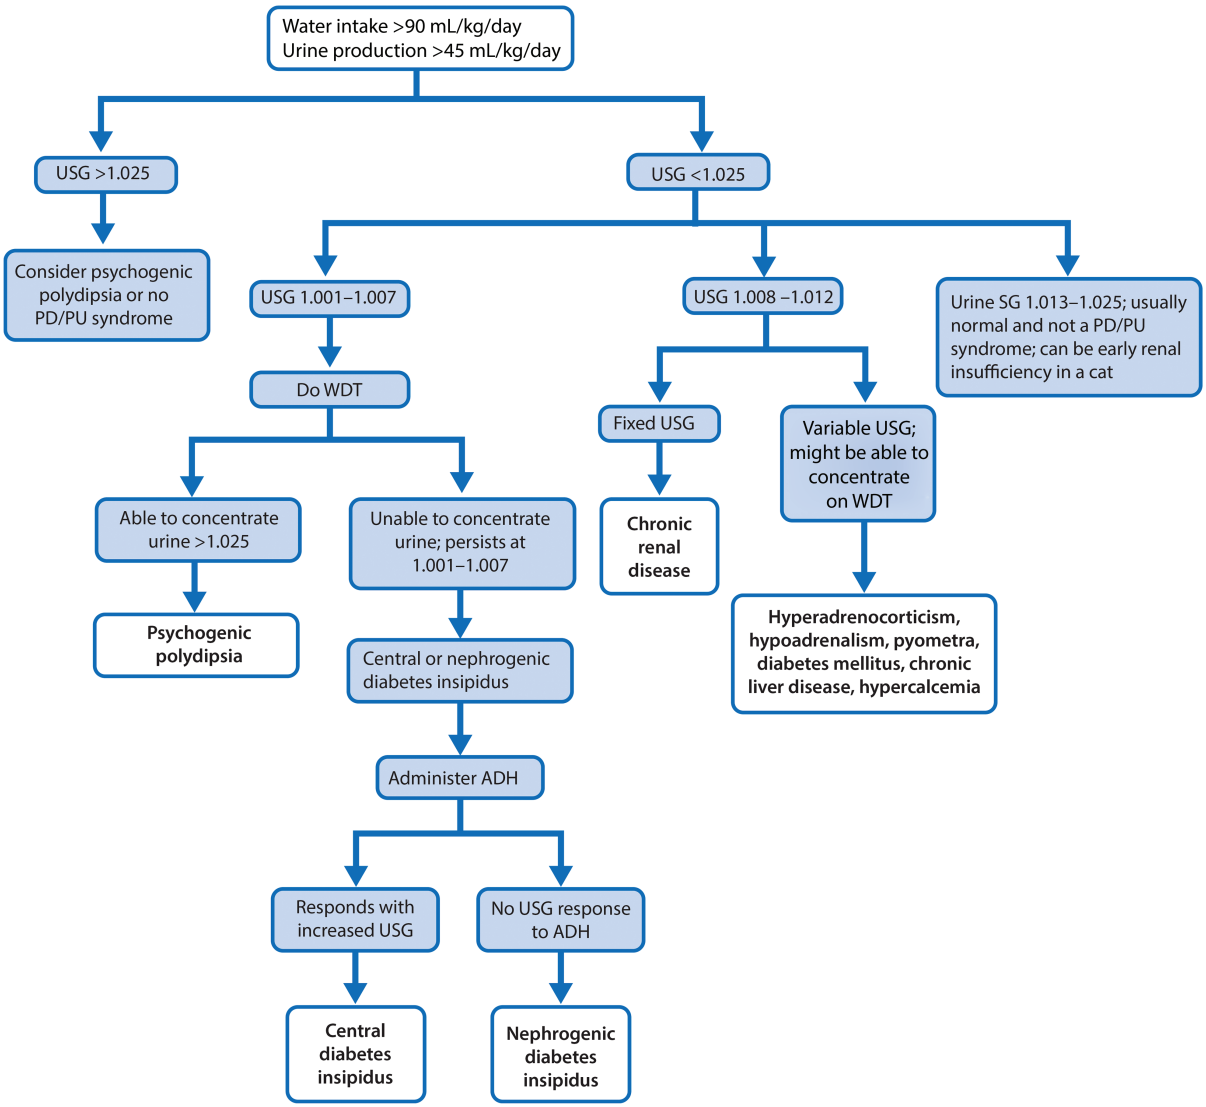

FIGURE 2.12.5 Algorithm demonstrating how to identify the polydipsia/polyuria syndromes using urine SG determination. WDT, water deprivation test; USG, urine specific gravity; ADH, antidiuretic hormone.

able to maintain normal serum sodium concentrations because they are able to excrete the extra water that they have imbibed. In rare situations in humans, the polydipsia can overwhelm the kidney's ability to excrete the excess water, and this can result in water retention and hyponatremia.

The characteristic features of each disorder are provided in Table 2.12.2. Urine specific gravity determination is a useful and practical test to help identify the cause of PD/PU (Figure 2.12.5), although its accurate application must always be used in light of the accompanying clinical findings.

TREATMENT AND PROGNOSIS

A disorder such as psychogenic polydipsia has a very good prognosis because it lacks any life-threatening pathophysiology as compared with other causes of PD/PU, such as chronic renal failure and diabetic ketoacidosis, which can progress to a clinically decompensating disease. A water deprivation test should not be done until the patient is first evaluated for other disorders causing PD/PU because it can cause a negative water balance that can have adverse effects on blood pressure and tissue perfusion. Furthermore, hyperadrenocorticism can cause clinical findings similar to diabetes insipidus.

INTRODUCTION

Proteinuria refers to increased levels of protein in the urine. Healthy glomeruli prevent filtration of most proteins into the urinary space. The few proteins and peptides that are filtered are degraded and reabsorbed in the proximal tubule. Glomerular disease causes loss of the normal filtration barrier, allowing abnormal amounts of protein to reach the tubules. Alternatively, proximal tubular dysfunction can allow filtered protein to escape reabsorption and make it to the urinary bladder, even if the glomerulus is functioning normally. Excessive amounts of protein are cytotoxic to the renal tubular epithelium over time, causing inflammation, fibrosis, degeneration, atrophy, and altered renal hemodynamics that reduce tubular perfusion. The net result is progressive loss of renal function. Detrimental sequelae like azotemia, thromboembolism, cachexia, hypertension, and nephrotic syndrome (hypoalbuminemia with associated effusion/edema/ascites and hypercholesterolemia) may develop. However, early on, affected animals may be asymptomatic, nonazotemic, and able to concentrate their urine. Early diagnosis and management of proteinuria may prevent uremic complications and death in affected animals.

SOURCES OF PROTEINURIA

Proteinuria resulting from abnormal glomerular filtration or tubular reabsorption of protein is termed renal proteinuria. Renal proteinuria is further subcategorized as glomerular or tubulointerstitial. However, proteinuria does not necessarily imply impaired renal function. Prerenal proteinuria results from systemic states which collaterally increase urine protein. These include fever, strenuous exercise, hyperthermia, seizures, and hypertension, and pathologic states which increase the amount of protein available for filtration such as hemolysis (hemoglobin), rhabdomyolysis (myoglobin), or plasma cell tumor/multiple myeloma (immunoglobulin). Postrenal proteinuria results from infiltration of inflammatory or neoplastic cells into the urine, as in urinary tract infections/prostatitis, urolithiasis, or urothelial cell carcinoma. Importantly, extrarenal neoplastic and inflammatory foci can also cause proteinuria, although the pathology is not fully understood.

TUBULOINTERSTITIAL PROTEINURIA

Proteinuria from proximal tubular dysfunction (tubular proteinuria; **Table 2.13.1**) is generally less severe than that from glomerular disease. The urine protein-to-creatinine ratio (UPC) often (but not always) remains below 2.0. Proximal tubular dysfunction often causes euglycemic glucosuria and/or urine casts alongside proteinuria, implying loss of reabsorptive function and epithelial damage. Inflammation of the renal interstitium (interstitial renal proteinuria) can allow proteins to infiltrate the tubular fluid past proximal tubule, which can also cause mild-to-moderate proteinuria.

GLOMERULAR PROTEINURIA ("PROTEIN-LOSING NEPHROPATHY")

Numerous glomerular diseases can impair the glomerular filtration barrier, causing severe, persistent proteinuria (**Table 2.13.1**); a more thorough discussion of specific glomerulonephropathies is provided in Chapter 13, Nephrology/Urology.

Practically, glomerular diseases in the dog and cat can be categorized as immune-complex glomerulonephritis (ICGN) or non-autoimmune. In ICGN,

Glomerular	Tubular
*Infectious**	*Infectious*
– Lyme nephritis – Leishmaniasis – Ehrlichiosis – Heartworm disease – Babesiosis – Hepatozoonosis – Coccidioidomycosis (Valley fever) – Feline immunodeficiency virus (FIV) – Feline leukemia virus (FeLV) – Feline infectious peritonitis (FIP)	– Leptospirosis – Pyelonephritis (severe) – Ehrlichiosis – Hepatozoonosis
Autoimmune	*Fibrotic*

– *Systemic*
  – Immune-mediated polyarthritis
  – Immune-mediated hemolytic anemia
  – Systemic lupus erythematosus
  – Autoimmune pododermatitis (cats)
– *Renal (ICGN)*
  – Membranous GN
  – Membranoproliferative GN
  – Proliferative GN
	– CKD (late stages)

Non-autoimmune	*Toxic*
– Amyloidosis – Focal segmental glomerulosclerosis – Podocytopathy (minimal change disease)† – Cutaneous and renal glomerular vasculopathy – Glomerular lipidosis – Glomerulosclerosis in late-stage CKD	– Ethylene glycol – Aminoglycosides – NSAIDs – Lily (*Lilium* and *Hemerocallis* spp.; cats) – Grapes/raisins (dogs) – Heavy metal toxicosis – Jerky treat toxicosis (dogs) – Chlorambucil (cats)
Anomalous (young dogs)	*Anomalous*
– Hereditary nephritis – Collagenofibrotic nephropathy	– Fanconi syndrome
Endocrine	
– Hyperadrenocorticism – Diabetes mellitus	
Iatrogenic	
– Glucocorticoids – Tyrosine kinase inhibitors (Palladia)	

* Infection associated with secondary ICGN; Lyme nephritis requires rapid and simultaneous therapy with antimicrobials (doxycycline) and immunosuppressive agents for survival.

† Despite being classified as non-ICGN, minimal change disease is corticosteroid responsive in humans.

CKD, chronic kidney disease; GN, glomerulonephritis; ICGN, immune-complex glomerulonephritis; NSAID, nonsteroidal anti-inflammatory drug.

glomerular dysfunction results from deposition of immune complexes within the layers of the filtration barrier. These incite an inflammatory response which damages the glomerulus, increasing its permeability. ICGN can occur primarily or may occur secondary to some infections (Table 2.13.1). Non-autoimmune glomerular dysfunction results from scarring, amyloidosis, or other processes; 48% of dogs and 74% of cats with glomerular disease have ICGN and thus may respond to immunosuppression. Non-autoimmune causes of proteinuria may or may not have specific treatments recommended for their management. If no specific treatments exist, proteinuria secondary to non-ICGN glomerulonephropathies must be managed symptomatically (see Figure 2.13.2 on page 73).

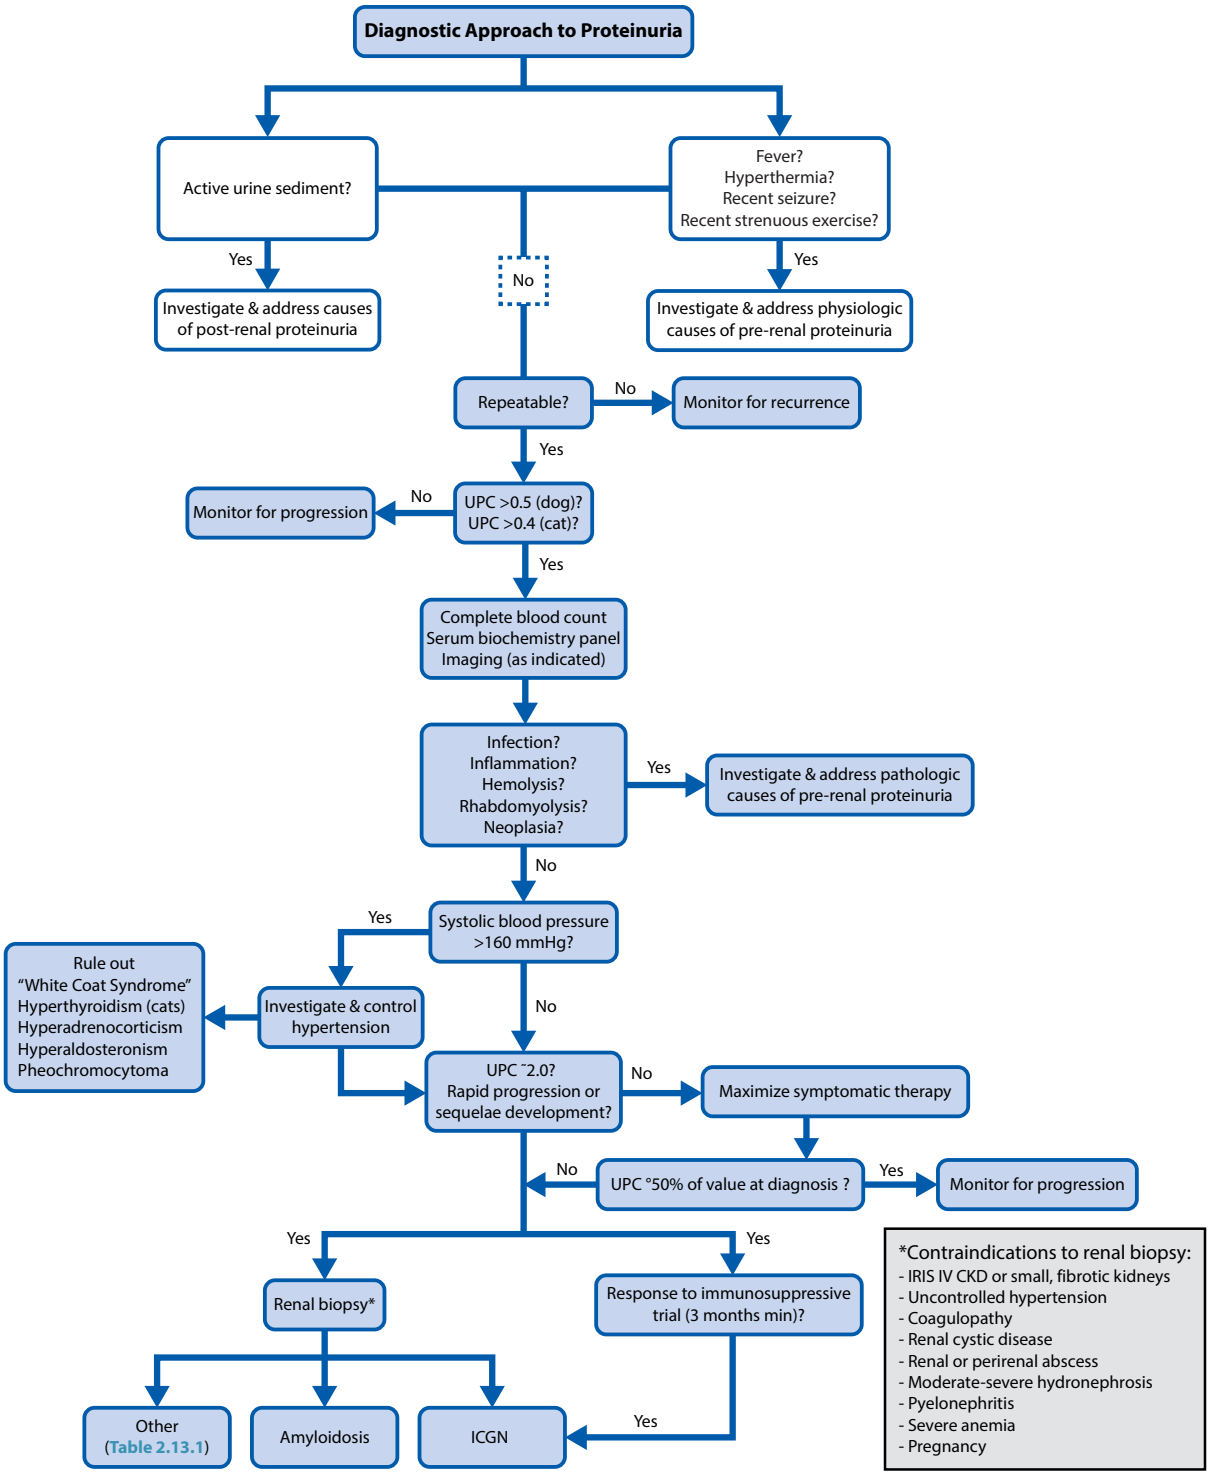

FIGURE 2.13.1 Diagnostic approach to the proteinuric patient.

Symptomatic Therapy for Persistent Renal Proteinuria

Proteinuria Reduction & RAAS Inhibition	Blood Pressure Management	Anticoagulation	Diet
Telmisartan 1 mg/kg PO SID (dogs and cats) Recheck UPC, BP, renal values, serum K q 4 wks Titrate dose upward in 0.5 mg/kg increments Stop titration if: UPC normal or < 50% of baseline SCr increases > 0.3 mg/dL Serum K > 6.0 mg/dL Hypotension Max dose 2 mg/kg PO SID If max dose reached and UPC >50% of baseline, consider adding ACE inhibitor Enalapril or benazepril 0.5–2 mg/kg PO SID-BID If adverse effects, consider switching from telmisartan to ACE inhibitor	Amlodipine starting dose: Cats: 0.625–1.25 mg PO SID Dogs: 0.1–0.2 mg/kg PO SID Combine with RAAS inhibition in dogs Recheck BP q 1 wk Titrate dose upward in 0.625 mg (cat) or 0.1 mg/kg (dog) increments Stop titration if: SBP < 160 mmHg Weakness, collapse, dull mentation Max dose: Cats: 2.5 mg PO SID Dogs: 0.5 mg/kg PO SID-BID If max dose reached & SBP >160 mmHg, consider: RAAS inhibitor (see left) Hydralazine (start low) Prazosin	Clopidogrel preferred: Cats: 18.75 mg PO SID Dogs: 1–3 mg/kg PO SID Or, if cost constraints, aspirin: Cats: 5–81 mg PO q72h Dogs: 1–5 mg/kg PO SID If thromboembolism while receiving, consider: Apixaban Rivaroxaban	Protein restriction: Reduce dietary protein 25–50% (in g/100 kcal) ***Account for treats*** Consider prescription renal diet if azotemic or current diet near AAFCO min protein requirement: Dogs: 4.5 g/100 kcal protein Cats: 6.5 g/100 kcal protein Note: Renal diets often contain less than AAFCO min protein Oral phosphate binder if P > 4.5 mg/dL despite renal diet: Aluminum hydroxide 30–100 mg/kg/day Ensure daily caloric intake above resting energy requirement RER = body weight $(kg)^{0.75} \times 70$ If voluntary caloric intake < RER: Appetite stimulation (mirtazapine, capromorelin) Nausea management (maropitant, ondansetron)

FIGURE 2.13.2 Symptomatic therapies for renal proteinuria. SCr, serum creatinine; K, potassium; RAAS, renin-angiotensin-aldosterone syndrome; UPC, urine protein-to-creatinine ratio; BP, blood pressure; AAFCO, Association of American Feed Control Officials; ACE, angiotensin-converting enzyme.

DIAGNOSTIC APPROACH

A typical diagnostic approach to incidental proteinuria is provided in Figure 2.13.1. In cases of subclinical, mild-to-moderate proteinuria, confirm persistence of proteinuria over three separate assays at least 2 weeks apart. However, a single increased UPC may be sufficient to begin workup or even treatment if markedly increased, or if sequelae associated with renal proteinuria such as azotemia or nephrotic syndrome are progressing rapidly. If disease is stable and UPC is mildly to moderately increased, pre- and postrenal sources should be ruled out. Complete blood count, serum biochemistry, and abdominal ultrasound to evaluate renal function and hunt for contributing extra-renal diseases, urine culture to rule out a postrenal infectious component, and evaluation of systolic blood pressure should be performed. Note that hypertension is both a cause and an effect of proteinuria. Extrarenal causes of hypertension such as hyperthyroidism (cats), hyperadrenocorticism (dogs), hyperaldosteronism, and pheochromocytoma should be ruled out prior to performing invasive diagnostics like renal biopsy or immunosuppressive trials. Thoracic radiographs to screen for metastatic neoplasia or pulmonary infectious/inflammatory disease can be considered based on clinical suspicion.

If investigation does not reveal a cause of pre- or postrenal proteinuria, renal proteinuria should be suspected. Infectious disease testing should be carried out within reason for the region and the patient's travel history (Table 2.13.1). If proteinuria is mild and disease is stable, attempting symptomatic management without further diagnostics is reasonable. No further diagnostics may be necessary if therapeutic goals are reached with symptomatic therapy alone. However, if UPC is markedly elevated, achievement of these goals without addressing the underlying condition is unlikely, and renal failure may develop rapidly. If UPC remains high despite symptomatic therapy, or if azotemia or nephrotic syndrome are developing, a lack of response to symptomatic treatment should prompt reconsideration of renal biopsy or immunosuppressive trials.

Renal biopsy is required for definitive diagnosis of most glomerular diseases and should be discussed if not contraindicated. Complications are uncommon if no contraindications exist, but life-threatening hemorrhage is possible postprocedure. Samples can be obtained surgically or percutaneously with ultrasound guidance and should be sent to an experienced nephron pathologist (United States: The Ohio State University International Veterinary Renal Pathology Service). If biopsy is unsafe or unfeasible, a diagnostic trial with an immunosuppressive medication is reasonable, if tolerated, for 3 months minimum. Risks of infection and adverse medication effects should be discussed prior to starting a trial.

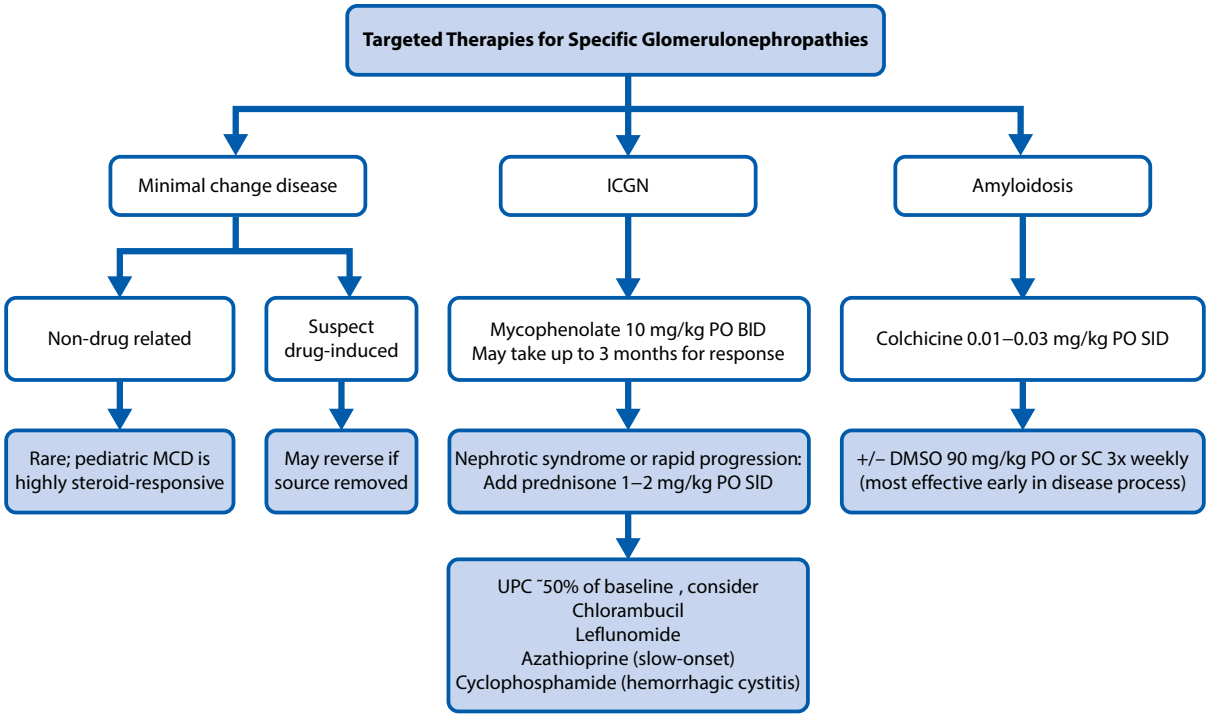

FIGURE 2.13.3 Targeted therapies for specific glomerulonephropathies.

THERAPEUTIC RECOMMENDATIONS

Symptomatic therapies for renal proteinuria are presented in Figure 2.13.2. Proteinuria can be reduced via inhibition of the renin-angiotensin-aldosterone system (RAAS), but controversy exists regarding the use of ACE inhibitors (e.g., enalapril, benazepril) versus angiotensin receptor blockers (ARBs; telmisartan). This author prefers ARBs due to anecdotal increased efficacy over ACEs but starting with either is reasonable. Combination therapy can be cautiously attempted in refractory animals but has not been scientifically evaluated. Goals of therapy include reduction in UPC to < 50% of baseline without significant hyperkalemia, worsening of azotemia, GI effects, or hypotension. Any animal receiving RAAS inhibition for proteinuria or hypertension should be evaluated for these adverse effects every 2–4 weeks during dose titration, then every 3–4 months once an optimal dose is determined. Additionally, management of sequelae such as hypercoagulability, hypertension, hyperphosphatemia, and dysrexia/hyporexia should be implemented (Figure 2.13.2).

Targeted therapy (Figure 2.13.3) should be initiated simultaneously when symptomatic if the specific underlying disease is known or strongly suspected (i.e., amyloidosis in a Shar Pei). If trialing an immunosuppressant without a pathologic diagnosis of ICGN, mycophenolate is recommended due to the relatively low risk of adverse effects. However, evidence to support one medication over another is lacking. For animals with a biopsy diagnosis of ICGN, chlorambucil or azathioprine could be considered alternatively to mycophenolate for animals with stable disease. In severely affected animals, a rapidly tapered course of immunosuppressive glucocorticoids in addition to slower-acting immune suppressants can be considered. However, glucocorticoids may increase UPC, so they are not recommended for long-term management. If the pet responds to immune suppressive, tapering to the lowest-effective dose is controversial, and life-long immunosuppression may be needed.

PROGNOSIS

Prognosis varies from fair to grave depending on underlying disease, severity of disease at diagnosis, and response to treatment.

CHAPTER 2

Common Clinical Problems
CHAPTER 2.14 Regurgitation

Roman Husnik

Introduction 75
Etiopathogenesis 75
Diagnostic Approach 76
History 76
Physical Examination 76
Paraclinical Diagnostic Tests 77
Treatment and Prevention 79
Recommended Further Readings 79

INTRODUCTION

Regurgitation is a passive oral evacuation of esophageal or pharyngeal content. It is almost always misinterpreted as vomiting by pet owners. Therefore, the first diagnostic step is to not only distinguish regurgitation from vomiting (Table 2.14.1) but also distinguish regurgitation from expectoration and dysphagia.

ETIOPATHOGENESIS

The esophagus is a tubular organ connecting the pharynx to the stomach. There is an important species difference between dogs and cats in the esophageal muscular is layers. In dogs, the esophagus is composed entirely of striated muscle, whereas in cats, only the distal half of the esophagus is composed of smooth muscle.

TABLE 2.14.1 Differentiation of regurgitation from vomiting

Clinical sign	Regurgitation	Vomiting
Abdominal contractions	Usually absent	Typically present
Evacuated content re-eaten	Often (not in cases of GER and esophagitis)	Absent
Prodromal signs (nausea, licking of the lips, salivation, excessive swallowing, hiding and depression)	Absent (excessive salivation and swallowing attempts due to dysphagia can imitate nausea in cases with pharyngeal disorder)	Typically present
Cervical esophageal distension	May be present	Absent
Time after eating	Variable	Variable
Character of ejected material	Usually undigested (depending on time interval after eating, whether the food is mixed with fluid and presence of GER)	Can be partially digested (depending on time between ingestion and vomiting)
Presence of bile	+/– (Duodenogastric reflux may occur under normal circumstances; bile may be present in regurgitant due to GER of bile from the stomach into the esophagus prior to regurgitation)	+/– (Duodenogastric reflux may occur under normal circumstances)
pH	Variable	Variable
Risk of aspiration pneumonia	High	Moderate

GER, gastroesophageal reflux.

DOI: 10.1201/9781003254591-16

Regurgitation can be caused by disease of the esophagus, as well as pharyngeal disorders and soft palate anomalies (Table 2.14.2). Regurgitated food can also come from the stomach and the oral cavity. Diseases that result in primary hypomotility, inflammatory/neoplastic infiltration, or obstruction of the esophagus may interrupt normal passage of food/fluid, compromising the normal contractile function of the esophageal wall and possibly result in esophageal dilation. Regurgitation is a passive process with minimum prodromal signs. It occurs mostly based on gravity and passive changes of intrathoracic and intra-abdominal pressures with change of body position, barking, or during activities, without involvement of a reflex arc. Nausea and retching are not usually present; however, terminal retch or gag can occur, which the owners can misinterpret as cough. Regurgitation puts patients at risk for aspiration-related diseases.

TABLE 2.14.2 Most common causes of regurgitation

Esophageal disease (most common cause)
Obstructive disorders
- Foreign bodies
- Stricture
- Vascular ring anomalies
- Peri-esophageal masses (external compression)
- Intraluminal neoplasia

Esophagitis (including reflux esophagitis)

Infectious
- *Spirocerca lupi*
- *Pythium insidiosum*

Neuromuscular disorders
- Megaesophagus (congenital, acquired – idiopathic or secondary [many possible causes])
- Motility abnormalities

Hiatal disorders

Esophageal diverticulum

Gastrointestinal disorders
Disease processes associated with frequent and severe vomiting, GER, reflux esophagitis, and secondary dysmotility
Gastric distension (e.g., pyloric obstruction)
Gastric hypomotility and functional ileus (e.g., CIRMD [e.g., severe acute pancreatitis, gastroenteritis, and peritonitis] and POI)

Pharyngeal disorders (usually accompanied by dysphagia)
Obstructive disorders
- Foreign bodies
- Pharyngeal, tonsillar neoplasia
- Retropharyngeal lymphadenopathy

Neuromuscular disorders
- Myasthenia gravis
- Cricopharyngeal achalasia
- CNS lesions (cerebellar disorders, brainstem lesions)
- Neuropathies of cranial nerves IX and X
- Rabies
- Botulism

Palate disorders
- Congenitally short or cleft palate

CIRMD, critical illness-related GI motility disorders; GER, gastroesophageal reflux; POI, postoperative ileus.

DIAGNOSTIC APPROACH

Signalment, history, and physical examination can be useful in prioritizing differential diagnoses and detecting underlying disorder. The detailed clinical approach is shown in Figure 2.14.1.

HISTORY

It is important to ask questions about potential foreign body (FB), caustics, recent carrion (botulism) ingestion, or general anesthesia. Regurgitation starting a few weeks after anesthesia can be caused by stricture as a consequence of severe reflux esophagitis. Rabies vaccination status and current medication should be assessed. Combination of opioids with recent anesthesia, abdominal surgery, electrolyte abnormalities, and stress of hospitalization increases the risk of critical illness-related GI motility disorders/postoperative ileus (CIRMD/POI) and contributes to the higher incidence of gastroesophageal reflux (GER) and regurgitation in hospitalized animals. The owner should be questioned about the presence of muscular weakness that might reflect a neuromuscular disorder such as myasthenia gravis.

The sudden onset of clinical signs indicates the possibility of ingestion of a FB or caustics. Gradual onset and progressive course are often related to megaesophagus, stricture, neuromuscular disease, or neoplasia. An intermittent course can be seen in cases of reflux esophagitis or hiatal disorders. Onset of problems during weaning and switching to solid food indicates congenital origin (megaesophagus, vascular ring anomaly [VRA], stricture, cricopharyngeal achalasia). Regurgitation immediately after feeding usually indicates a complete obstruction or involvement of the proximal esophagus, while regurgitation several hours after feeding is likely caused by megaesophagus or distal obstruction. Regurgitation of dry food but not liquids usually indicates stricture or partial obstruction. Normal appetite or polyphagia is most often seen in animals with benign stricture or megaesophagus, while esophagitis is accompanied by anorexia. Weight loss may occur due to malnutrition.

In adult dogs with confirmed megaesophagus, it is important to look for manifestations of its potential causes and complications. Cough and dyspnea accompanying regurgitation are usually a manifestation of aspiration pneumonia, less commonly bronchoesophageal fistula or rarely pressure of dilated esophagus. Especially in young animals, regurgitation can escape the attention of the owner, and they are presented for respiratory abnormalities.

PHYSICAL EXAMINATION

It is important to observe the patient while eating/drinking, as well as a thorough examination of the oropharynx, masticatory muscles, and neck, especially the thoracic inlet. Atrophy of the masticatory muscles (e.g., myasthenia gravis, chronic myositis) and FB can

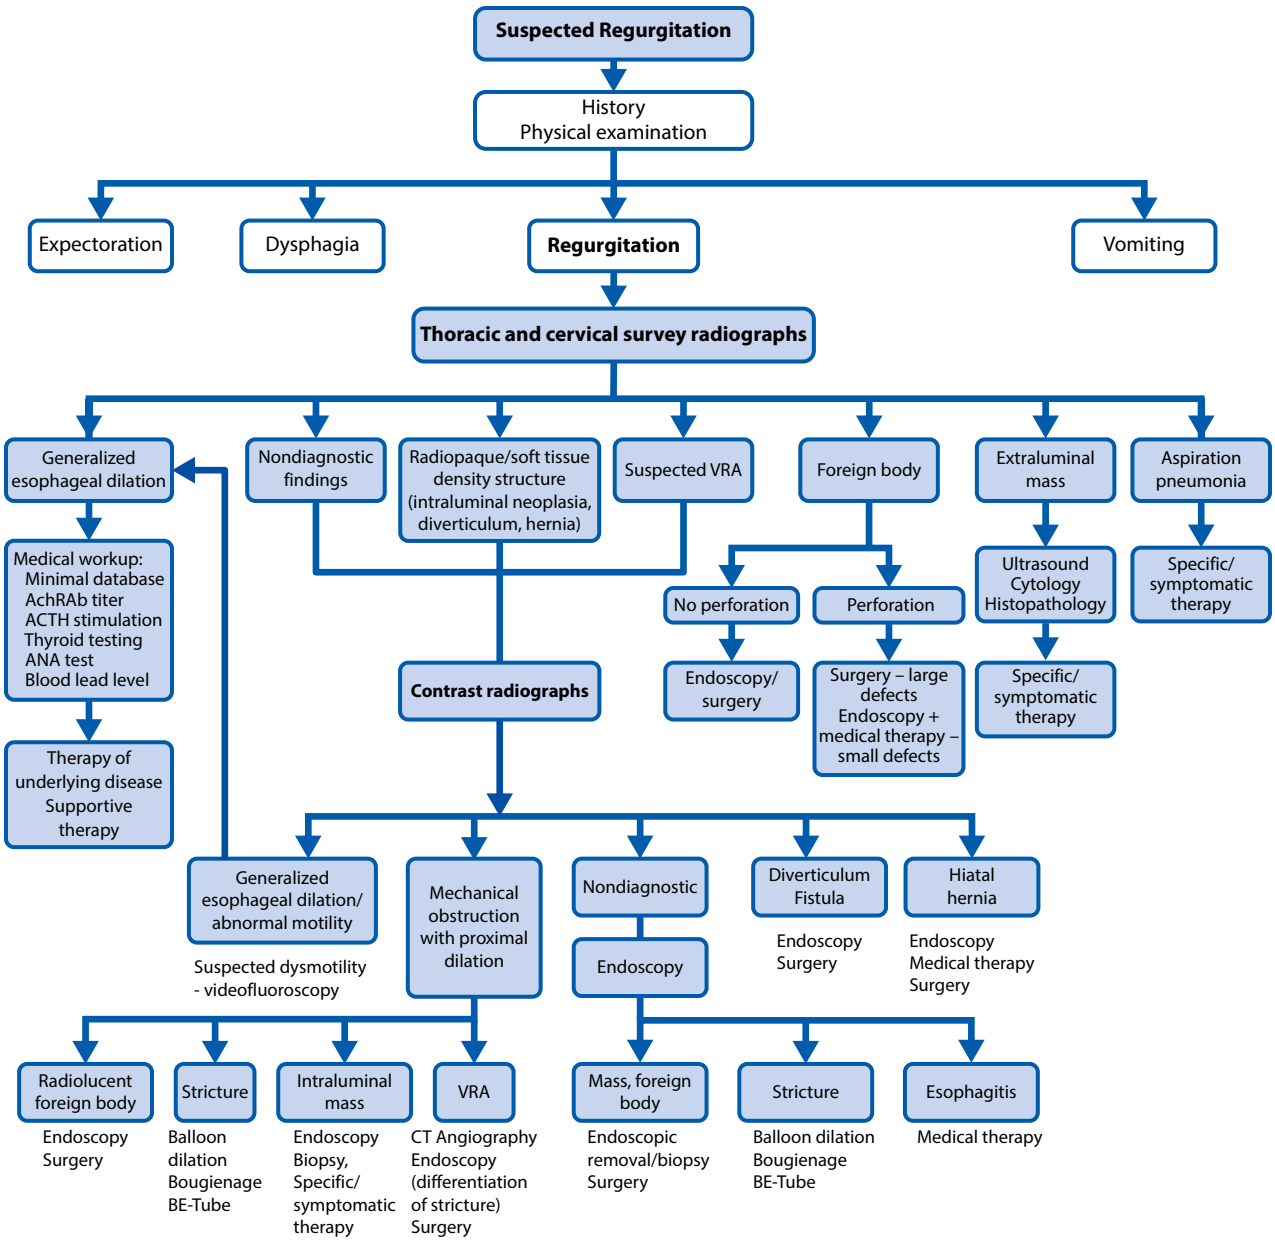

FIGURE 2.14.1 Algorithm for the clinical approach to regurgitation in dogs and cats. AchRAb, acetylcholine receptor antibody; ACTH, adrenocorticotropic hormone; ANA, antinuclear antibody; BE, balloon-esophageal; VRA, vascular ring anomaly.

be detected. In some cases, dilation of the cervical esophagus may be apparent on the left side of the neck (Figure 2.14.2). Examination of the respiratory system can reveal complicating aspiration pneumonia. With suspected secondary megaesophagus, attention should be paid to thorough examination of skin, mucous membranes, and mucocutaneous junctions (systemic lupus erythematosus), muscles (myopathy, botulism, myasthenia gravis, hypoadrenocorticism), exclusion of canine distemper and dysautonomia. In cases of mediastinitis due to esophageal perforation, a stiff posture, lethargy, and fever can be detected, and Horner syndrome may be present. Mediastinal masses in cats can be palpated during gentle compression of the anterior thorax. A neurological examination should be performed to evaluate for deficits consistent with generalized neuromuscular dysfunction. The blink reflex fatiguing over time increases the suspicion for myasthenia gravis.

PARACLINICAL DIAGNOSTIC TESTS

Survey radiography (SR), contrast radiography, fluoroscopy, ultrasonography, endoscopy, and computed tomography are diagnostic imaging methods often available in modern veterinary practice. In a patient presented with a history of regurgitation, initial diagnostic evaluation includes cervical, left/right lateral, and ventrodorsal thoracic radiographs (including cranial abdomen). Generalized (megaesophagus) or focal (VRA, stricture)

FIGURE 2.14.2 Two-year-old female spayed Pitbull. Dilation of the cervical esophagus is apparent on the left side of the neck. Histopathology of endoscopic biopsies confirmed diagnosis of fungal esophagitis (suggestive of *Pythium* spp.).

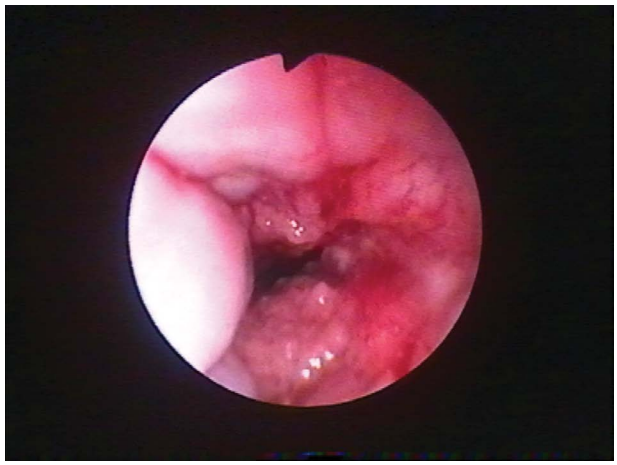

FIGURE 2.14.4 Nine-year-old male intact Belgian Shepherd. Esophageal undifferentiated carcinoma viewed via esophagoscopy. The mass was causing partial obstruction of the lower esophagus and subsequent regurgitation following ingestion of meals.

esophageal dilation, FB, masses, and aspiration pneumonia can be detected. Contrast radiography may be helpful if SRs are non-diagnostic. Disorders not readily diagnosed by SR include esophagitis, radiolucent FB, strictures, esophagobronchial fistula, and diverticulum. Video fluoroscopy is beneficial for better assessment of esophageal motility or for confirmation of hiatal hernia. In unclear cases, endoscopy and biopsy are useful in diagnosing stricture, esophagitis (**Figure 2.14.3**), intraluminal mass (**Figure 2.14.4**), FB, and diverticulum (**Figure 2.14.5**). Endoscopy may also be used therapeutically to remove an FB (**Figure 2.14.6**), to dilate a stricture, or to place a gastrostomy feeding tube. Computed tomographic angiography allows differentiation of VRA from other causes of esophageal obstruction and provides information to determine amenability of surgical correction. Ultrasonography can be used to further specify compressive masses and can guide fine-needle aspiration/biopsy. Scintigraphy and esophageal pH/impedance testing have been used to diagnose esophageal motility disorders, GER, unexplained esophagitis, or hiatal hernias. A minimal database consisting of CBC, serum chemistry (including serum creatinine kinase [CK]), and urinalysis is recommended to screen for underlying diseases in patients with systemic illness or secondary megaesophagus. Acetylcholine receptor antibody test, adrenocorticotropic hormone stimulation, thyroid tests, antinuclear antibody test, and blood lead assay should be considered in cases with megaesophagus or esophageal hypomotility. Edrophonium (if available) challenge test can support the diagnosis of myasthenia gravis. Electrodiagnostics and/or muscle and nerve biopsy can help to detect some neuromuscular disorders. In cases of POI and CIRMD, a minimal

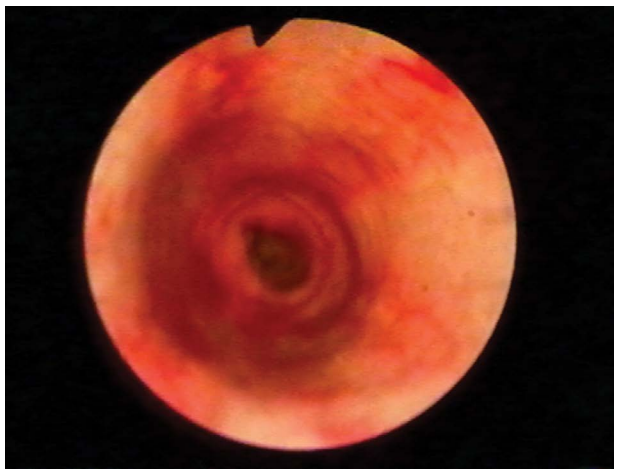

FIGURE 2.14.3 Four-year-old female spayed Yorkshire Terrier. Esophagoscopy is showing inflamed esophageal mucosa of distal third of the esophagus due to severe vomiting and gastroesophageal reflux caused by gastric foreign body retention and intermittent gastric outlet obstruction.

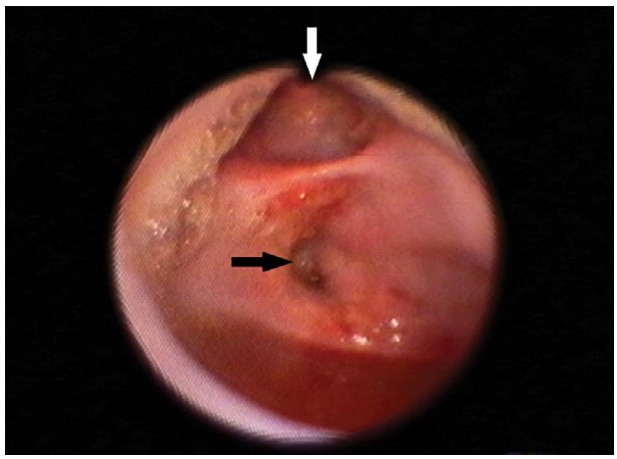

FIGURE 2.14.5 Three-year-old male neutered West Highland White Terrier. Caudal thoracic esophageal diverticulum (pulsion form, white arrow) as a consequence of increased esophageal luminal pressure caused by esophageal foreign body retention is shown. Cardia is also visible (black arrow).

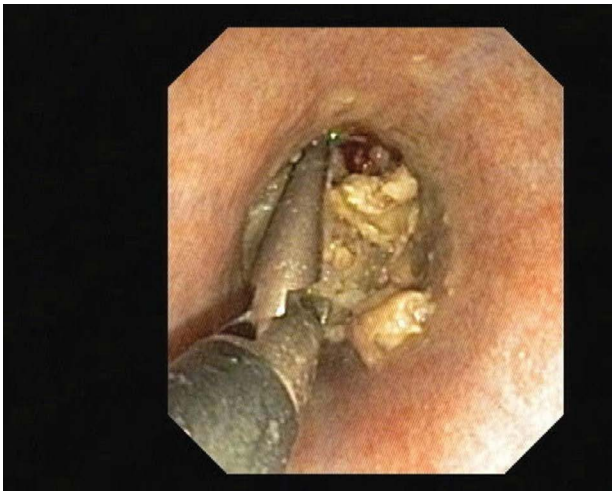

FIGURE 2.14.6 One-year-old female intact West Highland White Terrier. Esophageal foreign body (bone coated with connective tissue) was detected in the thoracic portion of the esophagus. Rigid grasping forceps were passed along the side of the flexible endoscope to grasp the object and remove it from the esophagus.

database and abdominal ultrasound are recommended to screen for underlying disease and monitor for metabolic consequences. Additionally, more targeted tests can be performed based on the list of differential diagnoses applying to each particular patient.

TREATMENT AND PREVENTION

Proper diagnosis and treatment of underlying disease as well as complications such as aspiration pneumonia are an essential premise. When primary disease is not identified or does not respond to therapy, strategies to reduce frequency and severity of regurgitation are used. Dietary modifications include small, frequent meals and feeding in upright position or through a gastrostomy tube. Keeping the patient in an upright position for 10–15 minutes after feeding (e.g., in Bailey chair) and between feedings may allow gravity to help with esophageal transit and evacuation. Some animals do better with a gruel consistency of the food, while others regurgitate less with canned food formed into a meatball shape or dry food (depending on the type of esophageal disease). If GER is present, judicious use of prokinetics and gastric acid suppressants may reduce the risk of esophagitis and regurgitation.

Preanesthetic administration of esomeprazole and cisapride significantly increases gastric pH and decreases the number of reflux events in anesthetized dogs. Therefore, administration of proton pump inhibitor and prokinetic agent may be beneficial for prevention of esophagitis secondary to GER.

CHAPTER 2

Common Clinical Problems
CHAPTER 2.15 Seizures

Gabriel A. Garcia

Introduction 80
Pathophysiology 80
Stages of a Seizure 80
Epilepsy Classification 81
Clinical Approach to the Seizure Patient 82
Miscellaneous 83
Recommended Further Readings 85

INTRODUCTION

Seizures are one of the most common neurological problems in veterinary medicine. Successful long-term management is dependent upon initially controlling clinical signs while trying to identify the underlying cause. Client education, setting realistic expectations, and working together with the primary veterinarian are essential. One can strive to eliminate seizures altogether, but this is an unrealistic goal, as approximately 15% of epileptics become seizure-free. Seizure events can be emotionally devastating for owners due to the peracute nature, frequency, and unpredictability.

PATHOPHYSIOLOGY

A seizure is the clinical manifestation of excessive, hypersynchronous electrical activity in the forebrain. It is the result of an imbalance of neuronal excitation from excitatory neurotransmitters (glutamate and aspartate) and neuronal inhibition from inhibitory neurotransmitters (gamma-aminobutyric acid [GABA] and glycine).

STAGES OF A SEIZURE

Identifying the different stages is helpful when trying to differentiate a seizure from other episodes. Owners commonly witness the final stages, ictus and postictal, but occasionally they may identify others. Thorough descriptions and videos of the events may help veterinarians characterize the episodes and assist in identifying seizure activity.

Stages include:

- *Prodrome:* Abnormal behavior, such as hiding, anxiousness, restlessness, or fearfulness. Occurs hours to days before the seizure.
- *Aura:* Difficult to identify in animals. Manifests as subtle behavioral changes.
- *Ictus:* Actual seizure event. Usually lasts less than 1–2 minutes. Commonly occurs at rest or sleep. Owners may overestimate the length of an episode due to its dramatic nature and their emotional response.

Cluster seizures refers to more than one seizure in a 24-hour period. Seizure events lasting longer than 5 minutes are termed status epilepticus (SE).

Seizures can be categorized as generalized or partial (focal). A partial seizure may progress to secondary generalization.

- *Generalized seizures:* Both cerebral hemispheres are involved. Motor manifestations are typically bilateral. Consciousness is impaired. Can include one or all of the following:
  - *Tonic:* Sustained muscle contractions resulting in recumbency (**Figure 2.15.1**)
  - *Myoclonic:* Brief, jerking, involuntary muscle contractions
  - *Clonic:* Repetitive, rhythmic, and prolonged muscle contractions
  - *Atonic:* Transient, sudden loss of muscle tone
- *Partial seizures:* Seizure focus in one cerebral hemisphere. The portion of the body involved is dependent on which portion of the forebrain is involved. If awareness is altered, it is referred to as a complex partial seizure (**Figure 2.15.2a, b**).
- *Partial motor seizures:* Disturbance of motor function with normal responsiveness.

DOI: 10.1201/9781003254591-17

FIGURE 2.15.1 Generalized seizure activity in a young puppy due to hypoglycemia. Generalized motor seizure with tonic (rigid) and clonic (contraction) manifestation resulting in lateral recumbency. The mostly tonic rigid extension is intermittently interrupted by the clonic contractions, resulting in the paddling or running appearance of generalized seizures. (*Courtesy of M. Schaer.*)

- *Partial sensory seizures:* Involves the limbic system. Behavioral seizures presenting as rage, aggression, fly biting, running fits, tail chasing, or vocalization.

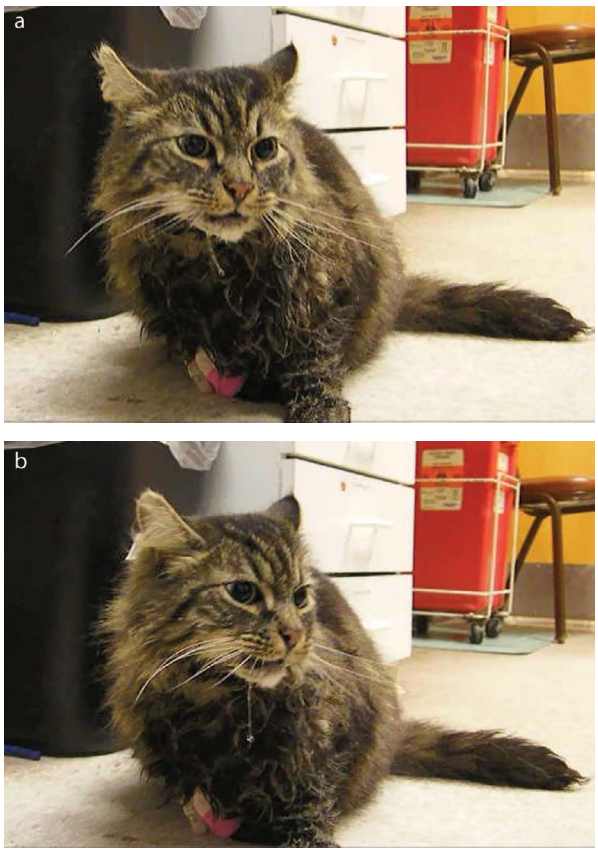

FIGURE 2.15.2 a, b Cats can commonly display partial to partial complex seizures where they may display altered consciousness, ataxia, hypersalivation, twitching of the ears and/or tail, and vocalization or growling. (*Courtesy of S. Carrera-Justiz.*)

- *Autonomic seizures:* Uncommon, predominantly autonomic signs (i.e., vomiting, diarrhea, or abdominal discomfort).
- *Postictal period:* Immediately follows the seizure and may last several hours. It is characterized by abnormal behavior such as aggression, restlessness, anxiety, lethargy, confusion, increased thirst, and appetite. Patients may display transient neurological deficits such as vision loss, obtundation, ataxia, and proprioceptive deficits.

- **Distinguishing signs of seizure:**
  - Peracute onset
  - Parasympathetic signs—hypersalivation, urination, or defecation
  - Tonic–clonic movements or rhythmic contracture of facial or appendicular muscles
  - Altered mentation—decreased responsiveness to stimuli
  - Postictal period

EPILEPSY CLASSIFICATION

The term epileptic describes a patient that experiences more than one seizure due to a forebrain abnormality. Certain breeds (Table 2.15.1) have a higher incidence of epilepsy. If inadequately treated, epilepsy can worsen over time, known as the "kindling effect."

Epilepsy is categorized by etiology – idiopathic epilepsy, symptomatic epilepsy, cryptogenic epilepsy, or reactive seizures. Regardless of the underlying cause, seizures are a clinical sign of forebrain dysfunction (Figure 2.15.3).

- *Idiopathic epilepsy:* Also known as primary or familial, is suspected to have a genetic basis. There are no structural forebrain abnormalities identified. Age of onset is typically 6 months to 6 years with an incidence of 0.5%–5% of the canine population. As many as 25%

TABLE 2.15.1 Breeds with predisposition to epilepsy

– Beagle	– Golden Retriever
– Belgian Shepherd	– Irish Setter
– Bernese Mountain Dog	– Irish Wolfhound
– Border Collie	– Keeshond
– Boxer	– Labrador Retriever
– Cocker Spaniel	– Lagotto Romagnolo
– Collie	– Miniature Schnauzer
– Dachshund	– Nova Scotia Duck Tolling Retriever
– Dalmatian	– Saint Bernard
– English Springer Spaniel	– Siberian Husky
– Finnish Spitz	– Standard Poodle
– German Shepherd Dog	– Vizsla

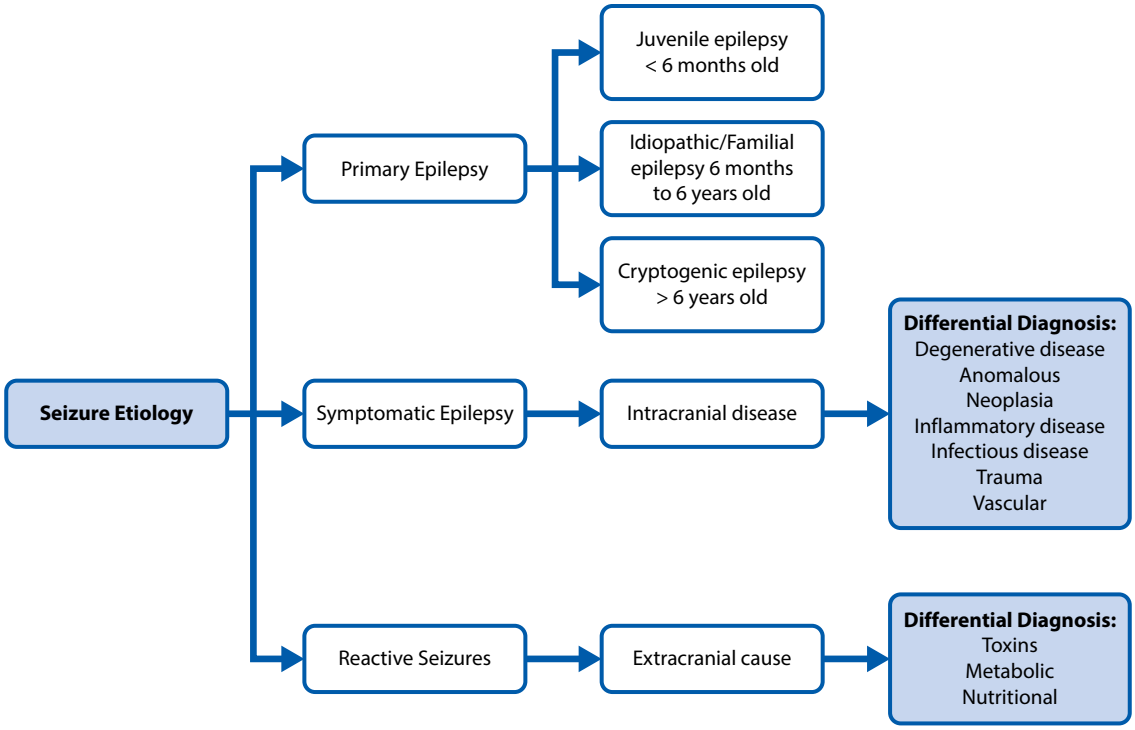

FIGURE 2.15.3 Seizure etiologies and differential diagnoses.

of epileptics are of the refractory type, whereby there is inadequate seizure control despite appropriate medication regimens.

- *Symptomatic epilepsy:* Seizures resulting from damage to the forebrain due to a structural lesion, such as inflammation (encephalitis), neoplasia, or congenital abnormalities (i.e., hydrocephalus).
- *Cryptogenic epilepsy:* Seizure focus is not compatible with idiopathic epilepsy, but no structural abnormalities are identified in the forebrain. These animals are typically older than 6 years of age.
- *Reactive seizures:* Describe recurrent seizures resulting from an extracranial cause, such as toxins and metabolic causes interfering with cerebral metabolism (a neurologic manifestation of systemic disease). There are no structural abnormalities noted in the forebrain, and the neurologic dysfunction will persist as long as the underlying cause is present.

CLINICAL APPROACH TO THE SEIZURE PATIENT

History

A thorough history is vital to differentiate seizures from other seizure-like episodes. Relevant questions include:

- When was first seizure and how many have occurred subsequently?
- Does the owner notice any atypical behavior prior to or after seizures?
- Describe the episode. Ask for videos.
- How long did the episode last?
- Is the pet normal in between episodes or is there abnormal behavior or motor deficits noted?
- Any precipitating factors prior to episodes such as feeding, sleep, or rest?
- Is the pet currently on any medications?
- Is the pet current on vaccines?
- Any exposure to toxins or human medications?

Exam Findings

A meticulous physical and neurological examination is essential for identifying any abnormalities and to appropriately localize lesions. Neurolocalization, signalment, and history allow for an accurate list of differential diagnoses (Table 2.15.2). Referral to a veterinary neurologist is recommended in patients with abnormal interictal exams, difficult or refractory epileptics, or in order to rule out any underlying intracranial pathology.

Diagnosis

Minimum database includes complete blood count (CBC), serum chemistry profile, urinalysis, blood pressure, and, when indicated, bile acids. It is important to initially rule out metabolic disease. Magnetic resonance imaging (MRI) and cerebrospinal fluid analysis are required to rule out structural or inflammatory forebrain disease. An electroencephalogram (EEG) can be helpful in confirming seizure activity; however, this diagnostic test requires specialized equipment and expertise in interpretation (Figure 2.15.4).

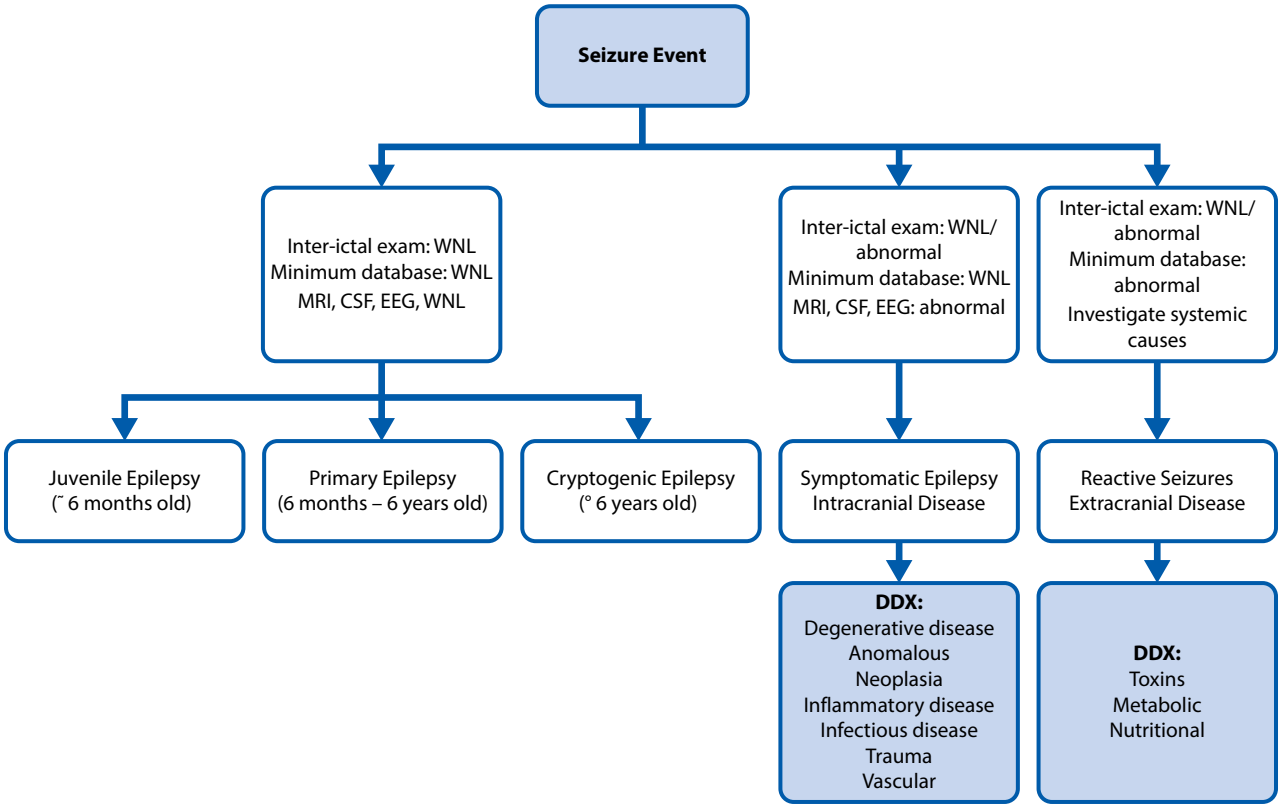

FIGURE 2.15.4 Diagnostic investigation and seizure etiology. WNL, within normal limits; MRI, magnetic resonance imaging; CSF, cerebrospinal fluid analysis; EEG, electroencephalogram; NSF, no significant findings; DDX, differential diagnosis.

Maintenance Treatment

The main goal of therapy is to decrease the frequency and the severity of the seizures, while maintaining a good quality of life for both the pet and the owner. There is a balance between medication side effects and seizure frequency. The first therapeutic objective is to maximize the benefits of one anticonvulsant medication before adding a new medication. The most commonly used anticonvulsants are phenobarbital, potassium bromide, zonisamide, and levetiracetam (Table 2.15.3). Monitor medication serum levels when indicated. It is important to discuss the potential of continued seizure activity despite treatment. There is some debate on when to initiate therapy.

The following guidelines provide indications for the commencement of treatment:

- Frequency ≥1 seizure every 6 weeks
- Cluster seizures or SE
- Seizures increasing in frequency or severity
- Postictal periods are prolonged or difficult for the owner to deal with

A positive response to therapy is shown by at least a 50% reduction in seizure frequency.

Treatment for Cluster Seizures and Status Epilepticus (SE)

The goal is to stop the prolonged seizure event. This may be achieved with either a bolus or a continuous rate infusion (CRI) of a benzodiazepine (diazepam versus midazolam), ketamine, dexmedetomidine, or propofol. Providing the animal with a loading dose of medication (i.e., phenobarbital or potassium bromide) might be necessary before providing for maintenance anticonvulsant treatment.

MISCELLANEOUS

Although a number of nonpharmacological alternatives such as vagal nerve stimulation, dietary alteration, acupuncture, cannabinoid nutraceuticals, and homeopathy have become increasingly available and investigated, no single one has shown enough response to replace standard of care with anticonvulsant medications. These can be considered as supplemental modalities.

TABLE 2.15.2 Common differential diagnoses

Degenerative	– Storage diseases – Leukodystrophy

Anomalous	– Hydrocephalus
	  – Congenital
	  – Acquired (obstructive)
	– Lissencephaly
	– Cysts

Metabolic	– Hepatic encephalopathies, uremia – Hypoglycemia, hyperglycemia – Intoxication – Hypocalcemia – Hypothyroidism – Electrolyte abnormalities – Disturbances in acid–base metabolism – Disturbances in osmolarity – Heat stroke
Nutritional	– Thiamine deficiency

Neoplastic	– Primary
	  – Meningioma
	  – Glioma / astrocytoma
	  – Ependymoma
	  – Choroid plexus tumors
	  – Lymphoma
	  – Histiocytic sarcoma
	  – Peripheral nerve sheath tumor (CN V)
	– Secondary
	  – Frontal sinus tumors
	  – Calvarial tumors
	  – Pituitary tumors
	– Metastatic

Inflammatory/Infectious	– Immune-mediated inflammation (dogs > cats)
	  – Meningoencephalitis of unknown etiology (MUE)
	  – Granulomatous meningoencephalitis (GME)
	  – Necrotizing leukoencephalitis (NLE)
	  – Necrotizing meningoencephalitis (NME)
	– Infectious (cats > dogs)
	  – Bacterial
	  – Protozoan (*Toxoplasma*, *Neospora*)
	  – Viral (rabies, distemper, coronavirus/FIP)
	  – Fungal (*Cryptococcus*)
	  – Rickettsia (*Ehrlichia canis*, *Rickettsia rickettsii*)
	  – Parasitic (aberrant migrations – *Dirofilaria*, *Cuterebra*, *Taenia*, *Baylisascaris*)

Idiopathic	– Idiopathic / primary / familial epilepsy – Juvenile epilepsy – Cryptogenic epilepsy
Traumatic	– Acute – Chronic (gliosis or scar)

Vascular	– Infarct
	  – Ischemic
	  – Hemorrhagic
	– Commonly there is an underlying systemic cause – hypertension
	  – Pheochromocytoma, cardiac disease, renal disease
	– Hypercoagulable states
	  – Hyperadrenocorticism

CN, cranial nerve; GME, granulomatous meningoencephalitis; MUE, meningoencephalitis of unknown etiology; NLE, necrotizing leukoencephalitis; NME, necrotizing meningoencephalitis.

TABLE 2.15.3 Common anticonvulsant medications

Medication	Recommended dosing	Serum level therapeutic ranges	Steady state	Monitoring	Side effects
Levetiracetam (Keppra®)	20–60 µg/kg t.i.d. p.o., IV	N/A	2–3 days	Levels not established in veterinary medicine	Sedation, ataxia
Levetiracetam extended release (Keppra XR®)	30–60 µg/kg b.i.d. p.o.	N/A	2–3 days	Levels not established in veterinary medicine	Sedation, ataxia May find empty extended-release capsules in feces
Phenobarbital (PB)	2–4 µg/kg b.i.d. p.o., IV, SQ Loading dose: 8–16 µg/kg	25–35 µg/mL	10–14 days	CBC, chemistry, serum level at 2 and 6 weeks Monitor levels every 6 months or 2 weeks after a dose change	Sedation, ataxia, polyphagia, polydipsia, polyuria, hepatotoxicity, bone marrow dyscrasias Induces P450 system
Potassium bromide (KBr)	40–60 µg/kg s.i.d. or split dose b.i.d. p.o.	Monotherapy = 1,000–3,000 µg/L With PB = 1,500–2,500 µg/L	3 months	CBC, chemistry, serum level at 1 and 3 months Monitor levels every 6 months or 1 month after a dose change	Sedation, ataxia, paresis, polyphagia, polydipsia, polyuria, behavioral changes, pancreatitis, pruritis Do not use in cats – pneumonitis can be fatal
Zonisamide (Za)	5–10 µg/kg b.i.d. p.o.	10–40 µg/mL	3–4 days	CBC, chemistry, serum level at 2 and 6 weeks Monitor levels every 6 months or 2 weeks after a dose change	Sedation, ataxia, hepatotoxicity, blood dyscrasias Induces P450 system
Benzodiazepines Emergency dosing	Diazepam –0.5 µg/kg IV, per rectum Midazolam – 0.5 µg/kg IV 0.25–0.5 µg/kg intranasal	N/A	N/A		Sedation, ataxia, prolong postictal period Oral diazepam hepatotoxic to cats Do not store diazepam in plastic syringe

CHAPTER 2

Common Clinical Problems
CHAPTER 2.16 Syncope, Episodic Weakness, and Collapse

Boyd R. Jones

Introduction 86
Clinical Signs 86
Diagnostic Investigation 87
Recommended Further Readings 89

INTRODUCTION

Syncope, episodic weakness, and collapse are clinical signs that are often easily recognized, but sometimes confirmation of their cause may be difficult. Owner descriptions of what they see may be confusing, or what they have seen may be misinterpreted. Syncope, weakness, or collapse may occur at rest but occur more frequently with exercise and activity.

Syncope (fainting) refers to the sudden loss of consciousness resulting from paroxysmal episodes of impaired cerebral blood flow, which deprives the brain of energy substrates, oxygen, and glucose. True syncope is most often related to cardiac disease but can be associated with coughing (cough syncope), hypoglycemia, severe anemia, polycythemia acid–base imbalance, and other causes.

Episodic weakness or exercise intolerance is weakness that occurs with activity and exercise and improves after rest. There is weakness and fatigue after mild exercise, but occasionally, more prolonged exercise is needed to cause clinical signs. The degree of weakness may vary from mild hindlimb ataxia to complete collapse. Most animals are normal in between episodes. Collapse may be acute with seizures, narcolepsy, cataplexy, or syncope but also may be a component of more chronic and progressive metabolic or neurologic disorders.

CLINICAL SIGNS

Syncope is characterized by a short period of flaccid collapse and loss of consciousness. Most dogs are motionless with relaxed skeletal muscles. Sometimes there is involuntary urination and vocalization. Recovery is rapid, but there may be confusion for a short time afterwards.

Signs of episodic weakness are often intermittent and include a degree of weakness, stiff stilted walk, ventroflexion of the neck and head, and reluctance to continue walking or exercising. Animals may lie down and refuse to move or collapse when they attempt to get up and walk. They may be alert or obtunded and sometimes pant as they appear to be, and are, apprehensive. Muscle strength improves after rest, and between episodes, the animal may appear normal. There may be key events that precipitate the clinical signs, such as exercise, feeding, or excitement; these triggers must be identified by careful and complete questioning of the owner.

Relying on the owner's description of clinical signs can be misleading. Their description of what they see may not give a true indication of the clinical signs. Most digital cameras and smart phones have movie capacity so that owners can be asked to record the event to confirm what they see. The clinician can then view the event to determine its true nature and have an accurate record of the clinical signs, which is essential to aid differential diagnosis and direct the next investigations. Furthermore, the video can be sent to a specialist clinician for interpretation and specialist advice if that is required.

A complete history and clinical examination are also essential to help localize the cause to a body system and, in the case of a neurologic disease, to localize the lesion(s). Some of the important questions to ask the owner of an animal with syncope, collapse, or weakness are included in Table 2.16.1, along with the object of the questioning. Clinical experience, the history, and findings from a physical examination may enable the clinician to characterize the condition so that the diagnosis only needs to be confirmed. However, especially with episodic weakness, the animal may be examined when it is, or appears to be, normal, making further investigation essential. A plethora of diagnostic tests and procedures may be considered; therefore, it is best to delay full investigation until an episode is viewed. For additional investigation, there needs to be a high index

DOI: 10.1201/9781003254591-18

TABLE 2.16.1 Questions for clients and their object, with specific outcomes related to syncope, episodic weakness, and collapse

History	Object and outcome
What did you see?	Try to determine from the description of the clinical signs if they are cardiac or neurologic in origin
How often have the signs occurred?	Increased frequency may suggest a progressive disease
Are the clinical signs always the same?	Episodic conditions usually show repeatable clinical signs
Is the animal normal immediately after an episode?	With syncopal causes and neuromuscular diseases, there are often no significant signs, in contrast to seizures
Is the animal normal in between episodes?	There may be no signs, but with some neuromuscular diseases, clinical signs can be detected
Is there anything that initiates an episode?	Exercise / coughing may induce syncope Feeding may induce narcolepsy; exercise is a trigger for weakness and collapse with neuromuscular diseases (e.g., myasthenia gravis)
Is there vomiting / regurgitation?	Regurgitation frequently occurs with metabolic and neuromuscular disease (e.g., myasthenia gravis, Addison's disease)
Have you seen the dog vomit or regurgitate?	Try to establish if esophageal signs are present suggesting muscle disease
Are litter mates affected?	Breed-related conditions that result in weakness and syncope are well known
Is the animal stiff or floppy during an episode?	Stiffness may be present with seizures or some myopathies but often not with cardiac and metabolic causes
What color are the tongue / gums?	Pale or cyanotic mucous membranes may indicate cardiovascular disease
What are the heart / pulse rates?	Detection of arrhythmias indicates cardiac disease

of suspicion as to whether the condition is neuromuscular, metabolic, or cardiovascular in origin. The investigation required for each is different. An approach to working up a case with syncope or episodic weakness is shown in Figures 2.16.1 and 2.16.2 and in Table 2.16.2. More information about each condition can be sought from other chapters in this book.

DIAGNOSTIC INVESTIGATION

Minimum Database

Hematology, biochemistry, including values for all electrolytes (sodium, potassium, calcium, phosphate), and urinalysis are the minimum required for most cases, and the results may provide a diagnosis or give an indication for further diagnostic tests (e.g., adrenocortical function, thyroid function, fasting blood glucose/insulin). Serum creatine kinase elevation is suggestive of muscle disease.

An electrocardiogram (ECG) should be performed if cardiac disease (especially an arrhythmia) is suspected. Owners can be taught how to check and determine the heart rate and rhythm during an attack if the animal is normal at the time of examination. An ECG is often normal, and, therefore, ambulatory ECG (Holter) monitoring may be required. Blood pressure should be determined if cardiac disease and/or hypertension is suspected.

Lactate and pyruvate analysis can assist with some rare metabolic muscle diseases that are classified as mitochondrial myopathies. These disorders are genetic in nature and are characterized by accumulation of vacuoles of lipid, glycogen, and other metabolites within certain muscle fibers, abnormal urine organic acid and blood amino acid profiles, lactate and pyruvate elevations, and abnormal lactate and pyruvate ratios.

Endocrine

Adrenal and thyroid function tests may be indicated in some cases. Measurement of insulin (with glucose) after fasting or at the time of an event is required if insulinoma or another hypoglycemia-causing tumor (e.g., gastric leiomyoma) is suspected.

Serology

Measurement of acetylcholine receptor antibodies is essential in dogs with suspected myasthenia gravis (MG) or in those with acquired megaesophagus. Serology may also be of value if specific infectious diseases are suspected.

Cerebrospinal Fluid Analysis

Cerebrospinal fluid (CSF) analysis is of limited value unless there is a high index of suspicion of a neurologic disease. CSF analysis rarely contributes unless there is a diffuse infectious or inflammatory disease of the central nervous system.

Electrophysiology

If neuromuscular disease is suspected, electrophysiologic investigation may help confirm the suspicion. Electromyogram (EMG) insertion activity can help confirm muscle or nerve disease and help differentiate muscular from axonal disease. Nerve conduction velocity might provide more definitive information with neuropathies.

Imaging

Dogs with suspected cardiac disease require echocardiography; plain radiographs of the thorax can help

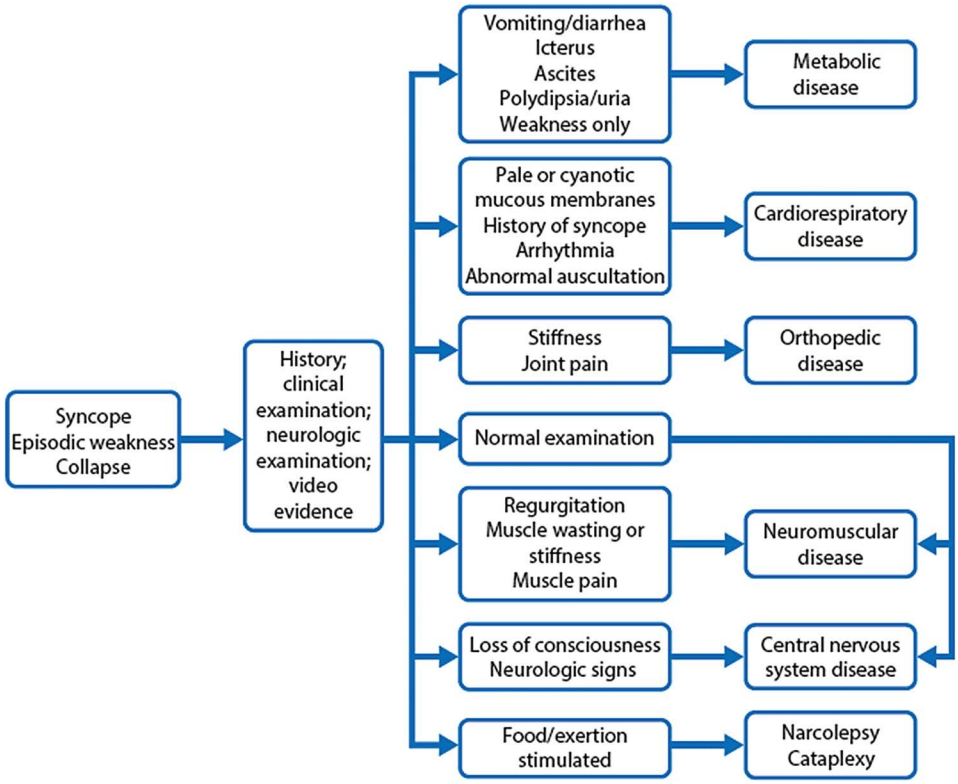

FIGURE 2.16.1 Algorithm for the general approach to the differential diagnosis of syncope, episodic weakness, and collapse.

if cardiorespiratory disease or megaesophagus is suspected. Contrast radiography or fluoroscopy can determine esophageal dilatation/function. Individual cases may have indication for CT/MRI investigation.

Muscle/Nerve Biopsy

Muscle biopsy is of particular value for the diagnosis of the inherited myopathies. Nerve biopsy can confirm axonal degeneration/regeneration, demyelination, and

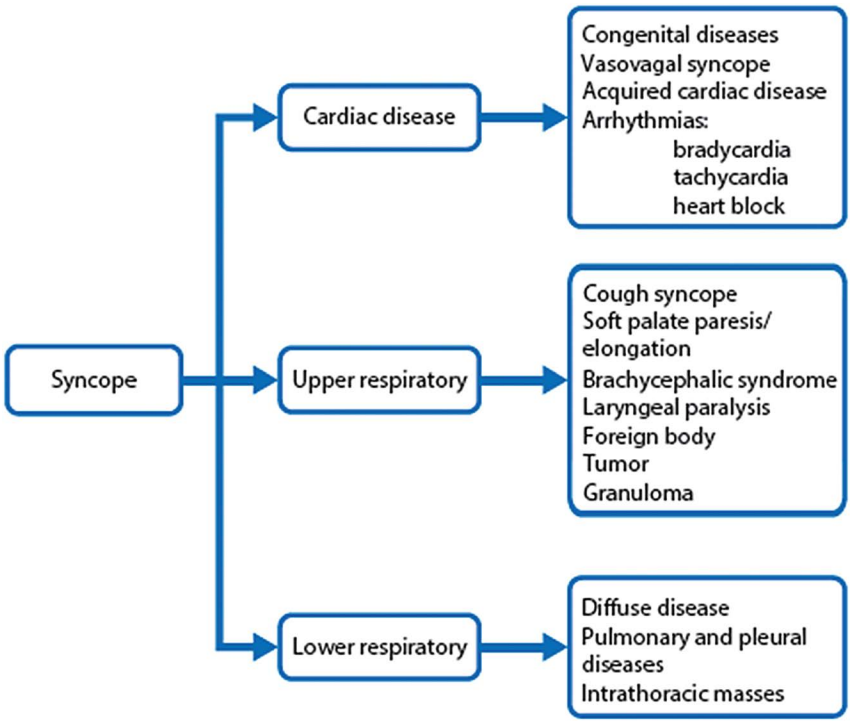

FIGURE 2.16.2 Algorithm for syncope.

TABLE 2.16.2 Differential diagnosis of weakness

Endocrine diseases	– Insulinoma – Hypoadrenocorticism – Hyperadrenocorticism (Cushing's myopathy) – Hypothyroidism (myopathy, neuropathy) – Hypoparathyroidism – Pheochromocytoma – Diabetes mellitus / ketoacidosis
Orthopedic diseases	– Degenerative joint disease (hips, stifles, spondylosis) – Polyarthritis – various types
Hematologic diseases	– Anemia – all causes – Myeloproliferative disease – Polycythemia – Hemoglobinopathies
Metabolic diseases	– Uremia – encephalopathy – Hyperglycemia / hypoglycemia – Hypernatremia / hyponatremia – Hypokalemia / hyperkalemia – Hypercalcemia / hypocalcemia – Acidosis – Hyperthermia – Hypoxia

Myopathies	– Inherited
	  – Labrador Retriever myopathy
	  – Sex-linked muscular dystrophies (dystrophin defects): Golden Retriever, Japanese Spitz
	  – Devon Rex cat myopathy
	  – Burmese cat hypokalemic myopathy
	  – Metabolic myopathies (e.g., pyruvate dehydrogenase deficiency)
	  – Myotonia
	  – Muscular dystrophies
	– Polymyositis
	  – *Infection:* Protozoan, viral, etc.
	  – Immune-mediated
	– Exertional myopathy
	– Malignant hyperthermia
	– Paraneoplastic (Lambert–Eaton syndrome associated with myasthenia gravis)
	– Nutritional
	– Endocrine–steroid, hypothyroid, hyperthyroid (cats)
	– Lipid storage myopathy
	– Miscellaneous
	  – Exercise-induced collapse (Labrador Retrievers)
	  – Ischemic myopathy (cat thromboembolism)

Neuromuscular junction	– Myasthenia gravis–acquired, congenital – Organophosphate toxicity – Tick paralysis – Snake bite (*Elapidae* and pit viper) – Botulism
Neurologic	– Episodic falling (Cavalier King Charles Spaniel) – Scottie cramp (also other breeds: Jack Russell, Norwich Terrier) – Narcolepsy / cataplexy (breed association) – Polyradiculoneuritis (Coonhound paralysis) – Inherited breed specific neuropathies – Motor neuron diseases – Endocrine (hypothyroid, insulinoma/ hypoglycemia, hyperlipidemia) – Neoplastic / paraneoplastic diseases – Distal denervating diseases – Lysosomal storage diseases – Axonopathies (e.g., Boxer)

fibrosis, findings that have diagnostic and/or prognostic significance.

Edrophonium Response

Slow intravenous administration of an ultrashort-acting anticholinesterase (0.1–1.0 mg edrophonium hydrochloride [Tensilon®]; note that this drug is no longer available in the United States and many other countries) is used for the diagnosis of MG. In dogs and cats with MG, there is a rapid improvement in the ability to exercise for several minutes.

Blood Gas Analysis

Blood gas analysis can assist with some cardiorespiratory diseases (hypoxemia) and some metabolic myopathies (metabolic acidosis with exercise).

Genetic Tests

Molecular (DNA) diagnostic testing is available for some inherited diseases (e.g., Burmese cat hypokalemic polymyopathy, Labrador Retriever myopathy, Japanese Spitz myopathy, narcolepsy). Your diagnostic laboratory should be consulted, or an internet search made for information on what diagnostic tests are available for that breed if you suspect a familial link.

CHAPTER 2

Common Clinical Problems
CHAPTER 2.17 Vomiting

Frédéric Gaschen

Introduction 90
Pathophysiology 90
Differential Diagnoses 91
Clinical Approach 91
Recommended Further Readings 93

INTRODUCTION

Vomiting is characterized by the forceful oral ejection of gastric content with or without addition of small intestinal content.

The vomiting response can be divided into three sequential phases. The prodromal phase is characterized by nausea with licking of the lips, yawning, hiding, and depression and occurs with hypersalivation and excessive swallowing. This is associated with relaxation of the lower esophageal sphincter and proximal part of the stomach. The second phase is retching, with retrograde giant small intestinal contractions that bring jejunal and duodenal chyme (and bile) back into the gastric lumen if the pylorus is patent, followed by rhythmic retching, inhibition of salivation, activation of the intercostal muscles, protection of the airways by laryngeal elevation, and increased upper esophageal sphincter tone. Finally, during the final expulsion phase, the cervical esophageal and pharyngeal tones decrease, the lower esophageal sphincter relaxes, the rectus abdominis muscle contracts, and the diaphragm squeezes the stomach. Breathing is momentarily inhibited, and the glottis is closed while the gastric content is propelled into the esophagus and ultimately out of the mouth.

Regurgitation, dysphagia (associated with oral and pharyngeal diseases), and coughing/gagging may be misinterpreted as vomiting by pet owners. Regurgitation is the passive oral evacuation of esophageal content associated with esophageal dysmotility, obstruction, and/or dilation (see Chapter 2.14 on Regurgitation). Typically, retching does not occur with regurgitation. Moreover, overall, regurgitation is less commonly observed because esophageal diseases are less common than disorders that trigger vomiting.

PATHOPHYSIOLOGY

The vomiting or emetic center is a conglomerate of nuclei located in the medulla oblongata. Vomiting can be elicited by activation of neural or humoral pathways. The emetic center is closely associated with the chemoreceptor trigger zone (CRTZ), an area lacking a blood–brain barrier where receptors are in direct contact with circulating blood. Stimulation of the CRTZ by blood-borne emetogenic substances (e.g., uremic toxins, endotoxins, drugs) is the basis of the humoral pathway of emesis. The emetic center may also be stimulated by the vestibulocochlear nucleus (e.g., motion sickness) and cortical centers. Additionally, it receives direct input from the peritoneum and abdominal organs via nerve fibers traveling with the vagus nerve, which constitutes the neural pathway of vomiting (Figure 2.17.1). The emetic center is responsible for the coordination of the vomiting

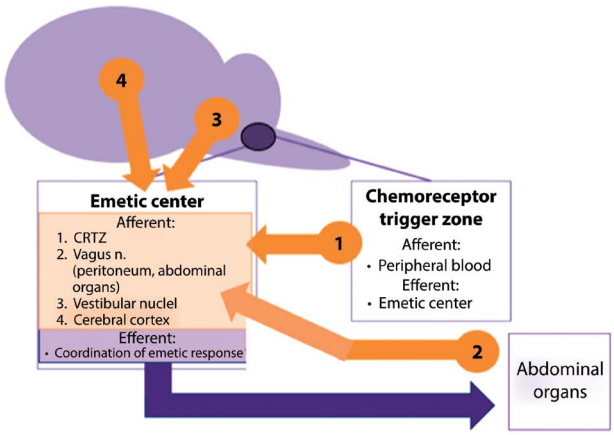

FIGURE 2.17.1 Afferent and efferent pathways to and from the emetic center and chemoreceptor trigger zone.

DOI: 10.1201/9781003254591-19

TABLE 2.17.1 Antiemetic drugs most commonly used in dogs and cats and their target receptors

Antiemetic drug	Target/antagonism	Dose and route	Other effects
Maropitant	NK1 receptors: Substance P antagonist	1 mg/kg per day SC or slowly IV (over 1–2 minutes)	
Metoclopramide	Dopamine2 receptor (D)	0.3–0.5 mg/kg SC q.8h. or 1–2 mg/kg CRI q.24h. (D)	Prokinetic effects on gastric antrum
Ondansetron	5-HT3 receptors in the CRTZ and afferent nerves	0.5–1 mg/kg slowly IV, p.o. q.8–12h. (D); 0.1–1 mg/kg slowly IV, IM, SC, p.o. q.6–12h. (C)	

C, cat; CRI, constant rate infusion; D, dog. If not specified, applies to both dogs and cats.

effort through efferent pathways. Numerous receptors are involved in the stimulation of vomiting, and some are the targets of antiemetic drugs (Table 2.17.1).

DIFFERENTIAL DIAGNOSES

A wide range of diseases may cause vomiting in dogs and cats through direct stimulation of the emetic center via afferent vagal branches or indirectly via stimulation of the CRTZ (Table 2.17.2). Diseases of the gastrointestinal (GI) tract generally act directly on the vomiting center through the neural pathway, while systemic disorders such as kidney diseases often stimulate the CRTZ via the humoral pathway.

CLINICAL APPROACH

Acute Vomiting

It is likely that many dogs and cats that experience a few episodes of acute vomiting are not presented for veterinary examination because the problem is self-limiting. If presenting to a veterinarian, acutely vomiting animals should be assessed for the severity of disease. A few episodes of vomiting in the absence of complications such as dehydration in an otherwise healthy animal may not require any further investigations or treatment, even though a bland diet and possible empirical prescription of antiemetics may be of benefit. However, dogs and cats that are ill need to undergo more detailed examination and investigations.

The most relevant differential diagnoses may differ on the basis of the animal's signalment. Younger animals are more prone to infectious diseases, such as parvovirus infection in dogs, and to ingestion of foreign objects.

A detailed history should be obtained. Important questions include diet, environment, duration and frequency of vomiting, relationship to eating, description of the vomiting process, appearance of the vomitus (e.g., presence of bile [Figure 2.17.2], hairballs [Figure 2.17.3], hematemesis (see Chapter 9, Digestive Diseases, Figure 9.26) frank blood, behavioral changes, and coexisting clinical signs, as well as previous illnesses, deworming history, and current medications. This information helps confirm the existence of vomiting, assess the disease severity, and may yield valuable data about any underlying disease(s).

TABLE 2.17.2 Common causes of vomiting in dogs and cats and their anatomic origin

Gastrointestinal	Outside gastrointestinal tract
Stomach – *Obstructive:* Gastric foreign body, space-occupying lesion in pylorus – Adverse reaction to food, including dietary indiscretion – *Infectious:* Viral, bacterial, parasitic – *Toxic:* Drugs, plants, chemicals – Chronic gastritis – Gastric neoplasia – Gastric ulcer – Gastric motility disorder	**Abdominal** – Acute and chronic recurring pancreatitis – Diseases of liver and biliary tree – Peritonitis – Diaphragmatic hernia – Neoplasia – Pyometra
Small bowel – *Infectious:* Viral, bacterial, parasitic – *Obstructive:* Foreign body, intussusception, space-occupying lesion – Adverse reaction to food, including dietary indiscretion – *Toxic:* Drugs, plants, chemicals – Inflammatory disease – Intestinal neoplasia – Paralytic ileus	**Metabolic** – Uremic syndrome – Electrolyte disorders – Acid–base disorders – Endocrine diseases – Hyperthyroidism (C), diabetic ketoacidosis, hypoadrenocorticism (D) – *Toxins:* Drugs, plants, chemicals – Sepsis, endotoxemia
Colon – Colitis – Severe constipation	**Neurologic** – Motion sickness – Vestibular disorders – Encephalitis/meningitis – Increased intracranial pressure – Psychogenic (excitation, fear, pain) – Dysautonomia

C, cat; D, dog. If not specified, applies to both dogs and cats.

A thorough physical examination should be performed. In cats particularly, it is important to visualize the sublingual frenulum by applying gentle dorsal pressure in the intermandibular space with a finger, searching for a piece of string looping around the base of the tongue at the origin of a linear foreign

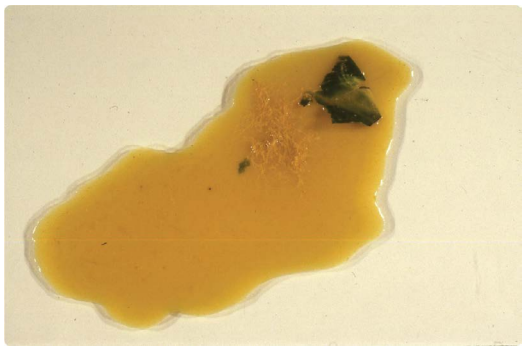

FIGURE 2.17.2 Canine vomit admixed with bile. (*Courtesy of M. Schaer.*)

FIGURE 2.17.3 Hairball vomited by a cat. (*Courtesy of M. Schaer.*)

FIGURE 2.17.4 A piece of thread (arrow) looped around the base of the tongue in a vomiting cat with a radiographic diagnosis of a linear foreign body. (*Courtesy of M. Schaer.*)

body (Figure 2.17.4). Abdominal palpation may reveal discomfort or pain (gastroenteritis, pancreatitis), or abdominal masses (foreign body, intussusception, granuloma, neoplasia). Hydration and cardiovascular status are important to guide the planning of fluid therapy.

In dogs presenting with acute vomiting, dietary indiscretion, GI foreign body, ingestion of toxic substances, and acute pancreatitis are the top four differential diagnoses and should be the focus of the initial diagnostic investigations (Figure 2.17.5). Gastric

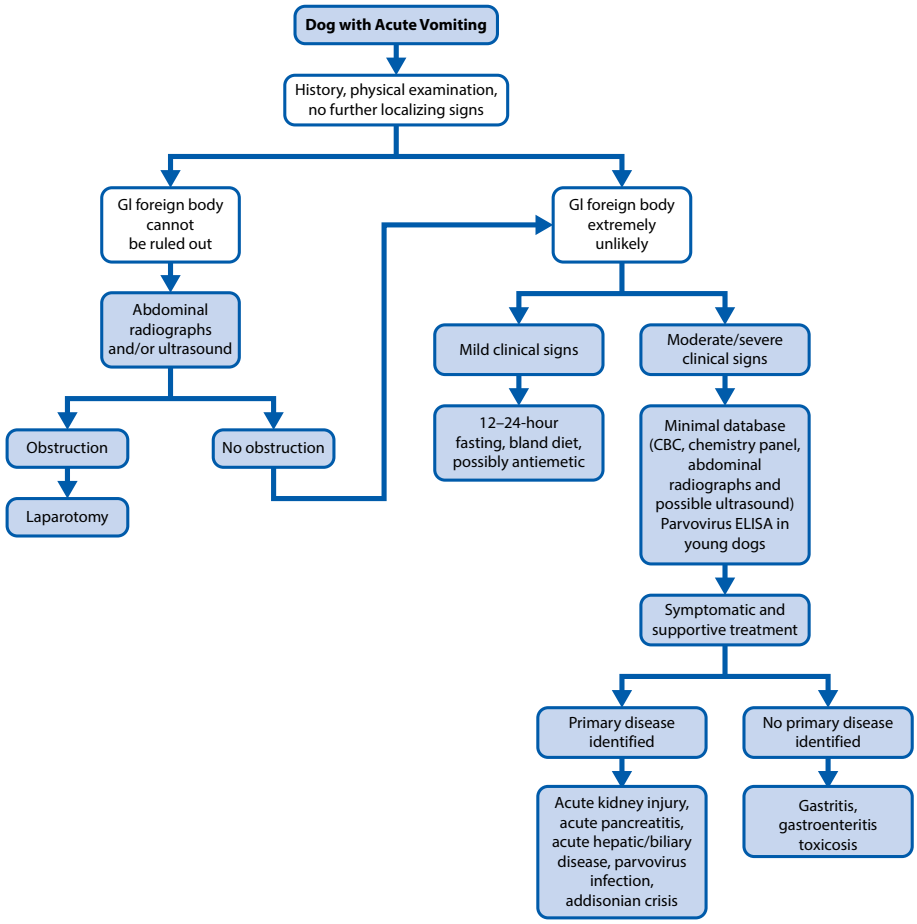

FIGURE 2.17.5 Algorithm for the clinical approach to acute vomiting in the dog after gastric dilatation-volvulus has been initially ruled out.

dilatation-volvulus (GDV) may be associated with vomiting, although the efforts are often unproductive. Moreover, abdominal distension with gastric tympany is often present and easily noticed. Abdominal radiographs are useful to evaluate gastric position and confirm the diagnosis of GDV. They are also necessary to rule out GI obstruction (two lateral views and a ventrodorsal view). Cats may ingest foreign bodies or chew on toxic plants; however, dietary indiscretion is less prevalent in this species, and pancreatitis is less commonly associated with significant vomiting.

Chronic Vomiting

Animals with chronic or chronic intermittent vomiting commonly have diseases affecting the digestive tract (including stomach, intestine, liver, and pancreas) or other organ systems such as the kidneys or the endocrine system. Sometimes, GI obstruction may take a more protracted course and should be ruled out by abdominal radiographs when supported by history and physical exam. Chronic vomiting is a more common presentation in cats (Figure 2.17.6). The search for an underlying cause is best started with a minimal database consisting of bloodwork (complete blood count [CBC], chemistry panel) and urinalysis to assess the function of various organ systems. A serum thyroxine level should be obtained in cats greater than 5 years old. Abdominal imaging (radiographs and/or ultrasound) can be carried out to assess the appearance of abdominal organs, including gastric and intestinal wall, kidneys, liver, and pancreas. If the primary problem cannot be identified based on the information obtained from the initial database, additional more specific tests can be performed in order to identify the primary problem. Cats may vomit chronically in the absence of any other problems (healthy chronic vomiters); this is sometimes associated with hairballs (Figure 2.17.3), but the cause often remains unknown. However, cats vomiting once weekly or more frequently should be examined to rule out an underlying disease. Moreover, increases in the vomiting frequency and onset of additional clinical signs such as hyporexia or weight loss also justify further investigations.

Treatment

Treatment of vomiting dogs and cats needs to focus on three points: (1) Stopping the vomiting process with judicious use of antiemetics (Table 2.17.1), particularly when vomiting is acute or frequent with debilitating consequences, (2) correcting the fluid and electrolyte deficits resulting from vomiting, and (3) addressing the underlying disease at the origin of vomiting.

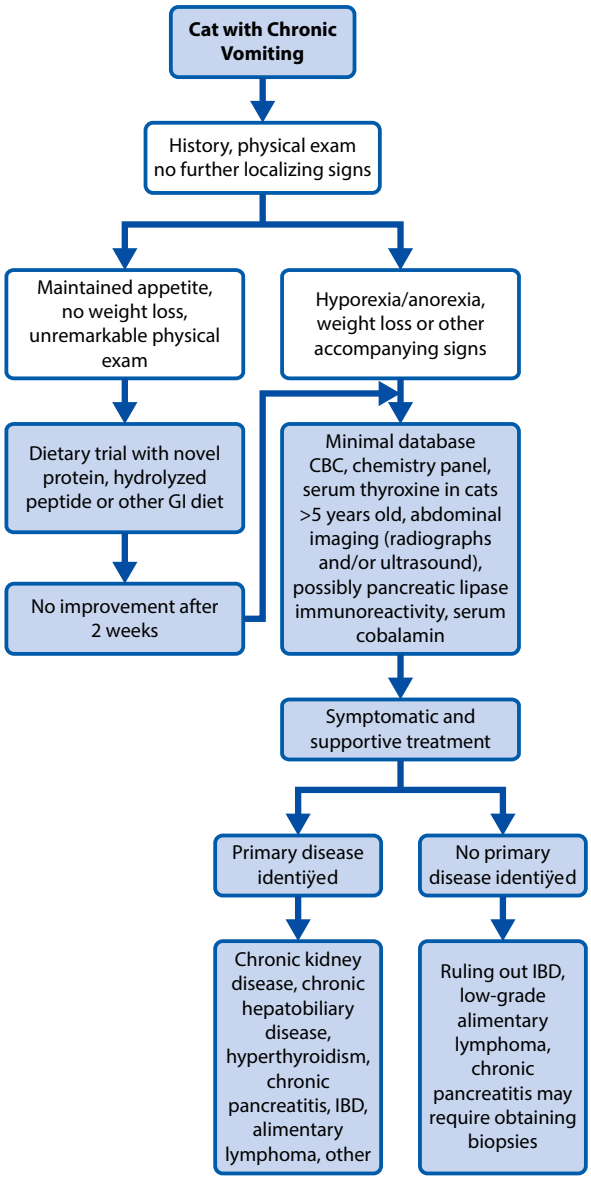

FIGURE 2.17.6 Algorithm for the clinical approach to chronic vomiting in the cat. IBD, inflammatory bowel disease.

BASICS OF THORACIC RADIOGRAPHY

Technique and Positioning

Choosing Thoracic Views

The effect of recumbency on lesion conspicuity requires consideration when selecting appropriate views to obtain of the thorax. The views chosen to complete a thoracic study impact visibility of pulmonary lesions due to recumbency-associated atelectasis. Given that most pulmonary lesions result in an increase in pulmonary opacity, requiring adjacent aerated lung to recognize, the effect of recumbency on lesion conspicuity is especially evident when clinical suspicion is present for aspiration or bronchopneumonia, pulmonary bullae, any unilateral or focal pulmonary disease, or when radiographs are obtained as a screening for metastasis (Figure 3.1a–c). As exact diagnosis is often unknown at the time of imaging due to overlapping clinical signs, many radiologists advocate 3- or 4-view thoracic studies, to include both lateral views and an orthogonal view as standard of care.

Positioning

To obtain a lateral view, position the animal in right or left recumbency and extend forelimbs as far as possible to remove superimposition over the cranial thorax. To avoid obliquity, a radiolucent positioning device such as a foam wedge is often needed at the level of the sternum, especially in deep-chested dogs. Rely on palpable

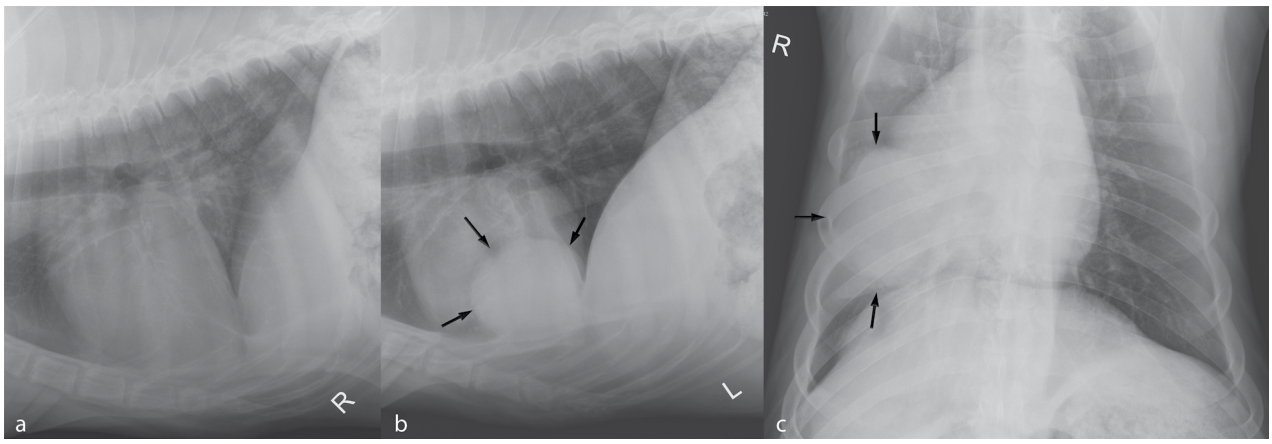

FIGURE 3.1 Right lateral (a), left lateral (b), and ventrodorsal (c) thoracic radiographs of a dog having a pulmonary mass. In spite of the large size of the mass (b and c, black arrows), it is nearly invisible on the right lateral view, while being well identified on the left lateral view. This variation in visibility of the mass with recumbency is due to poor aeration in gravity-dependent lungs when the dog is positioned on its right side, indicating that the mass is also right-sided. The mass is highlighted by adjacent aerated lung when the dog is positioned on its left side, making the mass clearly visible. The location of the mass as being right-sided is confirmed on the ventrodorsal view.

DOI: 10.1201/9781003254591-21

landmarks to appropriately center and collimate each view. Easily palpable landmarks include the thoracic inlet cranially and the proximal aspect of the 13th ribs caudally. The collimated beam should be centered at the caudal angle of the scapula, which is typically in the same plane as the central heart when forelimbs are extended (Figure 3.2a–c). The ventrodorsal or dorsoventral views should also be obtained with forelimbs extended with a radiolucent trough being an option to assist with positioning (Figure 3.3a–d). Sandbags, tape, and radiolucent wedges should be used to properly position patients and avoid personnel exposure. The entire thorax should be included each view, including the spine and the sternum. In some cases, patients are too large to fit onto one field of view and will require a cranial and caudal view. In such cases, it is also useful to obtain a view centered at the heart, especially when cardiac disease is a concern.

Exposure and Timing

Thoracic views should routinely be exposed on peak inspiration in order to maximize inherent contrast, using a low milliampere-seconds (mAs)/high kilovoltage peak (kVp) technique to reduce respiratory motion. Motion can also be limited by use of sedation. If full anesthesia is required, the patient must be intubated and the views obtained under positive pressure in order to avoid confounding results created by atelectasis, which can occur within 5 minutes when 100% inspired oxygen is used.

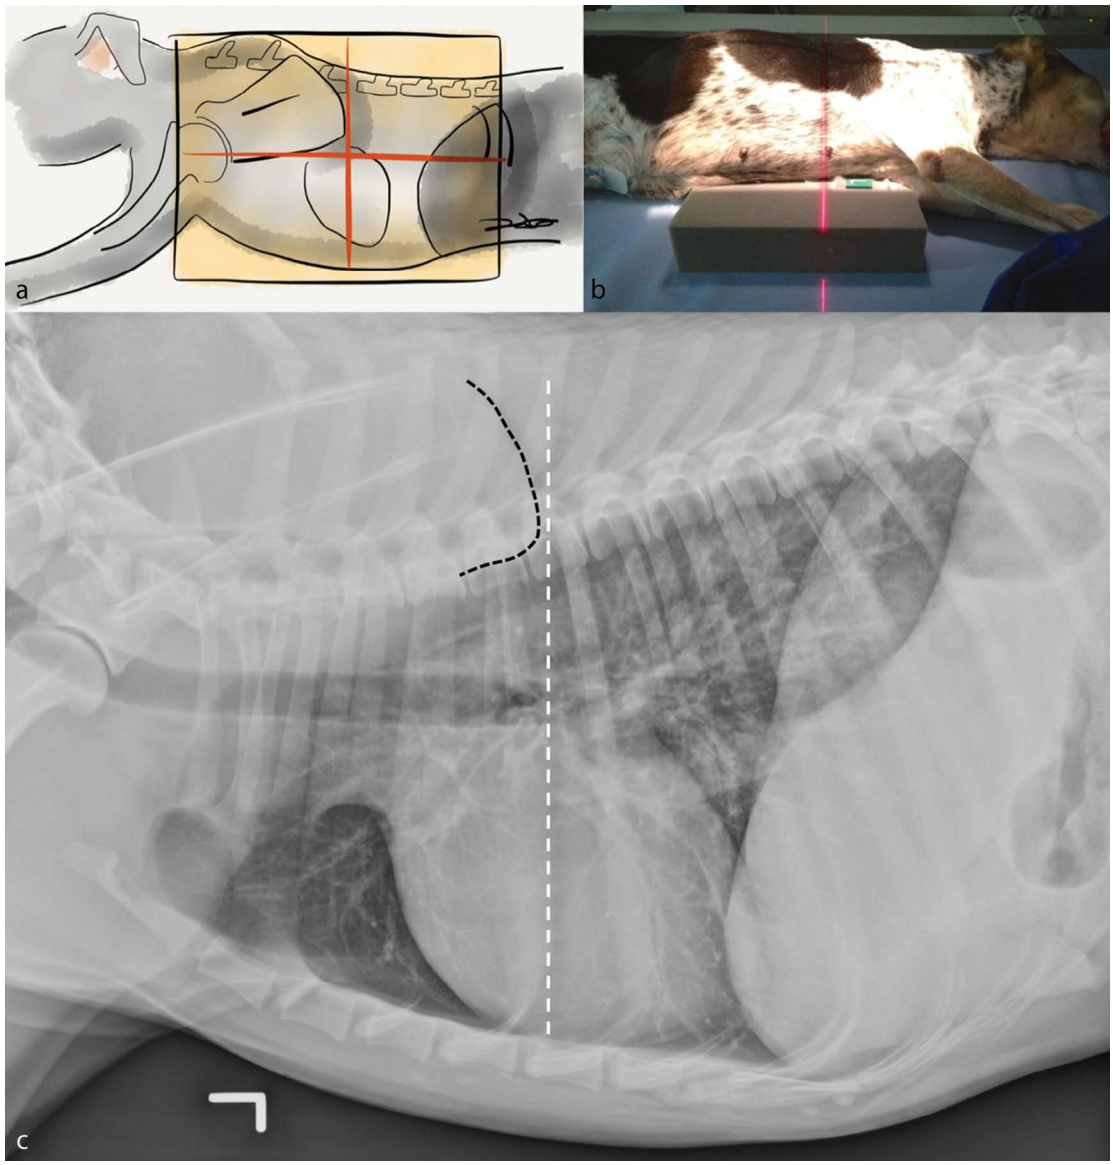

FIGURE 3.2 Palpable landmarks and positioning for a lateral thoracic view. The caudal angle of the scapula is a reliable landmark for centering the beam over the heart, as shown in (a) and (b). To correctly use this landmark and to limit superimposition over the cranial lungs, the forelimbs must be extended, as shown in part (c). A foam wedge is essential to preventing obliquity, in most cases. Radiographically the caudal angle of the scapula (dashed black line) is superimposed near the center of the heart (dashed white line).

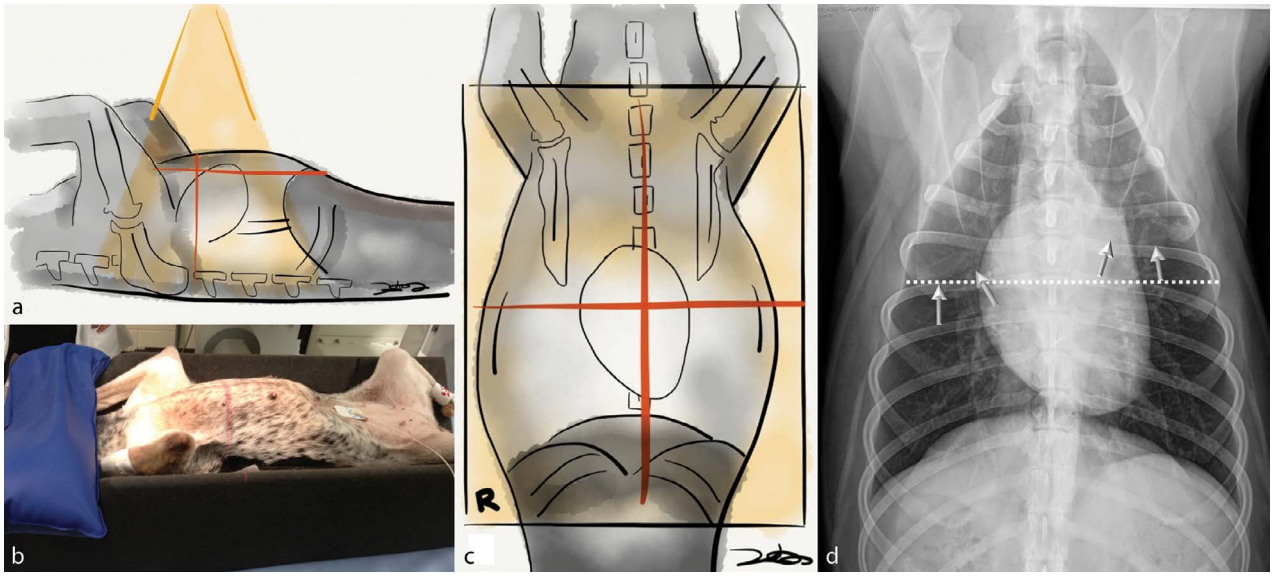

FIGURE 3.3 Positioning **(a–c)** to obtain a ventrodorsal view **(d)**. The thoracic inlet and the proximal aspect of the caudal ribs should be included to ensure all lungs are in the field of view. The view should be centered at the caudal angle of the scapula, a palpable landmark for the heart when forelimbs are extended. To avoid obliquity, a trough may be used, as shown in part (b). Sandbags can be used to avoid personnel exposure. On the ventrodorsal radiograph (d), the caudal margin of the scapulae (arrows) is superimposed near the plane of the center of the heart when the view is appropriately collimated and centered (dotted white line).

READING THE THORACIC RADIOGRAPH

Systematic Approach

Some indications for obtaining thoracic radiographs are listed in Table 3.1, and the influence of recumbency on the appearance of thoracic structures is detailed in Table 3.2. A systematic approach to interpreting thoracic radiographs will prevent the interpreter from seeking only an answer for the specific indication of the study and is essential to preventing abnormalities going undetected that may or may not relate to the presenting clinical complaint. A systematic approach also increases comfort level for interpretation of radiographic studies. A standardized protocol of thoracic views with each view being oriented and reviewed the same way each time allows the benefit of repetition to form a method that is thorough and more rapid than an approach that is haphazard and steered only towards viewing organs specifically associated with the indication for the study. All radiographic studies must be approached in the same way, analogous to completing a checklist of anatomical structures, as shown in Box 3.1.

Description

When an abnormality is detected during systematic evaluation of an imaging study, it must be described. The classic approach to radiographic description uses a list of signs: Size, shape, location, number, margination, and opacity. These can be used to prompt the interpreter of characteristics to consider when describing apparent lesions. Evaluating a lesion with respect to these descriptors ensures that the interpreter processes the abnormality thoroughly and has a starting point for researching causes of any lesions. These morphological descriptions are essential to recognizing abnormalities and differentiating their causes.

INTERPRETATION OF THORACIC ABNORMALITIES

1. Extrathoracic Structures

Extrathoracic structures should be evaluated early during interpretation, as the complexity of interpreting anatomy within the thorax can distract from investigating extrathoracic structures. The presence or lack of symmetry of the thoracic wall should be noted on the ventrodorsal/dorsoventral view. Oftentimes, enough of the abdomen is included to determine presence of cranial organomegaly or loss of detail. Regardless of whether lesions located in extrathoracic structures are related to clinical signs, they can influence appearance of structures within the thorax and should be noted prior to assessment of intrathoracic abnormalities.

Superficial Soft Tissues and Skeleton

Thoracic boundaries include the intercostal and paraspinal muscles, ribs, spine, diaphragm, and thoracic inlet. Opacities comprising the thoracic wall include soft tissue, fat, and mineral, and their appearance can vary based on conformation and body condition score. Lesions within the thoracic wall can be categorized as congenital or acquired. Additionally, acquired

TABLE 3.1 Indications for thoracic radiography

Indication	Associated clinical signs or history	Some common differential diagnoses

Thoracic barrier abnormality	– Palpable or visible defect
	– Thoracic wall pain
	– Known trauma
		– Rib or soft tissue thoracic wall mass
		  – Neoplasia
		  – Lipoma
		  – Sarcoma
		  – Abscess/cellulitis
		  – Trauma
		  – Migrating foreign body
		– Trauma
		  – Rib fracture
		  – Hematoma
		– Congenital malformation

Respiratory disease	– Cough
	– Dyspnea/tachypnea
	– Cyanosis
	– Exercise intolerance
	– Syncope
	– Altered respiratory sounds
		– Tracheobronchitis
		  – Inflammatory/allergic
		  – Infectious (viral, bacterial, parasitic)
		– Tracheomalacia/bronchomalacia
		– Bronchopneumonia/aspiration
		– Bronchiectasis
		– Tracheal hypoplasia
		– Cardiogenic edema
		– Noncardiogenic edema
		  – Near drowning
		  – Strangulation
		  – Electrocution
		  – Toxicity/drug reaction
		  – Neurogenic
		  – Barotrauma
		  – Acute lung injury (ALI) or acute respiratory distress syndrome (ARDS)
		  – Re-expansion pulmonary edema
		  – Aspiration of irritant
		  – Overhydration
		  – Vasculitis
		  – Uremic pneumonitis
		– Upper airway obstruction
		  – Tracheal/bronchial foreign body
		  – Mural abnormality
		  – Extramural compression by mass or cardiac enlargement
		– Interstitial infiltration
		  – Pneumonitis
		  – Inflammatory/allergic
		  – Infectious
		  – Neoplasia (e.g., lymphoma)
		– Pulmonary mass(es)
		  – Neoplasia
		  – Abscess
		  – Granuloma
		  – Cyst
		  – Hematoma
		– Pulmonary fibrosis
		– Hemorrhage
		– Lung lobe torsion
		– Anomaly
		  – Kartagener's syndrome or ciliary dyskinesia
		  – Surfactant deficiency

Cardiovascular disease	– Audible murmur
	– Dyspnea/tachypnea
	– Exercise intolerance
	– Syncope
	– Cough
	– Altered respiratory sounds
	– Cyanosis
	– Arrhythmia
		– Acquired cardiac diseases
		  – Endocardiosis
		  – Cardiomyopathy
		  – Heartworm infection
		– Congenital cardiac diseases
		  – Intra- and extracardiac shunts (L → R or R → L)
		  – Valvular malformations
		– Pericardial disease/effusion
		– Cor pulmonale

(*Continued*)

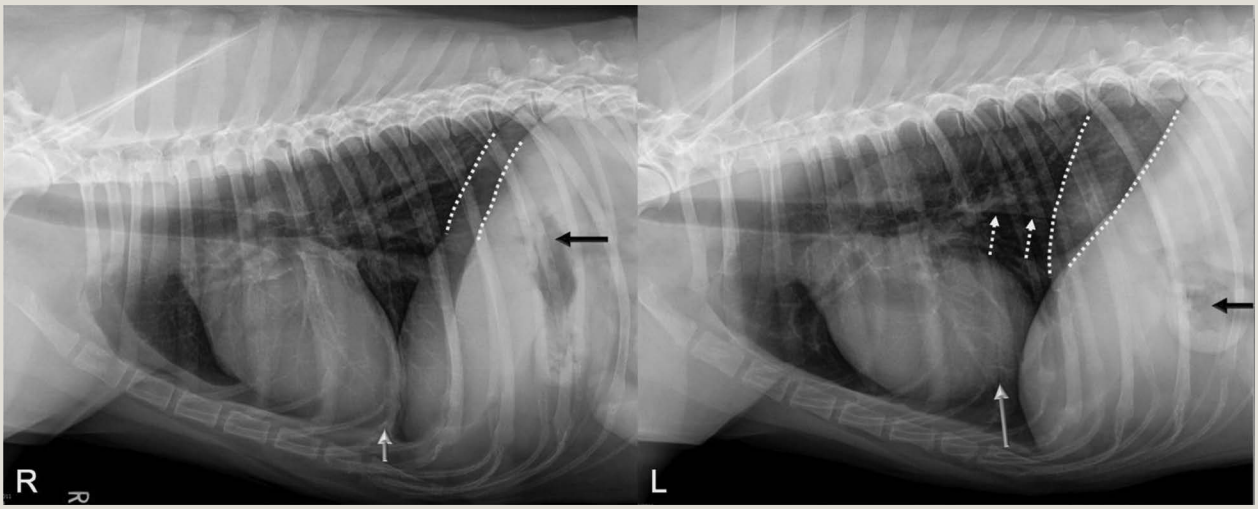
TABLE 3.1 Indications for thoracic radiography (*Continued*)

Indication	Associated clinical signs or history	Some common differential diagnoses

Pleural disease	– Dyspnea/tachypnea
	– Exercise intolerance
	– Altered respiratory sounds (decreased)
	– Decreased audibility of heart
		– Pleural effusion
		  – Transudates
		  – Exudates
		  – Hemorrhage
		  – Chyle
		– Pneumothorax
		– Diaphragmatic rupture
		– Pleural mass

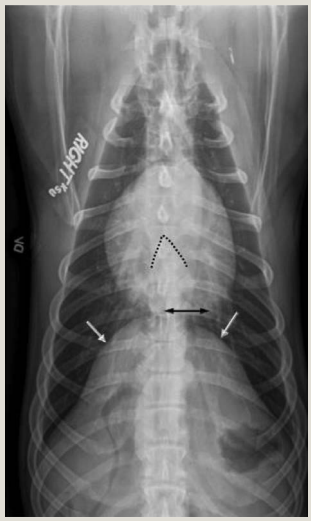
Mediastinal disease (noncardiac)	– Regurgitation/dysphagia
	– Dyspnea/tachypnea
	– Exercise intolerance
	– Altered respiratory sounds
		– Megaesophagus – generalized
		  – Metabolic
		  – Congenital
		  – Esophagitis
		– Focal esophageal dilation – esophageal obstruction
		  – Luminal foreign body
		  – Mural lesion
		  – Extraluminal compression
		  – Vascular ring anomaly
		  – Hiatal herniations
		– Mediastinal mass
		  – Lymph node (lymphoma)
		  – Thymus
		– Tracheal compression/obstruction
		– Pneumomediastinum
		– Mediastinitis

Trauma	– Dyspnea/tachypnea – Altered respiratory sounds – Thoracic wall pain – Palpable or visible thoracic wall defect	– Pulmonary contusions – Rib fractures – Pneumomediastinum – Pneumothorax and/or pleural hemorrhage – Shock – Diaphragmatic rupture
Systemic disease	– Fever – Lethargy – Weight loss – Neoplasia	– Numerous potential causes
Screening test	– Geriatric patient – Pre-anesthetic	– Maybe none
Monitor response to treatment	– Improved or worsened clinical signs	



abnormalities can be further categorized as traumatic or nontraumatic and as originating from skeleton versus soft tissue.

Congenital thoracic wall abnormalities include vertebral body malformations, transitional vertebrae, and sternal anomalies, such as pectus excavatum or carinatum. Most of these abnormalities do not create clinical signs requiring correction but can affect the overall appearance of intrathoracic structures, especially if the abnormality alters cardiac position or pulmonary inflation potential.



Differential diagnoses for thoracic wall mass are typical of a mass at any location and include neoplasia (skeletal or soft tissue), abscess/cellulitis, hematoma, granuloma, and cyst. Ranking of these differential diagnoses is based on full description of the abnormality along with clinical history. Neoplasia, cellulitis/abscess, and hemorrhage/hematoma formation are the three most likely causes of a thoracic wall mass.

Lipomas are the most common thoracic wall neoplasms. Most often, these are benign, slow-growing, well-demarcated nodules or masses that are located in the subcutaneous soft tissues, recognized by their fat opacity rather than soft tissue opacity. Nonlipomatous, focal, acquired nodules or masses associated with the thoracic wall may be soft tissue or mineral opaque. They may be broad-based (sessile) or have a stalk-like attachment to the thoracic wall (pedunculated). Neoplastic thoracic wall lesions are most often sarcomas originating from ribs, with primary osteosarcoma and chondrosarcoma being the most common. Radiographically visible rib lysis or periosteal proliferation are indicators of aggression (Figure 3.4a–c). Care must be taken to correctly categorize a lesion as originating within

TABLE 3.2 Influence of recumbency on the appearance of thoracic structures

Lateral view	
Right	**Left**
	

– Heart more elongated (apex contacts sternum, white arrow)
– Diaphragmatic crura parallel (dotted line)
  – Right crus more cranial
– Gas located in gastric fundus (black arrow)
– Esophagus often not visible
– Assess left-sided lungs
	– Heart more rounded (apex can appear elevated, white arrow)
	– Diaphragmatic crura diverge (dotted line)
	  – Left crus more cranial
	– Gas located in pylorus (black arrow)
	– Esophagus more readily seen (dotted arrow)
	– Assess right-sided lungs

Ventrodorsal/dorsoventral view	
Ventrodorsal	**Dorsoventral**
	
– Diaphragmatic crura seen (white arrows) in addition to the central cupola – Increased distance between cardiac apex and diaphragm – Heart elongated – Apex closer to midline (black double arrow) – Increased apparent divergence of principle bronchi (dotted line) – Accessory lung lobe better aerated and better assessed – Caudal vena cava better seen	– Only the cupola of the diaphragm is seen, creating a dome shape (white arrows) – Contact between diaphragm and cardiac apex – Heart rounded – Apex positioned further to left (black double arrow) – Position of principle bronchi less divergent (dotted line) – Caudal lung lobes better aerated and better assessed – Caudal lobar vessels better seen

Box 3.1 Systematic evaluation of the thorax

- Extrathoracic structures
  - Superficial soft tissues (skin, fat, muscle)
  - Skeleton (spine, sternum, ribs, visible forelimbs)
  - Diaphragm
  - Visible abdomen
- Pleural space
- Noncardiac mediastinum
  - Mediastinal reflections
  - Trachea
  - Esophagus*
  - Vascular structures (aorta, caudal vena cava, azygous*, etc.)
  - Thymus†
  - Sternal, cranial mediastinal, and tracheobronchial lymph nodes*
  - Lymphatics*
- Heart, great vessels, and pericardium
- Lungs
  - Airway (bronchi, bronchioles*, and alveoli*)
  - Pulmonary arteries and veins
  - Interstitium (elastic fibers, collagen, fibroblasts, smooth muscle, mast cells, mononuclear cells)

* Structures not radiographically visible in a normal animal.
† Structure not normally visible in a mature animal.

the thoracic wall rather than within lung, as differential diagnoses appropriate to the organ of origin must be assigned. Lesions extending into the thorax may be mistaken as having a pulmonary organ of origin. Lysis or periosteal proliferation of the skeleton of the thoracic wall is evidence of a thoracic wall lesion. Also, the presence of an extrapleural sign can differentiate mass lesions as being associated with thoracic wall rather than pulmonary. An extrapleural sign occurs when the margin of a thoracic wall lesion has a broad-based contact with the wall, and an obtuse angle is formed between the lesion and the normal pleural surface. This localizes a lesion to the extrapleural space, to include any structure superficial to the parietal pleura. A lung lesion would be expected to have a narrower point of contact, creating an acute angle between the mass and the thoracic wall. An extrapleural mass not located on tangent with the thoracic wall can create an apparent acute angle, falsely appearing pulmonary rather than extrapleural in origin (Figure 3.4a–c).

Most thoracic wall masses associated with neoplasia or infection are palpable on physical examination. The benefit of radiographic examination is to determine opacity and, therefore, potential tissue type of the mass, involvement of bone, or presence of intrathoracic extension.

In cases of trauma, hematoma formation may result in a soft tissue mass of the thoracic wall. The presence of concurrent rib fractures can also deform the thoracic wall, with serial and segmental rib fractures being most apt to create an alteration in thoracic shape on physical exam and radiographically, potentially resulting in paradoxical chest wall movement indicative of flail chest.

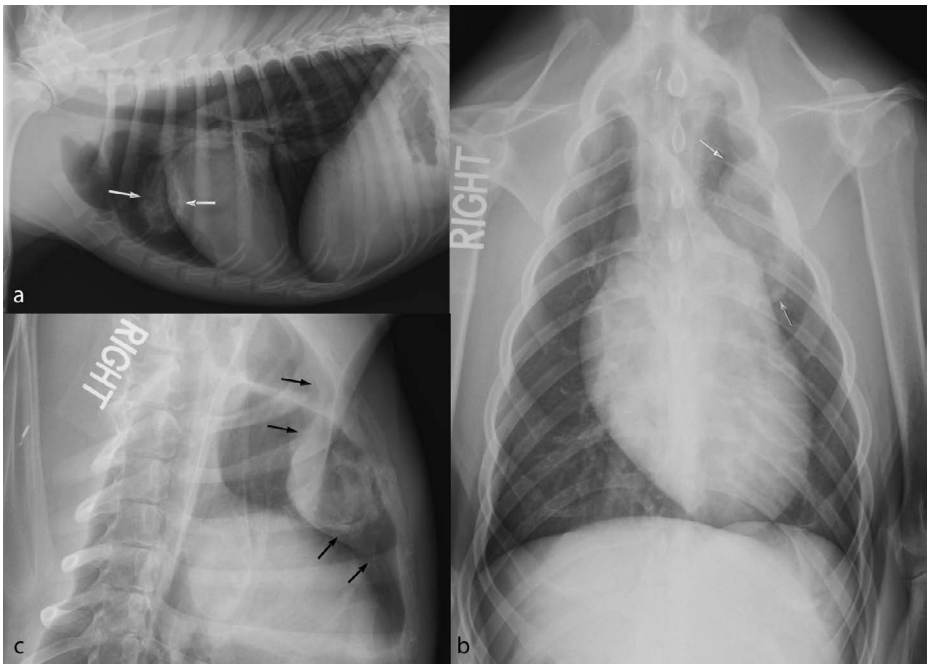


FIGURE 3.4 Extrapleural sign in a dog having chondrosarcoma of the left 3rd rib. A focal region of expansile rib lysis and surrounding mass are present within the left cranial thoracic wall (a and b, white arrows). On lateral and humanoid ventrodorsal projections **(a** and **b)**, the mass appears to have a narrow-based point of contact and creates an acute angle with the thoracic wall. On an oblique image obtained to view the lesion at its junction with the thoracic wall **(c)**, the soft tissue component of the mass is clearly broad-based, creating an obtuse angle between it and the thoracic wall (black arrows). The broad-based point of contact combined with the visible rib lysis confirms an extrapleural origin for the mass.

Diaphragm and Cranial Abdomen

The diaphragm defines the caudal thoracic boundary. On a normal thoracic study, the diaphragm should be positioned near the 11th or 12th thoracic vertebra on full inspiration. A diaphragmatic position cranial to this may indicate a technical failure to expose the view on inspiration and should be corrected, if so. If not due to technical factors, a cranially positioned diaphragm may be categorized as a primary disturbance of the diaphragm itself or secondary to abdominal or thoracic abnormalities. Primary diaphragmatic pathology is rare and includes unilateral or bilateral paralysis and malformation of the muscle itself (diaphragmatic eventration). Secondary causes may be related to increased abdominal mass or abnormalities within the lungs or pleural space. A caudally positioned diaphragm is typically not associated with any technical error, although extreme inspiration can result in a diaphragm that is positioned at T13 or caudally. Additional causes of a cranially or caudally positioned diaphragm are shown in Table 3.3. Diaphragmatic malpositioning may be unilateral or bilateral.

Loss of distinction of diaphragmatic margins is most often due to border effacement associated with pleural or pulmonary disease. If the diaphragm is effaced, its integrity should be questioned.

2. Pleural Space

The thoracic boundaries (thoracic wall and diaphragm) are lined by parietal pleura. The parietal pleura reflects onto itself dorsally to surround the right and left lungs forming a continuation, called the visceral pleura, that is tightly adhered to the lung surface. The two layers of pleura surrounding the right and left lungs form the pleural sacs. The pleural sacs each create boundaries of the mediastinum, which lies primarily on midline. The visceral pleura surrounding each lung lobe extends between each lobe as the lungs exit the hilus, creating fissures between each lobe that can be radiographically evident in cases of pleural disease.

Soft Tissue Opacity in the Pleural Space – Pleural Effusion

Pleural effusion is the accumulation of fluid within the pleural space. As the fluid volume exceeds 100 mL, it becomes radiographically evident in most dogs and cats. Several radiographic signs indicate the presence of pleural effusion as shown in Box 3.2 and Figure 3.5a, b. Oftentimes, multiples of these signs are present on each thoracic view, increasing support for diagnosis of pleural effusion. The visibility of each radiographic sign is more pronounced with increasing fluid volumes.

The position of the animal has an influence on the visibility of each of the radiographic signs presented in Box 3.2. First, pleural fissure lines are less prominently seen on the dorsoventral view than the ventrodorsal view. Also, the visibility of the cardiac silhouette varies with sternal or dorsal recumbency, as shown in Figure 3.6a, b. The heart is a soft tissue opaque, ventrally located structure. When the animal is placed in sternal recumbency, fluid within the pleural space moves ventrally and will surround the heart, causing border effacement of its margins. Oftentimes, the margins of the cardiac silhouette are readily visible when animals having pleural fluid are positioned in dorsal recumbency and a ventrodorsal view is obtained.

TABLE 3.3 Pathologic causes of unilateral or bilateral abnormal diaphragmatic positioning

Cranially positioned diaphragm	Caudally positioned diaphragm

– Study exposed on expiration
– Obese patient
– Abdominal mass effect
– Pulmonary atelectasis
– Upper airway obstruction
– Pain with inspiration
– Diaphragmatic paralysis (rare)
– Diaphragmatic eventration (rare)
	– Exaggerated inspiration
	– Air trapping (lower airway obstruction)
	– Pulmonary emphysema
	– Increased intrapleural/intrathoracic volume
	  – Pneumothorax
	  – Pleural effusion
	  – Thoracic mass(es)

Box 3.2 Radiographic signs indicating pleural effusion

- Separation of lungs from the thoracic wall by fluid opacity
  - Secondary decreased lung volume creating interstitial or alveolar pulmonary patterns
- Presence of pleural fissure lines that widen at the periphery seen on lateral and ventrodorsal views
- Blunting of the right and left costophrenic angles seen on the ventrodorsal view
- Scalloping of ventral lung margins on the lateral view(s)
- Border effacement of the mediastinum, heart, thoracic wall, and diaphragm
  - A hallmark of pleural effusion is effacement of the heart on the DV view and visibility of the heart on the VD view
- Increased thoracic diameter with severe fluid accumulations

Causes of Pleural Effusion

Pleural effusion could be due to primary pleural pathology or secondary to a systemic disease process. Since the causes of pleural effusion are numerous, categorizing differentials based on potential fluid type (transudates including modified transudates, exudates, hemorrhage, and chyle) can assist with considering differential diagnoses that can be a source of each. Causes for each of these types are shown in Table 3.4. The most common causes of pleural effusion in both dogs and cats are pyothorax, neoplasia, and cardiac failure. In many cases, the identification of the underlying cause of pleural effusion requires fluid analysis, systematic clinical workup, and advanced imaging such as thoracic ultrasound or computed tomography.

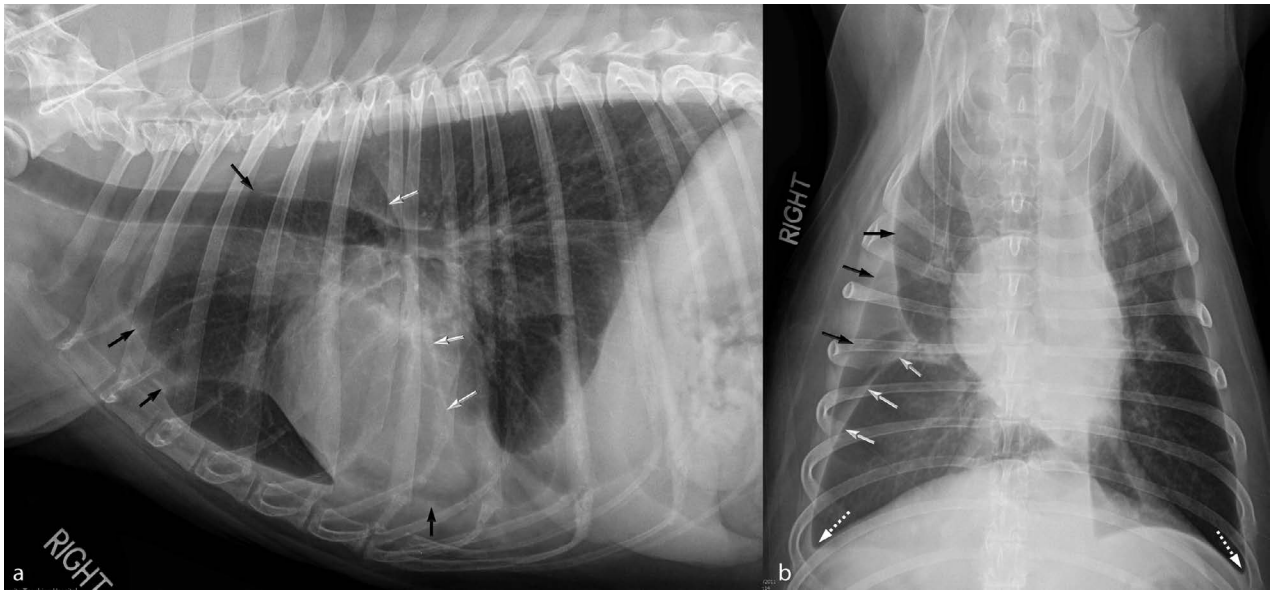

FIGURE 3.5 Right lateral **(a)** and ventrodorsal **(b)** views of a dog having moderate pleural effusion. There is separation of the lungs from the thoracic wall by fluid opacity (black arrows). Pleural fissure lines are present that widen at the peripheral aspect of the thorax further from the hilus (white arrows). The right and left costophrenic angles are blunted (dotted white arrows). Additionally, there is border effacement of the cardiac apex and ventral diaphragm on the lateral view (a). The presence of each of these findings will be more pronounced with increased fluid volumes.

Keys to Interpreting Cases with Pleural Effusion

Interpretation of thoracic studies having pleural effusion can be a challenge. Especially with moderate-to-severe fluid volumes, the visibility of soft tissue thoracic structures such as the heart, mediastinum, and pleural margins can be effaced, leaving many structures uninterpretable. In such cases, rely on clues that are visible in order to diagnose or at least rule out sources of pleural effusion, keeping in mind that pleural effusion is typically a secondary process, and nonpleural disease is often the cause of pleural effusion. Steps that can be used to investigate causes of pleural effusion are shown in Box 3.3.

Mediastinal masses often result in concurrent pleural effusion that can effectively efface the margins of the mass. An alteration in tracheal positioning, which remains readily distinct due to its being aerated, can be

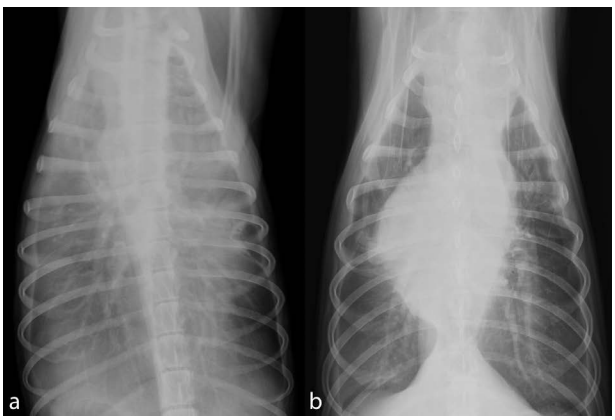

FIGURE 3.6 The mobility of fluid in the pleural space in sternal **(a)** and dorsal **(b)** recumbency. When an animal is positioned in sternal recumbency (a), gravity-dependent fluid accumulates ventrally and surrounds the ventrally located heart. Because the heart and fluid are of identical opacity and are in direct contact with each other, margins become effaced. When an animal is positioned in dorsal recumbency (b), the fluid accumulates dorsally. Lungs rise to the nongravity-dependent part of the thorax, which is ventral and surrounds the heart, making its margins evident.

TABLE 3.4 Causes of pleural effusion

Fluid type	Underlying causes
Transudates and modified transudates	– Congestive heart failure or systemic venous obstruction – Hypoproteinemia – Diaphragmatic translocation of peritoneal effusion – Diaphragmatic rupture – Neoplasia – Vasculitis – Lung lobe torsion – Pleuritis, mediastinitis
Exudates (septic/pyothorax or nonseptic inflammatory)	– Primary lung disease (pulmonary abscess or pneumonia) – Pleuritis, mediastinitis – Foreign body migration (grass awn)
Hemorrhage (hemothorax)	– Coagulation deficit – Trauma – Neoplasia
Chyle (chylothorax)	– Obstruction of lymphatic return (congestive heart failure, neoplasia) – Ruptured lymphatics (trauma, neoplasia)

Box 3.3 Next steps in analysis of cases with pleural effusion

- Obtain all four radiographic projections so that all lung fields, the mediastinum, and the cardiac silhouette can be best assessed
  - Ensure that the entire thoracic wall, including all ribs, are visible in the study
- When evaluating the radiographic study, pay close attention to the following:
  - Cardiac size and shape (need VD view)
  - Tracheal positioning for evidence of a cranial mediastinal mass
  - Ribs, sternum, and spine for evidence of an extrapleural lesion
  - Lungs for evidence of masses or nodules (all four views may be needed)
  - Bronchi for alterations in position or blunting, possibly indicating lung lobe torsion
  - Presence of a mediastinal shift in the face of bilateral pleural effusion indicating a thoracic mass or diaphragmatic rupture
  - Presence of abdominal disease at the edge of the study
  - Lung margination as being sharp or rounded
- Tap the fluid and repeat radiographic views
- Perform analysis of tapped fluid
- Perform thoracic ultrasonography or computed tomography

an indicator of a mass effect, regardless of the visibility of a mass itself. Marked deviation or compression of the trachea are indicators of potential underlying mediastinal mass effect, as shown in Figure 3.7a, b. In cases of pleural effusion, the trachea will elevate to some degree, but its path should remain straight with no focal changes in direction. Also, the tracheal hilus should be located at the 5th or 6th intercostal space in a normal animal or an animal having only pleural effusion. If a mediastinal mass is large enough, caudal displacement of the hilus may result. The cranial mediastinum is best assessed on the ventrodorsal view in cases of pleural effusion, as most masses are ventrally located and are effaced by any fluid located ventrally.

Primary or metastatic neoplasms resulting in pulmonary masses or nodules can be obscured by pleural effusion. In cases of moderate-to-severe pleural effusion, the lung volume will be decreased. This results in a secondary atelectasis and an increase in pulmonary opacity that is typically most severe in the cranial or right middle lung lobes. When atelectasis is severe, interpretation of lungs as normal or abnormal is impossible and can preclude visibility of masses and nodules. Additionally, border effacement of the heart, mediastinum, and thoracic wall by fluid can prevent interpretation of these structures. Removal of fluid and repeat radiographic examination can increase visibility of mass(es) within the thorax, as shown in Figure 3.8a, b. As with removal of any tissue, unless a diagnosis is known, the fluid sample should be analyzed for evidence of its underlying cause.

Soft Tissue Opacity in the Pleural Space – Diaphragmatic Rupture

Separation of the lungs from the thoracic wall by soft tissue opacity and border effacement of the diaphragm are most often caused by pleural fluid; however, these signs may be due to soft tissue rather than fluid. Diaphragmatic rupture must always be considered in thoracic studies where pleural soft tissue opacity is present and the diaphragmatic margins are effaced such that its integrity cannot be confirmed. In many cases

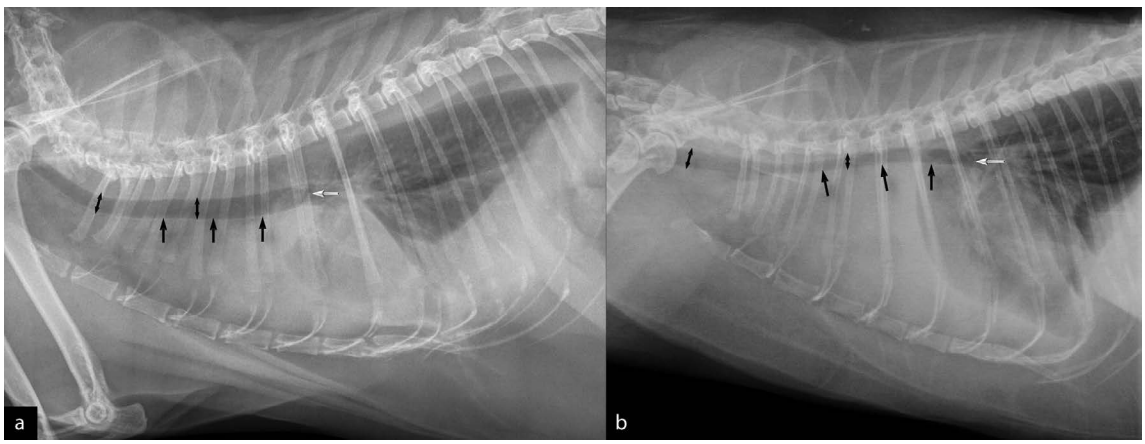

FIGURE 3.7 Lateral thoracic radiographs of a cat having only pleural effusion (a) and a cat having a mediastinal mass with concurrent pleural effusion (b). In the cat with pleural effusion, the trachea is mildly uniformly elevated (a, black arrows) due to the pleural fluid and the influence it has on lung and, subsequently, tracheal positioning. The tracheal hilus is in a normal position located at the junction between the 5th and 6th intercostal spaces (a, white arrow). Additionally, the tracheal lumen remains similar in diameter throughout its length (a, double-headed arrows). In the cat having concurrent pleural effusion and a cranial mediastinal mass, the trachea is markedly elevated and focally deviated in the region of the cranial mediastinum (b, black arrows). The trachea is compressed, as seen by a decrease in diameter at the level of the tracheal deviation (b, double-headed arrows). The tracheal hilus is also caudally displaced and is located at the center of the 7th intercostal space (b, white arrow).

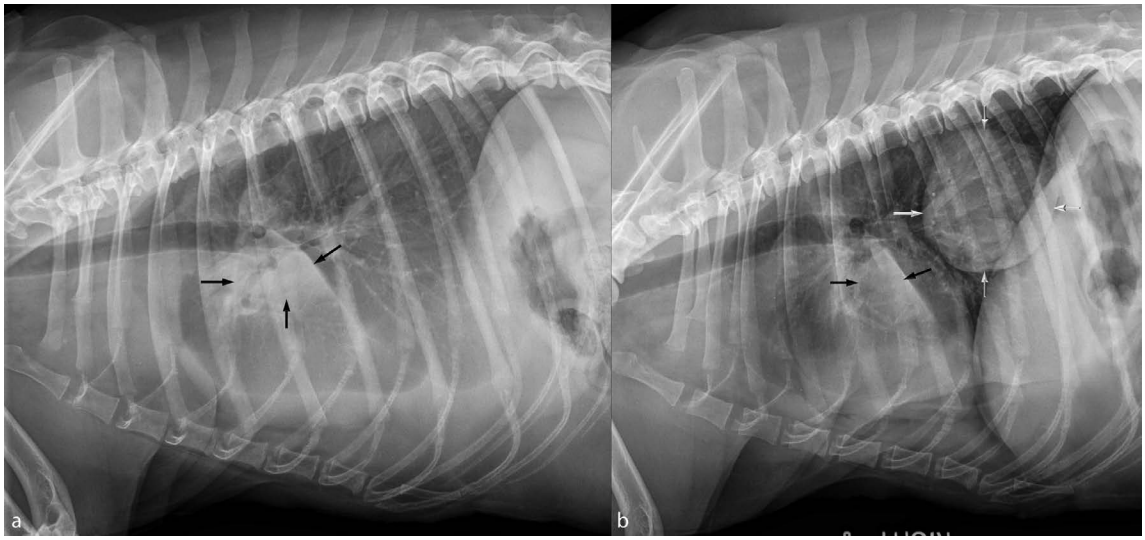

FIGURE 3.8 Right lateral views of the same dog before (a) and after tapping (b) pleural effusion that was secondary to a primary pulmonary carcinoma of the right caudal lung lobe. Prior to tapping (a), a pulmonary mass is not visible due to the presence of marked pleural effusion. A general increase in pulmonary opacity is present that is most severe near the tracheal hilus, where an alveolar pulmonary pattern is seen (a, black arrows). This is typical of the location for atelectasis when complete lung expansion is prevented by pleural fluid. After tapping the fluid, a well-defined, round mass within the caudal lung is clearly evident (b, white arrows). Cytologic fluid analysis was consistent with carcinoma. The region of atelectasis, though not completely resolved, is diminished (b, black arrows).

of diaphragmatic rupture, concurrent pleural effusion is present along with herniated abdominal organs, complicating radiographic confirmation of herniation. Several radiographic signs shown in Box 3.4 and Figure 3.9a, b raise suspicion of diaphragmatic rupture above that of pleural fluid occurring alone.

Soft Tissue Opacity in the Pleural Space – Pleural Masses

In addition to herniated abdominal organs, neoplasia or severe pleuritis can be responsible for pleural mass lesions. Oftentimes, concurrent, mobile pleural fluid is also present, resulting in border effacement of the pleural mass, rendering the soft tissue component invisible. Similar to diaphragmatic rupture with abdominal organ herniation, pleural masses due to neoplasia or pyogranulomatous pleuritis can be large enough to create a thoracic mass effect recognized as a deviation of the heart, trachea, or lungs away from the lesion (contralateral mediastinal shift). Again, the mediastinal shift may be the only indication of a pleural mass versus mobile pleural effusion that tends to distribute evenly.

Box 3.4 Radiographic signs indicating diaphragmatic rupture

- Partial border effacement of the diaphragm that is more prominent on one side versus the other
- Separation of lungs from the thoracic wall by soft tissue/fluid opacity that is more prominent in one hemithorax versus the other
- Contained tubular or round gas opacities within the thorax or crossing the diaphragm
- Decreased abdominal contents within peritoneal space
  - Absence of visible organs
  - Wasp-waist appearance to abdominal wall
- Cranially displaced gastric axis
- Evidence of pleural mass effect
  - Contralateral mediastinal shift with displaced heart and trachea away from the hemithorax having the most pleural opacity

Gas Opacity in the Pleural Space – Pneumothorax

Pneumothorax is accumulated gas within the pleural space between parietal and visceral pleura. It has multiple potential causes that are categorized as traumatic, spontaneous, or iatrogenic, as shown in Table 3.5. Pneumothorax may also be categorized as open or closed. An open pneumothorax implies a penetrating or perforating trauma with extension of air from the environment into the pleural space. Closed pneumothorax occurs when the respiratory system is the source of gas within the pleural space. Trauma is the most common underlying cause of pneumothorax and is the only category that can result both closed and/or open configurations.

Spontaneous pneumothorax is always closed and results from some extension of air from the respiratory system. It can be primary or secondary. Primary spontaneous pneumothorax occurs when there is no evidence of underlying pulmonary disease. In reality, most cases are assumed to be the result of a ruptured pulmonary bulla or bleb, which, of course, implies underlying

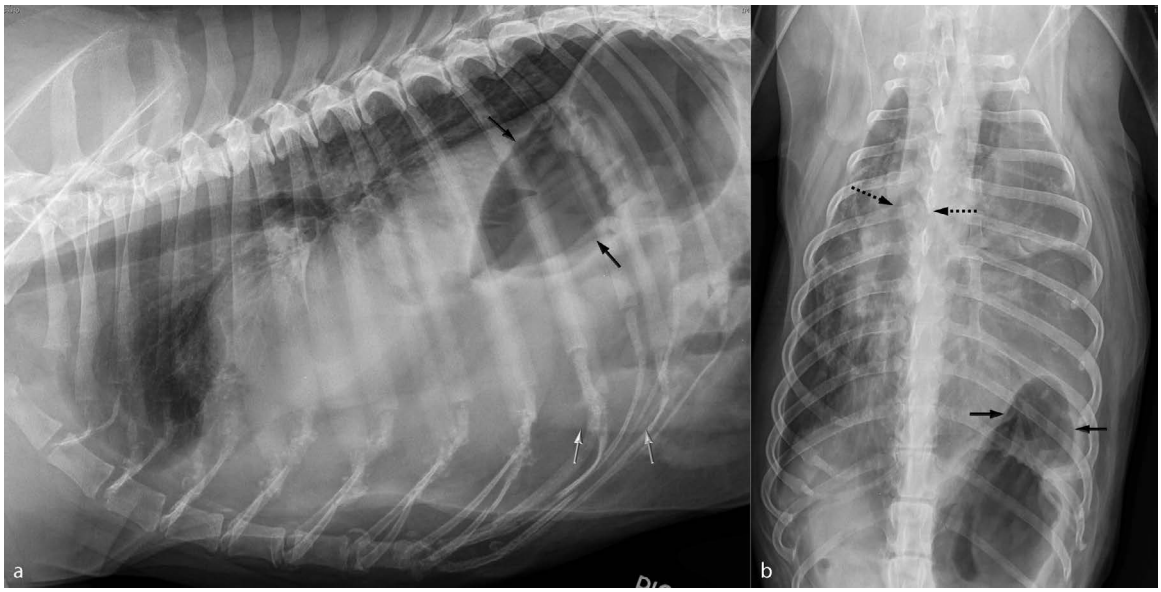

FIGURE 3.9 Lateral **(a)** and dorsoventral **(b)** views of a dog presented for increased respiratory effort after vehicular trauma. A marked increase in soft tissue opacity is present within the caudoventral thorax that is notably located on the left side. There is border effacement of most of the cardiac silhouette and the diaphragm. The left diaphragmatic margin is effaced on the dorsoventral view. The tracheal hilus is deviated to the right hemithorax (b, dotted black arrows) consistent with a mediastinal shift away from the hemithorax containing most of the increased soft tissue opacity. The normal caudoventral liver margin is not identified, and the tail of the spleen (a, white arrows) is cranially displaced. These findings support the diagnosis of diaphragmatic rupture with herniated abdominal organs. Finally, a gas-filled structure with visible rugal folds consistent with stomach is seen crossing from the abdomen to the thorax (black arrows), confirming diagnosis of herniation.

pulmonary pathology. Secondary spontaneous pneumothorax is associated with known underlying lung disease (except pulmonary bullae or blebs). Dogs most commonly have primary spontaneous pneumothorax; cats typically have secondary spontaneous pneumothorax.

TABLE 3.5 Categories and causes of pneumothorax

Category	Underlying cause(s)
Traumatic	**Open** – Penetrating or perforating wound **Closed** – Blunt force trauma
Spontaneous	**Primary** – Idiopathic – Presumed rupture of bulla or bleb **Secondary** – Rupture of necrotic or cavitary lung lesions (not bullae or blebs) – Pneumonia – Parasitic infection – Pulmonary abscess – Cavitary neoplasm – Congenital lobar emphysema – Bronchopulmonary dysplasia – Grass awn migration – Interstitial pneumonitis or fibrosis – Pulmonary thromboembolism
Iatrogenic	– Extreme positive pressure ventilation – Thoracocentesis

Radiographic signs of pneumothorax are summarized in Box 3.5. The right lateral view is the most sensitive view for detection of pneumothorax, where separation of the heart from the sternum is often the first sign identified (Figure 3.10a, b). Additionally, identifying separation of the lungs from the thoracic wall by gas opacity indicates pneumothorax. The key to diagnosing pleural gas is recognizing the absence of pulmonary vascular markings in the region suspected of absent lungs. In cases of spontaneous pneumothorax, the underlying pulmonary bulla or bleb is rarely evident radiographically. When

Box 3.5 Radiographic signs indicating pneumothorax

- Separation of the heart from the sternum (earliest visible sign seen on lateral view)
  - Absence of pulmonary vascular markings at the region of separation
- Retraction of lungs from the thoracic wall by gas opacity
  - Absence of pulmonary vascular markings at the region of retraction
- General increased pulmonary lung opacity
  - More evident with increasing pleural volume of gas
- Evidence of tension (only with severe gas accumulations)
  - Flattened or tented diaphragm
  - Mediastinal shift away from pleural space containing most gas
  - Barrel-shaped chest

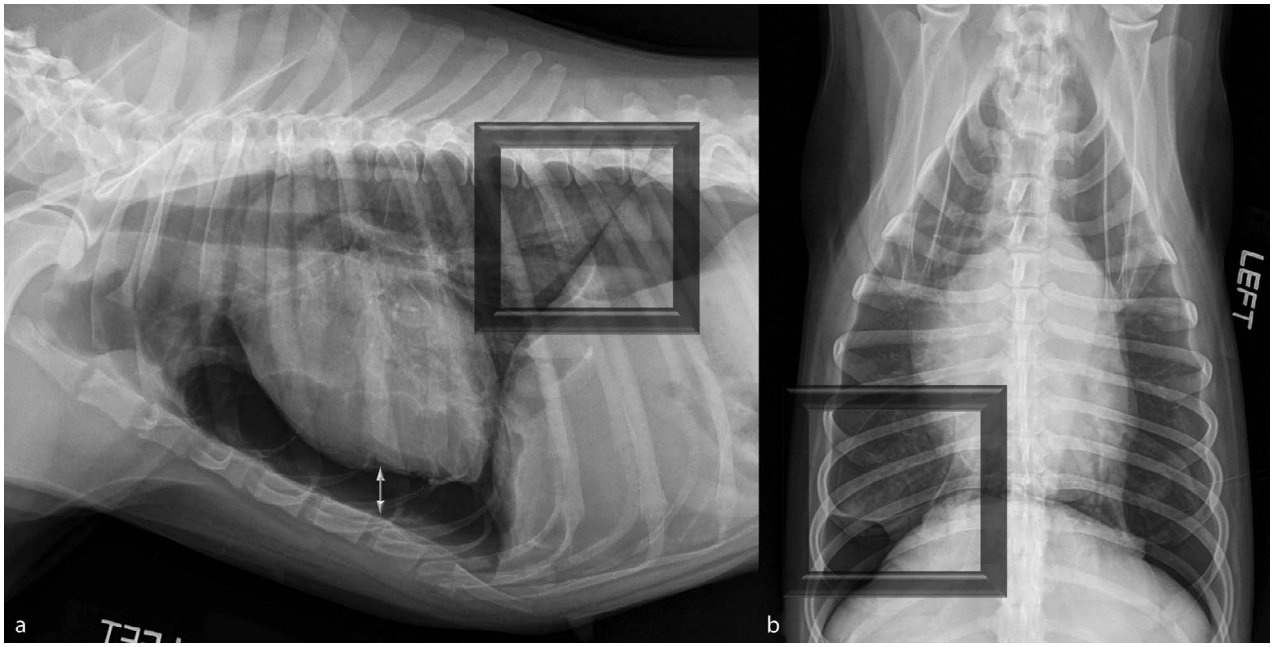

FIGURE 3.10 Lateral **(a)** and ventrodorsal **(b)** view of a dog having moderate pneumothorax with accompanying magnified views of the indicated regions. Moderate separation of the heart from the sternum with interposed gas opacity is present on the lateral view (white double arrow). Additionally, separation of the lungs from the thoracic wall is visible on both views (black boxes). The lungs are mildly, diffusely increased in opacity consistent with atelectasis due to increased pleural volume.

compared to radiographs, computed tomography is able to detect the underlying bullae with greater sensitivity, but the exact cause of pneumothorax often remains unidentified even with advanced imaging.

3. Noncardiac Mediastinum

As an entry point into the central thorax and evaluation of the mediastinum, the extrathoracic trachea should be followed, evaluating its margins until the bifurcation is reached. From this point, the mediastinum can be evaluated. Abnormalities would include alterations in margination (decreased visibility due to border effacement), position, size, or opacity of the mediastinum. The mediastinum spans from the thoracic inlet to the diaphragm and the entire dorsal to ventral dimension of the thorax. The mediastinal compartment communicates with fascial planes of the neck cranially and with the retroperitoneal space caudally (through the aortic hiatus). This communication is an important consideration when determining the underlying cause of pneumomediastinum, as discussed later. The mediastinum includes many structures that are not normally visible on thoracic radiographs due to border effacement, including sternal, cranial mediastinal, and tracheobronchial lymph nodes, thymus, esophagus, vessels (brachiocephalic trunk, left subclavian, azygous vein, etc.), nerves, and lymphatics. In the diseased state, these structures may become visible due to altered size or opacity. The main visible mediastinal structures are the trachea, heart, and great vessels. Cardiovascular mediastinal structures will be discussed in more detail in the next section. The thymus is visible only in young animals.

Mediastinal Gas – Pneumomediastinum

Mediastinal gas or pneumomediastinum can be seen independently or concurrent with pneumothorax. Radiographically, mediastinal gas is readily distinguished from pleural gas because it acts as a contrast, increasing visibility of soft tissue opaque from margins within the cranial mediastinum that are not normally seen (Figure 3.11). The most commonly seen

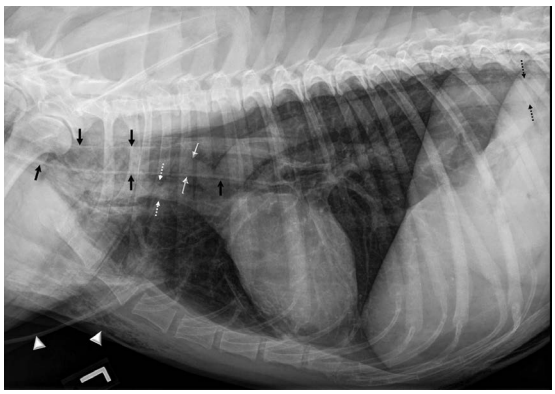

FIGURE 3.11 Pneumomediastinum in a dog having received multiple bite wounds. Subcutaneous emphysema is present superimposed over the thorax and located ventrally (white arrowheads). The outer margin of the trachea is visible (black arrows) due to adjacent gas creating contrast. The margins of the brachiocephalic trunk (dotted white arrows) and left subclavian (white arrows) are no longer effaced by surrounding soft tissue structures due to interposed gas highlighting their margins. The cranial abdominal aorta is visible (dotted black arrows) because it is surrounded by gas extending into the retroperitoneal space through the aortic hiatus.

Box 3.6 Causes of pneumomediastinum

- Cervical trauma
  - Penetrating wounds (e.g., bites) introducing gas into deep cervical soft tissues
- Tracheal or laryngeal rupture
- Alveolar rupture causing tracking of gas through interstitium
  - Blunt force thoracic trauma
  - Iatrogenic pulmonary hyperinflation
- Esophageal rupture (concurrent effusion is expected)
- Extension from the retroperitoneal space (uncommon)
- Mediastinitis due to gas-producing bacteria (concurrent effusion is expected)

radiographic sign of pneumomediastinum is increased delineation of the outer tracheal wall as it is highlighted by gas. The lateral view is typically the only view that is diagnostic, as superimposition precludes visibility of mediastinal gas on the orthogonal view. Pneumomediastinum has several potential causes, as shown in Box 3.6. In many cases, clinical history provides a clue as to the underlying cause. Trauma is the most commonly reported cause of pneumomediastinum. Given the potential causes of pneumomediastinum, it is recommended that radiographs be obtained of the entire neck in order to assess the larynx, trachea, and other cervical structures that may be the cause of mediastinal gas. In many cases of tracheal rupture, a lesion is not identified on radiographs, and tracheoscopy may be needed to assess the integrity of the trachea and esophagus. Typically, when esophageal rupture occurs, the leakage of fluid is far greater than gas, resulting in mediastinal and, therefore, pleural effusion that is in higher volume than any concurrent gas.

Regardless of the cause of pneumomediastinum, gas within the mediastinal space can leak into the pleural space due to fenestrations. However, gas within the pleural space will never leak into the mediastinum, as excess pleural pressure due to the pneumothorax collapses the mediastinum, effectively protecting gas from entering the mediastinum. Also, as previously mentioned, the mediastinum communicates with the cervical fascial planes cranially and the retroperitoneal space caudally through the aortic hiatus. Therefore, gas within the mediastinum can extend to these spaces, and gas within these spaces can extend to the mediastinum. Pneumomediastinum that is in such severity as to cause subcutaneous emphysema after tracking through the cervical soft tissues can be assumed to occur from tracheal rupture.

Mediastinal Shift

Mediastinal structures such as the trachea and heart can be displaced from their midline locations due to disease in the pleural or pulmonary space. A mediastinal shift can be categorized as contralateral or ipsilateral.

TABLE 3.6 Categorization and causes of a mediastinal shift

Ipsilateral
– Mediastinum is pulled *toward* the abnormality
	Pleural disease
	– Adhesions between mediastinal and thoracic wall pleura (uncommon)
	– Atelectasis caused by fibrotic pleura constricting lung(s) (uncommon)
	Pulmonary disease
	– Remaining causes of atelectasis (common)
	  – Positional/recumbency/anesthesia associated
	  – Bronchial obstruction

Contralateral – Mediastinum is pushed *away* from the abnormality	**Pleural disease** – Unilateral pleural effusion or pneumothorax (common) – Pleural mass (uncommon) – Diaphragmatic rupture with herniated abdominal organs (common) **Pulmonary disease** – Lung mass (common)

A contralateral mediastinal shift follows disease present in the right or left hemithorax that causes a *push* of the mediastinum *away* from the diseased side. An ipsilateral mediastinal shift occurs when disease within the thorax causes a *pull* of the mediastinum *toward* the diseased side, caused by a decrease in volume or a physical tethering of the mediastinum toward the lesion. Some diseases that may cause a mediastinal shift have been mentioned previously in the discussion on pleural diseases. Additional causes are shown in Table 3.6. Recognition of a mediastinal shift can be key to differentiating causes of pulmonary or pleural lesions seen but is almost never associated with mediastinal lesions alone, so its presence typically indicates disease outside the mediastinum.

Mediastinal Masses

Recognition of the position of the trachea is key to differentiating the most likely organ of origin for many mediastinal masses. As previously mentioned, many of the structures within the mediastinum, especially within the cranial mediastinum, are not visible in the normal animal. However, when mediastinal structures become enlarged, they create masses characteristic to their location within the mediastinum, assisting with distinguishing organ of origin for the mass. The location of mediastinal masses associated with specific organs is shown in Table 3.7. The effect that these masses have on the tracheal positioning is essential to distinguish likely organs of origin and, therefore, differential diagnoses for the mass effect.

Mediastinal Structures – Trachea

In most small animals, the normal tracheal path diverges from the thoracic spine from the thoracic inlet to the tracheal bifurcation. The normal tracheal diameter should be consistent throughout and should be slightly less than the diameter of the larynx. Ratios of the tracheal diameter to the thoracic inlet diameter measured on the

TABLE 3.7 Location of masses associated with mediastinal structures and their most common effect on tracheal positioning

Organ of origin	Mediastinal location for mass	Direction of tracheal deviation
Esophagus – Generalized enlargement – Focal enlargement	Dorsal – Cranial, middle, and caudal mediastinum – Craniodorsal or dorsal middle, most typically	Ventral
Sternal lymph nodes	Cranioventral	Dorsal, if severe enlargement
Cranial mediastinal lymph nodes	Cranioventral	Dorsal
Thymus	Cranioventral	Dorsal +/– right
Ectopic thyroid	Cranioventral	Dorsal
Mediastinal (pharyngeal) cyst	Cranioventral	Dorsal
Heart base	Cranial or middle	Dorsal and right
Tracheobronchial lymph nodes	Middle	Ventral
Left atrium	Middle	Dorsal
Hiatal hernia	Caudodorsal	None

lateral view can be used to determine appropriateness of overall tracheal size with variations of the ratio relative to breed listed in Table 3.8.

TABLE 3.8 Method of measurement and normal values for tracheal diameter to thoracic inlet ratios in normal dogs

Breed type	Ratio value
Nonbrachycephalic breeds	0.20 +/– 0.03
Non-Bulldog brachycephalic breeds	0.16 +/– 0.03
Bulldogs	0.13 +/– 0.04

TABLE 3.9 Causes of tracheal narrowing

Length of trachea affected	Differential diagnoses
Diffuse	**Mural abnormalities** – Tracheal hypoplasia – Tracheitis – Mucosal hemorrhage – Severe tracheal collapse
Focal or segmental	**Mural abnormalities** – Tracheal collapse – Tracheal stricture or cicatrix – Neoplasia – Osteochondroma, chondrosarcoma, osteosarcoma, papilloma – Polyp – Granuloma – Parasitic (*Filaroides osleri*) – Previous tracheal irritation or trauma **Extramural abnormalities** – Mediastinal mass – Pulmonary mass (rare) **Luminal abnormalities** – Foreign body

A decrease in tracheal luminal diameter may be diffuse throughout its length or segmental/focal. Also, any tracheal narrowing can be caused by extraluminal, luminal, or mural factors, as shown in Table 3.9. Diffuse narrowing of the tracheal lumen is caused by mural abnormalities, specifically tracheal hypoplasia, severe tracheal collapse (Figure 3.12), or severe thickening of the tracheal mucosa caused by tracheitis or hemorrhage. These causes may be radiographically indistinguishable;

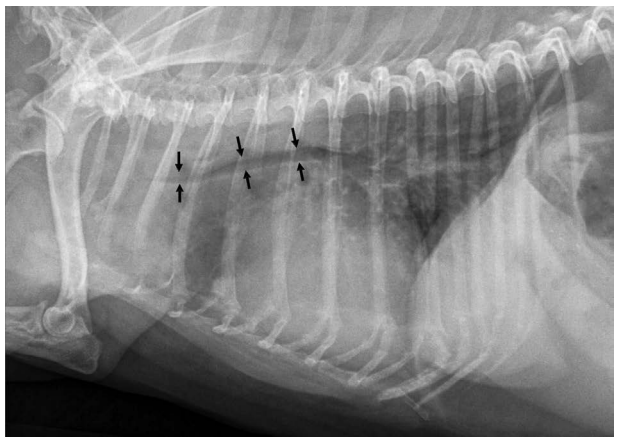

FIGURE 3.12 Lateral thoracic view of a dog having severe tracheal collapse. The view was obtained under attempted inspiration. The trachea at the thoracic inlet and cranial is collapsed and not radiographically visible. The intrathoracic trachea is visible but narrow. The severity of this dog's respiratory signs precluded evaluation of tracheal collapse during cough using fluoroscopy. The diaphragm is cranially positioned, overlapping with the cardiac silhouette. Also, the caudal lungs are mildly increased in opacity and reduced in size due to underaeration. These findings indicate a secondary upper airway obstruction.

Box 3.7 Radiographic signs indicating upper airway obstruction

- Tracheal narrowing at the obstruction
- Increased tracheal diameter cranial to the obstruction
- Decreased lung volume
  - Cranially positioned diaphragm
  - Increased opacity of caudal lungs
- Sternal elevation (most commonly seen in cats)
- Inward deviation of intercostal muscles (most commonly seen in cats)
- Hiatal herniation due to decreased intrathoracic pressure

however, tracheal hypoplasia is congenital, and a sudden decrease in tracheal luminal diameter in an animal with a previously normal tracheal diameter would not be expected with true hypoplasia, as may be seen with acquired tracheitis or hemorrhage. Tracheal hypoplasia that is typically seen in bulldogs is associated with other factors comprising brachycephalic airway syndrome and is often diagnosed in younger animals. The radiographic signs of upper airway obstruction are shown in Box 3.7.

Mediastinal Structures – Esophagus

Because of its dorsal position within the mediastinum, esophageal dilation usually causes ventral displacement of the trachea. A dilated esophagus may contain ingesta, foreign material, fluid, gas, or any combination. The radiographic signs and differential diagnoses for various esophageal diseases are listed in Table 3.10. Radiographic signs indicating esophageal dilation are shown in Box 3.8. Gas-filled esophageal dilation is sometimes more challenging to recognize because the gas within the esophagus creates little contrast with lungs (Figure 3.13a, b). The tracheal stripe sign can be seen when the ventral esophageal wall contacts the dorsal tracheal wall and creates a thick, soft tissue opaque line at the point of contact that is surrounded by luminal tracheal and esophageal gas. Also, in a gas-dilated esophagus, soft tissue opaque

Box 3.8 Radiographic signs of esophageal dilation

- Visibility of the esophagus on plain radiographs
  - Soft tissue opaque tube located dorsally and on midline (fluid or ingesta-filled esophagus)
  - Converging soft tissue opaque lines within the caudal mediastinum (gas-filled esophagus)
- Ventral displacement of the trachea
- Tracheal stripe sign (gas-filled esophagus)
- Secondary abnormalities
  - Aspiration pneumonia
  - Pneumomediastinum, pleural effusion, pneumothorax, gas within cervical soft tissues (esophageal perforation)

TABLE 3.10 Radiographic descriptors and some common differential diagnoses of esophageal disease

Radiographic descriptor	Differential diagnoses
Altered esophageal opacity	**Luminal material (obstructive or nonobstructive)** – Mineral, metal, or soft tissue opaque foreign body or ingesta – Megaesophagus with excess luminal gas or fluid **Mural mass (obstructive or nonobstructive)** – Soft tissue mass (granuloma, abscess, or neoplasia) – Mineralized mass (e.g., malignant transformation of *Spirocerca lupi* granuloma)

Esophageal dilation	**Generalized megaesophagus**
	– Idiopathic
	– Metabolic disease
	  – Hypoadrenocorticism
	  – Hypothyroidism
	– Infection
	  – Botulism
	  – Distemper
	– Toxicity
	  – Lead
	  – Organophosphate
	– Anesthetic induced (transient)
	– Esophagitis
	– Paraneoplastic
	  – Thymoma
	– Lower esophageal obstruction
	  – Hiatal hernia
	  – Lower esophageal mass
	– Neuromuscular diseases
	  – Dysautonomia
	  – Myasthenia gravis
	  – Storage diseases
	– Focal esophageal dilation
	– Obstruction (luminal, extraluminal, or mural causes)
	  – Foreign body
	  – Vascular ring anomaly
	  – Stricture
	  – Esophageal mass
	– Esophageal diverticulum

Pneumomediastinum (+/– pneumothorax) and mediastinal/pleural effusion	– Esophageal perforation

lines are seen within the caudal mediastinum representing the walls of the esophagus as they converge at the esophageal hiatus. These lines are visible in the expected location of the esophagus (within the caudal mediastinum between the aorta and the caudal vena cava on the lateral view and near midline on the orthogonal view). Megaesophagus is a risk factor for aspiration pneumonia. When megaesophagus is positively identified, the lungs should be carefully evaluated.

Focal esophageal dilation may be caused by luminal, extraluminal, or mural obstructions. Luminal causes

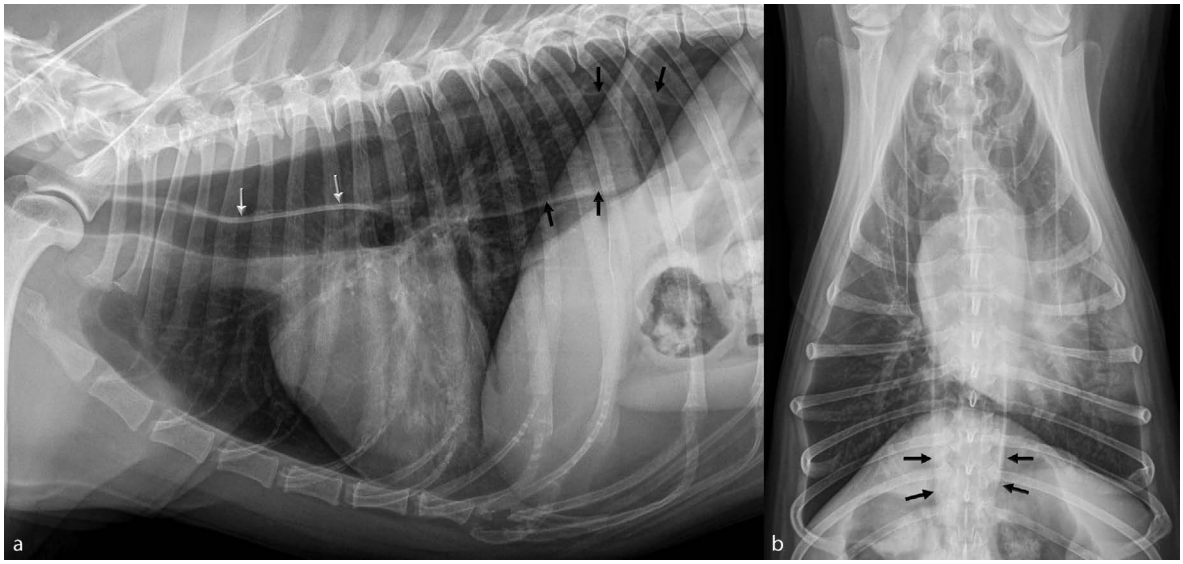

FIGURE 3.13 Lateral **(a)** and ventrodorsal **(b)** thoracic views of a dog having gas-filled megaesophagus. The thoracic trachea is ventrally displaced. A tracheal stripe sign is present (a, white arrows). Additionally, converging soft tissue opaque lines (a and b, black arrows) are visible in the caudal mediastinum between the aorta and the caudal vena cava on the lateral view and on midline on the ventrodorsal view consistent with margins of the esophageal wall, which are separated by excess luminal gas opacity. Increased left-sided pulmonary opacity is causing border effacement of the left cardiac margin consistent with alveolar disease due to secondary aspiration.

of obstruction occur with esophageal foreign bodies. Esophageal foreign bodies are most commonly confined between the heart base and the diaphragm (**Figure 3.14a, b**). Soft tissue opaque foreign bodies, such as rawhide treats, can look similar to esophageal mural masses; however, foreign bodies are more common and present more acutely than mural masses. Extraluminal causes of obstruction resulting in focal esophageal dilation are infrequent. Vascular ring anomalies are the most common cause of extraluminal obstruction. Typically, a vascular ring anomaly will cause the portion of the esophagus cranial to the cardiac base to be dilated along with focal leftward deviation of the esophagus and trachea. On some occasions, the entire esophagus may be dilated with a focal narrowing near the heart base. Mural esophageal masses caused by neoplasia, granuloma, or abscess are rare causes of esophageal obstruction that can appear similar to each other. Hiatal diseases, including sliding hiatal and paraesophageal hernias and gastroesophageal intussusceptions, also cause soft tissue opaque masses associated with the caudal mediastinum. Sliding hiatal hernias are the most common of the hiatal diseases and may be transient from radiographic view to view. The similarity in survey radiographic findings of the various causes of caudal esophageal masses is shown in **Figure 3.15a–c**. The

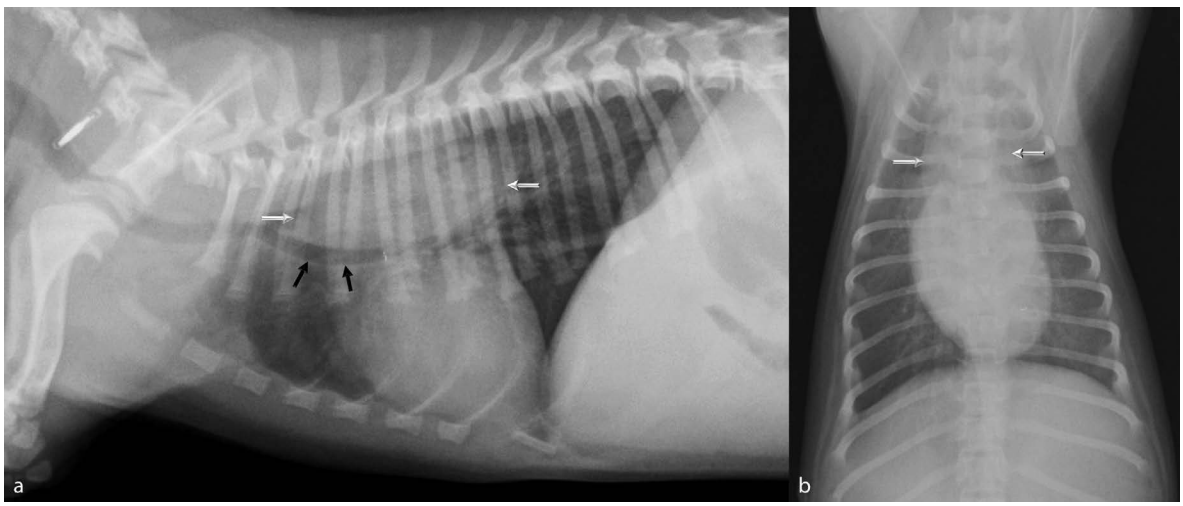

FIGURE 3.14 Lateral **(a)** and ventrodorsal **(b)** thoracic radiographs of a dog presenting for retching and gagging. A poorly defined soft tissue opaque mass is present within the dorsal thorax (a, white arrows). The mass is causing focal ventral deviation of the trachea (a, black arrows), and it is located in midline, causing widening of the mediastinum (b, white arrows). These findings confirm that the mass is mediastinal in origin, most likely originating from the esophagus. A leather belt was removed endoscopically.

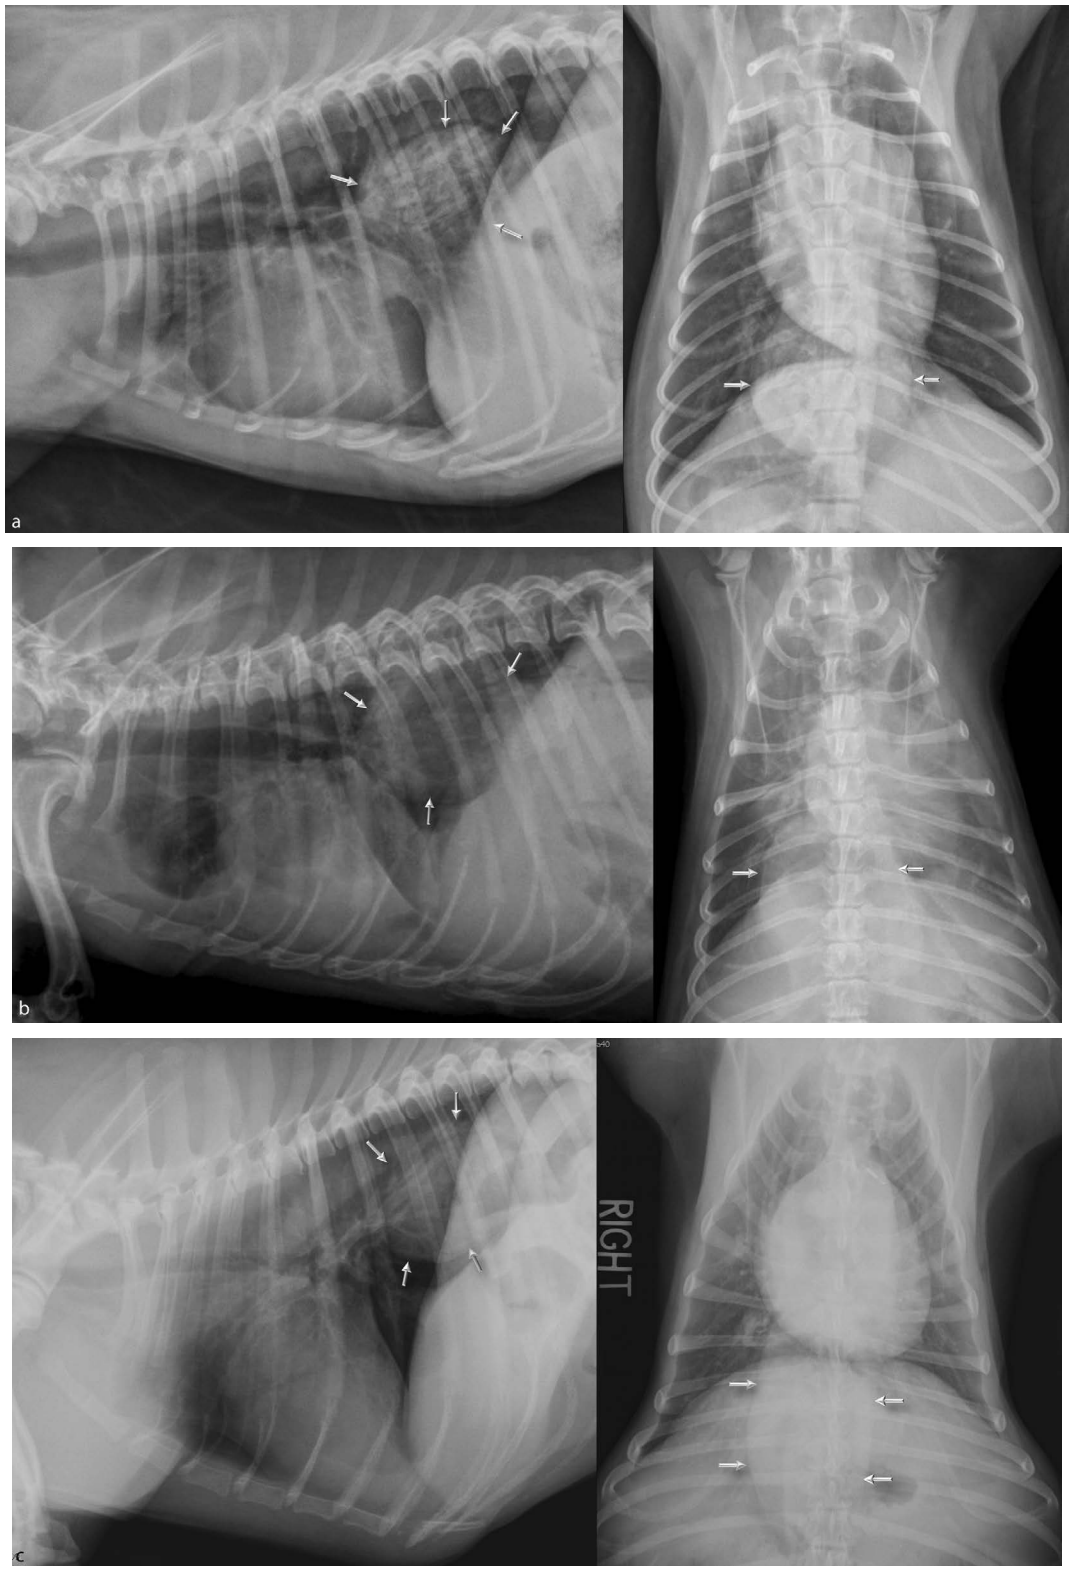

FIGURE 3.15 Lateral and ventrodorsal radiographs of caudal mediastinal masses due to esophageal diseases of different causes. In part **(a)**, a mixed gas and soft tissue opaque mass is seen in the caudal mediastinum (white arrows). Endoscopy confirmed the presence of an esophageal diverticulum. In part **(b)**, a soft tissue opaque mass with a central gas bubble is seen in the caudal mediastinum (white arrows). A rawhide foreign body was diagnosed endoscopically. In part **(c)**, a soft tissue opaque foreign body is present in the caudal mediastinum (white arrows) that has a focal gas bubble at its caudal margin. A sliding hiatal hernia was confirmed and surgically repaired. Oral administration of contrast could be performed to further characterize the lesions; however, barium would be contraindicated in part (b), as concurrent pleural effusion is present, indicating potential for esophageal rupture, which was confirmed during endoscopy.

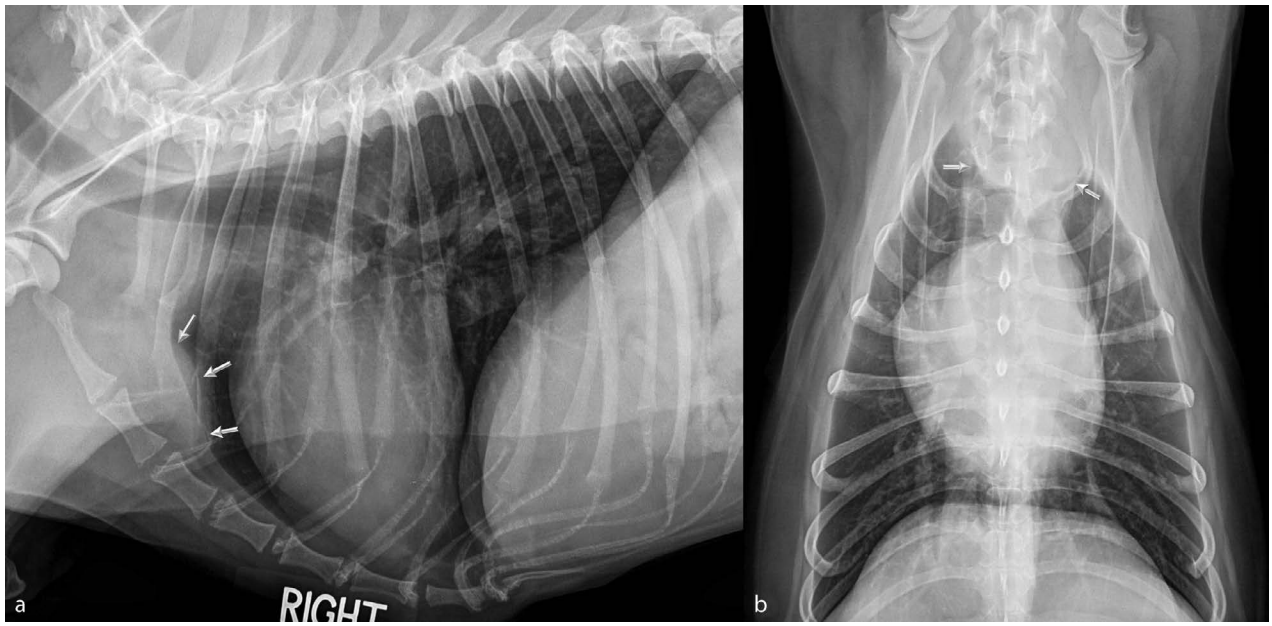

FIGURE 3.16 Lateral **(a)** and ventrodorsal **(b)** thoracic radiograph of a dog having sternal lymphadenopathy due to lymphoma. A broad-based soft tissue opacity is seen within the cranioventral thorax (a, white arrows) that is on midline, creating a widened cranial mediastinum on the ventrodorsal view (b, white arrows), confirming a mediastinal location for the lesion. The cranial mediastinum, in addition to being wide, is nonuniform in its width.

similarities often necessitate use of positive contrast esophagography or endoscopy to differentiate among them, with barium administration being contraindicated when accompanied by radiographic indication of esophageal rupture (e.g., concurrent pleural effusion).

Mediastinal Structures – Lymph Nodes

Three main lymph node centers are present within the mediastinum that can become radiographically visible when enlarged: The sternal (Figure 3.16a, b), cranial mediastinal (Figure 3.17a, b), and tracheobronchial

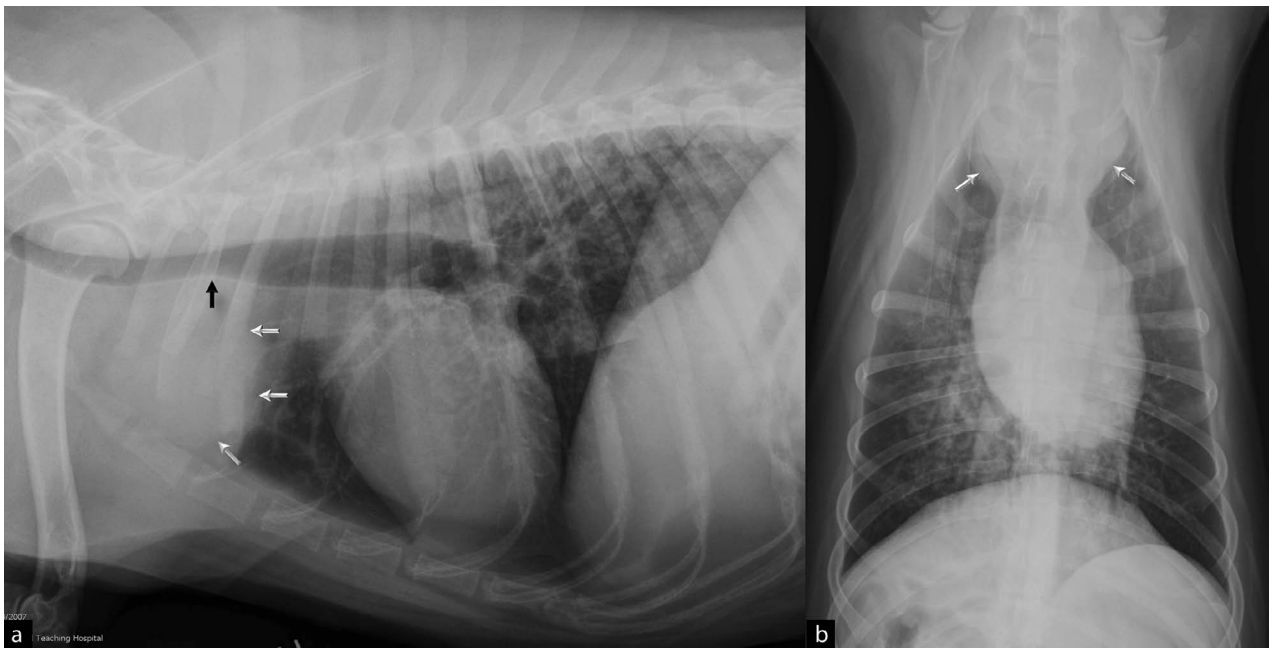

FIGURE 3.17 Lateral **(a)** and ventrodorsal **(b)** thoracic radiographs of a dog having cranial mediastinal lymphadenopathy due to lymphoma. A mass is located in the cranial and ventral aspect of the cranial mediastinum (white arrows) that causes dorsal deviation and compression of the cranial thoracic trachea (a, black arrow) and a widened cranial mediastinum (b, white arrows). An interstitial pattern is present, most evident in caudal lungs, that causes an increase in prominence of bronchi due to pulmonary lymphoma as well.

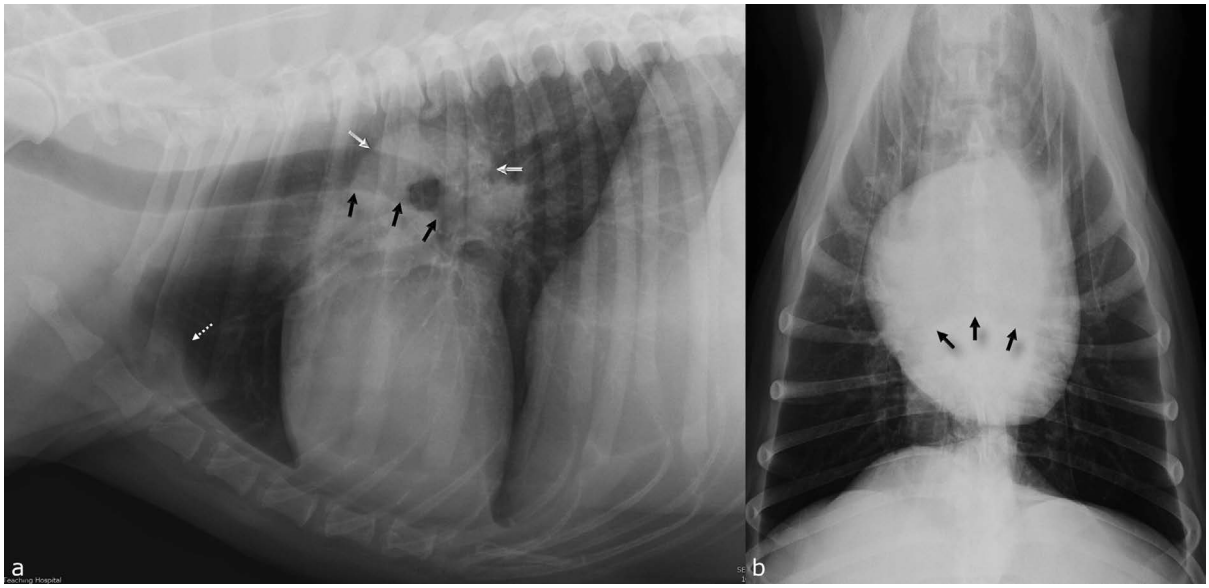

FIGURE 3.18 Lateral **(a)** and ventrodorsal **(b)** thoracic radiographs of a dog having lymphoma and tracheobronchial lymphadenopathy. The distal aspect of the trachea at the hilus and mainstem bronchi are focally ventrally deviated, giving the trachea a "J" shape (a, black arrows). A moderately well-defined soft tissue opacity is present in the region of the hilus on the lateral view (a, white arrows). This opacity is located between mainstem bronchi on the ventrodorsal view and causes widening of the angle between the right and left bronchus (b, black arrows). These findings confirm a mediastinal location for a mass due to tracheobronchial lymphadenopathy. Mild concurrent sternal lymphadenopathy is present that is only visible in the lateral view (a, dotted white arrow).

(Figure 3.18a, b). Both the sternal and cranial mediastinal lymph nodes are located in the cranial mediastinum, and the tracheobronchial lymph nodes are located in the middle mediastinum. In the normal animal, these lymph nodes are invisible. Most often, when lymph nodes become radiographically visible, the underlying cause is neoplastic or granulomatous disease and may be secondary to disease in locations that they drain along the lymphatic system.

Mediastinal Structures – Thymus

The thymus is located in the caudal part of the cranioventral mediastinum within the cranioventral mediastinal reflection. It is not radiographically visible in a normal animal that is greater than 1 year of age due to involution initiating at sexual maturity. In a young animal, the thymus may be visible, creating a soft tissue opacity within the cranioventral mediastinal reflection that is triangular in shape, appearing similar to a sail on the ventrodorsal/dorsoventral view. Thymic enlargement is more ventral in location than cranial mediastinal lymph node enlargement and is more caudal than sternal lymph node enlargement. However, when cranioventral mediastinal lesions approach massive sizes, their organ of origin is often impossible to distinguish with certainty. Masses associated with the thymus are typically caused by thymoma (in dogs) or thymic lymphoma (in cats). Additional potential causes of thymic enlargement include thymic cysts, hemorrhage, and amyloidosis. Thymic masses, especially those caused by thymomas, can be quite immense, causing dyspnea due to tracheal compression and decreased lung volume, as shown in Figure 3.19a, b.

4. Heart, Great Vessels, and Pericardium

Cardiac Radiographic Anatomy

Heart size can be evaluated by subjective assessment or objectively using a ratio of cardiac size to vertebral length, called a vertebral heart score. Cardiac shape is equally important in determining the presence of abnormalities, with alterations in cardiac shape not necessarily affecting cardiac size. Of important consideration is the alteration in apparent cardiac shape that can occur from poorly positioned radiographs that are not centered on the heart. The indications for cardiac imaging are listed in Box 3.9. Though variations in cardiac appearance can be particularly prominent among varying dog breeds, a general description of subjective cardiac assessment is shown in Box 3.10.

The vertebral heart score (VHS) is a method to objectively measure cardiac size that does not require a high experience level (detailed in Figure 3.20). The vertebral heart score can also be used to evaluate increasing size over time, especially useful in repeat evaluation of dogs having mitral valvular insufficiency in predicting onset of cardiac failure. Most normal dogs (98%) have a VHS less than 10.6. Some normal dogs regularly fall above this value. To address this, several breed-specific VHS values have been published in several barrel-chested small breed dogs and in Greyhounds. The reported upper limit of the VHS in cats (performed the same way as in dogs) is 8.0. Regardless of the VHS obtained, the cardiac silhouette must be examined for alterations in shape, which can be detected in hearts having a normal VHS.

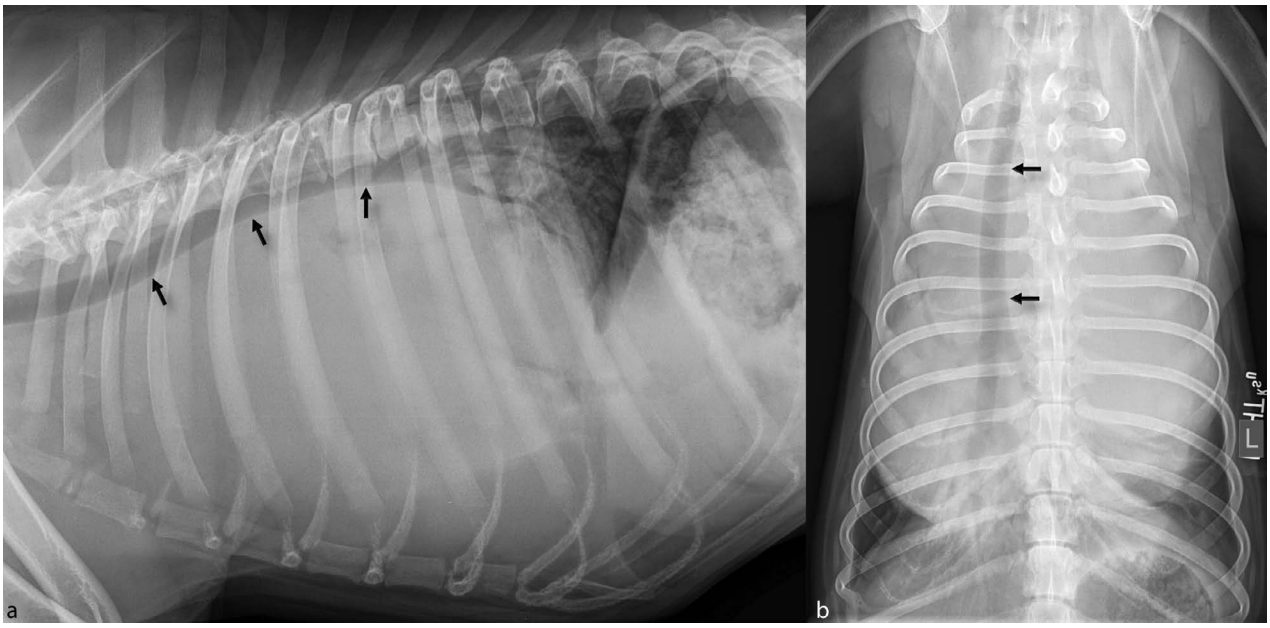

FIGURE 3.19 Lateral **(a)** and ventrodorsal **(b)** thoracic radiographs of a 2-year-old lab presenting for tachypnea and dyspnea. A large cranial mediastinal mass is present that is causing marked dorsal displacement of the trachea (a, black arrows) and caudal displacement of the tracheal hilus to the level of the 7th intercostal space. A mild rightward mediastinal shift is present, as shown by the position of the trachea on the ventrodorsal view (b, black arrows). The margins of the heart are effaced, and there is a marked decrease in lung volume due to the size of the mass. Thymoma was diagnosed histopathologically.

Box 3.9 Indications for cardiac imaging

- Audible murmur
- Exercise intolerance
- Coughing
- Dyspnea
- Increased lung sounds
- Cyanosis
- Syncope
- Abdominal distension/jugular pulses
- Heartworm infection
- Re-evaluation of previously diagnosed cardiac disease

In order to arrive at an appropriate differential list, specific chamber enlargement should be identified when cardiomegaly or altered cardiac shape is identified. Bulges seen within the cardiac silhouette must be anatomically differentiated within the overall shape of the heart. This can be accomplished by way of the clock-face analogy shown in Table 3.11. Chambers of the heart are located within specific "times" along the clock. The clock-face analogy is similar in cats, except that the left atrium is located more peripherally along the left aspect of the cardiac silhouette rather than dorsally at the caudal cardiac base.

Box 3.10 Cardiac size relative to thoracic cavity

Canine

Lateral View
- Length of the heart is less than two-thirds the dorsoventral diameter of the thorax
- Width of the heart is 2.5–3.5 intercostal spaces (deep-chested breeds narrower than barrel chested)
- Two-thirds of the width of the heart is cranial to the carina, and one-third is caudal
- Trachea nearly parallel to the sternum

Ventrodorsal view
- Left cardiac margin flatter than the right
- Width of the cardiac silhouette less than two-thirds the width of the thorax
- Apex positioned slightly left of midline

Feline

Lateral view
- Length of the heart is less than two-thirds the dorsoventral diameter of the thorax
- Width of the heart is 2–3 intercostal spaces
- Trachea diverges form spine and is nearly parallel to the sternum
  - Increased tracheal divergence from spine with age

Ventrodorsal view
- Left cardiac margin flat
- Width of the cardiac silhouette less than half the width of the thorax
- Apex positioned moderately left of midline

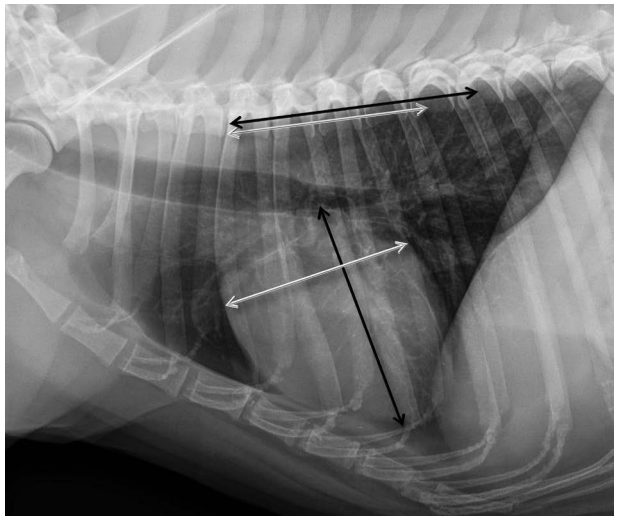

FIGURE 3.20 Technique for performing vertebral heart scale (VHS). A line is drawn along the long axis of the heart from the level of the cardiac base (black) to the cardiac apex. A second line is drawn along the short axis of the heart from the level of the dorsocaudal vena cava margin that extends to the cranial cardiac margin so that the second line is orthogonal to the original line (white). Both of these lines are then transposed onto the thoracic spine from the level of the cranial endplate of T4 extending caudally. The number of vertebrae encompassed within these lines constitutes the VHS, which measures 10 in this case.

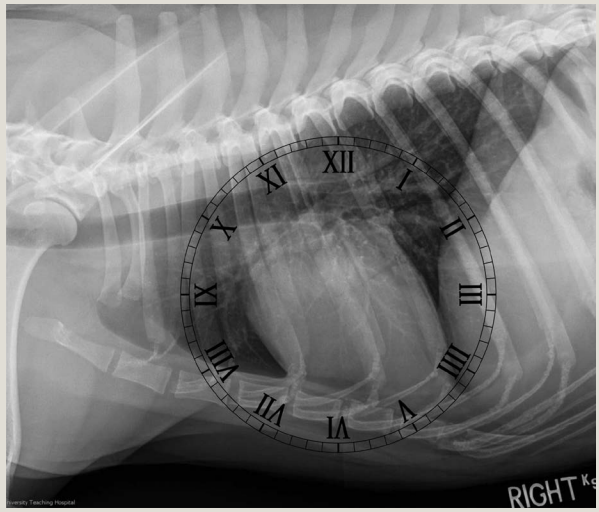
Radiographic Appearance of Right-Sided Cardiomegaly



Radiographically, right-sided cardiomegaly causes an increase in width of the cardiac silhouette on the lateral view and increased rounding of the right cardiac margin on the ventrodorsal/dorsoventral views. Bulges in the cardiac silhouette can be seen corresponding to the right atrium, right ventricle, or both according to the clock-face analogy.

Right atrial enlargement will cause an apparent increase in soft tissue opacity between the cranial cardiac base and the cranial mediastinum on the lateral view (8:00–11:00 position). On the orthogonal view, a bulge at the right cranial cardiac margin in the 9:00–11:00 position can be seen. This is shown in Figure 3.21a, b. Secondary to any cardiac enlargement, the trachea will often be elevated, especially cranial to the hilus. On some occasions, especially with concurrent right ventricular enlargement, the cardiac apex will be displaced to the left on the ventrodorsal/ventrodorsal views. In general, right atrial enlargement is more evident on the ventrodorsal view.

Right ventricular enlargement will cause a rounded cranial margin that creates an increase in the apparent width of the cardiac silhouette. The heart will appear to contact an increased length of sternum, though increased sternal contact alone is a poor indicator of cardiomegaly. A "reverse D" shape is often described in reference to right-sided enlargement on the ventrodorsal view. This shape is more specific for right ventricular enlargement rather than atrial enlargement.

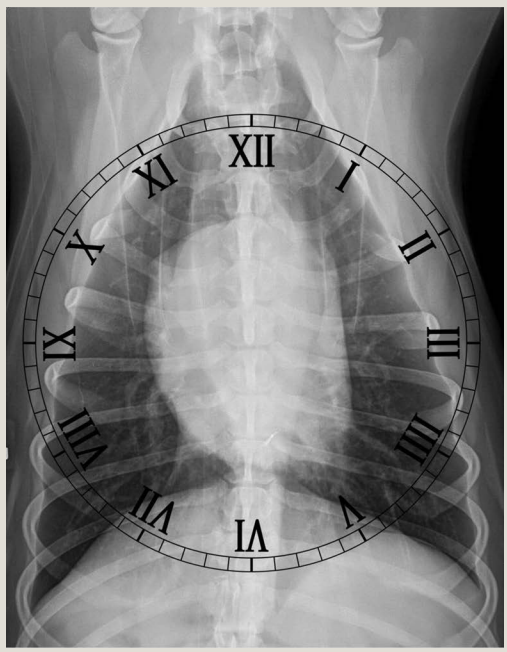


TABLE 3.11 Times corresponding to specific cardiac chambers using the clock-face analogy

Lateral view

Time	Cardiac chamber
12:00–3:00	Left atrium
3:00–5:00	Left ventricle
5:00–8:00	Right ventricle
8:00–11:00	Right atrium, main pulmonary artery, ascending aorta, and arch

Ventrodorsal view

Time	Cardiac chamber
11:00–1:00	Aorta
1:00–2:00	Main pulmonary artery
2:00–3:00	Left auricle
3:00–5:00	Left ventricle
5:00–9:00	Right ventricle
9:00–11:00	Right atrium
Center dial (between mainstem bronchi)	Left atrium

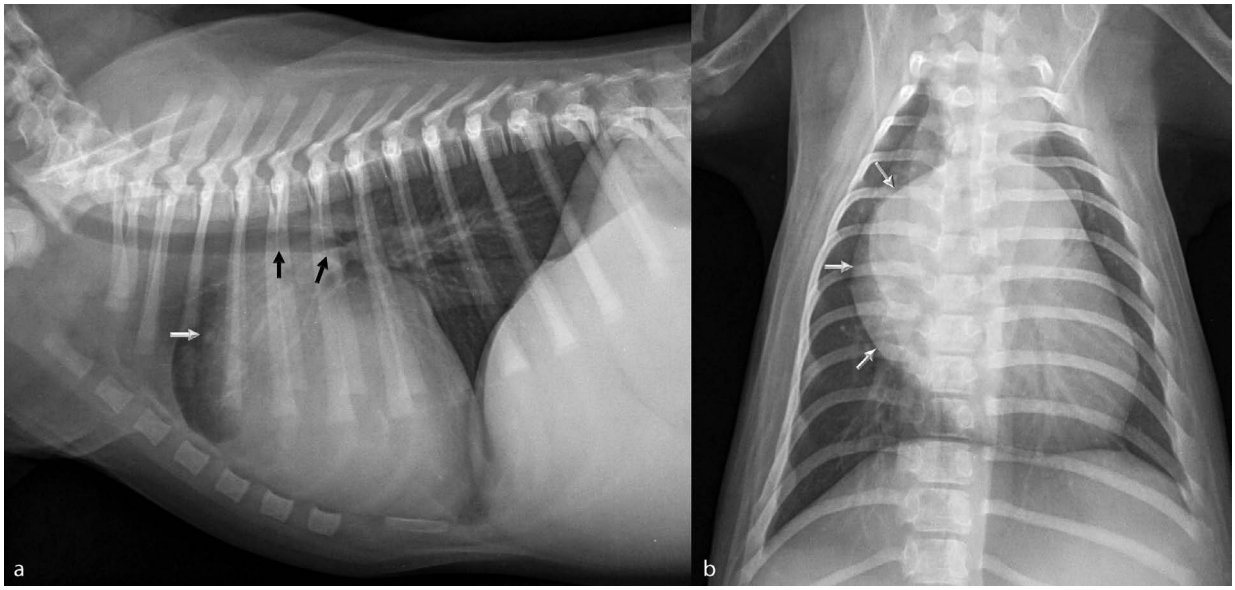

FIGURE 3.21 Lateral **(a)** and ventrodorsal **(b)** views in a puppy having marked right atrial enlargement due to tricuspid insufficiency secondary to a dysplastic tricuspid valve. On the lateral view, the trachea is elevated cranial to its hilus (a, black arrows). A bulge is present at the cranial cardiac base on the lateral view (a, white arrow) in the 8:00–11:00 position and at the right cranial cardiac margin on the ventrodorsal view (b, white arrows) in the 9:00–11:00 position. Also, note the subjective decrease in size of the pulmonary arteries and veins secondary to return flow of vascular volume into the right atrium rather than forward into the main pulmonary artery and lungs.

The reverse D is nonspecific for the underlying cause of right ventricular enlargement. When right ventricular enlargement is severe, the cardiac apex as seen on the lateral view will elevate. The enlarged cardiac silhouette will cause tracheal elevation, similar to that seen with right atrial enlargement. These findings are shown in Figure 3.22 a, b.

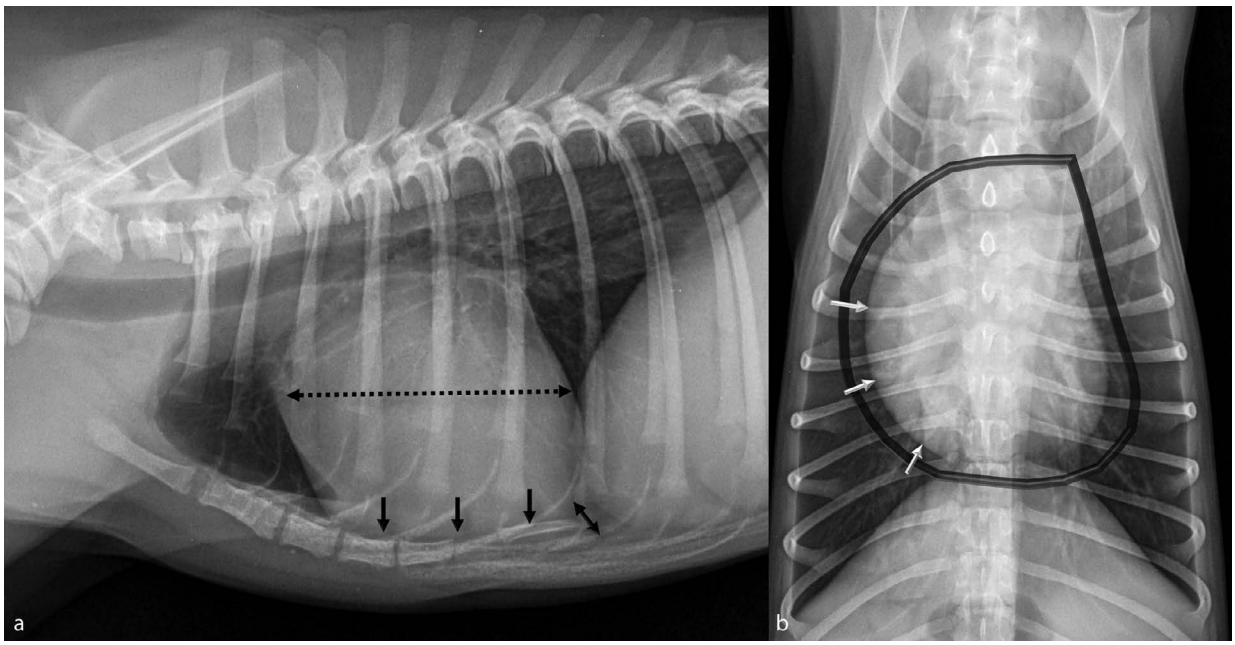

FIGURE 3.22 Lateral **(a)** and ventrodorsal **(b)** views in a dog having marked right ventricular enlargement due to severe pulmonic stenosis. The trachea is elevated being parallel to the spine. The cardiac silhouette is subjectively wide on the lateral view (a, dotted black line) encompassing over four intercostal spaces. Increased sternal contact is present (a, black arrows). The apex of the cardiac silhouette at the junction between the sternum and the diaphragm is mildly elevated (a, double-ended black arrow). The contour of the left margin of the cardiac silhouette is flat. The entire right cardiac margin is rounded with the ventricle (in the 5:00–9:00 position) being more peripheral than the atrium (b, white arrows), creating a silhouette whose outline is reverse D in shape (b, black outline surrounding the heart).

Radiographic Appearance of Left-Sided Cardiomegaly

Left-sided cardiomegaly causes increased height of the cardiac silhouette on the lateral view. Bulges in the cardiac silhouette are seen in the region of the left atrium and/or ventricle. Because of the prevalence of certain diseases in the canine and feline population, left-sided cardiomegaly is more common than right-sided. Additionally, most cardiomyopathies tend to cause left-sided cardiomegaly rather than right-sided in cats and dogs.

With left atrial or left ventricular enlargement, the caudal cardiac margin becomes flattened on the lateral view. This is often the first identifiable indication of mild enlargement. Left atrial enlargement will cause a bulge at the caudal cardiac base (12:00–3:00 position) on the lateral view. On the orthogonal view, the left atrium is not located at the periphery of the cardiac silhouette but is positioned between mainstem bronchi, being superimposed over the cardiac silhouette analogous to the center of the dial using the clock-face analogy. Left atrial enlargement can cause widening of the angle between mainstem bronchi, creating a "U" shape rather than the normal "V" shape, though this appearance can also be created by a thoracic view that is centered on the diaphragm rather than the heart. Sometimes the caudal margin of an enlarged left atrium will create a well-defined rounded margin parallel to the cardiac apex on the ventrodorsal view, referred to as the "double-bubble sign." An enlarged left auricle is peripheral in location along the cardiac silhouette on the ventrodorsal view at the 2:00–3:00 position. Loss of the normal, flat left-sided cardiac margin will be seen due to a bulge created by left auricular enlargement. Secondary to left atrial enlargement, the trachea will be elevated, which is similar to that seen in right-sided cardiomegaly. However, in the case of left atrial enlargement, the caudal mainstem bronchi are additionally elevated, as shown in Figure 3.23a, b.

Given the importance of detecting left atrial enlargement and the recognition that increases in left atrial size may assist in predicting imminent likelihood of left-sided cardiac failure, two objective measurements for left atrial size have been published, called the vertebral left atrial size (VLAS) and the radiographic left atrial dimension (RLAD), though both methods perform better when obtained by more experienced clinicians (Figure 3.24a, b).

Left ventricular enlargement without concurrent left atrial enlargement is uncommon. It is less apparent radiographically than left atrial enlargement and is generally considered the least recognizable chamber enlargement as a sole entity. The caudal cardiac margin may be flat similar to left atrial enlargement; however, with severe enlargement, a pronounced convexity may be seen. The heart may be tall, encompassing greater than two-thirds the dorsoventral diameter of the thorax on the lateral view and elevating the caudal vena cava. The cardiac apex may be rounded and may be displaced toward the left or right on the ventrodorsal view.

Generalized Cardiomegaly

When the cardiac silhouette is generally enlarged (instead of predominantly right-sided or left-sided), pericardial disease must be considered. Most often, if

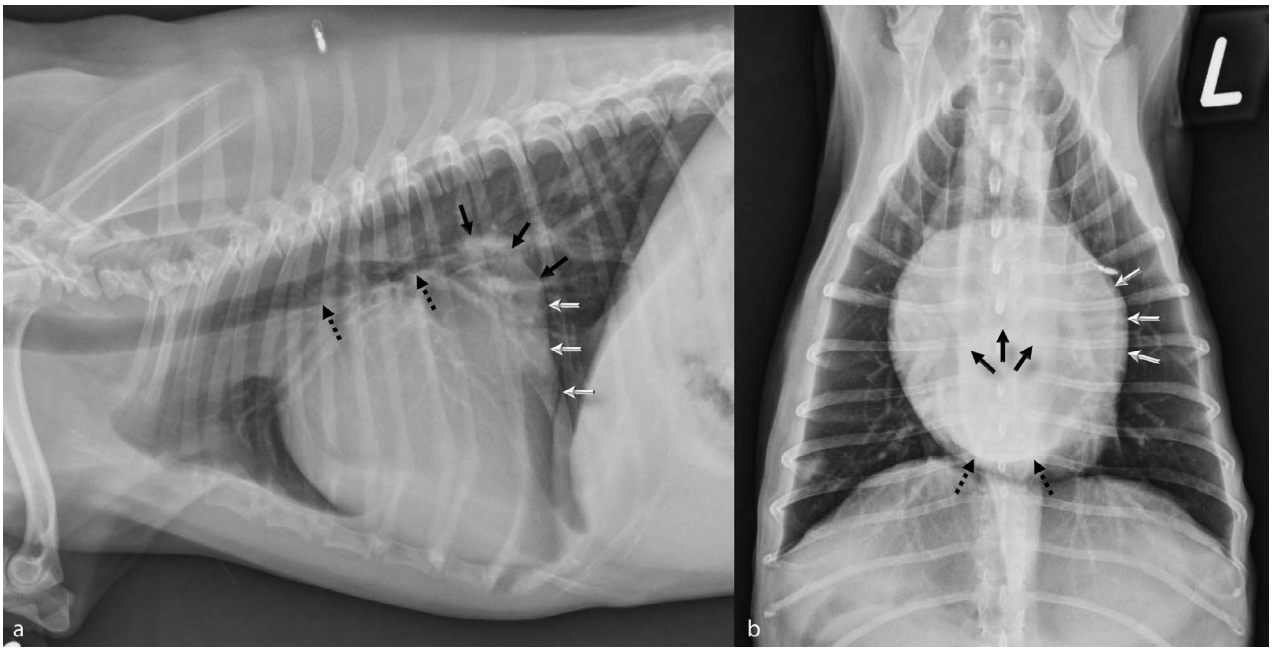

FIGURE 3.23 Lateral (a) and ventrodorsal (b) views in a dog having left atrial enlargement due to mitral valvular degeneration. The heart will often appear tall on the lateral view. The caudal cardiac margin is flat on the lateral view (a, white arrows). A bulge is visible in the caudal cardiac base (a, black arrows). The trachea and mainstem bronchi are elevated (a, black dotted arrows). On the ventrodorsal view, the angle between mainstem bronchi is widened (b, black arrows). The caudal margin of the enlarged left atrium is visible parallel to the cardiac apex (b, dotted black arrows). A left auricular bulge is visible peripherally along the left cardiac margin (b, white arrows).

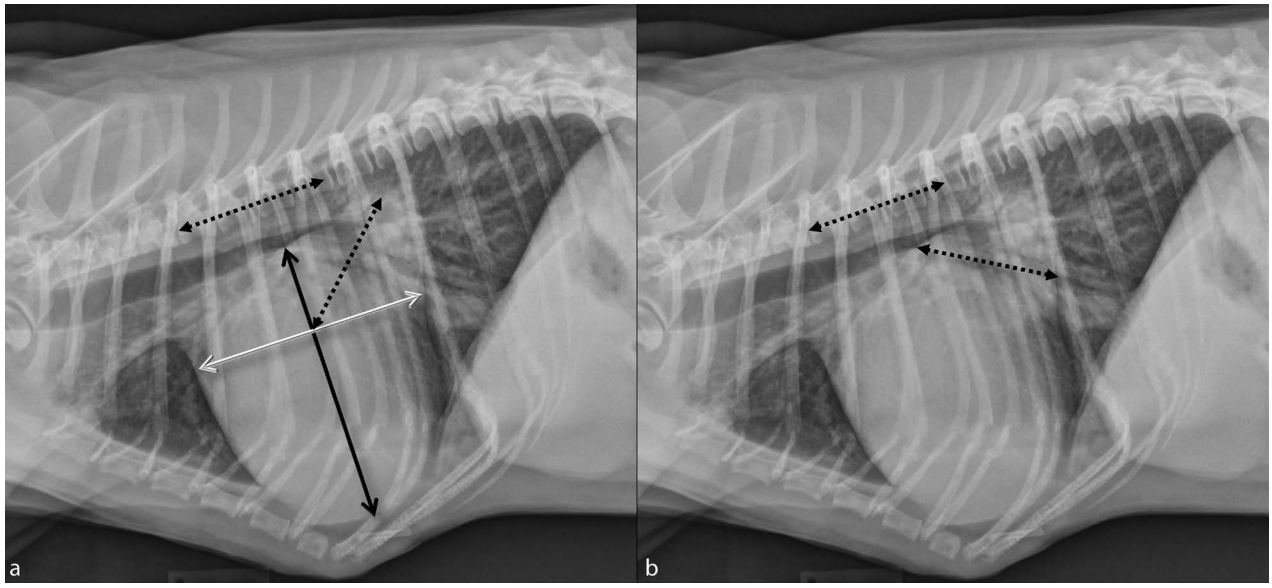

FIGURE 3.24 Right lateral thoracic views (a and b) in the same dog having left atrial enlargement due to degenerative mitral valvular disease and showing the measurement protocol for obtaining the radiographic left atrial dimension (RLAD; a) and the vertebral left atrial size (VLAS; b) intended to detect left atrial enlargement in dogs with mitral valvular insufficiency. To obtain the RLAD (a), intersecting lines are drawn identical to those required to obtain a vertebral heart score (black and white solid arrows). Then, an additional line is drawn bisecting the quadrant encompassed by the left atrium as shown (dotted black arrow). The length of this line is transposed onto the thoracic spine beginning at the cranial endplate of T4. The RLAD in this case measures 3.9 vertebrae. The optimal cutoff to distinguish normal from abnormal is reported to be 1.8 vertebrae, indicating left atrial enlargement in this case. To obtain the VLAS (b), a line is drawn from the most ventral aspect of the tracheal bifurcation to the caudal margin of the cardiac silhouette as it intersects with the dorsal aspect of the caudal vena cava (dotted black arrow). The length of this line is transposed onto the thoracic spine beginning at the cranial endplate of T4. The VLAS in this case measures 3.5 vertebrae. A VLAS > 2.3 vertebrae has been established as a useful predictor for left atrial enlargement in dogs.

the left atrium is detected as enlarged, the cardiomegaly is due to true heart enlargement rather than pericardial disease. If the heart is markedly enlarged and globoid while a dilated left atrium is not seen, pericardial disease/effusion should be ranked first. Keep in mind that severe right-sided cardiomegaly is similar in appearance to pericardial effusion.

Enlarged Great Vessels

Enlargement of the main pulmonary artery or aortic arch can occur due to turbulent blood flow or an increase in pressure downstream in the direction of vascular flow. Findings consistent with enlargement of great vessels should be correlated with additional abnormalities seen within the study (e.g., heart enlargement, peripheral pulmonary vascular size, and signs of failure) to decide on likely differential diagnoses.

An enlarged main pulmonary artery will cause a bulge in the cranial cardiac base (8:00–11:00 position) on the lateral view. This is also the location of the aorta and right atrium. The ventrodorsal view must be used to distinguish these three potential causes of a cardiac bulge in this location. On the ventrodorsal view, an enlarged main pulmonary artery causes a bulge in the left cranial cardiac margin at the 1:00–2:00 position, as shown in Figure 3.25a, b. The two main causes of a dilated main pulmonary artery are turbulent flow (poststenotic dilatation secondary to pulmonic stenosis or patent ductus arteriosus) or congestion due to pulmonary hypertension. All causes of an enlarged main pulmonary artery can result in right-sided cardiomegaly. The main distinguishing factor among the differential diagnoses is the appearance of peripheral pulmonary vasculature, as shown in Table 3.12.

An enlarged aortic arch will cause a bulge in a similar location to that of right atrial and main pulmonary arterial enlargement on the lateral view at the cranial cardiac base (8:00–11:00 position). On the orthogonal view, enlargement of the aortic arch will appear as a bulge in the cranial cardiac margin at the 11:00–1:00 position. Oftentimes, aortic arch enlargement will appear as a widening of the caudal aspect of the cranial mediastinum. Enlargement of the aortic arch is most often caused by turbulent flow and poststenotic dilatation secondary to aortic stenosis, as shown in Figure 3.26a, b.

Aortic enlargement can also occur at the level of the proximal descending aorta. Enlargement in this location is radiographically distinct from enlargement of the aortic arch due to aortic stenosis and nearly pathognomonic for a patent ductus arteriosus (PDA). The enlargement is due to turbulent flow caused by abnormal blood flow between the main pulmonary artery and aorta that occurs at the proximal descending aorta. This finding is most evident on the ventrodorsal view, as shown in Figure 3.27.

The caudal vena cava should be less than 1.5 times the width of the aorta. An enlarged caudal vena cava is

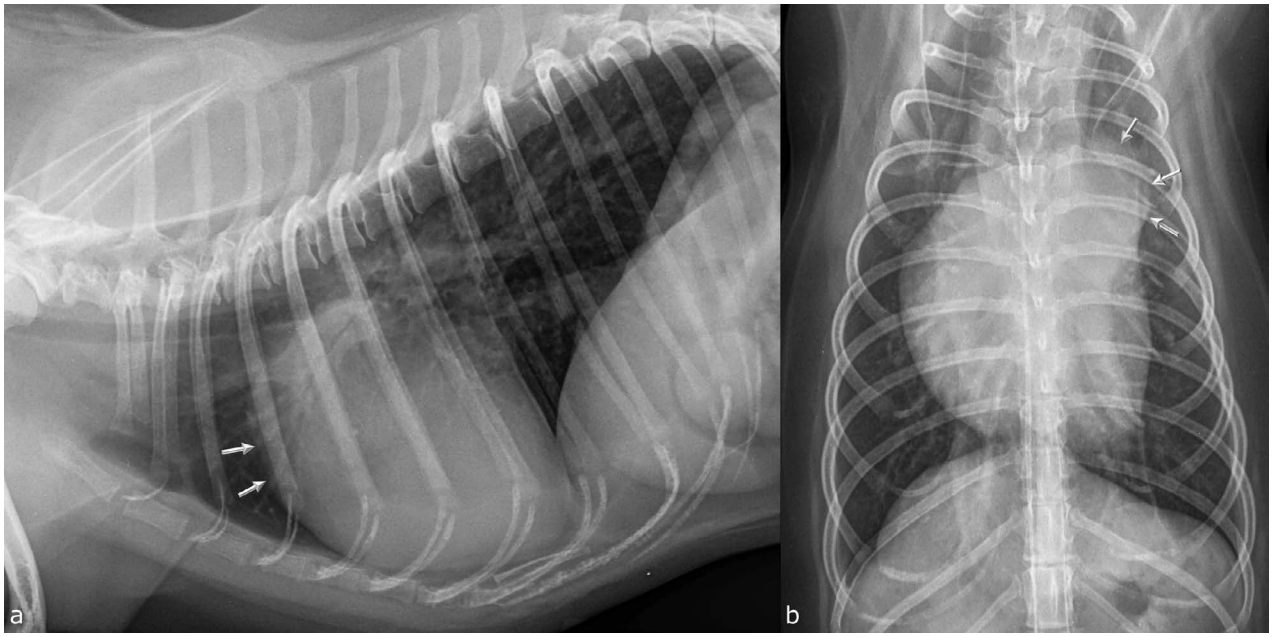

FIGURE 3.25 Lateral **(a)** and ventrodorsal **(b)** radiographs of a dog having radiographically evident main pulmonary arterial enlargement. An increased convexity is present at the cranial cardiac base on the lateral view (a, white arrows). A large focal bulge is present at the left cranial cardiac margin on the ventrodorsal view in the region of the main pulmonary artery (1:00–2:00 position; b, white arrows).

TABLE 3.12 Differential diagnoses and distinguishing factors for main pulmonary arterial (MPA) enlargement

Radiographic findings	Primary differential
Dilated MPA + small peripheral pulmonary vasculature	Pulmonic stenosis
Dilated MPA + dilated peripheral pulmonary arteries	Pulmonary hypertension (primary or secondary to heartworm infection)
Dilated MPA + dilated peripheral arteries and veins	Patent ductus arteriosus

MPA, main pulmonary artery.

most often due to congestion from right-sided heart failure. Radiographic changes consistent with right-sided cardiomegaly may be concurrently evident. The cranial vena cava is not seen as a distinct structure separate from other soft tissue opacities within the cranial mediastinum; therefore, its enlargement is not radiographically visible.

Pulmonary Arteries and Veins

Differentials diagnoses for cardiac enlargements should always be considered in combination with pulmonary vascular appearance. Pulmonary venous enlargement, pulmonary arterial enlargement, and combination pulmonary arterial and venous enlargement or hypovascularity have entirely separate differential diagnoses. Table 3.13 summarizes differential diagnoses for pulmonary arterial and/or venous enlargements.

The pulmonary arteries and veins are paired and surround the lobar bronchi, creating a triad of artery, bronchus, and vein. On the lateral view, the arteries are always located dorsal to the bronchus, and veins are located ventral. The size of the cranial lobar arteries and veins is best assessed on the lateral thoracic radiograph and should be similar in diameter to each other and to the proximal aspect of the 4th rib. The caudal lobar arteries and veins are best assessed on the ventrodorsal/dorsoventral view. The caudal lobar arteries are peripherally located relative to the bronchi and veins. As such, the veins are centrally located and are said to be "central and ventral" within the triad of artery, bronchus, and vein on the radiographic views. The size of the caudal lobar pulmonary arteries and veins can be compared to the diameter of the 9th ribs as they cross on the ventrodorsal view; they should be similar in size to each other and to the 9th rib at the location of their crossing. If the pulmonary arteries and veins are normal in size, the summation of the vasculature crossing the rib will form a square.

Congestive Heart Failure

Right-sided congestive heart failure is the inability of the heart (specifically the right atrium) to accommodate blood volume returning from systemic circulation. Increased right atrial pressure causes those vascular structures draining into the right atrium from the systemic circulation (cranial vena cava, caudal vena cava,

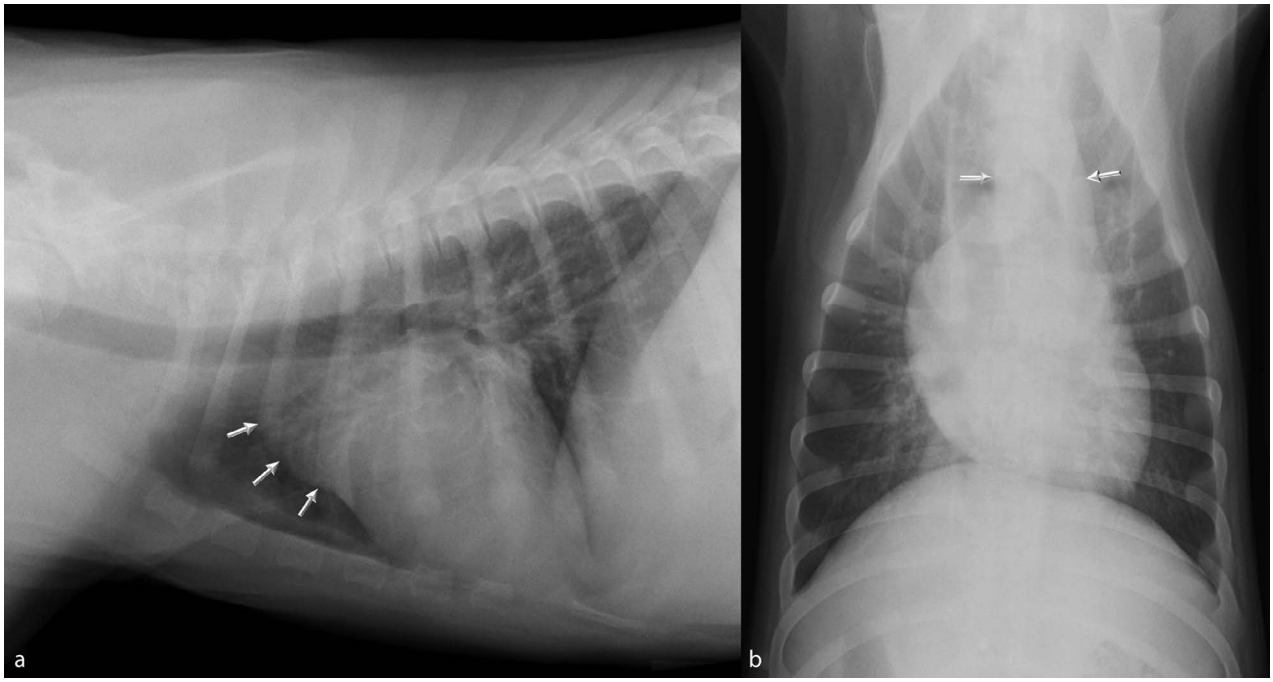

FIGURE 3.26 Lateral **(a)** and ventrodorsal **(b)** views in a dog having an enlarged aortic arch due to a poststenotic dilatation from subaortic stenosis. On the lateral view, a focal bulge is seen at the cranial cardiac base in the 8:00–11:00 position (a, white arrows). On the ventrodorsal view, an increase in soft tissue opacity is seen at the caudal aspect of the cranial mediastinum, also associated with the 11:00–1:00 position of the cardiac silhouette (b, white arrows).

lymphatics) to become congested and unable to transmit blood volume forward into the heart. The compensatory mechanisms of the heart are overwhelmed and result in congestive failure. Right-sided cardiomegaly does not automatically imply right heart failure; however, when right-sided cardiomegaly is diagnosed radiographically, evidence of failure should be intentionally sought. Radiographic signs indicating

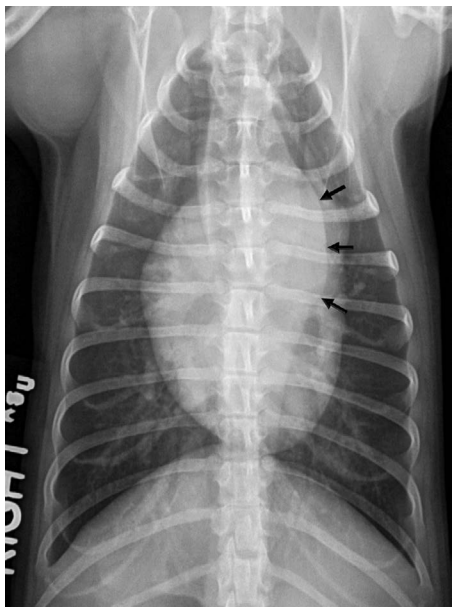

FIGURE 3.27 Ventrodorsal radiograph of a dog having enlargement of the proximal descending aorta secondary to a patent ductus arteriosus. The proximal aspect of the descending aorta has a focal convexity at the level of the proximal descending aorta (black arrows) that is distinct from aortic arch enlargement due to aortic stenosis.

TABLE 3.13 Differential diagnoses for abnormal pulmonary vascular size

Dilated pulmonary veins
- Elevated left atrial pressure
  - Mitral insufficiency, cardiomyopathy, etc.

Dilated pulmonary arteries
- Arteritis secondary to parasitic infection (e.g., heartworm infection)
- Pulmonary hypertension
- Pulmonary thromboembolism

Dilated pulmonary arteries and veins
- Left-to-right shunting of blood
  - PDA, VSD, ASD
- Volume overload
- Chronic or severe mitral valvular disease (pulmonary venous dilation expected prior to arterial dilation)

Small pulmonary arteries and veins
- Hypovolemia
- Shock
- Severe pulmonic stenosis
- Tricuspid dysplasia or severe tricuspid insufficiency
- Right to left shunts
  - Reverse PDA
  - VSD combined with pulmonic stenosis or pulmonary hypertension
  - Tetralogy of Fallot

Box 3.11 Radiographic findings of right heart failure include right-sided cardiomegaly or pericardial disease in combination with one or multiple of the following:

- Dilated caudal vena cava
- Generalized hepatomegaly
- Peritoneal effusion
- Pleural effusion*

* In dogs, effusion occurring in the pleural space due to right heart failure occurs only after effusion in the peritoneal space. Therefore, peritoneal effusion or bicavitary effusion has a differential diagnosis of right heart failure, but pleural effusion alone is not typically caused by right heart failure.

right-sided heart failure are shown in Box 3.11 and Figure 3.28.

Left-sided congestive heart failure is the inability of the heart (specifically the left atrium) to accommodate blood volume returning from pulmonary circulation. Increased left atrial pressure causes the pulmonary veins to become congested and unable to transmit blood volume into the chamber. The compensatory mechanisms of the heart are overwhelmed and result in congestive failure with excess blood volume in the pulmonary veins. Left-sided cardiomegaly does not imply left heart failure. The radiographic study must be specifically evaluated for indications of failure, which include dilated pulmonary veins and cardiogenic edema characterized by interstitial or alveolar pulmonary opacity typically having a perihilar/caudodorsal distribution. The edema is most often symmetrical but can be asymmetrical as well. An asymmetrical distribution tends to occur most often secondary to mitral valvular disease. Radiographic signs indicating left-sided heart failure are shown in Box 3.12 and Figure 3.29a–c. In cats, the distribution

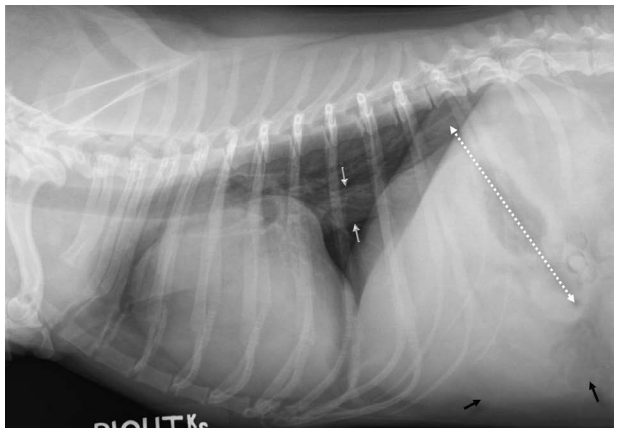

FIGURE 3.28 Lateral thoracic radiograph in a dog having right-sided cardiac failure due to pulmonic stenosis and tricuspid dysplasia. The caudal vena cava is dilated and fails to taper towards the diaphragm (between white arrows). The liver is enlarged, causing caudal displacement of the gastric axis (dotted white arrow). Peritoneal effusion is present, causing soft tissue opaque streaking and a decrease in detail of visible abdominal structures (black arrows). These findings combined with an enlarged, wide cardiac silhouette are indicative of right-sided heart failure.

Box 3.12 Radiographic findings of left heart failure include left-sided cardiomegaly in combination with one or multiple of the following:

- Dilated pulmonary veins
- Cardiogenic pulmonary edema
  - As pulmonary venous dilation and congestion progress, the increased pressure causes edema within the pulmonary interstitium. As edema worsens, the pulmonary pattern becomes alveolar
  - *Dogs:* Cardiogenic edema centered in perihilar/caudal lung lobe regions – symmetrical or asymmetrical
  - *Cats:* Cardiogenic edema has multifocal distribution and can be anywhere

of cardiogenic edema is often less predictable in regional distribution and can be diffuse or multifocal, as shown in Figure 3.30a, b. Additionally, although the mechanism is unclear, pleural effusion often accompanies cardiogenic edema in cases of left-sided failure in cats. This is not a feature seen in dogs, where only right-sided heart failure causes pleural effusion.

Pericardial Effusion

Pericardial effusion is most often idiopathic or neoplastic, such as right atrial hemangiosarcoma, heart base chemodectoma, or mesothelioma. Pericardial fluid increases pressure within the pericardium that can overwhelm the right atrial and ventricular pressure, resulting in cardiac tamponade and right-sided heart failure. Radiographic signs associated with pericardial effusion are summarized in Box 3.13 and Figure 3.31a, b. Effusion within the pericardial space creates a globoid cardiac silhouette, when severe, that precludes visibility of normal cardiac chambers. A key feature differentiating pericardial effusion from generalized cardiomegaly is the absence of visible left atrial dilation. Severe right-sided cardiomegaly and pericardial effusion can appear radiographically similar. Smaller volumes of effusion have potential for causing cardiac tamponade, with normal cardiac chambers still being visible radiographically, especially in acute cases. Secondary signs of right-sided heart failure are often seen at the time of diagnosis as part of the presenting complaint. Clinically significant pleural effusion that is severe enough to cause right heart failure is rare in cats. Small volumes of pericardial

Box 3.13 Radiographic appearance of pericardial effusion

  - Generalized hepatomegaly
  - Peritoneal effusion
  - Pleural effusion

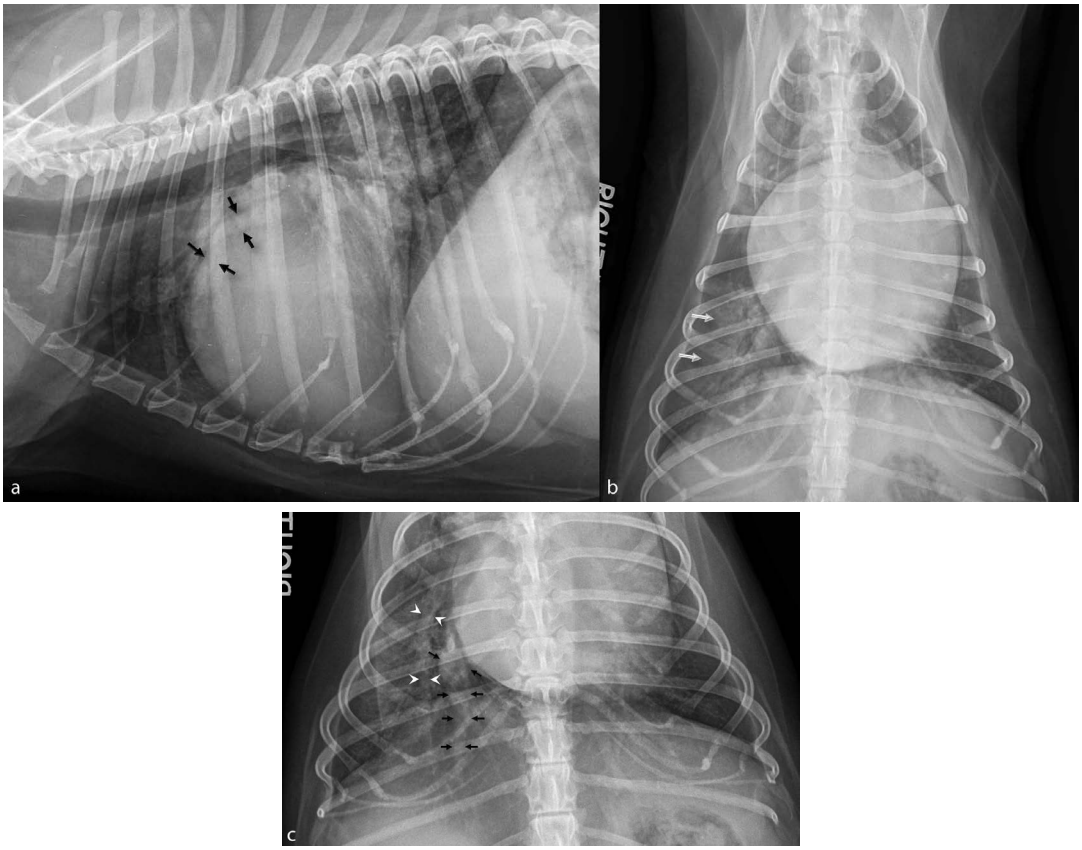

FIGURE 3.29 Lateral **(a)**, ventrodorsal **(b)**, and dorsoventral **(c)** thoracic radiographic views of a dog having left-sided cardiac failure due to mitral valvular insufficiency. The cranial lobar veins are increased in size (a, between black arrows). The caudal lobar vasculature is partially obscured by an increase in pulmonary opacity that is located in the perihilar and caudodorsal lungs, which is more severe on the right side (b, white arrows). On the dorsoventral view of the thorax, the dilated caudal lobar pulmonary veins (c, black arrows) are more clearly seen relative to the normal pulmonary arteries (c, white arrow heads). These findings combined with evidence of left-sided cardiomegaly (a tall cardiac silhouette and marked left atrial enlargement) indicate left-sided cardiac failure.

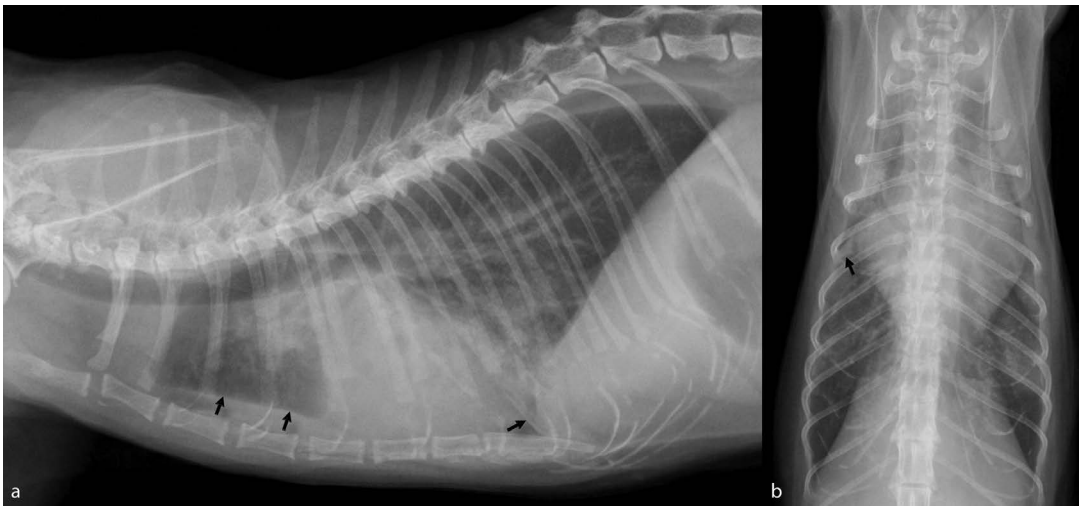

FIGURE 3.30 Lateral **(a)** and ventrodorsal **(b)** thorax radiographs in a cat with left-sided congestive heart failure due to feline cardiomyopathy. The regional distribution of cardiogenic edema is multifocal and predominantly ventral, causing partial border effacement of the cardiac silhouette. Cardiac enlargement can be assumed due to dorsal elevation of the trachea and the visibility of atrial enlargement on the ventrodorsal view. Additionally, evidence of mild pleural effusion is visible where lungs are retracted from the thoracic wall, and small pleural fissure lines are present (a and b, black arrows). A small volume of pleural fluid is a common finding in cats with left-sided cardiac failure.

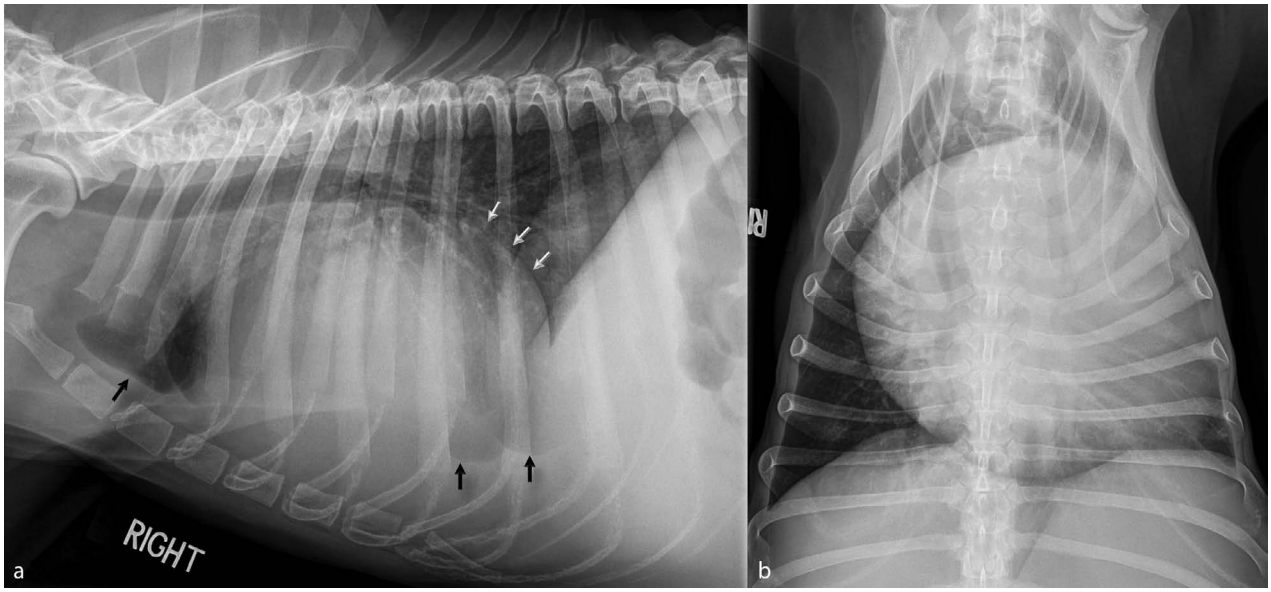

FIGURE 3.31 Lateral **(a)** and ventrodorsal **(b)** thoracic radiographs in a dog having marked pericardial effusion. The cardiac silhouette is globoid with no evidence of specific chambers that are enlarged. Notice the absence of visible left atrial enlargement (a, white arrows). Right heart failure is also present denoted by poor abdominal serosal detail and pleural effusion (retraction of lungs from the thoracic wall by fluid; b, black arrows).

effusion are often seen in cats presenting with heart failure secondary to feline cardiomyopathy.

Microcardia is a small heart due to decreased systemic venous return. Causes are similar to those for small pulmonary arteries and veins and include shock, dehydration/hypovolemia, hypoadrenocorticism, overinflated lungs, pneumothorax, and obstructed venous flow. Microcardia is often accompanied by a consistently small vena cava in addition to decreased pulmonary vascular diameter.

5. Lungs

Alveolar Pulmonary Pattern

Three descriptive hallmarks are seen with alveolar disease of any cause: Air bronchogram, lobar sign(s), and border effacement. Having any one of these three would classify the pulmonary pattern as alveolar. Often, not all hallmarks are present. An air bronchogram occurs when alveoli are not aerated, i.e., they contain fluid (edema, hemorrhage, pus) or are collapsed while the bronchi remain aerated. Its appearance is likened to a "tree in a snowstorm," where the branching lucent bronchus is evident against a white backdrop. A lobar sign occurs when alveolar disease is peripheral relative to lobar margins and inconsistent among lung lobes. This allows the margin of the lung lobe to be evident as a relatively distinct line between an affected lobe that is adjacent to a more aerated lobe. Border effacement is the most consistently present hallmark of alveolar disease. When objects are effaced, their margins can no longer be delineated. In order for this to occur, the objects have to be identical in opacity (usually both are soft tissue/fluid opaque), and they have to be in direct physical contact with each other. When alveolar disease is present, fluid within alveoli, which is identical in opacity to the heart, pulmonary vasculature, and bronchial walls, contacts any of these structures such that their margins are no longer distinguishable. The hallmarks of alveolar disease are depicted in Figure 3.32a–d.

The first descriptive discriminator in differentiating causes of alveolar disease is lung size. A decrease in lung size due to collapse of airways is called atelectasis. Atelectasis results in an increase in pulmonary opacity and decreased lung volume seen as a mediastinal shift towards the opaque lung (ipsilateral mediastinal shift) and ipsilateral cranial positioning of the diaphragm. Atelectasis can be due to obstructive or nonobstructive causes. Obstructive (or resorption) atelectasis occurs when the diameter of the airway is reduced or blocked, most commonly from mucus plugging, bronchial wall inflammation, or a neoplastic mass. The reduction in diameter may be luminal, mural, or extramural in origin. Regardless, trapped gas is resorbed and not replaced, resulting in decreased lung volume. This form of atelectasis is most commonly seen in cats with bronchial disease, resulting in mucus plugging and so-called right middle lung lobe syndrome or atelectasis of the right middle lung lobe. Nonobstructive atelectasis may be due to compression/relaxation, surfactant deficiency, or loss of pulmonary compliance due to cicatrization (e.g., fibrosis of pleura limiting lung expansion).

When not caused by atelectasis, alveolar disease is typically caused by fluid accumulation (edema, hemorrhage, or pus) or cells (granuloma or neoplasia) within alveoli. The regional distribution is the most effective means of distinguishing these, as shown in Table 3.14. Pulmonary edema can be caused by cardiogenic or noncardiogenic mechanisms. The causes of noncardiogenic pulmonary edema are listed in Box 3.14.

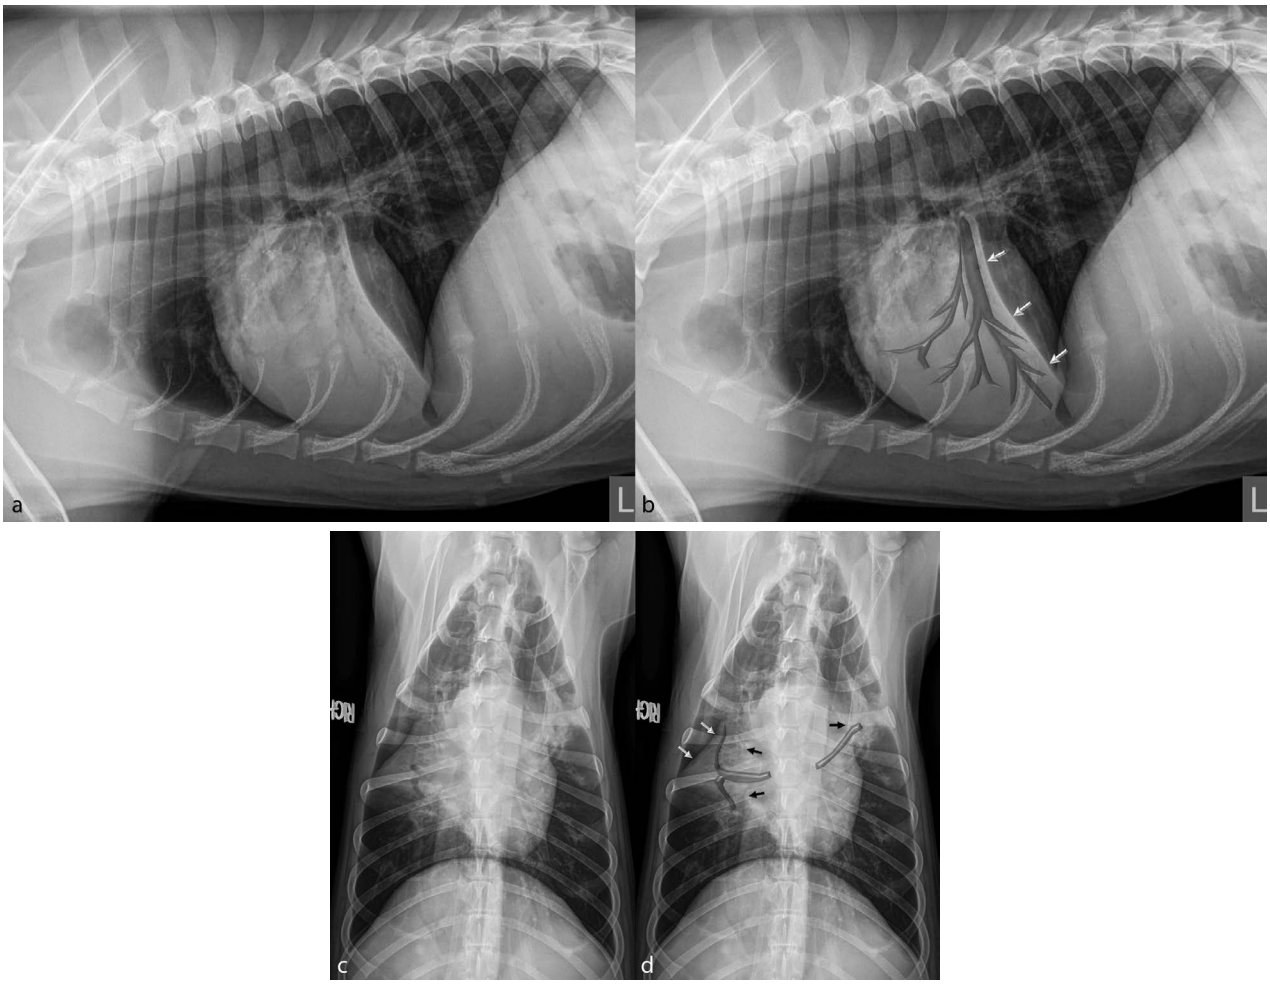

FIGURE 3.32 Lateral **(a)** projection with accompanying schematic **(b)** and ventrodorsal **(c)** projection with accompanying schematic **(d)** thoracic views of a dog having alveolar pulmonary disease within the right middle and left cranial lung lobes due to aspiration pneumonia. All hallmarks of alveolar disease are evident. Air bronchograms can be seen as gray branching structures (b and d, highlighted in gray) against a white backdrop and are visible on both projections, in this case. Lobar signs (b and d, white arrows) are visible between the right middle lung lobe and the more aerated adjacent lobes. Finally, border effacement prevents ability to see the right and left cranial cardiac margins (b and d, black arrows) and margins of vasculature/bronchi within the affected lobes.

Interstitial Pulmonary Pattern

The interstitial pulmonary pattern is subcategorized into structured and unstructured. The unstructured interstitial pulmonary pattern is notoriously difficult to diagnose, as the appearance of the interstitium is greatly influenced by technical factors and respiratory phase. Additionally, it may indicate active or past disease. An unstructured interstitial pulmonary pattern is described by an increase in pulmonary opacity that is less intense per unit area when compared to alveolar disease such that margins of vessels are less delineated but not totally effaced, as shown in Figure 3.33a–d. Any disease resulting in an alveolar pulmonary pattern can appear as an unstructured interstitial pulmonary pattern with a similar regional distribution. As the evolution of fluid changes from less to more severe or as resolution occurs with treatment, a shift can be seen from interstitial to alveolar and from alveolar to interstitial, respectively. Therefore, the distributions and differential diagnoses for interstitial disease can be described as that described previously for alveolar disease. Additionally, in cases of an unstructured pulmonary pattern that is distributed diffusely, fibrosis, neoplasia (lymphoma, hemangiosarcoma), or hematogenous pneumonitis (infectious/noninfectious inflammatory) should be considered.

The structured pulmonary pattern is reserved for any nodular or mass lesion(s) seen within the lung. This pattern can be relatively intense per unit area, depending on size of the nodule. The difference between a nodule and a mass is strictly size, where a mass is 3 cm or greater. Masses and nodules are best delineated from other lesions of high intensity per unit area (i.e., alveolar lung disease) by the rounded, sometimes well-defined margins seen with structured interstitial disease. The main differential diagnoses for this pulmonary pattern are summarized in Table 3.15. Granulomatous pneumonia tends to occur in younger animals, and the nodules

TABLE 3.14 Regional distribution of lung diseases resulting in an alveolar pulmonary pattern

Causes of alveolar pattern	Regional distribution
– Aspiration or bronchopneumonia	– Ventral to trachea
– Cardiogenic pulmonary edema	– Perihilar/ caudodorsal/diffuse – Multifocal in cats – Peribronchial in dogs with DCM
– Noncardiogenic pulmonary edema	– Caudodorsal
– Hemorrhage – Trauma – Coagulopathy	– Variable – Variable/ caudodorsal
– Interstitial pneumonia	– Caudodorsal/diffuse
– Pulmonary thromboembolism	– Variable
– Atelectasis	– Often ventral to trachea/variable
– Primary lung tumor	– Lobar/caudal lobes/ variable

DCM, dilated cardiomyopathy.

Box 3.14 Causes of noncardiogenic pulmonary edema

- Upper airway obstruction
- Head trauma
- Electrocution
- Uncontrolled seizures
- Hypoglycemia
- Thoracic trauma
- Smoke inhalation
- Near drowning
- Acute lung injury/acute respiratory distress syndrome
  - Acute interstitial pneumonia/pneumonitis
  - Systemic inflammatory response syndrome
  - Pancreatitis
  - Sepsis
  - Uremia

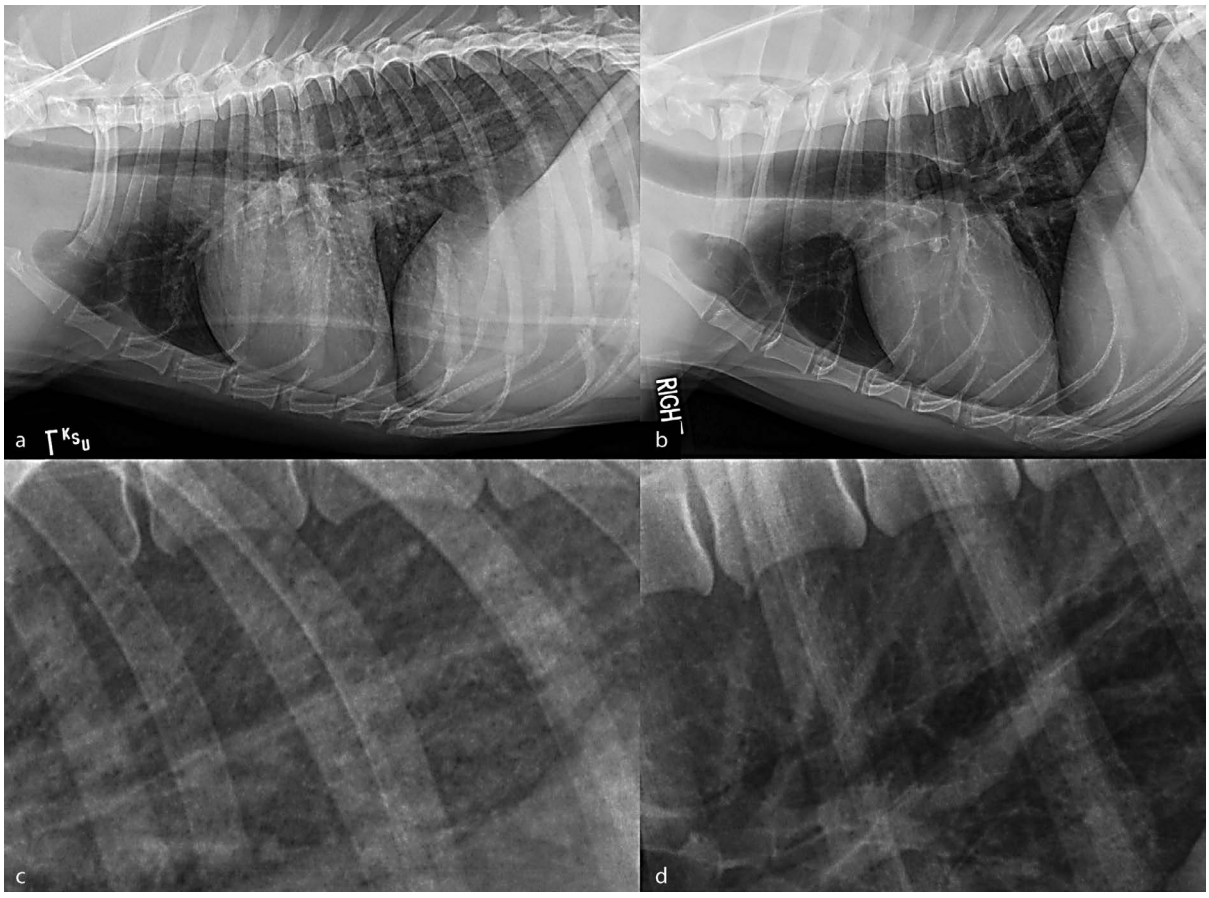

FIGURE 3.33 Unstructured interstitial pulmonary pattern. Lateral thoracic radiographic view **(a)** and closeup **(c)** of a dog with confirmed uremic pneumonitis creating an interstitial pulmonary pattern. A lateral thoracic radiograph **(b)** and closeup **(d)** of a normal dog not having clinical respiratory disease is shown for comparison. The caudodorsal distribution of pulmonary opacity makes noncardiogenic pulmonary edema more likely, which is a typical appearance for acute lung injury due to uremic pneumonitis.

TABLE 3.15 Differential diagnoses for a structured interstitial pulmonary pattern

Number and description	Differential diagnoses
Multiple soft tissue nodules	Metastasis, granulomatous pneumonia, septic emboli, parasitic (e.g., *Paragonimus kellicotti*), cysts, artifactual (end-on vasculature, superimposed superficial nipple or debris)
Solitary soft tissue nodule or mass	Primary tumor, single metastasis, granuloma (foreign body), abscess, fluid-filled cyst, artifactual (see mentioned in the text earlier)
Multiple or single cavitary nodule(s)/ mass(es)	*Thick-walled:* Neoplasia (primary or metastatic), abscess, granuloma, parasitic *Thin-walled:* Bulla, cyst, airway dilation (bronchus/bronchiectasis, alveoli/ emphysema)
Single or multiple mineral nodule(s)	Pulmonary osteomas, chronic fungal granulomas, rarely parasitic nodules, or neoplasia

tend to be of a similar size with indistinct margins. Sometimes, nodules can appear very small creating a miliary type of pulmonary pattern, as shown in Figure 3.34. Multiple nodules due to metastatic disease tend to occur in older animals. The nodules are more often variable in size with well-defined margins. Multiple mineralized pulmonary nodules, called pulmonary osteomas, pulmonary osteomata, or heterotopic bone, occur as a benign finding in dogs, especially Boxers and Shetland Sheepdogs. They are often in higher numbers ventrally and only a few millimeters in size. True soft tissue opaque nodules of this size would be poorly detected on radiographs, so when a nodule that is 3 mm or less is visible on radiographs, the interpreter must consider a mineralized nodule or end-on vessel. Additionally, these mineralized pulmonary osteomas are typically irregularly marginated when

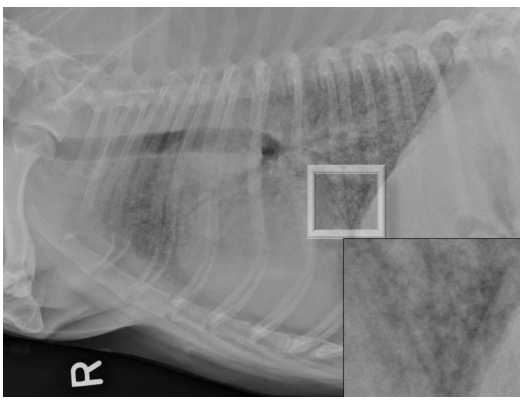

FIGURE 3.34 Lateral thoracic radiograph with magnified inset in a dog with a miliary structured interstitial pulmonary pattern due to Blastomycosis. The nodules are very small in size, resembling an accumulation of millet seeds, and have very indistinct margins, reflecting active inflammation. The diagnosis was achieved with lung aspiration.

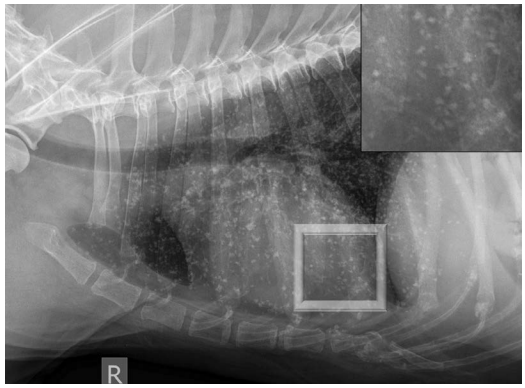

FIGURE 3.35 Lateral thoracic radiograph obtained of a Shetland Sheepdog for metastasis check. Numerous, well-defined mineralized nodules are present. Many of these nodules are less than 3 mm in size yet are highly visible, supporting suspicion of mineralized benign pulmonary osteomas. On close inspection of the magnified inset, the nodules are highly irregularly marginated rather than being round in shape.

inspected closely, also distinguishing them form many soft tissue opaque nodules. As mentioned, pulmonary osteomas are benign and can be quite numerous, as shown in Figure 3.35. Mineralized malignant nodules are extremely rare in veterinary medicine.

Regardless of whether or not the interstitial pulmonary pattern is structured or unstructured, a definitive diagnosis is most often determined via lung aspiration rather than airway sampling.

Bronchial Pulmonary Pattern

The bronchial pulmonary pattern implies disease that is airway related. Fluid or cells infiltrate bronchial walls and result in radiographically evident thickening. In most cases, the ailment affecting the bronchus extends into surrounding peribronchial interstitium. In some cases, the infiltration may be limited to peribronchial interstitium; however, airway-related disease remains the most common underlying cause. It is a common mistake to assign a bronchial pattern when normal bronchi are noticed, especially if clinical signs such as coughing are present. Seeing bronchi does not make the study abnormal. Disease can be assumed, however, when the bronchi are thickened, irregular, and/or indistinct in margination. Irregular and thickened bronchial walls create the so-called tram tracks and rings within the lungs, as shown in Figure 3.36a, b.

In addition to bronchial walls being thickened and irregular when radiographically visible disease is present, bronchi can fail to taper due to bronchiectasis (Figure 3.37). Bronchiectasis is important to recognize as an irreversible sequela of chronic airway-related disease and as a predisposing factor for future airway-related symptoms and bronchopneumonia.

Vascular Pulmonary Pattern

This pattern is reserved for cases where the pulmonary vasculature is too big or too small. Many do not

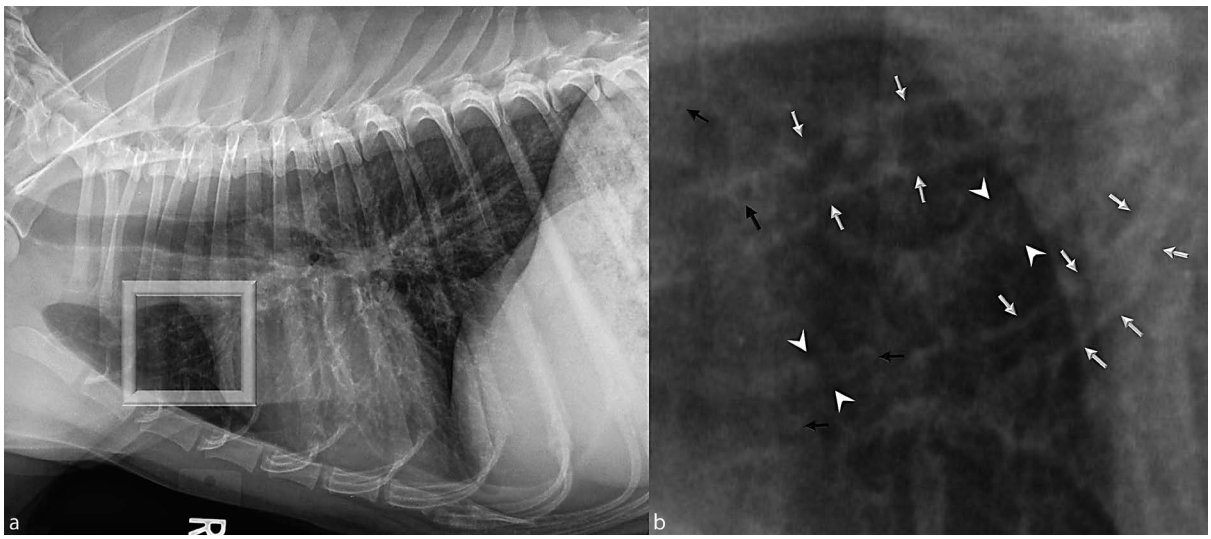

FIGURE 3.36 Lateral thoracic radiograph **(a)** and magnified inset **(b)** of a dog having chronic bronchial disease. The bronchial walls seen in longitudinal orientation (b, white arrows) and those seen end-on (b, black arrows) are thick and irregular, creating the tram-tracks and rings expected with bronchial disease. The walls are thinner and more irregular than adjacent pulmonary vasculature (between white arrowheads). A noninfectious, inflammatory airway inflammation was determined based on bronchoalveolar lavage.

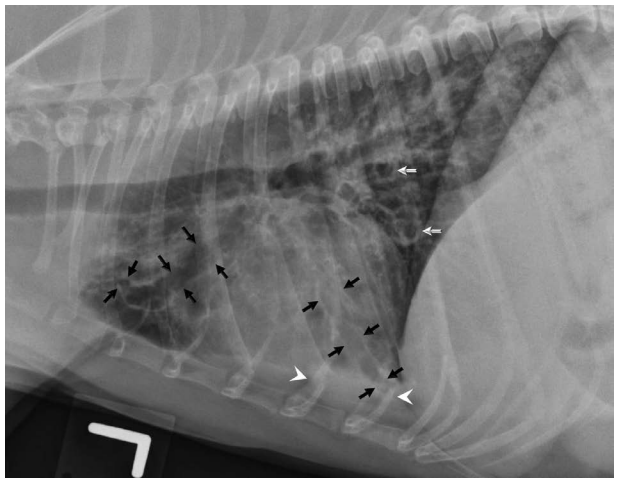

FIGURE 3.37 Left lateral thoracic radiograph in a dog having a chronic cough of 11 years' duration. Increased irregular, well-defined linear and ring markings are present in all lung lobes, consistent with a chronic bronchial pattern. Multiple bronchi fail to taper at the periphery of the lung (black arrows). The tubular shape of the bronchi is consistent with cylindrical bronchiectasis. Enlarged, dilated rings are also visible dorsally, consistent with bronchiectasis viewed end-on. Focal ventral alveolar disease is also present, consistent with bronchopneumonia (white arrowheads), a common predisposing factor and sequela seen in cases of bronchiectasis.

consider this a true pulmonary pattern. If arteries and/or veins are enlarged or small, causes of cardiopulmonary vascular disease should be pursued, as previously discussed. The most common causes of a vascular pulmonary pattern are left-to-right shunts (enlarged arteries and veins) and, in endemic regions, heartworm infection in dogs. The characteristic changes identified in heartworm infection are shown in Box 3.15.

Box 3.15 Radiographic appearance of heartworm infection

- Right ventricular enlargement
  - Concentric nature of hypertrophy makes radiographic detection insensitive until severe
  - *Lateral view:* Wide cardiac silhouette, increased sternal contact, elevated cardiac apex
  - *Ventrodorsal view:* Bulge in 5:00–9:00 position at the right cardiac margin
- Main pulmonary arterial enlargement
  - *Lateral view:* Bulge in the 8:00–11:00 position at the cranial cardiac base
  - *Ventrodorsal view:* Bulge in the 1:00–2:00 position at the left cranial cardiac margin
- Peripheral pulmonary arterial enlargement
- Pulmonary eosinophilic inflammation
  - Peribronchial interstitial to alveolar pulmonary opacity
  - Multifocal nodular pulmonary pattern, in some cases
- Right-sided heart failure
  - Dilated caudal vena cava
  - Generalized hepatomegaly
  - Peritoneal effusion
  - Pleural effusion

Recommended Further Readings 160

BASICS OF ABDOMINAL RADIOGRAPHY

To properly interpret abdominal radiographs, lesion description using the six Roentgen signs (size, shape, margination, opacity, location, and number) must be used to translate the image to text so that differential diagnoses can be researched using imaging resources. An understanding of the differing appearance of the five radiographic opacities is crucial to avoiding misinterpretation of findings, such as falciform fat being mistaken for fluid. The five radiographic opacities in order from most lucent to most opaque are: Air, fat, soft tissue/fluid, bone/mineral, and metal. The ability to distinguish organs in the abdomen is primarily created by soft tissue opaque structures being surrounded by fat. Fat is less opaque than soft tissue/fluid, making borders visible. Along similar lines, soft tissue and fluid are of identical radiographic opacity; therefore, thickness of gastrointestinal (GI) walls and the urinary bladder wall cannot be determined on radiographs without the use of contrast. Also, organs can be poorly visible when the peritoneum contains large volumes of fluid because organ margins become effaced when fluid (which has identical opacity as soft tissue) is in direct contact with their borders.

Technique and Positioning

Positioning

An abdominal study should include the entire diaphragm as the cranial boundary and the coxofemoral joints as the caudal boundary. The right and left lateral views are named according to the recumbency of the animal. The ventrodorsal view is obtained with the animal in dorsal recumbency and is the primary orthogonal view obtained in abdominal imaging. A dorsoventral view with the animal positioned in sternal recumbency is rarely obtained. With each view, the hindlimbs should be extended caudally to limit crowding of abdominal organs.

Choosing the Abdominal Views

Like any radiographic study, at least two views must be obtained of the abdomen in order to properly evaluate the study and reconstruct a 3D description from a set of 2D images. Most commonly, right lateral and ventrodorsal views are obtained. In the right lateral view, the tail of the spleen is more commonly visible, and the kidneys are better distinguished as separate structures when compared with the left lateral view. Gravity, mobility of organs, and the changes in distribution of gas and fluid with recumbency can be used to optimize the diagnostic capability of radiographic studies in many common clinical scenarios. Because of this, many radiologists advocate the use of right and left lateral views in addition to an orthogonal view as standard practice for imaging the thorax and the abdomen.

The variation in abdominal organ appearance with recumbency is most notable in the GI tract. Luminal contents within the stomach and small intestine often contain some degree of fluid and gas. Because patients are positioned in recumbency (rather than standing), and views are obtained with a vertical beam (rather than horizontal beam), the classic appearance of a combination of contents in the GI tract is a summation of opacities created by both gas and fluid that change with positioning (Figure 4.1). The redistribution of gas within the GI tract (without administration of additional contrast agents) by obtaining a left lateral view has been used to diagnose pyloric outflow obstructions, locate obstructions within small intestines, highlight intussusceptions, distinguish colon from dilated small intestine, rule out gastric malpositioning, and definitively locate the pylorus, among other applications.

DOI: 10.1201/9781003254591-22

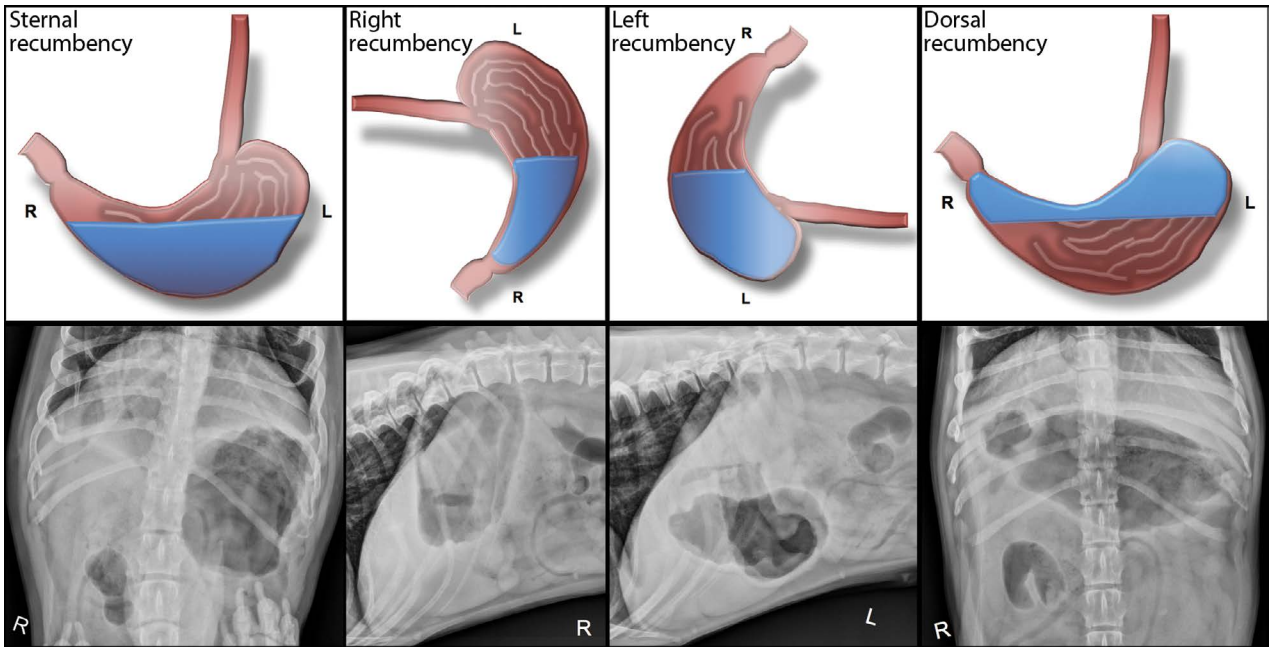

FIGURE 4.1 Diagram showing the distribution of gravity-dependent stomach contents with recumbency. Accompanying radiographic appearance is shown below each diagram. When the animal is positioned in sternal recumbency (dorsoventral view), gas rises to the most dorsal part of the stomach, the fundus, and fluid falls to the most ventral part, the gastric body. As a result, the gastric fundus is more apparent because luminal gas creates the most contrast with surrounding soft tissue opaque organs. In the right lateral view, mobile fluid falls to the most gravity-dependent part of the stomach, the pylorus, while gas rises to the fundus, the largest gastric compartment. As a result, the gas-containing gastric fundus is most visible on right lateral view. On the left lateral recumbent view, gas rises to the nongravity-dependent pylorus, while fluid falls to the fundus, making the region of the pylorus most radiographically evident. Finally, when animals are positioned in dorsal recumbency (ventrodorsal view), gas rises to the most ventral part of the stomach, the gastric body, while fluid falls to the gastric fundus and pylorus. This results in increased visibility of the gastric body.

Special Views

Depending on the clinical circumstances, an additional view outside the standard protocol may provide vital diagnostic information. For example, a flexed hindlimb view of the caudal abdomen can be obtained to evaluate the entire penile urethra for calculi in a male dog while avoiding superimposition of the femurs. Simple additional techniques include positional radiography (left lateral abdominal projection and horizontal beam radiography), compression radiography, and simple negative contrast radiography (pneumocolonogram and pneumogastrogram). These views will be addressed in appropriate sections throughout the chapter.

READING THE ABDOMINAL RADIOGRAPH

Systematic Approach

The interpretation of abdominal radiographs is best accomplished using a checklist-style systematic evaluation of each organ on each view (Box 4.1). Evaluating each organ on every study, regardless of clinical signs, increases the comfort level in recognizing normal from abnormal structures and prevents findings from going undetected. The familiarity gained from a systematic approach will prevent newly recognized organs or organs better seen in one patient versus another from being automatically or inappropriately deemed abnormal. Also, many structures within the abdomen are not seen in normal animals on radiographs. The location of these normally unseen structures should be considered, as disease has the potential to make them visible.

INTERPRETATION OF ABDOMINAL ABNORMALITIES

1. Extra-abdominal Structures

Review and consideration of extra-abdominal structures early in the interpretation process can prevent misplaced importance of those findings and allow limitations of the study to be considered. For example, wet hair can mimic peritoneal effusion, which is typically a significant finding, so early recognition can prevent misdiagnosis.

Abdominal Wall, Skeleton, and Visible Thorax

Initially, the ventral abdominal wall should be characterized as tucked, pendulous, or normal in contour. This will assist with differentiating potential causes of decreased detail, if it exists, and give an overall clue as to the body condition of the animal. An animal with a

† Organ visibility in normal dogs, dependent on neuter status.

tucked abdominal contour may have decreased abdominal detail because of thin body condition, whereas an animal with a pendulous contour and decreased peritoneal detail may have peritoneal effusion or large volumes of peritoneal fat deposition causing increased scatter. Young animals also tend to have a pendulous contour and decreased detail.

Abnormalities within the visible thorax and skeleton may not be responsible for clinical signs but could be significant regardless or could assist with appropriate ranking of differential diagnoses if given consideration.

2. Peritoneal Space

Peritoneal Effusion

The influence of fluid within the peritoneal space can range from a mild decrease in detail to total border effacement of abdominal organs (Figure 4.2a, b). Smaller volumes of peritoneal effusion may cause soft tissue opaque streaking within the falciform and mesenteric fat, making serosal margins less distinct. In some cases, fluid is so severe that the only indication of organ position is the gas within small intestinal loops. An asymmetric distribution of small intestine may indicate mass effect or may simply be due to an absence of gas-filled intestine in a particular region. When differentiating various causes of abdominal effusion, a fluid composition approach is most inclusive. Fluid may be due to transudates, exudate, hemorrhage, urine, bile, or chyle. The causes of each fluid type can then be considered as potential differential diagnoses. Clinical history is also very useful in differentiating causes of effusion. In many instances, fluid sampling and subsequent analysis is the next step with or without abdominal ultrasound.

Decreased serosal detail (Box 4.2) can include the entire abdomen or can have a clear regional distribution indicating disease limited to local organs. Focal or global regions of decreased detail may also be due to

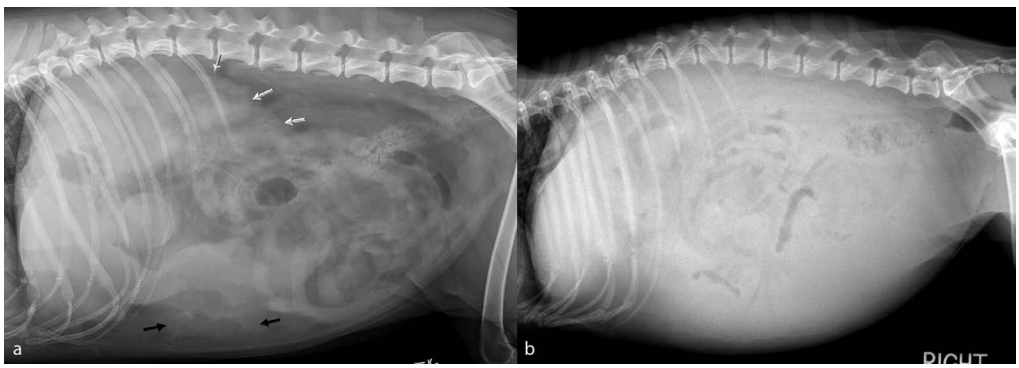

FIGURE 4.2 Lateral abdominal radiographs in a dog having a small volume of peritoneal effusion (a) and a dog having marked peritoneal effusion (b). In the dog having a smaller volume of peritoneal effusion, soft tissue opaque streaking can be seen within ventral abdominal fat (a, between black arrows). Margins of the liver spleen, intestines, and urinary bladder are somewhat visible but are less distinct than in a normal animal. The splenic tail, though less distinct, can be recognized as having a nodular appearance. In this case, the margins of the kidneys remain sharp because they are retroperitoneal in location, and effusion is not concurrently present in the retroperitoneal space. In the dog having a large volume of peritoneal effusion (b), serosal margins of peritoneal structures are completely obscured. The only indication of organ location is the distribution of intestines containing gas. Abdominal ultrasound and/or fluid analysis are the next logical steps in evaluating cases with this volume of effusion.

Box 4.2 Potential causes of reduced peritoneal detail

- Underexposure
- Wet air artifact
- Young animal (typically pendulous contour)
- Abdominal effusion (pendulous contour)
- Mass effect (pendulous contour)
- Obesity (pendulous contour)
- Emaciation or thin body condition (tucked contour)
- Peritonitis
- Carcinomatosis or neoplastic seeding (typically pendulous contour)

peritonitis, which appears similar to small volumes of effusion. In such cases, attempts to sample may be unrewarding, and ultrasound is recommended to determine the underlying cause.

Horizontal Beam Radiography

Abnormalities within the peritoneal space may manifest as excess lucency rather than increased opacity. Free gas within the abdomen can highlight serosal margins, making them apparent when otherwise invisible, e.g., gas dissecting between liver lobes, making their margins visible. Potential causes of free peritoneal gas are listed in Box 4.3. Additionally, most causes of free peritoneal gas also cause some degree of abdominal effusion, resulting in a mixed gray opacity that can be difficult to differentiate from GI contents if care is not taken to avoid misinterpretation. In such cases, horizontal beam radiography can be immensely helpful in confirming suspicion of free gas; however, suspicion of free gas must be present in order to consider use of horizontal beam radiographs.

Box 4.3 Causes of free peritoneal gas

- Perforated hollow viscus
  - Stomach
  - Small intestine
  - Colon
  - Uterus
  - Urinary bladder (gas rarely present)
- Penetrating or perforating injury
  - Bite wound
  - Gunshot
- Ruptured abscess (gas-producing bacteria)
- Recent abdominal surgery (within about 3 weeks)

Horizontal beam views of the abdomen can be obtained by placing the animal in left lateral or dorsal recumbency (Figure 4.3a–d). The basis of these views is to

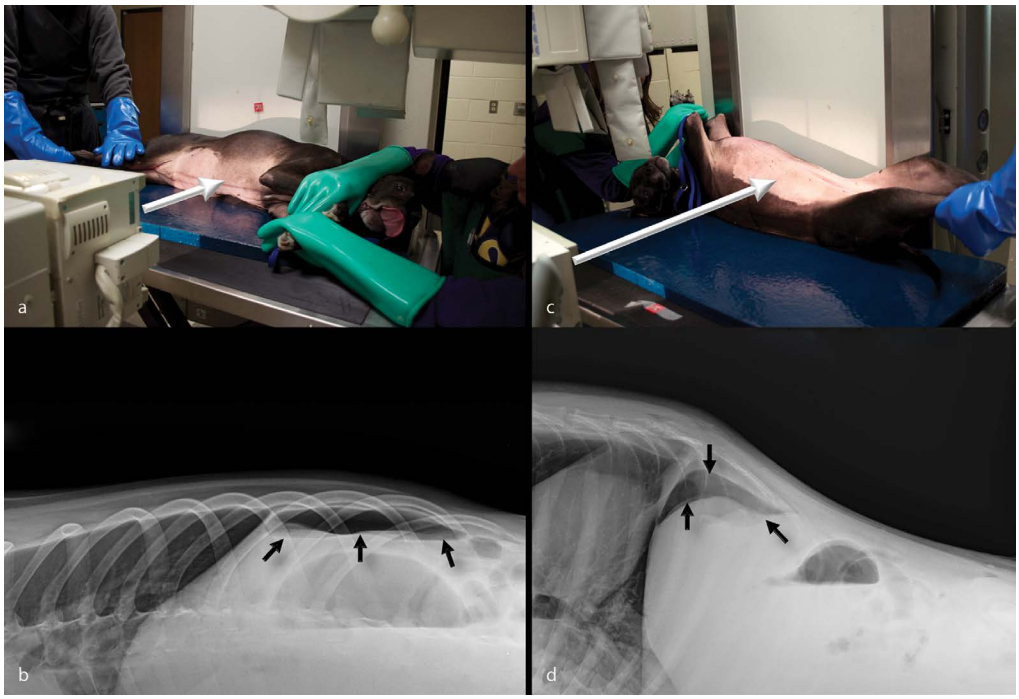

FIGURE 4.3 Horizontal beam radiography of the abdomen. Positioning **(a)** to obtain horizontal beam radiograph with the patient in left lateral recumbency; white arrow denotes direction of the x-ray beam. Resultant horizontal beam ventrodorsal view **(b)** showing free peritoneal gas accumulated caudal to the diaphragm on the right side (arrows). Positioning **(c)** to obtain horizontal beam radiograph with the patient in dorsal recumbency; white arrow denotes direction of the x-ray beam. Resultant horizontal beam lateral view **(d)** showing free peritoneal gas accumulated caudal to the diaphragm, ventrally (arrows).

force gas to accumulate in a predictable location (i.e., non-gravity dependent) and specifically image this location.

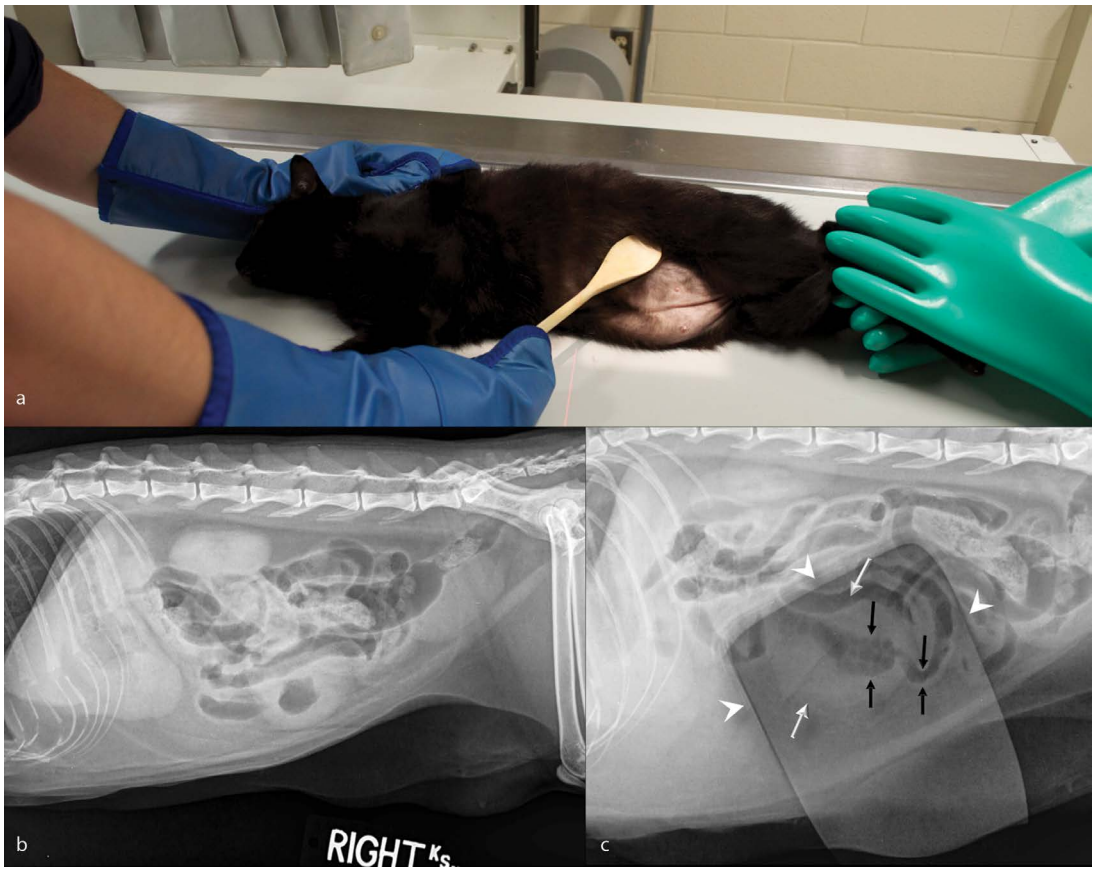
Pneumoperitoneum is most often caused by a penetrating/perforating wound or a perforated hollow viscus, usually the GI tract. Unless the cause of the pneumoperitoneum is iatrogenic (i.e., previous abdominal surgery within about 3 weeks), the diagnosis of pneumoperitoneum often indicates septic peritonitis, and surgical intervention is required.

Compression Radiography

The purpose of compression radiography is to isolate a specific region of interest or remove superimposition of peritoneal structures by use of a radiolucent compression device. The most typically used device is a radiolucent wooden spoon or spatula; however, any rigid radiolucent device with a handle can be used. The indications for this study include isolation of specific organs of interest that are otherwise obscured by superimposition or to better delineate margins of a normal or abnormal structure seen on survey radiographs. This technique has been used to better delineate palpable or radiographically visible abdominal masses, isolate the urinary bladder to prove presence or absence of calculi, remove superimposition of the GI tract on kidneys, separate small intestines from each other, and confirm the presence of uterine enlargement, among other potential applications.

Patient positioning depends on the region of interest to be evaluated. Often, standard abdominal views are used to assist in determining the region of interest and positioning for the compression study. Palpation may also dictate a specific region of interest. The specific location should be isolated with a hand, then the hand replaced by the wooden spoon or other compression device. The device should be similar in size to or 1.5 times larger than the specific organ or regions of interest being isolated. The act of compressing reduces the thickness in the region of interest; therefore, the radiographic technique should be reduced to avoid overexposure (decrease kilovoltage peak [kVp] by 10%). Collimating is advisable to avoid personnel exposure and optimize the image (**Figure 4.4a–c**).

Compression should be avoided in cases where rupture is a potential concern, such as a severely enlarged uterus or splenic mass, or in cases of diaphragmatic hernia where organs may be further displaced into the pleural space.



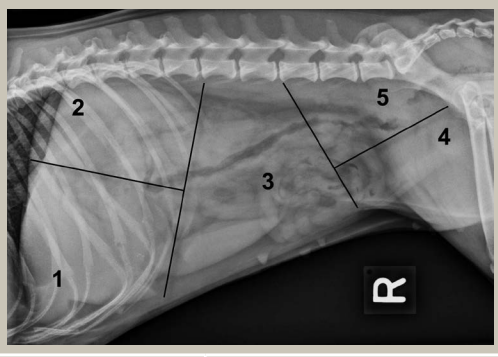


FIGURE 4.4 Technique for performing compression view **(a)** and lateral abdominal survey **(b)** and compression **(c)** radiographs in an 11-year-old female spayed Domestic Shorthair cat presenting with a yearlong history of intermittent vomiting. Typical positioning for a palpable abdominal mass is shown in (a). A ventrally located soft tissue opacity having an indistinct dorsal margin is seen on survey radiographs (b). A lateral radiograph was obtained after using a radiolucent wooden spatula to isolate the mass (c). The wooden spatula decreases thickness of tissues in the region of the mass, which results in an increase in overall apparent exposure in the location of the spatula (c, white arrowheads). The soft tissue opacity is better defined on the compression view (c, white arrows). Also, a gas-containing small intestinal loop leads into the mass, which has an irregular tubular gas center (black arrows), consistent with a small intestinal organ of origin for the mass.

Mass Effect

The visibility of serosal margins can be diminished when organ crowding occurs. Mass effect is the altered distribution of organs within the peritoneal space. A mass, which may or may not be discretely visible, is the object that causes the altered distribution of organs. The description of mass effect is the biggest clue as to the most likely organ of origin for an abdominal mass. For the sake of description of mass effect, the abdomen can be considered to have defined compartments on the lateral and ventrodorsal views. Potential organs of origin for visible masses correspond to the location of the mass effect related to these compartments, as shown in Table 4.1. Description of the organ displacement is the key to determining the most likely compartment for a mass effect and, therefore, the most likely organ of origin and the most likely differential diagnoses for the mass. Location of the mass effect needs to be considered on orthogonal views in order to assign the most likely organ of origin. Keep in mind that a mass effect can be identified without a well-defined mass

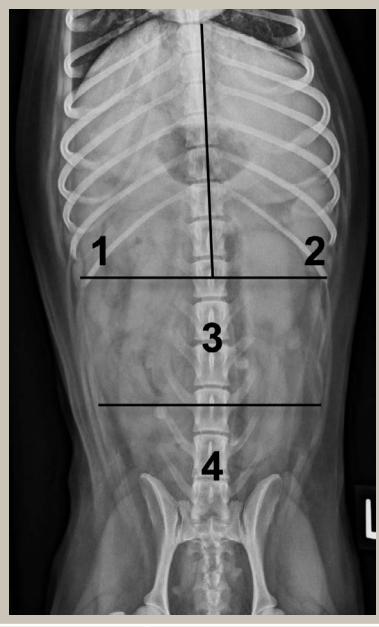

TABLE 4.1 Potential organs of origin for masses located in regions of the peritoneal space

Lateral view

Location of mass effect	Potential organ of origin
1. Cranioventral	– Liver – Spleen – Gastric body and pylorus – Right pancreatic limb – Gallbladder and biliary system – Hepatic and gastric lymph nodes
2. Craniodorsal	– Liver – Splenic head – Gastric fundus – Kidneys – Adrenal glands – Ovary – Left pancreatic limb – Splenic lymph nodes
3. Central	– Spleen – Mesenteric lymph nodes – Mesentery – Uterus – Intestine – Ovary – Retained testicle – Left kidney
4. Caudoventral	– Urinary bladder – Prostate – Uterus – Retained testicle
5. Caudodorsal	– Sublumbar lymph nodes – Distal descending colon – Ureters

Ventrodorsal view

Location of mass effect	Potential organ of origin
1. Right cranial	– Liver – Gallbladder and biliary system – Pancreas – Right kidney – Right adrenal – Pylorus and proximal duodenum – Gastric and hepatic lymph nodes
2. Left cranial	– Spleen – Liver – Gastric fundus – Left pancreatic limb – Left adrenal
3. Central	– Spleen – Mesenteric lymph nodes – Intestine – Left kidney – Uterus – Ovary – Retained testicle
4. Caudal	– Urinary bladder – Uterus – Prostate – Sublumbar lymph nodes – Distal descending colon

Note: Separate regions are delineated with black lines.

Box 4.4 Differential diagnoses for abdominal masses

- Cyst
- Hematoma
- Abscess
- Neoplasia
- Granuloma
- Nodular regeneration, hyperplasia, extramedullary hematopoiesis (liver and spleen)
- Physiologic enlargement (e.g., renal hypertrophy or splenomegaly due to tranquilization)
- Distension of a hollow viscus (gastrointestinal tract, urinary bladder, uterus)
- Organ torsion/congestion

being visible; however, displacement of organs such as the small intestines indicates the presence of an abnormality. Very few differential diagnoses exist for abdominal masses, and they are highlighted in Box 4.4 and are ranked according to the most likely organ of origin.

3. Liver

Hepatic size is a subjective determination based primarily on its shape and the position of the stomach. The axis of the stomach is a line drawn from the gastric fundus to the ventral aspect of the gastric body/pylorus. The gastric axis should be roughly parallel to the ribs or perpendicular to the spine. When the axis of the stomach is angled cranially, causes of microhepatia should be considered. When the axis is angled caudally, causes of hepatomegaly should be considered. The majority of the liver is within the confines of the costal arch; however, it can extend caudal to the arch in normal animals. Increased caudal extension of the caudoventral liver margin indicates hepatic enlargement. Additionally, in some cases of hepatic enlargement, the caudoventral liver margin will appear rounded rather than sharp and triangular.

Increased Liver Size

Hepatomegaly can be categorized as focal, generalized, or nodular. The distinction is important because differential diagnoses are based on the categorization (Table 4.2).

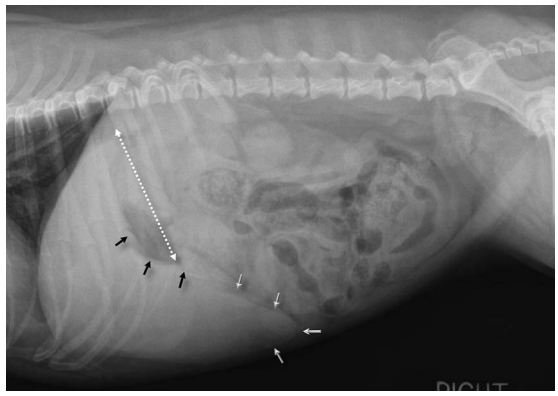

FIGURE 4.5 Lateral abdominal radiograph of a dog having generalized hepatomegaly due to vacuolar hepatopathy associated with hyperadrenocorticism. There is caudal extension of the caudoventral liver margin, which is rounded (white arrows). The gastric axis is caudally displaced (dotted white line) due to caudal and dorsal displacement of the gastric body and pylorus relative to the gastric fundus (black arrows).

Generalized hepatomegaly will most often appear as a rounded caudoventral margin with increased extension beyond the costal arch and caudal displacement of the gastric axis (Figure 4.5). The pylorus tends to be dorsally and caudally displaced, and the right kidney is often caudally displaced. With generalized hepatomegaly, often the right stomach (pylorus) is more caudally displaced than the left. Severe asymmetric displacement, however, often indicates focal hepatomegaly/hepatic mass.

Nodular hepatomegaly will appear as a generalized enlargement with irregular margins rather than the smooth margins maintained by generalized hepatomegaly. Differential diagnoses are ranked differently, with metastatic neoplasia, nodular regeneration, and hepatocutaneous syndrome being most likely.

Focal hepatomegaly is caused by a mass. Differential diagnoses for masses are listed in Box 4.4. However, once it is determined that the organ of origin is most likely to be liver, the ranking can be organized to include neoplasia, regenerative changes, cyst, and abscess at the top of the list. Focal hepatomegaly causes focal caudal displacement of the stomach to the right or left side, depending on its location. The margin of the liver at the location of the mass tends to be rounded rather than sharp. Most liver masses appear ventral in location, but dorsal masses can occur. Masses cranial to the stomach are typically hepatic in origin; however, in some cases, hepatic masses can extend caudal to the stomach (called

TABLE 4.2 Classification of hepatomegaly with respective differential diagnoses

Generalized hepatomegaly	Focal hepatomegaly	Nodular liver
– Vacuolar hepatopathy (e.g., steroid hepatopathy, hepatic lipidosis) – Passive congestion – Hepatitis (acute) – Infiltrative neoplasia (e.g., lymphoma, mast cell tumor) – Amyloid deposition	– Primary hepatic neoplasia (e.g., hepatocellular carcinoma in dogs, biliary cystadenoma in cats) – Regenerative changes – Cyst – Abscess – Hematoma – Granuloma – Liver lobe torsion	– Metastatic neoplasia (with hepatomegaly) – Nodular regeneration (with hepatomegaly) – Hepatocutaneous syndrome (with hepatomegaly) – Cirrhosis/fibrosis (with microhepatia)

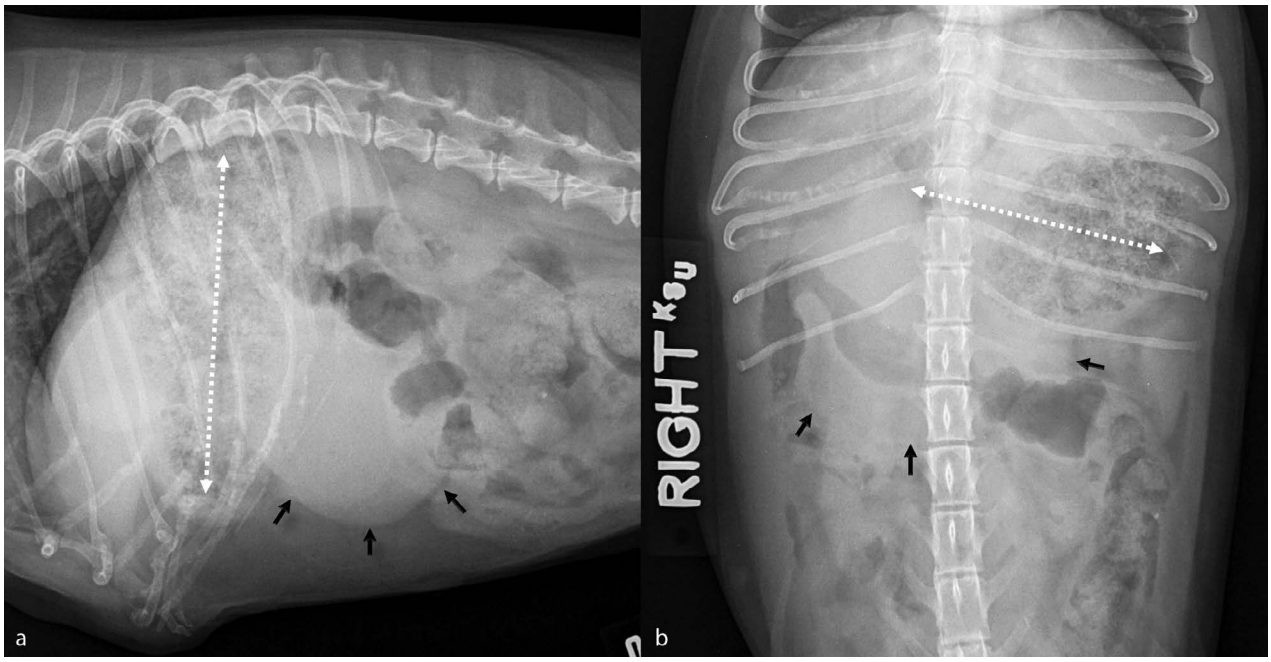

FIGURE 4.6 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in a dog having a pedunculated liver mass. A soft tissue opaque mass having a well-defined rounded ventral and caudal margin (black arrows) is located caudal to the gastric axis (dotted white line). The mass located on the right side is causing the stomach to be displaced to the left. Right-sided small intestines are caudally displaced. A single pedunculated hepatic mass was found on ultrasound examination. A hepatocellular adenoma was subsequently diagnosed with aspirates.

a pedunculated liver mass), appearing in the location of the splenic tail on lateral views (Figure 4.6a, b). Liver masses in dogs and cats are most often neoplastic. The most common mass-like neoplasm in the canine liver is hepatocellular carcinoma; in cats, it is biliary cystadenoma.

Reduced Liver Size

Microhepatia is diagnosed when the liver size is small, as denoted by a cranially positioned gastric axis. The causes of microhepatia are shown in Box 4.5. Shape can sometimes be used to distinguish the causes of microhepatia. In cases of cirrhosis/fibrosis, the liver margin may be irregular in shape, giving it a nodular appearance. This abnormal shape is not always radiographically apparent, however. Additionally, ascites is uncommonly present in dogs with a congenital portosystemic shunt, so the presence of peritoneal effusion makes cirrhosis, fibrosis, or noncirrhotic portal hypertension more likely.

Box 4.5 Differential diagnoses for microhepatia

- Congenital portosystemic shunt
- Cirrhosis
- Fibrosis
- Microvascular dysplasia
- Noncirrhotic portal hypertension (portal vein hypoplasia)

Alterations in Hepatic Opacity

Radiographic abnormalities within the liver can sometimes appear as an alteration in opacity. Hepatic mineralization is most commonly due to mineralization within the intrahepatic biliary system rather than within the hepatic parenchyma itself. This causes linear branching mineral opacities that are most commonly accumulated in the right liver. This finding is often incidental; however, previous biliary disease or active disease cannot be ruled out. Mineralized calculi can also accumulate within the gallbladder. These choleliths can be incidental findings or can result in obstruction of the common bile duct. They appear as single, rounded mineral opacities or as an accumulation of mineral opacities within the right ventral liver in the region of the gallbladder. When multiple smaller calculi are present, the ventral margin of the accumulated choleliths tends to be rounded. Finally, the gallbladder wall itself can mineralize due to chronic cholecystitis or cystic mucinous hyperplasia, appearing as a well-defined, rounded, thin, mineral-rimmed structure in the right cranial liver in the region of the gallbladder.

Hepatic gas accumulations occasionally occur within the liver parenchyma or gallbladder. Parenchymal hepatic gas is most often associated with a mass due to abscessation. Hepatic abscesses are uncommon, typically exist as a single mass lesion, and most often do not contain gas. On occasions where gas is present, it will accumulate

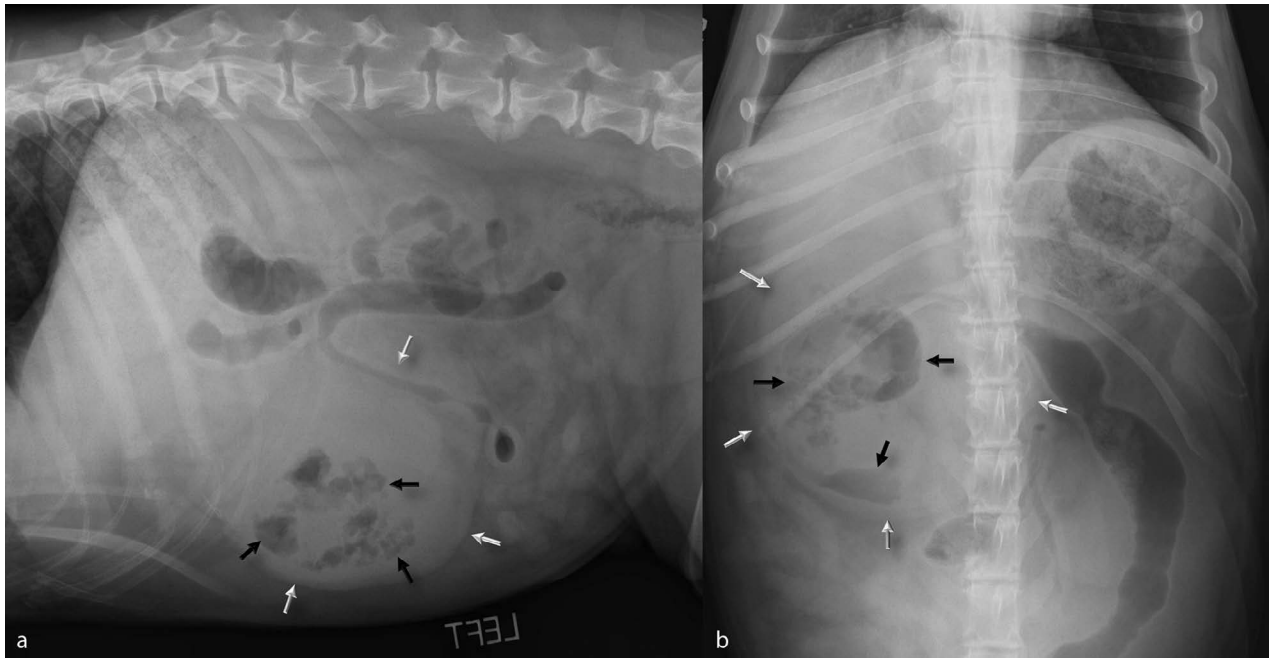

FIGURE 4.7 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in a dog having a hepatic abscess. A large, well-defined, rounded soft tissue opacity is present in the right cranioventral abdomen (white arrows). The mass causes caudal and dorsal deviation of small intestines and leftward deviation of the stomach. Multiple, well-defined, variably sized and shaped gas opacities are located within the mass (black arrows).

within the margins of the mass (Figure 4.7a, b) and will not relocate with the use of horizontal beam radiography. Concurrent peritoneal effusion is commonly present. Most often, gas located within the abscess does not extend to the peritoneal space, but locations within both spaces can occur with rupture.

4. Spleen

Next, the spleen should be located and evaluated. The spleen can be divided into a cranial head, body, and caudal tail. It can be variable in position due to the mobility of the splenic tail. On the lateral view in dogs, the tail of the spleen, when visible, is typically in the cranioventral abdomen caudal to the margin of the liver and stomach. This is most reliably seen on the right lateral projection. In normal cats, the splenic tail is typically not visible on the lateral view of the abdomen. The head of the spleen is often visible, though, on the lateral view in the craniodorsal abdomen near the plane of the right kidney. The head of the spleen is in a more predictable, stable position due to the presence of the gastrosplenic ligament. On the ventrodorsal view, the head of the spleen is the portion that is most consistently visible, caudal to the gastric fundus and cranial to the left kidney, as a triangular soft tissue opacity that is formed where the spleen appears end-on near the junction of the splenic head and body. The overall apparent size of the spleen is smaller in cats than in dogs. Abnormalities within the spleen will typically manifest as an alteration in size, shape, location/orientation, and, rarely, opacity.

Splenomegaly

Splenic size is subjectively assessed. Generalized splenic enlargement will appear as an increase in thickness of the splenic tail or head. The margins of the spleen will be rounded and may or may not be irregular, indicating nodular changes. Mass effect associated with generalized splenic enlargement will typically cause rightward displacement of small intestines on the ventrodorsal view and dorsal displacement of intestines on the lateral view (Figure 4.8a, b). Generalized splenomegaly can cause cranial and ventral displacement of the gastric fundus. In cats, if the splenic tail is visible on the lateral view, it is considered enlarged. Focal splenomegaly occurs when mass lesions are present within the spleen. Given the focal nature of many splenic masses, unaffected sections of the spleen can appear radiographically normal. Masses associated with the splenic head will be located in the craniodorsal abdomen and on the left side. Masses associated with the splenic body or tail are typically more ventral in location and can be right- or left-sided. Masses are more commonly seen within the splenic tail and body; therefore, most splenic masses are located in the ventral cranial to midabdomen. As a general rule, masses within the splenic body or tail can appear identical to pedunculated liver masses (Figure 4.9a, b). Distinction between generalized and focal splenomegaly is important, as differential diagnoses differ (Table 4.3).

Alterations in Splenic Location

Splenic malpositioning due to torsion can occur as a single event (isolated splenic torsion) or, more commonly,

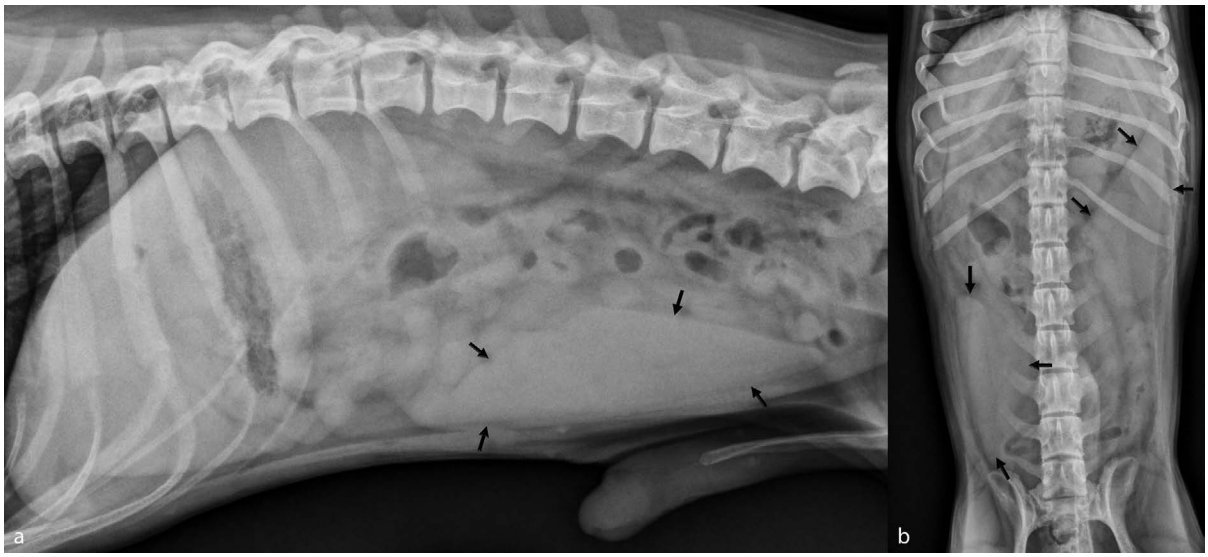

FIGURE 4.8 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in an anemic dog having marked generalized splenomegaly due to benign extramedullary hematopoiesis. The margins of the spleen are rounded, and there is subjectively increased thickness of the spleen on both views (black arrows). The spleen extends excessively caudal, approaching the pelvic inlet. Additionally, the spleen extends to the caudal abdomen on the right side, seen on the ventrodorsal view.

in association with gastric dilatation and volvulus (GDV). Splenic torsion is often accompanied by peritoneal effusion, making the margins of the spleen somewhat indistinct. Indications of splenic torsion include a mass effect in the cranial to midventral abdomen, a loss of visibility of the normal splenic head and body in the left cranial abdomen on the ventrodorsal view, visibility of overt splenomegaly, or gas accumulations within the spleen or within the mass effect associated with the ventral abdomen. Finally, in cases where splenic margins are readily identified, the position of the spleen may appear as a reverse "C" shape in the ventral midabdomen on the lateral view.

Alterations in Splenic Opacity

Splenic mineralization occurs, most often, secondary to metabolic diseases such as hyperadrenocorticism; however, it is uncommonly detectable on radiographs. Gas opacity within the splenic parenchyma rarely occurs but

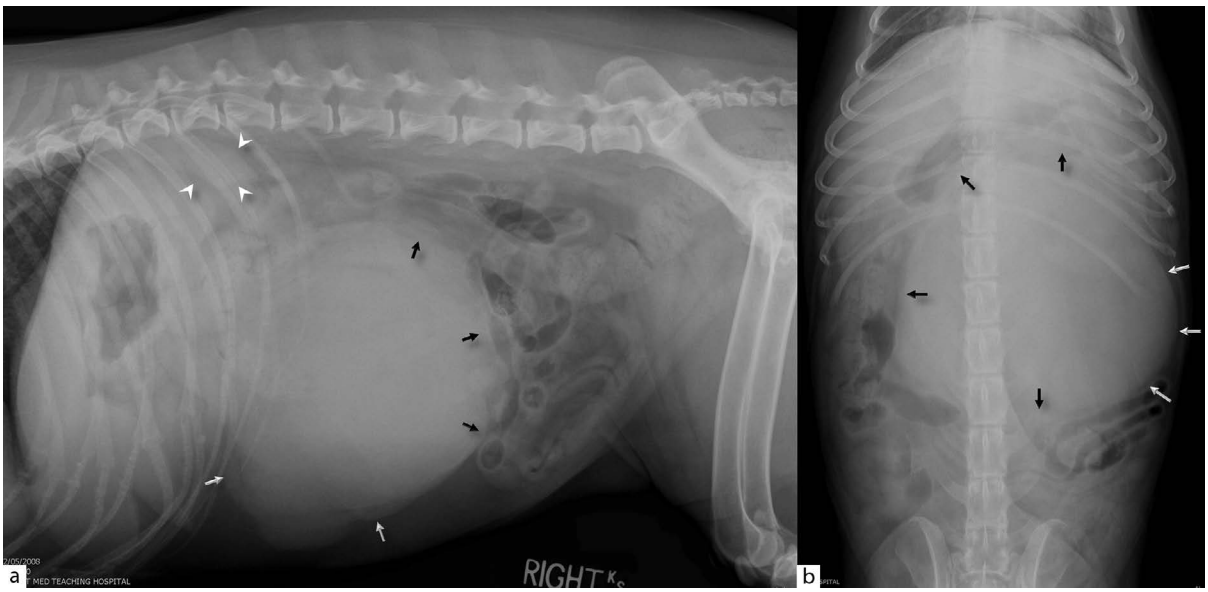

FIGURE 4.9 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in a dog having a splenic mass. In the lateral view, a normal splenic head is seen in the craniodorsal abdomen (white arrowheads). A large, predominantly round, well-defined soft tissue opacity is present in the left cranial to midventral abdomen (white arrows). The mass causes marked caudal, dorsal, and rightward displacement of the small intestines and cranial displacement of the gastric fundus (black arrows). The main differential for organ of origin is a pedunculated liver mass.

TABLE 4.3 Classification of splenomegaly with respective differential diagnoses

Generalized splenomegaly	Focal splenomegaly (mass)
Inflammatory splenomegaly (splenitis) – Systemic or peritoneal bacterial infection – Chronic systemic infection **Hyperplastic splenomegaly** – Chronic infection – Hemolytic disorders **Extramedullary hematopoiesis** **Congestion** – Tranquilization – Right heart failure – Portal hypertension (rare) – Splenic torsion **Infiltrative neoplasia** – Lymphoma – Mast cell tumor – Multiple myeloma – Acute and chronic leukemia – Malignant histiocytosis **Amyloid deposition**	**Nonneoplastic** – Hematoma – Abscess – Nodular hyperplasia – Infarction – Cyst – Granuloma **Neoplastic** – Hemangiosarcoma – Hemangioma – Leiomyosarcoma – Leiomyoma – Myelolipoma – Lymphoma

can be a sequela to necrotizing splenitis or gas-producing bacteria within the spleen. This most commonly occurs secondary to splenic torsion and creates a classic mass (Figure 4.10a, b).

5. Retroperitoneal Space

The retroperitoneal space should be the next area evaluated. This space, being physically divided from the peritoneal space, can serve as a comparison for detail of organ visibility, where effusion causing reduced detail in the peritoneal space often spares the retroperitoneal space and vice versa. Causes of retroperitoneal effusion or mass effect must be considered, with knowledge of organs that exist in this space, such as the kidneys, adrenal glands, lymph nodes, and ureters, many being radiographically invisible under normal circumstances.

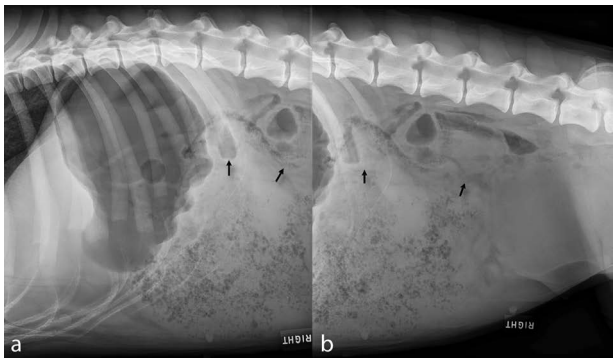

FIGURE 4.10 Lateral cranial (a) and caudal (b) abdominal radiographs in a dog having splenic torsion and secondary emphysematous splenitis. Peritoneal detail is reduced due to effusion. A large mass effect is present in the ventral abdomen that is causing dorsal displacement of small intestines (black arrows). A mass having indistinct margins is located in the ventral abdomen that is soft tissue opaque and contained numerous, well-defined gas bubbles. The location and opacity of the mass are classic for splenic torsion and splenitis.

Retroperitoneal Effusion and Mass Effect

Poor retroperitoneal detail is most often caused by effusion and/or mass. Retroperitoneal effusion causes a decrease in delineation of the renal margins. This may be unilateral or extend across the right and left peritoneal spaces. A large volume of fluid can cause a mass effect within the peritoneum where the colon and small intestines are pushed ventrally. When retroperitoneal detail is poor, the concurrent presence of a mass may not be readily visible. The masses themselves can cause similar border effacement of retroperitoneal structures. Causes of retroperitoneal effusion are shown in Box 4.6 and are best distinguished by considering fluid types. Causes of effusion must be considered together with history and clinical signs. For example, a history of trauma makes urine or hemorrhage the most likely cause of retroperitoneal hemorrhage, whereas a renal neoplasm is more likely if the animal has a history of hematuria.

Sublumbar Lymph Nodes

The medial iliac lymph nodes are located lateral to the aorta near the location of its trifurcation where the external iliac arteries branch from the abdominal aorta. Caudal to this, the internal iliac lymph nodes are located where the internal arteries branch. These lymph nodes combined are often called the sublumbar lymph nodes. They are radiographically invisible in normal cats and dogs. With severe enlargement, the sublumbar lymph nodes can cause a mass effect, displacing the distal descending colon ventrally near the pelvic inlet (Figure 4.11). When sublumbar lymphadenopathy is present, urogenital/perineal neoplasms or multicentric lymphoma should be considered first.

Box 4.6 Causes of retroperitoneal effusion

- Urine
  - Kidney rupture
  - Ureteral rupture
- Hemorrhage
  - Kidney rupture
  - Rodenticide/coagulopathy
  - Neoplasia
- Exudate
  - Renal abscessation
  - Retroperitoneal abscess
- Transudate/modified transudate
  - Urinary obstruction
  - Severe acute interstitial nephritis
- Neoplastic effusion

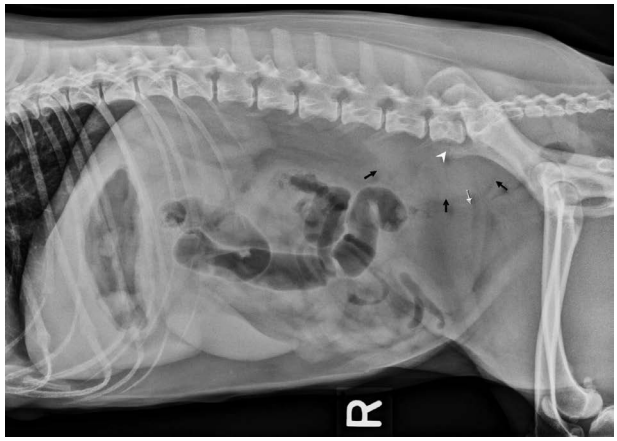

FIGURE 4.11 Lateral abdominal radiograph in a dog having transitional cell carcinoma of the urinary bladder. A moderately well-defined soft tissue opaque mass is present in the caudodorsal abdomen (black arrows). The mass causes ventral displacement of the distal descending colon (white arrow). Additionally, there is a very indistinct, irregular periosteal reaction associated with the ventral L7 vertebral body (white arrowhead) consistent with an aggressive bone lesion and metastatic disease.

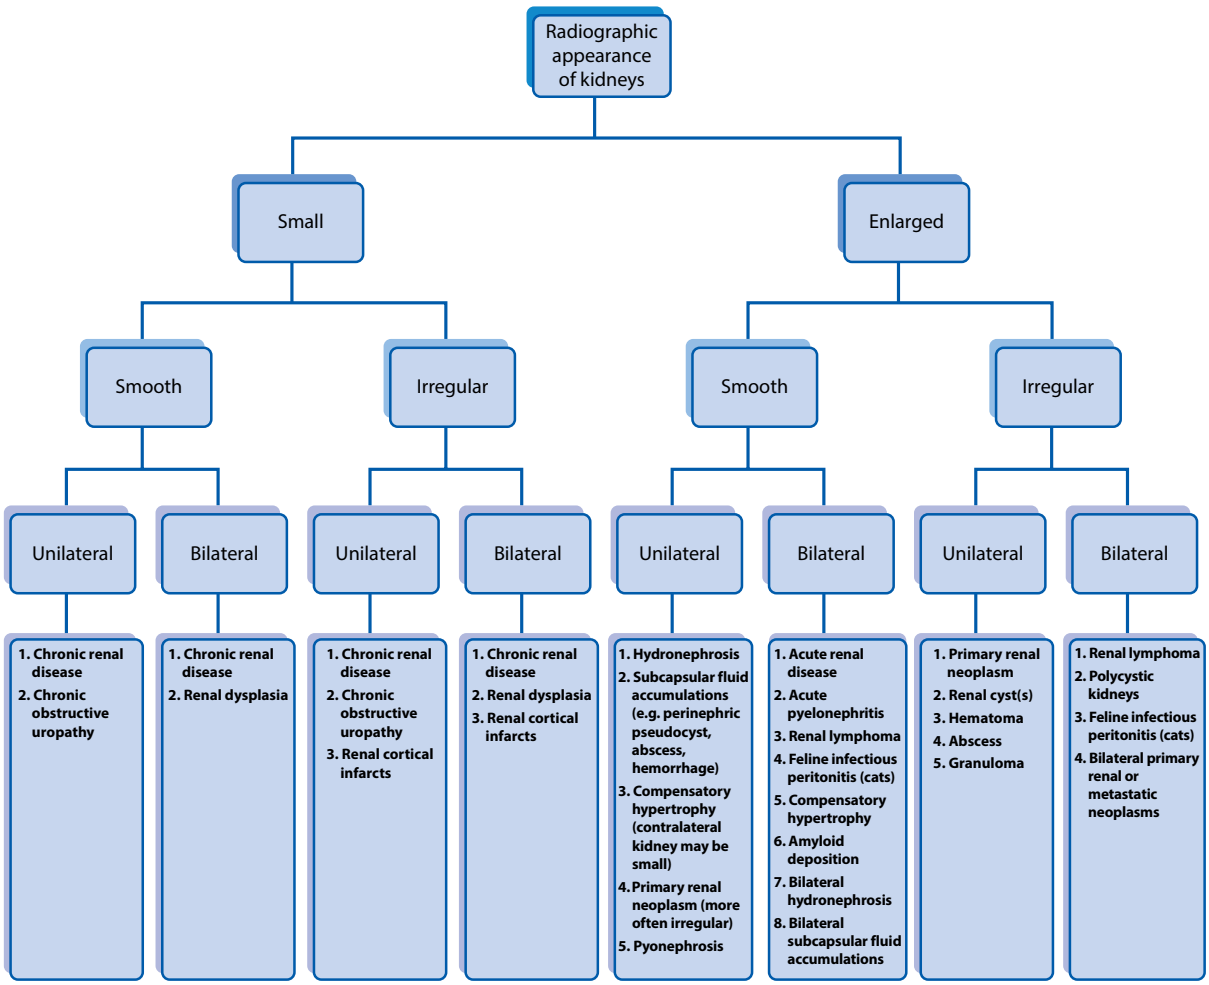

6. Upper Urinary Tract

Both kidneys and the ureters are retroperitoneal. The normal renal size in dogs is within 2.5–3.5 times the length of the L2 vertebral body as measured on the ventrodorsal view. In cats, the size of normal kidneys is within 2.0–3.0 times the length of the L2 vertebral body on the ventrodorsal view. Also, both kidneys should be similar in size and smooth. Normal ureters are never seen radiographically. Excretory urography is the only imaging modality that will allow assessment of the ureters.

Kidneys

Abnormalities associated with the kidneys will appear as an alteration in size, shape, opacity, and, rarely, number. Abnormal renal size must always be considered in combination with renal shape. Additionally, differential diagnoses are often ranked according to whether the radiographic abnormalities are unilateral or bilateral. An algorithmic approach can be used to determine differential diagnoses for the appearance of the kidneys, while taking clinical abnormalities into consideration (Box 4.7). Compression radiographs should be obtained

Box 4.7 Algorithmic approach to differentiating causes of abnormal kidneys

in cases where the kidneys are not easily seen due to a superimposed GI tract and when clinical evidence suggests renal disease.

Small Kidneys

Small, irregular kidneys (Figure 4.12a, b) are most often secondary to chronic renal disease or chronic obstructive uropathy. Renal dysplasia must also be considered in young animals having small, irregular kidneys, as the two causes can appear identical.

Renomegaly

Enlarged kidneys can cause a mass effect in the dorsal abdomen that can be right-sided, left-sided, or both, depending on the laterality of the diseased kidney(s). Ventral displacement of the intestines can be seen with renal masses or retroperitoneal effusion. Enlarged kidneys that are smoothly marginated or irregular have numerous causes that often require more advanced imaging, such as excretory urography or ultrasonography, to differentiate. Determination of the presence of unilateral or bilateral disease can assist with likely diagnoses, as some diseases such as acute kidney injury (AKI), pyelonephritis, lymphoma, feline infectious peritonitis, and amyloid deposition tend to be bilateral, while hydronephrosis and pyonephrosis tend to be unilateral. Renal carcinoma can be unilateral or bilateral and is often accompanied by retroperitoneal effusion due to hemorrhage. Peritoneal effusion is also occasionally seen because of invasion through the peritoneal lining. Subcapsular fluid accumulations due to perinephric pseudocyst occur in cats and dogs but are more commonly reported in cats having subcapsular edema accompanying AKI and urinary obstruction. Renomegaly can be severe and may be bilateral (Figure 4.13a, b) or unilateral. Polycystic kidneys are most commonly seen in Persian cats having an autosomal dominant mode of inheritance, but the condition has been reported in Bull Terriers, which also have an autosomal dominant mode of inheritance.

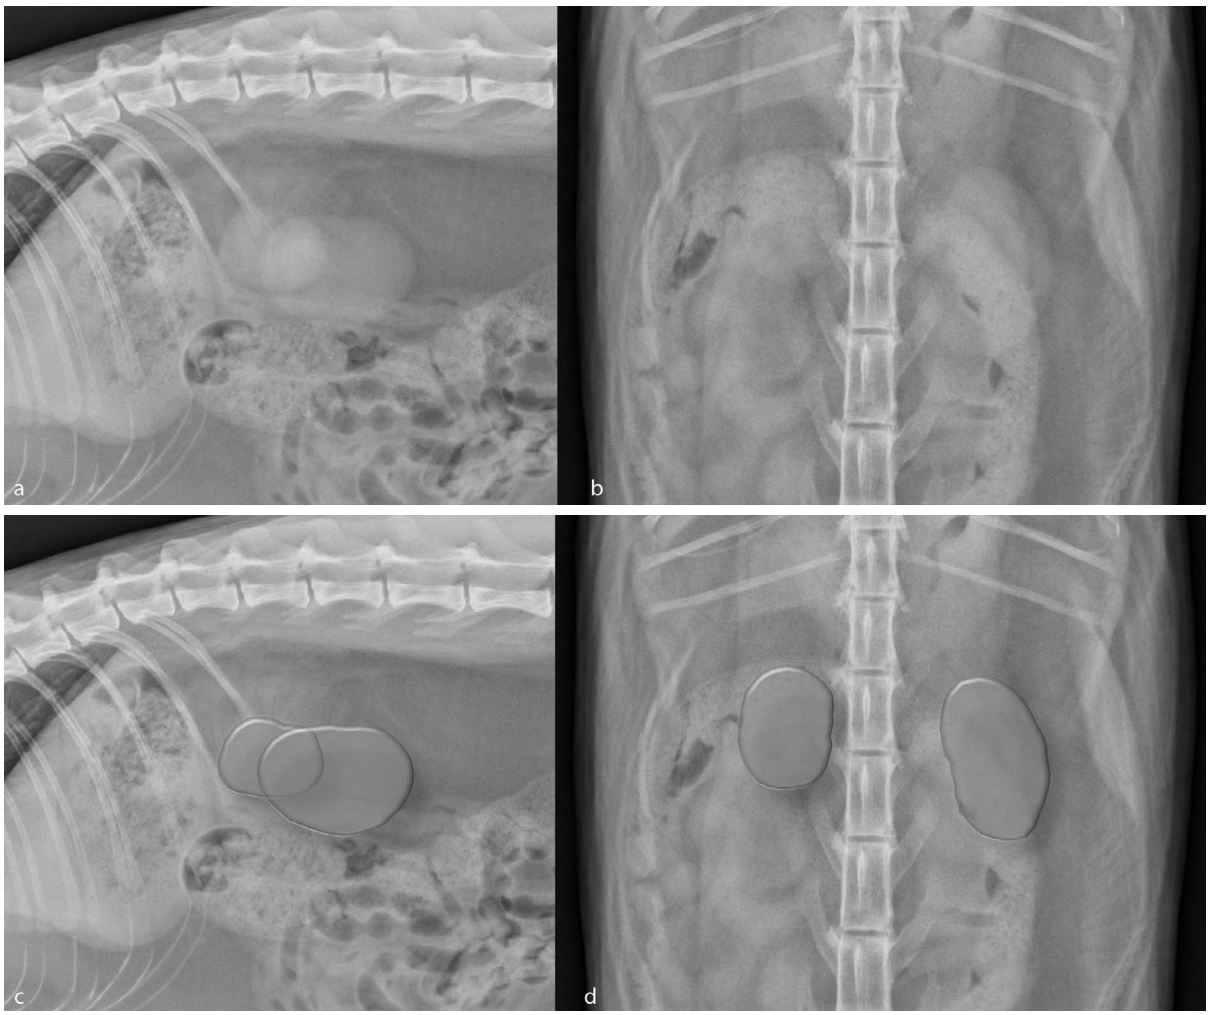

FIGURE 4.12 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs with accompanying schematic **(c** and **d)** showing small and irregular kidneys in a cat. Both kidneys are small in size and are markedly rounded and irregularly marginated (highlighted in schematic). In an older animal, this may be due to chronic kidney disease or chronic obstructive uropathy. In younger animals, renal dysplasia must also be considered.

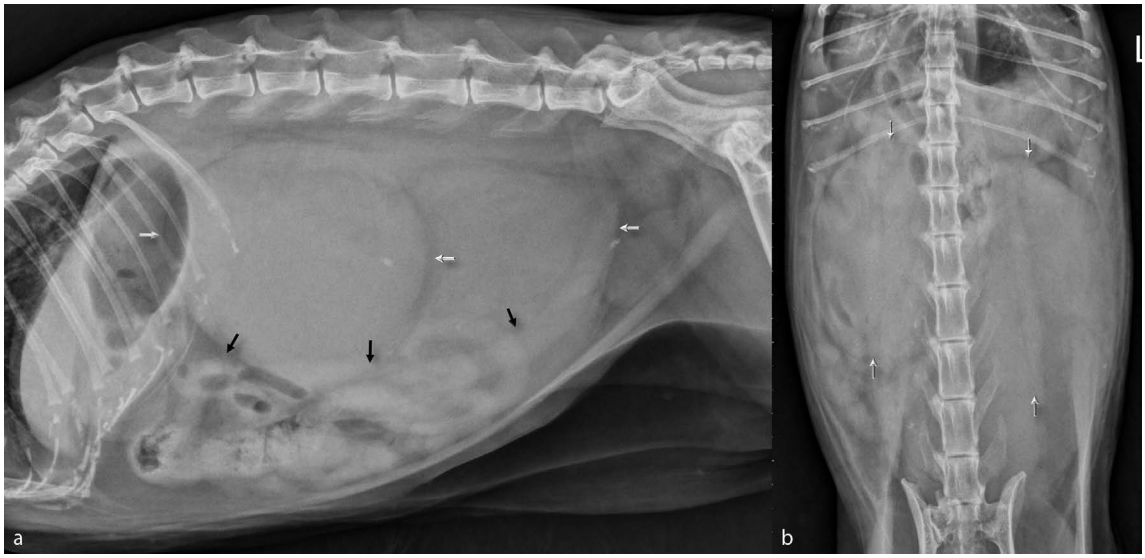

FIGURE 4.13 Lateral **(a)** and ventrodorsal **(b)** radiographs in a cat having a history of chronic renal disease and an increasingly distended abdomen. A marked mass effect is seen causing ventral displacement of the colon and small intestines, indicating a retroperitoneal organ of origin. The kidneys are markedly enlarged but remain smoothly marginated (white arrows).

Renal Mineral

Nephroliths associated with the kidneys are typically located in the region of the renal pelvises and can be variable in size. Nephroliths may persist indefinitely in the renal pelvis, or they may migrate into the ureter, increasing the risk of urinary obstruction. Nephrocalcinosis because of parenchymal mineralization may be dystrophic due to chronic disease or metastatic due to diseases resulting in altered calcium and phosphorus metabolism. Classic nephrocalcinosis appears as parallel linear mineralization located in the region of the renal diverticula. Parenchymal mineralization can accompany oxalate crystal deposition in ethylene glycol intoxication; however, this is generally not visible radiographically. When the presence of nephroliths or nephrocalcinosis is unclear because of superimposition, compression of the kidneys could be performed to confirm suspicion (Figure 4.14a, b).

Emphysematous Pyelonephritis

On rare occasions, gas can accumulate within the kidneys, most often within the renal pelvis, due to the presence of gas-forming bacteria or reflux of gas from the

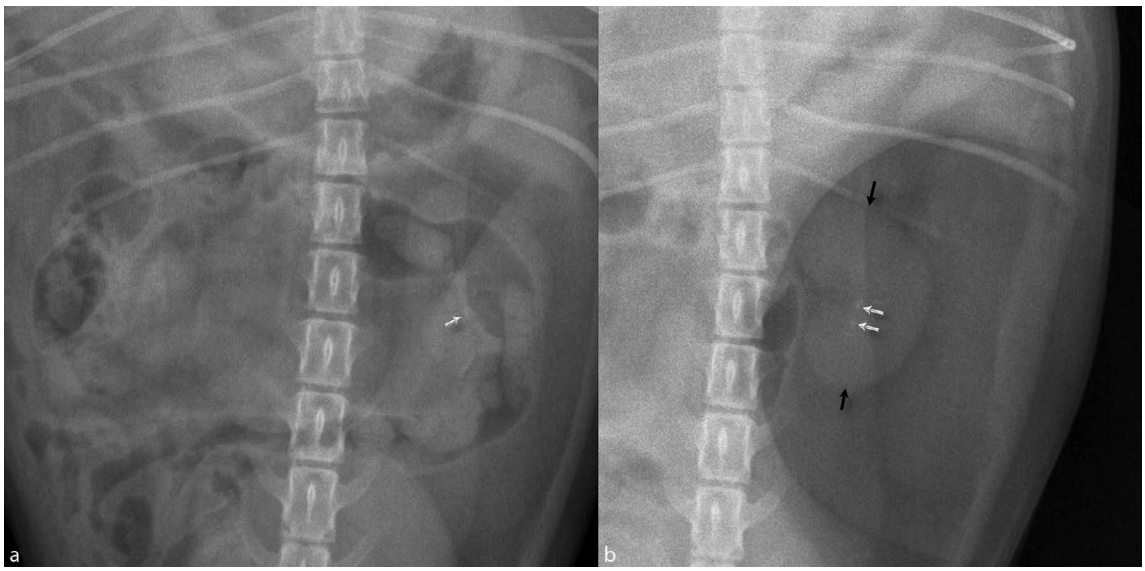

FIGURE 4.14 Ventrodorsal **(a)** and compression ventrodorsal **(b)** abdominal radiographs in a dog having small nephroliths. The kidneys were poorly seen on the survey study due to superimposed colon and small intestines. Superimposed over the left kidney, a small mineral opacity appeared to extend beyond the margins of the colon (a, white arrow). On the compression view, the margins of the left kidney are better identified (b, black arrows), and small calculi can be seen in the region of the renal pelvis (b, white arrows).

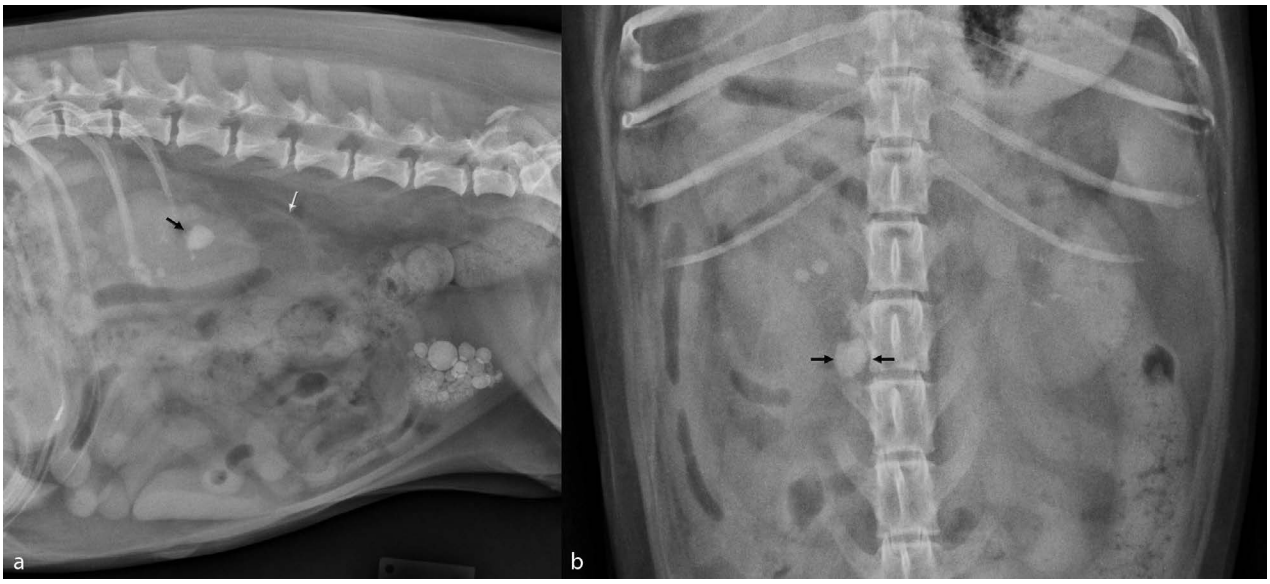

FIGURE 4.15 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in a dog with azotemia and lethargy. Multiple mineral opaque calculi are superimposed over the kidneys. The largest calculus (black arrows), however, is superimposed medial to the margin of the right kidney in the expected location of a ureter. A small amount of soft tissue opaque streaking is present in the retroperitoneal space (white arrow). Urinary obstruction due to ureterolithiasis was confirmed on ultrasound examination. Numerous, round, well-defined calculi are also present within the urinary bladder.

urinary bladder. Emphysematous pyelonephritis most often occurs in combination with emphysematous cystitis in diabetic animals (see Lower Urinary Tract).

Ureters

As previously mentioned, ureters should never be seen radiographically without contrast in normal animals. The most common cause of ureteral visibility is due to ureterolithiasis. Ureteroliths appear as mineral opacities that are superimposed in the presumed location of a ureter (Figure 4.15a, b). In many instances, excretory urography or abdominal ultrasound is needed to confirm the presumed location of the calculus within the ureter.

7. Adrenal Glands

Both adrenal glands are retroperitoneal in location. They are paired and located medial to the cranial poles of each kidney. The aorta borders the left adrenal gland medially. The right adrenal gland is bordered by the caudal vena cava medially. Adrenal glands are not identified radiographically in normal animals. However, their position relative to the kidneys creates a unique appearance when they are enlarged, and a mass effect is created. When an adrenal gland creates a mass effect, it can cause lateral displacement of the cranial pole of its adjacent kidney. When severely enlarged, adrenal masses cause caudal displacement of the adjacent kidney, and, often, the cranial pole of the kidney is dorsally displaced (Figure 4.16a, b). Masses associated with the adrenal glands are most commonly neoplastic. Animals with adenomas or adenomatous hyperplasia due to pituitary-dependent Cushing's disease do not usually have radiographically visible adrenal glands. Bilateral adrenal mineralization can occur as a normal aging process in cats.

8. Reproductive Tract

Female Reproductive Tract

The uterine body is a tube located between the urinary bladder and the descending colon; its horns extend to each ovary. The uterus is typically not radiographically visible in normal animals. Visibility of the uterus is considered abnormal and indicates enlargement. The uterus is not expected to be larger in diameter than the small intestines in the normal animal.

Uterine enlargement results in a mass effect that causes dorsal, cranial, and medial displacement of small intestines. Various degrees of uterine enlargement can be seen ranging from mild to severe (Figure 4.17a, b). Differential diagnoses for generalized uterine enlargement include pregnancy, pyometra, mucometra, and hydrometra. Incorporation of clinical signs and history are needed to distinguish these causes. Mass lesions due to neoplasia, abscess, granuloma, hematoma, or cyst can also occur and create a mass effect with similar displacement of organs. Concurrent peritoneal effusion is often present with pyometra, stump pyometra, or inflammatory uterine diseases.

Uterine enlargement is readily detectable in pregnant cats and dogs prior to fetal mineralization. In dogs, the uterus is visible at 30 days post luteinizing hormone (LH) surge. In cats, uterine swelling can be seen at 17–21 days. Mineralization of the fetal skeleton initiates in the axial skeleton, beginning at 45 days after the LH surge in dogs and at 36–45 days after breeding in cats. Mineralization of the skeleton can be used

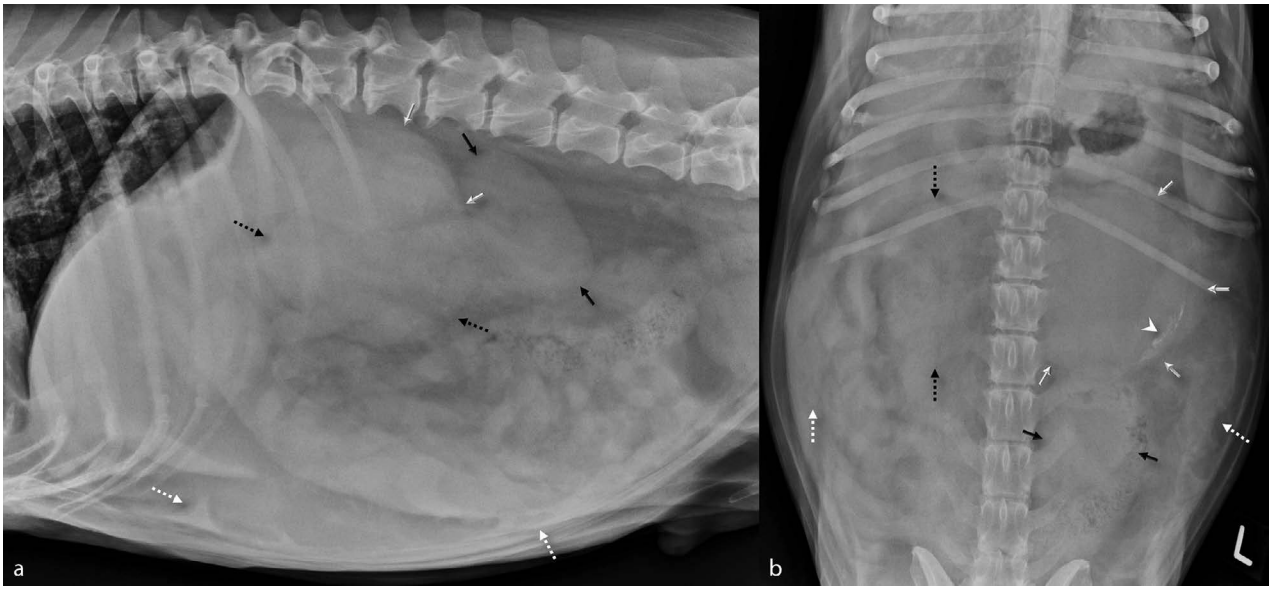

FIGURE 4.16 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in a dog presenting for acute vomiting and a suspected foreign body. A retroperitoneal mass effect is present causing ventral and rightward displacement of cranial abdominal small intestines. Normally shaped right (dotted black arrows) and left (black arrows) kidneys are visible. An additional, large, round, soft tissue opacity having a well-defined dorsal and lateral margin is visible in the left craniodorsal abdomen. This structure causes marked caudal displacement and altered orientation of the left kidney, causing its cranial pole to be dorsally displaced. A rim of mineral is present at the lateral caudal periphery of the mass (white arrowhead). A mild amount of soft tissue opaque streaking is present in the peritoneal space (dotted white arrows) that is causing mild decreased detail. The location of this mass is compatible with left adrenomegaly.

to roughly estimate the stage of pregnancy and the likelihood of imminent parturition. In dogs and cats, the final skeletal structures to mineralize are the distal limbs (metatarsi, metacarpi, and phalanges) and the teeth. Once these are radiographically mineralized and visible, parturition can be expected within 0–5 days in dogs and 0–6 days in cats.

Radiography is insensitive to detecting fetal distress compared with ultrasound. If fetuses have been dead for >24 hours, signs of death may be visible as emphysematous changes within the uterus or fetus (Figure 4.18a, b) or collapse of the axial skeleton. Additionally, some causes of fetal dystocia are radiographically visible, such as fetal malposition, extreme maternofetal disproportion, or narrowed pelvic canal due to previous trauma.

Male Reproductive Tract

The prostate gland encircles the proximal urethra. The prostate gland in cats is invisible. To the author's knowledge, abnormalities causing a radiographically visible prostate in cats have never been reported. In neutered dogs, the prostate gland is typically not identified but is occasionally seen when the colon is empty or when compression radiography is used. When an enlarged prostate is present, the most reliable indicator of a prostatic organ of origin is the fat opaque triangle located between the urinary bladder and the prostate gland.

In intact males, the prostate gland most often becomes radiographically visible because of benign hypertrophy, which is the most common cause of prostatic enlargement (Figure 4.19). The prostate usually encompasses <50% of the diameter of the pelvic inlet from the sacrum to the pubis on the lateral view. The prostate will be intrapelvic in young dogs and will become intra-abdominal as the prostate enlarges in older intact males. Scottish Terrier dogs are reported to have increased severity of prostatomegaly due to benign hypertrophy. Prostatitis can cause radiographically visible enlargement and is more commonly diagnosed in intact dogs. Occasionally, regional peritoneal effusion and peritonitis are present when prostatitis is severe. Regardless, prostatic disease should be considered in male dogs having a ventral caudal abdominal mass effect.

The incidence of prostatic neoplasia is similar in intact and neutered males; however, prostatic neoplasia is highly likely in neutered males having a radiographically visible prostate and signs associated with prostatic disease. Mineralization is a common feature of prostatic neoplasia, but it is also less commonly found in benign prostatic enlargements. Generally, mineralization that occurs with benign prostatic diseases is not radiographically visible but can be more readily identified on ultrasound examination. Prostatic neoplasms commonly metastasize to the sublumbar lymph nodes, caudal lumbar spine, and pelvis. In male dogs with visible sublumbar lymphadenopathy or aggressive bone lesions of the caudal lumbar spine or pelvis, prostatic neoplasia should be ruled out as an underlying cause regardless of whether prostatic enlargement or mineralization is radiographically visible or not (Figure 4.20).

Prostatic mass effects due to abscessation, cyst, or paraprostatic cyst occur less commonly. Prostatic

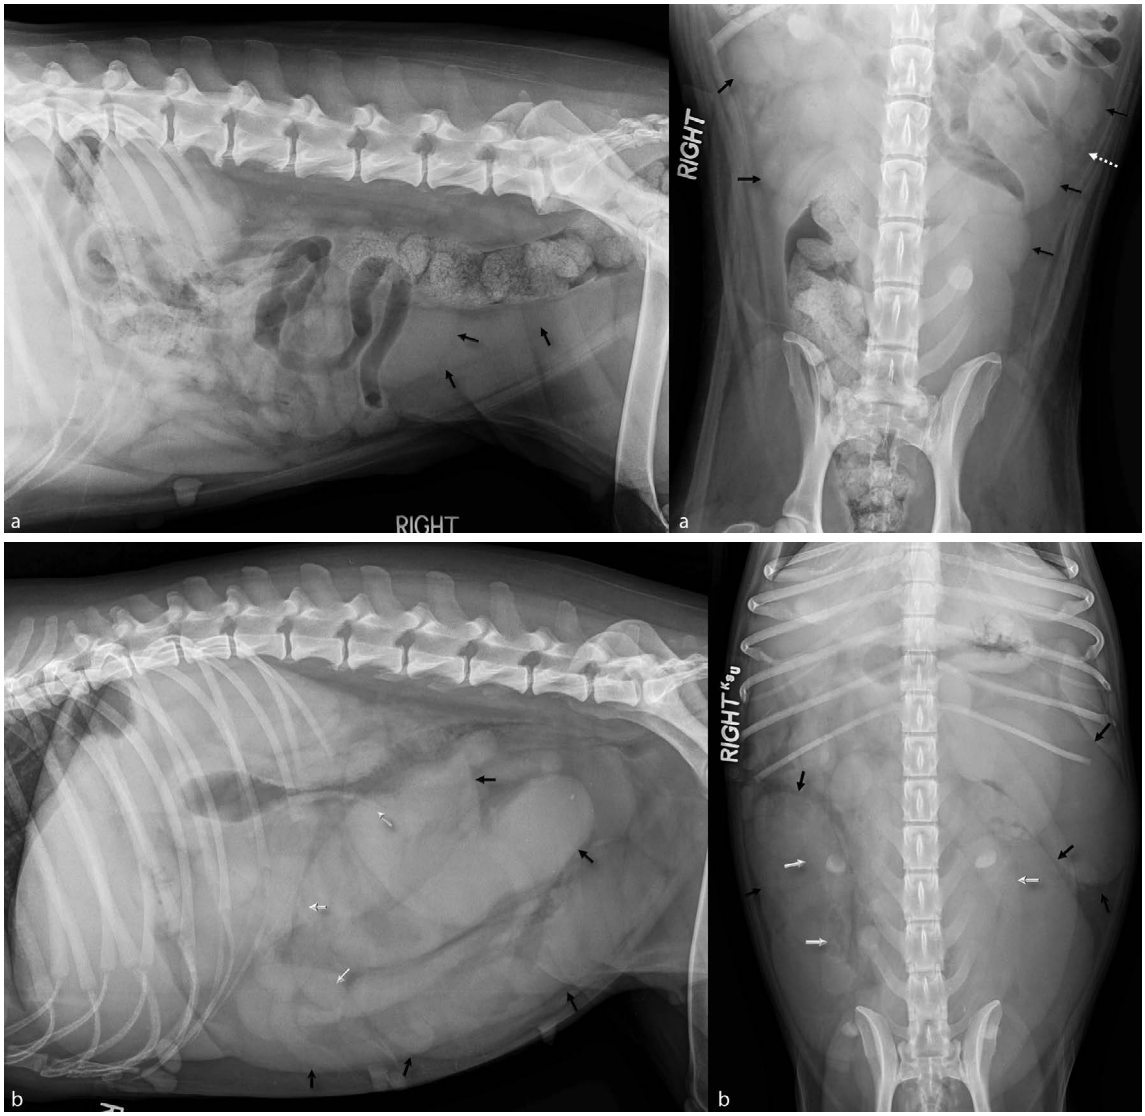

FIGURE 4.17 Lateral and ventrodorsal abdominal radiographs in two dogs having different degrees of uterine enlargement due to pyometra. In part **(a)**, there is moderate uterine enlargement with a soft tissue opaque tube visible bordering the dorsal aspect of the urinary bladder and located at the periphery of the right and left abdomen (a, black arrows). A small amount of soft tissue opaque streaking is present within abdominal fat near the left body wall (dotted white arrow) denoting a small volume of regional effusion. Marked uterine enlargement is shown in part **(b)**. Tubular-shaped soft tissue opacities are located in the caudal ventral to midabdomen (b, black arrows). The typical mass effect for uterine enlargement is cranial and dorsal displacement of intestines that are often pushed medially (b, white arrows). Mild soft tissue opaque streaking is visible at the periphery of the abdomen (white arrowheads).

abscesses and intraprostatic cysts will have a similar radiographic appearance to benign hypertrophy or prostatitis. However, inflammatory prostatic lesions due to abscessation are more likely to have regional peritoneal effusion. Paraprostatic cysts occur peripheral to the prostate and have a radiographic appearance that is distinct from prostatomegaly alone. In most cases, the paraprostatic cyst is located to the right or the left of the urinary bladder, thus overlapping the urinary bladder on the lateral view rather than being located caudal to the urinary bladder. Therefore, the typical fat opaque triangle associated with prostatic enlargement may not be a feature of paraprostatic cyst unless concurrent radiographically visible prostatomegaly is present. The appearance of paraprostatic cysts mimics that of a supernumerary urinary bladder.

9. Lower Urinary Tract

The Urinary Bladder

The urinary bladder is almost always visible on the lateral view in cats and dogs regardless of its size. It must be moderately distended before becoming visible on the ventrodorsal view. Bladder size can be variable; therefore, its position is inconsistent. Abnormalities associated with the urinary bladder are typically seen as an alteration in opacity or an abnormally large size

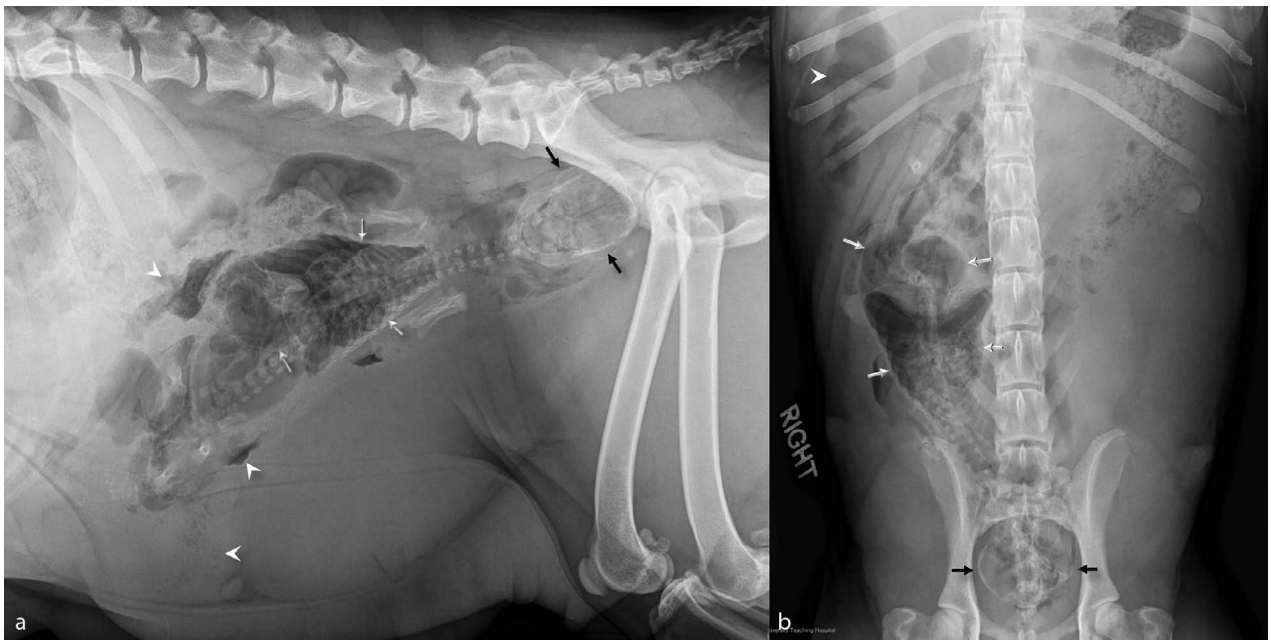

FIGURE 4.18 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in a dog having dystocia of unknown duration. A single full-term fetus is present. Dystocia likely occurred due to maternofetal disproportion where the skull (black arrows) was unable to pass through the pelvic canal. Emphysematous metritis is present (white arrowheads) so that gas accumulates within the uterus and surrounding the fetus. Gas is also present within the fetal thorax and abdomen (white arrows).

in an animal showing clinical signs associated with urinary obstruction. Urinary bladder position can also be abnormal, but this is less commonly encountered.

Mineral opacity associated with the urinary bladder is most commonly due to radiopaque urocystic calculi. Calculi are radiopaque because of the presence of calcium in their composition. This includes mainly calcium phosphate and calcium oxalate stones or combinations of stone that are mixed (e.g., magnesium ammonium phosphate, also called struvite, which often contains calcium phosphate). Urate and cystine urocalculi are often radiolucent but may contain some degree of calcification, making them faintly visible. In general, the determination of urocystic calculus composition cannot be definitively made radiographically. Urinary calculi can

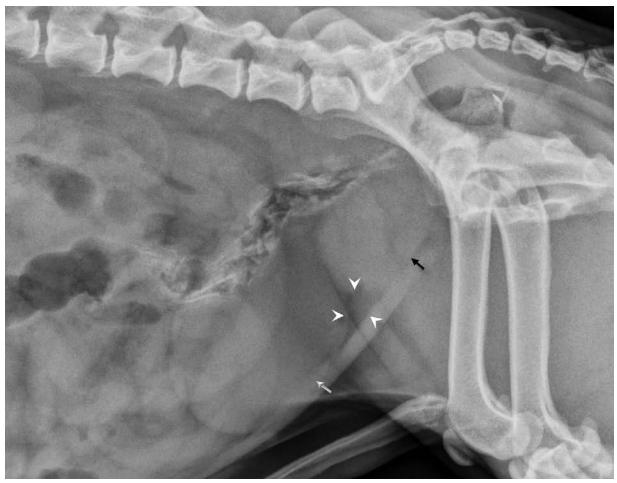

FIGURE 4.19 Lateral abdominal radiograph in a dog having prostatomegaly due to benign hypertrophy. The fat triangle (between white arrowheads) located between the prostate and the urinary bladder indicates a prostatic organ of origin for the rounded soft tissue opacity at the pelvic inlet. The prostate is enlarged (black arrow) but encompasses less than 50% of the dorsoventral diameter of the pelvic inlet. The urinary bladder is cranially positioned (white arrow) likely due to prostatomegaly.

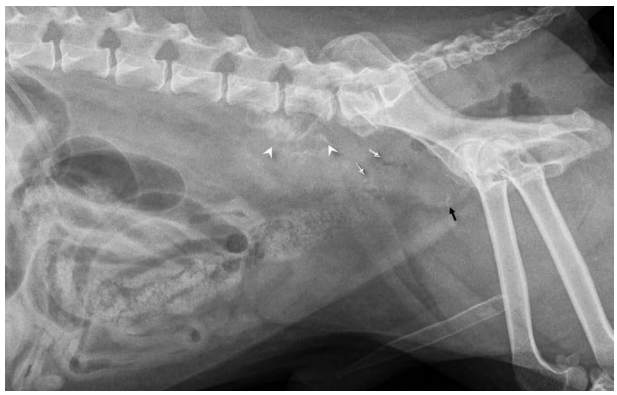

FIGURE 4.20 Lateral abdominal radiograph in a dog having prostatic neoplasia. The prostate is radiographically visible (black arrow) and contains a small amount of pinpoint mineral near its ventral margin. There is mass effect in the caudodorsal abdomen that is causing mild ventral displacement of the distal descending colon (white arrows) consistent with sublumbar lymphadenopathy. Indistinct mineral is superimposed ventral to the caudal lumbar spine (white arrowheads). The ventral margin of these vertebrae is indistinct, indicating an aggressive bone lesion. This is due to metastatic disease from prostatic neoplasia.

be variable in size and shape. Urocystic calculi should be mobile; therefore, they will most often be superimposed over the body of the urinary bladder centrally on orthogonal views. Mineral that is superimposed in a noncentral location over the urinary bladder indicates a lack of mobility and may be due to adherent luminal calculi or sediment, mineralization of the urinary bladder wall, or mineralized neoplasia.

Gas opacity is occasionally identified within the urinary bladder associated with the lumen or the urinary bladder wall. Most commonly, gas is found in the lumen and is iatrogenic due to catheterization or cystocentesis. In these cases, the gas bubble is mobile and will locate in the most nongravity-dependent part of the urinary bladder as the animal is positioned in lateral or ventrodorsal recumbency. As a result, the bubble will be located at the level of the urinary bladder body on both views. Rarely, gas can be located within the urinary bladder due to gas-forming bacteria, most commonly in diabetic animals with glucose-fermenting infections. Emphysematous cystitis can result in luminal gas or mural gas within the urinary bladder wall. When gas is located within the urinary bladder wall, it will remain superimposed over the same portion of the urinary bladder regardless of the view or the position of the animal and is curvilinear in shape, following the margin of the urinary bladder wall (Figure 4.21a, b). Reflux of gas through the ureters or presence of concurrent emphysematous pyelonephritis will cause gas to be located within the region of the renal pelvis.

The Urethra

In male dogs, the urethra can be divided into the prostatic urethra, the membranous urethra, and the penile urethra. As its name implies, the prostatic urethra is located in the prostate. The membranous urethra is located caudal to the prostate. The landmark for the junction between the membranous urethra and the penile urethra is the ischial arch. The penile urethra distal to the ischial arch is the longest portion in dogs. The male feline urethra is divided into pelvic and penile parts, where the ischial arch is the landmark for the junction between the two sections. The pelvic part is the longest portion of the urethra in the male cat and includes preprostatic, prostatic, and postprostatic parts. The female urethra in cats and dogs has a pelvic and postpelvic part. When the urinary bladder is distended, the pelvic urethra is more cranially positioned and can be radiographically visible within the abdomen, especially in cats. Otherwise, the urethra is not identified as a separate structure radiographically.

When assessing male dogs for suspected urinary calculi, especially if evidence of urinary obstruction is present or the urinary bladder is distended, a flexed hip lateral view centered at the pelvis and including the perineal region should be incorporated into the protocol so that the entire urethra is visible without superimposition by the femurs (Figure 4.22a, b). Evaluation of the urethra on both lateral and flexed lateral views will also prevent mistaking the fabellae for penile urethral calculi, as the fabellae will move with the femur with each view. Keep in mind that in male dogs urethral calculi tend to obstruct at the level of the os penis (Figure 4.22a, b). The flexed hip view is not necessary in cats or in female dogs; however, the views should include the entire perineal region. The pelvic urethra is another location common for obstruction, especially in female dogs. The portion of the urethra within the pelvis must be closely evaluated on both views to ensure that a calculus is not overlooked as a normal part of

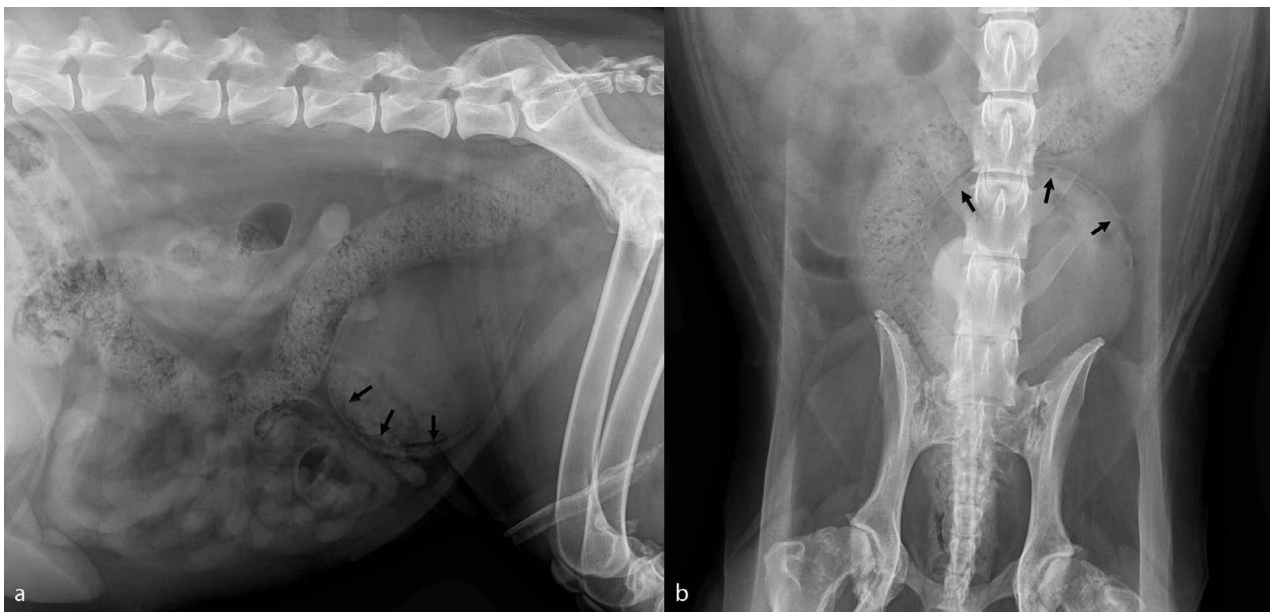

FIGURE 4.21 Lateral (a) and ventrodorsal (b) abdominal radiographs in a dog having emphysematous cystitis. Rather than gas being superimposed over the body of the urinary bladder, as would be expected with mobile luminal gas, a curvilinear rim of gas is present at the bladder apex consistent with its presence within the urinary bladder wall. Bilateral coxofemoral osteoarthritis is also evident.

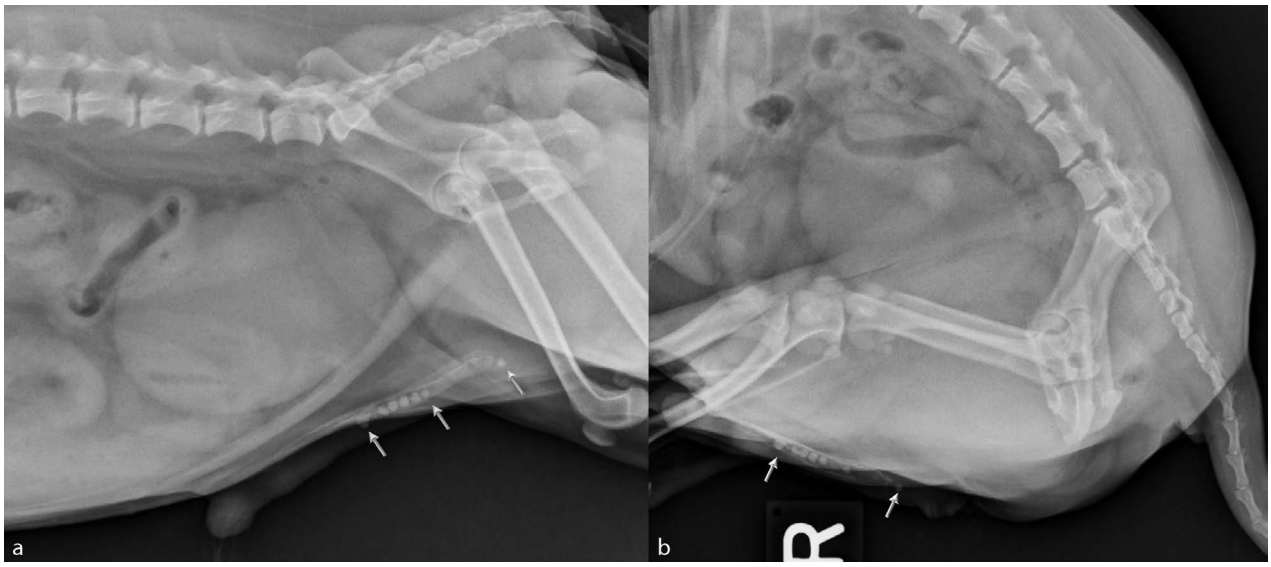

FIGURE 4.22 Standard lateral **(a)** and flexed hindlimb lateral **(b)** abdominal radiographs in a male dog having clinical signs consistent with urinary obstruction. Multiple, round, well-defined calculi are present within the penile urethra (white arrows). To confirm the correct number of calculi, a flexed hindlimb view (b) is needed to view the entire urethra and remove superimposition of the femurs over the urethra.

the bony pelvis (Figure 4.23a, b). The size of a urinary calculus that can pass through the entire urethra is not reliably predictable.

10. Gastrointestinal Tract

The stomach is typically readily identifiable unless void of any content, including gas. When evaluating the intestines, the colon should be identified first because it is in a more predictable location and is easier to recognize. Next, any remaining intestine that is distended or has abnormal contents is probably within small intestine, making it more likely to be of clinical significance. It is common for beginner interpreters to only recognize portions of the GI tract containing gas and ignore portions that are empty or contain only fluid opacity. Attempts must be made to evaluate portions that are soft tissue/fluid opaque, as they may be abnormal and the gas-filled loops more normal. Also, many beginner interpreters assume a decrease in peritoneal detail when evaluating the abdomen of an animal having little to no luminal gas within the intestines. Evaluation of serosal

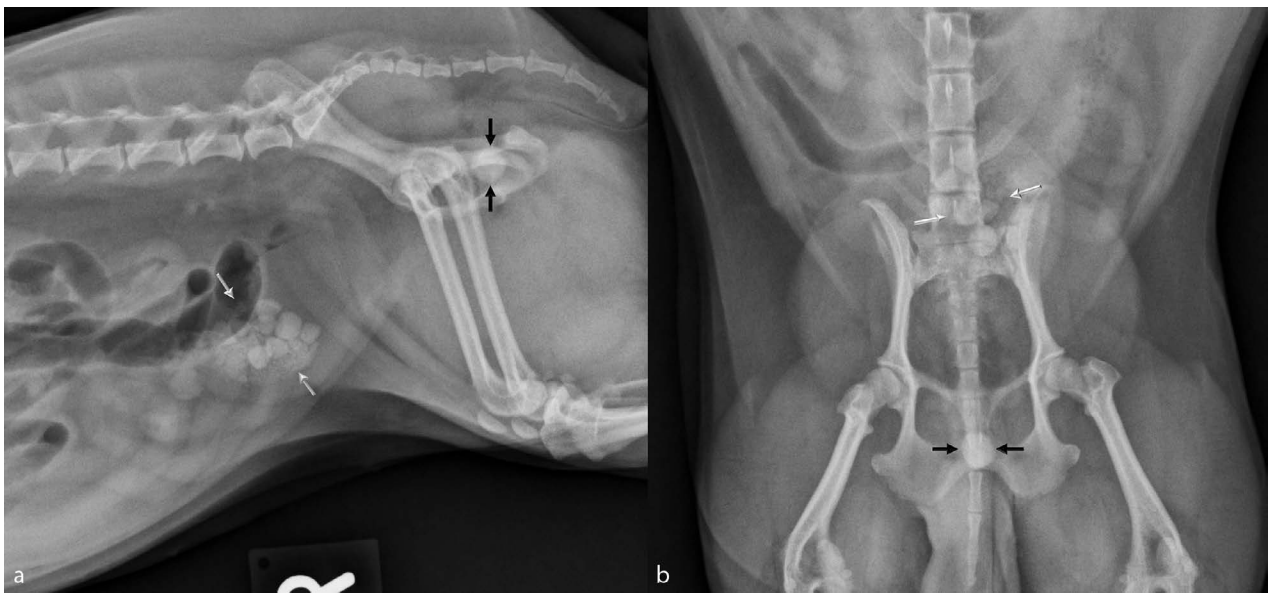

FIGURE 4.23 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in a female dog having clinical signs associated with urinary obstruction. Numerous calculi are readily visible within the urinary bladder (white arrows). A single, large calculus is present within the pelvic urethra that is superimposed over the bony pelvis on both views (between black arrows). This calculus was not initially identified prior to removal of the bladder calculi and was removed on a subsequent cystotomy.

margins to determine their visibility will confirm or reject the presence of decreased serosal detail.

Stomach

A normal size measurement for the stomach does not exist; therefore, distension is a subjective determination. An empty stomach is typically intercostal in location. With increasing distension, the stomach extends caudally and ventrally, as commonly seen in cats and especially dogs that have recently eaten large volumes. The fundus is always the largest portion of the stomach regardless of the degree of distension (this is useful when evaluating the stomach for malpositioning, often occurring with distension). The fundus should be located on the left side of the abdomen and is dorsal. In dogs, the gastric body crosses from left to right and is the most ventral portion of the stomach. The pyloric antrum and pylorus are slightly more dorsal in location than the gastric body and are located on the right side. In cats, the stomach is "J" shaped and is primarily located on the left side, with the pylorus being close to midline. Alterations in stomach size, position, and opacity can occur.

Gastric Distension

A distended stomach causes caudal displacement of small intestines and the head and tail of the spleen. Gastric dilatation can be caused by mechanical or functional ileus. Several considerations should be made when evaluating a distended stomach. The clinical signs, history, and description of the luminal content alter the ranking of differential diagnoses associated with a distended stomach. In the case of recent ingestion, the luminal content of the stomach is usually an inhomogeneous mixture of gas, soft tissue, and sometimes granular or faint mineral opaque material. The content of the stomach can rarely be definitively distinguished as food or foreign material. Foreign materials, such as tough, expansile glues containing diphenylmethane diisocyanate, and indigestible materials, such as fabric or grass, can have an inhomogeneous appearance similar to that of recently ingested food. When it is unclear whether or not the stomach is filled with food or foreign material, repeat radiographs should be obtained 6–8 hours after fasting to see if gastric emptying is occurring. If the stomach is identical after this period of time, foreign or indigestible material (Figure 4.24a, b) should be considered.

In an animal with a functional ileus or a pyloric outflow obstruction, the stomach may or may not be distended, depending on the effectiveness of vomiting. Gastric contents in an animal that is concurrently anorexic often appear as a homogeneous shade of gray consistent with a combination of gas and fluid (Figure 4.25a, b) rather than the inhomogeneous opacity seen with recent ingestion of food or a stomach filled with non-digestible material (Figure 4.24a, b). Pyloric outflow obstructions can occur due to luminal foreign material that is nonmobile and lodged within the pylorus/proximal duodenum or can be due to mural thickening or a mass at the same level. The most common causes of a functional gastric ileus are acute gastritis or pancreatitis.

When a stomach containing homogeneous gas and fluid is encountered, the next step is to obtain a left lateral view. The left lateral view allows luminal fluid to fall to the gravity-dependent gastric fundus on the left side, while gas rises to the nongravity-dependent pyloric antrum on the right side. This recumbency allows gas to highlight materials that may be obstructing the pylorus and are not mobile, given that these materials are often soft tissue opaque (Figure 4.26a, b). Mobile soft tissue opaque materials (food or foreign) will follow luminal fluid with recumbency, being similarly gravity dependent, and may remain effaced by any fluid present, depending on the volume of gas versus fluid present in the stomach. Therefore, mobile foreign objects are not readily identified unless they are mineral or metal opaque or are surrounded, at least in part, by gas,

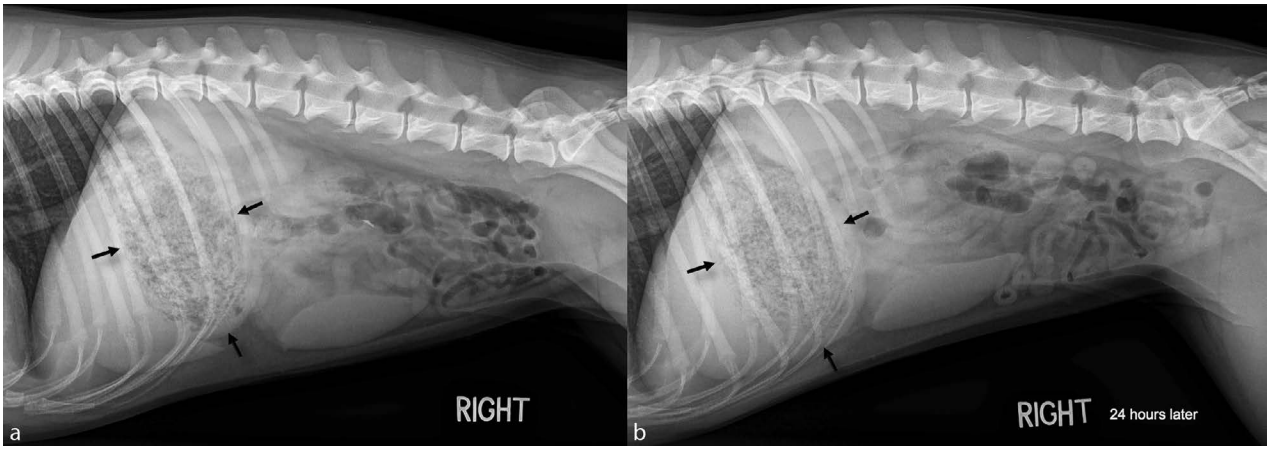

FIGURE 4.24 Lateral abdominal radiographs in an anorexic dog that vomited once prior to presentation. The stomach is moderately distended with inhomogeneous gas and soft tissue opaque material (**a**, black arrows). This could be due to recent ingestion of food or due to indigestible foreign material. The dog was fasted for 24 hours, and the study repeated **(b)**. The stomach is almost identical in appearance consistent with a lack of movement of content from the stomach and the presence of indigestible material. A large volume of hay was removed endoscopically.

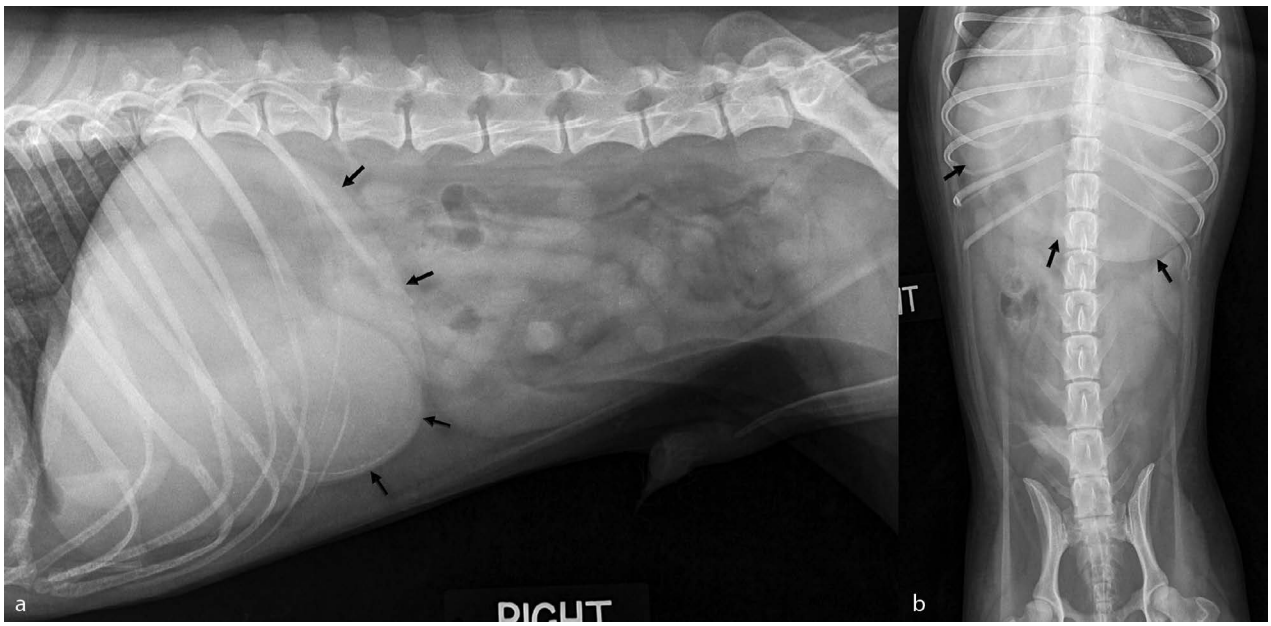

FIGURE 4.25 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in a dog presenting for vomiting. The stomach is distended (black arrows) causing caudal displacement of the small intestines and the spleen. The stomach is a homogenous shade of gray created by a combination of luminal gas and fluid. This appearance is not typical for an animal that has recently eaten. It is more typical for a functional ileus or a pyloric outflow obstruction.

allowing their structure to be revealed. Effort should be made to determine the degree to which foreign material extends into the small intestinal tract, as lengthy or linear foreign bodies must be removed surgically rather than endoscopically. The left lateral projection can be used to highlight some mural gastric wall or pyloric

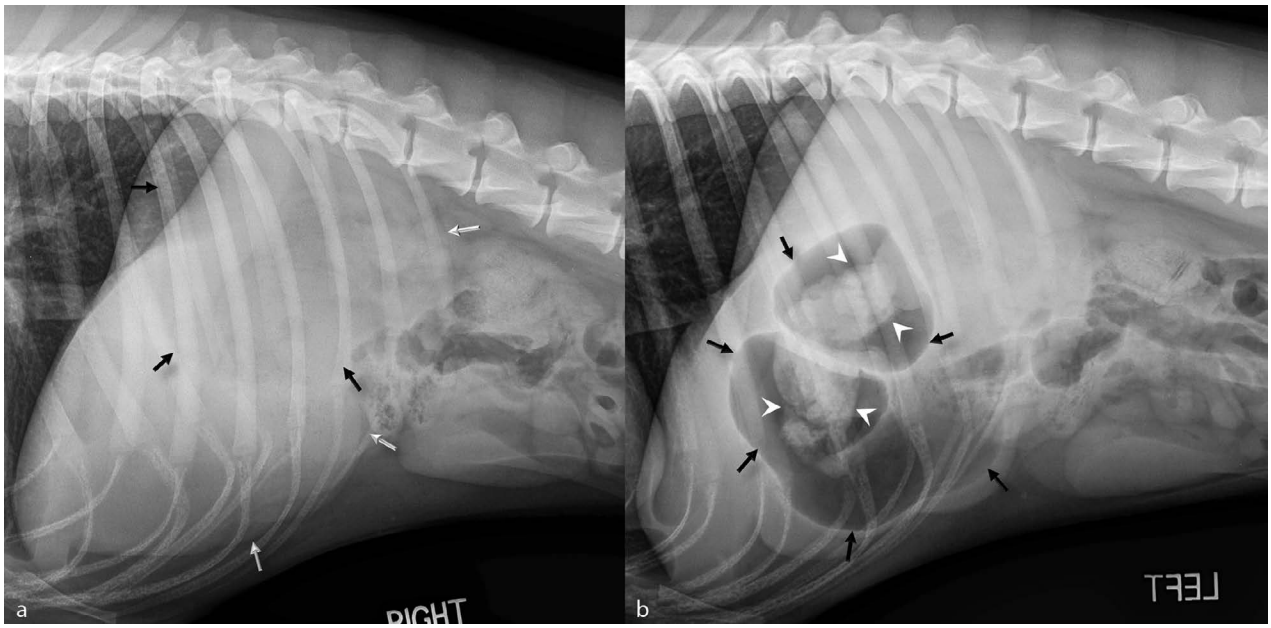

FIGURE 4.26 Right **(a)** and left **(b)** lateral radiographs in a dog presenting for acute and frequent vomiting. On the right lateral view, a distended stomach is seen (a, white arrows) which contained a shade of gray consistent with gas and fluid content. Due to recumbency in the right lateral view, faint gas is located in the gastric fundus (a, black arrows), and fluid is located at the level of the pylorus. Due to the clinical signs and appearance of the stomach, a left lateral projection was obtained. On this view, gas fills the nongravity-dependent pyloric antrum (b, black arrows) while fluid falls to the gastric fundus. Gas within the pylorus highlights a well-defined, tubular, soft tissue opacity (b, white arrowheads). This opacity is pyloric in location and must be nonmobile because it did not fall with luminal fluid to the gravity-dependent gastric fundus on the left lateral view, indicating positive evidence for obstruction. A sock was removed surgically.

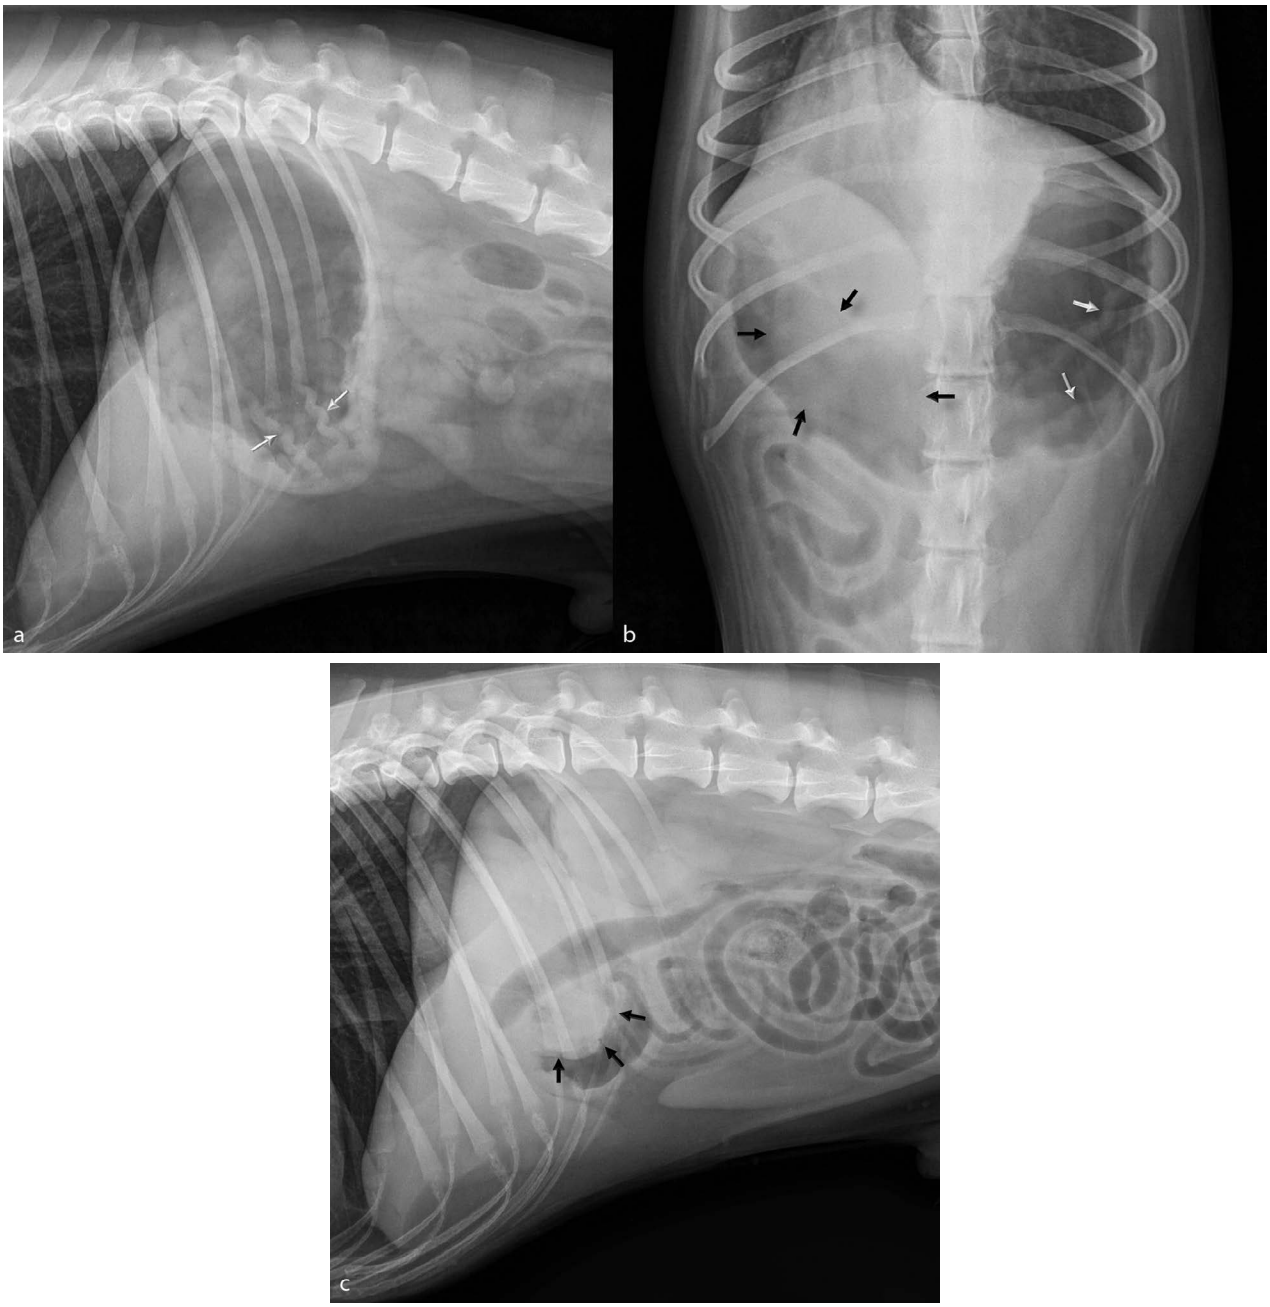

FIGURE 4.27 Right lateral **(a)**, ventrodorsal **(b)**, and left lateral **(c)** abdominal radiographs in a dog presenting for increasing episodes of vomiting over several weeks. The stomach is moderately distended and contains a large amount of gas causing a darker gray opacity; however, some fluid is also present that makes the gravity-dependent part of the stomach difficult to evaluate. In the right lateral projection, gas is present in the fundus, while luminal fluid falls to the gravity-dependent part of the stomach, the pylorus. Rugal folds located within the gastric body and fundus are highlighted by gas on the right lateral and ventrodorsal views (a and b, white arrows). Additionally, an indistinct soft tissue opacity is seen at the right gastric body and pyloric antrum on the ventrodorsal view (b, black arrows). This may be mobile luminal fluid or ingested content. On the left lateral view (c), gas has risen to the nongravity-dependent pyloric antrum and highlights a soft tissue mass that is partially surrounded by gas having an irregular luminal margin (c, black arrows), providing a more convincing view of a mural abnormality. Gastric adenocarcinoma was diagnosed via endoscopic samples.

abnormalities if they are large enough to extend into the lumen or create an irregular gas pattern in the pyloric antrum (Figure 4.27a–c).

In cases where the left lateral view does not reveal a luminal foreign object, a mural abnormality or luminal obstruction not highlighted by gas cannot totally be ruled out; however, causes of functional ileus such as gastritis and pancreatitis are considered higher on the differential diagnosis list, especially if acute vomiting is the predominant clinical sign. The left lateral projection

can also be used to prove that a cranioventral mass is a distended stomach rather than a liver or splenic mass.

Gastric wall masses are not usually diagnosed on radiographs alone because it can be difficult to differentiate a mass typically effaced by surrounding organs and luminal content unless a luminal abnormality can be highlighted by gas. A stomach wall mass can cause a similar mass effect to that seen with luminal gastric distension (i.e., caudal displacement of small intestines and the spleen). In many cases, a positive (barium sulfate, most commonly) or negative (room air, most commonly) contrast upper GI study or an abdominal ultrasound is ultimately required to determine the presence of a gastric wall mass.

Gastric Malpositioning

Alterations in stomach positioning can occur due to mass effect from surrounding organs or to volvulus. If the diaphragm is ruptured, the stomach can be cranially displaced within the pleural space or in the location of the liver and may be difficult to locate unless distended or contrast is administered. A small liver can cause a cranially positioned stomach. Conversely, hepatomegaly can cause caudal displacement of the stomach.

Volvulus occurs when the stomach axis rotates, typically clockwise when viewing the animal from caudal to cranial, altering the relative positions of the gastric fundus and pylorus. The pylorus rotates cranially, dorsally, and to the left while the fundus rotates to the right and ventrally. Often, the stomach is massively dilated concurrent with volvulus, hence the term GDV. In most cases, the stomach contains a large volume of gas; however, fluid or inhomogeneous ingesta may be the most notable luminal contents. The motion of gas and fluid within the normal stomach must be understood in order to appreciate the radiographic abnormalities that occur with GDV. The right lateral recumbent view is often the only view needed to evaluate for the presence of gastric malpositioning; however, additional views can be performed, if necessary. Due to gastric malpositioning with GDV, instead of fluid falling to the pylorus in the right lateral view, gas will rise to the pylorus, which is abnormally located on the left side. Therefore, having gas present in the pylorus on the right lateral view is a positive indication of gastric malpositioning (Figure 4.28). The volvulus combined with the severe distension creates a compartmentalized appearance to the stomach, which appears to be divided by a soft tissue band. This descriptive configuration of gastric malpositioning occurs with a 180-degree torsion, which is the most common torsion. In the case of a 360-degree torsion, gas and fluid will behave as expected in a normal animal, except that massive gastric distension will be seen, making this degree of volvulus more easily overlooked.

An alteration in stomach opacity occurs most commonly due to radiopaque luminal material that may be mineral or metal opaque and can be obstructive, or benign.

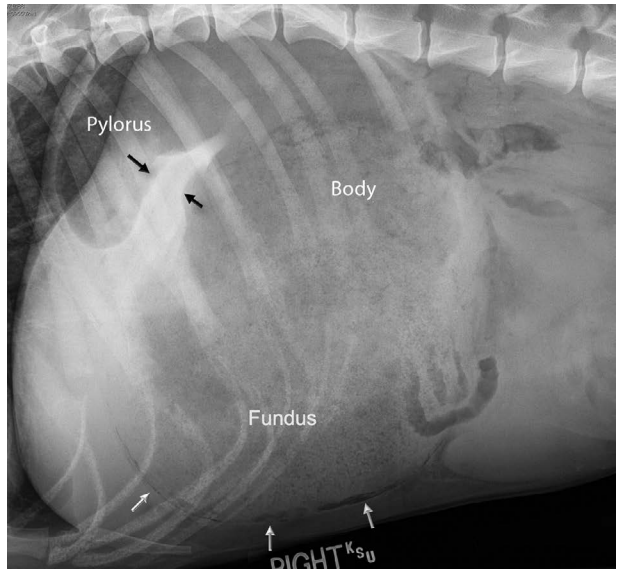

FIGURE 4.28 Right lateral abdominal radiograph in a dog having gastric dilatation and volvulus. Each portion of the stomach is labeled. On the right lateral view, the pylorus should contain fluid. In this case, the pylorus (identified as being the smallest gastric compartment) contains gas and is located dorsally and cranially. The fact that the pylorus contains gas in the right lateral recumbency indicates that it is located on the left side of the dog. A thick, soft tissue opaque band (between black arrows) is present between the gastric body and pylorus, typical for compartmentalization seen with massive distension and volvulus. Additionally, an irregular line of gas borders the ventral aspect of the gastric fundus, indicating intramural gas (gastric pneumatosis) and wall necrosis (white arrows).

Alterations in Gastric Wall Opacity

An alteration in stomach opacity occurs most commonly due to radiopaque luminal material that maybe mineral or metal opaque and can be obstructive, or benign. True alterations in stomach opacity can occur due to mural gas (gastric pneumatosis or emphysematous gastritis) or mucosal mineralization, as reported with uremic gastritis. In cats, fat within the submucosal layer of the stomach is sometimes radiographically visible as a lucent line paralleling the gastric wall and is a normal finding. This fat layer is not present in dogs, and its identification in cats must not be mistaken for pneumatosis. Mineralization associated with uremic gastritis occurs in the mucosal layer and can result in a faint mineral line that follows the rugal folds, likely due to metastatic mineralization and formation of whitlockite crystals. Mural gastric mineral can be identified in some dogs having schistosomiasis due to infection with *Heterobilharzia americana*. The mineral in this case is associated with heavy concentrations of mineralized parasitic eggs in the submucosa of the gastrointestinal tract.

Small Intestines

Inexperienced interpreters often rely solely on small intestinal diameter as an indication of abnormality.

Box 4.8 Descriptors for evaluation of small intestines

- Location
- Luminal content
- Serosal margin shape and margination
- Path of small intestinal loops
- Apparent number of small intestinal loop
- Diameter

Several other descriptors exist that should be evaluated when interpreting small intestine and are summarized in Box 4.8. With regard to small intestinal diameter, multiple measurements have been published for normal small intestine diameter. In dogs, the normal small intestinal diameter should be less than two rib widths. Also, an increase in diameter of a small intestinal segment >50% of the diameter of the remaining small intestinal loops is considered abnormal. Small intestinal dilation >1.6 times the dorsoventral diameter of the narrowest point of the L5 vertebral body is significantly associated with mechanical obstruction. Small intestines in cats should measure <12 mm in diameter. Small intestine must be distinguished from colon. The diameter of the colon can vary greatly, being quite large and often containing inhomogeneous fecal material in normal animals. Finding similar luminal material within small intestines to that normally seen within the colon is often of significance.

The luminal content in small intestines should be homogeneous in appearance. The small intestines normally contain gas or fluid, or are empty, producing a shade of gray depending on the volume of gas located within the segment. Additionally, normal luminal gas forms well-defined tubes or ovals without causing distension. Dogs tend to have more luminal gas than cats; however, great variation exists depending on the degree of aerophagia. Because they tend to be more evident, loops containing gas are often evaluated more closely by beginner interpreters than uniformly soft tissue opaque loops. Attempts must be made to evaluate loops that are empty or have homogeneous soft tissue opaque content. In homogeneous small intestinal content, having either definable structure or more descriptively matching luminal feces located within the large intestine, should raise suspicion of foreign material, especially when associated clinical signs are present. Obtaining right and left lateral recumbent views redistributes luminal gas and fluid within the small intestines and can make the presence of an abnormality more visible.

The serosal margin of small intestinal loops should be linear, smooth, and well defined. A roughened serosal margin most commonly occurs with fine plication due to the typically thin thread-like material, which causes linear foreign bodies in cats. Mural small intestinal masses can also cause an irregular serosal surface to small intestinal loops.

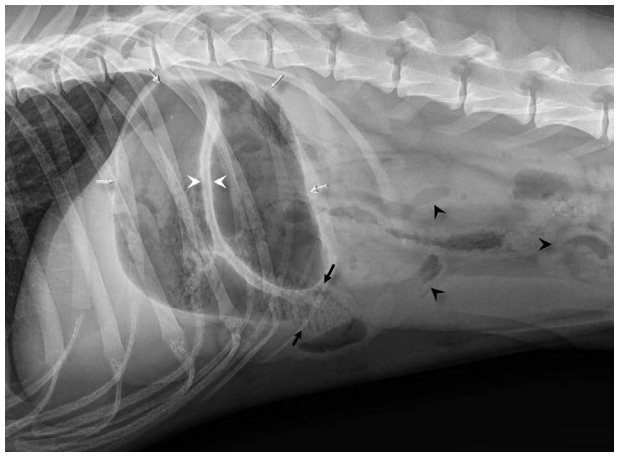

FIGURE 4.29 Lateral abdominal radiograph in a dog presenting for acute, frequent vomiting. A massively distended loop of small intestine containing mostly gas is present in the cranial abdomen (between white arrows). Due to the extreme distension, the loop of intestine is stacked upon itself and takes a hairpin turn, creating a squared-off end in the dorsal abdomen. The stacked intestinal walls create an apparent soft tissue opaque band (between white arrowheads) separating the luminal gas within each segment. Ventrally, a structured inhomogeneous opacity composed of gas and soft tissue is present that is partially surrounded by gas (between black arrows). Multiple small intestinal loops are normal in diameter (black arrowheads). Mechanical obstruction due to a corncob foreign body was diagnosed.

Normal intestinal loops have a path comprised of multiple broad turns. The presence of a tortuous path consisting of tight turns should raise suspicion for plication due to linear foreign material. Plication also tends to create a reduction in the apparent number of small intestinal loops. With severe small intestinal dilation, the small intestinal path can have extremely tight turns (so-called hairpin turns) giving the loops a stacked appearance with squared-off ends, indicating small intestinal crowding due to increased luminal volume (Figure 4.29).

The diameter of the small intestines should be uniform across all segments and should be within measurements previously discussed. When considering causes of dilated small intestines, segmental distribution of dilation is probably the most useful descriptor in determining the presence of obstruction. Uniform dilation is more often associated with a functional ileus, and the presence of dilated small intestinal loops in combination with loops that are normal in diameter is more characteristic of mechanical obstruction.

Small Intestinal Mechanical Obstruction

Small intestinal mechanical obstruction falls into two main categories, focal discrete obstruction and linear obstruction, and these have important differences in radiographic appearance. The typical radiographic appearance for a discrete obstruction is small intestinal

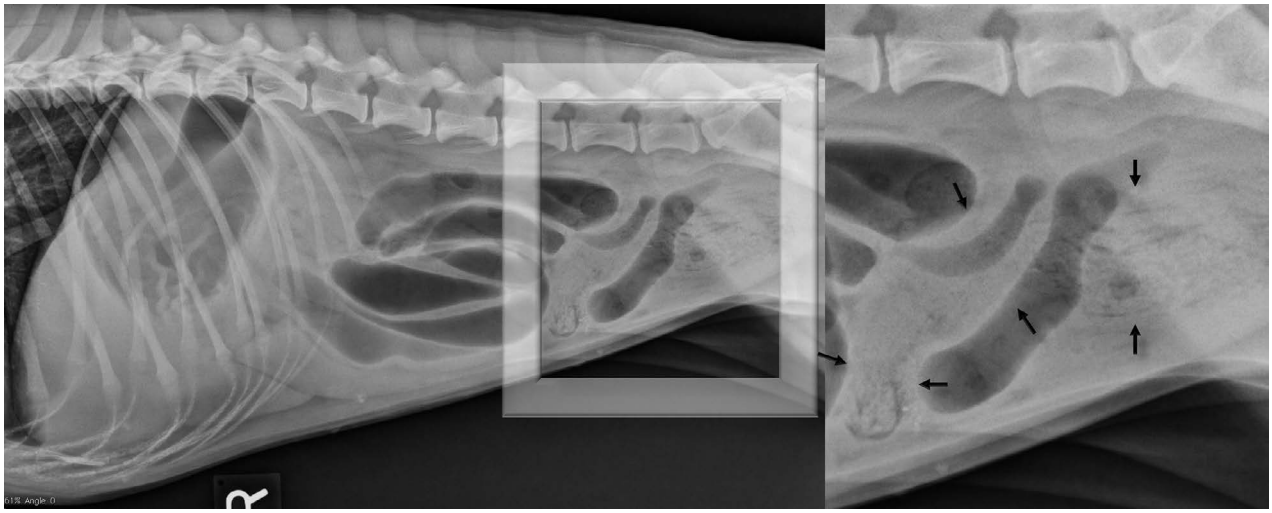

FIGURE 4.30 Lateral abdominal radiograph in a dog presenting with acute, frequent vomiting. Multiple gas-filled small intestinal loops are dilated. Too many visible dilated loops are present to be due to colon alone. In the caudoventral abdomen, a loop containing inhomogeneous luminal material having linear gas and soft tissue opaque striations is present (in boxed inset and between black arrows) that is typical for textile material. A hand towel was surgically removed.

dilation that is segmental in nature. In other words, some distended loops are identified, and, importantly, some loops that are normal in diameter are also identified. With more distal obstructions, an increase in the number of dilated small intestinal loops relative to normal ones is often identified because distension occurs orad to the obstruction. Potential causes for a discrete obstruction include luminal foreign material, a mural mass, or an intussusception. Close evaluation of small intestinal content may reveal the presence of focal structured or inhomogeneous material, further raising suspicion of mechanical obstruction due to foreign material. Sometimes, the discrete obstruction can have a characteristic appearance, such as a corncob having a lucent grid at regular intervals (Figure 4.29) or a textile having linear gas and soft tissue opaque striations (Figure 4.30). Additionally, luminal intestinal gas can highlight a foreign object, creating a gas–soft tissue interface that is inconsistent with a normal luminal gas bubble (Figure 4.31). Redistribution of gas using both lateral recumbencies can assist with foreign body diagnosis by potentially highlighting such interfaces. The lack of identification of the obstructing material should not preclude a diagnosis of obstruction when remaining descriptors indicate mechanical ileus.

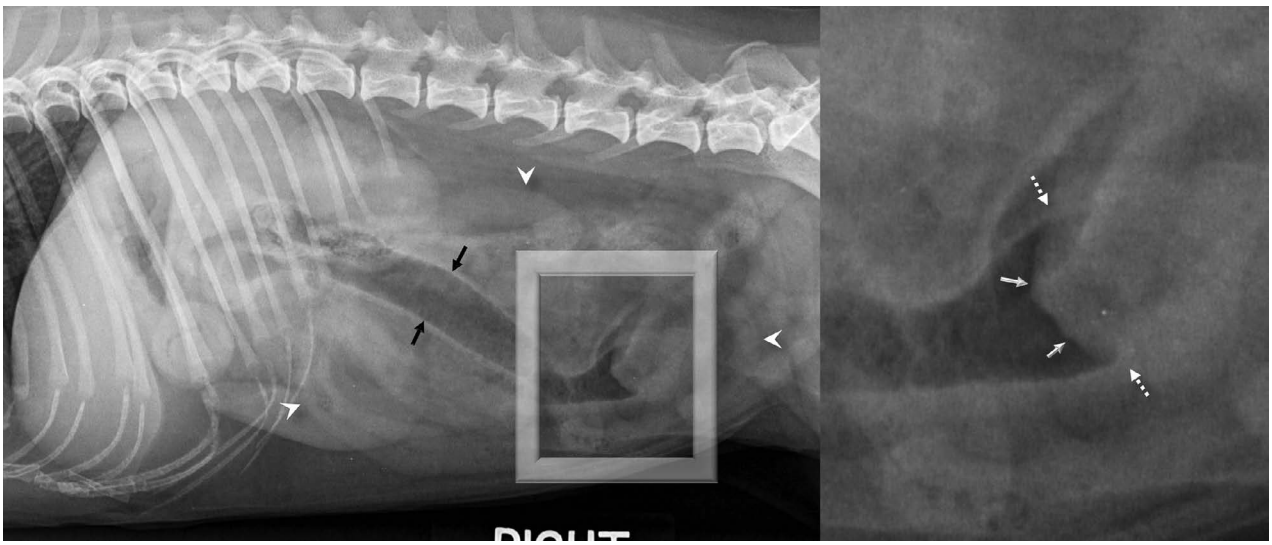

FIGURE 4.31 Lateral abdominal radiograph in a dog that was vomiting for one week. A gas-distended small intestinal loop is present (between black arrows). Several normal diameter loops are also present (white arrowheads). At the caudal aspect of the gas-distended loop, an irregularly marginated interface between the gas and a soft tissue opacity is seen (boxed inset, white arrows). The small intestinal loop visibly dilates at the level of this soft tissue opacity (dotted white arrows). A plastic toy nose was removed surgically.

Small intestinal masses can cause a focal, discrete obstruction. Small intestinal masses are most commonly neoplastic due to adenocarcinoma, lymphoma, or leiomyosarcoma. Focal masses can be circumferential surrounding the entire lumen (more typical of adenocarcinoma) or eccentric involving one side of the intestine (more typical of leiomyosarcoma). Diffuse or multifocal neoplasms such as lymphoma also occur. Focal, discrete, circumferential masses are most likely to cause mechanical obstruction. An accumulation of granular mineral material at a location within the intestinal tract (called a gravel sign) indicates a partial chronic obstruction, most likely due to a focal mural small intestinal mass where mineral opaque or desiccated material accumulates at the site of obstruction. The absence of small intestinal dilation does not rule a mechanical obstruction out. Especially with proximal small intestinal mechanical obstructions, frequent and effective vomiting can limit visible distension. In general, the small intestinal dilation seen with focal, discrete mechanical obstruction is often greater than the dilation seen with a paralytic or functional ileus.

Linear foreign material can span variable portions of the GI tract, causing small intestinal plication but not necessarily dilation. A tortuous path of small intestine or the presence of visible plication creating an irregular serosal margin is the most reliable evidence of a linear foreign body. Plication occurs because the material is anchored while the free end travels distally through the GI tract, where continual peristalsis causes the intestine to gather around the material like pleats in a drape. Two main features distinguish linear foreign bodies in cats from those in dogs. First, in cats, linear foreign material is usually very thin, such as thread or floss. Because of this, the plication that occurs with linear foreign material tends to be fine, appearing as an irregular serosal margin with little to no measurable small intestinal distension (Figure 4.32a, b). The small intestines can appear decreased in number and aggregated in a focal location (usually the right abdomen); however, these are often the least useful features for identification of linear foreign bodies and can be confused with the intestinal appearance in normal animals, especially obese cats. Some small intestinal loops may have small, irregular gas bubbles that are piriform in shape as gas becomes trapped in the pleats. Also, in cats, the material often becomes anchored at the base of the tongue, so examination of the mouth may confirm suspicion of linear foreign material. Linear foreign material in dogs tends to be thick textile material, such as socks, rope toys, and towels. This material tends to anchor at the level of the pylorus, causing an outflow obstruction. Because of the size of the linear material, small intestinal dilation is commonly seen with linear foreign body obstructions in dogs (Figure 4.33a, b). Also, due to the location of the obstruction at the pylorus, a left lateral view of a stomach containing adequate gas often reveals the origin of the linear object. Due to the thick nature of the textile causing most obstructions, the plication seen in a dog is characterized by frequent changes in direction of the small intestinal loop rather than the fine pleating that occurs with linear foreign material in cats, with an increase in likelihood for accompanying small intestinal dilation than is seen with linear foreign bodies in cats.

Functional Ileus

Functional ileus results in visible dilation of small intestines that is often diffuse but on some occasions can be focal, especially in association with pancreatitis. Focal narrowing of small intestine due to segmental peristaltic contractions is not seen radiographically when paralytic ileus is the cause of small intestinal dilation. Peritonitis, pancreatitis, enteritis, and infiltrative bowel neoplasms (e.g., lymphoma and mast cell tumor) are the most common causes of functional ileus. The distension that occurs with functional ileus is not usually as great as

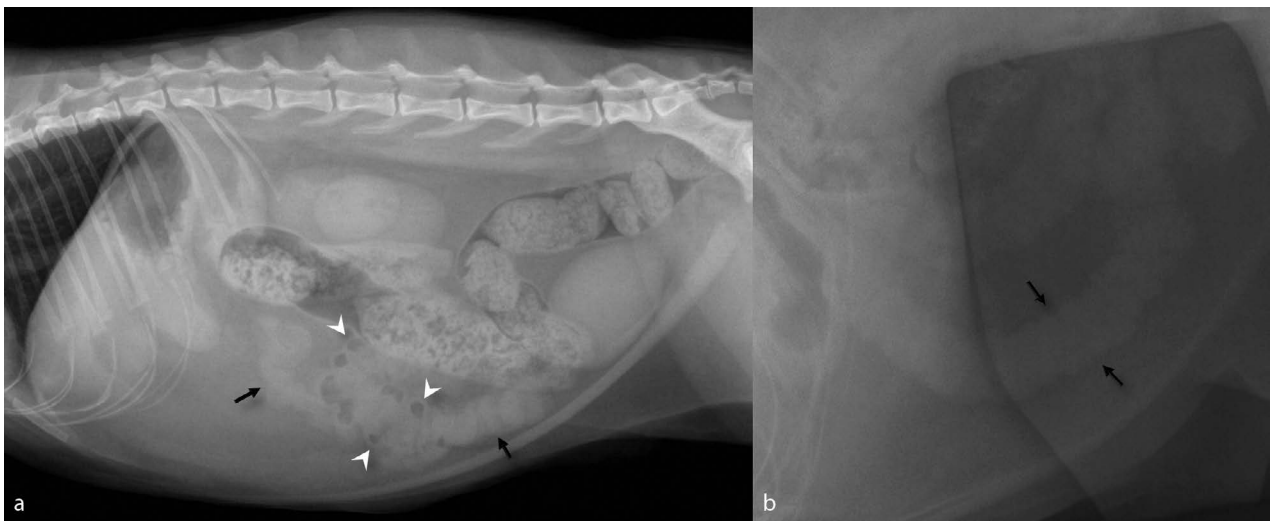

FIGURE 4.32 Lateral abdominal radiograph **(a)** and magnified compression view **(b)** in a cat presenting for acute vomiting. The apparent number of small intestines is subjectively decreased. The serosal margins of the loops are irregular with a tortuous path (a and b, black arrows). Several small gas bubbles are trapped within the pleats of the plicated intestinal loops (white arrowheads).

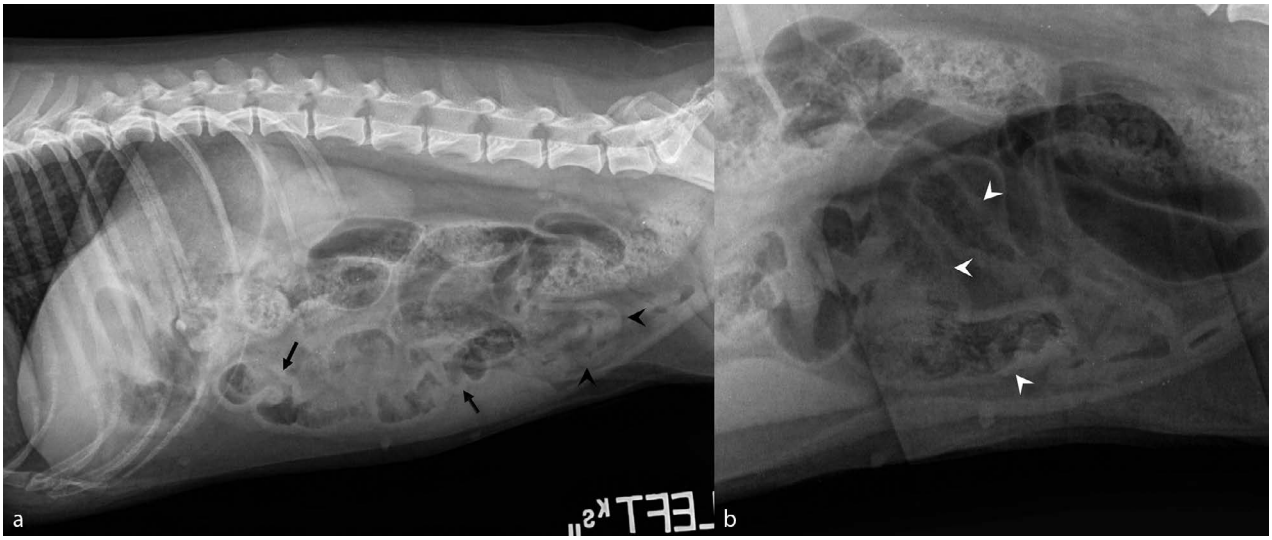

FIGURE 4.33 Lateral abdominal radiograph **(a)** and magnified compression view **(b)** in a dog presenting with acute, frequent vomiting. Multiple ventrally located small intestinal loops have a tortuous path (a, black arrows). The loops are also increased in diameter when compared to more normal loops (a, black arrowheads). The luminal content within the tortuous loops is inhomogeneous (b, white arrowheads), indicating foreign material.

that seen with mechanical obstruction. Regardless, functional ileus cannot always be distinguished from a distal mechanical obstruction without ultrasound examination or a positive contrast GI study. Less common causes of functional ileus, such as bowel ischemia and thrombosis or dysautonomia, can cause a profound small intestinal dilation that may be segmental rather than diffuse.

Colon

The colon is in a relatively predictable location and often contains luminal gas or feces, making it readily identifiable in most cases --Locating the colon should be the first step in evaluating the intestinal tract. The cecum is rarely identified in cats. The normal colon is typically larger in diameter than the small intestines and, as previously mentioned, is the only intestinal segment whose contents should be inhomogeneous, appearing as a mixture of gas, soft tissue, and granular mineral in locations where fecal material is present. Material of this characterization located in small intestines would be considered abnormal. Normal large intestinal diameter is difficult to characterize because it is so variable; however, the colon diameter should not exceed the length of the L7 vertebral body.

Alterations in colon location, size, and opacity can occur in diseased animals. Colon displacement occurs most commonly due to the abdominal mass effects previously discussed. Mass effects causing concurrent colon displacement and compression with subsequent extramural obstruction occur near the pelvic inlet, usually due to sublumbar lymph node or prostatic enlargement. Abnormal luminal distension is either due to functional or mechanical obstruction. Functional causes of colon enlargement due to nutritional, metabolic, neurologic, or chronic obstructive causes will result in a generalized enlargement of the colon (called megacolon). Mechanical causes of colon dilation result in enlargement orad to the obstruction and can be due to extramural, mural, or luminal causes. The most common location for a mechanical colon obstruction is at the level of the pelvic inlet; therefore, generalized megacolon tends to occur with functional or mechanical causes. Alterations in opacity of the colon most typically occur due to changes in luminal content. In animals having diarrhea, the colon will be characterized by a homogeneous gas or fluid opaque lumen rather than the inhomogeneous mixture typically seen with formed feces, making its contents similar in appearance to small intestinal content. Of course, an empty colon will appear soft tissue opaque and will be small in diameter. Colon masses or intussusceptions appear homogeneously soft tissue opaque. In many cases, an interface occurs where the homogeneously opaque obstructive mass or intussusceptum contacts inhomogeneous feces in a dilated colon (**Figure 4.34**). In most cases, when foreign material is positively located within the colon, surgical intervention is not required. Therefore, the interpreter must ascertain the origin of any radiopaque foreign objects or structured-appearing materials prior to deciding on a treatment plan. In some cases, contrast procedures are needed to confirm the exact location of suspicious material or a distended loop of intestine (pneumocolonography using room air is very useful to delineate the true location of the colon).

Pancreas

The right pancreatic limb borders the duodenum, the pancreatic body is located near the cranial duodenal

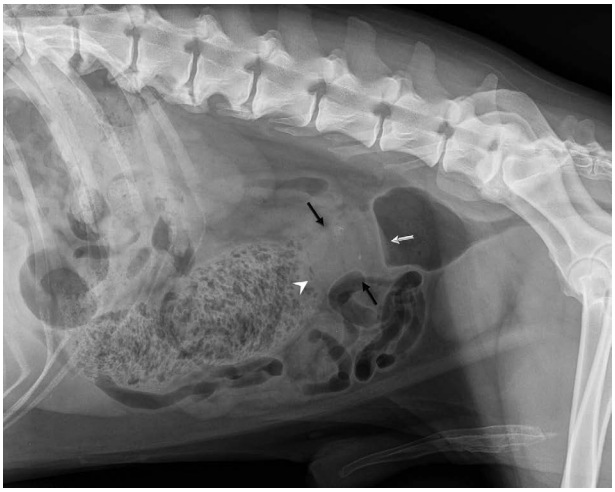

FIGURE 4.34 Lateral abdominal radiograph in a dog straining to defecate. The descending colon is markedly distended causing it to be ventrally located in the abdomen. A portion of the colon is homogenously soft tissue opaque (between black arrows). Homogenous soft tissue opacity is unexpected in a colon that is distended with fecal material. The cranial aspect of the soft tissue opacity interfaces with more typical inhomogeneous soft tissue and gas opaque fecal content (white arrowhead). The caudal aspect of the soft tissue opacity has a well-defined, flat interface with gas (white arrow). This configuration indicates gas highlighting a luminal structure. A circumferential colon wall mass was found on abdominal ultrasound. Colonic adenocarcinoma was diagnosed on aspiration.

flexure, and the left pancreatic limb borders the greater curvature of the stomach. The pancreas is never identified radiographically in the normal dog. Occasionally, in fat cats, the pancreas can be seen as an indistinct soft tissue opacity located between the gastric fundus, left kidney, and the spleen. Pancreatic diseases most often produce clinical GI signs. Rarely, radiographically visible changes are seen with pancreatic disease; however, radiographs are still recommended to assist with ruling out other potential causes of clinical signs. On occasions where radiographic changes of pancreatic disease are present, it will typically manifest as a loss in peritoneal detail (focal or diffuse), a right cranial abdominal mass effect, separation of the stomach from the transverse colon, and/or dilation of the stomach and the duodenum due to functional ileus (**Figure 4.35a, b**). The right cranial abdominal mass effect classically causes leftward displacement of the gastric body with rightward displacement of the duodenum toward the body wall. Additionally, the intestines are pushed caudally. Acute pancreatitis is the most common cause of a mass effect associated with the pancreas; however, pancreatic abscesses, pseudocysts, and neoplasms can have a similar appearance. Additionally, other organs of origin for a right cranial abdominal mass include liver, gallbladder, and duodenum.

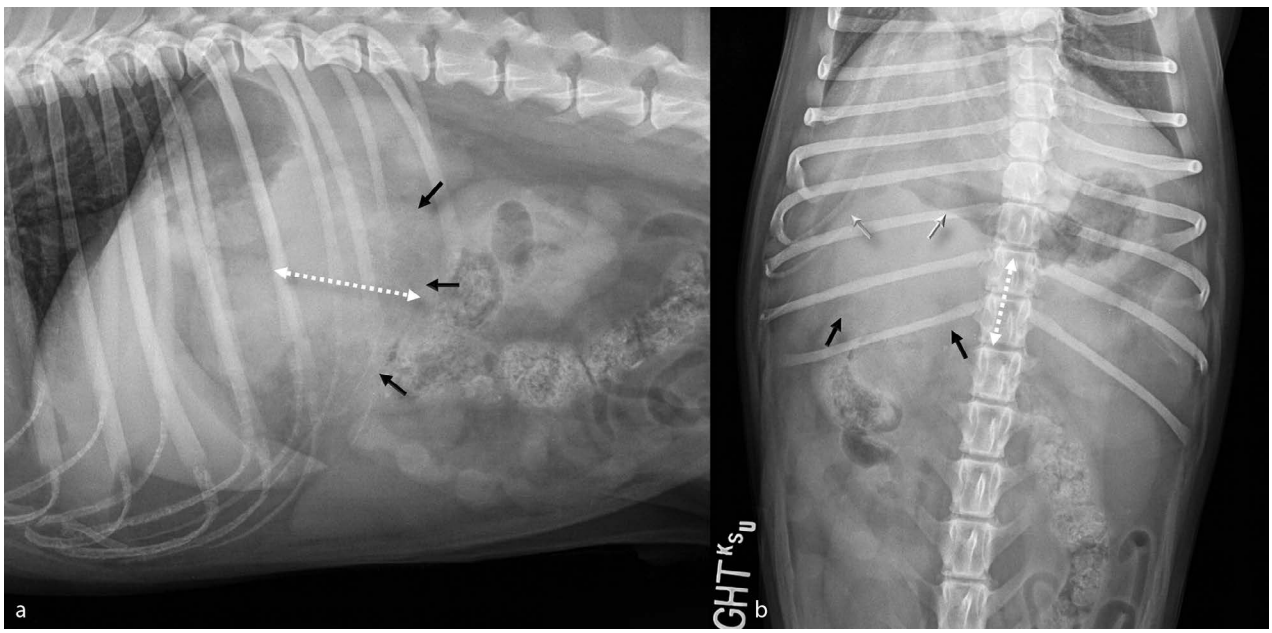

FIGURE 4.35 Lateral **(a)** and ventrodorsal **(b)** abdominal radiographs in a dog with acute pancreatitis. A focal loss of detail is present in the cranial abdomen with an indistinct increase in soft tissue opacity in the right cranial abdomen (black arrows). The gastric body and the pyloric antrum are cranially displaced and compressed with increased left-sided positioning of the stomach (white arrows). There is increased distance between the stomach and the transverse colon (dotted white line).

SUMMARY

When beginning a review of each study, the focus should be on systematic evaluation of each organ, keeping in mind those organs not normally seen radiographically. Also, an attempt should be made to increase the diagnostic usefulness of abdominal radiography with compression and positional views, and contrast procedures as warranted. When radiographs fail to diagnose or definitively rule out disease in a clinical patient, referral for abdominal ultrasound or computed tomography may be warranted.

INTRODUCTION

Veterinary dentistry and oral surgery is a quickly expanding field. Veterinarians and pet owners alike are learning the importance of good oral health for companion animals. Thanks to this and other medical and nutritional improvements, pets are living longer, healthier lives. Dental disease is more common in our small breed and aging pet populations, and without proper care throughout their lives, extensive treatment is increasingly necessary. Recent research supports the connection between oral and systemic health, including negative effects on diabetes, systemic inflammatory markers, cardiac, hepatic, renal, and pulmonary diseases, and an increased incidence of certain neoplasias (particularly oral). In this chapter, we aim to provide a basic overview of normal oral anatomy and physiology as well as some of the most common issues encountered in small animal clinical practice. The entire breadth of oral diseases cannot be covered completely in a single chapter; therefore, resources for more detailed information are provided at the end of this chapter.

ANATOMY

A firm understanding of oral anatomy and terminology is essential. The accepted dental formulas for the dog and cat are shown in Table 5.1.

Several tooth numbering systems exist for efficient written or verbal communication regarding the oral cavity. The most commonly used system is the modified Triadan system. Each quadrant of the mouth is given a number, as is each tooth. The right maxillary quadrant is the 100 arch (500 for deciduous teeth), left maxillary is 200 (600), left mandibular 300 (700), and right mandibular is 400 (800). Teeth are numbered beginning with the first incisor and moving distally (or caudally) as 01–10 in the canine maxilla and 01–11 in the canine mandible. Therefore, the permanent right maxillary canine tooth would be termed 104. The maxillary fourth premolars are 108 (right) and 208 (left), and the mandibular first molars are 309 (left) and 409 (right). These teeth are typically referred to as the carnassial teeth (Figure 5.1a, b).

TABLE 5.1 Dog and cat accepted dental formulas

Canine deciduous (Total = 28) – Maxilla (2×) – 3 incisors, 1 canine, 3 premolars – Mandible (2×) – 3 incisors, 1 canine, 3 premolars
Canine permanent (Total = 42) – Maxilla (2×) – 3 incisors, 1 canine, 4 premolars, 2 molars – Mandible (2×) – 3 incisors, 1 canine, 4 premolars, 3 molars
Feline deciduous (Total = 26) – Maxilla (2×) – 3 incisors, 1 canine, 3 premolars – Mandible (2×) – 3 incisors, 1 canine, 2 premolars
Feline permanent (Total = 30) – Maxilla (2×) – 3 incisors, 1 canine, 3 premolars, 1 molar – Mandible (2×) – 3 incisors, 1 canine, 2 premolars, 1 molar

Cats do not have a full complement of premolars and molars and so are "missing" several teeth, which are skipped in this system (Figure 5.2a, b).

The eruption times of deciduous and permanent teeth in the dog and cat are shown in Table 5.2.

Directionally, surfaces of teeth are referred to as (Figure 5.3a, b):

- *Mesial:* Nearer the rostral midline
- *Distal:* Away from the rostral midline
- Buccal surfaces face the inside of the cheeks
- Labial surfaces face the lips
- Lingual surfaces are next to the tongue
- Palatal surfaces face the palate

It is also important to understand tooth structure and development. The crowns of teeth are covered in enamel, which is the hardest substance in the body. Enamel cannot be regrown once it is lost and is much thinner in dogs and cats (<1 mm) than in humans. Beneath the enamel is dentin, which has a mineral content similar to bone. It is comprised of numerous microscopic dentinal tubules. Each dentinal tubule contains an odontoblastic process, which is essentially an extension of the root canal system. Dentin is produced throughout life, and this accounts for the decreasing width of the pulp canal evident on dental radiographs as patients age. Dentin is porous, and irritation or injury may incite its component cells to protect the tooth by forming reparative or tertiary dentin. Vessels and nerves enter and exit the teeth through the tip of the root or the apex. The entire root structure (in normal teeth) is surrounded and supported by the periodontal ligament, which holds teeth in place in the surrounding alveolar bone. The periodontium consists of the gingiva, periodontal ligament, cementum, and alveolar bone. The gingiva is part of the specialized

mucosa that protects the tooth and supporting structures from infection and detachment. Cementum covers the root much as enamel covers the crown of the tooth, increasing with age (Figure 5.4).

TABLE 5.2 Eruption times of deciduous and permanent teeth in the dog and cat

	Dogs				Cats

Permanent (months)	3–5	4–6	4–6	5–7	3–4	4–5	4–6	4–5

ORAL EXAMINATION

Conscious visual examination may be limited or fairly detailed, depending on the patient's temperament and the skill of the examiner. It may be possible to diagnose persistent deciduous teeth, fractured teeth, caries, tooth resorptions, masses, and malocclusions/orthodontic problems and develop a preliminary sense of the level of periodontal disease. (Note: The conscious evaluation is not a replacement for an anesthetized examination.) There are many factors that make a complete examination impossible in an awake animal, not least of which are pain and aggression. An anesthetized examination should include a complete visual assessment of the entire oral cavity, including all soft and hard tissues, periodontal probing and exploring of all aspects of individual teeth and gingival sulci, and intraoral radiography of any abnormalities (Figures 5.5–5.7). Further, many veterinary dentists recommend full mouth radiographs be obtained for all dental patients. A specific radiographic area of interest is shown in Figure 5.8.

FIGURE 5.5 Impacted right maxillary first molar (109) in a 7-month-old Golden Retriever presented for routine orchiectomy.

FIGURE 5.6 Complicated crown fracture with exposed pulp of the left mandibular second molar (310). This injury was noted by the technician monitoring anesthesia during a routine, elective ovariectomy in a 7-month-old mixed breed dog.

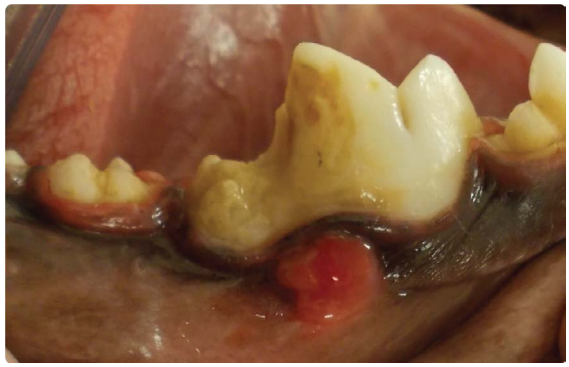

FIGURE 5.7 Evidence of developmental enamel abnormality and tooth root abscess were noted in the area of the tooth adjacent to the fractured molar.

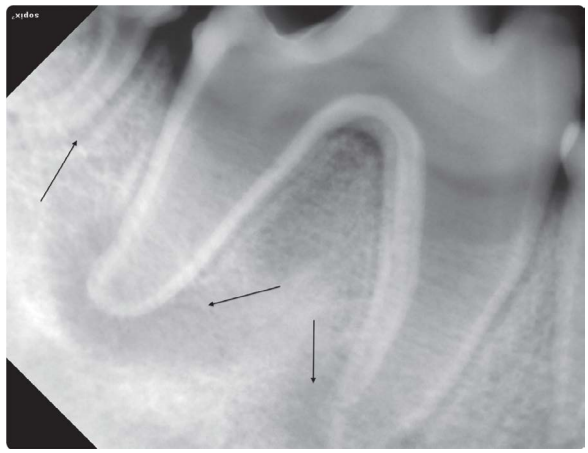

FIGURE 5.8 Dental radiographs were exposed, and the first molar was found to be nonvital. The teeth were deemed unsalvageable and surgically extracted during the same anesthetic episode. Note the periodontal lucency around tooth roots in the radiograph (black arrows). This is the same dog as in Figure 5.6.

PERIODONTAL DISEASE

Definition/Overview

Periodontal disease is the most common medical condition affecting small animal patients. It has long been established that 70% of cats and 80% of dogs exhibit some level of periodontal disease by 3 years of age. However, current research suggests that 90% or more of dogs have some degree of periodontal disease by just 1 year of age (Figure 5.9).

Periodontal disease encompasses gingivitis and periodontitis, which each represent a stage in the progression of the disease complex. Gingivitis is the earlier, reversible stage of inflammation confined to the gingival tissues. Once the inflammation reaches the deeper tissues of the periodontium (periodontal ligament and alveolar bone), it becomes periodontitis. Periodontal inflammation may result in osteoclastic resorption of the alveolar bone (Figures 5.9–5.11). This bone loss is considered irreversible without advanced periodontal surgeries and guided tissue regeneration. Therefore,

FIGURE 5.9 Canine periodontal disease. Note the red, swollen gingiva. The significant calculus build up does not equate to severity of periodontal disease.

FIGURE 5.10 Canine periodontitis. The probe is inserted to a depth of 11 mm. This is a deep periodontal pocket requiring radiographs to rule out periodontal–endodontic disease and open curettage or extraction.

FIGURE 5.11 Feline periodontal disease. The probe reaches to a depth of 4–5 mm, necessitating radiographs, closed root planing, and perioceutic administration at a minimum.

prevention is critical. There are numerous significant local/regional consequences of advanced periodontal disease, including ocular disease or damage, pathologic mandibular fractures, osteomyelitis, oral cancers, and periodontal–endodontic infections/abscesses.

In addition, recent research has linked periodontal disease to many deleterious systemic effects such as hepatic inflammation and disease, glomerulonephritis and renal insufficiency, valvular endocarditis and heart disease, cerebral infarction (strokes), diabetes mellitus, and early mortality.

Etiology

Plaque is the cause of periodontal disease. Plaque is a biofilm of oral bacteria. A biofilm is a unique compilation of organisms (bacteria), minerals, and proteins that develops into a complex structure, significantly more resistant to antibiotics and antiseptics than any of the individual bacteria themselves.

Pathophysiology

The development of periodontal disease begins with the adherence of plaque to oral structures, particularly teeth. The first step in the adherence of plaque to teeth is pellicle formation, followed by an initial adhesion and attachment and, finally, colonization and plaque maturation. There are a variety of conditions that result in roughened tooth surfaces and may increase plaque retention, including enamel hypoplasia, enamel defects, crown fractures, crowding, tooth resorptions, and malocclusions.

The rate and degree of progression of periodontal disease are determined by a combination of bacterial infection and host (patient) response. Systemic diseases (such as diabetes mellitus, endogenous or exogenous hypercortisolemia) that increase host susceptibility to infection and/or decrease wound healing also contribute to periodontal disease. It is more common in small and toy breed dogs, probably because of tooth crowding, extended life spans, and other genetic factors.

Clinical Presentation

The vast majority of patients with periodontal disease show no outward signs of disease. Patients with advanced disease may present with halitosis, ptyalism, pain, pawing at the mouth, tooth exfoliation, or even pathologic jaw fractures. Periodontal disease may be noted on routine conscious oral examination but is best diagnosed during anesthetized oral examination with probing and intraoral dental radiographs.

Differential Diagnosis

Neoplasia, immune-mediated disease, resorptive lesions, foreign bodies, candidiasis (thrush).

Diagnosis

Gingival inflammation (redness and swelling) is the first outward sign of periodontal disease. However, bleeding on probing or brushing is actually the first sign of periodontal disease; therefore, diagnosis is often delayed. These signs – redness, swelling, and bleeding – are enough to warrant a diagnosis of gingivitis. It is critical to note that while dental calculus (tartar) is typically associated with periodontal disease, it is not the source of the disease. Therefore, it should not be relied on to determine a

need for professional therapy. Orastrip (PDx Biotech) can be used quickly and easily in the conscious patient to test for the presence of thiol compounds, which are metabolic products of the subgingival bacteria which are the cause of periodontal disease. This will provide a diagnosis earlier in the disease process as well as an objective measure as to the level of periodontal disease. This knowledge may improve client compliance and allow earlier intervention.

Gingivitis may be diagnosed in the conscious patient by the gross appearance of red or swollen gums or in the owner's reporting of bleeding on brushing. Periodontitis generally requires anesthetized examination with probing and dental radiographs for diagnosis, unless there is marked gingival recession.

Periodontal probing of the circumference of each tooth during the anesthetized examination may reveal pocket depths greater than the normal gingival sulcular depth (generally 0–3 mm in dogs, 0–0.5 mm in cats). A normal probing depth does not necessarily indicate a disease-free state, as teeth affected by gingivitis can have normal sulcular depth or gingival recession. A simple color-coded probe (Niemiec periodontal probe, Dentalaire Products) has been developed to allow easy diagnosis of pathologic periodontal pockets. Periodontal disease may also be identified on dental radiography.

Management

Thorough anesthetized professional periodontal therapy and consistent home care are vital to the management of periodontal disease. Gingivitis can be reversed with such treatment. Pathologic pockets less than 6 mm are best treated with closed root planing and perioceutic treatment (Doxirobe, Zoetis; Clindoral, Trilogic Pharma). Deeper pockets or teeth with class II or III furcation defects must be treated with periodontal flap surgery and open curettage (+/– guided tissue regeneration) or extracted. Following these additional therapies, regular professional periodontal therapy and diligent home care are required. Teeth often become unsalvageable and require extraction. Examples include significantly mobile teeth or periodontal–endodontic lesions. Small teeth may also be sacrificially extracted to better access and treat more strategic teeth.

Prognosis

Outcomes depend much on severity of disease, quality of treatment, and client commitment to homecare and regular professional cleanings. Prognosis, therefore, ranges from good to guarded to poor.

MALOCCLUSION

Definition/Overview

A malocclusion is a deviation of one or more teeth and/or jaws from normal alignment. Malocclusions may be cosmetic only or result in slight to significant oral trauma. Malocclusions are categorized by class (Table 5.3 and Figures 5.12–5.14).

TABLE 5.3 Malocclusion classifications

- **Class 0:** Normal (orthoclusion). The mandibular canines are equidistant between the maxillary 3rd incisor and canine. The mandibular incisors sit just caudal to the maxillary incisors, and the premolars of the maxillary and mandibular arches interdigitate in a manner reminiscent of pinking shears, hence the term scissors bite.
- **Class I:** Normal jaw lengths (scissors bite) where one or more teeth are out of proper alignment (occlusion). These have been considered nonhereditary. However, the high incidence of certain syndromes in specific breeds does indicate a genetic predisposition. Class I malocclusions include linguoversed mandibular canines (base narrow) and mesioversed maxillary canines (lance effect). The former typically results in significant palatal trauma.
- **Class II:** Mandibular brachygnathism; the mandible is shorter than the maxilla. Also called overshot. This almost invariably causes significant palatal or tooth trauma.
- **Class III:** This is a jaw length discrepancy in which the mandible is longer than the maxilla and is also referred to as undershot. This class of malocclusion does not typically create significant trauma, but maxillary incisors may impinge on opposing soft and hard tissues and should be carefully examined.
- **Class IV** ("Wry bite"): This is a jaw length discrepancy in which one mandible or maxilla is shorter than the other. This results in a shift of the mandibular midline. A true class IV malocclusion occurs when one mandible is longer than the maxilla, and the other mandible is shorter than the maxilla.

FIGURE 5.12 Normoclusion. Scissors bite.

FIGURE 5.13 Class II malocclusion. Also termed overbite or overshot, the mandible is shorter than the maxilla. This malocclusion often requires interceptive orthodontia to relieve trauma and allow the mandible to develop to its full potential.

FIGURE 5.14 Class III malocclusion in an adult dog. Also termed under bite or undershot, the mandible is longer than the maxilla, and the mandibular incisors are rostral to the maxillary incisors.

Etiology

Most malocclusions are considered hereditary in nature, in particular the jaw length malocclusions (class II, III, IV). They may result from inbreeding to produce desirable head size or shape or from mating of parents with dissimilar jaw lengths. Mesioccluded or "lance" canines are also considered genetic (seen commonly in Shetland Sheepdogs and Persian cats). Nongenetic causes of malocclusions include trauma or systemic influences such as severe illnesses, nutritional disturbances, or endocrine diseases. In general, these nongenetic causes have historical or other clinical support.

Clinical Presentation

Patients often show no overt clinical signs but may present for oral pain, bleeding, ptyalism, aggression, "mouth shyness," halitosis, periodontal disease, or even an oronasal fistula.

Differential Diagnosis

Trauma, temporomandibular joint dislocation, mandibular fracture, normal bite for the breed.

Diagnosis

Diagnosis can usually be made with visual examination. Some malocclusions may require sedation for accurate and complete evaluation and diagnosis. Dental radiographs should be made to evaluate the involved teeth for periodontal or endodontic disease.

Management

Treatment depends on type and severity. If the malocclusion is purely cosmetic, intervention is neither warranted nor recommended, as orthodontic correction can be a long and uncomfortable process. If a malocclusion is diagnosed in the deciduous dentition, interceptive orthodontics can be attempted. This involves extraction of the deciduous dentition that is causing the trauma and/or resulting in an adverse dental interlock (not allowing the jaws to grow to their full genetic potential).

Malocclusions resulting in oral trauma or prevention of normal mandibular growth should be treated early and aggressively. This may be achieved by extraction of the offending tooth or teeth, coronal reduction and vital pulp therapy, or orthodontic appliances. All clients should receive genetic counselling. Orthodontic treatment should never be performed in patients destined for breeding or showing.

Prognosis

Successful treatment is dependent on early diagnosis and appropriate intervention. Clients should receive counselling on the genetic basis of most malocclusions. Neutering is generally recommended.

PERSISTENT PRIMARY (DECIDUOUS) TEETH

Definition/Overview

A deciduous tooth is considered persistent if it remains present in the oral cavity after the corresponding permanent tooth has erupted to any degree.

Etiology

The most common cause of this condition is an aberrant eruption path of the permanent tooth. Lack of a permanent tooth as well as nutritional or hormonal imbalances may also result in persistent deciduous teeth.

Pathophysiology

As the permanent tooth erupts along its natural path, the pressure it places on the apex of the root of the deciduous tooth results in resorption of the deciduous tooth root. As the permanent tooth continues its coronal advancement, the root continues to resorb and eventually exfoliates, and the permanent tooth assumes its place. When the permanent tooth fails to follow its natural path, the deciduous tooth root does not receive the proper pressure to result in adequate resorption for exfoliation.

Clinical Presentation

While they typically occur in toy and small breed dogs, persistent deciduous teeth may occur in any breed, as well as in cats. The condition is often bilateral and most commonly affects the canine teeth, followed by the incisors and premolars (Figure 5.15).

Differential Diagnosis

Supernumerary teeth, lack of associated permanent tooth, crown malformation.

FIGURE 5.15 A persistent deciduous maxillary incisor tooth (603) in an adult dog. Note the associated periodontal disease demonstrated by the placement of the probe.

Diagnosis

Conscious oral examination is usually sufficient for diagnosis of persistent canines and incisors; however, since the deciduous maxillary 4th premolars are palatal to the permanent ones, anesthesia may be required. Sedated or anesthetized examination and intraoral radiographs may be necessary to accurately distinguish between supernumerary teeth, crown malformation, and lack of permanent dentition (Figure 5.16).

Management

Early detection and extraction of offending teeth is critical. Two teeth of the same type should never occupy the same place at the same time, as periodontal and orthodontic damage can occur very quickly. The authors recommend enlisting clients in monitoring for the appearance of this condition, instructing them in home care from the time of the first puppy (or kitten) visit, and evaluating the oral cavity thoroughly at each vaccine booster appointment. The deciduous tooth should be extracted as soon as the permanent begins to erupt, unless the deciduous tooth is significantly mobile. Intraoral radiographs should be exposed prior to and following extraction, as these teeth can be quite difficult to remove because of their long roots and thin, fragile walls. In addition, partial and complete root resorption may further complicate extraction (Figure 5.16). Patience and great care must be taken to avoid damaging the unerupted permanent tooth. Root remnants should not be left behind if at all possible, as they may become infected and/or act as a foreign body and result in significant inflammation and discomfort (Figure 5.17).

FIGURE 5.16 Persistent deciduous maxillary canine tooth (604). Note the thin, fragile walls.

FIGURE 5.17 Dental radiograph of a persistent deciduous tooth root remnant with periapical lucency in an 8-year-old dog.

Prognosis

Prognosis is good if detected and treated very early and carefully. Permanent teeth damaged during extraction of deciduous teeth or retained roots may exhibit evidence of enamel defects. Orthodontic consequences may occur within 2 weeks of the first sign of eruption of secondary dentition, and irreversible periodontal disease may begin even earlier.

MISSING TEETH

Definition/Overview

Hypodontia is the congenital absence of one to five permanent teeth. Oligodontia is the congenital absence of six or more permanent teeth. Anodontia is the congenital lack of all permanent teeth.

Etiology

May be congenital or developmental.

Pathophysiology

Permanent teeth are formed from buds of the deciduous teeth with the exception of the molars and first

premolars, which have no corresponding deciduous. A truly missing deciduous tooth will result in lack of a permanent tooth. Hypodontia of deciduous dentition is extremely rare. More often, a deciduous tooth is prematurely lost to trauma.

Genetic conditions resulting in defects of tooth development are the most common cause of missing teeth. Developmental disturbances can also have a profound effect on tooth development. In addition, trauma, medications, and gestational problems can also result in significant tooth anomalies and defects.

Clinical Presentation

Most often an incidental finding, most patients are not clinically presented solely for missing teeth. However, they show signs of pain or discomfort, swelling, or mandibular fracture.

Differential Diagnosis

Previous tooth extraction, avulsion, or fracture; retained tooth root, impacted/embedded/unerupted tooth.

Diagnosis

Unless the practitioner has previous information from prior examination or surgery (including postoperative radiographs) that the tooth was extracted or otherwise not present, diagnosis must be confirmed with intraoral dental radiography. Missing teeth are generally diagnosed on conscious examination; however, sedation or anesthesia is often required to diagnose missing molars (Figures 5.18 and 5.19).

Management

All "missing" teeth should be radiographed to rule out impacted teeth or retained roots. These should be extracted once diagnosed unless the patient is geriatric, the tooth has undergone significant replacement resorption, and/or the extraction would be challenging, in which case referral to a veterinary dentist is recommended. A wait-and-see approach in a young patient is generally considered inappropriate. Congenitally missing teeth do not require intervention beyond intraoral radiography for diagnosis. Genetic counselling may be warranted.

FIGURE 5.18 Missing mandibular premolars in a 6-year-old male neutered Catahoula Leopard Dog.

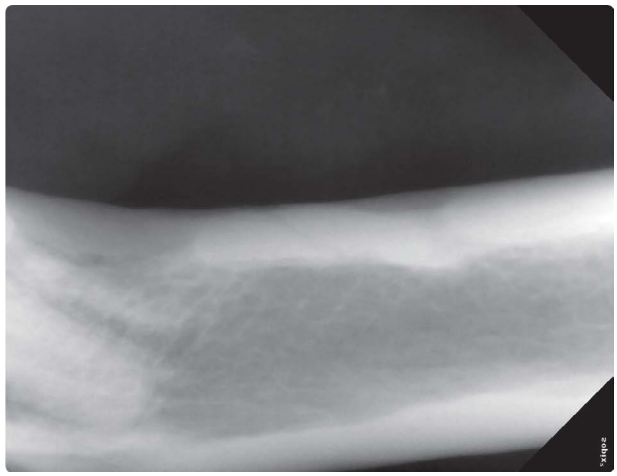

FIGURE 5.19 Congenital oligodontia was confirmed with intraoral radiography.

Prognosis

Prognosis is good if appropriate surgical intervention is taken when necessary. Impacted teeth that are not removed may develop dentigerous cysts, which can have significant consequences, such as tooth displacement, which may lead to malocclusion, tooth and/or bone resorption, or a pathologic fracture (see Case Examples: Cases 5.1 and 5.2 at the end of this chapter). Rarely, dentigerous cyst lining has been reported to undergo malignant transformation. Retained tooth roots can become infected and cause significant pain as well as local and systemic infection.

FRACTURED TEETH

Definition/Overview

Fractured teeth are classified by location of the fracture (crown, root, or both) and whether or not the pulp is exposed. Tooth fractures that result in pulp exposure are referred to as complicated. Those that do not result in pulp exposure are termed uncomplicated.

Etiology

Tooth fractures occur as a result of excessive force applied to a tooth or stresses that act on a tooth in a nonphysiological direction. They commonly occur secondarily to biting or chewing on rocks, bones, hard chew toys, and even hard rawhides. They may also be the result of impact trauma (e.g., automobile accidents, running into walls, horse kicks, falls) (Figures 5.20 and 5.21).

Pathophysiology

Enamel is the extremely hard, smooth, impervious substance covering the crowns of normal teeth. Underlying the enamel is dentin, a softer, rougher substance made

FIGURE 5.20 and **FIGURE 5.21** Complicated crown fractures of the right maxillary 4th premolar (108) and mandibular canine (404). Note the darkened, necrotic pulp and the explorer within the pulp cavity of 108 (**Figure 5.20**) and the fresh, hemorrhagic pulp of 404 (**Figure 5.21**).

up of millions of microscopic dentinal tubules that lead directly to the dental pulp.

When a crown fractures and the pulp is directly exposed, it is exceedingly painful. In addition, an open path to the blood vessels and nerves of the tooth is created, leading quickly to pulpitis, infection, and pulp necrosis. Following pulp necrosis, bacterial invasion of the periapical area occurs, which may create systemic spread of the infection.

Uncomplicated crown fractures result in direct dentinal exposure, which is considered indirect pulp exposure, as the dentinal tubules contain extensions of the root canal system called odontoblasts. These fractures also create significant pain for the patient. Furthermore, there is an opportunity for eventual infection of the pulp through the dentinal tubules. In fact, a recent study found that 24.3% of uncomplicated crown fractures in maxillary 4th premolars in dogs were endodontically infected, necessitating root canal therapy or extraction. How long that process takes is unknown and is likely affected by the amount of damage inflicted on the pulp and other tissues during the initial insult. Typically, the tooth will eventually respond to this exposure and seal off the tubules via tertiary dentin, but this process takes months and may not be effective. Finally, all fractures result in a roughened tooth surface increasing plaque adhesion and hastening the onset of periodontal disease.

Clinical Presentation

If the inciting cause is significant traumatic impact (i.e., hit by car/fall), patients may be presented with other injuries (e.g., facial or jaw fractures, head trauma, pulmonary contusions, or abdominal bleeding). These patients must be stabilized and treated appropriately prior to complete oral examination, assessment, and treatment. Owners may notice swelling or drainage in the area of the affected tooth, most commonly in the maxilla just ventral to the eye, but it may also occur in the ventral mandible.

The majority of the time tooth fractures are incidental findings, as pets very rarely show outward signs of oral pain. However, it is known that these conditions are very painful. Animals may present with some degree of pain, halitosis, reluctance to chew, or changes in eating behaviors (bear in mind that cats and dogs generally do not stop eating because of dental disease, except in very limited cases such as caudal stomatitis).

Differential Diagnosis

Abrasive wear, attrition (tooth on tooth wear), developmental malformation, oral tumor.

Diagnosis

Fractured teeth can typically be diagnosed on conscious examination or incidentally during a professional dental cleaning. Freshly fractured teeth are identified by an abnormally shaped area of the tooth and a roughened surface (dentin) compared with the surrounding tooth (enamel), if uncomplicated, and by a central area of pink or red (pulp) if complicated (**Figure 5.21**).

Older fractures may be more difficult to identify if they have been covered with calculus. Pulp necrosis may be evident as a dark brown, gray, or black central area of the tooth in an older, complicated crown fracture (**Figure 5.20**). Root fractures may not be apparent until sedated examination and radiographs are possible.

Management

All fractured teeth should be radiographed to evaluate for evidence of endodontic disease. Fractured deciduous teeth should be extracted urgently to prevent damage to the underlying permanent tooth bud. Uncomplicated crown fractures should be managed with bonded sealants if there is no radiographic evidence of endodontic disease and the pulp chamber cannot be accessed with a fine dental explorer. This will relieve the pain, block off the pathway of infection, and smooth the tooth. Crown/root fractures that are uncomplicated may be treated with a bonded sealant if the gingiva is

FIGURE 5.22 This is a slab-type fracture of the left maxillary 4th premolar (208). This particular tooth has a complicated crown-root fracture, but slab fractures are very common in dogs and may be complicated or uncomplicated.

first repositioned apically so that the sealant does not extend below the gingival margin (Figure 5.22). Some root fractures may be managed with benign neglect if no portion of the fracture extends into the oral cavity, the tooth is stable, and there is no evidence of endodontic disease. Complicated crown fractures and uncomplicated crown fractures with evidence of endodontic disease on intraoral radiographs must be treated either with root canal therapy or by complete extraction. Root fractures and teeth treated with bonded sealants or root canal therapy must be rechecked radiographically at 9–12 months and annually thereafter. Toys and chews should be evaluated for hardness, in order to avoid risk of tooth fracture. Proper items should be easily indented with a fingernail. Owners must be warned about the causes of tooth fractures and changes implemented at home if fractures are secondary to chew toys, treats, or housing. The inciting cause should be removed and replaced with softer, less dangerous options if at all possible. Veterinary Oral Health Counsel (VOHC) approved products may be recommended when evaluating proper chews and toys. Owners should also be counseled that bonded sealants are only effective for as long as they remain on the tooth; in other words, until the tooth breaks again. Referral to a veterinary dentist for crown placement should be considered, especially for working dogs and those extreme chewers that are at high risk for recurrent tooth fractures.

Prognosis

Early, appropriate treatment after complete examination, probing, and intraoral radiography provides the best outcome. Referral to a veterinary dental specialist for endodontic treatment, crown therapy, or to manage complicated or multiple tooth fractures when necessary is recommended. Fractured teeth are painful to the patient, although they will not complain. Recovery from surgical extraction is approximately 2 weeks; recovery from endodontic treatment is nearly immediate. In either case, prognosis is very good if the pet receives timely, appropriate treatment.

TEMPOROMANDIBULAR JOINT LUXATION

Definition/Overview

Temporomandibular joint (TMJ) luxation is usually a rostrodorsal displacement of the condylar process of the mandible from the articular surface of the mandibular fossa of the temporal bone. The TMJ may sometimes separate caudally, and this displacement is usually accompanied by a fracture of the retroarticular process.

Etiology/Pathophysiology

TMJ luxation is uncommon in cats and rare in dogs. It is usually traumatic in nature. It is, therefore, also often accompanied by other oromaxillofacial injuries. It may also be a result of TMJ dysplasia or disease.

Clinical Presentation

Patients often present with an open or dropped jaw appearance, an inability to close (or sometimes to open) the mouth, and lateral deviation of the lower jaw towards the side opposite the luxation. Joint pain, dysphagia, or ankylosis may accompany chronic TMJ luxation, as well as TMJ fractures or ramus fractures.

Differential Diagnosis

Mandibular fracture, maxillary fracture, TMJ dysplasia/fracture, periodontal disease, foreign body, idiopathic trigeminal neuritis, craniomandibular osteopathy.

Diagnosis

The classical dropped jaw appearance and inability to close the mouth is suggestive, although this may also be seen with idiopathic trigeminal neuritis or bilateral caudal mandibular fracture. Properly positioned dorsoventral radiographs may show an increased TMJ space. CT is the preferred imaging modality to diagnose TMJ issues. Radiographs should be exposed to evaluate for concurrent maxillary or mandibular fractures.

Management

Under general anesthesia, a fulcrum of an appropriate size for the patient (e.g., pencil, dowel, toothbrush, or syringe) is placed between the maxillary 4th premolar and mandibular 1st molar teeth on the affected side, and the mouth is gently forced closed to lever the condylar process back into the mandibular fossa. A return to normal dental occlusion is indicative of successful reduction. The joint should then be stabilized with a loose-fitting nylon or tape muzzle or with interarcade wiring for 1–2 weeks, especially if it easily reluxates. Unstable, refractory, or chronic luxations can be treated with open reduction and suture imbrication of the joint or, more commonly, with a condylectomy procedure.

Prognosis

Acute, uncomplicated luxations that are properly reduced and managed have a good prognosis. Those associated with chronicity, recurrence, underlying disease, dysplasia, or ramus fractures carry a less favorable prognosis and frequently result in condylectomy.

MAXILLOFACIAL/JAW FRACTURES

Definition/Overview

Oromaxillofacial fractures are usually the result of traumatic injury but may also occur secondary to a pathologic process. In the case of trauma, patients may have significant injury to other body systems or other serious complications and should be stabilized prior to treatment for oromaxillofacial injury. Pathologic fractures can be difficult to treat because of issues related to delayed healing or underlying neoplastic or infectious conditions.

Etiology/Pathophysiology

There is a wide variety of types and causes of maxillofacial and mandibular fractures. In the cat, symphyseal separation is the most common oral fracture, and mandibular ramus fractures are more common than those of the mandibular body. Fractures to the body of the mandible are most commonly seen in dogs and may be termed stable (Figure 5.23a) or unstable (Figure 5.23b) depending on the angle of the fracture line, with stable fractures running in a caudodorsal direction. The large muscles of the jaw insert at the caudal aspect of the mandible and compress the fragments of favorable fractures. In the dog, mandibular ramus fractures are less common than either symphyseal separation or mandibular body fractures, and repair can be very difficult because of the large amount of overlying musculature. TMJ fractures are uncommon. Maxillary fractures are often minimally displaced because of the inherent stability of the maxilla. Midline palatal features are commonly a result of high-rise syndrome in cats. Like mandibular symphyseal separation, these are not true fractures but a separation of the interincisive suture or the median palatine sutures. Pathologic fractures are not uncommonly seen and are usually the result of chronic, severe, untreated periodontal disease or, rarely, a neoplastic process.

Clinical Presentation

Patients may present with an obvious malocclusion or fracture, particularly of the mandible, or with symphyseal separation. Swelling, pain, soft tissue trauma, and ptyalism are common. Inability to open or close the mouth may be noted. Maxillary fractures in particular may present more subtly, with minimal displacement. In some patients, the maxillofacial or mandibular fracture is not noticed for a day or several days after the initial traumatic incident when the owner notes that the animal is reluctant or unable to eat, drops food from the mouth, or is malodorous. Patients with pathologic jaw fractures tend to be non-painful and often lack an obvious history of trauma. This is because the weakened bone took minimal force to fracture. Further, these fractures are typically seen in the areas of the mandibular 1st molars or canines of small and toy breed dogs. This is because their teeth are proportionally larger than those of large breed dogs and comprise a significant amount of the mandible.

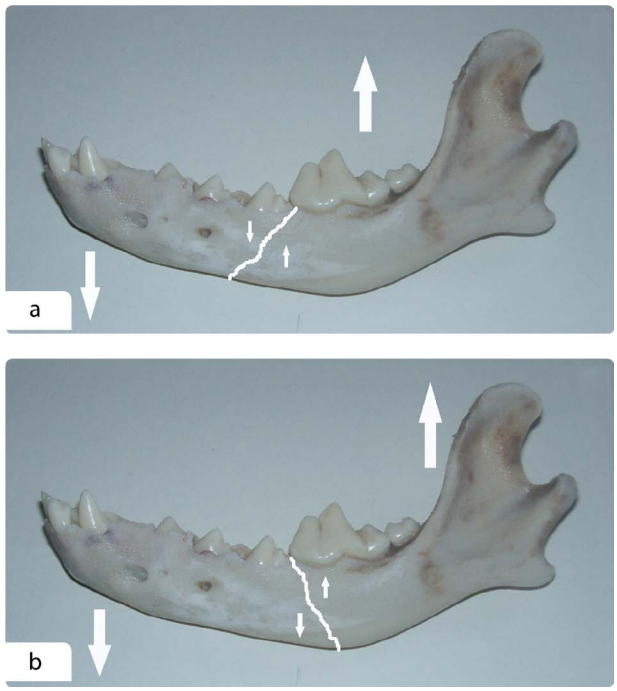

FIGURE 5.23 A left mandible demonstrating a stable (a) and an unstable (b) fracture line. The large white arrows indicate the directional pull of the masticatory muscles. Small white arrows illustrate the subsequent forces placed on the fracture line. In (a), the muscular forces keep the fracture in place. In (b), the unstable direction of the fracture leads to distraction of the fracture line.

Differential Diagnosis

Trauma, severe periodontal disease, neoplasia, TMJ luxation, osteomyelitis, hypoparathyroidism (rare).

Diagnosis

Careful examination under sedation or general anesthesia (if the patient is stable) combined with skull or, ideally, intraoral dental radiography may be utilized to determine the exact nature and extent of the injury. Depending on presentation, thoracic and abdominal radiographs, abdominal ultrasound, or CT may be indicated as well as complete blood count (CBC)/chemistry panel/urinalysis, T4, and parathyroid hormone level. Histopathology and bacterial culture and sensitivity may also be warranted in unusual cases.

Pathologic jaw fractures require intraoral dental radiographs to properly diagnose and treat. The subtle loss of bone is often not seen on skull radiographs. The classic appearance of a pathologic fracture is one located at the mandibular first molar or canine in a small breed dog with associated periodontal disease.

Management

Symphyseal separation can generally be treated with simple circumferential wire stabilization. Generally, mandibular body fractures are best repaired with intraoral splinting and either interdental or interosseous wiring techniques to recreate proper occlusion of the teeth. However, unstable or comminuted fractures may require more rigid fixation. Plates and external fixation techniques are occasionally indicated, but great care must be taken to avoid damaging tooth roots and neurovascular structures. Fractures of the mandibular ramus, condylar, coronoid, and angular processes are usually managed conservatively due to the great difficulty in performing internal repair. Many of these fractures are managed by interarch bonding or with loose nylon muzzles for 2–3 weeks (if a unilateral fracture dorsal to the condylar process) or 4–5 weeks (if below the condylar process). Maxillary fractures are often minimally displaced and more stable than mandibular fractures and require no more than digital reduction and soft tissue repair. However, more significant fractures require reduction and stabilization, typically an acrylic splint.

Pathologic jaw fractures carry a guarded prognosis for healing due to the lack of remaining bone, the low oxygen tension in the area, and the difficulty in rigidly fixating the caudal mandible. It is important to realize that a pathologic fracture will not heal (no matter how good the fixation is) if the diseased tooth root is not removed from the area of the fracture line. This is because a diseased root acts as a nidus of infection, which prevents healing. Extraction of the diseased root associated with the area of fracture is necessary but, unfortunately, creates a large defect in the bone, which makes alignment more challenging and increases healing time.

Prognosis

Oromaxillofacial fractures often occur concurrently with other serious injuries, and patients must be well stabilized prior to treatment of maxillary or mandibular fractures. Malocclusion is a serious potential complication of oromaxillofacial fracture and repair. Invasive fixation methods are only rarely necessary and often result in further damage to surrounding oral structures such as teeth and neurovascular tissues. There is a concern with mandibular ramus fractures for callus formation, which results in restriction of normal jaw movement. In addition, there is often damage to teeth during the initial insult that may not be immediately apparent. Recheck examination and radiographs are always indicated for jaw fractures.

Pathologic fractures caused by severe periodontal disease or neoplastic processes carry a guarded prognosis. These can be extremely difficult if not impossible to repair and, especially in the case of neoplasia, often result in mandibulectomy or maxillectomy. The underlying cause of any pathologic fracture must be investigated and addressed prior to attempting fixation. Stabilization or fixation of fractures caused by neoplastic processes should not be attempted; mandibulectomy, maxillectomy, radiation, and/or chemotherapy may be appropriate in such situations. Consultation with a veterinary dentist, surgeon, and/or oncologist is recommended.

ORAL MASSES AND NEOPLASIA

Definition/Overview

Oral masses are quite common in dogs and cats. In fact, the oral cavity is the fourth most common location for a tumor/neoplasm in the body in both canine and feline patients. Oral masses may be either benign or malignant. Like masses elsewhere, gross examination is generally insufficient for accurate diagnosis. All oral masses, no matter how small, should be biopsied and evaluated histopathologically. While most oral masses in dogs are benign, aggressive neoplasms are fairly common in the oral cavity.

Etiology

Oral tumors may be odontogenic or nonodontogenic, but a true etiology is unknown in most cases. An exception is canine squamous cell carcinoma (SCC), which is sometimes associated with papillomavirus.

Clinical Presentation

Presentation is variable depending on the type of tumor. Many masses are found incidentally during routine oral examination. Others may be erosive or ulcerated and secondarily infected or inflamed, causing discomfort, dysphagia, halitosis, or ptyalism.

Differential Diagnosis

Gingival hyperplasia (enlargement), granuloma, dentigerous cyst, abscess, eosinophilic granuloma.

Diagnosis

Intraoral dental radiographs and histopathology are required for accurate diagnosis of any oral mass. Palpable lymph nodes should be aspirated or excised in cases of malignant neoplasia. If cytopathology or histopathology is consistent with malignancy, standard clinical staging should be performed, including 3-view thoracic radiography, CBC, chemistry panel, urinalysis, +/– abdominal ultrasound.

Management

In general, surgical excision is the treatment of choice, with required margins and follow-up chemotherapy or radiation treatment dependent on histopathologic diagnosis.

Prognosis

Prognosis for benign tumors is excellent with adequate surgical resection. Malignant oral tumors may have a good prognosis if diagnosed and definitively treated very early. Advanced malignancies carry a poor to grave prognosis even with radical surgical excision and chemo or radiation therapy. (Note: Individual tumor types are discussed later.)

PERIPHERAL ODONTOGENIC FIBROMA/ FOCAL FIBROUS HYPERPLASIA (PREVIOUSLY TERMED EPULIS)

Epulis is not a diagnosis but a clinical description that includes neoplasia, fibromas, and odontogenic tumors. It refers to *any* swelling of the gingiva. Peripheral odontogenic fibroma is a benign neoplasm, previously classified as fibromatous or ossifying epulis. These are slow growing and usually found around maxillary premolars. They exhibit no evidence of bony involvement on radiographs but may show mineralized areas. The majority of gingival growths are histopathologically focal fibrous hyperplasia, frequently seen in Boxers. Marginal surgical excision of the tumor is generally curative.

CANINE ACANTHOMATOUS AMELOBLASTOMA

Previously known as acanthomatous epulis, these masses are now termed canine acanthomatous ameloblastoma (Figure 5.24). They most often occur around the mandibular incisors in large breed dogs (though may occur anywhere in either jaw) and are fleshy and proliferative masses. These tumors are locally aggressive but do not metastasize. Radiographs typically reveal local bone infiltration and tooth displacement. Local recurrence with marginal excision is common, so a minimum 0.5–1 cm of normal tissue surgical excision is recommended. Another treatment option is radiation therapy, which has a 90% control rate.

PAPILLOMATOSIS

These are generally pedunculated or cauliflower-like in appearance and white, gray, or flesh colored. Further, their appearance is benign mucosal thickening with finger-like projections. They may be solitary or multiple. They are of viral origin (papillomavirus) with a 2- to 6-month incubation and are spread usually through direct but sometimes indirect contact. Generally self-limiting, they resolve in weeks to months, and the patient is generally immune in the future. They are only cause for concern if they are large enough to interfere with mastication, are infected, or inflamed. They can mimic more aggressive tumors, and there are reports of transformation to SCC. No treatment is usually recommended; however, atypical appearance, failure to regress in the expected time period, and infection all are indications for excisional biopsy and histopathology. Removal may also be indicated if they are large enough to interfere with mastication. Excision may be accomplished with standard sharp excision, cryosurgery, electrocautery, or laser surgery. Vaccination, traumatic crushing, and chemotherapy have also been utilized but are generally no longer recommended.

FIGURE 5.24 Canine acanthomatous ameloblastoma associated with the maxillary left 3rd incisor (203) and affecting the 2nd incisor (202) and canine tooth (204).

ORAL MALIGNANT MELANOMA

Oral malignant melanoma (OMM) (Figure 5.25) is the most common malignant oral cavity tumor in dogs. They may be pigmented or amelanotic and are highly aggressive, with early metastasis to lymph nodes (less frequently to lungs and other organs). Palpable lymph nodes should be aspirated or excised at the time of diagnosis. Standard clinical staging after confirmatory cytopathologic or histopathologic diagnosis (3-view thoracic radiographs, CBC, chemistry panel, urinalysis, +/– abdominal ultrasound) should be performed prior to wide surgical excision (2–3 cm normal tissue). Follow-up chemotherapy, immunotherapy, or radiation therapy may also be indicated, as distant dissemination of disease is common, as is local recurrence. If complete resection is not possible, radiation therapy should be considered as a primary treatment. Prognosis is generally poor, but a fair to good response may be achieved with early diagnosis and aggressive treatment and follow-up.

FIGURE 5.25 Malignant melanoma affecting the left maxillary 4th premolar and molar teeth of a dog. Note the irregular, pigmented appearance. These are highly aggressive tumors that may or may not be pigmented.

FIBROSARCOMA

This is a malignant mesenchymal tumor, most often seen in young (4- to 5-year-old) large breed dogs and older (~8-year-old) small breed dogs. Fibrosarcomas are locally invasive with a high postsurgical recurrence rate. Prognosis is variable depending on location, size, grade, and stage at time of diagnosis. The maxilla is the most common site. This tumor can present as an innocuous, lobulated, sessile mass or, alternatively, as a rapidly growing, hemorrhagic, ulcerated lesion. They are often noted at dental margins and the palate but may also originate from nasal cartilages and the lateral surface of the maxilla or palate. Well-differentiated masses are best treated with wide surgical excision (2–3 cm margin). Poorly differentiated tumors require radical excision and postoperative radiation treatment.

A subcategory of fibrosarcoma, termed histologically low grade, biologically high grade, is most common in large breed dogs, particularly Golden Retrievers. These tumors are characterized by rapid growth, bony invasion, and high metastatic potential. Treatment for these tumors has not yet been optimized, and local recurrence is very common.

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC; Figure 5.26) is the most common oral neoplasm in cats and the second most common in dogs. These are large, locally aggressive tumors that exhibit lymph node and lung metastasis late in the course of disease. Feline maxillary and lingual SCC carries a poor prognosis, mandibular tumors a somewhat better prognosis, and rostral mandibular locations a fair prognosis. Cure is possible with very early lesions and wide surgical excisions. Papillomavirus DNA has been associated with canine oral SCC. These are erosive, fleshy lesions, and with local bony invasion, dental displacement may occur. There may be chronic,

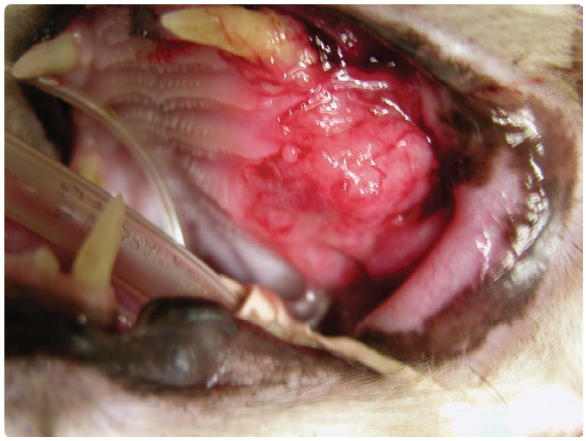

FIGURE 5.26 Squamous cell sarcoma in the left maxilla of a cat.

nonhealing ulcers of the associated skin. Wide surgical excision (2 cm) is recommended, including glossectomy for dogs with lingual tumors. Radiation treatment may be considered for local control or palliation but is fairly ineffective in cats. Chemotherapy is also an option for microscopic disease.

OSTEOSARCOMA

Osteosarcoma (OSA) may occur in either the mandible or maxilla. It is much less common in cats than in dogs. These tumors are locally aggressive but have less metastatic potential than appendicular OSA. Mandibular OSA carries a more favorable prognosis than maxillary, with a reported median survival time of 7 months, whereas the median survival of maxillary OSA is 5 months. It may be identified as a fleshy, expansile mass that may or may not be ulcerative in the early stages. The significant tissue destruction and locally aggressive bony swelling frequently lead to subsequent facial swelling and may be associated with pain and discomfort on opening or closing the mouth. Wide or radical surgical excision is recommended depending on stage, and radiation treatment should be considered for microscopic disease.

TOOTH RESORPTION

Definition/Overview

Previously called neck lesions, cervical line lesions, feline odontoclastic resorptive lesions, and several other names, these lesions are currently referred to as tooth resorption (TR). They represent noncarious odontoclastic destruction of teeth. There are two types of feline TR: Type 1 and type 2. Type 1 resorptions do not result in the replacement of roots by bone (Figure 5.27), while in type 2 resorptions, the lost root structure is replaced by bone (Figure 5.28). An individual tooth may exhibit both type 1 and type 2 resorption and is then classified as type 3. TR typically begins externally and may

FIGURE 5.27 Radiograph of the right mandible of a cat, demonstrating type 1 tooth resorption in all three teeth. Note the varying degrees of lucency, most obvious in the molar tooth (409). Complete extraction of crowns and all roots is the recommended treatment.

FIGURE 5.28 Type 2 tooth resorption in the right mandibular 3rd premolar of a cat. Note the lack of a visible periodontal ligament and how the roots have an appearance similar to that of the surrounding bone.

occur in the crowns, roots, or both (see Table 5.4 for American Veterinary Dental College [AVDC] classification). TR occurs in dogs and humans but is most commonly seen in cats and may represent different disease processes or etiologies in the different species. (Note: Internal resorption can also occur but is rare and more common in dogs than cats.)

TABLE 5.4 American Veterinary Dental College tooth resorption classification

Tooth resorptions are classified by radiographic type as well as stage of resorption:

- **Type 1.** Focal or multifocal radiolucency is present in the tooth with otherwise normal radiopacity and normal periodontal ligament space.
- **Type 2.** Radiographic narrowing or disappearance of the periodontal ligament space in at least some areas and decreased radiopacity of part of the tooth.
- **Type 3.** Radiographic features of both type 1 and type 2 are present in the same tooth. A tooth with this appearance has areas of normal and narrow or lost periodontal ligament space, and there is focal or multifocal radiolucency in the tooth and decreased radiopacity in other areas of the tooth.

- **Stage 1.** Mild dental hard tissue loss (cementum or cementum and enamel).
- **Stage 2.** Moderate dental hard tissue loss (cementum or cementum and enamel with loss of dentin that does not extend to the pulp cavity).
- **Stage 3.** Deep dental hard tissue loss (cementum or cementum and enamel with loss of dentin that extends to the pulp cavity); most of the tooth retains its integrity.
- **Stage 4.** Extensive dental hard tissue loss (cementum or cementum and enamel with loss of dentin that extends to the pulp cavity); most of the tooth has lost its integrity:
  - **Stage 4a.** Crown and root are equally affected.
  - **Stage 4b.** Crown is more severely affected than the root.
  - **Stage 4c.** Root is more severely affected than the crown.
- **Stage 5.** Remnants of dental hard tissue are visible only as irregular radiopacities and gingival covering is complete.

Etiology

Although there are several theories, the cause of tooth resorption remains unknown. Different theories have suggested either excess levels of dietary vitamin D or that feline teeth were not developed to masticate hard, dry kibble diets, leading to abfraction injuries. Type 1 TRs in cats are more commonly associated with oral inflammation (gingivitis, periodontitis, or stomatitis) than are type 2, but no clear cause and effect has been shown. Type 2 TRs are not as commonly associated with significant oral inflammation, but the lesion itself may create mild gingivitis. Neither form of TR has been shown to be related to the retroviral status of cats. In humans, abfraction (lateral forces that result in microflexure of the crown of the tooth) is a proposed cause of TR, and although not proven, this could also be a cause of TR in cats and other species.

Pathophysiology

As stated previously, type 1 TRs are typically associated with oral inflammation, especially in younger cats. There is an increasing likelihood for developing TRs (especially type 2) with age. Odontoclastic destruction of cementum usually begins in the apical third of the root

and generally extends into dentin. The dentinal destruction may eventually extend under the enamel and undermine it, at which point the enamel flakes off exposing the underlying dentin. This creates a significantly painful area of exposed tooth structure. Clinically, they are generally first noticed in the area of the cementoenamel junction. The tooth structure is damaged and eventually weakened to a point at which the crown of the tooth fractures, leaving roots behind. In type 1 lesions, these roots have intact endodontic systems and can create pain and/or infection, whereas in type 2 lesions, the roots have partially or completely been replaced by bone. In cases of complete replacement by bone, they are known as "ghost roots." It is possible that type 1 TRs are an early form of type 2 and that some type 1 lesions may progress to type 2 resorptions. However, the exact cause of TR is unknown at this time. In cats, it has also been proposed that type 2 lesions commonly seen in their canine teeth may not be related to inflammation but rather to ankylosis and age-related bone replacement.

Clinical Presentation

Type 1 lesions are often, but not always, accompanied by oral inflammation (gingivitis, stomatitis, and/or periodontal disease). In both type 1 and type 2 resorptions, there is often an associated area of gingival enlargement, which may or may not be inflamed, that covers or fills the lacuna that results from the resorption (Figures 5.29 and 5.30). Cats typically show no clinical signs even with advanced lesions, but they rarely may exhibit pain, dysphagia, decreased appetite, halitosis, depression, or other signs. (Note: One author [ER] has treated a cat whose only clinical sign was inappropriate urination that resolved with definitive treatment of the TR.) The mandibular 3rd premolars are often the first teeth affected, but TRs can occur in any tooth. Cats with one/any TR are at increased risk for developing future lesions. Dogs may present for pain or suspected tooth fracture or resorptions, but typically, TRs are incidental findings during routine dental prophylaxis or intraoral radiographs.

FIGURE 5.29 Tooth resorption of the left maxillary 3rd premolar (207) in a cat. Although the mandibular 3rd premolar is the most common location for tooth resorptions, they may occur in any tooth.

FIGURE 5.30 Tooth resorption in the left mandibular canine tooth (304) of a cat.

Differential Diagnosis

Gingivitis or periodontitis (without resorption), bone loss/furcation exposure in multi-rooted teeth, gingival hyperplasia or mass, fractured tooth, caries.

Diagnosis

Visual examination and subgingival exploration are often sufficient for identifying a clinical TR. However, intraoral radiography is essential for proper classification of the type and stage of the lesion and appropriate therapeutic planning, as well as finding incipient subgingival lesions.

Management

Extraction is the treatment of choice for TR. Crown amputation is only appropriate for type 2 lesions under the following conditions:

- No evidence of caudal stomatitis.
- No clinical or radiographic evidence of periodontal disease in the area of the root to be left.
- No identifiable tooth root structure, periodontal ligament, or root canal.
- There must be no evidence of endodontic disease.

If any of these criteria are not met, complete extraction is required. This may be very difficult due to root ankylosis. Radiographs must be obtained prior to and following extraction or crown amputation. Resorption that is completely subgingival and does not extend into the oral cavity may be monitored if there is no evidence of periodontal or endodontic disease, no stomatitis, and the patient is not showing clinical signs of pain, dysphagia, or inappetence. While there are no studies to this effect, crown amputation may be recommended for extremely advanced cases of TR in dogs. However, if at all possible, teeth and roots should be removed completely and complete extraction verified radiographically.

Prognosis

With appropriate diagnosis and treatment, prognosis is good. However, animals with TR lesions are at greater risk of developing lesions in other teeth. Some cats require full or near-full mouth extractions to alleviate their discomfort.

FELINE CAUDAL STOMATITIS

Definition/Overview

Stomatitis refers to inflammation and proliferation of the oral mucosa, while gingivitis more specifically refers to inflammation and proliferation of the gingival tissues. Gingivostomatitis is a clinical descriptive term, while lymphoplasmacytic stomatitis is the histopathologic diagnosis most commonly associated with this condition. It may range from mild to severe and generally increases with chronicity. The current terminology for this condition is caudal stomatitis, which is when the inflammation extends to the caudal oral tissues (caudal mucositis).

Etiology

The cause of caudal stomatitis is unknown and is possibly multifactorial. Suggested inciting causes or cofactors include an exaggerated inflammatory response to plaque, viral infection (particularly calicivirus), *Bartonella henselae* infection, and altered immune status.

Pathophysiology

Feline calicivirus (FCV) has been isolated from cats with caudal stomatitis, and cats exhibiting signs of the disease are more likely to be shedding FCV and feline herpesvirus-1 (FHV-1) from the oral mucosa. However, there is no evidence that FCV causes caudal stomatitis. Additional research is being done to more fully understand the role of FCV in chronic caudal stomatitis. Neither are feline leukemia virus (FIV) and feline immunodeficiency virus (FeLV) implicated directly in cases of caudal stomatitis, but infection with either virus may contribute to its development in individual cats. While cats that are positive for FIV and *B. henselae* exhibit increased levels of mandibular lymphadenopathy and gingivitis compared with non-infected cats, *B. henselae* is not currently believed to be a significant contributing factor in caudal stomatitis. An exaggerated response to bacterial plaque has been speculated to play a role in this disease, as cats with chronic caudal stomatitis exhibit significantly lower salivary IgA and higher serum IgA, IgG, and IgM levels than healthy cats. It has been proposed that the decreased salivary IgA in affected cats may have a contributing role in the development of chronic caudal stomatitis.

Clinical Presentation

It is not uncommon for affected cats to present for anorexia (complete or partial), dysphagia, pain, and ptyalism. They may also exhibit halitosis, pawing at the mouth, weight loss, vocalization, and an unkempt appearance due to lack of grooming (Figure 5.31). Paws and perioral areas may be stained with saliva, blood, and/or purulent material. Affected cats may have undergone behavior changes, becoming either more aggressive or more withdrawn than usual. Chronic caudal stomatitis is the oral disease most likely to result in anorexia. These patients are often extremely painful, and oral examination may prove very difficult, as opening the mouth can cause great discomfort. If oral examination is possible, the practitioner may note varying amounts of tissue inflammation, ulceration, and proliferation. The key clinical sign that differentiates this condition from periodontal disease is the caudal location of the stomatitis (Figure 5.32).

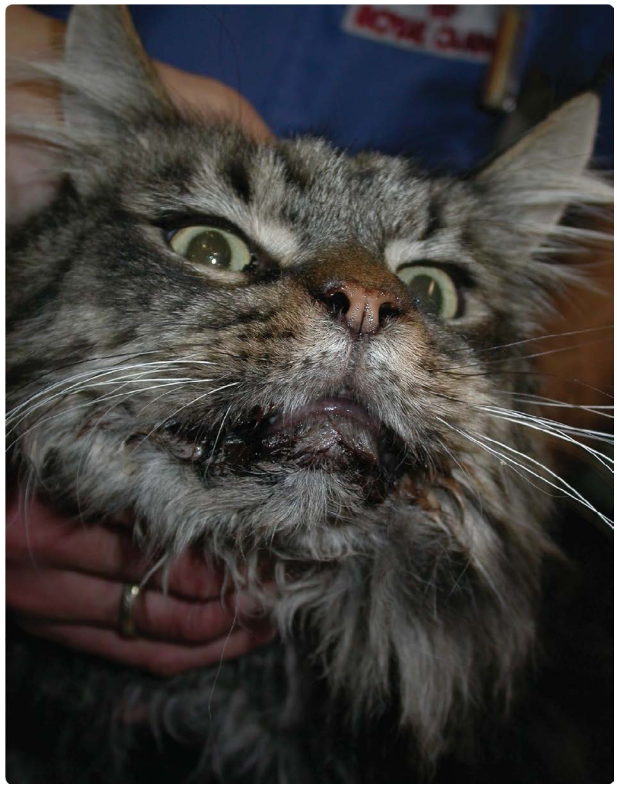

FIGURE 5.31 A cat with caudal stomatitis. Note the excessive ptyalism and unkempt coat.

Differential Diagnosis

Neoplasia (especially SCC), periodontal disease, eosinophilic granuloma complex (EGC), autoimmune disease, foreign body mucosal entrapment.

Diagnosis

As described previously, caudal stomatitis represents a clinical syndrome rather than a specific etiology or diagnosis. Therefore, diagnosis of caudal stomatitis is primarily a clinical one based on visual identification and testing for underlying contributing factors. A thorough visual examination under anesthesia, as well as dental radiographs to identify any retained root tips, periodontal disease, or any bony changes consistent with neoplasia,

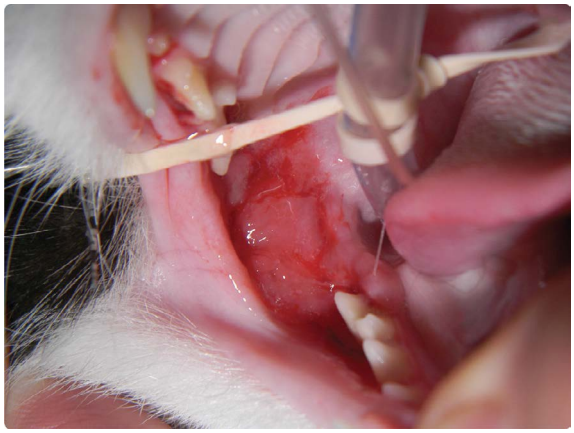

FIGURE 5.32 Caudal stomatitis in a cat. The severe erythema and inflammation in this area is pathognomonic for this condition.

is crucial. In addition, CBC and blood chemistry screening, including retroviral testing for FeLV and FIV status, are all indicated. Hyperglobulinemia may be present as a result of chronic antigenic stimulation. In addition, biopsies for histopathology should be collected if there is asymmetry in inflammation or ulceration, a nonclassical appearance to the inflammation, or if radiographs are suspicious for neoplasia.

Management

The goal of treatment is complete resolution of the oral inflammation. It has now been fairly well established that prolonged medical treatment with extensive or chronic use of steroids or nonsteroidal anti-inflammatory drugs (NSAIDs) results in poorer long-term responses than when early, aggressive surgical treatment is performed. Many, if not most, cats will respond best if all teeth and tooth remnants caudal to the canines are removed early in the course of the disease. Extraction of the canine and incisor teeth should also be considered, especially if the inflammation extends to the gingiva covering them. Aggressive management of periodontal disease is vital to treatment success. Some veterinary dentists are advocating CO_2 laser ablation of proliferative tissues following caudal mouth extractions; however, there is minimal research to support this procedure at this time. Patients may require some medical therapy with steroids or NSAIDs during the course of treatment, but these drugs are not a replacement for caudal to full-mouth extractions. Esterified fatty acid complex supplements have also shown some promise.

Prognosis

Extraction of all teeth and tooth remnants caudal to the canines (or full-mouth extractions if canine and incisor teeth are clinically abnormal) results in improvement in approximately 80% of affected cats. Of these, about 20% still show some signs of inflammation but do not demonstrate evidence of pain. The remaining 20% require additional care, which may include laser or surgical ablation, interferon therapy (used often in Europe but not widely available in the United States), or medical therapy (typically cyclosporine but also possibly steroids, NSAIDs, or fatty acid supplementation [1-TDC]). Early tooth extractions are indicated. Prolonged, repeated use of steroids not only has many undesirable side effects, but it also decreases the likelihood of resolution and worsens outcomes.

EOSINOPHILIC GRANULOMA COMPLEX

Definition/Overview

Eosinophilic granuloma complex (EGC) is, as the name suggests, a group of conditions that share a common etiology and some histopathological features. Seen most frequently in cats, EGC can also occur in dogs (Cavalier King Charles Spaniels, Siberian Huskies, and Malamutes, in particular).

Etiology

The true etiology remains unknown, but it is suspected to be a hypersensitivity or immune-mediated reaction. Most likely, EGC occurs in response to flea and/or food allergy or atopy. However, it should be noted that lesions have also been found in cases where infectious and allergic diseases have been essentially ruled out. Finally, there may be a genetic predisposition to EGC.

Pathophysiology

Inflammation and necrosis are seen and thought to be the result of the inflammatory agents released by accumulations of eosinophils in the lesions.

Clinical Presentation

The most common presentation is an indolent or rodent ulcer seen as a reddish brown lesion at the philtrum or around the maxillary canine teeth (Figure 5.33).

FIGURE 5.33 Typical rodent ulcer. This lesion is highly suggestive for eosinophilic granuloma complex in a cat.

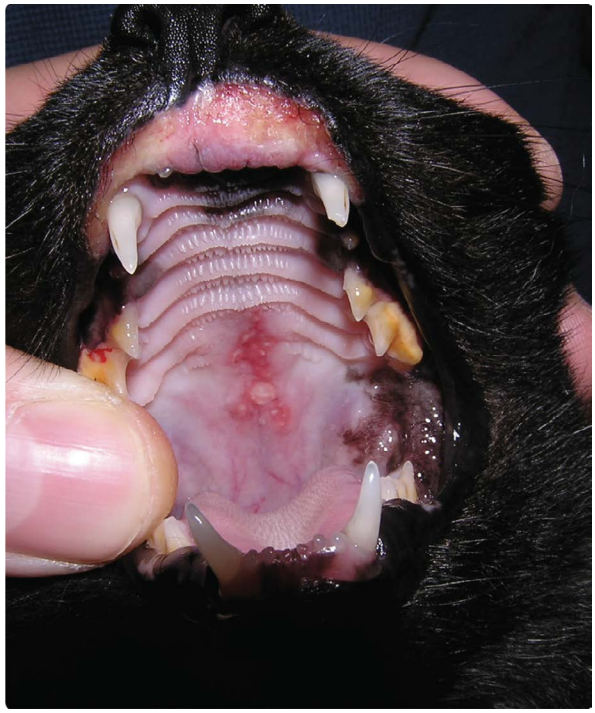

FIGURE 5.34 Palatal linear granuloma associated with eosinophilic granuloma complex. A rodent ulcer is also visible at the rostral maxillary lip. This is the same cat as in Figure 5.33.

Indolent ulcers may be unilateral or bilateral, and females appear to be overrepresented. Linear granulomas (Figure 5.34) are the second most common presentation and may be single or multiple. They are typically found on the lips, tongue, gingiva, and palate but can occur in any location in the mouth. These granulomas are yellow-pink, lobulated, raised masses and are generally nonpainful, although they may become secondarily infected and/or ulcerated. Occasionally, they can severely damage oral mucosa and even bone. There are reported cases of severe periodontal disease, oronasal fistulas, and even pathologic fractures as a result of eosinophilic granulomas. These lesions should not be taken lightly and should be on the differential list for any aggressive-appearing oral lesion. Another manifestation of EGC is the collagenolytic granuloma, a firmly swollen, rostral mandibular lip lesion most commonly seen in young female cats. Eosinophilic plaques may also be found (rarely) in the oral cavity where they appear much like a linear granuloma. These are more commonly seen as a dermatologic lesion. In fact, oral EGC very often occurs concurrently with dermatologic manifestations of the syndrome.

Differential Diagnosis

Neoplasia; gingival hyperplasia; uremic stomatitis; immune-mediated disease; trauma; periodontal disease; thermal, electric and chemical burns; foreign body mucosal entrapment.

Diagnosis

A minimum database (CBC, biochemical profile, urinalysis) should be obtained to rule out underlying disease. Histopathology should be performed to confirm the diagnosis. A thorough allergy evaluation (diet trial, serum, or intradermal testing) should be performed on histologic confirmation.

Management

Treatment is directed at the underlying cause of the disease, generally by controlling allergies. This may include strict flea control, hypoallergenic diets, and short-term (for acute control) steroids, but most often, long-term medical management is with cyclosporine or corticosteroids. Cyclosporine has proven effective for therapy of oral eosinophilic diseases, and a veterinary product is approved for use in dogs and cats for allergic disease. Weaning to the lowest effective dose at the longest interval that provides patient relief and disease control is recommended. Surgical removal has been occasionally successful, including cryosurgery and laser surgery. Finally, radiation therapy has been used in some cases.

CANINE CHRONIC ULCERATIVE STOMATITIS

Definition/Overview

Canine chronic ulcerative stomatitis (CCUS), also termed chronic ulcerative paradental stomatitis, or CUPS, is a painful, ulcerative condition seen in dogs. Like feline caudal stomatitis, this is one oral condition that will commonly cause anorexia in dogs. CCUS/CUPS is a severe form of inflammation and ulceration that extends beyond focal contact ulceration or "kissing" lesions and other forms of canine stomatitis.

Etiology

Etiology is unknown, but it is suspected to be a hypersensitivity or immune-mediated reaction to plaque or other allergen, drug administration, or other concurrent disease. Greyhound breeds appear to be overrepresented.

Pathophysiology

Various stages of ulceration and inflammation may be seen, with epithelial hyperplasia in nonulcerated areas. Plasma cells and lymphocytes may be predominant with intraepithelial neutrophils.

Clinical Presentation

Affected dogs may present for halitosis, difficulty eating, salivation/drooling, dropping food, pain, or general malaise. Awake exam is often sufficient to conclude CCUS as a likely diagnosis, but milder cases or patients with recent history of dental prophylaxis may be more difficult

FIGURE 5.35 Example of contact ulceration typical of CCUS/CUPS in a 7-year-old F/S Shih-Tzu.

to diagnose in the exam room and require anesthetized exam and even biopsy for reliable diagnosis. Contact ulcers or kissing lesions are usually easily diagnosed on awake exam and are recognizable as depigmented areas of erosion/ulceration in the buccal mucosa, in the shape of the tooth it contacts (Figure 5.35). Erosive or ulcerative lesions are also commonly seen on the lateral margins of the tongue where it contacts the lingual surfaces of the teeth and associated plaque. Gingival, palatal, and labial mucosa may also be significantly inflamed with severe redness, swelling, and/or ulcers, even if not in direct contact with tooth surfaces.

Differential Diagnosis

Eosinophilic granuloma complex; neoplasia; uremic stomatitis; immune-mediated disease; trauma; periodontal disease; thermal, electric and chemical burns; foreign body mucosal entrapment.

Diagnosis

A minimum database (CBC, biochemical profile, urinalysis) should be obtained to rule out underlying disease. Histopathology should be performed to confirm the diagnosis.

Management

Conservative treatment is directed at the strict control of plaque. This requires a significant commitment by pet owners: Daily home care, including tooth brushing; and regular, frequent anesthetized professional scaling and polishing, as often as every 3–4 months. Strategic, focused extractions may be performed in areas of ulceration and inflammation to provide relief in difficult-to-brush areas. Clients should be counselled that many dogs with CCUS eventually require complete, full-mouth tooth extractions, which is usually curative.

FELINE JUVENILE GINGIVITIS/ PERIODONTITIS

Definition/Overview

Feline juvenile gingivitis and periodontitis are separate entities from, though often mistaken for, feline caudal stomatitis. It occurs in cats less than 1 year of age and may be either destructive or hyperplastic (Figure 5.36). Hyperplastic gingivitis may precede or result in destructive periodontitis. Left untreated, it often leads to significant tooth loss. Cats may be able to outgrow the less aggressive form of the condition by approximately 2 years of age with appropriate professional treatment and home care.

Etiology

Etiology is unknown, but some pure breeds are overrepresented (Burmese, Siamese, and Maine Coon).

Pathophysiology

Various stages of ulceration and inflammation may be seen with epithelial hyperplasia in nonulcerated areas. Plasma cells and lymphocytes may be predominant with intraepithelial neutrophils.

Clinical Presentation

Kittens and juvenile cats may present for halitosis or bleeding but generally not pain. Juvenile gingivitis generally outlasts eruption gingivitis, which is associated with the eruption of permanent dentition and is usually short lived. Persistent, severe gingivitis with either hyperplasia or gingival recession requires complete anesthetized exam and dental radiographs.

Differential Diagnosis

Periodontal disease, feline caudal stomatitis, eosinophilic granuloma complex, neoplasia.

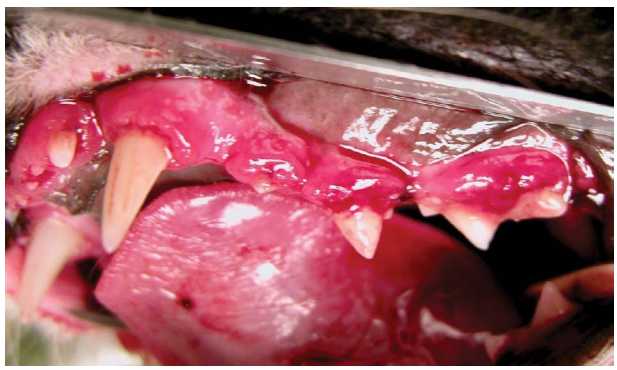

FIGURE 5.36 Feline juvenile gingivitis in a 9-month-old Domestic Shorthair cat. Note the significant erythema and swelling of the gingival tissues.

Diagnosis

A minimum database (CBC, biochemical profile, urinalysis), and viral testing (FIV, FeLV) should be obtained to rule out underlying disease. Complete anesthetized exam with full-mouth dental radiographs, complete prophylaxis, and implementation of strict home care should be performed. A positive response to treatment is consistent with diagnosis of juvenile periodontitis/gingivitis.

Management

Early (6–9 months of age) thorough exam, dental radiographs, and complete supra- and subgingival scaling are necessary to determine extent of the disease and implement treatments. Hyperplastic gingiva should be excised to reduce pseudopockets and risk of bone loss. In cases of destructive periodontitis, loose teeth, teeth with furcation defects, or significant periodontal pocketing should be extracted, or advanced periodontal surgical techniques may be attempted to maintain strategic teeth. Strict home care should be implemented, as well as frequent professional cleanings every 3–6 months regardless of quantity of visible plaque. Early, aggressive treatment and home care may allow patients to outgrow this condition and enjoy normal periodontal health in the future.

CASE EXAMPLES

Case 5.1

A 7-year-old female/spayed Maltese was referred for evaluation of missing teeth noted during routine dental prophylaxis approximately 3 months earlier.

Clinical Examination

On exam "Lea" was bright, alert, responsive and hydrated. Heart and lungs auscultated within normal limits. Preanesthetic lab work was unremarkable. Conscious oral exam revealed missing right (105) and left (205) maxillary first premolars, left mandibular canine (304) and first premolar (305), right mandibular first incisor (401), and a partially erupted right mandibular canine (404) (**Figure 5.37**). During anesthetized exam and probing, the left maxillary 2nd molar (210) and right and left 3rd molars (311, 411) were also discovered to be missing. In addition, the right maxillary 2nd incisor (102) was mobile and discolored, the left mandibular incisors (301–303) were mobile, and the remaining right mandibular incisors (402, 403) were crowded. Scant or mild tartar was noted throughout the mouth. The left mandibular first molar (309) was partially erupted, and a 4-mm periodontal pocket was probed at this tooth.

Questions

- What are the 4 differentials for missing teeth?
- What are the possible sequelae for impacted teeth?

FIGURE 5.37 Photograph of the rostral left mandible. The left mandibular canine (304) and 1st premolar (305) are missing.

Differential Diagnoses

Missing tooth: Congenitally missing permanent tooth, previously extracted tooth, fractured below the gingiva, impacted tooth. Partially erupted teeth: Congenital, developmental.

Provisional Diagnosis

Impacted tooth with possible dentigerous cyst formation, partially erupted permanent mandibular canines

Diagnostic Testing

Intraoral radiographs of the entire mouth were obtained. The left mandibular canine and 1st premolar teeth were impacted, and an associated dentigerous cyst was seen radiographically (**Figure 5.38**). Intraoral dental radiographs are a necessity for proper diagnosis of "missing" teeth.

Treatment

Full dental prophylaxis – scaling and polishing – was performed. A gingival incision was made over the area of the missing canine and premolar teeth and the tissue gently elevated from the bone with periosteal elevators to create a large envelope flap. Bone was carefully removed using a 701 cross-cut taper fissure bur on a high-speed, air-driven hand piece to expose the impacted teeth. Gentle luxation and elevation were performed to ease the teeth out of the mandible so as not to damage vital structures or fracture the jaw (**Figure 5.39**). The partially erupted right mandibular canine was treated with an apical repositioning flap to expose the enamel, lengthen the crown of the tooth, and prevent future periodontal pocketing. The left mandibular 1st molar was treated with closed root planing and a perioceutic to prevent further progression of periodontal disease. All mandibular incisors were removed as well as the right maxillary 2nd incisor, which was found to have an unstable root fracture on radiograph.

Conclusion

Impacted teeth are frequently diagnosed, particularly in small breed and brachycephalic dogs, and should

(*Continued*)

FIGURE 5.38 Radiograph of the rostral mandibles. Note the minimal amount of bone adjacent to the impacted left canine (304) compared with the right (404).

FIGURE 5.39 Intraoperative photograph showing the impacted left mandibular canine (304) and first premolar (305).

always be radiographed. Dentigerous cysts are a fairly common sequela of impacted teeth and, left untreated, can lead to serious consequences such as pathologic jaw fracture. Partially erupted teeth can lead to development of periodontal disease and should be treated with appropriate periodontal surgical techniques.

Case 5.2

A 9-year-old male neutered Poodle cross was presented for a nonhealing caudal mandibular fracture.

History

The patient had been first seen by a general practitioner for the fracture 4 months previous following a fight with a larger dog. According to referring veterinarian (RDVM) history, the pet was minimally painful on presentation and continued to eat following the injury. However, the pet was having increased difficulty chewing from the mandibular drift and was getting palatal trauma from the canine.

The patient was referred immediately to a surgeon at a local referral clinic for reduction and fixation. Surgery was performed the following day. The fracture was reduced and fixed with a bone plate and the patient discharged 48 hours later.

The patient initially did well. However, approximately 3 weeks following the initial surgery, the fixation failed, and the pet was returned to the referral center. The reduction and fixation was repeated and the patient again discharged. This time, the fixation only lasted 10 days when it broke down again. This process was repeated two more times. Following four plating procedures, the RDVM recommended that the pet be brought to a dental specialist for a second opinion.

Clinical Examination

Upon presentation, the jaw was misaligned, and there was purulent discharge from the surgery site.

Differential Diagnosis

Pathologic fracture secondary to periodontal disease, neoplasia, osteomyelitis (bacterial or fungal); nonunion.

Diagnostic Testing

The patient was placed under general anesthesia and dental radiographs exposed. These revealed the significant alveolar bone loss associated with the distal root of the mandibular first molar (**Figure 5.40**). This was conclusive evidence that this was indeed a pathologic fracture, and the infected distal tooth root was the reason for the nonunion.

Treatment

The plate was removed, and the right mandibular 1st molar was extracted (**Figure 5.41**). The fracture was reduced and stabilized with intraosseous wire (**Figure 5.42**). Intermittent rechecks confirmed that the patient was doing very well. Six weeks later, the patient was represented for wire removal. The dental radiographs revealed adequate healing. The splint/wire was removed and the soft tissues closed (**Figures 5.43** and **5.44**).

Conclusion/Discussion

Pathologic fractures are the result of a weakened area of bone secondary to a disease process. The most common etiology of these weakened areas is periodontal disease; however, fungal osteomyelitis and neoplasia can also degrade the bony integrity. Periodontal disease is the most commonly diagnosed problem in veterinary medicine. Bacteria and their by-products cause inflammation, which in combination with the patient's immune defenses leads to bony destruction. Over time,

(*Continued*)

FIGURE 5.40 Intraoral radiograph of nonhealing fracture site; attempted fixation with bone plate.

this chronic periodontal loss loosens the tooth support, resulting in exfoliation of the tooth. In the majority of teeth, this occurs before severe bone weakening. In some situations, however, the size of the tooth roots in relation to the mandible can cause significant bone weakening prior to tooth exfoliation. This scenario most commonly occurs in small breed dogs for several reasons. First, small dogs tend to have more severe periodontal disease than medium-to-large breed dogs.

FIGURE 5.41 Intraoral radiograph of pathologic fracture site after removal of bone plate.

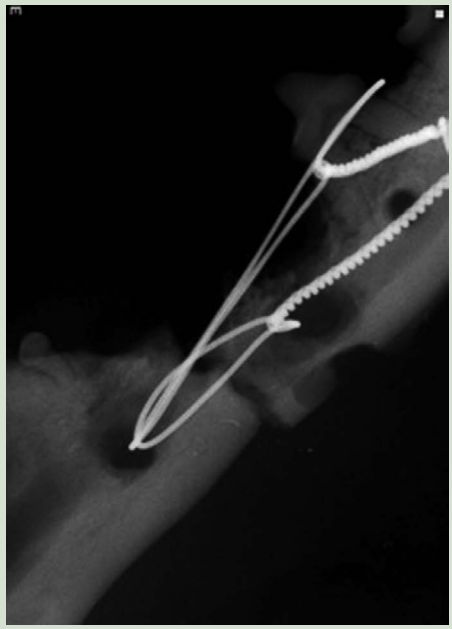

FIGURE 5.42 Intraoral radiograph after repair with interosseous wiring technique.

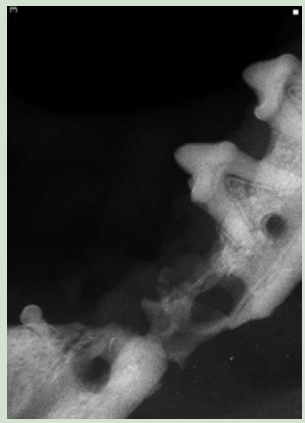

FIGURE 5.43 Intraoral radiograph after removal of interosseous wire, demonstrating healing.

FIGURE 5.44 Intraoral photograph of fracture site, caudal right mandible.

(*Continued*)

In addition, small dogs tend to live longer. Finally, and most importantly, small and toy breed dogs have proportionally larger 1st molars than do larger breeds. Consequently, the root apex of the mandibular 1st molar (especially the mesial root) lies within millimeters of the ventral cortex of the mandible. Another vulnerable area involves the mandibular canines, which comprise 60%–70% of the strength of the rostral mandible. Thus, the mandible weakens to the point of fracture before the tooth exfoliates. Pathologic jaw fractures typically happen as a result of just mild trauma, such as jumping off a bed, a dog fight, or quite commonly during dental extraction procedures. However, dogs can even break their jaw while simply eating.

Although this is typically thought of as a disease of older patients, the authors have treated a few cases in dogs less than 3 years of age. Therefore, it is of critical importance that these small patients have regular dental examinations (under anesthesia and ideally including dental radiographs) from an early age.

A pathologic fracture should be suspected in any case of a mandibular fracture, especially in the area of the mandibular 1st molar of small breed dogs. Additional supportive history is lack of obvious trauma, a nonpainful or mildly painful appearing patient, periodontal disease elsewhere in the mouth, and lack of response to adequate fixation.

Diagnosing a pathologic fracture is only possible with dental radiographs. In general, skull films are not detailed enough to diagnose periapical disease. The classic radiographic appearance is bone loss around the involved roots and/or a periapical lucency in the area of the fracture. Additionally, a periapical lucency may be seen on another root of a multi-rooted tooth.

It is important to realize that a pathologic fracture will not heal if the diseased tooth root is not removed. This is because a diseased root acts as a nidus of infection, which prevents healing. Extraction of the diseased root is necessary but, unfortunately, creates a large defect in the bone, which much be bridged.

All pathologic jaw fractures are typically difficult to heal due to the lack of remaining bone, the low oxygen tension in the area, and difficulty in rigidly fixating the caudal mandible.

This case demonstrates the importance of dental radiology when treating mandibular fractures. Skull films are generally not detailed enough to reveal the pathologic nature of these fractures. Referral of mandibular fractures to a facility with this capability is recommended.

Respiratory Disorders

Cécile Clercx

Introduction 188
Upper Airway Disorders 188
Lower Airway and Lung Disorders 207
Etiology 215
Recommended Further Readings 218

INTRODUCTION

Respiratory diseases are common clinical problems in small animal practice. Some are readily diagnosed on the basis of history and clinical signs while others can prove difficult to diagnose. Upper airways generally refer to the nasal cavities and frontal sinuses, nasopharynx and laryngopharynx, larynx, and extrathoracic trachea, while lower airways include organs inside the thoracic cage, including (1) the intrathoracic part of the trachea, the airways or "conducting pipes" (i.e., the bronchi and bronchioli) and (2) the lung parenchyma, composed of functional units (i.e., the alveoli surrounded by capillaries, where gas exchange takes place, and interstitial tissue). Pleural disorders and diseases involving other intrathoracic organs, such as the heart and vessels, and mediastinal organs will cause clinical signs similar to those encountered in parenchymal diseases.

Clinical history is of great importance, since a good description of the complaints can help determine the segment of the respiratory tree involved. A physical examination is essential and will often be very helpful in the diagnosis of upper airway diseases, while in respiratory diseases of intrathoracic origin, diagnosis is much more challenging, and several ancillary diagnostic tests, mainly imaging, will always be needed.

The clinical signs encountered in disorders of the different affected areas are summarized in Table 6.1.

UPPER AIRWAY DISORDERS

NASAL, SINUS, AND/OR NASOPHARYNGEAL DISORDERS

Nasal, sinus, and/or nasopharyngeal diseases will be presented together, since differentiation, based on clinical signs alone, is challenging and because in most diseases all three regions can be involved. Although the clinical signs (e.g., sneezing, discharge, reverse sneezing, stertor) localize the disease to this area, confirmation of the etiology depends on additional diagnostic tests, primarily imaging (mainly high-resolution computed tomography or HRCT) and rhinoscopy (direct and retrograde). Direct rhinoscopy can be performed using a rigid scope (Figure 6.1a, b), but investigation of the frontal sinus and nasopharynx usually requires a flexible endoscope (Figure 6.2a, b). These procedures require general anesthesia. When HRCT is indicated, it should preferably precede rhinoscopy, if performed during the same anesthetic procedure. During rhinoscopy, other procedures such as brushing, biopsies, nasal lavage, and sampling for microbiologic examination can be performed.

Disorders of the nasal cavities must be differentiated from nasal planum (planum nasale) disorders. Indeed, some disorders of the nasal cavities induce changes on the nasal planum (e.g., hyperkeratosis, erosions, and ulcerations together with local oozing or bleeding) that can be confused with nasal discharge. However, diseases of the nasal cavities are most often accompanied by sneezing and discharge coming from inside the nasal cavity, which is not the case in planum nasale disorders. These include skin or mucocutaneous junction disorders (e.g., tumors, immune-mediated diseases, or leishmaniasis), which can be associated with coagulopathy in addition to being associated with epistaxis unrelated to coagulopathy. In these cases, a full clinical examination must be performed before considering other diagnostic procedures such as rhinoscopy, nasal/sinus radiographs, or HRCT under anesthesia.

Stenosis of the nares (Figure 6.3) causes a decrease in the intranasal opening, resulting in a stertorous breathing during normal attempts to breathe. The noisy respiration can be associated with some degree of serous nasal discharge and sometimes sneezing. This pathology

TABLE 6.1 Clinical signs in respiratory tract diseases

	Major signs	Less common signs
Upper airway disorders		
Nasal cavities, sinuses, nasopharynx	– Sneezing – Nasal discharge – Reverse sneezing – Alterations of the nasal plane – Change in nostril patency – Stertor	– Facial deformity (tumor) – Systemic signs of illness (aspergillosis) (e.g., lethargy, inappetence, weight loss) – Seizures
Pharynx	– Stertor – Open-mouth breathing – Sneezing, nasal discharge – Cough	– Upper digestive symptoms – Gagging, retching – Dysphagia – Ptyalism
Larynx	– Exercise intolerance – Stridor – Difficult breathing/respiratory distress – Cough – Hypoxemia/cyanosis	– Modified barking sounds – Gagging or coughing with eating
Extrathoracic trachea	– Cough (mainly in dogs, not in cats) – Stridor (mainly in cats) – Retching, gagging	– Exercise intolerance – Dyspnea (when severe obstruction)
Lower airway disorders		
Intrathoracic trachea	– Cough (mainly in dogs, not in cats) – Stridor – Gagging	– Exercise intolerance – Difficult breathing (when severe obstruction)
Bronchi	– Cough – Dyspnea	– Exercise intolerance – Systemic signs of illness
Pulmonary parenchyma	– Exercise intolerance – Tachypnea – Dyspnea (obstructive or restrictive)	– Systemic signs of illness (depending on the cause) – Hypoxemia
Pleural space	– Exercise intolerance – Orthopnea – Dyspnea	– Varies with cause
Mediastinal	– Exercise intolerance – Orthopnea – Dyspnea	– Cough – Digestive signs

is encountered mainly in brachycephalic breeds of dogs and is often associated with the clinical signs reported in dogs with brachycephalic airway obstructive syndrome (BAOS).

In cats, although BAOS is appreciated less commonly than in dogs, stenotic nares area component which appears to play a major role.

MYCOTIC RHINOSINUSITIS (DOGS)

Definition/Overview

Sinonasal aspergillosis (SNA) is a common disease and affects between 12% and 34% of dogs evaluated for chronic sinonasal disease. The term "nasal aspergillosis," which was used in the past to describe this condition, is better replaced by the term sinonasal aspergillosis, since the infection involves the nasal cavity and frontal sinus in most cases. Aspergillosis in dogs typically causes destructive rhinitis and sinusitis. Most affected dogs are young to middle aged and of mesocephalic and dolichocephalic breeds.

Etiology

In most instances, *Aspergillus fumigatus* is the etiologic agent, but *A. niger, A. nidulans, A. flavus*, as well as *Penicillium* spp. may also be involved. *A. fumigatus* is a filamentous saprophyte and ubiquitous fungus.

Pathophysiology

Despite numerous investigations, the pathogenesis is, to date, poorly understood. As the disease usually affects systemically healthy dogs, and as *A. fumigatus* is a ubiquitous fungus, a local immune deficiency in affected dogs has been suggested. The fungus invades the nasal cavity and sinus and causes necrosis of the turbinates, which is painful. The fungus can also induce lysis of the medial septum and invade the contralateral nasal cavity/sinus or cause lysis of the cribriform plate.

Clinical Presentation

Clinical signs associated with the disease include, in decreasing frequency:

- Profuse nasal discharge, unilateral when the disease begins, then possibly bilateral when the disease progresses due to septal erosion. The discharge can be mucopurulent, although more often it is sanguinopurulent or bloody.
- Sneezing and reverse sneezing.
- Signs of nasal and frontal sinus pain, as evidenced by restriction of head movements, lethargy, and decreased appetite.
- Hyperkeratosis of the planum nasale and ulceration of external nares (Figure 6.4).

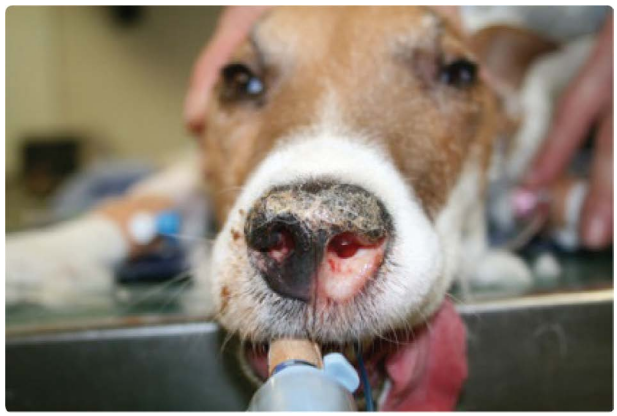

FIGURE 6.4 Ulceration of the external nares, hyperkeratosis, and discharge in a dog with sinonasal aspergillosis.

- Increased nasal airflow, as shown by placing a thin piece of cotton wool in front of each nostril alternately, related to the destruction of the turbinates (this abnormality is easily demonstrated from early in the course of the disease).
- Enlarged mandibular lymph node(s).

In advanced cases, other clinical abnormalities that can occur include facial deformity due to frontal bone hyperostosis, epiphora secondary to extension of the pathologic process into the orbit, or signs of forebrain dysfunction (e.g., seizures, dullness) if there is significant cribriform plate destruction.

Differential Diagnosis

Includes lymphoplasmacytic rhinitis, early nasal tumor, chronic nasal foreign body, bacterial rhinitis due to dental disease, and fungal rhinitis.

Diagnosis

SNA may be suspected based on signalment, history, and clinical signs, but reaching an early definitive diagnosis remains a clinical challenge. Medical imaging (HRCT or magnetic resonance imaging [MRI]), endoscopy, cytology/histology, fungal culture, serology, and fungal DNA quantification have been reported to help in the diagnosis of canine SNA. However, there is no single consistently reliable diagnostic method, as false-positive and false-negative results can occur with each test. Direct rhinoscopy may detect turbinate lysis in the affected cavity (or cavities) in addition to any fungal plaques with their associated accumulation of necrotic material in the affected cavity (Figure 6.5a–c). In early cases, rhinoscopy may not detect the presence of typical fungal colonies because the plaques might not yet be formed or because they are hidden inside the frontal sinus, which cannot easily be explored in the absence of severe nasal turbinate lysis in smaller dogs.

Radiographic signs of fungal rhinitis consist of a loss of the normal intranasal trabecular pattern together with an increased lucency of the affected nasal cavity (or cavities). High-resolution CT is much more useful. Typical features of nasal aspergillosis include cavitary destruction of the turbinates with abnormal soft tissue within the nasal cavity, a rim of soft tissue along the frontal and sinus bones, and thick, reactive bone (Figure 6.6a–c). The value of MRI for the diagnosis of aspergillosis is very similar to that provided by HRCT because of the greater detail they provide compared with radiography.

Rhinoscopy is required for a definitive diagnosis because it is the only technique that is able to show the presence (active overt aspergillosis) or absence of fungal colonies. It also allows access to the plaques for surgical debridement.

Direct endoscopic visualization of fungal plaques along with biopsy of the pathologic tissue and, preferably, positive culture and/or quantitative polymerase chain reaction (qPCR) results have become accepted as the gold standard for the diagnosis of SNA. Referral of suspect patients to veterinary centers that have the diagnostic expertise can be a great service for practices that are not equipped for such diagnostic testing.

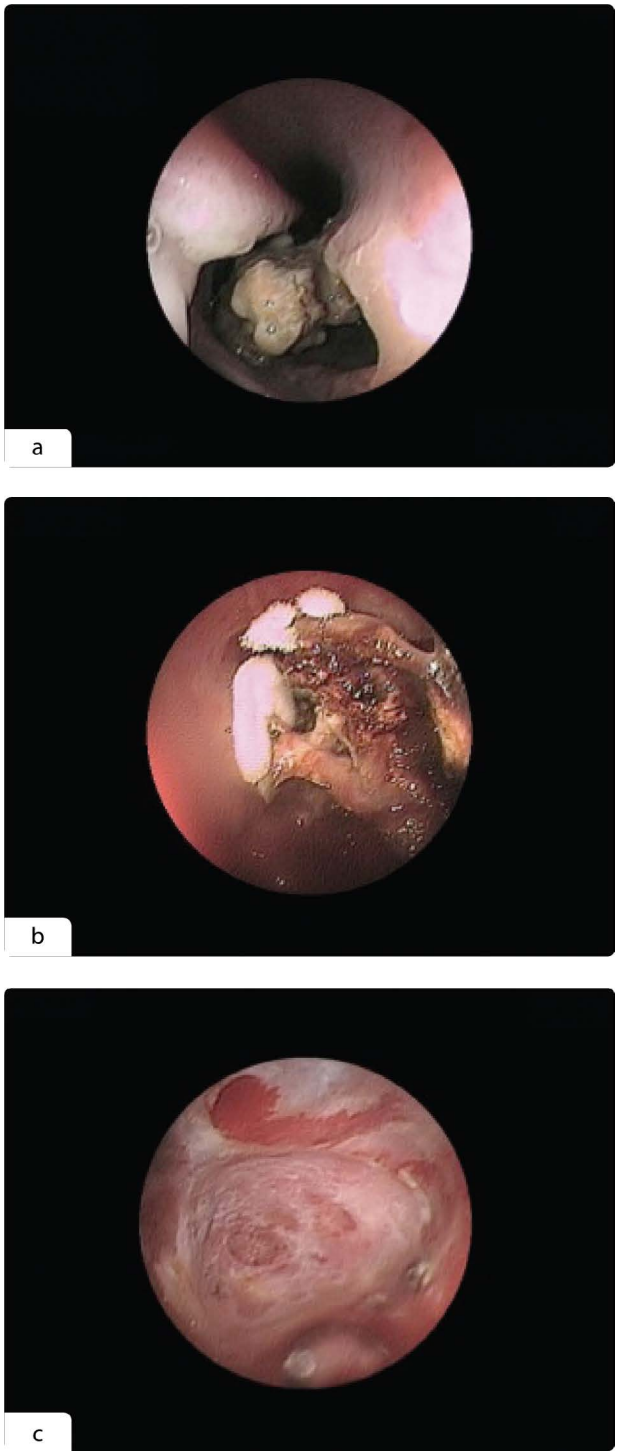

FIGURE 6.5 Rhinoscopy in a dog with SNA showing **(a)** important turbinate lysis and presence of necrotic material in the nasal cavity; **(b)** presence of typical fungal plaques and collection of necrotic material in the nasal cavity; and **(c)** a cleaned frontal sinus after debridement.

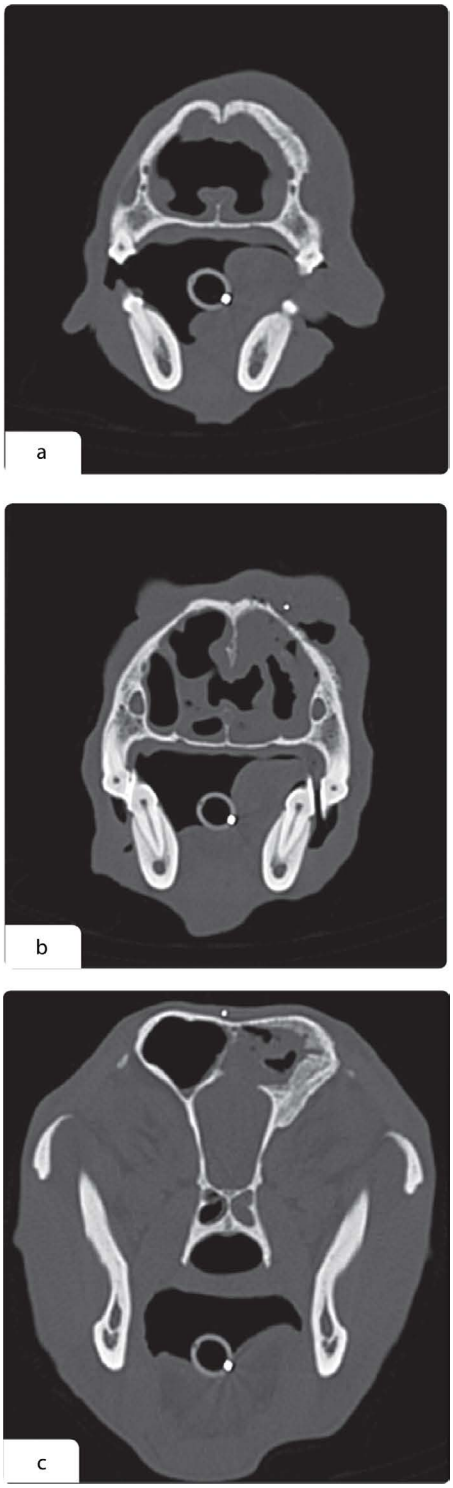

FIGURE 6.6 Transverse high-resolution CT images of a dog with severe nasal aspergillosis, showing **(a)** bilateral cavitary destruction of the turbinates with abnormal fluid/soft tissue within the nasal cavities and L>R frontal sinuses; **(b)** thickening of the mucosa along the inner surface of the bones of the left frontal sinus and nasal cavities; and **(c)** thick, reactive maxillary, incisive, nasal, and frontal bones (hyperostosis) as well as lysis of the maxillary, nasal, and incisive bones, nasal septum, frontal crest, and cribriform plate. Note the swelling of the dorsal subcutaneous tissue on the left side. (*Courtesy of G. Bolen.*)

Agar gel double immunodiffusion (AGDD) is the most commonly used serologic test for diagnosing SNA. Enzyme-linked immunosorbent assay (ELISA) techniques have at least similar performances but are not yet widely/commercially available. Serology is cheap, simple, and easy to perform and offers good specificity but moderate sensitivity. Although fungal culture of nasal specimens is highly specific for the diagnosis of SNA, nasal secretions sampled blindly with swabs are an unreliable source for fungal culture in contrast to fungal plaque and mucosal biopsy samples. Incubating samples for fungal culture at 98.6°F (37°C) improves the chance of fungal isolation in the laboratory.

Rarely, hyphae or conidia can be seen on cytologic or histopathologic preparations.

Management

Effective treatment of SNA in dogs is very challenging. Treatment options include systemic oral therapy, topical antimycotic therapy, and more invasive surgical procedures. The reported success rates, and short-term and long-term outcomes are variable.

Systemic oral treatments (ketoconazole, 5 mg/kg q.12h. or itraconazole 5 mg/kg q.12h.) are noninvasive but require prolonged administration (more than 4 weeks in all cases) because of poor efficacy and may have significant side effects, especially on liver function.

Currently, the most rewarding therapies include topical treatments. They have been associated with greater success and have improved the management of SNA. Various procedures have been developed to administer medication topically, and these procedures vary in invasiveness and ease of performance. Extensive debridement prior to infusion is a critical and essential step. Topical therapy includes mainly the use of enilconazole and clotrimazole at a concentration of 1%–2%. These methods have shown good efficacy and reach success rates of up to 80%–90%. Although the use of topical agents via noninvasive methods is well tolerated and shows a high success rate, these procedures are time-consuming and require general anesthesia. Infusion of 1% clotrimazole cream through bore holes into the frontal sinus, which acts as a depot agent to minimize anesthesia time while providing an extended period of drug contact, has been described.

Prognosis

Despite all these treatment procedures, some dogs remain refractory to any treatment, and the prognosis is then very poor. The inability to predict first-treatment success rate is frustrating. Severity of disease, experience of the treating clinician, and the ability and extent to which debridement is performed are contributing factors to treatment response. Recurrence after apparent remission is not uncommon and has been demonstrated to occur several years after an initial successfully treated episode of SNA.

MYCOTIC RHINOSINUSITIS (CATS)

Definition/Overview

In contrast to canine SNA, aspergillosis in cats is rare but is considered an emerging condition. In cats, upper respiratory tract (URT) aspergillosis can be divided into SNA and sino-orbital aspergillosis (SOA), with SOA being the most invasive form and also the most common. In contrast to canine SNA, purebred brachycephalic cats, predominantly of Persian or Himalayan breeds, account for most cases. The disease affects young to middle-aged cats, with evidence of immunocompromise in some cases but not in most. Previous viral URT infection or recurrent antimicrobial therapy might be additional risk factors.

Etiology

A diverse range of *Aspergillus* species has been identified in cats with URT aspergillosis.

Clinical Presentation

Feline SNA is characterized by more local signs of chronic nasal infection (e.g., sneezing, unilateral or bilateral serous to mucopurulent nasal discharge) and, sometimes, epistaxis. Soft tissue masses protruding from the nares and bone lysis are less frequent abnormalities. SOA probably represents an extension of SNA to orbital and subcutaneous tissues, caused by more invasive *Aspergillus* species. It is characterized by signs of orbital and surrounding tissue invasion, including unilateral exophthalmos, third eyelid prolapse, conjunctival hyperemia, and keratitis. In some cases, a mass in the pterygopalatine fossa or an ulceration of the hard palate can be seen. The CNS can also be involved, leading to neurologic signs.

Differential Diagnosis

Includes mainly viral upper URT infections, neoplasia (lymphoma, carcinoma), and severe chronic rhinosinusitis (idiopathic or secondary to polyp, nasopharyngeal stenosis or atresia, or palatal defect), cryptococcosis, foreign body.

Diagnosis

Confirmation of the diagnosis relies on advanced imaging (CT or MRI) and rhinoscopy. Biopsy or a nasal lavage specimen can be used for histology, cytology, culture, and even molecular identification when a negative fungal culture is suspected. In SOA, CT-guided biopsy of orbital or other paranasal mass lesions can be performed.

Management

Evidence-based treatment protocols are not available. Only small numbers of reported treated cases exist, and very little follow-up information is available. Successful treatment regimens have been described using systemic antifungal therapy alone or with topical intranasal antifungal infusion. As with canine SNA, debridement of fungal lesions appears to be a very important step in any treatment protocol. To date, optimal treatment regimens have not been investigated, confirmed, or identified.

Prognosis

SNA carries a favorable prognosis with treatment, whereas the prognosis for SOA is poor.

CRYPTOCOCCOSIS

Definition/Overview

Cryptococcosis is a dimorphic fungus that exists in the yeast form in the animal. In nature, it is found in bird guano. Various species exist (*Cryptococcus neoformans* var. *grubii* or var. *neoformans*, *Cryptococcus gattii*) with various geographic distributions. Feline cryptococcosis is most prevalent in Australia, Western Canada, and the Western United States and occurs sporadically in other countries. Cryptococcal infection is reported more commonly in cats than in dogs, with the disease being less frequently reported compared to aspergillosis.

Clinical Presentation

Clinical signs include facial distortion, sneezing, and chronic mucopurulent nasal discharge and can be accompanied by skin lesions, chorioretinitis, or CNS signs such as seizures.

Diagnosis

Diagnosis involves cytologic identification of the organism in nasal smears, exudates, aspirates, or impression smears. The organism is characteristic (3–8 microns round, surrounded by a clear capsule ranging in size from 10 to 30 microns). There is also a serum latex agglutination test that has shown reliable accuracy in detecting the cryptococcal antigen.

Management/Prognosis

Itraconazole (50–100 mg per cat per day) is reportedly efficacious in most cases.

TUMORS (DOGS)

Definition/Overview

Nasal and paranasal tumors account for 1%–2% of canine neoplasms. Dolichocephalic breeds and medium to large breeds of dogs are more often affected. Older

dogs are predominantly affected. The tumors are mostly malignant and include mainly carcinomas, but sarcomas also occur. Nasal lymphomas are infrequent in dogs but are not rare in cats. Benign tumors are very rare. Nasal tumors are locally invasive; systemic metastasis is infrequent, while local lymph node involvement can be seen.

Clinical Presentation

Dogs exhibit chronic nasal discharge, which is at first unilateral and can then become bilateral. The discharge is serous to mucopurulent and/or hemorrhagic. Epistaxis is common. Other clinical features include stertor, sneezing, and reverse sneezing. Ocular discharge, facial deformity, alteration of the nasal plane, weight loss, and CNS signs are less frequently encountered.

Diagnosis

History and clinical signs lead to a presumptive diagnosis in most cases. A very easy and interesting test is the airflow passage test, which is measured by placing a thin piece of cotton wool in front of each nostril alternately. Airflow passage is always decreased or absent when associated with nasal cavity tumors. Diagnostic imaging is useful to define the extent of the disease and provide a presumptive diagnosis. CT is the imaging modality of choice for diagnosing nasal neoplasia, although radiographs are often adequate. CT is superior for staging and is required before any surgical and/or radiation therapy treatment is started. MRI is more sensitive for identifying intracranial involvement.

Rhinoscopy is an important diagnostic procedure because it allows not only visualization of the mass but also the opportunity to take selective biopsies in order to confirm the diagnosis and determine the histopathologic type of the tumor.

A number of different techniques have been described for obtaining cytology or biopsy tissue samples from the nasal cavity. These include nasal flush, traumatic core biopsy, and rhinoscopy-assisted biopsy. Retrograde rhinoscopy allows for visualization of the posterior nasal cavity (Figure 6.7a). Imprint and/or brush cytology can be diagnostic for nasal tumors, but deep biopsy and histopathology are recommended, since biopsies that are too superficial may fail to confirm the neoplastic nature of the mass. Fine-needle aspiration of the submandibular lymph node is a simple, inexpensive, minimally invasive technique that can help detect metastasis.

Differential Diagnosis

Includes inflammatory rhinitis, aspergillosis, and intranasal foreign bodies.

Diagnosis

The diagnosis of intranasal neoplasia is complicated by the difficulty in obtaining a representative biopsy, and neoplasms are sometimes initially diagnosed as inflammatory disease.

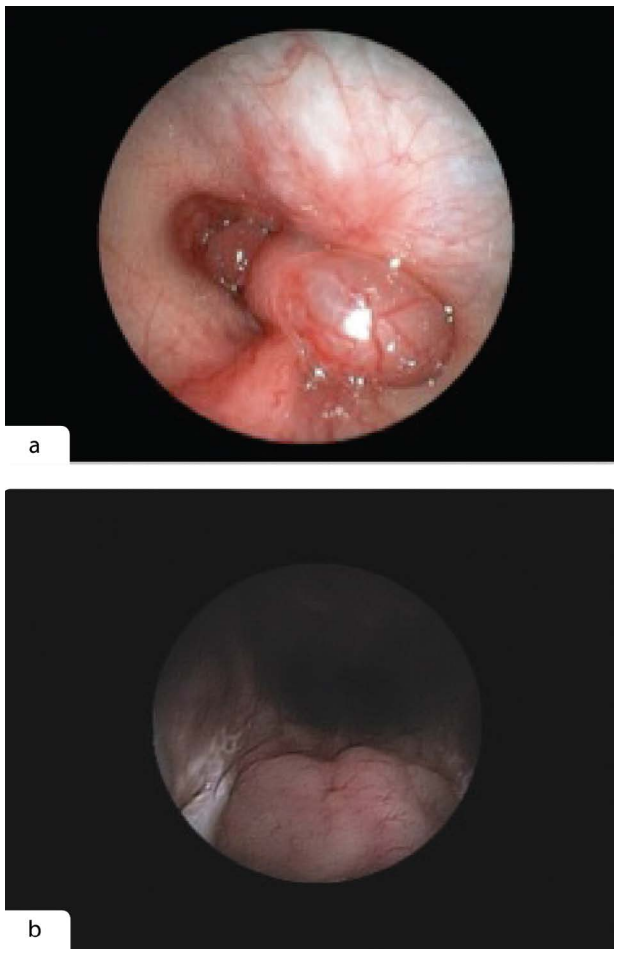

FIGURE 6.7 (a) Retrograde rhinoscopy in a dog, showing a nasal tumor invading and obstructing both choanae. **(b)** Retrograde rhinoscopy in a cat, showing an enlarged nasopharyngeal tonsil, infiltrated with a lymphoma.

Management/Prognosis

In dogs, regardless of the chosen therapeutic procedure, prognosis is poor. Chemotherapy will provide varying results with nasal lymphoma in dogs and cats but otherwise is not highly recommended with other tumor types.

Surgery alone is ineffective since local recurrence is a consistent outcome, resulting in survival times comparable to those observed in untreated dogs. However, surgery may be used to achieve cytoreduction, but it must be associated with other treatment modalities. Radiation alone or after cytoreductive therapy has been the standard of care for treating nasal tumors. The most common therapy currently used in veterinary medicine is high-voltage radiotherapy using megavoltage x-ray or cobalt-60 because this method has reportedly improved outcomes compared with other treatments. In order to minimize acute radiation

toxicity, palliative (hypofractionated) protocols are preferred to definitive ones.

Various treatments have been used in dogs for nasal tumors, including cryosurgery, iridium-192 brachytherapy, cisplatin chemotherapy, cyclo-oxygenase inhibitors (piroxicam), tyrosine kinase inhibitors, hydropulsion and some others, that all might have a role in a multimodality or palliative approach, since they showed some efficacy in scarce reports. However, results are difficult to interpret (different protocols, staging systems, tumor types, small number of dogs included, lack of control groups) and further research is needed to evaluate their efficacy.

TUMORS (CATS)

Overview

Lymphoma in cats normally carries a guarded prognosis; however, nasal lymphoma is prognostically the best variant, with a good chance of long-term remission and even a possibility of cure. Response rates to treatment (chemotherapy and/or radiation therapy) average 66%–75%, with reported median survival times of 12–30 months, even when chemotherapy is delivered intraperitoneally. The disease is often localized (**Figure 6.7b**), and the cats are often still eating well and are usually FeLV negative. Negative prognostic factors for nasal lymphoma include anorexia, anemia, and involvement of the cribriform plate, as seen with CT.

FOREIGN BODY

Etiology

Most intranasal foreign bodies are of vegetal origin. Foreign material can be inhaled into the nasal cavity. It can also be stopped at the entrance of the larynx or regurgitated from the esophagus and misdirected toward the nasopharyngeal area where it lodges in the nasopharynx above the soft palate behind the choanae (**Figure 6.8**). Dogs are more commonly affected than cats, and young animals are more frequently affected than older dogs, but the disease can be found in any breed and at any age.

Clinical Presentation

Clinical signs are quite suggestive and include sudden onset of sneezing bouts, nasal pruritus (the animal rubs his nose against the ground or with his paw), and a serous nasal discharge, which can become mucopurulent or even bloody with time. When the foreign body is blocked in the nasopharyngeal area, clinical signs will occur suddenly and consist of reverse sneezing, stertor if the choanal opening is reduced, ptyalism, and gagging. Later, nasal discharge, sneezing, anorexia, and halitosis can occur.

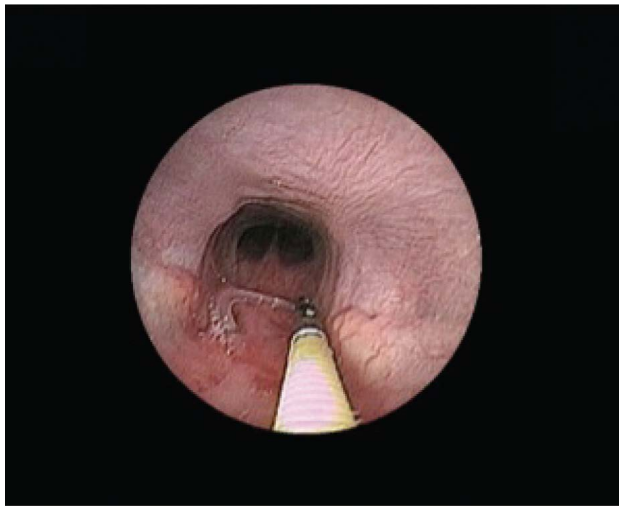

FIGURE 6.8 Retrograde rhinoscopy showing a foreign body in the nasopharynx.

Diagnosis

Diagnosis is confirmed by direct or retrograde rhinoscopy. If performed very early, the nasal foreign body can sometimes be visualized in the anterior nasal cavity and retrieved with the help of an otoscope. This approach will not be feasible if the foreign body has migrated to the caudal nasal cavity. In this case, a rhinoscope is needed. For detection and retrieval of nasopharyngeal foreign bodies, retrograde rhinoscopy is essential.

Management/Prognosis

Early removal is advised. No other treatment is warranted unless severe inflammation and/or turbinate lysis have occurred. In this case, nasal drops containing antibiotics can be prescribed and given intranasally 3–4 times a day for 1 week. Antibiotics can also be administered orally.

Unless the foreign body has caused chronic mucosal inflammatory changes, the prognosis is excellent. However, nasopharyngeal ulceration can potentially lead to secondary nasopharyngeal stenosis.

PARASITIC RHINITIS ("NASAL MITE")

Etiology

This is a rare disease associated with the presence of the nasal mite *Pneumonyssoides caninum*. This nasal cavity parasite of dogs has been reported worldwide; however, details of the parasite's life cycle remain to be elucidated.

Clinical Presentation

Clinical signs include daily repeated episodes of reverse sneezing, sneezing, and mild nasal discharge.

Diagnosis

Diagnosis is based mainly on clinical signs and rarely on visualization of the mites during retrograde or direct rhinoscopy. There is no valid serologic test to confirm the diagnosis, although antibodies were recently demonstrated by ELISA in naturally and experimentally infected dogs.

Management

Treatment is with milbemycin oxime (0.5–1.0 mg/kg p.o. once a week for 3 consecutive weeks). Selamectin (6 mg/kg SC) or ivermectin (0.2 mg/kg SC or p.o. given twice during 3 weeks) is generally successful as well.

NASOPHARYNGEAL STENOSIS AND CHOANAL ATRESIA

Definition/Overview

Nasopharyngeal stenosis is acquired and results from excessive formation of scar tissue in the nasopharynx secondary to a local inflammatory process of infectious, caustic (e.g., passage of acid gastric fluids during regurgitation and vomiting), or traumatic (e.g., foreign body, surgery) origin.

Choanal atresia is a congenital anomaly that results from failure in the development of the communication between the posterior nasal cavities and the nasopharynx (i.e., the formation of the choanae). Atresia can be unilateral or bilateral, partial or total, and bony or membranous.

Clinical Presentation

Both nasopharyngeal stenosis and choanal atresia lead to decreased nasal patency (obstruction of airflow through the nose). Progressive stertor and possibly secondary nasal discharge are present; sometimes, open-mouthed breathing is observed with subsequent respiratory discomfort and inappetence.

Diagnosis/Management/Prognosis

Retrograde rhinoscopy is required for both diagnosis and treatment.

The best therapeutic approaches include balloon dilation of the stenosis and stenting with a metallic stent or silicone tubing (**Figure 6.9a–d**). Balloon dilatation has been reported to result in an immediate improvement or resolution of clinical signs but with high recurrence rates, while stent placement would be associated with a higher success rate but also with a higher complication rate. This gives favorable results for nasopharyngeal stenosis and less favorable prognosis for choanal atresia.

NASOPHARYNGEAL POLYP

Etiology/Pathophysiology

Nasopharyngeal polyps usually affect young cats. Their etiology is unknown. They are made of pedunculated fibrous inflammatory tissue that originates in the eustachian tube and invades the nasopharyngeal area. The polyp may also grow into the middle ear and invade the external auditory tube. In dogs, aural and nasopharyngeal inflammatory polyps are rare.

Clinical Presentation

Because they can lead to unilateral or bilateral nasal obstruction, polyps in the nasopharynx cause stertorous breathing and inspiratory dyspnea. A chronic serous or mucopurulent nasal discharge may be present. Polyps in the middle ear may cause vestibular signs and Horner syndrome. In advanced cases, permanent open-mouthed breathing progressively leads to inappetence and poor general condition.

Diagnosis, Management, and Prognosis

The rostral part of the soft palate may be depressed by the polyp, which can be visualized under anesthesia after rostral retraction of the soft palate. Retrograde rhinoscopy can facilitate polyp visualization in the posterior nasal cavity. Ear canal examination will identify any polyp in this particular location. This is important since surgery, along with tympanic bulla curettage, is the preferred treatment option, leading to cure without recurrence. Radiographic examination of the bullae or high-resolution CT of the skull should be performed if the polyp cannot be visualized on direct examination prior to planning surgery (**Figure 6.10**).

RECURRENT INFECTIOUS RHINITIS IN DOGS

Definition/Overview

Primary acute rhinitis is rare in dogs. Canine distemper virus is the only virus able to induce rhinitis in dogs and is always accompanied by other, more severe, clinical signs.

Etiology, Clinical Presentation, and Differential Diagnosis

A primary etiology should be looked for when clinical signs of mucopurulent rhinitis improve with antibiotic therapy but recur after discontinuation of therapy. Tooth root infection as well as silent bacterial pneumonia

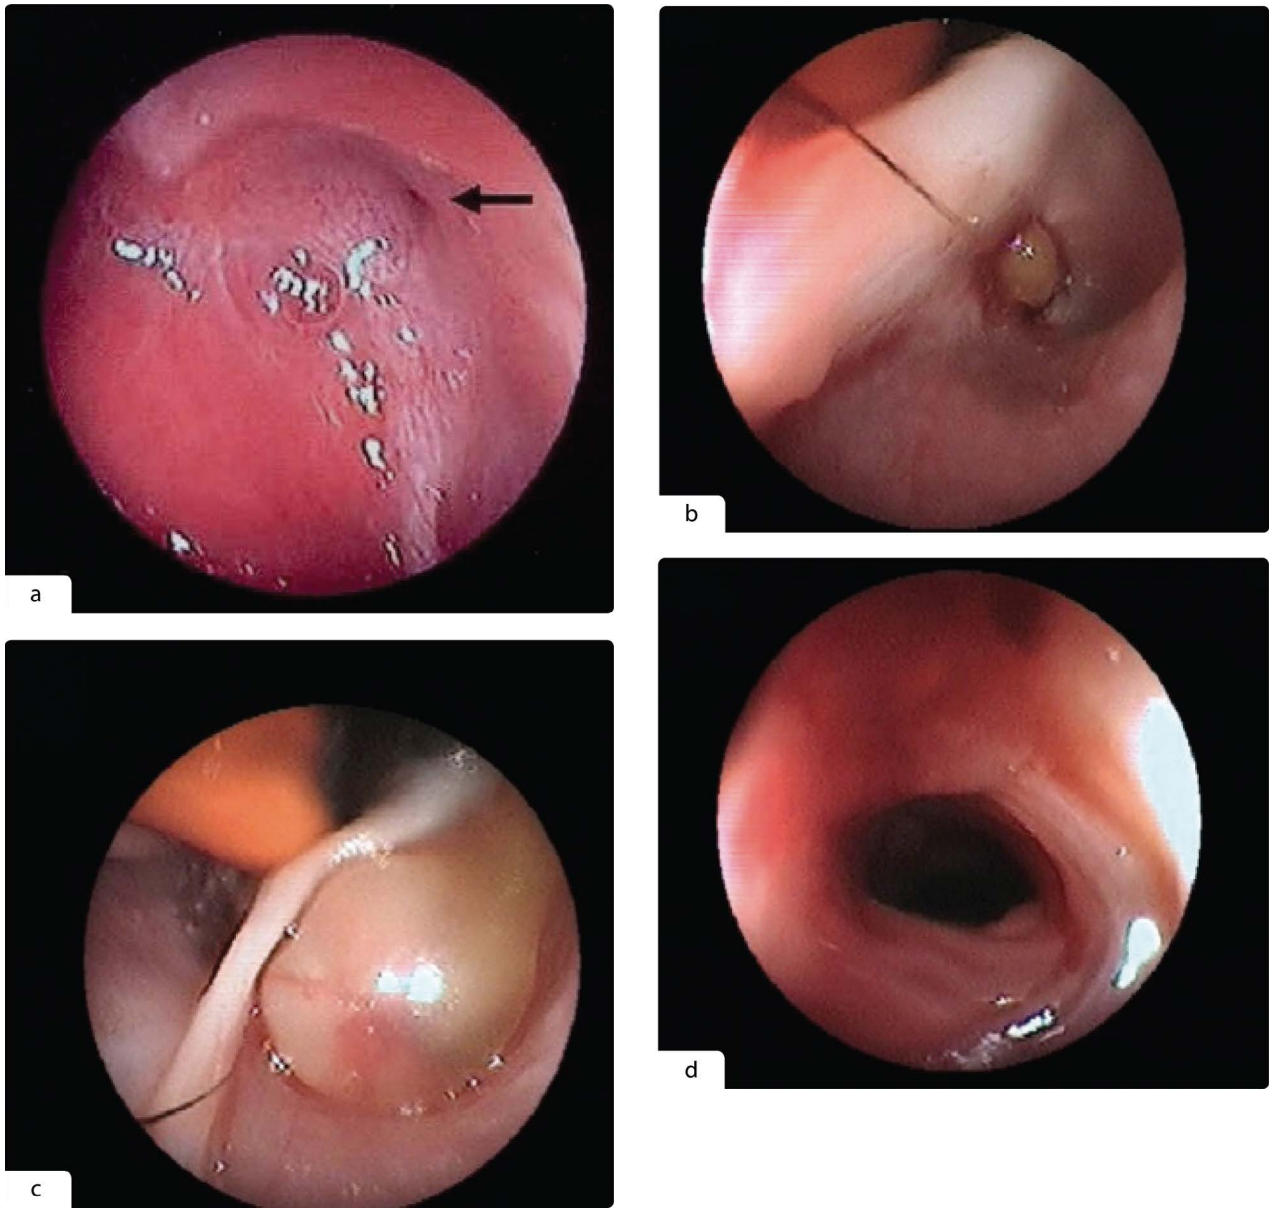

FIGURE 6.9 Retrograde rhinoscopy in a cat with left nasopharyngeal stenosis before **(a)**, during **(b, c)**, and after ballooning **(d)**.

must be ruled out as possible causes. Tooth root infection leading to chronic or recurrent mucopurulent rhinitis is most commonly encountered in middle-aged to old small breed dogs (e.g., Poodles, Yorkshire Terriers) with stomatitis associated with dental tartar. An oronasal fistula can be found in some cases, and the discharge can be malodorous and have a whitish, granular appearance. If clinical signs appear at a very young age, a severe metabolic problem such as immune deficiency (e.g., rhinitis/bronchopneumonia syndrome in Irish Wolfhounds) or a primary ciliary defect should be suspected. In such cases, the nasal discharge is mostly associated with other clinical signs, mainly related to lower airway recurrent infection.

ACUTE FELINE UPPER RESPIRATORY TRACT DISEASE

Definition/Overview

Acute feline URT disease is very common in cats. Young kittens are most commonly affected, but older cats can become infected when exposed to high concentrations of pathogens (e.g., in a shelter environment).

Etiology/Pathophysiology

The most commonly implicated organisms include feline herpesvirus type 1 (FHV-1), feline calicivirus (FCV),

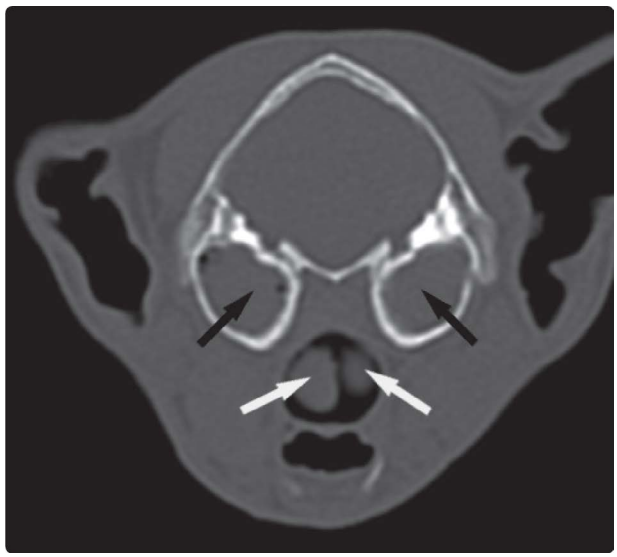

FIGURE 6.10 Transverse CT image of the skull of a cat with bilateral nasopharyngeal polyps showing both tympanic bullae totally filled with soft tissue attenuating masses (black arrows) and the presence of two soft tissue images in the nasopharyngeal lumen (white arrows). (*Courtesy of G. Bolen.*)

Chlamydophila felis, *Bordetella* spp., *Mycoplasma felis*, and influenza virus. Viral infection predisposes to bacterial infection, which can also act as a primary pathogen. Viral infection usually resolves within 10 days, but it is highly contagious, since viral shedding can persist for up to 3 weeks. Moreover, affected cats can become carriers, and viral shedding may be reactivated during periods of stress. FHV-1 is an important cause of morbidity and sometimes mortality. Virulent strains of FCV have been described, leading to pneumonia with a high mortality rate.

Clinical Presentation

Clinical signs are dominated by sneezing and a serous to mucopurulent oculonasal discharge, while fever and systemic illness (lethargy, anorexia, dehydration) are common. *C. felis* is often associated with unilateral or bilateral conjunctivitis and chemosis, and FCV causes lingual ulcers and sometimes pneumonia.

Diagnosis

Viral and bacterial confirmation using isolation or PCR or bacterial cultures are rarely necessary in acute cases in practice unless the disease is associated with high morbidity and mortality in a community of cats (shelters, cattery, or multihouse environments).

Management and Prognosis

Supportive care and systemic antibiotic therapy against secondary bacterial infection are indicated. Many antibiotics can be used. *Chlamydophila* is best treated with doxycycline (10 mg/kg per day for 6 weeks). The efficacy of novel treatments such as lysine and antiviral therapy have not yet been proven in large clinical settings, although the efficacy of some specific antiviral therapies such as oral administration of famciclovir has recently been reported.

Most kittens survive, but mortality is still quite high. Vaccination against viruses may reduce the clinical signs and limit the spread of the disease.

CHRONIC NONSPECIFIC LYMPHOPLASMACYTIC RHINITIS IN DOGS

Definition/Overview

Idiopathic lymphoplasmacytic rhinitis is a common, chronic, and gradually progressive inflammatory nasal disease of unknown etiology associated with varying severity of clinical signs. It is characterized by lymphoplasmacytic to mixed inflammation of the nasal mucosa.

Etiology

The pathogenesis of this disease remains unknown. An aberrant immune response to inhaled organisms or allergens but not to fungi is suspected.

Pathophysiology

In chronic conditions, persistent inflammation of the mucosa leads to loss of epithelium and squamous metaplasia, which reduces the population of ciliated cells present in the distal third of each nasal cavity. Furthermore, hyperplastic subepithelial glands secrete increasingly viscid mucus, which also impedes normal ciliary clearance. As a consequence, mucus plugs accumulate and entrap inhaled bacteria and irritating particles within the nasal cavities, thus perpetuating the inflammation. When this material accumulates in the distal part of the nasal cavities, it obstructs the choanae and tends to induce reverse sneezing as well as heavy efforts to clear the throat and nose.

Clinical Presentation

Clinical signs include sneezing, reverse sneezing, and chronic unilateral or bilateral serous or mucopurulent nasal discharge that is characterized as tenacious and sometimes hemorrhagic in nature. The patient's general condition is usually unaffected.

Differential Diagnosis

Before a diagnosis of chronic nonspecific lymphoplasmacytic rhinitis can be made, other underlying causes such as a nasal or nasopharyngeal foreign body, soft palate defects (where an increased opening between the oropharynx and the nasopharynx leads to misdirection of food/saliva), nasopharyngeal atresia or stenosis, or nasopharyngeal cysts or polyp must be excluded.

Any chronic inflammatory disease of the nasal cavities caused by bacteria or fungi can give rise to progressive chronic lymphoplasmacytic rhinitis. Xeromycteria (dry nose) can also cause mild signs of chronic rhinitis.

Diagnosis

Diagnosis cannot rely on clinical signs. Diagnostic imaging and gross rhinoscopic findings are variable and nonspecific. A nasal mucosal biopsy taken during rhinoscopy shows epithelial and glandular hyperplasia, lymphoplasmacytic infiltration, and sometimes fibrosis. It is important to perform these examinations in order to eliminate other potential causes, such as aspergillosis, tumors, chronic foreign body, tooth root infection, or anatomic abnormalities, which could be treated specifically.

Management

In all chronic nasal diseases with epithelial hyperplasia and glandular hyperplasia, treatment should include local therapy with saline and mucolytics, since the physiological mucociliary clearance protective mechanism is impaired. This can be administered intranasally or by aerosol therapy. Nebulization devices used in human medicine can be used. Treatment entails the intranasal instillation of saline or mucolytic drops 2–4 times daily. Sometimes, the addition of nasal antibiotics becomes necessary in case of secondary bacterial infection. Improvement should occur after 1–3 weeks in most cases; other cases can remain refractory. Some authors advise treatment with prednisone (1 mg/kg q.12h. for 1–2 weeks, followed by a gradual taper) in refractory cases, although this recommendation will vary among different authors.

Prognosis

Although the condition is benign, treatment is unrewarding in some dogs, where clinical signs will fluctuate and require prolonged treatment.

FELINE IDIOPATHIC CHRONIC RHINOSINUSITIS

Definition/Overview

Chronic rhinitis or rhinosinusitis is one of the most common chronic disorders in cats and is characterized by chronic and/or recurrent nasal discharge and sneezing.

Etiology

Although the underlying pathogenesis is unclear, the disease is likely multifactorial. Some chronic forms are presumed to be caused by FHV-1, FCV, *Chlamydophila felis*, or a combination of these agents. FHV-1 is most commonly implicated in the chronic form of disease, since more than half of the cats exposed to the virus remain latent carriers. Secondary bacterial infections and poorly regulated or improper immune responses also play a role in the pathogenesis. There is some evidence that *Bordetella bronchiseptica* is also a cause of chronic respiratory disease in cats. The low prevalence of FeLV and FIV infection in affected cats suggests that these viruses are not responsible for the disease.

Clinical Presentation

Clinical signs include sneezing and chronic unilateral or bilateral nasal discharge of a serous to mucopurulent nature, stertor, and intermittent open-mouthed breathing. The cat's general condition can be affected.

Diagnosis

Rarely, a primary defect can be identified (nasopharyngeal foreign body, soft palate defects, nasopharyngeal stenosis, or nasopharyngeal cysts or polyps). Imaging and/or rhinoscopy can reveal mild-to-severe turbinate remodeling. Microbiologic identification of microorganisms does not usually help manage the disease since they are usually secondary infections. The signs are mostly related to irreversible remodeling of intranasal lesions rather than to bacterial infections.

Management

Currently, treatment is supportive and aims at the consequences of nasal and sinus dysfunction, decreasing inflammation, and eliminating secondary bacterial infections. Cats with chronic rhinosinusitis often have a transient response to antimicrobial treatment. Many antibiotics can be used orally for prolonged periods (from 3 weeks up to 8 weeks or more). When *Chlamydophila* is suspected, doxycycline (10 mg/kg per day for 6 weeks) can be used. The use of azithromycin (10–15 mg/kg q.24h. followed by 5 mg/kg q.48h. or even q.72h.) is helpful for treating cats that are difficult to pill and need prolonged treatment. Intranasal administration of drugs is difficult in most cases because cats are usually intolerant of this treatment method.

Prognosis

Chronic rhinosinusitis is frustrating to manage. Owners must be informed that definitive cure is unlikely, and clinical signs will probably not resolve. Treatment aims at reducing the frequency and severity of clinical signs.

BRACHYCEPHALIC AIRWAY OBSTRUCTIVE SYNDROME

Definition/Overview

The term brachycephalic airway obstructive syndrome (BAOS) refers to a disorder resulting from multiple anatomic abnormalities commonly found in brachycephalic canine breeds, mainly the English and French Bulldog and the Pug. It is also recognized in Persian cats.

Etiology

Conformational anomalies in brachycephalic dogs are related to breeding selection of "hypertypes," which leads to progressive shortening of the face and nose, with subsequent shortening of the bony structures of the skull without concurrent reduction in surrounding soft tissues.

Pathophysiology

Primary inherited abnormalities include stenotic nares (Figure 6.3), elongated soft palate, hypoplastic trachea, and sometimes protrusion of the nasal turbinates into the nasopharynx. In some dogs, the soft palate can be too long in addition to being exceptionally thick; macroglossia can also occur. Secondary lesions develop as a consequence of increased pressures on the pharyngeal, laryngeal, and intrathoracic structures during breathing. These lesions include everted laryngeal saccules, progressive laryngeal collapse, and probably bronchial collapse (mainly collapse of the left main bronchus). In addition, subepiglottic cysts, severe edema of the dorsal aspect of the laryngopharynx, and laryngeal granulomas ("kissing lesions") all further narrow the air passage at the laryngeal inlet. The severity and the combination of these abnormalities will vary. To complicate matters even further, these same dogs can have various accompanying gastrointestinal abnormalities involving the distal esophagus, stomach, and duodenum, including inflammatory disease with coexisting functional or anatomic anomalies (cardiac atony, gastroesophageal reflux, gastric retention, pyloric mucosal hyperplasia, and pyloric stenosis).

BOAS shares some features with obstructive sleep apnea (OSA) in humans, a syndrome characterized by recurrent collapse of the upper airway during sleep leading to intermittent hypoxia. Like OSA, BAOS can also be associated with sleep apnea and decreased survival as a result of cardiovascular and thromboembolic disorders, metabolic derangements, and liver disease.

Clinical Presentation

The abnormalities associated with the BAOS impair air flow through the upper airways and cause clinical signs of upper airway obstruction, including noisy respiration, stridor, stertor, exercise and heat intolerance, respiratory distress, cyanosis, syncope, gagging and retching, and sometimes sleep apnea. The clinical signs are exacerbated by exercise, excitement, and high environmental temperatures. As a result, some dogs can be presented with life-threatening clinical signs of airway obstruction. Digestive signs such as regurgitation and vomiting are common. Secondary aspiration pneumonia is also a common associated finding and must be addressed.

Diagnosis

A tentative diagnosis can be based on the breed and clinical signs. Laryngoscopy (Figure 6.11a–e) and radiography (Figure 6.12) are essential diagnostics. Other procedures such as retrograde rhinoscopy, bronchoscopy, and gastroscopy might be necessary in order to assess the full scope of the existing abnormalities and will be helpful in providing an accurate prognosis and the best treatment recommendation. Additionally, HRCT of the skull and measurement of respiratory function using plethysmography allow to make a quantitative assessment of several causal anatomical lesions and can be used to both help predict severe disease and select the best surgical approach.

Management

Animals presented with life-threatening upper airway obstruction should be cooled, oxygenated, sedated, and if necessary anesthetized and intubated. A tracheotomy might be indicated in cases of severe upper airway occlusion. In other cases, medical therapy consisting of anti-inflammatory doses of short-acting glucocorticoids (prednisone, 0.5 mg/kg q.12h.) will suffice. Surgical widening of stenotic nares and surgical removal of excessive soft palate (Figure 6.13) and everted laryngeal saccules are classically performed if there are no complicating abnormalities, such as laryngeal or tracheal hypoplasia, which would impair treatment success.

Since computed tomography together with anterior and posterior rhinoscopy allow evaluation of the level endonasal obstruction, laser-assisted turbinectomy (LATE) using a diode laser can be used to remove nasal conchae that are causing airway obstruction and can be performed as part of a multilevel surgery. Additionally, isolated LATE of caudal aberrant turbinates (CAT) can be used for the treatment of brachycephalic dogs with obstructing CAT.

Corrective surgical procedures should be done as early in life as possible in order to decrease the consequences of long-term negative pressure on the airway structures (laryngeal cartilage collapse). Once severe laryngeal dysfunction occurs, successful management is much more difficult. Cricoarytenoid lateralization combined with thyroarytenoid caudolateralization, arytenoid laryngoplasty, or permanent tracheostomy might be necessary in the setting of severe laryngeal pathology. If tracheal hypoplasia with its associated ventilation impairment is still severe after reaching adult size (at 1 year of age), there is nothing else that can be done to remedy the situation. Stress, excitement, and weight gain must be avoided in these animals.

Digestive tract medical treatment combined with upper respiratory surgery appears to decrease the complication rate and improve the prognosis of dogs presented for upper respiratory syndrome.

Prognosis

Prognosis depends on the severity of the abnormalities and the ability to surgically correct them. Laryngeal collapse and tracheal hypoplasia are poor prognostic indicators.

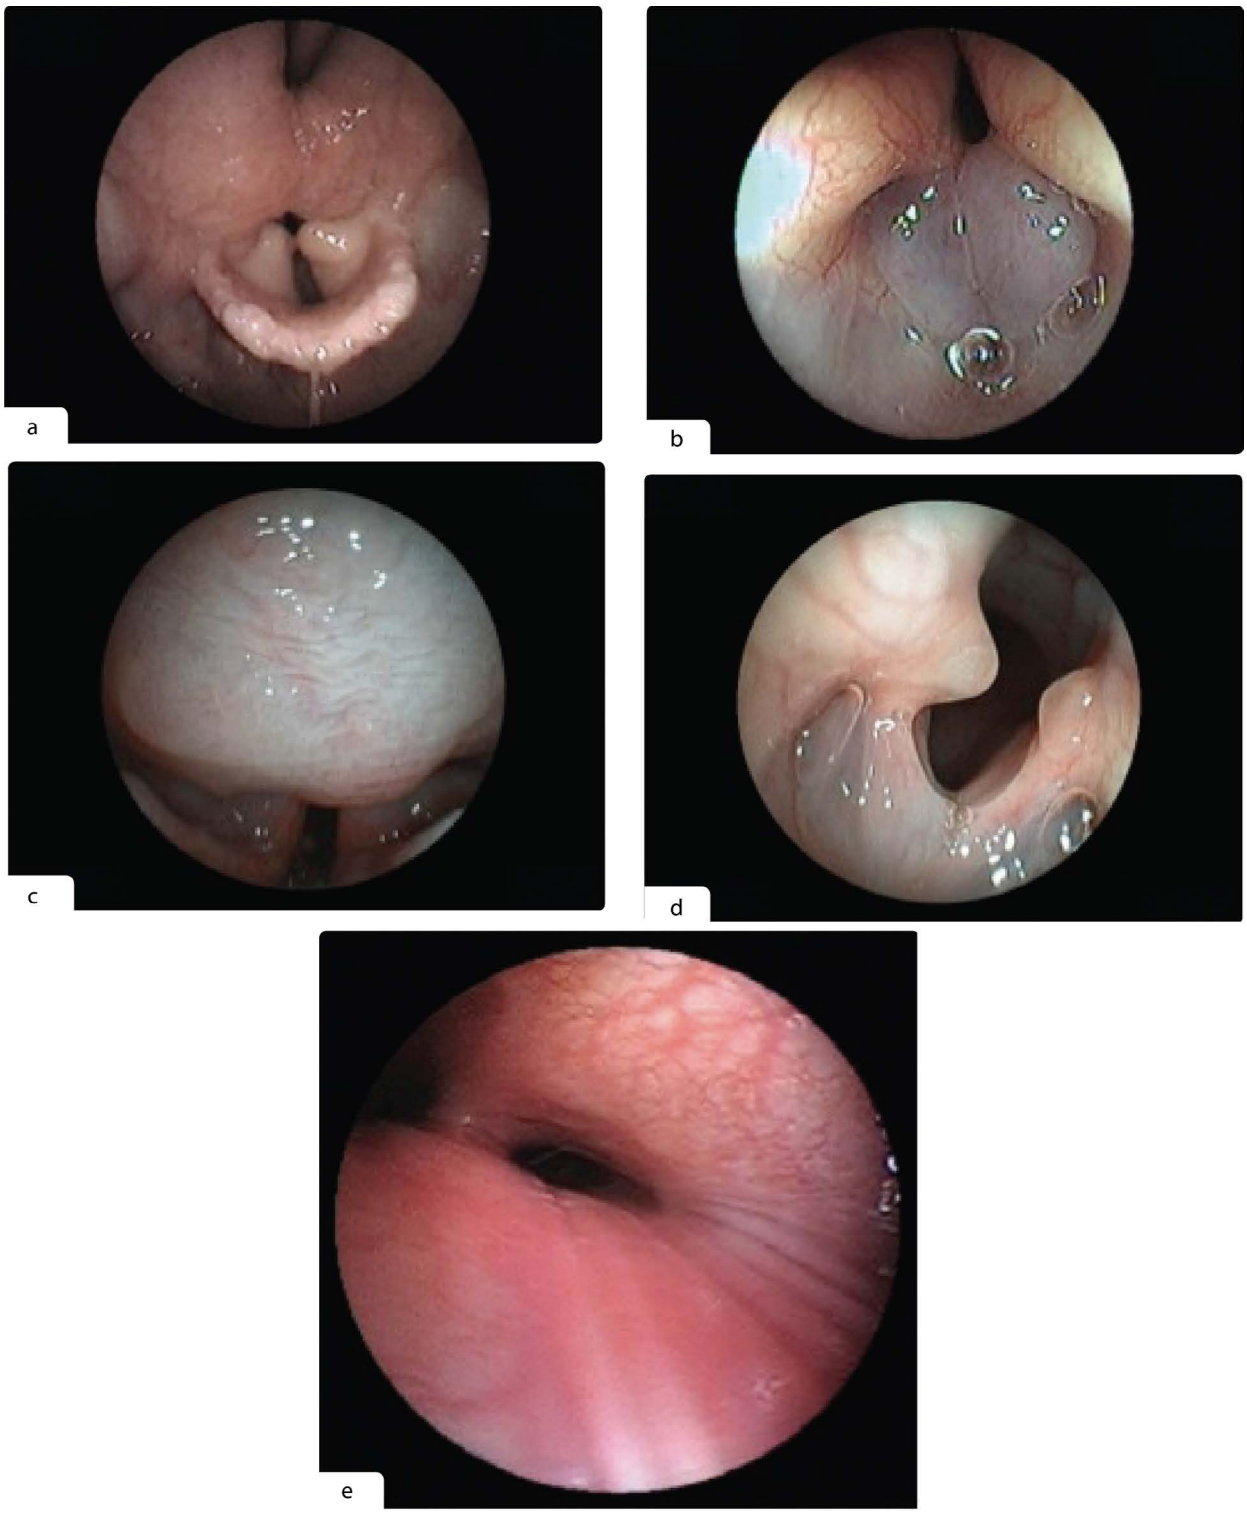

FIGURE 6.11 Laryngoscopic features of BAOS. **(a)** Elongated soft palate; **(b)** everted laryngeal saccules; **(c)** severe edema of the dorsal part of the laryngopharynx; **(d)** intralaryngeal granuloma ("kissing lesion"); **(e)** localized bronchomalacia at the level of the left mainstem bronchus.

A combination of primary and secondary changes can progress to life-threatening laryngeal collapse in many brachycephalic dogs. Early recognition of the primary anatomic abnormalities is essential, since it allows the clinician to make early recommendations for medical and surgical management, which can improve the quality of life in affected animals. Factors that may increase the risk and further complicate the condition include obesity, overexcitement, and exercise.

LARYNGEAL DISEASES

LARYNGEAL PARALYSIS (DOGS)

Definition/Overview

Laryngeal paralysis (Figure 6.14) refers to lack of abduction of the arytenoid cartilages during inspiration due to loss of innervation of the intrinsic musculature of the larynx through the recurrent laryngeal nerves and resulting in inspiratory dyspnea.

Etiology

Laryngeal paralysis is most often of unknown cause and is named idiopathic laryngeal paralysis, although some of the affected dogs may then develop a progressive generalized neuropathy. This is most commonly observed in middle-aged to old, large breed animals (Labrador Retrievers seem to be predisposed). Congenital laryngeal paralysis appears to be inherited and has been reported in breeds such as the Bouvier des Flandres and Husky. Young Dalmatians, Rottweilers, and Great Pyrenees can acquire laryngeal paralysis as part of a polyneuropathy complex. Masses or trauma involving the ventral neck region or the anterior thoracic cavity can damage the recurrent laryngeal nerves and cause unilateral or bilateral paralysis or paresis. Laryngeal paralysis has also been reported in dogs as a manifestation of various peripheral neuropathies or polyneuromyopathy complex, resulting from immune-mediated diseases (such as myasthenia gravis), endocrinopathies (such as hypothyroidism), or other systemic disorders.

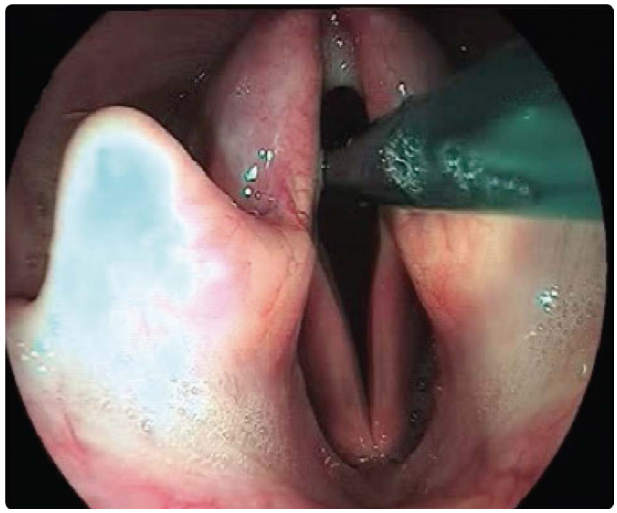

FIGURE 6.14 Laryngeal paralysis. Endoscopic image of the larynx during inspiration, showing a lack of abduction.

Clinical Presentation

The clinical signs vary in severity. The characteristic signs of dyspnea and stridor result from increased airflow resistance occurring during inspiration. They are initially prominent during the inspiratory phase of respiration in association with exertion, excitement, or exposure to high environmental temperatures. As the reduction in laryngeal diameter worsens, the signs can occur during both inspiration and expiration and even at rest. Changes in bark can also occur. Cyanosis and syncope are observed in advanced cases when secondary edema further narrows the glottis, exacerbating the signs and creating a vicious circle. As a result, some dogs may present with life-threatening upper airway obstruction. Some dogs with laryngeal paralysis exhibit gagging or coughing while eating. Secondary aspiration pneumonia is a possible complication.

Diagnosis

The clinical features of laryngeal dysfunction are easily identified. Direct laryngoscopic examination under light anesthesia allows for visualization of this disorder and differentiation from laryngeal edema,

laryngeal tumor, or collapse. Weak, fluttering movements of the arytenoid cartilages and vocal folds may be observed due to changes in airway pressure and airflow and should not be confused with normal movements. Since anesthesia impairs laryngeal motion (moderate-to-deep planes of anesthesia result in cessation of all laryngeal movement), administration of doxapram hydrochloride (1.1–2.2 mg/kg IV), a potent respiratory stimulant, during laryngeal examination is useful for differentiating normal dogs from dogs with laryngeal paralysis. Electromyographic studies of the intrinsic laryngeal muscles done under general anesthesia and ultra-sonographic evaluation of the larynx have also been used to assess laryngeal function. Once a diagnosis of laryngeal paralysis is established, additional diagnostic tests should be considered to identify an underlying cause.

Management/Prognosis

Animals presented with life-threatening upper airway obstruction should be cooled, oxygenated, and sedated. Some may require general anesthesia and intubation, while other extreme cases require a tracheotomy. In less severe situations, initial therapy can begin with anti-inflammatory doses of short-acting glucocorticoid drugs (prednisone, 0.5 mg/kg q.12h., followed by progressive tapering). This reduces the inflammatory reaction and alleviates some of the clinical signs. Surgery is inevitable and should be done as soon as possible. The recommended procedure is unilateral arytenoid lateralization. Aspiration pneumonia is the most common postoperative complication. Suture breakdown is another postoperative complication. However, most owners are ultimately pleased with the outcome. Poor outcomes are associated with underlying diseases causing a more generalized polyneuropathy.

LARYNGEAL PARALYSIS (CATS)

Laryngeal paralysis appears to be infrequent in cats. Both unilateral and bilateral dysfunctions have been documented, although left-sided unilateral paralysis is predominant. This condition can result from trauma or some other destructive process of the recurrent laryngeal nerves or in cases where the cause is idiopathic. Conservative management (weight loss, minimization of excitement, and anti-inflammatory therapy) and surgical treatment are mostly successful.

LARYNGEAL TUMORS

Definition/Overview

Laryngeal neoplasms are rare (Figure 6.15a–c). They are mainly carcinomas, which affect middle-aged to older dogs. However, younger dogs, especially Labrador Retrievers, can be affected with rhabdomyoma, which is a benign tumor. Tumors of tissues surrounding the larynx, such as thyroid carcinomas and lymphomas,

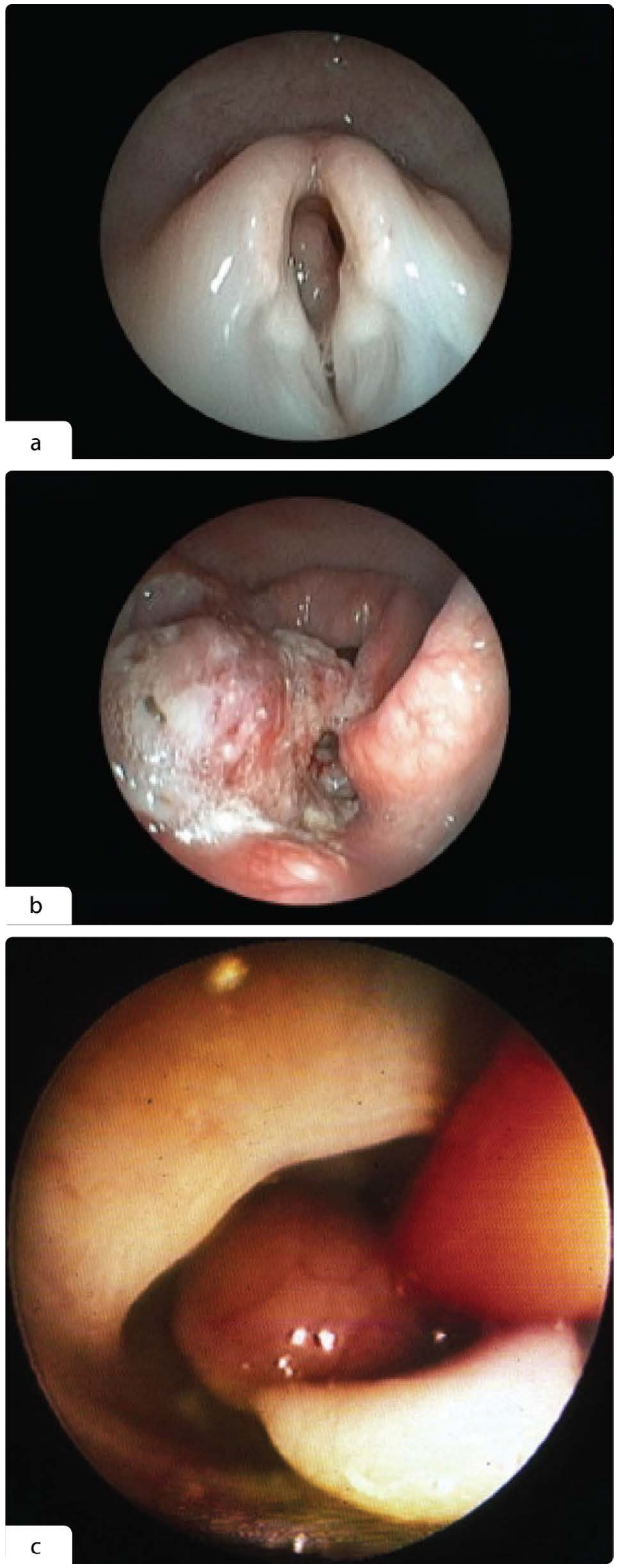

FIGURE 6.15 Laryngeal tumors in a cat **(a)** and two dogs [**(b)** adenocarcinoma; **(c)** rhabdomyoma].

can also compress and invade the larynx, causing similar signs of upper airway obstruction.

Clinical Presentation

The clinical features of laryngeal tumors are similar to those of other laryngeal diseases and include stridor, dyspnea, changes in bark, and cyanosis.

Differential Diagnosis

Includes laryngeal paralysis, foreign body, abscess, and traumatic granuloma.

Diagnosis

Primary laryngeal tumors are best identified by laryngoscopy. It is very important to make the diagnosis on the basis of histopathologic examination of a biopsy of the mass rather than on the gross appearance alone, since some tumors are benign, and some growths are actually granulomas. CT can be helpful in assessing the extent of the mass and in making a decision for surgery.

Management/Prognosis

Benign tumors should be excised surgically, and, in case of rhabdomyoma, the prognosis is excellent when surgical excision is complete. In cases of malignant tumors, complete surgical excision is rarely achievable, and complete laryngectomy and permanent tracheostomy are the only surgical options.

LARYNGEAL EDEMA

Definition/Overview/Etiology

Edema or infiltration of the larynx with inflammatory cells occurs frequently. It can be secondary to paralysis, tumor, or trauma and is seen in brachycephalic dogs with BAOS. In cats, the larynx is very sensitive, and edema can develop after faulty intubation technique or following an excessive application of local anesthetic agent. In some cases, the cause is not determined.

Clinical Presentation

Clinical signs are those typical of an upper airway obstruction and identical to those observed in laryngeal paralysis. They range from exercise intolerance and stridor after excitement to life-threatening respiratory distress.

Differential Diagnosis

Apart from the primary causes (paralysis, tumor, trauma, BAOS, intubation), chronic laryngitis, due to excessive and repeated barking, and laryngospasm ("glottis cramp") can also cause some degree of laryngeal edema. In cats, severe edema and laryngeal neoplasms can appear similar.

Diagnosis

Laryngoscopy shows irregular proliferation, hyperemia, and swelling of the larynx. Additional diagnostic procedures, such as biopsy or brush cytology or fine-needle aspiration, should not be performed when the laryngeal opening is severely reduced unless a temporary tracheostomy is in place, especially in cats. It is prudent to first treat the patient medically before instituting any interventional procedures.

Management/Prognosis

Most animals respond to glucocorticoid therapy within a couple of days. Prednisone (0.5–1.0 mg/kg q.24h. to q.12h.) is used initially. The dose can be gradually tapered over the next 3 weeks once the signs have resolved.

The prognosis is good unless the response to medical treatment is poor. In such cases, tracheostomy should be considered.

TRACHEAL DISORDERS

TRACHEAL COLLAPSE AND MALACIC AIRWAYS

Definition/Overview

Tracheal collapse is a very common disorder characterized by dorsoventral flattening of the tracheal rings with laxity of the dorsal tracheal membrane. Bronchial collapse, essentially of the left cranial lobar bronchus, is often present as well. The syndrome is encountered in middle-aged to older toy or miniature breeds (Yorkshire Terrier, Miniature Poodle, Chihuahua, Pomeranian, Shih Tzu, Lhasa Apso). The sound of the cough is a characteristic "honking noise" or "goose honk."

Etiology/Pathophysiology

The cause is complex and is best regarded as multifactorial. The development of the clinical condition requires the presence of a primary cartilage abnormality, resulting in intrinsic weakness of the tracheal rings, together with secondary factors capable of initiating progression to the symptomatic stage. These potential triggering factors include obesity, cardiomegaly, inhalation of irritants and allergens, periodontitis, respiratory infections, and recent endotracheal intubation. The dynamic changes of tracheal collapse may be confined to either the cervical or thoracic region of the trachea or both and are frequently more pronounced at the cervicothoracic junction. In dogs with tracheal collapse, concurrent bronchomalacia is frequently encountered.

Once clinical signs occur, the syndrome is perpetuated by the cycle of chronic inflammation of the tracheal mucosa and the accompanying cough reflex.

Clinical Presentation

Clinical signs include chronic cough, mild-to-severe panting, and varying degrees of inspiratory and expiratory dyspnea (respiratory distress). Cyanosis can occur in extreme cases. The cough is harsh, followed by a terminal retch, and is generally described as "goose honk," which is precipitated by activity, excitement, tracheal pressure (such as caused by pulling on a leash), or drinking. This characteristic cough can be easily elicited by palpation of the trachea.

Differential Diagnosis

Includes chronic mitral valvular heart disease, which can be a concurrent disease, chronic bronchitis, chronic tracheitis (both possibly secondary to tracheal collapse), and chronic pulmonary parenchymal disease such as idiopathic pulmonary fibrosis.

Diagnosis

Radiographic examination of animals with a collapsed trachea can be done with both still and motion studies. The most useful radiographic examinations include lateral projections of the thoracic inlet, a tangential (rostrocaudal) projection of the thoracic inlet, and fluoroscopic investigation to demonstrate movements of the dorsal membrane during the respiratory cycle. On lateral radiographs, a redundant dorsal tracheal membrane that invaginates into the tracheal lumen can be seen as a soft tissue opacity along the dorsal aspect of the caudal cervical tracheal lumen. During inspiration, it will cause an increased tracheal diameter. This condition can be seen in both small and large breed dogs as a consequence of coughing and must be differentiated from a superimposed esophagus. Therefore, lateral radiographs made during both the maximal inspiratory and expiratory phases (Figure 6.16) of the respiratory cycle are needed to demonstrate a dynamic collapse. Collapse of the cervical tracheal segment occurs in inspiration because of decreased pressure within the trachea, whereas the thoracic portion tends to collapse during the expiration phase as a consequence of increased intratracheal pressure. These dynamic changes are best viewed in real time using image-intensified fluoroscopy. In the skyline projection, the trachea is seen as an oval, "C" or crescent shape.

Tracheoscopy, although rarely needed to confirm the diagnosis, reveals a decreased dorsoventral diameter due to flattening of the cartilaginous rings, with a pendulous dorsal membrane. A severe collapse can cause complete obstruction of the tracheal lumen (Figure 6.17a, b). Tracheobronchoscopy is helpful in determining the degree of severity of the tracheal and, especially, the bronchial collapse, as well as in assessing concomitant airway disease. Radiographs greatly underestimate the incidence of bronchomalacia. Therefore, bronchoscopy is recommended in all cases of suspected tracheal collapse before stent placement is considered because the presence of severe bronchomalacia and/or lower airway disease may impact on the prognosis after stent placement.

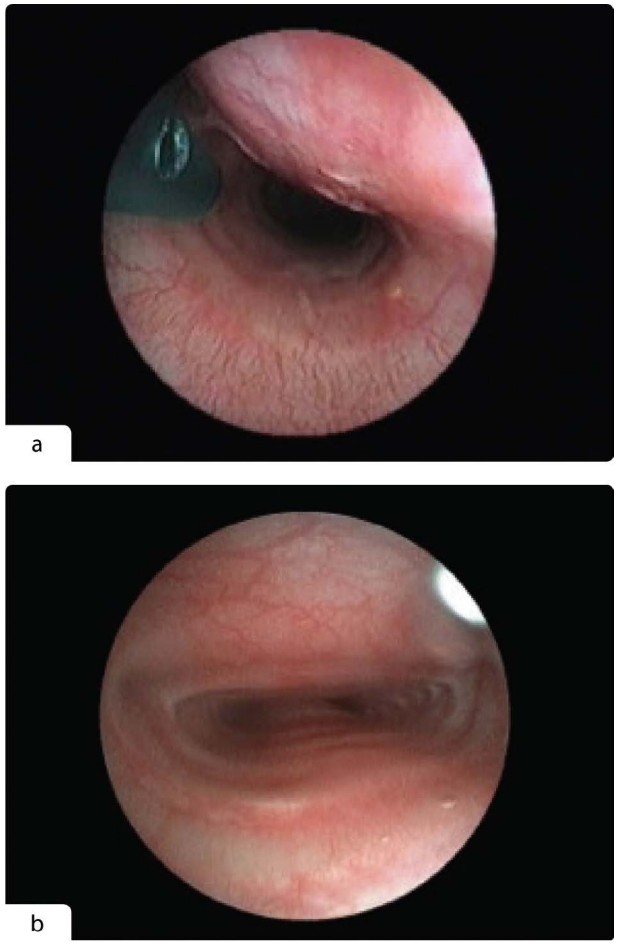

FIGURE 6.17 Endoscopic views of the trachea showing grade 2 **(a)** and grade 4 **(b)** tracheal collapse.

Management

In animals with marked respiratory difficulty, oxygen supplementation should be provided along with sedation and antitussive agents. Butorphanol (0.05–0.2 mg/kg q.4–6h.) and acepromazine (0.01–0.1 mg/kg) can be injected SC in order to alleviate anxiety, and prednisolone sodium succinate (15–30 mg/kg IV) can be administered to decrease acute inflammation.

Long-term treatment aims principally at decreasing potential promoting factors and the level of inflammation of the tracheal mucosa. Weight reduction in obese animals is essential. Weight loss alone can sometimes be curative in terms of dealing with the clinical signs. Likewise, removal of the neck collar and its replacement by a harness can be helpful. Removing the dog from respiratory irritants such as noxious gases, smoke, and dust is essential. It is also important to detect and treat other diseases such as chronic airway disease, cardiac disease, or Cushing's disease.

Some authors recommend short- to long-term therapy consisting of very low-dose steroids orally (prednisone, 0.2 mg/kg daily for 2 days to 2 weeks, followed by the same dose every other day, then at 3-month intervals) or by inhalation (fluticasone, 120 µg puff q.12h. using a face mask and spacer). Short-term administration of sedatives such as acepromazine can be useful in very excited animals to break the cough/excitation/cough cycle. However, oversedation must be avoided because the animal will benefit from limited exercise as far as weight gain and airway clearance is concerned. Oral antitussive agents are effective in controlling symptoms (e.g., hydrocodone 0.22 mg/kg q.12h. or butorphanol 0.55 mg/kg q.12h.). Bronchodilators (methylxanthines or beta agonists) can also be used, their benefits being due to a reduction in bronchoconstriction, thereby reducing intrathoracic pressures and the associated collapse of the larger airways. Furthermore, they improve mucociliary clearance and reduce diaphragmatic fatigue.

In dogs that do not respond to medical management, intraluminal self-expanding stenting devices may be placed. Determination of the appropriate size and type of the stent is a critical step. In some dogs, this minimally invasive technique is the only successful treatment option. Tracheal prosthetic devices are very expensive, and their use is not without complications. These include stent displacement/migration, rupture, stent detachment with development of purulent pockets between the stent and the tracheal mucosa, and inflammatory granuloma (Figure 6.18). The inflammatory complications might respond to oral or nebulized glucocorticoid drugs. It is important to note that the tracheal stent might not benefit the dog if bronchial collapse and bronchomalacia are present together with tracheal collapse.

Prognosis

Most animals can improve with an individualized treatment plan, but the condition is generally progressive and the long-term prognosis poor, especially when irreversible airway collapse is present.

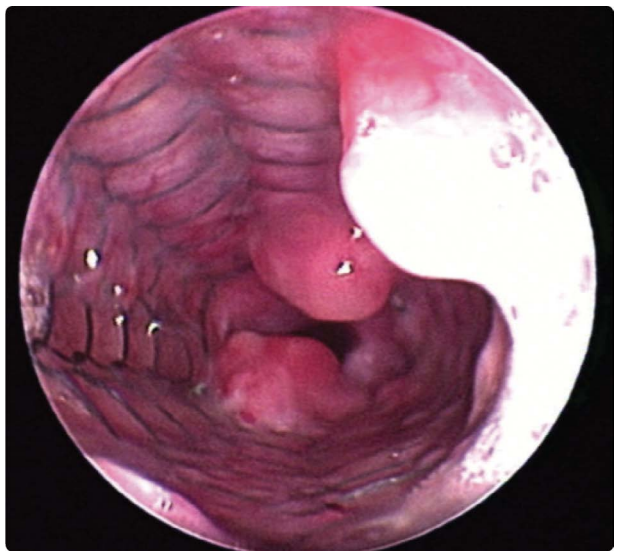

FIGURE 6.18 Endoscopic view of the trachea of a dog 6 months after stent placement, showing exuberant granulation tissue filling most of the tracheal lumen.

TRACHEAL INJURIES (CATS)

Definition/Overview

Tracheal injuries range from small lacerations to tracheal avulsions and can be caused by intraluminal or external trauma. Intraluminal trauma is mostly associated with endotracheal intubation, while external trauma is most commonly the result of blunt trauma to the thorax. Often the diagnosis and treatment are delayed, resulting in attempted surgical repair months or even years after the injury.

Etiology

Stenosis occurs after laceration, necrosis, or rupture following endotracheal intubation associated with over inflation of the endotracheal tube cuff. A blunt traumatic incident to the neck or thorax or both probably includes a hyperextension injury of the head and neck. This stretches the trachea and ruptures it intrathoracically.

Pathophysiology

After the avulsion injury, the airway lumen is thought to be maintained by either intact tracheal adventitia or by thickening of mediastinal tissue, leading to the development of a pseudoairway. Rupture and avulsion of the trachea result in stenosis of the lumen at both ends of the injury.

Clinical Presentation/Diagnosis

Apart from some possible cough, clinical signs of inspiratory distress and tracheal stridor are delayed and are due to tracheal obstruction. In acute cases, subcutaneous emphysema can be seen over the cervical and

thoracic areas due to air escaping from the trachea into the subcutaneous tissue.

Diagnosis is confirmed by thoracic radiography and tracheoscopy.

Management/Prognosis

Surgical management consists of resection of the stenosed end(s) of the injured trachea and subsequent repair by anastomosis. The prognosis is good.

TUMORS

Intratracheal tumors are rare. The tracheal lumen can also be reduced by an extrathoracic tumor, such as a mediastinal tumor, which will cause deviation or compression of the trachea.

LOWER AIRWAY AND LUNG DISORDERS

APPROACH TO PATIENTS WITH LOWER AIRWAY AND LUNG DISEASE

Diagnosis of lower airway disease is based on history, physical examination, blood testing, radiography, ultrasonography, CT, and on more invasive techniques (e.g., transtracheal aspiration, bronchoscopy and bronchoalveolar lavage [BAL], transthoracic fine-needle aspiration, transthoracic or open-chest lung biopsy). Pulmonary function tests are not commonly used.

Signalment, origin, present environment, vaccination, and prior medical problems must be assessed before detailing the current complaint and previous treatment. Signs typical of lower respiratory tract (LRT) disease include cough, exercise intolerance, dyspnea, hypoxemia, cyanosis, and systemic signs such as anorexia, depression, weight loss, and fever. Determination of the type of breathing pattern is provided by inspection of the thorax. Respiration should be observed for rate, depth, and regularity. Increased respiratory rate, which is sometimes the only visible sign, may be difficult to differentiate from stress-induced polypnea. Careful and symmetrical auscultation of the lung fields may indicate increased normal breath sounds, crackles, and wheezes as well as silent areas. The thorax should be percussed to assess resonance. A dull note will be obtained with significant lung consolidation and pleural effusion. Again, comparison of percussion notes obtained on the left and right sides is essential, especially in cases where there is a unilateral thoracic problem.

Noninvasive methods include radiography, ultrasonography, and CT. Radiography is still the preferred initial diagnostic test in respiratory medicine. Thoracic radiographs are absolutely essential for proper evaluation of dogs and cats with bronchopulmonary diseases. Thoracic radiographs should be obtained and interpreted before doing any other more invasive procedure. Correct radiographic technique, knowledge of thoracic anatomy, and skilled radiographic interpretation will maximize the amount of information derived from radiography.

Ultrasonography is used to evaluate pulmonary mass lesions adjacent to the body wall and consolidated lung lobes. The consistency of the lesions can often be determined (solid or fluid-filled), and vascular structures may be visible, which can help diagnose lung lobe torsion. It can also be used to guide biopsy instruments into solid masses for specimen collection. Point-of-care ultrasound (POCUS), including lung ultrasound (LUS), is gaining interest in veterinary medicine. Abnormalities found on LUS in dogs with various underlying causes of cough in the canine have recently been described. Echocardiography helps distinguish respiratory from cardiac diseases. High-resolution CT is used for evaluation of patients with intrathoracic diseases (e.g., interstitial pulmonary diseases such as idiopathic pulmonary fibrosis or lung lobe torsion) or for determining the extent of intrathoracic mass lesions before considering surgery.

More invasive techniques for cell and tissue sampling include transtracheal wash, endotracheal tube bronchial wash, bronchoscopy with BAL, percutaneous fine-needle aspiration, and lung biopsy obtained through surgical or endoscopic thoracic exploration.

Bronchoscopy allows for examination of the tracheobronchial tree and identification and localization of structural abnormalities of the major airways. It can detect the presence of mucus, pus, or hemorrhage in the airways. It is also used to assess for intraluminal foreign bodies, granulomas, neoplasia, and parasites. It allows for the detection of abnormal mucosal surfaces (Figure 6.19) as well as the presence of bronchiectasis and airway patency.

Specimen collection techniques performed in conjunction with bronchoscopy include BAL and various mucosal biopsy techniques. The latter include periendoscopic pinch mucosal biopsy, periendoscopic mucosal

FIGURE 6.19 Bronchoscopic view of a dog with eosinophilic bronchopneumopathy showing the thickened and polypoid appearance of the bronchial mucosa.

brush for cytologic smears, and transbronchial biopsy. A familiarity with the bronchoscopic anatomy of bronchopulmonary structures is helpful. An endobronchial nomenclature for a systematic evaluation of the canine and feline airway systems has been proposed. The nomenclature enables the bronchoscopist to locate the lesions, correlate bronchoscopic and diagnostic imaging findings, and assess the lesions throughout the course of the disease. The procedure also allows for photography of the lesions. Animals undergoing bronchoscopy require general anesthesia, even though they are at increased risk of anesthetic complications. Allowing for the delivery of oxygen before, during, and after the procedure helps avoid oxygen desaturation but does not remove the risk of iatrogenic pulmonary decompensation. Other concerns include the expense of the equipment and the need for proper training of the bronchoscopist. A pediatric bronchoscope (diameter of about 3.6–5.0 mm) is the preferred equipment for this procedure. Bronchoscopes are expensive, delicate, and fragile and need to be handled, used, and cleaned with the utmost care. Additional equipment for optimal sampling includes brush catheters and biopsy and retrieval forceps. If available, the endoscope should be connected to equipment with video projection capability.

In cats with chronic cough and/or dyspnea, the procedure is considered less safe than in dogs, mainly due to the small size of their airways and the greater degree of airway irritability. The procedure can be performed rapidly by a skilled, experienced endoscopist, which limits the risks to the patient.

The risk-to-benefit ratio should be evaluated before each endoscopy. BAL can be performed with or without an endoscope. The procedures require anesthesia, preoxygenation, and in cats premedication with a bronchodilator such as a single 100 μg puff of aerosolized albuterol, administered through an inhaler and a face mask, or terbutaline orally. Pulse oximetry should be available throughout the procedure until full recovery. When performing bronchoscopic BAL, several small aliquots of warmed sterile saline, using either weight-adjusted (2 mL/kg) or fixed-amount volumes of lavage fluid, are instilled either into the channel of the endoscope or through a sterile catheter passed into this channel. It is important that the endoscope is properly cleaned and disinfected, including the insertion and retrieval channels, prior to each procedure. Nonetheless, contamination of the endoscope by colonizing bacteria is not uncommon, and this possibility should always be kept in mind while interpreting microbiological results from BAL fluid analysis.

Alternatively, endotracheal tube bronchial washing or a tracheal wash (TW) can be performed to obtain a bronchial fluid specimen. A sterile catheter is passed through the endotracheal tube, or it can be inserted between two tracheal rings into the distal trachea. The recommended volume of fluid varies among different authors, with each aliquot ranging from 5 to 15 mL. A smaller volume consisting of 0.5 mL/kg is likely to cause less bronchospasm in cats and small breeds of dogs. For medium- to large-sized dogs, the lavage volume can range from 5 to 40 mL or approximately 2 mL/kg. The fluid is instilled through the catheter and immediately aspirated. The technique provides fluid and cells that can be used to identify diseases involving the major airways while bypassing the normal flora and debris of the oral cavity and pharynx. The advantages of this technique compared with BAL are that the procedure is inexpensive and minimally invasive. The procedure can be performed in awake or sedated animals. Potential complications are rare and include tracheal laceration, subcutaneous emphysema, and pneumomediastinum. Disadvantages are that the lesions and site of sampling cannot be visualized, and the TW fluid analysis is less likely to identify interstitial, alveolar, or focal disease processes compared with BAL fluid analysis.

Both BAL and TW fluids are evaluated cytologically and microbiologically and, therefore, should be collected before initiation of antibiotic treatment whenever possible. Semiquantitative bacterial culture allows for identification of organisms and antimicrobial susceptibility testing. Healthy dogs and cats have bacteria in their airways that can be cultured. Therefore, the significance of organisms must be interpreted in conjunction with the cytologic findings and other clinical data. Cells collected in BAL and TW fluids are fragile and must be quickly and meticulously processed. Nucleated cell counts and differential cell counts are performed. The cells are evaluated qualitatively for determination of the type of inflammation (neutrophilic, eosinophilic), evidence of macrophage activation, neutrophil degeneration, lymphocyte reactivity, characteristics of malignancy, and presence of infectious agents.

Transthoracic needle biopsy is very useful in identifying diffuse interstitial peripheral lesions and solitary lesions of the lung that are located adjacent to the thoracic wall. It also allows for sampling and identification of infectious agents. Samples can be collected using large-bore biopsy or fine-needle aspiration techniques. The site for sampling must be carefully selected radiographically, and the accuracy of sampling can be improved by using ultrasonograhic guidance. In most cases, this technique does not require general anesthesia and does not require expensive or sophisticated material. Potential complications with fine-needle aspiration, although rare, include pneumothorax, hemoptysis, and bleeding.

Open-chest biopsy is a diagnostic test of last resort because of the invasiveness, cost, degree of morbidity, and danger of mortality associated with this technique. It is advised when exploratory thoracotomy might also be therapeutic or when it will result in confirmation of a negative prognosis (diffuse metastasis) and justification for euthanasia during surgery.

Video-assisted thoracoscopy, allowing lung biopsy as well as therapeutic procedures, is a very helpful technique since it is much less invasive than open-chest procedures but offers the same advantages of direct visualization and sampling of the lesion. However, this technique requires special skills and expensive equipment, thus limiting its availability.

Pulmonary function tests can be useful in the diagnosis and evaluation of patients with pulmonary disease. LRT diseases can result in inadequate oxygenation due to decreased ventilation, improper matching of ventilation and perfusion within the lung (V/Q mismatching), and interference with the diffusion of gases across the alveolar membrane. Diseases in small animals can affect these two major physiological functions. Blood gas measurement and calculation of alveolar and arterial oxygen concentrations (A–a gradient) is currently available for assessment of impaired lung function with regard to gas exchange. Normal PaO_2 values range from 80 to 100 mmHg. Hemoglobin saturation with oxygen, and thus whole blood content, does not begin to decrease greatly until the PaO_2 falls below 60 mmHg. Other pulmonary function tests are difficult to apply in veterinary medicine because most of them depend on patient cooperation during the testing procedure or require expensive and sophisticated equipment. Among them, whole-body barometric plethysmography and tidal breathing flow volume loops have been used with some success in both awake, unrestrained cats and dogs. Pulmonary scintigraphy is another noninvasive technique used to assess pulmonary ventilation and perfusion. However, such tests are not routinely available to most veterinarians. Another noninvasive functional testing that is more readily available in practice is the 6-minute walk test.

CANINE INFECTIOUS RESPIRATORY DISEASE COMPLEX IN YOUNG DOGS ("KENNEL COUGH")

Definition/Overview

Canine infectious respiratory disease (CIRD) complex is also known as "kennel cough." The disease is commonly seen in young dogs that have been in boarding kennels. This contagious disease is often self-limiting in dogs, but a wide range of respiratory signs can be found.

Etiology

Although many agents have been implicated, CIRD usually results from infection by any one or more of the following pathogens: *Bordetella bronchiseptica*, canine parainfluenza virus, canine influenza virus, canine adenovirus, and canine respiratory coronavirus. *B. bronchiseptica* is a Gram-negative, aerobic coccobacillus that is recognized as a primary cause of respiratory disease in dogs. It can also be a serious complicating factor in dogs simultaneously infected with a viral pathogen. *Bordetella* and canine parainfluenza virus have commonly been described as the principal pathogens recovered from dogs involved in CIRD outbreaks.

Pathophysiology

Adherence of *B. bronchiseptica* to cilia via adhesion molecules, induction of ciliostasis, and damage to ciliated epithelium have been implicated in the pathogenesis of *Bordetella* infection. Given the ability of this bacterium to regulate its virulence and the likelihood that co-infected dogs tend to experience more serious clinical disease than dogs infected with single agents, viral coinfection could influence *B. bronchiseptica* virulence and clinical manifestations of CIRD in an individual patient.

Young dogs are more susceptible, especially those housed within a high population density environment, since the viruses and *Bordetella* are highly contagious. Despite the widespread availability of *Bordetella* vaccines, the disease is still common.

Clinical Presentation

CIRD is often self-limiting in dogs. In the typical infection, a mild dry cough is the only clinical symptom. However, infection with *Bordetella* can elicit a chronic cough that is more challenging to cure. Respiratory signs may range from mild illness to severe life-threatening pneumonia.

Diagnosis

Diagnosis of bordetellosis relies on positive bacterial culture or, more recently, on positive PCR from BAL fluid. Several laboratories offer PCR testing; however, studies investigating the reliability of this method are lacking. It is difficult to interpret the significance of a positive PCR test result for this disease because *B. bronchiseptica* can be commonly isolated from the URT of clinically healthy dogs, in addition to the fact that a recovered asymptomatic dog may still shed the organism for several weeks. Finding pleiomorphic cocci or coccobacilli adhering to the cilia of the epithelial cells is reported to be a characteristic cytologic feature (Figure 6.20).

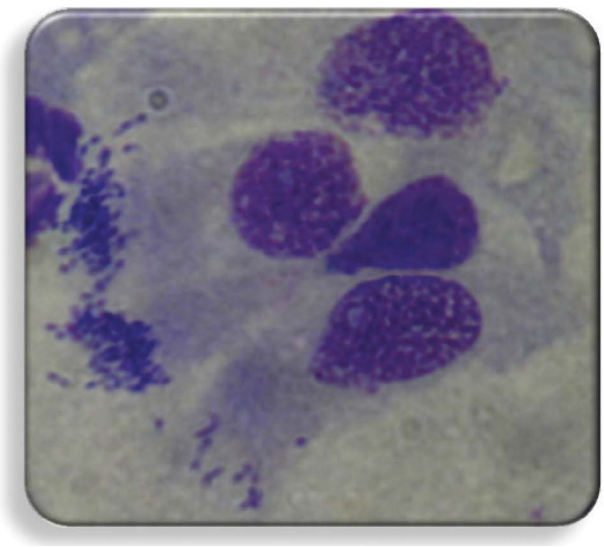

FIGURE 6.20 Pleiomorphic cocci or coccobacilli found adhering to the cilia of the epithelial cells in a dog with bordetellosis.

Management

Treatment generally consists of empirical antimicrobial therapy. Doxycycline is one of several drugs that can be used effectively. Dogs that are unresponsive to oral or parenteral antibiotics may respond to a nebulized form of administration. Aerosolized topically, nonabsorbable antibacterials such as gentamicin have been shown to be effective in reducing the population of *B. bronchiseptica* organisms in the trachea and bronchi of infected dogs.

BACTERIAL BRONCHOPNEUMONIA

Definition/Overview

Bronchopneumonia of bacterial origin is much more frequently diagnosed in dogs than in cats, although it might be underdiagnosed in cats. In dogs, many underlying problems can be associated with bacterial bronchopneumonia.

Etiology

A wide variety of bacteria can result in bronchopneumonia, mostly as opportunistic invaders. A single pathogen such as *Escherichia coli, Pasteurella multocida*, *Staphylococcus*, *Streptococcus*, or *Klebsiella pneumoniae* can be isolated in the majority of cases, but mixed infections are common. Bacteria enter the LRT primarily by inhalation or aspiration or by hematogenous routes. Whether or not a respiratory infection will develop depends on the complex interplay of many factors, such as interference with natural defense mechanisms. Multiple host defense mechanisms exist to protect the LRT from damage secondary to inhaled materials and from possible microbial invasion. These include the mechanisms of coughing and mucociliary clearance, local immunoglobulin (particularly IgA), and cellular and humoral defense mechanisms. Macrophages are responsible for phagocytosis and intracellular killing, and inhibition of macrophage function by viral infections, such as distemper, and corticosteroid use has a major role in the development of secondary bacterial infection.

Pathophysiology

The possibility of an underlying problem should not be overlooked, since bacterial infection can complicate nearly any other respiratory disease. There are many clinical conditions that predispose animals to bacterial pneumonia, and these include viral, mycoplasmal, or fungal respiratory infections; metabolic disorders; immunosuppressive therapy; therapy with specific drugs (aspirin, digoxin); functional and anatomic disorders (obstruction of upper airways, tracheal hypoplasia, primary ciliary dyskinesia); immunodeficiency (phagocyte or lymphocyte dysfunction); and contaminated indwelling catheters. Diseases causing dysphagia, vomiting, and reduced levels of consciousness can result in foreign material being inhaled into the lung and aspiration pneumonia (AP). In AP, pulmonary bacterial infection secondary to the aspiration of foreign contents is suspected but rarely confirmed, and AP is, therefore, rarely differentiated from sterile pneumonitis.

Clinical Presentation

Animals with bacterial bronchopneumonia can present with signs typical of lower respiratory disease such as cough, exercise intolerance, dyspnea, nasal discharge, and cyanosis in addition to systemic signs of anorexia, depression, weight loss, and fever, the degree of which will vary between patients. However, none of these signs can be used to confirm or rule out bacterial pneumonia. Animals with mild or localized disease show no obvious signs. Most dogs with bronchopneumonia will cough, but many will show only labored breathing. The severity of aspiration pneumonia will vary according to the characteristics of the inspired material and the patient's health status prior to aspiration.

Diagnosis

Diagnosis of bacterial bronchopneumonia is based on history, physical examination, blood testing, lung ultrasound (LUS), and radiographic findings. Other tests such as transtracheal aspiration, bronchoscopy and BAL, and transthoracic fine-needle aspiration are used if deemed necessary. Physical examination signs can include tachycardia and weak pulses, hyperemic oral mucous membranes, and dehydration. Determination of the type of breathing pattern is useful. An increased respiratory effort with an exaggerated abdominal component is common. Nasal flaring also occurs. Auscultation can detect absent or increased lung sounds depending on the degree of pulmonary consolidation.

Thoracic radiography is an essential component of the diagnostic evaluation. The radiographs may show only an interstitial pattern early in the disease. An alveolar pattern develops as the disease progresses. Distribution of lesions may also be helpful in identifying underlying problems. Focal lesions may be associated with foreign bodies. Involvement of the dependent lung lobes commonly occurs with pneumonia with or without aspiration (**Figure 6.21**). Hematogenous-borne infections may have a caudodorsal distribution. Diagnosis may be confirmed by microbiologic and cytologic examination of material from the tracheobronchial tree or lung through aspirates, washings, or brushing performed by transtracheal aspiration, bronchoscopy, or fine-needle lung aspiration.

A CBC may reveal neutrophilic leukocytosis and left shift with monocytosis. It is not uncommon to find only a stress response or even a normal leukogram.

Adequate bronchopulmonary sampling techniques for cytologic evaluation and culture of aspirates include tracheal washing, BAL or brushing, and percutaneous fine-needle aspirations. Bacterial culture is more sensitive than cytology for identifying organisms and also allows for susceptibility testing. However, bacteria

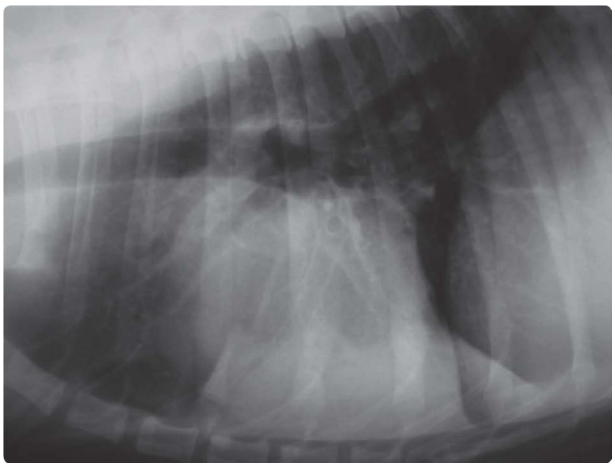

FIGURE 6.21 Thoracic radiograph of a dog with aspiration pneumonia showing ventral distribution of an alveolar pattern with air bronchograms and lobar signs.

can be cultured from the airways of healthy dogs. This microbial population has the potential to cause or complicate respiratory infections and clouds the interpretation of airway and lung cultures. Therefore, the significance of organisms must be interpreted in conjunction with the cytologic findings and other clinical data. Quantitative culture of BAL fluid is advised, since only a significant bacterial growth (1.7×10^3 colony forming units per milliliter of BAL) allows a diagnosis of LRT infection.

Management

Antimicrobial therapy is essential for the treatment of lower airway bacterial infections. The most important criterion for selection of an antibiotic is identification of the bacterial organism and the results of sensitivity testing. There appears to be much variability in the in-vitro sensitivity of common isolates in different countries, emphasizing the importance of culture and sensitivity testing for individual patients. Broad-spectrum coverage for life-threatening infections or sepsis can be obtained using combinations of either amoxicillin–clavulanic acid and enrofloxacin or amoxicillin–clavulanic acid and an aminoglycoside. Fluoroquinolones specifically achieve excellent concentrations within the lung.

Systemic oral or parenteral antibiotics should be administered in high doses for a minimum of 2 weeks and sometimes longer (up to 4–6 weeks is recommended according to the International Society for Companion Animal Infectious Disease) so that maximum concentrations are reached in lung tissue and airway secretions. Obvious clinical improvement will optimally be noted after 3–5 days of treatment. Ideally, the animal should be re-examined weekly in order to monitor the response to treatment based on clinical and radiographic findings. Therapy may be discontinued 1 week after resolution of all clinical signs and the disappearance of the radiographic infiltrates. In AP, several studies are presently investigating the validity of a much shorter course of antibiotics based on CRP values and LUS findings.

Maintenance of normal systemic hydration is very important for mucociliary clearance and secretion mobilization. Airway hydration can also be achieved using saline aerosol therapy followed by physiotherapy (mild forced exercise, increasing cough frequency by chest wall coupage or tracheal manipulation, and postural drainage). The use of aerosol administration of antibacterials or other drugs should be restricted to cases of bordetellosis.

Animals with severe tachypnea, dyspnea, or hypoxemia (PaO_2<60 mmHg) require oxygen therapy. The oxygen should be humidified to prevent drying of respiratory membranes. Oxygen can be administered by oxygen cage, mechanical ventilator, intratracheal cannula, or nasal catheter. Antitussives and antihistamines that inhibit mucokinesis and exudate removal are contraindicated with bacterial pneumonia.

Although the value of expectorant therapy (saline expectorants, guaifenesin, and inhaled volatile oils that are inhaled) has not been scientifically demonstrated, their use can be beneficial.

Pulmonary lobectomy can be an alternative in the management of pneumonia in dogs, especially if a diagnosis of abscessation is suspected or if a lesion does not resolve after several months of aggressive adequate antibiotic therapy.

Prognosis

Bacterial pneumonias are generally responsive to appropriate antibiotic therapy and supportive care. The severity and the chronicity of the infection, the presence of an underlying disease, and the development of complications can affect the long-term prognosis. Potential reasons for failure are many. They may be related to the organism involved (not sensitive to the antibiotic used or capable of developing resistance) or to the antibiotic itself. Failures attributable to the drug may relate to the dosage regimen, spectrum of activity, or ability to achieve effective concentration. Other causes of failure include inaccurate diagnosis or existence of an undiagnosed underlying disorder.

PRIMARY CILIARY DYSKINESIA

Definition/Overview

Primary ciliary dyskinesia (PCD), previously referred to as immotile cilia syndrome, results from a heterogeneous group of inherited diseases that cause defective ciliary motility mostly associated with ultrastructural abnormalities. It is a predisposing cause of recurrent bacterial pneumonia. In dogs, as in humans, the ineffectiveness and incoordination of ciliary function result in ineffective clearance of mucus from the airways, which in turn results in chronic mucus plugging and inflammation of nasal cavities and airways. Kartagener syndrome represents a triad of signs that includes bronchiectasis, complete transposition of viscera (situs inversus), and

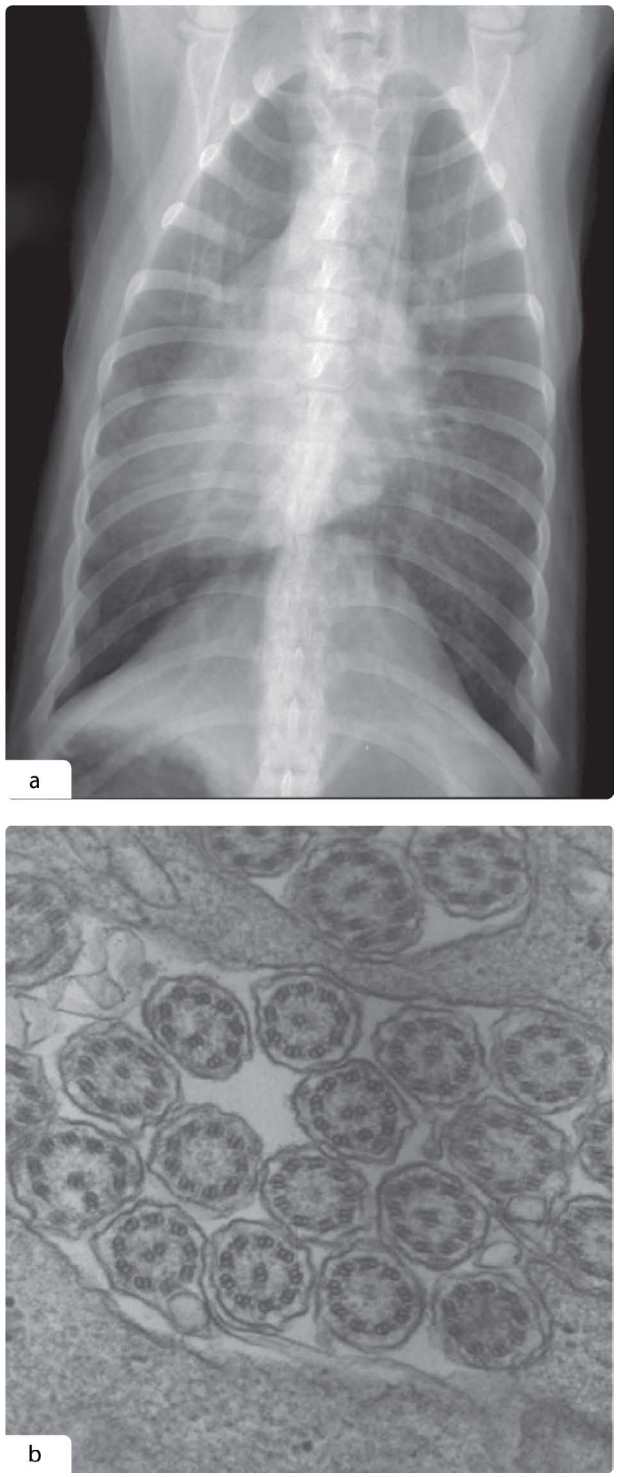

FIGURE 6.22 Old English Sheepdog with primary ciliary dyskinesia associated with situs inversus. **(a)** Dorsoventral thoracic radiograph. **(b)** Transmission electron microscope image of transverse sections of cilia showing a primary defect (absence of the central pair of doublets) and many secondary defects.

chronic rhinosinusitis (Figure 6.22a, b). This syndrome has been reported in humans and in dogs with PCD. In dogs, PCD is a rare disease that has been reported in more than 19 breeds.

Etiology

Currently, PCD-causing mutations have been identified in 20 human genes. Each causative gene can be associated with particular ultrastructural ciliary defects, and these 20 genes only explain 50% of human PCD cases; more genes need to be identified. In dogs, a recent mutation in a new causative gene (CCDC39) has been identified in the Old English Sheepdog. This new mutation is dispersed in a significant worldwide population and is responsible for PCD in this breed. A new genetic test has been developed and is currently available for breeding purposes.

Clinical Presentation

As a consequence of impaired mucociliary clearance, clinical signs include chronic respiratory abnormalities such as rhinosinusitis, bronchitis, bronchopneumonia, and bronchiectasis. Although the respiratory system signs are usually the presenting complaint, other signs related to pathology in other tissues with ciliated epithelia or microtubules can occur, such as otitis media, infertility in females, asthenoteratospermia in males, hydrocephalus, and renal fibrosis or dilation of renal tubules. The signs typically begin at an early age in a purebred vaccinated dog; however, some dogs have remained asymptomatic until several months to several years of age. Hallmark clinical features (i.e., recurrent bilateral nasal discharge and repeated episodes of bronchitis or bronchopneumonia since birth) should alert the clinician to include PCD in the differential diagnosis.

Diagnosis

Finding the hallmark clinical features in combination with situs in versus is even more suggestive. Most other potential possible causes should be excluded by a complete physical examination as well as currently available complementary tests. Confirmation of a diagnosis of PCD requires both in-vivo and in-vitro functional and ultrastructural analysis of cilia. Scintigraphy can be used for in-vivo functional analysis of mucociliary clearance. In-vitro functional analysis in PCD consistently demonstrates an uncoordinated or a dyskinetic ciliary beat. Transmission electron microscopy can reveal specific ultrastructural abnormalities, although regularly the distinction between PCD and secondary ciliary defects (caused by another primary disease) based on ultrastructural findings is difficult.

Other causes of recurrent bacterial infection of the lower airways should be investigated, such as the presence of an immune deficiency, a resistant bacterium, a bronchial foreign body, or any other predisposing cause. In Irish Wolfhounds, a rhinitis/bronchopneumonia syndrome characterized by transient to persistent mucoid or mucopurulent rhinorrhea, cough, and dyspnea since an early age has been described; so far, PCD has not yet been formally identified as the cause of the disease in this particular breed.

Management

Even though PCD is not a curable disease, it can frequently be managed for some years. A key element in successful management is adequate monitoring of infecting microorganisms and judicious use of antibiotics over time. Moreover, a regular routine consisting of good systemic and local hydration, daily coupage, and vigorous exercise will help to clear mucus from the airways.

Prognosis

The long-term prognosis is poor, since even in cases with adequate management the disease generally progresses over time, and the response to treatment worsens. It would be very useful to have a genetic test able to identify carriers in order to prevent their use for breeding.

PARASITIC BRONCHOPNEUMOPATHY IN DOGS, ANGIOSTRONGYLOSIS (FRENCH HEARTWORM DISEASE)

Definition/Overview/Etiology

The nematode worm *Angiostrongylus vasorum* is an emerging disease, with reported increases in both distribution and incidence in the United Kingdom, Europe, South Africa, and Canada. The expanding geographic range might be related to the influence of the climate on parasite distribution.

The worm infects dogs and foxes and is spread through ingestion of intermediate hosts, including slugs and snails harboring infective third-stage larvae. The adult parasites live in the pulmonary arteries and the right ventricle of the heart. The prepatent period is 40–60 days.

Respiratory disease results from the inflammatory response induced by migration of the larvae, causing granulomatous pneumonia and probably thrombotic disease.

Clinical Presentation

Infection seems more common in outdoor young dogs, especially those playing with/eating slugs. Dogs are presented for a combination of signs, including cough, exercise intolerance, respiratory distress, coagulopathy (hemoptysis, bleedings), lameness, neurologic signs, and syncope. However, clinical signs may be variable and range from subtle and chronic to more acute and severe.

Diagnosis

Eosinophilia, thrombocytopenia, and hyperglobulinemia are relatively common. Thoracic radiographs generally show an interstitial and/or alveolar pattern, most often present in the dorsocaudal lung fields. Definitive parasitologic diagnosis relies on observation of first-stage larvae (L1) in the respiratory tract or feces, using the Baermann test. L1 are sometimes observed on airway cytology. A major limitation of the Baermann test is that L1 excretion appears to be intermittent, and infected dogs might be negative on fecal examination. A single Baermann test is likely to detect at most 50% of infected dogs, although sensitivity can be increased by serial examination (e.g., of samples collected 3 days in succession, which is not always practical).

Improved diagnostic tests are likely to emerge. Parasite proteins or DNA can be detected in blood or BAL fluid using sandwich ELISA or PCR, respectively. Serologic ELISA tests to detect host antibodies to the parasite have also been developed.

Management

Fenbendazole (25–50 mg/kg p.o. q.24h. for 7–21 days) has been the most commonly used anthelminthic drug during the last decade. Milbemycin oxime and moxidectin (e.g., Advantage Multi, a spot-on combination formulation of moxidectin plus imidacloprid) both prevent establishment of adult parasites when given during the prepatent period and substantially reduce worm burdens. However, continued monitoring after treatment is advisable, with repeated treatment as necessary. Depending on the severity of clinical signs, additional therapy with corticosteroids, IV fluid support, and oxygen can be required.

Prognosis

Dogs carrying a low worm burden may remain subclinical. The prognosis is guarded in those animals with severe respiratory signs. The disease can be fatal if left untreated.

EOSINOPHILIC BRONCHOPNEUMOPATHY IN DOGS

Etiology/Pathophysiology

Canine eosinophilic bronchopneumopathy (EBP) is a disease characterized by eosinophilic infiltration of lung and bronchial mucosa, considered to be manifestations of immunologic hypersensitivity. Although the etiology of EBP is still unknown, the association of eosinophilic infiltration with $CD4^+$ T cells favors a likely Th2 immune response mounted in the lower airways. Suspected and known causes of pulmonary hypersensitivities in humans and animals include fungi, molds, drugs, bacteria, and parasites. However, in many cases, no underlying cause is found. The role of inhaled allergens in EBP is still unclear. EBP is mostly diagnosed in young dogs. Siberian Huskies and Malamutes are predominantly affected, but many other breeds also can be affected.

Clinical Presentation

Usually, the general condition of the animal is good unless the disease is associated with concomitant bacterial bronchopneumonia. Clinical signs include mainly

cough, gagging, and retching. In acute cases, gagging and retching are sometimes the main complaint, extending the differential diagnosis to dyspeptic problems. Dyspnea is a very frequent sign. Nasal discharge (about 50% of affected dogs) is less commonly encountered.

Differential Diagnosis

Several parasites including *Strongyloides* spp., *Ascaris* spp., *Toxocara canis*, and *Ancylostoma* spp. can lead to eosinophilic pneumonia in humans and probably in dogs as well. Respiratory symptoms are mild, and gastroenterologic signs usually predominate.

In the dog, occult heartworm disease caused by *Dirofilaria immitis* can cause eosinophilic pneumonitis. Migration of larvae of *Angiostrongylus vasorum* through pulmonary parenchyma may also result in eosinophilic pneumonia in dogs. Other bronchopulmonary parasites, such as *Capillaria aerophila, Oslerus osleri, Filaroides hirthi, Crenosoma vulpis*, or *Paragonimus kellicotti*, are also implicated in the migration of eosinophils into the airways (*O. osleri*) or lungs (other parasites) in dogs and can mimic EBP.

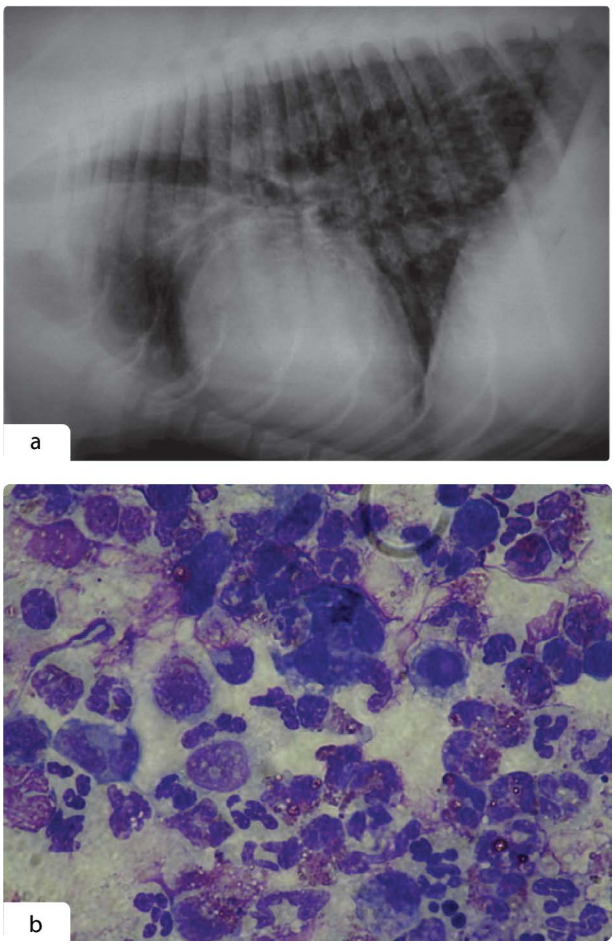

FIGURE 6.23 Four-year-old male Akita Inu with eosinophilic bronchopneumopathy. **(a)** Lateral thoracic radiograph showing a severe bronchointerstitial pattern with peribronchial infiltration. **(b)** Cytologic preparation (BAL fluid cytospin) showing 47% of eosinophils (total cell count = 7,000 cells/mL).

Diagnosis

The diagnostic workup of dogs with pulmonary disease should include a search for parasitic disease, using BAL fluid analysis or feces examination (fecal zinc sulfate centrifugation/flotation and Baermann sedimentation procedure). However, a single negative fecal examination by either method is not conclusive. The fecal examination should, therefore, be repeated, or, alternatively, the animal treated for potential parasites using a course of an appropriate anthelmintic (e.g., fenbendazole, thiabendazole, or levamisole). In endemic areas, it is strongly advised to run a heartworm antigen test to rule out occult heartworm disease.

The diagnostic criteria for the diagnosis of EBP include anamnestic factors (breed, young age, previous response to corticosteroids), clinical signs, radiographic and bronchoscopic findings, blood eosinophilia, tissue eosinophilic infiltration as demonstrated by cytologic and histopathologic examinations, response to adequate treatment, and the exclusion of other pulmonary conditions. The most common radiographic finding is a mixed moderate-to-severe bronchointerstitial pattern (**Figure 6.23a**), although some studies distinguish subgroups based on findings of thoracic imaging, from no changes to bronchial/peribronchial pattern or bronchointerstitial/interstitial/alveolar pattern. Bronchoscopy can reveal typical macroscopic features, which include the presence of abundant yellow–green mucus or mucopurulent material, severe thickening of the mucosa with irregular or polypoid surface (**Figure 6.19**), and in some cases partial airway closure during expiration. Peripheral blood eosinophilia is frequently found but not always observed. BAL fluid or brush cytology demonstrates a marked eosinophilic component (**Figure 6.23b**); frequently, more than 50% of the inflammatory cells are eosinophils. In most cases, eosinophilic infiltration of the bronchial mucosa can also be observed histopathologically in biopsy samples.

Management

The response to steroid therapy is generally very good (prednisone, initial dosage of 1 mg/kg q.12h. for the 1st week, then on alternate days during the 2nd and 3rd weeks, followed by a gradual decrease to the lowest possible maintenance dose) while achievement of long-term remission is only seen in about half of dogs.

Inhaled glucocorticoid therapy can be considered for long-term maintenance in order to help avoid the systemic complications of chronic glucocorticoid treatment, although this might not allow for complete clinical control of the disorder. This treatment modality is well tolerated, results in improvement in clinical signs and reduction in side effects, and allows for a reduction of oral steroid dosage in steroid-dependent animals.

Prognosis

Relapse frequently occurs within weeks to months after drug discontinuation, although some dogs may remain asymptomatic after discontinuing glucocorticoid treatment.

CHRONIC BRONCHITIS IN DOGS

Definition/Overview

Chronic bronchitis is mostly seen in middle-aged to old smaller breeds of dogs, but it can occur in larger breeds. It is a chronic inflammatory airway disease that results mainly in cough.

Chronic bronchitis in dogs is defined when three diagnostic criteria can be fulfilled:

- Chronic cough
- Evidence of excessive mucus or of mucus hypersecretion
- Exclusion of other chronic cardiopulmonary diseases (e.g., congestive heart failure, chronic infectious bronchopneumonia, pulmonary neoplasia, eosinophilic bronchopneumopathy)

Coexisting diseases (e.g., congestive heart failure and airway collapse) may be present and complicate diagnosis and treatment. The most common sequela is chronic airway obstruction, referred to as chronic obstructive pulmonary disease, a syndrome that is well described in humans.

ETIOLOGY

Many causes of chronic bronchitis are a result of chronic airway irritation and inflammation. The condition is usually diagnosed after a protracted period (> 2 months) of clinical signs that can result from exposure to passive smoking, excessive environmental perfumes, or atmospheric pollution.

Pathophysiology

Chronic bronchitis results in inflammatory changes within the bronchial mucosa, including increased mucus production. Bronchial wall thickening and progressive bronchomalacia contribute to airflow obstruction and further worsening of the inflammation and clinical signs, which consist mainly of a productive cough.

Clinical Presentation

Middle-aged to older smaller dog breeds are more often affected, although any dog that is exposed to chronic airway irritants or has suffered from smoke inhalation can be similarly affected. Most dogs with chronic bronchitis have a rather sonorous cough, which is followed by a retching movement.

Differential Diagnosis

Chronic cough related to specific causes should be ruled out, mainly tracheal collapse, lung fibrosis, EBP, parasitic lung diseases, bronchial or lung primary or secondary tumors, and mitral valve disease.

Diagnosis

Diagnostic tests are carried out to rule out other causes of chronic cough. The hemogram is usually normal, and thoracic radiographs show bronchial wall thickening or generalized increased airway-oriented interstitial density, or both. BAL cytology typically has excess mucus with hyperplastic epithelial cells and increased numbers of neutrophils, goblet cells, and macrophages. Echocardiography helps diagnose any concomitant disorders such as mitral valve disease and right heart enlargement associated with pulmonary arterial hypertension, which can occur secondary to chronic pulmonary disease.

Management

The bronchial alterations are not readily medically reversible. Therapy is based on an assessment of the nature and severity of the individual animal's problems and includes:

- Avoidance of airway irritants and neck compression.
- Control of body weight because obese dogs often show improvement associated with weight reduction.
- *Relief of airway inflammation:* Anti-inflammatory therapy using a low dose of glucocorticosteroids, which reduces mucus hypersecretion and mucosal bronchial wall thickening. Bronchodilators ($\beta_2$agonists, theophylline) are frequently used, although their effectiveness in the treatment of chronic bronchitis has not been widely addressed.
- Control of intractable cough (butorphanol 0.25–1 mg/kg b.i.d.).
- Control of infection and maintaining good dental hygiene.

Prognosis

Treatment can alleviate clinical symptoms, but ongoing airway disease will likely persist.

CHRONIC IDIOPATHIC PULMONARY FIBROSIS IN WEST HIGHLAND WHITE TERRIERS AND OTHER TERRIER BREEDS

Definition/Overview

Chronic idiopathic pulmonary fibrosis (IPF) in West Highland White Terriers and other terrier breeds is an emerging chronic and progressive pulmonary

condition. It has been described in middle-aged to old West Highland White Terriers but also in other young to middle-aged terrier dogs such as the Staffordshire Bull Terrier. A similar condition exists in humans. Very little is known about IPF prevalence, pathogenesis, and prognosis in dogs.

Etiology

As in humans, the etiopathogenesis of IPF in dogs is not known. There is emerging evidence for the role of genetic factors in the development of the disease. Most cases appear to be caused by an interaction between a specific environmental exposure and a genetic predisposition. In dogs, the predisposition of related terrier breeds combined with very low incidence within nonterrier breeds also strongly suggests an underlying genetic cause.

Pathophysiology

Current prevailing hypotheses for the condition focus on dysregulated epithelial–mesenchymal interactions promoting a cycle of continued epithelial cell injury and fibroblast activation leading to fibrosis. Multiple abnormalities in a myriad of biological pathways affecting inflammation and wound repair, including matrix regulation, epithelial reconstitution, the coagulation cascade, neovascularization, and antioxidants, modulate this defective process and promote fibrogenesis.

Clinical Presentation

The disease is clinically characterized by progressive dyspnea, exercise intolerance, and pronounced crackles on auscultation. General body condition is good, and dogs do not lose weight. Cough is described principally in the earliest phase of the disease. The condition might also be associated with some degree of tracheal collapse that develops secondarily in some dogs.

Differential Diagnosis

The disease is not easily distinguished from chronic bronchitis, which may coexist. In IPF, cough can be attributed to tracheal collapse, which is found in a proportion of affected dogs. Crackles might suggest cardiogenic edema; however, such a diagnosis is not compatible with other clinical findings.

Diagnosis

Radiographic, bronchoscopic, hematologic, or biochemical findings are nonspecific but help eliminate other possible disorders. Echocardiography may reveal signs of secondary pulmonary arterial hypertension. Arterial blood gas analysis shows low levels of $PaO_2$and a high alveolar–arterial oxygen gradient. Other noninvasive pulmonary function tests are rarely used in veterinary practice.

Lung imaging using high-resolution CT looks promising and is currently often used to evaluate IPF in humans. However, ultimate confirmation of the diagnosis requires (open chest) lung biopsy and histopathology. Histopathologically, the predominant changes include septal and interstitial fibrosis and pneumocyte hyperplasia.

Management/Prognosis

As the disease is a progressive condition, the long-term prognosis is poor. A mean survival time of about 18 months has been reported. The course of the disease is characterized by a slow progression together with episodes of worsening. Treatment of dogs with IPF is essentially symptomatic and supportive. Glucocorticoid drugs have been tried but have not proved beneficial, while subjecting the dog to potentially detrimental side effects.

BRONCHIECTASIS

Definition/Overview

Bronchiectasis is pathologically defined as an abnormal and permanent dilatation and distortion of subsegmental airways due to destruction of the elastic and muscular components of the bronchial walls. Several congenital or acquired conditions that lead to a cycle of chronic airway infection and inflammation may result in bronchiectatic changes.

Bronchiectasis can be accompanied by bronchomalacia, marked during the expiration phase.

Etiology/Pathophysiology

Focal bronchiectasis most often results from foreign body aspiration. Diffuse bronchiectasis often occurs subsequent to aspiration or inhalation injury, primary ciliary dyskinesis, infection with *Bordetella bronchiseptica* or *Pneumocystis carinii* (in relation to immune deficiency), eosinophilic bronchopneumopathy, and chronic bronchitis. Affected airways are usually partially obstructed by purulent or viscid exudates, since the dilation greatly interferes with normal airway clearance. Dysfunction of mucociliary clearance allows pooling of mucus, exudates, and microbes, which eventually leads to secondary infection and its accompanying inflammatory response, creating a vicious cycle of further damage to the airway wall and predisposition to recurrent bronchopulmonary infections.

Clinical Presentation/Diagnosis

There appears to be a breed predilection, since bronchiectasis is more prevalent in certain breeds such as the American Cocker Spaniel, Miniature Poodle, Siberian Husky, and English Springer Spaniel. Most dogs with bronchiectasis are 7 years of age or older. The clinical signs are typical of chronic bronchial disease and include cough, gagging, tachypnea, dyspnea, and occasionally fever.

Diagnosis

Bronchiectasis can be detected by thoracic radiography, high-resolution CT, or bronchoscopy.

Management

Treatment is the same as for chronic bronchitis, but the disease is more difficult to control. The goal of therapy is to control clinical signs and eliminate any bacterial infections. Removing any likely pulmonary irritants from the dog's environment is essential to slow the progression of bronchial wall destruction. Dogs with bronchiectasis may survive for years despite substantial clinical abnormalities. Patients with focal bronchiectasis might benefit from surgical resection of the pathologic lung lobe.

PULMONARY CONTUSIONS

Etiology

Pulmonary contusion is caused by blunt trauma. It is a common finding in dogs that have received thoracic trauma and can be associated with pneumothorax, pneumomediastinum, rib fracture, and many other adverse effects of the traumatic insult. Hemorrhage into the interstitium and alveoli occurs, usually in localized lung regions.

Clinical Presentation

Generally, there is historical and physical evidence of trauma. Increased respiratory efforts are usually obvious, but the clinical picture will depend on the effects of other ongoing injury.

Diagnosis

Alveolar infiltrates are seen on thoracic radiographs along with other signs of thoracic injury. They include large, localized areas of alveolar and interstitial opacities. Note that pulmonary hemorrhage can also occur from anticoagulant rodenticide ingestion. The history, absence of other signs of trauma, and abnormal blood clotting times will distinguish this from traumatic pulmonary contusions.

Management

Dogs should first be treated for life-threatening, trauma-related problems. Decreased physical activity and cage rest in a 40% oxygen-enriched environment is advised. Oxygen can also be provided with nasal cannulation. Pulmonary contusion will begin to show radiographic resolution after 3–5 days.

Prognosis

Prognosis varies from good to guarded depending on the extent of the injuries. Progression of pulmonary injuries to acute respiratory distress syndrome is an ominous complication.

FELINE BRONCHIAL SYNDROME

Definition/Overview

Cough is an infrequent clinical sign in cats. It is fairly specific for tracheobronchial disease in cats since cough of cardiac origin is rare. Feline bronchial disease (feline asthma or bronchitis) is characterized by inflammation of the lower airways without an obvious identifiable cause. Many other terms are found in the literature such as chronic bronchitis, allergic bronchitis, eosinophilic bronchitis, and bronchial asthma. It is recognized clinically with signs of cough, wheezing, exercise intolerance, and respiratory distress attributable to airway obstruction caused by bronchial inflammation.

Etiology

Feline asthma is thought to be an allergic disorder based on the associated tissue pathology and the response to glucocorticoid drugs, although it might be difficult to distinguish the condition from other types of chronic airway disease.

Pathophysiology

Clinical signs are related to reversible airway inflammation and obstruction linked to hyper-reactivity and smooth muscle hypertrophy, excessive mucus production (mucous gland hypertrophy) and accumulation, and bronchial wall edema. These changes are often reversible. However, chronic inflammation can lead to severe lower airway obstruction, which causes lung hyperinflation and air trapping. Lung hyperinflation may lead to permanent pathology, evidenced by progressive airway remodeling, including bronchiectasis, fibrosis, or emphysema. Sometimes reversible atelectasis can occur.

Clinical Presentation

Young to middle-aged cats are most commonly affected. The clinical signs are cough and increased breathing effort, which can vary in severity. The signs are often chronic or slowly progressive. Mildly affected cases may only have occasional and brief episodes of cough separated by long periods without symptoms, while in moderately or severely affected cases, cough occurs daily, and cats may have a decreased quality of life with breathing discomfort. Cats with severe exacerbations (also called "asthmatic crisis") may present acutely with open-mouth breathing, dyspnea, and cyanosis. Exacerbation may occur in association with exposure to potential allergens or irritants or after stress or exercise.

Differential Diagnosis

Includes any disease that can affect the feline airway. Pulmonary parasitic diseases, including infection with *Aelurostrongylus abstrusus* and *Dirofilaria immitis* (in endemic regions), will result in similar clinical findings including eosinophilic airway inflammation.

Diagnosis

Physical examination in the asymptomatic cat can be normal at rest, but those with active disease will show a prolonged expiratory phase of breathing with auscultable wheezes or crackles. The classic radiographic pattern with established disease includes signs of bronchial wall thickening (doughnuts or railroad tracks) and air trapping (increased lucency and flattening of the diaphragm). Some cats will have a right middle or some other lung lobe atelectasis.

The hemogram can range from normal to having an eosinophilia. Other abnormalities include a stress leukogram, a secondary polycythemia, or hyperglobulinemia. Fecal and blood smear examinations are recommended as part of the diagnostic workup in order to exclude a parasitic origin for the eosinophilic infiltration (*Aelurostrongylus* and *Dirofilaria*, respectively).

Cytologic examination of airway samples obtained by BAL or endotracheal wash generally provides evidence of airway inflammation, with increased numbers of eosinophils and/or neutrophils. Although a preponderance of eosinophils may be found in fluids from healthy cats, the number of eosinophils and neutrophils in BAL fluid has been shown to correlate with disease severity, both in cats with spontaneous disease and in those with experimentally induced bronchial disease. Feline asthmatic disease is primarily characterized by a predominance (as high as 17%) of eosinophils identified in the BAL fluid. Culture of BAL fluid and PCR for *Mycoplasma* detection can be useful, but its presence does not necessarily signify it being the cause of the airway disease. Feces examination (fecal floatation and Baermann) and heartworm antibody/antigen testing can help detect heartworm disease or *Toxocara cati* and *Aelurostrongylus abstrusus*.

Pulmonary function testing is not commonly used in the diagnostic assessment of cats with bronchial disease.

Management

Stress should be minimized, and an oxygen-enriched environment provided when managing any cat with acute respiratory distress. Parenteral therapy with beta-agonist bronchodilators such as terbutaline (0.01 mg/kg IV, IM, or SC) and a rapidly acting corticosteroid (e.g., dexamethasone, 0.25 mg/kg IV or IM) should be administered. Inhaled bronchodilator medication can be used as well.

Most retrospective studies involving cats with lower airway disease have documented a beneficial response to oral or parenteral glucocorticoids and/or bronchodilators. An initial dose of prednisone or prednisolone beginning at 1–2 mg/kg q.24h. over a 2-week period followed by a gradual tapering dose over another 2-week period has been shown to be a consistent, reliable, and effective treatment. Bronchodilators, such as inhaled salbutamol and albuterol, are very useful to alleviate acute clinical signs, but as they fail to control airway inflammation, they should not be used without glucocorticoid drugs.

FIGURE 6.24 Inhaled steroid therapy for a dog with a chronic cough using a spacer and face mask. (Aerokat, Trudell Medical International, Ontario, Canada.)

The use of inhaled medication using a face mask and spacing chamber (Figure 6.24) is popular. Medications given via inhalation offer the advantage of providing high drug concentrations within the airways while attenuating systemic side effects. Long-term treatment with inhaled corticosteroids (e.g., fluticasone propionate) and bronchodilators (e.g., albuterol) is the preferred medication.

PNEUMOTHORAX

Definition/Overview

Pneumothorax is a common disease among dogs and cats and is characterized by an accumulation of air in the pleural space and subsequent restriction to pulmonary inflation. The result is hypoxemia, which can be severe in many cases and eventually cause death of the animal.

Etiology

Two broad etiologic categories are recognized in dogs and cats: Traumatic and spontaneous pneumothorax. Traumatic pneumothorax (closed or open chest) is seen most commonly after blunt automobile trauma but is also observed following thoracic penetrating trauma (e.g., bite, gunshot, porcupine quill wounds). In contrast, spontaneous pneumothorax is not associated with thoracic wall trauma or any observed inciting cause. Subpleural blebs (Figure 7.1) and pulmonary bullae (Figure 7.8a, b) are the most common causes of spontaneous pneumothorax, but parasitic, infectious, and neoplastic diseases have also been documented. Disease-specific etiologies are summarized in Table 7.1.

Pathophysiology

Pulmonary expansion and effective gas exchange at the blood–pulmonary interface is dependent on a negative intrapleural pressure gradient. With significant pneumothorax, this pressure gradient is lost, and the lungs do not expand with air. This in turn limits the transfer of oxygen and other gases to and from the systemic arterial circulation, ultimately resulting in hypoxemia.

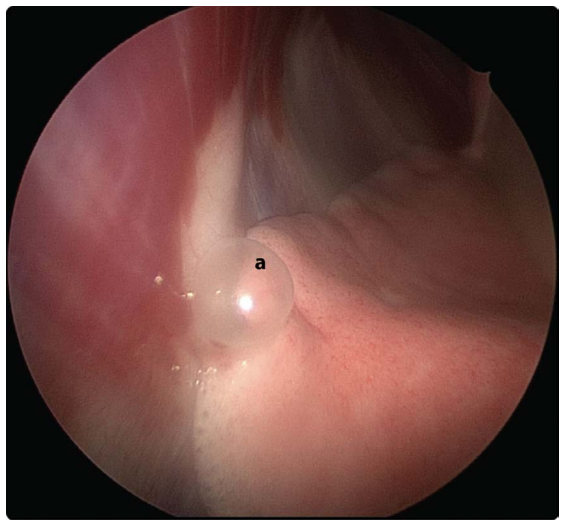

FIGURE 7.1 Thoracoscopic image of a subpleural bleb (a) in a dog with spontaneous pneumothorax.

Clinical Presentation

Dogs and cats with pneumothorax typically present with varying degrees of dyspnea, tachypnea, and restlessness. Dyspnea in animals with acute trauma should raise the index of suspicion for pneumothorax, and prompt support, therapy, and diagnostics should be performed. In most cases of closed traumatic pneumothorax, an obvious thoracic wound or communication with the pleural space will not be present. Furthermore, up to 50% of dogs with traumatic pneumothorax will also have significant concurrent musculoskeletal injuries. Animals with spontaneous pneumothorax often present with mild-to-moderate dyspnea and tachypnea with no other concurrent clinical signs.

DOI: 10.1201/9781003254591-26

TABLE 7.1 Causes of pleural space diseases

Pneumothorax
- Traumatic closed chest (blunt trauma)
- Open chest (penetrating projectiles, bites, automobile)
- Spontaneous (bullae, blebs, foreign bodies, bronchoesophageal fistula, abscess, bronchiectasis, pneumonia)

Pyothorax
- Pneumonia
- Bronchiectasis
- Foreign body
- Esophageal perforation
- Trauma
- Surgical
- Chest drain
- Feline infectious peritonitis/feline leukemia virus
- Abscess (common causative agents: *Actinomyces* spp., *Nocardia* spp., *Filifactor* spp.)

Chylothorax
- Idiopathic
- Lung lobe torsion
- Neoplasia
- Traumatic cardiomyopathy
- Pericardial disease
- Heartworm disease

Lung lobe torsion
- Spontaneous
- Neoplasia
- Pneumonia
- Pleural effusion
- Surgery

Diaphragmatic herniation
- Traumatic
- Congenital

Thoracic neoplasia
- Hemangiosarcoma
- Lymphosarcoma
- Osteosarcoma
- Chondrosarcoma
- Carcinoma
- Mesothelioma
- Lymphoma and others

Differential Diagnosis

See Tables 7.2 and 7.3.

Diagnosis

Diagnosis of pneumothorax is made either by visualization of a full-thickness thoracic wall lesion, thoracic radiography, or thoracocentesis. However, it is important that the examining clinician prioritize stabilization of the patient prior to thoracic radiography, as sudden stress can exacerbate the condition and lead to rapid deterioration of the patient. Typical survey radiographic findings include regions of radiolucency in the pleural cavity, which abut retracted lung lobes, and dorsal elevation of the cardiac silhouette off the sternum on the lateral projection (Figures 7.2–7.4). CT (Figure 7.5) is useful for identifying accompanying orthopedic injuries, bronchiectasis, neoplasia, and, in some cases, pulmonary foreign bodies. However, in most instances of spontaneous pneumothorax, it is associated with a low sensitivity and negative predictive value.

TABLE 7.2 Differential diagnosis of pleural versus pulmonary parenchymal and vascular diseases

Reduction of thoracic capacity
- Pleural effusions
  - Hydrothorax
  - Hemothorax
  - Chylothorax
  - Pyothorax
  - Neoplastic
  - Inflammatory
- Pneumothorax
- Diaphragmatic rupture/hernia
- Cardiac enlargement
- Intrathoracic masses
- Abdominal masses/fluid

Loss of pulmonary exchange capacity
- Bronchopneumonia
- Pulmonary edema
- Pulmonary hemorrhage/contusion
- Metastatic neoplasia
- Pulmonary emphysema
- Idiopathic pulmonary fibrosis
- Pulmonary thromboembolism
- Paraquat poisoning

Management

Initial stabilization of the patient is essential regardless of the ultimate management strategy (medical or surgical). Oxygen supplementation is administered and therapeutic thoracocentesis performed. The patient is then monitored for signs of worsening dyspnea. If dyspnea is progressive, a thoracostomy tube is placed. In the case of

TABLE 7.3 Types and causes of pleural effusion

Transudate
- Hypoproteinemia (gut or urine loss, severe liver disease)

Modified (protein-rich) transudate
- Congestive cardiac failure, particularly in cats
- Neoplasia (particularly cranial mediastinum, thoracic wall)
- Lung lobe torsion
- Diaphragmatic rupture and incarceration of liver

Hemothorax
- Trauma
- Coagulopathies
- Neoplasia
- Anticoagulant rodenticide

Chylothorax
- Trauma
- Neoplasia
- Congestive heart failure, especially in cats
- Heartworm disease
- Infections
- Lung lobe torsion
- Idiopathic

Pyothorax
- *Nocardia* spp.
- *Bacteroides* spp.
- Tuberculosis
- *Actinomyces* spp.

Inflammatory
- Feline infectious peritonitis
- Acute pancreatitis
- Feline pansteatitis

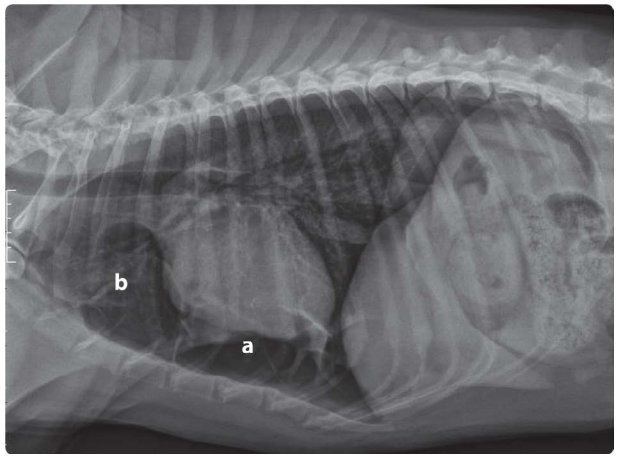

FIGURE 7.2 Lateral thoracic radiograph of a dog with a moderate pneumothorax showing cardiac elevation (a) and cranial lobe retraction (b).

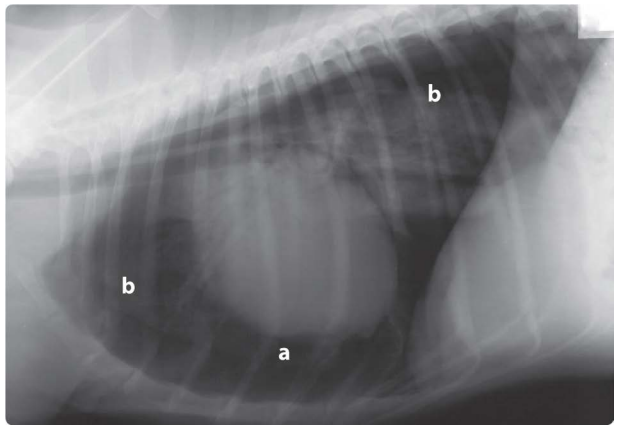

FIGURE 7.4 Lateral thoracic radiograph of a dog with a severe pneumothorax showing cardiac elevation (a) and minimal aeration of the pulmonary parenchyma (b).

flail or open chest pneumothorax, the wound is débrided and repaired to allow stabilization of the patient. In most instances of closed traumatic pneumothorax, intermittent needle thoracocentesis is effective in resolving the pneumothorax. If frequent, repetitive aspiration

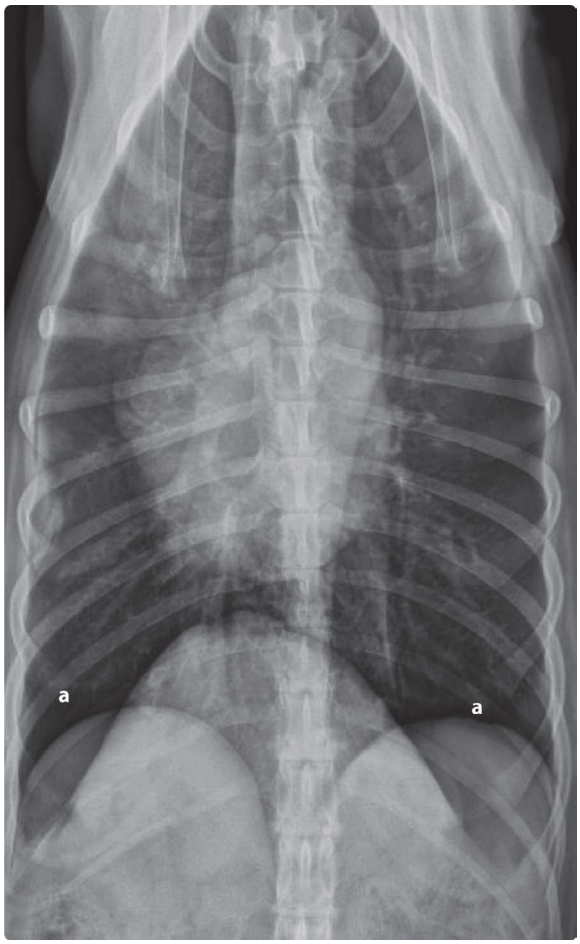

FIGURE 7.3 Ventrodorsal thoracic radiograph of a dog with pneumothorax demonstrating caudal lung lobe retraction (a).

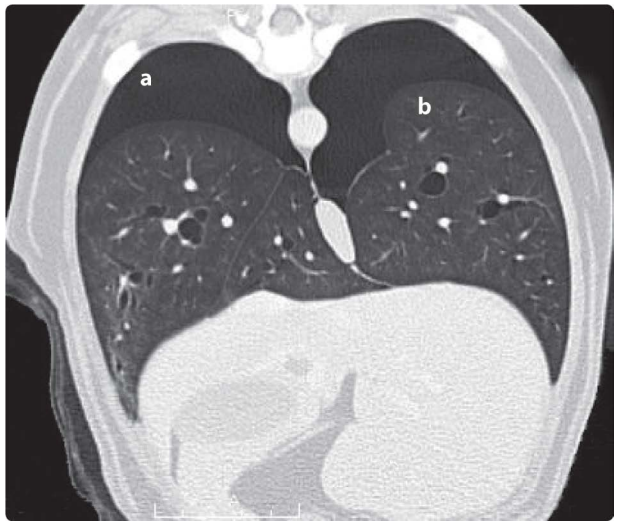

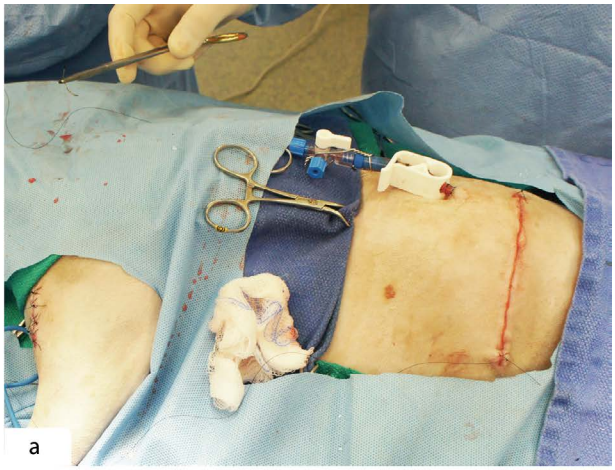

FIGURE 7.5 Transverse computed tomography scan of a dog with pneumothorax. Note the free gas in the pleural space (a) and retraction of the lungs (b).

of air from the pleural cavity is required, a chest tube should be placed (**Figure 7.6a, b**). Thoracostomy tubes can be aspirated intermittently or continuously depending on the production of air. The author prefers a continuous negative pressure approach if repeat aspiration is required more frequently than every 2 hours. A negative pressure between 2 and 4 cm H_2O is effective in most cases. If pneumothorax is continuous and persists longer than 2–3 days, surgical exploration and complete or partial lung lobectomy (**Figures 7.7–7.9**) of the pathologic lung lobe is indicated.

Dogs with spontaneous pneumothorax present a significant challenge and most often require surgical lung lobectomy for definitive resolution of the pneumothorax. Although many cases of spontaneous pneumothorax can resolve temporarily with medical treatment, recurrence is very common. Surgical exploration of the thoracic cavity is performed via a median sternotomy or exploratory thoracoscopy. Intercostal

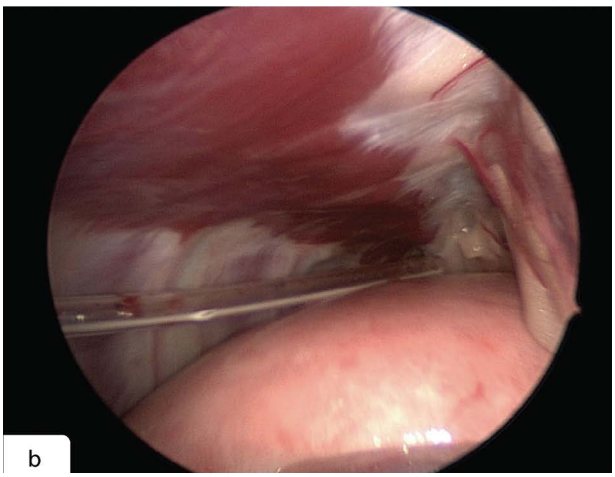

FIGURE 7.6 Extrathoracic **(a)** and intrathoracic **(b)** views of appropriate chest tube placement.

thoracotomy does not allow evaluation of both hemithoraces, which is necessary in most spontaneous pneumothorax cases.

Prognosis

Short-term prognosis for pneumothorax in dogs and cats is generally good provided that emergent and effective treatment is instituted. Long-term prognosis is dependent on the specific pathologic condition causing the pneumothorax. Spontaneous pneumothorax treated surgically is associated with a 10% mortality and 3% recurrence rate, whereas medically treated dogs have a 50% mortality and recurrence rate.

PYOTHORAX

Definition/Overview

Pyothorax, taken from the Greek words "py," meaning pus, and "thorac," pertaining to the chest, is a serious and life-threatening disease. The disease is characterized by accumulation of septic exudate within the thoracic cavity. Most cases of pyothorax are bacterial in origin; however, fungal pyothorax also occurs. Pyothorax is typically seen in young field dogs such as the German Shorthaired Pointer and is consistently more common in males. Pyothorax is commonly diagnosed in cats, and it can also be seen associated with a variety of diseases such as feline infectious peritonitis.

Etiology

Aerobic and anaerobic microbes are causative in most cases of pyothorax, and many infections are polymicrobial. *Actinomyces* and actinomyces-like bacteria (e.g., *Nocardia* spp. And *Filifactor* spp.) are also responsible for infections and can be associated with migrating grass awns. Migrating grass foreign bodies are thought to migrate through the respiratory system after inhalation, ultimately penetrating the pulmonary parenchyma. Other mechanisms of infection include esophageal perforation, hematogenous seeding, extension from a pneumonic infection, penetrating trauma, chest tube stoma, and surgical site infections. Often, the exact mechanism of infection is not identified. Disease-specific etiologies are summarized in Table 7.1.

Pathophysiology

In addition to restrictive pulmonary function due to fluid buildup within the pleural space, bacterial pathogens release endotoxins that act as pyrogens. This can lead to a myriad of untoward systemic sequelae, including systemic inflammatory response syndrome and multiple organ dysfunction/failure. Furthermore, inoculated foreign material within the thoracic cavity presents a significant challenge for clearance of infection. Specifically, foreign bodies can wall themselves off, thus preventing penetration and clearance by the immune system. The persistence of foreign material within the chest cavity is a common cause of long-term failure and recurrence.

Clinical Presentation

Most dogs and cats with pyothorax are dull, lethargic, hyporexic, often febrile, and have differing degrees of restrictive dyspnea. In severe cases, open-mouthed breathing, abducted elbows, and cyanosis may be observed. Clinical examination reveals variable findings, including elevated rectal temperature, diminished lung and heart sounds, and potentially penetrating thoracic wounds (e.g., dog bite).

Differential Diagnosis

See Tables 7.2 and 7.3.

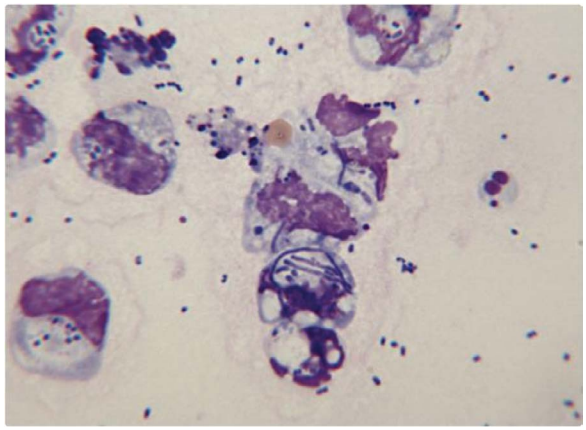

FIGURE 7.10 Cytologic example of a septic exudate from a dog with pyothorax. (*Courtesy of H. Wamsley.*)

Diagnosis

The definitive diagnosis of pyothorax is made by thoracocentesis and identification of a septic suppurative exudate on cytologic examination (Figure 7.10). *Actinomyces* is Gram positive and nonacid-fast, while *Nocardia* is Gram positive and partially acid-fast. Culture and susceptibility testing are necessary for species identification and for evaluation of appropriate antimicrobial therapy. Other important clinical diagnostics include complete blood count (CBC), serum biochemistry, urinalysis, and 2-view thoracic radiography. Thoracic radiographs demonstrate increased radiopacity in the pleural space, with concomitant dorsal elevation and scalloping of lung lobes on the lateral view. Pleural fissure lines are easily seen, and the cardiac silhouette is typically obscured (Figure 7.11a, b). Positive

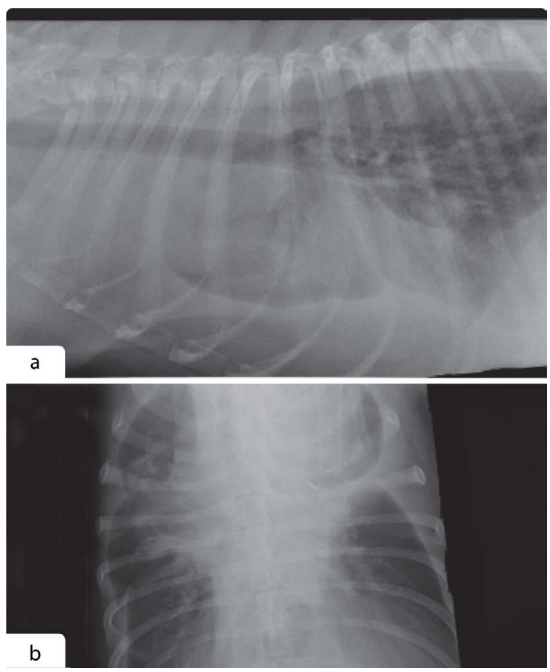

FIGURE 7.11 Lateral **(a)** and dorsoventral **(b)** thoracic radiographs of a dog with pyothorax.

contrast computed tomography (CT) is also recommended when available. This is helpful in cases where radiopaque foreign bodies may be present, as associated regions of tissue inflammation will typically demonstrate enhancement.

Management

Antimicrobial therapy is the cornerstone of treatment of pyothorax in dogs and cats. Broad-spectrum, empirical antibiotic therapy is indicated early and for an extended period of time (usually 6–8 weeks) in most cases. Popular and effective combinations of antibiotics include (1) a potentiated penicillin or (2) cephalosporin in conjunction with clindamycin or metronidazole. *Actinomyces* is most sensitive to penicillins, while *Nocardia* is often sensitive to sulfonamides. Other antibiotics can also be used effectively, as most infections are not particularly resistant. Antibiotic susceptibility testing should be utilized to guide therapy once results are available.

In addition to antimicrobial therapy, removal of septic fluid and any foreign or necrotic material is important, as treatment failure and recurrence may result if this is not performed. Thoracostomy drain placement either unilaterally or bilaterally is necessary in the initial treatment of pyothorax. Thoracostomy drains are used to drain and lavage the pleural space, which facilitates clearance of debris and septic material. Failure to place a thoracostomy drain is associated with an unacceptable level of treatment failure. Pleural lavage is performed using sterile physiologic 0.9% saline at 10–20 mL/kg up to 4 times daily. The addition of heparin to the lavage fluid at 5–10 U/mL has been recommended and theoretically may result in diminished adhesion formation.

Surgical intervention may be important in dogs with masses or cases where a foreign body is present or highly suspected (e.g., *Actinomyces* infection). Median sternotomy is indicated for exploration of both hemithoraces in cases of bilateral pyothorax when a cause is not identified or if medical treatment failure occurs. If a mass lesion is seen or if pus is limited to a single hemithorax, an intercostal thoracotomy may be an appropriate alternative to median sternotomy. Thoracic surgery regardless of the approach is challenging and marred with potential complications and should be performed only by experienced surgeons.

The author prefers exploratory thoracoscopy (Figures 7.12–7.14) as a diagnostic and therapeutic procedure in most cases of pyothorax. Exploratory thoracoscopy utilizes two to three 5.5-mm portals to explore, débride, and biopsy pleural and mediastinal tissues and is used to perform thorough lavage of both hemithoraces followed by video-assisted thoracostomy drain placement. A single thoracostomy drain is used after exploratory thoracoscopy as the mediastinal tissues are well débrided and, therefore, do not isolate one side of the thorax from the other. The efficacy of this treatment has recently been reported in the veterinary literature. All dogs resolved with thoracoscopic treatment, but two were converted to thoracotomy, and one dog developed

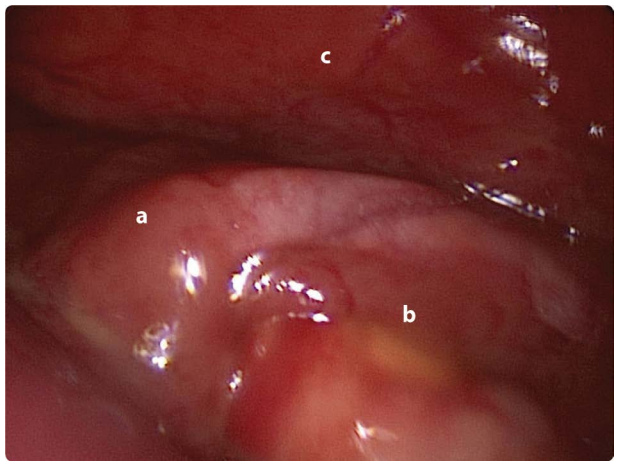

FIGURE 7.12 Dog undergoing thoracoscopic treatment for pyothorax. Purulent fluid (a) and fibrin (b) in the cranial thorax. The pulmonary pleura is inflamed (c).

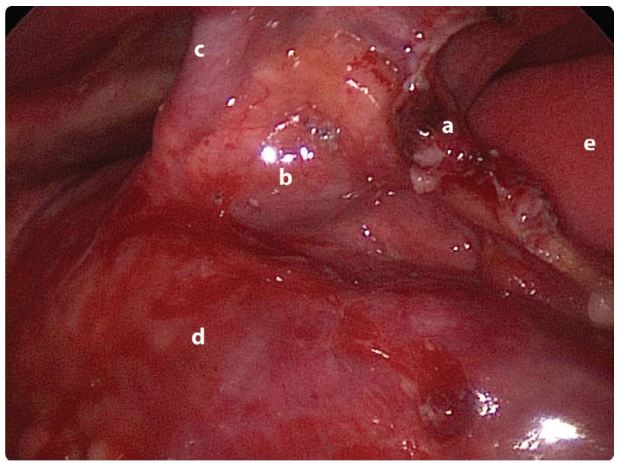

FIGURE 7.13 Thoracoscopic view of the cranial mediastinum after mediastinal débridement (a) and sternal lymph node (b) biopsy. The right internal thoracic artery (c), inflamed dorsal mediastinum (d), and left cranial lung lobe (e) are also visible.

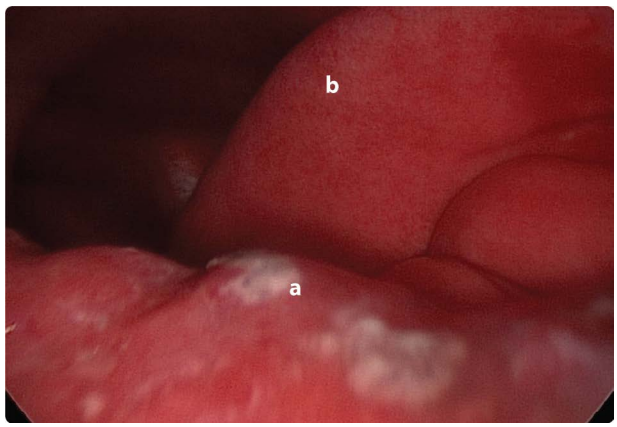

FIGURE 7.14 Thoracoscopic view of the cranial mediastinum. Note the fibrinous plaques (a) and left cranial lung lobe erythema (b).

recurrent disease in the long term (Scott J, et al., 2017—see Recommended Further Readings).

Prognosis

Overall prognosis for pyothorax in dogs and cats is good as long as appropriate and prudent medical treatment is instituted. The long-term success rate for dogs managed medically ranges from 30% to 70%, while dogs managed surgically experience a more consistent long-term success rate between 70% and 90%.

CHYLOTHORAX

Definition/Overview

Chylothorax is defined as a pathologic accumulation of chyle within the thoracic cavity. It is a relatively rare disease in dogs and cats but is associated with an untoward outcome in many cases despite treatment.

Etiology

There are a number of potential causes of chylothorax, including traumatic thoracic duct rupture, neoplasia, cardiomyopathy, heartworm disease, restrictive pericarditis, and lung lobe torsion. However, most cases in dogs are idiopathic. Because the exact cause is often unidentified despite appropriate diagnostic testing, target-based treatment can be challenging. Disease-specific etiologies are summarized in Table 7.1.

Pathophysiology

Direct injury to the thoracic duct can occur secondary to trauma or neoplastic disease. Disease processes that increase right-sided cardiac pressure, such as cardiomyopathy or restrictive pericarditis, also can induce chylothorax by causing extravasation of lymph from the lymphatic system. Similarly, lymphaticovenous obstructive diseases such as mediastinal lymphoma can cause chylothorax. Chylothorax induces significant inflammation within the pleural cavity, ultimately resulting in restrictive pleural fibrosis. Consequently, early and effective treatment is indicated to minimize the risk and severity of pleural fibrosis.

Clinical Presentation

Clinical signs typical of pleural effusion are seen in dogs and cats with chylothorax. Specifically, restrictive dyspnea, tachycardia, lethargy, and hyporexia are commonly reported. Reduced or absent bronchovesicular sounds on thoracic auscultation is a common finding. In chronic cases, poor body condition and cough may be observed. Among dogs, Afghan Hounds, Shetland Sheepdogs, and Shiba Inus are overrepresented.

Differential Diagnosis

See Tables 7.2 and 7.3.

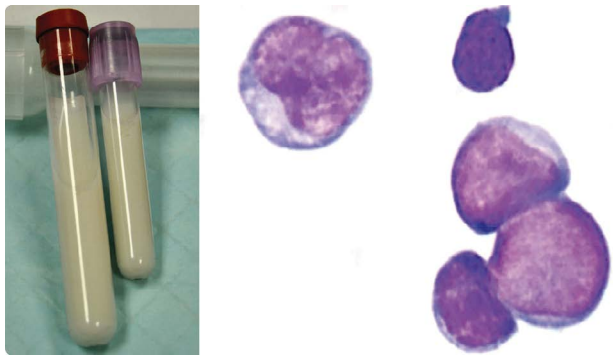

FIGURE 7.15 Pleural fluid. Gross appearance and cytology in a dog with chylothorax secondary to lymphangiosarcoma. Note the neoplastic characteristics of the cells: High nuclear to cytoplasmic ratio, multiple nucleoli, and anisokaryosis. (*Courtesy of H. Wamsley*.)

Diagnosis

Chylous fluid has a milky, white-to-pink, gross appearance (Figure 7.15) and is characterized as a modified transudate. The definitive diagnosis of chylothorax is based on pleural fluid analysis. Distinguishing between chyle and pseudochyle is typically done by measuring fluid triglyceride levels and then comparing those with serum triglyceride levels. Dogs and cats with a pseudochylous effusion will have equivalent fluid and serum triglyceride values, whereas patients with true chylous effusion will have fluid triglyceride levels significantly higher than serum levels. Other benchtop tests that can be performed to help differentiate a chylous effusion from a pseudochylous effusion include a positive ether clearance test and positive Sudan black uptake by chylomicrons. Cytology of pleural fluid is important to rule out other potential diseases such as neoplasia (Figure 7.15).

Thoracic radiographs demonstrate increased radiopacity in the pleural space with concomitant dorsal elevation and scalloping of lung lobes on the lateral view (Figure 7.16). Pleural fissure lines are easily seen, and the cardiac silhouette is typically obscured.

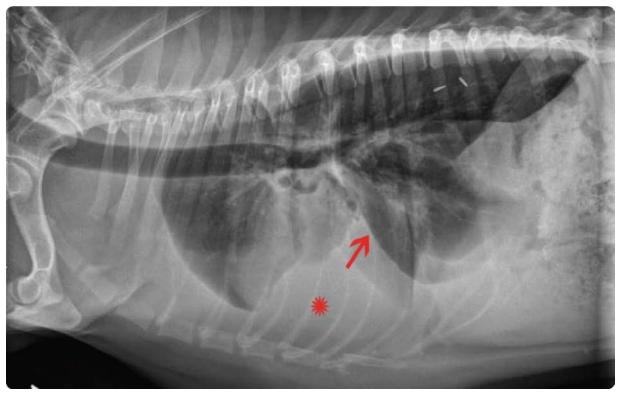

FIGURE 7.16 Lateral thoracic radiograph of a dog with recurrent pleural effusion 8 months after thoracic duct ligation and pericardectomy. This dog was eventually diagnosed with lymphangiosarcoma. Note the retracted lung lobes (arrow) and pleural fluid (asterisk).

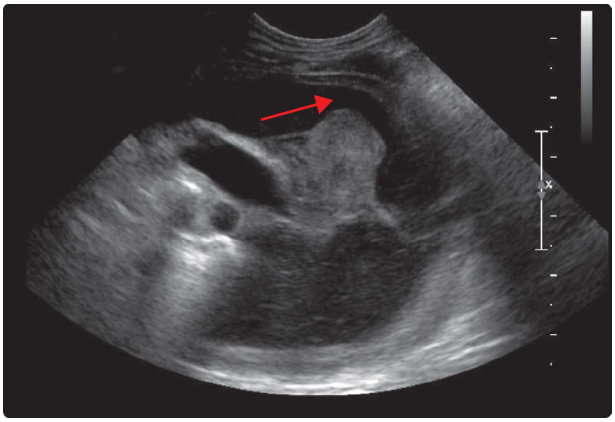

FIGURE 7.17 Thoracic ultrasonogram of a dog with pleural effusion. Note the hypoechoic shadow and linear hyperechoic fibrin strands indicative of pleural fluid. (*Courtesy of M. Winter.*)

Thoracic ultrasonography (Figure 7.17) can also be used to diagnose the presence of free pleural fluid and may be preferred in emergent cases, as it can be performed without significant restraint in most cases. Ultrasonography also allows for diagnostic and therapeutic image-guided thoracocentesis, which can be rapidly performed in emergency situations. Pleural fluid is identified as a hypoechoic to anechoic signal on ultrasound. Small volumes of fluid may not be easily visible using ultrasound. Presence of a thin hyperechoic pleural fissure line immediately adjacent to the body wall with associated gas shadow is consistent with significant pleural effusion.

CT lymphangiography is the procedure of choice for imaging of the thoracic duct (Figure 7.18) and cisterna chyli (Figure 7.19). While it is not necessary to perform CT lymphangiography to make the diagnosis of chylothorax, it is an important diagnostic test in the presurgical evaluation of patients with chylothorax.

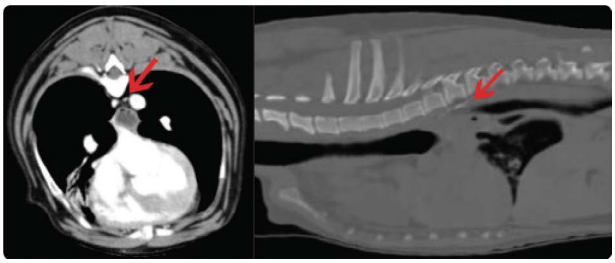

FIGURE 7.18 Transverse and sagittal computed tomography lymphangiography has been performed. Note the thoracic duct medial and dorsal to the descending aorta (arrows).

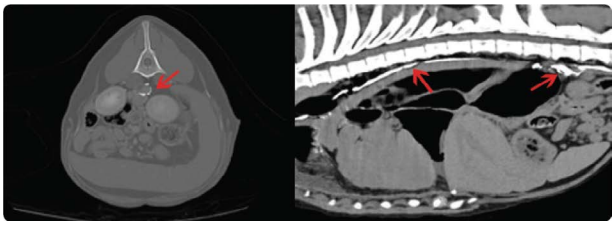

FIGURE 7.19 Transverse and sagittal computed tomography lymphangiography has been performed. Note the thoracic duct (sagittal view, left arrow) and cisterna chyli (both projections, right arrow on sagittal view).

Management

Conservative management of dogs and cats with chylothorax is rarely rewarding and is associated with a high degree of treatment failure. Medical options include feeding a low-fat/high-fiber diet to minimize the absorption and flow of chyle within the lymphatics. Nutraceuticals, such as bioflavonoids (e.g., Rutin, 20–50 mg/kg q.8h.), can also be supplemented to enhance macrophage activity. Other medications such as somatostatin and octreotide have also been used. Serial thoracocentesis is frequently required in medically managed dogs and cats with chylothorax. Because prolonged exposure of the visceral pleura to chylous fluid can result in pleural fibrosis, medical management should be attempted with caution. Owners should be counseled about the risks of pleural fibrosis at the time of diagnosis.

Surgical management is recommended in dogs and cats with idiopathic chylothorax, as it is associated with the best chance of treatment success. A number of surgical treatments have been recommended, but the most commonly performed are thoracic duct ligation (Figure 7.20), in combination with cisterna chyli ablation (Figures 7.21 and 7.22) and/or pericardectomy and thoracic cavity omentalization. Thoracoscopic thoracic duct ligation in combination with lymphatic embolization has recently been reported as well (Figures 7.23 and 7.24).

Prognosis

Prognosis with medical management alone is successful in less than 25% of cases. Surgical success varies among treatments but in recent reports ranges from 85% to 90% in the short and medium term. Long-term resolution of chylothorax is expected in about 80%–85% of dogs treated surgically.

LUNG LOBE TORSION

Definition/Overview

Lung lobe torsion occurs when a lung lobe becomes twisted about its longitudinal axis so as to obstruct the pulmonary vasculature and the bronchus. In most cases, the pulmonary artery is patent. Lung lobe torsion is a relatively uncommon disease. Male dogs and those with a narrow and deep chest appear to be predisposed to lung lobe torsion. Afghan Hounds and Pug dogs appear to be overrepresented. Lung lobe torsion does occur in the cat, but it is rare.

Etiology

The precise etiology of lung lobe torsion in many cases is unknown, and it is, therefore, referred to simply as spontaneous. In some dogs, the condition may be seen in conjunction with other pathology, including pulmonary neoplasia and chylothorax. Any disease process that results in collapse of the airway and which increases mobility of a particular lobe may predispose that lobe to torsion. Examples of associated diseases include bronchomalacia and bronchial collapse, pulmonary neoplasia, chylothorax, and alteration of normal anatomy due to previous thoracic surgery (e.g., lung lobectomy). Disease-specific etiologies are summarized in **Table 7.1**.

Pathophysiology

When a lung lobe undergoes torsion, the venous and lymphatic outflow becomes obstructed, resulting in fluid congestion and distension of the affected lobe. With time, the fluid accumulation becomes severe, eventually resulting in necrosis and pleural effusion formation. A low ventilation/perfusion mismatch results but may not be clinically apparent if the remaining lung lobes are healthy.

Clinical Presentation

Clinical signs include coughing, respiratory difficulty, tachypnea, lethargy, and hyporexia. Respiratory signs can be severe, especially if significant pleural effusion exists. In some cases, a history of previous thoracic surgery may be known, but in many instances, no significant medical history exists.

Differential Diagnosis

See **Tables 7.2** and **7.3**.

Diagnosis

Diagnosis is typically made via thoracic radiography (**Figures 7.25** and **7.26**) or CT (**Figures 7.27** and **7.28**). Survey radiographic findings may vary depending on the presence of pleural fluid and chronicity of the disease. In early cases without significant pleural effusion

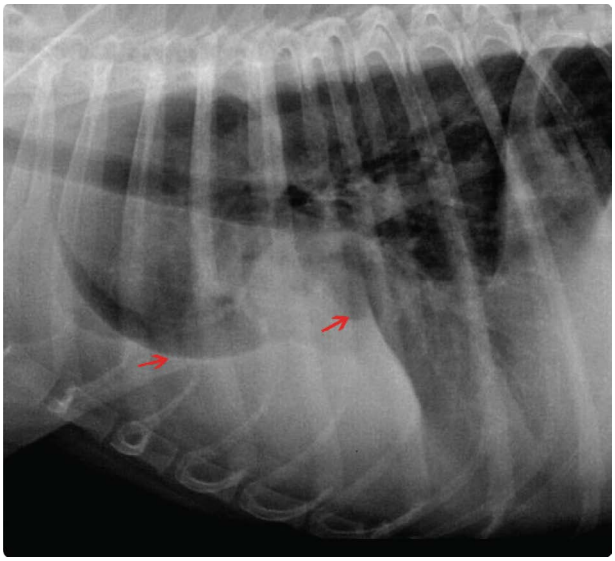

FIGURE 7.25 Dog with lung lobe torsion. Lateral thoracic radiograph. Note the pleural effusion (left arrow) and blunt-ended bronchus (right arrow).

or following thoracocentesis, consolidation with or without the presence of air bronchograms may be evident. In more chronic cases, complete consolidation of the lung lobe with blunting of the pulmonary bronchus may occur. CT is useful in identifying obstructed or narrowed bronchi and is more sensitive than survey radiography for detection of lung lobe torsion.

Pleural fluid analysis typically reveals a modified transudate, which may be chylous.

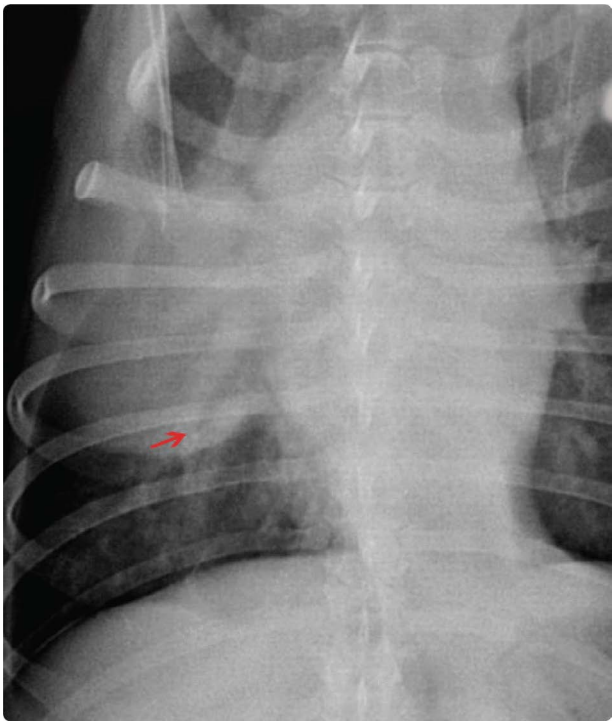

FIGURE 7.26 Ventrodorsal thoracic radiograph. Note the consolidated right middle lung lobe with blunted bronchus (arrow).

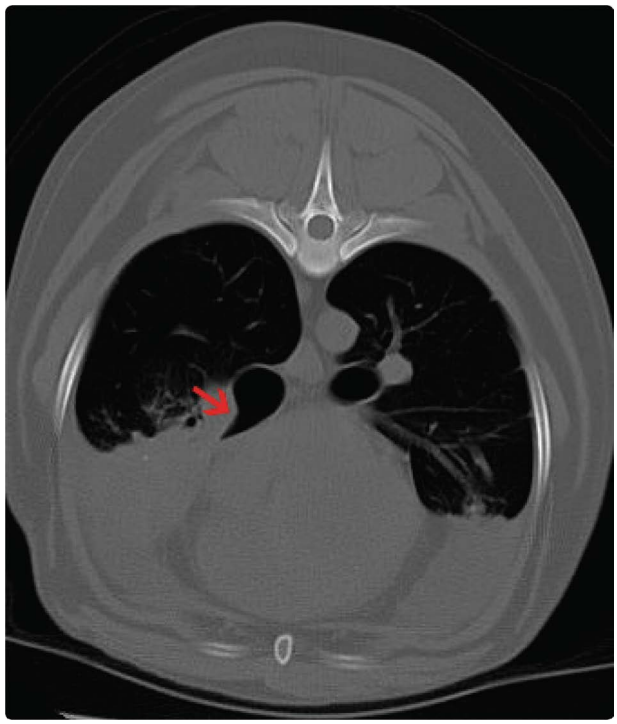

FIGURE 7.27 Transverse computed tomography view. The occluded bronchus and consolidated lung lobe are easily visualized (arrow).

Management

Surgical ligation and excision of the affected lung lobe is the recommended treatment. Dogs and cats with lung lobe torsion are stabilized prior to surgical lung lobectomy. Stabilization usually requires therapeutic thoracocentesis and IV fluid replacement. Any electrolyte or acid–base disruptions should be corrected prior to anesthesia and surgery. Dogs and cats undergoing thoracotomy should have a preoperative hematocrit of at least 30% (0.3 L/L), as hemoglobin is the most significant contributor to blood oxygen content, and hypoxemia and blood loss can be significant with thoracic surgery.

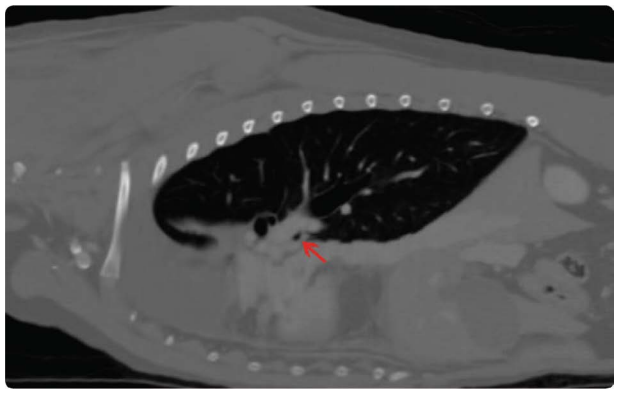

FIGURE 7.28 Sagittal computed tomography view. The occluded bronchus is demonstrated (arrow).

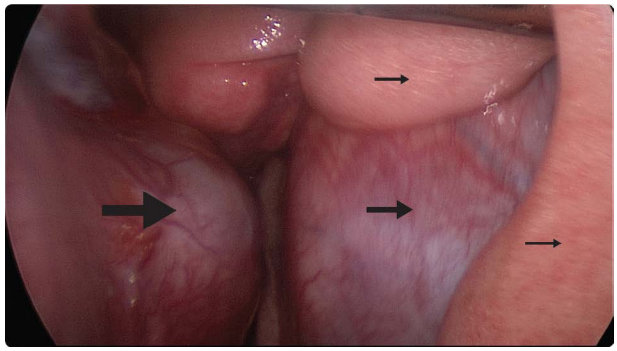

FIGURE 7.29 Same dog as in Figures 7.25–7.28. Video-assisted thoracic surgical view of the consolidated right middle lung lobe (thickest arrow), which was adhered to the chest wall. The heart (middle-thickness arrow) and lungs (thinnest arrows) are retracted to the right of the image.

Lung lobectomy can be performed via a video-assisted thoracic approach (Figure 7.29), median sternotomy, or video-assisted or intercostal thoracotomy (Figure 7.30). Video-assisted thoracic surgery is the author's preferred approach when feasible as exploration of the pulmonary parenchyma is possible, and the procedure can be performed with minimal tissue injury and postoperative pain. Regardless of the surgical approach, ligation of the vascular pedicle (without derotation of the lung lobe) using a triple-row surgical stapler or suture ligation is performed (Figure 7.31). Patients are monitored and supported in a critical care facility postoperatively.

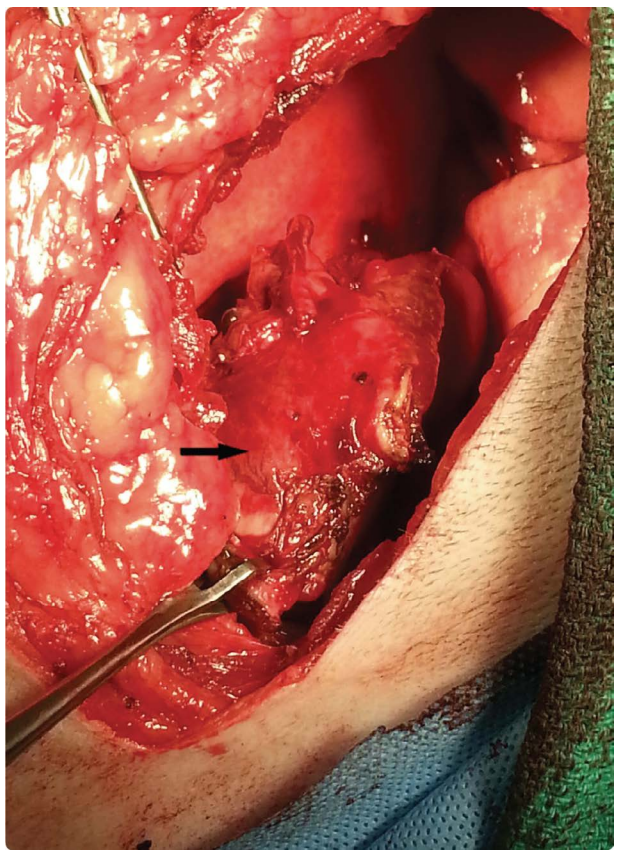

FIGURE 7.30 Intraoperative view of the torsed lung lobe (arrow) during intercostal thoracotomy just prior to lung lobectomy.

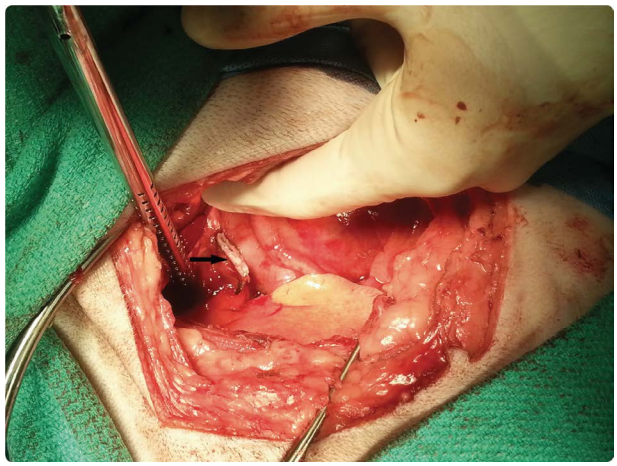

FIGURE 7.31 Intraoperative view of the ligated bronchus (arrow) following lung lobectomy.

Prognosis

Prognosis is dependent on the underlying disease process and the experience and ability of the anesthesia and surgery services. Mortality rates have been reported as high as 40%, but Pug dogs appear to have a much higher survival rate.

DIAPHRAGMATIC HERNIATION

Definition/Overview

Pleural–peritoneal diaphragmatic herniation results when the diaphragm is ruptured or when an abnormal communication of the peritoneal and pleural cavities exists. The diaphragm is composed of a large central tendon, which originates from the sternal, costal, and lumbar musculature. In health, the diaphragm maintains three normal ostia: The aortic, vena cava, and esophageal hiatus. Peritoneal–pericardial diaphragmatic hernias are not true pleural–peritoneal hernias as the communication exists only between the peritoneum and pericardial spaces.

Etiology

Diaphragmatic hernias are broadly classified as congenital or acquired, with acquired being most common. Congenital diaphragmatic hernias are rare and typically result from failure of the lumbar musculature to fuse. These hernias are typically located in the dorsolateral region of the diaphragm. Acquired diaphragmatic hernias are seen commonly following blunt trauma such as automobile-associated injury. Traumatic diaphragmatic herniation can develop in any part of the diaphragm. Tears can be multiple or single, large or small, and

radial or longitudinal. Disease-specific etiologies are summarized in Table 7.1.

Pathophysiology

The pathophysiologic effects of diaphragmatic herniation depend on the severity of the hernia, chronicity, and presence of concurrent injuries. The diaphragm plays an integral role in ventilation and oxygenation by altering intrapleural pressure and volume during respiration. Injury to the diaphragm impairs this function. Furthermore, with herniation of viscera (liver most commonly), compression of the pulmonary pleura and pleural vasculature results in compressive atelectasis and venous impairment. The end result is hypoxemia and reduced cardiac output. Concurrent rib fractures cause pain, which further reduces ventilatory capacity and exacerbates hypoxemia. Herniation of intestine into the pleural space can result in intestinal obstruction and intestinal ischemia.

Clinical Presentation

The clinical presentation for dogs and cats with diaphragmatic herniation is variable and can range from minimal or no clinical signs to severe dyspnea and hypovolemic shock. It is important to remember that small diaphragmatic tears may not elicit significant clinical signs and may go undetected until herniation of abdominal viscera occurs. This may take years in some cases. Thus, diaphragmatic injury should be considered even in dogs and cats without respiratory signs following significant thoracic trauma. Dogs with herniated gastrointestinal (GI) organs may be obstructed and will often present with vomiting and anorexia.

Physical examination may reveal concurrent soft tissue and orthopedic injuries, reduced abdominal organ content, or minimal-to-absent bronchovesicular and heart sounds.

Differential Diagnosis

See Tables 7.2 and 7.3.

Diagnosis

Survey thoracic radiography is the most commonly performed diagnostic procedure and is very sensitive for diagnosing herniation of peritoneal contents in the pleural space (Figures 7.32 and 7.33). Typical radiographic findings include retracted pulmonary parenchyma, presence of increased soft tissue opacity in the pleural cavity, loss of normal cardiac silhouette, presence of gas-filled viscera in the pleural cavity, loss of a normal hepatic shadow, and cranial gastric axis shift. Contrast abdominal radiography can be performed to help identify intestinal herniation and obstruction (Figures 7.34 and 7.35).

CT is also useful and is more sensitive at detection of small diaphragmatic hernias with minimal or no herniation of GI viscera (Figures 7.36 and 7.37).

Arterial blood gas analysis and calculation of the alveolar–arterial oxygen gradient is helpful in diagnosing hypoxemia.

Management

Hypoxemic and hypovolemic patients should be resuscitated and stabilized on an emergency basis. Replacement IV fluid therapy and increased inspired oxygen content can be started immediately. Most dogs and cats will respond well to fluid therapy, but response to increased inspired oxygen may be poor due to the ventilation–perfusion mismatch that frequently exists. Reduction of herniated organs and repair of the diaphragm are required before significant improvement in oxygenation will occur.

Diaphragmatic herniorrhaphy by laparotomy (Figures 7.38–7.40) or laparoscopy (Figures 7.41 and 7.42) in stable dogs only, following reduction of herniated viscera is the definitive treatment for pleural–peritoneal diaphragmatic herniation. Adjunctive surgical procedures such as resection and anastomosis of devitalized bowel or liver lobectomy for refractory hemorrhage may also be indicated.

Prognosis

Prognosis for dogs and cats with traumatic diaphragmatic herniation is good to excellent, with overall survival around 90%. Dogs and cats with traumatic diaphragmatic hernias undergoing surgery without effective resuscitation and support have a higher mortality.

THORACIC NEOPLASIA

Definition/Overview

Thoracic neoplasia is common in aged dogs and cats. The result in most cases is production of malignant pleural effusion and respiratory difficulty. Space-occupying masses can also impair normal respiratory effort and function. Thoracic neoplasia is almost exclusively malignant, but effective treatment can be accomplished in many cases depending on the owner's expectations and the biology of the particular disease.

Etiology

Thoracic neoplasia is most commonly mesenchymal or epithelial and can originate from the ribs, pleura, lungs, mediastinum, thymus, lymph nodes, pericardium, heart, trachea, and esophagus. Mediastinal lymphoma and lymphangiosarcoma are also commonly diagnosed. Disease-specific etiologies are summarized in Table 7.1.

Pathophysiology

Thoracic neoplasia commonly results in malignant pleural effusion, while pericardial and cardiac neoplasms

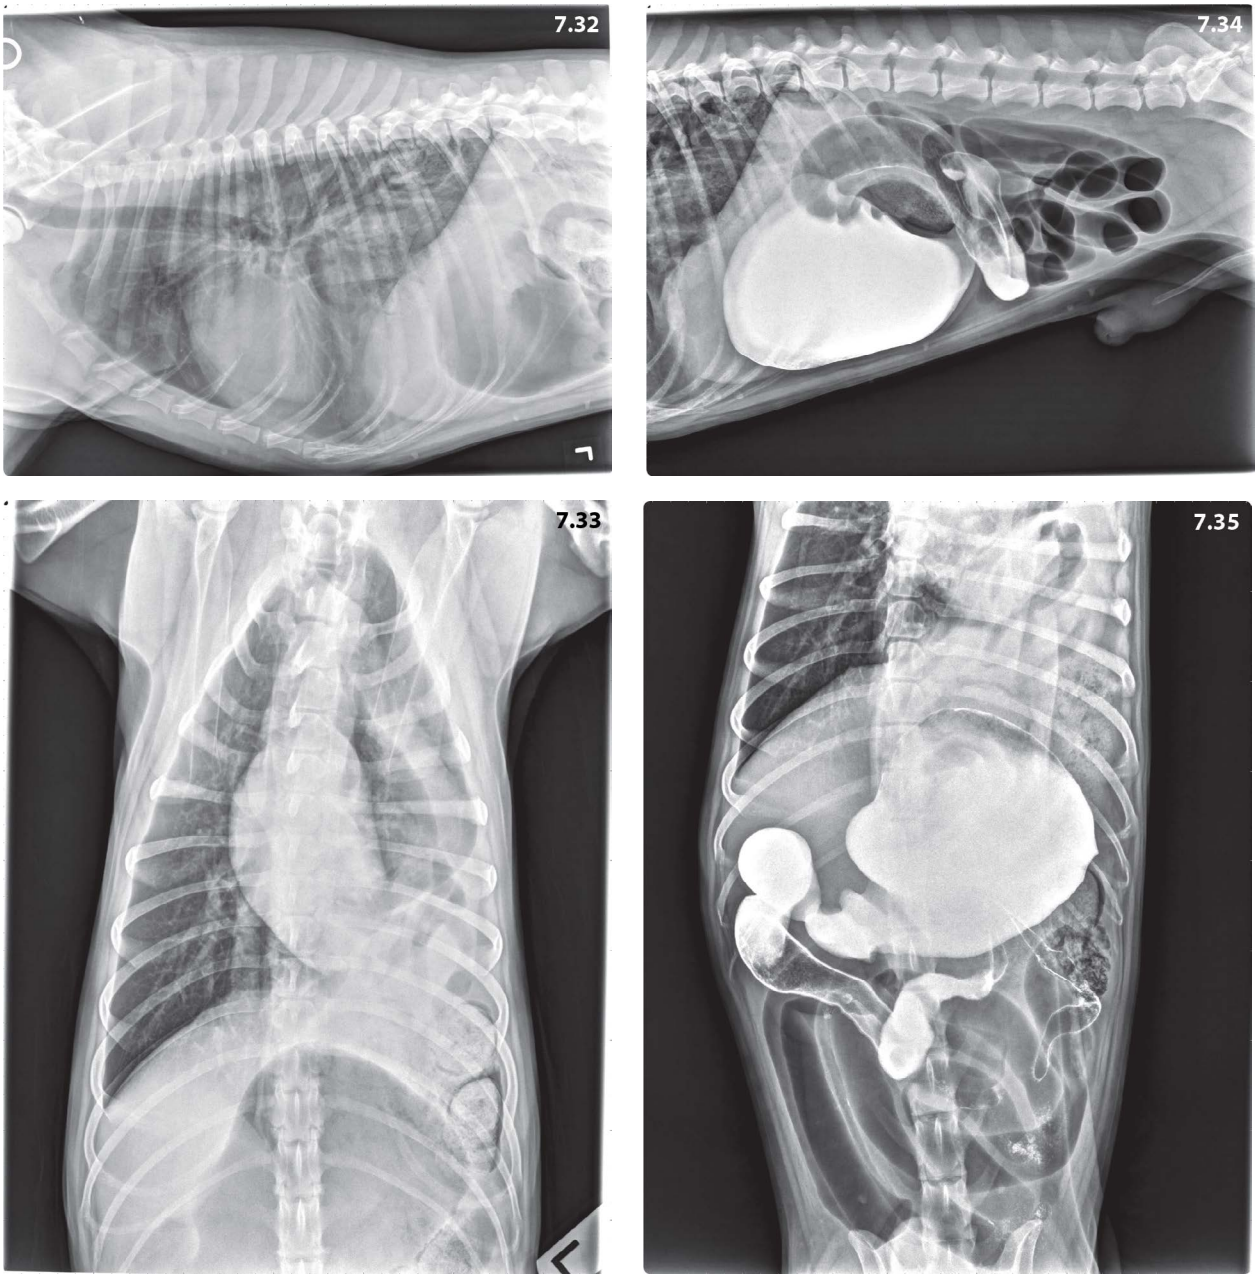

FIGURE 7.32 Dog with a diaphragmatic hernia. Lateral thoracic radiograph. Note the cranial displacement of the gastric axis and gas-filled viscus in the pleural cavity.

FIGURE 7.33 Ventrodorsal thoracic radiograph. Note the loss of liver shadow and the gas-filled viscus in the pleural cavity.

FIGURES 7.34, 7.35 Contrast lateral **(Figure 7.34)** and ventrodorsal **(Figure 7.35)** abdominal radiographs. This dog had persistent emesis, which was thought to be secondary to intestinal obstruction. Contrast was retained in the duodenum due to herniation and occlusion of the orad jejunum. Note the absence of a splenic shadow.

frequently engender pericardial effusion with or without pleural effusion. Consequently, respiratory and diastolic cardiac function are compromised in affected dogs and cats. Moderate-to-marked volumes of pleural space fluid cause restriction of the pulmonary parenchyma, which results in hypoxemia. Excessive pericardial effusion or mechanical compression of the right cardiac chambers by a mass results in tamponade and diastolic compromise.

Clinical Presentation

Dogs with thoracic neoplasms can present in significant distress depending on the location and size of the mass as well as the location and volume of malignant effusion. Common clinical signs include dyspnea, coughing, lethargy, and hyporexia. Cough is usually associated with a lesion that compresses a bronchus. In some cases, cyanosis and syncope may be reported. Dogs and cats

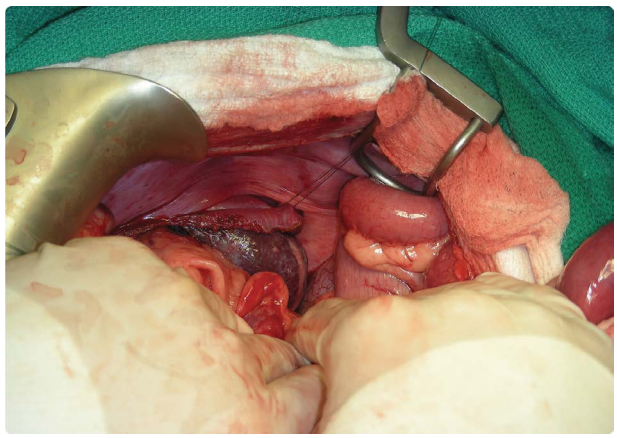

FIGURE 7.39 Intraoperative view of the dog in **Figures 7.32–7.35**. Note that the bowel has been reduced, and the herniated spleen is now visible.

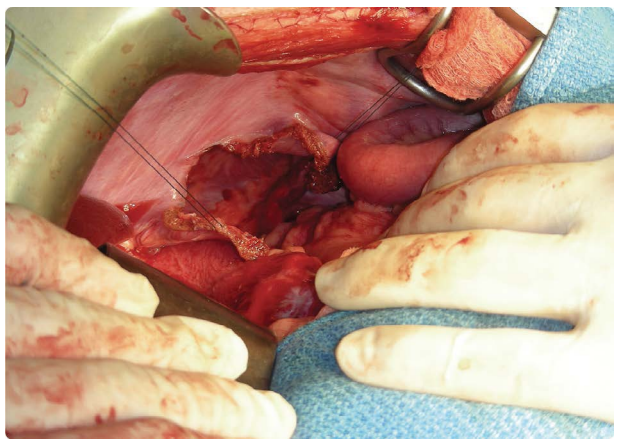

FIGURE 7.40 Intraoperative view of the dog in **Figures 7.32–7.35**. Note that all of the abdominal viscera has been reduced.

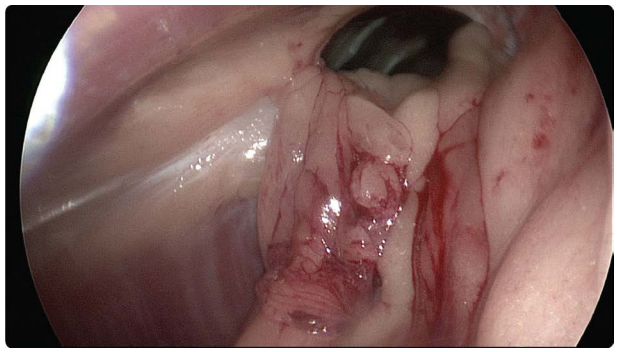

FIGURE 7.41 Laparoscopic view of the dog in Figures 7.32–7.35. The greater omentum is herniated into the pleural space.

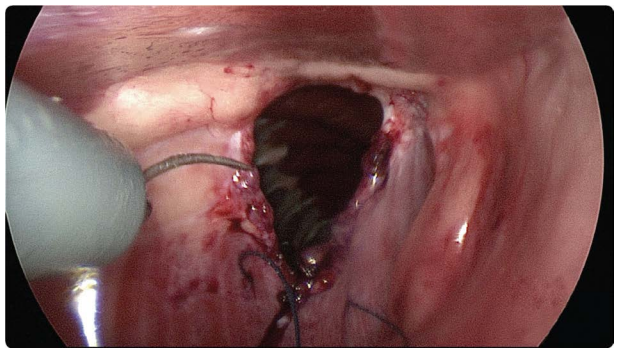

FIGURE 7.42 Laparoscopic view of the dog in Figures 7.32–7.35. An intracorporeal knotless herniorrhaphy is being performed.

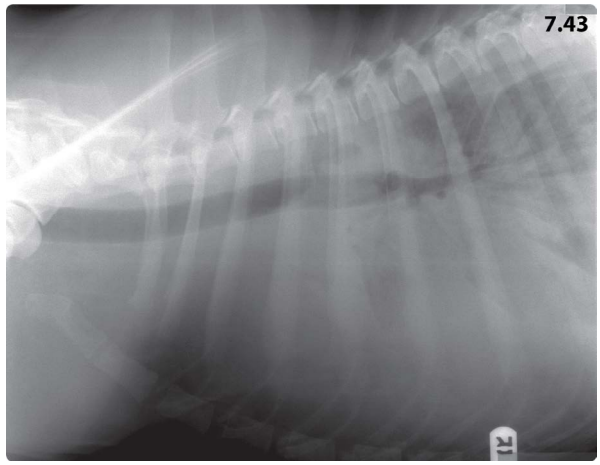
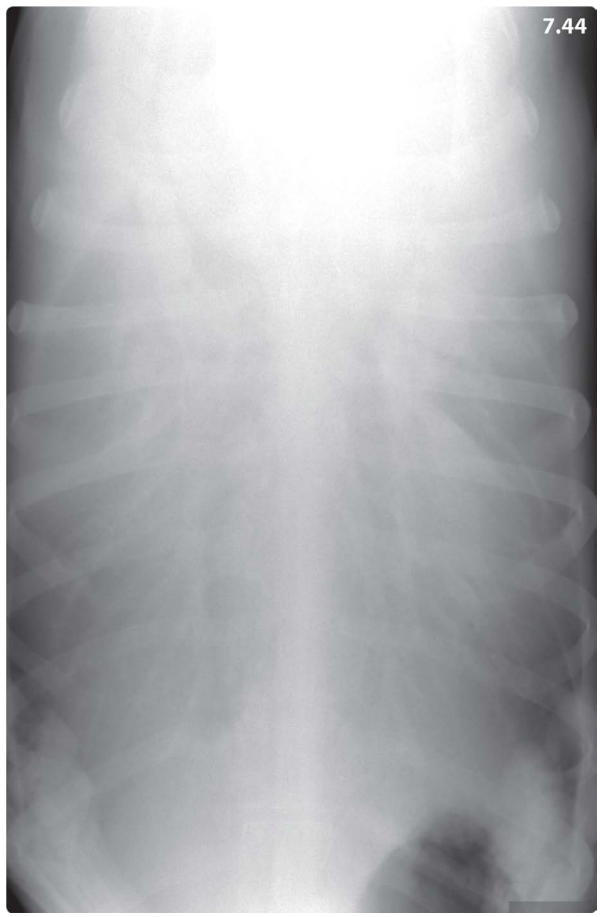


with thoracic wall tumors may have a visible or palpable mass present on physical examination. Cardiothoracic auscultation may reveal diminished or absent bronchovesicular or cardiac sounds.

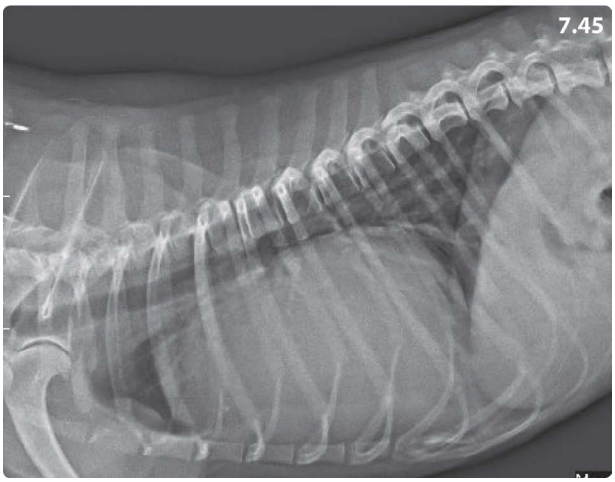


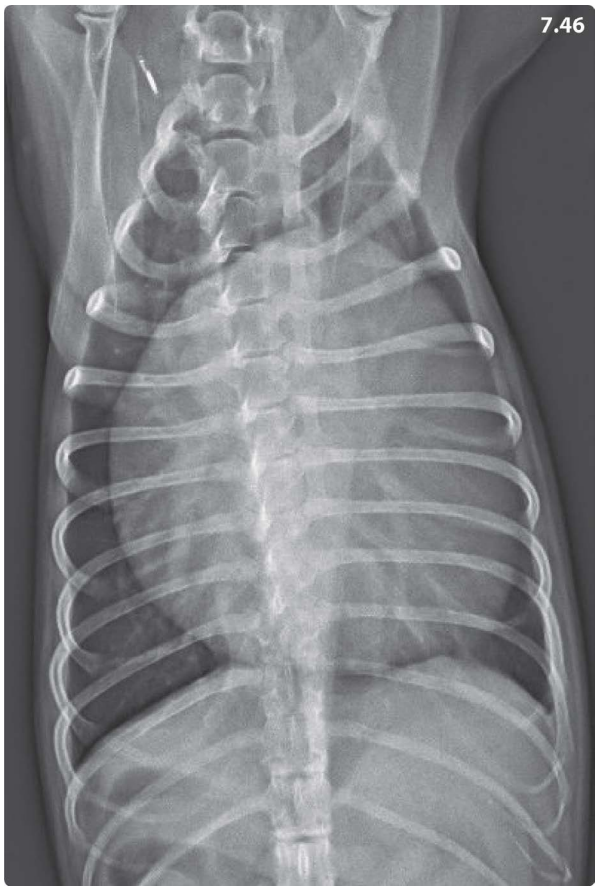
Differential Diagnosis

See Tables 7.2 and 7.3.

Diagnosis

Cytologic analysis of malignant effusions is often inconclusive either due to lack of representative cells in the sample or because of similarity of reactive mesothelial cells to malignant mesothelial cells. Routine blood work is typically nonspecific. Radiographic and echocardiographic imaging usually reveals the presence of pleural and/or pericardial effusion. Mediastinal, pulmonary, and thoracic wall masses can be identified with thoracic radiography (Figures 7.43–7.46), but masses within the pericardial space typically are only seen via echocardiography. Three-dimensional imaging with CT or MRI is ideal for imaging the thoracic cavity (Figure 7.47). Cytology obtained from ultrasound-guided fine-needle aspirates may be useful, but tissue biopsy and histopathology are often essential for a definitive diagnosis (Figures 7.48–7.50).

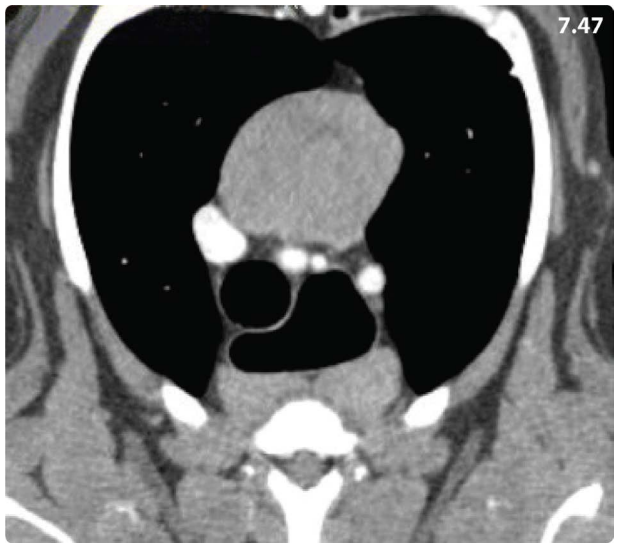


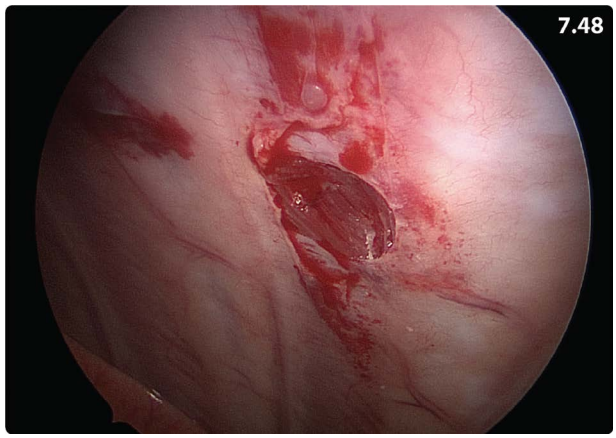


FIGURES 7.43, 7.44 Dog with severe malignant pleural effusion. Lateral (Figure 7.43) and ventrodorsal (Figure 7.44) thoracic radiographs. This dog was diagnosed with pleural mesothelioma.

Management

Initial medical treatment may include thoracocentesis, pericardiocentesis, IV fluid resuscitation, and oxygen supplementation. Tissue diagnosis and staging is recommended (although sometimes not possible) before prescribing a treatment plan. Surgery is often indicated for a variety of neoplastic processes, and chemotherapy





FIGURES 7.45, 7.46 Dog with severe malignant pericardial effusion. Lateral (**Figure 7.45**) and ventrodorsal (**Figure 7.46**) thoracic radiographs. This dog was diagnosed with a right auricular hemangiosarcoma.

may also be indicated depending on the biologic behavior of the cancer.

Prognosis

Prognosis is dependent on the clinical health of the subject, the specific neoplasm, and the treatment elected. In general, thoracic neoplasms have a poor long-term prognosis, but disease-free intervals and survival times

FIGURES 7.47, 7.48 Dog with a noninvasive thymoma. Transverse computed tomographic view. Note the thymoma (center of image), left subclavian artery, left internal thoracic artery, brachiocephalic artery, and cranial vena cava (**Figure 7.47**). Thoracoscopic pleural biopsy has been performed. Note the pleural nodule above the biopsy site (**Figure 7.48**).

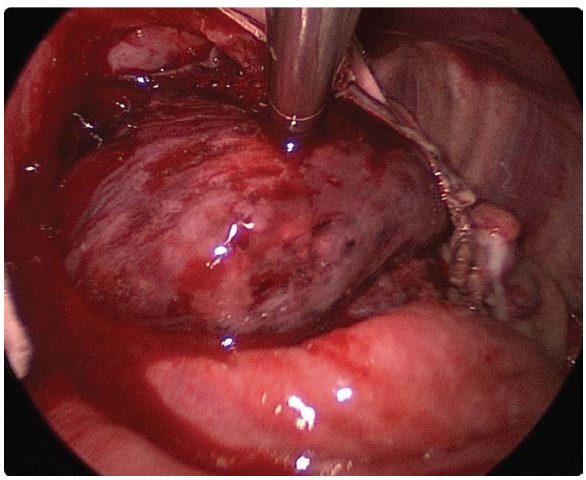


FIGURE 7.49 Pericardioscopic view of a massive right atrial appendage hemangiosarcoma that is compressing the right atrium.

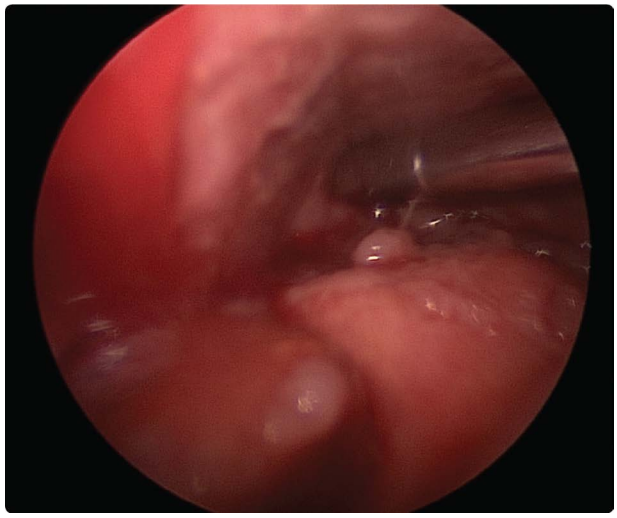

FIGURE 7.50 Pericardioscopic view of a dog with multiple small heart base nodules. These nodules were not seen on echocardiography or preoperative computed tomography. The diagnosis was pericardial and pleural mesothelioma.

up to years can be achieved in some cases. Prognosis should be based on histopathology, if possible, as some diseases (e.g., idiopathic pleural effusion) can mimic malignant thoracic neoplasms.

HISTORY AND PHYSICAL EXAMINATION

Introduction

Cardiovascular disease is common in dogs and cats, and a thorough history and physical examination are crucial steps in making the diagnosis of heart disease. They not only can assist in differentiating respiratory from cardiac disease but also help determine the severity of the disease and response to therapy.

Signalment

Age, breed, and sex are useful information to establish a short list of differential diagnoses. Young animals tend to present with congenital defects, while acquired diseases should be suspected in older animals. There are known breed predispositions, and males are more susceptible to certain diseases. However, there are exceptions in all of these cases, and care should be taken not to exclude diseases simply from signalment. Signalment in combination with heart murmur characteristics and pulse quality are particularly useful to shorten differential lists in puppies with congenital heart disease.

History

A thorough history should include questions about onset, duration, and progression of presenting signs; current medications and the response to those medications; travel history and possible infectious disease exposure; a complete diet history; and concurrent medical problems.

Presenting Complaints

Common presenting signs of cardiac disease include tachypnea, dyspnea, cough, exercise intolerance, syncope, abdominal swelling, decreased appetite, weight loss, cyanosis, paresis/paralysis, and poor growth.

Tachypnea/Dyspnea

Tachypnea is an overly rapid respiratory rate. Owners of pets with cardiac disease should be instructed to keep a resting respiratory rate log at home, and this should be reviewed as part of the history. If the resting respiratory rate is steadily increasing, or is > 40 bpm, cardiogenic pulmonary edema should be suspected in animals previously diagnosed with cardiac disease. Dyspnea is labored breathing and can be caused by primary respiratory disease or decompensated cardiac disease. Caution should be taken with dyspneic animals, as they may quickly become unstable if placed in a stressful environment.

Cough

Cats rarely cough with cardiac disease, although it is reported with heartworm infection. However, cough is the most common complaint in dogs with cardiac disease. It is important to differentiate cough due to cardiac disease from that due to respiratory causes. A high-pitched or honking cough is more commonly associated with

DOI: 10.1201/9781003254591-27

TABLE 8.1 Causes of syncope in dogs and cats

Arrhythmia
- *Bradyarrhythmia*
  - High-grade second-degree atrioventricular block, third-degree atrioventricular block, sick sinus syndrome
- *Tachyarrhythmia*
  - Sustained supraventricular tachycardia, ventricular tachycardia
  - Severe pulmonary hypertension
  - Vasovagal syncope associated with coughing, urination, defecation
- *Systemic hypotension*
  - May be induced by vasodilatory therapy
  - Severe decrease in cardiac output (dilated cardiomyopathy [DCM], obstructive cardiomyopathy)
  - Cardiac tamponade

tracheobronchial collapse, whereas dogs with heart disease will tend to have an intermittent, harsh, low-pitched cough. Cough can be more specific for congestive heart failure (CHF) in large breed dogs than in small breeds.

Syncope

Syncope is a loss of consciousness associated with decreased cerebral blood flow. It is important to differentiate syncope from seizures. Syncopal episodes are generally brief, and the animal is normal immediately preceding and following the episode. Syncope has a variety of causes (Table 8.1).

Abdominal Distension

Abdominal swelling from cardiac disease is due to ascites, which can be caused by right-sided heart disease, pericardial effusion, constrictive pericardial disease, severe pulmonary hypertension (PH), and obstructions to venous return. Ascites develops secondary to congestion in the liver and spleen. It can lead to dyspnea and tachypnea because of increased pressure on the diaphragm, as well as decreased appetite due to abdominal discomfort. Increased intra-abdominal pressure impairs renal blood flow and intestinal absorption of nutrients and drugs. Ascites can be differentiated from other causes of abdominal swelling (organomegaly) by the presence of a palpable fluid wave.

Weight Loss/Cachexia

Cardiac cachexia is a generalized loss of muscle, bone, and adipose tissue mass secondary to CHF. It is due to a catabolic/anabolic imbalance and carries a poor prognosis. High-calorie diets and more frequent feeding are often required to limit the effects of cardiac cachexia. Patients with ascites usually develop more profound and rapid cardiac cachexia.

Cyanosis

Cyanosis is associated with decreased oxygenation of blood and leads to blue-tinged mucous membranes (Figure 8.1). Cyanosis is most commonly seen secondary to cardiac defects leading to right-to-left blood shunting, although it can also be due to severe left heart failure or respiratory disease. There will often be a concurrent polycythemia.

FIGURE 8.1 Cyanosis in a dog with a right-to-left intracardiac shunt.

Paresis

Paresis is most commonly seen in cats with arterial thromboembolic disease. The limb affected depends on the location of the thromboembolus, with the hind limbs being most frequently affected.

Physical Examination

The physical examination should begin with inspection from a distance to collect information on respiratory status and mentation.

Examination of the Mucous Membranes

Mucous membrane color and perfusion should be examined. Cyanosis is due to poor ventilation or alveolar diffusion. Pallor can indicate anemia, hypoxemia, or poor perfusion, and hyperemia may indicate polycythemia or sepsis. The color of the oral mucous membranes should be compared with caudal membranes to assess for differential cyanosis, which is characteristic of a right-to-left patent ductus arteriosus (PDA). Capillary refill time (CRT) is a poor indicator of tissue perfusion.

Palpation of the Pulses

The femoral pulse should be evaluated in every patient. The palpated pulse pressure is determined by the difference between systolic and diastolic pressures and the rate at which pressure reaches its peak systolic value. For example, a large difference between diastolic and systolic pressures or a rapid rise of pressure results in a "bounding" or "hyperdynamic" pulse. Pulse quality

TABLE 8.2 Description of pulses and their causes

Pulse type	Description	Cause
Bounding / hyperkinetic	"Water hammer" forceful pulse	Aortic insufficiency, PDA, thyrotoxicosis, anemia
Pulsus bisferiens (bifid)	Double pulse for each beat	Hypertrophic cardiomyopathy (HOCM), subvalvular aortic stenosis (SAS), aortic insufficiency
Pulsus alternans	Alternating pulse strength with each beat	Severe myocardial disease
Pulsus paradoxus	Inspiration is associated with weakened or absent pulse	Pericardial effusion and tamponade
Pulsus parvus et tardus	Delayed onset of pulse and weak pulse	SAS
Pulsus bigeminus	Pulses come in pairs with pause between each pair and the second pulse weaker than the first	Bigeminal arrhythmias
Pulse deficits	Auscultated heart beats do not have coinciding pulse	Arrhythmias
Hypokinetic pulses	Weak and difficult to palpate	Hypotension, hypovolemia, SAS, congestive heart failure
Absent pulses	No pulse palpated	Thromboembolism

HOCM, hypertrophic obstructive cardiomyopathy; PDA, patent ductus arteriosus; SAS, subaortic stenosis.

cannot be used to estimate actual arterial blood pressure values. Both femoral pulses should be evaluated and the pulse rate compared with the auscultated heart rate. The detection of changes in pulse quality and pattern can help establish a list of differential diagnoses (Table 8.2).

Examination of the Jugular Veins

The jugular veins should be examined while the animal is standing with its head in a neutral position. Any pulse extending above the lower third of the neck is considered abnormal and may be due to right-sided CHF, pulmonic stenosis (PS), severe pulmonary hypertension (PHT), pericardial disease, heartworm disease, or arrhythmias. In addition to abnormal pulses, generalized jugular distension may be noted. This finding indicates increased systemic venous pressures secondary to right heart failure, pericardial disease, or cranial vena cava obstruction that can occur with mediastinal or heart base masses. The hepatojugular reflux sign, which corresponds to a distension of the jugular veins when pressure is applied to the cranial abdomen, can be seen with right-sided heart disease and occurs due to the inability of the diseased heart to compensate for the increased return of blood occurring during abdominal compression (Figure 8.2).

FIGURE 8.2 Hepatojugular reflux sign. There is marked distension of the jugular veins (right) when pressure is applied to the cranial abdomen, compared with baseline (left).

Palpation

The apex beat should be felt most strongly on the left side of the thorax between the 4th and 6th intercostal spaces. The apex beat may be shifted due to cardiac enlargement, intrathoracic masses, collapsed lung lobes, diaphragmatic hernias, or sternal abnormalities. A decreased intensity of the apex beat may be secondary to pericardial effusion, pleural effusion, pneumothorax, diaphragmatic hernia, thoracic masses, or obesity. A precordial thrill, a localized vibration of the chest caused by turbulent blood flow, can be felt when a severe murmur is present.

Auscultation

Auscultation should be performed in a quiet room with both the bell (for low-frequency sounds) and diaphragm (for high-frequency sounds) of the stethoscope. Auscultation should be performed in a systematic manner, evaluating all areas of the thorax and each valve region (Table 8.3). The animal should be in a standing position for auscultation. The heart and lungs should be auscultated separately to avoid confusing or overlooking abnormal sounds. Heart rate and rhythm should be noted, as well as the presence or absence of heart sounds and abnormalities. The normal heart sounds

TABLE 8.3 Areas of auscultation in dogs

Mitral area	Left hemithorax	5th intercostal space at costochondral junction
Aortic area	Left hemithorax	4th intercostal space just above costochondral junction
Pulmonic area	Left hemithorax	2nd–4th intercostal space just above sternal border
Tricuspid area	Right hemithorax	3rd–5th intercostal space near costochondral junction

are S1, associated with closure of the atrioventricular (AV) valves, and S2, associated with closure of semilunar valves. S1 is normally longer and louder than S2. A split S1 may be auscultated and indicates asynchronous closure of the AV valves. S2 is shorter and higher pitched than S1 and is loudest over the pulmonic and aortic areas. Splitting of S2 indicates asynchronous closure of the aortic and pulmonic valves (Table 8.4).

Abnormal heart sounds in small animals include S3, due to rapid ventricular filling, and S4, due to atrial contraction into overly distended or noncompliant ventricle. Both S3 and S4 are quiet, low pitched, and occur in diastole. An audible S3 is indicative of dilated ventricles, and S4 indicates a thickened or noncompliant ventricle or atrial contraction against an already closed AV valve. When S3 or S4 is audible, it is called a gallop rhythm and normally indicates advanced cardiac disease. A midsystolic click is a transient sound that may mimic a gallop rhythm. It is caused by the prolapse of the AV valves, typically in the early stage of degenerative mitral valve disease in dogs.

TABLE 8.4 Abnormal heart sounds and their causes

Abnormal heart sound	Causes
Split S1	– Normal in some large breed dogs – Right bundle branch block – APCs – VPCs – Mitral valve / tricuspid valve stenosis – Cardiac pacing
Split S2	– Normal during inspiration in some animals – Pulmonary hypertension – Right bundle branch block – VPCs – Pulmonic stenosis – Left bundle branch block – SAS – Heartworm disease – Atrial septal defect – Severe hypertension – Aortic insufficiency
S3	– DCM – Decompensated AV valve disease – PDA with left ventricular dilation
S4	– HCM – Third-degree AV block
Midsystolic click	– Mitral valve prolapse

APC, atrial premature complex; AV, atrioventricular; DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; PDA, patent ductus arteriosus; SAS, subaortic stenosis; VPC, ventricular premature complex.

TABLE 8.5 Causes of functional murmurs in dogs and cats

Physiologic
- Anemia
- Fever
- Hypoproteinemia
- Hypertension
- Pregnancy
- Hyperthyroidism

Innocent
- No known cause or underlying cardiac disease

Cardiac murmurs are abnormal sounds caused by turbulent blood flow. Murmurs may be functional or pathologic. Functional murmurs are further divided into physiologic and innocent. Physiologic murmurs have a known cause unrelated to primary cardiac disease and are associated with increased cardiac output or altered blood viscosity. Innocent murmurs occur in young animals and have no known cause or associated cardiac disease. They should be no louder than a grade 3 and should disappear by 5 months of age (Table 8.5). Pathologic murmurs are caused by an underlying cardiac disease (Table 8.6).

Murmurs should be described by their timing, duration, grade, and point of maximal intensity (PMI). Additional information includes quality and pitch of the murmur. The timing of the murmur is either systolic, diastolic, continuous, or to-and-fro. Systolic murmurs are the most common and can be further classified into early, mid-, or late systolic; holosystolic (murmur extends throughout systole, but heart sounds remain audible); or pansystolic (murmur extends through systole, but S2 is obscured). Diastolic murmurs are often quiet and are much less common. Continuous murmurs can be

TABLE 8.6 Causes (and location) of pathologic murmurs in dogs and cats

Systolic murmurs
- AV valve regurgitation (left or right apical)
- Right ventricular outflow tract obstruction; pulmonic stenosis or dynamic right ventricular outflow tract obstruction (right basilar)
- Left ventricular outflow tract obstruction; subaortic stenosis or dynamic left ventricular outflow tract obstruction (left basilar)
- Ventricular septal defect (right apical, sternal, left basilar)
- Valvular endocarditis (left apical)

Diastolic murmurs
- Aortic insufficiency (left basilar)
- Mitral valve stenosis (left apical)
- Valvular endocarditis (left basilar)

Continuous murmurs
- Patent ductus arteriosus

TABLE 8.7 Murmur intensity grading system

Murmur grade	Description
1	Can only be heard after several minutes of listening in a silent room
2	Soft and only heard in a focal region of the thorax
3	Heard throughout one side of the thorax but does not radiate to the opposite side; equal in volume to normal heart sounds
4	Loud murmur that radiates to the opposite side of the thorax, no precordial thrill
5	Palpable precordial thrill, very loud murmur
6	Audible with the stethoscope slightly off the thorax

heard during all phases of the cardiac cycle. To-and-fro murmurs occur when there is a distinct systolic and diastolic murmur. Murmurs are graded on a 1–6 scale (Table 8.7). Murmur grade does not necessarily correlate with the severity of the underlying disease.

The PMI is the location where the murmur is heard loudest. If possible, it should be localized to a single valve region. However, in small dogs and cats, the distinction of apical versus basilar is acceptable. Additionally, the locations of the radiation of the murmur should be described.

ELECTROCARDIOGRAPHY AND HOLTER MONITORING

Definition

The electrocardiogram (ECG) records the electrical activity of the heart from electrodes positioned at the surface of the body. A normal ECG displays three distinct events: P wave during atrial depolarization; followed by QRS complex during ventricular depolarization; and finally, T wave, which corresponds to ventricular repolarization (Figure 8.3). The atrial repolarization is usually not detected. The duration and the amplitude of the waves can be measured from the ECG. The duration (or width) of a wave depends on the time it takes for the electrical impulse to propagate within the cardiac chambers. The amplitude, or height, of a wave usually changes with the size of the cardiac chambers. All measurements should be made in lead II. The amplitude of the waves can decrease when fluid, air, fat, or a large mass interferes with the propagation of the electrical signals to the surface of the body. The PR interval reflects the conduction time through the AV node (Figure 8.3 and Table 8.8).

Ambulatory electrocardiography devices, known as Holter systems, allow clinicians to record a 24- to 72-hour ECG recording while the animal has a normal activity level in a familiar environment (Figure 8.4). Implantable

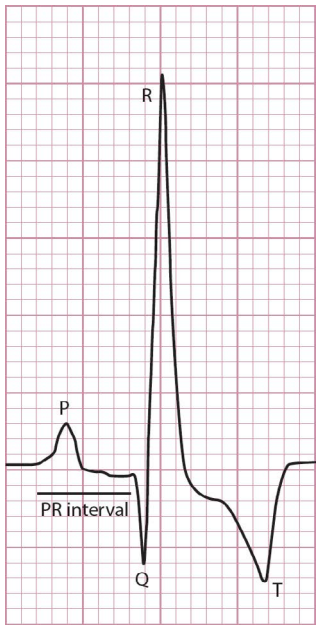

FIGURE 8.3 P-QRS-T illustrating the sequence of activation of the heart. Note that on this ECG there is no clearly defined S wave.

FIGURE 8.4 A 24-hour Holter recording on a dog.

devices are now available to collect ECG data. These devices are event recorders that can be manually triggered to save an ECG whenever clinical signs are observed by the owner of a pet. They are indicated in animals that only present with rare episodes of weakness or syncope.

Indications

The ECG is used to measure heart rate and evaluate cardiac rhythm. It is less reliable for gathering information about structural cardiac changes, such as hypertrophy. Therefore, it should be performed when an arrhythmia is detected on physical examination and when the presenting complaint may be explained by an arrhythmia.

The main indications for Holter recordings are the detection of an arrhythmia as the cause for unexplained syncope, the quantification of arrhythmias, and monitoring of the response to antiarrhythmic therapies. This

TABLE 8.8 ECG features of the normal dog and cat

	Dog	Cat
Heart rate	– 60–170 bpm for adult dogs – 60–140 bpm for giant breeds – Up to 180 bpm for toy breeds – Up to 220 bpm for puppies	– Range 140–220 bpm – Mean 197 bpm
Rhythm	– Normal sinus rhythm – Sinus arrhythmia – Wandering SA pacemaker	– Normal sinus rhythm
P wave	– Duration: Maximum 0.04 sec; 0.05 s in giant breeds – Amplitude: Maximum 0.4 mV – Mean electrical axis: –18 to +90 degrees	– Duration: Maximum 0.04 sec – Amplitude: Maximum 0.2 mV
PR interval	– Duration: 0.06–0.13 sec	– Duration: 0.05–0.09 sec
QRS complex	– Duration: Maximum 0.07 sec – R-wave amplitude: Maximum 2.5 mV in small breeds, 3 mV in large breeds – Mean electrical axis: +40 to +100 degrees	– Duration: Maximum 0.04 sec – R-wave amplitude: Maximum 0.9mV – Mean electrical axis: 0 to +160 degrees
ST segment	– No depression: Not more than 0.2 mV – No elevation: Not more than 0.15 mV	– No marked depression or elevation
T wave	– Positive, negative, or biphasic – Not greater than one-fourth amplitude of R wave	– Positive, negative, or biphasic – Most often positive – Maximum amplitude 0.3 mV
QT interval	– Duration: 0.15–0.24 s at normal HR, varies with HR	– Duration: 0.16–0.22 s at normal HR, varies with HR

Adapted from Santilli R, Moïse NS, Pariaut R, Perego M (2018). *Electrocardiography of the Dog and Cat*, 2nd ed. Edra, Milano. All measurements made in lead II.

technique is also used to screen predisposed breeds for signs of specific cardiac diseases, in particular arrhythmogenic right ventricular cardiomyopathy (ARVC) in Boxers.

Method

Recording artifacts caused by poor contact between the skin and the electrodes, breathing, shivering, or electrical interference frequently interfere with the interpretation of ECG recordings. It is, therefore, critical to dedicate enough time and personnel to obtain a good quality ECG. First, the animal should be restrained in right lateral recumbency. Although ECGs can be recorded in a standing position or in sternal recumbency in patients in respiratory distress or that are uncooperative, it may change the appearance of the ECG tracing. The electrodes should be secured at the level of the elbows and knees or as distal as possible on the four limbs to reduce artifacts secondary to the motion of the chest during breathing (Figure 8.5). Alcohol or a specifically formulated conducting gel is applied to improve contact between the skin and the electrodes. The recording sensitivity is usually selected at 10 mm/mV but should be increased or decreased according to the amplitude of the waves on the ECG. A recording speed of 50 mm/s is usually preferred. Some filters can be applied to the recording to reduce artifacts.

The placement of four electrodes on the surface of the body allows recording of six leads: I, II, III, aVR, aVL, and aVF. These six leads display simultaneously the ECG from six different directions. If a wave is mostly above the baseline, it indicates that the electrical signal travels toward the recording electrode. The wave is below the baseline if the signal moves away from the recording electrode.

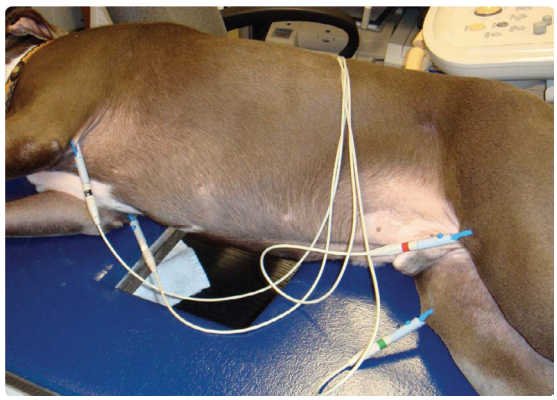

FIGURE 8.5 Electrode placement for good-quality ECG recording.

Tracing Interpretation

First, the heart rate (in beats per minute [bpm]) should be calculated manually because the number displayed by some electronic ECG systems may be inaccurate. Usually, an average heart rate calculated over a few seconds is sufficient. For example, the number of QRS complexes can be calculated for 3 seconds (which corresponds to 15 cm, or the length of a regular pen, when the recording speed is set at 50 mm/sec), and the number obtained is multiplied by 20 to obtain the heart rate per minute. Second, the waves should be identified on the tracing, and their duration and amplitude measured (Table 8.8).

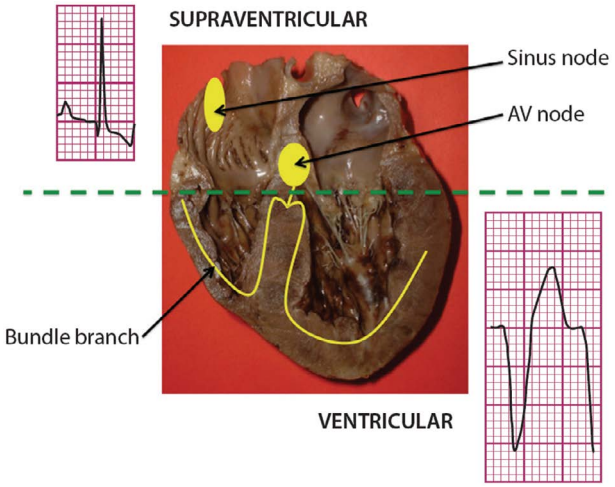

FIGURE 8.6 QRS complex morphology based on the origin of the electrical impulse. Electrical impulses originating at or above the atrioventricular node, that is the supraventricular area, conduct through the specialized conduction system (in yellow). Electrical impulses originating in the ventricles travel within nonspecialized tissue at a lower speed. Supraventricular QRS complexes are narrow; ventricular QRS complexes are wide.

The P waves can be absent in some arrhythmias, but the T waves are always present following QRS complexes. Next, the heart rhythm is analyzed in order to evaluate if it is regular or irregular and if the rhythm is sinus (each P wave related to each QRS complex with a constant PR interval) or not. Analysis of the morphology of the QRS complexes provides information on the origin (e.g., supraventricular or ventricular) of the rhythm. QRS complexes of normal duration indicate that the electrical impulse travels through the specialized conduction system within the ventricle and, therefore, that the rhythm originated in the atrium or the AV node. Conversely, wide QRS complexes usually indicate that the electrical impulses originate within the ventricles (Figure 8.6). Alternatively, it may indicate a bundle branch block, which is a lesion of part of the specialized conduction system requiring the electrical depolarization to travel slowly between cardiomyocytes. Left and right ventricular hypertrophy and intraventricular conduction disturbances can change the amplitude, duration, and/or the direction of the QRS complexes during sinus rhythm. The direction of the QRS complexes is determined by calculation of the mean electrical axis. In dogs, the QRS complex in lead I should always be positive (larger amplitude R wave), indicating that the mean electrical axis of the QRS complexes is oriented toward the left. A negative QRS complex (larger amplitude S wave) in lead I indicates a right-axis shift. In cats, the QRS complex in lead aVF should always be positive, indicating that the mean electrical axis is oriented caudally. When the QRS complex is negative in lead aVF and positive in lead I, it indicates a left-axis shift. When it is negative in lead aVF and lead I, it indicates a right-axis shift (Figures 8.7–8.12).

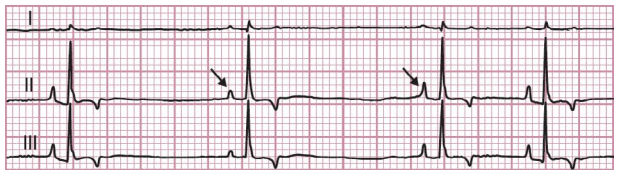

FIGURE 8.7 ECG showing respiratory sinus arrhythmia with wandering pacemaker (arrows) in a dog. Both result from variation of vagal tone with breathing in a healthy dog. Wandering pacemaker is a variation in the amplitude of the P waves with breathing caused by a shift of the origin of the electrical impulses within the sinus node (amplitude 10 mm/mV, speed 50 mm/s).

FIGURE 8.8 ECG showing sinus rhythm with a tall and wide P wave suggesting atrial enlargement (most likely left atrium) (amplitude 10 mm/mV, speed 50 mm/s).

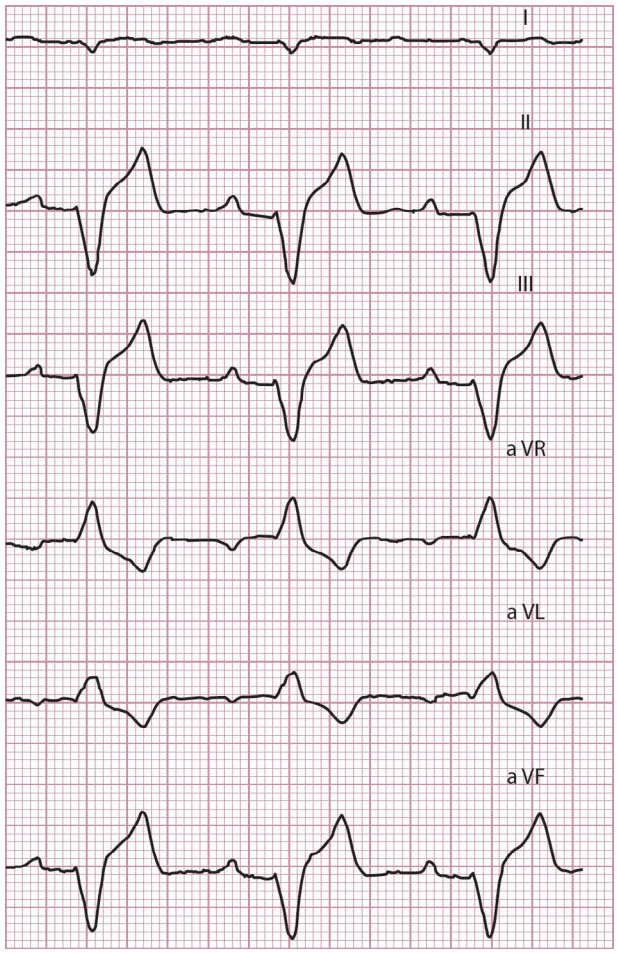

FIGURE 8.9 ECG showing sinus rhythm with a right-axis shift (negative QRS in lead I, II, III, and aVF) and wide QRS complexes, consistent with a right bundle branch block (amplitude 10 mm/mV, speed 50 mm/s).

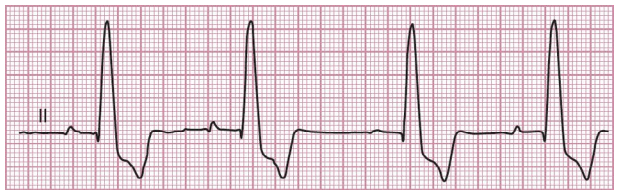

FIGURE 8.10 ECG showing sinus rhythm with positive and wide QRS in lead II, consistent with a left bundle branch block (amplitude 10 mm/mV, speed 50 mm/s).

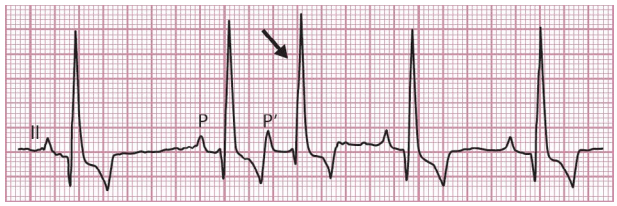

FIGURE 8.11 ECG showing sinus rhythm with one atrial premature contraction (APC) (arrow). The morphology of the QRS complex of APCs is similar to the QRS of sinus beats, as the electrical impulse uses the specialized conduction pathways in the ventricles. A P wave is visible just after the T wave, and its morphology slightly differs from the P wave of sinus beats (amplitude 10 mm/mV, speed 50 mm/s).

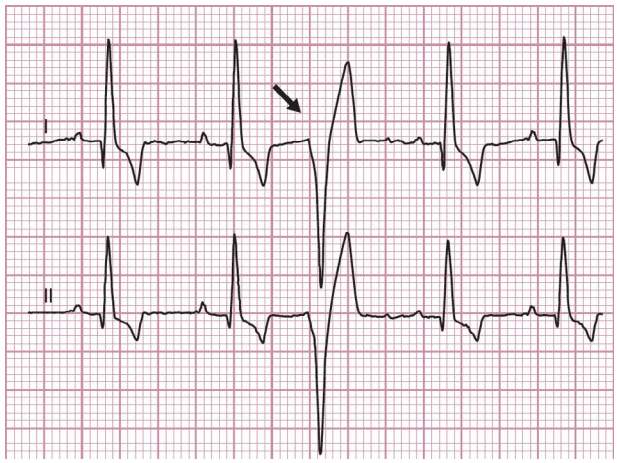

FIGURE 8.12 ECG showing sinus rhythm with one ventricular premature contraction (VPC) (arrow). The morphology of the QRS is "wide and bizarre" and very different from the QRS complexes of sinus beats. It indicates the slow conduction of the electrical impulse in the ventricles.

ECHOCARDIOGRAPHY

Indications

Echocardiography is a noninvasive method of evaluating cardiac anatomy and function. Thoracic radiography and echocardiography are complementary in the evaluation of an animal with cardiac disease. Presence or absence of CHF and size of the pulmonary vessels can only be evaluated from chest radiographs, while information about chamber size, valve motion, and ventricular function can only be obtained via echocardiography. A comprehensive echocardiographic examination requires the use of various modalities, including 2D, M-mode, and Doppler echocardiography (Figure 8.13a–d).

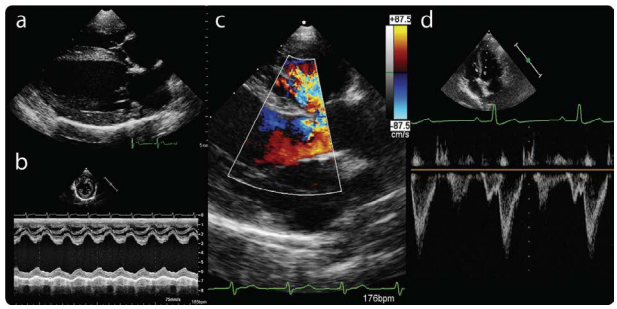

FIGURE 8.13 Echocardiographic modalities: Two-dimensional **(a)**, M-mode **(b)**, color Doppler **(c)**, spectral Doppler **(d)**.

At the end of an echocardiogram, the clinician should have identified the primary lesion and its severity, the presence of coexisting abnormalities, and the size and function of all four cardiac chambers. Finally, the initial echocardiographic examination provides baseline information for assessing the progression of the disease and monitoring the response to treatment of individual patients on follow-up examinations.

Imaging Techniques

Echocardiographic Windows

Transthoracic images of the heart can be obtained where lung tissue is not interposed between the heart and the chest wall. A parasternal window is present on the right side of the thorax between the sternal border and the costochondral junction from the 3rd to the 6th intercostal spaces. On the left side, it is close to the sternal border between the 5th and 7th intercostal spaces (caudal or apical views) and between the sternum and the costochondral junction at the 3rd or 4th intercostal space (cranial views) (Figure 8.14a–f).

Animal Positioning

Echocardiograms are usually obtained with the patient in lateral recumbency on a "cutout" table that allows transducer manipulation from beneath the animal. One or two assistants help restrain the patient in left and right lateral recumbency. ECG cables should be attached to the animal's limbs, and an ECG tracing should be continuously displayed on the monitor. Sedation is usually not needed. Dogs and cats can also be examined in standing position.

Transducer Selection

Transducers with a small contact surface are preferred. The optimal transducer frequency is, therefore, determined by the size of the animal: 8–10 MHz for cats and small breed dogs, 5–8 MHz for medium-size dogs, and 2–5 MHz for large breed dogs.

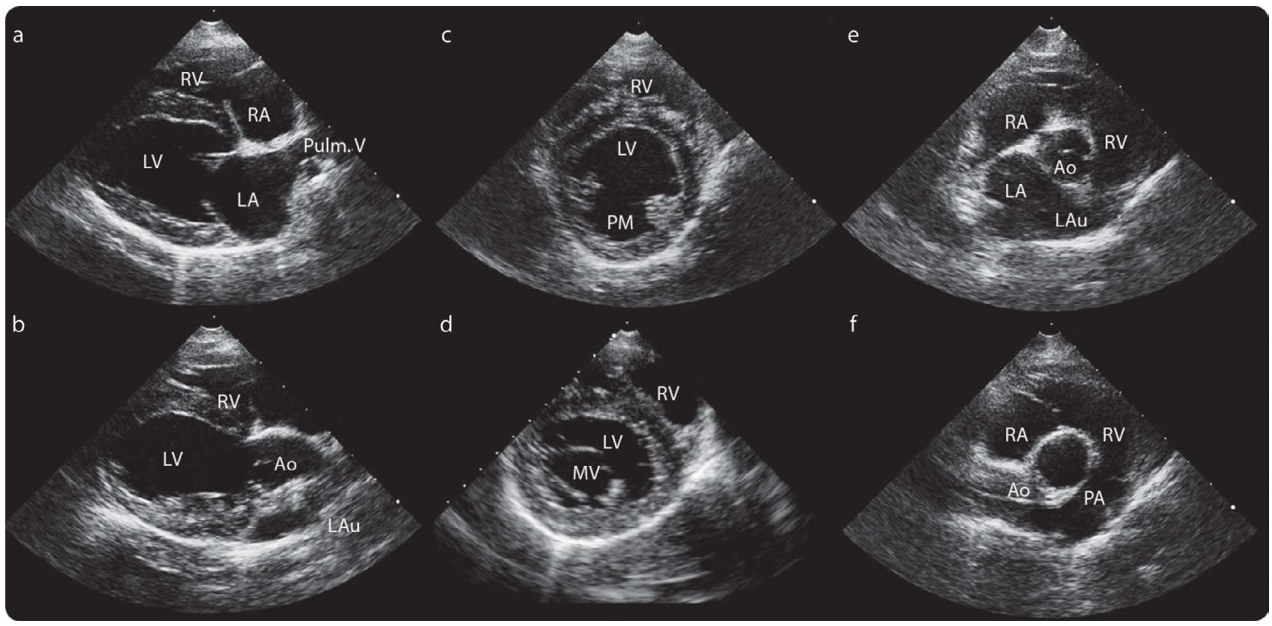

FIGURE 8.14 Standard 2D echocardiographic views. **(a)** Right parasternal long-axis four-chamber view allows visualization of all four cardiac chambers. **(b)** Right parasternal long-axis outflow view. **(c)** Right parasternal short-axis view at the level of the left ventricular papillary muscles. This view is used to measure wall thicknesses and the diameter of the left ventricle in diastole and systole. **(d)** Right parasternal short-axis view at the level of the mitral valve; also called "fish-mouth" view. **(e)** Right parasternal short-axis view at the left atrium/aorta level. This view is used to measure the diameter of the left atrium. **(f)** Right parasternal short-axis view at the pulmonary artery level. The pulmonic valve and the diameter of the pulmonary artery and its main branches can be evaluated from this view.

Echocardiographic Evaluation of Cardiac Chamber Size and Function

Every clinician should be able to evaluate left atrial size, left ventricular size and function, and the size of the right-sided cardiac chambers (Box 8.1).

Left Ventricle

The left ventricle is the largest cardiac chamber. It is conical in shape and forms the apex of the heart. The cavity of the left ventricle is divided into an inflow and an outflow region. The inflow region is directly below the mitral valve and is best assessed from the right parasternal long-axis four-chamber view and the left apical four-chamber view. The interventricular septum limits the outflow tract medially, and the septal leaflet of the mitral valve forms an intermittent lateral boundary at the base of the heart. There is no anatomic partition of the outflow tract in the apical and midventricular regions. The outflow tract is best imaged from the right parasternal long-axis outflow view and the left apical five-chamber view. The interventricular septum separates the left ventricle from the right ventricle and is best imaged from a right parasternal long-axis view. It is thick and muscular for most of its length but has a thin membranous part at the origin of the aorta.

Standard measurements include the interventricular septum thickness, the left ventricular internal diameter, and the left ventricular posterior wall thickness in end-diastole and end-systole. End-diastole is measured at the onset of the QRS complex on ECG, which also corresponds to the frame following mitral valve closure. End-systole occurs at the end of the T wave. In the absence of an ECG, end-systole coincides with the frame preceding mitral valve opening or the frame in which the left ventricular internal diameter is the smallest. Measurements are made on the right parasternal short-axis view at the chordae tendineae level, either directly with calipers on a 2D still frame or on an M-mode display (Figure 8.15).

Qualitative assessment of left ventricular function should be complemented with quantitative measurements. In dogs and cats, left ventricular systolic function is usually determined by measuring the left ventricular internal diameter at end-systole (LVIDs). Measuring

Box 8.1 Qualitative echocardiographic evaluation of cardiac structure and function in the dog

- Left and right atrium are approximately the same size
- The diameter of the left atrium is less than 1.5 times the diameter of the aortic valve annulus
- The right ventricular internal diameter is approximately one-third of the left ventricular internal diameter
- The thickness of the right ventricular wall is approximately one-third of the thickness of the left ventricular free wall
- The interventricular septum is approximately the same thickness as the left ventricular free wall
- The left ventricular internal diameter should decrease by 30%–40% in systole compared with diastole
- The diameter of the main pulmonary artery is the same as the aortic root diameter

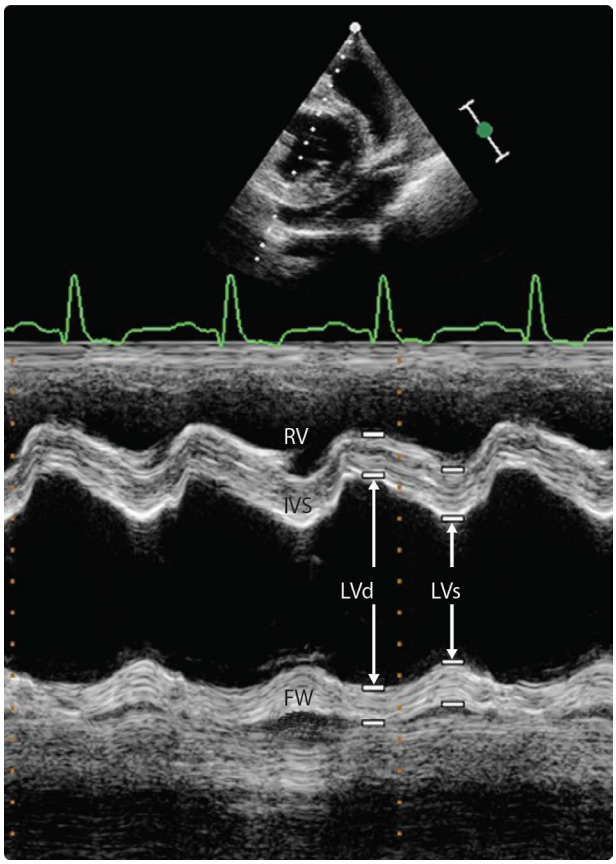

FIGURE 8.15 M-mode view of the left ventricle at the chordae tendineae level. The M-mode cursor is placed perpendicular to the interventricular septum and bisects the left ventricular free wall between the two papillary muscles. FW, left ventricular free wall; IVS, interventricular septum; LVd (LVIDd), left ventricular internal diameter in diastole; LVs (LVIDs), left ventricular internal diameter in systole; RV, right ventricle.

the left ventricular internal diameter at end-diastole (LVIDd) in either 2D or M-mode determines whether chamber dilation (eccentric hypertrophy) is present. In dogs, an allometric equation normalizing chamber dimension to body weight is used (LVIDDN). Left ventricular dilation is present when the normalized left ventricular internal dimension at end-diastole is equal to or greater than 1.7.

$$\text{LVIDDN} = \frac{\text{left ventricular internal diameter indiastole (cm)}}{(\text{body weight [kg]})^{0.294}}$$

Right Ventricle

The right ventricle has a complex geometry, described as crescent shaped or pyramid shaped. This, in addition to its smaller size and thinner walls, makes the echocardiographic assessment of the right ventricle difficult. Qualitatively, the right ventricular internal diameter is approximately one-third of the left ventricle, and the right ventricular free wall is equal to one-third or one-half the thickness of the left ventricular free wall.

The right ventricle chamber is divided into an inflow and an outflow region by a ridge of muscular tissue known as crista supraventricularis. Both regions cannot be fully examined on the same echocardiographic view. The inflow region is directly beneath the tricuspid valve. It is best assessed from the right parasternal long-axis four-chamber view and the left apical four-chamber view. The outflow region is best imaged from the right parasternal short-axis view at the aorta level and the left cranial short-axis views.

Left Atrium

The left atrium is an oval-shaped chamber positioned caudal to the aorta and above the left ventricle. It is divided into the body of the atrium and the auricle. The auricle is heavily trabeculated. The left atrium is best imaged from a right parasternal short-axis view at the aortic valve level. Contraction of the left atrium delivers 15%–30% of left ventricular filling at the end of diastole. The left atrium receives blood from five to eight (usually seven) pulmonary veins, which enter the craniodorsal and caudodorsal part of the chamber. They are usually not clearly visible on the echocardiogram, but pulmonary venous inflow can be identified and studied by pulsed-wave Doppler. The interatrial septum separates the left atrium and the right atrium. The flap of the foramen ovale may be seen from a right parasternal long-axis four-chamber view on the left atrial side in animals with a patent foramen ovale.

Linear measurements of the left atrium are used to calculate the left atrium-to-aortic ratio (LA:Ao). LA:Ao ratio is independent of body weight. In healthy dogs and cats, the LA:Ao ratio is between 1.3 and 1.5 (Figure 8.16). It is usually not > 1.6.

Right Atrium

The right atrium is an ovoid structure divided into a main chamber and the right auricle. In clinical practice, qualitative assessment of the right atrium is made by

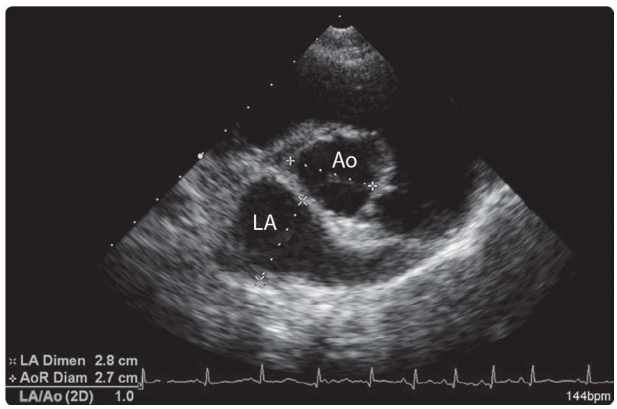

FIGURE 8.16 Measurement of the left atrium and aortic valve annulus from a 2D right parasternal short-axis view. The LA:Ao ratio should be less than 1.6 in healthy animals. Ao, aorta; LA, left atrium.

comparing its size with the left atrium. In healthy animals, left and right atrium are of comparable size.

Doppler Echocardiography

Doppler echocardiography provides information on blood flow direction and velocity. Color-flow Doppler is used to map blood flow on a 2D view of the heart. Blood flow velocity across valves, septal defects, and at the level of extracardiac vascular shunts is measured via pulsed-wave and continuous-wave Doppler. Pressure gradients between cardiac chambers can be calculated from blood flow velocity using the simplified Bernoulli equation (pressure gradient = 4 × peak velocity^2), which makes Doppler echocardiography a practical and noninvasive technique for estimating intracardiac chamber pressures.

CARDIAC BIOMARKERS

Cardiac biomarkers are biological molecules found in the blood that inform about the presence of cardiac disease.

Natriuretic Peptide

Natriuretic peptides are released by the atria and ventricles in response to stretch caused by excessive volume or pressure. A nonbiologically active fragment of the B-type natriuretic peptide (NT-proBNP) has been extensively studied. It has been suggested that NT-proBNP might be useful in identifying a cardiac cause for dyspnea, detecting occult cardiac disease (dilated cardiomyopathy [DCM], hypertrophic cardiomyopathy [HCM]), and predicting mortality in dogs with heart disease. Studies have shown that NT-proBNP has limited value as a stand-alone test but can be used to orientate a decision to pursue more advanced tests (chest radiographs, echocardiogram, Holter recording). Typically, NT-proBNP level is elevated in dogs with heart failure and increases as the heart enlarges. In cats with HCM, NT-proBNP concentration is increased. High NT-proBNP levels in a cat with pleural effusion strongly suggest a cardiac cause for the effusion. However, increased NT-proBNP concentration is also detected with hyperthyroidism, systemic hypertension, PH, and renal failure because it is renally excreted. Noncardiac disease should be suspected in a dyspneic cat with normal NT-proBNP levels.

Cardiac Troponin I

Cardiac troponin I (cTnI) is one of the proteins involved in contraction of cardiomyocytes. Disruption of the membrane of some cardiomyocytes leads to leakage of cTnI into the circulation. Moderate-to-large elevations in cTnI concentration can be detected with current assays. Moderate elevations (approximately ten-fold increase compared with healthy animals) are common in the presence of CHF, third-degree AV block, or subaortic stenosis (SAS). Large elevations (approximately 50- to 200-fold increase compared with healthy animals) are thought to indicate myocarditis if this diagnosis is supported by the history and clinical presentation. Important elevations of cTnI concentration also occur with myocardial infarction, which is rare in dogs and cats.

HEART FAILURE

Definition/Overview

Heart failure occurs when there is inadequate delivery of oxygen to the tissues of the body from impaired cardiac function and maldistribution of blood despite adequate venous return to the heart. CHF occurs with impaired cardiac function and a concurrent increase in venous and capillary pressures, which result in fluid accumulation in tissues and organs of the body.

Pathophysiology

Biochemical, mechanical, and functional alterations occur in the failing heart. Biochemical changes are dominated by a decrease in the rate of adenosine triphosphate (ATP) hydrolysis. Cardiac contraction depends on the interaction between actin and myosin proteins, particularly the heavy meromyosin heads that repeatedly bind to actin. Decreased ATP hydrolysis leads to less interaction of heavy meromyosin heads with actin. The primary mechanical derangement in the failing heart is a reduction of the maximal velocity at which the heavy meromyosin heads can cycle, resulting in a decrease in myocardial fiber shortening. Overall, this is a decrease in contractility or pump function that is observed with heart failure. In a healthy heart, increased ventricular filling (or preload) results in a more forceful contraction. The failing heart, however, generates a lower force of contraction (systolic function) than expected despite an increased preload present prior to contraction. Hence, for any given preload, the systolic function is less than anticipated when compared with normal.

A small decrease in cardiac output is detected by high-pressure baroreceptors in the aorta and triggers an activation of the adrenergic system. Alpha and beta-adrenergic stimulation results in an increase in heart rate and cardiac contractility, as well as peripheral vasoconstriction. In addition to the stimulation of the sympathetic nervous system, renin is released from the kidneys secondary to decreased renal blood flow. Angiotensinogen is cleaved via renin to angiotensin I in the liver. Angiotensin I is then cleaved by the angiotensin-converting enzyme (ACE) to angiotensin II in the vasculature. Angiotensin II activation results in vasoconstriction; antidiuretic hormone (ADH) release from the posterior pituitary gland, which further constricts small arteries, arterioles, and veins and decreases urine production; and aldosterone release from the adrenal medulla, which results in sodium and water retention in the distal collecting duct. Moreover, over

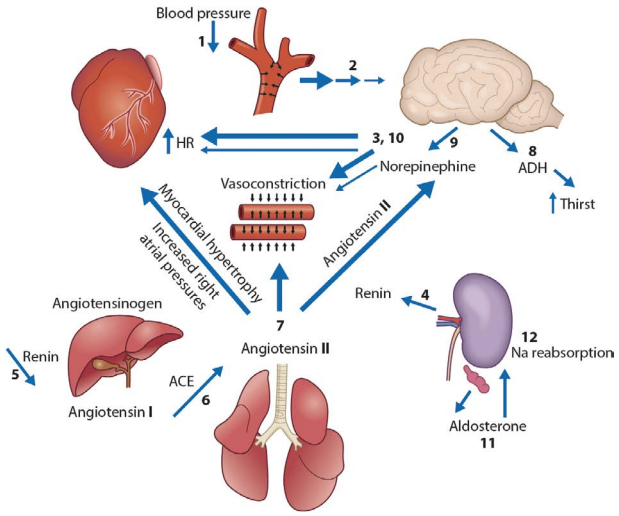

FIGURE 8.17 Sequence of compensatory mechanisms during heart failure. Numbers indicate the sequence of events. Vascular under filling (1) detected by the arterial baroreceptors activates the sympathetic nervous system (2), resulting in vasoconstriction and tachycardia (3), and renin release (4). Activation of the renin angiotensin system (5–7) contributes to activation of the sympathetic system (9) and vasoconstriction (10). Release of ADH (8) causes thirst, and aldosterone (11) is responsible for sodium and water retention (12).

time, angiotensin II stimulates myocardial hypertrophy, fibrosis, and vascular smooth muscle growth, leading to arteriolar narrowing (Figure 8.17).

Pulmonary edema from left-sided CHF occurs typically when left atrial pressure is above 18–22 mmHg (normally 7 mmHg), and a large volume of serum begins to weep from the pulmonary capillaries into the lung inter stitium and alveolar space at a rate above the capacity of the pulmonary lymphatics to drain it in accordance with the principles of Frank-Starling law.

Clinical Presentation

Animals with left-sided CHF (pulmonary edema) typically present with tachypnea and dyspnea depending on the chronicity and amount of edema accumulation. Thoracic auscultation most commonly reveals tachycardia; however, some cats and, rarely, dogs are bradycardic. Cardiac auscultation may also reveal the presence of heart murmurs, gallop sounds, and arrhythmias. Respiratory sounds are usually increased, and crackles may or may not be present. Tachycardia with increased respiratory rate and effort in a dog is a more reliable indicator of pulmonary edema than the presence of crackles alone. Cough may be present but can commonly occur with airway disease in small breed dogs with concurrent mitral valve degeneration and tracheal collapse. Cough in a large breed dog is a more reliable indicator of pulmonary edema. Syncope may also be reported in dogs with mild pulmonary edema. More severe clinical signs include coughing up pink-tinged sputum; these animals require immediate emergency attention and exceptional measures such as intubation and mechanical ventilation (Figure 8.18).

FIGURE 8.18 Dog with severe pulmonary edema coughing up pink, blood-tinged sputum.

Left-sided CHF in cats may differ from dogs in terms of clinical signs and fluid accumulation. Cats more frequently develop bradycardia, hypotension, and hypothermia. Additionally, left-sided CHF can also lead to pleural effusion and/or small amounts of pericardial effusion. Dual venous drainage of the pleural surfaces in cats can allow pleural effusion with left- and/or right-sided CHF. It is hypothesized that in cats with left-sided CHF the visceral lung drainage via the pulmonary veins is impaired and pleural effusion results. Conversely, pleural effusion in cats with right-sided CHF would result from impaired drainage of the parietal lung via the systemic veins.

Right-sided CHF in dogs typically causes ascites. Pleural effusion, pericardial effusion, and subcutaneous edema can also be seen but tend to occur at a later stage of the disease than ascites. Pleural effusion alone is unusual but can be seen with tricuspid valve dysplasia (TVD)/stenosis, pericardial disease, cranial caval obstruction, and supraventricular tachyarrhythmias. Signs of right-sided CHF include abdominal distension, jugular pulsation and distension, positive hepatojugular reflex, and possibly swollen subcutaneous tissue. Limb edema is most commonly seen with advanced disease, and focal facial and neck swelling may suggest cranial caval obstruction or pericardial disease. Auscultation most commonly reveals tachycardia. Murmurs, gallop sounds, split S2 heart sounds, and arrhythmias may also be noted. Lung sounds and heart sounds may be decreased in the presence of a large volume of pleural effusion.

In cats, right-sided CHF is rare, and ascites alone in a cat is usually not cardiac related. Pleural effusion is the most common presentation for right-sided CHF in cats.

Differential Diagnosis

Conditions that mimic left-sided CHF include pulmonary thromboembolism (PTE), noncardiogenic pulmonary edema (airway obstruction, electrocution, strangulation, near-drowning, neurogenic), hemorrhage, neoplasia, systemic inflammatory response syndrome, and acute respiratory distress syndrome. Differential diagnoses for ascites and pleural effusion should include right-sided CHF, hypoalbuminemia, hepatic disease, vasculitis, hemorrhage, infection, and neoplasia.

Diagnosis

Diagnosis of left-sided CHF can be made readily from thoracic radiographs (see Chapter 6). Pulmonary edema can be noted in canine patients, and pulmonary edema and/or pleural effusion may be noted in cats. In dogs, pulmonary infiltrates are most commonly seen in the caudodorsal lung lobes and typically in the right caudal lung lobe first. Left-sided cardiomegaly will often be present, as well as pulmonary venous distension unless the patient is already being administered furosemide (Figure 8.19). In cats, pulmonary edema has a more diffuse distribution, and cardiomegaly may be more difficult to recognize than in dogs. Ultrasonography is a useful tool to detect pleural effusion.

Diagnosis of right-sided CHF can be made from physical examination, radiographs, and/or ultrasound. Thoracic radiographs may show pleural effusion and suggest ascites as a loss of detail in the cranial abdomen. Abdominal ultrasound shows abdominal effusion and hepatic venous congestion.

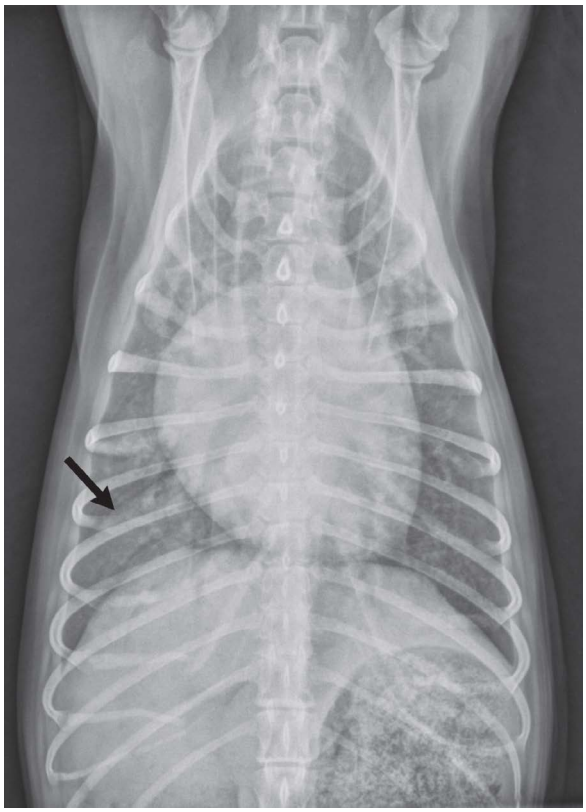

FIGURE 8.19 Radiograph from a dog with cardiogenic pulmonary edema. Note that the alveolar pattern is predominantly right-sided (arrow).

Management

Treatment recommendations are made according to a classification of the consecutive stages of heart failure (Table 8.9). Drugs indicated for the treatment of heart failure include diuretics, inodilators (pimobendan), ACE inhibitors, aldosterone antagonists, vasodilators,

TABLE 8.9 Classification of heart disease stages (based on American College of Veterinary Internal Medicine [ACVIM] consensus statement)

Stage of heart disease	Description
A	Animals at high risk for developing heart disease but currently have no identifiable structural disorder of the heart
B	Animals with structural heart disease (e.g., the typical murmur of mitral valve regurgitation is present) but have never developed clinical signs caused by heart failure – *Stage B1:* Asymptomatic animals that have no radiographic or echocardiographic evidence of cardiac remodeling in response to CVHD MMVD as well as those in which remodeling changes are present but not severe enough to initiate medical therapy (pimobendan) – *Stage B2:* Asymptomatic animals that have hemodynamically significant valve regurgitation, as evidenced by radiographic or echocardiographic findings of left-sided heart enlargement and for whom medical therapy is warranted (pimobendan)
C	Animals with past or current clinical signs of heart failure associated with structural heart disease May or may not require hospitalization and aggressive therapy
D	Animals with end-stage disease with clinical signs of heart failure caused by MMVD that are refractory to standard therapy Such patients require advanced or specialized treatment strategies in order to remain clinically comfortable with their disease As with stage C, some animals in stage D will require acute, hospital-based therapy, and others can be managed as outpatients

CVHD, chronic valvular heart disease; MMVD, myxomatous mitral valve disease.

TABLE 8.10 Drugs commonly used in treatment of congestive heart failure*

Diuretics	– Furosemide 0.5–4 mg/kg p.o., IM or IV q.8–12h.; usually 0.3–0.5 mg/kg/h CRI (up to 1 mg/kg/h in refractory cases) – Spironolactone 0.5–2 mg/kg p.o. q.12–24h. – Hydrochlorothiazide 0.5–1 mg/kg p.o. q.12–48h. – Torsemide—total daily furosemide dose divided by 10–20 and split into p.o. q.12–24h. dosing (author currently uses total daily furosemide dose divided by 10 and split into q.12h. dosing)
ACE inhibitors	– Benazepril 0.25–0.5 mg/kg p.o. q.24h. – Enalapril 0.25–0.5 mg/kg p.o. q.12–24h.
Positive inotropes	– Pimobendan 0.2–0.4 mg/kg p.o. q.12h. – Digoxin 0.005 mg/kg p.o. q.12h. – Dobutamine 3–10 μg/kg/min IV CRI
Calcium channel blockers	– Amlodipine 0.1–0.5 mg/kg p.o. q.24h. – Diltiazem 0.5–2 mg/kg p.o. q.8–12h. – Diltiazem extended release 2–5 mg/kg p.o. q.12h.
Beta-adrenergic receptor blockers	– Atenolol 0.5–2 mg/kg p.o. q.12–24h. – Propranolol (beta 1 & 2) 0.25–2 mg/kg p.o. q.8h.
Vasodilators	– Nitroprusside 2–5 μg/kg/min CRI – Hydralazine 0.5–3 mg/kg p.o. q.12h.
Nitrates	– Nitroglycerin small dogs: 1/4–1/2 inch topically; medium dogs: 1/2–1 inch; large dogs 1–2 inches q.6–12h. for 24–48 hours (wear gloves) – Isosorbide dinitrate 0.2–2 mg/kg p.o. q.12h.
PDE-5 inhibitor	– Sildenafil 1–3 mg/kg p.o. q.8–12h.

* All doses are for canines unless otherwise indicated. CRI, continuous rate infusion; PDE-5, phosphodiesterase-5.

positive inotropes, and modulators of the autonomic tone (Table 8.10).

In dogs with valvular disease or dilated cardiomyopathy, pimobendan should be initiated once radiographic and echocardiographic evidence of heart enlargement are present (stage B2). The initiation of ACE inhibitors in dogs with severe cardiac disease but no evidence of decompensation (stage B2) is controversial. Dogs with stage B1 and B2 heart disease should be rechecked every 6–12 months to monitor progression of the disease, and owners should be educated to recognize the signs of CHF. Whenever the risk of CHF is high, the pet owner should monitor the animal's resting respiratory rate on a daily basis. A resting respiratory rate above 40 bpm is a sensitive indicator of CHF and should trigger evaluation by a veterinarian.

Treatment of left-sided CHF in dogs always involves administration of furosemide. IV, SC, or IM furosemide and oxygen therapy should be considered in patients with moderate-to-severe pulmonary edema and clinical signs. IV furosemide is beneficial in these patients to rapidly clear edema and cause release of prostaglandins, which increase renal blood flow. Administration of furosemide as a constant rate infusion (CRI) is a good alternative to repeated boluses every few hours; however, a bolus of furosemide should always be given when the CRI is started. In hospitalized patients, IV dobutamine administration for positive inotropic support via direct beta-adrenergic stimulation can be considered, especially in patients with DCM or advanced mitral valve disease. Pimobendan should be administered during hospitalization as part of the management of acute heart failure. Afterload reduction with IV nitroprusside through direct vasodilatory properties can be considered, especially in cases that are refractory to standard diuretic therapy. Mild edema may be treated on an outpatient basis with possible single-dose administration of furosemide (IV, SC, or IM) and continued therapy at home with oral furosemide. Pimobendan should always be initiated at the time of diagnosis if the dog is not already taking it, as long as there are no known contraindications to its use (left ventricular outflow tract obstruction). An ACE inhibitor should always be instituted for the long-term management of all cardiac patients with left-sided CHF as long as renal values and clinical signs related to renal disease are reasonable and the patient is eating well at home. ACE inhibitors are imperative for blunting the neurohormonal activation of the renin–angiotensin–aldosterone (RAAS) system, which is stimulated by the continuous administration of furosemide. Further RAAS blockade can be considered with spironolactone administration, an aldosterone blocker and weak potassium-sparing diuretic. Arrhythmias that are present may also require treatment. Chronic, refractory left-sided CHF can be managed by multinephron blockade with additional diuretics that work at different levels of the kidney (spironolactone, hydrochlorothiazide). Hydrochlorothiazide must be used very cautiously in patients with concurrent kidney disease, low sodium, and refractory CHF, as this diuretic will interfere with the ability of the patient to dilute urine and excrete solute free water. Torsemide, a diuretic 10 to potentially 20 times more potent than furosemide can be used to replace furosemide in chronic cases. Finally, sildenafil administration for treatment of severe PH can be considered with caution, as treatment may worsen left-sided CHF.

Treatment of right-sided CHF in canine patients is similar to that for left-sided CHF. Typically, treatment

FIGURE 8.20 Abdominocentesis in a dog using a 16-gauge catheter.

is not as urgent, but initiation of injectable furosemide may be beneficial in cases with ascites where abdominal organs surrounded by fluid may not readily absorb oral furosemide. Body cavity fluid removal is as imperative as furosemide administration, and as much fluid as possible should be removed from the abdominal and/or pleural spaces (Figure 8.20). Oral administration of the medications previously discussed is also recommended for right-sided CHF, with an emphasis on diagnosing and treating PH. Administering spironolactone is recommended by some, as normal aldosterone breakdown by the liver may be inhibited with a congested liver and right-sided CHF. Additionally, atrial tachyarrhythmias should also be investigated and treated, as loss of atrial contraction may worsen right-sided CHF more than left-sided CHF. Furosemide doses may also be more conservative in cases of severe PH where dramatic preload reduction may result in poor forward flow and systemic hypotension.

Treatment of cats with CHF will vary from dogs in five major ways: (1) Furosemide dosage will be lower and more conservative; (2) efforts should be made to correct hypothermia and hypotension; (3) pimobendan is only indicated if there is no evidence of a left ventricular outflow tract obstruction; (4) hypokalemia is a common side effect of furosemide therapy; therefore, potassium concentration should be monitored frequently and oral supplementation initiated before signs of hypokalemia occur; (5) diuretics other than furosemide and spironolactone must be used with extreme caution.

PH, cough from bronchi compression by an enlarged heart, and syncope are also complications of heart failure that may require specific therapies (Table 8.11).

TABLE 8.11 Treatment of clinical signs of heart failure in the absence of congestive heart failure

Clinical sign	Treatment
Syncope	Rule out CHF with radiographs and consider ruling out an arrhythmia via Holter monitor Start or adjust dosage of ACE inhibitor, spironolactone, or pimobendan or increase current dose of furosemide to alter loading of the heart
Pulmonary hypertension	Sildenafil 1–3 mg/kg p.o. q.8–12h.
Cough	Hydrocodone 0.25 mg/kg p.o. q.6–12h. or butorphanol 0.2–0.4 mg/kg p.o. q.6–12h.

Prognosis

The average survival time for a patient with CHF is approximately 6–14 months with aggressive medical management. Dogs with right-heart failure and recurrent ascites quickly develop cardiac cachexia, which significantly impairs their quality of life.

CONGENITAL HEART DISEASES

Congenital heart diseases (CHDs) are morphologic abnormalities of the heart and great vessels present at birth. CHDs are uncommon in dogs and rare in cats. The most common CHDs in the dog are SAS, PS, and PDA. The most common CHDs in the cat are atrial septal defects (ASDs), ventricular septal defects (VSDs), and valvular dysplasias. Although many CHDs have breed predispositions and some have been shown to be heritable traits, not all CHDs are inherited (Table 8.12). CHDs are often diagnosed based on auscultation of a significant or unusual murmur in a young patient, leading to further cardiac workup. Swift detection may allow for treatment at an earlier stage of disease, improving patient prognosis and quality of life.

SUBAORTIC STENOSIS

Definition/Overview

Aortic stenosis results from a narrowed left ventricular outflow tract in the region of the aortic valve, which can occur at a subvalvular, valvular, or supravalvular level. In dogs, the most common manifestation is subaortic stenosis (SAS).

Etiology

A genetic mutation responsible for SAS has been identified in Newfoundlands.

Pathophysiology

Stenosis occurs from anomalous development of a fibrous band or ring of tissue at the subvalvular level which interferes with blood flow. The induced pressure overload on the left ventricle causes left ventricular concentric hypertrophy and sometimes left atrial enlargement. The turbulence and increased velocity of flow through the stenotic outflow tract creates a left systolic basilar murmur. SAS predisposes to ventricular arrhythmias secondary to myocardial ischemia due to the increase in myocardial volume, diminished coronary blood flow, and subendocardial fibrosis. Less commonly, the increase in pressure in the left atrium can lead to left-sided CHF.

Clinical Presentation

Animals with moderate-to-severe SAS often present with signs of failure to thrive, exercise intolerance, and syncope. Tachypnea or dyspnea associated

TABLE 8.12 Breed predisposition for congenital heart diseases

Congenital defect	Breed predisposition	Known heritable mutation
Subaortic stenosis	Newfoundland, Rottweiler, Golden Retriever, Boxer, Great Dane, German Shorthair Pointer, German Shepherd Dog, Bouvier des Flandres, English Bulldog, Samoyed, Bull Terrier (valvular stenosis)	Newfoundland
Pulmonic stenosis	English Bulldog, French Bulldog, West Highland White Terrier, Beagle, Mastiff, Samoyed, Miniature Schnauzer, American Cocker Spaniel, Keeshond, Boxer, Chihuahua, Airedale Terrier	Beagle
Tricuspid valve dysplasia	Labrador Retriever, Golden Retriever, German Shepherd Dog	Labrador Retriever
Ventricular septal defect	Beagle, English Springer Spaniel, Keeshond, English Bulldog	Beagle, English Springer Spaniel
Atrial septal defect	Poodle, Dobermann, Boxer, Samoyed	Poodle
Mitral valve dysplasia	Bull Terrier, Rottweiler, Golden Retriever, Newfoundland, Mastiff, German Shepherd Dog	
Patent ductus arteriosus	Poodle, German Shepherd Dog, Pomeranian, Shetland Sheepdog, Collie, Maltese, Yorkshire Terrier, Chihuahua, Bichon Frise, Keeshond, American Cocker Spaniel, Rottweiler, English Springer Spaniel, Labrador Retriever, Newfoundland	Poodle
Tetralogy of Fallot	Keeshond, English Bulldog, Wire-haired Fox Terrier, Miniature Schnauzer, West Highland White Terrier	Keeshond
Persistent right aortic arch	German Shepherd Dog, Irish Setter, German Short-haired Pointer, Greyhound	German Short-haired Pointer

with the development of CHF occurs in older dogs. Animals that develop rapid and sustained ventricular tachyarrhythmias may die suddenly. Physical examination reveals a left basilar systolic murmur whose grade correlates with the degree of SAS, weak femoral pulses when the stenosis is severe, and, on occasion, arrhythmias.

Differential Diagnosis

PS, VSD, physiologic murmur.

Diagnosis

Thoracic radiographs may show a poststenotic dilation of the aortic root. Definitive diagnosis is accomplished via echocardiography, which allows visualization of the location of the stenosis and the fibrous anomaly itself, as well as the severity of secondary changes, including left ventricular concentric hypertrophy and atrial dilation (Figure 8.21a, b). Aortic insufficiency is often present. Color-flow echocardiography may show turbulent blood flow through the left ventricular outflow tract, and Doppler echocardiography is used to quantify the severity of the stenosis based on the peak systolic aortic blood flow velocity (Figure 8.22). A pressure gradient above 80 mmHg across the stenosis is consistent with severe SAS. Boxers and Golden Retrievers, which are predisposed to SAS, can also have mild forms of the disease that result in soft murmurs that can be difficult to differentiate from physiologic murmurs. In Boxers, a narrow left ventricular outflow tract compared with similar-sized dogs may explain the high prevalence of physiologic murmurs in this breed.

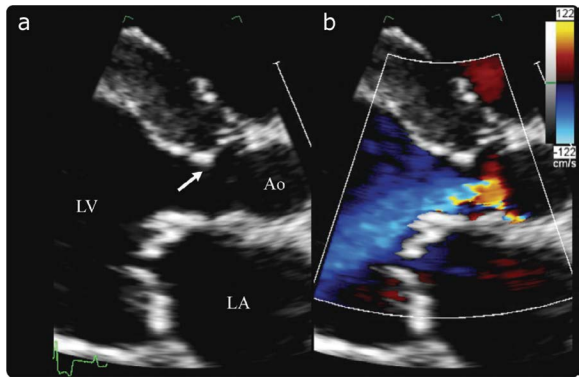

FIGURE 8.21 (a) Right parasternal long-axis echocardiographic view showing a subaortic ridge (arrow). **(b)** Color Doppler reveals turbulence in the aorta beyond the stenotic lesion.

Management

Moderate-to-severe SAS can be medically managed with beta-blockers (atenolol, 0.5–1 mg/kg p.o. q.12–24h.) to slow the heart rate, reduce myocardial oxygen demand, and for their antiarrhythmic properties. The goal of medical therapy is to decrease the frequency of syncopal episodes, improve exercise tolerance, and reduce the risk of sudden death. Interventional procedures to relieve the stenosis have had mixed results. Severe cases of SAS with a poor long-term prognosis may benefit from balloon valvuloplasty with a cutting and/or high-pressure balloon to relieve the pressure gradient across the stenosis, but this technique is as yet unproven in terms of improving quality of life and long-term survival. The less common cases of valvular stenosis may improve with a

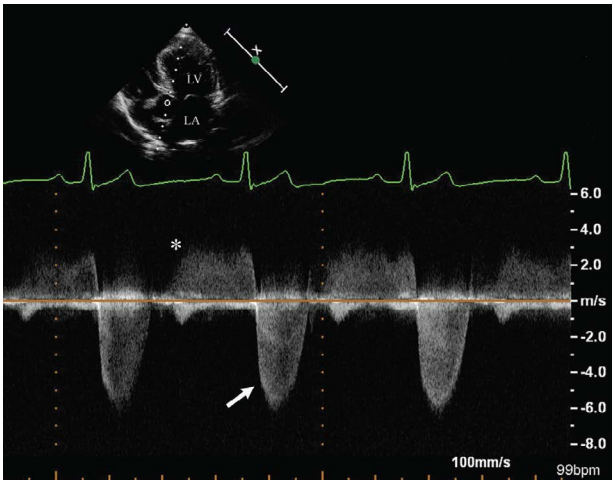

FIGURE 8.22 Continuous-wave Doppler recording of aortic flow in a dog with severe subaortic stenosis. The ultrasound beam has been oriented parallel to the blood flow from a left-sided apical four-chamber echocardiographic view. Peak velocity in systole is 6 m/s (pressure gradient of 164 mmHg) and consistent with severe subaortic stenosis (arrow). There is also aortic insufficiency in diastole (asterisk).

more traditional balloon valvuloplasty technique. CHF is managed as appropriate with diuretic and ancillary medications. Antibiotics are recommended during surgery and for dental prophylaxis procedures because of the mildly increased risk of infective endocarditis found in patients with SAS.

Prognosis

Mild SAS has a good prognosis, but cases of moderate SAS tend to develop CHF later in life. Dogs with severe SAS are at significant risk of sudden death before 3–5 years of age.

PULMONIC STENOSIS

Definition/Overview

Pulmonic stenosis (PS) results from a narrowed right ventricular outflow tract in the region of the pulmonic valve, which can occur at a subvalvular, valvular, or supravalvular level. The most common manifestation in dogs is valvular. PS is less common in cats. The lesion consists of thickening or fusion of the valve leaflets and may be accompanied by hypoplasia of the valve annulus. English Bulldogs and some Boxers may have an abnormal coronary vasculature, which consists of a single right coronary artery circling in front of the pulmonary artery to supply blood to the left ventricle (R2A anomaly) (Figure 8.23). This vessel might contribute to the stenosis and may rupture or be occluded during balloon valvuloplasty, resulting in the dog's death. Other coronary vasculature anomalies have been described, such as a single left coronary artery, but they do not always preclude from performing a valvuloplasty.

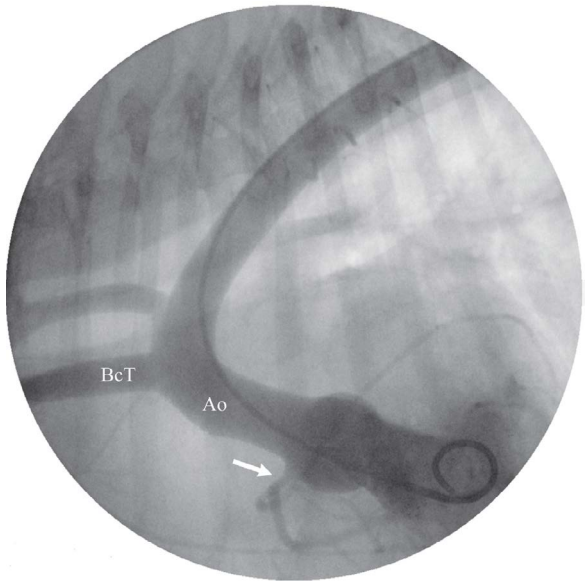

FIGURE 8.23 R2A anomaly in an English Bulldog. Aortogram using a pigtail catheter reveals a single coronary artery originating from the right coronary cusp (arrow). A branch crosses in front of the aorta and supplies blood to the left ventricle. Ao, aorta; BcT, brachiocephalic trunk.

Etiology

PS is heritable in Beagles.

Pathophysiology

The obstruction to flow results in an increased pressure within the right ventricle, causing concentric right ventricular hypertrophy and myocardial fibrosis with possible dilation of the right atrium. Turbulent blood flow and increased velocity through the stenotic valve result in a left basilar systolic murmur. Patients with severe PS develop right-sided diastolic dysfunction and ultimately are at risk of right-sided CHF from chronic pressure overload. Right ventricular myocardial failure may eventually result from severe PS. TVD is an occasional concurrent congenital defect and results in exacerbation of right heart dysfunction and more severe clinical signs.

Clinical Presentation

Most animals with PS will have no clinical signs to mild clinical signs. The approximately one-third of dogs with PS that do exhibit clinical signs often present with dyspnea, lethargy, exercise intolerance, or syncope. In later stages, signs associated with right-sided heart failure may be present. Physical examination reveals a left-sided systolic basilar murmur (with a concurrent right apical murmur if tricuspid regurgitation is present). Jugular distension is associated with an increase in right atrial pressure. If right-sided CHF is present, abdominal palpation may reveal the presence of ascites and hepatomegaly. The presence of a patent foramen ovale at the atrial level can be the site of right-to-left blood shunting, leading to cyanosis, hypoxemia, and polycythemia.

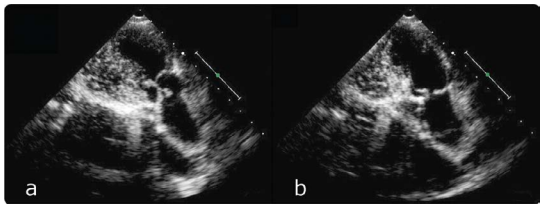

FIGURE 8.24 Right parasternal short-axis echocardiographic view from a dog with pulmonic valve stenosis. The valve is shown in diastole **(a)**. In systole, the valve takes a dome-like shape **(b)**.

Differential Diagnosis

SAS, physiologic murmur, tetralogy of Fallot (TOF), VSD.

Diagnosis

Thoracic radiographs often show the presence of post-stenotic dilation of the pulmonary trunk and right-sided cardiomegaly. Echocardiography is used to determine the structure of the pulmonic valve and the severity of ventricular concentric hypertrophy and to detect the presence of tricuspid insufficiency (Figure 8.24a, b). Doppler echocardiography is essential to determine the severity of the stenosis. Continuous-wave Doppler is used to determine the peak systolic pressure gradient across the stenosis. Good alignment of the Doppler beam with blood flow can usually be obtained from the right parasternal short-axis view at the level of the pulmonary artery or from a left cranial window along the sternum. The severity of the stenosis is based on peak systolic pressure gradient. It is mild when the peak gradient is between 20 and 49 mmHg (velocity of 2.25–3.5 m/s), moderate when peak gradient is between 50 and 80 mmHg (velocity of 3.5–4.5 m/s), and severe if the peak gradient is above 80 mmHg (velocity above 4.5 m/s).

Management

The goal of treatment is to reduce the systolic right ventricular pressure overload. This is accomplished in cases of moderate-to-severe PS via surgical procedures or balloon valvuloplasty. Balloon valvuloplasty works best in cases of valvular stenosis without hypoplasia of the valve annulus (Figure 8.25). Generally, a reduction of 40%–50% can be expected in the pressure gradient, and this reduction is maintained in the majority of cases. In cases of mild PS or those with mild clinical signs, beta-blockers can be used to reduce myocardial oxygen demand and for their antiarrhythmic properties.

Prognosis

Prognosis varies based on the severity of the stenosis.

PATENT DUCTUS ARTERIOSUS

Definition/Overview

The ductus arteriosus during fetal development serves to shunt oxygenated blood from maternal circulation away from the fetal lungs directly to the systemic circulation. When the lungs inflate at birth, reversal of the blood flow brings oxygenated blood from the aorta through the ductus and stimulates constriction of the ductus smooth muscle. Normally, the ductus closes by 7–10 days after birth. A patent ductus arteriosus (PDA) occurs when the ductus remains patent past this period, allowing blood to shunt according to the pressure gradient.

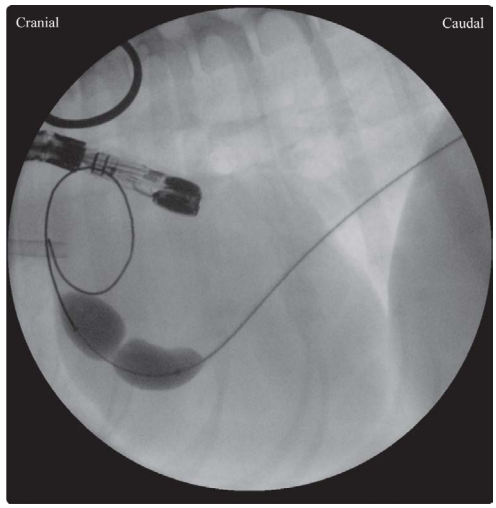

FIGURE 8.25 Fluoroscopic view during balloon valvuloplasty. The catheter is inserted from a femoral vein and positioned at the level of the pulmonic valve. During inflation, a waist is seen in the center of the balloon. Rapid expansion of the balloon usually results in a successful procedure.

Etiology

PDA is considered heritable in Poodles.

Pathophysiology

In most cases, a PDA results in blood shunting from the aorta to the pulmonary artery (left-to-right shunt) and left-sided volume overload. The blood shunting directly to the pulmonary circulation returns to the left side of the heart. As a result, the left ventricle and the left atrium become dilated. Large shunts increase the filling pressure in the left heart and pulmonary veins, with the end result being left-sided CHF. The severity of the shunt (mostly determined by the size of the patent vessel) and the presence of other defects result in varying progression of secondary changes. In rare cases with large shunts and severe PH, shunt reversal is observed. Blood thus flows from the pulmonary artery to the aorta—a right-to-left shunt—causing a differential cyanosis, hypoxemia, and eventually polycythemia (Eisenmenger physiology). Shunt reversal typically occurs in puppies that are a few days to a few weeks old. It is not the usual progression of a PDA in adult dogs.

Clinical Presentation

Clinical signs vary based on the size of the shunt, the direction of the shunt, and the presence of CHF. Signs

may include exercise intolerance, syncope, cough, dyspnea, and, in the case of a reverse shunt, hind limb weakness or seizures. On physical examination of animals with a left-to-right PDA, a pathognomonic continuous (machinery) murmur is heard cranially in the left axillary region. Bounding femoral pulses may be palpated due to diastolic runoff. In animals with a reverse PDA, there is no audible murmur, but careful inspection of the mucous membranes should reveal differential cyanosis, that is cyanosis limited to the caudal mucous membranes.

Differential Diagnosis

Aorto pulmonary window, which is a connection between the ascending aorta and the pulmonary trunk. A to-and-fro murmur from aortic stenosis and insufficiency could mimic the continuous murmur heard with a PDA.

Diagnosis

Thoracic radiographs may show left-sided cardiomegaly, pulmonary over circulation, signs of CHF, and a ductal aneurysm of the aorta at the insertion of the ductus. Electrocardiography frequently shows a tall R wave in lead II (indicative of left ventricular enlargement). Echocardiography is necessary to confirm the presence of the shunt, evaluate the severity of left heart chamber enlargement, and identify concurrent CHDs and the presence of mild-to-severe PH. Measurement of the shunt is performed to determine suitable procedures for shunt closure (Figure 8.26a, b).

Management

PDAs are best treated with early closure, either by surgical or cardiac catheterization procedures. Medical treatment for patients in CHF is indicated prior to closure. Surgery performed by experienced surgeons has a success rate of up to 95% (Figure 8.27), and there are comparable results for catheterization procedures, even in very small dogs. Current interventional procedures used to close shunts use catheterization to place coils (coil embolization) or other devices produced specifically to interrupt blood flow across the shunt (occluder, vascular plug) (Figure 8.28). Residual flow after intervention, if present, may decrease over time. The risk of infection of the implants is unknown. Antibiotics are recommended during surgery and for dental prophylaxis procedures for 1 year after the implant is placed. Closure of reverse PDAs is contraindicated.

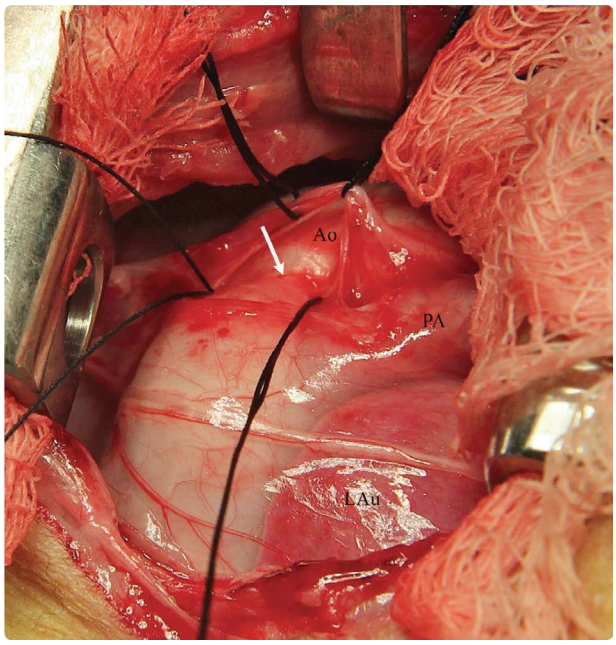

FIGURE 8.27 Surgical ligation for a patent ductus arteriosus (arrow) from a left thoracotomy. Ao, aorta; LAu, left auricle; PA, pulmonary artery.

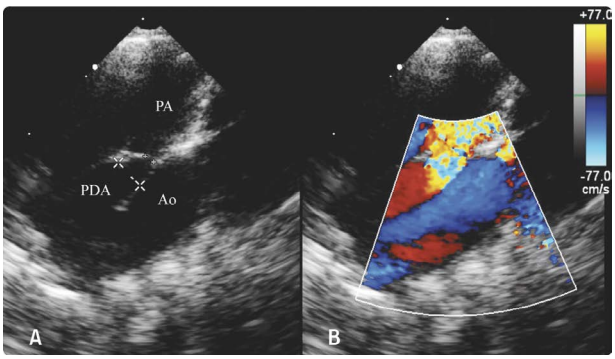

FIGURE 8.26 (a) Transthoracic echocardiographic view of a patent ductus arteriosus (PDA). Measurements of the PDA diameters are obtained. **(b)** Color Doppler reveals turbulence (mosaic of colors) in the pulmonary artery. Ao, aorta; PA, pulmonary artery; PDA, patent ductus arteriosus.

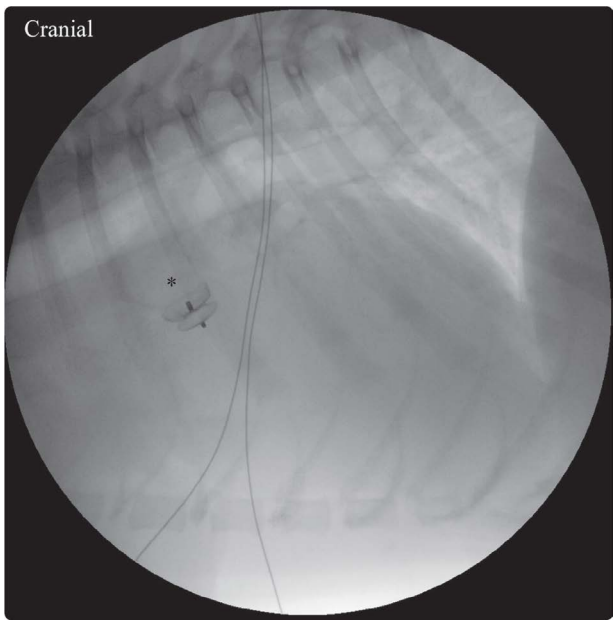

FIGURE 8.28 Lateral thoracic radiograph from a dog after patent ductus arteriosus occlusion with an Amplatzcanine duct occluder (asterisk). (*Distributor: Infiniti Medical, LLC.*)

Prognosis

Secondary changes can reverse with early and successful closure of the PDA, and in these cases, prognosis is excellent. Animals with a PDA that is not closed rarely live past 1 year of age, although rarely some can live well into adulthood with an uncorrected PDA.

VENTRICULAR SEPTAL DEFECTS

Definition/Overview

Ventricular septal defects (VSDs) are defects that allow communication between the left and right ventricles. The most common form is a defect in the membranous or upper portion of the septum. It is the most common congenital cardiac defect in cats.

Etiology

VSDs are heritable defects in Keeshonds and English Springer Spaniels.

Pathophysiology

Blood shunts from left to right during systole. Because of the location of VSDs in the upper portion of the outflow tract, the increased blood flow enters almost immediately into the pulmonary artery and returns to the left heart. Therefore, VSDs in dogs and cats typically result in volume overload of the left ventricle and atrium. The outcome of a VSD depends on the size of the defect and the pressure gradient between the systemic and the pulmonary circulation. Small VSDs that restrict blood flow have minimal hemodynamic consequences. Larger VSDs can result in left-sided volume overload and, subsequently, left-sided CHF. They also have the potential to cause significant pulmonary over circulation and lead to PH. In the presence of severe PH, right ventricular pressure may exceed left ventricular pressure during part of or the entire duration of the cardiac cycle, resulting in reversal of the shunt (right-to-left shunt) and cyanosis (Eisenmenger physiology).

Clinical Presentation

Physical examination findings associated with a VSD depend on the size of the shunt and the pressure gradient between the pulmonary and the systemic circulation. Left-to-right shunts result in a right-sided, sternal, or left basilar systolic murmur depending on the location of the septal defect on the interventricular septum. Smaller VSDs often result in a greater velocity of blood flow through the shunt and may have a louder murmur but are often associated with fewer secondary changes. Blood overflow through a VSD located in the basilar portion of the septum may damage the cusps of the aortic valve, leading to aortic insufficiency and a left basilar diastolic murmur on auscultation. A large VSD can allow pressures between the two ventricles to equalize and may cause a softer murmur or no audible murmur at all. Signs associated with CHF or hypoxemia may be present.

Differential Diagnosis

Mitral regurgitation, tricuspid regurgitation, SAS, PS.

Diagnosis

Diagnosis is made by visualization of the defect or the shunt with color-flow Doppler echocardiography. On echocardiography, the size of the VSD can be compared with the diameter of the aortic annulus. Small VSDs are less than 25%, moderate VSDs are between 25% and 75%, and large VSDs are more than 75% the aortic diameter. Various parameters are assessed to determine the clinical significance of VSDs. Color Doppler technique is used to scan the surface of the interventricular septum from different views and demonstrates a left-to-right turbulent, high velocity jet during systole (**Figure 8.29**). Blood flow velocity measurements recorded by continuous-wave Doppler are used to estimate the pressure gradient across the defect using the simplified Bernoulli equation. Assessment of left atrium and ventricle size and assessment of left ventricular function can be done with Doppler imaging. A right-to-left shunting VSD can be confirmed via contrast echocardiography.

The size of restrictive VSDs determines the risk of left ventricular volume overload and CHF. The clinical significance is better determined by measuring the size of the left-sided cardiac chambers. Follow-up examinations are usually necessary to determine the long-term hemodynamic consequences of a VSD.

Management

VSDs are treated based on the severity of secondary changes and clinical signs. Small VSDs may not require any intervention and carry a good prognosis.

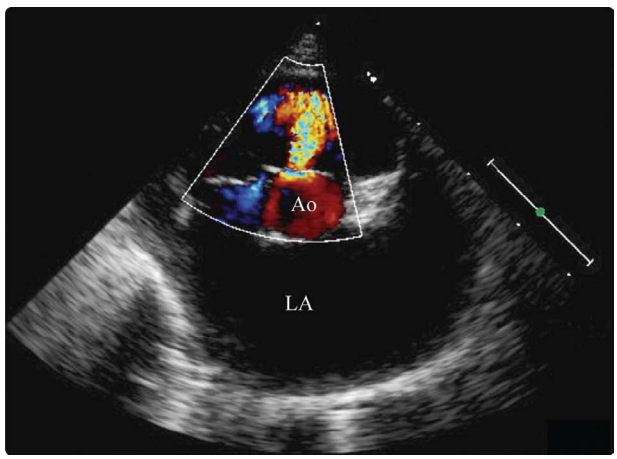

FIGURE 8.29 Right parasternal short-axis echocardiographic view confirming the presence of a ventricular septal defect with color-flow Doppler. Turbulent blood flow is seen entering the right ventricle from a defect located just below the aorta in the perimembranous portion of the interventricular septum. Ao, aorta; LA, left atrium.

Hemodynamically significant left-to-right VSDs are managed medically when signs of left-sided CHF occur. The cyanosis and polycythemia that result from right-to-left VSDs may improve with sildenafil, which targets PH.

Prognosis

Prognosis varies based on the size of the VSD.

ATRIAL SEPTAL DEFECTS

Definition/Overview

Atrial septal defects (ASDs) are defects that occur due to malformation of the septum primum and the septum secundum.

Pathophysiology

ASDs typically result in a left-to-right shunt of blood. This may cause dilation of the right heart, pulmonary over circulation, and right heart failure. Most shunts, however, are small and have minimal hemodynamic consequences. When right-sided heart disease results in elevated right atrial pressures, the direction of blood flow across the ASD may change.

Clinical Presentation

ASDs rarely cause a murmur because the low-volume and low-pressure gradient across the defect do not result in high-velocity turbulent blood flow. On occasion, a soft left basilar systolic murmur is auscultated. This is due to the increased volume of blood circulating within the right ventricular outflow tract, which becomes turbulent. Most ASDs remain asymptomatic. Large defects or those associated with another congenital defect may result in signs of right heart failure or shunt reversal with various degrees of cyanosis and hypoxemia.

Differential Diagnosis

Mild SAS, mild PS, physiologic murmur.

Diagnosis

Diagnosis is made by echocardiographic visualization of the defect.

Management

Most small ASDs do not require treatment. Large defects cause right heart failure if not treated surgically, which may be difficult due to limited access and expense. Right heart failure is managed medically if it develops.

Prognosis

Prognosis varies based on the size of the ASD. Most small ASDs have an excellent prognosis.

MITRAL VALVE DYSPLASIA

Definition/Overview

Mitral valve dysplasia (MVD) occurs from malformation of the mitral valve apparatus and can include the valve leaflets, chordae tendineae, or papillary muscles. Large breed dogs are predisposed.

Pathophysiology

Severe MVD causes significant mitral regurgitation and can cause secondary changes similar to degenerative valvular disease. In dogs, valvular insufficiency frequently occurs in combination with valve stenosis. Long-term complications include the development of left-sided CHF.

Clinical Presentation

Physical examination findings with MVD include a left apical systolic murmur whose intensity correlates with the severity of the regurgitation. Signs associated with arrhythmias or CHF may be present.

Differential Diagnosis

Mitral regurgitation from degenerative valve disease, DCM.

Diagnosis

Thoracic radiographs and echocardiography may show variable levels of left-sided heart enlargement. If CHF is present, signs of pulmonary edema in dogs or edema and/or pleural effusion in cats may be present. Echocardiography will reveal the abnormalities of the mitral valve apparatus.

Management

MVD is managed medically by treating CHF and arrhythmias.

Prognosis

Prognosis is poor due to the typical early onset of arrhythmias and/or CHF.

TRICUSPID VALVE DYSPLASIA

Definition/Overview

Tricuspid valve dysplasia (TVD) occurs from malformation of the tricuspid valve apparatus and can include the valve leaflets, chordae tendineae, or papillary muscles.

Etiology

TVD is the most common CHD in Labrador Retrievers and is heritable in that breed.

Pathophysiology

TVD causes significant tricuspid regurgitation and can cause elevations in right atrial pressures and development of right-sided CHF.

Clinical Presentation

Physical examinations findings with TVD include a right apical systolic murmur; however, mild TVD may not result in an auscultable murmur. Signs associated with arrhythmias or CHF may be present. A common arrhythmia in dogs with TVD is atrial fibrillation (AF).

Differential Diagnosis

Tricuspid regurgitation from degenerative valve disease, VSD, DCM.

Diagnosis

Radiographically, dogs with TVD often have dramatic right atrial enlargement, a dilated caudal vena cava, and hepatomegaly. Cats have an enlarged right atrium and a dilated, tortuous caudal vena cava. Right heart failure in dogs may cause signs of jugular venous distension, hepatomegaly, and ascites. Electrocardiography may show supraventricular arrhythmias, and splintered QRS complexes are a common finding in dogs (Figure 8.30). Echocardiography reveals structural abnormalities of the tricuspid valve apparatus (Figure 8.31).

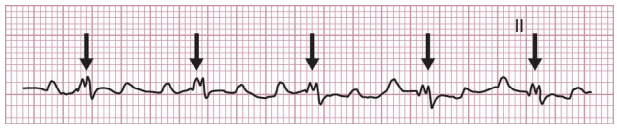

FIGURE 8.30 ECG from a dog with tricuspid dysplasia. There is a sinus rhythm with splintered QRS complexes (arrows) (amplitude 10 mm/mV, speed 50 mm/s).

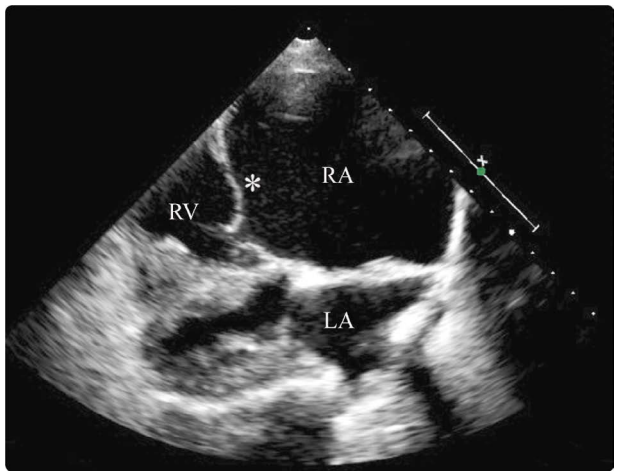

FIGURE 8.31 Right parasternal long-axis echocardiographic view from a dog with tricuspid dysplasia. The right atrium is markedly dilated, and the parietal leaflet of the tricuspid valve is elongated (asterisk). LA, left atrium; RA, right atrium; RV, right ventricle.

Management

TVD is treated medically by managing CHF and arrhythmias.

Prognosis

Prognosis is poor when tricuspid valve regurgitation is severe due to the early onset of arrhythmias and/or CHF. Dogs with mild TVD have a normal life expectancy.

TETRALOGY OF FALLOT

Definition/Overview

The four defects that form the tetralogy of Fallot (TOF) consist of a VSD, dextroposition of the aorta, PS, and the resulting right ventricular concentric hypertrophy.

Etiology

TOF is heritable in Keeshonds.

Pathophysiology

PS increases the right ventricular pressures and results in various degrees of right-to-left shunting across the VSD. The consequences include cyanosis, hypoxemia, and polycythemia. Concurrent CHD may be present.

Clinical Presentation

TOF is usually accompanied by a systolic murmur originating from the PS and/or the VSD. Animals with TOF may develop episodes of respiratory difficulties when the right-to-left shunting worsens, causing systemic hypoxemia.

Differential Diagnosis

PS, VSD.

Diagnosis

Thoracic radiographs show right heart enlargement and pulmonary under circulation. Echocardiography allows for visualization of the VSD, quantification of PS severity, the displacement of the aortic root toward the right side, and right ventricular hypertrophy. Color-flow Doppler is needed to visualize the shunt.

Management

Medical management is aimed at limiting right-to left shunting and hypoxemia by blunting the decrease in systemic vascular resistance in response to exercise with the administration of oral nonselective beta-blockers (propranolol). Phlebotomies are indicated when polycythemia is severe (usually PCV above 70%).

Prognosis

Prognosis varies based on the severity of the shunt and right ventricular pressure overload. Most dogs with TOF reach the age of 5 years.

VASCULAR RING ANOMALIES

Definition/Overview

Vascular ring anomalies occur from persistence of vessels that normally regress during development or abnormalities in vessel formation. The most common vascular ring is a persistent right aortic arch (PRAA).

Etiology

There is evidence that PRAA is heritable in German Shorthair Pointers and Greyhounds.

Pathophysiology

Normally, the right aortic arch develops into the brachiocephalic trunk and right subclavian artery, and the left aortic arch persists as the dorsal aorta. When the right aorta persists with a left ligamentum arteriosum, a vascular ring forms around the trachea and esophagus, with the heart base forming the last portion of the ring. A retroesophageal subclavian artery is the most common concurrent anomaly. PRAA alone does not result in cardiac abnormalities.

Clinical Presentation

PRAA is usually suspected based on the onset of regurgitation when a puppy is introduced to solid food. This occurs due to esophageal constriction by the vascular ring. Signs of aspiration pneumonia may be present.

Differential Diagnosis

Esophageal stricture, congenital megaesophagus, other gastrointestinal (GI) disorders.

Diagnosis

Diagnosis is often made based on clinical signs and thoracic radiographs. Thoracic radiographs show leftward deviation of the trachea cranial to the border of the heart in VD, and a barium esophagram can aid in diagnosis based on constriction of the esophagus at the heart base with cranial dilatation (see Figures 8.14–8.16). Definitive diagnosis may require advanced imaging or surgical exploration.

Management

Surgical ligation is the treatment of choice for PRAA and other vascular anomalies resulting in constricting vascular rings. Surgical procedures vary based on the type of vascular ring and the presence of concurrent anomalies. Early surgical treatment is recommended to prevent progressive esophageal dysfunction, although there have been reports of successful surgical treatment in adult dogs.

Prognosis

Prognosis is good with early intervention and dietary modification.

ACQUIRED VALVULAR DISEASES

DEGENERATIVE MITRAL VALVE DISEASE

Definition/Overview

Degenerative mitral valve disease is the most common form of acquired cardiovascular disease in dogs, representing approximately 75% of all cardiology cases seen in practice. It particularly affects small breed, middle-aged to older dogs and is approximately 1.5x more common in males. There are known breed predispositions, such as the Cavalier King Charles Spaniel and Dachshund; however, large breed dogs may also develop the disease. The mitral valve is affected alone in 60% of cases, the tricuspid valve alone in 10% of cases, and both valves are affected in 30% of cases. Rarely, involvement of the aortic and pulmonic valves is seen.

Etiology

The etiology is unknown, although there is a known genetic component. It has been suggested that there are predisposing abnormalities/disruptions in the collagen and extracellular matrix components, with accumulation of proteoglycans and glycosaminoglycans in the spongiosa layer of the valve. Although the inciting factor for degenerative valve disease is not certain, high levels of circulating serotonin have been shown to cause valvular changes.

Pathophysiology

Myxomatous lesions of the valve progress over time. These abnormalities also extend to the chordae tendineae. These changes lead to thickening of the free edge of the valve leaflets, and secondary fibrosis causes contracture of the valve leaflets and chordae, preventing normal coaptation. This scenario leads to various degrees of regurgitation, leading to left-sided volume overload and atrial and ventricular enlargement.

Clinical Presentation

The clinical presentation varies with the severity of the disease. Very early in the disease process, the only abnormality on physical examination may be a midsystolic click associated with mitral valve prolapse. In most cases, the first clinical sign is a systolic murmur with a PMI in the region of the mitral valve. Worsening of

the murmur intensity usually coincides with worsening disease severity. Coughing and exercise intolerance are also common presenting complaints. Often dogs will remain preclinical for long periods of time and will only show clinical signs at the onset of CHF (Table 8.9).

Differential Diagnosis

The differential diagnoses for systolic heart murmurs are reviewed in the physical examination section of this chapter. Differential diagnoses for the respiratory signs seen include CHF, pneumonia, compression of the left mainstem bronchus by the enlarged left atrium, tracheal collapse, and primary lower airway disease such as chronic bronchitis.

Diagnosis

The diagnosis of degenerative mitral valve disease is generally easily made based on physical examination findings and patient signalment. However, it is important to confirm the diagnosis with echocardiography. Radiography should also be used to assist in assessing disease severity, presence/absence of CHF, and disease progression. Generalized cardiomegaly with left atrial and left ventricular enlargement is seen radiographically in dogs that are stage B2 and higher. If CHF is present, an interstitial-to-alveolar pattern is commonly seen in the perihilar and caudal lobar regions. Echocardiography will show a thickened and irregular valve (Figure 8.32), valvular insufficiency during systole (Figure 8.33), and atrial and ventricular eccentric hypertrophy depending on the valve(s) affected.

Management

In 2019, the ACVIM released updated guidelines for staging and treatment of degenerative valvular disease, which are briefly summarized as follows:

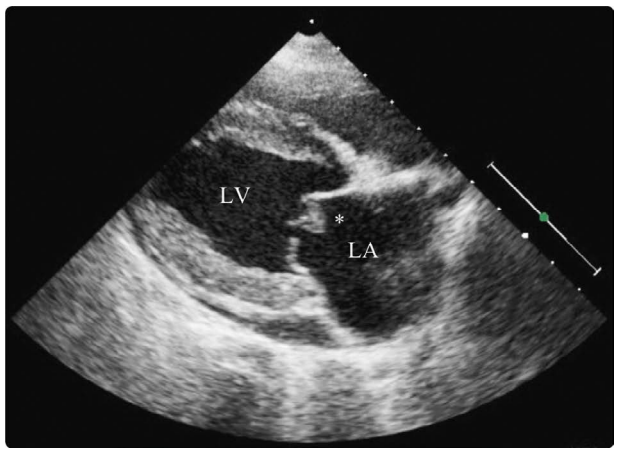

FIGURE 8.32 Right parasternal long-axis echocardiographic view from a dog with severe degenerative mitral valve disease. The septal leaflet of the mitral valve (asterisk) is markedly thickened and prolapses into the left atrium. LA, left atrium; LV, left ventricle.

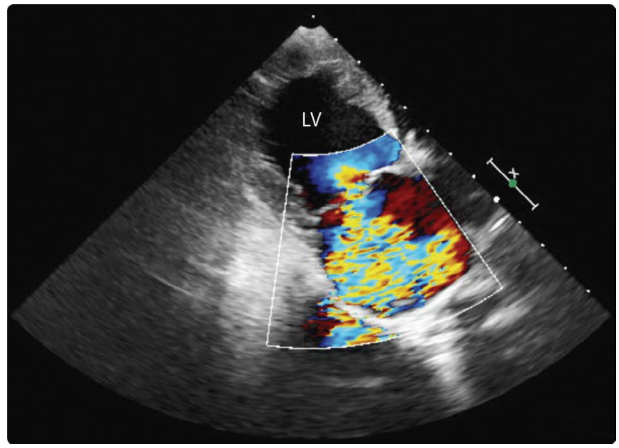

FIGURE 8.33 Color Doppler showing severe mitral valve regurgitation filling more than 50% of the left atrium. The mosaic of color indicates turbulent blood flow. LV, left ventricle.

Stage A classifies dogs that are at risk for developing valvular disease in the future but do not have current clinical signs. This includes all dogs with known breed predispositions to valve disease (such as Cavalier King Charles Spaniels). No medication is warranted, and full physical exam, including careful auscultation, should be performed annually.

Stage B1 classifies dogs with evidence of valvular disease (small breed dog with left apical systolic heart murmur) but who have never had clinical signs associated with heart disease and do not have radiographic or echocardiographic evidence of heart enlargement. Stage B1 also describes dogs who have mild heart enlargement but do not yet qualify for medication (pimobendan).

Stage B2 classifies dogs with valvular disease that have radiographic and echocardiographic evidence of left atrial and ventricular enlargement and who will benefit from medication. Specifically, animals with stage B2 valvular disease have a breed-adjusted VHS > 10.5, moderate left atrial enlargement (LA:Ao > 1.6), and mild left ventricular eccentric hypertrophy (LVIDDN > 1.7). If echocardiography is unavailable, a general VHS > 11.5 or progressive left-sided heart enlargement on radiographs can be used to identify stage B2. Pimobendan (0.25–0.3 mg/kg p.o. q.12h.) should be administered to all stage B2 dogs and has been shown to delay the time to progression to CHF by about 15 months. There is controversy as to whether ACE inhibitors and/or spironolactone should be given to stage B2 dogs, but many cardiologists prescribe these medications, especially if there is evidence of progressive heart enlargement and kidney function is adequate. Surgery can be considered if finances and availability allow.

Stage C classifies dogs with current or former signs of CHF, and stage D classifies those that are refractory to standard treatment. Dogs in these stages should be treated with the appropriate medications to control the signs of CHF (see Congestive Heart Failure, Management).

Prognosis

Disease progression and prognosis are variable, with many dogs remaining asymptomatic for their entire lifetime. However, from onset of CHF, the average survival time is 12–18 months with medical management.

BACTERIAL ENDOCARDITIS

Definition/Overview

Endocarditis corresponds to an infection and secondary inflammation of the endocardial surface following a transient or persistent bacteremia. Vegetative endocarditis occurs when vegetation composed of platelets, fibrin, bacteria, and inflammatory cells are found adhered to heart valves. Clinical signs vary widely and are vague, making recognition difficult. The reported incidence of infectious endocarditis in dogs and cats is very low, with the highest incidence in male, middle-aged, medium-to-large breed dogs, particularly German Shepherd Dogs.

Etiology

Endothelial damage in conjunction with bacteremia is required for infectious endocarditis to develop. The underlying cause of the damage to the endothelium is unproven, although patients with SAS are at increased risk. It is usually not possible to identify the origin of the bacteremia. The most common bacterial isolates are *Staphylococcus* spp. and *Streptococcus* spp., with *Escherichia coli*, *Corynebacterium* spp., and *Erysipelothrix rhusiopathiae* also reported. Recently, *Bartonella* spp. have emerged as important causative agents.

Pathophysiology

In companion animals, infectious endocarditis involves mitral and aortic valve tissue in the majority of cases. Once endothelial damage has occurred, bacteria bind and are covered by fibrin. Additional layers of bacteria and fibrin are deposited to form vegetative lesions, which lead to the destruction of normal valvular and chordal tissue, leading to valvular insufficiency and possible stenosis. These vegetations are friable and commonly embolize to distant sites (Figure 8.34).

Clinical Presentation

The clinical presentation is highly variable and nonspecific, with the most common clinical signs being waxing/waning fever, lethargy, depression, anorexia, weight loss, shifting leg lameness, dyspnea, and tachypnea. These signs can be acute or chronic and are related to the organs affected by bacteremia, septic thrombi, and secondary immune complex formation and deposition.

A new or changing murmur is considered highly suggestive for endocarditis, although lack of a murmur should not preclude the diagnosis. Both systolic (more common) and diastolic murmurs occur, along with arrhythmias. CHF, polyarthritis, and glomerulonephritis are common sequelae.

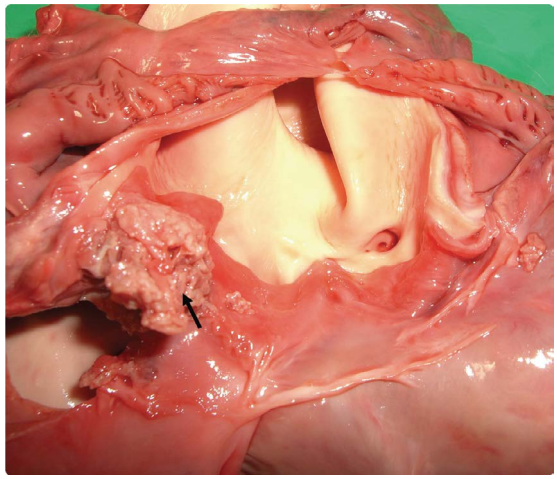

FIGURE 8.34 Vegetative lesion (arrow) on the aortic valve of a dog.

Differential Diagnosis

Differential diagnoses for systolic heart murmurs are reviewed in the physical examination section of this chapter. Infectious, inflammatory, and immune-mediated causes of glomerulonephritis, polyarthritis, and fever of unknown origin should also be ruled out.

Diagnosis

Recognition and diagnosis of endocarditis can be very difficult, in part because of the vague clinical signs and clinicopathologic findings. Radiography may be unremarkable or may show cardiomegaly and signs of left-sided CHF. ECG will often show rhythm disturbances, with ventricular rhythms and AV block being most common. Echocardiography is the gold standard for diagnosis and will often show a hyperechoic, independently oscillating lesion on the affected valve (Figure 8.35). Clinicopathologic laboratory findings can help support the diagnosis but are often nonspecific. They include leukocytosis, nonregenerative anemia, thrombocytopenia, hypoalbuminemia, elevated alkaline phosphatase, and azotemia. Urinalysis may show changes consistent with a glomerulonephritis or bacterial infection, which may be the source of bacteremia or secondary to it. Blood cultures should be taken, although they have both a low sensitivity and specificity. A negative culture should not be used to exclude the diagnosis of endocarditis.

Management

The goals of treatment are to sterilize the vegetative lesion and address cardiac and systemic complications. Bactericidal therapy should be instituted based on culture and sensitivity. Prior to obtaining culture results, or if culture is negative, empiric broad-spectrum coverage with clavulanate-potentiated penicillin,

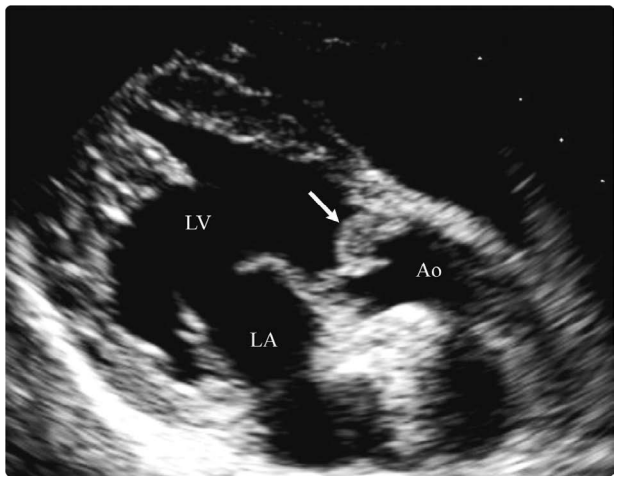

FIGURE 8.35 Right parasternal echocardiographic view from a dog with a vegetative lesion (arrow) on the aortic valve. Ao, aorta; LA, left atrium; LV, left ventricle.

or first- or second-generation cephalosporin along with either a fluoroquinolone or an aminoglycoside should be chosen. Antibiotics at the upper end of the dosing range should be administered orally for a minimum of 6–8 weeks. Parenteral antibiotic therapy is useful especially early in therapy to ensure fast achievement of high serum drug levels. If *Bartonella* is suspected or confirmed, azithromycin (5–10 mg/kg p.o. q.24h. for 7 days, then every other day for 6–12 weeks) or doxycycline should be administered. Treatment with corticosteroids is contraindicated and confers a negative prognosis. Though anticoagulation therapy was proposed in the past, no benefit has been proven, and it may increase the risk of hemorrhage. Cessation of therapy should be determined based on serial monitoring of echocardiograms, body temperature, CBC, and repeat blood and urine cultures.

Prognosis

Prognosis for vegetative infectious endocarditis is guarded to grave in both canine and feline patients. Aortic valve endocarditis, thrombocytopenia, and glomerulonephritis are also associated with worse prognosis.

CANINE CARDIOMYOPATHY

Cardiomyopathies are diseases that affect the heart muscle. When the cause is unknown, the term primary cardiomyopathy is used. When a cause can be identified for the heart muscle disease, the term secondary cardiomyopathy is used. The disease can then be described based on the underlying cause; for example, "Adriamycin (doxorubicin) cardiomyopathy." Cardiomyopathy is one of the most common acquired cardiovascular diseases in dogs, second only to degenerative valve disease and heartworm disease depending on the geographical location. The most common myocardial disease in dogs is DCM.

DILATED CARDIOMYOPATHY

Definition/Overview

Dilated cardiomyopathy (DCM) is a primary myocardial disease characterized by decreased systolic function and subsequent ventricular dilation. This disease is most commonly seen in large breed dogs with Dobermanns, Great Danes, and Irish Wolfhounds being overrepresented. Some medium-size breeds such as Cocker and English Spaniels may also develop the disease. Significant variation of disease presentation, progression, and prognosis can be seen depending on the breed of dog.

Etiology

The cause of DCM is not known, but a genetic cause is suspected. In Dobermanns, DCM has been shown to be inherited as an autosomal dominant trait. A splice deletion in the pyruvate dehydrogenase kinase 4 gene (a gene involved in the regulation of myocardial energy utilization) has been associated with DCM in this breed. More recently, a missense variant in the titin gene of this breed was also identified. The mutation occurs within the immunoglobulin-like domain of the titin protein and is found in cardiac and skeletal muscle. Titin is involved in muscle active contraction and passive stiffness' however, its contribution to DCM is currently unclear.

Over the past few years, diet has been implicated in the development of DCM in unusual breeds. While still under investigation, it is thought that alternative carbohydrate sources such as peas and lentils in diets labeled as "exotic," "boutique," or "grain-free" interfere with the body's ability to manufacture and utilize amino acids, specifically taurine.

Pathophysiology

Myocardial changes secondary to DCM lead to eccentric hypertrophy of the ventricles, which is usually more pronounced on the left side. In addition, left ventricular systolic function is markedly reduced. Over time, left ventricular enlargement leads to dilation of the mitral valve annulus and secondary mitral regurgitation. Left atrial enlargement results from volume overload, impaired ventricular filling, and secondary mitral regurgitation. Ventricular arrhythmias are caused by the disruption of the normal architecture of the ventricular myocardium and various triggers such as increased adrenergic tone, electrolyte imbalances, and hypoxemia. AF is more likely to occur when the left atrium is markedly dilated and fibrotic.

Clinical Presentation

In general, DCM has an adult onset, with male dogs being affected more commonly; however, Portuguese Water Dogs often develop the disease before 12 weeks of age. Clinically, two phases of the disease can be detected: An occult or asymptomatic phase and an overt phase. In the occult phase, there are no clinical signs;

however, arrhythmias or myocardial changes are present. The occult phase is variable and may last months to years. More commonly, the disease is not diagnosed until the overt stage when exercise intolerance, CHF, or syncope is noted. In some dogs, sudden death may be the first and only sign of disease. This is especially true for Dobermanns, in which sudden death can be the first sign of disease in approximately 30%–50% of affected dogs.

Differential Diagnosis

Other causes of left ventricular dilation in large breed dogs, including tachycardiomyopathy, cardiomyopathy secondary to taurine deficiency or doxorubicin toxicity, and myocarditis. Primary mitral valve insufficiency is associated with left ventricular systolic dysfunction, which may mimic DCM. Chronic cardiac changes of left-to-right shunt, especially PDAs in adult dogs, resemble those of DCM.

Diagnosis

During physical examination, a grade 1 to 3/6 systolic murmur (a result of mitral insufficiency due to annular dilation) and/or an S3 gallop sound (indicating left ventricular dilation) may be noted over the left apex. A weak femoral pulse (a result of decreased stroke volume due to poor contractility) is a common finding. An irregular rhythm along with pulse deficits may be present as ventricular arrhythmias and AF are commonly seen in these dogs. Arrhythmias are often an early indication of disease, and breeds predisposed should be screened with ECG and Holter monitor. Detection of ventricular premature complexes in an asymptomatic dog, particularly a Dobermann, should raise a high level of suspicion for occult cardiomyopathy. Sinus tachycardia, AF, and ventricular tachycardia are commonly seen in dogs with DCM. Giant breeds such as the Great Dane and Irish Wolfhound are more likely to develop AF, whereas Dobermanns are more likely to have ventricular arrhythmias. Arrhythmias are often noted around 2–4 years of age and can vary from single ventricular premature complexes to life-threatening ventricular tachycardia. Electrocardiographic changes suggesting left ventricular enlargement (R-wave amplitude > 3.0 mV) and conduction disturbances such as right or left bundle branch block may also be noted. It is important to note that a normal ECG does not rule out the presence of DCM. Thoracic radiography may reveal generalized cardiomegaly; however, radiographs are not sensitive to mild cardiac changes. Therefore, cardiomegaly is better assessed with echocardiography, particularly in the occult stage of the disease. In the overt stage, radiographs are more valuable in helping to diagnose CHF, showing pulmonary venous distension and pulmonary edema. Due to their chest conformation, the degree of cardiomegaly may be underestimated in Dobermanns. Echocardiography is essential for the evaluation of cardiac enlargement and function. The classic sign of DCM on an echocardiogram is systolic dysfunction. This is seen as reduction in fractional shortening (FS) and ejection fraction along with increases in E-point-to-septal separation and left ventricular end-systolic diameter. Increased left ventricular end-diastolic diameter as well as left atrial enlargement are seen as the disease progresses (Figure 8.36a, b). Early in the disease, affected individuals may only have ventricular arrhythmias and normal echocardiograms. Therefore, it is important that when screening for the occult phase of the disease both echocardiogram and Holter monitor evaluation are performed.

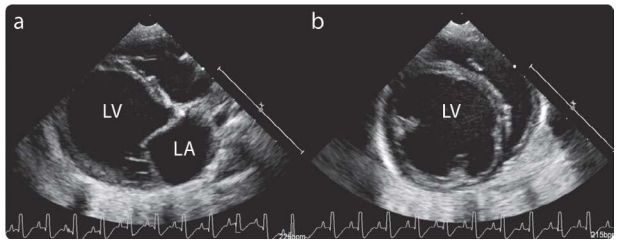

FIGURE 8.36 Right parasternal long-axis **(a)** and short-axis **(b)** views from a dog with dilated cardiomyopathy. The left ventricle appears markedly dilated. The ECG shows sinus tachycardia with wide QRS complexes, consistent with a left bundle branch block. LA, left atrium; LV, left ventricle.

Management

In dogs with DCM and heart failure, standard CHF therapy is initiated, with antiarrhythmic therapy used as needed based on the arrhythmia burden. Administration of pimobendan delays the onset of CHF and extends survival in Dobermanns with occult DCM. Syncope is often the result of rapid ventricular tachycardia in DCM dogs. When this is seen, antiarrhythmic treatment is needed to control the syncope. Antiarrhythmic treatment does not prevent sudden death, and many dogs with syncope will die suddenly, especially Dobermanns. Less likely causes of syncope in DCM include collapse due to decreased cardiac output, vasovagal syncope, or, on occasion, secondary to the onset of AF. Treatment of ventricular arrhythmias includes the use of sotalol monotherapy or a combination of mexiletine and a beta-blocker. A thorough diet history should be performed, and diet change should be considered if a "boutique" or "grain-free" diet is fed. If the owner is unable or unwilling to change diets, taurine should be supplemented.

Prognosis

Prognosis with DCM varies with breed and severity of disease but mostly is considered fair to poor, especially after the onset of CHF. Dobermanns with DCM may carry a worse prognosis compared with other breeds. The majority of dogs with DCM presenting with CHF survive approximately 6–12 months. In some Cocker Spaniels, the disease may be associated with taurine deficiency, and subsequent improvement may occur with supplementation. Diet-associated DCM may also improve with a diet change and initiation of taurine supplementation. Onset of CHF at a young age and the presence of ascites and AF also carry a negative prognosis.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY (BOXER CARDIOMYOPATHY)

Definition/Overview

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a myocardial disease dominated by ventricular arrhythmias and clinical signs of syncope. Most dogs have normal ventricular size and function at the time they develop the arrhythmia. The disease is primarily seen in Boxers but has also been documented in other breeds, including English Bulldogs. It is typically an adult-onset disease, but it can be diagnosed in dogs as young as 1 year of age.

Etiology

In humans, mutations in multiple genes coding for intercalated disc proteins have been associated with ARVC. In Boxers, only one genetic mutation has been associated with ARVC to date; it affects the striatin gene. Boxers positive for the striatin mutation have a higher number of VPCs on 24-hour Holter recordings. Boxers without this mutation can also get ARVC.

Pathophysiology

ARVC is characterized by fatty or fibro fatty myocardial replacement, predominantly in the right ventricle and, to a lesser extent, the left ventricle and both atria (Figure 8.37).

Clinical Presentation

Clinically, the disease is characterized by ventricular tachycardia, right ventricular enlargement, syncope, and sudden death. There are three stages to the disease, which may be observed in succession as ARVC worsens: (1) Initially, the patient is asymptomatic, and ventricular arrhythmias are an incidental finding; (2) the patient presents for syncope associated with the ventricular arrhythmias; and (3) the patient presents with signs of CHF secondary to systolic dysfunction and frequently a history of weakness or syncope related to the arrhythmias. Similar to Dobermanns with DCM, in some cases sudden death is the first and only sign of the disease. Sudden death due to ventricular arrhythmias is more common than death associated with complications of CHF.

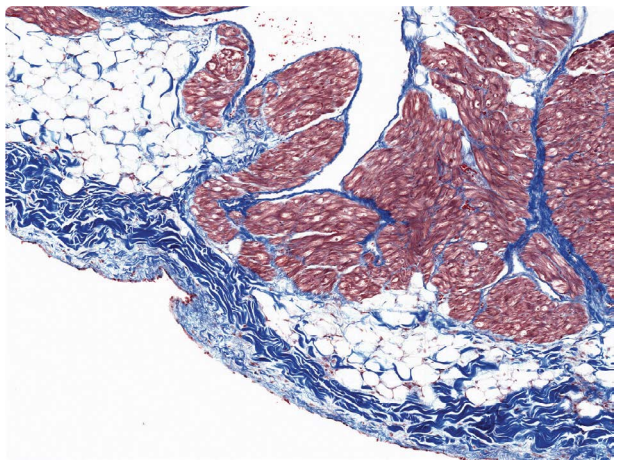

FIGURE 8.37 Histopathology of the myocardium of a Boxer with arrhythmogenic right ventricular cardiomyopathy revealing fatty replacement of the myocytes and interstitial fibrosis. The Masson trichrome stain shows collagen in blue. Magnification ×70.

Differential Diagnosis

Myocarditis and other causes for left ventricular enlargement and arrhythmias, including DCM, tachycardiomyopathy and doxorubicin toxicity.

Diagnosis

The most common physical examination finding reported is the detection of an arrhythmia. This can be either single premature beats or paroxysms of tachycardia. On occasion, the arrhythmia is permanent when AF is present. Another physical examination abnormality common with ARVC is the presence of a systolic murmur on auscultation. Apical systolic murmurs result from mitral or tricuspid insufficiency caused by the annular dilation that accompanies cardiomegaly. Less frequently, a cardiac gallop is detected. Left basilar systolic murmurs may be noted in some Boxers, but these should not be linked to ARVC as they are usually physiologic or secondary to SAS. The most common electrocardiographic change noted is ventricular ectopy in the form of ventricular premature complexes (singles, couplets, triplets, or bigeminy) or ventricular tachycardia. The ventricular ectopic beats tend to arise from the right ventricular myocardium and are classically described as having a left bundle branch block pattern morphology with a predominantly positive deflection of the QRS complex in leads II, III, and a VF. If severe, the ventricular tachycardia can lead to syncopal episodes and potentially sudden death. The frequency of the ventricular beats can have as much as an 80% day-to-day variation with ARVC. To increase the possibility of identifying these arrhythmias, 24-hour Holter monitoring is recommended if there is evidence of arrhythmia on auscultation or a history of clinical signs such as syncope (Figure 8.38). Repeating a Holter recording or the use of an event monitor may increase the likelihood of arrhythmia detection in cases where an arrhythmia is not detected on initial evaluation. Although ARVC is a primary myocardial disease, structural changes may only be present on histopathology and not be evident on echocardiography. The expected findings on echocardiography vary depending on the stage of disease progression. The majority of asymptomatic Boxers, as well as most dogs suffering from syncopal episodes, have normal echocardiograms, but signs of depressed ventricular function and chamber dilation are reported on occasion. Atrial enlargement also develops as a result of ventricular dysfunction and is more pronounced in dogs with CHF.

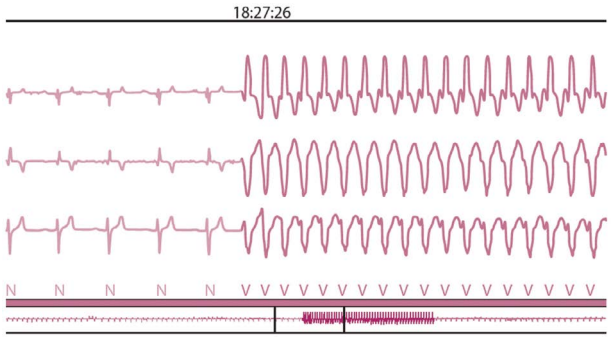

FIGURE 8.38 Holter recording from a Boxer with arrhythmogenic right ventricular cardiomyopathy showing a run of ventricular tachycardia.

Ultimately, disease progression may lead to biventricular failure, making it difficult to distinguish ARVC from idiopathic DCM.

Management

Treatment of ARVC aims at alleviating the clinical signs, as there is no specific treatment for the disease. In the absence of clinical signs and if the arrhythmia burden is mild, no treatment may be necessary. However, if the arrhythmia is of clinical concern, or if there are collapsing episodes, antiarrhythmic therapy is implemented. In dogs, the most common treatment of ventricular arrhythmias consists of sotalol monotherapy. Whenever sotalol alone fails to control the arrhythmia, it is typically combined with mexiletine. Alternatively, mexiletine can be associated with atenolol. The response to antiarrhythmic therapy should be assessed via 24-hour Holter monitoring, since a large daily variation in the number of ventricular arrhythmias may be seen in dogs with ARVC. In cases where CHF is present, standard heart failure therapy is initiated with the need for addition of antiarrhythmic therapy determined by the patient's underlying rhythm. Administration of antiarrhythmic drugs can lead to a reduction in clinical signs and, therefore, improve quality of life, but the risk for sudden death from ARVC is not decreased by these medications.

Prognosis

ARVC progresses over several years, and the rate of progression varies between dogs. In dogs with severe arrhythmia or syncope but normal cardiac function, a 2- to 3-year survival is not unusual when the clinical signs are controlled with antiarrhythmic therapy. Survival is usually less than 1 year once myocardial failure and CHF occur.

HYPERTROPHIC CARDIOMYOPATHY

Definition/Overview

Hypertrophic cardiomyopathy (HCM) is a rare primary myocardial disease in dogs. It is characterized by concentric hypertrophy of the left ventricle in the absence of a reason for the hypertrophy. Therefore, the diagnosis excludes valvular stenosis, hypertension, or other systemic illness that may stimulate left ventricular hypertrophy.

Clinical Presentation

Most dogs with HCM are males and most are diagnosed before 3 years of age. In humans and cats with HCM, asymmetrical hypertrophy of the left ventricle is seen; however, dogs with HCM more commonly have symmetrical hypertrophy of the left ventricle. The vast majority of dogs also have systolic anterior motion of the mitral valve causing dynamic left ventricular outflow tract obstruction (LVOTO). Some dogs may have myocardial hypertrophy as a result of the LVOTO and not because of a primary myocardial disorder such as HCM. Concurrent abnormalities of the mitral valve have been described in patients with HCM and LVOTO. In addition, treatment with beta-blockers causes significant reduction of the LVOTO and may lead to improvement or resolution of the hypertrophy in some cases.

Differential Diagnosis

Rule out systemic hypertension and other causes of increased afterload, such as SAS. Infiltrative myocardial disease, in particular lymphoma, may be responsible for concentric ventricular hypertrophy.

Diagnosis

Diagnosis relies on an echocardiogram to demonstrate left ventricular concentric hypertrophy in the absence of an obstruction to ejection of blood in the aorta or systemic hypertension.

Management

Treatment is primarily aimed at reducing or eliminating the LVOTO with beta-blockers (e.g., atenolol: 1 mg/kg q.12–24h.), which slow the heart rate and decrease contractility.

Prognosis

In most of the described cases, HCM was a fatal disease. The primary concern is sudden death; less commonly, dogs may develop CHF secondary to diastolic dysfunction and severe left atrial enlargement.

INFILTRATIVE DISEASE

Definition/Overview

Infiltrative myocardial disease is infrequent in dogs. The most commonly seen cause is a cardiac tumor. Infiltration by a tumor to the degree that it impairs myocardial diastolic or systolic function is rare.

Etiology

Lymphosarcoma is usually suspected. Lapland dogs have been reported to develop myocardial infiltration with glycogen secondary to glycogen storage disease. These dogs had clinical signs associated with skeletal muscle disease; however, arrhythmias were also noted.

Clinical Presentation

Most often dogs will present with clinical signs related to cardiac arrhythmia, pericardial effusion, and, on occasion, obstruction to blood flow by the cardiac tumor.

Differential Diagnosis

The degree of infiltration of the myocardium can be severe enough to resemble HCM.

Diagnosis

Diagnosis is based on a detailed echocardiographic examination. If pericardial effusion is present, a sample should be obtained via pericardiocentesis and submitted for cytologic evaluation. An abdominal ultrasound and fine-needle aspirates of enlarged organs and lymph nodes may help reach the diagnosis of lymphoma.

Management

Treatment is aimed at addressing the underlying cause for the myocardial infiltration and the use of antiarrhythmic medication determined by the underlying rhythm.

Prognosis

If cardiac lymphoma is diagnosed, survival depends on response to chemotherapy, with some dogs living more than 6 months after diagnosis.

FELINE CARDIOMYOPATHY

Definition/Overview

Cardiomyopathies are diseases of the myocardium associated with cardiac dysfunction and are the most common form of cardiac disease in felines. HCM is associated with increased cardiac mass due to a hypertrophied, nondilated left ventricle in the absence of a hemodynamic load or metabolic cause. It is the most common form of cardiomyopathy in felines (60% of cases) with a higher prevalence in certain breeds (Maine Coon, Ragdoll, Norwegian Forest Cat, British Shorthair, American Shorthair, Sphynx, Siberian, and Persian), although Domestic Shorthairs are seen most commonly. Males are predisposed (65%–70% of cases) possibly related to comodifying genes or hormonal influences. Prevalence within the feline population is estimated to be about 15%, although the criteria for diagnosis vary between studies and prevalence may be higher in some breeds.

Restrictive cardiomyopathy (RCM) is defined as restrictive diastolic filling with normal left ventricular dimensions and wall thickness with accompanying left atrial or biatrial enlargement (myocardial form). An endomyocardial form of this disease also exists wherein an endocardial scar spans the left ventricle, causing a fixed obstruction to blood flow. It is the second most common form of cardiomyopathy (20% of cases). DCM is associated with dilation and impaired contractility of the left ventricle or both ventricles. Arrhythmogenic cardiomyopathy (ACM) is characterized by progressive fibrofatty replacement of the myocardium that is regional or global, leading to a dilated and hypocontractile right ventricle with various arrhythmias and conduction abnormalities. It may also affect the left ventricle. A "nonspecific phenotype" is diagnosed when there is echocardiographic myocardial disease that does not readily fit into other categories.

Etiology

Familial HCM has been documented in Maine Coon cats as an autosomal dominant trait with incomplete penetrance. Separate mutations in different regions of the myosin-binding protein C (MyBPC3) gene are considered causative of HCM in both Maine Coon and Ragdoll breeds. Importantly, these mutations have not been identified in other breeds, and it is likely that other mutations in this gene or in genes for other sarcomeric proteins exist but have not yet been discovered. Over 1,400 mutations in 27 genes coding for sarcomeric or other structural proteins have been identified in humans with HCM. Development of the HCM phenotype is not an inevitable consequence in individuals with an HCM genotype, as there is a low penetrance for the MyBPC3 mutation, and it is likely age related. Additionally, epigenetic factors and environmental influences may affect phenotypic expression.

Myocardial hypertrophy can occur secondary to pressure overload (outflow obstruction, systemic hypertension), hyperthyroidism, hypersomatotropism, and infiltrative diseases of the myocardium. These causes should be excluded as soon as possible before a diagnosis of HCM is made.

The other forms of cardiomyopathy (RCM, DCM, ACM) are idiopathic and likely have a genetic basis. DCM was historically due to a taurine deficient diet and is now rare due to supplementation in commercial diets. Current cases of DCM may be found in feline patients on nontraditional diets (vegetarian diet, home-cooked diet, or being fed canine food). RCM and ACM may be associated with an inflammatory process secondary to infectious, neoplastic, or immune-mediated disorders.

Pathophysiology

In HCM, it is hypothesized that the production of abnormal sarcomeric proteins creates a functional defect in the process of muscle contraction, leading to increased

myocyte stress with subsequent activation of trophic factors (angiotensin II, aldosterone, insulin-like growth factor) that induce myocyte hypertrophy. Early nutrition may also affect circulating growth factors and phenotypic expression of disease. Diastolic dysfunction is the primary mechanism responsible for clinical signs in HCM and RCM. Hypertrophy of the left ventricle wall (HCM) causes impaired or delayed relaxation, and interstitial/endomyocardial fibrosis (HCM and RCM) increases myocardial stiffness and reduces distensibility. These changes impair left ventricular filling and result in filling only at higher pressures. Elevated filling pressures lead to left atrial enlargement, pulmonary venous hypertension, and CHF.

HCM generally leads to normal or increased global systolic performance of the left ventricle; however, regional systolic impairment has been documented in HCM patients using tissue Doppler imaging. Systolic dysfunction may be present in any myocardial disease due to ischemia and replacement fibrosis. Regional systolic impairment may increase regional wall stress and stimulate myocardial hypertrophy. DCM results in left ventricular or biventricular systolic dysfunction. ACM affects systolic performance primarily of the right ventricle and leads to a dilated, thin-walled, hypokinetic right ventricle and may affect the left ventricle. Tachyarrhythmias can affect diastolic performance and lead to myocardial dysfunction.

Clinical Presentation

Most cats with cardiomyopathy are diagnosed at a mean age of 5–7 years (range 3 months to 18 years), and HCM is typically diagnosed at an earlier age than other forms of cardiomyopathy. Certain breeds may present more commonly at a younger age. They may be presented in the asymptomatic phase due to the presence of auscultatory abnormalities such as a heart murmur or gallop sound. Various prevalence studies have shown that nearly 50% of apparently healthy cats with heart murmurs do not have evidence of cardiac disease; however, the presence of a heart murmur warrants further evaluation. In one study, 70% of cats with HCM did not have auscultatory abnormalities, so the absence of these findings does not exclude the presence of cardiac disease. Cats with occult cardiomyopathy (more common for RCM, DCM, ACM, nonspecific phenotype) are often not identified until clinical signs are present, including dyspnea, tachypnea, lethargy, poor appetite, hind limb paresis, collapse, or sudden death. Clinical signs are not an inevitable consequence for individuals with HCM.

Differential Diagnosis

Includes cardiomyopathy secondary to systemic disease (hypertension, hyperthyroidism, hypersomatotropism), degenerative valve disease, congenital heart disease, and myocarditis. Differentials for respiratory signs include feline lower airway disease (feline asthma), pneumonia, noncardiogenic pleural effusion or pulmonary edema, hemorrhage, and PTE.

Diagnosis

Diagnosis is based on the phenotypic expression of disease. HCM, RCM, DCM, ACM, and nonspecific phenotype (previously unclassified cardiomyopathy) are diagnoses based primarily on imaging and electrocardiographic tests as well as elimination of other possible etiologies (hyperthyroidism, systemic hypertension).

Echocardiography is the gold standard for diagnosis and permits evaluation of morphologic and functional abnormalities of cardiac structures. Diagnosis of HCM is based on the identification of a diastolic wall thickness > 6 mm on 2D or M-mode echocardiography, though some cats with HCM will have wall thickness between 5 and 6 mm. Hypertrophy may be diffuse or segmental and may be symmetric or asymmetric (**Figure 8.39**). Other findings on echo may include papillary muscle hypertrophy, end-systolic cavity obliteration, left atrial enlargement (identified as left atrial dimension > 16 mm or LA:Ao > 1.5) or spontaneous echo contrast (SEC, "smoke"). HCM may uncommonly affect the right ventricle. There is a subset of patients with hypertrophic obstructive cardiomyopathy due to obstruction in the left ventricular outflow tract associated with systolic anterior motion of the mitral valve (**Figure 8.40**). It is unclear if the obstruction leads to hypertrophy of the left ventricle or if obstruction is the result of abnormalities in left ventricular geometry, the mitral valve apparatus, or loading conditions associated with hypertrophy of the left ventricle.

Thoracic radiographs may identify cardiomegaly, although changes may be subtle especially if atrial enlargement is not present. The classic valentine shape results from severe biatrial enlargement. Pulmonary venous congestion, a patchy or diffuse interstitial to alveolar pattern, and/or pleural effusion may be present in cats with CHF.

ECG may show evidence of chamber enlargement, though these are not sensitive findings. Various arrhythmias and conduction abnormalities may be present. A

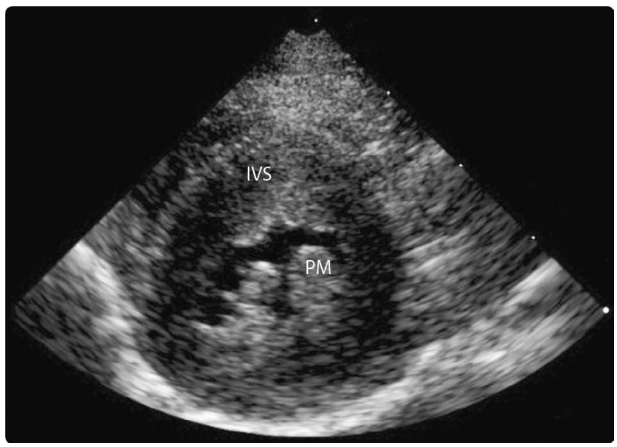

FIGURE 8.39 Right parasternal short-axis echocardiographic view from a cat with hypertrophic cardiomyopathy. There is concentric hypertrophy of the interventricular septum and the left ventricular free wall. The papillary muscles are prominent. IVS, interventricular septum; PM, papillary muscle.

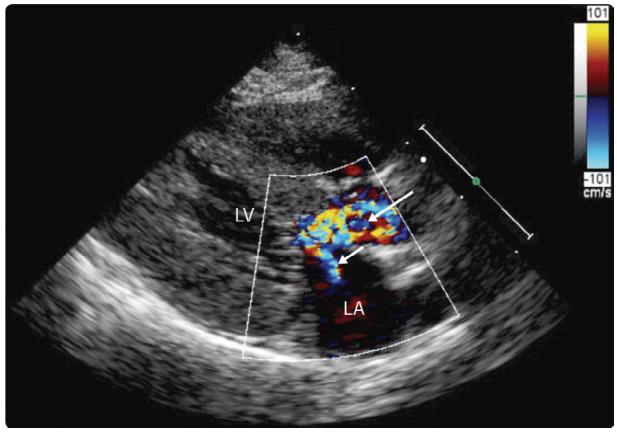

FIGURE 8.40 Color Doppler from a cat with hypertrophic obstructive cardiomyopathy showing two areas of turbulence: One in the left ventricular outflow tract caused by the septal leaflet of the mitral valve (long arrow); the other in the left atrium corresponds to a small amount of mitral regurgitation resulting from the incomplete closure of the mitral valve in systole (short arrow). LA, left atrium; LV, left ventricle.

left anterior fascicular block is the most common finding in cats with HCM (Figure 8.41). Supraventricular tachycardia and, rarely, AF may be present in cats secondary to severe atrial enlargement.

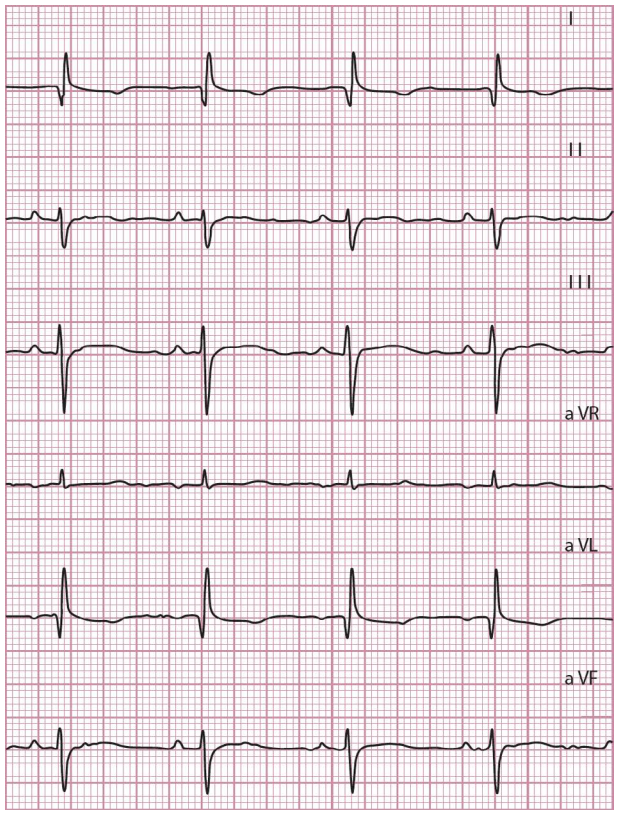

FIGURE 8.41 ECG from a cat with hypertrophic cardiomyopathy showing a sinus rhythm with a left axis deviation (lead I mostly positive, lead a VF mostly negative), also called left anterior fascicular block.

NT-proBNP has been shown to be a fairly sensitive and specific screening tool for the identification of subclinical HCM, though false negatives may occur in cats with mild disease. It has been shown to discriminate between cats with respiratory signs due to CHF and cats with primary respiratory disease. An elevated NT-proBNP warrants further diagnostic evaluation. A normal value should not be used to rule out cardiac disease if other findings are supportive. cTnI may also be elevated in cats with moderate-to-severe HCM with or without CHF.

Genetic testing for a specific genetic mutation is currently only available for Maine Coon and Ragdoll cats. These tests are most useful for identifying breeding cats that carry this mutation, although cats that do not carry the mutation may still develop HCM. Genetic testing should be utilized in addition to echocardiographic screening in breeding cats to avoid the production of individuals homozygous for the mutation.

Management

A new staging system has recently been proposed to classify cats based on their risk and in order to guide therapeutic recommendations. Staging and treatment (Table 8.13) recommendations are summarized as follows:

TABLE 8.13 Drugs used in the management of cardiomyopathy in cats

Drug	Dosage	Comment
Atenolol	0.5–2 mg/kg p.o. q.12–24h.	In cats with dynamic left ventricular outflow tract obstruction with relatively normal LA size Consider long-term treatment if improvement of hypertrophy Start with low dose and increase slowly over a few weeks Consider for complex ventricular arrhythmias
Enalapril, benazepril	0.25–0.5 mg/kg p.o. q.12–24h.	Start q.24h.
Furosemide	1–2 mg/kg IM or IV q.1–8h. 1–3 mg/kg p.o. q.8–24h.	Monitor BUN, creatine, and blood potassium concentration
Torsemide	0.1–0.2 mg/kg p.o. q.24h.	Monitor BUN, creatine, and blood potassium concentration
Pimobendan	0.25 mg/kg p.o. q.12h.	Administered in the absence of significant LVOTO when CHF is present
Clopidogrel	18.75 mg p.o. q.24h.	In cats after episode of thromboembolism or if severe left atrial enlargement +/– visible thrombus or SEC

Stage A classifies cats who are at risk for developing cardiomyopathy (are a breed predisposed to cardiomyopathy). Genetic testing (if Maine Coon or Ragdoll) and routine echocardiograms can be considered for these pets.

Stage B1 classifies cats who have evidence of cardiomyopathy but do not have moderate-to-severe LA enlargement. These cats are considered at low risk for CHF or arterial thromboembolism (ATE). No treatment is generally recommended. Atenolol may be considered in cats who have severe LVOTO, but atenolol has not been shown to prolong survival.

Stage B2 classifies asymptomatic cats with cardiomyopathy who are at increased risk of developing CHF or ATE. Findings on echocardiogram may include moderate-to-severe left atrial (LA) enlargement, low LA FS%, low LA appendage velocities, and SEC. Clopidogrel is warranted in these cats, and other antithrombotic drugs (aspirin, factor Xa inhibitors) can be considered in addition to clopidogrel. ACE inhibitors have not been shown to prolong time to CHF, and studies on pimobendan are currently lacking. Complex ventricular ectopy should be treated with atenolol. AF with fast ventricular response rate should be treated with either diltiazem, atenolol, or sotalol.

Stage C classifies cats that are currently experiencing or have experienced CHF or ATE. Chronic treatment of CHF in cats with cardiomyopathy includes furosemide and clopidogrel. ACE inhibitors are used by some cardiologists, though compelling evidence of their effectiveness is lacking. ACE inhibitors are consistently used in conjunction with furosemide in feline patients that are not of advanced age or significantly azotemic. Pimobendan may be considered in cats without significant LVOTO. Spironolactone may also be considered. Patients presenting with evidence of ATE should be provided pain medication and antithrombotic therapy (clopidogrel, heparin). Taurine should be supplemented in cats with DCM phenotype. Serum creatinine and electrolyte concentrations should be monitored, and potassium supplementation should be initiated in hypokalemic cats.

Stage D classifies cats that are refractory to treatment of CHF. These cats are receiving furosemide doses in excess of 6 mg/kg per day. Furosemide may be replaced with torsemide (starting dose of 0.1–2.0 mg/kg p.o. q.24h.). Pimobendan and taurine are recommended in cats with decreased global systolic function (unless taurine levels are normal).

Prognosis

Prognosis for cats with HCM is variable. Asymptomatic patients may live several years after diagnosis, and there are a modest number of cats with mild HCM that do not experience disease progression and live a normal life span. Other cats experience more aggressive disease progression and die suddenly at a young age, develop CHF, or suffer thromboembolic complications (Figure 8.42). Extreme hypertrophy (> 9 mm), decreased left ventricular systolic function (FS < 30%), and decreased left atrial systolic function (↓ left atrial FS%) are associated with increasing risk of cardiac death.

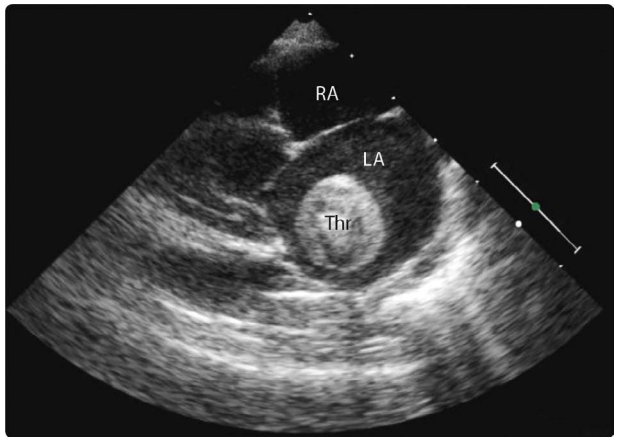

FIGURE 8.42 Right parasternal echocardiographic view of a cat showing a large thrombus in the left atrium. LA, left atrium; RA, right atrium; Thr, thrombus.

In acute CHF, there is an approximate 80% survival to discharge. Patients with systolic dysfunction and CHF have historically had a poor prognosis; however, there may be improved survival with the addition of pimobendan. The prognosis from the first episode of heart failure is generally 6–12 months among the various cardiomyopathies; however, it is quite variable with some patients having shorter survival and others surviving well beyond 1 year (some up to 2–3 years). Cats with thromboembolic complications generally have a poor long-term prognosis, with an average survival of 6 months and up to 30% mortality during the immediate hospitalization period; however, some cats live for several years. Cats who experience CHF as a consequence of stress, fluid administration, general anesthesia, or steroid intolerance tend to have a better prognosis.

MYOCARDITIS

Definition/Overview

Myocarditis is defined as an inflammation of the myocardium associated with myocyte necrosis. Although myocardial inflammation is present in all forms of cardiac disease, the term myocarditis is reserved for inflammation of the heart as the result of pathogens (viruses, bacteria, parasites), drug exposure, or immune-mediated diseases. The expression traumatic myocarditis is also used for inflammation of the myocardium following blunt trauma.

Etiology

Myocarditis in dogs (Table 8.14) and cats (Table 8.15) may be secondary to pathogens (viruses, bacteria, parasites, fungal), immune-mediated diseases, drug toxicity, or trauma. *Trypanosoma cruzi* (Chagas disease) is one of the pathogens most commonly recognized as a cause of myocarditis in endemic areas, particularly in

the southern part of the United States (**Figure 8.43**). In patients from nonendemic areas, myocarditis has been seen secondary to systemic bacterial infection and septicemia.

In cats, transmissible myocarditis–diaphragmitis is reported to affect adult cats in California and Florida during the summer months and has been associated with *Bartonella henselae* and other infectious causes. Unfortunately, identifying the definitive cause of myocarditis remains unsuccessful in most cases.

Pathophysiology

Myocardial lesions can be a direct effect of infectious agents or drugs, but they can also be secondary to an immune response. Viruses can enter myocytes and interfere with cell metabolism, which may induce cell death, hypertrophy, or dysfunction. By modifying the myocyte cytoskeleton, viruses can lead to cardiac dysfunction with echocardiographic characteristics of DCM. The immune response can lead to cytokine release and enzyme activation. During the inflammatory process, activated collagenase and elastase enzymes contribute to cardiac remodeling. Activation of specific cytokines, especially transforming growth factor-beta, may predispose to pathologic fibrosis.

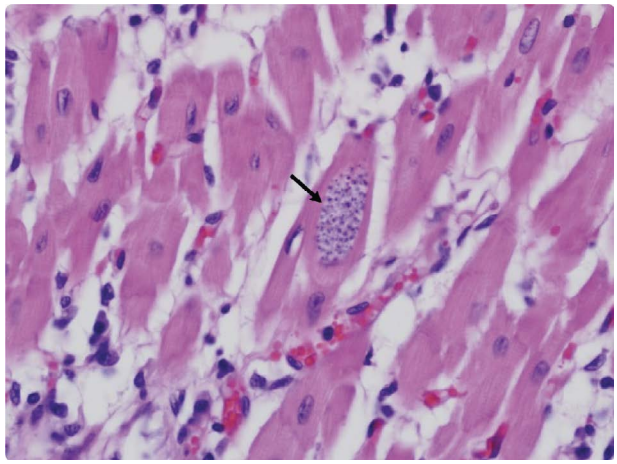

FIGURE 8.43 Histologic section of a canine heart infected with *T. cruzi*. H&E stain. Magnification ×40.

Clinical Presentation

Myocarditis can affect dogs and cats of all ages. However, several diseases are more likely in the young dog (Chagas disease, parvovirus) or in immunocompromised animals (e.g., leishmaniasis, toxoplasmosis). Obtaining a complete history is essential because living conditions or travel to endemic area may help the clinician identify an etiologic factor for a specific disease.

Dogs and cats with myocarditis can present with signs of CHF such as weakness, syncope, exercise intolerance, respiratory difficulties, and/or abdominal distension. Clinical signs are most commonly acute, but these signs can be insidious (e.g., chronic phase of Chagas disease). Fever and a heart murmur are common findings. Complex arrhythmias are frequent and should alert the clinician to the possibility of myocarditis when they occur in a breed that is not predisposed to cardiomyopathy. Tachyarrhythmias (ventricular or supraventricular) and bradyarrhythmias (most commonly second- or third-degree AV block) are reported. Systolic dysfunction is the most common echocardiographic finding. Left- and right-sided CHF are complications of myocarditis.

Differential Diagnosis

Myocarditis is characterized by nonspecific clinical signs; therefore, differential diagnoses include other cardiac diseases and other cause of arrhythmias.

When myocarditis is associated with both systolic dysfunction and ventricular and/or supraventricular arrhythmias, the differential diagnosis should include DCM, tachycardia-induced cardiomyopathy, and infiltrative cardiomyopathy (e.g., lymphoma). However, myocarditis is usually acute compared with other causes of systolic dysfunction.

It is suspected that in cats as in humans, myocarditis may also lead to myocardial concentric hypertrophy. Differential diagnosis for feline ventricular hypertrophy includes HCM, systemic hypertension, hyperthyroidism, acromegaly, muscular dystrophy, myocarditis, and cardiac lymphoma. Therefore, the differential diagnosis of myocarditis in cats should include all causes of ventricular hypertrophy and other cardiomyopathies.

Diagnosis

Myocarditis is usually suspected in dogs and cats (especially in young animals) with acute clinical signs consistent with arrhythmias and systolic dysfunction, especially in those with a fever and new heart murmur. A complete biochemistry profile and hemogram are necessary to assess organ dysfunction, inflammation, or the presence of blood parasites. The most common bloodwork findings are a neutrophilia with a left shift, monocytosis, anemia, increased ALT, and azotemia.

In all dogs and cats with suspected myocarditis, an ECG (+/– Holter recording) should be performed, especially if arrhythmias are detected during physical examination, or if the reason for the consultation includes weakness, exercise intolerance, or syncope. A complete echocardiogram is essential to exclude other cardiac diseases and evaluate systolic function. cTnI serum level increases secondary to massive myocardial cell death. A marked elevation in circulating cTnI level is common with myocarditis.

Thoracic radiography is indicated if respiratory signs are present to evaluate the possibility of pulmonary edema or pleural effusion. Any pleural, pericardial, or abdominal fluids removed should be submitted for bacterial culture and cytology. Any accessible lesions should be aspirated or biopsied for analysis.

Diagnosis of Chagas disease can be made by direct observation of *Trypanosoma cruzi* on a stained blood smear or buffy coat smear, on lymph node aspirates, or in abdominal effusion. PCR is sensitive in the acute phase, but the sensitivity decreases with chronicity. Antibody titer is usually positive by 3 weeks post infection. The most commonly used serologic tests are the indirect immunofluorescent antibody test and the ELISA test (possible cross reaction with *Leishmania*).

Management

Treatment should be directed at improving cardiac function, decreasing arrhythmia burden, controlling CHF, and treating the underlying cause if possible. Inotropes (pimobendan) are indicated to improve systolic function. Diuretics (furosemide) should be used with pimobendan if CHF is present. Abdominocentesis and thoracocentesis should be performed in all animals with ascites or pleural effusion. Pericardiocentesis should be performed if a large amount of effusion is present. High-grade second- and third-degree AV blocks do not respond to medical treatment; therefore, pacemaker implantation is needed to increase the heart rate and improve cardiac output in these cases. Tachyarrhythmias are treated according to the underlying mechanism involved (see Tachyarrhythmias).

No effective treatment is currently available to treat Chagas disease in dogs. Nifurtimox, benzimidazole, itraconazole, and allopurinol have been used with varying success. Prednisolone (0.5–1 mg/kg p.o. q.12–24h.) may increase survival. Because the immune system is involved in the mechanism of myocardial lesions even in infectious myocarditis, glucocorticoids are often recommended to reduce inflammation. Antibiotics can be effective against bacterial myocarditis, and the choice of antibiotic should ideally be made on the basis of blood culture results.

Prognosis

Prognosis is generally guarded and unpredictable. Chagas disease is usually associated with poor outcomes because even if a dog survives the acute phase, the chronic phase may induce severe cardiac dysfunction. Young dogs have a worse prognosis (< 5 months survival) than adult or old dogs (30–60 months survival), probably because of a different immune response to the disease.

Most of the time, puppies that develop myocarditis secondary to parvovirus die in a few days because of severe myocardial necrosis. However, myocarditis can also resolve in a few days or a few weeks without specific treatment or with empirical treatment with broad-spectrum antibiotics. Some authors report that cats may develop myocardial hypertrophy and CHF secondary to anesthesia or surgery and occasionally recover spontaneously.

PERICARDIAL DISEASES

Definition/Overview

The most common manifestation of pericardial disease is pericardial effusion. Cardiac tamponade describes pericardial effusion associated with clinical signs because a large volume of effusion is present or because fluid has accumulated very fast. Constrictive pericarditis is caused by a markedly thickened pericardial sac that prevents adequate cardiac filling.

Etiology

Pericardial effusion in dogs is frequently caused by cardiac tumors. Cardiac hemangiosarcoma is the most common tumor responsible for cardiac tamponade. Golden Retrievers and German Shepherd Dogs are overrepresented. Brachycephalic breeds are predisposed to

chemodectomas. Other tumors include mesothelioma, lymphoma, and ectopic thyroid carcinoma. Idiopathic pericardial effusion is another common cause of cardiac tamponade. Unusual causes for tamponade include trauma, coagulation disorders, and an atrial tear in dogs with severe mitral valve regurgitation and a dilated left atrium. Pericardial effusion is less common in cats and is usually associated with CHF. Tamponade is rare in cats but could result from lymphosarcoma or feline infectious peritonitis (FIP). Constrictive pericarditis can be a complication of any chronic effusion or pericarditis. It has been described as a complication of *Coccidioides immitis* infections.

Pathophysiology

Pericardial fluid has little effect on cardiac function unless the intrapericardial pressure equals or exceeds cardiac diastolic pressure. The pericardium can accommodate a moderate amount of fluid that accumulates slowly with little change in pericardial pressure. However, large amounts of fluid, or even small amounts that accumulate quickly (hemorrhage), can cause a significant increase in pericardial pressure leading to cardiac tamponade. Tamponade impedes diastolic filling. As a result, cardiac output falls. When pericardial fluid accumulates over days or weeks, this decrease in cardiac output results in increased adrenergic tone and activation of neurohormonal mechanisms. This includes activation of the RAAS, leading to increased circulating angiotensin II, aldosterone, and vasopressin. This results in an increase in heart rate and fluid retention. Renal fluid excretion is not promoted because there is no increase in secretion of atrial natriuretic peptide. Over time, right-sided CHF occurs. Conversely, when hemorrhagic pericardial effusion accumulates within a few seconds, there is no time for water retention to occur and prevent a rapid drop in cardiac filling. Subsequently, an important reduction in cardiac output occurs. Cardiogenic shock is, therefore, the typical consequence of acute cardiac tamponade. Reduced coronary perfusion during tamponade can also impair ventricular systolic function.

Clinical Presentation

Clinical signs of cardiac tamponade are consistent with right-sided CHF and reduced cardiac output. History may include weakness, lethargy, exercise intolerance, collapse, syncope, abdominal distension, and tachypnea, as well as weight loss in chronic cases. Signs of right-sided CHF predominate. Physical examination may reveal jugular vein distension, weak femoral pulses, and muffled heart sounds (Beck triad). Also, a positive hepatojugular reflux, hepatomegaly, ascites, tachypnea, and dyspnea can be present. Pleural effusion from right-sided CHF may also muffle heart sounds and lung sounds ventrally. Sinus tachycardia, pale mucous membranes, and prolonged CRT are common due to increased sympathetic tone. A murmur may be present if there is underlying cardiac disease; however, pericardial effusion will not cause a heart murmur on its own. Pulsus paradoxus is not always present but is characteristic of pericardial effusion. It results in weaker femoral pulses during inspiration and stronger pulses during expiration.

Differential Diagnosis

Congenital causes of canine pericardial disease include pericardial cysts, partial/total pericardial agenesis, and peritoneopericardial diaphragmatic hernia (PPDH). PPDH is the most common congenital pericardial disease in cats. Causes of acquired pericardial disease and pericardial effusion in dogs include hemangiosarcoma, heart base tumor, idiopathic pericardial effusion, malignant mesothelioma, hypoalbuminemia, uremia, CHF, septic pericarditis (bacterial, fungal [coccidiomycosis], protozoal [leishmaniasis]), left atrial rupture, trauma, and hemorrhage (coagulopathy). Causes of acquired pericardial disease in cats include CHF, feline infectious peritonitis (FIP), hypoalbuminemia, idiopathic, and lymphosarcoma.

Diagnosis

Radiography

Radiographic findings are not always reliable for diagnosing pericardial effusion. The typical, large, globoid cardiac silhouette results when there is a moderate accumulation of chronic effusion. Acute effusions causing clinical signs of cardiac tamponade may not always be evident on thoracic radiographs.

Radiographs of animals with PPDH show convergence of the cardiac silhouette and the diaphragm. GI segments may be evident as gas opacities within the pericardial space, and depending on the amount of organ displacement, the abdomen may be partially devoid of intestinal segments or other organs. Liver and omental fat are most commonly herniated through the defect. Sternal defects are often found concurrently with PPDH. Other congenital cardiovascular defects have also been reported in dogs and cats with PPDH.

Electrocardiography

Animals with cardiac tamponade are tachycardic. In addition, low-amplitude QRS complexes are common in animals with a moderate amount of pericardial effusion. Electrical alternans (a beat-to-beat variation in the R-wave amplitude) is less common (Figure 8.44).

Echocardiography

Two-dimensional echocardiography is the most sensitive, noninvasive test for confirming the presence of pericardial effusion and elucidating the cause. Pericardial effusion is seen as an anechoic space between the epicardium and the pericardium (Figure 8.45). The amount of effusion can be roughly quantitated, and signs of cardiac tamponade can be identified. The areas of the right atrium/auricle, heart base, and main pulmonary

FIGURE 8.44 ECG (lead II) from a dog with cardiac tamponade. There is sinus tachycardia with a beat-to-beat variation in QRS complex amplitude, called electrical alternans.

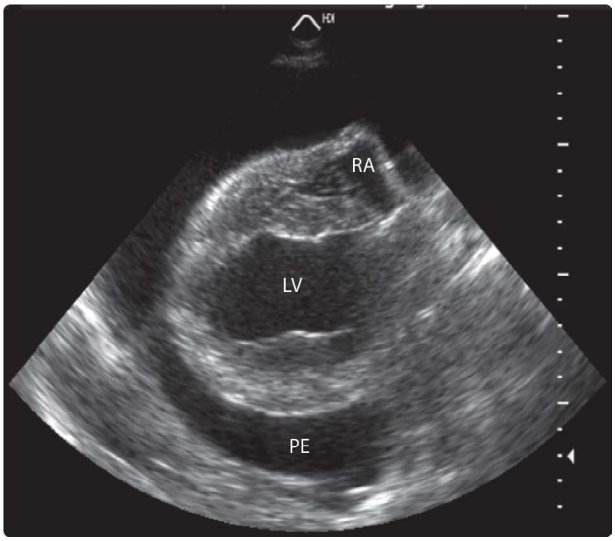

FIGURE 8.45 Echocardiographic view from a dog with pericardial effusion. The effusion is seen as an anechoic space around the heart. LV, left ventricle; PE, pericardial effusion; RA, right atrium.

artery should be examined carefully since these are common locations for cardiac masses (Figure 8.46). The specific tumor type can often be suspected based on location. Overall, echocardiography is estimated to be 90% sensitive for detecting cardiac masses. Heart base tumors are commonly found adjacent to the aorta on standard transthoracic views. Right atrial/auricular masses (commonly hemangiosarcoma) may be difficult to see, so the absence of a mass in this location does not necessarily rule neoplasia out. Transesophageal echocardiography may more easily reveal masses, but this technique requires special equipment and general anesthesia. False-positive findings have been reported, and normal cardiac structures can be misidentified as a mass when imaged in oblique positions, especially by inexperienced echocardiographers. In cases of cardiac tamponade, the ventricular walls may show pseudohypertrophy due to external compression and collapse of the right atrial and ventricular walls during diastole. The myocardial texture should be observed for any signs of tumor infiltrate (primary or metastatic neoplasia such as lymphoma). In the case of a left atrial tear, a clot may be visualized in the pericardial space along with the pre-existing valvular disease.

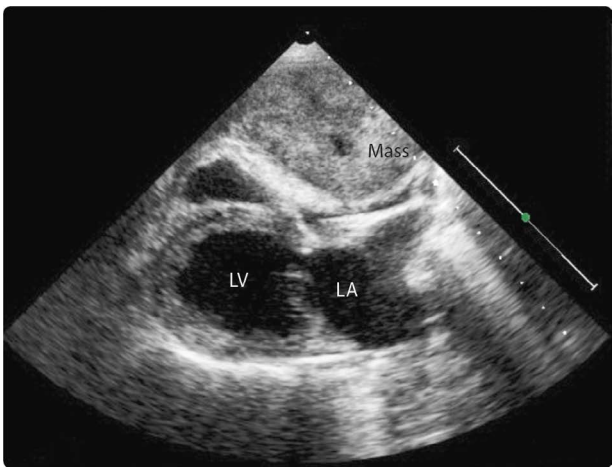

FIGURE 8.46 Right parasternal echocardiographic view from a dog with a large cardiac mass expanding along the right atrium and ventricle. The mass is so large that it is compressing the right atrium and ventricle. LA, left atrium; LV, left ventricle.

Pericardial Fluid Analysis

Pericardiocentesis is frequently necessary for emergency stabilization of a patient with pericardial effusion and cardiac tamponade; however, fluid analysis is rarely diagnostic. Fluid samples are often hemorrhagic or serosanguineous, sterile, inflammatory exudates. Not surprisingly, hemangiosarcoma and aortic body tumors are rarely confirmed on cytologic examination of pericardial fluid. Less common causes of pericardial effusion, such as lymphosarcoma or infectious pericarditis, are more reliably diagnosed with pericardial fluid analysis.

Management/Prognosis

Acute management of pericardial effusion requires pericardiocentesis in most cases. The pericardium should be approached from the right side to reduce the risk of lacerating a coronary vessel. Many animals will tolerate the procedure without sedation, but a sedative such as butorphanol can be used. The right thorax is clipped and aseptically prepared. The ideal location for entry can be determined with ultrasound. Typically, a 14- or 16-gauge over-the-needle catheter is used along with an extension set and a three-way stopcock. The skin, intercostal muscles, and parietal pleura are infiltrated with local anesthetic. The catheter is then inserted while applying negative pressure. Once the needle enters the pericardium and fluid flows into the extension set, the catheter can be advanced. To distinguish red pericardial fluid from blood within the heart or blood vessels, a sample of fluid is collected in

an activated clotting time tube. Blood should normally clot within 60–90 seconds, unlike sanguineous body cavity effusions in which clotting factors and platelets are depleted. Ventricular arrhythmias are common during this procedure, so ECG monitoring should be available. The treatment and prognoses for specific pericardial diseases are described here.

Hemangiosarcoma

Cardiac hemangiosarcoma has usually metastasized by the time of diagnosis. Commonly, palliation with pericardiocentesis alone is elected; however, the fluid and cardiac tamponade can return quickly and result in death or euthanasia. Median survival time for dogs treated with pericardiocentesis alone is approximately 2 weeks. Other aggressive therapies include tumor resection, pericardectomy, chemotherapy, and splenectomy. Some dogs live up to 3–6 months. Adjuvant chemotherapy has been shown to provide little survival advantage.

Heart Base Tumors

Complete surgical resection of these tumors is usually impractical because they are highly vascular and surround major blood vessels. Palliation with pericardectomy alone commonly results in prolonged survival with good quality of life, sometimes over 2 years after pericardectomy. Radiation therapy and chemotherapy with toceranib phosphate (Palladia) have emerged as viable treatment options.

Mesothelioma and Other Cardiac Tumors

There are only a few case reports of successful treatment for mesothelioma. However, complete pericardectomy followed by intracavitary cisplatin and IV doxorubicin have been reported to result in a disease-free state 2 years later. Patients may also require periodic thoracocentesis for pleural effusion. Since mesothelioma can be difficult to diagnose even with histopathology, accumulation of a large amount of pleural effusion 4–6 months after pericardectomy increases the suspicion for the disease. Cardiac lymphosarcoma, rhabdomyosarcoma, and fibrosarcoma are rare. Cardiac lymphosarcoma is treatable with chemotherapy.

Infectious Pericarditis

Bacterial infections of the pericardium are thought to arise most commonly from foreign body penetration, often migrating foxtails (*Hordeum* spp.). Therefore, pericardectomy and removal of the foreign body is crucial for resolution of the disease. Therapy, including pericardectomy, removal of any foreign bodies, and long-term antibiotic therapy (up to 6 months), results in a good prognosis. Treatment for coccidioidomycosis is similar except that antifungal medications replace antibiotics. Prognosis for *Coccidioides* infection involving the pericardium is guarded, as constrictive pericarditis is a common complication after the fungal infection is treated.

Idiopathic Pericardial Effusion and Constrictive Pericarditis

Idiopathic pericardial effusion is a diagnosis of exclusion and often not completely distinguishable from mesothelioma. Animals with idiopathic pericardial effusion can develop effusive–constrictive pericarditis over time with repeated thoracocentesis. For this reason, pericardectomy is recommended. Many animals go on to do well after successful surgery.

PULMONARY HYPERTENSION

Definition/Overview

Pulmonary hypertension (PH) is defined as pathologically elevated blood pressure within the pulmonary vasculature with a mean pulmonary artery pressure of ≥ 25 mmHg. Recognition of PH has increased since the widespread availability of Doppler echocardiography. PH occurs most commonly in middle-aged to older small breed dogs but can be seen in canine patients of any age and less commonly in cats.

Etiology

The etiology of PH is multifactorial and requires multidisciplinary collaboration for appropriate diagnosis and medical management. PH can be classified based on anatomical location: Precapillary causes wherein an increase in pulmonary vascular resistance is observed without an increase in left atrial pressures verses post capillary causes which occur secondary to an increase in pulmonary artery wedge pressure observed secondary to left heart enlargement and increased left atrial pressure.

Pathophysiology

The pulmonary vasculature is normally a low-pressure system with minimal resistance and high capacitance (highly distensible). Disruption of the pulmonary circulation can cause an increase in pulmonary blood flow, pulmonary vascular resistance, or pulmonary venous pressures, which can secondarily lead to architectural changes typical of PH. Increased flow causes vascular endothelial damage, vasoconstriction, and remodeling of small pulmonary arteries leading to development of PH; irreversible damage to the pulmonary vasculature may occur. Hypoxia and release of vasoactive substances from activated platelets causes reactive vasoconstriction, increasing pulmonary vascular resistance. Post capillary PH causes increased filling pressure, which impedes drainage of the pulmonary capillaries and leads to a compensatory increase in pulmonary artery pressure to maintain forward flow. Chronic post capillary PH may lead to irreversible changes within the pulmonary vasculature consistent with precapillary PH, and thus, a combination of precapillary and post capillary PH may occur. PH creates a pressure overload on the right ventricle, leading to right heart enlargement, right ventricular dysfunction, and tricuspid valve

insufficiency. It may progress to right-sided CHF. PH may also limit preload (filling) to the left ventricle, decreasing cardiac output to the systemic circulation.

PH was recently separated into 6 major groups based on primary underlying etiology. Primary pulmonary arterial hypertension (group 1) is very uncommon in veterinary patients. Specific etiologies include idiopathic PH, drug-induced PH, congenital heart shunts, pulmonary vasculitis or amyloid deposition, pulmonary veno-occlusive disease, or pulmonary capillary hemangiomatosis. PH secondary to increased left atrial pressure (group 2) is the most common cause of PH and occurs secondary to cardiac diseases, including mitral valve insufficiency, DCM, and myocarditis. Primary lung pathology (group 3) is the second most common cause for PH in veterinary patients. This group is expansive, including numerous etiologies such as obstructive airway disease (tracheal or mainstem bronchi collapse, bronchomalacia), interstitial lung diseases (fibrotic lung disease, eosinophilic disorders), diffuse neoplasia, obstructive sleep disorders and brachycephalic airway syndrome, high altitudes, and bronchiolar diseases, among others. Hypoxia secondary to these disorders leads to pulmonary arteriolar constriction as an adaptive mechanism to shunt pulmonary blood flow to regions of the well-oxygenated lung tissue. The pulmonary vasculature may also be distorted and pulmonary arterioles narrowed secondary to chronic lung diseases. PH from either acute or chronic pulmonary thromboembolism is classified under group 4. Group 5 includes PH due to *Dirofilaria immitis* and *Angiostrongylus vasorum*. Lastly, group 6 encompasses PH secondary to more than one cause listed in groups 1–5, a mass compressing the pulmonary artery, or PH for which an underlying etiology cannot be identified.

Clinical Presentation

Clinical signs that are strongly suggestive of PH include syncope, respiratory distress at rest, or activity ending in respiratory distress. Findings possibly suggestive of PH include tachypnea at rest, increased respiratory effort at rest, or prolonged tachypnea after activity. Nonspecific clinical signs such as lethargy, hyporexia, or cough may also be observed. Patients with mild-to-moderate PH are often asymptomatic. Like clinical signs, physical exam findings are dependent on the underlying disease and could include systolic heart murmurs due to tricuspid or mitral valve insufficiency, a diastolic murmur of pulmonic insufficiency, split S2 sound, jugular distension or pulsation, abdominal distension or fluid wave with right-sided CHF, cyanosis, tachypnea, increased respiratory effort, crackles, wheezes, or increased bronchovesicular sounds.

Differential Diagnosis

Differentials for respiratory signs include PTE, pneumonia, CHF, pleural effusion, chronic bronchitis, pulmonary hemorrhage or contusions, and lung lobe torsion. Differentials for syncope or exercise intolerance include arrhythmias, cardiomyopathy, vasovagal syncope, hypotension, acute pericardial effusion, and anemia.

Diagnosis

The gold standard diagnostic test is right heart catheterization and direct measurement of pulmonary pressures; however, this technique is impractical in most clinical situations. Doppler echocardiography is an excellent, noninvasive method of estimating pulmonary pressures and is considered the practical diagnostic of choice in veterinary medicine. In the absence of pulmonic stenosis, the velocity of tricuspid valve regurgitation is used to estimate the right ventricular end-systolic pressure (RVESP). The systolic pulmonary artery pressures are then calculated using the modified Bernoulli equation ($P = 4v^2$) where P is the pressure gradient between the right ventricle and right atrium, and v is the velocity of the regurgitant jet (**Figure 8.47**). Pulmonic valve insufficiency may be used to estimate diastolic pulmonary artery pressure (PAP). While historically classified as mild, moderate, or severe (RVESP 36–60 mmHg, 60–80 mmHg, and ≥ 80 mmHg, respectively), newer recommendations propose a pressure gradient of > 46 mmHg as the cutoff to indicate a high probability of PH. Other echocardiographic changes that may be observed with PH include interventricular septal flattening (**Figure 8.48**), paradoxical septal motion, decreased left ventricular size, right ventricular eccentric or concentric hypertrophy, right atrial enlargement, caudal vena cava enlargement, pulmonary artery to aorta ratio > 1.0, pulmonic regurgitation velocity > 2.5 m/s, right pulmonary artery distensibility index < 30%, dilation of the main pulmonary artery (**Figure 8.49**), or type II or III pulmonary artery systolic flow profile. If PH is due to left-sided heart disease, evidence of significant structural disease should be present.

Ancillary diagnostics should start with a full systemic evaluation by means of CBC, biochemistry, urinalysis, heartworm antigen test, and thoracic radiographs. Evidence of right heart enlargement, main pulmonary artery bulge, dilation of lobar pulmonary arteries, or pulmonary disease may be identified on

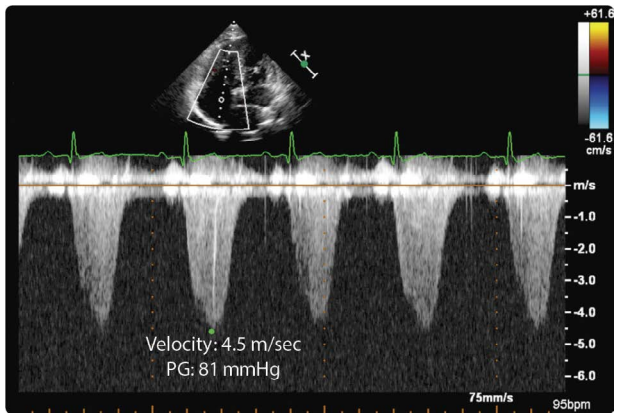

FIGURE 8.47 Spectral Doppler of a tricuspid valve regurgitation jet consistent with severe pulmonary hypertension.

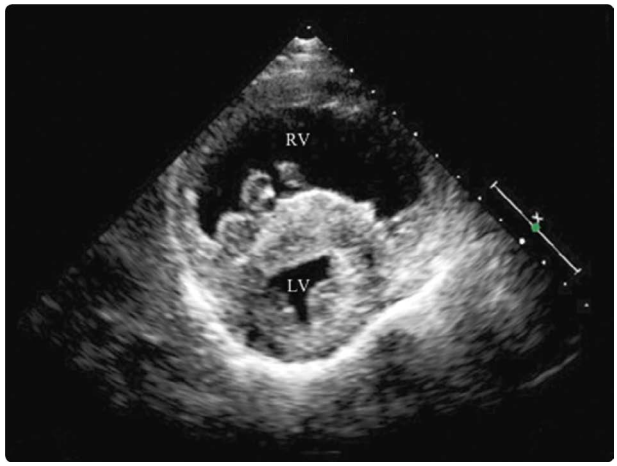

FIGURE 8.48 Echocardiographic short-axis view from a dog with severe pulmonary hypertension. The right ventricle is severely dilated. There is marked thickening of the interventricular septum, with prominent papillary muscles on the right side. The left ventricle is small as a result of decreased filling. LV, left ventricle; RV, right ventricle.

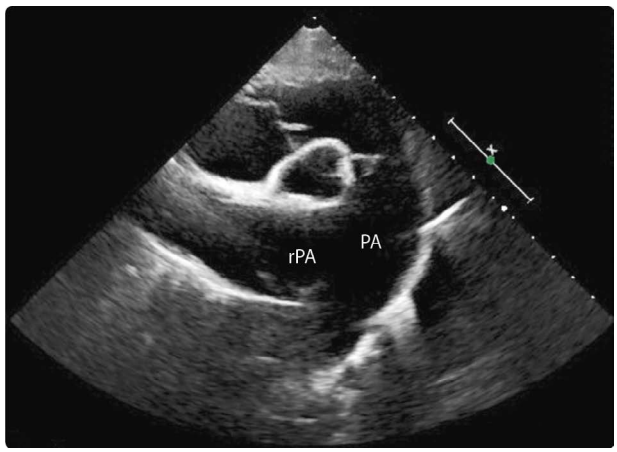

FIGURE 8.49 Echocardiographic view of the main pulmonary artery of a dog with pulmonary hypertension. There is severe dilation of the main and right pulmonary arteries. PA, pulmonary artery; RPA, right pulmonary artery.

thoracic radiographs. Further diagnostic testing may be indicated based on the suspected differentials after initial evaluations. These tests include arterial blood gas, abdominal ultrasound, urine protein-to-creatinine ratio, fluoroscopy, thoracic CT, angiography, bronchoscopy, bronchoalveolar lavage, and a coagulation profile, including D-dimers or thromboelastography.

Management

Treatment is directed at resolving or treating the underlying cause of PH if one is identified. Supplemental oxygen, which can directly improve PH by causing pulmonary artery dilation, and sedatives (opioids) should be provided to patients in respiratory distress. Patients with PH from diseases in group 1 could benefit from congenital shunt repair (if possible) or therapeutic phlebotomy plus/minus hydroxyurea for treatment of erythrocytosis. PH due to left-sided heart disease often improves with standard treatment of CHF. Treatment for PH from diseases in group 3 varies vastly but could include antibiotics, steroids, and chemotherapeutic agents. Anticoagulants such as heparin, factor Xa inhibitors like rivaroxaban, and antithrombotics like aspirin or clopidogrel are necessary for patients with thromboembolic disease. Due to the low shear conditions, anticoagulants are preferred to antithrombotic drugs but are typically more cost prohibitive. Lastly, the underlying helminthic infection should be treated for patients in group 5. The majority of patients with PH will benefit from the implementation of a phosphodiesterase-5 inhibitor such as sildenafil or tadalafil. These drugs cause pulmonary vasodilation associated with the nitric oxide pathway. However, they should be avoided with suspected pulmonary veno-occlusive disease, pulmonary capillary hemangiomatosis, or significant left-sided heart disease because the increased blood return to the left side of the heart may result in fatal pulmonary edema.

Prognosis

Prognosis is related to the underlying disease process and response to treatment. PH can rarely be completely reversed unless it is due to a left-to-right shunt that can be surgically corrected (such as a PDA). Due to the progressive nature of a majority of the processes leading to PH, the prognosis for long-term survival is generally considered poor. There is a paucity of information regarding prognosis, and confounding factors such as client funds may make determining this more difficult. However, data shows that dogs with primary respiratory disease and a tricuspid regurgitation pressure gradient of > 47 mmHg have a low probability of long-term survival. Conversely, patients with these diseases treated with PDE-5 inhibitors experience longer survival times. Lastly, the development of right-sided congestive heart failure may limit survival.

SYSTEMIC HYPERTENSION

Definition/Overview

Systemic hypertension is defined as a systolic blood pressure > 160 mmHg or diastolic pressure > 100 mmHg. Hypertension is divided into three categories: Situational, secondary, or idiopathic ("primary" or "essential").

Etiology

Systemic hypertension has been documented in veterinary patients most commonly from secondary disease processes and is rarely essential/primary. Causes of secondary hypertension can be classified as volume-loading hypertension or not. Diseases that result in increased circulating blood volume or peripheral vasoconstriction include hyperaldosteronism, hyperthyroidism, primary renal disease, diabetes mellitus, Cushing's disease,

pheochromocytoma, hyperviscosity syndrome (polycythemia, multiple myeloma, macroglobulinemia), and acromegaly. These diseases result in either activation of the RAAS at different levels or osmotic increases due to glucose, steroids, red blood cells, proteins, or growth hormones. Essential hypertension has been documented in a line of Siberian Husky mixed breed dogs.

Pathophysiology

Systemic hypertension is associated with increased systemic vascular resistance. Four target organs are particularly affected by a chronic elevation in blood pressure: The heart, kidneys, eyes, and brain.

Clinical Presentation

Most hypertensive dogs and cats are middle aged to older. Signs reported by the owner are usually caused by the various diseases that lead to systemic hypertension or by evidence of target organ damage. For example, hypertensive animals may develop acute blindness or seizures. Target organ consequences caused by uncontrolled hypertension are listed in Table 8.16. Physical examination may reveal epistaxis, a palpable thyroid slip, a gallop rhythm, and/or heart murmur.

Differential Diagnosis

Differential diagnosis for pathologic systemic hypertension includes physiologic hypertension from stress (situational hypertension).

Diagnosis

Diagnosis of systemic hypertension is based on invasive or noninvasive measurements of blood pressure. Invasive blood pressure measurements are made most commonly with the animal restrained in lateral recumbency and a 22- to 25-gauge catheter inserted into the femoral artery connected by a heparinized saline-filled tubing to a physiologic pressure transducer and hemodynamic oscilloscope recorder. Tubing should not be excessively long and should be kept at the level of the heart.

CHF, congestive heart failure; CKD, chronic kidney disease.

Noninvasive blood pressure measurement can be obtained by auscultation of Doppler signals with Korotkoff sounds when blood flow to a limb or the tail is obstructed with an appropriately sized and inflated cuff. The choice of cuff is based on the patient's distal limb size. Additionally, noninvasive oscillometric blood pressure measurement is a common technique that relies on detection of arterial pulsation through the use of an automatically inflating and deflating cuff that is wrapped around a distal limb or tail. The accuracy of such devices may be limited in smaller patients, where Doppler measurement is preferred. Consistency in personnel, equipment, and technique is critical to obtain accurate measurements.

Systemic hypertension is currently classified as falling into one of three groups:

1. Prehypertension (140–159 mmHg)
2. Moderate hypertension (160–179 mmHg)
3. Severe hypertension (> 180 mmHg)

Diagnostic tests for secondary causes of systemic hypertension are listed in Table 8.17.

TABLE 8.16 Target organ consequences of systemic hypertension

Target organ	Consequences
Cardiovascular	– Left ventricular concentric hypertrophy – Aortic valve insufficiency – Arteriosclerosis – Atherosclerosis – CHF (uncommon) – Aortic dissection/aneurism (rare)
Cerebrovascular	– Encephalopathy – Cerebrovascular accidents (strokes)
Renal	– Progression of CKD – Proteinuria
Intraocular	– Blindness – Retinal detachment, hemorrhage, and/or hyphema – Choroidopathy

TABLE 8.17 Diagnostic tests for hypertensive diseases

Disease	Test
Thyroid disease	T4, free T4, antibody panel
Hyperadrenocorticism	ACTH stimulation test, dexamethasone suppression test, urine cortisol-to-creatinine ratio, abdominal ultrasound
Pheochromocytoma	Abdominal ultrasound, plasma/urinary catecholamine levels
Hyperaldosteronism	Serum sodium and potassium levels, aldosterone assay, abdominal ultrasound
Renal disease	CBC, chemistry, urinalysis, urine culture, urine protein-to-creatinine ratio, abdominal ultrasound, renal biopsy, creatinine clearance
Polycythemia	Primary versus secondary, CBC, erythropoietin assay, bone marrow biopsy, cardiopulmonary evaluation, abdominal radiographs and ultrasound
Hyperviscosity	Chemistry, protein electrophoresis, bone marrow biopsy
Intracranial disease	MRI
Acromegaly	Growth hormone assay, clonidine stimulation test
Hyperestrogenism	Estrogen assay, abdominal ultrasound

TABLE 8.18 Emergency treatment of systemic hypertension*

Autonomic independent vasodilators	– Nitroprusside IV CRI at 0.5–1 µg/kg/min carefully titrated to effect by increasing by 1 µg/kg/min increments every 15 minutes as long as the blood pressure decreases to desired degree (usually 2–5 µg/kg/min with upper limit of 8–10 µg/kg/min) – Hydralazine (loading dosage of 0.1 mg/kg IV over 2 minutes, followed by a CRI of 1.5-5.0 µg/kg/min) or 0.5–2 mg/kg p.o. q.12h.
Calcium channel blockers	– Amlodipine 0.2–0.4 mg/kg p.o. q.24h.
Dopamine-1 Agonist	– Fenoldopam IV CRI at 0.1 µg/kg/min with frequent (every 10 minutes) BP monitoring – Titrate dose up by 0.1 µg/kg/min increments every 15 minutes to the desired SBP – Maximum dose: 1.6 µg/kg/min

* All doses are for canines unless otherwise indicated.

Management

Underlying causes of secondary systemic hypertension should be treated if possible. Additionally, medical management with antihypertensive medications may be needed acutely and in the long term for treatment of hypertension, with the goal of avoiding target organ damage. Emergency treatment for severe hypertension is described in Table 8.18. The goal of emergency treatment is a gradual decrease in blood pressure rather than an acute fall to normal blood pressure. Emergency treatment of hypertension should take place at a facility that provides 24-hour care. Drugs commonly used for treatment of hypertension are listed in Table 8.19.

Prognosis

Prognosis for systemic hypertension is good if an underlying cause is identified and treated appropriately and if end-organ damage is minimal.

HEARTWORM DISEASE

Heartworm disease (or dirofilariasis) occurs worldwide. The dog is the typical host of the parasite, but cats can also develop infection. Heartworm disease has been diagnosed in all 50 states and around the globe. It is critical to administer year-round chemoprophylaxis, which is highly effective at protecting dogs and cats from heartworm disease.

CANINE HEARTWORM DISEASE

Etiology

Heartworm disease is caused by *Dirofilaria immitis*, a filarial nematode that resides in its adult form in the pulmonary arteries of canids and uses several species of mosquitoes as vector. Adequate temperature and humidity are necessary to support a viable mosquito population and allow maturation of the heartworm larvae to the infective stage.

Pathophysiology

Infected mosquitoes deposit 1-mm long stage 3 larvae on the dog's skin at the time of a blood meal. Larvae reach the dog's subcutaneous tissues and muscle from the puncture side and then molt to stage 4 larvae by day 3. Larvae then migrate between muscle fibers where they mature to immature adult worms that enter the circulatory system, which transports them to the pulmonary artery by day 70. Worms measure 10 cm and become sexually mature 6–7 months post infection. Mature females release microfilariae, a prelarval stage, into the bloodstream where they are picked up by mosquitoes, which completes the worm's life cycle. Microfilariae first appear in the circulation 6 months post infection. Microfilariae live up to 2.5 years. Heartworms harbor an endosymbiotic bacterium, *Wolbachia* spp. Elimination of *Wolbachia* has negative effects on *Dirofilaria immitis* fecundity and

TABLE 8.19 Treatment of systemic hypertension*

ACE inhibitors	Benazepril 0.5 mg/kg p.o. q.12–24h. Enalapril 0.5 mg/kg p.o. q.12–24h.
Angiotensin receptor blocker	Telmisartan 1 mg/kg p.o. q.24h.
Calcium channel blocker	Amlodipine 0.1–0.25 mg/kg p.o. q.24h. (Cat: 0.625–1.25 mg per cat q.24h.)
Beta-adrenergic receptor blockers	Atenolol 0.25–1.0 mg/kg p.o. q.12h. (Cat: 0.625–1.25 mg per cat q.24h.) Propranolol (beta 1 and 2) 0.25–1.0 mg/kg p.o. q.8h. (titrate to effect)
Alpha-adrenergic receptor blockers	Prazosin 0.5–2 mg/kg p.o. q.8–12h. (Cat: 0.25–0.5 mg per cat q.24h.)
Vasodilators	Hydralazine 0.5–2.0 mg/kg p.o. q.12h. (start at low range)
Diuretics	Furosemide 1.0–4.0 mg/kg p.o. q.8–24h. Spironolactone 1.0–2.0 mg/kg p.o. q.12h. Hydrochlorothiazide 2–4 mg/kg p.o. q.12–24h.

* All doses are for canines unless otherwise indicated.

development. It is also believed that *Wolbachia* trigger an immune response in the dog, which may be responsible for some of the clinical signs associated with heartworm disease.

Live worms cause vascular inflammation with thickening of the pulmonary artery wall and pneumonitis. Additional thromboembolic lesions occur when the worms die, and worm fragments obstruct branches of the pulmonary arteries. Over time, lung lesions result in the development of PH and, in severe cases, congestive right heart failure.

Clinical Presentation

Most dogs with heartworm disease do not have clinical signs. When present, typical signs include cough, tachypnea, dyspnea, and exercise intolerance. Rarely, syncope associated with exercise, hemoptysis, and CHF (ascites) are observed.

Caval syndrome occurs when adult worms move into the right ventricle and atrium where they interfere with tricuspid valve closure (Figure 8.50). Caval syndrome is most likely triggered by a profound alteration in hemodynamics, such as the one that accompanies a PTE, and usually a large worm burden. Most dogs with caval syndrome usually show signs of poor perfusion (weakness, tachycardia), dyspnea, tachypnea, ascites, and hemoglobinuria.

Differential Diagnosis

Other causes of PH, including PTE, and angiostrongylosis where it is prevalent (historically Europe and parts of Canada, though infections have been reported in the United States and South America). *Angiostrongylus vasorum*, also referred to as the French heartworm, resides in the pulmonary arteries of dogs. Infected dogs may show respiratory signs, including chronic cough, dyspnea, and exercise intolerance. Others develop PH. Diagnosis is by detection of larvae in feces. Cross-reactions with the *Dirofilaria* antigen tests have been reported.

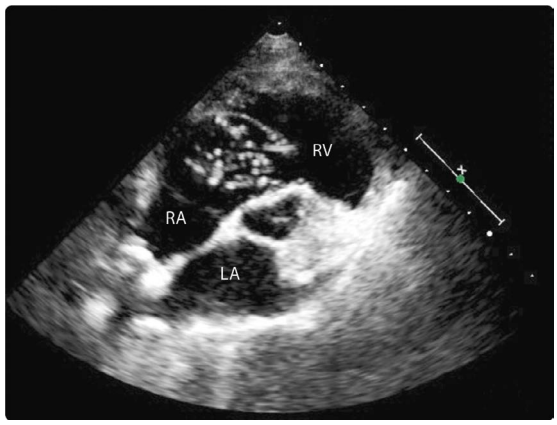

FIGURE 8.50 Echocardiographic view from a dog with caval syndrome. Worms are visible within the right cardiac chambers. The reflection of the ultrasound on the surface of segments of the worms give this typical image of an "= sign." LA, left atrium; RA, right atrium; RV, right ventricle.

Diagnosis

Heartworm disease is usually detected during routine yearly screening. The heartworm antigen test, which detects circulating adult female antigens, is a very sensitive and specific test as long as it is performed at least 6 months after infection. A test in an infected dog may be falsely negative if it is performed too early, if only male worms and/or nonreproductive females are present, or if there is a small worm burden.

Microfilariae can be detected in some dogs in the peripheral circulation on a direct blood smear or using a Knott's test. However, many dogs experience occult heartworm infections (i.e., microfilariae are not present in the circulation). It is currently recommended to test for both heartworm antigen and microfilaria annually.

Thoracic radiographs, blood work, and urinalysis are usually performed in heartworm-positive dogs to determine the severity of the disease. Radiographs may reveal large and tortuous pulmonary arteries, interstitial to alveolar lung patterns, and, on occasion, right-side cardiomegaly. Eosinophilia and basophilia can be identified on CBC, and proteinuria secondary to heartworm-induced glomerulonephritis may be detected on urinalysis. Echocardiography is indicated in dogs presenting with severe signs of heartworm disease. Adult worms are sometimes visible in the right and main pulmonary arteries. The presence of worms in the right cardiac chambers is diagnostic for caval syndrome. In these dogs, a loud intensity right-sided apical systolic murmur, caused by tricuspid valve regurgitation, is usually present.

Management

In infected dogs, the goal of therapy is to kill the adult worms in order to prevent additional damage to the lung vasculature. All dogs with heartworm disease should be treated, and the treatment should include adulticide therapy. The only adulticide currently available is melarsomine dihydrochloride (Immiticide). Before treatment with melarsomine, preventive medications should be administered for 2–3 months to prevent reinfection and allow heartworm larvae to mature to a young adult stage, which is more sensitive to the effects of melarsomine. A tapering dose of prednisone (0.5 mg/kg b.i.d. first week, 0.5 mg/kg once daily for the second week, 0.5 mg/kg every other day for the 3rd and 4th weeks) as well asdoxycycline (10 mg/kg p.o. q.12h.) should be given for 1 month to eliminate *Wolbachia* spp. Melarsomine is administered following a three-dose protocol (one injection followed by two injections 24 hours apart 1 month later) and 2 months of strict exercise restriction starting the day of the first injection in order to limit the risk of thromboembolism. Animals should be monitored for side effects for a few hours following injection of melarsomine. Dogs should be retested with a heartworm antigen test and microfilaria test 6–9 months later to confirm successful treatment.

Caval syndrome is managed by surgical extraction of the heartworms. Access to the right heart chambers

is obtained from a jugular vein. Wire baskets designed for endoscopy inserted in the right atrium and right ventricle under fluoroscopy guidance can be used to fish the worms out. Despite surgical extraction, the mortality of dogs with caval syndrome approaches 40%–50%. It is usually not necessary to extract worms that are visible in the pulmonary arteries on echocardiography. Adulticide therapy must be initiated as soon as the animal has recovered from the surgical extraction in order to eliminate the worms still present in the distal pulmonary vessels.

In all dogs that test negative for heartworm disease, macrocyclic lactones (ivermectin, selamectin, moxidectin, milbemycin) are used to prevent the development of stage 3 and stage 4 larvae after mosquito bites. Macrocyclic lactones also have adulticide properties. For example, ivermectin has been shown to kill adults in 31 months. Macrocyclic lactones may not eliminate microfilariae at preventive doses. Year-round prophylaxis is recommended, and most drugs are approved for monthly administration. We recommend reviewing updated guidelines for the treatment and prevention of heartworm diseased regularly published by the American Heartworm Society.

Heartworm Resistance

Most cases of drug failure to prevent heartworm infection can be traced back to poor owner compliance. However, there has been documented resistance to macrocyclic lactones in some regions. One cause for resistance might be the chronic use of macrocyclic lactones in heartworm-positive dogs, which selects a resistant population of microfilariae. Results from experimental studies suggest that the resistance is heritable. It is, therefore, important to not only eliminate adult worms but also eliminate microfilariae with microfilaricidal doses of macrocyclic lactones.

Prognosis

Dogs with low-burden infection and limited lung lesions may fully recover after adulticide therapy. However, dogs with severe lesions and PH may develop right-heart failure over time. Once ascites is present, survival is usually less than 1 year.

FELINE HEARTWORM DISEASE

Introduction/Overview

Heartworms rarely develop to the adult stage in cats. Most commonly, the manifestations of feline heartworm disease are described as heartworm-associated respiratory disease (HARD), which occurs in response to an inflammatory response to larvae and mimics the signs of feline asthma.

Pathophysiology

In regions where canine heartworm disease is present, prevalence in unprotected cats is between 5% and 15% of their canine counterparts. In cats, development of the worms usually stops at larval stage 5 (immature worms), and the presence of adult worms is uncommon. Despite incomplete worm development and the absence of long-lasting infection, pulmonary vascular and parenchymal inflammatory lesions are responsible for clinical signs. In cats with mature infection, thromboembolism from dead worms, fatal acute lung injury, and PH causing right-sided heart failure are major complications of the disease. Finally, aberrant larval migration is more common in cats than dogs, resulting in neurologic signs if larvae reach the central nervous system.

Clinical Presentation

It is important to distinguish cats with mature heartworm infection and cats exposed to larvae that failed to develop into adult worms. HARD occurs in response to the short-lived presence of larvae in the pulmonary vasculature. Its clinical manifestations are similar to feline bronchial disease, including dyspnea and wheezes. Cough is frequent. When a small number of adult worms survive in the pulmonary circulation, cats usually develop severe respiratory signs, PH, right heart failure, syncope, and sudden death.

Differential Diagnosis

It is challenging to differentiate HARD from feline bronchitis and asthma.

Diagnosis

It is difficult to establish a definitive diagnosis of heartworm disease in cats because most of the available tests lack sensitivity or specificity. Antigen tests, which only detect mature female heartworms, are rarely positive in cats because they typically only harbor fewer than six worms and sometimes all males. Antibody tests, when positive, indicate that the cat has been exposed to heartworm disease, and larvae have developed at least to stage 5 (immature worms). However, they do not indicate the presence of adult worms nor that the infection is ongoing. A negative antibody test usually rules out the presence of adult worms. It is usually recommended to start with an antibody test and perform an antigen test when the antibody test is positive. The presence of circulating microfilariae in the peripheral circulation of cats is unusual. Indirect signs of heartworm disease, such as eosinophilia and basophilia, enlarged pulmonary arteries and bronchointerstitial lung pattern on chest radiographs, and echocardiographic evidence of adult worms in the branches of the pulmonary artery, are inconsistent. Therefore, when HARD or adult worm infection is suspected, diagnosis of heartworm disease relies on suggestive clinical signs, in particular cough, and the results of laboratory tests and imaging.

Management

HARD usually responds to medications used for the treatment of feline asthma, including steroids and

bronchodilators. If adult worms are present, the high incidence of life-threatening complications associated with use of melarsomine limits the use of this drug in cats. Alternatively, cats can be administered monthly preventive therapy, and steroids should be used to control inflammation. The authors use doxycycline for 1 month. Sildenafil can be used if severe PH is present. Surgical removal can be considered, but fatal complications are common if worms are not removed intact.

Prognosis

Mortality is high in cats that harbor adult worms.

BRADYARRHYTHMIAS

Bradycardia corresponds to a heart rate less than 60 bpm in dogs and approximately 100 bpm in cats. Bradyarrhythmias can result from an increase in vagal tone, drugs, electrolyte abnormalities, inflammation or infiltration of the myocardium, and degenerative disease of the conduction system. Although the etiology frequently remains unclear, the clinician needs to determine from the ECG and the clinical signs whether extracardiac factors are the cause for the arrhythmia, if treatment is needed, and how to choose between medical and pacemaker therapy.

SICK SINUS SYNDROME (SINUS NODE DYSFUNCTION)

Definition/Overview

Sick sinus syndrome is a disease of the conduction system in dogs characterized by periods of normal sinus rhythm or sinus bradycardia interspersed with long periods of sinus arrest or block that can last up to 10–12 seconds. The pauses result from a failure of the junctional and ventricular pacemakers to initiate escape beats, indicating that this disease involves the conduction system beyond the sinus node (Figure 8.51). A variant of the disease, sometimes called tachy–brady syndrome, is characterized by periods of paroxysmal supraventricular tachycardia followed by a temporary failure of the sinus rhythm to resume when the tachycardia abruptly terminates.

Etiology

The cause for sick sinus syndrome is unknown. However, there is a breed predisposition, with Miniature Schnauzers and West Highland White Terriers being overrepresented, and the condition typically occurs in older dogs.

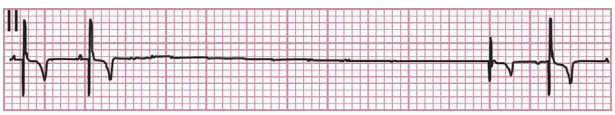

FIGURE 8.51 ECG (lead II) from a dog with sick sinus syndrome. The initial sinus rhythm is followed by a long period of sinus arrest that is interrupted by a junctional escape beat.

Clinical Presentation

Exercise intolerance, lethargy, and weakness are some of the clinical signs reported with sick sinus syndrome. Syncope occurs when periods of sinus arrest last more than 6–8 seconds. The use of opioids as sedatives frequently results in a prolongation of the periods of asystole, and dogs that were asymptomatic while awake may commonly become hemodynamically unstable after sedation or general anesthesia.

Differential Diagnosis

Other bradyarrhythmias that may cause clinical signs, in particular those resulting from high vagal tone in the presence of GI, respiratory, neurologic, and ocular diseases. Marked vagotonia may cause sinus bradycardia, pronounced respiratory sinus arrhythmia, and occasionally second-degree AV block, which may mimic a mild form of sick sinus syndrome.

Diagnosis

In older small breed dogs, the suspicion of sick sinus syndrome is usually confirmed on an ECG recording. To differentiate sick sinus syndrome from vagally induced bradycardias, response to the administration of parasympatholytic medications can be evaluated. A rapid increase in heart rate following IV administration of atropine (0.04 mg/kg) or glycopyrrolate (0.01 mg/kg) strongly suggests the contribution of vagal tone to the bradyarrhythmia. However, an increase in heart rate may also be observed in dogs with sick sinus syndrome. It is, therefore, recommended to evaluate the ECG over a longer period of time using a 24-hour Holter recording.

Management

Temporary response to terbutaline (0.2 mg/kg p.o. q.8–12h. or 0.01 mg/kg IV), a selective beta-2 agonist commonly used as bronchodilator, or theophylline (5–10 mg/kg p.o. q.12h.), a phosphodiesterase inhibitor and bronchodilator with mild chronotropic effect, is observed in some dogs with sick sinus syndrome. However, dogs frequently develop side effects with chronic use of these drugs, and the clinical signs frequently recur as the disease progresses (Table 8.20).

Permanent pacemaker implantation is indicated in dogs that display clinical signs. The simplest and most commonly used type of pacing in veterinary patients involves a single lead placed in the right ventricle via the jugular vein and a generator placed subcutaneously in the cervical region. Pacemakers are able to detect spontaneous activity and stimulate cardiac contraction if the heart rate drops below a preprogramed number. In dogs with sick sinus syndrome, the pacemaker maintains a regular rhythm and adequate cardiac output during periods of sinus arrest. Because the rhythm abnormalities associated with sick sinus syndrome are intermittent, the pacemaker is usually activated less than 50% of the time in these dogs. It, therefore, mimics a ventricular escape rhythm with an adjustable rate.

TABLE 8.20 Drugs for the treatment of bradycardia

Drug	Dosage	Indications
Atropine	0.02–0.04 mg/kg SC, IM, IV (D,C)	Sinus bradycardia Sick sinus syndrome first- and second-degree AV block
Glycopyrrolate	0.005–0.01 mg/kg SC, IM, IV (D,C)	Sinus bradycardia Sick sinus syndrome first- and second-degree AV block
Terbutaline	0.2 mg/kg p.o. q.8–12h. (D) 0.625 mg p.o. q.8–12h. (C) 0.01 mg/kg IV (D,C)	Sinus bradycardia Sick sinus syndrome
Isoproterenol	0.04–0.09 µg/kg/min, to effect (D,C)	Second- and third-degree AV block
Aminophylline Theophylline	10 mg/kg p.o. q.12h. (extended release) (D,C) 5–10 mg/kg IV (D)	Sick sinus syndrome

AV, atrioventricular; C, cat; D, dog.

Prognosis

Clinical signs worsen as the disease progresses, and without treatment, some dogs experience several syncopal episodes daily. Sudden death can occur, but it is common for dogs with sick sinus syndrome to experience signs for months and even years before they die. Long-term prognosis is good after pacemaker implantation if complications associated with the procedure do not occur within 1 month and in the absence of underlying structural heart disease, such as degenerative mitral valve disease. Major but rare pacemaker complications include lead dislodgement during the first 4 weeks following implantation, device infection that is more likely to occur during the first year, and hemodynamically significant tricuspid valve regurgitation.

ATRIOVENTRICULAR BLOCK

Definition/Overview

AV block corresponds to a delay of conduction or the inability for an impulse originating from the atrium to cross the AV node. The AV node is the only pathway for electrical impulses to travel from atrium to ventricle.

Etiology

Fibrosis of the AV node is the most common cause for AV block in older dogs and cats. Inflammation and infiltration of the AV node by neoplastic cells (e.g., lymphoma) may also be seen. Elevated vagal tone can delay AV node conduction. Drugs such as beta-blockers and calcium-channel blockers can also cause AV block.

Pathophysiology

Three forms of AV block corresponding to different degrees of disease severity are recognized. In the mild form of the disease, all impulses originating at the supraventricular level (usually the sinus node) cross the AV node but with some delay (first-degree AV block). As the disease progresses, some impulses are unable to reach the ventricles (second-degree AV block). In the most severe form of the disease, there is complete dissociation between impulses in the atrium and an escape rhythm originating in the ventricles that maintains a low heart rate and a decreased cardiac output (third-degree AV block). Clinical signs occur when too many supraventricular impulses are blocked at the AV node, which results in the absence of ventricular contraction for 4–8 seconds, or when the slow ventricular escape rhythm does not maintain adequate cardiac output

Clinical Presentation

Animals with first-degree AV block do not display clinical signs, as all the impulses from the atrium are transmitted to the ventricles with a short delay. Clinical signs of lethargy, weakness, or syncope only occur in the severe forms of second-degree AV block and third-degree AV block. Surprisingly, some dogs with third-degree AV block and an average heart rate between 20 and 60 bpm do not show overt clinical signs. Cats commonly lack clinical signs because the ventricular escape rhythm is usually around 100 bpm in this species. However, if a slow heart rate persists for several months, it will lead to progressive cardiac enlargement and possibly CHF (usually right-sided).

Differential Diagnosis

Other cardiac causes of syncope and lethargy.

Diagnosis

Diagnosis is usually easily reached with an ECG. With first-degree AV block all the atrial impulses are conducted to the ventricles, but the PR interval is prolonged (PR > 130 ms in dogs, PR > 90 ms in cats). Second-degree AV block is diagnosed when some P waves are not followed by a QRS complex on the surface ECG (Figure 8.52).

Two types of second-degree AV blocks are recognized. Mobitz type I second-degree AV block is characterized by a progressive increase or variable PR interval duration ending with a blocked P wave, known as Wenckebach phenomenon. It usually results from a combination of AV node fibrosis and a progressive increase in vagal tone. This

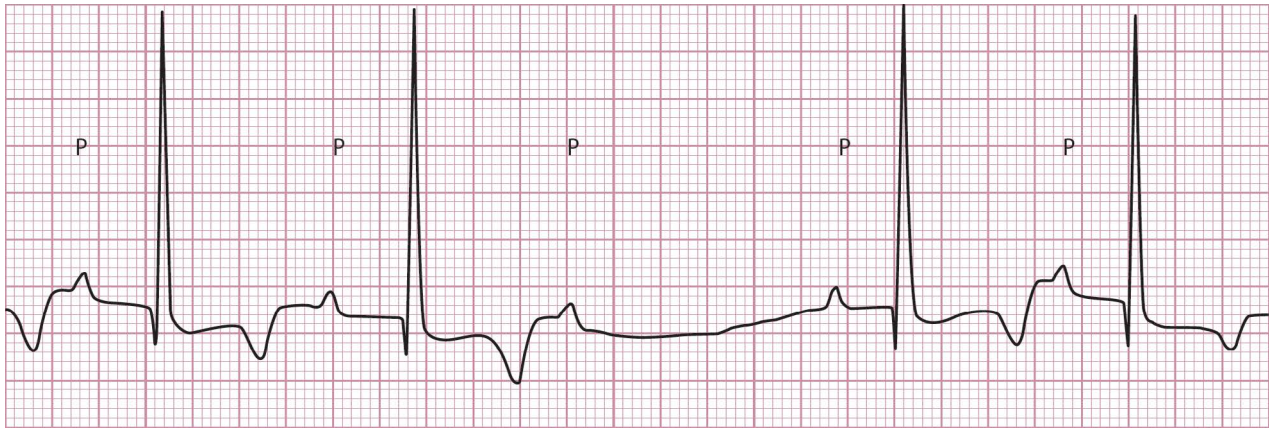

FIGURE 8.52 ECG (lead II) from a dog with first-degree and Mobitz type I second-degree atrioventricular block. The baseline PR interval is prolonged. There is one nonconducted P wave consistent with second-degree atrioventricular block. Note the variable PR interval indicating the effects of vagal tone on atrioventricular conduction.

form of AV block is usually benign and does not require specific treatment. Mobitz type II second-degree AV block is characterized by the unexpected occurrence of blocked P waves. PR intervals before and after the blocked P waves are identical. The QRS complexes of conducted beats can be wide when the area of block is below the His bundle, causing bundle branch blocks and intraventricular conduction delays. This form of block is more likely to worsen and result in clinical signs. Administration of atropine (0.04 mg/kg IV) can help the clinician differentiate between the two forms of block. Type I usually improves after atropine and type II worsens.

Third-degree or complete AV block is characterized by an absence of conducted P waves to the ventricles (Figure 8.53). The ECG displays independent atrial and ventricular activities. Cardiac output is dramatically reduced. In response, the atrial rate, which is under control of the adrenergic tone, is elevated. Electrical activation of the ventricles is dependent on an escape rhythm beyond the site of the block. The QRS complexes are generally wide and bizarre at rates of around 20–60 bpm in dogs and 60–120 bpm in cats. In addition, the ventricular rate is regular unless ventricular premature beats originating from an ischemic myocardium are present.

A 24-hour Holter recording is sometimes necessary to identify occasional second-degree AV block as the cause for syncope. An echocardiogram is always indicated to identify a tumor as the cause for AV block and identify concomitant structural cardiac disease. AV block is often associated with structural cardiac disease in cats. Although a mild elevation of serum cTnI concentration is common in dogs with third-degree (complete) AV block, a marked increase in concentration suggests myocarditis as the cause for the arrhythmia.

Management

Pacemaker implantation is usually the best treatment option when clinical signs are present. AV node conduction may improve in some dogs with second-degree AV block after administration of theophylline or terbutaline.

Prognosis

Good after pacemaker implantation in dogs with clinical signs. Some dogs with myocarditis spontaneously return to sinus rhythm.

ATRIAL STANDSTILL

Definition/Overview

Atrial standstill corresponds to the absence of visible atrial electrical activity (and therefore contraction) on the ECG. It can be permanent or temporary. Permanent atrial standstill is rare.

Etiology

Permanent atrial standstill affects young dogs, and a genetic etiology is likely. It may be more prevalent in English Springer Spaniels. Hyperkalemia is the cause for temporary atrial standstill.

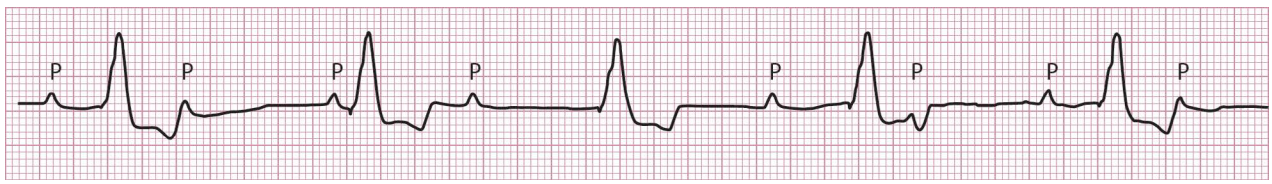

FIGURE 8.53 ECG (lead II) from a dog with third-degree atrioventricular block. There is complete dissociation between the P waves and QRS complexes. Some P waves overlap T waves.

FIGURE 8.54 ECG (lead II) from a dog with atrial standstill. There are no visible P waves, and the ventricular rhythm is regular.

Clinical Presentation

Dogs with permanent atrial standstill usually present with signs associated with severe bradycardia. Animals with hyperkalemia have signs caused by the underlying disease, including hypoadrenocorticism, urinary tract obstruction or rupture, severe arterial thromboembolism in cats, and tumor lysis syndrome.

Diagnosis

Permanent atrial standstill is recognized on the ECG as a lack of P waves with a regular ventricular or AV nodal escape rhythm at rates of 20–60 bpm in dogs (Figure 8.54). The ECG changes of hyperkalemia include a narrowing and increased amplitude of the T wave as plasma concentration of potassium increases above 5.5 mmol/L. As potassium continues to rise, it leads to a decrease in heart rate associated with reduced P-wave amplitude and a widening of the QRS complexes. P waves then become invisible, consistent with a sinoventricular rhythm that cannot be distinguished from atrial standstill.

Management

Permanent atrial standstill requires permanent pacemaker implantation. Successful management of hyperkalemia results in return of normal cardiac rhythm and ECG trace.

Prognosis

Permanent atrial standstill carries a poor prognosis, as the disease affecting the atrium and causing a progressive replacement of the myocytes by fibrous tissue seems to progress to the rest of the myocardium.

TACHYARRHYTHMIAS

Tachycardia is defined by a heart rate typically greater than 180–200 bpm in dogs and greater than 220–240 bpm in cats. Tachyarrhythmias are divided into supraventricular tachycardia, which originates from structures above the ventricles (sinus node, atrial myocardium, AV node), and ventricular tachycardia. AF, a form of supraventricular tachycardia, and ventricular tachycardia are the most common types of tachyarrhythmias. Other types of supraventricular tachycardias are rare and can usually be managed in the same way as AF (Table 8.21).

ATRIAL FIBRILLATION

Definition/Overview

Atrial fibrillation (AF) is characterized by uncoordinated atrial activation from multiple simultaneous electrical wavelets resulting in inadequate mechanical contraction of the atrium and an irregular ventricular response rate.

Etiology

Atrial dilation is a risk factor for developing AF. Therefore, AF commonly occurs in large breed dogs with only mild-to-moderate atrial dilation but is rarely present in small breed dogs with degenerative mitral valve disease despite extreme atrial dilation. It is rarely diagnosed in cats. Fibrosis, inflammation, and autonomic imbalances are other important contributors to the initiation of AF.

Pathophysiology

Most dogs with AF have underlying primary cardiac disease in the form of dilated cardiomyopathy (DCM) or degenerative mitral valve disease. The atrial enlargement provides the substrate for maintenance of the arrhythmia. During AF, the AV node is bombarded

TABLE 8.21 Drugs for the treatment of supraventricular tachycardia

Drug	Dosage	Comment
Digoxin	0.005 mg/kg p.o. q.12h. (D)	AF (rate control)
Diltiazem	0.1–0.4 mg/kg IV over 5 min (D,C) 0.05–0.15 mg/kg/h CRI (D,C) 1–2 mg/kg p.o. q.8h. (D,C) 3 mg/kg p.o. q.12h. (extended release) (D) 15–30 mg p.o. q.12–24h. (extended release) (C)	SVT (rate control or conversion) AF (rate control)
Atenolol	0.2–1 mg/kg p.o. q.12–24h. (D) 6.25–12.5 mg p.o. q.12–24h. (C)	SVT (rate control or conversion) AF (rate control)
Esmolol	0.2–0.5 mg/kg IV over 1 minute, repeat q.5 min (D,C)	SVT conversion
Procainamide	5–15 mg/kg IV over 1 minute (D) 1–2 mg/kg IV (C) 20–50 µg/kg/min CRI (D)	SVT conversion
Lidocaine	2 mg/kg IV over 30 sec Maximum 3 boluses (D) 0.25–0.5 mg/kg IV (C)	SVT conversion Vagally mediated AF conversion
Sotalol	1–3 mg/kg p.o. q.12h. (D,C)	SVT conversion SR maintenance

AF, atrial fibrillation; C, cat; D, dog; SR, sinus rhythm; SVT, supraventricular tachycardia.

by hundreds of impulses originating from the atria. Because the AV node has the role of a filter, only some of the impulses are able to reach the ventricles, with an irregular response to the supraventricular impulses. In the presence of heart failure, elevated adrenergic tone decreases the filtering property of the AV node, resulting in tachycardia. Less commonly, "lone" AF occurs in giant breed dogs with structurally normal hearts. In this instance, vagal tone, which is typically high in dogs in the absence of heart failure, increases the filtering effect of the AV node, resulting in a heart rate within the normal range for dogs. AF is rarely identified in cats. However, most cats with AF have underlying structural cardiac disease with atrial enlargement. Many of these cats also show signs of CHF. Once initiated, AF does not spontaneously resolve.

Clinical Presentation

The vast majority of dogs with AF are giant and large breed dogs. In the giant breed group, Irish Wolfhounds, Mastiffs, Newfoundlands, Rottweilers, and Great Danes are overrepresented, with a male predisposition. Cats with AF are usually older males. Most dogs with lone AF are asymptomatic. Conversely, some dogs with compensated cardiac disease and AF show signs of lethargy, exercise intolerance, and, rarely, anorexia, cough, or syncope. When AF occurs in the presence of CHF, generalized weakness, dyspnea, cough, and abdominal distension from ascites are usually present. Cats frequently show signs of an underlying cardiac disease, including dyspnea and arterial thromboembolism. However, AF can also be an incidental finding on auscultation in this species.

Differential Diagnosis

Other permanent tachyarrhythmias. The distinctive feature of AF is that it is irregular, whereas most sustained tachyarrhythmias are regular.

Diagnosis

On physical examination, AF is identified as a sustained and "irregularly irregular" rhythm accompanied by pulse deficits. A murmur may be auscultated, as underlying cardiac disease is common in dogs with AF.

On the surface ECG, AF is an irregular tachyarrhythmia, with usually narrow QRS complexes and no P waves, which can be replaced by an undulation of the baseline, or F waves (Figure 8.55). It is also permanent, indicating that sinus rhythm never spontaneously resumes following initiation of AF, and the average heart rate is typically > 180–200 bpm. The rate is much lower with lone AF, usually approaching 100–120 bpm at rest. Although AF is a supraventricular tachycardia, lesions of the ventricular conduction system (bundle branch block) may result in a widening of the QRS complexes, which may resemble those of ventricular tachycardia.

Determination of the average ventricular rate during AF provides critical information in deciding on a treatment strategy. Unfortunately, brief ECG recordings obtained in an unfamiliar environment do not adequately reflect the daily variations of heart rate. Heart rate is, therefore, better assessed from a 24-hour Holter recording. For reference, the average heart rate of healthy dogs varies between 85 and 100 bpm. Conversely, it is approximately 120 bpm in dogs with lone AF, 155 bpm in dogs with underlying cardiac disease, and 200 bpm in dogs with CHF.

Management

A rate-control strategy is usually applied to the treatment of AF. The rate-control approach aims at slowing ventricular rate in response to the rapid supraventricular impulses. However, this does not terminate the arrhythmia. Rate control is based on using drugs to decrease the ability of the AV node to conduct impulses. Ideally, the need for pharmacologic control of the heart rate is determined from the heart rate distribution obtained from a baseline 24-hour Holter recording. The effect of rate-control drugs is then assessed on a follow-up Holter 2 weeks after treatment initiation. As for defining adequate control, an average heart rate of no more than 120–140 bpm is considered adequate to observe clinical improvement. If the average heart rate is considered too high, drug dosages are increased by small increments, with close monitoring of the animal's clinical status, as the response to antiarrhythmics varies between patients. In contrast, medical therapy is usually not needed in dogs with lone AF; in these dogs, AF can be reverted to normal rhythm using direct-current (DC) electrical cardioversion.

Diltiazem is widely used for the management of AF. A graded dose of diltiazem results in a decrease in ventricular response rate because of slower action potential propagation in the AV node. Oral formulations include an extended-release form. A dose of 3–4 mg/kg p.o. q.12h. of the extended-release formulation usually achieves satisfactory rate control. Better rate control, especially during periods associated with high adrenergic tone, can be obtained by adding digoxin to the

FIGURE 8.55 ECG (lead II) from a dog with atrial fibrillation. Noted here is an irregular tachycardia. The QRS complexes are narrow, indicating that it is supraventricular in origin. In addition, there are no visible P waves.

treatment regimen. Calcium channel blockers decrease ventricular contractility and may cause hypotension when used in animals with severely depressed cardiac function.

The range of indications and side effects for beta-blockers are very similar to those of calcium channel blockers. Beta-1 selective agents, such as atenolol, are preferred to nonselective agents that can cause bronchospasm (Table 8.21).

Prognosis

Long-term prognosis is good for dogs with lone AF; however, in some breeds, in particular Irish Wolfhounds, it may be an early sign of DCM. In dogs with AF with underlying structural heart failure, median survival has been reported to be 32 months; however, it was only 5 months when CHF was present. In cats, treatment targeted at AF is rarely required as their ventricular response rate usually approaches the heart rate recorded in cats with sinus rhythm and heart failure.

VENTRICULAR TACHYCARDIA

Definition/Overview

Ventricular tachycardia is a rapid rhythm originating from the ventricles. A ventricular rhythm with a rate above the typical ventricular escape rhythm seen with AV block, but slower than ventricular tachycardia, is called accelerated idioventricular rhythm.

Etiology

Ventricular tachycardia is usually diagnosed in Boxers and English Bulldogs with ARVC and in Dobermanns with DCM. It can also occur in the presence of myocarditis, infiltrative cardiac disease, electrolyte imbalances, pheochromocytoma, or hypoxemia/ischemia. Cats are rarely diagnosed with ventricular tachycardia that requires treatment. In this species, it is associated with HCM and hyperthyroidism. Accelerated idioventricular rhythm is triggered by episodes of ischemia/reperfusion involving extracardiac tissues (e.g., gastric dilatation volvulus, trauma, arterial thromboembolism, or pancreatitis).

Pathophysiology

The two factors that determine the clinical consequences of ventricular tachycardia are rate and duration. Ventricular tachycardia must be sustained (more than 30 seconds) and rapid (usually more than 220–240 bpm) to cause clinical signs. Some forms of ventricular tachycardia can degenerate into ventricular fibrillation, resulting in sudden death.

Clinical Presentation

Dogs with intermittent ventricular premature contractions do not show clinical signs. It is only when the rate of the ventricular tachycardia is rapid (> 250–300 bpm) that signs of poor cardiac output may be present, and syncope may occur. Clinical signs will also be influenced by the degree of underlying heart disease. Thus, a patient with systolic dysfunction and ventricular arrhythmia may exhibit clinical signs at a slower rate of ventricular firing than a patient without underlying myocardial disease and ventricular tachycardia.

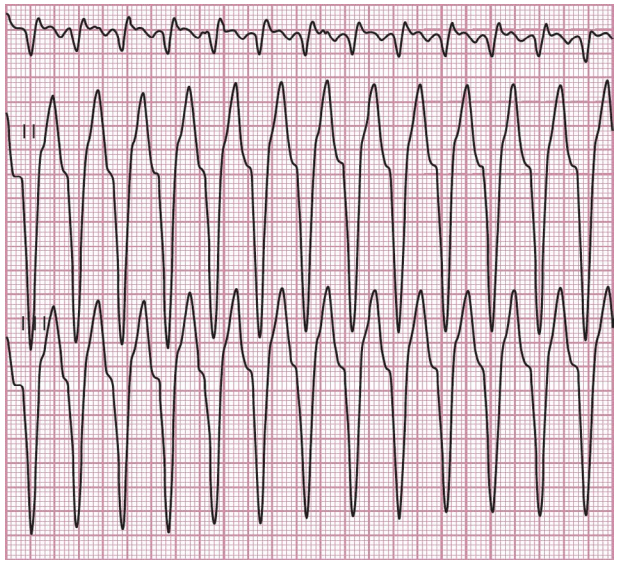

FIGURE 8.56 ECG from a dog with ventricular tachycardia. The QRS complexes are "wide and bizarre," and the rhythm is regular.

Diagnosis

Ventricular arrhythmias are diagnosed on ECG by the presence of wide and bizarre complexes (Figure 8.56). Beats originating in the ventricles are wide because the electrical impulse depolarizing the ventricles does not use the specialized cells of the conduction system. The QRS complex of ventricular beats is followed by a large T wave opposite to the direction of the QRS complex. Ventricular tachycardia is usually regular. It can last for a few seconds or be sustained for hours. A 24-hour Holter recording is indicated to evaluate the frequency of the arrhythmia and determine if its severity explains the clinical signs present. An echocardiogram is recommended to identify underlying structural heart disease and measure the left ventricular function. Thoracic radiographs and blood work are indicated to rule out any extracardiac cause for the arrhythmia, especially in the presence of an idioventricular accelerated rhythm.

Management

Treatment of ventricular tachycardia is justified when it causes hemodynamic compromise and clinical signs (Table 8.22). Hemodynamic compromise is typically related to the rate of the tachycardia and its duration. Sometimes treatment is initiated in apparently nonclinical animals based on the arrhythmia burden in on a

TABLE 8.22 Drugs for the treatment of ventricular tachycardia

Drug	Dosage
Amiodarone	10–20 mg/kg p.o. q.24h. for 7–10 days then reduce to 3–15 mg/kg p.o. q.24–48h. thereafter (D)
Atenolol	0.2–1 mg/kg p.o. q.12–24h. (D) 6.25–12.5 mg p.o. q.12–24h. (C)
Esmolol	0.2–0.5 mg/kg IV over 1 min, repeat q.5 min (D,C)
Lidocaine	2 mg/kg IV over 30 seconds Maximum 3 boluses (D) 0.25–0.5 mg/kg IV (C) 25–80 µg/kg per min CRI (D)
Mexiletine	4–8 mg/kg p.o. q.8h. (D)
Procainamide	5–15 mg/kg IV over 1 minute (D) 1–2 mg/kg IV (C) 20–50 µg/kg per minute CRI (D)
Sotalol	1–3 mg/kg p.o. q.12h. (D,C)

C, cat; D, dog.

Holter recording and the concern that the arrhythmia could worsen or result in sudden death. The risk of sudden death is likely higher in the presence of structural cardiac disease.

For a dog presented in an emergency with rapid sustained ventricular tachycardia, initial treatment with lidocaine boluses is recommended. It is important to measure serum potassium concentration, as lidocaine works better with normal potassium levels. Procainamide is an alternative to lidocaine when it fails to terminate the arrhythmia. Lidocaine should be used carefully in cats because they are more likely to develop neurologic side effects.

Long-term management of ventricular tachycardia is based on oral drugs and frequent monitoring with 24-hour Holter recordings to evaluate response to treatment. Sotalol, which shares antiarrhythmic and beta-blocking properties, is usually very effective at controlling ventricular arrhythmias in dogs. Mexiletine is another good antiarrhythmic agent but has become increasingly difficult to obtain for veterinary patients and has several times come off the market. It can cause significant gastrointestinal upset and has historically been difficult to obtain. It is often used in combination with atenolol or sotalol for resistant arrhythmias or as an initial antiarrhythmic agent for dogs with systolic dysfunction. Amiodarone appears to be effective for arrhythmias refractory to other drugs; however, it has been reported to have significant and severe side effects in dogs. The low end of the dosage range should be used first and titrated upwards only if necessary. Amiodarone very commonly causes adverse clinical signs with chronic use. It may cause anorexia due to elevated liver enzymes. Liver enzymes should be evaluated prior to initiating therapy, periodically while receiving amiodarone, and any time anorexia develops. It may also cause neutropenia of unknown clinical significance and neurologic signs and/or ataxia, especially at higher doses and with prolonged use. IV antiarrhythmic agents are rarely needed in the cat. Oral products, in particular atenolol and sotalol, are usually sufficient for clinical needs (Table 8.22).

Prognosis

Prognosis depends more on the underlying etiology than the tachycardia itself.

PART 1: DISEASES OF THE PHARYNX, MASTICATORY MUSCLES, AND SALIVARY GLANDS

DYSPHAGIA

Definition/Overview

The word "dysphagia" is derived from Greek and means difficulty in eating and swallowing. A closely related term is odynophagia, which describes pain while eating/swallowing. The three phases of the normal swallowing reflex are described in Table 9.1.

Etiology and Pathophysiology

Three types of dysphagia are recognized.

Oral Dysphagia

Oral dysphagia relates to a difficulty prehending food and forming a bolus of food. It can occur with most oral and dental diseases. Additionally, cleft palate, tongue atrophy or paralysis, and diseases of the masticatory muscles, retrobulbar space, and temporomandibular joint can also lead to oral dysphagia.

Pharyngeal Dysphagia

Pharyngeal dysphagia is characterized by abnormal passage of food through the oropharynx. It may occur with pharyngeal diseases such as pharyngeal edema, trauma and foreign bodies, intraluminal masses, and extraluminal masses (e.g., grossly enlarged lymph nodes, retropharyngeal abscess, salivary gland enlargement), or result from abnormalities in the tightly regulated swallowing reflex. Affected animals may show numerous unsuccessful attempts to swallow, regurgitate immediately, gag, cough, and experience nasal reflux. Aspiration pneumonia is a common complication. Diagnosis is confirmed by a video fluoroscopic swallow study (VFSS) that shows failure of the pharynx to constrict and the upper esophageal sphincter (UES) to relax. In the absence of an obvious cause for dysphagia, rabies should be considered in unvaccinated dogs. Dogs

DOI: 10.1201/9781003254591-28

TABLE 9.1 Physiology of swallowing

Oropharyngeal phase	– Voluntary oral stage – Formation of food bolus in the oropharynx, passage to the base of tongue, pharyngeal peristaltic contractions, bolus propelled to the laryngopharynx
	– Pharyngeal phase – Contraction of oral and tongue muscles with closure of pathway between oral cavity and pharynx, elevation of the soft palate, glottis closure, and tipping of the epiglottis after rostral displacement of the larynx
	– Cricopharyngeal phase – Relaxation of the UES (cricopharyngeal and thyropharyngeal muscles) to allow food bolus to be propelled into the upper esophagus
Esophageal phase	– A primary peristaltic wave is generated in the pharynx and propagated through the esophagus to propel the bolus to the LES – If the primary wave is not successful, a secondary wave is quickly generated by esophageal distension
Gastroesophageal phase	– Relaxation of the LES and passage of the bolus into the stomach

LES, lower esophageal sphincter; UES, upper esophageal sphincter.

with laryngeal paralysis, hypothyroidism, or myasthenia gravis may show concurrent pharyngeal dysphagia. If no cause can be identified, the prognosis of pharyngeal dysphagia is generally poor.

Cricopharyngeal Dysphagia

Cricopharyngeal dysphagia (CD) is characterized by a failure of the UES to relax (achalasia) or a lack of coordination between pharyngeal contraction and UES relaxation (dyssynchrony). Clinically, it may be difficult to differentiate CD from pharyngeal dysphagia. CD is rare and usually observed in puppies at the time of weaning or before the 1 year of age. Affected dogs may show nasopharyngeal reflux and nasal discharge. Detailed oropharyngeal inspection yields no abnormal findings. Diagnosis is confirmed with VFSS showing that the food bolus is unable to move past the UES despite normal pharyngeal motility. A congenital neurologic disorder is suspected. In the absence of complicating factors, the prognosis for dogs with confirmed cricopharyngeal achalasia is good after myotomy or myectomy of the cricopharyngeal muscle. Injection of botulinum toxin A into the muscle through an oral approach with endoscopic guidance has been anecdotally successful. However, this method is only performed at few referral centers worldwide and its effect is limited to 2–4 months.

Breed Predispositions

A congenital pharyngeal myopathy has been described in Bouvier des Flandres dogs. Cricopharyngeal achalasia is most observed in Dachshunds, Cocker Spaniels, Maltese Terriers, and Springer Spaniels. Golden Retrievers are overrepresented among dogs with cricopharyngeal dyssynchrony. Large breed dogs are also predisposed to laryngeal paralysis, a disease more commonly associated with pharyngeal and upper esophageal dysfunction.

Clinical Presentation

- *Oral dysphagia:* Dogs and cats are reluctant or unable to chew properly. They may show halitosis and oral pain or be painful on opening their mouth.
- *Pharyngeal or oropharyngeal dysphagia:* Animals are unable to swallow the food bolus in spite of repeated attempts. If the affected animal takes a quick breath of air between swallowing actions, food may enter the larynx and trachea, eliciting a cough. Dogs will try again and again and will sometimes succeed in achieving a more adequate swallowing action. They regurgitate the food bolus, which is covered with saliva. Their ability to drink from a water bowl may be maintained or impaired as well. Animals are generally hungry, and weight loss, lean body condition, and small stature (in puppies) are common. Other signs include coughing in case of aspiration and nasal discharge in association with nasopharyngeal reflux.

Diagnosis

Diagnosis relies on clinical signs (Box 9.1). A thorough oral and pharyngeal examination, ideally in the sedated animal, is often valuable. Radiographs of the pharynx are recommended in animals with suspect foreign body (FB) or other causes of obstruction. To confirm the type of dysphagia, VFSS can be very useful but is only available in referral centers. If aspiration pneumonia is suspected, chest radiographs are helpful to evaluate the severity and extent of the process.

Management

Nonspecific measures include optimizing the consistency of the food (generally, moist food is best tolerated). Specific treatments correcting the primary disease

Box 9.1 Practical tip on the clinical approach to dysphagic dogs and cats

First, observe the animal while it is eating. Videos filmed by the owner can be helpful as well. This allows recognizing the different types of dysphagia and designing a targeted further approach.

are most helpful if available. Additionally, in severe or untreatable cases, endoscopically or surgically placed low profile gastrostomy tubes allow bypass of the pharynx and proximal esophagus in order to provide enteral nutrition.

PHARYNGITIS AND TONSILLITIS

Definition/Overview

Inflammation causes hyperemia and swelling of the pharyngeal mucosa, which may be associated with tonsillar enlargement and protrusion of the tonsils out of the palatine fossae. Tonsillitis is not uncommon in the dog, particularly in young miniature and toy breeds but is quite rare in the cat. The inflammation is usually bilateral; however, it may be unilateral in association with FBs such as grass blades, pieces of wood, and grass seeds.

Etiology

Acute pharyngitis with or without secondary tonsillitis may occur following trauma, foreign bodies, insect stings, snake bites, allergic reactions, chemical or thermal injuries, and viral infection of the upper respiratory tract (cat). Additionally, disorders causing chronic vomiting, gagging, coughing, or regurgitation may be associated with acute tonsillitis.

Clinical Presentation

Coughing, gagging, retching, or expectorating white foamy mucus (which may be confused with vomiting by the pet's owner) are commonly reported. Dysphagia, repeated swallowing attempts, odynophagia, hypersalivation, excessive licking, and pica can also be observed. Some animals can present with decreased appetite, malaise, and fever. Pharyngeal examination reveals a hyperemic (dog) or injected (cat) pharynx, possibly with enlarged tonsils protruding out of the palatine fossae. Hyperemia, mottled appearance, petechiation, and white specks are reliable signs of acute inflammation. Chronically inflamed tonsils may just be enlarged with an irregular surface.

Differential Diagnosis

Tonsillitis should be differentiated from tonsillar neoplasia such as lymphoma (unilateral or bilateral enlargement [Figure 9.1]) or squamous cell carcinoma (SCC) (unilateral, highly malignant).

Diagnosis

Diagnosis is based on the abnormal appearance of the pharynx and tonsils in association with the existence of compatible clinical signs. Secondary tonsillitis is common, and a thorough search for a primary underlying disease should be performed. Radiographs of the pharynx and retropharyngeal area may reveal the presence of FBs or space-occupying processes (Figures 9.2 and 9.3).

FIGURE 9.1 Bilaterally enlarged tonsils in a middle-aged mixed-breed dog. Cytology from a fine needle aspirate revealed lymphoma. (*Courtesy of R. Husnik.*)

FIGURE 9.2 Proximal cervical radiograph from a 5-year-old Belgian Shepherd Dog taken 2 hours after the owner pulled a stick that appeared to be stuck in the dog's throat. There is retropharyngeal accumulation of air. Persistent wood fragments cannot be ruled out based on these films. Esophagoscopy was negative, and the dog recovered with antibiotic treatment.

FIGURE 9.3 Proximal cervical radiograph of an 8-year-old Bernese Mountain Dog with dysphagia. A space-occupying lesion is pushing the pharynx, esophagus, and trachea ventrally. Fine-needle aspiration revealed histiocytic sarcoma.

Fine-needle aspiration or brush cytology may help rule out neoplasia and confirm inflammation.

Management

For acute cases, treatment usually consists of a 7- to 14-day course of antibiotics (e.g., amoxicillin and clavulanic acid), possibly with analgesics if indicated. In chronic cases with significantly enlarged tonsils, tonsillectomy may be required if the tonsils become an obstacle preventing passage of food into the pharynx.

Prognosis

Good, although acute tonsillitis may recur. The disorder usually resolves spontaneously with time.

DISEASES OF THE SALIVARY GLANDS

The four salivary glands of dogs and cats are the submandibular (located rostrolateral from the submandibular lymph node), sublingual, parotid (under mandibular ramus), and zygomatic (infraorbital) glands. Salivary gland diseases are uncommon in dogs and very rare in cats.

MUCOCELE, SIALOCELE

Definition/Overview

Sialocele is the most frequently diagnosed salivary gland disorder of dogs. It consists of an accumulation of saliva in the periglandular tissues due to salivary duct obstruction and/or rupture. The wall of the mucocele is not epithelial; therefore, mucoceles are not true salivary gland cysts. They can occur in the vicinity of each salivary gland; however, the sublingual and submandibular glands are the most frequently affected. German Shepherd Dogs and Poodles appear to be more susceptible to developing sialoceles.

Etiology

Trauma is thought to be the most frequent cause of sialocele (direct trauma, FB, sialadenolith), although signs of original trauma have usually resolved by the time the sialocele is diagnosed.

Clinical Presentation

A large, usually nonpainful mass is observed in the upper cervical region, the pharynx, or the oral cavity (Figure 9.4). Oral and pharyngeal sialoceles may cause dysphagia and oral bleeding following self-trauma. Pharyngeal and cervical mucoceles can occasionally cause dyspnea.

FIGURE 9.4 A ranula or sialocele affecting the sublingual salivary gland is visible at the base of the tongue of this dog (arrows). (*Courtesy of R. Husnik.*)

Differential Diagnosis

Other causes of salivary gland enlargement such as inflammation (sialadenitis) and neoplasia.

Diagnosis

Diagnosis is based on history, physical examination, and results of fine-needle aspiration of the mucocele with a large-bore needle (blood-tinged, thick mucoid fluid with few neutrophils). Diagnostic imaging (ultrasound, sialography) can help confirm which gland is involved.

Management

Treatment consists of removal of the ipsilateral sublingual and submandibular gland as well as drainage of the fluid accumulation.

Prognosis

Prognosis is good following surgery.

SIALADENITIS

Sialadenitis describes inflammation of the salivary glands. A syndrome of inflammation and necrosis is occasionally observed in dogs. The condition leads to enlargement of one or several glands (e.g., zygomatic or mandibular gland). In the presence of severe inflammation and swelling, pain and dysphagia can occur. Confirmation of diagnosis may require fine-needle aspirate for cytology, cross-sectional imaging, and/or surgical biopsy. Therapy for sialadenitis usually includes antibiotics and pain management. In severe cases, surgical removal of the gland may be indicated. Sialadenosis is a nonpainful, noninflammatory swelling that may

cause lip smacking, hypersalivation, retching, and gulping and seems to respond to phenobarbital therapy.

SALIVARY GLAND NEOPLASIA

Salivary gland neoplasia occurs rarely (more frequently in cats than in dogs). The submandibular gland is most commonly affected. Adenocarcinoma is the most common type.

MASTICATORY MYOSITIS

Definition/Overview

Masticatory myositis is a common focal inflammatory myopathy of dogs. It selectively affects the muscles of mastication, including temporalis, masseter, pterygoid, and rostral digastricus muscles, while sparing the spinal and limb muscles. The disease is discussed in further details in Chapter 14.

PART 2: DISEASES OF THE ESOPHAGUS

Overview

Esophageal diseases occur relatively commonly in dogs but are infrequent in cats. They may have serious implications and severely debilitate affected animals. The resulting esophageal dysfunction may lead to regurgitation of undigested food with a high risk of food inhalation and aspiration pneumonia. Additionally, chronic esophageal problems may lead to undernourishment and associated complications. Foreign bodies, strictures, and neoplasia may cause intraluminal obstructions. Vascular abnormalities with compression of the esophagus may also compromise the esophageal lumen. Esophagitis is a frequent complication of esophageal diseases and gastroesophageal reflux and vomiting. Severe cases may result in development of strictures. Congenital or acquired functional disorders cause esophageal dysmotility and may eventually result in megaesophagus (ME).

Esophageal Anatomy

The UES consists of striated muscle fibers of both cricopharyngeal and esophageal origin. The two spirally arranged muscularis layers of the esophagus wind in opposite directions. In cats, they consist of striated muscle fibers in the proximal third of the esophagus (cervical segment), while they only contain smooth muscle fibers in the distal two-thirds of the esophagus (thoracic segment). In contrast, the muscularis layers of the canine esophagus are made exclusively of striated muscle fibers over the whole length of the esophagus. The lower esophageal sphincter (LES) is a thickening of the esophageal muscle located before the gastroesophageal junction.

TABLE 9.2 Clinical signs associated with esophageal diseases in dogs and cats

- Regurgitation
- Dysphagia
- Swallowing attempts “on empty”
- Halitosis
- Excessive salivation
- Odynophagia (esophagitis)
- Anorexia/inappetence (esophagitis)
- Ravenous appetite (motility disorders, megaesophagus)
- Tachypnea, dyspnea, cough, exercise intolerance, fever (aspiration pneumonia)

Normal Esophageal Function

Esophageal motility is triggered by passage of a food bolus through the pharynx (Table 9.1). Afferent impulse is conducted by the glossopharyngeal and vagus nerves to the nucleus solitarius in the brainstem. The information is processed with the help of the reticular formation and the nucleus ambiguus, where the motor neurons are located. These are activated and transmit impulses to the vagus nerve.

Clinical Presentation

The clinical signs consistent with esophageal disease are summarized in Table 9.2. Regurgitation describes passive retrograde evacuation of undigested food or liquids and may be associated with pharyngeal or esophageal dysfunction. Differentiation of regurgitation and vomiting relies on several well-defined clinical parameters but can be challenging at times (Table 2.14.1).

ESOPHAGEAL OBSTRUCTION

ESOPHAGEAL FOREIGN BODY

Esophageal FBs are a common problem in dogs while they are infrequently diagnosed in cats.

Etiology

In dogs, esophageal FBs are frequently observed in small breeds but may occur in any size dog. The foreign material often consists of beef, pork, veal, or chicken bone(s) coated with various amounts of connective tissue. Dog treats swallowed with insufficient chewing have also been reported. Fishing hooks when swallowed also get stuck in the esophagus. Esophageal FBs are most often located at one of three sites: Thoracic inlet, heart base, or cranial to the lower esophageal sphincter.

Clinical Presentation

Animals are often presented with a suggestive history (e.g., ingestion of bones, toys missing). The clinical signs typically include regurgitation, excessive drooling, odynophagia, halitosis, hyporexia/anorexia, and retching. Additional signs (e.g., lethargy, dyspnea, shock

associated with systemic inflammatory response syndrome [SIRS], or sepsis) may occur in association with complications such as esophageal perforation with mediastinitis or pleuritis or aspiration pneumonia.

Differential Diagnosis

Other esophageal diseases: Stricture, esophagitis, ME, and esophageal tumors. Additionally, differentiation between clinical signs of esophageal FB and those of vomiting and associated diseases can be difficult at times (Table 2.14.1).

Diagnosis

The presence of an esophageal FB is best confirmed using chest radiographs that reveal a soft-tissue mass in the esophagus at the level of the obstruction (Figures 9.5 and 9.6). In most instances, the use of barium sulfate is not required, and risks associated with its use can be avoided (aspiration pneumonia, damage to endoscopic equipment if esophagoscopy is performed soon after the esophagram). It is important to evaluate radiographs for the presence of free air in the mediastinum and pleural effusion, as these may indicate esophageal perforation or rupture.

Management/Prevention

Treatment consists of extracting the FB under endoscopic or fluoroscopic guidance as soon as possible (Figure 9.7). If extraction through the oral cavity is too difficult, the FB can be pushed into the stomach. Bone, cartilage, and fibrous tissue material can generally be digested by gastric juice and eliminated naturally. If passage through the pyloric canal seems impossible, gastrotomy and extraction of the FB is performed.

In case of esophageal perforation or rupture, a surgical approach is generally necessary. If severe esophageal mucosal lesions are present following extraction, a 24- to 48-hour fasting period is recommended. In the most severe cases, endoscopic placement of a regular or low-profile gastrostomy tube is required to provide nutrition without compromising mucosal healing for the period following FB removal. Additionally, treatment of esophagitis and

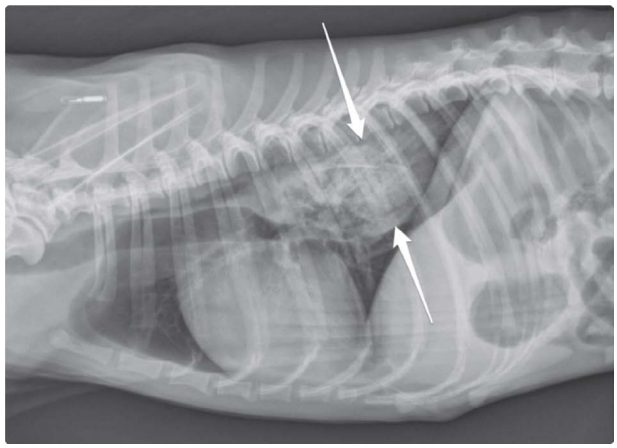

FIGURE 9.5 Four-year-old male Papillon Spaniel. Right lateral thoracic radiograph. A large soft tissue opacity is visible in the caudal half of the thoracic esophagus (dorsal and ventral limits shown by arrows). Interpretation: Esophageal foreign body without indication of esophageal perforation and pleuritis.

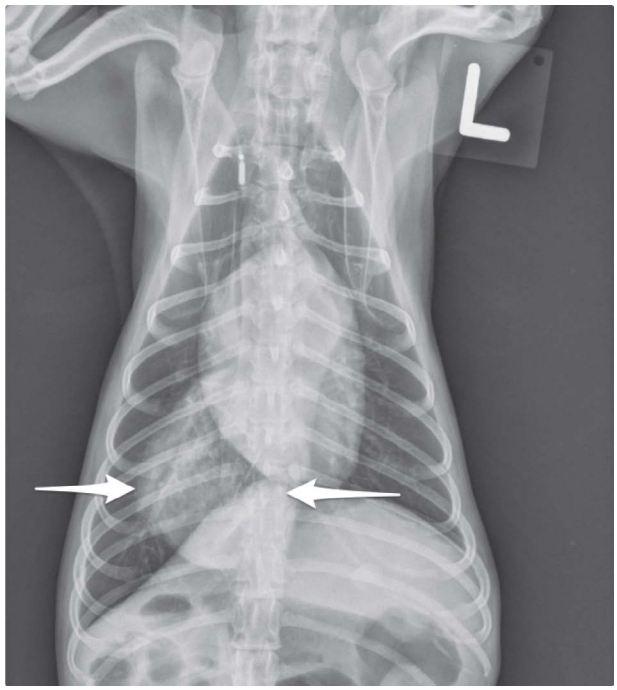

FIGURE 9.6 Four-year-old male Papillon Spaniel (same dog as Figure 9.5). The ventrodorsal thoracic radiograph shows the same soft tissue opacity in the esophagus caudal to the heart base (arrows).

FIGURE 9.7 Esophagoscopy showing a bone foreign body in the caudal thoracic esophagus (same dog as Figures 9.5 and 9.6).

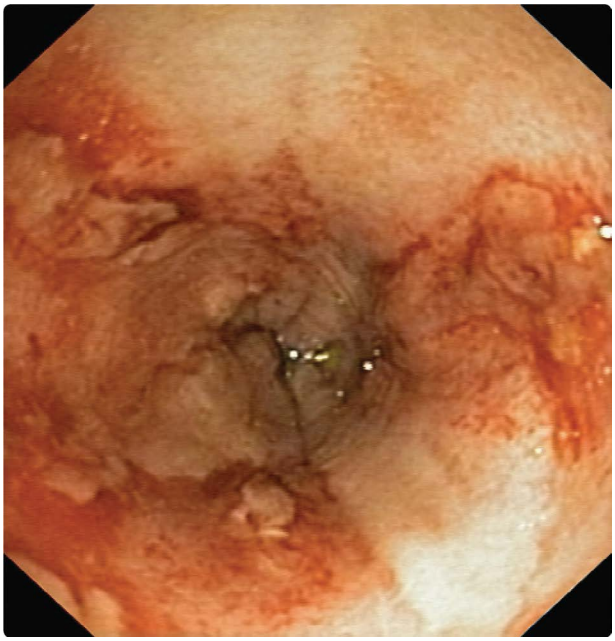

FIGURE 9.8 Endoscopic view of moderate esophageal mucosal lesions located cranial to the lower esophageal sphincter after removal of an esophageal foreign body in a dog. (*Courtesy of R. Husnik.*)

prevention of gastroesophageal reflux and further esophageal mucosal damage is recommended (see Esophagitis).

Access to bones or disproportionately large pieces of meat that are unlikely to reach the stomach should be restricted if the dog does not chew them. Approximately 5–6 mL of water should be administered with a syringe after pilling cats with any drug, particularly doxycycline and clindamycin tablets.

Prognosis

Generally, the prognosis for esophageal FB after nonsurgical removal is good to excellent. Esophagitis is present in up to 80% of dogs after FB removal (Figure 9.8) but seems to resolve relatively rapidly. Esophageal strictures are a feared complication that may develop over time, particularly in dogs with severe esophageal mucosal lesions.

BENIGN ESOPHAGEAL STRICTURE

Strictures occur less commonly than FBs in dogs and in cats.

Etiology/Pathophysiology

Benign strictures are a complication of severe esophagitis (FB, gastroesophageal reflux, dry swallow of pills to cats, ingestion of caustic substances). They occur with deep inflammation when lesions extend to the submucosa and muscularis layers of the esophageal wall. They are characterized by excessive scar tissue formation with narrowing of the esophageal lumen and resulting partial or total obstruction.

Clinical Presentation

The history often reveals esophageal disease (e.g., esophageal FB) or general anesthesia (with gastroesophageal reflux) prior to the development of signs. The animal shows frequent regurgitation, which can be associated with a particular food consistency. A dog with esophageal stricture may regurgitate dry food but not a puréed diet. Moreover, the clinical signs typical of esophagitis may also be present.

Differential Diagnosis

See Esophageal Foreign Body.

Diagnosis

Thoracic radiographs are useful to rule out other causes of esophageal obstruction (e.g., esophageal FB, external compression). Diagnosis is confirmed either by esophagoscopy (see Case 9.1) or contrast esophagram. Administration of contrast agents may lead to aspiration pneumonia and may damage endoscopic equipment if an esophagoscopy is performed soon after the contrast study. If esophageal perforation is suspected, and an esophagram is indispensable, low osmolar iodinated contrast agents are preferred over barium sulfate. It is essential to differentiate stricture of the esophageal lumen from external compression.

Management

Treatment involves dilating the stricture(s) under endoscopic or fluoroscopic control using balloons of different diameters (Figure 9.9) or "bougies" of different sizes. Multiple sessions at intervals of 1–2 weeks are often necessary. Submucosal injection of triamcinolone at the level

FIGURE 9.9 A balloon catheter filled with saline is in place to dilate an esophageal stricture.

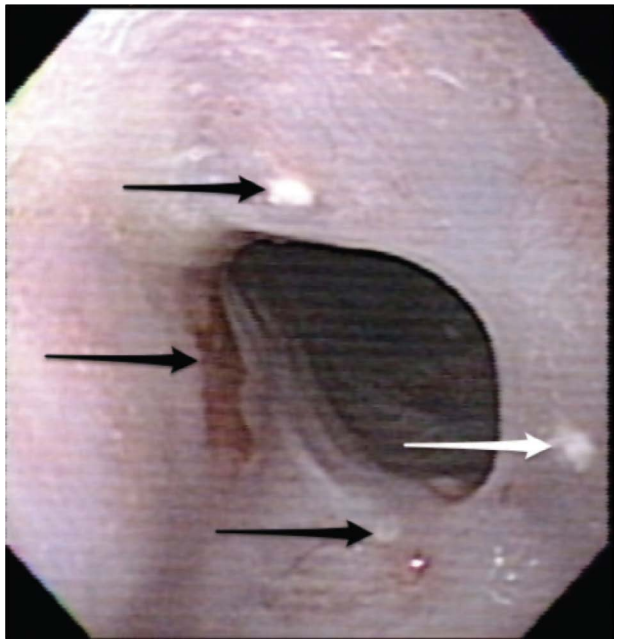

FIGURE 9.10 Triamcinolone acetate was injected submucosally in four sites at the base of the stricture in this dog (arrows).

of the stricture prior to or after dilation or bougienage can help reduce the number of procedures required (Figure 9.10). Drug therapy is similar to that for esophagitis. Systemic administration of prednisone/prednisolone is ineffective. Esophageal stenting is an option to consider in cases refractory to dilation attempts.

Prognosis

Without treatment, the prognosis is poor to grave due to the risk of aspiration pneumonia and esophageal perforation. After stricture dilation, the prognosis is guarded to good. Several dilation attempts may be required to re-establish patency of the lumen for a normal-size food bolus. In some instances, patency can only be partially restored, thus requiring liquid or moist food (and not dry kibbles) to be fed. Occasional regurgitation episodes may not be avoidable.

OTHER CAUSES OF OBSTRUCTION

VASCULAR RING ANOMALIES

Vascular ring anomalies cause entrapment of the esophagus at the level of the heart base. The most common vascular ring anomaly is persistent right aortic arch (PRAA), which is characterized by the presence of a fibrous band that connects the main pulmonary artery and the anomalous aorta and causes extraluminal compression and entrapment of the esophagus. Regurgitation typically occurs when puppies or kittens are weaned to solid food, and aspiration pneumonia is a common complication. Affected puppies are generally

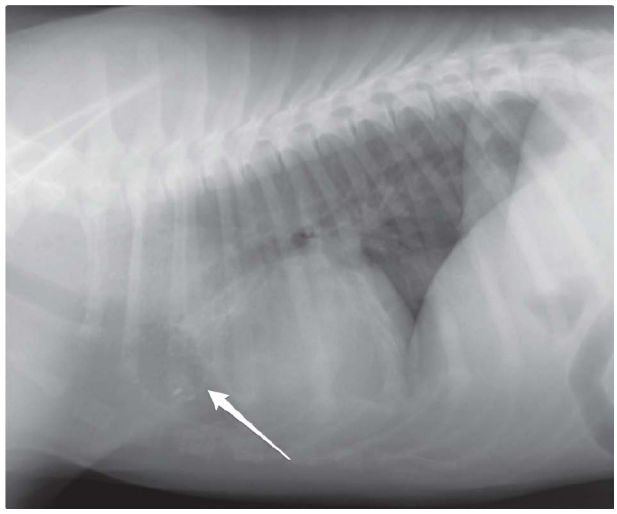

FIGURE 9.11 A 3-month-old German Shepherd Dog with a persistent right aortic arch. Lateral radiograph. The dilated esophagus is seen as a soft tissue opacity in the cranial mediastinum that displaces the trachea ventrally. Note the presence of granular material in the dilated esophagus cranial to the cardiac silhouette (arrow).

hungry and with time become malnourished and lose weight. Diagnosis relies on the typical history and clinical signs and is confirmed with thoracic radiographs that reveal esophageal dilation cranial to the heart base and deviation of the trachea to the left, cranial to the cardiac silhouette that is visible on ventrodorsal

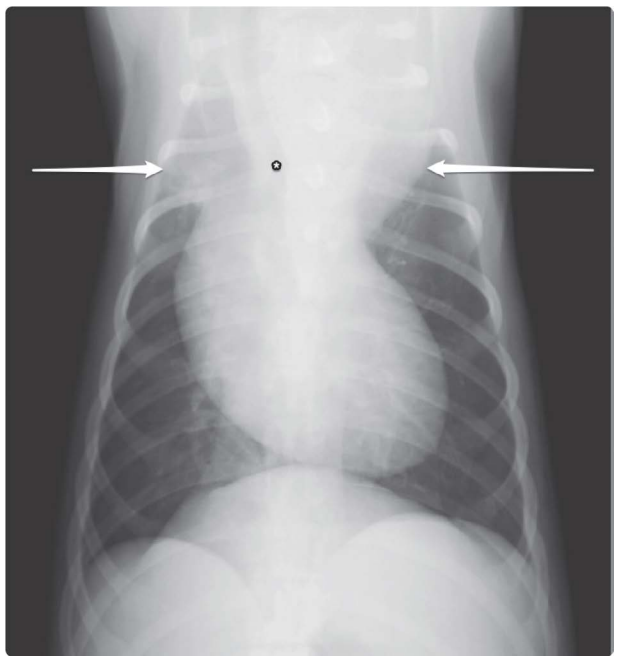

FIGURE 9.12 A 3-month-old German Shepherd Dog with a persistent right aortic arch (same dog as Figure 9.11). Ventrodorsal radiograph. The dilated esophagus is recognizable as a structure of soft tissue density in the cranial mediastinum (white arrows). Note the deviation of the trachea to the left cranial to the heart base (asterisk).

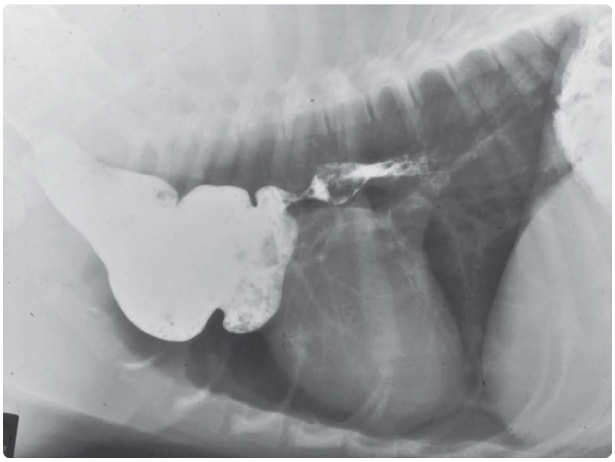

FIGURE 9.13 Contrast esophagram of a dog with a persistent right aortic arch. The dilated esophageal pouch located in the cranial mediastinum is clearly visible.

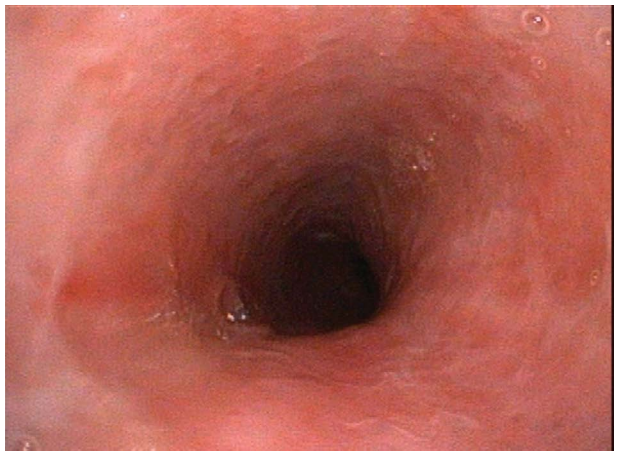

FIGURE 9.14 Esophagoscopy showing severely inflamed esophageal mucosa with multiple ulcerations at the level of the heart base in a dog with esophagitis following severe vomiting due to pancreatitis.

or dorsoventral views (Figures 9.11–9.13). Treatment of vascular ring anomalies consists of thoracotomy and transection of the compressive fibrous band. Prognosis of PRAA is generally good after surgery. In some cases, normal motility may not return if the cervical esophagus was severely dilated or if an esophageal diverticulum was formed. While most dogs are reported to do well, some may need continuous support such as upright feeding (see Megaesophagus, Management).

ESOPHAGEAL TUMORS

Esophageal tumors occur rarely. Leiomyoma is the most common benign neoplasm in dogs and often occurs in the caudal esophagus. Fibrosarcoma and osteosarcoma may develop in dogs infected with *Spirocerca lupi*. Other tumors include leiomyosarcoma, lymphoma, and metastatic lymphoma. The most common primary esophageal neoplasia of cats is squamous cell carcinoma (SCC). Clinical signs may be very discrete unless the tumor causes significant luminal obstruction. Diagnosis relies on radiographs, which may show esophageal dilation cranial to the mass. A contrast esophagram may be helpful. Esophagoscopy is required for final confirmation, with collection of biopsies for histopathologic analysis. Tumor excision with esophageal resection and anastomosis can be attempted, but the surgical procedure may be associated with postoperative morbidity. Esophageal stenting is a palliative option to consider.

ESOPHAGITIS

Definition/Overview

Esophagitis is a disease characterized by inflammation of the esophageal mucosa. It may occur in dogs and cats, and mild cases may go unnoticed.

Etiology/Pathophysiology

Noninfectious Inflammation

The esophageal mucosa may easily be damaged by gastric acid, pepsin, and bile in gastroesophageal reflux disease, as they induce the formation of proinflammatory cytokines in the esophageal mucosa (Figure 9.14). Esophagitis may be a complication of LES relaxation during general anesthesia. Esophagitis may also occur in animals with frequent and severe vomiting. In addition, esophageal FBs and swallowing of caustic substances may cause esophageal mucosal inflammation. In cats, administration of doxycycline, clindamycin, and other drugs in the form of oral tablets without subsequent water flush may cause severe esophagitis and possibly esophageal stricture.

Infectious Inflammation

In endemic areas (worldwide tropical and subtropical regions), *Spirocerca lupi* is a common cause of esophagitis. The ingested larvae migrate extensively and eventually mature into adults after a prepatent period of 3–9 months. The adult worms generally inhabit the esophageal submucosa and adventitia and cause the formation of granulomatous nodules of less than 1 cm to more than 4 cm diameter in the caudal esophageal wall. Esophageal infections with the oomycetal agent *Pythium insidiosum* occur infrequently in endemic areas (worldwide tropical and subtropical regions) and may cause severe esophagitis.

Clinical Presentation

Clinical signs are characteristic of esophageal diseases (Table 9.2). Mild cases of esophagitis may remain subclinical, or mild signs may go unnoticed by the owners.

Differential Diagnosis

Includes all the other esophageal diseases described in this chapter.

Diagnosis

A tentative clinical diagnosis is made on the basis of clinical signs and history. Confirmation of diagnosis and assessment of the extent and severity of lesions requires endoscopic examination. Collection of esophageal wall biopsies is often challenging, but histologic evaluation may yield additional information on the cause of the esophagitis. For the diagnosis of spirocercosis, diagnostic tests have the following sensitivities: Esophagoscopy 100%, presence of parasite ova on fecal flotation 80%, and radiographic detection of esophageal nodules 50%. Diagnosis of esophageal pythiosis relies on histopathology and immunochemical stains of esophageal biopsies. The typical esophageal wall thickening with involvement of local lymph nodes may be apparent on thoracic radiographs, ultrasound, and CT (Figure 9.15). An enzyme-linked immunosorbent assay (ELISA) test for serum antibodies is available.

Management

Symptomatic treatment of esophagitis is focused on protection of the mucosa against further damage and facilitation of mucosal healing. Fasting for 24–48 hours is recommended, if feasible without compromising the dog's condition. In severe cases, placement of a gastrostomy tube via endoscopy or surgery is beneficial to provide enteral nutrition and prevent complications associated with malnutrition. A diet low in fat is recommended because high-fat diets may be associated with increased episodes of gastroesophageal reflux.

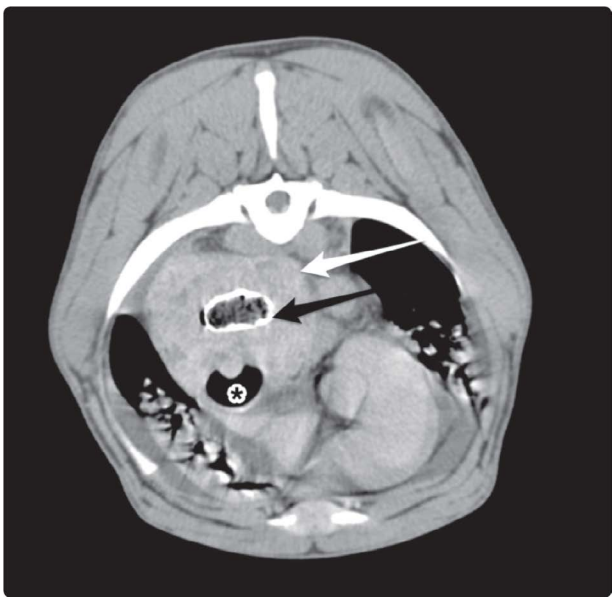

FIGURE 9.15 Mixed-breed dog with dysphagia and esophageal obstruction. Post-contrast CT scan of the cranial mediastinum. The esophageal wall is severely and irregularly thickened (white arrow, serosal surface; black arrow, mucosal surface covered with a fine layer of barium; asterisk, trachea). Infection with *Pythium insidiosum* was confirmed at necropsy. (*Courtesy of LSU SVM Diagnostic Imaging Service.*)

Sucralfate suspension is used to promote mucosal healing (1 g q.8h. for large dogs, 0.5 g q.8h. for smaller dogs). Inhibitors of gastric acid secretion, preferably a proton pump inhibitor such as omeprazole (1 mg/kg p.o. q.12h.), and a prokinetic agent that accelerates gastric emptying (metoclopramide, 0.5 mg/kg p.o., SC q.8h., or CRI of 1–2 mg/kg over 24 hours) or promotes gastric emptying and increases the distal esophageal sphincter tone (cisapride, 0.5–1 mg/kg p.o. q.8h.) should be administered, preferably 30–60 minutes before meals.

Treatment of spirocercosis consists in administration of specific parasiticides. Doramectin is an avermectin licensed for use in cattle but used off-label in dogs. Recommended protocols include 0.2–0.4 mg/kg SC every 14 days for 3–6 injections, or 0.5 mg/kg p.o. q.24h. for 6 weeks. These very high doses of avermectins must not be administered to Collies and other herding breeds that are prone to develop potentially lethal central nervous complications due to a mutation in the MDR-1 gene.

Treatment of esophageal pythiosis is challenging. Surgical excision of the lesion with safe tissue margins is the preferred treatment of gastrointestinal (GI) pythiosis but is not feasible in the esophagus. Medical treatment of unresectable pythiosis is often unrewarding (itraconazole, 10 mg/kg p.o. q.24h. and terbinafine, 5–10 mg/kg p.o. q.24h.). Anti-inflammatory doses of prednisone can be used in the hope of decreasing local inflammation and to palliate clinical signs.

Prognosis

Noninfectious Inflammation

Mild and moderate cases generally have a good prognosis. Severe inflammatory mucosal lesions may lead to esophageal stricture development.

Infectious Inflammation

Esophageal neoplasia (osteosarcoma, fibrosarcoma) is a common complication of *S. Lupi* infection and requires a surgical approach if the mass significantly obstructs the esophageal lumen. Esophageal pythiosis carries a poor to grave prognosis.

MEGAESOPHAGUS

Definition/Overview

Megaesophagus (ME) is characterized by generalized dilatation of the esophagus. It is the most common cause of regurgitation and a common esophageal disease in dogs but is a rare occurrence in cats.

Etiology

Congenital ME occurs in puppies and rarely in kittens, while acquired ME is seen mostly in middle-aged to older adult animals. The diseases frequently associated with ME in the dog are listed in Table 9.3. Among those, idiopathic ME and ME secondary to focal myasthenia

TABLE 9.3 Causes of megaesophagus in the dog

Congenital megaesophagus
- Congenital myasthenia gravis
- Congenital neuropathy

Acquired megaesophagus
- Idiopathic megaesophagus
- Myasthenia gravis
- Esophagitis
- Endocrine diseases (hypoadrenocorticism, possibly hypothyroidism)
- LES-achalasia-like syndrome
- Toxicosis (e.g., lead toxicity)
- Polymyositis, polyneuropathy
- Less common causes: Other neurologic diseases (botulism, tetanus, dysautonomia, rabies), systemic lupus erythematosus

gravis (MG) are most common. Acquired ME is also a feature of feline and canine dysautonomia.

Pathophysiology

With the exception of focal MG, the pathogenesis of canine and feline ME has not been fully elucidated. In dogs with MG, autoantibodies are formed against nicotinic acetylcholine receptors located at the neuromuscular junction in striated muscle. MG is discussed in further detail in Chapter 14. Congenital ME and other forms of acquired ME most likely result from malformation or changes in the complex neural network responsible for esophageal innervation. Recently, a syndrome resembling achalasia (or failure to relax) of the lower esophageal sphincter (LES) called LES-achalasia-like-syndrome has been described and may account for an important proportion of dogs previously diagnosed with idiopathic ME.

Miniature Schnauzers, Fox Terriers, German Shepherd Dogs, Great Danes, Irish Setters, Labrador Retrievers, Shar Peis, and Newfoundlands are at increased risk for development of primary idiopathic ME.

Clinical Presentation

The clinical signs are similar to those of other esophageal diseases (Table 9.2), and regurgitation is the most frequent complaint in dogs with ME. Secondary esophagitis is a common complication. The risk of aspiration pneumonia is high. Accordingly, affected animals may present with exercise intolerance, cough, tachypnea, and dyspnea.

Differential Diagnosis

Includes all the other esophageal diseases described in this chapter.

Diagnosis

The first step in the diagnostic approach is to rule out esophageal obstruction (FB, stricture) by taking a detailed history and obtaining good quality thoracic radiographs. A generalized dilatation of the esophagus is usually easily identified on the thoracic films

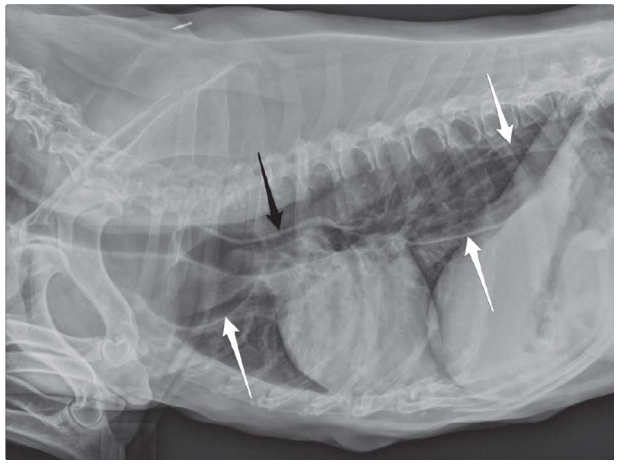

FIGURE 9.16 Nine-year-old female spayed Basset Hound with megaesophagus due to focal myasthenia gravis. Right lateral radiograph. The white arrows point to the dorsal and ventral walls of the esophagus, which are both clearly visible. The black arrow points to summation of the dorsal tracheal and ventral esophageal walls (tracheal stripe sign).

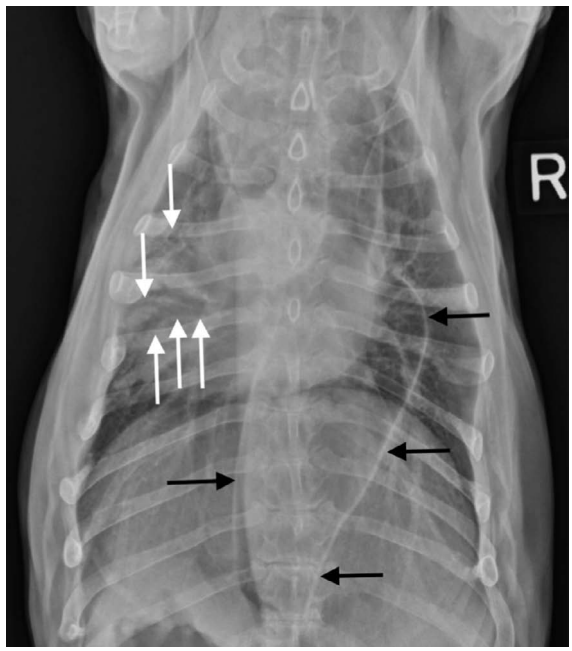

FIGURE 9.17 Nine-year-old female spayed Basset Hound with megaesophagus due to focal myasthenia gravis (same dog as Figure 9.16). Ventrolateral radiograph. The walls of the dilated esophagus are clearly visible in the caudal mediastinum (black arrows). Air bronchograms are visible in the caudal and cranial subsegments of the left cranial lung lobe (white arrows) together with increased opacity of the lung parenchyma.

(Figures 9.16 and 9.17). It is important to carefully check for aspiration pneumonia in these patients. This is best done by thoroughly examining the ventral parts of the lung lobes, in particular the right middle and left and right cranial lobes for presence of interstitial or alveolar infiltrate (Figure 9.17). VFSS is required to confirm the diagnosis of LES-achalasia-like syndrome.

The systematic approach is continued by screening animals for primary diseases associated with secondary ME. A minimal database consisting of complete blood count (CBC), biochemistry panel (including serum creatinine kinase [CK]), and urinalysis is recommended. Next, screening for endocrinopathies (basal serum cortisol concentration, possibly serum thyroxine and endogenous thyroid-stimulating hormone [TSH]), and a search for opacities in the cranial mediastinum (looking for possible thymoma associated with MG) are recommended. A sensitive and specific serum assay documenting the presence of autoantibodies against nicotinic acetylcholine receptors is available for the diagnosis of MG (http://vetneuromuscular.ucsd.edu). Endoscopic examination of the esophagus may be useful in unclear cases to allow visualization of the extent and severity of the esophagitis, if present. In cases with suspected polymyositis or polyneuropathy, electrodiagnostics (electromyogram [EMG], nerve conduction studies) and collection of muscle and nerve biopsies for histopathologic evaluation should be considered.

Management

Dietary management is essential. It is important to try various options such as dry food kibble, canned food formed into meatballs, and food blended with water in different consistencies (thick or thin slurry) because each animal may respond differently. Dogs and cats with ME should be fed a calorie-dense diet in a vertical position and be maintained in that position for 10–15 minutes after the meal to use gravity to facilitate aboral movement of the food bolus. Small dogs can be held on a person's lap for that time. Medium-size and large dogs can be fed on stairs and maintained with their forelimbs higher than their hind limbs. The Bailey chair is a useful device to keep medium-size and large dogs in a vertical position during and after meals (**Figure 9.18**). This aspect of treatment can be a challenge for older dogs with pre-existing orthopedic diseases such as coxofemoral arthritis.

In severe cases, placement of a gastrostomy tube may be beneficial to ensure appropriate nutrition and timely delivery of oral medications to the stomach and prevent aspiration pneumonia.

Identified underlying diseases need to be treated. For instance, the recommended treatment of MG includes administration of the acetylcholinesterase inhibitor pyridostigmine (1–3 mg/kg p.o. q.12h., start with a low dose to minimize risk of cholinergic crisis) and immunosuppressive doses of prednisone or prednisolone (e.g., 1 mg/kg p.o. q.12h.).

In dogs, there is no drug treatment that can successfully increase esophageal motility. In recent years, sildenafil, a phosphodiesterase-type 5 (PDE-5) inhibitor which relaxes smooth muscle, has been anecdotally used in dogs with ME under the assumption that LES relaxation would facilitate the passage of ingesta into the stomach. It was shown to decrease the frequency of regurgitation episodes, cause weight gain, and reduce esophageal diameter on radiographs in dogs with congenital ME (1 mg/kg p.o. q.12h.). In LES-achalasia-like

FIGURE 9.18 A 10-year-old female spayed Border Collie with idiopathic megaesophagus eating in a custom-made Bailey's chair. The dog is kept in an upright position in the chair for 20 minutes after each meal.

syndrome, recent research has documented the value of endoscopically guided LES balloon dilation and *C. botulinum* toxin A injection into the sphincter in providing time-limited improvement of clinical signs and identifying patients that would respond to surgical myotomy and fundoplication. In cats, cisapride may be useful as prokinetic agent for the distal esophagus. Because of the high prevalence of esophagitis in patients with ME, sucralfate suspension maybe beneficial to facilitate mucosal healing (0.5–1.0 g/dog q.8h., 0.25–0.5 g/cat q.8–12h.).

Treatment of aspiration pneumonia is mostly supportive. If secondary bacterial infection is suspected, antibiotic treatment is best based on culture and sensitivity from a bronchial wash; however, empiric treatment with a broad-spectrum antibiotic may be necessary in some cases (e.g., amoxicillin and clavulanic acid, ampicillin and sulbactam).

Home management of pets with ME is complex and time-consuming. Owners may feel overwhelmed and discouraged at first. Therefore, optimal communication between the veterinary care team and the animal's owners is essential for successful management of this condition (**Box 9.2**).

Prognosis

Studies from Scotland and Germany reported a short median survival time of 3 months after diagnosis

Box 9.2 Practical tip for support of owners of dogs with megaesophagus

The management of dogs with megaesophagus requires considerable dedication from the pet's owners and can be overwhelming at times. Clients should be made aware of the existence of support groups on the web or on social media. These owner-driven groups provide useful tips to optimize the quality of homecare and to make it possible for owners to include these new tasks in their busy daily routines.

regardless of the etiology in dogs with ME. In the Glasgow study, only 41% of dogs survived 1 year, 31% were alive at 2 years, and 22% survived for 5 years. Identified risk factors for shorter survival were dogs older than 13 months of age at the time of diagnosis and presence of aspiration pneumonia at diagnosis. However, ME may be reversible when associated with a treatable underlying disease.

HIATAL HERNIA

Definition/Overview

Hiatal hernia (HH) involves herniation of parts of the stomach through the esophageal hiatus into the mediastinum. Four types of hiatal hernias have been described in people, and most cases documented in dogs and cats are type I or sliding HH.

Etiology/Pathogenesis

Type I HH are usually due to a congenital weakness of the esophageal hiatus. They have been reported most frequently in brachycephalic breeds and also in cats. Acquired type I HH may occur following trauma or in combination with obstructive upper respiratory disease and abnormally high negative intrathoracic pressure during inspiration, such as may occur in dogs with brachycephalic syndrome and laryngeal paralysis.

Clinical Presentation

Common clinical signs are due to the secondary reflux esophagitis and include regurgitation, hypersalivation, vomiting, dysphagia, dyspnea, anorexia, and weight loss. Puppies and kittens with congenital HH are often presented at the time of weaning to solid food, but onset of clinical signs can also be delayed into adulthood. In some cases, acquired HH may remain subclinical. Aspiration pneumonia is possible and affected animals may show typical respiratory signs.

Differential Diagnosis

Esophageal diseases, in particular esophageal obstruction (FB, stricture), vascular ring anomaly in puppies, and acute or chronic gastritis.

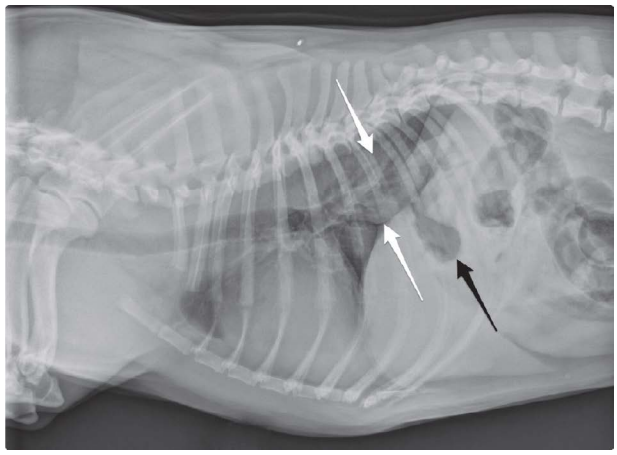

FIGURE 9.19 Right lateral thoracic radiograph of a 1-year-old male French Bulldog with hiatal hernia. The stomach is not in a normal anatomic position within the abdomen (black arrow) and is displaced cranially into the caudal thorax and confluent with the soft tissue opacity in the region of the esophagus (white arrows). (*Courtesy of LSU SVM Diagnostic Imaging Service.*)

Diagnosis

Diagnosis is confirmed with survey thoracic radiographs (Figure 9.19) and positive contrast esophagram (Figure 9.20) to confirm the type of HH. Sliding hernias may not be visible at the time of the examination, and fluoroscopy may be required for confirmation. The HH may also be viewed using ultrasound from an abdominal approach. Esophagoscopy allows visualization of the extent and severity of the esophagitis.

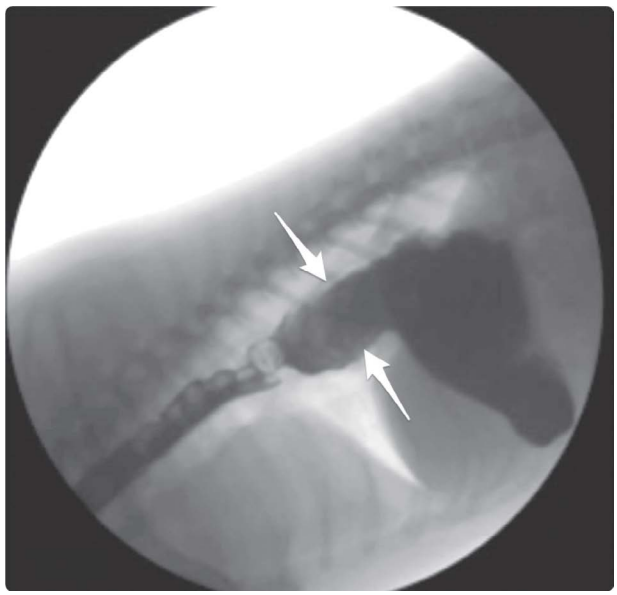

FIGURE 9.20 Right lateral view from a 6-year-old male neutered Welsh Corgi with dysphagia. The dog was given a kibble meal mixed with barium. A sliding hiatal hernia is visible. The arrows show the dorsal and ventral walls of the herniated stomach.

Management

Medical management is aimed at treating the secondary esophagitis and protecting esophageal mucosa from further damage (see Esophagitis, Management). A 30-day trial of medical therapy is often recommended prior to making plans for surgical correction as it may cause clinical signs to abate with restitution of adequate quality of life in a significant proportion of dogs. However, medical treatment was not successful in a series of Shar Peis presented before the age of 5 months, and surgery was recommended with no delay in such puppies. Surgical techniques include reduction of the abnormal diaphragmatic hiatus (phrenoplasty), esophagopexy, and left-sided gastropexy used alone or in combination. Surgical management of brachycephalic obstructive airway syndrome, if present, should be considered as well. Clinical signs may persist after surgical reduction until resolution of secondary esophagitis.

Prognosis

Prognosis for dogs and cats with HH is generally good. Animals that respond to medical management will probably require long-term treatment (continuous or intermittent). If medical treatment fails, surgical correction has a favorable outcome in most cases.

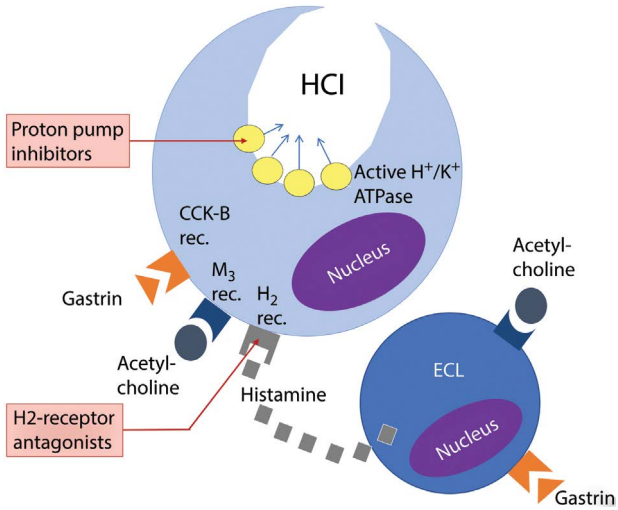

FIGURE 9.21 Schematic representation of a canine parietal cell and its neighboring enterochromaffin-like cell (ECL). Apical proton pumps actively secrete protons into the glandular lumen under stimulation by one of three basolateral receptors: CCK-B (gastrin), M_3 (acetylcholine), and histamine type 2. The ECL releases histamine in response to stimulation with acetylcholine or gastrin. The site of action of proton pump inhibitors and H_2 histamine receptor antagonists is illustrated. Rec, receptor.

PART 3: DISEASES OF THE STOMACH

Overview

Gastric diseases are common in dogs and cats. The stomach plays a key role in the digestive process through gastric acid and pepsinogen production. It functions both as a storage organ (fundus and body) and as a grinder (antrum), reducing the size of food particles until they are small enough to pass through the pyloric sphincter, and be further processed in the small intestine.

Gastric Anatomy

The stomach can be divided into five anatomic parts: Cardia, fundus, body, pyloric antrum, and pylorus. The mucosa of the fundus and body folds into countless gastric glands that are lined with cells responsible for secretion of acid (parietal cells), mucus (neck cells), pepsinogen (chief cells), and GI hormones (endocrine cells). The pyloric mucosa is thinner and contains a lower density of glands. Pyloric glands mostly consist of mucous cells and endocrine cells (many of them producing gastrin).

Normal Gastric Function

Acid and Enzyme Production

While unstimulated gastric acid production is minimal in dogs and cats, postprandial acid production is considerable, with gastric acidity reaching a pH as low as 1 or less. Acid is produced in the parietal cells in response to three types of stimuli: Activation of histamine type 2 receptors by histamine produced by neighboring enterochromaffin-like cells; muscarinic type 3 receptors activated by vagal nerve endings; or gastrin receptors (also called CCK type 2 receptors) activated by gastrin produced by antral G-cells (Figure 9.21). Enzyme secretion is limited to pepsinogen, released by chief cells, and broken down to the proteolytic enzyme pepsin, and gastric lipase.

Gastric Motility

After ingestion of solid food, the gastric antrum acts as a pump from which peristaltic waves originate while the gastric body acts as a high compliance reservoir. The mechanical action of the antral pump is divided into three phases: (1) Propulsion, (2) emptying of fine particles into the duodenum and mixing, and (3) retropulsion of particles > 1–2 mm for continued grinding. In dogs, complete emptying of the stomach is followed by synchronized housekeeping contractions (phase III migratory motor complexes).

GASTRITIS

ACUTE GASTRITIS

Definition/Overview

Acute gastritis is a clinical syndrome that occurs commonly in dogs and occasionally in cats. The diagnosis is rarely confirmed histopathologically, and affected

animals are usually treated symptomatically with good success.

Etiology

The most common cause of acute gastric inflammation is dietary indiscretion or food intolerance. Other common causes include gastric FBs (including hairballs), drugs (e.g., antibiotics, nonsteroidal anti-inflammatory drugs [NSAIDs]), toxins (plant material, bleach, cleaners, heavy metals), bacteria (*Helicobacter* spp.), toxins, and viruses. Additionally, acute gastritis may also be associated with diseases primarily affecting other organs (e.g., hypoadrenocorticism, acute kidney injury, acute hepatitis, cholangitis, cholecystitis).

Clinical Presentation

Sudden-onset vomiting, possibly associated with hyporexia/anorexia and lethargy. Hematemesis may occur as well. The history may reveal exposure to spoiled food, drugs, or toxins. Untreated animals become dehydrated and hypovolemic. Hypokalemia may occur as well due to potassium loss associated with vomiting and onset of metabolic alkalosis.

Differential Diagnosis

Other diseases causing sudden-onset vomiting such as GI FB, acute pancreatitis, endocrine diseases (e.g., hypoadrenocorticism, diabetic ketoacidosis), acute kidney injury (e.g., toxicosis with ethylene glycol or grapes/raisins, Easter lily, leptospirosis), acute hepatitis, cholangitis, or cholecystitis.

Diagnosis

History and clinical signs are usually suggestive. Abdominal radiographs should be obtained in order to rule out the presence of a GI FB. Underlying diseases should be ruled out, particularly in older animals or in atypical cases, with the help of a minimal database (CBC, serum biochemistry, urinalysis).

Management

Treatment is mostly symptomatic and consists of antiemetics, parenteral fluids to correct fluid and electrolyte deficits, and analgesia with opiates in case of abdominal pain. Animals usually benefit from a short fast (12 hours) until vomiting has subsided, followed by frequent feedings of small quantities of an easily digestible bland food (e.g., boiled chicken and rice or commercial prescription food) for 2–3 days. Once the animal feels better, the usual diet can be reintroduced progressively over 2–3 days.

Prognosis

Most dogs and cats with acute gastritis respond very well to symptomatic treatment. In cases with severe underlying conditions, the prognosis of the primary disease is determinant.

CHRONIC GASTRITIS

Definition/Overview

Chronic gastritis is a common disease in dogs with clinical signs such as chronic vomiting. Histopathologic lesions of gastric inflammation can also be present in significant numbers of asymptomatic dogs. The prevalence of chronic gastritis in cats has not been established.

Etiology

Possible causes of chronic gastritis include infectious agents or parasites, drugs (see Gastric Ulcers and Erosions), or chronic FBs (see Gastric Outlet Obstruction). In many cases, a specific cause cannot be identified, and the term idiopathic gastritis is used. Food intolerance or allergy, occult parasitism, or other mechanisms are thought to play a role in the pathogenesis of idiopathic gastritis.

Ollulanus tricuspis is the small gastric worm that infests the feline stomach. It is 0.7–1 cm in length and is transmitted directly from cat to cat through ingestion of vomitus. Depending on the severity of the infestation, cats may remain subclinical or show severe signs of chronic gastritis. *Physaloptera* spp. are larger (2–6 cm long) and may be found in dogs and cats (Figure 9.22), although their final host appears to be the coyote. *Pythium insidiosum* is an oomycetal microorganism that may infect the canine GI tract in subtropical climates (such as the southeast and Gulf of Mexico regions of the United States) and sporadically in other areas. Young, large breed dogs with access to the outdoors are most commonly affected and typically vomit regularly without losing their appetite. Gastric pythiosis is characterized by severe transmural antral thickening

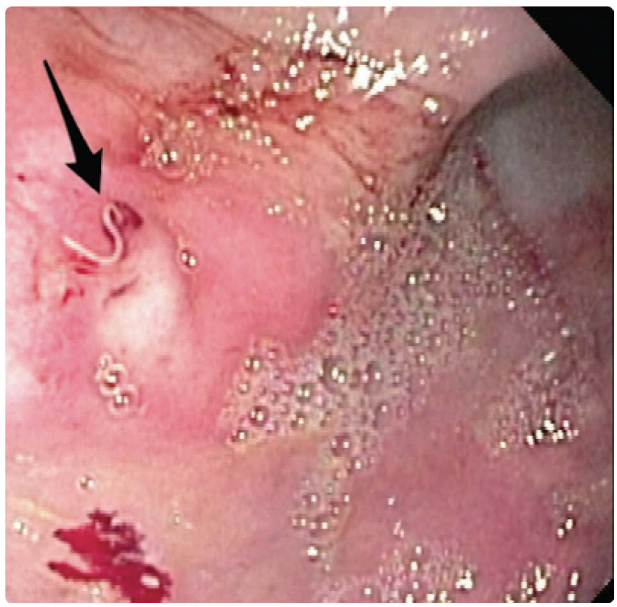

FIGURE 9.22 Endoscopic view of a *Physaloptera* worm (arrow) found in the gastric mucosa of a young adult male dog with chronic vomiting. (*Courtesy of K. Harkin.*)

and possible gastric outflow obstruction and may be difficult to differentiate from gastric antral neoplasia. *Helicobacter* infection is discussed in further detail on page 305.

Clinical Presentation

Chronic or chronic-intermittent vomiting of food and/or bile is the main clinical sign associated with chronic gastritis. Depending on the severity of the disease, varying combinations of hyporexia, weight loss, melena, or hematemesis may be observed.

Differential Diagnosis

All diseases that may cause chronic vomiting need to be considered. These include chronic enteropathies (vomiting, hyporexia, and/or weight loss may be the only signs of inflammatory bowel disease [IBD] in cats), chronic pancreatitis, chronic diseases of the liver and biliary tree, chronic kidney disease, and endocrinopathies (dog: hypoadrenocorticism, cat: hyperthyroidism).

Diagnosis

A minimum database consisting of CBC, biochemistry panel, and urinalysis is useful to assess the presence of underlying conditions with secondary gastritis and the systemic impact of gastritis. For instance, eosinophilia may be suggestive of parasites, allergic reactions, hypoadrenocorticism, or mast cell tumor. Hypoalbuminemia may occur with severe GI bleeding or with concurrent small intestinal involvement. Abdominal radiographs may reveal delayed gastric emptying (i.e., presence of food in the stomach after a 12-hour fast). Abdominal ultrasound is useful to assess antral wall thickness and overall gastric motility. Fecal flotation is not very helpful for diagnosis of *Ollulanus* or *Physaloptera*. In dogs with history, physical examination, and abdominal imaging findings suggestive of gastric pythiosis, serum ELISA documenting the presence of specific antibodies may be helpful. In cases refractory to symptomatic treatment, gastroscopy allows visualization of the gastric lesions (**Figure 9.23**) and collection of gastric mucosal biopsies, which are evaluated histopathologically. The duodenum should also be evaluated and biopsied, since gastric diseases may extend to the small intestine as well. Lymphoplasmacytic infiltrates are the most common, but infiltrates may also consist of eosinophils or other inflammatory cells. Eosinophilic gastritis may reflect the presence of parasites or allergic processes. In cats, it may be part of the feline hypereosinophilic syndrome.

Management

Symptomatic treatment is initiated with antiemetics (see Chapter 2.17), and protection of the gastric mucosa (**Table 9.4**). In addition, identified underlying diseases also need to be addressed. In dogs and cats with unexplained gastritis, empirical treatment with broad-spectrum anthelminthics such as fenbendazole (50 mg/kg q.24h. for 5 days

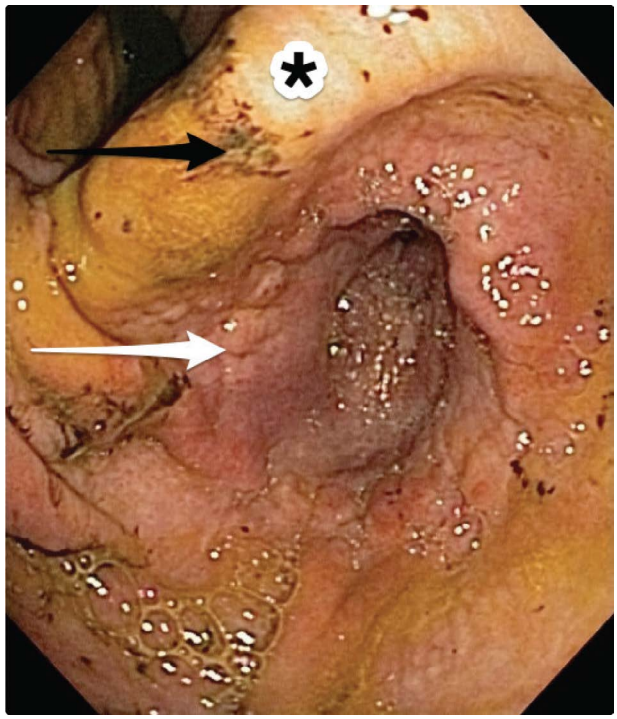

FIGURE 9.23 Gastroscopic view of a dog with chronic vomiting and hyporexia after endoscopic extraction of a plastic foreign body. The pyloric antrum can be seen below the incisura angularis (asterisk). The antral mucosa looks thickened (white arrow), and there are multiple mucosal erosions (black arrow). (*Courtesy of R. Husnik.*)

[*Ollulanus* and *Physaloptera* spp.]) or pyrantel pamoate (5–10 mg/kg [*Physaloptera* spp.]) may be warranted.

Regardless of the cause of the chronic gastritis, a sensible dietary approach is necessary. Obtaining a good dietary history is helpful. For idiopathic chronic gastritis, the recommended diets are based on novel proteins or hydrolyzed peptides. They should be easily digestible and fed in several small meals throughout

TABLE 9.4 Recommended dosages for inhibitors of gastric acid production, prostaglandin analogs, and sucralfate

Drug	Dog	Cat
Omeprazole	1.0 mg/kg p.o. q.12h.	Same
Pantoprazole	1.0 mg/kg IV q.12h.	Same
Famotidine*	1 mg/kg p.o., IV q.12h., if renal azotemia is present q.24h.	Same
Ranitidine*	1–2 mg/kg p.o., SC, IV q.12h., use low end of range if renal azotemia present	Same
Misoprostol	2–5 µg/kg p.o. q.8–12h.	Unknown
Sucralfate	0.5–1 g/dog p.o. q.8–12h.	0.25–0.5 g/cat p.o. q.8–12h.

* H2-receptor antagonists have been shown to be inferior to proton pump inhibitors in their ability to suppress gastric acid production in dogs and cats.

the day to optimize gastric emptying. Dietary management may be sufficient in mild cases with few or no systemic signs, and improvement generally occurs within 2 weeks of receiving the new diet. If this is not the case, a different diet may be tried for another 2 weeks, or immunosuppressive therapy may be initiated. In moderate and severe cases, immunosuppressive doses of glucocorticoids are often required (e.g., prednisone, 1–2 mg/kg q.24h. for 2 weeks, then slowly taper in 2-week steps to every other day or lowest effective dose over 8–12 weeks). Additional immunosuppressives may be required in refractory cases.

GI pythiosis is best managed with surgical resection of the lesion with sufficient margins. This is often difficult to achieve in the stomach. Medical treatment of unresectable pythiosis is often unrewarding (itraconazole, 10 mg/kg p.o. q.24h.; terbinafine, 5–10 mg/kg p.o. q.24h.). Anti-inflammatory doses of prednisone can also be used in the hope of decreasing local inflammation and to palliate clinical signs.

Prognosis

All identifiable causes and underlying diseases should be addressed and properly managed. Idiopathic chronic gastritis generally has a fair to good prognosis.

HELICOBACTER spp. INFECTION

Definition/Overview

Helicobacter spp. are spiral-shaped Gram-negative bacteria that can live in an acidic environment. While their association with peptic ulcer and gastric neoplasia in people has been clearly documented, their pathogenic potential in dogs and cats is less well defined. *H. pylori*, the most prevalent *Helicobacter* infecting people, does not represent a significant problem in small animals. *H. heilmannii* is the predominant species isolated from cats, while *H. bizzozeronii* and *H. salomonis* are the most common species in dogs. The bacteria colonize mucus in the gastric glands and cause local inflammation.

Clinical Presentation

The main clinical sign is chronic, intermittent vomiting.

Diagnosis

Diagnosis is based on ruling out other causes of chronic gastritis and confirming with gastroscopy, which may show gross lesions (Figure 9.24). Gastric mucosal biopsies are collected and evaluated cytologically (Figure 9.25), and histopathologically. *Helicobacter* is often observed on cytologic or histopathological slides. The current consensus is that diagnosis of clinically relevant infection requires the presence of the organisms together with histopathologic evidence of follicular lymphocytic gastritis.

FIGURE 9.24 Gastroscopic view showing the pyloric antrum of a 12-year-old male neutered Domestic Shorthair cat with a 15-month history of intermittent vomiting, hyporexia, and weight loss. There are multiple erosions associated with mucosal bleeding (brown spots). Histopathology revealed follicular lymphocytic inflammation and numerous spiral-shaped bacteria on the mucosa. The cat responded to treatment with amoxicillin, clarithromycin, and metronidazole.

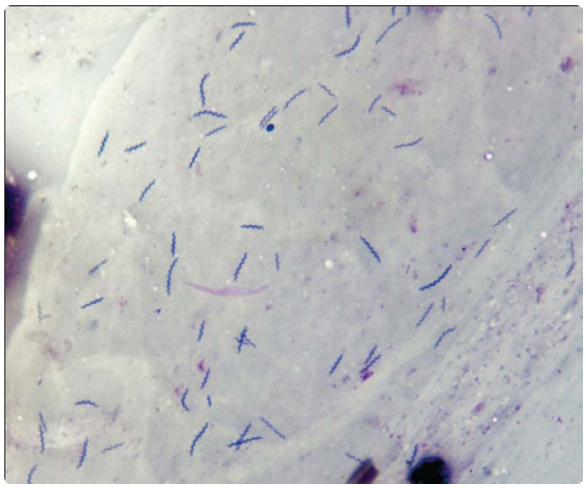

FIGURE 9.25 Cytology picture of a gastroscopic mucosal brushing showing multiple spiral-shaped bacteria in a dog. (*Courtesy of R. Husnik.*)

Management

While the pathogenic potential of *Helicobacter* spp. in dogs and cats is still subject to discussion, animals presented with clinical signs of chronic gastritis, histologic evidence of gastric inflammation, and concurrent presence of spiral-shaped bacteria in the gastric mucosa and gastritis should be treated. Eradication requires treatment with different drugs, usually consisting of one or more antimicrobial(s), an acid-reducing drug,

TABLE 9.5 Examples of oral treatment protocols used in clinical studies for eradication of *Helicobacter* spp. in dogs and cats

Antimicrobial	Antacid	Other	Comments
Metronidazole (10–15 mg/kg q.12h.) Amoxicillin (20 mg/kg q.12h.)	Famotidine (0.5 mg/kg q.12h.)		D: 2-week duration
Metronidazole (10–15 mg/kg q.12h.) Amoxicillin (20 mg/kg q.12h.)		Bismuth subsalicylate (0.22 ml/kg q.6–8h.)	D, C: 3-week duration
Amoxicillin (20 mg/kg q.12h.) Clarithromycin (7.5 mg/kg q.12h.) Metronidazole (10 mg/kg q.12h.)			C: 2-week duration

C, successful use reported in cats; D, successful use reported in dogs.

and bismuth in some protocols for a duration of 14–21 days. Examples of eradication protocols are listed in Table 9.5.

Prognosis

Prognosis is good; however, many animals may reinfect themselves in their home environment.

GASTRIC ULCERATIONS AND EROSIONS

Definition/Overview

Ulcers are mucosal lesions that extend to the muscularis mucosae and the deeper layers (submucosa, muscularis), and erosions are more superficial and limited to the lamina propria. While there are no reported numbers for the prevalence of GI ulcers in small animals, they appear to be uncommon in dogs and rare in cats.

Etiology

The main reported causes of gastric ulcer in dogs and cats are listed in Table 9.6. Long-term treatment with NSAIDs is probably the most common cause of canine GI ulcers. Administration of NSAIDs using a higher dose than that recommended by the manufacturer, or in combination with other NSAIDs or corticosteroids, significantly increases the risk of GI lesions. Dogs treated for intervertebral disc disease are also at high risk of developing ulcerative lesions in the GI mucosa. Additionally, GI ulceration may represent a complication of a variety of diseases originating in or outside the GI tract. Gastric tumors frequently ulcerate due to inadequate vascularization to maintain the integrity of the gastric mucosa. Finally, secretion of gastrin by gastrinomas and histamine by mast cell tumors may lead to excessive gastric acid production and disruption of the gastric mucosal barrier, with resulting erosions and ulcerations.

TABLE 9.6 Causes of gastrointestinal ulceration in dogs and cats

Dogs	Cats
Drugs NSAIDs 1. Accidental ingestion (acute toxicosis) 2. Chronic administration (to treat orthopedic conditions) Steroids 1. With intervertebral disc disease 2. Other	**Drugs** NSAIDs, steroids
Neoplasia Gastric carcinoma, and other gastric tumors Mast cell tumor Gastrinoma	**Neoplasia** Alimentary lymphoma, and others Systemic mastocytosis Gastrinoma
Poor perfusion of gastric mucosa Hypoadrenocorticism, shock, inadequate fluid therapy during anesthesia	**Poor perfusion of gastric mucosa** Shock, inadequate perfusion during anesthesia
Other *Helicobacter* spp. infection, inflammatory bowel disease, pancreatitis, liver disease, uremic syndrome, prolonged intensive physical activity (sled dogs), pyloric outflow obstruction, gastric dilatation–volvulus, gastric FB	**Other** Inflammatory bowel disease, hypereosinophilic syndrome, *Dieffenbachia* toxicosis, stress, gastric FB

Pathophysiology

The gastric mucosal barrier protects the gastric mucosa from the acidic environment of the gastric lumen. The hydrophobic mucous layer produced by the mucous neck cells provides a physical barrier separating the gastric epithelium from the gastric lumen and its content. It is rich in bicarbonate, which acts as a buffer against acid. Other factors involved in maintaining the mucosal barrier include the high mucosal blood flow providing nutrients, bicarbonate, and oxygen to the mucosa and eliminating acid residues, the local production of prostaglandin E2, and the rapid turnover of epithelial cells. Gastric ulcers and erosions occur in the presence of drugs or disease processes that weaken or disrupt the gastric mucosal barrier.

Clinical Presentation

In dogs, the typical presentation revolves around vomiting with or without hematemesis (Figure 9.26). Cranial abdominal pain may be present. Signs resulting from

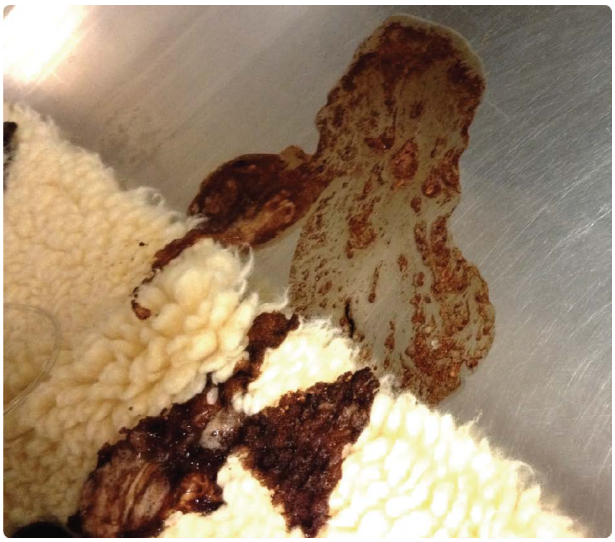

FIGURE 9.26 Bloody vomit with typical coffee-grounds appearance from a dog with a gastric ulcer due to acute NSAID toxicosis. (*Courtesy of R. Husnik.*)

fluid and possibly blood loss (dehydration, shock, anemia) may become apparent. While melena may be observed during the rectal examination (**Figure 9.27**), it is only obvious in case of significant blood loss (> 2.5–3.5 mL/kg body weight). In case of perforating ulcer, septic peritonitis usually develops with systemic inflammatory response syndrome (SIRS, sepsis).

Cats with GI ulceration may also be presented with vomiting, hematemesis, abdominal pain, and melena. However, some cats may only show vomiting with nonspecific signs such as anorexia and lethargy. GI ulcers associated with neoplasia (e.g., gastric tumor, mastocytosis) tend to have a more protracted course with weight loss and other clinical signs caused by the underlying disease.

Differential Diagnosis

Vomiting (see Chapter 2.17, **Table 2.17.2**). Severe gastric inflammation, duodenal ulcers, and acute pancreatitis may also cause hematemesis. Furthermore, mucosal bleeding associated with coagulopathies or platelet diseases may also lead to hematemesis and melena. Abdominal pain may be associated with acute pancreatitis, GI FBs, and gastroenteritis.

FIGURE 9.27 Melenic feces recovered from the rectum of a dog with gastric adenocarcinoma.

Diagnosis

In animals with suggestive evidence of GI ulceration, the diagnostic approach should focus on two objectives: (1) Confirm the presence of an ulcerative GI lesion and (2) search for an underlying disease predisposing the animal to develop GI ulcers.

A minimal database consisting of CBC, serum biochemistry, urinalysis, and abdominal imaging should be obtained. The CBC may show evidence of blood loss anemia (microcytic hypochromic anemia), which may be regenerative or nonregenerative depending on the duration of blood loss and/or changes associated with the underlying disease. Serum biochemistry may reveal an increased blood urea nitrogen (BUN) in an otherwise fasted patient (suggestive of GI bleeding) and/or abnormal results due to fluid and electrolyte loss or to an underlying disease. Abdominal radiographs are important to rule out a GI obstruction. Additionally, they may identify signs of perforation and peritonitis (e.g., peritoneal effusion with decreased serosal detail, pneumoperitoneum). Abdominal ultrasound allows a more detailed assessment of the gastric pylorus, antrum, and body and is useful to confirm the presence of free fluid or gas in the peritoneum. Moreover, a full abdominal scan allows evaluation of the other abdominal organs in the search for underlying disease. Masses detected during the physical examination (e.g., skin masses [mast cell tumors]) or during the ultrasound examination should be aspirated and evaluated cytologically.

The diagnostic examination of choice to confirm GI ulceration is endoscopy. Ulcers may be disseminated throughout the gastric mucosa (long-term use of NSAIDs in dogs) or present on the lesser curvature at the entrance of the pyloric antrum (acute NSAID toxicosis, gastric tumors) (**Figures 9.28** and **9.29**). Mucosal biopsies should be collected around the ulcer margins and in other areas and evaluated histologically. In cases of gastric neoplasia, an effort should be made to collect deep biopsies of the tissue surrounding the ulcer(s).

Management/Prevention

Supportive treatment is essential and includes correction of fluid and electrolyte deficits and administration of antiemetics as needed. If the animal is in pain, appropriate analgesia should be provided using opioid drugs. A surgical approach is required after initial stabilization of the patient in cases of perforated ulcers and associated peritonitis.

Protection of the gastric mucosa with inhibitors of acid secretion is essential. Proton pump inhibitors (PPI; e.g., omeprazole) are considered more effective than histamine type-2 receptor antagonists (H2-RA;

FIGURE 9.28 Gastroscopic view from a young Dalmatian that accidentally ingested a high dose of naproxen. A sharply delineated peptic ulcer is visible on the lesser curvature.

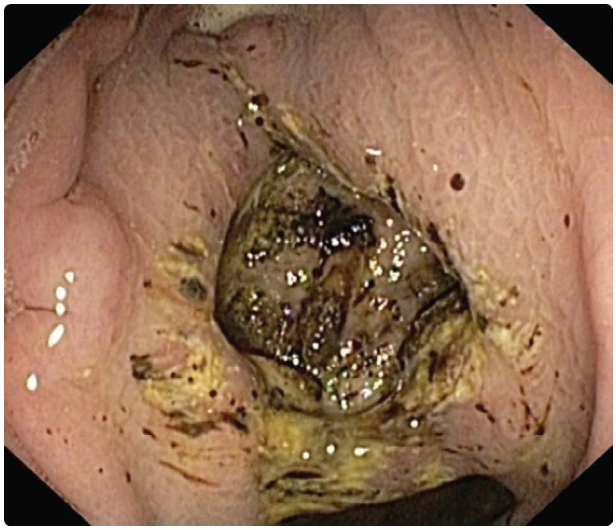

FIGURE 9.29 Gastroscopic view from an older mixed-breed dog showing an ulcerated gastric adenocarcinoma with a deep ulcerated center and raised edges. (*Courtesy of R. Husnik.*)

e.g., famotidine, ranitidine) for providing continuous acid suppression during their duration of action. Among H2-RA, famotidine is more reliably efficacious than ranitidine and cimetidine. Inhibitors of acid secretion should be administered over a prolonged period of time to dogs and cats with GI ulcers (4–6 weeks). Additionally, sucralfate is the drug of choice to coat ulcers and promote a quicker re-epithelization and healing. It is usually administered simultaneously with an H2-RA or PPI, although there is still some debate about the value of staggering oral administration of sucralfate and acid suppressants. Misoprostol is an oral prostaglandin E analog that has been used with success in dogs with NSAID toxicosis (see dosage in Table 9.4). Additionally, treatment of identified underlying conditions should be initiated as early as possible.

Dietary support for gastric ulcers should consist of an easily digestible diet that is low in fiber and fat and promotes rapid gastric emptying. Alternatively, in some patients, the preferred diet may need to be selected on the basis of identified underlying diseases (e.g., hydrolyzed diet in IBD, "renal diet" in chronic kidney disease).

Prevention of GI ulcers is recommended in patients at risk. First, simultaneous administration of steroid and NSAIDs or treatments involving combinations of NSAIDs should be avoided at all costs. In animals with severe joint pain that are unresponsive to single-agent therapy, opioids and/or gabapentin should be considered as part of the analgesic protocol. Dogs and cats with a significant burden of mast cell tumors are likely to benefit most from H2-RA therapy. In high-risk patients such as dogs with intervertebral disc disease treated with corticosteroids or NSAIDs, PPIs or H2-RA are often administered in the hope of limiting the extent of gastric mucosal lesions. Similarly, dogs receiving long-term NSAIDs chronic osteoarthritis or other orthopedic problems may benefit from preventive gastroprotective treatment, particularly once they have experienced signs of erosive/ulcerative gastritis. Misoprostol may be of benefit as well. Other risk situations include dogs receiving high immunosuppressive doses of corticosteroids to treat various immune-mediated diseases, although there is no documented benefit of preventive use of inhibitors of gastric acid production in these patients.

Prognosis

In the absence of perforation, canine GI ulcers are usually associated with a good outcome if their cause can be identified and eliminated (e.g., acute NSAID toxicosis). However, in many instances, the underlying disease may significantly compromise the prognosis (e.g., gastric neoplasia, chronic liver failure, chronic kidney disease). Cats with GI ulcers secondary to gastric lymphoma, gastrinoma, and mastocytosis appear to have a good prognosis.

Dogs with perforated gastric or duodenal ulcers that undergo surgery usually have a reasonable survival if the underlying problem can be successfully addressed. However, only 50% of dogs with nonmalignant perforated ulcers survived in a study from the UK. In cats, surgically treated perforated GI ulcers appear to have a good prognosis.

GASTRIC DILATATION AND VOLVULUS

Definition/Overview

Gastric dilatation–volvulus (GDV) is a syndrome that occurs in large to giant breed dogs and is characterized

by rotation of the stomach on its mesenteric axis followed by gaseous gastric distension.

Etiology

The precise etiology of GDV is unknown. Identified risk factors include a narrow and deep thoracic conformation, stress, and nutritional factors that ultimately lead to rapid filling of the stomach with large quantities of food or water. For instance, once-daily feeding, rapid ingestion of a meal, exercising after a meal, and eating from a raised platform all have the potential to trigger GDV.

Pathophysiology

The pylorus moves ventrally from the right to the left with a resulting rotation of 90–360 degrees and positions itself near the gastric cardia on the left side. Gas accumulates in the stomach, since neither eructation nor aboral emptying is possible. The distended stomach compresses the caudal vena cava and the portal vein, resulting in decreased venous return to the heart, decreased cardiac output, and ultimately cardiovascular collapse.

Clinical Presentation

Abdominal distension with tympany, abdominal pain, retching or vomiting (often nonproductive), hypersalivation, and acute collapse are common presenting signs. Hypovolemic and/or distributive shock may be noticeable on presentation (tachycardia, weak pulses, pale mucous membranes with abnormal capillary refill time).

Differential Diagnosis

Gastric dilatation secondary to food engorgement, mesenteric volvulus, splenic torsion, diaphragmatic tear with gastric herniation.

Diagnosis

Typical history and physical examination are suggestive; however, they do not allow differentiation between gastric dilatation and GDV. Gastric volvulus is confirmed with right lateral abdominal radiographs (Figure 9.30). However, aggressive shock treatment and attempts to deflate the stomach are often necessary before obtaining survey abdominal films.

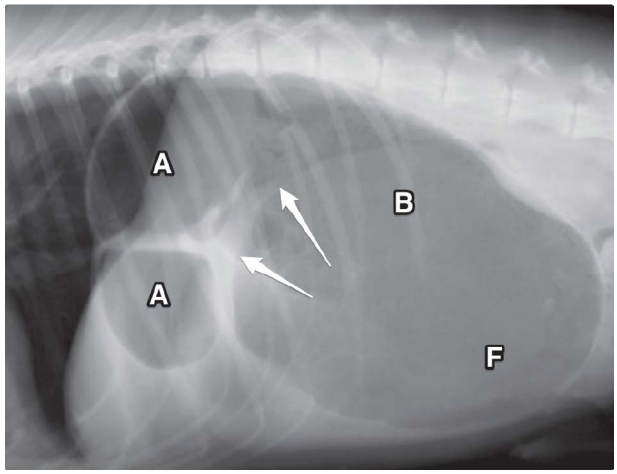

FIGURE 9.30 Right lateral abdominal radiograph of a dog with gastric dilatation–volvulus. The antrum (A) is visible in the dorsocranial aspect of the abdomen while the fundus (F) and body (B) are located more caudal. Compartmentalization of the stomach is visible (arrows). (*Courtesy of L. Gaschen.*)

Box 9.3 Procedure for passage of an orogastric tube in a dog with gastric dilatation–volvulus

- **Material:** Use largest-diameter, smooth-surfaced, flexible orogastric tube possible (e.g., greater than 9.5 mm outside diameter in large dogs). Water-soluble lubricating jelly. Canine mouth speculum (e.g., roll of 2-inch adhesive tape).
- **Sedation:** With exception of recumbent or severely affected dogs, mild sedation is usually required. One option is IV administration of butorphanol (0.2–0.4 mg/kg) with diazepam (0.2–0.5 mg/kg).
- **Preparation:** Mark the distance from the canine tooth to the last rib on the tube using piece of tape.
- **Introduction:** Cover the end of the tube with lubricating jelly and gently introduce the tube through the speculum, pharynx, and esophagus. When the level of the tape marking is reached, the tube should be at the lower esophageal sphincter. Gently rotating the tube may be required to pass the sphincter. Passage through the lower esophageal sphincter should not require force.
- **Limit:** The procedure should be aborted if the stomach cannot be intubated after a few attempts. Consider percutaneous gastric trocharization (see text).

Management

Aggressive treatment of cardiovascular collapse using two large bore catheters placed in each cephalic vein is lifesaving and needs to be initiated immediately after presentation. (See Chapter 23 for proper choice of fluids and required doses.) If surgery needs to be delayed (e.g., because of fluid resuscitation), orogastric intubation is attempted in order to decompress the stomach and lavage its content (Box 9.3). If attempts at orogastric intubation are unsuccessful, percutaneous trocharization may be performed using a 3-inch 12- to 14-gauge IV catheter that is introduced into the stomach caudally to the last rib in the left flank after the region is clipped and aseptically prepared. This usually causes some peritoneal contamination with gastric content. Ultimately, explorative celiotomy with repositioning of the stomach is followed by evaluation of gastric wall vitality (Figure 9.31). Partial gastrectomy may be required if segments of the stomach are devitalized; partial or total splenectomy

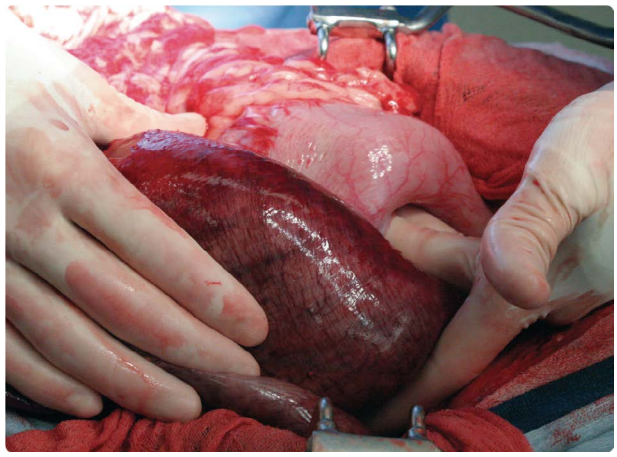

FIGURE 9.31 Exploratory celiotomy of a dog with gastric dilatation–volvulus after repositioning of the stomach. A devitalized portion of the stomach (antrum) is shown in the foreground and compared with the normally perfused body. (*Courtesy of D. Ogden.*)

may be necessary in the presence of splenic necrosis, infarction, or torsion. Gastropexy (pyloric antrum to right abdominal wall) is recommended to lower the likelihood of recurrence. Cardiac dysrhythmias commonly occur and need to be addressed if they significantly compromise cardiac output. Hypokalemia and hypomagnesemia need to be diagnosed and treated as they may complicate cardiac arrhythmias.

Prognosis

The overall mortality rate is currently between 10% and 27%. Negative prognostic factors include > 6-hour duration of clinical signs, post-fluid therapy serum lactate concentration > 6.4 mmol/L or < 4 mmol/L decrease between pre- and post-fluid lactate, and devitalized gastric wall with need for gastric resection.

GASTRIC OUTLET OBSTRUCTION

Causes of gastric outlet obstruction include gastric FBs, antral pyloric hypertrophy, and gastric neoplasia as well as gastric pythiosis.

GASTRIC FOREIGN BODY

Definition/Overview

Young animals are more likely to play with foreign objects, but ingestion of gastric FBs may occur in animals of any age. While many dogs are indiscriminate eaters at risk for any type of GI FB, cats are more likely to ingest linear FBs.

Etiology

FBs may consist of bones, toys, socks, towels, or linear material such as string or wool. Linear FBs may lodge at the pylorus and cause intestinal perforation and peritonitis. Hair balls may be a problem, especially in long-haired cats (Box 9.4).

Box 9.4 The problem of feline hairballs

While hairballs commonly occur, particularly in long-haired cats, they do not usually cause significant health problems. Typically, affected cats vomit occasionally while remaining otherwise healthy ("healthy vomiters"). The formation of hairballs may be related to the unusual fasted digestive motility pattern displayed in cats, which may make the emptying of hair material into the duodenum more difficult. This promotes gastric retention of swallowed hair and ultimately formation of a hairball.

In most cats, treatment involves administration of a petroleum laxative or dietary supplementation with a bulk laxative. Psyllium is sufficient to control the problem. Long-haired cats may benefit from regular clipping. In some cats, trichobezoars may form, cause chronic gastritis, and/or obstruct the gastric outlet and, therefore, require endoscopic or surgical extraction. Frequent vomiting of hairballs may also be an early sign of chronic enteropathies and should prompt clinicians to initiate further diagnostic tests. This is particularly true in short-haired cats, which are usually not prone to having hairballs.

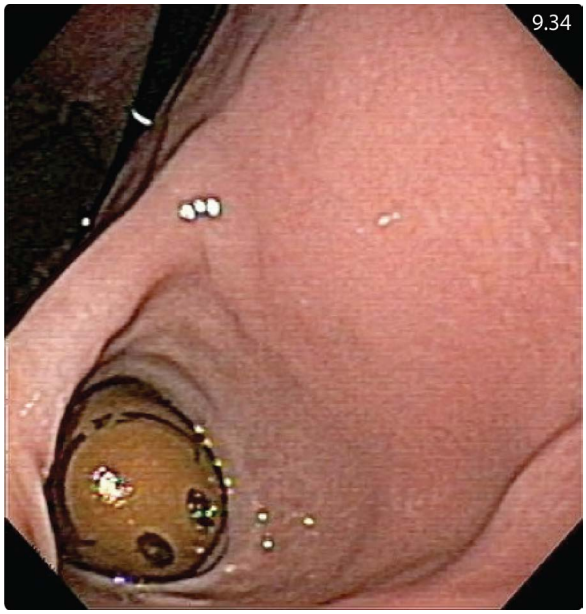
Pathophysiology

Gastric outlet obstruction may cause hypokalemic metabolic alkalosis.

Clinical Presentation

History of possible FB ingestion and acute-onset vomiting in an otherwise normal animal. Anorexia and lethargy are commonly associated signs. Cranial abdominal discomfort or pain may be elicited on palpation. Dehydration and electrolyte and acid–base abnormalities are frequent complications.

Differential Diagnosis



Dietary indiscretion and GI infections (e.g., parvovirus) are the most important differential diagnoses in puppies. In adult dogs, acute gastritis due to dietary indiscretion and acute pancreatitis are the top two differentials. However, any GI or systemic disease-causing acute vomiting should be considered both in dogs and cats.

Diagnosis

Diagnosis is confirmed with abdominal imaging. Survey radiographs may show a dilated stomach full of food or secretions for a prolonged period after meals. In some cases, the foreign object may be visible (Figures 9.32 and 9.33). In case of doubt, contrast radiographs may help to visualize the obstruction more accurately. Alternatively, ultrasound examination of the stomach may confirm the presence of a foreign object.

FIGURES 9.32–9.34 Eight-year-old male neutered Pekingese presented with a 10-day history of anorexia, vomiting, and lethargy. (**Figure 9.32**) Ventrodorsal abdominal radiograph. A round structure of soft tissue density is visible surrounded by gas in the pyloric antrum. (**Figure 9.33**) The foreign body is not visible in this dorsoventral view where gastric gas has accumulated in the fundus. This highlights the importance of obtaining both ventrodorsal and dorsoventral views for an optimal evaluation of the stomach. (*Radiographs courtesy of LSU SVM Diagnostic Imaging Service.*) (**Figure 9.34**) Gastroscopic view. A bouncing ball with a smiley face is visible in the pyloric antrum and could easily be extracted using an endoscopic snare.

Management

Gastric FBs need to be removed either endoscopically (Figures 9.34 and 9.35) or surgically. Foreign material that has partially passed into the duodenum (e.g., socks, towels) should be removed surgically. Fluid therapy is promptly initiated to replace deficits and stabilize the patient prior to inducing anesthesia.

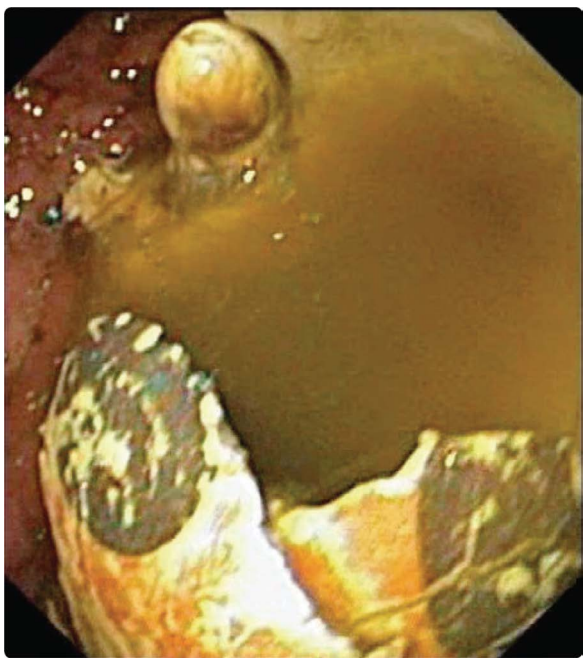


FIGURE 9.35 Gastroscopic view of a dog that had chewed and swallowed parts of a plastic soccer ball. Typical clinical signs had been present for 3 weeks.

Prognosis

Prognosis is generally good once the foreign material has been removed. It may be guarded to poor in severely debilitated animals or in cases with gastric perforation and peritonitis. Possible surgical complications include dehiscence and peritonitis.

GASTRIC ANTRAL PYLORIC HYPERTROPHY

Definition/Overview

Thickening of the antral wall may be due to hypertrophy of the mucosa, the muscularis, or both layers. Acquired pyloric antral hypertrophy is most commonly due to hyperplasia of the antral mucosa and occurs preferentially in middle-aged to older small breed dogs (e.g., Lhasa Apso, Pekingese, Maltese, and Shih Tzu). Congenital pyloric hypertrophy characterized by hyperplasia of the antral muscularis is a rare congenital disorder of brachycephalic breeds such as Boxers, Boston Terriers, and Bulldogs and has also been reported in Siamese cats.

Etiology/Pathophysiology

The exact causes and pathophysiology remain unknown. An increased frequency of GI tract lesions was reported in brachycephalic dogs, and acquired pyloric antral hypertrophy was diagnosed endoscopically in > 80% of examined dogs, although most of the dogs did not show any clinical signs. An association was suggested between the chronic inspiratory dyspnea seen in these breeds and chronic duodenogastric reflux, which may be the cause of the antral mucosal hypertrophy.

Clinical Presentation

Chronic, intermittent vomiting that worsens progressively with severity of the mucosal hypertrophy and resulting pyloric obstruction. In puppies and kittens with the congenital form, signs start after weaning. Projectile vomiting may occur.

Differential Diagnosis

Other diseases of the stomach, chronic pancreatitis, diseases originating outside the GI tract (e.g., chronic kidney disease).

Diagnosis

Survey abdominal radiographs or abdominal ultrasound may suggest delayed gastric emptying and show thickening of the antral wall. Barium contrast studies may be useful to visualize the narrowing of the pyloric passage. Diagnosis is confirmed with gastroscopy or surgical exploration and histologic evaluation of mucosal or full-thickness biopsies. Antral mucosal folds can easily be viewed on endoscopic evaluation of the stomach (Figures 9.36 and 9.37). Histopathologic examination of mucosal biopsies confirms the mucosal hyperplasia.

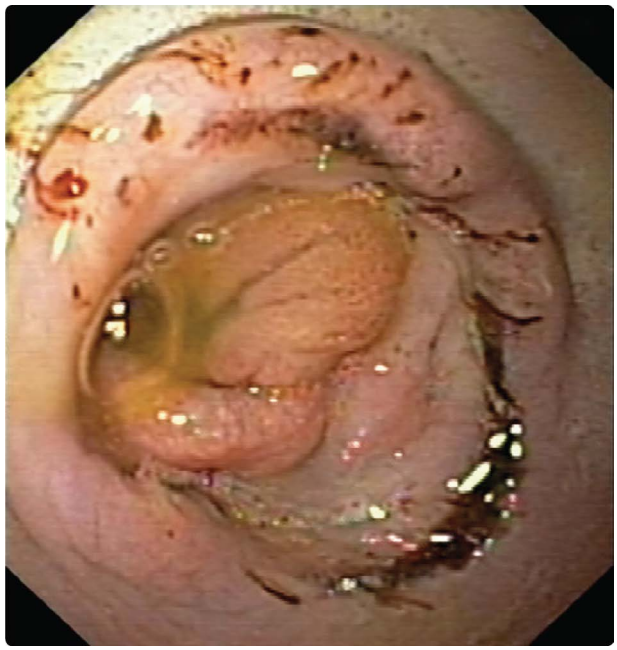

FIGURE 9.36 Gastroscopic view of the pylorus in a French Bulldog with gastric antral pyloric hypertrophy. Note the prominent mucosal folds surrounding the pylorus, with multiple erosions (bleeding) that may be associated with duodenogastric reflux. (*Courtesy of P. Lecoindre.*)

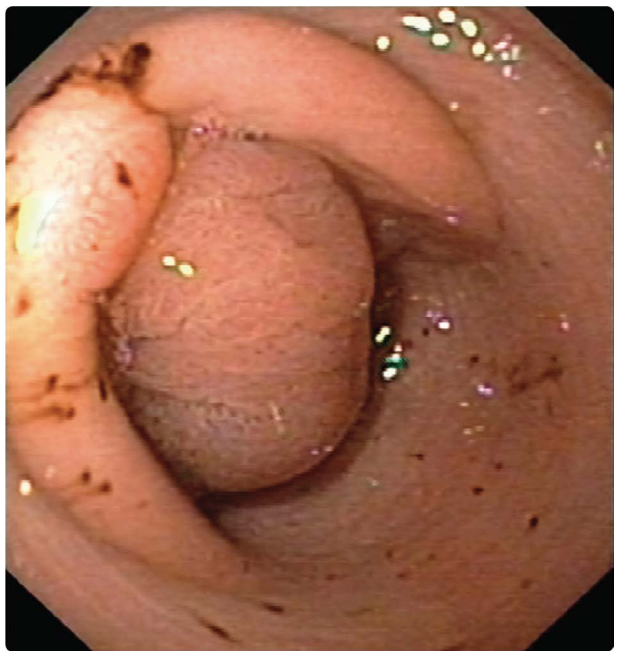

FIGURE 9.37 Gastroscopic view of the pylorus in a Boxer dog with gastric antral pyloric hypertrophy. Note the prominent mucosal fold obstructing the pylorus. There are multiple erosions (bleeding) surrounding the pylorus. (*Courtesy of P. Lecoindre.*)

Management

Treatment is surgical and consists of removing the redundant tissue and performing a Y-U pyloroplasty. Tissue specimens should be submitted for histologic confirmation. In some instances, pyloric antral resection may be required. Pyloric myotomy, while easier to perform, is usually not successful in these animals. In brachycephalic dogs, surgical correction of brachycephalic airway obstructive syndrome should be considered to address the underlying factor.

Prognosis

Surgery is curative, and the prognosis is good. Possible surgical complications include dehiscence or lack of improvement due to inappropriate surgical technique.

NONOBSTRUCTIVE GASTRIC EMPTYING DISORDERS

Definition/Overview

Motility is often the "missing link" in the complex equation of GI health in dogs and cats. The prevalence of GI motility disorders in small animals cannot be precisely documented because obtaining a definitive diagnosis is often difficult, sometimes even impossible. However, it is thought that these disorders are of significant clinical importance.

Etiology

Elucidating the origin of nonobstructive GI dysmotility is often challenging. Often, it results from diseases located outside the stomach and intestines, including abdominal inflammation (e.g., acute pancreatitis), immune-mediated diseases, and metabolic diseases. Alternatively, motility disorders may also result from primary GI disorders such as GI inflammation or neoplasia. Furthermore, diseases affecting the autonomic nervous system, such as dysautonomia, also impact GI motility. Finally, postoperative ileus has been shown to cause a significant delay in gastric emptying of up to 48 hours in dogs undergoing abdominal surgery.

Clinical Presentation

Vomiting of more or less digested food is the most common clinical sign, particularly when it occurs long after food intake (e.g., > 10–12 hours), when the stomach should be empty. Projectile vomiting may occur in the absence of a prodromal phase. Additionally, the animal may be bloated and have pain on cranial abdominal palpation and/or signs of colic. Hyporexia or anorexia, signs of nausea, increased belching, pica, and/or polydipsia may also be observed.

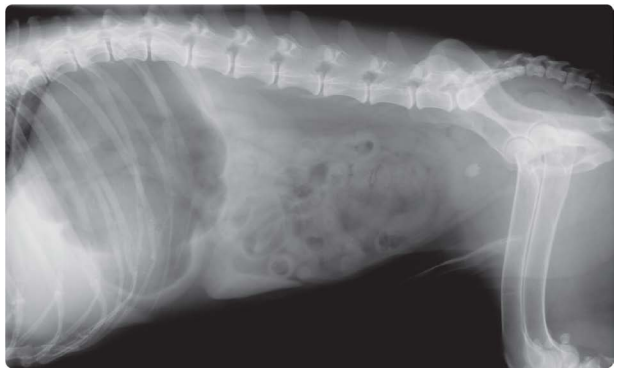

FIGURE 9.38 Right lateral abdominal radiograph of a 15-year-old male neutered Cocker Spaniel with recurrent episodes of bloat and colic. The stomach is dilated with gas, but there is no indication of gastric outlet obstruction. Note that a radiopaque cystourolith is visible.

Differential Diagnosis

Due to the relatively vague clinical signs, the list of differential diagnoses is long. It is essential to first rule out GI obstruction, which may require immediate surgical management.

Diagnosis

Since many underlying disorders may affect gastric motility, a minimal database (CBC, chemistry panel, urinalysis) plus survey abdominal radiographs are necessary to screen for underlying diseases and confirm the absence of GI obstruction (Figure 9.38). Accurate assessment of gastric emptying is difficult under practical conditions. Radionuclide scintigraphy is recognized as the current gold standard in dogs and cats but is only available at select referral centers. Radiographic studies are easily accessible in clinical veterinary practice. However, assessment of gastric emptying of liquid barium is an insensitive technique, with the exception of diagnosis of mechanical obstructions. Mixing barium with food may allow better evaluation of the solid phase of gastric emptying. Unfortunately, barium can easily dissociate from the test meal and cause the study to be unreliable. Barium-impregnated polyethylene spheres (BIPS) have been used for evaluation of GI transit times in dogs and cats. However, correlation between gastric emptying of BIPS and the gold standard has been disappointing in dogs and in cats, and the use of these spheres has been limited. Abdominal ultrasound is a promising and widely available modality for the evaluation of gastric antral motility and gastric emptying.

Management

Proper diagnosis and treatment of any underlying disease that may affect gastric motility are essential. Therapy of functional, nonobstructive disorders of gastric motility is based on dietary modification and judicious use of prokinetic drugs.

Dietary modifications designed to facilitate gastric emptying are based on knowledge of digestive

TABLE 9.7 Site of action and recommended dosage of gastrointestinal prokinetics

Name	Site of action	Dose
Metoclopramide	Pyloric antrum, duodenum (?)	0.2–0.5 mg/kg p.o., SC q.8h. CRI: 1–2 mg/kg/24h.
Cisapride	Lower esophagus (C), lower esophageal sphincter, pyloric antrum, small intestine, colon	0.1–0.5 mg/kg p.o. q.8–12h.; dose can be progressively increased up to 1 mg/kg q.8h.
Mosapride	Pyloric antrum	0.25–2 mg/kg p.o. q.12–24h. (D); currently only available in Asia
Prucalopride	Pyloric antrum, small intestine (?), colon	0.01–0.6 mg/kg p.o. q.12–24h.
Erythromycin	Lower esophageal sphincter (D), pyloric antrum, small intestine, colon	0.5–1.0 mg/kg p.o. or IV q.8h. (after dilution)

C, cat only; CRI, constant rate infusion; D, dog only.

physiology. First, gastric emptying of liquid food is faster than that of solid foods. Also, diets with high-caloric density tend to remain longer in the stomach. In addition, gastric emptying of fat is slower than that of proteins, which is slower than that of carbohydrates. Consequently, feeding a liquid or semi-liquid diet of low-caloric density, low in fat and protein should maximize gastric emptying. Finally, increased meal frequency and decreased meal size are also useful. Dietary treatment of bilious vomiting or duodenogastric reflux consists of feeding a light meal late at night. Additionally, prokinetic drugs may be beneficial in nonobstructive disorders of gastric emptying (Table 9.7).

Prognosis

Prognosis is good if the primary cause of delayed gastric emptying can be identified and corrected. Idiopathic GI dysmotility can be a challenge to manage efficiently. Dysautonomia carries a poor prognosis in cats and dogs.

GASTRIC NEOPLASIA

Definition/Overview

Stomach tumors are uncommon and typically occur in older in dogs and cats. Benign canine gastric neoplasms include adenomatous polyps and leiomyomas. Adenocarcinoma and lymphoma are the most prevalent tumor types diagnosed in the dog, followed by leiomyosarcoma and stromal tumors. Lymphoma is the most common gastric neoplasia found in cats.

Etiology

The etiology of gastric tumors has not been elucidated. Canine breeds at risk for adenocarcinoma include the Belgian Shepherd Dog, Rough Collie, and Staffordshire Bull Terrier. A predisposition in male dogs has been reported for gastric adenocarcinoma and gastric lymphoma.

Clinical Presentation

The early stages of gastric neoplasia usually remain subclinical. Hyporexia is the most common clinical sign followed by vomiting and weight loss. In advanced stages with ulceration of the gastric mucosa, hematemesis and melena may occur. Vomiting is due either to gastric outflow obstruction or to abnormal gastric motility associated with the neoplastic wall infiltration. Adenomatous polyps are usually subclinical unless they cause gastric outflow obstruction.

Differential Diagnosis

Other disease processes causing gastric outflow or small intestinal obstruction (FBs, pythiosis). Other conditions associated with hyporexia/anorexia and vomiting that originate from the GI tract or from other organ systems.

Diagnosis

A minimal database consisting of CBC, biochemistry panel, and urinalysis is recommended to evaluate the general condition of the animal and screen for possible systemic repercussions of gastric tumors such as blood loss anemia. Diagnosis is confirmed with abdominal imaging. In some instances, survey abdominal radiographs may reveal an enlarged stomach with delayed emptying (Figure 9.39). Filling defects or ulcerated areas

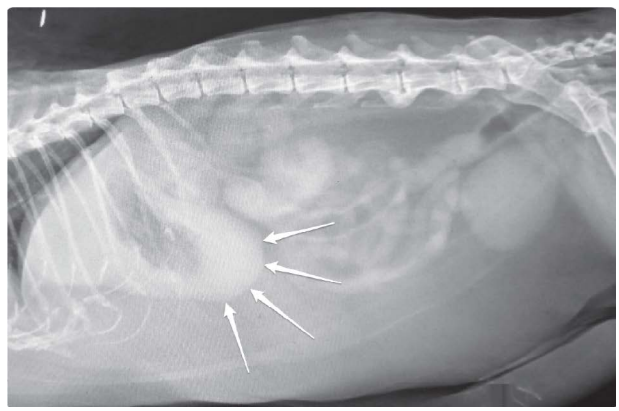

FIGURE 9.39 Twelve-year-old Domestic Shorthair cat with anorexia, weight loss, and lethargy of 4 weeks' duration. Right lateral abdominal radiograph. The cat was severely overweight. Although the cat did not eat for 2 days, the stomach is distinctly visible and partially filled with gas (arrows). The gastric wall appears thickened at the level of the pyloric antrum (although this could also be due to summation of gastric fluid and gastric wall), and the serosal contour of the stomach is somewhat irregular. (*Courtesy of C. Montgomery.*)

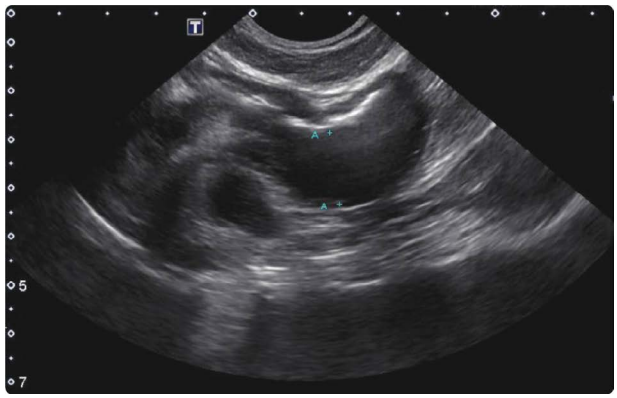

FIGURE 9.40 Abdominal ultrasound of the same cat as Figure 9.39. The gastric wall at the level of the pyloric antrum was severely thickened (14.8 mm between the two calipers).

may be detected on contrast studies. Abdominal ultrasound often shows thickening of the gastric wall (Figure 9.40). Most canine gastric adenocarcinomas are located in the antral area or on the lesser curvature, while lymphomas are often diffusely infiltrative. Enlarged lymph nodes and/or hepatic nodules suggestive of local metastases may be visible (Figure 9.41). Double lateral thoracic radiographs are useful to screen for pulmonary metastases. Cytologic evaluation of ultrasound-guided aspirates of the abnormal gastric wall may be helpful to diagnose lymphoma (Figure 9.42). Endoscopic evaluation with sampling of mucosal biopsies in and around the suspect areas (Figures 9.29 and 9.43) and histologic evaluation are useful to confirm the tumor type. While no appearance is typical for one specific tumor type, most adenocarcinomas are ulcerated. Occasionally, tumors are located in the submucosal layers (linitis plastica) and obtaining representative endoscopic biopsies may be challenging.

Management/Prognosis

By the time animals develop clinical signs and are presented to a veterinarian, the neoplastic process is often advanced and severe. Probably due to a high prevalence

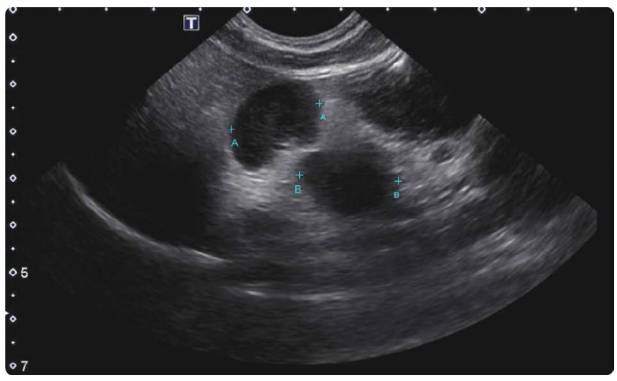

FIGURE 9.41 Abdominal ultrasound of the same cat as Figures 9.39 and 9.40. The gastric lymph nodes were very prominent (distance "a", 19.6 mm; distance "b", 21.2 mm). (*Ultrasound images courtesy of LSU SVM Diagnostic Imaging Service.*)

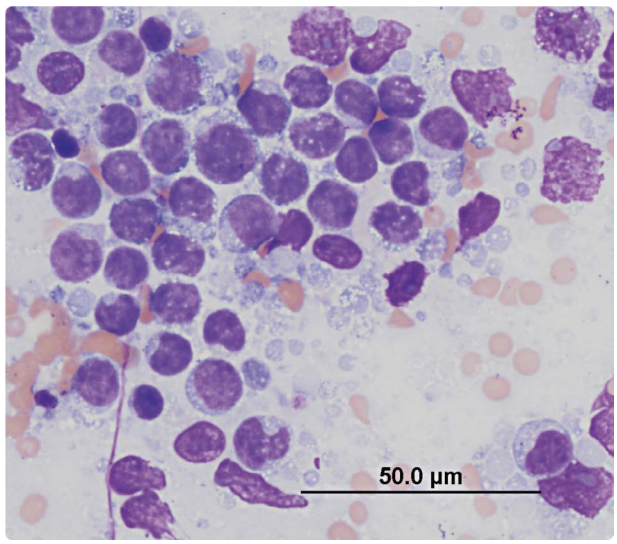

FIGURE 9.42 Cytologic evaluation of a fine-needle aspirate from the gastric wall depicted in Figures 9.39–9.41. A dense population of medium-sized lymphocytes and a few large lymphoblasts are visible, confirming the diagnosis of gastric lymphoma (50× objective). (*Courtesy of V. Le Donne.*)

of metastases at the time of diagnosis, surgical resection (antral resection and gastroduodenostomy, or Billroth type I procedure) does not significantly improve the prognosis of dogs with gastric adenocarcinomas. However, surgery may be a successful option for canine leiomyosarcomas, with a reported median survival time of 12 months. While canine gastric lymphomas usually carry a poor prognosis, feline alimentary lymphomas

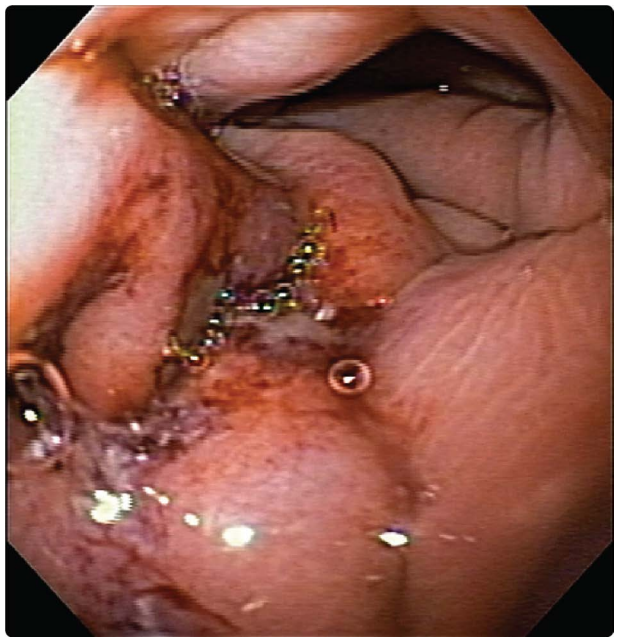

FIGURE 9.43 Close-up endoscopic view of a gastric adenocarcinoma in a 15-year-old female spayed Miniature Schnauzer. There are thickened mucosal folds surrounding an ulcerated area.

may respond to specific chemotherapy protocols. Small-cell feline alimentary lymphomas usually achieve prolonged remission with prednisolone (1–2 mg/kg p.o. daily) and chlorambucil (2 mg p.o. q.48h.) therapy. Large-cell alimentary lymphomas require more aggressive chemotherapy protocols, and their prognosis is less favorable.

PART 4: DISEASES OF THE SMALL INTESTINE

Overview

Small intestinal diseases are common in dogs and cats. The small intestine is the intestinal segment where absorption of nutrients, electrolytes, and water takes place. Small intestinal brush border enzymes are essential for activation of pancreatic enzymes and final processing of nutrients before they can be absorbed through the mucosa using active and passive diffusion mechanisms.

Small Intestinal Anatomy

The small intestine is divided into three anatomic segments: Duodenum, jejunum, and ileum. The total surface of the small intestinal mucosa is multiplied by a factor of 500 through formation of mucosal villi and presence of microvilli on the luminal surface of the enterocytes. The microscopic structure consists of mucosa, submucosa, and both the internal and external muscular layers. The mucosa consists of villi, lamina propria, and muscularis mucosae (Figure 9.44). The epithelial cells multiply in the small intestinal crypts and migrate over a few days to the tips of the small intestinal villi while they are undergoing maturation.

Normal Small Intestinal Function

Digestion and Absorption

In the small intestine, pancreatic and gastric enzymes facilitate luminal digestion, while enzymes produced by epithelial cells and located in the brush border of enterocytes are responsible for triggering the activation of pancreatic enzymes and further processing of oligo- and disaccharides, small peptides, and lipids. Carbohydrates, amino acids, and fatty acids are transported actively or passively through the epithelial barrier using transcellular and paracellular pathways. Lipids undergo complex transformations in order to be absorbed into the epithelial cells. Chylomicrons are formed in the enterocytes and diffuse into the lacteals to the thoracic duct. The intestinal barrier prevents free passage of intestinal content into the body and consists of the enterocytes with the glycocalyx that bathes their microvilli and the tight junctions that connect them on their lateral membrane.

FIGURE 9.44 Photomicrograph of the jejunal mucosal layer in a cat. (1) Jejunal crypt; (2) tip of jejunal villus; (3) lamina propria; (4) muscularis mucosae (arrow). H&E stain, 40× objective.

Importance of the Gut Microbiome

The development of molecular biology techniques for rapid sequencing has made it possible to fully map the composition of the gut microbiome. Microbial profiling based on 16S rRNA genes was the first culture-independent method used to study the composition of the gut microbiota. In addition, metabolomics provides information about the production of microbial metabolites to define the metabolic activity of the microbiome and its interactions with the host. The intestinal microbiota contains 10× more cells and 150× more genes than the host animal. It consists of bacteria (by far the most common microorganisms), archaea, viruses, fungi, and protozoa. The most common bacterial sequences in the gut typically belong to five phyla: Firmicutes, fusobacteria, bacteroidetes, proteobacteria, and actinobacteria. The exact composition varies along the digestive tract depending on the prevailing microenvironment and the physiological function of the individual intestinal segments. For example, the small intestine is home to a mixture of aerobic and facultative anaerobic bacteria, while the large intestine is almost entirely populated by anaerobes.

The intestinal microbiome contributes to numerous metabolic functions, protects against pathogens, and promotes the development of the immune system. It thus directly or indirectly influences numerous physiological processes in the host animal. The intestinal microbial community is involved in various metabolic and physiological activities including breaking down otherwise indigestible complex carbohydrates, providing energy

sources to support the integrity of the intestinal epithelium, educating the immune system, protecting against colonization with pathogens and producing metabolites such as short-chain fatty acids, secondary bile acids, and vitamins. The gut microbiota plays an essential role in the health of the gut and other organs such as the liver and even the brain. As a result, any imbalance in intestinal microbiota (intestinal dysbiosis) can have an adverse effect on the general health of the host.

Small Intestinal Motility

Three physiologic motility patterns are described in the small intestine: Peristaltic waves (aboral movement of chyme over long intestinal segments), stationary contractions (leading to intestinal segmentation), and clusters of contraction (mixing and aboral movement of chyme over short segments). Diarrhea usually is associated with the occurrence of pathologic giant aboral contractions.

ACUTE ENTERITIS

Overview

Acute enteritis occurs frequently in dogs and cats and can be a sign of many diseases affecting the small intestine primarily or secondarily. The approach to diarrhea is explained in Chapter 2.3 (**Table 2.3.1** lists the characteristics of small and large bowel diarrhea; **Table 2.3.2** lists the various causes of acute diarrhea). This chapter provides further details on common causes of acute enteritis. Overall, viral and parasitic causes of enteritis are more commonly diagnosed in puppies and kittens, while dietary indiscretion can occur at all ages; finally, acute hemorrhagic diarrhea syndrome (AHDS) affects middle-aged to older dogs.

VIRAL ENTERITIS

CANINE PARVOVIRAL ENTERITIS

Overview

The etiology, pathogenesis, diagnosis, and prevention of canine parvovirus infection are also discussed in Chapter 21. The virus targets rapidly dividing cells such as small intestinal crypt cells (**Figures 9.45** and **9.46**). The associated damage eventually greatly diminishes the absorptive capacity of the small intestine and compromises the intestinal barrier. The risk of bacterial translocation, bacteremia, and sepsis is greatly enhanced by the concurrent neutropenia.

Clinical Presentation

The following breeds are at higher risk of infection: Rottweiler, Dobermann, Labrador Retriever, American Staffordshire Terrier, German Shepherd Dog, and Alaskan Malamute. The most severe cases occur in

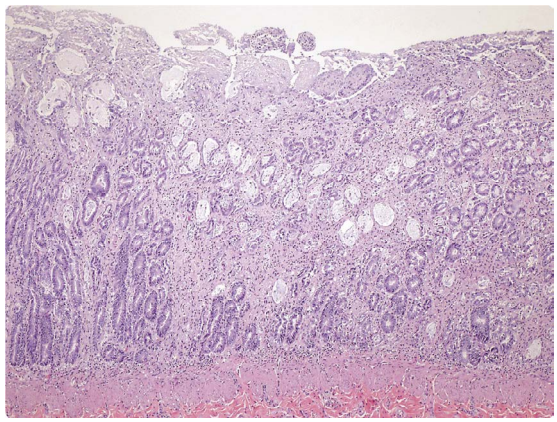

FIGURE 9.45 Six-month-old dog with parvovirus infection. Photomicrograph of the jejunal mucosa. There is severe villous atrophy with necrotic crypts (see **Figure 9.46**). Hematoxylin and eosin (H&E) stain, 40x objective. (*Courtesy of N. Wakamatsu.*)

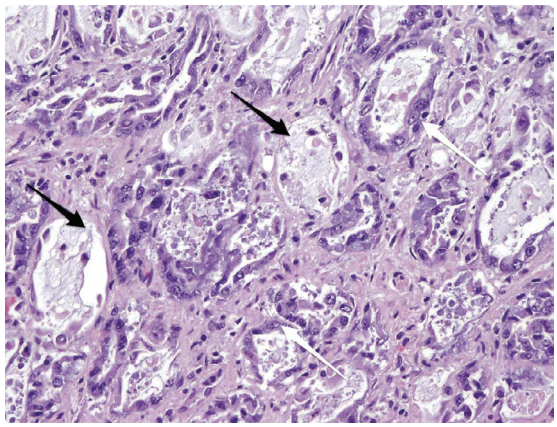

FIGURE 9.46 Photomicrograph of the jejunal crypts (same dog as **Figure 9.45**). Several crypts lack epithelial lining (black arrows) and are filled with necrotic material, while others show evidence of epithelial regeneration (white arrows). (*Courtesy of N. Wakamatsu.*)

puppies between the ages of 4 and 12 weeks, at the time when maternal immunity fades away. However, parvovirus infection is prevalent in dogs until 6 months of age. Anorexia and vomiting are often the first clinical signs observed. They are followed a few hours later by foul smelling, often bloody diarrhea (see **Figure 2.3.7**). Without treatment, puppies rapidly dehydrate. Fever is generally associated with secondary bacterial infection.

Intense vomiting and diarrhea may cause metabolic acidosis that often responds well to IV fluid therapy with crystalloids and generally does not require administration of sodium bicarbonate. Hypokalemia results from GI loss and may contribute to the occurrence of small intestinal intussusception. In severe cases, life-threatening complications, including sepsis and disseminated intravascular coagulation, may occur.

Differential Diagnosis

In puppies or in young dogs presented for acute vomiting, the differential diagnosis must include GI FB and

intestinal intussusception, which should be ruled out with abdominal radiographs. "Garbage can gut" and severe infestation with intestinal parasites may also cause hemorrhagic gastroenteritis.

Diagnosis

A preliminary diagnosis of parvovirus infection is made in the presence of acute hemorrhagic gastroenteritis in a young dog that is not adequately vaccinated. The probable presence of a highly contagious disease justifies drastic measures to prevent the spread of the infection in the veterinary hospital (isolation of the sick dog, thorough disinfection). Confirmation of diagnosis requires fecal testing for parvoviral antigen using a cage-side test. The antigen test may be positive during the viral shedding period, which lasts for 10–12 days after infection. However, the result may be falsely negative as viral shedding may wax and wane. Also, the test can give a false-positive result in dogs that have been recently vaccinated with a modified live vaccine. In such cases, fecal PCR may be useful to differentiate vaccine and wild-type virus. Neutropenia is a typical finding in dogs with parvovirus infection; however, it is not always present at the time of the initial veterinary visit. Detection of other laboratory changes may be useful to set up an adequate treatment plan. Electrolyte abnormalities, especially hypokalemia, should be corrected. Panhypoproteinemia (characterized by simultaneous presence of hypoalbuminemia and hypoglobulinemia) is due to intestinal protein loss. Depending on the severity of the problem, there may be a need for colloids (e.g., plasma) to support oncotic pressure.

Management

Aggressive treatment is required and consists of rapid correction of fluid deficits and electrolyte imbalances. Crystalloids are used in adequate amounts with added electrolyte solutions as needed. However, a recent study has suggested good success in treating dogs with parvovirus infection on an outpatient basis (**Box 9.5**).

It is essential to stop the vomiting as quickly as possible. A variety of antiemetic agents are available (see Chapter 2.17, **Table 2.17.1**). A combination of antiemetic drugs with different modes of action is sometimes required to obtain the desired result. Recent research has shown the benefits of early feeding in very small amounts; dogs that received early nutrition after they stopped vomiting had a lower mortality and a faster weight gain during recovery.

Because of the risk of secondary bacterial infection, parenteral administration of broad-spectrum antibiotics such as amoxicillin and clavulanic acid (12.5–20 mg/kg IV q.12h.) is recommended. Parenteral aminoglycosides (with risk of nephrotoxicity) or fluoroquinolones (e.g., enrofloxacin 10 mg/kg q.24h. off-label in growing dogs) may be added to improve efficacy against Gram-negative bacteria. The value of fecal microbiota transplantation (FMT) was highlighted in a recent study where puppies with parvovirus infection that received daily FMT in addition to conventional treatment had faster resolution of diarrhea and shorter hospitalization times than those that did not.

Box 9.5 Practical tip: Outpatient treatment of canine parvovirus infection

An outpatient treatment for dogs with parvoviral enteritis was evaluated in a recent study. After initial in-hospital stabilization with IV fluids, the outpatient treatment consisted of:
- SC administration of isotonic fluids (30 mL/kg q.6h. after replacement of fluid deficits)
- Enteral nutrition (commercial recovery diet approx. 1–1.2 kcal/kg q.6h. syringe-fed PO)
- Daily SC injections of maropitant (1 mg/kg)
- One SC injection of cefovecin (8 mg/kg), a proprietary long-acting third-generation cephalosporin

The 80% survival rate compared favorably with the 90% recovery rate in hospitalized parvovirus patients treated with IV fluids. Also, there was no difference in time to recovery between the hospitalized and the outpatient group. This study shows that an outpatient protocol may be a reasonable alternative option for owners who cannot afford the costly hospitalization for puppies and young dogs infected with parvovirus. However, adequate supportive care and monitoring remain essential to maximize the chances of a rapid recovery.

Source: Venn EC, Preisner K, Boscan P, et al. (2017). Evaluation of an outpatient protocol in the treatment of canine parvoviral enteritis. *J Vet Emer Crit Care* 27(1):52–65.

Disinfection of contaminated surfaces is essential to prevent spread of infection. Disinfectants with demonstrated efficacy against parvovirus include sodium hypochlorite, aldehydes, and oxidizing agents. A 1:30 dilution of commercially available bleach is efficacious after 10 contact minutes. However, bleach is a mucosal irritant and may damage metals, rubber, plastic, and cement. It is inactivated by light; thus, it is preferable to prepare solutions immediately before their use. It is also inactivated in the presence of organic material such as mud or feces. Oxidizing solutions such as hydrogen peroxide (Virox, Accel) and potassium peroxymonosulfate (Virkon, Trifectant) claim extremely high efficacy within minutes with minimal corrosive effect.

Prognosis

Dogs with mild-to-moderate disease generally have a good prognosis if appropriate treatment is initiated early. In severe cases, the prognosis is fair because complications are more common, and therapy is more intensive. Overall, quick diagnosis and early and aggressive treatment optimize therapeutic success.

OTHER VIRAL INTESTINAL INFECTIONS

Feline panleukopenia and canine and feline coronavirus infections are discussed in detail in Chapter 21.

BACTERIAL ENTERITIS

Overview

Rarely, dogs and cats may develop bacterial enteritis. Responsible pathogenic agents include *Campylobacter*, *Clostridium perfringens*, *Clostridium difficile*, and *Salmonella* spp., as well as specific strains of *Escherichia coli*. However, these same bacteria can also be isolated in the feces of healthy dogs and cats, and it is believed that they are often opportunistic agents. Overall, the exact role of bacterial enteropathogens in dogs and cats with enteritis remains controversial. In some instances, they may present a risk of zoonotic infection for people at risk after contact with shedding dogs and cats that often do not show any sign of disease. These facts have contributed to an unclear situation that renders diagnostic and therapeutic decisions difficult. If these bacteria are not the source of the animal's problems, use of antibiotics is not recommended because it may lead to development of resistant strains, which in the long term may have repercussions on public health. Additional research is necessary to define the role of enteropathogens more clearly in canine and feline intestinal diseases.

SALMONELLOSIS

Etiology

Salmonella is rod-shaped facultative anaerobic Gram-negative bacteria of the Enterobacteriaceae family. The majority of *Salmonella* relevant to veterinary medicine are serovar *S. enterica* sub species *enterica*.

Pathophysiology

Salmonella are enteroinvasive bacteria that may induce acute mucosal inflammation resulting in enterocolitis, mucosal sloughing, and secretory diarrhea. While most *Salmonella* infections remain localized to the GI tract, bacterial translocation and septicemia may occur and cause severe systemic complications. Generally, healthy adult carnivores are resistant to salmonellosis. Consumption of raw-meat-based diets is a risk factor for *Salmonella* infection in dogs and cats. The prevalence of healthy carriers is highest in shelters.

In people, salmonellosis is characterized by diarrhea, fever, and abdominal cramps, often mild to moderate in severity and followed by spontaneous recovery. The most common infection pathway is through ingestion of contaminated food, in particular chicken eggs and egg-based products, but also pork and chicken meat or contaminated vegetables. Even though dogs and cats are only rarely implicated in outbreaks of human salmonellosis, isolated foci have been associated with visits to a veterinary hospital. This is why excellent hygiene is recommended around dogs and cats shedding *Salmonella*, particularly if sensitive subjects such as very young children, elderly people, and immunocompromised patients may be exposed.

Clinical Presentation

Fever, lethargy, and anorexia often start 3–5 days post infection or onset of immune suppression. They may be followed by vomiting and often bloody small and/or large bowel diarrhea and abdominal pain, weight loss may ensue. In case of bacterial translocation, signs of sepsis and involvement of other organs. The clinical course is usually acute to subacute.

Differential Diagnosis

Other causes of acute enteritis and/or colitis such as parvovirus infection (in puppies), parasite infestation with hookworms, whipworms, *Giardia, Cryptosporidium*, or *Tritrichomonas* (cats), other bacterial infections, dietary indiscretion, AHDS.

Diagnosis

Fecal isolation and serotyping of *Salmonella*, PCR. CBC may show changes suggestive of systemic inflammation, and biochemistry profile may indicate involvement of other organs.

Management

Treatment consists of administration of antimicrobial drugs based on documented sensitivity of the isolated strain.

Prognosis

Animals recovering from clinical salmonellosis may become healthy *Salmonella* carriers for weeks after the clinical signs have subsided. This may be due to persistence of *Salmonella* in the lymph nodes. *Salmonella* may survive for long periods in the environment.

PARASITIC ENTERITIS

The Companion Animal Parasite Council (CAPC) and the European Scientific Counsel Companion Animal Parasites (ESCCAP) maintain very informative and freely accessible websites on intestinal parasitoses of small animals that should be consulted for additional information on the parasites listed here and on other GI parasites (www.capcvet.org; www.esccap.org).

HOOKWORMS

Etiology

Hookworms are common in tropical and subtropical areas (*Ancylostoma caninum*—dog; *A. tubaeforme*—cat) and warm coastal regions (*A. braziliense*—dog, cat) but also in cooler climates (*Uncinaria stenocephala*—dog). Adult hookworms live in the small intestine and produce eggs that are shed with the host's feces and develop to third-stage larvae (L3), which are infectious.

Dogs and cats infect themselves by ingesting L3 (direct fecal–oral transmission, ingestion of infected paratenic hosts such as flies, cockroaches, and dung beetles), or through penetration of the skin by L3. In dogs, puppies can be infested by nursing an affected bitch (transmammary infection). Some larvae undergo arrested development in muscle and can be reactivated during stressful events and migrate to the intestine.

Pathophysiology

Adult hookworms ingest the host's blood and cause intestinal inflammation (Figure 9.47).

Clinical Presentation

The clinical signs consist mainly of small bowel diarrhea. Blood loss anemia can be life threatening in puppies (Figure 9.48). Hyporexia, weight loss, poor hair coat, and pica may also be observed. In dogs that were infected percutaneously, pruriginous skin lesions may occur at the points of entry, particularly in the interdigital spaces.

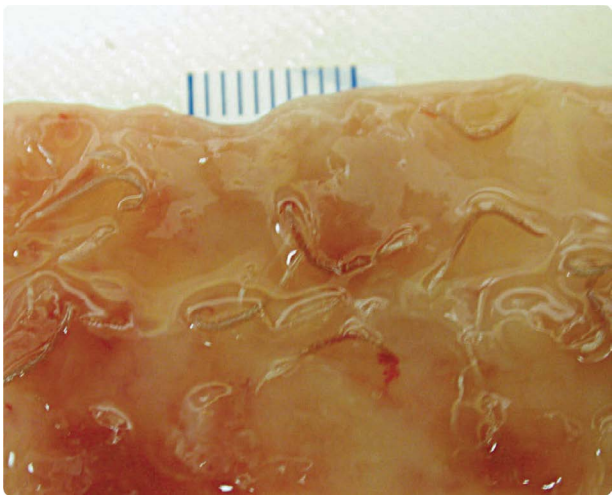

FIGURE 9.47 Postmortem view of hookworms causing damage to a dog's small bowel mucosa.

FIGURE 9.48 Pale oral mucous membranes in a 12-week-old mixed-breed puppy with massive hookworm infestation.

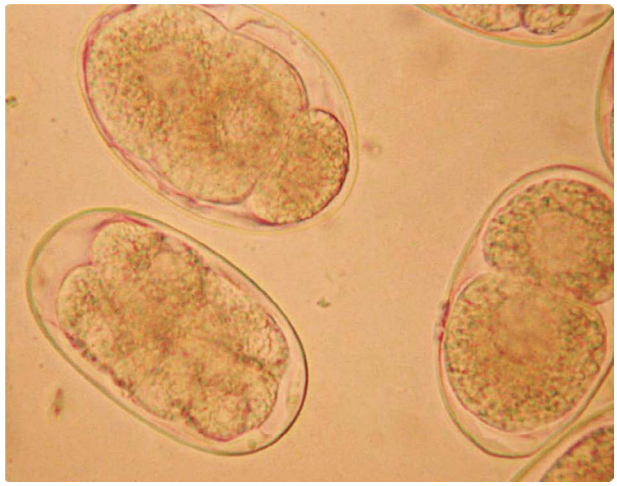

FIGURE 9.49 Photomicrograph of an *Ancylostoma caninum* ova. (*Courtesy of E. Greiner.*)

Differential Diagnosis

Other causes of acute enteritis. Acute blood loss anemia in puppies may also be caused by heavy flea infestation, which may occur concurrently to hookworm infestation in stray puppies and kittens from tropical and subtropical areas.

Diagnosis

Fecal flotation and visualization of the parasite ova (Figure 9.49).

Management/Prevention

Treatment with pyrantel pamoate (5–10 mg/kg p.o., repeat after 7–10 days) is approved for all hookworm species. Fenbendazole (50 mg/kg p.o. q.24h. for 3 consecutive days) is also efficient. The efficacy of macrocyclic lactones such as moxidectin, milbemycin oxime, and ivermectin differs between species. Alarmingly, multidrug resistance of *A. caninum* has been reported to occur in U.S. greyhounds. Supportive treatment as required: For example, anemic puppies and kittens often require blood transfusion (whole blood or packed red blood cells).

Detailed preventive treatment protocols can be found on the CAPC and ESCCAP websites.

Public Health Consideration

Cutaneous larva migrans can occur when hookworm larvae penetrate human skin and result in a pruriginous but self-limiting dermatitis ("creeping eruption").

Prognosis

Good to excellent.

ROUNDWORMS

Etiology

Ascarids that may infest small animals include *Toxascaris leonina* (dogs and cats), *Toxocara canis* (dog), and *Toxocara cati* (cat). Additionally, *Baylisascaris procyonis* (the raccoon roundworm) may also occasionally infest dogs in North America. Adult roundworms live in the small intestine (Figure 9.50) and produce eggs that are shed in the feces. Larvae are released upon ingestion of embryonated eggs and migrate to the liver and lungs. Pulmonary lesions can induce clinical signs in puppies. Larvae then undergo tracheal migration and eventually infest the small intestine, or somatic migration, with formation of cysts in tissues with possible reactivation in stressful situations.

Pathophysiology

Adult roundworms cause enteritis, particularly in puppies and kittens.

Clinical Presentation

Puppies and kittens: Vomiting, small intestinal diarrhea, poor general health, and development of a pot-belly are common. Heavy infestation can result in small intestinal obstruction or intussusception. It can also cause pulmonary signs such as coughing and tachypnea. **Adult dogs and cats:** Infestation is less common and less likely to cause clinical signs.

Differential Diagnosis

In puppies and kittens, other causes of acute enteritis; intestinal FBs if the roundworms cause bowel obstruction.

Diagnosis

Fecal flotation and visualization of the parasite ova (Figure 9.51).

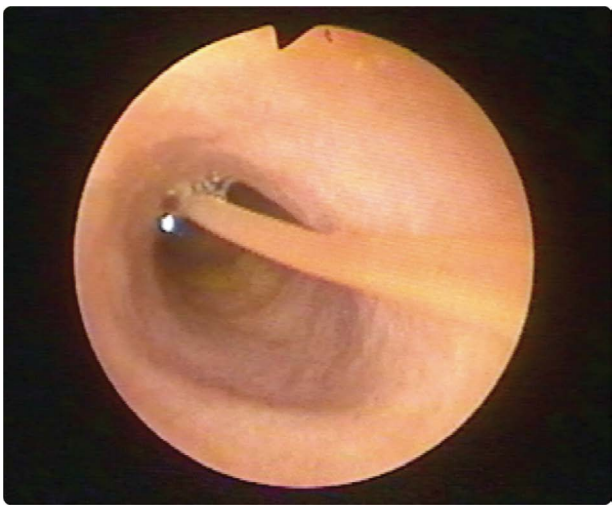

FIGURE 9.50 Endoscopic view of an adult roundworm in the duodenum of a cat. (*Courtesy of R. Husnik.*)

FIGURE 9.51 Photomicrograph of a *Toxocara canis* egg. (*Courtesy of E. Greiner.*)

Management/Prevention

Piperazine, pyrantel pamoate, fenbendazole, and selected macrocyclic lactones (e.g., milbemycin oxime, moxidectin) should be given to eliminate roundworms. Supportive treatment should be administered as required.

Detailed preventive treatment protocols can be found on the CAPC and ESCCAP websites.

Public Health Consideration

In people, ingestion of embryonated eggs from *Toxocara* spp. may lead to larva migrans and cause pulmonary and hepatic disease, retinitis, and neurologic disease. *Toxocara* larva migrans can have a devastating outcome in people.

Prognosis

Excellent.

ISOSPORA spp.

Etiology

Dog—*Isosporacanis, I. ohiensis, I. neorivolta, I. burrowsi.* Cat—*I. felis, I. rivolta.* Sporulated oocysts are ingested (directly or via paratenic hosts) and further develop in the small intestinal enterocytes (enteroepithelial cycle).

Pathophysiology

Isospora spp. replicate in the small intestine and may induce villus atrophy, lacteal dilation, and hyperplasia of the lymphatic follicles in Peyer's patches.

Clinical Presentation

Clinical signs generally only occur in puppies and kittens and may consist of vomiting, watery diarrhea, abdominal pain, and dysorexia. Dehydration and death can occur in severe cases.

Differential Diagnosis

Other causes of acute enteritis in puppies and kittens.

Diagnosis

Isospora spp. oocysts are usually large and easy to detect on microscopic examination of supernatant fluid after fecal flotation.

Management

While the disease is generally self-limiting, treatment may be required in clinical situations. The poorly absorbed sulfa drug sulfadimethoxine (50–60 mg/kg p.o. q.24h. for 5–20 days) is the only approved anticoccidial drug for dogs and cats in the United States and the United Kingdom. Other antiprotozoal drugs, such as ponazuril (20 mg/kg p.o. q.24h. for 1–3 days), are frequently administered off-label to dogs and cats after adequate compounding. In breeding facilities and shelters, proper cleaning of the environment (prompt elimination of feces before oocysts sporulate, steam cleaning of contaminated surfaces), treatment of dams prior to parturition, and preventive anticoccidial treatment of all puppies and kittens may be required.

Prognosis

Excellent.

DIETARY INDISCRETION

Definition/Overview

Dietary indiscretion is probably the most common cause of acute gastroenteritis in dogs. Overall, puppies and young dogs are more commonly affected than older dogs. Some canine breeds such as Retrievers are known to be prone to dietary indiscretion. Cats are more discriminant eaters, and dietary indiscretion is rarely diagnosed in this species.

Etiology

Ingestion of unusual food such as food prepared for human consumption, garbage that may contain food in various stages of decomposition, or any other food not usually part of the affected dog or cat's diet.

Pathophysiology

Toxins from rotting food cause small intestinal mucosal irritation and may cause osmotic and secretory diarrhea. Unusual food, such as food prepared for human consumption, cannot be properly digested and absorbed and thus can cause osmotic diarrhea.

Clinical Presentation

Acute diarrhea (with or without vomiting) is the most common presentation. Lethargy, hyporexia, dehydration, electrolyte imbalances, and abdominal discomfort are common accompanying signs.

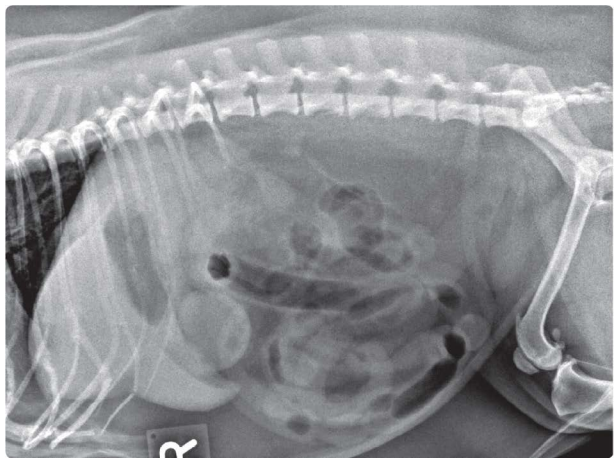

FIGURE 9.52 Right lateral abdominal radiograph from an adult mixed-breed dog with dietary indiscretion and functional ileus. Generalized distension of small intestinal loops is present. (*Courtesy of L. Gaschen.*)

Differential Diagnosis

Other causes of acute gastroenteritis/enteritis such as parasite infestation and viral or bacterial enteritis. In vomiting animals, intestinal obstruction should be ruled out with appropriate abdominal imaging (Figure 9.52). In puppies with possible exposure and questionable immune status, parvovirus infection should be ruled out prior to hospitalization.

Diagnosis

History and presentation are often very suggestive.

Management

Supportive, with administration of fluids (IV, SC, or p.o. depending on the severity of clinical signs), and antiemetics in vomiting or nauseous animals. A 12- to 24-hour fast is implemented (small puppies may require parenteral glucose solution during fasting to avoid hypoglycemia), followed by offering small meals consisting of commercial or home-made, easily digestible diet for 3–5 days and progressive return to a balanced diet after that. Probiotics may be useful (Box 9.6). In dogs with severe diarrhea and abdominal discomfort, loperamide (0.1–0.2 mg/kg p.o. q.8h.) or diphenoxylate (0.1 mg/kg p.o. q.8h.) may be indicated for 24–72 hours, although this is only rarely necessary. Dogs that live in multistory high-rise buildings might also be candidates for antidiarrheal drugs because of the difficult logistics for bringing them outdoors for defecation.

Prognosis

Good to excellent in most cases. Recurrences are common in dogs prone to eating offending foods.

Box 9.6 Practical tip: Use of probiotics in acute or chronic enteritis

- Probiotics are living microorganisms that may modulate intestinal immune function, promote epithelial cell homeostasis, exert neuromodulatory effects, block the effects of pathogenic bacteria, and have nutritional benefits.
- Probiotics designed for use in dogs and cats and manufactured by reputable pharmaceutical or pet food companies are preferred, as over-the-counter products have been shown not to be as reliable. Some products contain one bacterial strain while others include several strains. Also, concentrations of colony-forming units (CFU) vary from 1×10^8 to 1.1×10^{11} CFU per sachet or capsule.
- Very little data is available to support clinically appreciable beneficial effects of probiotics on the GI tract of dogs and cats. Various probiotics have been shown to shorten the duration of acute diarrhea in shelter cats, decrease the time to first normal feces in dogs with acute enteritis, and accelerate improvement of clinical score and recovery of the fecal microbiome in dogs with AHDS. Additionally, a recent pilot study suggested a beneficial effect of probiotics in dogs with lymphoma receiving standard chemotherapy. In an open study of dogs with IBD, a multistrain highly concentrated probiotic administered for 60 days appeared to be as efficient as a combination of prednisone and metronidazole. They were found to increase tight-junction protein expression in another study, suggesting that they may support quicker normalization of mucosal permeability.
- There is a lack of data evaluating optimal treatment duration. The author administers probiotics daily for 2–4 weeks to animals with acute enteritis and for months in dogs and cats with chronic enteritis if positive effects are seen in the first 2–4 weeks.

ACUTE HEMORRHAGIC DIARRHEA SYNDROME

Definition/Overview

Acute hemorrhagic diarrhea syndrome (AHDS) is the name currently used to describe the canine syndrome known in the past as hemorrhagic gastroenteritis (HGE). It has been shown that affected dogs do not have any gastric inflammation. The syndrome can affect dogs of all breeds and all ages, although middle-aged dogs of small and toy breeds seem to be predisposed.

Etiology and Pathophysiology

The etiology of AHDS is not fully understood. *Clostridium perfringens* and its recently discovered pore-forming toxin Net F is present in the feces of many dogs with AHDS and thought to play a key role in the pathogenesis. However, other yet unidentified factors may play a role as well. It is unclear if the clostridial proliferation observed in the duodenum is a cause or a consequence of the disease. AHDS has severe repercussions on species diversity of the intestinal microbiota and causes acute dysbiosis. However, recovery of the microbiome is quick after the affected dogs improve clinically following appropriate treatment.

FIGURE 9.53 Hemorrhagic diarrhea from a dog with acute hemorrhagic diarrhea syndrome.

Clinical Presentation

Acute-onset bloody diarrhea (Figure 9.53), possibly with vomiting and anorexia. Affected dogs are usually very dehydrated and in various stages of hypovolemic shock. Lethargy and abdominal pain are also common.

Differential Diagnosis

Parvovirus infection, bacterial infections, salmon poisoning disease, severe parasite infestations, dietary indiscretion, intestinal volvulus or intussusception, acute pancreatitis, acute liver or kidney disease, hypoadrenocorticism, sepsis, immune-mediated thrombocytopenia, and anticoagulant rodenticide and other toxicoses.

Diagnosis

Initially, affected dogs typically have a high packed cell volume (PCV; sometimes above 65%) and a normal or low serum concentration of total solids (or total proteins, albumin, or globulins). White blood cell counts may be normal, high, or low depending on the severity of disease. Mild thrombocytopenia is common.

Other serum biochemistry changes may include prerenal azotemia, increased liver enzymes, hypoglycemia, and electrolyte abnormalities. Metabolic acidosis is often present. Abdominal radiographs usually show an enteritis pattern with fluid- and gas-filled small intestinal loops.

Management

Aggressive fluid therapy. IV boluses of isotonic crystalloid solutions (10–20 mL/kg) should be given to treat hypovolemic shock if present. Perfusion and cardiovascular status should be reassessed every 15 minutes and further boluses administered as required until normal blood pressure is restored. Fluid deficits should be replaced over a 6- to 12-hour period with crystalloid solutions, adding the maintenance requirements and estimated ongoing losses due to continuing diarrhea. Electrolyte deficits such as hypokalemia should also be corrected. Other treatments include antiemetics and possibly gastric antacids if decreased perfusion of the gastric mucosa is suspected (see Table 9.4). The PCV generally normalizes in response to aggressive fluid therapy, and the serum protein concentration usually drops to levels indicative of hypoproteinemia (transient), with both low serum albumin and globulin concentrations (Figure 9.54).

Systemic use of antibiotics should be avoided in the treatment of AHDS. When endpoints such as time to resolution of diarrhea and length of hospital stay were compared between dogs given amoxicillin and clavulanic acid and those receiving placebo, affected dogs did not benefit from antibiotics. Intravenous broad-spectrum antibiotics should be reserved for severe cases with existing or impending sepsis (Box 9.7). A highly concentrated multistrain probiotic improved recovery of clinical and laboratory parameters in dogs with AHDS (Box 9.6).

Affected dogs should be fasted for 12–24 hours and then offered small quantities of easily digestible food frequently (boiled chicken and rice, adequate commercial prescription diets).

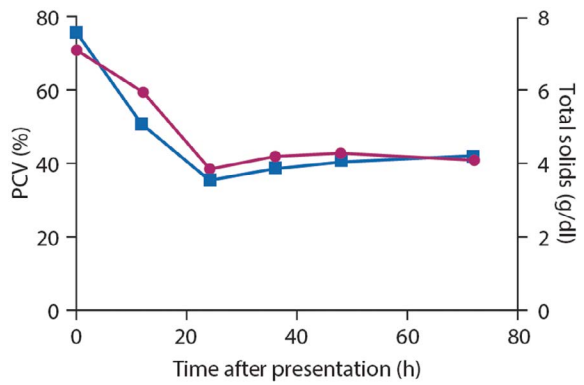

FIGURE 9.54 Evolution of PCV (red line) and total solids (blue line) with treatment in a 6-year-old Miniature Schnauzer dog with acute hemorrhagic diarrhea syndrome. The initial PCV was 70% (reference range 35–55). The total solids plummeted from 7.5 to 3.5 g/dL within 24 hours with aggressive fluid therapy (reference range 5.8–7.5).

Box 9.7 Indications for antibiotic use in dogs with AHDS

- Systemic signs of illness that persist after rehydration, pain management, and symptomatic treatment, for example:
  - Depressed mental status
  - *Tachycardia:* Heart rate > 120/min small-breed dogs, > 100/min large-breed dogs
  - *Tachypnea:* Respiratory rate > 30/min
  - *Hypotension:* Mean arterial pressure < 80 mmHg
  - Evidence of bowel mucosa in the diarrhea
- Signs of systemic inflammation at presentation, for example:
  - Rectal temperature > 39.5°C or 103.1°F
  - WBC < 4,000 or > 25,000/µL
  - Band neutrophils > 2,500/µL
- Presence of an immunocompromising underlying disease, for example:
  - Immunosuppressive treatment
  - Neutropenia
- High probability of ineffective clearance of bacteria by the liver, for example:
  - Portosystemic shunt flow
  - Liver dysfunction

Modified from Unterer S, Busch K: Acute hemorrhagic diarrhea syndrome in dogs. (2021): *Vet Clin North Am Small Anim Pract* 51: 79–92.

Prognosis

Good when dogs are presented early in the course of the disease. Most dogs can be discharged following after a median of 3 days of fluid therapy (range 1–7 days). Serious complications may include disseminated intravascular coagulation, sepsis, and aspiration pneumonia in vomiting animals. AHDS may be fatal if the emergent needs of the patient are addressed too late.

INTESTINAL OBSTRUCTION

Etiology

Small intestinal obstruction most often results from FBs such as peach pits, corncobs, toys, and fishhooks in dogs and linear foreign bodies in cats. Other differential diagnoses for intestinal obstruction include intussusception and neoplasia. Intussusceptions (Figure 9.55) are seen mostly in young animals, particularly in conjunction with severe acute enteritis, such as parvovirus infection or ascarid infestation but can also be seen in cases of chronic diarrhea, such as IBD and intestinal neoplasia. Intestinal volvulus (torsion) is a rare disorder in dogs that involves intestinal rotation at the root of the mesentery, with complete occlusion of the cranial mesenteric artery (Figure 9.56). This results in bowel necrosis, release of toxins, and life-threatening hypovolemic and septic shock. Most cases

FIGURE 9.55 An ileocolic intussusception was diagnosed and surgically removed from a 1-year-old male Beagle with chronic diarrhea. Shown is the cecum that was prolapsed into the ascending colon. (*Courtesy of A. Grooters and K. Saile.*)

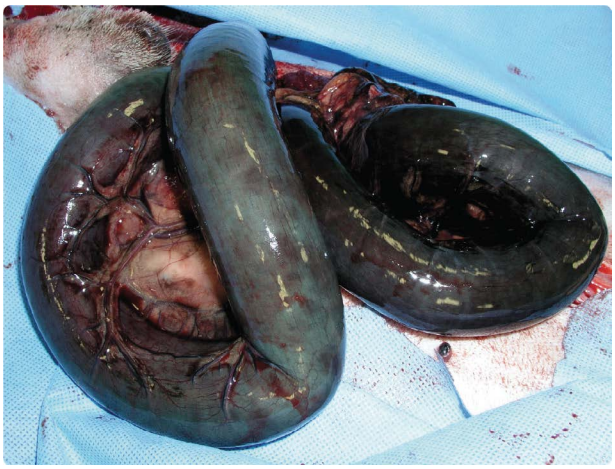

FIGURE 9.56 Intestinal volvulus in a dog. The small bowel loops are dilated with a hemorrhagic, necrotic wall. (*Courtesy of R. Husnik.*)

have been reported in adult, medium-to-large breed male dogs.

Pathophysiology

Small intestinal obstruction generally causes an accumulation of intestinal content, fluid, or gas in the loops located craniad to the site of obstruction. Intussusceptions are thought to occur as a complication of abnormal intestinal motility associated with enteritis or with abnormal intestinal masses.

Clinical Presentation

Clinical findings are related to the site, severity, and cause of the obstruction. Complete upper intestinal obstruction results in severe vomiting associated with fluid loss and dehydration and possible hypovolemic shock. Partial obstructions often present with an insidious onset of vomiting and intermittent chronic diarrhea.

Differential Diagnosis

Dietary indiscretion or other causes of acute gastroenteritis and acute pancreatitis are the top differentials.

Diagnosis

The history is sometimes helpful for raising suspicion of a FB. A thorough physical examination is important in all cases, including inspection of the base of the tongue for linear foreign bodies, especially in cats (see Chapter 2.17, **Figure 2.17.4**). Abdominal palpation may reveal discomfort or pain, and an FB or intussusception may be identifiable. Abdominal radiographs are essential to document or rule out obstruction (**Box 9.8**). Signs of intestinal obstruction are readily recognizable (**Figures 9.57–9.61**). In severe cases, signs of bowel

Box 9.8 Practical tip: Antiemetics may mask the signs of gastrointestinal foreign bodies

Several effective antiemetics are currently available to veterinarians:
- Maropitant (1 mg/kg IV or SC q.24h.)
- Metoclopramide, which can be administered as a CRI to dogs and cats receiving IV fluids (1–2 mg/kg q.24h.)
- Ondansetron (0.5–1 mg/kg IV or SC q.12h.)

These antiemetics may suppress vomiting in patients with gastric or small intestinal foreign bodies and thus delay proper treatment involving foreign body retrieval via exploratory celiotomy or endoscopy (for gastric foreign bodies only). Delayed treatment may make it necessary to resect intestinal tissue (when enterotomy would have been sufficient with early intervention) or even increase the risk of perforation. Consequently, abdominal radiographs should be performed as soon as possible in dogs and cats with history and clinical signs compatible with a GI foreign body in order to rule out obstruction.

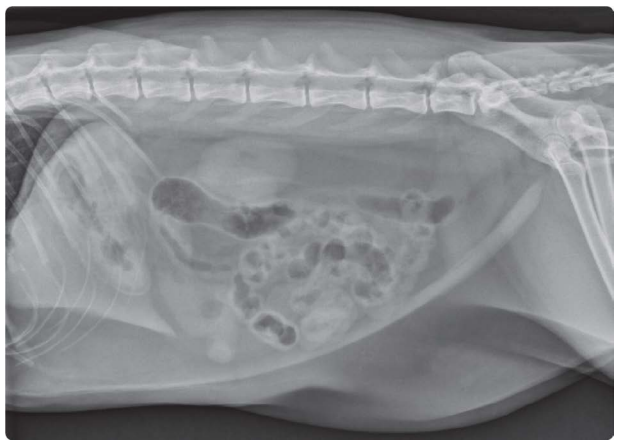

FIGURE 9.57 Cat with a linear foreign body. Right lateral abdominal radiograph. All small intestinal loops are located centrally, diffusely plicated, and corrugated in appearance. There are multiple, rounded, comma-shaped, and paisley-shaped gas opacities of varying size throughout the small bowel.

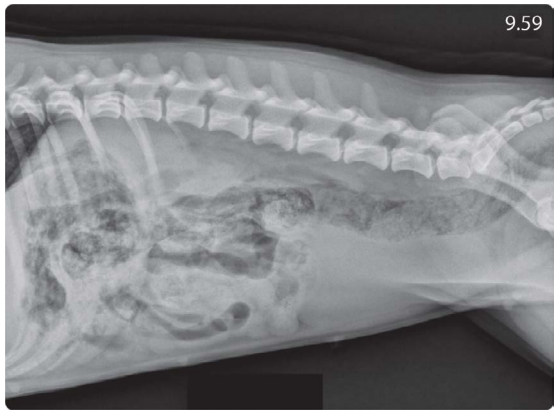
FIGURE 9.58 Ventrodorsal radiograph of the same cat as Figure 9.57. The arrow points to a caudally displaced small bowel loop that displays a plicated appearance with content of mixed soft tissue and gas density. (*Courtesy of L. Gaschen.*)



perforation, such as decreased serosal detail and free abdominal gas, may be present as well. Additionally, abdominal ultrasound may help confirm the diagnosis of intussusceptions and masses. A minimum database consisting of CBC, biochemistry panel, and urinalysis may help characterize the fluid and electrolyte losses and document inflammation or sepsis in complicated cases.

Management

Treatment of intestinal obstruction involves surgical removal of the cause of the obstruction (Figure 9.61). Broad-spectrum antibiotics should be given IV to patients with signs of intestinal perforation (e.g., amoxicillin 20 mg/kg q.8h., enrofloxacin 10 mg/kg q.24h., and metronidazole 10–15 mg/kg q.12h.).

Prognosis

In the absence of complications such as intestinal perforation, the prognosis after surgical extraction of a FB is excellent. The risk of suture dehiscence at the enterotomy or enterectomy site is higher in the presence of peritonitis (i.e., perforation). There is a risk of recurrence for intussusceptions unless the underlying disease is controlled. For intestinal volvulus, the prognosis is usually grave.

FIGURES 9.59–9.61 A 2-year-old female Jack Russell Terrier presented with a 4-day history of vomiting. (Figure 9.59) Right abdominal radiograph. The serosal detail is decreased throughout the abdomen. The stomach, small intestines, and colon contain a large amount of material with heterogeneous soft tissue and gas density. (Figure 9.60) Ventrodorsal radiograph of the same dog. (*Courtesy of LSU SVM Diagnostic Imaging Service.*) (Figure 9.61) Grass is extracted through a midjejunal enterotomy. Large amounts of grass were present throughout the gastrointestinal tract and were impacting the small intestine. (*Courtesy of A. Grooters and K. Saile.*)

CHRONIC ENTERITIS

PARASITIC ENTERITIS

CANINE SCHISTOSOMIASIS

Etiology

Heterobilharzia americana is the agent of canine schistosomiasis, an uncommon disease endemic in the Southeast United States and areas bordering the Gulf of Mexico. Raccoons are the parasite's reservoir host. Freshwater snails are obligatory intermediate hosts.

Pathophysiology

Percutaneous infection occurs through free-swimming cercariae. After migration, adult *Heterobilharzia* produce ova in the terminal branches of the mesenteric veins. The ova are shed through the intestinal mucosa in the feces. Granulomatous inflammation can be found in the intestinal submucosa (Figure 9.62) and in other organs as well.

Clinical Presentation

Acute-to-chronic mixed small and large bowel diarrhea. Hyporexia/anorexia, weight loss, often cachexia, lethargy, melena, and/or hematochezia are common.

Differential Diagnosis

Includes IBD (including protein-losing enteropathy [PLE]), severe parasitic enteritis, intestinal neoplasia.

Diagnosis

Blood work may reveal anemia, hypoalbuminemia, hyperglobulinemia, and eosinophilia. Hypercalcemia is present in 11%–50% of affected dogs and may be associated with polyuria/polydipsia and/or azotemia. Abdominal radiographs and ultrasound may show evidence of mineralization of the small intestinal wall, particularly in the submucosal layer. Diagnosis is confirmed with saline sedimentation of feces or a commercially available fecal PCR.

Management

Praziquantel (25 mg/kg q.8h. for 2–3 days), possibly in combination with fenbendazole (50 mg/kg q.24h. for 10 days).

Prognosis

Depends on the severity of lesions at presentation. In retrospective studies, the survival rate 6 or more months after diagnosis was between 55% and 73.5%.

GIARDIASIS

Definition/Overview

Studies concerning the prevalence of giardiasis in the canine and feline populations report rates of 5%–10% in healthy pets and pets presented for veterinary care. The prevalence is greatest in patients that live in high-density group housing, especially when recommended disinfecting protocols are not carried out optimally. In such cases, *Giardia* cysts can easily survive in the environment and continuously infect new animals or reinfect animals after they have been treated.

Etiology

Giardia duodenalis is a flagellated protozoan that exists in two forms: A motile trophozoite of piriform to ellipsoidal shape (Figure 9.63) and a cyst form that is highly resistant in the environment. Cysts are absorbed with contaminated

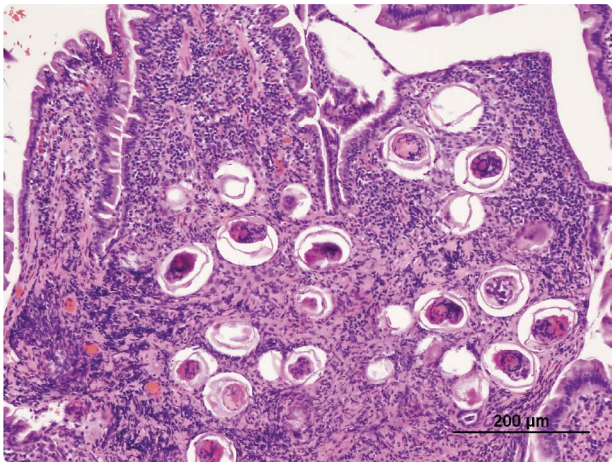


FIGURE 9.62 Photomicrograph of a duodenal mucosal sample from a dog with canine schistosomiasis. There are numerous eggs present in the mucosa that are associated with granulomatous inflammation. (*Courtesy of M. Im Hof.*)

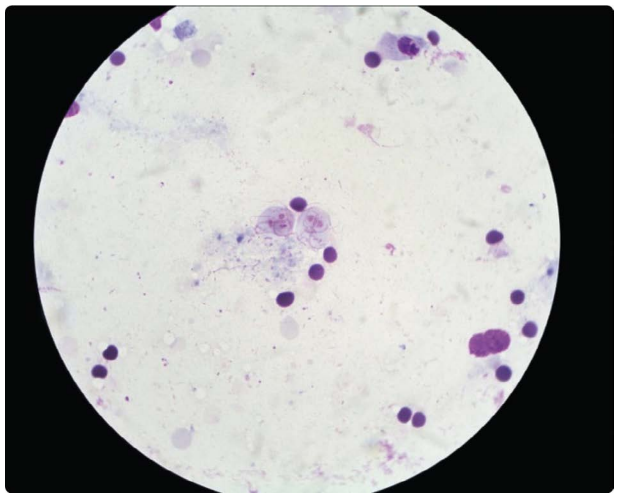

FIGURE 9.63 Photomicrograph of a fecal smear from a dog with *Giardia* infection. Two trophozoites are visible in the middle of the picture. Wright–Giemsa stain. (*Courtesy of R. Husnik.*)

food or water and release trophozoites into the small intestinal lumen. Trophozoites multiply by cell division and become encysted. *Giardia* cysts have four nuclei and a thin envelope. Under favorable conditions, they can persist for 3 weeks or even longer in the environment.

Giardia isolates are further divided into several different genotypes or assemblages with specific host ranges. The zoonotic potential of canine and feline giardiasis is very low. Consumption of water contaminated with *Giardia* cysts is the main origin of infections in people.

Pathophysiology

Trophozoites are found in highest concentration in the duodenum. They attach to the mucosal epithelium and cause disease by affecting epithelial permeability.

Clinical Presentation

Diarrhea with watery feces and admixed mucus. In severe and chronic infections, malabsorption and weight loss may occur and the animal may be in poor general condition. Importantly, many infected dogs and cats do not show clinical signs.

Differential Diagnosis

Other causes of chronic, intermittent diarrhea and malabsorption, such as other parasite infections, chronic enteropathies, exocrine pancreatic insufficiency, and possibly alimentary lymphoma.

Diagnosis

Several diagnostic tests are available for the diagnosis of *Giardia* infections in dogs and cats (Table 9.8 and Figure 9.63). Confirmation of diagnosis can be complicated by the fact that cysts are shed intermittently.

TABLE 9.8 Diagnostic tests for *Giardia* in the feces of dogs and cats

Diagnostic test	Target	Sensitivity
Flotation with zinc sulfate or sugar centrifugation	Cysts	– Intermediate, operator dependent – Can be increased from 70% to 90% if three samples collected at 2- to 3-day intervals are examined
IFA or ELISA	Specific antigens	– Intermediate to good – Diagnostic accuracy of cage-side ELISA test is equivalent to that of antigen tests run in the laboratory
PCR	DNA sequences	– Intermediate to high – Only recommended for determination of specific assemblage

DNA, deoxyribonucleic acid; ELISA, enzyme-linked immunosorbent assay; IFA, immunofluorescence assays; PCR, polymerase chain reaction.

Management

The goal of treatment is to stop diarrhea and attempts to fully eliminate *Giardia* infection may not be successful. In dogs, metronidazole (25–30 mg/kg p.o. q.12h. for 5–8 days) and fenbendazole (50 mg/kg p.o. q.24h. for 5 days) are most used and appear to be equally efficacious. In cats, metronidazole benzoate (25 mg/kg p.o. q.12h. for 7 days) is well tolerated and eliminates cyst shedding within 7–10 days of treatment. Fenbendazole can also be used at the same dose as in dogs, although its efficacy may be inferior. Other drugs, including tinidazole (44 mg/kg p.o. q.24h. for 3 days), can also be used in cats.

An increased rate of resistance of *Giardia* spp. to metronidazole and other antigiardial agents has been reported in human patients. However, no published data concerning drug resistance of canine or feline giardiasis are currently available.

Dogs kept in group housing should be removed from their runs, shampooed, and rinsed with quaternary ammonium-based disinfectants. The runs should be cleaned and disinfected before reuse. Quaternary ammonium containing disinfectants have shown an excellent efficacy for inactivating *Giardia* cysts in a short period of time.

Prognosis

Good.

FUNGAL AND OOMYCETAL ENTERITIS

HISTOPLASMOSIS

Etiology

Histoplasma capsulatum is a dimorphic saprophytic fungus that can be found in temperate and subtropical climates. Most cases of canine or feline histoplasmosis described in the literature come from the Americas, particularly from the Ohio, Missouri, and Mississippi River Valleys. Other endemic regions include Mexico and South American areas.

Pathophysiology

Infection occurs predominantly infected by inhalation of microconidia (mycelium) that transform into yeast and infect macrophages in the lungs. The infection can remain local (respiratory tract). If it propagates, it generally also involves the GI tract. Sporting and working dogs are at increased risk.

Clinical Presentation

GI signs include chronic small or large bowel diarrhea. Weight loss and poor body condition score are common. Affected animals are sometimes presented with PLE. Other organ systems may be infected and cause additional clinical signs.

Differential Diagnosis

Other causes of chronic diarrhea and weight loss such as parasite infections, IBD, and alimentary lymphoma.

Diagnosis

The most reliable diagnosis consists in identifying the organism on cytologic smears from fine-needle aspirates of lymph nodes, from rectal scrapings (Figure 9.64), or on histologic analysis of intestinal biopsies. Alternately, urine antigen tests have a reasonable sensitivity, although there is cross-reactivity with other systemic fungi such as *Blastomyces*.

Management

First-line treatment includes itraconazole (10 mg/kg once daily) and must be continued for at least 6 months. Lesion resolution (as evidenced with clinical and imaging examinations) should guide the decision to discontinue treatment.

Prognosis

Intestinal histoplasmosis carries a fair to good prognosis, which is negatively affected by multisystemic extent and increasing severity of the disease.

PYTHIOSIS

Etiology

Pythium insidiosum is a eukaryotic microorganism from the class Oomycota found in subtropical climates (such as the southeast and Gulf of Mexico regions of the United States) and sporadically in other areas. It causes severe, progressive GI disease. It affects particularly large breed male dogs, probably because of their increased risk of environmental exposure. High infection rates occur where dogs are exposed to small bodies of water which is favored by the organism.

Pathophysiology

Motile *Pythium* zoospores are attracted to and invade damaged GI mucosa. The disease is characterized by transmural inflammation that may affect one or more of the following sites: Stomach, gastric antrum, small intestine, colon, and rectum (rarely the esophagus) (Figures 9.15 and 9.65). Local lymph nodes are often reactively enlarged.

Clinical Presentation

Young, large breed dogs with access to the outdoors and swimming areas are most commonly affected. History commonly indicates a progressive illness. Vomiting, diarrhea, and weight loss (Figure 9.66) are also commonly observed, with possible hyporexia. In advanced cases, clinical features are suggestive of obstruction of the proximal GI tract, with vomiting and a palpable intestinal mass. Poor body condition is frequently present. Interestingly, lethargy and other signs of systemic illness are observed only in severe cases as a consequence of complete GI obstruction or GI perforation.

Differential Diagnosis

Intestinal FB, histoplasmosis, parasitic enteritis, IBD, small intestinal neoplasia.

Diagnosis

Peripheral eosinophilia, anemia, hypoalbuminemia, and hyperglobulinemia may be present. Abdominal

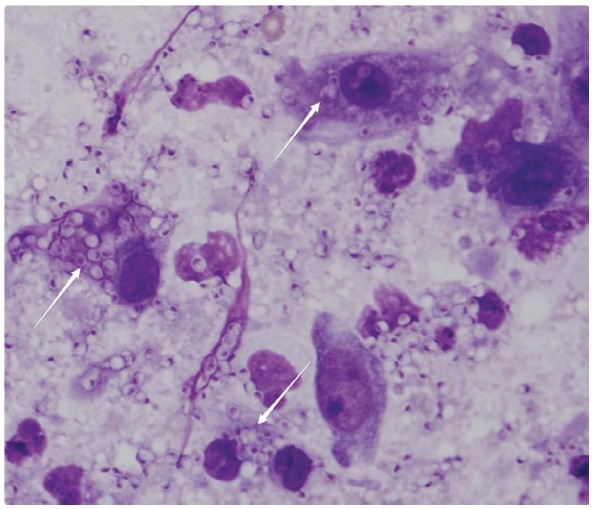

FIGURE 9.64 Photomicrograph of a fine-needle aspirate of a mesenteric lymph node from a dog with intestinal histoplasmosis. The arrows point to macrophages filled with yeast forms of *H. capsulatum*. Wright–Giemsa stain. (*Courtesy of S. Gaunt.*)

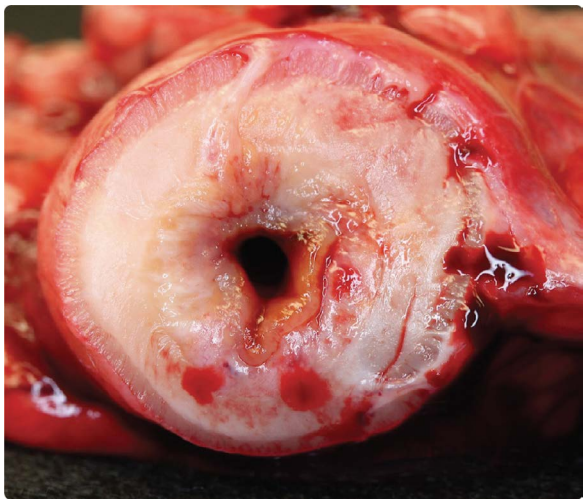

FIGURE 9.65 Cross-section of a resected jejunal segment from a 2-year-old mixed-breed dog with intestinal pythiosis. The wall is severely thickened, and the normal structure is not recognizable. The severe narrowing of the jejunal lumen caused partial intestinal obstruction. (*Courtesy of A. Grooters.*)

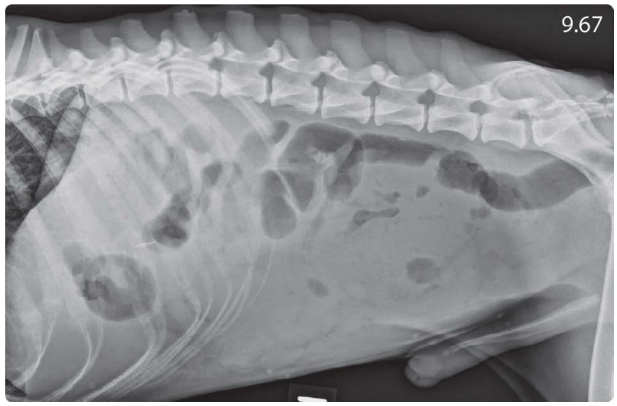

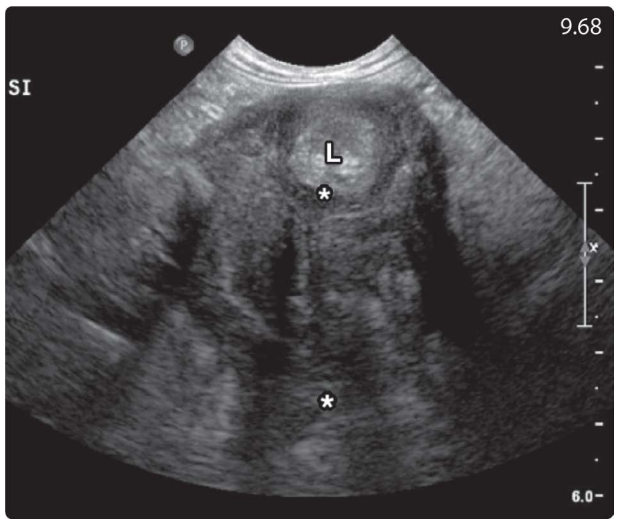

FIGURE 9.66 Two-year-old female spayed Boxer dog with a progressive history of chronic, intermittent vomiting. The dog has lost weight and is in poor body condition. Gastric antral pythiosis was diagnosed. (*Courtesy of K. Ryan.*)

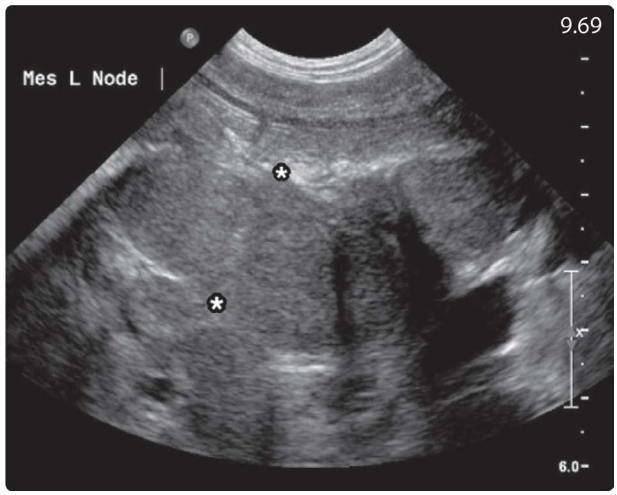
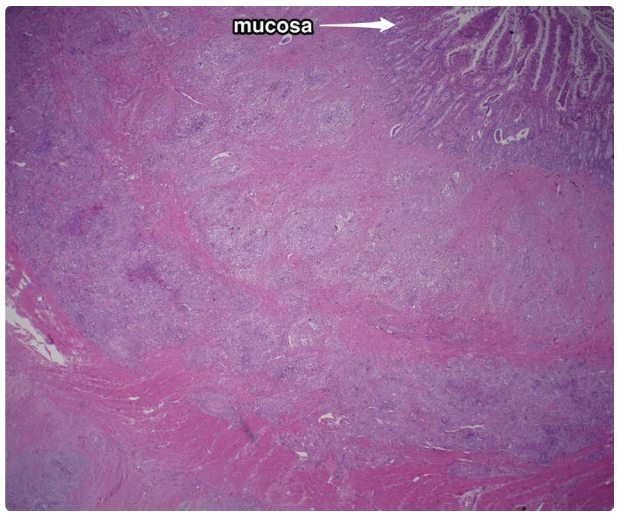
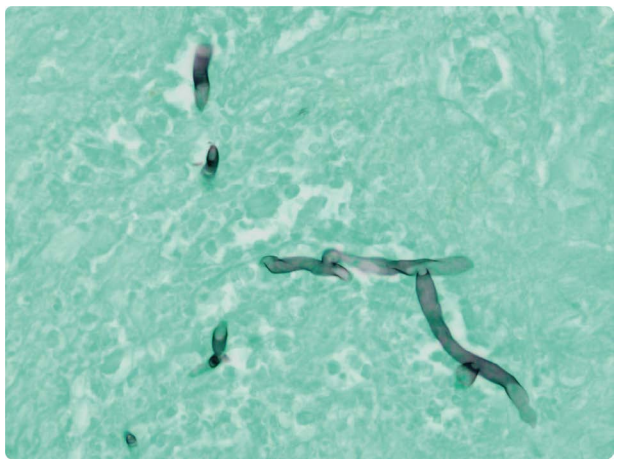


imaging: Radiographs may reveal an abdominal mass with or without obstructive pattern (Figure 9.67); ultrasound helps locate the affected segment, which is characterized by transmural thickening with disappearance of the normal small intestinal wall structure (Figure 9.68) and lymph node enlargement (Figure 9.69). Ultrasound-guided fine-needle aspirates can be performed. An ELISA test for detection of serum antibodies is available (locations can be found on the web). Histopathologic diagnosis is granulomatous enteritis affecting mostly the submucosa and muscularis layers (Figure 9.70). Oomycetal organisms may be detected with special stains (Figure 9.71) or with immunohistochemistry. Fresh infected tissue may also be cultured to confirm the diagnosis.

Management



Aggressive surgical resection of the lesion with 5 cm clean tissue margins on both sides is the preferred treatment for GI pythiosis. Enlarged abdominal lymph nodes should be biopsied, but their resection is not absolutely essential since they are rarely infected. Except in cases where total resection with 5 cm clean margins could be performed (usually midjejunal masses), medical treatment with a combination of itraconazole (10 mg/kg p.o. q.24h.) and terbinafine (5–10 mg/kg p.o. q.24h.) is recommended. Prednisone (1 mg/kg p.o. q.24h.) can also be used to decrease local inflammation and to palliate clinical signs in the short term. ELISA serology should be performed at the time of diagnosis and 3 months postoperatively, and medical treatment can be discontinued if the titer decreases by greater than 50%.



FIGURES 9.67–9.69 Two-year-old male Catahoula Cur with intestinal pythiosis. **(Figure 9.67)** Left lateral abdominal radiograph. There is an ill-defined central abdominal soft tissue mass that displaces the intestines dorsally and ventrally. **(Figure 9.68)** Abdominal ultrasound. The cross-section of this small intestinal segment reveals a markedly eccentrically thickened wall (~3 cm) with abnormal layering (between asterisks). L, intestinal lumen. **(Figure 9.69)** Abdominal ultrasound. Note the much enlarged mesenteric lymph node (between asterisks). The measured size was 2.2 × 6.4 cm. (*Courtesy of LSU SVM Diagnostic Imaging Service.*)

FIGURES 9.70 and 9.71 Dog with pythiosis affecting the jejunum. **(Figure 9.70)** Low-magnification photomicrograph of the intestinal wall. The mucosa is visible at the top right of the image (arrow); the deeper structures (submucosa, muscularis) are obliterated by granulomatous and eosinophilic inflammation. Grocott methenamine silver stain. (*Courtesy of LSU SVM Pathology Service.*)

Prognosis

Poor, except if complete surgical resection of the GI lesion is possible. Recurrence is common unless full resection with clean margins could be achieved. The disease is fatal if untreated.

CHRONIC CANINE ENTEROPATHY

Definition/Overview

The general term "chronic enteropathy" (CE) is used frequently to describe dogs and cats with chronic intestinal diseases of unknown origin. Diet-responsive CE (DRCE), idiopathic gut dysbiosis (also called antibiotic-responsive diarrhea), and inflammatory bowel disease (IBD) are different forms of chronic enteropathy. They may form a continuum, with diet responsive diarrhea (DRD) being the mild form of CE and IBD requiring immunosuppressive treatment representing the severe form of the disease.

Etiology

Based on research in rodent models, people, dogs, and cats, IBD results from a combination of factors that include dysregulation of the immune system and its interactions with intestinal microbiota and/or dietary components, severe changes in the gut microbiota affecting its richness, diversity, and the abundance of various bacterial taxa, and compromised integrity of the intestinal mucosal barrier.

Specific forms of CE have been recognized as occurring more frequently in several canine breeds. For instance, in the Southeast UK, Weimaraners, Rottweilers, German Shepherd Dogs, Border Collies, and Boxers were at increased risk of developing IBD. Examples of established breed associations include lymphangiectasia and duodenal crypt inflammation with protein-losing enteropathy (PLE) in Yorkshire Terriers, PLE also in Border Collie, German Shepherd Dog, and Rottweiler, PLE and protein-losing nephropathy in Soft-Coated Wheaten Terriers, and cobalamin deficiency in Shar Peis. German Shepherd Dogs have a high prevalence of idiopathic intestinal dysbiosis and IBD.

Pathophysiology

Recognition of commensal intestinal microbiota by the innate immune system is altered. Toll-like receptors (TLRs) are pattern-recognition receptors located on immune and epithelial cells that mediate the interactions between intestinal microbiota and the host. Polymorphisms in various TLRs have been identified in the intestinal mucosa of dogs with CE, which may trigger an inflammatory response. In addition, significant changes in the gut microbiota were detected. In dogs and people, IBD reduces the diversity of the intestinal microbiome. Furthermore, in dogs with IBD, the bacterial taxa *Firmicutes* (including the *Clostridiales*), *Bacteroidetes*, and *Fusobacteria* are diminished, and *Proteobacteria* (including *Enterobacteriaceae*) are increased. It is not clear whether these changes are the origin of the intestinal inflammation or if they reflect the altered environment in the chronically inflamed gut, or both. Intestinal dysbiosis is accompanied by changes in the gut metabolome. For instance, *Clostridium hiranonis* is a bacteria involved in transformation of primary into secondary fecal unconjugated bile acids (FUBA). These have numerous important functions locally and act as signaling molecules to remote organs. Abundance of *C. hiranonis* and concentration of secondary FUBA are decreased in dogs with IBD, and this has consequences both within and beyond the GI tract. Similarly, *Faecalibacterium* is associated with production of

short-chain fatty acids that are used as a source of energy by colonic epithelial cells and are decreased in the presence of intestinal inflammation.

Clinical Presentation

Chronic or chronic, intermittent diarrhea of more than 3 weeks' duration. Mild CE may cause intermittent clinical signs, whereas progressive and severe clinical signs are common in severe IBD. Poor body condition with poor hair coat is frequent with severe disease. Dehydration is possible. Thickened small intestinal loops may occasionally be palpated. Animals may show pain or discomfort on abdominal palpation. Ascites, hydrothorax, and peripheral edema may occur in cases of significant protein loss (e.g., PLE). Clinical activity scoring systems have been validated for use in the dog: CIBDAI (Canine Inflammatory Bowel Disease Activity Index) and CCECAI (Canine Chronic enteropathy Clinical Activity Index) (Table 9.9). Clinical activity scoring is useful for documenting the severity of clinical signs at presentation and for accurate evaluation of clinical response to treatment.

Differential Diagnosis

General differentials include chronic intestinal FB, intestinal parasitoses, fungal enteritis, bacterial enteritis, and diseases originating outside the GI tract such as chronic kidney disease, chronic liver disease, chronic pancreatitis, exocrine pancreatic insufficiency, and atypical hypoadrenocorticism.

Diagnosis

Diagnosis of CE consists of an elimination process to rule out other diseases of known etiology that may cause similar clinical signs: Fecal flotation and a *Giardia* antigen test should be performed in all dogs. Alternatively, empiric parasiticide treatment can be administered (e.g., fenbendazole, 50 mg/kg q.24h. for 3–5 days). Subsequently, the diagnostic process is different for dogs with mild clinical signs and no evidence of complications such as hypoproteinemia and for dogs that are more severely affected.

Mildly affected dogs can undergo a treatment trial with a novel protein or hydrolyzed peptide diet without further diagnostics (see Management), while severely affected dogs should be evaluated more thoroughly with collection of a minimal database, including CBC, serum biochemistry, and urinalysis. Presence of hypoalbuminemia, often accompanied by hypoglobulinemia, suggests PLE, particularly if other causes can be ruled out. Sensitivity of abdominal ultrasound is intermediate, and scans may be normal or show focal or diffuse loss of wall layering, presence of mucosal striations or spicules, wall thickening, and enlarged and/or hypoechoic mesenteric lymph nodes. If lesions are present, localization to a specific intestinal segment may be helpful (Figures 9.72 and 9.73).

Upper GI endoscopy and exploratory celiotomy are both good procedures for collecting intestinal mucosal biopsy samples, and each offers different advantages and drawbacks. Observation of severe mucosal lesions during duodenoscopy is a negative prognostic factor.

Procurement of biopsy samples may be useful to further evaluate disease severity. Biopsy specimens of adequate quality and quantity are required for accurate interpretation by pathologists. The most important justification for histology is to rule out a neoplastic infiltrate. However, it is also useful to evaluate the magnitude of intestinal mucosal inflammation based on the severity and type of the infiltrate and the severity of the architectural mucosal changes, although histopathological and clinical severity of disease correlate poorly overall. There

are now established scoring systems that take both architectural and inflammatory mucosal changes into account. Inflammatory infiltration may be of varying severity and consist of lymphocytes and plasma cells (lymphoplasmacytic enteritis), eosinophils, neutrophils or macrophages, or combinations thereof (Box 9.9). Examples of small intestinal mucosal architectural changes include villus stunting and/or fusion (Figure 9.74), surface epithelial injury, crypt distension (Figure 9.75), lacteal dilation (Figure 9.76), and mucosal fibrosis. It is noteworthy that in animals responding to treatment, histopathologic

Box 9.9 Further considerations with different types of intestinal infiltrates

Lymphoplasmacytic enteritis: Most common type of inflammatory infiltrate, nonspecific. A mild-to-moderate lymphoplasmacytic mucosal infiltrate may be present in the absence of clinical signs.

Eosinophilic enteritis: Rule out parasitic enteritis or allergic causes and in cats eosinophilic syndrome. Idiopathic eosinophilic enteritis may occur in dogs and cats. While it usually responds well to steroids in dogs, this disorder is often steroid resistant in cats.

Neutrophilic (or suppurative) enteritis: Bacterial infectious component cannot be ruled out, and treatment with broad-spectrum antibiotic should be considered alone or in association with immunosuppressive drugs.

Granulomatous enteritis: Rule out fungal enteritis. Idiopathic transmural granulomatous enteritis usually carries a poor prognosis. See also granulomatous colitis below.

lesions do not seem to improve in correlation with clinical signs. This finding suggests that CE can be controlled clinically but not healed.

Management

In most instances, the goal of treatment is to manage the clinical signs. Full recovery is possible in mild cases.

The standard approach for a dog with mild-to-moderate chronic recurrent diarrhea of unknown origin without systemic repercussions is to initiate a food trial with a novel protein or hydrolyzed peptide diet. In numerous studies from locations around the world, between one-half and two-thirds of dogs with signs of CE responded to this simple dietary approach within 10–14 days. Because DRCE is so common, a second

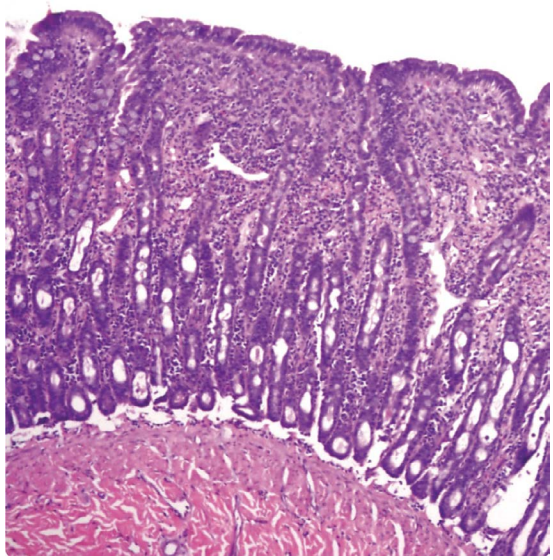

FIGURE 9.74 Photomicrograph of the duodenal mucosa of a 10-year-old female spayed Domestic Shorthair cat with chronic inflammatory bowel disease. There is marked blunting and fusion of the intestinal villi (compared with **Figure 9.44**), and a moderate lymphoplasmacytic infiltrate. H&E stain.

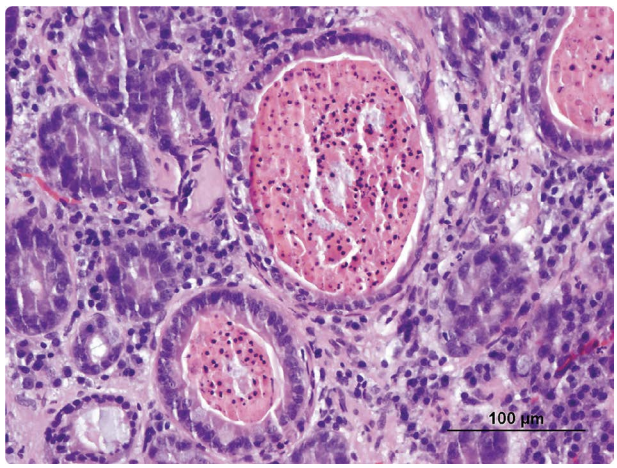

FIGURE 9.75 Photomicrograph of the duodenal mucosa of a dog with protein-losing enteropathy. Two intestinal crypts are markedly distended and filled with necrotic material. The diagnosis was moderate lymphocytic plasmacytic duodenitis with severe crypt lesions. H&E stain.

food trial with another novel protein or hydrolyzed peptide diet should be considered for dogs who do not respond to the first trial.

Although there is only little evidence supporting their beneficial effects in dogs with CE, probiotics, particularly the high-dose multistrain products, are often included in the treatment plan (Box 9.6).

While dysbiosis occurs in most dogs with IBD, a subset of young large breed dogs with CE (particularly but not exclusively German Shepherd Dogs) respond to prolonged treatment with antimicrobials such as tylosin (20 mg/kg p.o. q.12h.) or metronidazole (10–15 mg/kg p.o. q.12h.). This may result from an inability of these dogs' immune systems to interact adequately with their intestinal microbiota. Clinical experience accumulated over the past decades indicates that prolonged treatment (4–8 weeks) is necessary, and that relapses are common.

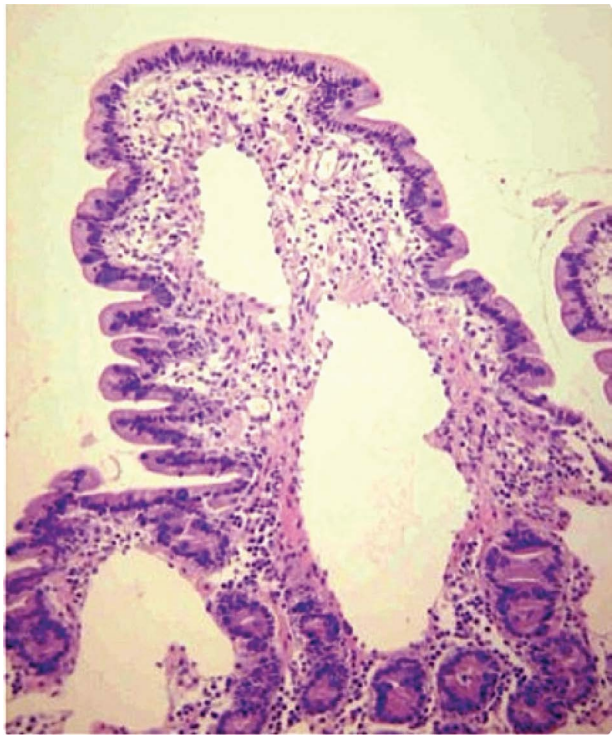

FIGURE 9.76 Photomicrograph of the duodenal mucosa of a Yorkshire Terrier with protein-losing enteropathy. The villus is markedly distended, and dilated lacteals partially filled with eosinophilic material are visible. The diagnosis was moderate idiopathic lymphangiectasia. H&E stain.

In refractory cases, and in dogs with severe disease and evidence of systemic involvement, a more thorough workup with acquisition of a minimal database should be initiated (see Diagnosis).

In dogs with histopathologic evidence of IBD, immunosuppressive doses of prednisone or prednisolone (Table 9.10) are generally the mainstay of initial treatment.

TABLE 9.10 Dosage of oral immunosuppressive drugs used in the treatment of inflammatory bowel disease in small animals

Drug	Canine dose	Feline dose	Side effects
Prednisone, prednisolone	– 1–2 mg/kg q.12–24h. – For dogs > 25 kg, 50–60 mg/m^2 body surface area per day is recommended with a maximum daily dose is 80 mg per dog	– Prednisolone preferred – Same dose as canine	– In dogs, they include polyuria/polydipsia, panting, alopecia, pot-bellied appearance, calcinosis cutis – Rare in cats, may cause diabetes mellitus
Budesonide	– 3 mg/m^2 q.24h.	– 1 mg per cat q.24h.	– Same as above
Azathioprine	– Initially 2 mg/kg q.24h. for 3 weeks, then 1–2 mg/kg q.48h. – Up to 3 weeks of treatment may be necessary for the drug to reach maximal effect	– Do not use in cats	– Hepatotoxicity, pancreatitis, rarely bone marrow suppression
Chlorambucil	– Initially 4–6 mg/m^2 q.24h. for the first 7–21 days, then the dose can be decreased by 25%–33% or the dosage interval increased to every 2–3 days	– 2 mg per cat 3 times weekly	– Rarely bone marrow suppression
Cyclosporine	– 5 mg/kg q.12–24h.	– Same as canine	– Vomiting, nausea, gingival hyperplasia

Initially, very high doses (e.g., 2 mg/kg q.12h.) are recommended for a few days, followed by a regular immunosuppressive dose (2 mg/kg per day in 1 dose or divided into 2 doses). Dietary treatment consists of hydrolyzed peptide or novel protein diet, which has been shown to be superior to easily digestible low-fat diet for long-term maintenance of remission in moderate-to-severe canine IBD. A recheck is scheduled after 1–2 weeks to reassess the situation. In cases showing good response, the dose of prednisone should be maintained for another 2 weeks, then slowly decreased in 2- to 4-week steps.

Treatment failure should prompt the clinician to review the diagnosis and ascertain that no mistakes or erroneous assumptions were made in the diagnostic process. Refractory IBD patients must be examined thoroughly to detect intercurrent diseases that may be contributing to treatment failure. For instance, a significant proportion of dogs with IBD (particularly those with PLE) may develop hypocobalaminemia because of severe involvement of the distal small intestine. Cobalamin deficiency may cause a delayed response or lack of response to adequately designed immunosuppressive treatment. Serum cobalamin concentration should be determined. Supplementation is essential in these animals and can occur either subcutaneously or orally (Table 9.11). Relatively frequently, dogs with moderate-to-severe IBD require treatment with a combination of immunosuppressive agents (Table 9.10). In cases with unacceptable corticosteroid side effects, another immunosuppressive drug should be added to allow decreasing the prednisone dose. Alternatively, budesonide can be used. Budesonide is a glucocorticoid that undergoes high first-pass hepatic metabolism after intestinal absorption but still affects the pituitary–adrenal axis. Budesonide may cause fewer side effects than prednisone. It has been used in large breed dogs, which tend to be more prone to severe polyuria and polydipsia. There is no documented benefit in using the controlled release formulation compared with the generic substance.

TABLE 9.11 Treatment protocol for hypocobalaminemic dogs and cats with chronic enteropathy

Species	Weight	SC dose	Oral dose
Cats	Any weight	250 µg	250 µg
Dogs	< 4.5 kg	250 µg	250 µg
	4.5–9 kg	400 µg	250 µg
	9–18 kg	600 µg	500 µg
	18–27 kg	800 µg	1,000 µg
	27–36 kg	1,000 µg	1,000 µg
	36–45 kg	1,200 µg	1,000 µg
	> 45 kg	1,500 µg	1,000 µg

Schedule

Subcutaneous administration: Administer once weekly dose for 6 weeks, then one dose 30 days later. Recheck serum cobalamin 30 days after the last injection.

Oral administration: Administer once daily for 12 weeks and recheck serum cobalamin 1week after discontinuation of treatment.

Serum cobalamin at recheck

- Above the reference range and the underlying process has been successfully managed, discontinue cobalamin injections or oral therapy.
- Within the reference range, continue monthly injections or daily oral administration.
- Below the reference range, reassess the patient and continue supplementation.

Texas A&M University GI Laboratory website (http://vetmed.tamu.edu/gilab), with permission.

Prognosis

Good in mild cases that respond to dietary trials. Return to a less expensive commercial food may be possible after 2–3 months of dietary treatment; however, some dogs require life-long administration of an elimination diet. A UK study showed that only a quarter of dogs with DRCE required any additional treatment (e.g., antibiotics or immunosuppressives) 1 year after diagnosis. In contrast, the prognosis is guarded to poor in dogs requiring immunosuppression.

PROTEIN-LOSING ENTEROPATHY

Definition/Overview

Intestinal protein loss is a sign of failure of digestive function that may result from severe acute inflammation, acute blood loss, chronic inflammatory or neoplastic lesions, or from a disruption of chyle absorption and intestinal lymph flow.

Etiology/Pathophysiology

Primary intestinal lymphangiectasia occurs preferentially in Yorkshire Terriers, Shar Peis, Maltese, Norwegian Lundehunds, and Rottweilers. The pathogenesis of primary intestinal lymphangiectasia is still poorly understood. It results from obstruction to the flow of lymph in the intestinal wall. Secondary intestinal lymphangiectasia is commonly associated with significant intestinal mucosal inflammation (e.g., IBD) and neoplasia (alimentary lymphoma).

IBD may also directly cause PLE. The inflammatory process located in the GI mucosa may lead to protein loss both by preventing absorption of nutrients and by compromising the integrity of the intestinal mucosal barrier, leading to exudation of proteins into the intestinal lumen. PLE of Soft-coated Wheaten Terriers is a specific form of IBD affecting this breed worldwide. In approximately 50% of these dogs, PLE and protein-losing nephropathy (PLN) occur concurrently, and the pathogenesis includes a hypersensitivity component.

Crypt dilation and necrosis have been frequently associated with PLE. Dogs with small intestinal crypt abscesses have significant hypoalbuminemia and ultrasound changes of their intestinal mucosa, and their clinical presentation is generally severe.

FIGURE 9.77 Four-year-old male neutered Maltipoo with severe chronic inflammatory bowel disease and protein-losing enteropathy. The dog is cachectic and has a pot-bellied abdomen (ascites).

Clinical Presentation

Chronic, intermittent small intestinal diarrhea with possible vomiting is a common presentation. In severe cases, hyporexia/anorexia and malnutrition with evidence of malabsorption and weight loss may be observed (Figure 9.77). Importantly, significant intestinal protein loss and hypoalbuminemia may also occur without obvious diarrheic episodes. In the presence of severe hypoalbuminemia (serum albumin < 2.0 g/dL, often ≤ 1.5 g/dL), the main complaint may relate to significantly decreased oncotic pressure causing cavitary effusion (Figure 9.78) and subcutaneous edema (Figure 9.79).

Differential Diagnosis

Hypoalbuminemia and associated signs may also occur with liver failure, PLN, third spacing of proteins (vasculitis), or cutaneous loss.

FIGURE 9.78 Ten-year-old female spayed English Bulldog with chronic inflammatory bowel disease and protein-losing enteropathy. The abdomen is severely distended due to ascites. The dog also had pleural effusion.

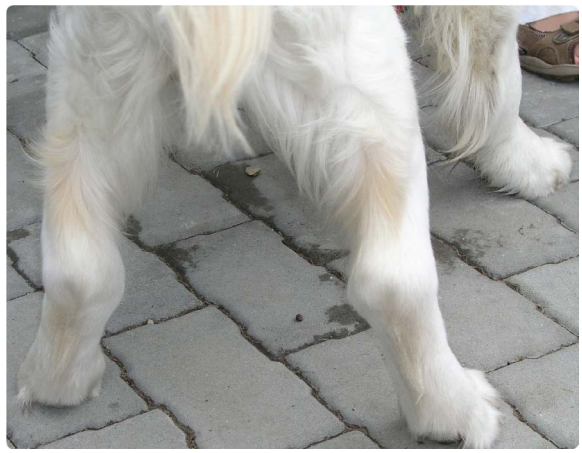

FIGURE 9.79 One-year-old male Montagne des Pyrenees with inflammatory bowel disease and protein-losing enteropathy. There is subcutaneous edema around both hocks. (*Courtesy of R. Husnik.*)

Diagnosis

First, the origin of the protein loss should be established by ruling out other processes. Generally, PLE is associated with panhypoproteinemia due to nonselective protein loss, but exceptions may occur. Other common abnormalities of dogs with PLE include hypocholesterolemia, hypocalcemia (total and ionized), hypomagnesemia, and lymphopenia.

Once the GI tract has been confirmed as the site of protein loss, further workup should include abdominal ultrasound, a technique with acceptable sensitivity that often helps assess the severity and anatomic distribution of intestinal lesions. Hyperechogenic mucosal striations are frequently observed in dogs with PLE and appear to be quite specific (Figure 9.71).

Once this initial database has been obtained, two options for diagnosis confirmation and management of the dog should be considered (Figure 9.80). In some instances, dogs with severe hypoalbuminemia are poor anesthetic candidates, and it is sometimes preferable to avoid taking excessive risks and postpone or cancel endoscopy or surgery. Additionally, many dogs with PLE have bicavitary effusion, and thoracic radiographs are recommended as a screening tool for the presence of thoracic effusion, which may represent an additional anesthetic risk. If endoscopy is performed, it may reveal a broad range of changes of varying severity (Figures 9.81 and 9.82). The diagnosis of the cause of PLE requires histopathologic analysis of intestinal biopsies (Figures 9.74 and 9.75).

Management

Dogs with PLE are in a catabolic state, and adequate nutrition is essential. Recent studies have highlighted that an important proportion of PLE dogs completely or partially responded to a 2-week dietary trial with a homemade ultralow-fat diet (ULFD). Examples of homemade ULFD include boiled, baked, or microwaved skinless chicken or turkey breast (one part) and peeled

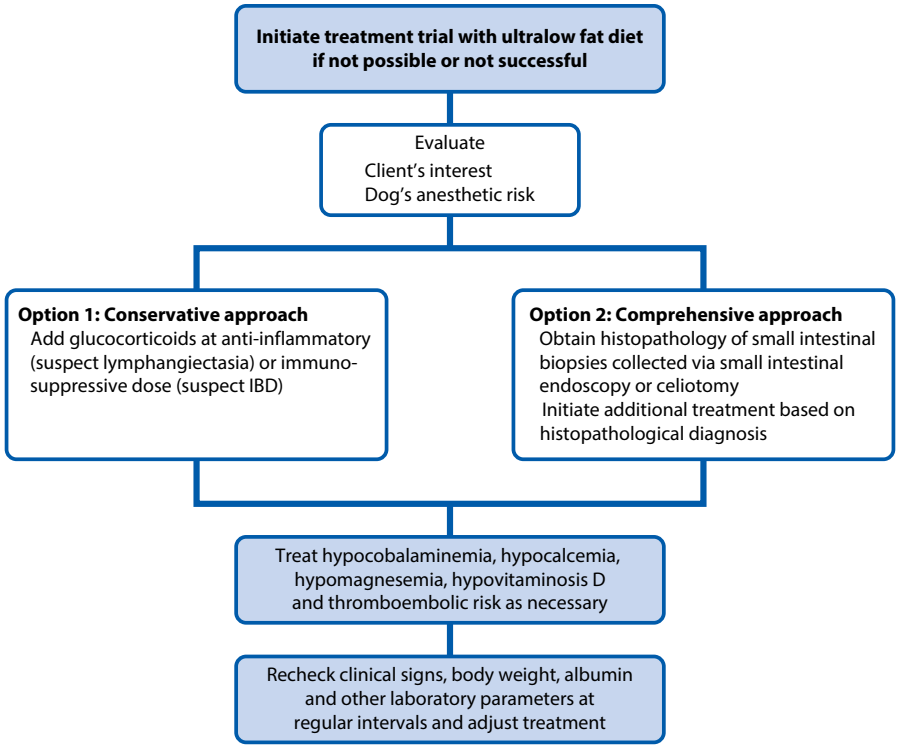

FIGURE 9.80 Recommendations for diagnostic confirmation and management of PLE in dogs.

white potatoes or boiled rice (two parts). The diet has a total caloric content of approximately 93–98 kcal/100 g (potato) or 123–128 kcal/100 g (rice). Its fat content of 0.35 g/100 kcal while conventional commercial low-fat diets have 2 g fat/100 kcal. While the diet is not balanced for long-term nutrition, it is palatable. Dogs that complete the trial successfully can progressively be switched to a commercial low-fat diet. Alternately, veterinarians can enroll the help of a board-certified small animal nutritionist to design an optimal dietary approach. In dogs with PLE associated with underlying IBD, a progressive switch to a diet consisting of hydrolyzed or novel proteins could be considered after the initial ULFD trial. In a recent study from Japan, dogs responding to this initial dietary approach were a little younger and had lower clinical scores (Table 9.9) than those that didn't. Their median survival was also markedly longer.

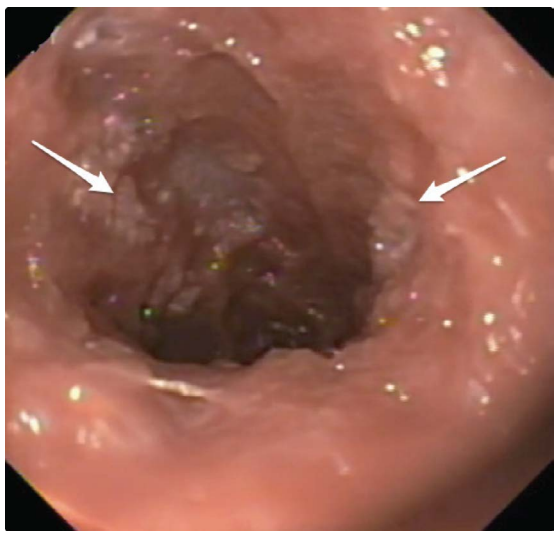

FIGURE 9.81 Endoscopic picture from the duodenum of the same dog as in **Figure 9.72**. The surface of the intestinal mucosa is very irregular and abnormal, and patches of recognizable villi are visible (arrows).

FIGURE 9.82 Endoscopic view of the duodenum of a 5-year-old Yorkshire Terrier. There are numerous multifocal white spots in the mucosa that represent dilated villi filled with chyme. The histopathologic diagnosis was idiopathic lymphangiectasia.

In dogs with primary intestinal lymphangiectasia that do not or only partially respond to the ULFD trial, anti-inflammatory glucocorticoid therapy (e.g., prednisone, 1 mg/kg per day) should be initiated. The main desired effect is to decrease the inflammation associated with lipogranulomas secondary to chyle leakage and, therefore, help restore an adequate flow in the intestinal lymphatics. In some dogs, anti-inflammatory treatment can be slowly weaned off over 2–3 months or longer. Dietary nonresponders with severe IBD and PLE should be treated with immunosuppressives (Table 9.10).

Complications

Low serum cobalamin concentrations are commonly found in dogs with PLE, especially in the presence of underlying IBD, and may delay proper healing of intestinal inflammation. Treatment is described earlier (Table 9.11).

The decrease in serum total calcium is associated with severe hypoalbuminemia, and serum ionized calcium should be measured. Ionized hypocalcemia occurs secondary to low 25-hydroxyvitamin D level which is presumably secondary to decreased ability to absorb fat in dogs with PLE. Hypovitaminosis D negatively impacts the immune system and is a negative prognostic factor. Although PLE dogs rarely experience clinical signs of hypocalcemia, those with moderately to severely decreased ionized calcium concentrations (< 2.5 mg/dL or < 1 mmol/L) should receive oral calcium carbonate supplementation (25 mg/kg p.o. q.8–12h.). Dogs with documented hypovitaminosis D should be given vitamin D supplementation. Concurrent hypomagnesemia may compromise the success of treatment and should be corrected if present (oral Mg supplementation with 1–2 mEq/kg daily).

Recent studies have revealed the high prevalence of hypercoagulability in dogs with PLE, which increases the risk of potentially fatal thromboembolic events. Hypercoagulability does not appear to resolve after successful treatment of PLE. However, clinical signs of thromboembolic disease are rare. Administration of low doses of aspirin (0.5–1 mg/kg per day) and/or clopidogrel (1–5 mg/kg per day) may be considered in order to prevent thrombosis, but this approach is controversial among specialists.

Prognosis

Generally, moderate-to-severe hypoalbuminemia (serum albumin < 2 g/dL), hypocobalaminemia and hypovitaminosis D are associated with a less favorable outcome. A few studies show a high mortality among Yorkshire Terriers with idiopathic intestinal lymphangiectasia (50%–60%). In the author's practice, these dogs often respond well to the initial dietary approach alone or with anti-inflammatory doses of glucocorticoids. A CECCAI below 8 offers an 83% sensitivity and 89% specificity of predicting clinical response to ULFD. Additionally, presence of crypt abscesses in the small intestine was associated with significantly shorter survival.

CHRONIC FELINE ENTEROPATHY

Definition/Overview

While the etiology and pathophysiology are thought to be similar to canine CE, the clinical presentation and approach of cats with CE is somewhat different. The terms CE and IBD are often used interchangeably in cats to describe chronic intestinal inflammation of unknown origin.

Clinical Presentation

The most commonly observed clinical signs are vomiting, anorexia, diarrhea, and weight loss (Figure 9.83). However, some cats may have a normal to increased appetite, and many cats, unlike dogs, will not have diarrhea at presentation. Other cats will be presented for hyporexia/anorexia and weight loss. The signs are often waxing and waning, and the owners may seek veterinary attention only late in the course of disease. Abnormal findings on physical examination of cats with CE include loss of body condition, dehydration, palpation of thickened bowel loops, and/or abdominal pain.

Differential Diagnosis

Particularly in the absence of specific signs, diseases originating outside the digestive tract such as hyperthyroidism, diabetes mellitus, chronic kidney disease, and heartworm disease, but also, liver disease and pancreatitis may share the same clinical presentation. Alimentary lymphoma, particularly diffusely infiltrative low-grade alimentary lymphoma (LGAL), is often very difficult to differentiate from IBD.

Diagnosis

The clinical signs may be very nonspecific, and the first step is to rule out diseases that may present with a similar clinical picture. A minimal database of CBC, chemistry profile, serum thyroxin concentration, and abdominal imaging (particularly ultrasound, Figure 9.114) is recommended. Serum cobalamin concentrations should be evaluated, as many cats with CE are hypocobalaminemic

FIGURE 9.83 Fourteen-year-old male neutered Domestic Longhair cat with chronic diarrhea and occasional vomiting. The cat was lethargic, cachectic, and his hair coat was in poor condition. Inflammatory bowel disease and alimentary lymphoma were among the top differentials.

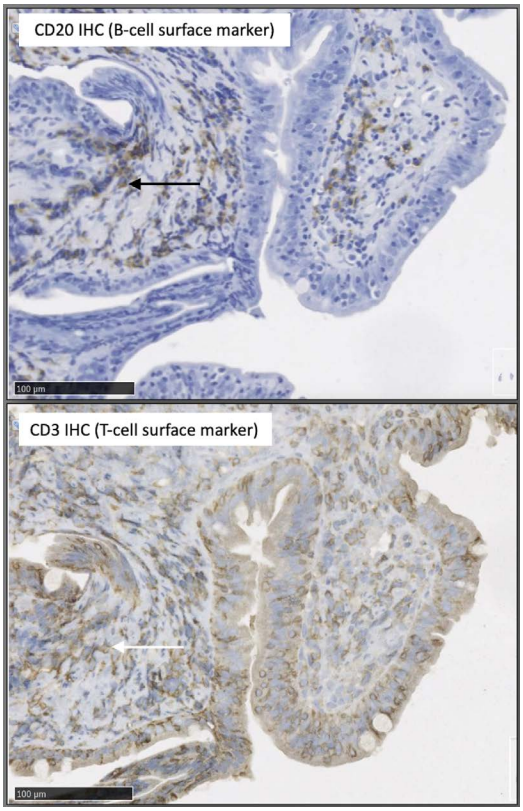

FIGURE 9.84 Photomicrograph of mucosal intestinal biopsies from a cat with IBD. There are CD20 (top, black arrow) and CD3 positive (bottom, white arrow) lymphocytes in the lamina propria showing the presence of a mixed population of B and T lymphocytes in the same areas of these sequential slices. This is typical of inflammation. Biopsies from a cat with LGAL would only show CD3 positive cells.

and require supplementation. Confirmation of diagnosis is based on histologic evaluation of intestinal biopsies collected using endoscopy or celiotomy. Differentiation between CE and low-grade alimentary lymphoma is challenging and often requires immunohistochemistry for lymphocytic surface markers (Figure 9.84). PCR for T-cell receptor rearrangement (PARR) performed on intestinal biopsies may also be helpful although false negatives and positives may occur.

Management

As is the case in dogs, a high proportion of cats with CE, particularly those with mild-to-moderate disease, may respond to an appropriate diet change (e.g., novel protein or hydrolyzed peptides). Some cats with dysbiosis may respond to concentrated probiotics or to antimicrobials (e.g., metronidazole, 10–15 mg/kg p.o. q.12h., although its therapeutic margin in cats is narrow).

Immunosuppressive therapy is the mainstay of IBD treatment. It is best initiated when histologic evidence of intestinal mucosal infiltration is available but could also be the final option of the empirical treatment sequence. Prednisolone (2–4 mg/kg p.o. q.24h. or divided into 2 daily doses) is administered for 2 weeks. If successful, once the clinical signs have been controlled for 2 weeks or longer, the dose is reduced by 25% every 2 weeks. The final goal is to maintain the cat on the lowest effective dose or even to consider discontinuation of steroid treatment if feasible. If the owner is unable to pill the cat, methylprednisolone acetate can be given (10 mg/kg SC q.2–4 weeks and tapered to q.4–8 weeks). However, repository steroids may cause more side effects and do not appear to be very successful in the author's experience. Failure to respond to treatment may indicate refractory IBD or lymphoma. Treatment of hypocobalaminemia, if present, with parenteral or oral cobalamin supplementation is necessary (Table 9.11). Refractory cases are usually treated with chlorambucil or cyclosporine (Table 9.10). Chlorambucil (2 mg per cat p.o. every other day [in cats > 4 kg body weight] or every 3 days [in cats < 4 kg body weight] and then tapered to the lowest effective dose) is generally used in combination with prednisolone. A CBC should be checked every 2–4 weeks for signs of myelosuppression. Although there are no published studies on cyclosporine use in cats with IBD, the dose generally recommended is approximately 5 mg/kg once daily (25 mg per cat).

Prognosis

In one study, the 3-year survival of cats with IBD was 77%. Many cats treated with diet change and prednisone have a positive response to treatment, although clinical signs may not completely resolve. Cats with severe histologic lesions or eosinophilic inflammation may be more difficult to manage. Feline IBD is a disease that is managed but rarely cured.

PARALYTIC ILEUS

Etiology

Primary nonobstructive disorders of intestinal motility are rare. Secondary alterations in motility of the small intestine occur with many diseases. Enteritis is associated with abnormal intestinal motility patterns that resolve with successful treatment of the inflammation. Intestinal hypomotility and ileus may occur after abdominal surgery (postoperative ileus [POI]) or during ischemic or inflammatory conditions affecting abdominal organs, such as peritonitis, pancreatitis, or parvovirus infection. Hyperthyroidism in cats may also alter intestinal transit time and cause diarrhea.

Pathophysiology

POI is thought to be due to inhibition of neural pathways and release of proinflammatory mediators and corticotrophin-releasing factor. They may be complicated by the use of opiates for analgesia.

Clinical Presentation

Vomiting (including silent vomiting without abdominal contraction), bloated abdomen, abdominal discomfort

or pain, and/or signs of colic. Hyporexia/anorexia, nausea, increased belching, pica, and/or polydipsia may also be observed.

Differential Diagnosis

Differential diagnoses are numerous. Small intestinal obstruction can result in a very similar presentation, and all necessary steps must be taken to rule it out. Autonomic neuropathy (dysautonomia) is a rare disease but should also be considered in the appropriate clinical setting.

Diagnosis

Clinical signs, abdominal radiographs often show dilated small intestinal segments in the absence of an obstructive pattern (see Figure 9.52). Precise evaluation of small intestinal motility is difficult under clinical conditions.

Management

Proper diagnosis and treatment of any underlying disease that might affect gastric motility is an essential premise. Therapy of functional, nonobstructive disorders of gastric motility is based on dietary modification and judicious use of prokinetic drugs. Dietary management is attempted at first: Small amounts of a low-fat, low-protein diet given at frequent intervals can help reduce the symptoms of delayed gastric emptying. Medical therapy can be attempted if dietary management alone is unsuccessful (Table 9.7).

Prognosis

Generally good if the problem is secondary to an underlying disease that can be treated successfully. Idiopathic disorders of small intestinal motility often represent a therapeutic challenge.

MALIGNANT SMALL INTESTINAL NEOPLASIA

Etiology

In dogs, small intestinal tumors occur relatively frequently (1%–8% of all canine cancers). Epithelial tumors include adenocarcinoma, mucinous adenocarcinoma, ring cell carcinoma, and undifferentiated carcinoma and represent 29% of all small intestinal tumors, as does lymphoma. Furthermore, 23% of small bowel neoplasms are leiomyosarcoma. These tumors may metastasize to mesenteric lymph nodes, liver, peritoneum, and lungs (adenocarcinoma metastasis rate is ~50%). Although low-grade alimentary lymphoma(LGAL) occurs much less frequently in dogs than in cats, it is a relevant differential diagnosis in dogs with CE and PLE.

In cats, small intestinal tumors are also relatively common (6%–13.5% of all feline cancers) and consist mostly of alimentary lymphoma (74%) and adenocarcinoma (17%). Siamese cats appear to be predisposed. Depending on the source, between one-third and three-quarters of all feline lymphomas are localized in the GI tract. Two main forms are recognized: LGAL, which causes a diffuse infiltration of the intestinal wall and consists of T cells, and high-grade alimentary lymphoma (HGAL), which causes focal or segmental disease and consists of B cells.

Pathophysiology

The cause of intestinal neoplasia in dogs and cats is unknown. An association between alimentary lymphoma and chronic inflammation (IBD) has been hypothesized in cats.

Clinical Presentation

Clinical signs develop late in the course of disease. They include chronic progressive vomiting, small bowel diarrhea, hyporexia/anorexia, hematochezia, and melena. An abdominal mass is palpable in 50% of cases with a discrete neoplasm. In diffusely infiltrative tumors, thickening of the small intestinal wall may also be palpable. Enlarged abdominal lymph nodes may also be detected. Clinical features of cats with LGAL are often identical to those of cats with IBD (Figure 9.83).

Differential Diagnosis

For occlusive tumors, intestinal FB, granulomatous disease (e.g., pythiosis), other causes of vomiting such as pancreatitis, metabolic disease (e.g., chronic kidney disease). Feline IBD is the top differential diagnosis for cats with LGAL.

Diagnosis

As stated previously, it may be very difficult to differentiate cats with moderate-to-severe IBD from those with LGAL. Collection of intestinal biopsies of adequate size for histopathologic interpretation is essential but does not guarantee that a final diagnosis will be reached. Both endoscopy and surgery allow collection of quality diagnostic samples. Multiple mucosal biopsies can be obtained endoscopically from the duodenum and ileum, while several full-thickness biopsies can be sampled surgically from the various sections of the small intestine. Special immunohistochemistry stains evaluating lymphocytic surface antigens (Figure 9.84) and to some extent PCR for antigen receptor rearrangement (PARR) can be of further help in attempting to confirm a diagnosis of LGAL.

CBC may reveal anemia (chronic disease or blood loss), serum chemistry may show hypoalbuminemia and increased liver enzymes. An obstructive pattern may be seen on abdominal radiographs; thoracic films may reveal metastases. Abdominal ultrasound is the most sensitive imaging method. It allows evaluation of localization, size, and extent of the mass and can be used to guide fine-needle aspiration for cytologic evaluation.

Management

In the absence of distant metastases, surgical resection with appropriate margins is the treatment of choice for most small intestinal tumors, with the exception of feline LGAL.

LGAL can be treated efficiently with a combination of prednisolone and chlorambucil (Table 9.10). Between 55% and 76% of cats achieve complete remission with a median survival time (MST) of 14–36 months. As is the case for CE, serum cobalamin concentration should be monitored, and supplementation started as necessary (Table 9.11). Chemotherapy for HGAL is best initiated after the mass has been resected. The CHOP protocol, consisting of prednisolone, vincristine, cyclophosphamide, and doxorubicin, is preferred. The rate of complete remission is 38%–87%, with an MST of 8 months.

Prognosis

Canine adenocarcinoma carries a good prognosis with > 2-year survival documented in the absence of metastases and with clean margins and an MST of 15 months. In cases with metastasis, the MST is usually significantly shorter (3 months). In cats, survival ranges from 5 to 13 months. The benefit of postsurgical chemotherapy has not been scientifically evaluated. MST for canine leiomyosarcoma with or without metastasis ranges from 9 to 22 months.

PART 5: DISEASES OF THE LARGE INTESTINE

Overview

Inflammatory diseases of the colon are frequently encountered in dogs and are less common in cats. In many instances, acute nonspecific colitis is self-limiting. Chronic colitis is often associated with a long, sometimes waxing and waning clinical course and specific treatments. Constipation is an uncommon clinical sign usually encountered in older animals and affects cats more frequently than dogs.

Anatomy and Physiology of the Large Intestine

The large intestine consists of six segments: Cecum (a short blind pouch), ascending colon, transverse colon, descending colon, rectum, and anus. The ileocolic valve and its sphincter separate the distal small intestine and the large intestine (Figure 9.85). The microscopic structure of the large intestine resembles that of the small intestine. However, the large intestinal mucosa does not form villi, the epithelial cells have fewer microvilli on their apical surface than enterocytes, and numerous goblet cells are interspersed in the epithelial layer (Figure 9.86). The colon has two main functions: Water absorption, which takes place in the proximal colon, and storage and elimination of feces. Colonic motility includes a few patterns with different functions: Stationary contractions mix the content and indirectly promote water absorption and peristaltic contractions move the feces aborally over small distances. Eventually, giant contractions precede defecation and move feces over longer segments. The gastrocolic reflex is mediated by enteric nerves and enhances colonic motility after a meal, leading to defecation.

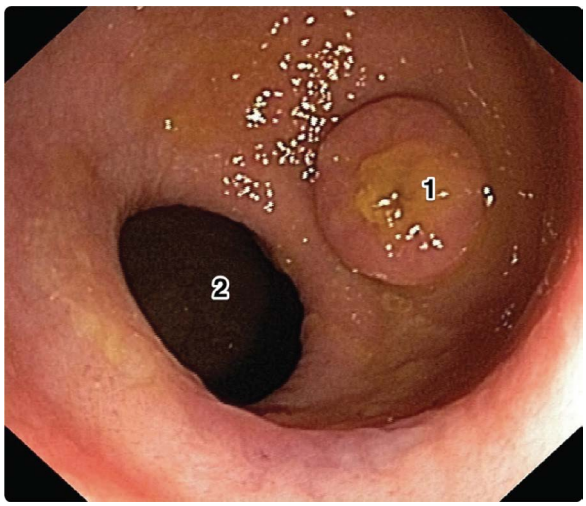

FIGURE 9.85 Endoscopic view from the ascending colon of a dog. The ileocolic junction (1) and the entrance to the cecum (2) are visible. (*Courtesy of R. Husnik.*)

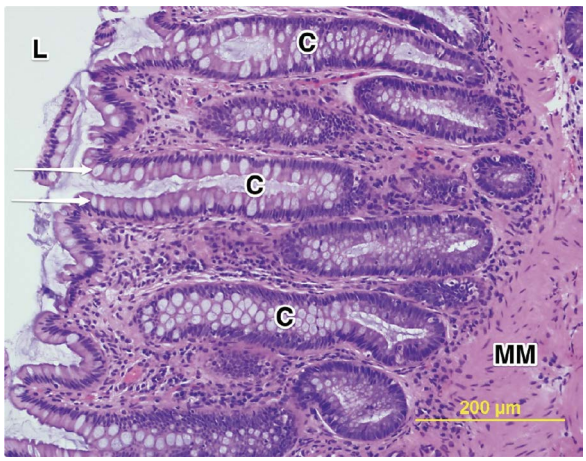

FIGURE 9.86 Photomicrograph of the canine colonic mucosa. The arrows point to a few of the numerous goblet cells. Mucus can be observed on the surface of the epithelium and in the colonic crypts. There is mild expansion of the lamina propria, with lymphoplasmacytic inflammation. C, colonic crypts; L, lumen; MM, muscularis mucosae.

ACUTE COLITIS

PARASITIC COLITIS (WHIPWORMS)

Definition/Overview

As stated earlier, the CAPC maintains a very informative and freely accessible website on intestinal parasites

of small animals, and this should be consulted for additional information (www.capcvet.org).

Etiology

Trichuris vulpis is a common cause of large bowel diarrhea in dogs. Whipworm infestation in cats is rare and caused by *T. campanula* and *T. serrata*. The infection mode is fecal–oral. Eggs develop into larvae in the small intestine, and larvae ultimately migrate to the cecum and colon, where they develop to adult worms.

Pathophysiology

Adult whipworms feed on cecal and colonic epithelial cells. Severe typhlitis and colitis may occur with heavy infestations; however, many dogs infested with few whipworms do not show clinical signs.

Clinical Presentation

Acute or chronic large bowel diarrhea that may occur in dogs of all ages. Severely affected animals may present with lethargy, hyporexia, and dehydration. Abdominal discomfort or abdominal pain due to accumulation of gas in the large intestinal lumen may also be present. Rarely, whipworm infested dogs may show hyperkalemia and hyponatremia, which is suggestive of hypoadrenocorticism, even though their adrenal glands are fully functional.

Differential Diagnosis

Other causes of acute colitis (dietary, idiopathic) or chronic colitis (IBD, granulomatous colitis). In the presence of hyperkalemia and hyponatremia, hypoadrenocorticism.

Diagnosis

Fecal flotation allows identification of the bipolar operculated eggs (Figure 9.87). However, fecal shedding of ova may only occur intermittently, particularly if immature worms are involved. Therefore, repeated fecal examinations usually increase the diagnostic yield. Alternatively, empirical treatment may be initiated with a broad-spectrum anthelminthic. Further diagnostic testing is generally not required with the exception of severely dehydrated dogs and animals with pre-existing conditions. In dogs with recurrent episodes of acute diarrhea, a more detailed workup may be indicated.

FIGURE 9.87 *T. vulpis* egg. The egg is lemon-shaped with a plug (operculum) at each pole. (*Courtesy of B. Delcambre.*)

Management

Fenbendazole (50 mg/kg per day for 3 days) or febantel (25 mg/kg once) are the anthelminthic drugs of choice. Because immature adults and larval stages are less sensitive to the drugs, treatment should be repeated 3 weeks later and again after 3 months. Milbemycin oxime and moxidectin used monthly to prevent heartworm infection are also useful for prevention and treatment of whipworm infestations. Whipworm ova are resistant to unfavorable environmental conditions and may represent a problem in shelter situations.

ACUTE IDIOPATHIC COLITIS

Etiology

Unknown. Some form of dietary indiscretion is usually present.

Pathophysiology

Colonic inflammation is associated with decreased nonpropulsive motility and excessive propulsive motility that results in diarrhea with frequent defecation of feces of decreased consistency.

Clinical Presentation

Large bowel diarrhea with all typical components including hematochezia (Figure 2.3.3), mucoid feces (Figure 2.3.6), and tenesmus (Figure 9.88), as listed in Table 2.3.1. Acute nonspecific colitis may occur in dogs of any age.

Diagnosis

Elimination of known causes of acute colitis such as whipworm infestation.

FIGURE 9.88 Tenesmus in a 2-year-old Boxer with chronic colitis. When walked, the dog immediately attempted to defecate. It remained in this position for more than 2 minutes and produced only a small quantity of liquid feces.

Management

The disease is usually self-limiting. Mild cases may not require any treatment. Moderate cases respond well to symptomatic treatment that includes dietary manipulations with a 12- to 24-hour fasting period. An easily digestible low residue diet should be fed for 3-5 days (small meals several times daily), with progressive return to a good-quality commercial diet over the following 3–5 days. Systematic use of antimicrobials in cases of acute nonspecific colitis is not recommended because increases in the resistance of *C. perfringens* to metronidazole have been reported and are concerning. Metronidazole has been commonly used in the treatment of acute colitis because of its effects on the intestinal microbiota, its properties as a modulator of inflammation, and its spectrum against anaerobic infections. The use of probiotics provides a good alternative to antimicrobials (Box 9.6).

In cases with clinical evidence of dehydration, IV fluids should be administered using balanced isotonic crystalloid solutions at appropriate rates to rapidly replace fluid deficits and provide maintenance requirements. In dogs with severe acute colitis and consistent abdominal pain, analgesic treatment should be considered.

Prognosis

Good to excellent. The disease is generally self-limiting, or it responds well to symptomatic treatment.

CHRONIC COLITIS

FUNGAL AND OOMYCETAL COLITIS

Overview

Animals infected with histoplasmosis may show signs of large bowel diarrhea. Rectal scraping or fine-needle aspiration of enlarged abdominal lymph nodes may be diagnostic and reveal large numbers of fungal organisms phagocytized by macrophages (see Figure 9.64). Pythiosis is caused by an oomycetal organism and may occasionally diffusely infiltrate the colonic and rectal wall and cause severe clinical signs. The prognosis is generally poor.

Further details about histoplasmosis and pythiosis can be found in Part 4: Diseases of the Small Intestine.

PARASITIC COLITIS

WHIPWORMS

See Acute Colitis.

TRICHOMONIASIS

Etiology

Tritrichomonas blagburni, also named *T. foetus*, is a protozoal organism associated with chronic, recurring feline colitis in large multicat households. Most affected cats come from shelters or belong to breeders, and it is suspected that environmental stress plays a role in their susceptibility to the infection. Coinfections with *Giardia* are common. *T. blagburni* is not very resistant in the environment and direct fecal–oral contact is required for transmission (e.g., multicat litterbox).

Pathophysiology

T. blagburni live in the cecum, descending colon, and ileum and may cause lymphoplasmacytic and/or neutrophilic inflammation of the mucosa with secondary architectural changes.

Clinical Presentation

The disease affects young cats, with onset between birth and 2 years of age. Seventy-five percent or more of affected cats are younger than 1 year of age at the time of diagnosis. Affected cats either live or have lived in a large multicat household. Typical clinical signs include waxing and waning large bowel diarrhea, which may contain mucus and blood. The feces are soft and malodorous (Figure 9.89). Secondary anal inflammation may be observed.

Differential Diagnosis

In shelter or other large multicat household situations, other infectious diseases such as infestation with *Giardia* or *Cryptosporidium* (see Chronic Enteritis), alone or in combination, may also occur. However, these protozoa more often cause small intestinal or mixed diarrhea. In spite of the young age of cats with suspect *T. blagburni* infections, CE should also be considered (DRD, IBD).

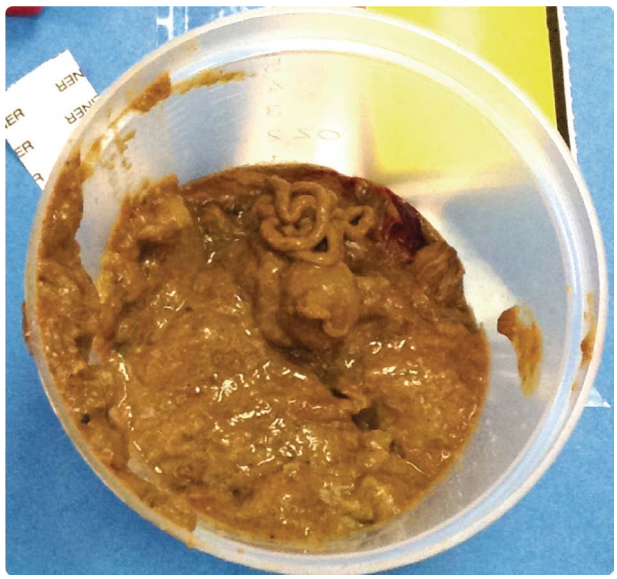

FIGURE 9.89 Soft and malodorous diarrhea from a cat with *T. blagburni* infection. (*Courtesy of M.K. Tolbert.*)

Diagnosis

Three methods are available for detection of *T. blagburni* in the feces. Direct analysis of fresh feces after dilution with saline is an insensitive method (14%) but may yield a positive result in diarrheic feces of severely affected cats (Figure 9.90). Feces are best sampled by flushing the colon with saline and should be analyzed within 2 hours. Under the microscope, *T. blagburni* trophozoites may be misdiagnosed as *Giardia*; however, they have a characteristic forward motion that contrasts with the "falling leaf" motion of *Giardia* trophozoites. Another method is to inject a small amount of fresh feces into a special culture medium (In Pouch TF-Feline) and evaluate the medium under the microscope at daily intervals for the presence of *T. blagburni* trophozoites. The sensitivity of culture is intermediate (55%). Fecal PCR is the most sensitive method to detect *T. blagburni*, particularly when samples are collected using a fecal loop. Recommendations to increase the yield of fecal PCR can be found at www.JodyGookin.com.

Management

Treatment of *T. blagburni* infection in cats is problematic as fenbendazole and metronidazole, as well as many other drugs, are ineffective. In a recent study, ronidazole (30 mg/kg p.o. q.24h. for 2 weeks) was effective at resolving clinical signs in 23 of 27 cats, with most cats becoming PCR negative. Only three cats developed side effects consisting mostly of lethargy, vomiting, and lack of appetite that resolved after discontinuation of the drug. Ronidazole neurotoxicity has been reported within 3–9 days after initiation of treatment and resolved after discontinuation of the drug. Therefore, ronidazole should be administered only after a definitive diagnosis has been made and only at the dosage listed earlier. Natural resistance of *T. blagburni* to ronidazole has been demonstrated in up to 21% of cats. Ronidazole is not approved for use in cats and must be compounded in capsules.

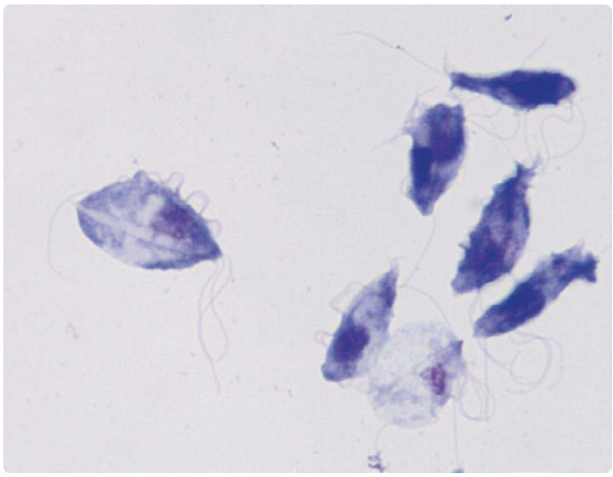

FIGURE 9.90 Microphotograph of stained *T. blagburni* trophozoites. (*Courtesy of M.K. Tolbert.*)

Prognosis

Spontaneous resolution of *T. blagburni* infection usually occurs within 2 years of onset. However, many cats may remain silent carriers and be able to infect other cats. Ronidazole treatment is most efficacious in animals relocated to single-cat households, as the risk for reinfection is low.

CHRONIC IDIOPATHIC COLITIS

DIET-RESPONSIVE CHRONIC COLITIS

Overview

In a study of 70 dogs with chronic diarrhea, 39 (56%) responded to an elimination trial with a novel protein diet. Of those, 27 (69%) exclusively showed large bowel diarrhea while nine (23%) had mixed large and small bowel signs. Similarly, in another study, 27 (49%) of 55 cats with chronic intestinal disease were diet responsive, while 16 (29%) were diagnosed as food sensitive. Two-thirds of the feline group had abnormal findings on colonic or rectal histopathology.

Based on these data, an elimination trial with hydrolyzed peptide or novel protein diets chosen on the basis of the animal's dietary history should be initiated in all dogs with mild-to-moderate chronic idiopathic colitis. Clinical signs generally abate within 10–14 days of treatment.

INFLAMMATORY BOWEL DISEASE

Etiology/Pathophysiology

The etiology and pathophysiology of IBD are described in Part 4 (Diseases of the Small Intestine, Chronic Enteropathy). While it appears that IBD most often affects the small intestine or both small and large intestine concurrently (especially in cats), colonic IBD is a recognized disease. Synonyms include lymphoplasmacytic colitis, eosinophilic colitis.

Differential Diagnosis

Whipworms, diet-responsive colitis, possibly colorectal neoplasia. In cats with compatible signalment and history, *T. blagburni* infection.

Diagnosis

The diagnostic approach must be comprehensive to rule out all other known causes of colitis (Figure 2.3.8). While a treatment trial with sulfasalazine or olsalazine may be appropriate in dogs with suspect colonic IBD, colonoscopy with collection and histologic evaluation of mucosal biopsies is recommended prior to initiating immunosuppressive treatment. This will confirm the presence and assess the severity of colonic inflammation (Figures 9.91 and 9.92) and rule out other diseases such as granulomatous colitis or neoplasia (e.g., lymphoma, especially in cats). Colonoscopy

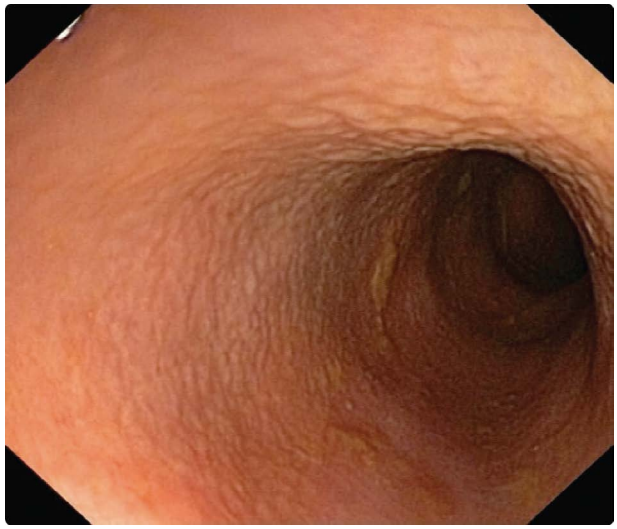

FIGURE 9.91 Colonoscopy view of a dog with chronic large bowel diarrhea. The inability to see submucosal vessels indicates thickening of the mucosa. The mucosal surface is irregular with a cobblestone pattern. The histopathologic diagnosis was severe lymphoplasmacytic colitis. (*Courtesy of R. Husnik.*)

requires appropriate preparation with prolonged fasting (24–48 hours), administration of osmotic laxative polyethylene glycol solution, and possibly enemas. A full examination of the rectum, colon, and cecum is only possible using flexible endoscopes under general anesthesia.

Management

In dogs with suspect colonic IBD, an anti-inflammatory treatment trial with sulfasalazine may be attempted (10–30 mg/kg [maximum 1 g total dose] p.o. q.8h. for 4–6 weeks). Sulfasalazine liberates 5-aminosalycilic acid in the colon and is widely used in the treatment of dogs with colitis. After successful completion of the initial treatment regimen, it is best to slowly decrease the dose in stages of 10–14 days. Monitoring tear production regularly during treatment is essential as keratoconjunctivitis sicca is a common complication. Olsalazine (5–15 mg/kg q.8–12h.) may be used in dogs that do not tolerate sulfasalazine. In addition, dietary fiber supplementation is often helpful (see Box 9.10). In cats with colonic IBD and in dogs with confirmed colonic IBD refractory to sulfasalazine or olsalazine, immunosuppressive prednisone should be initiated (Table 9.10).

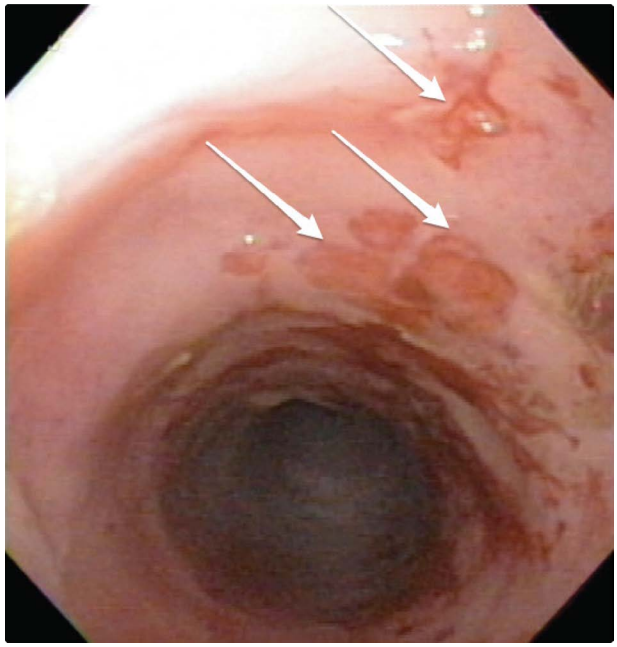

FIGURE 9.92 Colonoscopy picture of a 6-year-old cat with chronic large bowel diarrhea and hematochezia. There are numerous mucosal ulcerations (arrows). The histopathologic diagnosis was severe, ulcerative lymphoplasmacytic colitis. The cat improved when fed a novel protein diet and treated with immunosuppressive doses of prednisolone.

Box 9.10 Fiber supplementation in dogs with colitis and chronic idiopathic large bowel diarrhea

Overall, dietary fibers enhance the structure and function of the intestinal epithelium and also have beneficial effects on colonic motility. As a trade-off, they may have a negative impact on nutrient digestibility depending on the specific fiber type. Soluble fibers are fermented to short-chain fatty acids (SCFAs) by the colonic microbiota. SCFAs are an essential source of energy for colonic epithelial cells.

- Psyllium is a soluble fiber derived from the seed of *Plantago ovata*. It has great water-holding capacities and forms gels in water, two properties that can contribute to improvement of fecal consistency. Psyllium was very efficient when added to a highly digestible diet in the treatment of chronic idiopathic colitis. The initial daily dosage is 0.5 tablespoon (T) for toy breeds, 1 T for small dogs, 2 T for medium dogs, and 3 T for large dogs. The fiber supplement should be administered with each meal in two divided doses, and the dose increased to effect. Psyllium is included as an ingredient in a few commercial prescription diets.
- Canned pumpkin is another source of soluble fiber. It is administered with an initial dosage comparable to that of psyllium, and the dose is adapted to effect.

Other sources of SCFAs include fructooligosaccharides and beet pulp, which are included in some commercial diets.

Prognosis

Prognosis for IBD is generally better when only the colon is affected. However, one retrospective study of dogs with IBD did not find any association between localization of disease and outcome. Nevertheless, clinical studies demonstrated that many dogs and cats with colitis respond completely to dietary modification and/or, for dogs only, to sulfasalazine treatment.

GRANULOMATOUS COLITIS

Definition/Overview

Granulomatous colitis (GC) is a form of IBD that occurs most frequently in young Boxer dogs or, infrequently, in other breeds such as Mastiffs, Alaskan Malamutes, French Bulldogs, and English Bulldogs.

Etiology

Adherent-invasive *E. coli* that adhere to and invade intestinal epithelial cells and have been identified as the cause of GC. These bacteria are taken up by endosomes and persist in the macrophages instead of being cleared. A genetic predisposition for GC is suspected due to the preponderance of cases in young Boxer dogs. Preliminary results from genetic studies in Boxers with GC and healthy controls point to a defective clearance of *E. coli* in macrophages.

Clinical Presentation

The onset of disease generally occurs before 2 years of age. Clinical signs include severe chronic large intestinal inflammation with diarrhea, hematochezia, increased frequency of defecation, tenesmus, and presence of excessive mucus in the feces. Although physical examination is most frequently unremarkable, weight loss and inappetence can be seen in severe cases (Figure 9.93).

Diagnosis

Signalment, history, and clinical signs are usually very suggestive. While it is tempting to initiate a treatment trial in these dogs, a comprehensive diagnostic workup including endoscopic biopsies is the recommended approach.

Colonoscopy typically reveals sites of severe colonic hemorrhage and ulcerations interspersed with stretches of normal-appearing mucosa. Histology may show severe infiltration with neutrophils, macrophages, lymphocytes, plasma cells, and mast cells. Accumulation of large macrophages staining strongly positive with periodic acid Schiff (PAS) in their cytoplasm is pathognomonic for GC (Figure 9.94). Confirmation of the presence of *E. coli* using fluorescent in situ hybridization (FISH) analysis on formalin-fixed biopsies is now recommended as part of the detailed diagnostic workup of dogs with suspect histiocytic ulcerative colitis (HUC; Figure 9.95).

FIGURE 9.93 An 18-month-old Boxer with granulomatous colitis and chronic intermittent large bowel diarrhea, episodes of anorexia, and weight loss.

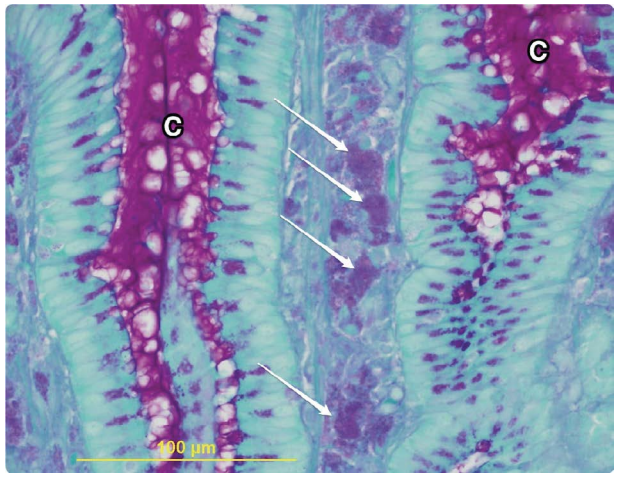

FIGURE 9.94 Photomicrograph from a colonic biopsy from a Boxer with granulomatous colitis. There are numerous, purple-stained macrophages in the lamina propria (arrows point to four such cells). It is thought that the PAS-positive intracellular material represents accumulation of *E. coli*. C, colonic crypts; PAS, periodic acid Schiff stain.

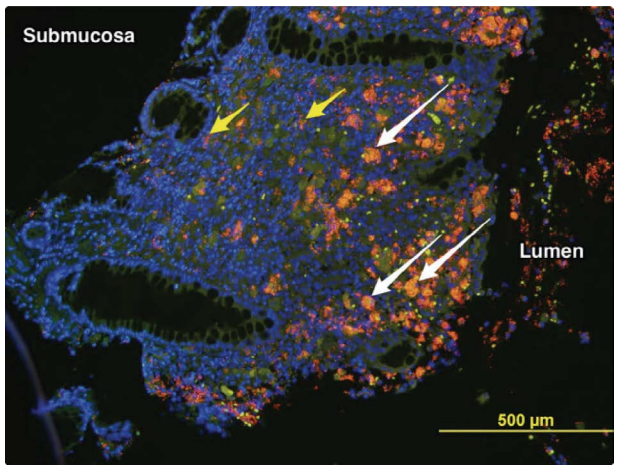

FIGURE 9.95 Photomicrograph of a colonic biopsy from a dog with granulomatous colitis (fluorescent in situ hybridization or FISH). Long white arrows show some of the macrophages filled with *E. coli* while short yellow arrows show examples of clusters of *E. coli* within the mucosa. *E. coli*-Cy3 probe stains *E. coli* in red orange; 4′, 6-diamidino-2-phenylindole (DAPI) stains nuclei in blue. (*Courtesy of K. Simpson.*)

Management

Treatment of the disease consists of enrofloxacin at 10–20 mg/kg p.o. q.24h. for 4–6 weeks. Most affected dogs respond within 10–14 days of initiating therapy. While several dogs were reportedly disease-free after the drug had been discontinued, there is increasing evidence that GC may relapse after treatment. Recent reports suggest that up to 43% of dogs with GC/HUC develop enrofloxacin resistance early in the disease process and may be refractory to treatment if they are treated empirically. Therefore, it is prudent to send colonic biopsies for culture and sensitivity before starting treatment and

tailor the choice of antibiotics to the specific sensitivity profile of the cultured *E. coli*.

Prognosis

The long-term prognosis is guarded to poor.

COLORECTAL OBSTRUCTION

Etiology/Pathophysiology

Luminal colonic or rectal obstruction may result from a FB or from the presence of hardened feces such as may be the case in constipated or obstipated patients. Alternatively, benign rectal strictures may occur in response to significant trauma of the rectal or distal colonic mucosa (e.g., FB, anorectal surgery). Fibrosis and cellular proliferation are responsible for narrowing of the lumen. Neoplastic masses arising from the colonic wall may also cause an obstruction to the passage of feces in the distal colon and rectum. They may cause malignant strictures. Finally, space-occupying lesions occurring in neighboring organs such as the prostate or sublumbar lymph nodes (**Figure 9.104**) may also compromise passage of feces through the distal large bowel.

Clinical Presentation

Dyschezia, tenesmus (**Figure 9.96**), passage of ribbon like feces (**Figure 9.97**), and hematochezia are frequently observed in association with partial or total colorectal obstruction. Severe retention of feces may lead to systemic repercussions such as hyporexia, lethargy, and vomiting.

Differential Diagnosis

Primary colonic dysmotility, perineal hernia, anal sacculitis, and pseudocoprostasis may all cause dyschezia.

Diagnosis

In animals with a suggestive presentation, abdominal palpation and digital rectal examination often allow confirmation of the presence of partial or total obstruction of the distal large bowel. Sedation may be required for a thorough rectal examination, particularly in animals who are in pain. Radiographs and ultrasound of the abdomen and pelvic canal may be useful to detect a radiopaque FB and/or evaluate the severity of fecal retention and examine the surrounding structures. Endoscopic evaluation can be performed using a rigid proctoscope or a flexible endoscope. This allows visualization of the rectum and distal colon and collection of mucosal biopsies if a neoplastic process is suspected.

Management

Most FBs can be dislodged using repeated warm water enemas with added water-soluble gel. Digital dilation of mild rectal strictures may be successful, although several procedures at intervals of 1 week are generally required. Balloon dilation usually has a higher success rate. In severe cases or cases refractory to dilatory procedures, surgical removal is required (rectal pull-through if possible or other procedure). The treatment of obstructive neoplasia relies on surgical excision if feasible.

FIGURE 9.96 Severe tenesmus and dyschezia in a 4-year-old Husky with constipation due to a rectal stricture. The anus was scarred and extremely painful to palpation. The dog vocalized loudly each time it tried to defecate. Eventually, defecation ceased, presumably because it was too painful. Attempts at surgical correction, including anal resection, were unsuccessful, and the dog was euthanized. (*Courtesy of C. Burrows.*)

Prognosis

FB, benign polyp –good to excellent. Stricture, other neoplasia –guarded to poor. Anorectal surgery may lead to fecal incontinence or recurrence of stricture.

FIGURE 9.97 This 13-year-old Dachshund was presented with the complaint of tenesmus and "narrow stools." The dog strained hard to defecate and passed pencil-thin feces. Rectal examination revealed a stricture. Biopsy revealed scar tissue, and the dog responded well to balloon dilation and sulfasalazine. (*Courtesy of C. Burrows.*)

FUNCTIONAL LARGE BOWEL DISORDERS

CHRONIC IDIOPATHIC LARGE BOWEL DIARRHEA

Definition/Overview

Chronic idiopathic large bowel diarrhea (CILBD) affects dogs and is characterized by recurrent large bowel diarrhea in the absence of histopathologic evidence of inflammation. It appears to be comparable to irritable bowel syndrome with diarrhea (IBS-D), a disease that is relatively common in people.

Etiology/Pathophysiology

The etiology of CILBD is unknown. In people, IBS is associated with visceral hypersensitivity, and patients have enhanced perception of visceral events such as contractions and gas throughout their GI tract. Stress, diet, and intestinal and colonic microbiota are all thought to play a role in the pathogenesis. Approximately 40% of dogs with CILBD have abnormal personality traits and/or are exposed to environmental stress factors (e.g., working dogs, boarding). Associated behavioral issues may include separation anxiety, submissive urination, noise sensitivity, aggression, or nervous, high-strung dogs. Environmental factors may range from presence of visitors in the household and construction in the house to traveling and moving.

Clinical Presentation

Dogs of all ages may be affected (median age 6 years old) and exhibit chronic intermittent large bowel diarrhea. Excessive mucus in the feces, hematochezia, increased number of daily defecations, and/or tenesmus are common. Appetite may be decreased during diarrheic episodes, and abdominal pain may be present. Vomiting may occur as well.

Differential Diagnosis

Whipworm infestation, diet-responsive colitis, colonic IBD, granulomatous colitis (in Boxer dogs and Bulldogs), colonic neoplasia.

Diagnosis

CILBD is a diagnosis by exclusion, and all other causes of chronic, intermittent large bowel diarrhea must be ruled out (Figure 2.3.8). Diagnostic criteria for CILBD include chronic or chronic recurring large bowel diarrhea of at least 4 weeks' duration, absence of or only minimal abnormal findings on physical examination and blood work, no other identifiable cause of diarrhea, and lack (or only minimal) changes observed during colonoscopy with unremarkable histopathologic evaluation of the colonic mucosa. Predisposing environmental factors or behavioral issues may be present.

Management

Between 63% and 96% of dogs with CILBD respond to fiber supplementation alone (Box 9.9). In fiber-refractory dogs, a full behavioral assessment should be performed, and behavior-modifying drugs prescribed as appropriate. In one study, approximately 60% of dogs requiring drug treatment responded, while 40% did not.

Prognosis

Prognosis is good considering the high response rate to fiber supplementation.

CONSTIPATION

Definition/Overview

Constipation is characterized by infrequent or difficult evacuation of feces. Obstipation is the result of recurrent, intractable constipation. Constipation and obstipation may culminate in the syndrome of megacolon. In the cat, constipation is a relatively frequent problem, while obstipation and megacolon are less common. Constipation and associated problems occur less frequently in the dog.

Etiology

Primary constipation is due to abnormal colonic motility. Neuromuscular dysfunction may occur in animals with lumbosacral disease or in cats with idiopathic megacolon. Dehydration, hypokalemia, and hypocalcemia may all negatively impact colonic motility. Inactivity and obesity may also cause prolonged large bowel transit time. Furthermore, use of opiates and anticholinergics may also lead to constipation.

Secondary constipation is more common and is associated with processes that impair the transit and evacuation of colonic content, such as mechanical obstruction of the colon or rectum. Obstructions can be intraluminal (e.g., fecal impaction, FB, stricture), intramural (neoplasia), or extramural (e.g., narrowing of the pelvic canal, space-occupying lesions impinging on the descending colon or rectum).

Clinical Presentation

Typical clinical signs include reduced, absent, or painful defecation, which may be progressive. Other clinical signs associated with a primary underlying disease might be present, such as those associated with hypothyroidism, which is more common in dogs. The onset of distal bowel signs may be insidious, and animals may be presented late when the problem is severe. Dyschezia may be observed (Figure 9.96). Chronic constipation/obstipation may have systemic repercussions such as anorexia, lethargy, weight loss, and vomiting.

Differential Diagnosis

Diseases of the anorectum such as perineal hernia and anal sacculitis may cause painful defecation. Pseudocoprostasis can be caused by matted hair around the anus, which occasionally occurs in dogs and cats with long hair. Importantly, some cat owners may not be able to differentiate stranguria and dyschezia, and lower urinary tract diseases should always be ruled out.

Diagnosis

A detailed physical examination is required. This may reveal varying degrees of dehydration, weight loss, and abdominal pain. Rectal palpation should be performed and may reveal pelvic canal abnormalities, a rectal FB, a stricture, or presence of a perineal hernia.

A thorough screening of animals presented with recurrent constipation is recommended to identify obstructions and underlying diseases and assess the systemic repercussions of the problem. A minimal database consisting of CBC, biochemistry panel, and urinalysis should be obtained in all cats presented for constipation to rule out metabolic causes and underlying chronic diseases such as chronic kidney disease. Abdominal radiographs help characterize the severity of colonic impaction (**Figures 9.98** and **9.99**) and identify predisposing factors such as intraluminal radiopaque foreign material, intraluminal or extraluminal mass lesions, pelvic fractures, and spinal abnormalities. Extraluminal mass lesions may be further evaluated by abdominal ultrasonography and guided biopsy, whereas intraluminal mass lesions are best evaluated by endoscopy.

Management

All identified underlying problems should be treated. If the cause of the obstruction can be addressed in a timely manner, colonic function may be preserved. However, prolonged obstruction is ultimately associated with loss of colonic contractility.

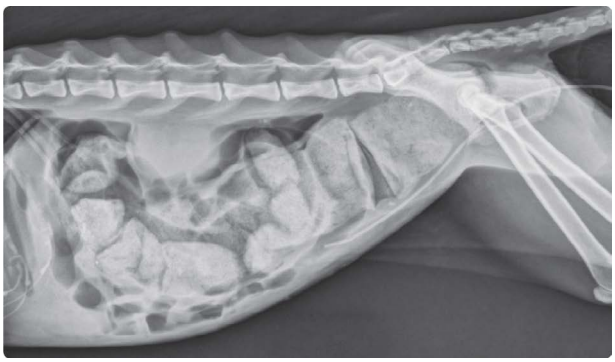

FIGURE 9.98 Ten-year-old female spayed Domestic Shorthair cat. Right lateral abdominal radiograph. There is severe dilation of the entire colon from the cecum to the rectum with large amounts of radiopaque fecal material. The cat is in poor body condition. Radiographic diagnosis is megacolon. A urinary catheter is present.

FIGURE 9.99 Ventrodorsal abdominal radiograph from the same cat as **Figure 9.98**. The severely dilated and impacted colon is displaced to the right. (*Courtesy of L. Gaschen.*)

The different methods for treatment of idiopathic, nonobstructive constipation include administration of oral laxatives, enemas (**Table 9.12**), and prokinetic agents such as cisapride (**Table 9.7**).

In cats with chronic recurrent idiopathic constipation, a stepwise approach has proven useful. Mild-to-moderate constipation (e.g., first occurrence, recurrence after a long interval with normal defecation) is best treated with an initial enema followed by treatment with laxatives. High-sodium and phosphate-containing enemas are not recommended because of their tendency to cause acute hyperphosphatemia and severe hypocalcemia. Maintaining these cats on a psyllium-enriched diet or continuing daily administration of laxatives is recommended. Addition of prokinetics is necessary when management with diet and laxatives fails. Early use of cisapride is likely to prevent the progression of constipation to obstipation and dilated megacolon in these cats. However, some cases become refractory to conservative treatment and slowly progress to obstipation and dilated megacolon.

TABLE 9.12 Therapeutic options for conservative management of constipation in cats

Laxatives (administer in well-hydrated cats only)	**Bulk-forming** (add to moist cat food) More useful in mild cases	Psyllium (1–4 teaspoons per meal); also available incorporated in a proprietary dry extruded diet (Royal Canin Intestinal Fibre Response)
		Wheat bran (1–2 tablespoons per meal)
	Emollient	Dioctyl sodium succinate (10–15 mL per cat p.o.)
	Lubricant	Mineral oil (10–15 mL per cat p.o.) Administer with caution due to risk of aspiration
		White petrolatum (1–5 mL per cat p.o.)
	Osmotic	Lactulose (0.5 mL/kg p.o. q.8–12h.)
		PEG 3350 (Colyte) 1.9 g per cat Dose can be doubled if no results are seen after 48 hours (see **Box 9.11** for CRI instructions)
	Stimulant	Bisacodyl (5 mg p.o. q.24h.)
Removal of feces	**Enemas**	Warm water (5–10 mL/kg)
		Dioctyl sodium succinate or DSS (5–10 mL per cat)
		Mineral oil (5–10 mL per cat)
		Lactulose (5–10 mL per cat)
	Manual extraction	Under anesthesia

Box 9.11 Conservative treatment of moderate-to-severe colonic impaction on cats

Polyethylene glycol (PEG) 3350 is an osmotic laxative that has been shown to be safe and palatable in cats. PEG 3350 can be administered to constipated or obstipated cats through a nasoesophageal tube as a CRI at a rate of between 6 and 10 mL/kg per hour. In a study of constipated cats, the mean total dose required was 80 mL/kg (range 40–156), and defecation occurred on average 8 hours after initiation of treatment (range 5–24). The technique has considerably decreased the need for enemas in feline practice (**Figure 9.100**).

FIGURE 9.100 Constipated cat receiving PEG 3350 as a constant rate infusion via a nasoesophageal tube. (*Courtesy of S. Little.*)

From Carr AP, Gaunt MC (2010). Constipation resolution with administration of polyethylene-glycol solution in cats. *J Vet Intern Med* 24(3):753–754. Little S (2014). Personal communication.

When treating a constipated cat, enemas should be given slowly, as rapid administration may cause reflex vomiting and rapid and excessive efflux of the liquid and may also increase the risk of colonic perforation. If several enemas fail to induce defecation, nasoesophageal administration of PEG 3350 is a relatively noninvasive method with an excellent success rate (**Box 9.11** and **Figure 9.100**). This technique has significantly decreased the number of cases that need to undergo manual extraction of feces, a technique used when all other options have failed. It is best performed on an anesthetized cat with careful transabdominal colonic massage and simultaneous rectal administration of a combination of warm water or physiologic saline with water-soluble lubricants to break down the impacted feces. Some authors recommend administering a low dose of metronidazole (7.5–15 mg/kg p.o. q.12h.) in order to limit the risk of bacterial translocation during or after the procedure.

A surgical approach is the last option for severe cases with obstipation or megacolon that does not respond to conservative treatment options. Different techniques for colectomy have been successful.

Prognosis

Many cats have one or two episodes of constipation without further recurrence, although others may progress to complete colonic failure. When conservative management

has failed, colectomy is usually associated with a favorable prognosis, although mild-to-moderate diarrhea may persist for 4–6 weeks postoperatively in some cases.

RECTAL PROLAPSE

Definition/Overview

Prolapse can be partial with protrusion of anal mucosa only (anal prolapse) or complete with protrusion of all layers of the rectum (rectal prolapse).

Etiology

Prolapse occurs secondary to tenesmus associated with disorders of the colon, anorectum, or urogenital tract. Prevalence appears to be higher in young animals. Predisposing factors include GI parasitism, typhlitis, colitis, proctitis, colorectal neoplasia, rectal FBs, perineal hernia, diseases of the urinary bladder, prostatic disorders, and dystocia.

Clinical Presentation

Anal prolapse is characterized by the presence of red, swollen mucosa protruding from the anus, particularly after defecation. In animals with a rectal prolapse, there is an often round or cylindrical mass protruding from the anus (Figure 9.101). The everted rectal mucosa and other wall layers can become ischemic and damaged and necrotic after prolonged exposure.

Diagnosis

A thorough physical examination is necessary to screen for the underlying diseases listed previously predisposing to prolapse. If indicated, additional tests, such as fecal parasitologic examination, blood analyses, and abdominal imaging should be performed.

FIGURE 9.101 Young mixed-breed dog with rectal prolapse. Sugar has been applied to the mucosa to decrease the swelling.

Management

Reduction under sedation is easiest in animals with anal prolapse using saline and water-soluble lubricant gel. When a significant amount of mucosa is exposed or in rectal prolapse, 50% dextrose can be applied to the mucosa to reduce edema prior to careful repositioning. Corticosteroid cream can also be used to decrease inflammation and straining. A purse-string suture is applied around the anus to narrow the anal orifice while allowing soft feces to pass through and kept in place for 3–5 days. The animal should be fed a low residue diet. Administering lactulose orally to effect (Table 9.12) may be helpful. If the prolapsed rectal mucosa is traumatized or necrotic, surgical resection is required. Underlying conditions must be addressed to prevent recurrence. Colopexy may be required in animals experiencing recurrent episodes despite appropriate treatment.

Prognosis

Generally good if the mucosa is viable and the prolapse can be reduced. Guarded to poor if resection is required because of the risk of stricture.

COLORECTAL NEOPLASIA

Etiology

In dogs, the prevalence of colorectal neoplasia is higher than that of gastric and small intestinal tumors. The sites of predilection are the descending colon and rectum. Adenomas and polyps are relatively common (Figure 9.102), and in situ progression to carcinoma has been documented. The most common type of malignant neoplasia is adenocarcinoma, followed by lymphoma and stromal tumors such as leiomyosarcoma. Local tumor invasion appears to be slow, and metastasis to distant sites is uncommon.

In cats, adenocarcinoma and lymphoma are the two most frequent types of colorectal neoplasia, followed by mast cell tumors. Sites of predilection are the descending colon and ileocolic junction. Malignant feline colorectal tumors have a high rate of metastasis. Alimentary lymphoma often involves both the small and large intestines.

Pathophysiology

Colorectal neoplasms may cause mechanical obstruction. Colonic dysfunction with abnormal motility and decreased water reabsorption capacity (with subsequent diarrhea) may also occur.

Clinical Presentation

In dogs, common clinical signs include hematochezia, mucoid feces, and dyschezia, with or without concurrent diarrhea. Dyschezia may be associated with passage of feces of a smaller than usual diameter (see Figure 9.97). Systemic neoplasia such as lymphoma may be associated with signs suggesting involvement of other

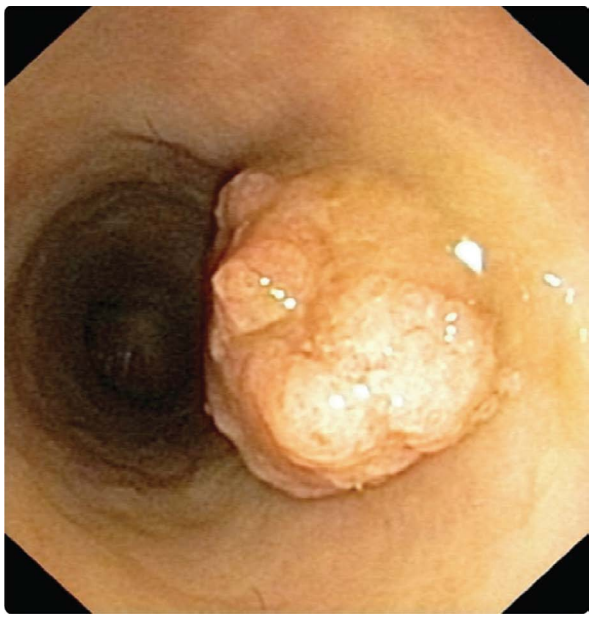

FIGURE 9.102 Colonoscopic view of an adenoma located in the distal colon of a dog. The parietal mass is pedunculated and could be removed with an electrocautery snare passed through the biopsy channel of the endoscope. (*Courtesy of R. Husnik.*)

organs, hyporexia, and weight loss. In cats, vomiting, diarrhea, and weight loss are common with or without clinical signs of large bowel disease.

Differential Diagnosis

Causes of chronic colitis such as IBD, GC, heavy whipworm infestation in dogs, IBD in cats. Also, distal colonic or rectal FB or stricture.

Diagnosis

In dogs, rectal palpation can detect up to 80% of rectal tumors. In cats, more than half of colonic masses can be palpated abdominally. Survey radiographs may show an accumulation of feces orad to the neoplasm. Mural masses can be visualized using abdominal ultrasound, and surrounding lymph nodes can also be evaluated. Cytologic evaluation of ultrasound-guided fine-needle aspirates can be useful, particularly for diagnosis of lymphoma. However, the diagnosis of most other tumors requires histopathology from a biopsy collected during colonoscopy. Endoscopy also allows a good evaluation of the severity and extent of the tumor (Figures 9.102 and 9.103). Thoracic radiographs and abdominal ultrasound are used to stage the tumor, looking for pulmonary masses and abnormal abdominal lymph nodes.

Management

Rectal tumors are usually amenable to surgical resection using the rectal pull-through technique. Masses located in the cecum and colon require standard celiotomy for resection. The benefit of chemotherapy has not been established except for alimentary lymphoma.

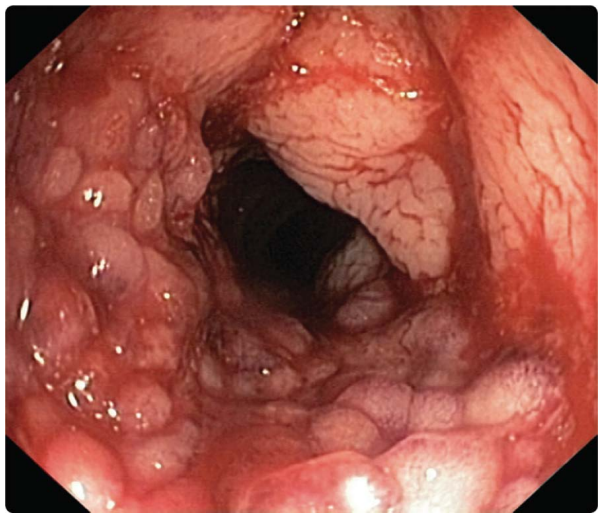

FIGURE 9.103 Endoscopic view of a dog with a severely abnormal rectal and colonic wall. The histopathologic diagnosis was adenocarcinoma. (*Courtesy of R. Husnik.*)

Currently, recommended chemotherapy protocols are best found in recent oncology texts.

Prognosis

Surgical excision is generally curative for benign tumors. The rectal pull-through technique has few complications; however, secondary infections may occur after celiotomy and resection of large bowel masses.

Canine carcinomas have been associated with a median survival of 32 months after removal in pedunculated tumors, 12 months for sessile tumors, and less than 2 months for annular tumors. The median survival time for leiomyosarcoma is 9–22 months after resection. Even though feline carcinomas benefit from an aggressive approach (subtotal colectomy), the median survival is only 4–5 months. The approach to alimentary lymphomas in cats is discussed in more detail in Part 4: Diseases of the Small Intestine.

PART 6: DISEASES OF THE ANUS AND PERINEUM

DISEASES OF THE ANAL SACS

Definition/Overview

Anal sac impaction, anal sacculitis, and abscess formation are common anal sac diseases that may occur in dogs and occasionally in cats. Small breed dogs and some large canine breeds (e.g., German Shepherd Dog) appear to be at higher risk of developing anal sac diseases.

Etiology

The exact cause of anal sac disorders is unknown. Abnormal anal sac emptying may occur with decreased fecal consistency, obesity, and inactivity or in association

with painful perianal processes such as anal furunculosis. Anal sac impaction increases the risk of infection and/or abscessation.

Clinical Presentation

Anal sac disease commonly causes anal or perianal pruritus and pain, with excessive licking and/or biting of the area, tail chasing, scooting, and rubbing the anus on the ground. If the perineal area is swollen and painful, the animal may not want to sit. Other frequently associated signs include dyschezia, tenesmus, or even reluctance to defecate. A detailed examination of the perineal area, including rectal palpation, may reveal swelling and pain to the touch.

Differential Diagnosis

Anal furunculosis, perianal or anal tumors, and bite wounds (especially in cats).

Diagnosis

History and clinical signs are suggestive. Swelling may be visible in the 4- and 8-o'clock positions ventral to the anus. Rectal palpation confirms the presence of swollen anal sacs, which are often painful. With impaction, pasty, thick, and malodorous material can be expressed from the swollen sacs. If the expressed material is bloody and/or purulent, anal sacculitis is likely and can be confirmed cytologically by the presence of large amounts of neutrophils with intracellular bacteria. Abscesses often involve the surrounding tissues, and cytology of a fine-needle aspirate is diagnostic.

Management

Anal sac impaction is treated with gentle expression of the swollen anal sacs. If digital massage and expression are not successful, flushing the anal sacs with saline is recommended. Instillation of an antibiotic and steroid ointment into the empty sacs is generally recommended. In animals with infected sacs, treatment also consists of emptying and flushing the sacs and instillation of an antibiotic ointment. However, this generally requires sedation or light anesthesia. Systemic antibiotic treatment with a broad-spectrum antibiotic for 10–14 days is usually recommended. Topical treatment with hot compresses several times daily may help reduce swelling and pain. Abscesses should be lanced, flushed, and treated with systemic antibiotics. Anal sacculectomy is a last resort option for recurring cases.

Prognosis

Usually very good. Fecal incontinence is a possible complication of anal sacculectomy.

ANAL SAC TUMORS

Definition/Overview

Anal sac tumors are uncommon and very often malignant neoplasms that occur in dogs. They may metastasize to regional lymph nodes and invade surrounding tissues.

Etiology/Pathophysiology

The etiology is unknown. Between 50% and 90% of dogs with anal sac adenocarcinomas are hypercalcemic due to production of parathyroid hormone-related peptide by cancerous cells. This malignancy-associated hypercalcemia may ultimately lead to irreversible kidney injury.

Clinical Presentation

Anal sac tumors most commonly affect older dogs, with a predilection for females. Dyschezia and perianal swelling may be observed. Up to 40% of dogs may only show clinical signs associated with hypercalcemia of malignancy: Polyuria, polydipsia, vomiting, and constipation. A thorough rectal examination is essential to identify nodules associated with the anal sacs. Metastasis to sublumbar lymph nodes is very common at the time of diagnosis (Figure 9.104), and liver and lungs may be affected as well.

Differential Diagnosis

Other perianal tumors, perineal hernia, rectal FB, or stricture. Other causes of hypercalcemia such as hyperparathyroidism, lymphoma, and other tumors should also be considered.

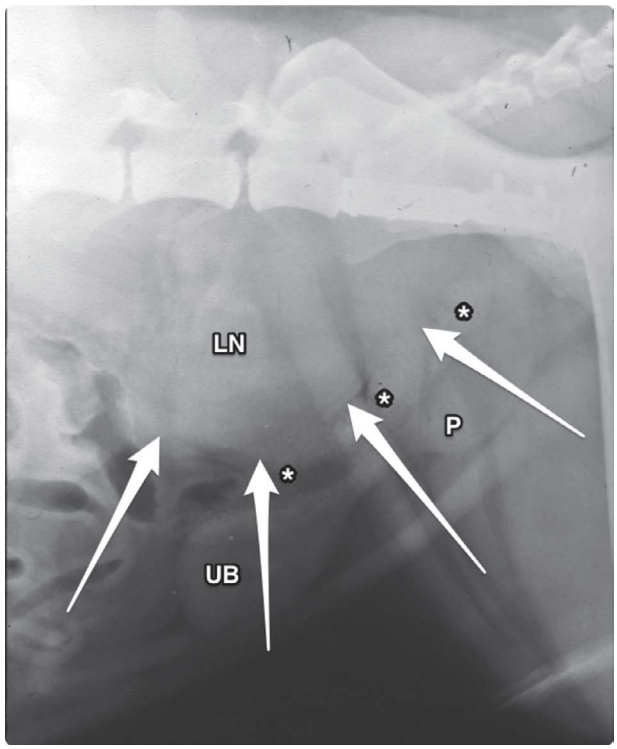

FIGURE 9.104 Radiograph of the caudal abdomen of a 10-year-old male Akita Inu. The dog was presented with severe hypercalcemia and dyschezia. While the primary anal sac tumor was a few millimeters in diameter, the sublumbar lymph node (LN) was severely enlarged (arrows). Note the ventrally displaced colon (asterisks), urinary bladder (UB), and prostate (P). A metallic plate used to repair a pelvic fracture several years prior to presentation is visible on the ileum.

Diagnosis

History and physical examination are suggestive. If a mass is present, cytologic evaluation of a fine-needle aspirate may be diagnostic. Radiographs and ultrasonography are useful to evaluate the sublumbar area, liver, and lungs for metastasis (Figure 9.104). Cross-sectional imaging may also be helpful in complicated cases. A CBC, serum chemistry profile, and urinalysis are essential to detect the presence of hypercalcemia (associated with hypophosphatemia) and possible secondary kidney damage.

Management

Wide surgical excision of the primary tumor and regional lymph node. The benefits of chemotherapy and/or radiation treatment have not been clearly established. Hypercalcemia may need to be addressed prior to surgery to avoid additional end organ damage (see Chapter 11).

Prognosis

Poor to fair, with a 40% 1-year survival. Negative prognostic factors include presence of lymph node or distant metastases and tumor size.

ANAL FURUNCULOSIS/ PERIANAL FISTULAE

Definition/Overview

Anal furunculosis is a chronic and painful disease of the canine anorectum that seems to preferentially affect middle-aged to old German Shepherd Dogs and German Shepherd Dog mixed breeds, although dogs from other breeds may be also affected. The condition is characterized by inflammation, ulceration, and sinus tracts.

Etiology

The etiology is unknown but is likely multifactorial.

Pathophysiology

The inflammatory process is chronic and consists of a mononuclear to granulomatous infiltrate. It may involve the anal sacs, their excretory ducts, the anal sphincter, and the circumanal glands. Immune dysregulation with aberrant cell-mediated immune response and excessive local production of matrix metalloproteinases has been reported in dogs with anal furunculosis. The lower carriage of the tail in affected dogs may provide the necessary environment for worsening inflammation and infection.

Clinical Presentation

Clinical signs include a painfully ulcerated perineal region with perianal discharge (Figure 9.105) and associated tenesmus, dyschezia, hematochezia, and/or constipation. In severe cases, anorexia, weight loss, and behavioral changes may be observed. Intensive perianal licking may be an early sign.

FIGURE 9.105 View of the cleaned and clipped perianal area of an 8-year-old female spayed German Shepherd Dog with anal furunculosis. Note several fistulous tracts oozing bloody or purulent exudate. (*Courtesy of LSU SVM Dermatology Service.*)

Differential Diagnosis

Anal sac abscessation, perianal tumor, bite wound, or other traumatic injury.

Diagnosis

Thorough examination of the perianal area may be difficult without sedation. The perineum should be cleaned to appreciate the extent of the disease process. The anus and rectum should be evaluated in detail, as they may be involved as well.

Management

Immunosuppression with cyclosporine (5 mg/kg p.o. q.12–24h. for 1–3 months) is effective in 60%–98% of cases but can be costly in large dogs. Concurrent use of ketoconazole, an inhibitor of cytochrome P450 enzymes, to increase the half-life of cyclosporine is not recommended because combination therapy results in unpredictable and often subtherapeutic cyclosporine levels. Immunosuppressive doses of prednisone (at least 2 mg/kg p.o. q.24h.) only help in one-third of cases. The effect of other immunosuppressive drugs has not been evaluated. Medical treatment followed by surgery (excision of remaining tracts, anal sacculectomy) is associated with a lower risk of recurrence. A significant number of dogs with anal furunculosis have concurrent adverse reaction to food

and feeding an elimination novel-protein or hydrolyzed diet may contribute to decreasing the recurrence rate.

Prognosis

Overall guarded. Recurrence is common. Anal sphincter incompetence and fecal incontinence are well known complications of surgery.

PERINEAL HERNIA

Definition/Overview

Perineal hernia results from weakness and breakdown of the pelvic diaphragm, with deviation and herniation of the rectum (and, possibly, the urinary bladder, prostate, and small intestine) into the perineum. The pelvic diaphragm consists of the levator ani and coccygeus muscles and the perineal fascia.

Etiology

The condition occurs in middle-aged, intact male dogs. Predisposed breeds include Pekingese, Boston Terrier, Welsh Corgi, Boxer, Poodle, Bouvier, and Old English Sheepdog. It is occasionally seen in cats as a surgical complication of perineal urethrostomy or colectomy.

Pathophysiology

The exact pathophysiology is unknown, and the disease is most likely multifactorial. The existence of rectal abnormalities (dilation, diverticulum), androgens, gender-related anatomic differences, relax in (a hormone synthesized in the prostate), prostatic disease, and neurogenic atrophy have all been associated with perineal hernia in dogs.

Clinical Presentation

Typical presenting signs include reducible perineal swelling (Figure 9.106), tenesmus, dyschezia, and constipation. The disease can be unilateral (if so, the right side is more commonly affected) or bilateral. Rectal examination reveals a defect in the pelvic diaphragm surrounding the rectum. If the bladder is retroflexed, dogs may not be able to void urine and develop postrenal azotemia with associated signs such as vomiting, anorexia, and lethargy.

Differential Diagnosis

Perineal tumor.

Diagnosis

History and clinical signs are usually sufficient. Survey and contrast radiographs (Figures 9.107 and 9.108) or ultrasonography (Figure 9.109) are necessary to confirm retroflexion of the urinary bladder or other organs. CBC, serum chemistry, and urinalysis are useful to evaluate kidney function.

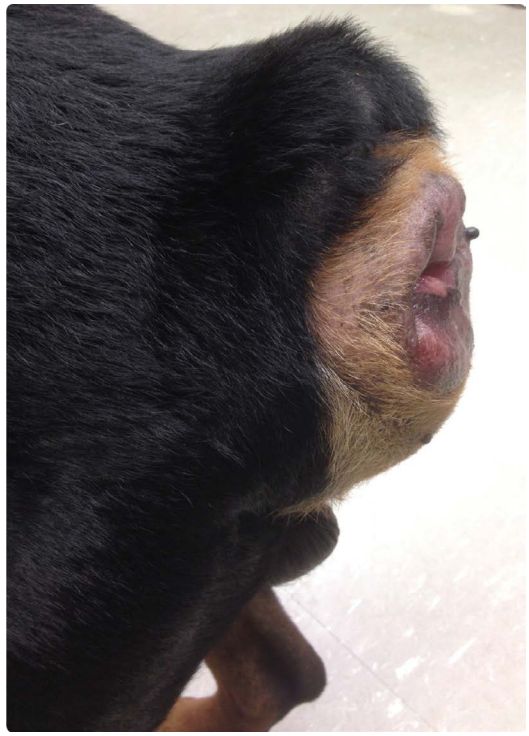

FIGURE 9.106 Severe bilateral perineal hernia in a 10-year-old intact male Rottweiler.

Management

Medical management, consisting of maintaining a soft fecal consistency with laxatives such as lactulose (0.5 L/kg p.o. q.8–12h.) or a bulk-forming agent such as psyllium (Box 9.9), and occasional enemas, may be successful in the short term with mild cases. However, most cases require surgical treatment. Herniorrhaphy using the internal obturator transposition technique is usually

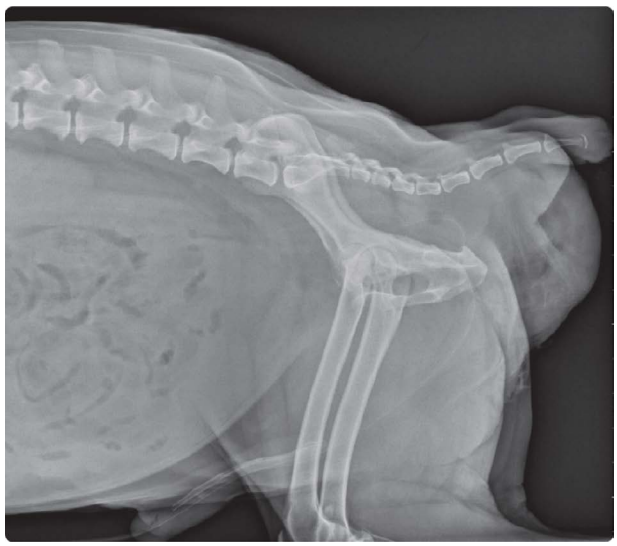

FIGURE 9.107 Another dog with a perineal hernia. Caudal abdominal radiograph. A large soft tissue mass representing the hernia can be seen in the perineum. The urinary bladder is not visible in the caudal abdomen.

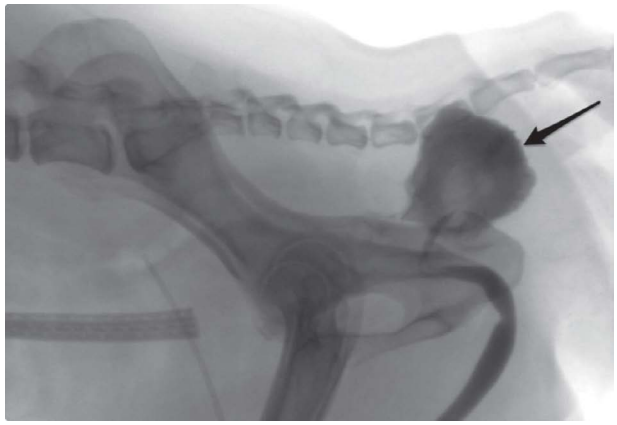

FIGURE 9.108 Positive contrast retrograde urethrocystography from the same dog as **Figure 9.107**. The bladder is retroflexed in the perineal hernia. (*Courtesy of L. Gaschen.*)

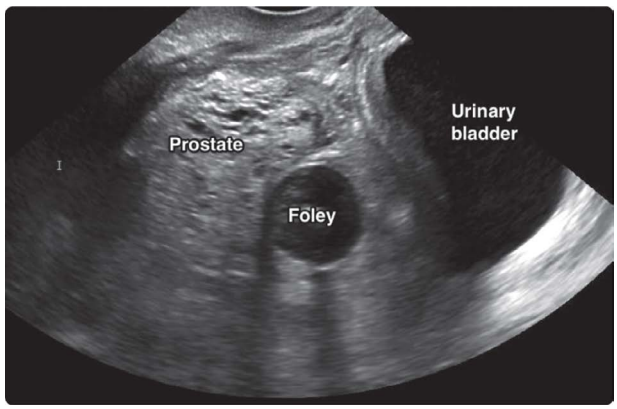

FIGURE 9.109 Ultrasound image of the dog in **Figure 9.106**. The prostate and urinary bladder are retroflexed in the retroperitoneal space. The balloon of a Foley catheter passed into the bladder is visible. Orientation: Left is cranial; right is caudal.

successful. (See surgery textbooks for further details.) Surgical complications include seroma, wound infection, fecal incontinence, and sciatic nerve paralysis.

Prognosis

Good if the hernia can be repaired early, guarded in dogs with chronic perineal hernia. In the latter group, recurrence is frequent, and repeat surgical intervention is often challenging.

PERINEAL TUMORS

Definition/Overview

The perianal region of dogs contains perianal (or circumanal) glands that are located in the dermis in a circular pattern around the anus. Perianal adenomas are the most common perianal tumors, while perianal adenocarcinomas occur considerably less frequently.

Etiology

Perianal adenomas are sex hormone dependent and occur mostly in middle-aged to older males. Cocker Spaniels, Beagles, Bulldogs, and Samoyeds may be predisposed. Adenocarcinomas are not influenced by sex hormones and occur in neutered or intact male and female dogs.

Clinical Presentation

Adenomas are slow growing, single, multiple, or diffuse nonpainful masses located around the anus or on the perineum and occasionally also on the prepuce, scrotum, and tailhead. Adenocarcinomas grow faster and may be similar to adenomas but may be firmer, adhere to underlying tissues, and become ulcerated.

Differential Diagnosis

Differentiating adenoma from adenocarcinoma is challenging but important, as more aggressive treatment is required for the malignant perineal tumor. Detection of metastases is strongly indicative of adenocarcinoma.

Diagnosis

Signalment, history, and physical examination are suggestive. Cytologic evaluation of a fine-needle aspirate reveals typical sebaceous cells that resemble hepatocytes. However, cytology does not allow reliable differentiation between adenoma and adenocarcinoma.

Management

Adenoma: Castration and conservative surgical removal. Adenocarcinoma: Wide excision of the primary tumor and affected lymph nodes. Postoperative radiation therapy may be useful. Inoperable cancers may benefit from palliative radiation treatment and chemotherapy.

Prognosis

Adenoma: Excellent, low risk of recurrence after excision if the dog is neutered. Adenocarcinoma: Removal at an early stage (diameter less than 5 cm) is associated with good survival.

CASE EXAMPLES

Case 9.1

Signalment

8-year-old female spayed Chihuahua

History

The dog was presented for a 3-week history of regurgitation. She would spit up her food with a lot of white foam approximately 5 minutes after eating but was able to hold down water and the liquid diet prescribed by her family veterinarian. Regurgitation had started around 2 weeks after having been diagnosed with pyometra and having undergone emergency ovariohysterectomy to treat pyometra.

(*Continued*)

Physical Examination

Body weight: 2.3 kg, weighed 3.1 kg 3 months ago

Body condition score: 3/9

Vital parameters: Within normal limits

Physical exam: The dog was quiet, alert, and responsive, and the exam did not reveal any abnormalities except a pre-existing grade 2/6 systolic heart murmur loudest in the left apical area.

Initial Assessment

An esophageal disorder was suspected. Because regurgitation had started a couple of weeks after general anesthesia and abdominal surgery, the most likely differential diagnoses included esophagitis and esophageal stricture occurring after severe intraoperative or postoperative gastroesophageal reflux. Recommended additional exams included a minimal database (CBC, chemistry panel and urinalysis) to evaluate the systemic impact of the disease. All laboratory parameters were within normal limits. Survey thoracic radiographs did not show any esophageal abnormality or evidence of aspiration pneumonia.

Further Investigations

As the top differential diagnoses were esophageal stricture and/or esophagitis, esophagoscopy was recommended and performed under general anesthesia. The mucosa was abnormal in both the cervical and thoracic esophagus. It appeared irregular and thickened with a cobblestone appearance (**Figure 9.110**). An intrathoracic esophageal stricture was present just cranial to the lower esophageal sphincter (**Figure 9.111**). These findings supported the hypothesis of severe intraoperative or postoperative gastroesophageal reflux causing esophagitis and the development of a stricture.

FIGURE 9.110 Endoscopic view of the cervical esophageal mucosa, which appears irregular with a cobblestone pattern (instead of smooth and shiny). The findings are indicative of chronic esophagitis.

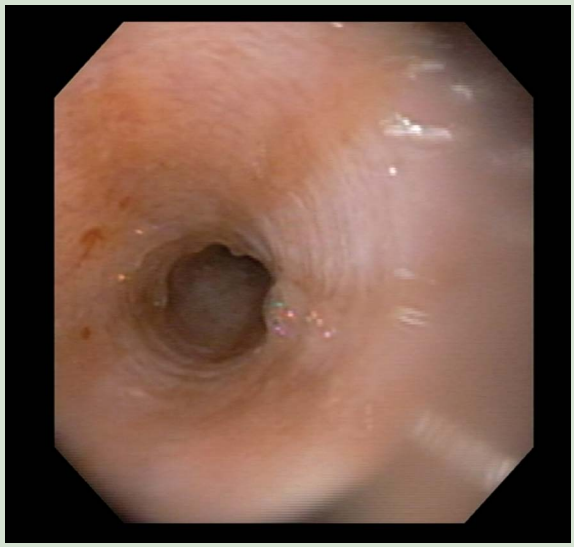

FIGURE 9.111 This endoscopic view of the thoracic esophagus past the heart base also shows an abnormally thickened mucosa and a narrowing (stricture) just craniad to the lower esophageal sphincter. The diameter of the stricture was approximately 6 mm.

Initial Treatment

The stricture was dilated using inflatable balloon dilation catheters of increasing diameters. Dilation was started with a 6 mm diameter balloon and discontinued after the 10 mm diameter balloon had been used due to moderate mucosal trauma (**Figure 9.112**). Then, triamcinolone was injected submucosally in four sites of the stricture

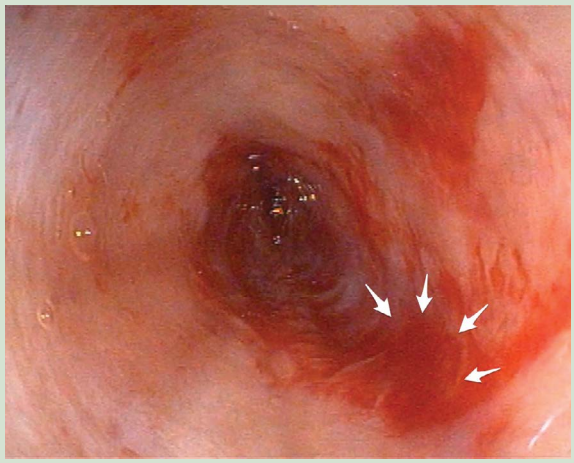

FIGURE 9.112 Following balloon dilation of the stricture to a diameter of 10 mm, there are several areas of focal bleeding. The white arrows delineate a superficial tear in the mucosa that occurred during the dilation.

(*Continued*)

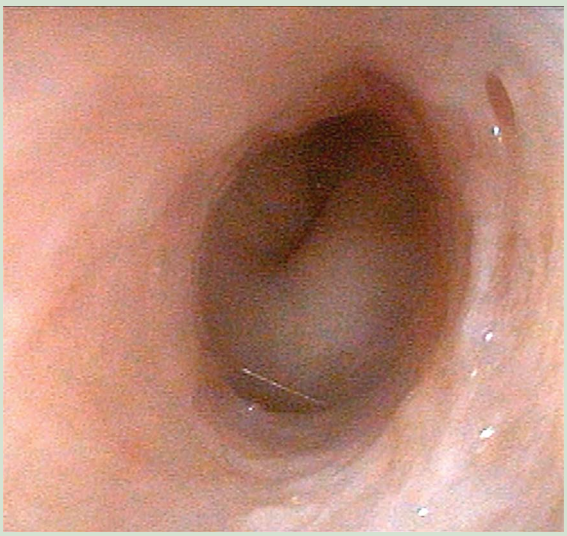

FIGURE 9.113 Endoscopic view of the stricture site 7 days after the initial dilation; the lower esophageal sphincter is visible. The opening is now approximately 8 mm. An endoscope with an outer diameter of 7.8 mm at the tip could be passed through it.

circumference to a total dose of 1 mg/kg. The dog recovered well. She was able to eat small balls of canned food without regurgitating on the day following the procedure. She was discharged with a standard treatment for gastroesophageal reflux, which included omeprazole (1 mg/kg p.o. q.12h.), sucralfate slurry (0.5 g per dog p.o. q.8h.) and metoclopramide as a gastric prokinetic (0.5 mg/kg p.o. q.8h.).

Further Treatment

The initial plan included three dilation procedures at weekly intervals. At the time of the first recheck, the dog was able to eat canned food without regurgitating. The abnormal appearance of the esophageal mucosa was unchanged. The site had strictured down to approximately 8 mm (**Figure 9.113**) and could be safely dilated to 10 mm again. The dog kept doing well, and the owner elected not to have any additional procedure performed. Medical treatment was discontinued after 4 weeks, and the dog was lost to followup.

Final Assessment

The dog was able to enjoy a good quality of life after partial restoration of the esophageal diameter leaving a focal luminal narrowing to approximately 8–10 mm, which was deemed to be between 66% and 75% of the normal diameter, i.e., 44%–56% of the normal cross-sectional area.

Case 9.2

Signalment

9-year-old female spayed Siamese mixed breed cat

History

The cat was presented for a 6-month history of small bowel diarrhea, vomiting, weight loss, and occasional hyporexia. She had initially responded to a diet change but then relapsed and was refractory to new dietary trials. She had received 1 injection of methylprednisolone acetate SC without improvement. At the time of presentation, the cat was vomiting approximately twice a week and passing soft feces resembling cow pats and had a normal appetite.

Physical Examination

Body weight: 4 kg, weighed 4.5 kg 1 year prior

Body condition score: 4/9

Vital parameters: Within normal limits

Physical exam: The cat was bright, alert, and responsive. During abdominal palpation, it was felt that the small intestinal loops were noticeably easy to palpate. No further abnormalities were noted.

Initial Assessment

Top differential diagnoses for a middle-aged to older cat with chronic vomiting, diarrhea and weight loss included chronic intestinal diseases such as inflammatory bowel disease (IBD) and low-grade alimentary lymphoma (LGAL). However, metabolic disorders such as hyperthyroidism or chronic kidney disease could not be ruled out. Recommended additional exams included a minimal database (CBC, chemistry panel, and urinalysis) and serum thyroxine concentration. The laboratory parameters were all within their reference ranges. An abdominal ultrasound exam was performed and revealed diffuse thickening of the small intestinal muscularis layer (**Figure 9.114**) and enlarged hypoechoic jejunal lymph nodes.

Further Investigations

Given the probable diagnoses, serum cobalamin and folate concentrations were evaluated, and the cat was hypocobalaminemic. Further recommendations to differentiate IBD and LGAL included exploratory laparotomy and collection of full-thickness small intestinal biopsies or upper and lower GI endoscopy to collect

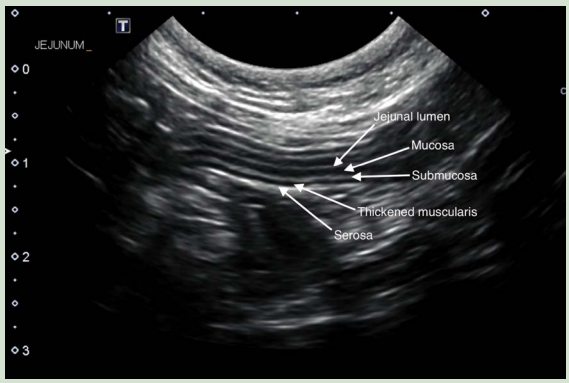

FIGURE 9.114 Sagittal ultrasonographic view of a jejunal loop. The 5 layers of the small intestinal wall are identified with arrows. While the intestinal wall thickness is not visibly abnormal, the muscular is layer is markedly thickened.

(*Continued*)

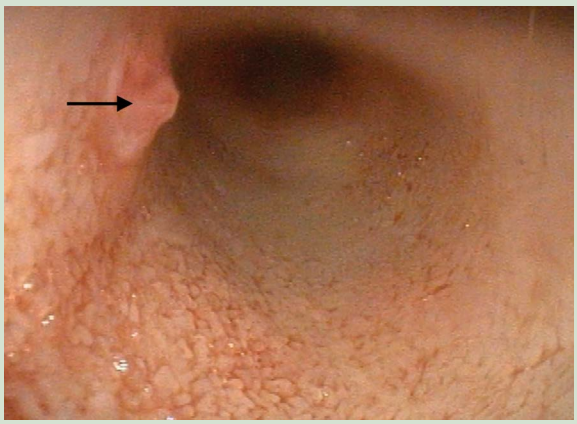

FIGURE 9.115 Endoscopic view of the proximal duodenum. The mucosa appears somewhat irregular. The black arrow points to the major duodenal papilla.

biopsies from stomach, duodenum, proximal jejunum, and ileum. They elected to proceed with endoscopy. The small intestinal mucosa appeared mildly irregular; however, no obvious lesions could be identified (**Figure 9.115**). The histological and appearance of the duodenal mucosa did not allow to differentiate between IBD and LGAL. Immunohistochemistry revealed that the lamina propria infiltrate consisted mostly of T-cells, which confirmed the diagnosis of LGAL.

Initial Treatment

The cat was administered vitamin B12 (250 ug per cat SC) and initially sent home on an immune-suppressive dose of prednisolone (1 mg/kg p.o. q.12h.) and a hydrolyzed protein diet.

Further Treatment

Upon reception of the final biopsy results, chlorambucil was added at 2 mg per cat p.o. every 3 days. The cat went into complete clinical remission and regained the weight she had lost. Over the following 3 months, the prednisolone dose was reduced in 25% steps to 1 mg/kg p.o. q.24h., and cobalamin injections were continued on a weekly basis for 6 weeks, then another dose 4 weeks later, and the serum cobalamin was checked 4 weeks later and found to be within the reference range. Starting approximately 3 months after initiation of chlorambucil treatment, the cat became moderately neutropenic. The dose was decreased to 1 mg per cat every 3 days, and the neutrophil count normalized without recurrence of GI signs.

Final Assessment

At the time of this writing, the cat has been in clinical remission for 12 months and currently receives prednisolone 0.5 mg/kg p.o. q.24h. and chlorambucil 1 mg per cat p.o. twice weekly. It is not uncommon for cats treated chronically with chlorambucil to develop neutropenia, and this cat responded well to a dose reduction that did not compromise success of LGAL treatment. Based on the literature, the median survival time for LGAL is between 14 and 36 months.

INTRODUCTION

Canine and feline hepatobiliary disease occurs commonly but can be challenging to diagnose and treat. Frequently, the clinical signs of hepatobiliary disease are nonspecific, and abnormalities are incidentally identified on clinicopathologic screening. Recognition of characteristic clinical presentations and application of targeted diagnostic algorithms are key to improving patient outcomes.

CONGENITAL PORTOSYSTEMIC VASCULAR ANOMALIES AND MICROVASCULAR DYSPLASIA

Definition/Overview

A portosystemic vascular anomaly is a grossly apparent abnormal connection between the portal vasculature and the systemic circulation bypassing the liver. Congenital portosystemic vascular anomalies include extrahepatic portosystemic shunts connecting a branch of the portal vein to the vena cava or azygous vein, intrahepatic portosystemic shunts (persistent ductus venosus), and, rarely, arteriovenous malformations.

Microvascular dysplasia (primary hypoplasia of the portal vein) refers to malformed intrahepatic portal microvasculature. Histologically, most cases of microvascular dysplasia are indistinguishable from portosystemic vascular anomalies.

Etiology

Congenital portosystemic vascular anomalies and microvascular dysplasia are heritable traits. Despite extensive efforts, a single causal genetic mutation has not been identified. A complex polygenic etiology is probable.

Pathophysiology

Hepatic venous hypoperfusion in dogs with macroscopic shunting reduces clearance of nutrients and waste products derived from gastrointestinal portal drainage by the liver. This results in reduced hepatic size and histomorphologic changes within the liver, including lobular atrophy, small arterialized portal tracts, and increased binucleate hepatocytes in the periportal region. Systemically, the reduced hepatic metabolism of ammonia and other substances enriched in the portal circulation upregulates inflammatory cytokine production, provokes hepatic encephalopathy through enhanced GABA receptor stimulation and astrocyte glutamine accumulation, and alters normal metabolic function.

Microvascular dysplasia causes abnormal blood flow through the hepatic sinusoids with minimal systemic consequences. Dogs with microvascular dysplasia do not have signs of illness nor do they require specific therapy.

Clinical Presentation

Dogs with congenital extrahepatic portosystemic shunts are usually identified within the first 2 years of life, but minimally symptomatic dogs may be diagnosed at any age. Dogs with intrahepatic shunts tend to have more severe clinical signs and are usually diagnosed before

DOI: 10.1201/9781003254591-29

FIGURE 10.1 Dachshund littermates. The dog on the left has a portoazygous shunt.

1 year of age. Cats with portosystemic shunts can be challenging to identify and may present at any age. Extrahepatic shunts usually occur in small breed dogs. Yorkshire Terrier (19%–31%), Shih Tzu, Maltese, Pug, Miniature Schnauzer, West Highland White Terrier, Bichon Frise, Border Terriers, Jack Russell Terriers, Miniature and Toy Poodles, Havanese, Cairn Terriers, Silky Terriers, and mixes of these breeds are overrepresented. Intrahepatic shunts usually occur in large breed dogs. Labrador Retrievers, Siberian Huskies, and Irish Wolfhounds are overrepresented. There is no gender predisposition. Dogs with microvascular dysplasia have the same signalment as small breed dogs with portosystemic vascular anomalies. In some cases, both vascular malformations occur in the same dog.

Commonly noted features of dogs with portosystemic shunts are small body stature (Figure 10.1), pediatric hypoglycemia, polyuria/polydipsia, vague gastrointestinal signs, overt hepatic encephalopathy, and urinopathies associated with ammonium biurate urolithiasis. Ptyalism and atypical copper irises are frequently noted in cats with portosystemic shunts, but they may present for lower urinary tract signs, vague gastrointestinal illness, or overt hepatic encephalopathy.

Differential Diagnosis

Reactive hepatopathy, portal hypertension (prehepatic, hepatic, or posthepatic) with multiple acquired portosystemic shunts.

Diagnosis

Complete blood count abnormalities in dogs with portosystemic shunts include microcytic red blood cells and occasionally a mild mature neutrophilic leukocytosis. Dogs with portosystemic shunts typically have mild to moderately elevated hepatic transaminases (alanine aminotransferase, aspartate aminotransferase [ALT, AST]), hypoalbuminemia, low blood urea nitrogen (BUN), and hypocholesterolemia; however, one or more of these clinicopathologic values may be normal. Urine specific gravity may be normal, isosthenuric, or hyposthenuric. Urine sediment will contain ammonium biurate crystals in some dogs with portosystemic shunts (Figure 10.2). Elevated arterial and venous blood ammonia is sensitive and specific for portosystemic shunting, but false negatives are possible. Paired (2 hours apart) total serum bile acids are the best screening test for dogs and cats with portosystemic shunts. A small meal of the pet's normal food is fed after the first sample is collected. Even if the patient will not eat, the paired sample is collected at 2 hours. Cyclic contraction of the gallbladder occurs at regular intervals even in fasted patients. If either the preprandial or the postprandial bile acid is >30 µmol/L, additional testing is indicated. Protein C, an anticoagulant protein synthesized in the liver, is measured as a secondary biomarker of portosystemic shunting. Citrated plasma is frozen and submitted to the Cornell Animal Health Diagnostic Center. In dogs with abnormal bile acids and no evidence of severe liver injury, protein C <70% activity is consistent with the presence of a

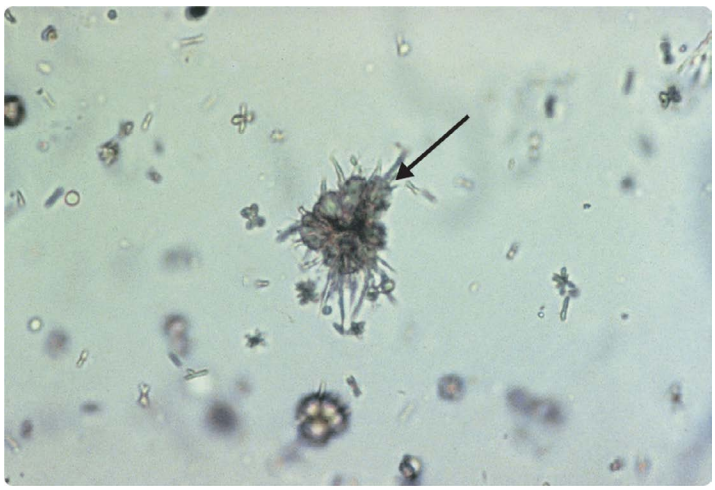

FIGURE 10.2 Ammonium biurate crystal (arrow) in the urine sediment in a dog with a portacaval shunt. (*Courtesy of J. Taboada.*)

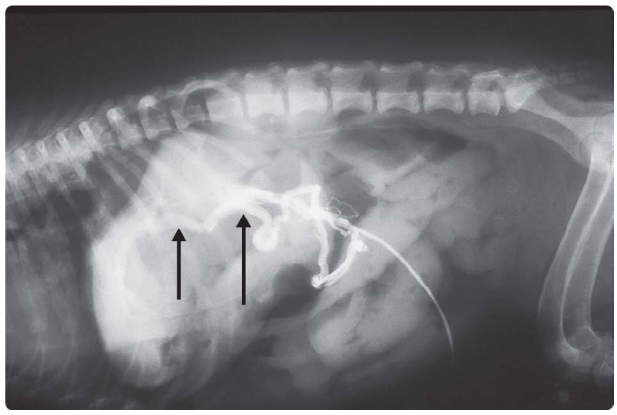

FIGURE 10.3 Mesenteric venous portography confirmed a shunt (arrows) in this 2-year-old Lhasa Apso. (*Courtesy of J. Taboada.*)

portosystemic shunt, values >100% suggest microvascular dysplasia, and values between 70% and 100% are in the gray zone, requiring diagnostic imaging.

Computed tomography angiography (CTA) is the gold standard diagnostic imaging modality for portosystemic shunt detection. Results are invaluable for surgical shunt attenuation planning. Estimates suggest that 75%–92% of portosystemic shunts may be diagnosed by abdominal ultrasonography. Abdominal ultrasound is dependent on the skill of the operator and the location of the shunt. The modality can support a diagnosis of portosystemic shunting (microhepatica, enlarged kidneys, nephrolithiasis, urolithiasis, and smaller portal vein to aorta ratio (≤0.65). Splenic or transcolonic scintigraphy has historically been used to diagnose portosystemic shunting, but the use of a radionuclide and suboptimal shunt localization limits its usefulness. Intraoperative mesenteric portovenography has also been used to locate portocaval anomalies (Figure 10.3)

Dogs with microvascular dysplasia may have mild hepatic transaminase elevations but do not routinely have other clinicopathologic abnormalities; however, serum bile acids are elevated. In many cases, protein C distinguishes between macroscopic shunting and microvascular dysplasia. Occasionally, CTA is needed to confirm the diagnosis. Liver histology will not differentiate portosystemic shunting from microvascular dysplasia.

Management

Medical management is recommended in all dogs with a portosystemic shunt regardless of whether shunt attenuation will be pursued (Table 10.1). The goal of medical management is to reduce elevated systemic ammonia levels. The therapeutic strategy consists of dietary modification to a soy- or dairy-based protein, hastening gastrointestinal transit time and modulation of gut microbiota (Table 10.1). Most owners describe an improvement in their pet's neurobehavioral condition after starting medical management. In patients that cannot undergo attenuation, medical therapy continues lifelong but is reduced to what is minimally necessary to control clinical signs. If antibiotics are used, these are withdrawn first. Diet modification is continued indefinitely. Owners are advised that medically managed patients will experience more profound episodes of illness than normal dogs or cats. Owners are encouraged to have antibiotics and lactulose available to administer as needed, thus avoiding expensive hospitalizations.

Surgical attenuation for extrahepatic portosystemic shunts may be completed using silk suture ligation, ameroid constrictor application, or cellophane banding. A recent systematic review found that ameroid constrictors were superior to thin film banding for shunt

TABLE 10.1 Medical management of hepatic encephalopathy (HE)

Therapeutic goals
- Limit hepatic encephalopathy
- Reduce adverse health events

Nutrition
- Tailor diet to the individual
- Avoid overzealous restriction of dietary protein
- Commercially available liver diets are a good starting point
- Begin with ~2.5 g/kg of protein per day and titrate up to a level that is tolerated without signs of HE
- Soy or dairy protein is better tolerated in dogs with HE
  - Adjust protein with supplementary dairy (cottage cheese, cheese, yogurt) or tofu
- Dietary fiber enhances enteric nitrogen elimination
- Avoid red meat, fish, and organ meat

Nonabsorbable disaccharides
- Lactulose (0.25–0.5 mL/kg p.o. q.8–12 h., titrate dose to achieve soft stool)
  - Laxative effects to decrease gut transit time
  - Decreases activity of bacterial ureases and enteric peptidases, increasing bacterial nitrogen fixation
  - Acidification of enteric pH traps protonates of ammonia trapping it in the gut lumen
- Lactitol (0.5–0.75 g/kg p.o. q.8–12 h.)
- Lactose (to effect)

Modulation of gastrointestinal microbiota
- Antibiotics (amoxicillin 10 mg/kg p.o. q.12 h., metronidazole 7.5 mg/kg p.o., future option: Rifaximin)
- Probiotics as an alternative to antibiotics (e.g., Visbiome, Prostora, Proviable)

Treatment of severe, overt encephalopathy
- Maintain euhydration, normal electrolyte balance, and euglycemia
- Elevate patients head (30°) to reduce risk of aspiration
- Intravenous antibiotics (metronidazole or ampicillin) to modify gut flora
- Cleansing enema (10 mL/kg warm isotonic crystalloid, repeat until clear)
- Lactulose retention enemas reduce ammonia resorption (5–15 mL 1:3 in water, use Foley catheter)
- Seizures
  - Levetiracetam (30–60 mg/kg IV loading dose, 30 mg/kg IV q.8 h.)
  - Propofol (0.3–0.6 mg/kg/min CRI) for refractory seizures
  - Mannitol (0.5–1.0 g/kg IV once or twice) to induce osmotic diuresis if intracranial pressure elevates, monitor for hypernatremia
  - **Avoid benzodiazepines**

attenuation. Both methods rely on slow occlusion of the shunting vessel; thus, incomplete occlusion or delayed portal hypertension with acquired portosystemic shunting can occur. Silk suture ligation attenuates the shunting vessel partially or fully based on portal pressure measurements at the time of surgery. Attenuation of intrahepatic shunts may be accomplished with suture ligation or endovascular coil embolization; portal pressures are routinely measured in both procedures.

Critical observation is required during the immediate postprocedure period. Common complications include hypoglycemia and hypotension, which are easily corrected if addressed early. Postoperative neurologic complications including seizure are less common. Preoperative medical management rather than pre-emptive administration of antiepileptic is currently recommended to limit postoperative neurologic decompensation (Table 10.1). The development of portal hypertension is a serious postoperative complication manifesting with melena, hemorrhagic diarrhea, ascites, and hemorrhagic shock. Aggressive supportive care and monitoring are indicated if this occurs.

Post attenuation rechecks are planned at 2 weeks, 1 month, 3 and 6 months. If clinical signs are improved, medical management is tapered over the first 1–3 months. Complete blood count (CBC) and chemistry are rechecked at each visit. Protein C is re-evaluated beginning at 1 month and every subsequent recheck. If protein C does not improve or remains below normal (<70), then a CTA is recommended after 6 months. Some dogs continue to have residual shunting and require a second procedure or ongoing medical management.

Dogs with microvascular dysplasia do not require medical management but may have delayed clearance of drugs metabolized in the liver.

Prognosis

Prognosis is dependent on the severity of clinical signs and management strategy. Portosystemic shunt attenuation reportedly results in longer survival times than medical management. Quality of life questionnaires are helpful to determine how medically and surgically managed dogs are faring long term. Dogs with microvascular dysplasia have a good prognosis.

DUCTAL PLATE MALFORMATIONS

Definition/Overview

Hepatic polycystic and fibropolycystic disorders encompass a heterogeneous group of embryologic malformations of the anatomic precursor of the intrahepatic bile ducts, the ductal plate. Malformations affecting the small bile ducts with variable severity fibrosis (congenital hepatic fibrosis) and segmental dilations of the larger intrahepatic ducts with (Caroli's syndrome) and without (Caroli's disease) small duct abnormalities have been described in dogs and cats.

Etiology

The specific environmental and molecular mechanisms leading to ductal plate malformations in dogs and cats are largely unknown. Some cats with feline polycystin-1 mutation, which causes polycystic kidney disease, will develop concurrent hepatic cysts.

Pathophysiology

Progressive expansion of cystic ductal structures and periductal fibrosis cause hepatic parenchymal damage. In cases of canine congenital hepatic fibrosis, multiple acquired portosystemic shunts eventually develop due to intrahepatic portal hypertension. Noncontiguous fluid filled cystic bile ductal structures may become infected, bleed, or develop choleliths.

Clinical Presentation

The polycystic liver diseases of dogs and cats are rare. Patients of both species may present at any age, but severe juvenile phenotypes are the most commonly reported. Persian, Siamese, Abyssinian cats and Boxer, Cairn Terrier, and West Highland White Terrier dogs are overrepresented. Clinical signs include anorexia, vomiting, diarrhea, abdominal discomfort, or ascites once portal hypertension develops. The liver is normal to small in congenital hepatic fibrosis but is enlarged in polycystic liver disease.

Differential Diagnosis

Inflammatory liver disease

Diagnosis

B-mode abdominal ultrasonography, computed tomography, and magnetic resonance imaging can identify macroscopic cysts of the intrahepatic (Figure 10.4) and extrahepatic biliary tree, but histology is necessary to identify microscopic fibropolycystic ductal disorders such as congenital hepatic fibrosis. Gallbladder agenesis is associated with ductal plate malformation.

FIGURE 10.4 Abdominal ultrasound image of polycystic liver disease in a 15-year-old male cat. Multiple large, anechoic, fluid-filled cysts compress the hepatic parenchyma.

Clinicopathologic features include mild to severe increases in liver enzymes (ALT, AST, alkaline phosphatase [ALP], gamma-glutamyl transferase [GGT]). Hyperbilirubinemia occurs in congenital hepatic fibrosis. In dogs with acquired portosystemic shunts, red blood cell microcytosis, subnormal albumin, BUN, and cholesterol may be present along with elevated total serum bile acids.

Management

There is no specific treatment for canine and feline ductal plate malformations. Extrapolating from human medicine, treatment with octreotide (canine: 1–10 µg/kg SQ q.6–8 h., feline: 10 µg/kg SQ q.8 h.) may be attempted to reduce cyst volume in patients with multiple macroscopic cysts. Antioxidants and antifibrotics are routinely initiated but with limited success (Table 10.2). Management largely focuses on treatment of disease sequelae. Antiemetics and appetite stimulants are used for gastrointestinal signs. Diuretics are instituted as needed to manage ascites (Table 10.2).

Prognosis

Prognosis is variable dependent on the type of malformation. Congenital hepatic fibrosis has a guarded to poor prognosis.

ACUTE LIVER INJURY/ ACUTE LIVER FAILURE

Definition/Overview

Acute liver injury refers to severe hepatocellular damage in a patient without a previous history of liver disease. Clinical and biochemical signs of liver failure are not apparent until >70% of functional hepatic mass is lost. Acute liver failure manifests with hyperbilirubinemia, impaired coagulation (prothrombin time >1.5× upper limit of reference interval), and overt hepatic encephalopathy.

TABLE 10.2 A general list of various drugs used for treating various forms of liver disease in the dog and cat, depending on underlying pathology

Drug	Dose	Route	Frequency
Antibiotics			
Ampicillin sodium/sulbactam sodium	22–30 mg/kg	IV	q.8 h.
Clindamycin	10–12.5 mg/kg	IV	q.12 h.
Metronidazole	7.5–10 mg/kg	IV, p.o.	q.12 h.
Ticarcillin disodium/clavulanate potassium	15–25 mg/kg infusion over 15 minutes, followed by 7.5–15 mg/kg CRI	IV	CRI
Neomycin is no longer recommended due to potential for nephrotoxicity and ototoxicity			
Antioxidants			
N-acetylcysteine – Nonpyrogenic, 0.25 µm filter – Dilute 1:2 or 1:4 – Give over 20 minutes	140 mg/kg once, then 70 mg/kg	IV	q.6–8 h.
Ursodeoxycholic acid (UDCA) – *Do not administer in cases of bile duct obstruction or ductopenia*	5–10 mg/kg	p.o.	q.12 h. with food
S-adenosylmethionine (SAMe) – *Use a reputable manufacturer* – *Must be complexed with stable synthetic salts (disulfonate salt, tosylate salt, phytate salt) to be bioavailable*	20–40 mg/kg *Phytate salt complex may increase bioavailability, and dose reduction should be considered (8–10 mg/kg)*	p.o.	q.24 h. on an empty stomach
Vitamin E	10–15 IU/kg *Do not exceed 400 IU per dog*	p.o.	q.24 h.
Excluding the use of injectable silibinin for amatoxin ingestion, the benefit of silymarin (milk thistle) in the treatment of human liver disease has not been supported by recent prospective studies			

(*Continued*)

TABLE 10.2 A general list of various drugs used for treating various forms of liver disease in the dog and cat, depending on underlying pathology *(Continued)*

Miscellaneous vitamins			
Vitamin K_1	0.5–1 mg/kg	SQ	q.12 h. ×3 doses
Pyridoxine, vitamin B_6 – *Administered during D-penicillamine therapy*	25 mg	p.o.	q.24 h.
Immunosuppressives			
Azathioprine – *Canine only*	2 mg/kg (>25 kg, 50 mg/m^2)	p.o.	q.24 h. ×14 days, then q.48 h.
Budesonide – *If no portosystemic shunting*	3 mg/m^2	p.o.	q.24–48 h.
Cyclosporine – *Modified: Neoral or Atopica* – *Trough levels may optimize dosing*	5 mg/kg	p.o.	q.12 h. on an empty stomach if tolerated, taper to once daily at remission
Dexamethasone	0.2 mg/kg, taper to lowest effective dose	SQ, IV	q.48–72 h.
Mycophenolate mofetil	10 mg/kg	p.o.	q.12 h. with food
Prednisone, prednisolone (cats) – *If no ascites*	2–4 mg/kg, taper to lowest effective dose	p.o.	q.24 h. p.o. with food
Copper chelators			
Ammonium tetrathiomolybdate – *Cost prohibitive*	0.5 mg/kg	p.o.	q.6 h.
D-penicillamine	10 mg/kg	p.o.	q.12 h. on an empty stomach, maintenance therapy 2-3 times per week
Trientine – *Cost prohibitive*	5–7.5 mg/kg	p.o.	q.12 h.
Copper uptake antagonist			
Zinc – *Zinc acetate (30% zinc)* – *Zinc gluconate (13% zinc)* – *Monitor serum zinc levels (effective dose >200 µg/dL; toxic levels >800 µg/dL)*	8–10 mg/kg of elemental zinc	p.o.	q.24 h., give 30 minutes before meals
Diuretics			
Furosemide – Use adjunctively with spironolactone – Monitor for hypokalemia/alkalosis – Titrate to effective dose	1–4 mg/kg	p.o.	Divided q.12 h. daily
Spironolactone – Titrate to effective dose	1–4 mg/kg	p.o.	Divided q.12 h. daily
Antifibrotics			
Polyunsaturated phosphatidylcholine (PhosChol)	15–25 mg/kg *Do not exceed 4g*	p.o.	q.24 h. with food
Losartan – *Check renal panel 7–10 days after starting and full chemistry at scheduled rechecks*	0.25–0.5 mg/kg	p.o.	q.24 h.
Colchicine is no longer recommended due to unacceptable side effects			

Etiology

In canine and feline patients, acute liver injury is caused by hepatotoxin ingestion (*Amanita* sp mushrooms (amatoxin), aflatoxin, blue green algae (microcystin), sago palm (cycasin), xylitol), drugs (acetaminophen, oral diazepam (cats), carprofen, lomustine, methimazole, mitotane, phenobarbital, phenytoin, tetracycline, sulfa drugs), infection (histoplasmosis, leptospirosis, *Mycobacterium*, *Neospora*, *Sarcocystis*, schistosomiasis, toxoplasmosis), ischemia, sepsis, heatstroke, and neoplasia.

Pathophysiology

Synthetic failure results from severe, acute hepatocellular injury leading to cell death and organ dysfunction. The specific mechanism of action is dependent on etiology. The pathophysiology of acute hepatic encephalopathy is multifactorial involving increased circulating ammonia, failed intracranial oxidation-reduction mechanism, and systemic upregulation in inflammatory mediators.

Clinical Presentation

Clinical signs may include circulatory or hemorrhagic shock, hypotension, anorexia, vomiting, diarrhea, altered mental status, ascites, and jaundice (**Figure 10.5**).

Differential Diagnosis

Hemolytic crisis, severe systemic disease

Diagnosis

Laboratory tests to confirm acute liver injury/failure include elevated liver enzymes (ALT, AST), abnormal liver function tests (hyperbilirubinemia, hypocholesterolemia, hypoglycemia, hypoalbuminemia), and abnormal coagulation parameters (prolonged prothrombin and activated partial thrombin time, hypofibrinogenemia).

Management

Isotonic crystalloid fluid therapy with supplementation is initiated to address volume deficits, maintain euhydration, correct electrolyte abnormalities, and treat hypoglycemia. Impaired liver function may reduce hepatic capacity to metabolize lactate; therefore, isotonic crystalloids devoid of lactate buffer are selected. In patients with hepatic encephalopathy, 0.9% sodium chloride is administered to maintain serum osmolality and prohibit intracranial pressure elevation. In hypotensive patients that fail to respond to volume administration, vasopressors are initiated (norepinephrine, vasopressin) to address hypotension.

Decontamination of known hepatotoxins is indicated when toxin ingestion was observed. Emesis is induced (apomorphine 0.03–0.04 mg/kg IM, IV [dog], xylazine 0.44 mg/kg IM [cat]) if ingestion is recent and mentation status is appropriate. This is routinely followed by administration of activated charcoal with sorbitol (2 g/kg p.o. once); charcoal without sorbitol may be repeated every 6–8 hours. Cholestyramine (0.3–0.5 g/kg in food p.o. q.6–8 h. for 3–5 days), an anion exchange resin that binds bile acids in the gastrointestinal tract, may be useful to treat toxins that have enterohepatic recirculation (blue-green algae [microcystin], piroxicam, phenobarbital, phenytoin, sago palm [cycasin]). Antidotes are administered when appropriate (e.g., N-acetylcysteine for acetaminophen intoxication, intravenous silibinin for amatoxin ingestion (not commercially available in the United States). Specific recommendations should be sought from the ASPCA Animal Poison Control.

Hepatoprotectants (**Table 10.2**) are routinely administered to attenuate oxidative injury, replenish metabolic cofactors, and limit cell membrane lipid peroxidation (N-acetylcysteine or SAMe, vitamin B complex, vitamin E). Therapy with vitamin K_1 is started if coagulation tests are abnormal (**Table 10.2**). In patients with overt hepatic encephalopathy, management is dependent on the severity of clinical signs. In mild, overt encephalopathy, administration of oral lactulose and gastrointestinal flora modulation may be the only treatment necessary. Severe, overt hepatic encephalopathy requires aggressive supportive care (**Table 10.1**). The patient's head is elevated (30°) to reduce risk of aspiration. Intravenous antibiotics (metronidazole or ampicillin sodium/sulbactam sodium) are used to modify gut flora. Cleansing and lactulose retention enemas may reduce ammonia resorption. If seizures occur, levetiracetam is the first-line therapy followed by propofol continuous rate infusion. Benzodiazepines are avoided because they agonize GABA-mediated neurotransmission, which exacerbates encephalopathy. Mannitol may be given to induce osmotic diuresis if intracranial pressure elevation is suspected.

The extent of patient monitoring in acute liver injury/failure is dependent on the severity of illness. CBC, biochemistry, urinalysis, and coagulation panel are evaluated initially, and abnormalities are rechecked regularly. Hepatic transaminase reduction may signal improvement or loss of functional hepatic mass. Bilirubin and hepatic synthetic factors are better indicators of function, but the latter can be skewed if acquired portosystemic shunts develop.

FIGURE 10.5 Icteric patient with acute liver injury.

Prognosis

Prognosis is variable. Severely elevated transaminases are not poor prognostic indicators. Normal albumin in acute liver failure is a good indicator of survival.

CANINE CHRONIC HEPATITIS

Definition/Overview

Chronic hepatitis is an inflammatory reaction in the liver, as demonstrated by liver histology, continuing without improvement for at least 6 months. Canine chronic hepatitis is caused by a diverse group of infectious, metabolic, toxic, and immune-mediated diseases.

Etiology

Infectious organisms are an uncommon cause of canine chronic hepatitis. Leptospirosis causes acute hepatitis, which may evolve to a chronic pyogranulomatous inflammatory process. Leishmaniasis causes a granulomatous chronic hepatitis. *Ehrlichia canis* and babesiosis are sporadically associated with chronic hepatitis.

Several drugs and toxins (carprofen, amiodarone, aflatoxin, and cycasin) may lead to chronic hepatitis following acute liver injury. Drug-induced chronic hepatitis may be caused by phenobarbital, primidone, phenytoin, and lomustine (CCNU). Excess hepatic copper accumulation due to genetic (Bedlington Terrier, copper metabolism domain-containing 1 [COMMD1] mutation) or metabolic derangements is the most common cause of toxin induced chronic hepatitis.

In dogs, autoimmune chronic hepatitis is a diagnosis of exclusion dependent upon supporting evidence, including lymphocytic hepatic infiltrates, abnormal expression of major histocompatibility complex class II proteins, positive serum autoantibodies, familial liver disease, concurrent immune-mediated disorders, female gender, and response to immune modulation.

Pathophysiology

The initiating pathophysiology is dependent on etiology. Hepatic injury results in hepatocellular death and the release of inflammatory mediators. Inflammatory cell infiltration and immune regulatory dysfunction perpetuate ongoing injury, leading to necrosis and fibrosis.

Clinical Presentation

Chronic hepatitis is a disease of middle-aged to older dogs. Chronic hepatitis can occur in any breed, but some breeds are predisposed (asterisk denotes copper associated hepatitis): Bedlington Terrier*, Dalmatian*, Dobermann Pinscher*, Labrador Retriever*, West Highland White Terrier*, American Cocker Spaniel, English Cocker Spaniel (Europe), English Springer Spaniel (UK), Scottish Terriers (Sweden). The clinical signs of chronic hepatitis are often episodic and may include anorxia, fever, abdominal pain, vomiting, diarrhea, weight loss, polyuria/polydipsia, lethargy, jaundice, and weakness.

Differential Diagnosis

Reactive hepatopathy secondary to systemic disease, degenerative hepatopathy, neoplasia.

Diagnosis

The diagnosis and treatment of chronic hepatitis is a complex process that requires integration of clinical presentation with clinicopathologic findings, diagnostic imaging, and hepatic biopsy. Initially, hepatocellular leakage enzyme (ALT, AST) elevations predominate, but the cholestatic enzymes may also become elevated. These values wax and wane over the course of months. As hepatocytes are lost and fibrosis limits normal sinusoidal blood flow, the markers of hepatic synthetic function are disturbed. Diagnostic ultrasonography is helpful to identify neoplastic masses, ascites, and acquired portosystemic shunting vessels but is not sensitive nor specific for the diagnosis of chronic hepatitis. Hepatic cytology is typically performed to rule out diffuse neoplastic infiltration and identify suppurative inflammation, but it is inadequate for the diagnosis of chronic hepatitis.

Hepatic biopsy is necessary for definitive diagnosis (Table 10.3 and Figures 10.6 and 10.7). The characteristic histologic features of chronic hepatitis include hepatic inflammation (lymphocytic, plasmacytic, or granulomatous) in any region of the liver in conjunction with hepatocellular death and variable grades of fibrosis. In addition to the histology panel, liver tissue is submitted for aerobic/anaerobic culture and dry weight copper quantification (20–40 mg of tissue is required) by atomic absorption spectroscopy.

TABLE 10.3 Liver biopsy guidelines

Histology
- 15 portal tracts needed for accurate histologic evaluation
  - 5 laparoscopic or surgical samples, multiple 14- to 16-G needle biopsies
- Biopsy multiple lobes (n ≥ 2)
- Handle tissue carefully to avoid crush artifact and immediately place in neutral buffered formalin (10:1, fixative to tissue, no sample should be >0.5–1 cm to ensure proper fixation)
- Histology should include
  - H&E stain
  - Rhodanine or rubeanic acid stain—quantify and localize copper
  - Masson's trichrome or Picrosirius red—fibrosis
  - Reticulin stain—lobular architecture
  - Perls' Prussian blue stain—quantify and localize iron
  - Special stains added to identify infectious organisms if granulomatous or pyogranulomatous inflammation is present

Aerobic and anaerobic culture
- Use appropriate transport media

Copper quantification (canine)
- Dry weight atomic absorption spectrometry
- 20–40 mg of liver (wet weight)
- Empty glass tube; if using red top tube, do not allow sample to contact top as it contains copper
- Tissue can be frozen or extracted from paraffin block for copper quantitation later
- Normal hepatic copper quantification is <400 μg/g dry weight liver

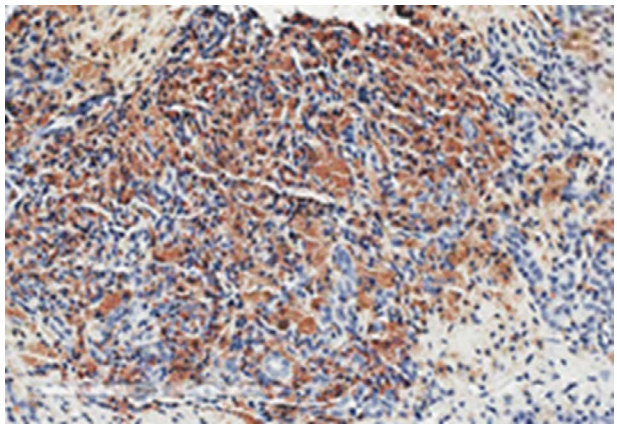

FIGURE 10.6 Rhodanine stain (orange) to identify copper on hepatic histology from a dog with chronic hepatitis. Copper grade is 5 out of 5. Photomicrograph at 10× magnification.

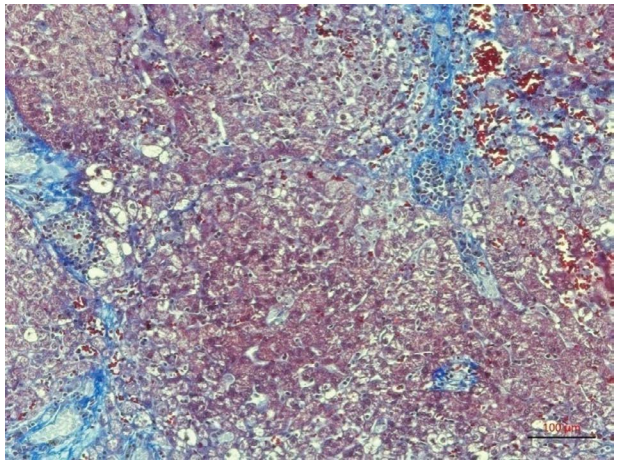

FIGURE 10.7 Masson's trichrome stain on liver histology from a dog with chronic hepatitis demonstrating increased deposition of extracellular collagen matrix (blue) and sinusoidal distortion. Photomicrograph at 10× magnification.

Management

Treat the underlying etiology. Discontinue hepatotoxic drugs. Monotherapy targeted at infectious organisms may be sufficient to halt progression of the inflammatory process. In all causes of chronic hepatitis, antioxidant therapy is added to treat ongoing necroinflammatory (SAMe, vitamin E) and cholestatic processes (ursodeoxycholic acid). Antioxidants are administered until liver enzymes normalize (Table 10.2). Antifibrotic medications (phosphatidylcholine or losartan) are initiated if fibrosis is present on histology (Table 10.2). Human and murine research has shown that fibrosis can be reversible with targeted therapy. Treatment with a protein-restricted liver diet is contraindicated in patients with chronic hepatitis unless multiple acquired shunts or overt hepatic encephalopathy exist.

Increased hepatic copper concentration (>600 µg/g) in dogs with chronic hepatitis is treated with lifelong dietary copper restriction (<0.12 mg of copper per 100 kcal). The commercially available liver diets are appropriately copper restricted and may be used as a base diet but must be supplemented with low-copper protein sources (cheese, yogurt, eggs, white meat, chicken, and turkey) to achieve 3–4 g of protein intake per kilogram body weight a day. Chelation therapy is indicated in dogs with >1,000 µg/g of copper per dry weight liver or centrilobular hepatic copper accumulation associated with hepatitis on histology. D-penicillamine is the most popular chelator due to affordability and patient tolerance (Table 10.2). The most common side effect is vomiting, which may be managed by dividing the dose or administering an antiemetic. Rare side effects include immune-mediated diseases of the kidney and lung. Pyridoxine is supplemented during therapy because D-penicillamine antagonizes vitamin B_6. D-penicillamine binds hepatic copper, enhancing renal clearance. It secondarily upregulates metallothionein in enterocytes, promoting fecal elimination of dietary copper. D-penicillamine therapy is continued for 2–6 months or until ALT improves to less than twice the upper limit of normal. At that time, the frequency of D-penicillamine therapy may be reduced for maintenance therapy, or zinc may be initiated to block enteric copper absorption (Table 10.1). D-penicillamine and zinc should not be administered concurrently because zinc will be preferentially chelated, negating the benefit of both drugs.

Immune modulatory drugs are initiated if nonsuppurative immune-mediated disease is suspected. Prednisone is the first-line glucocorticoid (Table 10.2). Dexamethasone is selected if ascites is present because prednisone's mineralocorticoid component may exacerbate effusion. Glucocorticoids are administered in combination with a second immunosuppressive drug (azathioprine, mycophenolate, or cyclosporine) for 2–4 weeks. Clinical and biochemical parameters are reevaluated before medication modification (every 2–4 weeks initially). Prednisone is rapidly tapered if there is a good response to therapy. The second immunosuppressive is continued with CBC and chemistry rechecks occurring initially every 2–4 months. The second immunosuppressive drug is tapered when biochemical remission is achieved, or adverse drug effects are noted. Biochemical values are rechecked 1 month and 6 months after discontinuation of therapy. Most dogs require lifelong therapy.

Prognosis

Prognosis is dependent on the etiology and histologic grade of chronic hepatitis. The prognosis for infectious and copper associated hepatopathy is good. Inadequate canine studies exist to comment on the outcome of drug-induced, idiopathic, or autoimmune hepatitis in dogs. Accumulating evidence in human and research models suggest that fibrosis is a reversible process; therefore, treatment is indicated even if severe fibrosis is identified.

FELINE CHOLANGITIS

Definition/Overview

Feline cholangitis is an inflammatory process targeting the bile ducts/ductules expanding within the portal tract. The classification of cholangitis is based on the predominant cellular infiltrate and duration of illness. There are three main subtypes: Chronic cholangitis (fluke associated), neutrophilic cholangitis (acute and chronic), and lymphocytic cholangitis. Common co-morbidities frequently include pancreatitis and inflammatory bowel disease.

Etiology

Fluke-associated cholangitis is caused by trematodes from the *Dicrocoeliidae* (*Platynosomum concinnum* (previous nomenclature fastosum) (feline specific), *Eurytrema procyonis*, and Opisthorchiidae (*Opisthorchis* spp., *Amphimerus* spp., *Clonorchis* spp., and *Metorchis* spp.) families. Infection with *Platynosomum concinnum* is reported most often. This species requires two to three intermediate hosts, a snail, a terrestrial isopod, and a lizard, toad, gecko, or skink (paratenic host). Cats are infected after ingesting the vertebrate host. The disease is also referred to as "lizard poisoning." Metacercariae excyst in the feline gastrointestinal tract and migrate to the common bile duct, hepatic bile ducts, and the gallbladder where the adult flukes reside. Once mature (12 weeks post infection), the flukes reproduce. Ova are shed intermittently in feces.

Acute and chronic neutrophilic cholangitis also has an infectious etiology and is most commonly caused by bacterial infection and rarely protozoal (toxoplasmosis, hepatozoonosis) infection. The inciting factor for lymphocytic cholangitis is unknown but may be due to an overzealous immune response or molecular mimicry, resulting in adaptive immune response to a biliary epithelial epitope.

Pathophysiology

Infectious organisms cause direct injury to the biliary epithelium. Secondary induction of innate and adaptive immune responses targeted at clearing dead cells and eliminating the infection may perpetuate inflammation and tissue damage. Extrahepatic duct obstruction may occur due to fluke obstruction, inspissated bile, or cholelithiasis. Lymphocytic cholangitis is an immune-mediated disease targeting the biliary epithelium. This results in periductal and intraductal lymphoplasmacytic infiltration, activation of myofibroblasts, leading to extracellular matrix deposition and, in some cases, bile duct destruction.

Clinical Presentation

Trematode-associated cholangitis occurs in free-roaming cats in tropical and subtropical regions. Acutely, cats with fluke-associated cholangitis may be asymptomatic or experience anorexia and lethargy. Cats with chronic infections may present for cyclic abdominal pain, chronic mucoid diarrhea, and icterus. High fluke burden can result in severe inflammation, extrahepatic bile duct occlusion, and death.

Cats with acute neutrophilic cholangitis are often young with a short duration of illness. Clinical signs include abdominal pain, dehydration, fever, gastrointestinal signs, and jaundice. Chronic neutrophilic cholangitis affects cats of any age and shares clinical signs with waxing and waning clinical signs.

Lymphocytic cholangitis is typically identified in middle-aged to older cats but can occur at any age. There is no breed or gender predisposition. Clinical signs include intermittent vomiting, diarrhea, anorexia, and jaundice.

Differential Diagnosis

Differential diagnoses for neutrophilic and fluke-associated cholangitis include hepatic abscess, pancreatitis, or extrahepatic bile duct obstruction due to cholelithiasis, stricture, or neoplasia. Differential diagnoses for lymphocytic cholangitis include hepatobiliary neoplasia, chronic pancreatitis, or reactive hepatopathy.

Diagnosis

Clinicopathologic Abnormalities

Complete blood count abnormalities with fluke-associated cholangitis may include mild nonregenerative anemia, hypereosinophilia, and lymphocytosis. Biochemical derangements may include hyperbilirubinemia and hepatic transaminase elevations in severely infected cats. Definitive diagnosis is through identification of fluke ova in feces (double centrifugation with Sheather's sugar flotation solution, formalin-ether sedimentation), but intermittent ova shedding may lead to a false-negative result.

Approximately one-third of cats with acute neutrophilic cholangitis have a neutrophilia with left shift and toxic change. Hyperbilirubinemia is the most common biochemical abnormality. Transaminases are moderately to severely elevated (ALT, AST). ALP and GGT may be modestly increased, but concurrent hepatic lipidosis will cause marked ALP elevations. Hyperglobulinemia is occasionally reported. Severe systemic illness can precipitate electrolyte derangements, coagulopathy, prerenal and renal azotemia.

Cats with lymphocytic cholangitis commonly have a regenerative or nonregenerative anemia with poikilocytosis. White blood cell counts are not reliably elevated. Moderate-to-severe elevations in ALT and AST are the most common biochemical abnormality. Relatively higher GGT-to-ALP ratios are consistent with cholangitis, but cholestatic enzyme elevations may not be present. Mild hyperglobulinemia is present in approximately 50% of cats. Hyperbilirubinemia is common but cyclic.

Diagnostic Imaging

B-mode abdominal ultrasonography may identify hepatobiliary abnormalities, including heterogenous liver

with hyperechoic periportal markings and hyperechoic gallbladder contents, but the majority of cats with neutrophilic and lymphocytic cholangitis have normal hepatobiliary ultrasounds. The modality is more helpful in cats with fluke-associated cholangitis where hyperechoic/thickened gallbladder wall, double-rimmed gallbladder, and gallbladder sludge are common. Gallbladder distention or common bile duct dilation (>4 mm) may be present if flukes are obstructing the biliary outflow tract.

Percutaneous ultrasound-guided cholecystocentesis is a valuable means of obtaining bile samples for cytology, Gram stain, and aerobic/anaerobic bacterial culture. Direct bile microscopy is the preferred diagnostic modality for ova detection and may also identify suppurative inflammation in neutrophilic cholangitis.

Histology (See Biopsy Guidelines in Table 10.3)

Hepatic histology in fluke-infected cats has lymphoplasmacytic and occasional eosinophilic portal infiltrates. Severe fibrosing cholangitis, cholangiectasis, and bile duct hyperplasia may be observed. Adult flukes can be identified in the bile ducts (Figure 10.8a–c).

Neutrophilic cholangitis is defined by bile duct centric neutrophilic infiltrates within the portal tract. Lymphoplasmacytic inflammation may be present. Variable grades of periductal fibrosis are present dependent on chronicity. Bacteria are rarely visualized on histology.

Liver biopsy is required for the diagnosis of lymphocytic cholangitis. Cats with lymphocytic cholangitis have lymphocytic or lymphoplasmacytic duct centric infiltrates within portal tracts (Figure 10.9). Periductal fibrosis increases with chronicity (Figure 10.10). Bile ducts may involute (ductopenia), which marks a more serious disease process. Immunohistochemical staining and clonality testing may help to distinguish lymphocytic cholangitis from small-cell lymphoma in cases where profound lymphocytic proliferation makes definitive diagnosis challenging.

Management

Fluke-associated cholangitis is treated with praziquantel. High-dose (praziquantel 20–25 mg/kg q.24 h. for 3 days) and low-dose (Droncit, Bayer, 5.75 mg/kg, p.o. repeated in 3 weeks) protocols are both reportedly effective. Response is measured by improvement of biochemical parameters, clinical signs, and negative fecal analyses (every 3 months for 1 year).

Treatment for neutrophilic cholangitis is initially centered on broad-spectrum antimicrobial therapy. Bile/hepatic Gram stain or culture should guide antibiotic selection. Commonly isolated organisms include *Escherichia coli*, *Enterococcus* spp., *Streptococcus* spp., *Clostridium* spp., *Bacteroides* spp., *Pseudomonas* spp., and *Actinomyces*. Aggressive supportive care, including intravenous fluid administration to correct volume deficits and electrolyte abnormalities, is critical. Cats are treated with vitamin K_1 (Table 10.2) prior to invasive procedures, particularly if hyperbilirubinemic. Antioxidants are administered in the initial course of treatment (N-acetylcysteine, SAMe, vitamin E, or ursodeoxycholic acid) and continued dependent clinical response for 2–4 weeks. Enteral nutrition is implemented

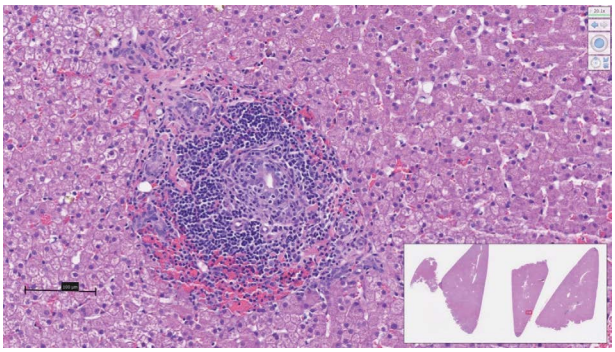

FIGURE 10.9 Hematoxylin and eosin stain on hepatic histology from a cat with lymphocytic cholangitis. Dense lymphoplasmacytic infiltrates expand the portal tract.

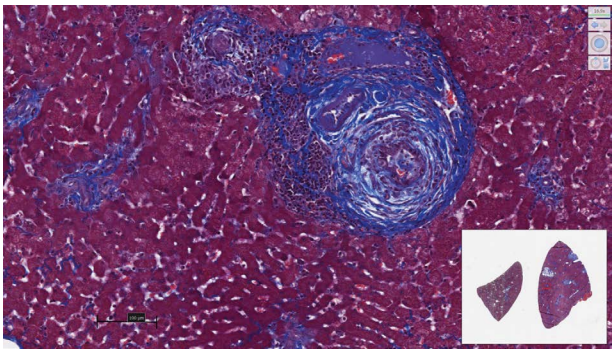

FIGURE 10.10 Masson's trichrome stain on hepatic histology from a cat with lymphocytic cholangitis. Concentric fibrosis (blue) encircles the bile duct.

via nasoesophageal feeding once the patient is hydrated and emesis is controlled. Antibiotic therapy is continued for a minimum of 4–6 weeks. Because antibiotics are often initiated prior to obtaining a culture, failure to identify the inciting organisms is possible, but empiric antibiotic therapy is continued if cytologic or histologic evidence of neutrophilic cholangitis is present.

The mainstay of treatment for lymphocytic cholangitis is immunosuppression with prednisolone (Table 10.2). If a clinical response is noted, glucocorticoid therapy is titrated to the lowest effective dose after the first 2–4 weeks of treatment. Ursodeoxycholic acid is used in cats without ductopenia. SAMe and vitamin E can be added as additional or alternative antioxidants. Modulation of gut flora is an important component of therapy. Historically, metronidazole was administered, but probiotics are a viable alternative. If clinical response (reduction in clinical signs, normalization of bilirubin, reduction in ALT) is not achieved after 2 months, an additional immunosuppressive is added (chlorambucil 2 mg p.o. q.48–72 h., advise owners to wear gloves when administering). CBC and chemistry are rechecked monthly for the first 6 months after starting chlorambucil and then every 2–3 months. Ductopenic cats should be monitored closely for weight loss and signs of malabsorption due to insufficient bile acid release into the gut.

Cats with cholangitis often have concurrent inflammatory bowel disease and pancreatitis. These comorbidities should be identified and treated concurrently.

Prognosis

The prognosis is good for fluke-associated and neutrophilic cholangitis if identified early in the course of disease.

Lymphocytic cholangitis requires chronic therapy and monitoring. Many cats achieve long-term remission (years) with immunosuppressive and antioxidant therapy, but relapse or progression to lymphoma eventually occur. Ductopenic cats have a poorer long-term prognosis.

GALLBLADDER MUCOCELE

Definition/Overview

Gallbladder mucoceles are an abnormal accumulation of mucin and inspissated bile within the gallbladder lumen.

Etiology

Although multiple predisposing factors have been associated with gallbladder mucocele formation, the specific etiology remains unknown. Correlated co-morbidities include dyslipidemia, endocrinopathy (diabetes mellitus, hyperadrenocorticism, and hypothyroidism), gallbladder hypomotility, and cholelithiasis.

Pathophysiology

Excessive secretion of abnormal gel-forming mucin from the gallbladder epithelium, which results in gallbladder distension, mural ischemia, and necrosis. Obstruction of the cystic and common bile ducts may occur secondary to extension or migration of mucin.

Clinical Presentation

Gallbladder mucoceles occur most commonly in older, small to mid-sized dogs, but any dog may be affected. Overrepresented breeds include Shetland Sheepdogs, Bichon Frisé, Cocker Spaniels, Chihuahuas, Miniature Schnauzers, Scottish Terriers, Shih Tzu, and Pomeranians. Dogs may be asymptomatic or present with gastrointestinal signs (anorexia, vomiting, and diarrhea), cranial abdominal pain, or icterus. Elevations in cholestatic hepatic enzymes predominate (ALP, GGT) in most cases but may be accompanied by elevated leakage enzymes (ALT, AST) and variable disturbances in white blood cell count, bilirubin, and cholesterol.

Differential Diagnosis

Cholecystitis, hemocholecyst, or accumulation of gravity-independent gallbladder sludge due to outflow obstruction (cholelithiasis, neoplasia, bile duct stricture).

Diagnosis

Gallbladder mucoceles are diagnosed via ultrasonography and are characterized by accumulation of intraluminal hypoechoic mucus adjacent to the gallbladder

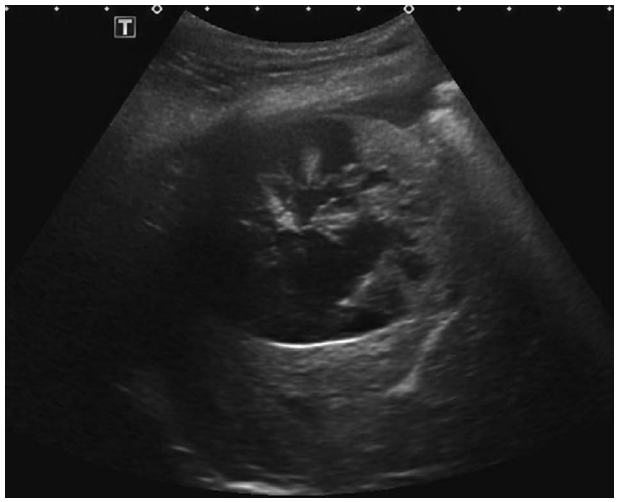

FIGURE 10.11 Gallbladder mucocele with gallbladder wall rupture. The pericholecystic echogenic free fluid, free gas, and hyperechoic mesentery suggest gallbladder wall rupture. (*Courtesy of K. Wilson.*)

wall with central hyperechoic, nongravity-dependent biliary sludge with a stellate pattern (kiwi fruit-like). Gallbladder rupture is suggested by discontinuity of the gallbladder wall, pericholecystic hyperechoic fat, or effusion (Figure 10.11).

Management

Cholecystectomy is the only treatment option for dogs with ruptured gallbladder mucoceles (Figure 10.12). Surgery is indicated for symptomatic patients and those with moderate-to-severe biochemical derangements. Preoperatively, parental fluid therapy with a balanced electrolyte solution and parental pain control are the top treatment priorities. Bacterial cholecystitis is emerging as a common co-morbidity. Broad-spectrum antibiotics are administered pre-emptively to limit complications from septic peritonitis in patients with fever or CBC alterations consistent with infection. Antimicrobials are continued pending gallbladder wall culture results or 2 weeks beyond resolution of clinical signs. Vitamin K_1 (0.5–1 mg/kg SQ ×3 doses) is administered perioperatively in cases of bile duct obstruction because of the inhibition of fat-soluble vitamin absorption. Choleretics should not be administered preoperatively in dogs with a compromised gallbladder wall or evidence of bile duct obstruction. Ursodeoxycholic acid may promote smooth muscle contraction of the gallbladder wall, potentiating rupture, and will increase bile flow, enhancing bile volume and elevating intraluminal pressure in bile duct occlusion. Clinicopathologic abnormalities will normalize within 2–3 weeks of surgery.

Medical management with oral choleretics may be attempted in asymptomatic or minimally affected patients (intermittent gastrointestinal signs, mild ALP/GGT elevations). Ursodeoxycholic acid stimulates bile acid dependent bile flow (10 mg/kg q.12 h. with food). Choleresis is also stimulated with high-dose S-adenosylmethionine (SAMe, 40 mg/kg p.o. q.24 h.) through a nonbile acid dependent mechanism. Medical management includes treatment of underlying dyslipidemias and endocrinopathies. Serial reassessment during medical therapy, including CBC, chemistry, and recheck abdominal imaging, is performed every 1–2 months initially. Monitoring frequency is reduced if improvement in biochemical parameters and gallbladder ultrasonographic appearance are noted. Cholecystectomy is recommended if no improvement occurs after 4–6 months of therapy or there are worsening clinical signs, biochemical parameters, or ultrasonographic changes.

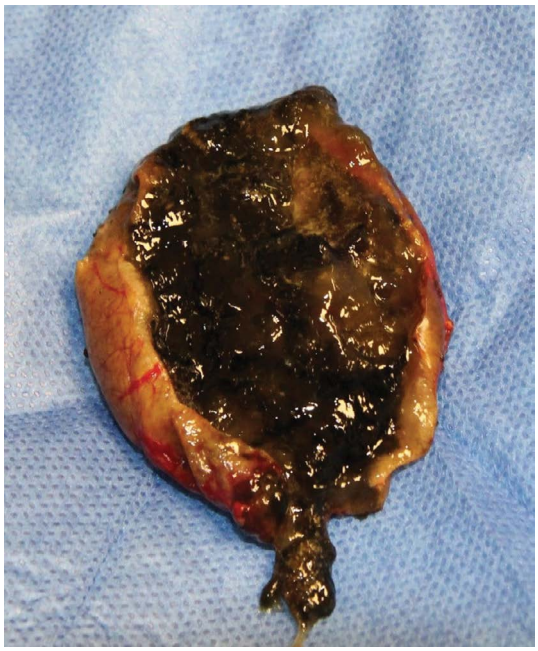

FIGURE 10.12 Gross image of a gallbladder mucocele opened to reveal bile and mucin.

Prognosis

Reported postoperative survival following cholecystectomy ranges from 68% to 91%. Survival rates improve substantially in patients undergoing elective surgery. Hyperbilirubinemia is a consistent poor prognostic indicator in the majority of retrospective studies.

CANINE VACUOLAR HEPATOPATHY

Definition/Overview

Vacuolar hepatopathy is the excessive accumulation of cytosolic glycogen within hepatocytes.

Etiology

Known causes of hepatocyte glycogen overload include rare genetic abnormalities (congenital glycogen storage diseases), glucocorticoid administration, and endogenous hypercortisolemia. Vacuolar hepatopathy has been correlated with chronic systemic inflammatory conditions,

dyslipidemias, endocrinopathies (diabetes mellitus, hyperadrenocorticism, hypothyroidism), gallbladder mucoceles, hepatocutaneous syndrome, necroinflammatory liver disease, neoplasia, nodular hyperplasia, and pancreatitis. A breed-specific vacuolar hepatopathy occurs in Scottish Terriers, which has been correlated to abnormal androgenic hormone production. In some cases, the cause of vacuolar hepatopathy is idiopathic.

Pathophysiology

Hepatic glycogen storage is a normal metabolic process, but dysregulation in the synthesis, storage, and catabolism of glycogen leads to hepatocellular dysfunction. If the underlying disease process is not addressed, hepatocellular swelling due to glycogen accumulation will affect normal intracellular processes and mechanically disrupt extracellular canalicular bile flow. Cellular degeneration and dropout will eventually ensue leading to stromal collapse and distortion of sinusoidal blood flow.

Clinical Presentation

Vacuolar hepatopathy affects middle-aged to older dogs. Any breed or gender may be affected, but some studies report a female predisposition. An enlarged liver may be palpable on physical exam or visualized radiographically. The primary clinicopathologic feature is a moderate-to-severe elevation of ALP and ALT, while the AST and GGT are initially normal to mildly elevated. The hepatic leakage enzymes will progressively increase with ongoing hepatocellular damage and cell death. Other biochemical abnormalities are dependent on the etiology or correlated disease process. For example, exogenous glucocorticoid administration frequently results in an increased GGT activity.

Differential Diagnosis

Primary or secondary cholestatic liver diseases, neoplasia (osteosarcoma, mammary carcinoma)

Diagnosis

In many cases, a moderate-to-severe ALP elevation, the characteristic features of an enlarged liver on abdominal radiographs and hyperechoic hepatic parenchyma with poorly defined hypoechoic nodules on ultrasound, and hepatocyte rarefaction on cytology are sufficient for a preliminary diagnosis. These findings should prompt a more in-depth search for an underlying cause or correlated condition prior to biopsy. Hepatic histology is necessary to identify concurrent necroinflammatory liver disease. In isolated vacuolar hepatopathy, hematoxylin and eosin staining highlights hepatocytes with lacy cytoplasm, defines zonal distribution, and identifies lobular distortion. Periodic acid Schiff (PAS) staining differentiates glycogen from lipid vacuolation. Rhodanine staining will identify copper accumulation, which is a common co-morbidity in vacuolar hepatopathy of Scottish Terriers.

Management

Treat underlying conditions. Discontinue glucocorticoids, steroidogenic drugs, or herbal remedies. Initiate antioxidant therapy (vitamin E, SAMe; Table 10.2).

Prognosis

Prognosis is good if an underlying etiology can be identified and treated. In some dogs, such as Scottish Terriers, vacuolar hepatopathy is a progressive degenerative process that is correlated with the development of hepatocellular carcinoma.

CANINE HEPATOCUTANEOUS SYNDROME

Definition/Overview

Hepatocutaneous syndrome is a metabolic disease affecting the liver and skin. The liver has a characteristic honeycomb pattern on ultrasound with a glycogen-type vacuolar change on histology. Skin lesions are histologically classified as necrolytic migratory erythema (superficial necrolytic dermatitis). The syndrome is associated with hypoaminoacidemia and aminoaciduria.

Etiology

The etiology is unknown, but hepatocutaneous syndrome is associated with dysregulated protein metabolism.

Pathophysiology

Progressive skin lesions result in discomfort when ambulating and progressive glycogen accumulation in the liver leads to degenerative vacuolar hepatopathy. Some dogs develop diabetes mellitus.

Clinical Presentation

Hepatocutaneous syndrome affects middle-aged to older dogs that are predominantly male. Shih Tzus, Maltese, Schipperkes, West Highland White Terriers, Shetland Sheepdogs, and Labrador Retrievers are overrepresented. Dogs may present for pain associated with their paw pad, hyperkeratosis, fissures, and erosions (Figure 10.13). Crusting and ulceration of mucocutaneous junctions is also typically present. Additionally, ALP and/or ALT elevations are usually identified in combination with diffuse hypoechoic nodules surrounded by a hyperechoic parenchyma.

Differential Diagnosis

Necrolytic migratory erythema with endocrine neoplasia (glucagonoma), pemphigus foliaceus, leishmaniasis, zinc responsive dermatitis, cutaneous or hepatic neoplasia

FIGURE 10.13 Typical paw pad lesions associated with hepatocutaneous syndrome in the dog. Erythema, crusting, ulceration, and hair loss are evident. (*Courtesy of R. Marsella.*)

Diagnosis

Diagnosis is based on skin histology that identifies the necrolytic migratory erythema in combination with either hepatic histology that identifies glycogen-type vacuolar hepatopathy or the characteristic hepatic honeycomb appearance on ultrasound. Plasma hypoaminoacidemia and aminoaciduria (lysinuria and prolinuria) confirm the diagnosis.

Management

Treatment focuses on pain management for paw pad lesions and correction of the amino acid deficit. Aminosyn 10% crystalline amino acid solution is administered (24 mL/kg or 500 mL per dog,) through a central venous catheter over 8–12h and repeated every 7–10 days until skin lesions improve. Aminosyn infusion frequency is adjusted based on patient response. Hepatic encephalopathy can occur following infusions but will usually resolve within 12 hours. Ancillary therapy incudes feeding a high-protein commercial diet is fed and supplementation with body builder amino acid concentrate. Secondary skin infections are treated as they arise. Antioxidants may be added to support hepatic health (Table 10.2). Patients are monitored for hyperglycemia and progressive liver enzyme elevations.

Prognosis

Prognosis is poor for long-term survival.

FELINE HEPATIC LIPIDOSIS

Definition/Overview

Feline hepatic lipidosis is a metabolic syndrome that manifests with hepatocellular lipid overload. Cytosolic distension with triglyceride causes intracellular dysfunction and extracellular compression of the canaliculi, resulting in cholestasis.

Etiology

Hepatic lipidosis is a consequence of negative energy balance due to anorexia, typically occurring in over conditioned cats. The inciting cause of the anorexia, and thus hepatic lipidosis, is usually secondary to another disease process. Causal conditions include gastrointestinal disease, pancreatitis, and cholangitis. In cases where an underlying etiology is not identified, hepatic lipidosis is considered idiopathic.

Pathophysiology

The specific mechanisms leading to dysregulated lipid metabolism are unclear.

Peripheral fat mobilization occurs secondary to a negative energy balance. The delivery of nonesterified fatty acids to the liver exceeds the mitochondrial β-oxidative capacity, resulting in triglyceride accumulation in the hepatocyte.

Clinical Presentation

Hepatic lipidosis tends to affect middle-aged cats but can occur in cats of any age, breed, or gender. Many cats are over conditioned prior to onset of the syndrome. Owners typically report hyporexia, anorexia, vomiting, weight loss, diarrhea, or lethargy. Physical exam abnormalities may include dehydration, hepatomegaly, and icterus.

CBC findings are nonspecific but may include a mild nonregenerative anemia with poikilocytosis and Heinz bodies. There is occasionally a mature neutrophilic leukocytosis. The most common and earliest clinicopathologic abnormality is a marked ALP elevation. Hyperbilirubinemia, ALT, and AST elevations occur as hepatic lipidosis progresses and with other underlying diseases. Electrolyte derangements and mild hyperglycemia are also common. Dependent on concurrent disorders, elevated GGT, hypoalbuminemia, and hyperglobulinemia may also be present. Urine sediment frequently contains lipid. Coagulation parameters may be abnormal. Characteristic abdominal ultrasound findings include a diffusely hyperechoic liver and hepatomegaly.

Differential Diagnosis

Cholangitis, extrahepatic bile duct obstruction, hepatocellular neoplasia

Diagnosis

Definitive diagnosis is based on consistent clinical signs, clinicopathology abnormalities, and hepatic cytology wherein >80% of the hepatocytes have lipid-type vacuolation. Hepatic biopsy is not recommended unless another hepatobiliary disease is suspected (Figure 10.14).

Management

Treatment is targeted at achieving euhydration, correcting electrolyte derangements, and reversing the negative energy balance. Impaired liver function may reduce hepatic capacity to metabolize lactate; therefore, isotonic crystalloids devoid of lactate buffer are

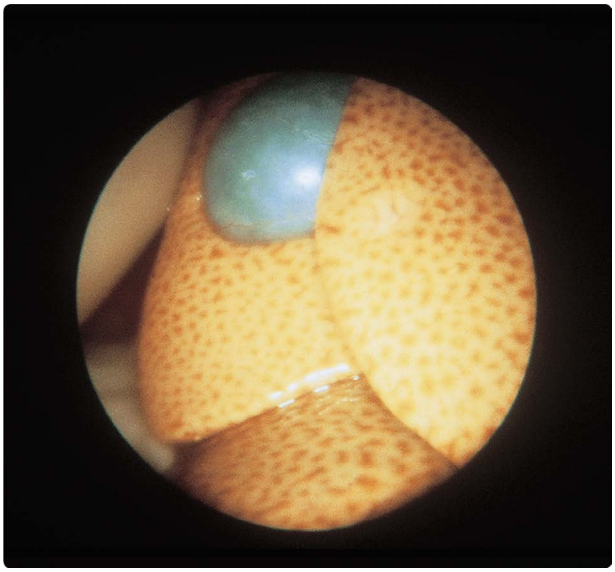

FIGURE 10.14 Laparoscopic view of the liver of a cat with hepatic lipidosis. Note the fatty liver. (*Courtesy of J. Taboada.*)

used for volume replacement. Fluid administration rate is calculated based on lean body mass to avoid overhydration. Crystalloids are supplemented with potassium and phosphorous based on basal electrolyte levels. Phosphorous supplementation (0.01–0.03 mmol/kg per hour) is pre-emptive during refeeding to avoid profound hypophosphatemia. Fluids are also supplemented with water soluble B-vitamin complex (2 mL/L). If this is unavailable, thiamine is administered orally (50–100 mg/d), and cyanocobalamin is administered SQ (250–500 µg) following blood collection for B_{12} quantification. Vitamin K_1 (Table 10.2) is supplemented prior to invasive procedures such as fine-needle aspirate. Dextrose supplementation is avoided because it delays catabolism of hepatic triglycerides. Antioxidants (N-acetylcysteine or SAMe, vitamin E, Table 10.2), excluding ursodeoxycholic acid which may be detrimental in a state of profoundly elevated bile acidemia, are administered throughout treatment to combat excess glutathione consumption. Metabolic supplements, particularly L-carnitine (250–500 mg per cat per day) which shuttles fatty acids into the mitochondria enhancing β-oxidation, may expedite recovery.

The cornerstone of hepatic lipidosis therapy is nutritional support. Enteral feeding is started once the cat is euhydrated and electrolytes are normal. Gut motility may be adversely affected if feeding is started too early. Nasoesophageal or nasogastric feeding tubes can be placed with minimal to no sedation. Placement is confirmed radiographically. Feeding of a protein enriched diet (e.g., Royal Canin, Recovery Liquid, 1 kcal/mL) is initiated at a quarter to a third of the resting energy requirement (RER = 70 × $(kg)^{0.75}$), which is increased gradually over 2–3 days. Feedings are administered as a continuous rate infusion or in 4–6 small bolus feedings per day. Placement of an esophagostomy tube is postponed until the patient is stable and has received 2–3 doses of vitamin K_1. Esophageal feeding tubes

CASE EXAMPLE

Case 10.1

Signalment

"Bob," 2-year-old male neutered Domestic Shorthair cat from Baton Rouge, Louisiana

History

Bob presented to the LSU School of Veterinary Medicine Teaching Hospital Emergency Service for 48 hours of anorexia, multiple episodes of bilious vomiting, and lethargy. He has no previous health problems. His medical records indicate that he tested negative for FeLV/FIV at 6 months of age, is up to date on vaccinations, and is with heartworm preventative monthly. He is an indoor cat but goes out into the backyard occasionally. There is one other cat in the household, and she has no clinical signs of illness.

Physical Examination

Body weight: 4.1 kg

Vital parameters: T = 103.9°F, HR = 250 beats per minute, RR = 24 breaths per minute, BP = 90 mmHg

Physical exam: Bob was quiet, alert, responsive, and ~8% dehydrated. Abnormal physical exam findings included enophthalmos and icteric sclera OU, dry and icteric mucous membranes, diminished skin turgor, discomfort on palpation of the cranial abdomen, and mild hepatomegaly.

Clinicopathologic Findings

Point of care analysis: PCV/TS: 30%/8.0. BG: 135 mg/dL (90–120 mg/dL). Lactate: 3.0 mmol/L (0.5–1 mmol/L).

CBC: Mild nonregenerative anemia with normal red blood cell morphology, moderate mature neutrophilic leukocytosis with toxic change, and normal platelet count.

Plasma chemistry: Mild ALT and AST elevation 3× the upper limit of normal (ULN), normal ALP, mild GGT elevated 1.5× ULN, severe hyperbilirubinemia (10× ULN), high-normal albumin and globulin, normal cholesterol, BUN and creatinine (2× ULN), mild hypokalemia and hypochloremia, high-normal sodium.

Urinalysis: USG 1.050, no abnormalities on urine dipstick, clear sediment

Diagnostic Imaging

Abdominal radiographs: No abnormalities identified

Abdominal ultrasound: The liver was normal, and the gallbladder contained a small amount of dependent sludge but had a normal wall. The extrahepatic bile duct was normal. The remainder of the exam was unremarkable.

Cytology and Culture

Cytology liver: Liver cytology mild hepatocyte rarefaction. No other abnormalities.

Cytology bile: Bile cytology identified multiple bacterial organisms with rare with degenerate neutrophils cells (Figure 10.15).

Aerobic and anaerobic bacterial culture: Escherichia coli >100,000 CFU/µL, sensitive to Clavamox (MIC <0.4).

(Continued)

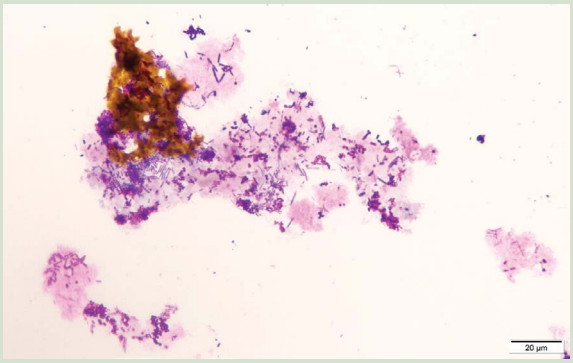

FIGURE 10.15 Bile cytology. Multiple bacterial species identified on bile cytology. (*Courtesy of S. Dehghanpir.*)

Comments

Bob's hypotension was responsive to a bolus of isotonic crystalloids. Abdominal focused assessment with sonography for trauma (AFAST) and thoracic focused assessment with sonography for trauma (TFAST) were negative for free fluid. Abdominal radiographs were normal. Maintenance fluids with deficit replacement over 12 hours were continued. Fluids were supplemented with 20 mEq KCl/L. Maropitant (1 mg/kg IV q.24 h.) and vitamin K1 (0.5 mg/kg SQ q.12 h. ×3 doses) were initiated pending invasive diagnostics the following day. Vital parameters were monitored every 6 hours. His heart rate improved, but he remained febrile overnight. Point-of-care analysis and electrolytes were rechecked 8 hours post admission and identified a mild reduction in PCV, total solids, lactate, and normalization of chloride with persistent mild hypokalemia. Bob was transferred to the internal medicine service 12 hours after hospital admission. He was sedated with butorphanol (0.3 mg/kg) for his abdominal ultrasound, which was normal excluding a small amount of sludge in the gallbladder. Hepatic fine-needle aspiration was performed and identified lipid-type rarefaction in 20% of hepatocytes but no other abnormalities. Supportive care was continued for 24 hours, but Bob remained febrile and anorexic. Recheck serum chemistry 24 hours after admission identified persistently elevated liver enzymes and bilirubin. Antibiotics were initiated due to concern for cholangitis (ampicillin sodium/sulbactam sodium 22 mg/kg IV q.8 h.). Approximately 36 hours after admission, the anesthesia service anesthetized Bob for cholecystocentesis. Bile was collected from gallbladder by percutaneous ultrasound-guided cholecystocentesis (PUC) without complication (**Figure 10.16**). Complications of PUC include vasovagal response, bile or septic peritonitis, and hemorrhage. Bile samples were submitted for cytology and aerobic/anaerobic culture. Bob's temperature normalized following anesthesia, and he ate a small meal. Bile cytology identified bactibilia and scant neutrophilic inflammation.

Bob's clinical signs continued to improve, and he was discharged 3 days after admission with oral SAMe (Denamarin 20 mg/kg p.o. q.24 h.), Clavamox (15 mg/kg p.o. q.12 h.), and maropitant (2 mg/kg p.o. q.24 h. p.r.n.). The culture identified *E. coli*, the most common bacterial isolate in cats with neutrophilic cholangitis. An empiric broad-spectrum antibiotic was initiated prior to sample collection, which likely limited the number of organisms cultured. Recheck serum chemistry 2 weeks was normal. Antibiotics and SAMe were continued for 6 weeks. Recheck serum chemistry at 8 weeks and 3 months remained normal.

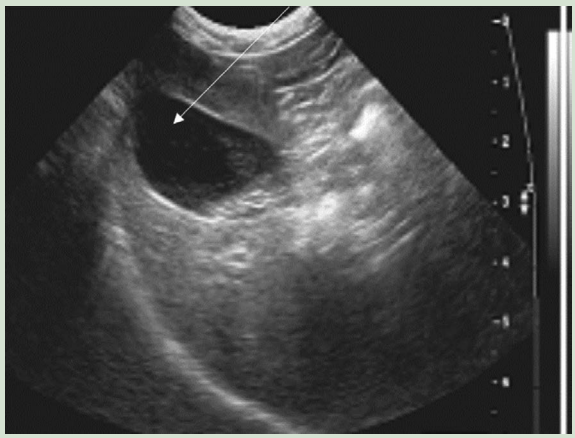

FIGURE 10.16 Percutaneous ultrasound guided cholecystocentesis. Arrow depicts the right transhepatic approach to access the gallbladder. The gallbladder was emptied completely to limit bile peritonitis. Repeat imaging to check for leakage was performed immediately and 6 hours after the procedure to check for pericholecystic fluid.

facilitate medication administration, increase food options, and can be managed by owners at home. Antiemetics (maropitant, metoclopramide, or ondansetron) are frequently added to prevent vomiting and expulsion of the tube. Cats will rarely develop hepatic encephalopathy. Begin antibiotic modulation of gastrointestinal flora if this occurs (**Table 10.1**).

Owners are informed that 1–4 weeks of esophagostomy tube feeding may be necessary. Owners are advised to offer a palatable diet every 12 hours prior to esophagostomy tube feeding to encourage the cat to eat on its own. Owners are shown how to check and clean the esophagostomy tube site daily and how prepare administer food and water through the tube. Rechecks are scheduled weekly to evaluate the esophagostomy tube site and recheck laboratory values.

Prognosis

The prognosis is good if hepatic lipidosis is diagnosed early, treated aggressively, and if an underlying problem is identified and addressed. A reduction in β-hydroxybutyrate during hospitalization and a reduction in bilirubin within the first 1–2 weeks of therapy are good prognostic indicators. Poor prognostic indicators include hypotension, effusions, and progressive hypoalbuminemia and hyperbilirubinemia.

In acute neutrophilic cholangitis, a presumptive diagnosis can be made based on clinical signs, biochemical

abnormalities, bile cytology/culture, and response to antibiotics. In some cases, histology is needed for definitive diagnosis.

PANCREATITIS

Definition/Overview

The exact prevalence of pancreatitis in dogs and cats is unknown. However, studies have shown that up to 51% of dogs and 66% of cats undergoing necropsy have histologic evidence of pancreatic inflammation. Thus, the prevalence of pancreatitis is probably largely underestimated clinically in dogs and cats. These observations show that most pancreatitis cases have a subclinical, often chronic course. Accordingly, the typical picture of acute pancreatitis (AP) only represents the very tip of the iceberg and is not representative of the most frequent form of pancreatic inflammation. Moreover, these facts also underscore how difficult it is to diagnose milder forms of chronic pancreatitis in small animals

Acute pancreatitis is a common disease that must be included in the differential diagnosis of dogs presented with acute vomiting with or without abdominal pain. In cats, the clinical signs may mimic those of acute canine pancreatitis or, more frequently, be so vague that veterinarians need to consider chronic pancreatitis (CP) among a wide range of other chronic diseases. Most frequently, CP is considered a late complication of AP. However, in dogs, it may also be part of a chronic immune-mediated inflammation, as was reported in English Cocker Spaniels.

Epidemiological studies reviewing the signalment of dogs diagnosed with AP in the United States identified an increased risk for small and toy breed dogs such as terriers (e.g., Yorkshire Terrier), Toy Poodles, and Miniature Schnauzers. Moreover, Yorkshire Terriers were also significantly overrepresented among the dogs with AP with a fatal outcome. Case series of confirmed CP in dogs identified an increased relative risk for nonsporting and toy breeds in the United States and Cavalier King Charles Spaniels, Boxers, Cocker Spaniels, and Border Collies in the UK. There is no documented breed predisposition in cats.

Etiology

The cause of pancreatitis remains largely unknown in dogs and cats. Several risk factors have been identified in dogs (Table 11.1). Most cases of feline pancreatitis appear to be idiopathic, even though associations have been reported with trauma (e.g., high rise syndrome), systemic hypotension (e.g., general anesthesia), and pancreatic duct obstruction (e.g., feline liver and pancreatic flukes). Genetic mutations have been associated with pancreatitis in people, but none could be identified in dogs and cats to date. Several widely used drugs have been suspected to rarely trigger AP in dogs. These include azathioprine, clomipramine, and potassium bromide. Consequently, it might be prudent to exercise caution when prescribing these drugs to dogs that have had a prior episode of pancreatitis.

Based on research done in rodent models, inflammation results either from a failure of protective mechanisms in the acinar cells or from abnormal intracellular activation of proinflammatory cytokines and chemokines. This causes activation of trypsinogen to trypsin within the pancreas with ensuing self-digestion of the glandular tissue.

Pathophysiology

Activation of trypsinogen within the pancreas is the initial event leading to activation of other enzymes causing severe damage to the acinar cells, pancreatic interstitium, and vascular endothelium with further amplification and extension of the reaction throughout the pancreas. Pancreatic histopathology in animals with AP reveals neutrophilic inflammation and necrotic foci (Figure 11.1). In addition, the proteolytic cascade may propagate to neighboring structures (e.g., with necrosis of parapancreatic fat, Figure 11.2) and via the bloodstream, which may cause repercussions in remote organs. Conversely, chronic pancreatitis as it frequently occurs in cats is characterized by intralobular and extralobular fibrosis, acinar atrophy, and lymphocytic or lymphoplasmacytic inflammation (Figure 11.3).

Pancreatic perfusion may be compromised, leading to formation of free oxygen radicals and to the disproportionate amplification of the inflammatory process (Figure 11.4). Thus, severe AP may elicit a systemic inflammatory response (SIRS) and multiple organ dysfunction (MODS) (Figure 11.5). These two conditions are responsible for the high mortality associated with this form of disease.

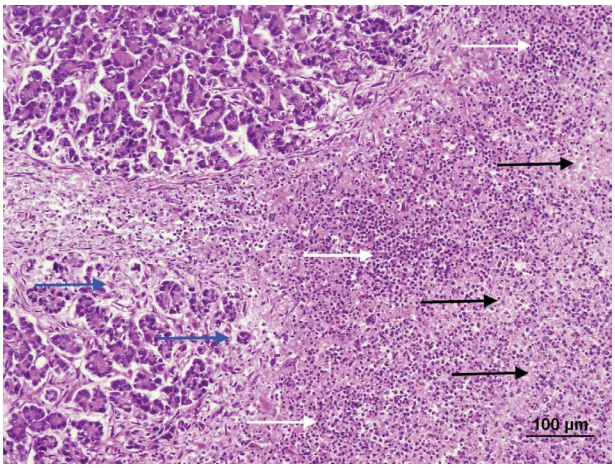

FIGURE 11.1 Histopathologic micrograph of the pancreas of an 8-year-old female spayed Miniature Schnauzer with diabetes and AP and fatal outcome. There is severe neutrophilic infiltration (white arrows) interspersed with areas of necrosis (black arrows). Lesions to the pancreatic acinar cells in the lobules are also visible (blue arrows). The final diagnosis was severe necrotic suppurative pancreatitis.

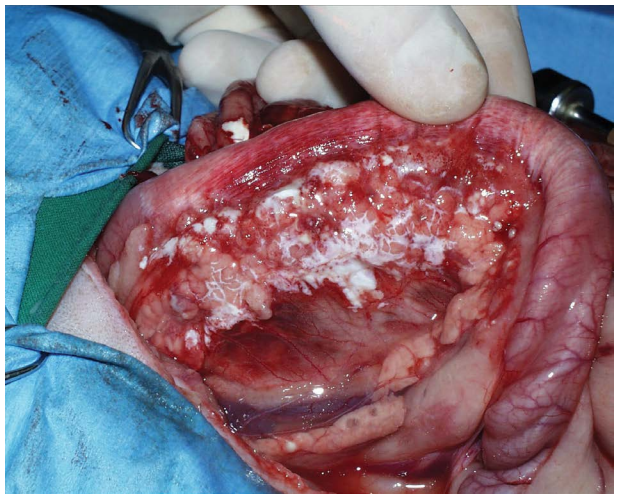

FIGURE 11.2 Intraoperative view during laparotomy of a 7-year-old MN Domestic Shorthair cat with severe AP. The right limb of the pancreas and the duodenum are visible. The pancreas is thickened, nodular, and edematous with hemorrhagic areas extending to the duodenal wall. There is diffuse saponification and necrosis of the peripancreatic fat.

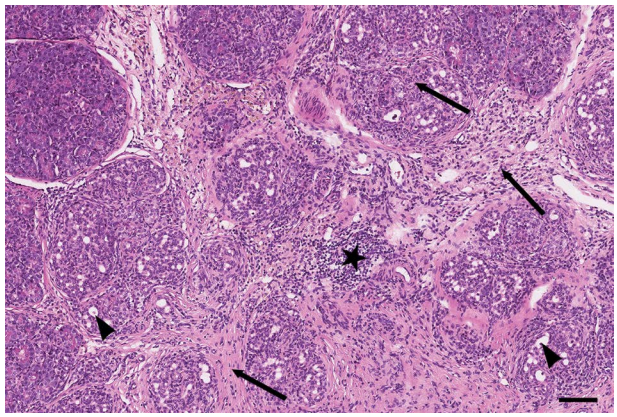

FIGURE 11.3 Histopathologic image of chronic pancreatitis in a cat, showing moderate lymphocytic infiltration (star), interlobular and intralobular fibrosis (arrows), and acinar-to-ductal metaplasia (arrowheads). Scale bar = 100 µm. (*From Forman MA, Steiner JM, Armstrong PJ, et al. (2021). ACVIM consensus statement on pancreatitis in cats.* J Vet Intern Med *35(2): 703–723. With permission.*)

CANINE PANCREATITIS

ACUTE PANCREATITIS

Clinical Presentation

While mild pancreatic inflammation may go unnoticed, moderate-to-severe AP is associated with a characteristic set of clinical signs that includes vomiting, abdominal pain, anorexia/hyporexia, and lethargy (Figures 11.6 and 11.7). Moderate-to-severe dehydration may occur due to lack of fluid intake and vomiting, and cause weakness. Diarrhea, sometimes with

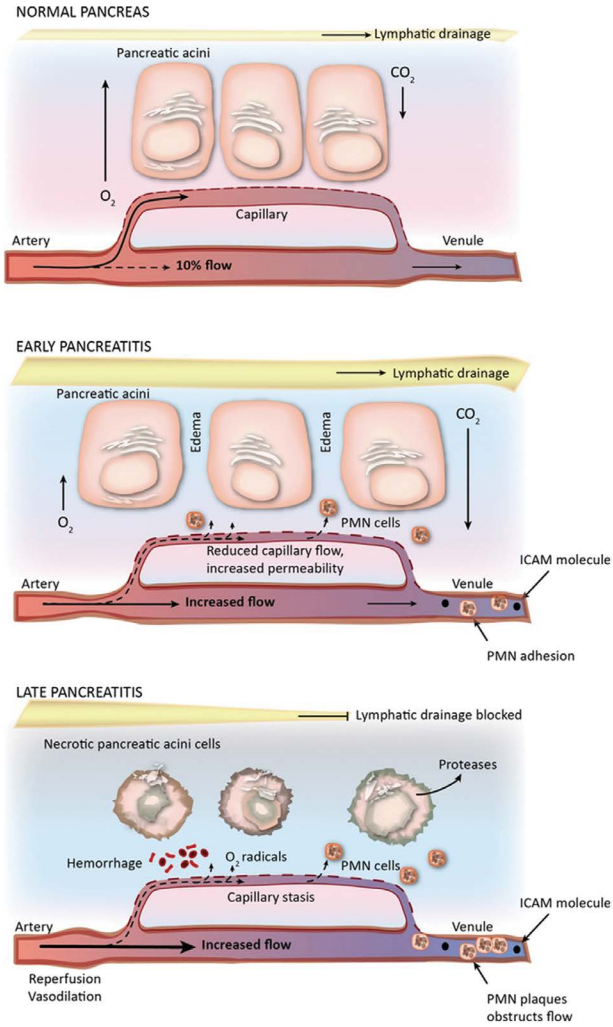

FIGURE 11.4 Pancreatic microcirculation in health and disease. Early pancreatitis is associated with decreased perfusion and increased shunting of blood away from the pancreatic acinar cells. In late pancreatitis, reperfusion injury with generation of free oxygen radicals is associated with capillary stasis, continued bypass of the acinar cells, possible hemorrhage in the tissue, and formation of PMN plaques that further compromise perfusion. Lymphatic drainage is also blocked. (*From Mansfield CM (2012). Pathophysiology of acute pancreatitis: Potential application from experimental models and human medicine to dogs.* J Vet Intern Med *26(4):875–887. With permission.*)

hematochezia or melena, may reflect the extension of inflammation to neighboring structures such as the small intestine or the colon.

The physical examination findings vary with the severity of the problem. Dogs with mild pancreatitis might only show mild lethargy, normal vital signs, and equivocal palpable abdominal tenderness. Signs associated with more severe forms include marked lethargy, fever, hypotension with accompanying tachypnea, tachycardia, weak femoral pulse, a painful abdomen, and a moderate-to-marked degree of dehydration. Clinically detectable icterus will not occur initially with pancreatitis, but it might be evident by the third day and usually results from cholestasis or more rarely pancreatitis-associated bile duct obstruction (PABDO). Abdominal distension can result from paralytic ileus. Presence of abdominal fluid consisting of a reddish brown colored exudate can sometimes be detected with hemorrhagic necrotic pancreatitis.

Diagnosis

Typically, the clinical diagnosis of canine AP is based on a combination of four factors (**Box 11.1**). In the presence of acute vomiting and abdominal pain, abdominal radiographs are essential to rule out gastric or intestinal obstruction (e.g., by a foreign body) and should be obtained as a first step in the diagnostic workup.

A wide range of abnormal laboratory results may occur with AP depending on the extent of the secondary systemic inflammatory process and the consequences of vomiting and anorexia (**Table 11.2**). Complete blood count (CBC) may reveal leukocytosis, often with neutrophilia and left shift, and sometimes thrombocytopenia. Chemistry panel may show electrolyte abnormalities such as hypokalemia and hypochloremia secondary to vomiting. Azotemia may initially be of prerenal origin, associated with dehydration, but may evolve into renal azotemia due to ischemic kidney injury. Hypoalbuminemia and hypoproteinemia are seen in approximately 50% of severe cases. Hyperbilirubinemia may reflect cholestasis due to extension of inflammation to the biliary tree and liver or indicate the presence of PABDO. It may be accompanied by increased serum activity of liver enzymes (alkaline phosphatase [ALP], gamma-glutamyl transferase [GGT], alanine aminotransferase [ALT], and aspartate aminotransferase [AST]). However, liver enzymes may also be increased in association with hypovolemia and poor liver perfusion. Rarely, hyperglycemia may be present due to diabetes mellitus. This may occur following widespread destruction of pancreatic tissue. However, pancreatitis may also occur in dogs diagnosed with diabetes mellitus. It is often associated with diabetic ketoacidosis, particularly in toy and small breed dogs. In addition, serum triglyceride concentration should be measured as high concentrations have been reported to be a risk factor for development of AP.

There is ongoing debate about the most accurate test to document the presence of increased pancreatic enzymes in the bloodstream. A recent study showed that pancreatic lipase immunoreactivity (PLI) and 1,2-o-dilauryl-rac-glycero-3-glutaric acid-(6'-methylresorufin) ester (DGGR) lipase are most useful in the presence of additional supporting clinical data to diagnose pancreatitis. Generally, these tests are quite sensitive, but their specificity is not optimal, as they can be positive for instance in association with other gastrointestinal diseases. The poor diagnostic accuracy of serum total activities of amylase and lipase is the reason why their use in the diagnosis of canine AP cannot be recommended any more.

Diagnostic imaging is a central element in the diagnosis of pancreatitis. Abdominal radiographs are very helpful in ruling out gastrointestinal (GI) obstruction. However, with a reported sensitivity of 24%, they have a low yield to confirm the diagnosis of AP. Radiographic changes, if present, consist of decreased abdominal contrast mass effect in the right cranial quadrant with

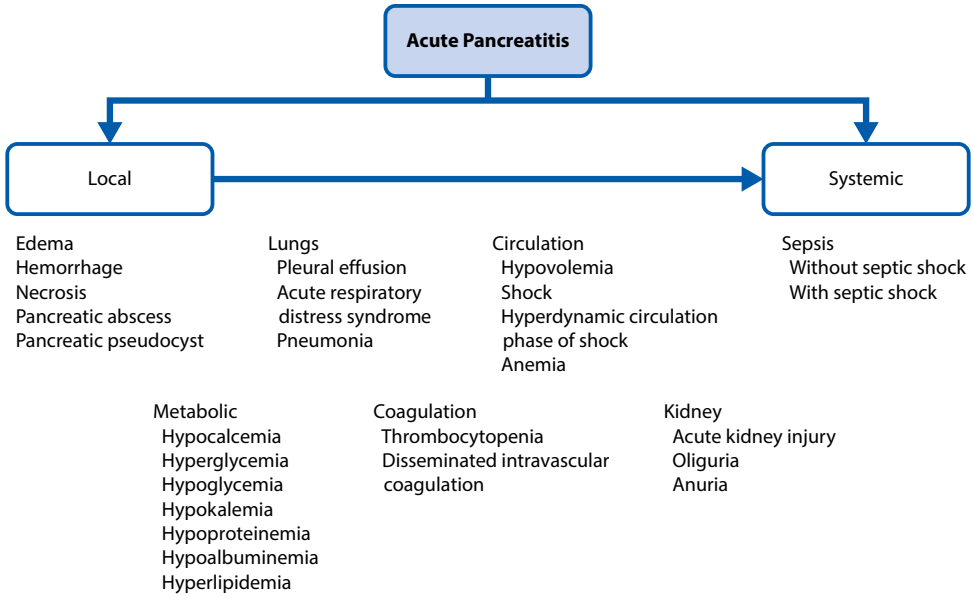

FIGURE 11.5 Pathophysiologic consequences of acute pancreatitis. The adverse effects of acute pancreatitis are far reaching, with involvement of several organ systems. In many cases, this can lead to multiple organ dysfunction and the patient's demise. (*Modified from Büchler MW, Uhl W, Malfertheiner P, et al. (2004).* Diseases of the Pancreas. *Karger, Basel.*)

FIGURE 11.6 This 5-year-old, male, neutered West Highland White Terrier had acutely developed profuse vomiting followed by anorexia, lethargy, and abdominal pain. He vomited bile and water on the exam table.

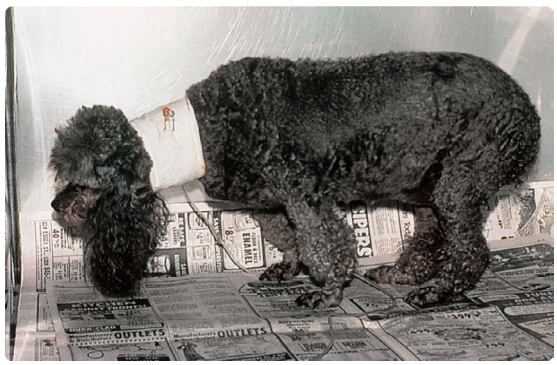

FIGURE 11.7 This 13-year-old female Poodle had acute vomiting, mental depression, and marked abdominal pain peracutely immediately after dinner. Despite the use of intensive fluid therapy, the dog died from hemorrhagic necrotic pancreatitis. (*Courtesy of M. Schaer.*)

Box 11.1 Elements required for a diagnosis of acute pancreatitis in dogs

- Presence of typical clinical signs
- Elimination of other possible differential diagnoses
- Increased serum pancreatic lipase (pancreatic lipase immunoreactivity [cPL®, Idexx] or DGGR lipase activity)
- Presence of typical ultrasonographic lesions of the pancreas and surrounding tissue

lateral displacement of the descending duodenum, which may have a rigid appearance and contain gas due to localized paralytic ileus (Figures 11.8 and 11.9).

Because it is widely available, abdominal ultrasound is the preferred modality to examine the pancreas. Numerous lesions can be detected such as increased in pancreatic volume, presence of nodules, cysts or abscesses, hypoechoic or hyperechoic lesions in the pancreas and in the peripancreatic mesentery, peripancreatic abdominal effusion, etc. Diagnostic sensitivity of ultrasound is good for moderate to severe pancreatitis (Figures 11.10 and 11.11). However, the detailed ultrasonographic evaluation of the pancreas, in particular its left lobe, may be challenging in obese dogs, if the abdomen is painful, or when excessive amounts of gas are present in the stomach and small intestine. A recent study showed the value of repeating the ultrasound exam within the first 2 days, particularly in dogs with suspect pancreatitis based on clinical signs and an increased pancreatic lipase immunoreactivity, but mild or absent ultrasound changes.

Multislice CT scanners are now increasingly available to veterinarians and allow sedated examinations

TABLE 11.2 Clinicopathologic abnormalities accompanying acute pancreatitis in the dog

Abnormality	Proposed mechanism(s)
Anemia	Hemorrhagic abdominal effusion
Azotemia	Prerenal from dehydration, renal from hypovolemia, SIRS or DIC
Hemoconcentration	Dehydration, translocation of plasma into abdominal cavity
Hyperglycemia	Diabetes mellitus
Hyperlipidemia	Might pre-exist as separate entity Can occur with pancreatitis, but exact mechanism unknown
Hypernatremia	Dehydration
Hypoalbuminemia	Abnormal capillary permeability with loss of albumin in the interstitial space, possibly into the abdominal cavity if effusion
Hypocalcemia	Calcium soap formation is most widely accepted mechanism
Hypoglycemia	SIRS or sepsis with impaired gluconeogenesis
Hypokalemia	Vomiting, failure to supplement parenteral fluids, osmotic diuresis from hyperglycemia
Hyponatremia	Vomiting, pseudohyponatremia from hyperlipidemia
Leukocytosis	Inflammation, stress, hemoconcentration, secondary infection
Leukopenia	Mobilization to inflamed site, bone marrow suppression from endotoxemia
Liver enzyme and bilirubin elevations	Cholangitis, hepatic inflammation, PABDO, hepatic lipidosis (in dogs with diabetes mellitus)
Prolonged prothrombin and partial thromboplastin times, thrombocytopenia, low antithrombin level, hypofibrinogenemia	DIC
Thrombocytopenia	Consumption from thrombus formation, SIRS

DIC, disseminated intravascular coagulation; PABDO, pancreatitis-associated bile duct obstruction; SIRS, systemic inflammatory response syndrome.
Source: Modified from Table 10.5 in 3rd ed.

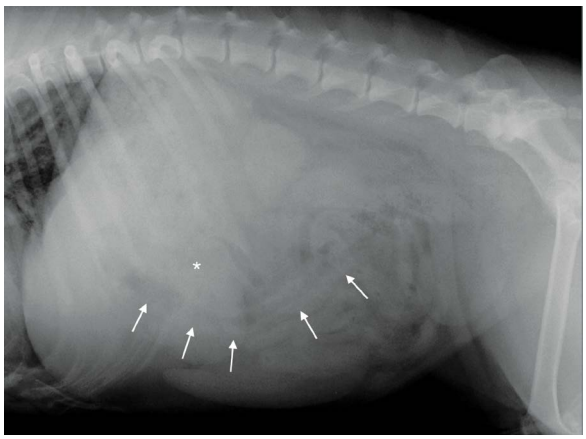

FIGURE 11.8 Radiographic appearance of AP in a dog. Right lateral view: There is decreased contrast in the cranial abdomen (asterisk). Content can be seen in the stomach. The descending duodenum is visible (arrows), filled with gas and shows a rigid appearance.

of dogs and cats. CT provides useful additional information about the pancreas, including evaluation of vasculature through intravenous contrast administration (Figure 11.12). Recent studies have shown that CT angiograms can highlight poorly vascularized areas in

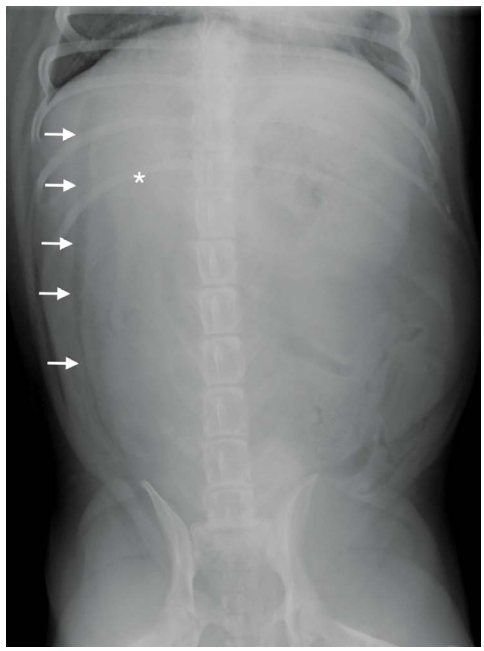

FIGURE 11.9 Ventrodorsal view from the same dog as Figure 11.8. There is decreased contrast in the right cranial abdominal quadrant (asterisk). The duodenum is laterally displaced (arrows) and has a rigid appearance. There is gas in the duodenal lumen.

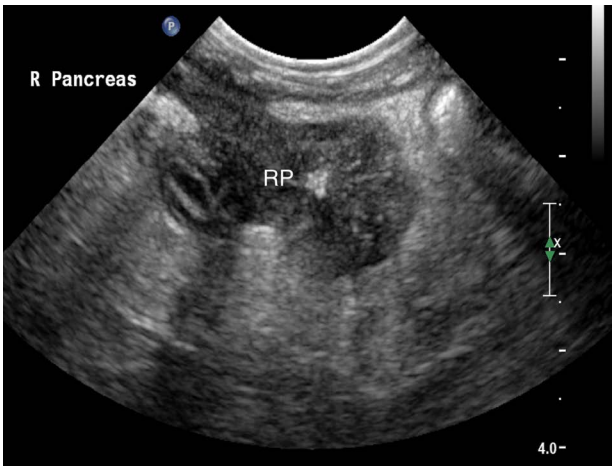

FIGURE 11.10 Ultrasound appearance of AP in the dog. A 5-year-old, male neutered West Highland White Terrier shown in **Figure 11.6**. The right pancreatic limb (RP) is enlarged, hypoechoic, and has a lobulated shape, and the peripancreatic mesentery is hyperechoic.

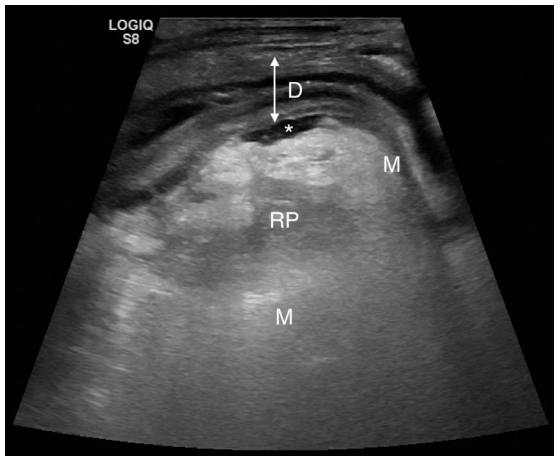

FIGURE 11.11 A 13-year-old, male neutered Maltese Terrier with severe AP. The duodenum (D) is fluid filled and appears rigid. The right pancreatic limb (RP) is enlarged and irregularly shaped. The surrounding mesentery (M) is very hyperechoic indicating peripancreatic inflammation, and a pocket of free abdominal fluid is visible (asterisk).

the pancreas that represent tissue necrosis and portal vein thrombosis, conditions that are associated with prolonged hospital stay and more relapses.

Differential Diagnosis

The initial differential diagnosis of AP includes many clinical disorders that share the same clinical signs, which may mimic most acute abdominal syndromes (**Table 11.3**). Several differential diagnoses are surgical emergencies that require rapid diagnosis and treatment.

Management

Any possible predisposing factor such as hyperlipidemia, drugs that might cause idiosyncratic reactions, etc., should be addressed. However, treatment of AP in dogs is essentially supportive and relies on four important components (**Box 11.2**).

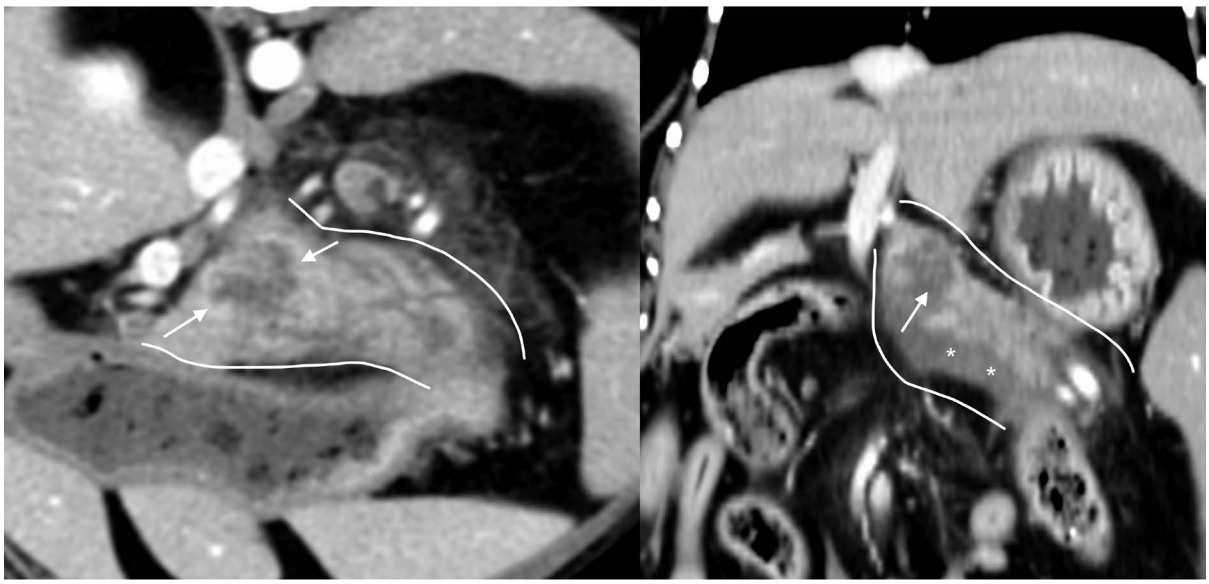

FIGURE 11.12 Contrast-enhanced CT of a 5-year-old female spayed Beagle presented for acute onset vomiting and abdominal pain. The body and left pancreatic limb (outlined in white lines) are enlarged with ill-defined margins and widened interlobular fissures that are fluid attenuating. In the body of the pancreas, there is an irregularly shaped zone of poor intralesional contrast enhancement and a thin irregular rim of enhancement (white arrows). There is extensive fat stranding extending from the pancreas into the mesentery and peritoneal effusion around the left limb of the pancreas (asterisks). The right lobe of the pancreas is normal. Diagnosis was pancreatitis in the body and left limb with a focal region of necrosis and secondary peritonitis. The nonenhancing lesion with an enhancing rim could represent an abscess. (*Courtesy of L. Gaschen.*)

TABLE 11.3 Differential diagnoses of acute pancreatitis in the dog

- Acute gastroenteritis
- Gastrointestinal obstruction
- Gastrointestinal perforation
- Intestinal volvulus
- Intestinal ischemia and infarction
- Intoxications
- Blunt abdominal trauma
- Emphysematous cholecystitis
- Ruptured organs (e.g., uterus, urinary bladder, gallbladder)
- Acute kidney injury
- Acute hepatopathy

Box 11.2 Essential components of the supportive treatment of acute pancreatitis in dogs

- Quick reestablishment of fluid and electrolyte balance
- Successful management of vomiting
- Pain management
- Early enteral nutrition

Rapid support of pancreatic perfusion is essential. Aggressive fluid therapy is required, and large intravenous fluid volumes are often necessary to compensate the losses that occurred with vomiting and diarrhea. Electrolyte disturbances (particularly hypokalemia) should be corrected as needed. Acid–base imbalances (often due to metabolic acidosis) can usually be corrected with proper fluid therapy and do not require administration of alkalinizing solutions. Plasma transfusion is beneficial if DIC is present. Guidelines for treatment of dehydration and hypovolemic shock can be found in Chapter 23.

Antiemetics are important as well. Available drugs and recommended doses are described in Table 2.17.1. The efficacy of metoclopramide is maximal when administered as a constant rate infusion (CRI). A combination of antiemetics is often required to address vomiting and nausea in dogs with moderate and severe AP. Antiemetic treatment should be continued beyond the resolution of vomiting to control nausea to maximize the chances for a rapid return of appetite.

Pain control is traditionally attempted with opiate analgesics, using buprenorphine or fentanyl CRI. Transdermal fentanyl patches are also useful, but there is generally a 12- to 24-hour lag time before therapeutic levels can be reached in serum. However, opiates further compromise the already delayed GI motility in dogs with AP. Therefore, preference should be given to other analgesics such as lidocaine, ketamine, or dexmedetomidine that can be administered alone or in combination with reduced doses of opiates as CRI and provide analgesic relief without delaying GI motility. Guidelines for pain management including dose recommendations can be found in Chapter 24.

It is not advisable to fast dogs for longer than 24–48 hours, starting when they last ate at home. Longer fasting may suppress the immune system, delay healing, compromise the integrity of the intestinal mucosal barrier, and increase the risk of bacterial translocation through the intestinal mucosa and the risk of sepsis. Early enteral feeding improves intestinal mucosal function and has proven beneficial in dogs with AP. However, the dog's interest in food may be compromised if dehydration, vomiting/nausea, and pain are not controlled. Appetite stimulants such as ghrelin agonists (capromorelin 3 mg/kg p.o. q.24 h.) may help accelerate the return of appetite. Importantly, many dogs with moderate-to-severe pancreatitis experience delayed gastric emptying with generalized adynamic ileus in association with their pancreatic and abdominal inflammation. In these patients, support of GI motility is a prerequisite to return of appetite. GI prokinetics can be administered alone or in combination if necessary. Recommended drugs include metoclopramide administered as a CRI (1–2 mg/kg over 24 hours), erythromycin (0.5–1 mg/kg IV q.8 h.), or azithromycin (2 mg/kg IV q.8 h.) (Figure 11.13). Cisapride, another good choice, is not easily available as an injectable drug (0.1–0.5 mg/kg IV q.8–12 h.).

Recommended diets should be easily digestible with a low-fat content and be fed in small amounts several times daily. Initially, it is not necessary to cover the dog's energy and protein requirements. In dogs that remain anorexic for more than 2–4 days since their last meal in the home environment, a nasoesophageal (NE) tube should be placed. Easily digestible, low-fat liquid diets are available commercially for NE tube feeding. Oral feeding or, in anorexic dogs, feeding via NE tube was shown to be superior to prolonged fasting. Guidelines for enteral nutrition and placement of feeding tubes can be found in Chapter 25.

Bacteria do not play a role in the pathogenesis of canine AP. Consequently, the use of antibiotics should be limited to dogs that are in a critical condition with evidence of sepsis. Therefore, there is no indication to use antimicrobials in most dogs with AP. Similarly, there is no benefit in treating AP dogs with gastric protectants such as proton pump inhibitors (PPI) except for those showing intractable vomiting and/or signs of esophagitis.

FIGURE 11.13 A 10-year-old female spayed Miniature Schnauzer with acute-onset anorexia, vomiting, and lethargy that was diagnosed with acute pancreatitis. The dog was hospitalized in the intensive care unit and treated with IV fluids and constant rate infusions of lidocaine and metoclopramide.

Local and Distant Complications

Complications occur relatively commonly in dogs with moderate-to-severe AP (Table 11.4). They can be local and affect the pancreas and immediate surrounding structures, including the GI tract and the liver. They can occur in distant organs such as the lungs and the kidneys, or they can be systemic (SIRS, sepsis, DIC, MODS) (Figure 11.5).

Various lesions may develop as local complications of severe pancreatic inflammation. They include necrotic foci, abscesses, and pseudocysts. Necrotic foci are typically associated with peripancreatic fat necrosis. In human patients, pancreatic abscesses are characterized by a septic purulent inflammation. In dogs, most abscesses are sterile; however, positive bacterial culture of peritoneal exudate was shown in up to one-third of cases. Abscesses occur in <6.5% of cases of AP. The associated clinical signs cannot be differentiated from those of severe AP. Diagnostic confirmation of local complications relies mainly on abdominal ultrasound or CT scans. Cytological exam of an ultrasound-guided fine-needle aspirate may allow differentiation of abscesses from other lesions (Figure 11.14). Emptying of pseudocysts may be attempted under ultrasound guidance or with celiotomy. Therapeutic approach of necrotic foci and abscesses is more challenging. Currently, surgical intervention is only recommended in the presence of infected necrotic foci and fluid accumulations (abscesses), and possibly with total obstruction of bile flow due to PABDO. Importantly, affected dogs are often severely debilitated and surgical interventions are usually associated with a high mortality in the post-operative period (up to 70%).

TABLE 11.4 Complications of pancreatitis in dogs

Complication	Phase of disease
Acute kidney injury	Acute
Acute lung injury, acute respiratory distress syndrome	Acute
Adynamic ileus	Acute
Cholestasis (cholangitis, PABDO)	Acute
Diabetes mellitus	Acute or chronic
DIC	Acute
EPI	Chronic
MODS	Acute
Pancreatic abscess, pseudocyst	Acute
Pleural effusion	Acute
Relapsing pancreatitis	Chronic
SIRS, sepsis	Acute

DIC, disseminated intravascular coagulation; EPI, exocrine pancreatic insufficiency; MODS, multiple organ dysfunction; PABDO, pancreatitis-associated bile duct obstruction; SIRS, systemic inflammatory response syndrome.

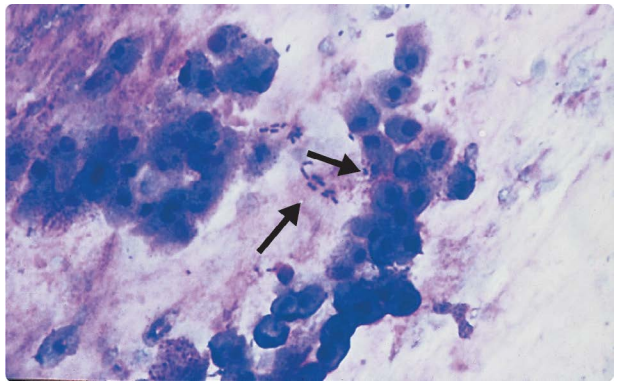

FIGURE 11.14 Cytology sample, from abdominal fluid in a dog with marked pancreatic necrosis with abscess formation, shows toxic neutrophils containing bacteria as well as free bacteria (arrows). Gram-negative bacteria are the most common organisms present on culture if infection occurs. (*Courtesy of D.J. Meyer.*)

As shown in Table 11.4, while acute complications of AP often concern the GI tract (with decreased GI motility) and the liver and biliary tract (with cholestasis and, less frequently, PABDO), organs and systems outside the GI tract and pancreas are also important targets, with the potential for life-threatening consequences. These "remote" complications may occur in the lungs and pleural space (acute lung injury, pleural effusion, with onset of sudden acute respiratory distress) (Figures 11.15 and 11.16), the kidneys (acute kidney injury), or impact hemostasis (DIC). Treatment for these disorders is outlined in other chapters of this book. In addition, inflammation may extend beyond the pancreas and cause SIRS. Ultimately, MODS can lead to the demise of the dog.

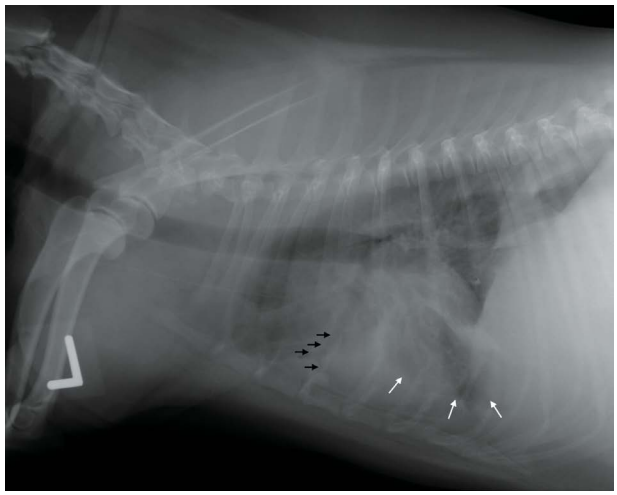

FIGURE 11.15 Chest radiographs of an 11-year-old, male neutered Miniature Poodle with AP and sudden-onset tachypnea and dyspnea due to acute lung injury. Left lateral view—a large air bronchogram is visible in the right cranial lung lobe (black arrows) indicating alveolar infiltration. There is scalloping in the caudal lung lobe (white arrows) indicating presence of pleural fluid.

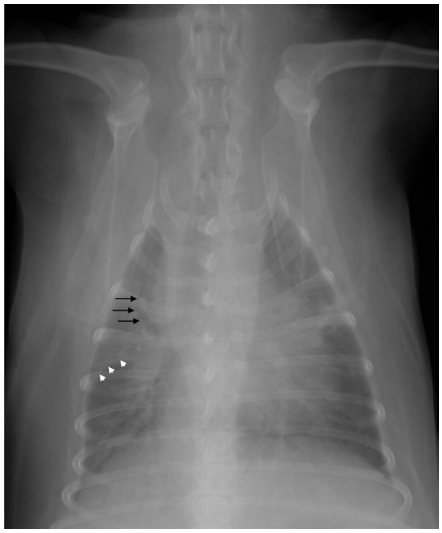

FIGURE 11.16 Ventrodorsal view—The air bronchogram is visible in the right cranial lung lobe (black arrows). There is a lobar sign between the right cranial and middle lung lobes (white arrowheads) and interstitial infiltration in the caudal lobes.

Prognosis

Most cases of mild-to-moderate pancreatitis respond favorably to supportive treatment. Early and aggressive treatment is thought to mitigate the risk of systemic complications. In severe cases, pancreatitis may trigger an uncontrollable cascade of complications that leads to SIRS and MODS. Severely affected dogs should be treated in a hospital offering intensive care with 24-hour monitoring. Prognosis for abscesses and necrotic foci is generally guarded to poor.

Several scoring systems have been established with the goal to help with management decisions and prognostication of AP. A severity score established >20 years ago remains valid and useful to date and is shown in Table 11.5. In addition, a canine acute pancreatitis severity (CAPS) score and a simplified version (sCAPS) have been established recently with the goal to identify dogs with AP at increased risk of death. (Table 11.6). In the sCAPS, checking for presence of SIRS is replaced by evaluation for tachypnea (respiratory rate ≥24 breaths per minute) which, if present, adds 3 points to the sCAPS. A CAPS score ≥11 or a sCAPS score ≥6 were shown to be accurate predictors of short-term death (within 30 days of initial presentation).

CHRONIC PANCREATITIS

Clinical Presentation

Chronic pancreatitis (CP) causes a more varied clinical picture than AP in dogs. In short, patients can present with recurrent signs of generally mild-to-moderate AP (acute-on-chronic pancreatitis) or with a more subtle set of clinical signs that may originate from the GI tract or other organ systems. Common clinical signs of CP are listed in Table 11.7. CP may ultimately lead to organ failure with onset of exocrine pancreatic insufficiency (EPI) and diabetes mellitus (Figure 11.17). In a necropsy case control study, dogs with CP were more likely to have concurrent endocrine diseases (particularly diabetes mellitus) than the reference population or than dogs with AP. They were also more likely to have hepatobiliary or neurologic disease compared to the reference population.

Diagnosis

The diagnosis of CP is often challenging, particularly when the clinical signs are vague and mild. In addition, the diagnostic tests used with success in AP have lower sensitivity for CP. Based on one study, PLI had a low

TABLE 11.5 Practical AP severity scoring in dogs

Disease severity	Score*	Prognosis	Clinical presentation and required support
Mild	0	Excellent	– Often resolves spontaneously – Recovery is uncomplicated – Managed as an outpatient if hydration status is good – Antiemetics are commonly prescribed
Moderate	1	Good to guarded	– Usually dehydrated—prerenal azotemia is common – Recovery is usually uncomplicated, provided adequate supportive treatment can be administered (see text)
	2	Guarded to poor	– Dehydrated, hypovolemic, often prerenal azotemia and neutrophilia with degenerative left shift – Pulmonary and renal function and hemostasis need to be closely monitored – Referral to a 24-hour intensive care unit is often required – Dogs usually recover with intensive therapy
Severe	3	Poor	– These dogs are in critical condition – Intensive monitoring of these critical patients is critical – Extensive therapy and life support are required – Death is a common outcome
	4	Grave	

Modified from Ruaux and Atwell (1998). A severity score for spontaneous canine acute pancreatitis. *Aust Vet J* 76(12):804–808.

* The severity scoring system is based on the number of organ systems, apart from the digestive tract, that show evidence of failure or compromise at initial presentation.

TABLE 11.6 Canine acute pancreatitis severity (CAPS) score

Parameter	Definition	Present	Absent
Systemic inflammatory response syndrome (SIRS)	≥2 of the following criteria – Heart rate >120/min – Respiratory rate >20/min – Body temperature <38.1C (100.6F) or >39.2C (102.6F) – White blood cell count <6,000/μL or >16,000/μL	8	0
Coagulation disorder	Thrombocytopenia (platelet count <63,000/μL), prothrombin time (PT), activated partial thromboplastin time (APTT) prolonged by more than 25% of the upper end of the reference interval, or both	3	0
Increased creatinine	Serum creatinine concentration above the reference range	4	0
Ionized hypocalcemia	Serum ionized calcium concentration below the reference range	3	0

From Fabrès V, Dossin O, Reif C, et al. (2019). Development and validation of a novel clinical scoring system for short-term prediction of death in dogs with acute pancreatitis. *J Vet Intern Med* 33(2): 499–507.

sensitivity (58%), even though it appeared to be the most sensitive laboratory test. Therefore, it is extremely important for clinicians to keep the disease "on their radar" when they see dogs with vague GI-related signs such as those listed in Table 11.7. The test of reference for diagnosing CP is pancreatic histology; however, pancreatic biopsies are infrequently collected in dogs with suspect CP. In addition, disease distribution throughout the pancreas may be patchy, and a negative biopsy may not allow to rule out CP.

The recommended diagnostic workup for a dog with suspect CP consists of a minimal database, including CBC, chemistry profile, and urinalysis. Abdominal imaging (radiographs, ultrasound, possibly CT) can help rule out other possible diagnoses and hopefully identify pancreatic changes. Abdominal ultrasound was shown to have a low-to-moderate sensitivity for CP (56%). PLI or DGGR lipase may also help confirming the presence of pancreatic inflammation. If EPI is suspected, serum concentration of trypsin-like immunoreactivity (TLI) should be assessed. Therefore, the purpose of the diagnostic workup is to rule out other diseases that could cause similar signs and define the extent of CP complications.

TABLE 11.7 Common clinical signs in dogs with chronic pancreatitis

Gastrointestinal signs	Other signs
Low-grade waxing and waning intermittent anorexia with or without vomiting or (large bowel) diarrhea	Sudden onset of extrahepatic biliary obstruction
Occasional anorexia and frequent evidence of postprandial pain and learned food aversions, without other gastrointestinal signs	Back pain (when all other causes such as intervertebral disc disease have been ruled out)
Acute presentation with signs typical of AP as a single episode or recurrent acute flare ups	Polydipsia/polyuria
Diabetes mellitus developing in an older dog of a predisposed breed	Keratoconjunctivitis sicca or protein-losing nephropathy in an English Cocker Spaniel
Exocrine pancreatic insufficiency in an older dog of a breed other than German Shepherd Dog Concurrent diabetes mellitus and exocrine pancreatic insufficiency in any dog	

Adapted from Watson P (2012). Chronic pancreatitis in dogs. *Topics in Comp An Med* 27(3): 133–139. With permission.

FIGURE 11.17 5-year-old FS Cavalier King Charles Spaniel with chronic relapsing pancreatitis, PU/PD, polyphagia, and weight loss. The dog was diagnosed with diabetes mellitus and exocrine pancreatic insufficiency.

Differential Diagnosis

Due to the vague signs associated with CP, many differential diagnoses need to be considered. These may include chronic gastritis, chronic enteropathies, chronic hepatitis and/or cholangitis, and hypoadrenocorticism, to name a few.

Management

For dogs presenting with acute-on-chronic disease, recommended treatment is identical to what is outlined earlier for treatment of AP.

For dogs with a more chronic presentation, the three main components of treatment for CP are analgesia, appropriate nutrition, and addressing functional loss (EPI, diabetes mellitus). Postprandial pain has been described in dogs with CP, and the currently recommended approach is to feed a low-fat diet. If the dog is hospitalized, parenteral analgesia is provided as recommended for AP. For use at home, acetaminophen has been recommended if there is no concurrent liver disease (10 mg/kg p.o. q.12–24 h.). Gabapentin is another analgesic to consider (10–20 mg/kg p.o. q.12 h.). NSAIDs are best avoided because they can cause GI and renal side effects. Chapter 24 extensively discusses pain and its management. Pancreatic enzyme supplementation is recommended in the presence of EPI or weight loss in CP dogs. Immune-suppressive glucocorticoid treatment has been suggested in English Springer Spaniels, a breed in which CP is thought to be a manifestation of polysystemic autoimmune disease.

Prognosis

CP is a disease that can be managed but not eradicated. Ultimately, prognosis depends on the success of prevention of recurrence of acute episodes through feeding of a low- to ultralow-fat diet and avoidance of dietary triggers. In patients with a more chronic course, success of pain management and the ability to efficiently address exocrine and/or endocrine pancreatic dysfunction if present are other important factors.

FELINE PANCREATITIS

Feline pancreatitis has been the subject of a recent consensus statement by the American College of Veterinary Internal Medicine (ACVIM). This open access document is an excellent resource (see Recommended Further Readings).

In a necropsy study, 67% of cats showed histological lesions in their pancreas. More than half of necropsied cats had chronic changes, while only 6% of lesions were indicative of acute disease, and acute and chronic pancreatic changes were present in simultaneously in approximately 10% of cats. These statistics underscore the importance of CP in the feline population, even though most cases seem have a subclinical course. Two forms of AP have been described: Necrotizing pancreatitis and suppurative pancreatitis. CP is often recurring, not suppurative, and can lead to EPI.

Clinical Presentation

Feline pancreatitis can be associated with a wide range of nonspecific clinical signs (Table 11.8). Most cats are presented to their veterinarian because of lethargy and lack of appetite; insidious weight loss may also be one of the presenting complaints (Figure 11.18). Because it has been historically challenging to assess pain in cats, it is likely that the prevalence of abdominal pain is underestimated in feline pancreatitis. The type and severity of clinical signs are generally not helpful to differentiate acute from chronic pancreatitis.

TABLE 11.8 Clinical signs of feline pancreatitis

Clinical signs	Prevalence in %
Reported by owners	
Lethargy	51–100
Hyporexia/anorexia	62–97
Vomiting	35–52
Weight loss	30–47
Diarrhea	11–38
Dyspnea	6–20
Documented during physical exam	
Dehydration	37–92
Hypothermia	39–68
Icterus	6–37
Apparent abdominal pain	10–30
Hyperthermia/fever	7–26
Abdominal mass or organomegaly	4–23

Adapted from Forman MA, Steiner JM, Armstrong PJ, et al. (2021). ACVIM consensus statement on pancreatitis in cats. *J Vet Intern Med* 35(2): 703–723.

Diagnosis

The diagnostic workup of cats with acute or chronic pancreatitis has two main goals: First to rule out the numerous other diseases that could cause similar clinical

FIGURE 11.18 10-year-old MN Domestic Shorthair cat with acute-on-chronic pancreatitis. The cat was presented because of ongoing lethargy, anorexia, and occasional vomiting. He was dehydrated and in poor body condition.

signs and second to confirm pancreatic inflammation. Therefore, obtaining a minimum database consisting of CBC, chemistry profile, urinalysis, and imaging is essential.

CBC may show neutrophilia or neutropenia, reflecting acute inflammation, particularly in AP. The chemistry panel may reveal increased activity of hepatic enzymes (ALT, GGT, ALP) and hyperbilirubinemia because of concurrent inflammation of the biliary tree, extrahepatic biliary obstruction, hepatic lipidosis, or some combination of these. In cats with severe AP, azotemia may be present as exemplified by increased creatinine, urea, or symmetric dimethylarginine (SDMA) concentrations. Hyperglycemia may be associated with stress and concurrent diabetes mellitus. Azotemia, changes in blood glucose, and ionized hypocalcemia have been identified as negative prognostic factors.

A feline specific PLI test is available both for in hospital and laboratory use. A recent retrospective study reported a positive predictive value of 90% and a negative predictive value of 76% for the proprietary PLI performed in labs. Therefore, the test was found to have good but not excellent sensitivity. A biochemical test with increased affinity for pancreatic lipase (DGGR lipase) appears to be diagnostically useful as well. However, the specificity of that test for pancreatic lipase is the subject of ongoing debate.

Abdominal radiographs can be very useful in ruling out differential diagnoses such as diseases causing GI obstruction (e.g., foreign bodies and neoplasia compressing the intestinal lumen, see Chapter 9); however, they do not offer much help in the assessment of the pancreas with exception of large pancreatic masses.

Abdominal ultrasound findings in feline AP may include pancreatic enlargement, a hyperechoic surrounding mesentery, and focal abdominal effusion. The duodenum can be distended or corrugated. The sensitivity of ultrasound for diagnosis of AP varied widely between studies (11%–67%) and is considered to depend on severity of disease and operator skills. Sonographic features of CP are not well established in cats. They may include a hyperechoic or mixed echoic pancreas, a dilated common bile duct, enlarged pancreas, and irregular pancreatic margins (**Figure 11.19**). Importantly, in most cases, ultrasound does not allow to differentiate acute from chronic pancreatitis. Pancreatic nodular hyperplasia with enlargement and nodules up to 1 cm is an incidental finding in older cats and should not be misinterpreted. Advanced imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) have not been established as routine diagnostic tools for feline pancreatitis.

Pancreatic cytology from ultrasound-guided aspirates may be useful to confirm inflammation in cats with AP (neutrophils present in close vicinity to pancreatic acinar cells). However, aspirates from cats with CP are often poorly cellular.

Histological evaluation of pancreatic biopsies collected during exploratory laparotomy or laparoscopy remains the reference to which other methods are compared (**Figure 11.3**).

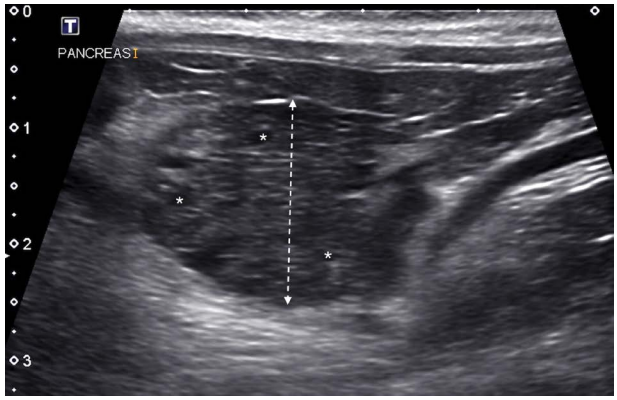

FIGURE 11.19 Ultrasound appearance of the pancreas of an 8-year-old female-spayed Domestic Shorthair cat with suspected acute-on-chronic pancreatitis. The pancreas is enlarged (1.7 cm, double arrow), irregularly shaped, of heterogenous echogenicity, with multiple small, ill-defined hypoechoic nodules (asterisks). The peripancreatic tissue is hyperechoic.

In summary, diagnosis of feline pancreatitis may be challenging, particularly in CP. Therefore, the best approach consists of combining several diagnostic modalities to achieve the best possible accuracy.

Differential Diagnosis

The clinical signs of pancreatitis in cats are nonspecific; therefore, many differential diagnoses need to be considered. The most important ones include chronic intestinal diseases (obstruction with foreign body or neoplasia, chronic enteropathy, IBD, alimentary lymphoma), cholangitis, chronic kidney disease, and hyperthyroidism.

Management

Treatment of AP in cats focuses on the same priorities as listed for treatment of canine AP (see **Box 11.2**): Fluid therapy, antiemetics, pain management, and nutrition. However, a few feline specificities must be considered. Metoclopramide does not have any antiemetic effect in cats due to lack of dopamine-2 receptors in the chemoreceptor trigger zone (CRTZ) (see Chapter 2.17). However, it was shown to have good gastric prokinetic effect and can be used to treat functional ileus, if present, preferably as a CRI. Recommendations for feline analgesia can be found in Chapter 24. Also, mirtazapine is an appetite stimulant that has proven useful in various feline diseases. The ghrelin analogue capromorelin has recently been approved for use in cats as well. Early feeding is recommended and should be initiated within 2–4 days after the last meal. While cats with mild-to-moderate AP will often resume eating rapidly, severe cases and cases with comorbidities will benefit from nasoesophageal tube feeding (see Chapter 25). The optimal diet for cats with AP has not been defined; cats have high dietary protein requirements and a higher tolerance to fat compared to dogs. Highly digestible diets are recommended. Importantly, severely ill cats often develop food aversion. It is, therefore, preferable to

delay use of the long-term diet of choice until after the cat is discharged from the clinic.

Fluorescent in situ hybridization revealed the presence bacteria (probably ascending from the gut) in 35% of cats with moderate-to-severe pancreatitis. However, the ACVIM consensus statement does not recommend treating cats with AP with broad-spectrum antibiotics unless definite clinical indications are present: Infection in the pancreas (e.g., abscess), ascending bile/pancreatic duct infection, or CBC findings suggestive of sepsis.

The treatment of CP is also mostly supportive in addressing the four priorities listed for AP earlier. In addition, it should include management of any concurrent disease such as chronic enteropathy and/or cholangitis (see Chapters 9 and 10). There is currently no data suggesting that dietary fat should be avoided in cats with pancreatitis. Cobalamin supplementation may be indicated, particularly in cats with concurrent chronic enteropathy (**Table 9.13**). Corticosteroids have been used successfully in cats with CP. Recommended prednisolone doses vary between 0.5 and 2 mg/kg per day. In the absence of evidence from the literature, there is still debate on the best dosing regimen, but periodic reassessment of the cat with measurement of PLI is recommended to guide treatment. Corticosteroids should be avoided in cats with hyperglycemia. Cyclosporine has also been used with success in the treatment of feline CP (5 mg/kg q.24 h.). However, immune suppression could potentially unmask latent infectious diseases such as toxoplasmosis.

Prognosis

The prognosis of feline pancreatitis varies considerably between studies with a mortality rate between 9% and 41% for cats with AP. Cats with mild-to-moderate disease generally have a good prognosis when appropriately managed. Some laboratory abnormalities have been identified as negative prognostic factors. Cats with mild-to-moderate recurring chronic pancreatitis usually have a guarded to good prognosis. However, the prognosis may vary due to concomitant diseases (cholangitis, chronic enteropathy) and complications such as EPI or diabetes mellitus.

FELINE TRIADITIS

Triaditis describes a chronic condition with simultaneous occurrence of CP, neutrophilic cholangitis, and chronic enteropathy. While the cause of triaditis is not known, it is suspected that the three diseases share a common etiology. One hypothesis is that enteropathy causes small intestinal dysbiosis, which facilitates penetration of bacteria in the common bile duct and then in the pancreatic and bile ducts and ascending infection or inflammation. Alternately, chronic enteropathy could also facilitate translocation of bacteria into the portal system.

As can be seen in this chapter and Chapters 9 and 10, many of the clinical signs of CP, chronic enteropathy, and cholangitis are nonspecific and overlap. The minimal database may also identify changes in laboratory parameters that are known to occur in all three diseases. Evaluation of serum cobalamin concentration and PLI is recommended. Abdominal ultrasound examination is used to investigate the small intestinal wall (thickness, layering), the liver and biliary system, and the pancreas and may provide useful information about the presence of multiorgan disease. Even though it is not indicated or feasible for each animal, laparotomy and biopsy of all three organs is the diagnostic standard.

Management of cats with triaditis revolves around the same components recommended for chronic enteropathy, cholangitis, and pancreatitis. These include fluid therapy, antiemetics, analgesics, appetite stimulants, early enteral nutrition, vitamins, nutraceuticals, and possibly immunosuppressants and/or antibiotics. Importantly, antibiotics should only be used after sampling of material for culture and sensitivity (e.g., bile in cholangitis) or in patients with signs and laboratory changes suggestive of sepsis.

The prognosis is generally good for cats with mild disease. Reported negative prognostic factors include hypoalbuminemia and hypoglycemia, and systemic hypotension also negatively affect prognosis in severely ill cats. Cats recovering from triaditis may experience recurrent episodes overt time. EPI and diabetes mellitus are chronic complications of CP. Biliary cirrhosis and possibly cholangiocarcinoma are long-term complications of chronic cholangitis, and alimentary lymphoma is a complication of chronic enteropathy.

EXOCRINE PANCREATIC INSUFFICIENCY

Definition/Overview

While the prevalence of exocrine pancreatic insufficiency (EPI) in the general canine population is unknown, it was approximately 9% among dogs with gastrointestinal clinical signs suggestive of EPI for which a TLI test was requested in a study from the UK. Thus, it is a relatively rare condition in dogs and occurs even less frequently in cats.

Etiology

In the dog, several etiologies have been identified. Congenital pancreatic hypoplasia is a very rare disorder. In German Shepherd Dogs, Rough Hair Collies, and Eurasian Dogs, pancreatic acinar atrophy (PAA) causes pancreatic insufficiency when more than 90% of the gland has disappeared. PAA was shown to be is a slowly progressive immune-mediated disease. It is characterized by lymphocytic plasmacytic infiltration that may lead to the destruction of the gland. An autosomal recessive heredity pattern has been shown. However, no specific gene defect could be identified to date despite intensive research. Therefore, a multifactorial etiology with a strong hereditary component is suspected.

In dogs with CP, pancreatic parenchymal destruction can occur because of chronic recurring inflammation, and diabetes mellitus may also occur when the endocrine pancreas is affected. However, signs of EPI usually precede those of diabetes. Finally, pancreatic neoplasia or masses impinging the pancreatic duct may also cause progressive destruction of glandular tissue and EPI.

In the cat, EPI is typically associated with chronic pancreatic inflammation, pancreatic neoplasm, or pancreatic duct obstruction. Diabetes mellitus may also develop.

Pathophysiology

EPI causes a deficiency in digestive enzymes. This prevents adequate predigestion of macromolecules in the intestinal lumen. Moreover, lack of pancreatic bicarbonate can lead to an acidic intestinal content and dysfunctional transport mechanisms for monosaccharides and disaccharides, amino acids, and fatty acids in the enterocyte brush border. The absence of pancreatic trophic factors also has negative effects. Maldigestion leads to malabsorption or malassimilation of nutrients, which can cause nutritional deficiencies. Lack of pancreatic intrinsic factor prevents absorption of cobalamin in the ileum. Low concentrations of fat-soluble vitamins (A, D, E) have been reported in dogs with EPI. Additionally, dogs with EPI develop gut dysbiosis with a loss of alpha-diversity of microbiota, which most likely has a significant impact on their gut metabolome.

Clinical Presentation

The clinical signs of EPI in dogs and cats result from a maldigestion/malabsorption syndrome. Dogs lose weight and may become emaciated despite a good and sometimes voracious appetite (Figures 11.17, 11.20, and 11.24a). Defecation frequency is increased with large amounts of feces of cow-patty consistency (Figure 11.21).

Feces may contain excessive amounts of fat (steatorrhea) that can give them a gray color. Liquid or severe diarrhea is rarely observed in dogs. Coprophagia may occur in some canine cases. Borborygmus and flatulence

FIGURE 11.21 Feces of cow-patty consistency from a 9-month-old female Mastiff with EPI.

may elicit a nervous, sometimes aggressive behavior in affected dogs. Moreover, skin lesions and greasy hair coat with a rancid smell have been described in some canine cases. These clinical signs are typical but not pathognomonic for EPI. In a retrospective study of 199 German Shepherd Dogs with EPI, 10.5% developed a mesenteric torsion, a complication unknown to occur in other breeds.

In a recent retrospective study of EPI in cats, 91% of cats had lost weight for a median duration of 6 months (Figure 11.22). Only two-thirds of cats with EPI had unformed feces (Figure 11.23), and diarrhea was occasionally watery. Half of the cats were presented with increased appetite, while 42% had decreased appetite, which may have been due to ongoing CP, and 50% had poor hair coat. Importantly, only one-third of cats presented with a combination of weight loss, unformed feces, and increased appetite (as is typical for dogs), and 56% had weight loss and unformed feces.

Diagnosis

The test of reference for diagnosis of EPI is the serum level of trypsin-like immunoreactivity (TLI), which detects circulating concentration of cationic trypsinogen

FIGURE 11.20 A 10-month-old male German Shepherd Dog showing its frail body and stunted growth. (*Courtesy of M. Schaer.*)

FIGURE 11.22 A 10-year-old male neutered Domestic Shorthair cat with EPI. The cat had lost weight over the previous 6 months despite a maintained appetite. He had a 3/9 body condition score. (*Courtesy of M. Cousins.*)

FIGURE 11.23 The feces from the cat shown in **Figure 11.22** are voluminous and of pale consistency but well formed. (*Courtesy of M. Cousins.*)

and trypsin produced by the pancreas and cleared by the kidneys. Because the functional mass of their pancreas is significantly decreased, animals with EPI show very low serum concentrations of TLI. The test is strictly species specific. It is best performed after a 12-hour fast. Results can be falsely high in animals with decreased renal function or those with chronic pancreatitis (even if the amount of functional pancreatic tissue is severely diminished). EPI dogs with clinical signs generally have serum TLI values below 2.5 µg/L. Values between 2.5 and 5.0 µg/L may indicate early pancreatic dysfunction. A subclinical phase of unknown duration may precede clinical EPI. In such cases, the test should be repeated after a few weeks. In cats, values below 8 µg/L are indicative of EPI.

Serum cobalamin should be measured in all animals with suspect EPI. Studies have shown that 36%–76% of dogs and 65% of cats with EPI have hypocobalaminemia.

Differential Diagnoses

Other chronic diseases that cause maldigestion/malabsorption may cause a similar clinical picture (e.g., severe parasite infections, chronic enteropathy, CP without EPI [dogs, cats], low-grade alimentary lymphoma, hyperthyroidism [cats], etc.)

Management

Treatment of EPI in dogs and cats relies on pancreatic enzyme supplementation (**Figure 11.24a, b**). Enzyme supplements derived from pancreatic extracts of bovine or porcine origin can be administered in powder form. Treatment is initiated with a standard dose of powder (1 teaspoon per 10 kg of body weight) mixed with the meal, which can then be increased or decreased to effect. There is no added benefit to incubate the food with the supplement prior to feeding. Treatment with pancreatic enzyme supplement is lifelong and can be expensive, particularly in large breed dogs. In some dogs, enzyme supplementation may cause oral mucosal ulcerations with bleeding. Though thorough mixing of the powder with food is generally sufficient to resolve the problem, reducing the dose of enzyme may be necessary in some cases. Also, it is prudent to check animals with oral bleeding for coagulopathies and treat if present (vitamin K, 2.5 mg/kg SC q.12 h.). Importantly, full restoration of digestive activity is not an achievable goal, and the realistic objective is successful management of clinical signs and restoration of appropriate quality of life for the animal. In most animals, special diets are not required in the long term, and a high-quality regular diet may be appropriate.

In case of failure of initial enzyme supplementation, a systematic approach is recommended (**Table 11.9**). Fat digestion remains a problem in dogs and cats with EPI despite treatment, since most of the supplemented lipase is destroyed in the stomach. It was recently shown that deficiencies in fat-soluble vitamins persist after treatment; however, no study to date documented any benefit from supplementation of these vitamins, and empirical treatment with vitamins A and D may induce toxicosis. Vitamin E supplementation is generally well tolerated (dog: 100–400 U p.o. daily for 1 month, then as needed; cat: 10–15 U/kg p.o. daily). Gut dysbiosis is probably the consequence of both a lack of pancreatic bacteriostatic factors and the high concentration of organic substrate in the intestinal lumen due to maldigestion/malabsorption secondary to EPI. Enzyme supplementation does not lead to normalization of the gut microbiota.

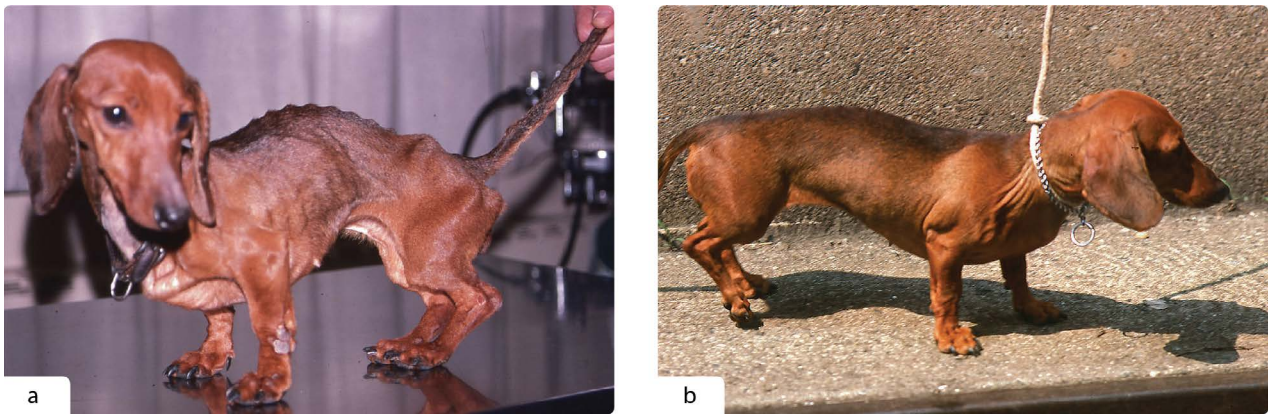

FIGURE 11.24 This young female Dachshund suffered severe emaciation from exocrine pancreatic insufficiency **(a)**. The same dog is shown approximately 4 months after pancreatic enzyme replacement treatment **(b)**. (*Courtesy of M. Schaer.*)

TABLE 11.9 Recommended procedure when initial enzyme therapy fails

- Modification of enzyme supplementation
  - Increase the dose of enzyme supplement (excessive doses generally do not cause side effects, except oral ulcerations)
  - Change to another brand of enzyme supplement
  - Consider raw porcine or bovine pancreas (30–90 g replace 1 teaspoon powder) (raw pancreas may be stored frozen in aliquots)
- Make sure hypocobalaminemia is appropriately corrected; recheck serum cobalamin may be required, followed by dose correction if needed (see **Table 9.14**)
- Dietary modification
  - Highly digestible diets
  - Low-fat diet, with associated risk of further decreasing intake of fat-soluble vitamins
- Other options
  - Evaluate for concurrent disease such as diabetes mellitus or IBD
  - Treat probable gut dysbiosis (consider measuring fecal dysbiosis index)
    - High-potency multistrain probiotic or
    - Tylosin 20–25 mg/kg p.o. q.12 h. for 4 weeks

Prognosis

A recent study reviewed the initial response to treatment in a cohort of 127 dogs with EPI. The response was good in 60%, partial in 17%, and poor in 23% of cases. The mean survival of the group was more than 5 years; however, 19% of the dogs were euthanized in the year following diagnosis. The authors concluded that long-term prognosis was favorable for dogs that survived the initial treatment period. Hypocobalaminemia at initial presentation was shown to be a negative prognostic factor in several studies. In addition, in a recent study of 299 dogs with EPI, lack of appetite at the initial visit, male sex, and not receiving cobalamin supplementation were independent risk factors for decreased survival, while hyperfolatemia was associated with an improved prognosis. In other studies, type of enzyme supplementation and diet, administration of antimicrobials, and gastric acid suppression were all without effect on the prognosis.

Response to enzyme supplementation was reported in a cohort of 121 cats with EPI. It was good in 60%, partial in 27%, and poor in 13% of cats. In that group, TLI concentration between 4 and 8 µg/L (versus below 4 µg/L) and ongoing treatment with cobalamin were predictors of a higher likelihood of response to treatment. Antibiotic treatment did not have any beneficial impact on outcome.

CASE EXAMPLE

Case 11.1

Signalment

13-year-old female spayed Terrier mixed breed weighing 6 kg

History

The dog was presented for a 1-month history of lethargy, hyporexia/anorexia, and markedly increased serum liver enzymes and total bilirubin at the referring veterinarian. She was treated with amoxicillin, clavulanic acid, and S-adenosylmethionine with silymarin. She had stopped eating and vomited twice on the day of prior to presentation.

Physical Examination

Body condition score: 5/9; however, had lost 1.5 kg over 2 months

Vital parameters: Within normal limits

Physical exam: The dog was quiet, alert, responsive, and diffusely icteric (**Figure 11.25**). Cranial abdominal pain was noticed during abdominal palpation.

Initial Assessment

The dog's main problems were chronic hyporexia/anorexia, weight loss, icterus, and increased liver enzymes. The top differential diagnoses included hepatopathies (e.g., toxicosis, inflammation) or liver neoplasia, diseases of the biliary tract (e.g., cholecystitis, cholangitis), and pancreatitis.

Further Investigations

In the minimum database, CBC showed revealed moderate leukocytosis and neutrophilia suggestive of active inflammation. The chemistry panel showed markedly increased ALT, ALP, and GGT and a total bilirubin of 19.8 mg/dL (reference range 0.2–0.4). Abdominal ultrasound showed an irregularly shaped, hypoechoic pancreas surrounded by hyperechoic mesenteric fat. The common bile duct was

FIGURE 11.25 A 13-year-old mixed-breed dog with icteric sclera and probable acute-on-chronic pancreatitis with pancreatitis-associated bile duct obstruction (PABDO).

(*Continued*)

segmentally enlarged but could not be followed over its whole length. Pancreatitis-associated bile duct obstruction (PABDO) was suspected. The PLI was severely increased, indicating pancreatitis. Bile was obtained from a cholecystocentesis and submitted for aerobic and anaerobic cultures, which were negative.

Initial Treatment

The dog was treated with fluid therapy, antiemetics (maropitant 1 mg/kg SC q.24 h. and ondansetron 0.7 mg/kg q.12 h.), capromorelin 3 mg/kg p.o. q.24 h., SAMe and silymarin (225/24 mg q.24 h.), and ursodiol (10 mg/kg p.o. q.24 h.). She started eating again 2 days after admission and was offered a home-cooked, low-fat diet (boiled skinless chicken breast and rice).

Further Treatment

The treatment with antiemetics, appetite stimulants, liver protectants, and ursodiol was continued after discharge from the hospital. The dog was rechecked weekly and continued improving clinically with increased appetite and energy and activity levels. Serum bilirubin and liver enzymes started decreasing significantly at week 4. All were back to the reference range by week 6 except ALP, which was still mildly increased (**Figure 11.26**).

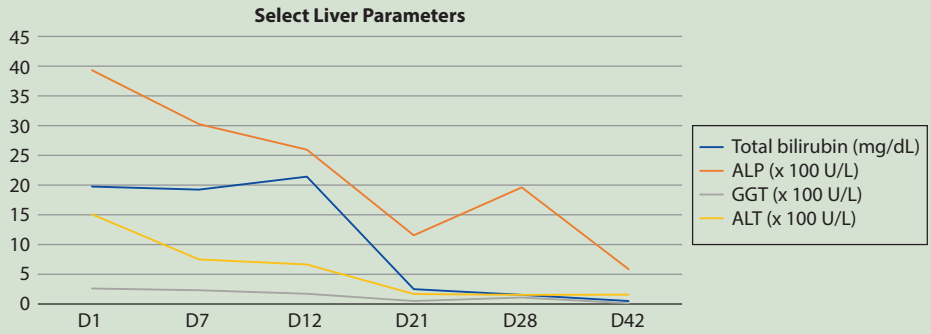

FIGURE 11.26 Evolution of select liver parameters on serum chemistry over 6 weeks in a dog with pancreatitis and PABDO.

Final Assessment

The dog had an acute-on-chronic pancreatitis with PABDO. A recent review of 42 dogs with PABDO reported 79% survival rate, with 94% of dogs receiving medical management alone. Median time to peak bilirubin elevation and initial decline in serum bilirubin were 8 and 15 days, respectively.

INTRODUCTION

The presentations of endocrine diseases are diverse, and the findings in the history and physical examination reflect this diversity. Some of the more common presentations are listed in Table 12.1. Although multiple endocrine disorders can occur in the same animal (for example, autoimmune polyendocrine syndromes or multiple endocrine neoplasia), most abnormalities affect a single hormone system. A working knowledge of endocrine physiology is essential not only for a good understanding of the pathophysiology of endocrine disease but also for understanding the rationale and limitations of endocrine function tests.

Advances in our knowledge of endocrine diseases have been made possible by the widespread availability of sensitive methods for measuring hormone concentrations and improved diagnostic imaging techniques. The release of some hormones shows marked diurnal variation, making single determinations difficult to interpret. The pattern of release may also vary with age, sex, stress, diet, or concurrent disease or medication. In the laboratory, hormone assays can vary in their performance, and it is important to consult individual laboratories and equipment manufacturers regarding the precision and accuracy of their hormone test results. The reference intervals given in this chapter are only intended as a general guide. Commercial diagnostic laboratories and veterinary practices should be members of a quality-control scheme and should be comparing their results with other laboratories to ensure that their interpretation is fully justified.

In order to overcome some of these problems of interpretation, dynamic tests have been developed that determine the response of a gland to stimulation or suppression. Stimulation tests assess the functional reserve of an endocrine gland by its ability to increase its hormonal output. The response may be exaggerated in conditions where there is excessive function or reduced if the gland is structurally or functionally damaged. Suppression tests use the administration of a pure hormone to test the negative feedback mechanism. Hormonal production is normally suppressed in these tests, but production persists where the gland is hyperplastic or if a functional endocrine tumor is present.

This chapter has been structured to provide a practical guide for veterinarians in the diagnosis and management of the more common endocrine disorders.

TABLE 12.1 Common presentations of endocrine disease

DISORDERS OF THE PITUITARY

The pituitary gland is a small, ovoid structure that lies in a distinct fossa, the sella turcica, just ventral to the hypothalamus and caudal to the optic chiasma. The pituitary consists of two distinct parts, an anterior and a posterior lobe, each of which has separate functions. The hypothalamus and the pituitary form a complex functional unit that controls much of the endocrine system, and any space-occupying lesions arising in this area can, therefore, cause a wide range of effects.

DOI: 10.1201/9781003254591-31

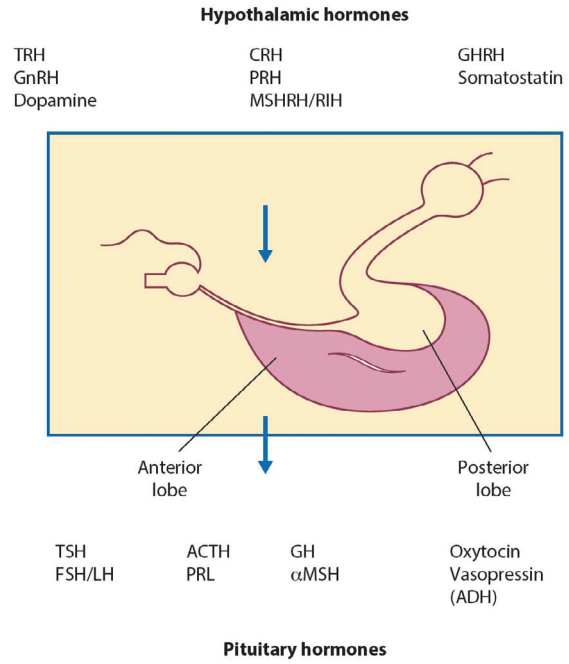

FIGURE 12.1 Physiology of hypothalamic–pituitary function.

The hypothalamus is important in the regulation of anterior and posterior pituitary function. The release of hormones from the anterior lobe of the pituitary is controlled by hypothalamic peptides, which are transported to the anterior pituitary by the capillaries of the hypothalamic–hypophyseal portal circulation (Figure 12.1). The hypothalamus contains a number of autonomic centers that control thirst, satiety, body temperature, emotional reactions, and sympathetic responses, and it serves as an important link between the brain and the endocrine system.

The posterior pituitary releases stored vasopressin (antidiuretic hormone [ADH]) and oxytocin, which have been synthesized in the supraoptic and paraventricular nuclei of the hypothalamus.

CONGENITAL HYPOPITUITARISM

Definition/Overview

Congenital hypopituitarism results from inadequate secretion of growth hormone (GH) and resultant retardation of growth (pituitary dwarfism).

Etiology

The condition is rare, but it has been reported in a number of breeds of dog. It is most commonly seen in German Shepherd Dogs, where it has been shown to be inherited as an autosomal recessive trait. In the dog, pituitary dwarfism is most commonly associated with cystic dilatation of Rathke's cleft, which arises as a result of the failure of the anterior lobe of the pituitary to develop normally and results in reduced secretion of anterior pituitary hormones (Figure 12.2). Hypoplasia of the pituitary has been reported in the cat but also appears to be rare (Figure 12.3).

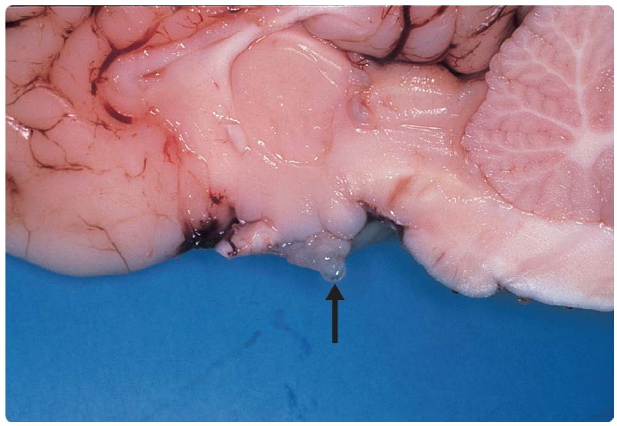

FIGURE 12.2 Cystic dilatation of Rathke's cleft cysts (arrow) in a German Shepherd Dog with hypopituitarism.

Pathophysiology

In many affected animals, a cystic vestigial adenohypophysis is present, although some animals have either a hypoplastic pituitary or one that appears grossly normal. Pituitary dwarfism is not usually caused by isolated GH deficiency but is due to a combined pituitary hormone deficiency affecting anterior lobe function.

Clinical Presentation

Affected animals appear normal at birth, but growth retardation is usually evident by weaning (Figure 12.4).

FIGURE 12.3 A 5-month-old kitten with congenital hypopituitarism.

FIGURE 12.4 Three 6-week-old German Shepherd puppies. The middle puppy is affected with congenital hypopituitarism and shows obvious growth retardation compared to its littermates.

A deficiency of GH produces proportionate dwarfism (Figure 12.5). The degree of stunting is variable and probably depends on the extent of the pituitary compromise. Delayed growth plate closure and dental eruption have been reported in some cases.

GH is required to produce a normal adult hair coat in the dog. In pituitary dwarfism, the fine puppy coat is retained and becomes matted and woolly in appearance (Figure 12.5). The hair coat is slowly lost from the trunk, leading to the development of bilaterally symmetrical, nonpruritic alopecia by 1 year of age (Figure 12.6). Other areas, such as the head and feet, are generally spared, and affected dogs retain the facial characteristics of a puppy (Figure 12.7). Hair loss does not appear to be a feature of congenital hypopituitarism in the cat.

The function of other endocrine systems controlled by the anterior pituitary is also often affected. In German Shepherd Dogs with congenital hypopituitarism, there is usually a combined deficiency of GH, thyroid-stimulating hormone (TSH), and prolactin together with impaired release of gonadotropins. While clinical signs of secondary hypothyroidism may develop, signs of secondary hypoadrenocorticism are not seen in the German Shepherd Dog and Tibetan Terrier because adrenocorticotropic hormone (ACTH) secretion is preserved. Gonadal involvement may result in testicular atrophy in the male and abnormal estrous cycles in the bitch.

FIGURE 12.5 An 8-month-old German Shepherd Dog with congenital hypopituitarism demonstrating proportionate dwarfism and a woolly coat.

FIGURE 12.6 An 18-month-old German Shepherd Dog with congenital hypopituitarism showing bilaterally symmetrical alopecia. The hair loss is mainly from areas of friction, such as the flanks, neck, and ventral abdomen, and where hair is lost, the skin usually becomes hyperpigmented.

FIGURE 12.7 The same dog as in **Figure 12.6** showing the retention of puppy-like facial features.

Differential Diagnosis

See Table 12.2 for the list of differentials for failure to thrive, poor growth, or stunted growth.

Diagnosis

Diagnosis of congenital hypopituitarism can be made by measurement of plasma GH concentrations. Since GH is secreted in pulsatile fashion, basal plasma GH concentrations may be low in healthy animals, and a stimulation test using GH-releasing hormone or an alpha-2 adrenergic agonist, such as clonidine or xylazine, should be performed (Table 12.3). GH concentration can be assessed indirectly by measuring insulin-like growth factor-1 (IGF-1). IGF-1 has the advantage of a long half-life, and its secretion is not episodic. Pituitary dwarfs also have abnormally low serum IGF-1 concentrations.

TABLE 12.2 Differential diagnosis of poor growth or stunting

Endocrine causes
- Congenital hypopituitarism (pituitary dwarf)
- Congenital hypothyroidism (disproportionate dwarf)
- Juvenile-onset diabetes mellitus
- Hyperadrenocorticism
- Hypoadrenocorticism
- Diabetes mellitus

Nonendocrine causes
- Malnutrition
- Maldigestion (e.g., exocrine pancreatic insufficiency)
- Malabsorption (e.g., villous atrophy)
- Severe intestinal parasitism
- Severe metabolic disorders associated with major organ dysfunction, for example
  - Portosystemic shunting
  - Congenital renal dysplasia
  - Congenital heart defects (e.g., tetralogy of Fallot)
  - Mucopolysaccharidoses
- Osteochondral dysplasias causing disproportionate dwarfism, for example
  - Chondrodystrophy in the English Pointer
  - Chondrodysplasia of the Alaskan Malamute and Labrador Retriever

Thyroid function tests and, if necessary, adrenal function tests should be performed to assess thyroidal and adrenal function (see Tables 12.8 and 12.15).

Genetic testing is available for German Shepherd Dogs and related breeds such as the Saarloos and Czechoslovakian Wolfdogs and, more recently, Tibetan Terriers with pituitary dwarfism, which have a mutation of the gene encoding the transcription factor LHX3. The genetic test not only identifies affected individuals in these breeds but also identifies carriers of the mutation, which is important eradication of the condition.

Management

Canine GH is not available for therapeutic use, but bovine, porcine, and human GH preparations have been used for treatment. The diagnosis of hypopituitarism is usually made too late in development to influence growth significantly, and affected animals are likely to remain permanent dwarfs. However, GH administration (0.1 IU/kg SC 3 times a week for 4–6 weeks) has been shown to be effective in some cases in producing regrowth of hair. Treatment with exogenous GH can be associated with the development of antibodies, which could interfere with its subsequent action. GH is expensive, and its repeated use may result in the development of diabetes mellitus.

More recently, progestogens, principally proligesterone and medroxyprogesterone acetate, have been used to stimulate endogenous GH production and release from the mammary gland in both male and female pituitary

TABLE 12.3 Protocols for testing growth hormones

GH stimulation test
Indication – Used to diagnose pituitary dwarfism (congenital hypopituitarism) and acromegaly and to evaluate patients with adult-onset GH-responsive alopecia – Basal concentrations of GH are often difficult to interpret due to the overlap between normal dogs and those with GH deficiency; therefore, provocative testing with GH-releasing hormone (GHRH) or an alpha-2 adrenergic agonist (such as clonidine or xylazine) is recommended
Method – Collect 5 mL of blood into EDTA, centrifuge immediately, and store plasma frozen (<–20°C) for basal GH concentration – Inject either GHRH (1 µg/kg IV) or clonidine (10 µg/kg IV, maximum dose 300 µg) or xylazine (100 µg/kg IV) – Collect second 5 mL blood sample into EDTA 20 minutes later, centrifuge immediately, and store plasma frozen (<–20°C) for GH concentration
Interpretation – Reference range in dogs for basal GH concentration is 1–4 ng/mL (µg/L), and peak poststimulation value is 10–58 ng/mL (µg/L), but check laboratory reference range – GH concentrations are generally reduced in pituitary dwarfism (<1 ng/mL [µg/L]) and show little or no response to stimulation with GHRH, clonidine, or xylazine – Reduced GH concentrations and little or no response to stimulation may be found in adult-onset GH-responsive alopecia; however, reduced responses may be found in dogs with hypothyroidism or hyperadrenocorticism, and these more common disorders must be excluded as possible diagnoses first – Basal GH concentrations are generally elevated in acromegaly (>100 ng/mL [µg/L]) and are not usually further stimulated by GHRH, clonidine, or xylazine
Basal serum insulin-like growth factor-1
Indication – Used in the diagnosis of pituitary dwarfism and acromegaly – IGF-1 concentration is regulated by GH and nutritional status and is less subject to fluctuation than GH – This makes a single determination more meaningful. The assay is more readily available.
Interpretation – Reference range for IGF-1 in normal adults is >200 ng/mL and for animals up to 1 year of age is >500 ng/mL – Serum IGF-1 concentrations are decreased in pituitary dwarfs (<50 ng/mL). The sensitivity can be increased by comparing IGF-1 concentrations with those of normal littermates. IGF-1 concentrations may also be depressed in chronic debilitating disease. – Elevated IGF-1 concentrations are seen in dogs and cats with acromegaly (>1,000 ng/mL)

dwarfs with some success. This treatment avoids the development of autoantibodies to GH. Proligesterone given subcutaneously at a dose of 10 mg/kg every 3 weeks until the serum IGF-1 concentration has normalized has been recommended. Adverse effects such as cystic endometrial hyperplasia, pyometra, and acromegaly have been reported in some cases.

Thyroid hormone replacement should be used in cases of secondary hypothyroidism (see Hypothyroidism). Thyroid hormone therapy has been used, with variable success, in an attempt to stimulate hair growth in pituitary dwarfs with normal thyroid function. Half the normal replacement dose of thyroxine is administered for several months to assess the response to treatment.

Quality of life and survival times are improved with treatment. The administration of progestogens or GH has been shown to improve body size.

ACROMEGALY

Definition/Overview

The excessive secretion of GH in adult animal results in acromegaly, an insidious condition associated with overgrowth of connective tissue and bone.

Etiology

In the dog, acromegaly is mainly caused by progestogen therapy or by endogenous progesterone produced during the diestrus phase of the estrous cycle, which induces GH secretion. Progesterone-induced GH excess originates from hyperplastic ductular epithelium in the mammary gland and not from the pituitary.

In the cat, acromegaly is caused by a pituitary tumor that secretes excess GH. This cause has been reported in one dog.

Pathophysiology

GH antagonizes the effects of insulin. In acromegaly, mild glucose intolerance or overt diabetes mellitus develops, which can lead to polyuria and polydipsia. Diabetes mellitus induced by GH may be reversible or permanent depending on the duration and degree of the excessive GH secretion. Initially, hyperglycemia is associated with increased insulin concentrations, but as the disease progresses, beta-cell exhaustion will result in lowered insulin secretion. Most cases of acromegaly present with insulin-resistant diabetes mellitus, and patients usually require abnormally high doses of exogenous insulin to control blood glucose concentrations.

Clinical Presentation

Clinical signs of acromegaly develop slowly and insidiously in middle-aged to older cats and bitches. The bitches are entire and are either cycling normally or being given regular treatment with progestogens to prevent estrus.

FIGURE 12.8 A 14-year-old Domestic Shorthair cat with acromegaly. Note the broad muzzle.

Initially, patients may be presented for investigation of insulin-resistant diabetes mellitus without phenotypic changes associated with acromegaly. Later, there is increased soft tissue swelling, particularly around the head and neck, and this may result in excessive panting, inspiratory stridor, and exercise intolerance (Figure 12.8). There may be excessive skin folds and thickened skin around the head, neck, and distal extremities (Figures 12.9 and 12.10) and separation of the teeth with increased interdental spacing, particularly of the incisor teeth (Figure 12.11).

FIGURE 12.9 A 9-year-old Burmese cat with acromegaly showing enlargement of the paw.

FIGURE 12.10 A 12-year-old Collie-cross dog with acromegaly showing increased soft tissue around the head and neck.

FIGURE 12.11 A 12-year-old Labrador Retriever with acromegaly showing separation of incisor teeth with increased interdental spacing.

Differential Diagnosis

Hyperadrenocorticism, hypothyroidism, diabetes mellitus.

Diagnosis

Laboratory findings of uncontrolled or poorly regulated diabetes mellitus with hyperglycemia and glycosuria are found in most cases. A definitive diagnosis of acromegaly can be made by demonstrating elevated serum concentrations of GH or IGF-1.

CT or MRI of the cranium is required in the cat to demonstrate the size and the position of the pituitary tumor (Figure 12.12).

Management

Successful treatment of acromegaly in the bitch involves the withdrawal of progestogen therapy and ovariohysterectomy for estrus control. Insulin requirements may decrease dramatically or even cease completely following the withdrawal of progestogen therapy or after ovariohysterectomy. Patients should, therefore, be monitored very closely to avoid insulin over dosage and the development of hypoglycemia.

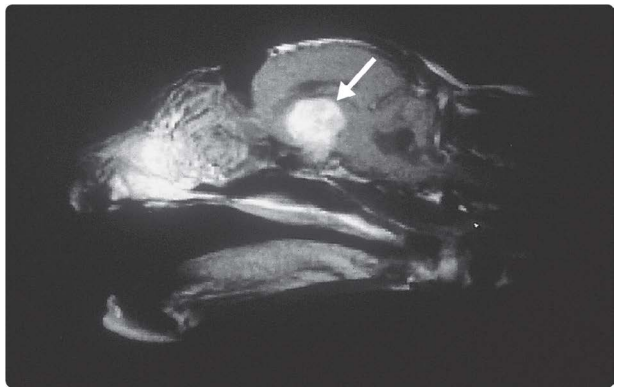

FIGURE 12.12 A T1-weighted MR image of the brain of a Domestic Shorthair cat with acromegaly showing a large pituitary mass (arrow) after gadolinium contrast.

In the cat, pituitary irradiation using a linear accelerator and transsphenoidal hypophysectomy have been successful in treating acromegaly and reducing the GH secretion to provide improved control or even resolution of the diabetes mellitus.

PITUITARY TUMORS

Definition/Overview

Primary and secondary tumors can involve the pituitary. Primary tumors may be functional or nonfunctional. Adenomas of the anterior lobe of the pituitary are the most common tumor, and many of these will secrete adrenocorticotropic hormone (ACTH), resulting in pituitary-dependent hyperadrenocorticism.

Pathophysiology

Functional pituitary tumors may produce signs associated with excess hormone production by the tropic endocrine glands. The space-occupying effects of large tumors may cause compression and destruction of surrounding pituitary tissue (Figure 12.13, arrows), leading to a reduction in the secretion of tropic hormones, which may result in clinical signs of hormone deficiency.

Clinical Presentation

Clinical signs may include those associated with endocrine upset such as polyuria and polydipsia due to excess secretion of ACTH by a functional corticotroph adenoma or impaired vasopressin synthesis or release by compression of the posterior pituitary, lethargy and weight gain due to secondary hypothyroidism, or atrophy of the sex organs due to reduced gonadotropin release.

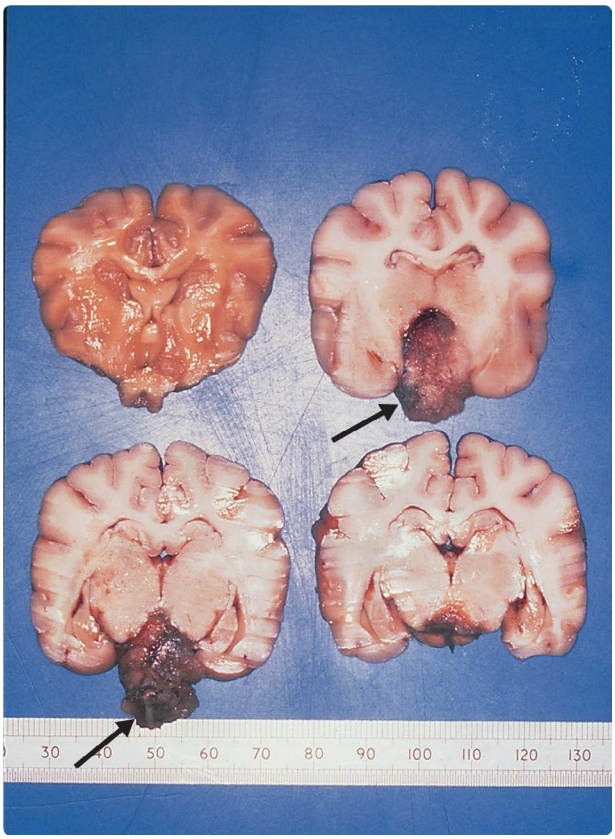

FIGURE 12.13 Postmortem specimen showing the effects of a large pituitary tumor (arrows).

Space-occupying effects of a pituitary tumor include listlessness, depression, anorexia, vomiting, adipsia, aimless wandering, head pressing, staring, apparent blindness, ataxia, incoordination, head tilt, circling, and seizures (Figure 12.14).

Pituitary apoplexy is occasionally recognized with pituitary tumors and is a clinical syndrome characterized by sudden onset of neurological signs and endocrine dysfunction resulting from acute hemorrhage or infarction of the pituitary.

FIGURE 12.14 A 5-year-old Chow Chow with signs of depression and circling due to a pituitary tumor.

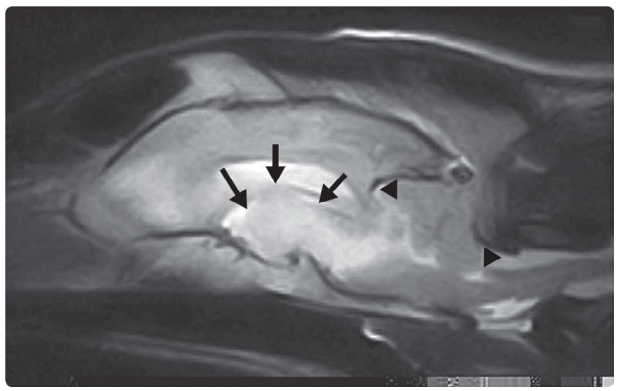

FIGURE 12.15 Sagittal T2-weighted MR image of a 12-year-old Dalmatian with a large pituitary mass (arrows) causing both caudal transtentorial and foramen magnum herniation (arrowheads).

Differential Diagnosis

Hyperadrenocorticism, acromegaly, hypothyroidism, diabetes insipidus, hypophysitis, neurologic conditions.

Diagnosis

Diagnosis of a pituitary mass can be confirmed by computed tomography (CT) or magnetic resonance imaging (MRI; Figure 12.15). Endocrine function tests will help demonstrate if the tumor is functional or not, or if hypopituitarism is present.

Management

If neurologic signs are present, radiotherapy using megavoltage radiation is the treatment of choice and has proved successful in reducing the size of the pituitary mass. Pituitary-dependent hyperadrenocorticism can be treated with trilostane or mitotane (see p. 430). Secondary hypothyroidism can be treated by replacement thyroxine (see p. 402).

DIABETES INSIPIDUS

Definition/Overview

Vasopressin (ADH) released from the posterior lobe of the pituitary increases the permeability of the distal convoluted tubules and collecting ducts of the kidney and thus controls water excretion. Diabetes insipidus results from a deficiency of vasopressin or a failure of vasopressin to act on the kidneys and is characterized by severe and uncontrolled polyuria, with resultant polydipsia.

Etiology

Diabetes insipidus can be caused by either a partial or total failure to synthesize or release vasopressin (central diabetes insipidus [CDI]) or a partial or total failure of the renal tubules to respond to vasopressin (nephrogenic diabetes insipidus [NDI]).

Both forms of diabetes insipidus may be congenital or acquired. CDI may result from neoplasia or head trauma but is usually idiopathic in the dog and cat. Rarely, inflammatory and parasitic lesions have been associated with CDI. NDI may be secondary to various drugs, a variety of renal and metabolic disorders, including chronic kidney disease, renal medullary fibrosis, tubular necrosis, hyperadrenocorticism, pyometra, and hypercalcemia, or it may be idiopathic.

Pathophysiology

Plasma osmolality is the major determinant of vasopressin release, but hypovolemia and hypotension can also stimulate ADH production. In total CDI, there is little increase in urine osmolality with increasing plasma osmolality. In partial CDI, vasopressin is released with increasing plasma osmolality, but concentrations and action are subnormal.

Clinical Presentation

Clinical signs of diabetes insipidus include marked polyuria, frequently with nocturia and incontinence, and severe polydipsia, with the animal often drinking more than 100 mL/kg per 24 hours. In acquired cases, the onset of clinical signs is usually sudden. Affected dogs and cats start searching for water and may become anorexic and lose weight as a result. Despite their increased thirst, affected animals remain mildly to moderately dehydrated. Affected animals generally show no other clinical signs, although neurologic signs may be noted, particularly if diabetes insipidus is associated with a space-occupying mass such as a pituitary tumor or if the animal becomes severely hypernatremic when deprived of water.

Differential Diagnosis

The differential diagnosis of polyuria and polydipsia is given in Table 12.4. Diabetes insipidus must be differentiated from primary polydipsia with resultant polyuria, so-called psychogenic polydipsia (PP), where there is a relative lack of vasopressin due to over hydration and, frequently, reduced renal concentrating power due to a decrease in medullary hypertonicity from the wash-out effect of handling large quantities of fluid.

Diagnosis

Hematologic, biochemical, and electrolyte profiles are generally unremarkable in animals with CDI or idiopathic NDI. When abnormalities are noted, they are usually secondary to dehydration. The most significant finding is very dilute urine of low specific gravity (SG), usually between 1.001 and 1.005. The urine SG is almost invariably less than that of glomerular filtrate (i.e., <1.010), indicating good renal tubular function with resorption of solute in excess of water.

TABLE 12.4 Differential diagnosis of polydipsia–polyuria

Polyuria with compensatory polydipsia
- Osmotic diuresis
  - Diabetes mellitus
  - Primary renal glycosuria/Fanconi's syndrome
  - Polyuric renal failure/postobstructive diuresis

Interference with ADH release and / or renal response to ADH

- Glomerulopathy / nephrotic syndrome
- Pyelonephritis
- Pyometra
- Hyperadrenocorticism
- Chronic liver disease
- Hypercalcemia
- Hypoadrenocorticism
- Central diabetes insipidus
- Nephrogenic diabetes insipidus
- Hypokalemia
- Hyperthyroidism
- Drugs/diet

Primary polydipsia
- Psychogenic polydipsia

ADH, adrenal-dependent hyperadrenocorticism.

Urine osmolality is low and typically below that of plasma, which is often mildly or moderately elevated due to the concomitant dehydration (Table 12.5). In PP, the plasma osmolality is usually decreased due to the over hydration.

A carefully monitored water deprivation test (Table 12.6) will confirm the animal's inability to concentrate its urine in diabetes insipidus despite becoming dehydrated. Renal function must be assessed before undertaking this test, and the test must always be discontinued if the patient loses more than 5% of its body weight. Urine and plasma osmolality measurements

TABLE 12.5 Differentiation of central diabetes insipidus, nephrogenic diabetes insipidus, and psychogenic polydipsia

Parameter	Before water deprivation	After water deprivation		
		CDI	NDI	PP
Urine				
Specific gravity	<1.010	<1.010	<1.010	<1.025
Osmolality	<300	<300	<300	<700
Plasma				
Osmolality	>300 CDI or NDI <295 PP	>310	>310	±310
U:P osmolality	<1.0	<1.0	<1.0	2–3
ADH response test				
Urine specific gravity	<1.010	>1.015	<1.010	<1.025
U:P osmolality	<1.0	>1.0	<1.0	>1.0

Note: Osmolality measured in mOsm/kg.

TABLE 12.6 Protocol for water deprivation and antidiuretic hormone response testing

Water deprivation test
Indication – Used in the diagnosis of diabetes insipidus – Does not differentiate between the central and nephrogenic forms of the disease – The test should only be performed in animals with normal blood urea and creatinine concentrations
Method – Collect 5 mL of urine and plasma if osmolality is being measured; if specific gravity is to be measured, only urine is required – Weigh patient – Withhold all fluids and food – Collect urine and plasma after 8 hours and then at 2-hour intervals until the test is complete; it is rarely safe or necessary to continue this test for 24 hours – Weigh patient each time urine and plasma are collected – Stop test if patient demonstrates adequate concentrating ability (specific gravity >1.020) or if patient becomes dehydrated and loses 5% of its body weight or more
Interpretation – Cases of central or nephrogenic diabetes insipidus fail to concentrate urine (specific gravity <1.010), and urine osmolality remains low and does not exceed that of plasma – This test does not always give conclusive results, especially if plasma and urine osmolality are not measured
Vasopressin (ADH) response test
Indication – Used to differentiate between central and nephrogenic diabetes insipidus
Method – Collect 5 mL of urine and plasma if osmolality is being measured; only urine is required if specific gravity is to be measured – Inject desmopressin intramuscularly; use 2 µg for dogs <15 kg and 4 µg for dogs >15 kg – Collect urine and plasma samples every 2 hours
Interpretation – Dogs with nephrogenic diabetes insipidus will show very little or no response to exogenous vasopressin, and the urine specific gravity and osmolality will remain low – Dogs with central diabetes insipidus will concentrate their urine, usually within 6 hours (specific gravity >1.015); the urine osmolality will rise by 50% or more and will exceed the plasma osmolality

provide more definitive information than urine SG alone (Figure 12.16).

The ADH response test (Table 12.6) is used to distinguish CDI from NDI. Dogs and cats with CDI will concentrate their urine in response to the administration of exogenous ADH, whereas dogs with NDI will show no response.

Management

Successful treatment of CDI requires long-term replacement therapy using desmopressin, a vasopressin analog. Desmopressin is available in the form of an injection, intranasal drops, or tablets. It can provide antidiuretic activity for about 8 hours. One to four drops of the intranasal preparation placed in the conjunctival sac twice daily will control the polydipsia and polyuria in most dogs and cats with CDI. Oral therapy (5 µg/kg p.o. q.8–24 h. initially, up to a maximum dose 400 µg p.o. q.8 h.) has proved effective in some cases, but generally, the tablets appear to be less effective due to reduced bioavailability.

FIGURE 12.16 Urine samples from a dog with central diabetes insipidus taken during a water deprivation test. The specific gravity never increased above 1.008 despite the dog losing 5% of its body weight during the test.

Chlorpropamide, an oral sulfonylurea hypoglycemic agent, potentiates the effects of vasopressin on the renal tubules and, therefore, requires at least the presence of some endogenous vasopressin in order to be effective. Chlorpropamide has been shown to be effective in partial CDI in humans; however, the results in dogs with CDI have been inconsistent. In some cases, it may take several weeks to obtain an effect. Hypoglycemia is a potential adverse effect. A dose of 10–40 mg/kg p.o. q.24 h. has been suggested in dogs. Chlorpropamide is not recommended for use in cats.

Thiazide diuretics such as hydrochlorothiazide and chlorothiazide have a paradoxical effect in both CDI and NDI. Urine output may be decreased by up to 50%, although the urine is still dilute. The suggested doses for hydrochlorothiazide and chlorothiazide are 2–4 mg/kg q.12 h. and 20–40 mg/kg q.12 h., respectively. The precise dose should be tailored to each patient, and the effect may be enhanced by concurrent use of a sodium-restricted diet. Patients should be monitored periodically for electrolyte disturbances, particularly hypokalemia.

Idiopathic CDI has a favorable prognosis with treatment. Animals with an expanding hypothalamic or pituitary tumor have a more guarded prognosis, especially if neurologic signs are present. CDI following head trauma carries a variable prognosis; spontaneous recovery may occur within a few days or weeks in some cases, but in other cases the damage is permanent. NDI tends to have a more guarded prognosis, and a search for a primary cause should be undertaken in order to provide more appropriate therapy.

DISORDERS OF THE THYROID GLAND

The thyroid gland consists of two lobes, which are not normally palpable in healthy dogs or cats. Palpable enlargement of the thyroid from any cause is referred to as goiter. Two parathyroid glands are associated with each thyroid lobe. The internal parathyroids usually lie within the thyroid capsule at the caudal pole of each lobe.

The thyroid gland actively takes up inorganic iodide, resulting in concentrations that are 10–200 times that of serum. The inorganic iodide enters the thyroid follicular cells and is transformed into the metabolically active thyroid hormones thyroxine (T4) and triiodothyronine (T3). The synthesis and secretion of T4 and T3 are controlled by TSH secreted by the thyrotroph cells of the anterior pituitary. Secretion of TSH is stimulated by thyrotropin-releasing hormone (TRH), a hypothalamic tripeptide. A classic negative feedback system operates to maintain the plasma concentrations of T4 and T3 within close limits (Figure 12.17).

In plasma, more than 99% of T4 and T3 is bound to plasma proteins, mainly albumin and globulins. It is the free (unbound) hormones that are metabolically active. Although T4 is the major secretory product of the thyroid gland, the metabolic activity of T3 is much greater. About 80% of the plasma T3 concentration is produced by deiodination of T4 in peripheral tissues, mainly the liver, muscle, and kidneys. In catabolic states, such as those produced by starvation, anorexia, or debilitating disease, T4 is deiodinated to reverse T3 (rT3), an inactive metabolite, at the expense of T3 production.

Thyroid hormones play a dominant role in controlling metabolism. They increase basal metabolic rate, stimulate cellular oxygen consumption, promote carbohydrate absorption from the intestine, and regulate lipid metabolism. Thyroid hormones are also essential for normal growth and development, and they activate the anagen (growth) phase of the hair cycle. Some effects of thyroid hormones, such as stimulation of the nervous and cardiovascular systems, are mediated by increased sensitivity to catecholamines.

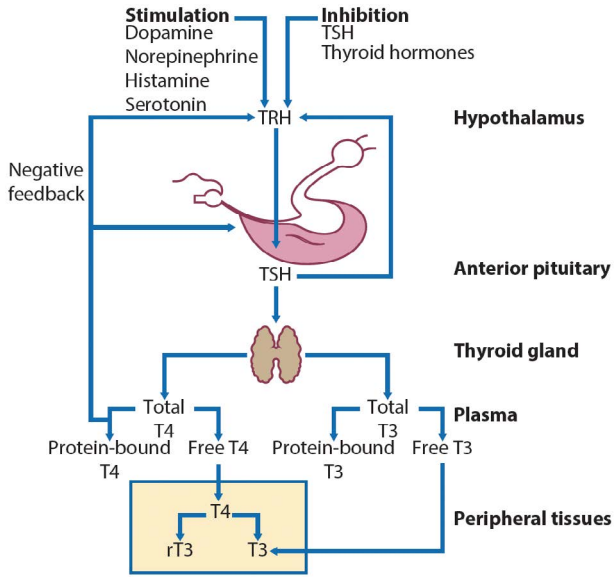

FIGURE 12.17 Physiology of thyroid function.

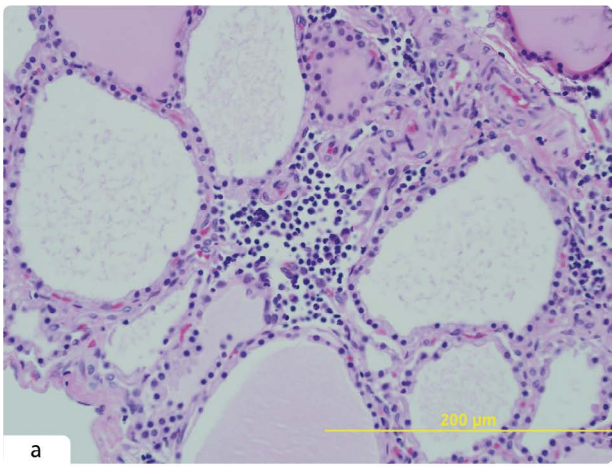
HYPOTHYROIDISM

Definition/Overview

Hypothyroidism is a multisystemic disorder resulting from inadequate circulating thyroid hormone concentrations. It is considered a common endocrinopathy in the dog and estimates of incidence range from 1 in 156 to 1 in 500 depending on the criteria for diagnosis. However, in the past, hypothyroidism may have been over diagnosed, as the clinical signs are vague and nonspecific, and diagnostic tests frequently give false positive results in euthyroid dogs.

Naturally occurring hypothyroidism is a rare clinical disorder in cats, but cases of both primary congenital and adult-onset hypothyroidism have been reported. However, iatrogenic hypothyroidism following any of the three common treatments for feline hyperthyroidism is well recognized.



Etiology

Primary hypothyroidism is caused by an intrinsic disorder of the thyroid gland and is the most common type of hypothyroidism in the dog. Hypothyroidism usually results from lymphocytic thyroiditis or thyroid atrophy. Thyroid atrophy may be the end stage of lymphocytic thyroiditis (Figure 12.18a, b). Thyroid neoplasia can occasionally be associated with hypothyroidism, although most dogs with thyroid tumors have normal thyroid function. Congenital hypothyroidism is rare and may be caused by thyroid agenesis, dysgenesis, or dyshormonogenesis. Secondary hypothyroidism is usually associated with pituitary neoplasia, but it may also occur with congenital panhypopituitarism or following head trauma. Hypothalamic dysfunction, iodine deficiency, and serum transport defects are rare causes of hypothyroidism.

The most common cause of feline hypothyroidism is iatrogenic destruction or removal of the thyroid gland following radioiodine therapy or surgery for the treatment of hyperthyroidism. Spontaneous acquired hypothyroidism has been reported in a cat with lymphocytic thyroiditis. Congenital hypothyroidism has been reported in the cat and may be associated with goiter.

Pathophysiology

Hypothyroidism may result from dysfunction of any part of the hypothalamic–pituitary–thyroid axis. In lymphocytic thyroiditis, there is infiltration of the thyroid gland by lymphocytes, macrophages, and plasma cells. Leukocytes and degenerate follicular cells may be found within vacuolated colloid. The parenchyma becomes progressively destroyed and replaced by fibrous connective tissue. In follicular atrophy, the parenchyma

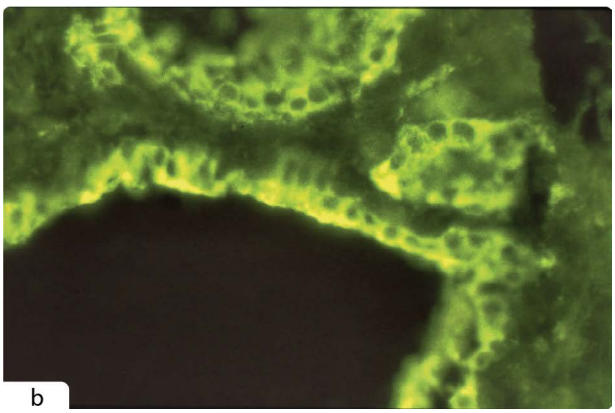


FIGURE 12.18 Hypothyroidism. **(a)** Histopathologic microscopic view of lymphocytic thyroiditis in a dog showing the infiltrating lymphocytes (hematoxylin and eosin [H&E] stain). **(b)** Histopathologic indirect immunofluorescent demonstration of autoimmune thyroiditis. The immunofluorescence represents antibodies that are bound to the thyroid epithelial cells. (*Courtesy of M. Schaer.*)

is replaced by adipose connective tissue. In secondary hypothyroidism, the follicular epithelial cells become flattened, and the follicles become distended with colloid.

Clinical Presentation

The clinical signs of hypothyroidism are very variable and often vague. Some cases present with a classic combination of clinical signs, whereas others may exhibit only one sign. Hypothyroidism usually affects young to middle-aged dogs of the larger breeds. Golden Retrievers, Dobermanns, Boxers, Great Danes, and Irish Setters appear to be overrepresented.

Lethargy, mental dullness, bradycardia, poor exercise tolerance, weight gain without an increase in food intake, intolerance to cold, and hypothermia are the most common clinical signs associated with hypothyroidism. Bilaterally symmetrical, nonpruritic alopecia affecting the flanks, thorax, ventral trunk, and neck is associated with failure to stimulate the anagen (growth) phase of the hair cycle (Figure 12.19). The remaining

FIGURE 12.19 A 6-year-old Dobermann with bilaterally symmetrical alopecia due to hypothyroidism.

hair coat is dry and dull. The skin is often thickened (myxedematous) and hyperpigmented. Myxedema of the skin is most evident on the head, resulting in a "tragic" facial expression (Figure 12.20). The skin, particularly on the ventral abdomen, may be cold and clammy to the touch. Comedones, seborrhea, and recurrent pyoderma may also be noted. Intact females often have abnormal estrous cycles and reduced fertility. Constipation and corneal lipidosis (Figure 12.21) may occasionally be noted.

Neurologic signs may be seen in some dogs with hypothyroidism and include neuromuscular dysfunction with cranial nerve abnormalities, laryngeal paralysis, megaesophagus, lower motor neuron disease, and encephalopathy (Figures 12.22 and 12.23). Clinical signs of lameness, dragging of the feet, quadriparesis, hearing impairment, and nystagmus have also been reported. Electromyography may reveal fibrillation potentials and positive sharp waves. Motor nerve conduction velocities may be decreased, and tendon reflexes appear sluggish.

Congenital hypothyroidism has been reported in a number of breeds, including the Boxer and the Giant Schnauzer. Clinical signs of congenital hypothyroidism include hypothermia, lethargy, disproportionate

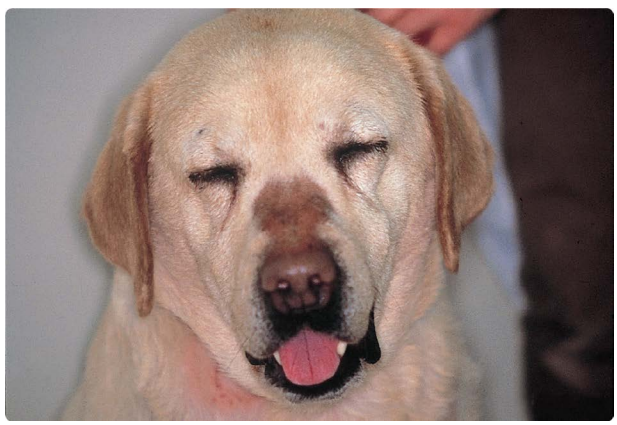

FIGURE 12.20 A 7-year-old Labrador Retriever with hypothyroidism showing a "tragic" expression.

FIGURE 12.24 Two 7-month-old Boxer littermates. The puppy on the left has congenital hypothyroidism.

dwarfism with a short, broad skull, short thick limbs and kyphosis, delayed dental eruption, thickened skin, and a dry hair coat (**Figure 12.24**). Radiographic changes include delayed epiphyseal ossification and epiphyseal dysgenesis (**Figure 12.25**). Congenital hypothyroidism has also been seen in the cat (**Figure 12.26**).

Differential Diagnosis

Pituitary tumor or cyst, hypophysitis, surgery (thyroidectomy or hypophysectomy), drugs (particularly antithyroid drugs and glucocorticoids), diet/obesity, hyperadrenocorticism.

Diagnosis

Laboratory Findings

Hypercholesterolemia is found in about 70% of hypothyroid dogs. Thyroid hormones stimulate biliary excretion

FIGURE 12.25 Craniocaudal radiograph of the carpus of a 10-month-old Boxer with congenital hypothyroidism showing delayed ossification and epiphyseal dysgenesis.

FIGURE 12.26 This approximately 6-month-old kitten was the runt of the litter due to its congenital hypothyroid condition. (*Courtesy of A. Specht.*)

of cholesterol, and a deficiency of these hormones results in an increase in the cholesterol content of the liver. To prevent overloading the liver with cholesterol, the low-density lipoprotein receptors are downregulated to limit low-density and high-density lipoprotein uptake from the circulation. Plasma concentrations of these lipoproteins rise, causing hypercholesterolemia. Causes of hypercholesterolemia are listed in Table 12.7.

Mild normocytic, normochromic, nonregenerative anemia occurs in about 30% of hypothyroid dogs and represents a physiologic response to the lowered basal metabolic rate.

Mild-to-moderate increases in serum activity of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and creatinine kinase (CK) may be noted. Increased CK activity is particularly associated with myopathy in cases of hypothyroidism.

Thyroid Function Tests

The dynamic thyroid function tests and their protocols are listed in Table 12.8.

Serum Total and Free T4

Baseline serum T4 concentration using a validated assay is more accurate than serum T3 in assessing the status of thyroid gland function and is recommended for initial evaluation of the thyroid gland. Random fluctuations in serum T4 concentrations occur, but a true circadian rhythm has not been identified.

Serum T4 concentrations can be affected by breed, age, illness, and drug administration. Certain breeds, particularly sighthounds, have lower serum T4 concentrations than other breeds, and this is important when interpreting results from Greyhounds or Afghan Hounds, for example. Serum T4 concentrations tend to be higher in young growing puppies and lower in old dogs when compared with normal adult concentrations. Concurrent illness can suppress serum thyroid hormone concentrations (sick euthyroid syndrome). The degree of suppression is dependent on the severity of the illness or catabolic state rather than the specific disorder. Various drugs can alter thyroid hormone metabolism and serum binding, particularly glucocorticoids, anticonvulsants, NSAIDs, potentiated sulfonamides, furosemide, and anesthetic agents.

Serum free T4 concentrations measure metabolically active T4 and should not be influenced by the effects of serum binding. However, measurement of serum free T4 by most assays, which do not employ equilibrium dialysis, has not proved to be any more reliable than total T4 concentrations in the diagnosis of hypothyroidism. Serum free T4 measured by equilibrium dialysis

Secondary hyperlipidemia – Hypothyroidism – Hyperadrenocorticism – Diabetes mellitus – Cholestatic liver disease – Nephrotic syndrome
Primary (idiopathic) hyperlipidemia

TABLE 12.8 Protocol and interpretation of the TSH and TRH stimulation tests

TSH stimulation test
Protocol – Collect plasma or serum sample for basal T4 concentration – Administer 50–100 μg per dog recombinant human TSH intravenously – Collect second sample for T4 concentration 6 hours later
Interpretation – A diagnosis of primary hypothyroidism can be confirmed if both the pre- and post-T4 samples are below the reference range for basal T4 concentration – In normal animals, the T4 concentration should be stimulated to well within or above the normal reference range for T4; in most animals, the T4 concentration should increase by at least 1.5 times the basal concentration – Interpretation of intermediate results is more difficult and may occur in association with nonthyroidal illness, treatment with certain drugs, secondary hypothyroidism, or possibly in the early stages of primary hypothyroidism
TRH stimulation test
Protocol – Collect plasma or serum sample for basal T4 concentration – Administer 200 μg per dog protirelin (TRH) intravenously; injection may cause salivation, vomiting, and tachycardia – Collect second sample for T4 concentration 4 hours later
Interpretation – Similar to TSH stimulation test, although stimulation of T4 concentrations is less than with TSH and the response to TRH shows greater individual variation

TRH, thyrotropin-releasing hormone (protirelin); TSH, thyroid-stimulating hormone.

can prove useful in differentiating genuine hypothyroidism when the total T4 concentration is in the reference range.

A low basal serum T4 concentration, with a history and clinical signs compatible with hypothyroidism, may be sufficient evidence to warrant a therapeutic trial. In one study, the predictive value of a positive test result was 0.75 and of a negative test result was 0.87 when using T4 concentrations to diagnose hypothyroidism. Serum T4 concentrations in the low normal or nondiagnostic range should have further tests performed (e.g., a canine TSH concentration and/or a TSH or TRH stimulation test) provided the index of suspicion is still high for hypothyroidism.

Serum T4 concentrations in the normal range are unlikely to be associated with hypothyroidism. However, antibodies to thyroid hormone can cause discordance between measured thyroid hormone concentrations and the clinical status of the dog. Depending on their concentration, binding affinity, and the assay method employed, thyroid antibodies can result in either falsely elevated or falsely low thyroid hormone concentrations. Autoantibodies to T4 and T3 can be measured in these cases.

Serum Total T3 and Free T3

Baseline serum T3 concentrations are less accurate for predicting hypothyroidism than serum T4. Random fluctuations in serum T3 concentrations are greater than with serum T4 and have a greater tendency to be misleading with respect to the status of thyroid gland function. Possible explanations for this discrepancy include the normal thyroid gland's preference for secreting T4, the intracellular formation and location of most T3, the preferential secretion of T3 compared with T4 as thyroid function progressively fails, and the development of anti-T3 antibodies. The diagnostic value of serum T3 concentrations in hypothyroidism is therefore inferior to serum T4.

Endogenous Canine TSH

Measurement of canine TSH (c-TSH) has revolutionized the testing for hypothyroidism, particularly in primary hypothyroidism where the concentrations should be high because of loss of the negative feedback effect of thyroid hormones. A validated c-TSH assay is now widely available, but unfortunately, it has been shown that not all cases of primary hypothyroidism exhibit elevated c-TSH concentrations and that some euthyroid dogs as well as some dogs with nonthyroidal illness may have elevated TSH concentrations. Studies have shown that a high serum c-TSH measurement together with a low serum total T4 or free T4 concentration has a high specificity (>90%) for the diagnosis of hypothyroidism; however, the sensitivity and specificity of the assay, particularly at lower concentrations, are insufficient to obviate the need for a dynamic test (TSH or TRH stimulation test) to confirm the diagnosis in some cases of hypothyroidism.

TSH Stimulation Test

The administration of exogenous TSH to measure thyroid secretory reserve is the most definitive method currently available for the diagnosis of hypothyroidism. Unfortunately, pharmaceutical grade bovine TSH has limited availability, but more recently, recombinant human TSH has become available. The protocol and interpretation criteria are given in Table 12.8. The use of this test is limited by the expense of the TSH injection.

Peak serum T4 responses are decreased by breed, nonthyroidal illness, and drug administration in the same way as basal T4 concentrations. Thyroid function testing is thus best performed after resolution of nonthyroidal illness and, if possible, with the patient off all medication.

TRH Stimulation Test

TRH is readily available and less expensive than TSH. However, the T4 response to TRH is less predictable, and peak concentrations tend to be lower than with TSH stimulation. Increasing the dose of TRH increases the duration but not the magnitude of the T4 response. TRH administration may cause cholinergic signs such as salivation, vomiting, and defecation. Responses are also affected by nonthyroidal illness and drug administration.

Reverse T3 (rT3)

Measurement of serum rT3 concentration can be useful in identifying cases with significant nonthyroidal illness and should be reserved for those cases with discordant or equivocal T4 concentrations. If the serum rT3 concentration is high in a dog with low or low-normal T4, hypothyroidism is unlikely to be the cause of the animal's clinical signs.

Thyroglobulin Autoantibodies (TgAA)

Lymphocytic thyroiditis is a major cause of canine hypothyroidism, and, as part of the inflammatory process, antibodies to thyroid antigens are released into the circulation. Thyroglobulin is the principal antigen for which measurable serum antibodies are present. Therefore, measurement of TgAA provides evidence of an active inflammatory process in the thyroid gland. However, the presence of TgAA does not provide information about thyroid function, since at least 60%–70% of the gland has to be destroyed before thyroid dysfunction occurs. Consequently, both lymphocytic thyroiditis and TgAA can be found in dogs that are not hypothyroid, and in dogs where hypothyroidism is caused by thyroid atrophy, circulating TgAA may not be present at all.

Thyroid Biopsy

Although not commonly performed, histologic examination of a thyroid gland biopsy provides an accurate method of differentiating between primary and

secondary hypothyroidism. In primary hypothyroidism, there is loss of thyroid follicles resulting from either lymphocytic thyroiditis or thyroid atrophy. In secondary hypothyroidism, the thyroid follicles become distended with colloid, and the follicular epithelial cells are flattened. Testing thyroid function is still required to make a diagnosis of hypothyroidism, since the degree of histologic change does not always relate to reduced hormone production and release.

Management

Thyroid hormone replacement is required for the treatment of hypothyroidism. Synthetic forms of T4 and T3 are available. Oral sodium levothyroxine (L-thyroxine) is the treatment of choice because it most closely resembles the preferential secretion of T4 by the normal thyroid gland. Synthetic T4 is readily deiodinated to T3 in peripheral tissues and, therefore, does not bypass the normal cellular regulatory processes that control the production of the more potent T3 in those tissues.

An initial replacement dose of L-thyroxine is 20–40 µg/kg p.o. daily in divided doses. Although it has been suggested that once-daily dosing is sufficient in many cases, the author has documented a number of cases where once-daily administration has failed to maintain adequate serum concentrations throughout the day, with a consequent failure of the clinical signs to resolve fully. Poor absorption and a shorter half-life for T4 explain why dogs require higher doses and more frequent administration than human patients with hypothyroidism.

Therapy should always be continued for a minimum of 3 months. Improved activity and mental alertness are usually seen within 2 weeks, but skin and hair coat changes may take up to 6 months to resolve.

The effect of treatment can be monitored by measurement of post-pill serum T4 concentrations. Sampling 4–6 hours after dosing will give a peak serum T4 concentration, and a sample taken just prior to dosing will give the lowest serum T4 concentration. The dose and frequency of administration should be adjusted to maintain the serum T4 concentration in the high end of the reference range throughout the day. Under dosage may lead to treatment failure, and over dosage can lead to iatrogenic hyperthyroidism. Replacement therapy is required for life.

Possible causes for cases failing to respond to replacement therapy include misdiagnosis, inadequate dose or frequency of administration, poor gastrointestinal (GI) absorption, and peripheral tissue resistance.

Congenital hypothyroidism should be treated as early as possible to achieve normal growth and development. The dose will require adjustment as the patient grows and becomes older, so post-pill assessments are required at monthly intervals during the first year of life.

HYPOTHYROID MYXEDEMA

Definition/Overview

Myxedema coma is an extreme form of hypothyroidism with an acute presentation that can prove life-threatening. It is considered to be a complication of chronic hypothyroidism and is manifest by impaired mental status, thermoregulation, respiratory and cardiovascular function.

Clinical Presentation

Affected dogs, mostly Dobermanns, are profoundly dull and present stuporous or comatose with hypothermia in the absence of shivering (Figure 12.27a–c). The skin can be myxedematous due to the accumulation of mucopolysaccharides and hyaluronic acid. Bradycardia, hypotension, and hypoventilation are also evident.

Diagnosis

Laboratory test results are characteristic of hypothyroidism.

Management

Treatment entails gradual warming, avoiding over hydration from IV fluids, monitoring ventilation and providing support if needed, and administration of glucocorticoids and L-thyroxine.

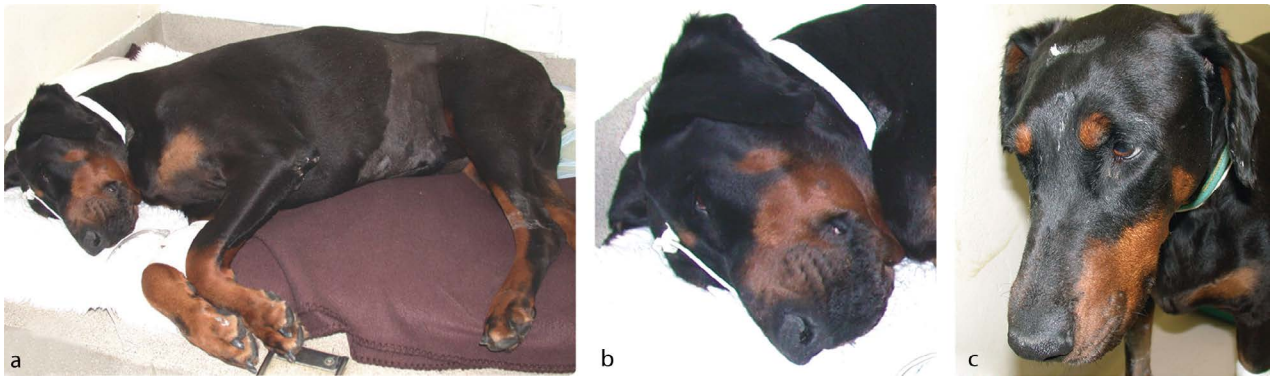

FIGURE 12.27 This Dobermann was referred to the neurology service to evaluate generalized weakness. The dog was profoundly mentally depressed and recumbent. Shown is the dog initially **(a, b)** and subsequently improved with treatment **(c)**.

HYPERTHYROIDISM

Definition/Overview

Hyperthyroidism (thyrotoxicosis) is a multisystemic disorder resulting from excessive circulating concentrations of T4 and/or T3. Hyperthyroidism is the most common endocrine disorder of the domestic cat but is rare in the dog.

Etiology

Functional adenomatous hyperplasia (adenoma) affecting one or, more commonly, both thyroid lobes is the most common cause of feline hyperthyroidism. Iatrogenic hyperthyroidism caused by excessive thyroid hormone supplementation is recognized occasionally. Thyroid carcinoma is a rare cause of hyperthyroidism in the cat. In the dog, although thyroid carcinoma is the most common thyroid tumor, it is rarely functional.

Pathophysiology

The pathogenesis is unknown, but the frequent involvement of both thyroid lobes would suggest a circulating factor may be involved. Recent epidemiologic studies suggest there is an increased risk of developing feline hyperthyroidism associated with indoor living and consumption of canned cat food, in particular fish flavors.

Clinical Presentation

Hyperthyroidism is a disease of middle-aged to older cats, with a mean age of 13 years and a range of 6–21 years. Only about 6% of hyperthyroid cats are younger than 10 years of age at the time of diagnosis. There is no breed or sex predisposition, but pure-bred cats, particularly Siamese and Himalayan cats, have a decreased risk of developing hyperthyroidism.

The clinical signs of hyperthyroidism relate to the excessive secretion of thyroid hormones and their general stimulatory effect on different body systems. The frequency and severity of the clinical signs are highly variable in cats with hyperthyroidism and are influenced by the duration of hyperthyroidism, the ability of the body systems to cope with the demands imposed by thyroid hormone excess, and the presence of concomitant disease in the older animal. In most cases, the clinical signs of hyperthyroidism are slowly progressive, with an insidious onset.

The major presenting sign, therefore, is progressive weight loss frequently accompanied by polyphagia (Figure 12.28). Since most cats maintain a good appetite and remain active for their age, owners frequently feel the cat is in good health until weight loss or other signs develop. Affected cats are often hyperactive and become irritable or aggressive, which can make clinical examination difficult (Figure 12.29). Polydipsia and polyuria are common. Intermittent GI signs such as vomiting, diarrhea, and the passage of voluminous fatty feces are also frequent clinical signs. Occasionally, systemic hypertension with retinal hemorrhages and/or detachment may occur, but generally, hypertension, if present, is only mild to moderate in severity.

FIGURE 12.28 A 13-year-old Domestic Shorthair cat with hyperthyroidism.

FIGURE 12.29 A 15-year-old Domestic Shorthair cat with hyperthyroidism showing irritation.

Cardiac abnormalities are frequently recognized in hyperthyroid cats. There is usually a tachycardia with a heart rate in excess of 240 bpm. Systolic murmurs, gallop rhythms, or dysrhythmias are frequently detected on auscultation. In severe cases, clinical signs of congestive heart failure (CHF) may develop, and these may include dyspnea resulting from pulmonary edema or accumulation of pleural fluid and ascites. The cardiac signs are associated with cardiomyopathy, usually the hypertrophic form, which develops secondarily to excessive thyroid hormone secretion. Electrocardiographic abnormalities may include tachycardia, increased R-wave amplitude, particularly in lead II, and various atrial and ventricular dysrhythmias and conduction disturbances (Figure 12.30).

Although there are no specific skin lesions, the coat of cats with hyperthyroidism is often matted and

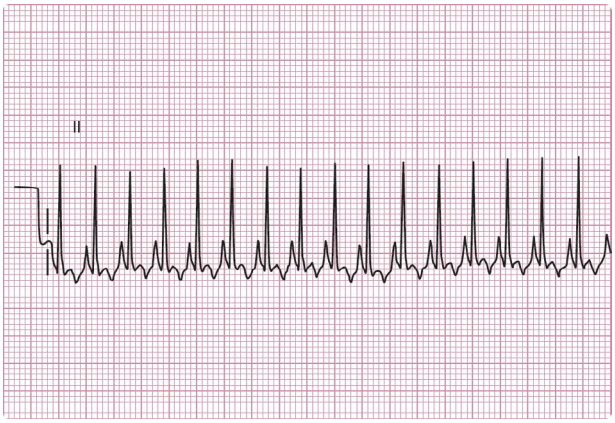

FIGURE 12.30 ECG from a 13-year-old Domestic Shorthair cat with hyperthyroidism showing sinus tachycardia. The heart rate is approximately 260 bpm.

FIGURE 12.31 Hyperthyroid cat showing its unkempt hair coat. (*Courtesy of M. Schaer.*)

unkempt (Figure 12.31). Affected cats may also develop heat intolerance with panting and dysphonia. Although most hyperthyroid cats are polyphagic and hyperactive, about 10% of cases are presented with severe depression and muscle weakness, which may result in ventroflexion of the neck. Weight loss remains a feature but is usually associated with anorexia rather than increased appetite. Cardiac abnormalities are also common. This clinical presentation is referred to as "apathetic" hyperthyroidism.

In most cases, there is palpable enlargement of one or both thyroid lobes (Figure 12.32). Thyroid palpation requires both skill and practice. The thyroid gland is not usually palpable in the normal cat. Enlarged lobes of the thyroid are usually located just distal to the larynx, but they can be quite mobile and descend down the neck and occasionally pass into the thoracic inlet. Ectopic thyroid tissue located anywhere from the base of tongue to the base of the heart is occasionally involved in the pathogenesis of the condition.

Differential Diagnosis

Chronic kidney disease, intestinal disorders (e.g., inflammatory bowel disease), lymphoma, diabetes mellitus, chronic liver disease, hypertrophic cardiomyopathy.

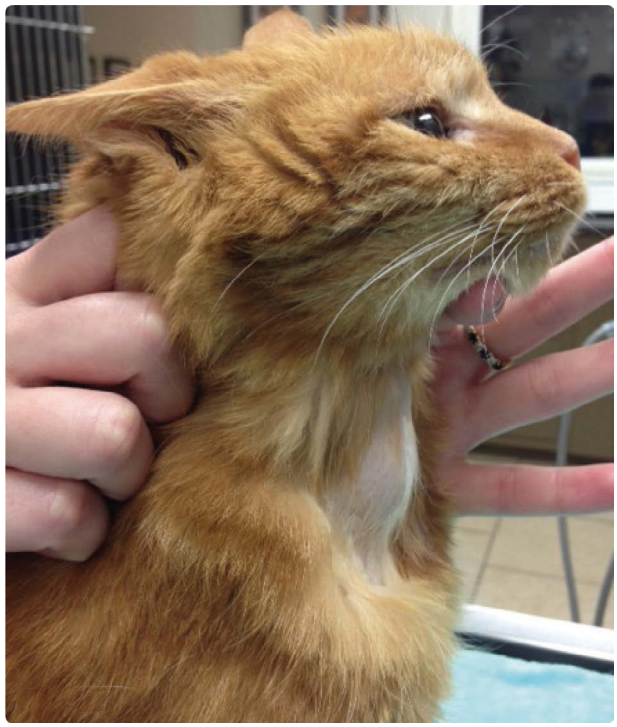

FIGURE 12.32 Hyperthyroid cat showing a large goiter. (*Courtesy of M. Schaer.*)

Diagnosis

Laboratory Findings

Routine hematologic and biochemical screening tests are useful not only because results may show alterations that support a diagnosis of hyperthyroidism, but because they may also indicate evidence of concurrent disease in the older cat. The most frequent hematologic change is a relative polycythemia with a mild-to-moderate increase in red cell parameters (red blood cell count, packed cell volume [PCV], and hemoglobin [Hgb] concentration). A mature neutrophilia with lymphopenia and eosinopenia is also common and probably reflects a stress response. However, eosinophilia and lymphocytosis are found in some cats with hyperthyroidism.

A mild-to-moderate increase in serum activity of the enzymes ALT, AST, ALP, and lactate dehydrogenase (LDH) is a frequent but nonspecific finding. The reason for the increase is not clear, but in some cases, it might be related to a relative hypoxemia in the portal circulation. Evidence of concurrent renal dysfunction in hyperthyroidism is common, with mild-to-moderate elevations in serum creatinine and urea. These increases may be related to increased protein catabolism and prerenal azotemia. Careful consideration should be given to the method of treatment selected for hyperthyroid cats with concomitant azotemia, since some of these cats may develop clinical signs of renal failure caused by a deterioration in renal function when the hyperthyroid state is corrected.

Thyroid Function Tests

Increased serum basal thyroid hormone concentrations are diagnostic of hyperthyroidism. In the majority of cases, both serum T4 and T3 concentrations are increased, often markedly; however, in a few cases, serum T3 concentrations are in the normal range despite obvious elevation of the serum T4 concentration. There is, therefore, usually no advantage in determining serum T3 concentrations, and in most cases, serum total or free T4 concentrations provide a reliable indication of hyperthyroidism. Measurement of TSH has limited utility in the diagnosis of hyperthyroidism. Most hyperthyroid cats will have barely detectable concentrations, but such low values are also found in normal cats and those with other diseases.

About 5% of cases of hyperthyroidism have serum thyroid hormone concentrations within the upper reference intervals at the time of examination, and this may be due to an early stage of the disease, significant daily fluctuations of thyroid hormone concentrations, or the effect of concurrent nonthyroidal illness. In cases where hyperthyroidism is still suspected on clinical grounds, a diagnostic T4 concentration may be obtained by retesting the animal in 3–6 weeks. Alternative diagnostic tests for equivocal cases of hyperthyroidism include the TRH stimulation test and the T3 suppression test.

Diagnostic Imaging

Hyperthyroid cats with secondary cardiomyopathy usually show cardiac enlargement, which is evident on both radiographic and echocardiographic examinations. However, it is important to recognize that significant concentric hypertrophy can occur without affecting the appearance of the cardiac silhouette on thoracic radiographs (Figure 12.33), and the diagnosis of cardiomyopathy in these cases can only be made on echocardiographic findings (Figure 12.34).

Thyroid imaging using radioactive iodine or Tc-99m pertechnetate is a useful diagnostic technique if gamma camera facilities are available. The technique determines whether there is unilateral or bilateral lobe involvement, which is valuable if surgical thyroidectomy is to be performed (Figure 12.35). The technique also determines any alteration in the position of the thyroid gland, the rare case of abnormal ectopic thyroid tissue within the thorax, or the presence of distant metastases from a functioning thyroid carcinoma. Thyroid scintigraphy can also be used to determine the dose of radioiodine for the treatment of hyperthyroidism.

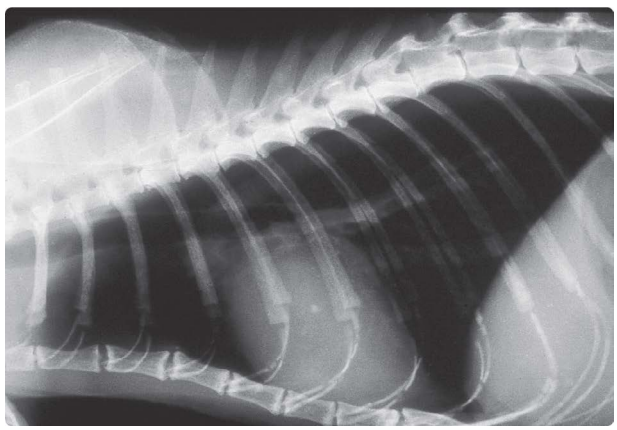

FIGURE 12.33 Lateral thoracic radiograph of a 12-year-old Domestic Shorthair cat with hyperthyroidism and hypertrophic cardiomyopathy. Note the cardiac silhouette is not enlarged.

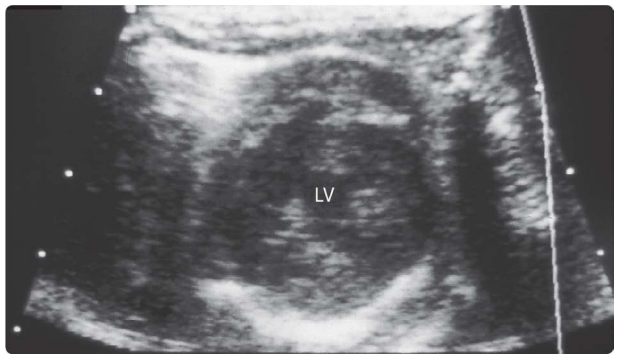

FIGURE 12.34 Short-axis 2D echocardiogram from the cat in Figure 12.33 showing the degree of concentric hypertrophy and the reduction in the size of the left ventricular lumen (LV).

Management

There are four options for treatment of hyperthyroidism: Dietary management, medical management (antithyroid medication), surgical thyroidectomy, and radioiodine. Each treatment modality has advantages and disadvantages which need to be considered when deciding on the most appropriate treatment for a case.

Dietary Management

The release of a prescription diet with ultra-low iodine content (Hills y/d) in 2011 provided an alternative option for the management of feline hyperthyroidism. The mechanism of action is simple. Without sufficient ingested iodine, the patient cannot synthesize and secrete the same amount of thyroid hormones. The diet must be used as the sole food source for the affected cat,

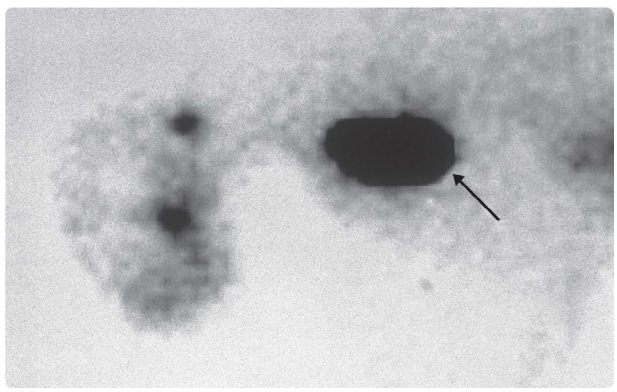

FIGURE 12.35 Thyroid scan using Tc-99m pertechnetate of a cat with hyperthyroidism. The head is seen to the left, with uptake in the salivary glands. The greatest uptake of technetium is by the thyroid adenoma (arrow).

as even small quantities of other foods (including milk) are likely to make the diet ineffective. The diet must not be used as the sole food source for healthy cats, which may restrict its use in multicat households. In addition, the diet must not be used at the same time as antithyroid medication or radioiodine as hypothyroidism may result. The diet needs up to 14 weeks to work, so for cats that are seriously ill with hyperthyroidism, other management options would be preferred.

The diet does not treat the underlying adenoma, which will continue to grow and become more able to produce thyroid hormone. Ultimately, the adenoma is likely to "break through," and conventional medical, surgical, or radioiodine treatment will be needed. However, for mildly affected animals, this may to be an effective treatment. Monitoring serum total T4 concentrations is essential to judge the effect of therapy.

Antithyroid Drugs

Medical management of hyperthyroidism using antithyroid drugs is indicated when preparing hyperthyroid cats for surgical thyroidectomy in order to improve their general condition and reduce the risk of complications arising during or following surgery. Antithyroid drugs are also recommended for the initial treatment of hyperthyroid cats with concurrent azotemia in order to ascertain whether significant deterioration in renal function is likely to occur after medical control of the hyperthyroid state. If there is no deterioration in renal function after 3–4 weeks of treatment, surgical thyroidectomy or radioiodine therapy for hyperthyroidism can be considered. Antithyroid drugs can also be used for long-term management of hyperthyroidism, particularly in cases where owners refuse surgical or radiative iodine treatment.

Methimazole and its pro-drug carbimazole inhibit thyroid hormone synthesis. Carbimazole is rapidly converted to methimazole after oral administration. They are a safe and effective form of treatment and are undoubtedly the treatment of choice for aged cats and those with concurrent disease.

Methimazole is initially administered at a dose of 2.5 mg p.o. q.12 h. and carbimazole at a dose of 5 mg p.o. q.8 h. and subsequently titrated to effect in order to obtain circulating total thyroxine concentrations in the lower half of the reference interval. Serum total thyroxine concentrations decrease to within the reference interval after 3–15 days. When euthyroidism has been achieved, monitoring is recommended at 1 month, 3 months, and biannually thereafter. These doses can usually be continued for the remainder of the cat's life. Adjustment of the dosage is required in some cases to maintain the euthyroid state. A sustained-release form of carbimazole is available in some countries, which only requires once daily administration. The sustained release form is initiated at a dose of 10–15 mg p.o. q.24 h. and titrated to effect. Monitoring of medical management should pay special attention to the possible development of azotemia, hypertension, and iatrogenic hypothyroidism.

Adverse reactions to methimazole and carbimazole include anorexia, vomiting, and lethargy, which are usually transient, but more serious reactions such as pruritus, self-induced excoriation, hepatopathy, jaundice, and bleeding diatheses have been reported and may necessitate withdrawal of these drugs.

Surgical Thyroidectomy

The aim of surgical thyroidectomy is to remove all of the abnormally functioning thyroid tissue. Surgical thyroidectomy is a highly effective treatment for feline hyperthyroidism, but it can be associated with significant morbidity and mortality if cats are not carefully assessed and stabilized prior to surgery. Preoperative treatment with carbimazole or methimazole and propranolol (2.5–5 mg p.o. q.8 h. for 7–14 days before surgery) will control the excessive thyroid hormone production and protect the heart against the effects of excess thyroid hormone.

The anesthetic protocol for the hyperthyroid cat should be carefully considered, using agents that have the minimum effect on cardiac rhythm. Techniques for unilateral and bilateral thyroidectomy have been reported for cats with hyperthyroidism. Both intracapsular and extracapsular techniques have been designed to preserve parathyroid function after removal of the abnormal thyroid tissue.

The potential complications associated with thyroidectomy include hypoparathyroidism, Horner's syndrome, and laryngeal paralysis. The most serious complication is hypocalcemia associated with damage to, or removal of, the parathyroid glands. Since only one parathyroid gland is required for maintenance of normocalcemia, hypoparathyroidism is mostly identified in cats treated by bilateral thyroidectomy. Hypocalcemia is usually transient and may be manifested by clinical signs, including anorexia, vocalization, lethargy, muscular tremors, tetany, and convulsions. The treatment of postoperative hypocalcemia is outlined in Table 12.9.

TABLE 12.9 Management of postoperative hypocalcemia

Immediate therapy
- Administer 1.0–1.5 mL/kg of 10% calcium gluconate or calcium glubionate by slow intravenous injection
- Stop injection if bradycardia develops; repeat as necessary

Maintenance therapy
- Begin oral supplementation as soon as possible using 50–75 mg/kg per day of calcium equivalent in three or four divided doses (equivalent to 500–750 mg/kg per day of calcium gluconate or 400–600 mg/kg per day of calcium lactate) and 0.03 mg/kg/day of dihydrotachysterol (unavailable in the United States) or 0.05 µg/kg per day of alfacalcidol calcitriol
- Monitor the serum calcium concentration and decrease the dihydrotachysterol by 0.01 mg/kg every other day or alfacalcidol calcitriol by 0.01 µg/kg every other day once serum calcium is within the reference range
  - Adjust doses of dihydrotachysterol, alfacalcidol, calcitriol, and calcium supplementation according to subsequent serum calcium concentrations; in most cases, hypocalcemia is temporary

Radioiodine Therapy

Radioiodine therapy is a safe and effective method of treating hyperthyroidism; however, it does require the cat to be housed in licensed premises with restricted access until the radiation dose rate has decreased to an acceptable level. This usually requires hospitalization for between 3 days and 3 weeks, depending on local regulations on the use of radioisotopes. The radioisotope used most commonly is iodine-131 (^{131}I), which has a half-life of 8 days and emits both beta particles and gamma radiation. The beta particles cause most of the required tissue damage. Radioiodine can be administered subcutaneously and is associated with few adverse reactions, although iatrogenic hypothyroidism and persistent hyperthyroidism can result from treatment.

Iatrogenic Hypothyroidism

Iatrogenic hypothyroidism is a recognized complication of all four treatment options for hyperthyroidism. Clinical signs of iatrogenic hypothyroidism include lethargy, inappetence, weight gain, and skin changes, particularly seborrhea sicca, alopecia of the pinnae, and an easily epilated, dull, dry, unkempt haircoat. However, a low total T4 concentration is not always associated with clinical signs in cats treated for hyperthyroidism. In one study, 37% of cats were classified as hypothyroid, defined as a decreased total T4 concentration and an elevated c-TSH concentration, 6 months after the start of treatment for hyperthyroidism. The importance of monitoring for iatrogenic hypothyroidism is that hypothyroidism can contribute to the development of azotemia and reduced survival times after treatment for hyperthyroidism and that restoration of euthyroidism by reducing antithyroid medication or by supplementation with L-thyroxine for those cats permanently treated by thyroidectomy or radioiodine can improve renal function.

DISORDERS OF THE PARATHYROID GLAND

The normal dog or cat usually has four small parathyroid glands. One pair of glands is generally found in the fascia cranial to each of the thyroid lobes. The caudal pair of parathyroid glands is embedded in the parenchyma of each thyroid lobe. The location and number of the parathyroid glands can vary. Each parathyroid gland contains chief cells, which synthesize and secrete parathyroid hormone (PTH).

PTH secretion is controlled by the serum-ionized calcium concentration in order to maintain the serum-ionized calcium within narrow limits. If the serum-ionized calcium concentration falls below the set point (reference range: dog, 1.2–1.5 mmol/L [4.8–6.0 mg/dL]; cat, 1.1–1.4 mmol/L [4.4–5.6 mg/dL]), PTH release is enhanced. Concentrations of serum-ionized calcium above the set point inhibit PTH secretion. Total serum calcium consists of ionized and protein-bound calcium. Although serum protein-bound calcium is affected by several factors, including the circulating albumin concentration and the acid–base status, it is only the ionized calcium that is physiologically active. It is important to appreciate this, since most laboratories only measure total serum calcium.

PTH tends to increase serum-ionized calcium concentrations through a number of integrated actions. In the kidney, PTH increases tubular reabsorption of calcium and enhances renal excretion of phosphate. PTH also activates 1-alpha-hydroxylase, the renal enzyme that converts 25-hydroxycholecalciferol to the active form of vitamin D, 1,25-dihydroxycholecalciferol (calcitriol). Increased circulating 1,25-dihydroxycholecalciferol enhances calcium and phosphate absorption by the intestine. In bone, PTH promotes the release of calcium and phosphate into the extracellular fluid by stimulating osteoclast and osteocyte activity and by suppressing osteoblastic activity. The combination of calcium mobilization from bone and retention of calcium by the kidneys causes the serum-ionized calcium concentration to rise.

Calcium plays an important role in neuromuscular excitability, membrane permeability, muscle contraction, enzyme activity, hormone release, and blood coagulation, as well as acting as an essential structural component of the skeleton.

HYPOPARATHYROIDISM

Definition/Overview

Hypoparathyroidism is caused by inadequate production and secretion of PTH (primary hypoparathyroidism) or, more rarely, by deficient end-organ responsiveness to circulating PTH (pseudohypoparathyroidism).

Etiology

The two most common causes of primary hypoparathyroidism are iatrogenic injury or removal of the parathyroid glands during thyroidectomy (see pp. XX) and idiopathic hypoparathyroidism due to destruction and atrophy of the parathyroid glands. Idiopathic hypoparathyroidism probably results from immune-mediated destruction of the parathyroid glands, and this is supported by the diffuse lymphocytic infiltration found in the parathyroid glands of some affected animals.

Pathophysiology

Cessation of parathyroid gland activity results in increased plasma phosphate concentrations and decreased serum calcium concentrations. Loss of PTH leads to changes in calcium and phosphate mobilization from bone, increased intestinal absorption of calcium and phosphate, and retention of calcium and enhanced renal excretion of phosphate. Neuronal membrane permeability is increased when extracellular calcium ion

FIGURE 12.36 Lenticular cataracts in a Springer Spaniel with primary hypoparathyroidism.

concentrations are below normal, and the nervous system becomes more excitable. Spontaneous discharge of nerve fibers initiates impulses to peripheral skeletal muscles, causing tetanic contractions.

Clinical Presentation

Idiopathic hypoparathyroidism is rare, but it has been reported in the dog and cat. The disease affects young to middle-aged animals of various breeds. A female bias has been reported in dogs. The clinical signs relate to neuromuscular abnormalities that develop secondary to hypocalcemia and include seizures, focal trembling or twitching, generalized muscle fasciculations, ataxia, stiff gait, weakness, panting, anorexia, and lethargy. The fact that the clinical signs tend to be intermittent, often precipitated by exercise, excitement, or stress, suggests a physiologic adaptation to severe hypocalcemia. Posterior lenticular cataract formation can occur secondary to hypocalcemia in dogs and cats (Figure 12.36). Electrocardiography may show prolongation of QT interval in some cases of hypoparathyroidism.

Differential Diagnosis

See Table 12.10 for the differential diagnosis list for hypocalcemia.

Diagnosis

Profound hypocalcemia (serum total calcium <2 mmol/L [<8 mg/dL]) and severe hyperphosphatemia (serum phosphate >1.3 mmol/L [>4 mg/dL]) with normal renal function (blood urea and serum creatinine) are found in cases of primary hypoparathyroidism.

PTH assays are available and have been validated for use in the dog and cat. Inappropriately low plasma PTH concentration in a hypocalcemic animal is diagnostic of primary hypoparathyroidism. Careful sample handling is essential to avoid erroneous results, since PTH is heat labile. Simultaneous measurement of serum calcium and PTH is essential in order to be able to interpret the PTH result.

TABLE 12.10 Differential diagnosis of hypocalcemia

- Primary hypoparathyroidism
- Chronic kidney disease*
- Hypoalbuminemia*
- Intestinal malabsorption*
- Hypovitaminosis D associated with inflammatory bowel disease and hypoalbuminemia
- Acute pancreatitis*
- Eclampsia
- Acute kidney injury
- Ethylene glycol toxicity
- Phosphate-containing enemas

* Not usually associated with clinical signs of tetany.

Management

The treatment protocol for hypocalcemia is outlined in Table 12.9; similar principles are used when treating dogs and cats. Parenteral calcium preparations should be used as emergency therapy to correct hypocalcemic tetany. Maintenance therapy using calcium and vitamin D supplementation must be tailored to the individual patient and the dose adjusted according to the serum calcium concentration. Dihydrotachysterol (commercial availability varies) supplementation can prove expensive in larger dogs. Vitamin D2 (1,000–6,000 IU/kg per day), alfacalcidol (0.05 µg/kg per day), or calcitriol (0.03–0.06 µg/kg per day) may be used as alternatives. These starting doses may need to be exceeded to bring the serum calcium into the reference range.

With adequate monitoring of the serum calcium concentration, the prognosis in cases of primary hypoparathyroidism is usually excellent, but supplementation is usually required for life.

Some cases with suspected lymphocytic parathyroiditis have responded to immunosuppressive treatment with cyclosporine. Glucocorticoids should not be used for immunosuppression due to their calciuretic action. Calcium and vitamin D supplementation is required initially but can be phased out in those cases that respond to cyclosporine.

HYPERPARATHYROIDISM

Definition/Overview

Hyperparathyroidism is caused by excess production and secretion of PTH, which can be primary or secondary. Primary hyperparathyroidism is an uncommon disease of older dogs and cats. There is no sex predisposition, but there is a breed predilection, as the Keeshond is overrepresented.

FIGURE 12.37 Necropsy specimen from a Dachshund that had several endocrinopathies. Shown are both thyroid glands, with one containing a parathyroid adenoma. (*Courtesy of M. Schaer.*)

Etiology

Primary hyperparathyroidism is a disorder resulting from autonomous and excessive secretion of PTH by one or more of the parathyroid glands. Secondary hyperparathyroidism is an adaptive increase in PTH secretion as a result of chronic stimulation from conditions that tend to reduce the concentration of ionized calcium in plasma. Secondary hyperparathyroidism may occur as a result of chronic kidney disease (see Chapter 12) and calcium deficiency during growth (see Chapter 14).

Primary hyperparathyroidism is most commonly caused by a small, solitary parathyroid adenoma (**Figure 12.37**). PTH excess may also be caused by nodular hyperplasia in one or more parathyroid glands. Very rarely, the disease is caused by a parathyroid carcinoma. The Keeshond has an autosomal dominant form of primary hyperparathyroidism that has partial age-dependent penetrance.

Pathophysiology

The normal negative feedback control regulating calcium concentration is lost by the entry of excess calcium into the extracellular fluid. The kidneys lose their ability to excrete the excess calcium and are unable efficiently to reabsorb sodium and water.

Clinical Presentation

The clinical signs in hyperparathyroidism are variable. The disease may be asymptomatic or may result in mild-to-severe systemic illness. The clinical signs relate to hypercalcemia and include polyuria, polydipsia, anorexia, vomiting, depression, muscle weakness, constipation, and weight loss. Urinary calculi can occur. Clinical examination may reveal bradycardia. The small size of the parathyroid lesions means that the nodules are rarely palpable.

TABLE 12.11 Differential diagnosis of hypercalcemia

– Cancer-associated hypercalcemia
  – Lymphoproliferative disease
  – Apocrine cell adenocarcinoma of the anal sac
  – Multiple myeloma
  – Other solid tumors

– Hypoadrenocorticism
– Chronic kidney disease (particularly in cats or as a result of familial nephropathies in dogs)
– Primary hyperparathyroidism
– Idiopathic hypercalcemia of cats
– Granulomatous diseases (e.g., the systemic mycoses)
– Vitamin D intoxication

Differential Diagnosis

See Table 12.11 for the differential diagnosis list for hypercalcemia.

Diagnosis

Laboratory Findings

Hypercalcemia (serum total calcium >3 mmol/L [>12 mg/dL]) and hypophosphatemia (serum phosphate concentration <1.3 mmol/L [<4 mg/dL]) are found in cases of primary hyperparathyroidism provided that renal function is normal. Prolonged increases in the circulating calcium concentration will facilitate calcium deposition in the kidneys, causing renal function to deteriorate and serum phosphate concentrations to rise. If renal failure develops, primary hyperparathyroidism is difficult to differentiate from secondary renal hyperparathyroidism.

Circulating PTH concentrations are inappropriately increased in animals with primary hyperparathyroidism. A PTH assay provides a useful differentiation in hypercalcemic patients because plasma PTH concentrations are low in dogs with cancer-associated hypercalcemia. Careful handling of the sample is essential to avoid erroneous results, since PTH is heat labile. Plasma PTH-related protein (PTH-rp) concentrations are elevated in most cases of cancer-associated hypercalcemia but are low in primary hyperparathyroidism.

Diagnostic Imaging

Ultrasonographic examination of the parathyroid glands is useful in the evaluation of hypercalcemic dogs and can be used to identify hyperplastic parathyroid glands and parathyroid adenomas (**Figures 12.38–12.40**). Ultrasound examination of the kidneys in the dog may also reveal the hyperechoic medullary band characteristic of nephrocalcinosis (**Figure 12.41**). This medullary band may be seen in normal cats.

Management

Treatment of the Hypercalcemic Crisis

The hypercalcemic crisis should be treated by aggressive IV fluid therapy using 0.9% sodium chloride solution. Saline will restore the circulating fluid volume and

promote calcium excretion. Furosemide (2–4 mg/kg IV q.12 h.) may also be administered to enhance calcium excretion. Bisphosphonates are osteoclast inhibitors and have also been used in dogs to control hypercalcemia. Clodronate, etidronate, alendronate, and pamidronate have been used. Pamidronate is the most commonly used parenteral preparation (1–2 mg/kg IV administered with 0.9% saline over 2 hours), and alendronate is the most commonly used oral preparation (0.5–1.0 mg/kg p.o. q.24 h. in dogs and 5–10 mg/cat per week in cats).

Surgical Treatment

Primary hyperparathyroidism should be resolved following parathyroidectomy. Parathyroid adenomas are usually easily identified and removed (Figure 12.42). Postoperative complications include hypocalcemia, since the remaining parathyroid glands may be atrophic and require a period of adaptation before control of circulating calcium is regained. For this reason, it is advisable to begin supplementation with vitamin D (dihydrotachysterol or alfacalcidol) and calcium gluconate at the time of surgery in those patients with calcium concentrations >3.75 mmol/L (>15 mg/dL).

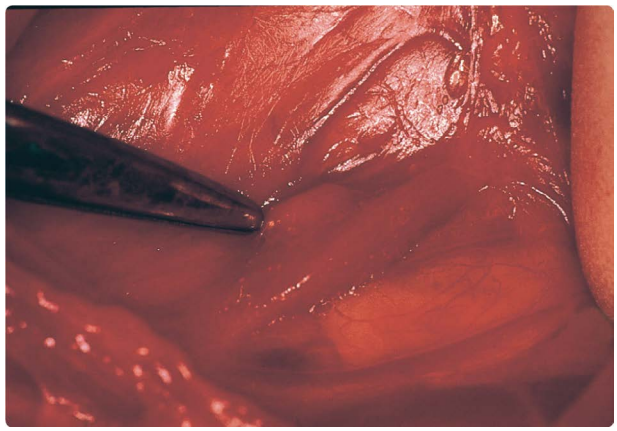

FIGURE 12.42 Parathyroid adenoma adjacent to the thyroid gland being pointed out at surgery.

DISORDERS OF THE ADRENAL GLANDS

The adrenal glands are located craniomedially to each kidney in retroperitoneal fat. Each gland consists of a cortex and a medulla. The cortex completely surrounds the medulla and consists of three distinct zones: The outer zona glomerulosa, the middle zona fasciculata, and the inner zona reticularis.

The adrenal cortex produces about 30 different hormones, many of which have little or no clinical significance. The hormones can be divided into three groups based on their predominant actions: Mineralocorticoids, which are important in electrolyte and water homeostasis; glucocorticoids, which promote gluconeogenesis and are potent inhibitors of inflammatory processes; and small quantities of sex hormones, particularly male hormones that have weak androgenic activity. Aldosterone is the most important mineralocorticoid and is produced by the zona glomerulosa. The principal glucocorticoid (cortisol) and the sex hormones are produced in the zonae fasciculata and reticularis.

Glucocorticoid and mineralocorticoid release are controlled by different mechanisms. Glucocorticoid release is controlled almost entirely by ACTH secreted by the anterior lobe of the pituitary, which in turn is regulated by corticotropin-releasing hormone (CRH) from the hypothalamus (Figure 12.43). CRH is secreted by the neurons in the anterior portion of the paraventricular nuclei within the hypothalamus, and it is transported to the anterior pituitary by the portal circulation, where it stimulates ACTH release. There is probably an internal or "short loop" negative feedback control by ACTH on CRH. ACTH secreted into the systemic circulation causes cortisol release, with concentrations rising almost immediately. Cortisol has direct negative feedback effects on the hypothalamus (decreases formation of CRH) and on the anterior lobe of the pituitary (decreases the formation of ACTH). These feedback mechanisms help regulate the plasma concentration of cortisol.

Secretion of CRH and ACTH is normally episodic and pulsatile, which results in fluctuating cortisol concentrations during the day. Diurnal variation is superimposed on this type of release. It is usually stated that in the dog CRH and ACTH, and thus cortisol concentrations, are highest in the early hours of the morning and that in the cat they are greatest in the evening. However, a true circadian rhythm of cortisol concentrations has been difficult to confirm in the dog and the cat. The episodic release of CRH and ACTH is perpetuated by the reciprocal effect of cortisol acting through negative feedback control. This reciprocal arrangement does not hold during periods of stress when both ACTH and cortisol are maintained at high concentrations because the effects of stress tend to override the normal negative feedback control.

Aldosterone release is influenced primarily by the renin–angiotensin system and by plasma potassium concentrations (Figure 12.44). Renin is secreted into the blood by the cells of the juxtaglomerular apparatus, which consists of specialized cells in the wall of the afferent arteriole immediately proximal to the glomerulus and the specialized epithelial cells of the distal convoluted tubule adjacent to that arteriole, the macula densa. Renin release may be stimulated by stretch receptors in the juxtaglomerular apparatus in response to hypotension or reduced renal blood flow or by sodium and chloride receptors in the macula densa. Renin is also released by sympathetic nerve stimulation and is

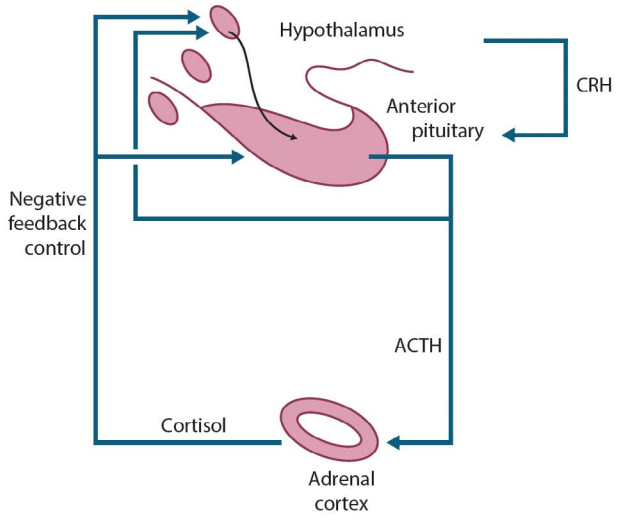

FIGURE 12.43 Physiology of the hypothalamic–pituitary–adrenal axis.

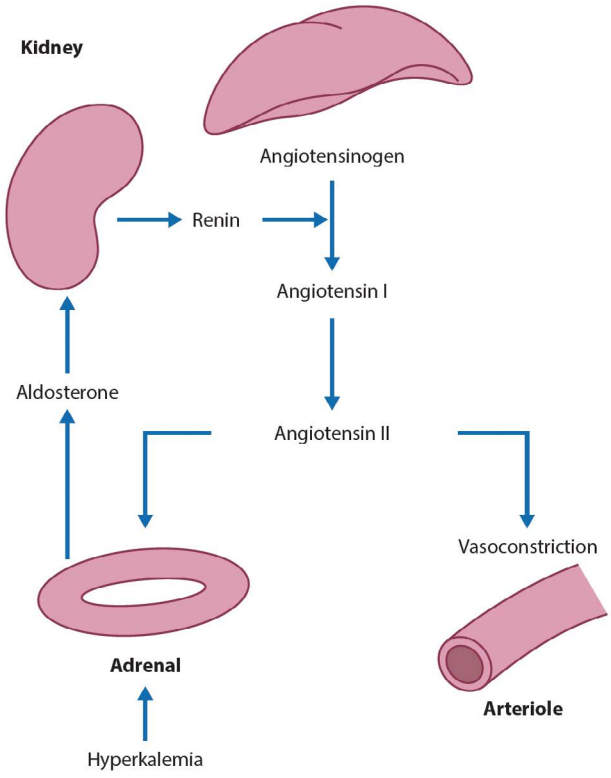

FIGURE 12.44 Physiology of the renin–angiotensin system.

inhibited by angiotensin II, ADH, hypertension, and increased reabsorption of sodium by the renal tubules.

Renin is an enzyme that splits circulating angiotensinogen, produced by the liver, into angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme, which is located almost entirely in the pulmonary capillary endothelium. Angiotensin II is a powerful vasoconstrictor, and it stimulates aldosterone secretion from the zona glomerulosa. Through its action on the distal convoluted tubule, aldosterone has a negative feedback effect on the juxtaglomerular apparatus.

Potassium has a direct stimulatory effect on the zona glomerulosa cells to release aldosterone. ACTH and sodium play a less significant role in aldosterone secretion. ACTH is necessary to maintain normal aldosterone output. In the absence of ACTH, the zona glomerulosa partially atrophies, causing mild-to-moderate aldosterone deficiency, whereas there is almost total loss of glucocorticoid synthesis and release.

The main function of aldosterone is to protect against hypotension and potassium intoxication. Aldosterone promotes sodium, chloride, and water reabsorption, as well as potassium excretion, in many epithelial tissues including the intestinal mucosa, salivary glands, sweat glands, and kidneys. Its main site of action is the renal tubule, where it promotes sodium and chloride reabsorption in the proximal convoluted tubule and sodium reabsorption by exchange with potassium in the distal convoluted tubule. It is one of the complex regulatory systems for the regulation of extracellular fluid electrolyte concentrations, extracellular fluid volume, blood volume, and arterial pressure.

HYPOADRENOCORTICISM

Hypoadrenocorticism is a syndrome that results from a deficiency of both glucocorticoid and mineralocorticoid secretion from the adrenal cortices. Destruction of more than 95% of both adrenal cortices causes a clinical deficiency of all adrenocortical hormones and is termed primary hypoadrenocorticism (Addison's disease). Secondary hypoadrenocorticism is caused by a deficiency in ACTH, which leads to atrophy of the adrenal cortices and impaired secretion of glucocorticoids. The production of mineralocorticoids, however, usually remains sufficient to maintain normal electrolyte concentrations.

PRIMARY HYPOADRENOCORTICISM (ADDISON'S DISEASE)

Definition/Overview

Primary hypoadrenocorticism is caused by the destruction or loss of the adrenal cortices. Addison's disease occurs more frequently in the dog than is recognized, but it is much less common than hyperadrenocorticism (Cushing's disease). Hypoadrenocorticism is rare in the cat. The clinical signs, diagnosis, and treatment of hypoadrenocorticism in the dog and cat are similar.

Etiology

Primary hypoadrenocorticism in the dog has been associated with the following conditions:

- *Idiopathic adrenocortical insufficiency:* This is the most common cause in the dog and is thought to result from immune-mediated destruction of the adrenal cortex. The presence of antiadrenal antibodies in two dogs and characteristic histopathologic findings in another support this hypothesis (Figures 12.45–12.47). In humans, hypoadrenocorticism has been found to be associated with other immune-mediated endocrine disorders such as lymphocytic thyroiditis, diabetes mellitus, hypoparathyroidism, primary gonadal failure, and atrophic gastritis. A similar autoimmune polyglandular disease has also been recognized in dogs.
- *Mitotane-induced adrenocortical necrosis:* Although mitotane usually spares the zona glomerulosa and,

therefore, mineralocorticoid secretion, cases of complete adrenocortical failure can occasionally occur (Figure 12.48) (see Hyperadrenocorticism).

- *Trilostane-associated adrenocortical necrosis:* Although trilostane is a competitive inhibitor of steroid synthesis, it can cause acute adrenal necrosis, which can lead occasionally to complete adrenocortical failure (see Hyperadrenocorticism).
- *Other causes:* Bilateral adrenalectomy, hemorrhage or infarction of the adrenal cortex, or mycotic or neoplastic involvement of the adrenal glands can also lead to adrenal insufficiency, but these are rare causes.

Pathophysiology

Loss of or damage to the adrenal cortex leads to mineralocorticoid and glucocorticoid deficiency. Aldosterone is the major mineralocorticoid, and deficiency causes impaired ability to conserve sodium and water and failure to excrete potassium, leading to hyponatremia and hyperkalemia. Hyponatremia induces lethargy, depression, and nausea and leads to the development of hypovolemia, hypotension, reduced cardiac output, and decreased renal perfusion. Hyperkalemia causes muscle weakness, hyporeflexia, and impaired cardiac conduction. Glucocorticoid deficiency causes decreased tolerance to stress, loss of appetite, and a mild normocytic normochromic anemia.

Clinical Presentation

There are no breed predilections, but the possibility of a hereditary factor has been suggested in some breeds, for example Standard Poodles, Bearded Collies, Portuguese Water Dogs, Nova Scotia Duck Tolling Retrievers, and Leonbergers. Hypoadrenocorticism appears to be a disease of the young and middle-aged dog, with an age range of 3 months to 14 years and a median age of 4–5 years. Approximately 70% of reported cases are female. The progression of adrenocortical insufficiency may be acute or chronic. Chronic hypoadrenocorticism is far more common than the acute disease in the dog.

Acute Primary Hypoadrenocorticism

The clinical appearance of the acute form is that of hypovolemic shock (adrenocortical crisis). The animal is usually found in a state of collapse or collapses when stressed. Other signs include a weak pulse, profound bradycardia, abdominal pain, vomiting, diarrhea, dehydration, hypotension, and hypothermia. Hypotension is present in approximately 90% of humans with primary hypoadrenocorticism and has certainly been documented in dogs with adrenal insufficiency and is likely to be common among the most severely affected cases. The condition is rapidly progressive and life-threatening. Aggressive fluid therapy will help most patients and allow more time to make a diagnosis.

Chronic Primary Hypoadrenocorticism

The clinical signs in the chronic form are often vague and nonspecific (Table 12.12). The diagnosis should be considered in any dog with a waxing and waning type of illness or who shows episodic weakness and collapse.

TABLE 12.12 Clinical signs of primary hypoadrenocorticism (in approximate decreasing order of frequency)

– Anorexia
– Lethargy/depression
– Vomiting
– Weakness
– Weight loss
– Waxing/waning course
– Dehydration
– Diarrhea
– Previous response to therapy
– Collapse
– Hypotension
– Hypothermia
– Slow capillary refill time
– Shaking
– Polyuria/polydipsia
– Melena
– Weak pulse
– Bradycardia (<60 bpm)

The most consistent clinical signs include anorexia, vomiting, lethargy, depression, and/or weakness. The severity of each sign can vary during the course of the disease and may be interspersed with periods of apparent good health, often following nonspecific veterinary therapy, usually consisting of corticosteroid medication and/or fluid administration. Other common clinical signs include dehydration, bradycardia, and weak femoral pulses. In a few cases, severe GI hemorrhage can occur resulting in profound anemia.

Differential Diagnosis

Chronic renal insufficiency, primary neuromuscular disorders, diseases that cause weight loss, weakness, anorexia, vomiting, and diarrhea.

Diagnosis

Laboratory Findings

The most common laboratory findings are listed in Table 12.13. Hematologic changes may include lymphocytosis, eosinophilia, and mild normocytic, normochromic nonregenerative anemia. However, these findings are not as consistent as those changes seen in hyperadrenocorticism. Normal or elevated eosinophil and lymphocyte counts in an ill animal with signs compatible with hypoadrenocorticism are significant because the expected response to stress is eosinopenia and lymphopenia. The mild anemia may not be obvious until the dog has been rehydrated, since dehydration may mask the anemia.

The most consistent laboratory findings in hypoadrenocorticism are prerenal azotemia, hypocholesterolemia, hyponatremia, and hyperkalemia. Blood urea and serum creatinine and phosphate concentrations are increased as a result of reduced renal perfusion and decreased glomerular filtration rate. Reduced renal perfusion results from hypovolemia, reduced cardiac output, and hypotension, which in turn result from chronic fluid loss through the kidneys, acute fluid loss through vomiting and/or diarrhea, and inadequate fluid intake.

TABLE 12.13 Laboratory findings in primary hypoadrenocorticism

Hematology
– Lymphocytosis
– Eosinophilia
– Relative neutropenia
– Anemia (usually a normocytic, normochromic, nonregenerative anemia but can be blood loss anemia associated with GI hemorrhage)
Biochemistry
– Azotemia
– Hyponatremia (<135 mmol/L [<135 mEq/L])
– Hyperkalemia (>5.5 mmol/L [5.5 mEq/L])
– Reduced sodium-to-potassium ratio (<25:1)
– Reduced bicarbonate and total CO_2 concentrations
– Hypochloremia
– Hypercalcemia
– Hypoglycemia
Urinalysis
– Specific gravity variable (but usually poorly concentrated 1.015–1.030)
Endocrine testing
– Low basal serum cortisol concentration with a failure to stimulate in response to ACTH administration
– Raised plasma ACTH concentration

Prerenal azotemia is usually associated with concentrated urine (SG >1.030), whereas the urine in primary renal failure is often isosthenuric or only mildly concentrated (1.008–1.025). However, some severe cases of hypoadrenocorticism may develop impaired concentrating ability because the chronic sodium loss reduces the renal medullary concentration gradient. Therefore, the laboratory findings may resemble those of chronic kidney disease. With adequate fluid therapy, the blood urea will return to normal in most cases of hypoadrenocorticism.

Sodium concentration is usually <135 mmol/L (<135 mEq/L) and potassium concentration >5.5 mmol/L (>5.5 mEq/L). The ratio of sodium to potassium may be more reliable than the absolute values. The normal ratio of sodium to potassium varies between 27:1 and 40:1, whereas in patients with hypoadrenocorticism, the ratio is commonly <25:1 and may be below 20:1; however, there are other medical disorders that can produce a similar serum electrolyte pattern. Blood samples must be collected before IV fluids are administered. Otherwise, the electrolyte concentrations can quickly return to normal. Despite this, approximately 10% of cases may have normal electrolyte concentrations (referred to by some authors as atypical hypoadrenocorticism) at the time of presentation, and these are usually thought to be early cases of hypoadrenocorticism.

Mild-to-moderate hypercalcemia is seen in about one-third of cases of hypoadrenocorticism, usually those dogs that are most severely affected by the disease. Hypercalcemia is caused by hemoconcentration, increased renal tubular reabsorption, and decreased glomerular filtration.

Cases of hypoadrenocorticism tend to develop hypoglycemia because glucocorticoid deficiency reduces glucose production by the liver and peripheral cell receptors become more sensitive to insulin. Severe hypoglycemia is uncommon, but the potential should remain a concern for the clinician.

Electrocardiographic Findings

Hyperkalemia impairs cardiac excitation and conduction, which can be assessed by an ECG examination (Figure 12.49). Although the ECG changes do not correlate directly with serum potassium levels, the guidelines shown in Table 12.14 have proved helpful. Changes in the ECG can also be used for monitoring the patient during treatment.

Radiographic Findings

Dogs with hypoadrenocorticism may show radiographic signs of hypovolemia, which include microcardia, decreased size of pulmonary vessels, and reduced size of

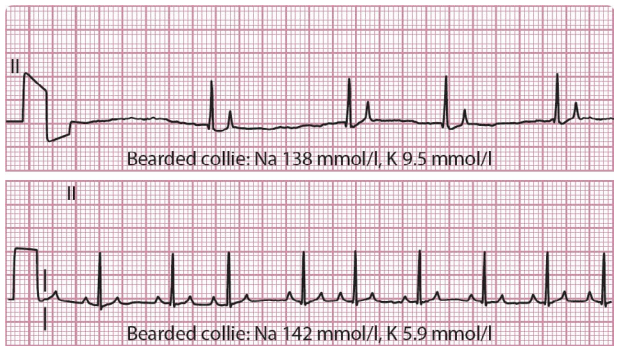

FIGURE 12.49 Electrocardiogram from a Bearded Collie in an Addisonian crisis. Note the slow ventricular rate and absence of P waves. The serum potassium was 9.5 mmol/L (9.5 mEq/L). Shown are the pre- and post-treatment electrocardiograms.

TABLE 12.14 ECG changes with hyperkalemia

>5.5 mmol/L (>5.5 mEq/L)—peaking of the T wave, shortening of the Q-T interval
>6.5 mmol/L (>6.5 mEq/L)—increased QRS duration
>7.0 mmol/L (>7.0 mEq/L)—P-wave amplitude decreased; P-R interval prolonged
>8.5 mmol/L (>8.5 mEq/L)—P wave absent, severe bradycardia (sinoventricular rhythm)

the caudal vena cava (Figure 12.50). The changes are not specific and only represent changes associated with hypovolemia and dehydration, irrespective of the cause. A few dogs with hypoadrenocorticism develop esophageal dilatation as a result of generalized muscle weakness, and this can be seen on thoracic radiographs (Figure 12.51).

Endocrine Testing

Basal cortisol has been shown to be a useful screening test for dogs with signs compatible with hypoadrenocorticism.

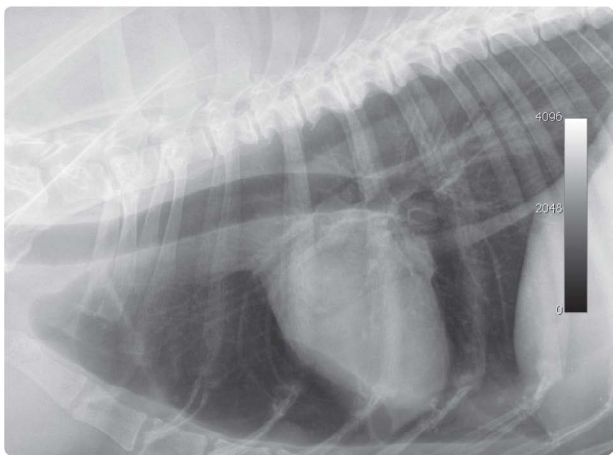

FIGURE 12.50 Lateral thoracic radiograph of a Bearded Collie with hypoadrenocorticism showing microcardia due to dehydration and hypovolemia.

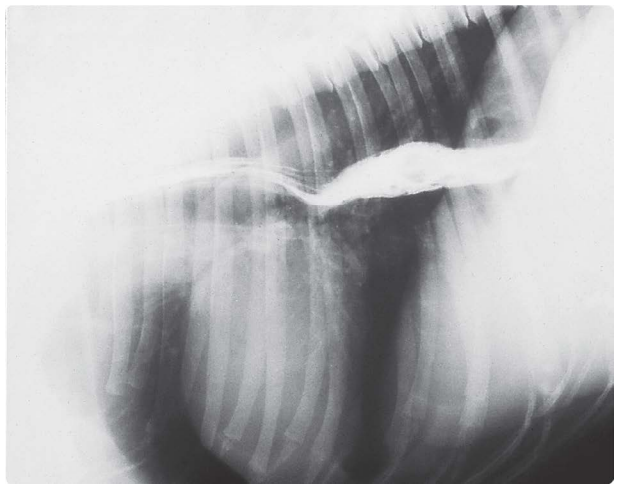

FIGURE 12.51 Lateral thoracic radiograph of a Dobermann with hypoadrenocorticism. A barium swallow has been performed to show a megaesophagus, which resolved following treatment of the hypoadrenocorticism.

The disease is unlikely when serum cortisol concentrations are >55 nmol/L. Basal cortisol concentrations <55 nmol/L cannot confirm a diagnosis of hypoadrenocorticism, and an ACTH stimulation test should be performed.

The ACTH stimulation test (Figure 12.52) is used to confirm the presence of hypoadrenocorticism; the protocol is described in Table 12.15. The IV preparation of ACTH (tetracosactin [cosyntropin in the United States]) should be used, as absorption by other routes cannot be relied on if the patient is collapsed or dehydrated. The ACTH stimulation test, however, does not distinguish

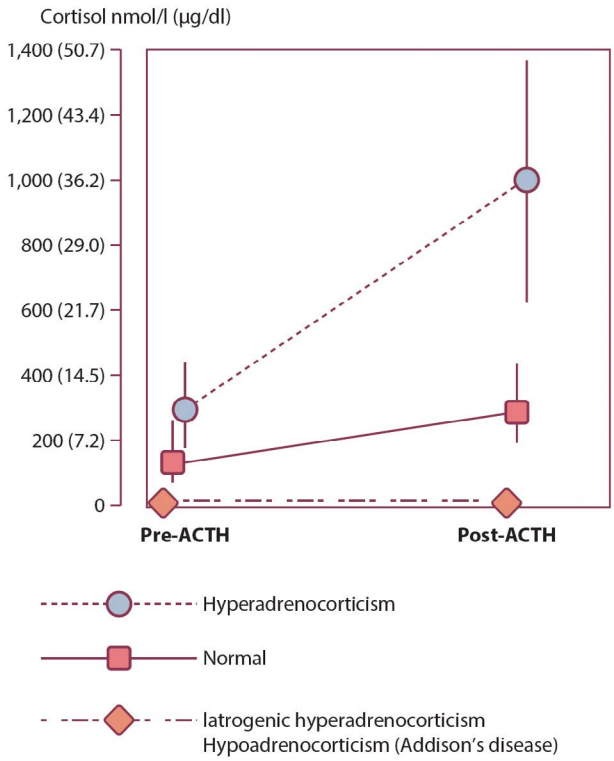

FIGURE 12.52 ACTH stimulation test.

TABLE 12.15 Protocol for endocrine testing for hypoadrenocorticism

ACTH stimulation test
Protocol – Collect 3 mL plasma or serum sample for basal cortisol concentration* – Inject 5 μg/kg of synthetic ACTH (tetracosactide [tetracosactrin]; Synacthen) IV in dogs and cats – Collect a second sample for cortisol concentration 30–60 minutes later
Interpretation – In normal dogs, pre-ACTH cortisol concentrations are usually between 20 and 250 nmol/L (0.7 and 9.1 μg/dL), with post-ACTH cortisol concentrations between 200 and 450 nmol/L (7.2 and 16.3 μg/dL) – Reduced responses to ACTH are also seen in primary hypoadrenocorticism (Addison's disease); usually both pre- and post-ACTH cortisol concentrations are <20 nmol/L (<0.7 μg/dL), but rarely the post-ACTH cortisol concentration may show some response up to 100 nmol/L (3.6 μg/dL)

* The recent administration of glucocorticoids, such as hydrocortisone, prednisolone, or prednisone, may result in elevated cortisol concentrations due to cross-reactivity in many cortisol assays. For this reason, these glucocorticoids should be withheld for at least 24 hours before testing. There is no cross-reactivity with dexamethasone, although dexamethasone will suppress cortisol concentrations in patients with an intact hypothalamic–pituitary–adrenal axis.

between primary and secondary hypoadrenocorticism. While aldosterone concentrations pre- and post-ACTH are not routinely measured, they may be useful in addition to cortisol concentrations in those cases with normal electrolyte concentrations (so-called atypical hypoadrenocorticism) to determine whether mineralocorticoid supplementation is likely to be indicated.

Plasma ACTH concentrations are required to differentiate primary and secondary hypoadrenocorticism. Plasma ACTH concentrations are usually below the detection range of the assay in secondary hypoadrenocorticism and markedly increased in primary hypoadrenocorticism.

Management

Acute Primary Hypoadrenocorticism

Aggressive IV fluid therapy using 0.9% saline should be used in the acute crisis to treat the hyperkalemia, which is life-threatening. Once stabilized, 0.45% saline may be used, since the serum sodium should not be increased by more than 8–12 mmol/L (8–12 mEq/L) per 24 hours in order to avoid causing central pontine myelinosis (osmotic demyelination). This is particularly important when the serum sodium level is <120 mmol/L (<120 mEq/L). The response to treatment is predictable and often dramatic, while acute kidney injury will slow down the improvement process. Glucose and insulin therapy or calcium administration are, therefore, not usually required for the treatment of hyperkalemia due to hypoadrenocorticism unless there are life-threatening ECG abnormalities such as atrial standstill or the appearance of sine waves. The serum potassium falls because of the dilution effect of the saline and the improvement in renal perfusion. The increased renal blood flow allows further excretion of potassium into the urine.

Glucocorticoid therapy should be used early in the treatment of the acute crisis. Once the animal has improved with saline and glucocorticoids, maintenance therapy with mineralocorticoids can be instigated (see ahead given in the text). Glucocorticoids of choice in the acute crisis include:

- Hydrocortisone sodium succinate (10 mg/kg IV repeated every 3–6 hours or a CRI of 0.5 mg/kg per hour)
- Prednisolone sodium succinate (5 mg/kg IV repeated every 3–6 hours)
- Dexamethasone sodium phosphate (0.5–1.0 mg/kg IV given once)

If plasma cortisol concentrations are to be measured for the diagnosis of hypoadrenocorticism, dexamethasone should be used, as the other preparations cross-react with cortisol in the assay.

Chronic Primary Hypoadrenocorticism (Maintenance Therapy)

Desoxycorticosterone pivalate, a long-acting ester of desoxycorticosterone, can be used for the replacement of mineralocorticoid deficiency in dogs and cats with primary hypoadrenocorticism. It only replaces mineralocorticoid hormones and, therefore, must be combined with glucocorticoid replacement therapy. The dose recommended starting dose is 2 mg/kg IM or SC every 28–30 days (lower doses and longer treatment intervals have been efficacious in some dogs). Fludrocortisone acetate is an oral synthetic adrenocortical steroid with mineralocorticoid effects. An initial dose of 15 μg/kg per day of fludrocortisone is given and serum electrolytes measured after 5–7 days. The dose rate should then be adjusted until the sodium and potassium concentrations are within the reference range. The daily maintenance dose required is usually between 15 and 30 μg/kg. The dose may have to be increased during the first 6–18 months of therapy, and the drug may need to be administered twice daily in some cases.

Prednisolone at a dose of 0.1–0.2 mg/kg daily should be sufficient for physiologic glucocorticoid replacement, although the dose may need to be tailored to the individual patient. Daily glucocorticoid supplementation is required when using desoxycorticosterone pivalate but not required after initial treatment with fludrocortisone acetate in the majority of cases, as fludrocortisone has some glucocorticoid activity. However, the owners of animals with hypoadrenocorticism treated with fludrocortisone should be given a supply of prednisolone tablets to be administered if the patient appears unwell.

Salt supplementation using salt tablets or salting the food may be instigated initially to help correct hyponatremia, but this can be gradually reduced and phased out as it is not usually required long term. However, dogs requiring unusually high doses of fludrocortisone may respond to oral salt and fewer fludrocortisone tablets.

The prognosis for primary hypoadrenocorticism is generally excellent providing owner education is adequate. Hypoadrenocorticism can occur in conjunction with other endocrine deficiencies, such as hypothyroidism, diabetes mellitus, and hypoparathyroidism or with other immune-mediated diseases, such as immune-mediated hemolytic anemia or thrombocytopenia.

SECONDARY HYPOADRENOCORTICISM

Definition/Overview

Secondary hypoadrenocorticism is associated with a deficiency of glucocorticoids caused by a deficiency in ACTH production and/or release. The production of mineralocorticoids, although reduced, generally remains adequate. Secondary hypoadrenocorticism occurs in both dogs and cats.

Etiology

Secondary hypoadrenocorticism can be associated with congenital panhypopituitarism (q.v.) or destructive lesions (e.g., nonfunctional tumors, hemorrhage, trauma, or hypophysitis) affecting the hypothalamus or anterior pituitary. More commonly, however, the condition is iatrogenic, with clinical signs occurring after the cessation of glucocorticoid therapy. In these cases, secondary hypoadrenocorticism is caused by prolonged suppression of ACTH secretion from glucocorticoid therapy. In the cat, secondary hypoadrenocorticism is also seen following prolonged megestrol acetate therapy.

Pathophysiology

Destructive lesions in the pituitary or hypothalamus may result in deficiencies of several pituitary hormones, including ACTH. Alternatively, exogenous glucocorticoid administration may suppress ACTH production and release. Both situations result in atrophy of the adrenal cortices and decreased glucocorticoid synthesis and release.

Clinical Presentation

The clinical signs are variable and may include depression, anorexia, occasional vomiting or diarrhea, a weak pulse, and sudden collapse when stressed. If the secondary hypoadrenocorticism is associated with cessation of glucocorticoid therapy, clinical signs of iatrogenic hyperadrenocorticism (Cushing's disease) are usually present.

Differential Diagnosis

Diabetic ketoacidosis, septic peritonitis, acute necrotizing pancreatitis.

Diagnosis

Diagnosis of secondary hypoadrenocorticism is based on a failure of the animal's cortisol concentrations to respond to ACTH stimulation and an endogenous plasma ACTH concentration below the detection range of the assay.

Management

Glucocorticoid replacement using prednisolone (0.1–0.2 mg/kg q.24 h.) is indicated for immediate correction of the clinical signs. Further treatment and the prognosis depend on the cause and whether glucocorticoid therapy can be eliminated.

HYPERADRENOCORTICISM (CUSHING'S DISEASE)

Definition/Overview

Hyperadrenocorticism is associated with excessive production or administration of glucocorticoids and is one of the most commonly diagnosed endocrinopathies in the dog. Hyperadrenocorticism is rare in the cat.

Etiology

Hyperadrenocorticism can be spontaneous or iatrogenic. Spontaneously occurring hyperadrenocorticism may be associated with inappropriate secretion of ACTH by the pituitary (pituitary-dependent hyperadrenocorticism [PDH]) or with a primary adrenal disorder (adrenal-dependent hyperadrenocorticism) (Figure 12.53a–c).

Pathophysiology

Pituitary-Dependent Hyperadrenocorticism

PDH accounts for 80%–85% of dogs and the majority of cats with naturally occurring hyperadrenocorticism. Excessive ACTH secretion results in bilateral adrenocortical hyperplasia and increased cortisol secretion. There is a failure of the negative feedback mechanism of cortisol on ACTH. However, episodic secretion of ACTH results in fluctuating cortisol concentrations that may at times be within the normal range. The presence of excessive cortisol secretion can be confirmed by measuring urine cortisol excretion over a 24-hour period.

Pathologic changes in PDH include microadenomas and macroadenomas of the corticotroph cells and a primary failure of the negative feedback response. Microadenomas are <1 cm in diameter. The incidence of corticotroph adenomas associated with PDH varies widely, probably because detection of small tumors requires careful microdissection, experience, and special stains. In one study using immunocytochemical staining, more than 80% of dogs with PDH were positive for pituitary adenomas. Macroadenomas are >1 cm in diameter, and only a small percentage of dogs have large corticotroph adenomas (Figure 12.54). These may compress the remaining pituitary and extend dorsally into the hypothalamus. However, they are generally slow growing and do not always

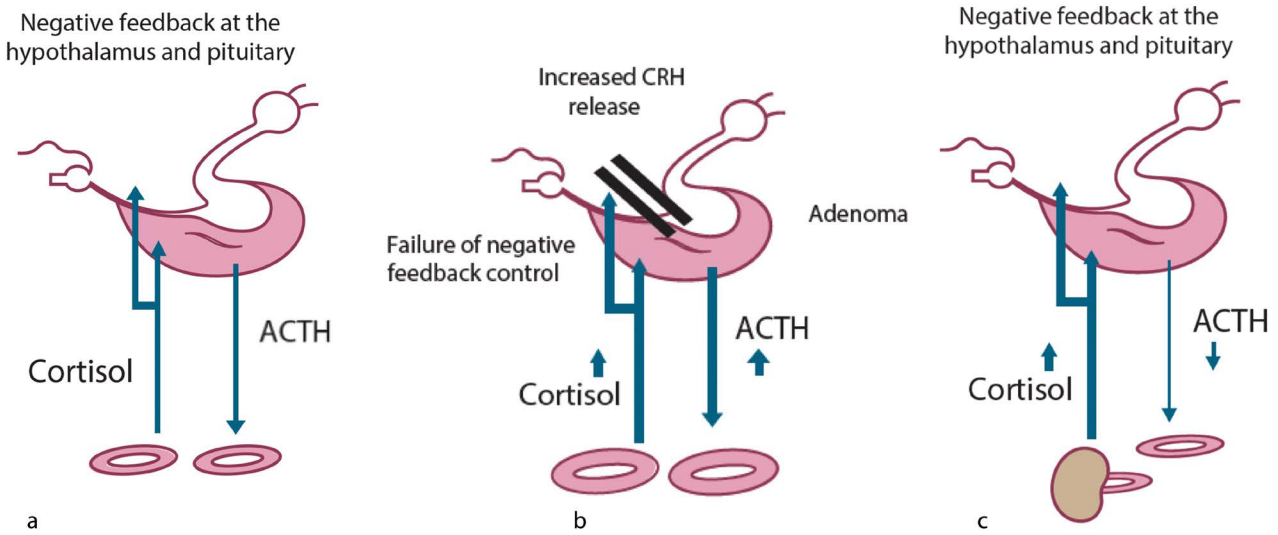

FIGURE 12.53 (a) Physiology of the hypothalamic–pituitary–adrenal axis. Corticotropin-releasing hormone (CRH) is released from the hypothalamus into the portal circulation which stimulates the release of adrenocorticotropic hormone (ACTH) from the corticotrophs in the anterior lobe of the pituitary. ACTH stimulates the release of cortisol from the adrenal cortex, which has a negative feedback control at the hypothalamus and pituitary level to regulate glucocorticoid release. **(b)** The hypothalamic–pituitary–adrenal axis in pituitary-dependent hyperadrenocorticism. Increased ACTH release, usually from a pituitary adenoma, results in symmetric enlargement of the adrenal cortices and increased capacity to release cortisol in response to the ACTH release. **(c)** The hypothalamic–pituitary–adrenal axis in adrenal-dependent hyperadrenocorticism. The adrenocortical tumor autonomously secretes cortisol, which has a negative feedback control at the hypothalamus and pituitary level halting the release of CRH and ACTH. The reduced release of ACTH leads to adrenocortical atrophy of the contralateral adrenal cortex as well as any remaining cortex in the affected adrenal gland.

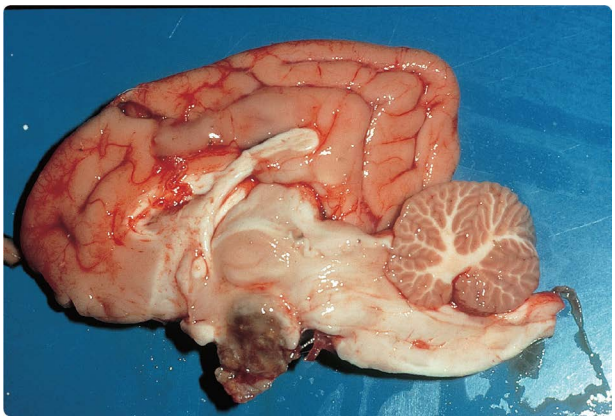

FIGURE 12.54 A large corticotroph adenoma associated with pituitary-dependent hyperadrenocorticism. The dog was successfully treated for 5 years while the tumor was gradually enlarging.

produce neurologic signs. Malignant pituitary tumors are rare.

The defect responsible for PDH unassociated with pituitary neoplasia is unknown. A primary failure of the negative feedback response by cortisol has been proposed. Others suspect an overproduction of CRH from the hypothalamus, which may cause diffuse hyperplasia of ACTH-producing cells in the anterior pituitary. From a clinical point of view, the precise pituitary pathology is not of great importance unless neurologic signs are present at the time of diagnosis or become apparent during the initial treatment.

Adrenal-Dependent Hyperadrenocorticism

The remaining 15%–20% of spontaneous cases of hyperadrenocorticism in dogs and cats are caused by unilateral or, occasionally, bilateral adrenal tumors, which can be benign or malignant. Adrenocortical adenomas are small (usually <4 cm in diameter), well-circumscribed tumors that do not metastasize and are not locally invasive. Approximately 50% are partially calcified. Adrenocortical carcinomas are usually larger, locally invasive, hemorrhagic, and necrotic. Tumor calcification also occurs in about 50% of dogs. The tumors frequently invade the phrenicoabdominal vein and caudal vena cava and metastasize to the liver, lung, and kidney.

In dogs, adrenocortical adenomas and carcinomas occur in approximately equal proportions. The cortex contiguous to the tumor and that of the contralateral gland will tend to become atrophied in the presence of functional adenomas and carcinomas (Figure 12.55). This is important if the tumor is removed surgically, as postoperatively the animal may not be able to secrete sufficient glucocorticoids. Function of the zona glomerulosa should not be affected.

Clinical Presentation

Any breed of dog can develop hyperadrenocorticism, but Poodles, Dachshunds, Bichon Frise, Spaniels, and small terriers (e.g., Yorkshire Terrier, Jack Russell Terrier, and Staffordshire Bull Terrier) appear more at risk of developing PDH. Adrenocortical tumors occur more frequently in larger breeds of dog, with approximately

FIGURE 12.55 A large adrenal tumor invading the kidney from a dog with adrenal-dependent hyperadrenocorticism.

FIGURE 12.56 A 10-year-old Yorkshire Terrier with hyperadrenocorticism showing a pot-bellied appearance and bilaterally symmetrical alopecia.

50% of affected dogs weighing >20 kg. No breed predisposition has been recorded in cats.

PDH is usually a disease of the middle-aged to older dog, with an age range of 2–16 years and a median age of 7–9 years. Dogs with adrenal-dependent hyperadrenocorticism tend to be older, with a range of 6–16 years and a median age of 10–11 years. There is no significant difference in sex distribution in PDH; however, female dogs are three times more likely to develop adrenal tumors than males. Affected dogs usually develop a classic combination of clinical signs associated with increased glucocorticoid levels. These are listed in Table 12.16 in approximate decreasing order of frequency. Some dogs, however, may only show a few characteristic signs rather than the classic array of clinical signs. Hyperadrenocorticism has an insidious onset and is slowly progressive over many months or even years. Many owners consider the early signs as part of the normal aging process of their dog. In a few cases, clinical signs may be intermittent with periods of remission and relapse, and in other cases, there may be rapid onset and progression of clinical signs.

Polydipsia, defined as water intake in excess of 100 mL/kg body weight per day, and polyuria, defined as urine production in excess of 50 mL/kg body weight per day, are seen in virtually all cases of hyperadrenocorticism. Excessive thirst, nocturia, and/or urination in the house are usually noted by owners. The polydipsia occurs secondary to the polyuria, which is only partially responsive to water deprivation.

TABLE 12.16 Clinical signs of hyperadrenocorticism (in approximate decreasing order of frequency)

- Polydipsia and polyuria
- Polyphagia
- Abdominal distension
- Liver enlargement
- Muscle wasting/weakness
- Lethargy, poor exercise tolerance
- Skin changes
- Alopecia
- Panting
- Hypertension
- Persistent anestrus or testicular atrophy
- Calcinosis cutis
- Myotonia neurologic signs

Increased appetite is common, but most owners often assess this as a sign of good health. However, a voracious appetite and scavenging or stealing food may give rise to concern, especially if the dog previously had a poor appetite. Polyphagia is assumed to be a direct effect of glucocorticoids.

A pendulous abdomen or pot-bellied appearance is very common in hyperadrenocorticism, but it may be so gradual that owners fail to recognize its significance (Figure 12.56). The abdominal distension is associated with redistribution of fat to the abdomen, liver enlargement, and abdominal muscle wasting and weakness.

The gradual onset of lethargy and poor exercise tolerance are usually considered by most owners to be compatible with aging. Only when muscle weakness is severe, as reflected by an inability to climb stairs or jump into the car, does the owner become concerned. Lethargy, excessive panting, and poor exercise tolerance are probably an expression of muscle wasting and weakness. Apart from the development of a pendulous abdomen, decreased muscle mass may be noted around the limbs, over the spine, or over the temporal region. Muscle weakness is the result of muscle wasting caused by protein catabolism.

Occasionally, dogs with hyperadrenocorticism develop myotonia, characterized by persistent active muscle contractions that continue after voluntary or involuntary stimuli (Figure 12.57). All limbs may be affected, but the signs are usually more severe in the hind limbs. Animals with myotonia walk with a stiff, stilted gait. The affected limbs are rigid and rapidly return to extension after being passively flexed. Spinal reflexes are difficult to elicit because of the rigidity, but pain sensation is normal. The muscles are usually slightly hypertrophied rather than being atrophied, and a myotonic dimple can be elicited by percussion of the affected muscle. Bizarre high-frequency discharges are noted on electromyography.

FIGURE 12.57 An 11-year-old Poodle with hyperadrenocorticism showing rigidity associated with myotonia.

FIGURE 12.59 A close-up of comedones around the nipple of a Poodle with hyperadrenocorticism.

FIGURE 12.58 Thin, inelastic skin on the ventral abdomen of a Dachshund with hyperadrenocorticism.

FIGURE 12.60 Stretching of an abdominal scar and striae on the ventral abdomen of a Boxer with hyperadrenocorticism.

The skin, particularly over the ventral abdomen, becomes thin and inelastic (Figure 12.58). Elasticity can be assessed clinically by tenting the skin between the thumb and forefinger. In the normal dog, the skin will flow back to a smooth contour, but in hyperadrenocorticism, it remains tented. Striae can form as a result of this inelasticity. The abdominal veins are prominent and easily visible through the thin skin. There is often excessive surface scale and comedones, caused by follicular plugging, are seen, especially around the nipples (Figure 12.59). Hyperpigmentation of the skin is rare in canine hyperadrenocorticism.

Protein catabolism, causing atrophic collagen, also leads to excessive bruising following either venipuncture or other minor trauma. Wound healing is extraordinarily slow, presumably because of inhibition of fibroblast proliferation and collagen synthesis. Healing wounds often undergo dehiscence, and even old scars may start to break down (Figure 12.60).

Calcinosis cutis is a frequent finding in biopsy material from the skin; however, clinical evidence of calcinosis cutis is less common. The gross appearance can vary, but the predilection sites are the neck, axilla, ventral abdomen, and inguinal areas (Figure 12.61). Calcinosis cutis usually appears as a firm, slightly elevated, white or cream plaque surrounded by a ring of erythema. Large plaques tend to crack, become secondarily infected, and develop a crust containing white powdery material. The exact pathogenesis is unknown, but plasma calcium and phosphorus concentrations are usually normal. Mineralization of the soft tissues may be seen at other

FIGURE 12.61 Calcinosis cutis (arrow) and comedones on the ventral abdomen of a Poodle with hyperadrenocorticism.

FIGURE 12.62 Bilaterally symmetrical alopecia in a Wirehaired Dachshund with hyperadrenocorticism.

sites (e.g., the bronchial walls and kidneys) on radiographic examination.

Thinning of the hair coat, leading to bilaterally symmetrical alopecia, is frequently seen with hyperadrenocorticism and occurs because of the inhibitory effect of cortisol on the anagen or growth phase of the hair cycle. The remaining hair is dull and dry because it is in the telogen or resting phase of the hair cycle. The alopecia is nonpruritic and affects mainly the flanks, ventral abdomen and chest, perineum, and neck. The head, feet, and tail are usually the last areas to be affected (Figure 12.62). The coat color is often lighter than normal.

Systemic hypertension and associated proteinuria may be found in >80% of cases with untreated hyperadrenocorticism, with 46% of classified as severe hypertension (>180 mmHg). In the majority of cases, the degree of hypertension is moderate and not associated with clinical signs; however, hypertension-induced blindness due to intraocular hemorrhage and retinal detachment and ischemic arterial infarcts have occasionally been reported.

Entire bitches with hyperadrenocorticism usually cease to cycle. The length of anestrus (often years) indicates the duration of the disease process. In the intact male, both testes become soft and flabby. Anestrus and testicular atrophy occur due to the negative feedback effect of high concentrations of cortisol on the pituitary, which also suppresses secretion of gonadotropic hormones.

Although uncommon at the time of presentation, a few cases develop neurologic signs associated with large, expanding functional pituitary tumors. The most common manifestations of a pituitary tumor are vague neurological signs such as lethargy, mental dullness, depression, disorientation, loss of learned behavior, and anorexia rather than more specific neurological signs such as aimless wandering, head pressing, circling, ataxia, blindness, anisocoria, and seizures. More often, however, neurologic signs develop during initial treatment of PDH with trilostane or mitotane. This is thought to involve removal of the negative feedback of cortisol, which can cause some pituitary tumors to enlarge rapidly, resulting in edema and increased intracranial pressure.

Differential Diagnosis

Causes of polydipsia/polyuria (Table 12.4), liver disease, hypothyroidism, Sertoli cell tumor, ovarian imbalance.

Diagnosis

Laboratory Findings

The main hematologic, biochemical, and urinalysis findings are listed in Table 12.17. The most consistent hematologic finding is a stress leukogram with a relative and absolute lymphopenia (<1.5 × 10^9/L [<1.5 × 10^3/μL]) and eosinopenia (<0.2 × 10^9/L [<0.2 × 10^3/μL]). Lymphopenia is most likely the result of steroid lymphocytolysis and/or redistribution of T cells to lymphoid tissues, and the eosinopenia results from bone marrow sequestration of eosinophils. A mild-to-moderate neutrophilia and monocytosis may be present, and it is thought that excessive glucocorticoids result in decreased capillary margination and diapedesis and increased release from the bone marrow. The red cell count is usually normal, although mild polycythemia may occasionally be noted. Platelet counts may also be elevated. These findings are thought to result from stimulatory effects of glucocorticoids on the bone marrow.

Glucocorticoids, both endogenous and exogenous, induce a specific hepatic isoenzyme of ALP in the dog. The increase in serum ALP is commonly 5–40 times the normal level and is perhaps one of the most reliable indicators of hyperadrenocorticism. Measurement of the specific steroid-induced isoenzyme of ALP has been used for more accurate assessment of elevated serum ALP activity. A marked increase in serum ALP is rarely seen in cats with hyperadrenocorticism because they do not

TABLE 12.17 Laboratory findings in hyperadrenocorticism

Hematology
– Lymphopenia (<1.5 × 10^9/L [<1.5 × 10^3/μL])
– Eosinopenia (<0.2 × 10^9/L [<0.2 × 10^3/μL])
– Neutrophilia
– Monocytosis
– Erythrocytosis
Biochemistry
– Increased ALP (often markedly elevated); dog only
– Increased ALT
– High normal fasting blood glucose; rarely diabetic except for the cat where the majority of the cases are diabetic
– Decreased blood urea nitrogen
– Increased cholesterol (>8 mmol/L [>309 mg/dL])
– Hypertriglyceridemia
– Lipemia
– Increased bile acid
Urinalysis
– Urine SG <1.015
– Urinary tract infection
– Increased urine protein-to-creatinine ratio
– Glycosuria (<10% of canine cases)
Other findings
– Low T4 concentrations
– Subnormal T4 response to TSH or TRH stimulation
– Increased parathyroid hormone concentrations

possess a steroid-induced isoenzyme and have the ability to clear serum of excess ALP. ALT is commonly elevated in hyperadrenocorticism, but the increase is usually only mild and is believed to result from liver damage caused by swollen hepatocytes due to glycogen storage. Blood glucose is usually in the high normal range, but about 10% of canine cases will develop overt diabetes mellitus. The gluconeogenic effect of glucocorticoids results in insulin antagonism and subsequent development of pancreatic islet cell exhaustion. Cats appear to be more prone to developing hyperglycemia and overt diabetes. In contrast to the dog, where polydipsia and polyuria are among the earliest clinical signs of hyperadrenocorticism, the onset of polydipsia and polyuria is delayed in the cat and coincides with the development of moderate-to-severe hyperglycemia and glycosuria. Hyperadrenocorticism should be suspected in any cat that requires high daily insulin doses to control the hyperglycemia and glycosuria.

Blood urea is usually below normal due to the continual urinary loss associated with glucocorticoid-induced diuresis. Serum creatinine concentrations also tend to be in the low to normal range. Cholesterol and lipid concentrations are usually increased due to glucocorticoid stimulation of lipolysis. Cholesterol is usually >8 mmol/L (>309 mg/dL), but this is not a specific finding as cholesterol is also raised in hypothyroidism, diabetes mellitus, chronic liver disease, and chronic renal disease, all of which may be differential diagnoses. Lipemia is important as it can interfere with the accurate assessment of a number of laboratory parameters. Resting and postprandial bile acid concentrations may show a mild-to-moderate increase in some cases of hyperadrenocorticism due to steroid hepatopathy.

The SG of the urine is usually <1.015 and is often hyposthenuric (<1.010) provided water has not been withheld. Dogs with hyperadrenocorticism can concentrate their urine if deprived of water, but their concentrating ability is usually reduced. Urinary tract infection is common and occurs in about half the cases of hyperadrenocorticism; however, it does not result in typical signs of cystitis due to the anti-inflammatory effects of excess glucocorticoids. Proteinuria, defined as a urine protein-to-creatinine ratio of ≥1.0, is present in over 40% of untreated cases of hyperadrenocorticism. Glycosuria is present in the 10% of cases with diabetes mellitus.

Basal thyroxine concentrations are decreased in about 70% of dogs with hyperadrenocorticism. This is, in part, due to inhibition of TRH and reduced pituitary secretion of TSH. Excess cortisol, however, may also alter thyroid hormone binding to plasma proteins and enhance the metabolism of thyroid hormone. The response to stimulation by TSH usually parallels that of normal dogs, but thyroxine concentrations both before and after stimulation with TSH are subnormal. Endogenous canine TSH concentrations are usually low but may be increased in some cases, mimicking the changes seen in hypothyroidism.

Glucocorticoids are known to increase urinary calcium excretion in canine hyperadrenocorticism. In order to maintain normal circulating concentrations of calcium, parathyroid hormone (PTH; parathormone) concentrations are increased in >80% of cases of hyperadrenocorticism.

TABLE 12.18 Radiologic signs of hyperadrenocorticism

Abdominal radiographs
- Liver enlargement
- Good radiographic contrast
- Pendulous abdomen or pot-bellied appearance
- Calcinosis cutis/soft tissue mineralization
- Distended bladder
- Cystic or renal calculi
- Adrenal enlargement/calcification
- Osteopenia

Thoracic radiographs
- Tracheal and bronchial wall calcification
- Pulmonary metastasis from adrenocortical carcinoma
- Osteopenia
- Pulmonary interstitial mineralization (rare)
- Congestive heart failure (rare)
- Pulmonary thromboembolism (rare)

Diagnostic Imaging

Radiography

Radiographic examination of the thorax and abdomen is advisable in all cases of suspected or proven hyperadrenocorticism. Although positive diagnostic information is only obtained in the small number of cases in which adrenal enlargement can be detected, the number and the frequency of radiologic changes consistent with hyperadrenocorticism provide a useful aid to diagnosis. In addition, survey radiographs may reveal significant concurrent disease. The most common radiologic signs of hyperadrenocorticism are listed in Table 12.18.

Hepatomegaly is the most consistent radiographic finding in hyperadrenocorticism. Good radiographic contrast permits easy identification of the abdominal structures because of the large deposits of intra-abdominal fat. Hepatomegaly may be mild to severe, and the ventral lobe borders vary in shape between distinctly rounded and sharply wedge shaped. Abdominal distension and a pendulous abdomen are usually very obvious on the recumbent lateral projection (Figure 12.63). Hepatomegaly

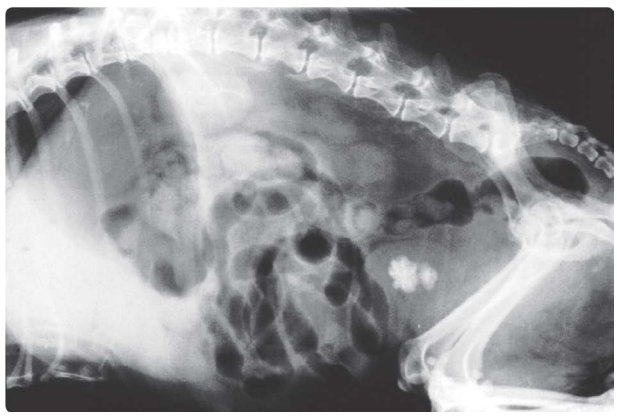

FIGURE 12.63 Lateral abdominal radiograph of a case of hyperadrenocorticism. Cystic calculi are also present.

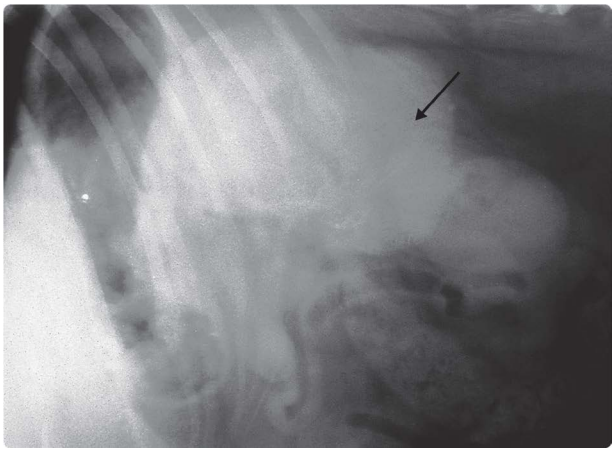

FIGURE 12.64 Lateral abdominal radiograph of a 9-year-old German Shepherd Dog with a right adrenal tumor (arrow).

and a pendulous abdomen are the most consistent radiographic findings in cats with hyperadrenocorticism.

Adrenal enlargement is the least common finding on abdominal radiographs. Gross enlargement is suggestive, although not diagnostic, of an adrenocortical carcinoma. Unilateral mineralization in the region of an adrenal gland suggests the possibility of an adrenal tumor (Figure 12.64). Both adrenocortical adenomas and carcinomas can become calcified. Radiography of the abdomen not infrequently demonstrates calcification of the adrenal glands in normal older cats and is not associated with any functional abnormality.

Calcinosis cutis tends to have a nodular mineralization pattern, whereas calcification in the fascial planes (e.g., just dorsal to the thoracolumbar spine) tends to be linear. Mineralization may also be seen in the renal pelvis, liver, gastric mucosa, and abdominal aorta.

A grossly distended urinary bladder may be seen radiographically even when the animal has been allowed to urinate prior to the radiographic examination. Cystic calculi may also be present and are usually associated with urinary tract infection. Occasionally, the impression of osteopenia is gained from a distinct reduction in radiographic density of the lumbar vertebral bodies relative to the vertebral endplates. Tracheal and bronchial wall calcification is frequently seen radiographically in cases of hyperadrenocorticism. However, calcification of these structures can be seen in animals as part of the normal aging process and is not considered to be a highly significant finding.

The thoracic radiographs should also be examined for evidence of pulmonary metastases from an adrenocortical carcinoma, CHF, osteoporosis of the thoracic spine, or pulmonary thromboembolism. The latter is a rare complication of hyperadrenocorticism and may be suspected when the radiographic signs include pleural effusion, increased diameter and blunting of pulmonary arteries, decreased vascularity of the affected lobes, and overperfusion of the unobstructed pulmonary vasculature. However, in some cases of pulmonary thromboembolism, the radiographs may reveal no abnormalities.

FIGURE 12.65 Ultrasonogram of a Boxer with adrenal hyperplasia due to PDH.

Ultrasonography

Abdominal ultrasonography is frequently used to examine the adrenal glands. The challenge for the ultrasonographer is to distinguish consistently between normal and hyperplastic adrenal glands, since the diagnosis of adrenal hyperplasia is somewhat subjective. Measurement of the thickness (ventrodorsal dimension) of the adrenal gland has been shown to be more sensitive than either the length or width of the gland. A thickness of >7.5 mm for the left adrenal gland would be suggestive of adrenal hyperplasia (Figures 12.65 and 12.66). If both adrenal glands are of similar size and normal shape in a dog or cat with hyperadrenocorticism, it confirms the disease is PDH.

Abdominal ultrasonography can also detect adrenocortical tumors (Figure 12.67). Adrenal masses are diagnosed by the location of the mass and the clinical signs exhibited by the animal. However, the appearance of adrenal nodules and masses is not specific for the underlying pathology. The differential diagnosis for solid nodules or masses within the adrenal gland includes adrenocortical adenoma, adrenocortical carcinoma, pheochromocytoma, myelolipoma, metastasis, nodular hyperplasia, and granuloma. Adrenal masses exceeding 2 cm in diameter generally predict benign or malignant neoplasia rather than hyperplasia.

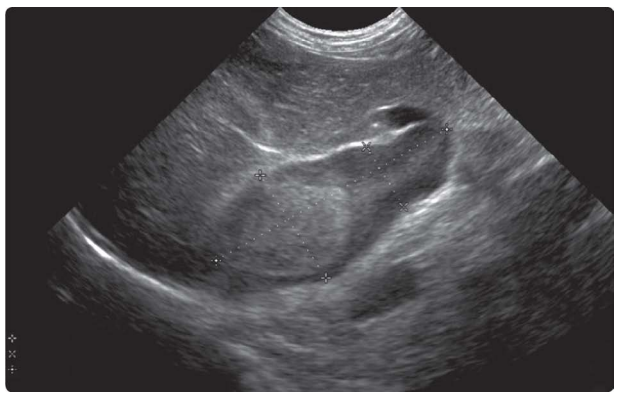

FIGURE 12.66 Ultrasonogram showing right-sided adrenal enlargement with nodular hyperplasia. The dog was being treated with trilostane, which can cause treatment-associated adrenomegaly.

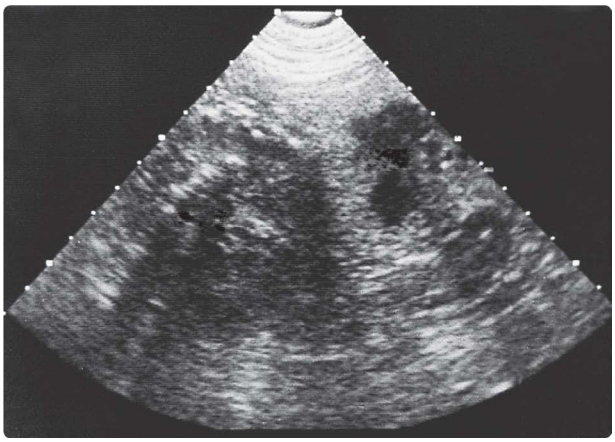

FIGURE 12.67 Ultrasonogram of a large adrenal tumor adjacent to the left kidney in a Rottweiler with adrenal-dependent hyperadrenocorticism.

Percutaneous ultrasound-guided fine-needle aspiration of adrenal masses is relatively safe and provides useful cytological information regarding the origin of the tumor (cortical or medullary), although it cannot distinguish between benign or malignant lesions. There is a propensity for malignant adrenal tumors to invade nearby vessels and surrounding tissues; therefore, a thorough ultrasonographic examination of adjacent vessels and tissues should be performed (Figures 12.68 and 12.69a, b). Mineralization is frequently associated with benign and malignant adrenocortical tumors in the dog, and acoustic shadowing may aid in localizing the adrenal tumor. If an adrenal mass is identified, the liver should also be examined ultrasonographically for evidence of hepatic metastases.

CT and MR Imaging

Cross-sectional imaging using CT and MR imaging has proved helpful in the diagnosis of adrenal tumors, adrenal hyperplasia, and pituitary tumors (Figure 12.70), but these techniques are more expensive.

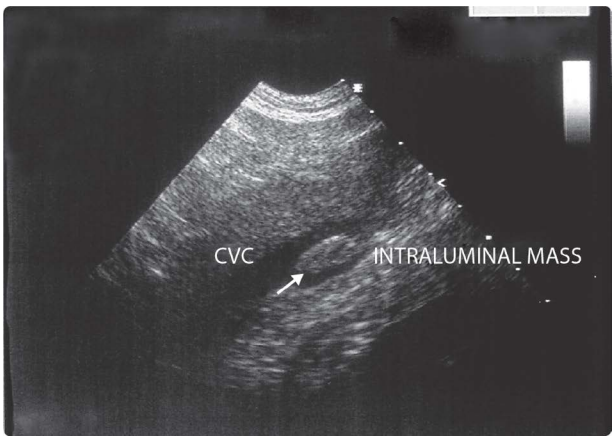

FIGURE 12.68 Ultrasonogram of an adrenal tumor (arrow) invading the caudal vena cava in a Labrador Retriever with adrenal-dependent hyperadrenocorticism.

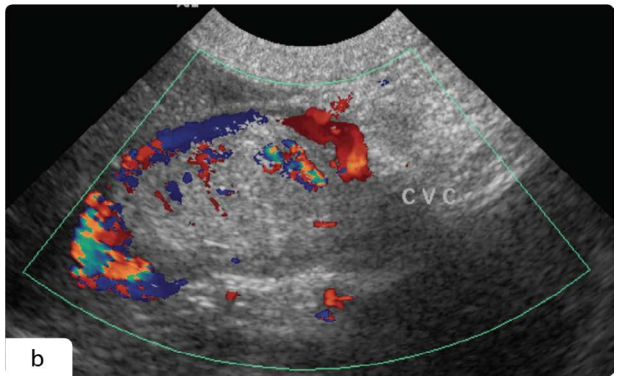

FIGURE 12.69 A plain abdominal ultrasound examination **(a)** and a flow Doppler evaluation **(b)** showing invasion of the caudal vena cava by a malignant adrenocortical carcinoma.

Abdominal and thoracic CT with contrast should be performed before adrenalectomy, as the presence of vascular or tissue invasion and distant metastasis can be more readily identified with CT than with any other imaging modality.

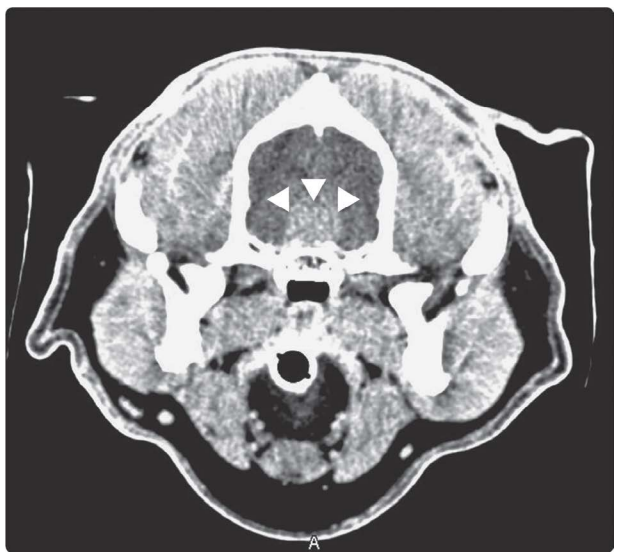

FIGURE 12.70 A contrast CT scan of a cushingoid dog showing a large pituitary macroadenoma (arrowheads) expanding deep into the diencephalon. (*Courtesy of M. Schaer.*)

Endocrine Screening Tests

A presumptive diagnosis of hyperadrenocorticism can be made from clinical signs, physical examination, routine laboratory tests, and diagnostic imaging findings, but the diagnosis must be confirmed by either an ACTH stimulation test or a low-dose dexamethasone suppression test (LDDST); however, the urinary corticoid-to-creatinine ratio has also proved useful in certain situations (see Table 12.19). A single resting or basal plasma or serum cortisol determination is of limited diagnostic value because of the overlap in cortisol concentrations obtained from normal and abnormal disease states.

ACTH Stimulation Test

The ACTH stimulation test (see Figure 12.52) is the best screening test for distinguishing spontaneous from iatrogenic hyperadrenocorticism. It reliably identifies about 85% of dogs with PDH but only about 50% of those dogs with adrenal-dependent hyperadrenocorticism. It is a simple test to perform and the only one that directly documents excessive production of glucocorticoids by the adrenal cortex. The information gained also provides a baseline for monitoring trilostane or mitotane therapy. However, the ACTH stimulation test does not reliably differentiate adrenal-dependent hyperadrenocorticism from PDH. A diagnosis of hyperadrenocorticism should not be excluded on the basis of a normal ACTH response if the clinical signs are compatible with the disease. Occasionally, an animal under chronic stress may develop some degree of adrenal hyperplasia, which produces an abnormal or equivocal ACTH response result. The author has seen this in a

TABLE 12.19 Protocols for endocrine screening tests for hyperadrenocorticism

ACTH stimulation test
Protocol – Collect 3 mL plasma or serum sample for basal cortisol concentration* – Inject 5 µg/kg of synthetic ACTH (tetracosactide [tetracosactrin]; Synacthen**) IV in dogs and cats – Collect a second sample for cortisol concentration 30–60 minutes later
Interpretation – In normal dogs, pre-ACTH cortisol concentrations are usually between 20 and 250 nmol/L (0.7 and 9.1 µg/dL), with post-ACTH cortisol concentrations between 200 and 450 nmol/L (7.2 and 16.3 µg/dL) – An exaggerated response (post-ACTH cortisol concentrations >600 nmol/L [>21.7 µg/dL]) is expected in dogs and cats with hyperadrenocorticism. The ACTH stimulation test reliably identifies more than 50% of dogs with adrenal-dependent hyperadrenocorticism and about 85% of dogs with PDH. Exaggerated responses to ACTH may also be seen in chronic illness (e.g., uncontrolled diabetes mellitus). – The ACTH stimulation test is the best screening test for distinguishing spontaneous hyperadrenocorticism from iatrogenic Cushing's disease where reduced responses to ACTH are recorded due to adrenocortical suppression as a result of long-term or high-dose glucocorticoid administration
Low-dose dexamethasone suppression test (LDDST)
Protocol – Collect 3 mL plasma or serum sample for cortisol determination – Inject 0.01 mg/kg of dexamethasone IV – Collect a second sample for cortisol concentration 4 hours later and a third sample 8 hours after dexamethasone administration
Interpretation – A plasma or serum cortisol concentration exceeding 40 nmol/L (1.5 µg/dL) at 8 hours is regarded as diagnostic for hyperadrenocorticism. The LDDST reliably identifies all dogs with adrenal-dependent hyperadrenocorticism and about 90% of PDH. However, stress during therapy may cause animals without hyperadrenocorticism to break the suppressive effect of dexamethasone. – Cortisol concentrations at 0 and 4 hours are not required for the diagnosis of hyperadrenocorticism but may be informative in the differential diagnosis. Suppression of the cortisol concentration to <30 nmol/L (<1.1 µg/dL) at 4 hours with a rebound escape of suppression at 8 hours would be suggestive of PDH. Cases of adrenal-dependent hyperadrenocorticism do not show significant suppression of cortisol at 4 hours; however, up to 40% of dogs with PDH will not show suppression at 4 hours either.
Urine cortisol-to-creatinine ratio
Protocol – Urine (5 mL) is collected in the morning for cortisol and creatinine measurements. It is preferable for the dog to be at home for this test so that it is as little stressed as possible. The urine cortisol-to-creatinine ratio is determined by dividing the urine cortisol concentration (in nmol/L) by the urine creatinine concentration (in µmol/L).
Interpretation – The reference ratio for normal dogs is $<10 \times 10^6$. The urine cortisol-to-creatinine ratio is increased above the normal ($>10 \times 10^6$) in dogs with hyperadrenocorticism. However, the ratio is also increased in many dogs with nonadrenal illness. Therefore, while this simple test appears highly sensitive in detecting hyperadrenocorticism in dogs, it is not specific. The test does provide a good screening test for hyperadrenocorticism, and values in the normal range make a diagnosis of hyperadrenocorticism highly unlikely.

* The recent administration of glucocorticoids, such as hydrocortisone, prednisolone, or prednisone, may result in elevated cortisol concentrations due to cross-reactivity in many cortisol assays. For this reason, glucocorticoids should be withheld for at least 24 hours before testing. There is no cross-reactivity with dexamethasone, but dexamethasone will suppress cortisol concentrations in patients with an intact hypothalamic–pituitary–adrenal axis.

** Sold in the United States as cosyntropin (Cortrosyn, Amphastar Pharmaceuticals).

number of severe systemic diseases (e.g., uncontrolled diabetes mellitus and pyometra) and has documented a normal ACTH response after treatment in each case. The ACTH response test is not as reliable for diagnosing this disorder in the cat.

Low-Dose Dexamethasone Suppression Test

The LDDST (Figure 12.71) is more reliable than the ACTH stimulation test in confirming hyperadrenocorticism, since the results are diagnostic in most adrenal-dependent cases and in 90% of dogs with PDH. However, it is not as useful as the ACTH stimulation test for the detection of iatrogenic hyperadrenocorticism. It is also affected by more variables, takes 8 hours to complete, and does not provide pretreatment information that may aid in monitoring the effects of trilostane or mitotane therapy. The LDDST, like the ACTH stimulation test, does not reliably differentiate PDH from adrenal-dependent hyperadrenocorticism.

Interpretation of the results of a LDDST must be based on the laboratory's normal range of cortisol values for the dose and preparation of dexamethasone administered. If the dose of dexamethasone fails to suppress adequately circulating cortisol concentrations in a dog with compatible clinical signs, a diagnosis of hyperadrenocorticism is confirmed. While basal and 8-hour post-dexamethasone samples are most important for interpretation of the test, one or more samples taken at intermediate times (for example, 2, 4, or 6 hours) during the test period may also prove helpful. If a plasma cortisol concentration determined 2–6 hours after dexamethasone injection is suppressed to <40 nmol/L (<1.5 µg/dL), while the 8-hour sample shows escape from cortisol suppression, then a diagnosis of PDH can be made. While some cases of PDH will not suppress at any stage during a LDDST, any suppression during the 8-hour period essentially rules out a diagnosis of adrenal-dependent hyperadrenocorticism. This test is variable and thus not always reliable for diagnosing hyperadrenocorticism in the cat.

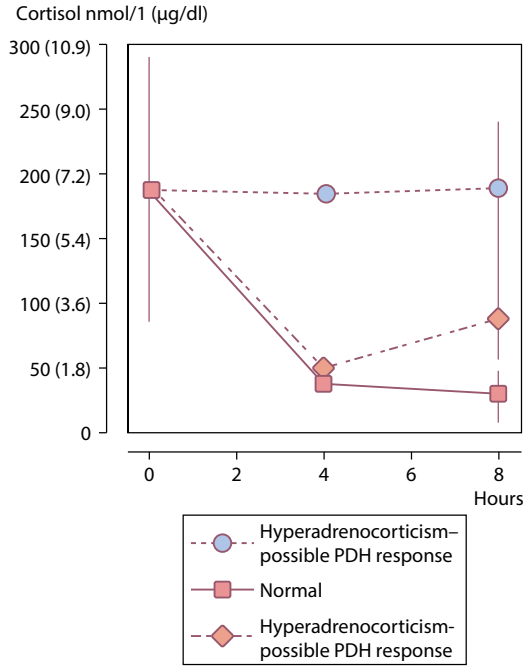

FIGURE 12.71 Low-dose dexamethasone suppression test.

Other Screening Tests

Evaluation of urinary corticoid-to-creatinine ratio rather than the more laborious 24-hour urinary corticoid excretion has been shown to be a simple and valuable screening test that is highly sensitive in detecting hyperadrenocorticism; however, it lacks specificity and is affected by many variables. The test does provide useful information in that values within the reference range make a diagnosis of hyperadrenocorticism highly unlikely.

Endocrine Tests to Differentiate the Cause of Hyperadrenocorticism

The ability to differentiate between PDH and adrenal-dependent hyperadrenocorticism is important in order to provide a better prognosis and the most effective method of management for the disease. An accurate test is therefore required to differentiate pituitary from adrenal causes of hyperadrenocorticism. The protocols for such tests are listed in Table 12.20.

Plasma ACTH Concentration

The determination of plasma ACTH concentrations in the dog provides a reliable test for differentiating pituitary and adrenal causes of hyperadrenocorticism providing sample handling is meticulous. Dogs with adrenal tumors have undetectably low endogenous ACTH concentrations, whereas cases of PDH have normal or high concentrations.

TABLE 12.20 Protocols for endocrine tests to differentiate the cause of hyperadrenocorticism

High-dose dexamethasone suppression test
– Collect 3 mL serum or plasma sample for cortisol determination
– Inject 0.1 mg/kg (although some authors recommend 1.0 mg/kg, especially for cats; see ahead given in the text) of dexamethasone IV
– Collect two post-dexamethasone samples, one at 4 hours and a second at 8 hours after the dexamethasone
Plasma endogenous ACTH concentration
– Blood (5 mL) is collected into a cooled plastic EDTA tube and centrifuged at 4°C immediately
– The plasma should then be harvested and stored frozen (at < –20°C) in a plastic tube
– Samples must be transported to the laboratory frozen and kept frozen until assayed (best not send over the weekend or holiday because of inherent delays)
– Stringent and meticulous sample handling is crucial, since hormone activity in the plasma will reduce rapidly, resulting in falsely low values and incorrect interpretation
– The endogenous ACTH assay must be validated for use in dogs, otherwise the test may provide spurious results that could be misleading

High-Dose Dexamethasone Suppression Test

The high-dose dexamethasone suppression test was the most commonly used test for differentiating the cause of hyperadrenocorticism, but it is less accurate than abdominal ultrasonography or plasma ACTH measurements. This test may be indicated in cases where the diagnosis of hyperadrenocorticism has been established by a screening test, but the differentiation between adrenal-dependent hyperadrenocorticism and PDH has not been determined. The high dose of dexamethasone inhibits pituitary ACTH secretion through negative feedback in PDH, thus suppressing serum cortisol concentrations by 50% or more by 4 hours. Adrenocortical tumors are autonomous; therefore, serum cortisol is not suppressed at 4 hours if an adrenocortical tumor is present. However, approximately 20%–30% of PDH cases will not suppress with this test, which limits the utility of the test for distinguishing PDH from ADH cases. In addition, the test does not differentiate adrenocortical adenomas from adrenocortical carcinomas. This test has been recommended for diagnosing hyperadrenocorticism in the cat, but the high dose of dexamethasone can cause or worsen concurrent diabetes mellitus.

Management

Treatment of Pituitary-Dependent Hyperadrenocorticism

Trilostane Therapy

Trilostane (Vetoryl, Dechra) is a short-acting, synthetic steroid analog that competitively inhibits 3 beta-hydroxysteroid dehydrogenase, thus interfering with adrenal steroid biosynthesis. It has been successfully used to treat hyperadrenocorticism in dogs with relatively few adverse effects.

Treatment is initiated at 2–6 mg/kg once daily with food. Although this once-daily treatment regimen is usually effective, there is an increasing body of evidence and experience that starting treatment with lower doses given twice daily results in faster control, a lower rate of adverse events, and lower total daily doses.

The dosage should be adjusted on basis of the clinical signs and the results of the ACTH stimulation test carried out 4 hours after the administration of trilostane. Following the introduction of trilostane therapy, patients should be re-examined, and an ACTH stimulation performed at 10 days and then at 4 weeks, 12 weeks, and thereafter every 3 months or more frequently if problems occur. If the post-ACTH cortisol concentration is <20 nmol/L (<0.7 μg/dL), trilostane should be stopped for 5–7 days and then restarted at a lower dose. If the post-ACTH cortisol concentration is >120 nmol/L (>4.3 μg/dL), the dose of trilostane should be increased. If the post-ACTH cortisol concentration is between 20 and 120 nmol/L (0.7 and 4.3 μg/dL) and the patient appears clinically well controlled, the dose should remain unchanged. If, however, the patient's clinical signs appear poorly or only partially controlled, trilostane may need to be given twice daily.

Minor adverse effects such as mild lethargy, diarrhea, or decreased appetite may occur soon after starting therapy and are usually transient and respond to a reduction in dose. If more serious adverse effects such as vomiting, severe or hemorrhagic diarrhea, or severe depression develop, trilostane should be stopped and prednisolone replacement therapy instigated. Acute adrenal necrosis has been associated with death in a few cases. Hypoadrenocorticism has also been associated with trilostane therapy. The median survival time for dogs with PDH treated with trilostane is 22 months. Trilostane is effective for treating cats with PDH. The starting dose for cats is 1.0 mg/kg per day, and this is subsequently titrated to effect.

Mitotane Therapy

Mitotane (o'p'DDD; Lysodren, Bristol Laboratories) was formerly the treatment of choice for PDH, but many clinicians have since switched to trilostane as their preferred treatment. During its evaluation as an insecticide, mitotane was discovered to have adrenocorticolytic effects. It selectively destroys the zona fasciculata and zona reticularis while tending to preserve the zona glomerulosa.

Mitotane (Bristol Meyers-Squibb) therapy should only be considered once the diagnosis of hyperadrenocorticism has been confirmed. Because of its powerful effects, it should never be used empirically. Before treatment is instigated, the patient's daily water consumption should be measured over at least two consecutive 24-hour periods. If the water intake and appetite are not increased, baseline lymphocyte and eosinophil counts and an ACTH stimulation test are required to monitor the response to therapy.

The author prefers to hospitalize the patient for the initial course of treatment, although many clinicians have dogs treated by their owners at home, with the owners doing the necessary monitoring. Mitotane is given orally with food at a dose rate of 50 mg/kg per day. Concomitant glucocorticoid treatment is not advised, although if the dog is being treated at home, the owner should be given a small supply of prednisolone tablets. Daily mitotane therapy should be continued until any of the following changes are noted:

- The water intake of a polydipsic dog drops to below 60 mL/kg per day.
- The dog takes longer to consume its meal than before treatment or stops eating completely.
- The dog vomits or has diarrhea.
- The dog becomes listless and depressed.

The initial course of mitotane is then stopped and the dog put on maintenance therapy (see ahead given in the text). The importance of close monitoring of the patient during this period cannot be overemphasized.

Mitotane therapy is comparatively safe, and the side effects that commonly occur (e.g., anorexia, vomiting, or diarrhea) are rarely serious providing they are noticed early so that the mitotane can be withheld. Some of the problems occasionally encountered during

treatment are summarized in Table 12.21, together with their suggested management. Mitotane is ineffective in dogs being treated with phenobarbital because the latter drug will enhance mitotane hepatic metabolism.

The majority of dogs with PDH require between 7 and 14 days of treatment, with an average of 10 days, before water consumption drops to below 60 mL/kg per day. If the dog is not polydipsic or polyphagic, treatment should continue until the lymphocyte count is above 1.0×10^9 cells per liter or the eosinophil count is above 0.3×10^9 cells per liter. However, the best method of evaluating treatment is by use of the ACTH stimulation test. In adequately treated cases, the basal and ACTH stimulated serum cortisol concentrations should be <120 nmol/L (<4.3 µg/dL). If the serum cortisol concentrations exceed 200 nmol/L (7.2 µg/dL) with ACTH stimulation, further mitotane should be administered until the cortisol concentrations are adequately suppressed. A few dogs respond in 2–3 days, and occasionally others require more than 60 consecutive days of treatment. It is important to emphasize that each dog must be treated as an individual if treatment is to be successful.

Having produced sufficient adrenocortical damage with daily mitotane treatment, it is important to continue therapy, albeit at a lower dose. Otherwise, the zona glomerulosa will regenerate a hyperplastic zona fasciculata and zona reticularis, and the clinical signs will recur. Mitotane is given at a dose of 50 mg/kg per week with food. Cases that are well controlled may sleep for a few hours after the weekly dose, and for that reason, it is often recommended that the treatment is given in the evening. More profound depression or weakness requires re-evaluation and possibly a reduction of the maintenance dose. Failure to control the polydipsia may require an increased dose of mitotane (Table 12.21).

Treated dogs should be re-examined 6–8 weeks after completion of the initial therapy, unless there are any problems. Marked improvement should be noted at this time. The most obvious response is a rapid reduction in water intake, urine output, and appetite, and this is usually obvious at the end of the initial course of therapy. Muscle strength and exercise tolerance improve over the first 3–4 weeks. Skin and hair coat changes take longer, and the progress is variable. The skin and alopecia may deteriorate markedly before improving; alternatively, there may be a gradual and noticeable resolution of the dermatologic signs. Although improvement should be noted at 8 weeks, the skin and hair coat may not return to normal for 3–6 months (Figures 12.72 and 12.73). A few dogs have dramatic changes in coat color following successful therapy.

Re-examination every 3–6 months is recommended for the remainder of the animal's life. Relapses and episodes of overdosage do occur, and reassessment of adrenal reserve by ACTH stimulation testing is indicated. Relapses may require a short course of daily mitotane therapy or an increase in the maintenance dosage. Overdosage requires reassessment by an ACTH stimulation test and a reduction of the maintenance dose. The median survival time of treated dogs is 30 months with a range of a few days to over 7 years.

TABLE 12.21 Possible problems arising from mitotane therapy and their management

Problem	Management
Vomiting or anorexia within the first 3 days of treatment (gastric irritation)	– Discontinue mitotane and reassess patient – Divide dose and give 2–4 times per day
Profound weakness, depression, and anorexia usually around 4th or 5th day of treatment	– Discontinue mitotane and reassess patient – Check sodium and potassium levels and institute prednisolone (0.2 mg/kg per day) – Reassess ACTH stimulation test – Start maintenance therapy with mitotane
Acute onset of neurologic signs (due to sudden expansion of the pituitary tumor)	– Reassess patient – Continue mitotane unless the dog is anorexic, vomiting, or depressed – Give prednisolone (2.0 mg/kg per day) or dexamethasone (0.1 mg/kg per day) and decrease dose slowly once neurologic signs have resolved
Failure to resume normal water intake	– Recheck urinalysis and blood urea – Reassess ACTH stimulation test – Increase mitotane by 50% if post-ACTH cortisol level is >200 nmol/L (>7.2 µg/dL)
Failure to regrow hair	– Reassess ACTH stimulation test – Determine baseline T4 – Increase mitotane by 50% if post-ACTH cortisol level is >200 nmol/L (>7.2 µg/dL) – If <120 nmol/L (<4.3 µg/dL), perform a TRH/TSH stimulation test
Excessive depression or weakness related to weekly maintenance therapy	– Reassess patient – Check sodium and potassium levels – Repeat ACTH stimulation test – If cortisol level post-ACTH is <15 nmol/L (<0.5 µg/dL), reduce maintenance dose or give every other week

FIGURE 12.72 Uncontrolled hyperadrenocorticism prior to mitotane therapy. An 8-year-old Cocker Spaniel before medical treatment.

FIGURE 12.73 Response to mitotane therapy. Four months post-mitotane treatment in the same 8-year-old Cocker Spaniel.

Mitotane has been shown to be ineffective in the cat because of its rapid hepatic metabolism.

Other Therapeutic Options for Pituitary-Dependent Hyperadrenocorticism

- L-deprenyl (selegiline hydrochloride [Somerset Pharmaceuticals]) is a monoamine oxidase inhibitor that inhibits ACTH secretion by increasing dopaminergic tone to the hypothalamic–pituitary axis. The use of L-deprenyl for treatment of hyperadrenocorticism has been evaluated in dogs. Although the effectiveness of treatment is variable, one major advantage of L-deprenyl is the lack of any severe adverse effects, including iatrogenic hypoadrenocorticism. Treatment is initiated at a dosage of 1 mg/kg daily. If an inadequate response is seen after 2 months, the dosage is increased to 2 mg/kg per day. If this dosage also proves ineffective, alternative treatment is required. However, if the treatment with L-deprenyl is effective, daily treatment should be continued for the remainder of the dog's life. Response to treatment is evaluated by the resolution of clinical signs, since there is minimal measurable endocrinological improvement. More than 50% of dogs fail to respond adequately to L-deprenyl.
- Ketoconazole (LGM Pharma) has a reversible inhibitory effect on glucocorticoid synthesis while having minimal effects on mineralocorticoid production. Ketoconazole has been used effectively to control hyperadrenocorticism in dogs, but it is not effective in cats. However, ketoconazole is not uniformly efficacious in dogs, and between one-third and one-half of all dogs treated fail to respond adequately. The initial recommended dosage of ketoconazole is 10 mg/kg q.12 h. for 14 days. Alternatively, treatment is initiated at 5 mg/kg q.12 h. for the first 7 days to assess drug tolerance, then increased to 10 mg/kg. The efficacy of the initial 14-day course of treatment is determined by an ACTH stimulation test. To ensure adequate control of hyperadrenocorticism, both the pre- and post-ACTH serum cortisol concentrations must be lowered into the basal reference range. If the serum cortisol concentrations remain above this range, the dosage is increased to 15 mg/kg q.12 h., and an ACTH response test repeated in 14 days.
- Bilateral adrenalectomy has been employed successfully, but it involves the risk of putting an ill animal with a compromised immune system and poor wound healing through a difficult surgical procedure. Bilateral adrenalectomy used to be the recommended treatment for feline hyperadrenocorticism despite its accompanying postoperative morbidity. Patients treated by this approach require lifelong treatment for hypoadrenocorticism. More recently, trilostane has been found to be an effective treatment option for treating PDH in the cat.
- Pituitary irradiation is indicated for dogs with neurological signs associated with pituitary tumors. CT or MRI of the brain is required to plan the treatment protocol. Radiotherapy using megavoltage irradiation from a linear accelerator is required to penetrate to the depth of the pituitary gland without seriously injuring overlying soft tissues. Most treatment protocols involve the administration of 40–50 Gy in 3–4 Gy fractions, since it has been shown that increasing the number of fractions and reducing the dose per fraction, whilst keeping the total dose at the low end of the range, can give increased survival times. There is often a dramatic response, although in some cases improvement takes several weeks. The resolution of neurological signs parallels the reduction in size of the tumor, which can continue to decrease for a year or more after the completion of the radiotherapy. Reduction in ACTH secretion by the tumor is less predictable, occurring in only about 20% of cases and, if it does occur, may not be evident for 6–12 months after therapy. Therefore, medical management of hyperadrenocorticism with trilostane or mitotane is indicated, at least initially.
- Hypophysectomy has been successfully performed in the dog for the treatment of PDH using the transsphenoidal approach. The operation is technically difficult and should only be carried out by a surgeon with considerable skill and experience of the technique and the immediate aftercare. Otherwise, it is associated with high morbidity and mortality.

Treatment of Adrenal-Dependent Hyperadrenocorticism

Dogs diagnosed as having adrenal-dependent hyperadrenocorticism carry the best prognosis if the tumor can be completely removed surgically, although mitotane (for dogs) or trilostane (for dogs and cats) therapy is also recommended.

Unilateral Adrenalectomy

This procedure requires considerable expertise because of the complex anatomy. Preoperative staging using ultrasonography and radiography or CT is essential. Adrenalectomy is best performed via a ventral midline laparotomy (Figure 12.74). It should only be performed by experienced surgeons, as perioperative mortality is high. Postoperative support is important, as the contralateral adrenal cortex will be atrophic and unable to respond to the stress. Replacement glucocorticoid and mineralocorticoid therapy may, therefore, be required

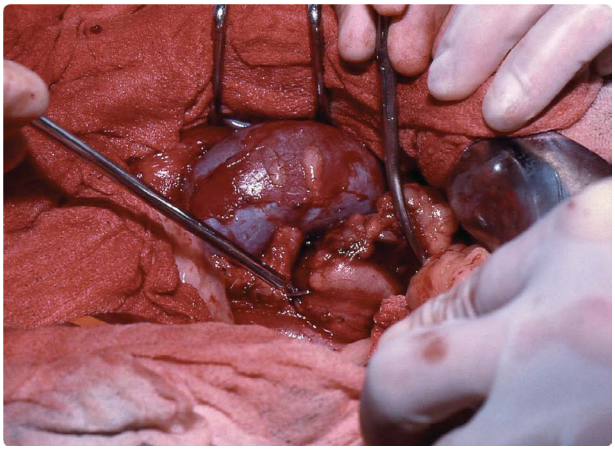

FIGURE 12.74 Surgical view of an adrenocortical carcinoma that had a spontaneous bleed into the retroperitoneal space. (*Courtesy of M. Schaer.*)

for 7–10 days postoperatively. Even with experienced surgeons, there is a high morbidity and mortality rate, and perioperative mortality can be as high as 30%. The median survival time is around 2 years, with some dogs surviving for longer than 4 years. Heparin has been recommended for some dogs in the perioperative period because of hypercoagulability.

Mitotane Therapy

Mitotane is effective and relatively safe in dogs with adrenal-dependent hyperadrenocorticism. Dogs with adrenal tumors, however, tend to be more resistant to mitotane than dogs with PDH. Generally, dogs with adrenal-dependent hyperadrenocorticism require higher daily induction doses (50–75 mg/kg per day) and a longer period of induction (>14 days) than dogs with PDH. Frequent monitoring of treatment by ACTH stimulation testing is important to ensure adequate control of the hyperadrenocorticism. Maintenance doses are also generally higher (75–100 mg/kg per week) and, again, frequent monitoring of the cortisol response to ACTH stimulation is required to maintain optimal control of the disease. Adverse effects of treatment are similar to those described for PDH. Those dogs requiring higher dose rates tend to be more prone to adverse effects. The adrenal tumor and metastatic mass will often reduce in size due to the cytotoxic effects of mitotane, but in other cases, the tumor will continue to grow despite increasing doses of mitotane. The median survival time is 11 months, with a range from a few weeks to more than 5 years.

Trilostane Therapy

Trilostane is also effective and relatively safe in dogs and cats with adrenal-dependent hyperadrenocorticism. The dose of trilostane needs to be tailored to the individual patient with an adrenal tumor on the basis of the results of regular ACTH stimulation testing. There is a tendency for the dose to increase as the tumor continues to grow. Survival times similar to mitotane therapy (in dogs) for adrenal tumors have been reported.

PRIMARY HYPERALDOSTERONISM

Definition/Overview

Primary hyperaldosteronism is characterized by excessive autonomous secretion of aldosterone from one or both adrenal glands resulting in clinical signs relating to hypertension and/or hypokalemia. It is a disease of middle-aged to old-aged cats, with a mean age of 12 years. There is no breed or sex predisposition. The condition is rare in dogs.

Etiology

Adrenocortical tumors are the most common cause of primary hyperaldosteronism in cats. There is an approximately equal incidence of adenomas and carcinomas, with the right and left adrenal glands being affected with almost equal frequency. Rarely, bilateral tumors have been reported. More recently, primary hyperaldosteronism has been recognized in association with adrenocortical hyperplasia.

Pathophysiology

Increased autonomous secretion of aldosterone leads to excessive sodium and water retention, with resultant hypertension, and excessive potassium secretion leading to hypokalemia. The elevated plasma aldosterone and increased circulating blood volume have a negative feedback effect on renin release, resulting in reduced plasma renin activity.

Clinical Presentation

The most common presenting sign is muscular weakness due to the hypokalemia. This can range from mild weakness and lethargy to severe generalized weakness, ataxia, depressed spinal reflexes, and flaccidity. Ventroflexion of the neck may be noted (Figure 12.75). Blindness, which may be sudden or gradual in onset, is due to systemic hypertension and usually results from retinal detachment and intraocular hemorrhage. Systemic hypertension can also lead to left ventricular hypertrophy and cardiac murmurs. Impaired renal function is common, and many cats also exhibit polydipsia and polyuria.

FIGURE 12.75 A Burmese cat showing ventroflexion of the neck due to hypokalemia.

TABLE 12.22 Differential diagnosis of feline hypokalemia

Decreased intake
– Anorexia
– Potassium-deficient intravenous fluids
– Potassium-deficient diet
Potassium translocation
– Metabolic alkalosis
– Insulin administration
– Diabetic ketoacidosis
– Periodic hypokalemia (Burmese cats)
Increased gastrointestinal loss
– Vomiting
– Diarrhea
Increased renal loss
– Polyuria/osmotic diuresis
– Chronic kidney disease
– Acute kidney injury (polyuric phase)
– Diuretic administration (loop or thiazide diuretics)
– Renal tubular acidosis
– Primary hyperaldosteronism
– Liver failure
– Congestive heart failure

Note: Hypokalemia in some diseases may have more than one mechanism.

Differential Diagnosis

The differential diagnoses of hypokalemia and hypertension are given in Tables 12.22 and 12.23, respectively.

Diagnosis

The most consistent routine laboratory finding in primary hyperaldosteronism is hypokalemia. Some cases may also have an increased plasma creatine kinase concentration caused by hypokalemic myopathy with rhabdomyolysis. The diagnosis of primary hyperaldosteronism is based on demonstrating the presence of an adrenal tumor or bilateral adrenal hyperplasia together with an elevated plasma aldosterone concentration with a concomitant decreased plasma renin activity.

Adrenal tumors can usually be identified using ultrasonography (Figure 12.76). Abdominal ultrasonography can also be used to identify metastases and evidence of invasion of surrounding structures, particularly the caudal vena cava. CT and MRI have also been used to identify these changes.

Plasma aldosterone concentrations are usually raised to between 2 and 30 times the reference range. Although ACTH stimulation has been described when measuring plasma aldosterone, there is no clear evidence of improved diagnostic performance following ACTH stimulation. It should be noted, however, that raised aldosterone concentrations are not pathognomonic for primary hyperaldosteronism and that diseases that activate the renin–angiotensin–aldosterone system (RAAS), especially chronic kidney disease and CHF, will cause secondary hyperaldosteronism.

TABLE 12.23 Differential diagnosis of feline hypertension

– Chronic kidney disease
– Hyperthyroidism
– Diabetes mellitus
– Hyperaldosteronism
– Hyperadrenocorticism
– Pheochromocytoma
– Chronic anemia
– Liver disease

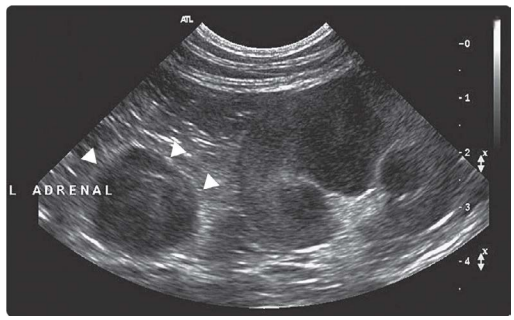

FIGURE 12.76 Ultrasonogram of an adrenal tumor (arrowheads) in a Domestic Longhair cat with primary hyperaldosteronism.

In primary hyperaldosteronism, plasma aldosterone is raised, which exerts a negative feedback effect on renin, resulting in reduced plasma renin activity, resulting in a raised plasma aldosterone-to-renin ratio as distinct from secondary hyperaldosteronism where the RAAS has been activated resulting in a lowered plasma aldosterone-to-renin ratio. Adrenal hyperplasia can only be diagnosed by demonstrating a raised plasma aldosterone-to-plasma renin activity ratio. When renin assays are unavailable, the combination of clinical signs and elevated serum aldosterone concentration in the absence of any demonstrable adrenal mass is highly suggestive of adrenocortical hyperplasia as the cause of the hyperaldosteronism.

Management

Initial therapy should be aimed at controlling hypokalemia and hypertension. Hypokalemia can be treated with potassium supplementation and the competitive aldosterone antagonist spironolactone. Hypertension can usually be controlled with amlodipine, telmisartan, and beta-blockers. Treatment with these drugs can be continued for life, and survival times from 4 months to 2.5 years have been reported. Medical management is the recommended treatment for cases associated with adrenal hyperplasia.

Although unilateral adrenalectomy is the treatment of choice for adrenal tumors, perioperative mortality is relatively high, with intraoperative and postoperative hemorrhage the most common cause of death. However, those patients who survive surgery frequently live for more than a year.

PHEOCHROMOCYTOMA

Definition/Overview

Tumors of the adrenal medulla (pheochromocytomas) are rare in dogs and have only been reported rarely in cats. They are usually unilateral, benign, slow-growing

tumors that may reach a considerable size. Rarely, they are malignant and may invade the caudal vena cava or metastasize to lung, liver, or bone. Pheochromocytomas may secrete excessive amounts of catecholamines.

Pathophysiology

The physiologic effects of catecholamines secreted by pheochromocytomas account for many of the diverse clinical signs. The presence of the tumor mass may also contribute to the clinical presentation.

Clinical Presentation

Clinical signs of a pheochromocytoma may relate to an abdominal mass compressing adjacent structures or to the secretion of catecholamines. Clinical signs related to tumor size might include a palpable abdominal mass, ascites, and hindlimb weakness. Secretion of catecholamines may be intermittent or persistent and can cause hypotension or hypertension, tachycardia, tachyarrhythmias with episodic weakness and trembling, head pressing, or seizures. Epistaxis and retinal hemorrhages may also be noted. The clinical signs vary depending on whether an excess of epinephrine or norepinephrine is predominant. In some cases, there may be no reported clinical signs, and an adrenal mass is found incidentally, usually during abdominal ultrasonography.

Differential Diagnosis

Causes of episodic weakness (Table 12.24).

TABLE 12.24 Differential diagnosis of episodic weakness

Cardiovascular disorders
- Bradyarrhythmia
- Tachyarrhythmia
- Congenital heart disease (e.g., aortic or pulmonic stenosis, tetralogy of Fallot, reverse shunting PDA)
- Acquired heart disease (e.g., valvular, myocardial, pericardial)
- Heartworm disease (dirofilariasis, angiostrongylosis)
- Vasovagal syncope
- Vasodilation
- (Aortic) thromboembolism

Respiratory disorders
- Laryngeal paralysis
- Brachycephalic airway disease
- Tracheal collapse
- Severe coughing
- *Filaroides osleri*
- Pulmonary disease
- Pleural effusions
- Thoracic masses
- Hematologic disorders

Anemia
- Myeloproliferative disorders
- Polycythemia
- Hyperviscosity syndrome
- Hemoglobinopathies
- Pyrexia of unknown origin
- Orthopedic disorders

TABLE 12.24 (*Continued*)

Degenerative joint disease, particularly hips or stifles
- Polyarthritis—various types

Neuromuscular disorders
- Myasthenia gravis
- Polymyositis
- Hereditary myopathy of Labrador Retrievers
- Sex-linked muscular dystrophy—Irish Terriers, Golden
- Retrievers
- Myotonia in Chow Chows, Staffordshire Terriers
- Malignant hyperthermia
- Mitochondrial myopathies
- Exertional myopathy (rhabdomyolysis)

Neurologic disorders
- Congenital or acquired spinal disorders, including wobbler syndrome
- Epilepsy (various causes)
- Vestibular disease
- Cerebellar disorders
- Thiamine deficiency
- Congenital disorders (e.g., hydrocephalus)
- Acquired disorders (e.g., old dog encephalitis, cerebral vascular accident, tumors)
- Lysosomal storage diseases
- Giant axonal neuropathy
- Progressive axonopathy—Boxer
- Tetanus
- Botulism
- Narcolepsy/cataplexy—Dobermann, Poodle, Labrador Retriever
- Generalized tremor
- Jack Russell Terrier ataxia
- Scottie cramp—also in the Norwich and Jack Russell Terrier, Dalmatian
- Episodic falling in the Cavalier King Charles Spaniel

Metabolic disorders
- Hepatic encephalopathy
- Uremic encephalopathy
- Hyperglycemia
- Hypoglycemia
- Hyponatremia
- Hyperkalemia
- Hypokalemia
- Hypercalcemia
- Hypocalcemia
- Hypermagnesemia
- Hypomagnesemia
- Acidosis
- Hyperthermia (heatstroke)
- Hypoxia
- Shock

Endocrine disorders
- Insulinoma
- Hyperadrenocorticism—myotonia
- Hypoadrenocorticism
- Diabetic ketoacidosis
- Hypoparathyroidism
- Hypothyroidism
- Pheochromocytoma
- Primary hyperaldosteronism
- Diabetic ketoacidosis

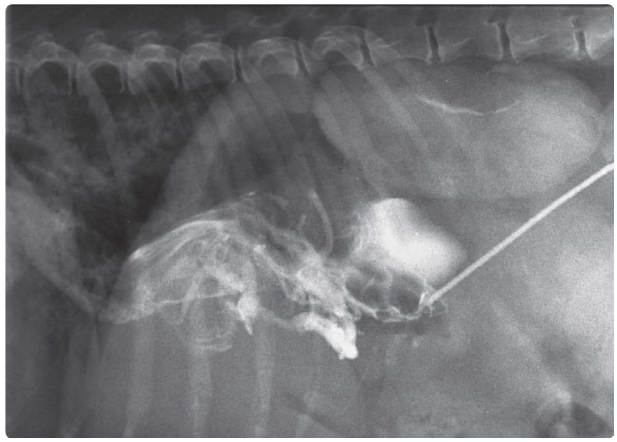

FIGURE 12.77 Contrast venogram radiographic study showing abnormal dispersion of the contrast medium in the posterior vena cava. This was caused by a pheochromocytoma invading the vessel. (*Courtesy of M. Schaer.*)

Diagnosis

A diagnosis of pheochromocytoma should be suspected in any unexplained case of episodic weakness. Radiographic and ultrasonographic examinations will often reveal a mass in the adrenal area, although cross-sectional imaging with CT or MRI have also been used (Figures 12.77–12.79). Confirmation of functionality requires quantification of plasma catecholamines and their metabolites or urinary excretion of catecholamines and their metabolites, but these tests are not widely available, and the results can be unreliable, if the tumor only intermittently secretes catecholamines.

Abdominal and thoracic CT with contrast should be performed before adrenalectomy, as the presence of vascular or tissue invasion and distant metastasis can be more readily identified with CT than with any other imaging modality.

Management

Surgical removal (Figures 12.80 and 12.81) is the treatment of choice, but this should only be performed by

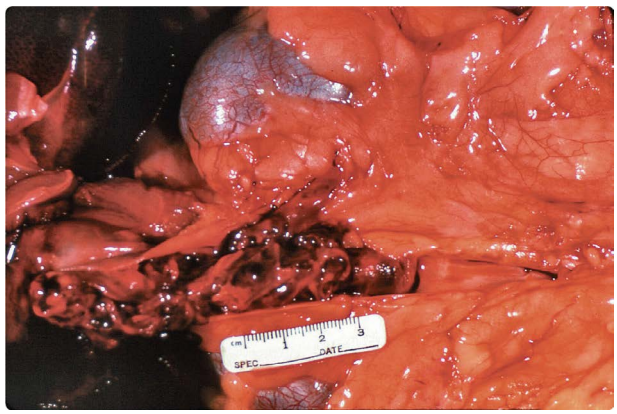

FIGURE 12.78 The pathology at postmortem is shown. (*Courtesy of M. Schaer.*)

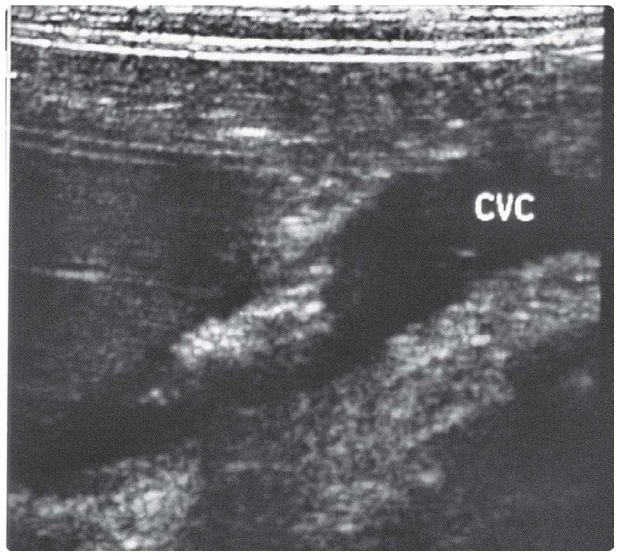

FIGURE 12.79 Ultrasonogram of a dog with a pheochromocytoma invading the postcava. (*Courtesy of M. Schaer.*)

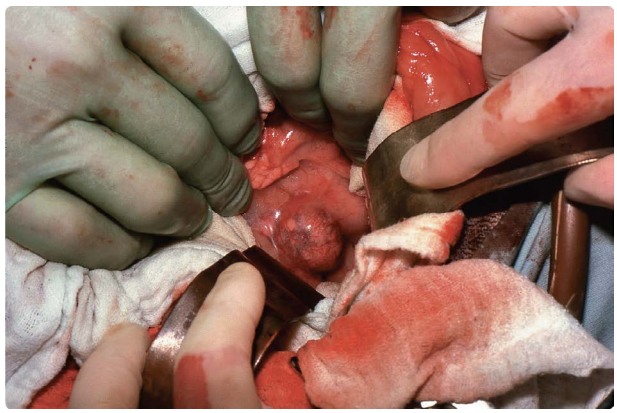

FIGURE 12.80 Surgical view of a well-localized and noninvasive pheochromocytoma. (*Courtesy of M. Schaer.*)

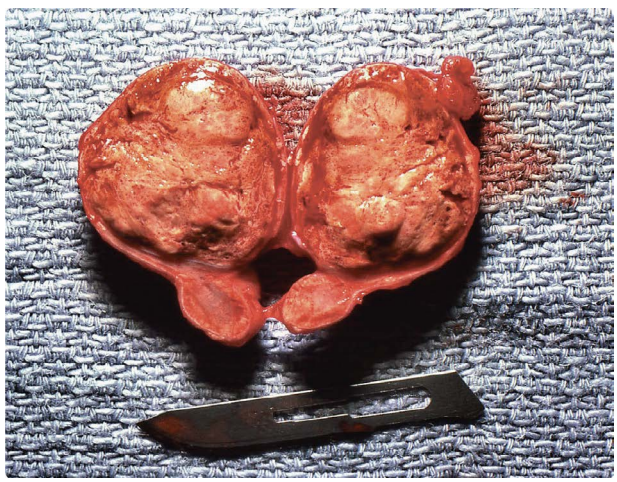

FIGURE 12.81 Excised noninvasive pheochromocytoma from Figure 12.80. (*Courtesy of M. Schaer.*)

experienced surgeons, since excessive handling of the tumor during surgery may provoke massive secretion of catecholamines, and the tumors tend to be invasive. Phentolamine, an alpha-adrenergic antagonist for IV use, can be used at a dose of 0.02–0.1 mg/kg to lower blood pressure while manipulating the tumor. However, phenoxybenzamine (0.2–1.5 mg/kg p.o. q.12 h.) may be the drug of choice due to its long duration of action. Improved surgical survival has been associated with the use of oral phenoxybenzamine treatment for 2 weeks prior to surgery. Lidocaine or propranolol can be administered intravenously as necessary during surgery to control tachycardia or tachyarrhythmias.

DIABETES MELLITUS

Definition/Overview

Diabetes mellitus is a heterogeneous syndrome in the dog and cat rather than a single disease entity. It is characterized by a relative or absolute deficiency of insulin secretion by the beta cells of the islets of Langerhans in the pancreas.

Etiology

Carbohydrate metabolism, and in particular blood glucose concentration, is controlled by the balance between the action of catabolic hormones (e.g., glucagon, cortisol, catecholamines, and GH) on the one hand and the principal anabolic hormone, insulin, on the other.

Pathophysiology

A relative or absolute deficiency of insulin results in decreased utilization of glucose, amino acids, and fatty acids by peripheral tissues, particularly liver, muscle, and adipose tissue. Failure of glucose uptake by these cells leads to hyperglycemia. Once the renal threshold for glucose reabsorption is exceeded, an osmotic diuresis ensues with loss of glucose, electrolytes, and water in the urine. A compensatory polydipsia prevents the animal becoming dehydrated. The loss of glucose leads to catabolism of the body's reserves, especially of fats. Excessive fat catabolism leads to the production and accumulation of ketone bodies and the onset of diabetic ketoacidosis (Figure 12.82). In diabetic ketoacidosis, the patient is unable to maintain an adequate fluid intake and becomes rapidly dehydrated due to the uncontrolled osmotic diuresis. The dehydration and acidosis require emergency care if the animal is to survive.

In humans, diabetes is classified as type 1 insulin-dependent diabetes mellitus and type 2 noninsulin-dependent diabetes mellitus. This classification has not proved very useful in veterinary medicine, since nearly all dogs with diabetes mellitus require insulin therapy regardless of the underlying etiology. However, in cats, type 2 diabetes mellitus is the most common form of the disease and is characterized by variable loss of insulin secretory capacity and insulin resistance. Classifying diabetes mellitus into primary and secondary causes is of more use clinically in the dog and cat (Table 12.25). In secondary diabetes, which is caused by peripheral insulin resistance, there is initially a compensatory increase in insulin secretion, but after a period of time, the islet cells become exhausted, the beta cells are destroyed, and their function is permanently lost.

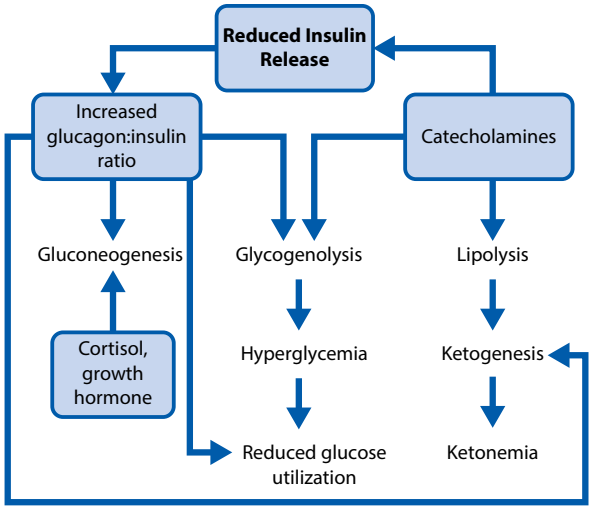

FIGURE 12.82 Etiology of diabetic ketoacidosis.

Clinical Presentation

Diabetes mellitus is a disease of middle-aged dogs, with a peak incidence around 8 years of age. Genetic predisposition to diabetes has been found in Keeshonds and Samoyeds. Cairn Terriers, Tibetan Terriers, Poodles, and Dachshunds may also be overrepresented and certain breeds, e.g., Boxers appear to be underrepresented. Entire bitches are more frequently affected than male dogs due to diestrus diabetes, which is due mainly to the induction of GH by progesterone but can also be associated with the use of progestogens.

Diabetes mellitus is the second most common endocrine disorder in cats after hyperthyroidism. Its incidence

TABLE 12.25 Etiology of diabetes mellitus in the dog and cat

Primary islet cell degeneration (insulin-deficient diabetes mellitus)
– Islet cell destruction (? autoimmune)
– Chronic pancreatitis (beta-cell loss)
– Glucotoxicity
– Amyloidosis
Secondary diabetes mellitus (insulin-resistant diabetes mellitus)
Obesity—causing downregulation of insulin receptors
Antagonism to insulin by counterregulatory hormones
– Hyperadrenocorticism
– Diestrus diabetes (progesterone-induced GH excess [dogs only])
– Acromegaly
– Antagonism to insulin by drug therapy
– Glucocorticoids
– Progestogens

FIGURE 12.83 A 12-year-old Labrador Retriever with diabetes mellitus. Note the weight loss.

appears to be increasing, probably due to an increase in obesity in the cat population. Several risk factors have been identified, including age, obesity, neutering, and sex. The disease is seen in middle-aged to older cats and appears to be more common in males than females and in neutered cats rather than entire cats.

Polyuria, polydipsia, increased appetite, and weight loss develop over a few weeks in uncomplicated cases (Figure 12.83). In entire bitches, this usually occurs in the diestrus phase of the estrous cycle. Hepatomegaly, muscle wasting, and infections of the urinary or respiratory tract may be noted on clinical examination. Ulcerative skin lesions and cutaneous xanthomata have occasionally been reported. If the diabetes remains uncontrolled, an accumulation of ketone bodies may occur, which causes metabolic acidosis and leads to depression, anorexia, vomiting, and rapid dehydration (Figure 12.84). Coma and death may result from severe hypovolemia and circulatory collapse.

Differential Diagnosis

Primary renal glycosuria, stress, hyperadrenocorticism, pancreatitis, renal insufficiency, exocrine pancreatic neoplasia, acromegaly, diestrus, pheochromocytoma, postprandial hyperglycemia.

FIGURE 12.84 A 3-year-old Cavalier King Charles Spaniel in a diabetic ketoacidotic coma.

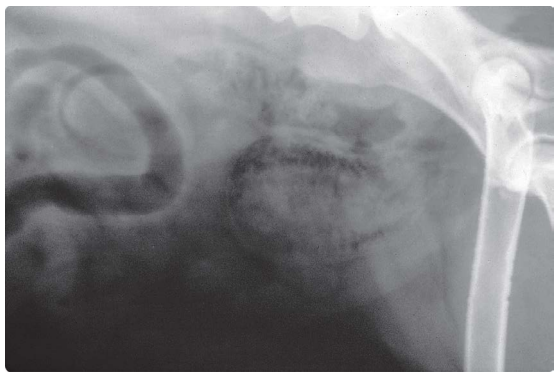

FIGURE 12.85 Abdominal radiograph of a diabetic dog showing emphysematous cystitis. (*Courtesy of M. Schaer.*)

Diagnosis

Urinalysis reveals persistent glycosuria and often ketonuria. Despite the high solute load in the urine, which would tend to increase the SG of the urine, many older dogs and cats may have impaired renal concentrating power, and thus, the SG of the urine is variable, typically between 1.015 and 1.045. Bacterial cystitis is common and occasionally may involve Gram negative gas-producing organisms, which can cause emphysematous cystitis (Figure 12.85).

Plasma biochemistry reveals hyperglycemia (>9 mmol/L [>162 mg/dL]) and hyperlipidemia. In some patients, the blood will be lactescent due to lipemia. Liver enzymes are usually raised, and liver function tests such as bile acid concentrations may be abnormal. In cases where diabetes is associated with pancreatitis, canine or feline-specific pancreatic lipase immunoreactivity may be elevated.

Diabetic ketoacidosis is often triggered by an underlying condition such as systemic inflammatory disease (pancreatitis, urinary tract infection, pyometra, or pneumonia) or a condition that causes dehydration. In diabetic ketoacidosis, there are serious derangements in fluid, electrolyte, and acid–base status. The most frequent abnormalities are prerenal azotemia, hyponatremia, hypokalemia, and acidosis.

Management

Treatment can be divided into the acute management of diabetic ketoacidosis and the stabilization of the uncomplicated diabetic. The ketoacidotic dog can be stabilized as for the uncomplicated case, once it has started to feed normally.

Acute Management of Diabetic Ketoacidosis

Although the healthy (still eating and drinking) ketotic diabetic can usually be managed conservatively without fluid therapy or intensive care, diabetic ketoacidosis characterized by hyperglycemia, ketonemia, metabolic acidosis, dehydration, and electrolyte imbalance is a medical emergency that is associated with a high mortality. Treatment should consist of replacement of fluid and electrolytes, reduction of blood glucose concentrations, correction of acidosis, and identification

of precipitating causes. A treatment protocol is given in Table 12.26, but diagnosis and treatment of the underlying trigger is also important.

Fluid Therapy

IV replacement of fluid and electrolytes is essential for the successful management of diabetic ketoacidosis. Unless serum electrolytes suggest otherwise, 0.9% sodium chloride or lactated Ringer's solution is the initial fluid of choice. The fluid deficit is usually about 10% of body weight and this should be replaced over a period of 24–48 hours. Sodium chloride may be alternated with lactated Ringer's solution or, if the blood glucose falls below 10 mmol/L (180 mg/dL), a solution containing 0.18% sodium chloride and 4% glucose (or some other comparable isotonic crystalloid–glucose solution). Urine output should be measured and, if possible, a central venous catheter used so that central venous pressure can be monitored during fluid therapy.

TABLE 12.26 Treatment protocol for diabetic ketoacidosis in the dog

Intravenous fluid and electrolyte replacement
- 0.9% sodium chloride initially then alternate with lactated Ringer's solution
- Monitor urine output and, if possible, central venous pressure

Insulin therapy
- *Low-dose insulin infusion:* Add 25 units soluble (regular) insulin or lispro to 500 mL 0.9% sodium chloride solution or 2.5 units in a 50 mL syringe (0.05 U/mL) and infuse at a rate of 0.1 U/kg/h through a separate IV catheter
- Use of an infusion pump, syringe driver, or pediatric burette is helpful in controlling the rate of infusion
- Monitor blood glucose concentration every 2 hours
- *Soluble insulin injection:* A dose of 1 U/kg is divided, and one-quarter of the dose is given IV and three-quarters IM
- The dose is repeated every 4–6 hours
- Monitor blood glucose concentration every 2 hours

Continue intravenous fluid and electrolyte replacement
- Continue alternating 0.9% sodium chloride with lactated Ringer's solution while blood glucose remains >10 mmol/L (>180 mg/dL)
- Use 0.18% sodium chloride with 4% glucose solution when blood glucose falls to <10 mmol/L (<180 mg/dL)

Potassium supplementation
- Ideally, supplementation with potassium should be based on serum potassium concentrations, in the absence of serum potassium measurements, add 20 mmol/L (20 mEq/L) of potassium chloride to each 500 mL bag of IV fluid solution
- Two to three times more potassium will be necessary with potassium concentrations <3.0 mmol/L. The rate of administration should not exceed 0.5 mmol/kg/h, although in dire circumstances (potassium <2.0 mmol/L), the rate can be increased to 1.5 mmol/kg/h with simultaneous ECG monitoring
- This treatment will be safe providing the patient has adequate urine production

Phosphate supplementation
- Phosphate shifts in the same way as potassium
- Hypophosphatemia is only likely to occur in severe diabetic ketoacidosis but can be severe (<0.5 mmol/L [0.5 mEq/L])
- Dose of 0.01–0.03 mmol/kg/h of potassium phosphate in calcium-free fluid (e.g., normal saline) is required if hypophosphatemia is detected
- In cases of severe hypophosphatemia, the dose may be increased to 0.12 mmol/kg/h

Correction of acidosis
- Bicarbonate therapy is not necessary provided renal function has been re-established
- It is only indicated in life-threatening (pH <7.0) acidosis, and only one-third of the calculated replacement dose should be used to prevent excessive blood HCO_3^- concentrations

Antibiotic therapy
- If indicated

Insulin Therapy

Soluble insulin ("regular") or lispro (a genetically engineered human analog insulin) should be used in the treatment of diabetic ketoacidosis. Although intermittent administration using the IV and IM routes has been used, low-dose IV insulin infusion (0.1 U/kg/h) is effective and appears to be associated with fewer side effects, such as hypokalemia and hypoglycemia. Low-dose IV insulin infusion provides a steady, gradual reduction in blood glucose and ketone concentrations and is less likely to cause the increases in glucagon, cortisol, and GH that can occur with intermittent bolus administration of insulin.

Blood glucose should be monitored every 2 hours. Glucose-containing fluids should be introduced when the blood glucose concentration falls below 10 mmol/L (180 mg/dL), and the insulin infusion should be stopped when the blood glucose reaches 6 mmol/L (108 mg/dL). Once the insulin infusion is halted, blood glucose concentrations will increase, so that further infusion of insulin may be required if the patient is not eating, or a longer-acting insulin preparation may be introduced if its appetite has returned.

Potassium Supplementation

A deficit in total body potassium is usually masked by the acidosis, which sometimes causes potassium to move extracellularly. Serum potassium concentration can decrease rapidly as renal function improves and insulin therapy causes potassium to move back into the cells. Although hypokalemia is less likely to occur with low-dose insulin infusion, replacement therapy should be started within a few hours of instigating fluid and insulin therapy. In the absence of serum potassium measurements, 20 mmol of potassium chloride should be added to every 500 mL of IV fluid solution. Insulin treatment is best delayed for several hours if the patient is initially hypokalemic in order to avoid a further lowering of the serum potassium concentration (see Table 12.26).

Phosphate Supplementation

Phosphate moves between the intracellular and extracellular compartments in the same way as potassium. Hypophosphatemia can cause hemolytic anemia, weakness, ataxia, and seizures. Phosphate supplementation is only usually required in dogs and cats with severe diabetic ketoacidosis. Potassium phosphate

(0.01–0.03 mmol/kg/h IV) is recommended to correct hypophosphatemia.

Bicarbonate Therapy

The use of sodium bicarbonate to correct the acidosis in diabetic ketoacidosis is controversial. Rapid correction of the acidosis with bicarbonate can lead to metabolic alkalosis, tissue anoxia due to a shift to the left of the hemoglobin–oxygen dissociation curve, and paradoxical cerebral acidosis because carbon dioxide crosses the blood–brain barrier more rapidly than bicarbonate ions. For these reasons, bicarbonate should be used only in life-threatening acidosis (arterial pH <7.0). Provided normal renal function is restored and adequate fluid therapy is given, the acidosis will resolve without bicarbonate administration.

Antibiotic Therapy

Initially, broad-spectrum antibiotic therapy might be preferred by some clinicians because bacterial infection is a common precipitating factor for diabetic ketoacidosis, and the use of IV and urinary catheters may predispose the patient to infection.

Concurrent Problems

Other common concurrent illnesses in the dog and cat with diabetic ketoacidosis include pancreatitis, renal failure, CHF, hyperadrenocorticism, and pyometra. Entire bitches may be resistant to insulin therapy during the diestrus phase of their estrous cycle, thus requiring ovariohysterectomy as soon as the patient is physiologically stable during the first 2–3 days of hospitalization.

Stabilization of Uncomplicated Diabetes Mellitus

The primary goal of diabetes therapy is to maintain normoglycemia and thereby control the signs that occur secondary to hyperglycemia and glycosuria and result in the development of complications (Table 12.27). The essentials of good stabilization of diabetes mellitus require understanding by the owner and adherence to a regular daily routine that involves diet, insulin administration, and regular controlled exercise. Stabilization can be carried out satisfactorily at home, but, particularly if the patient is ketotic, it may be preferable to hospitalize the animal during stabilization, since it is easier to monitor blood glucose more closely.

TABLE 12.27 Complications associated with diabetes mellitus

- Hypoglycemia
- Ketoacidosis
- Cataract formation
- Hepatic lipidosis
- Pancreatitis
- Infections
- Retinopathy
- Diabetic neuropathy
- Diabetic nephropathy
- Skin disease

Most diabetic dogs are presented with complete islet cell degeneration and atrophy. Therefore, diabetes mellitus in dogs is insulin dependent. Rarely, bitches may be presented during the diestrus phase of the estrous cycle before islet cell exhaustion has occurred. If ovariohysterectomy is performed in these patients immediately when the signs of diabetes become apparent, there can be complete resolution of the disease. However, in the majority of bitches, this opportunity is missed or goes unnoticed, and permanent damage to the islet cells occurs.

While a small percentage of cats may respond to diet and oral hypoglycemic agents, principally glipizide (a sulfonylurea), it is generally considered that insulin provides better glycemic control and, therefore, more chance of attaining diabetic remission. Remission of diabetes in cats usually occurs within 1 month of beginning insulin therapy but can occur as late as 6–8 months after the start of treatment.

Dietary Therapy

Appropriate dietary therapy is an essential part of the management of diabetes. The diet must be well balanced and constant in both composition and the amount fed at each meal. It is, therefore, most convenient to use a commercial diet. Canned or dry foods that contain digestible complex carbohydrates should be fed, as slow digestion minimizes the fluctuations in postprandial blood glucose concentrations. Semi-moist foods containing a predominance of easily assimilated carbohydrates in the form of disaccharides and propylene glycol should be avoided because of marked postprandial hyperglycemia. There is evidence that diets with a high-fiber content improve glycemic control by delaying starch hydrolysis and glucose absorption, thereby reducing postprandial fluctuations in blood glucose. High-fiber diets are also beneficial in correcting obesity. However, there may be disadvantages in using high-fiber diets (e.g., reduced palatability and the fact that the low-caloric density may cause patients to lose excessive weight or fail to gain weight if already below ideal body weight). The author tends to reserve high-fiber diets for those patients that are difficult to stabilize and/or are obese.

Correction of obesity and minimizing the impact of the diet on postprandial blood glucose concentrations are also important dietary considerations in diabetic cats. Following weight reduction, glycemic control often improves, and, in some cats, remission of diabetes may occur. Although high-fiber diets have been used in cats with diabetes, palatability can prove a problem. More recently, high-protein, low-carbohydrate diets have been used in the management of feline diabetes. Since cats are strict carnivores and maintain their blood glucose mainly through gluconeogenesis from amino acids, these diets produce a more stable blood glucose level, and insulin requirements are reduced.

Finally, the feeding schedule should be designed to enhance the action of insulin and minimize postprandial hyperglycemia. The daily caloric intake should

occur when insulin is present in the circulation and capable of handling glucose absorbed from the intestine. Several small meals are preferable to one large feed, as these will help minimize postprandial hyperglycemia and thus help to control fluctuations in blood glucose. The author routinely recommends two equal meals fed at times to coincide with insulin activity. In cases that prove difficult to stabilize, 3–4 smaller meals are fed during the day. Titbits and scavenging must be avoided as they tend to destabilize diabetic patients.

Insulin Therapy

For routine stabilization in the dog, insulin zinc suspension (lente), which contains a mixture of 30% insulin zinc suspension (amorphous) and 70% insulin zinc suspension (crystalline), is the preparation of choice in the UK (Vetsulin® in the United States). When given by subcutaneous injection, it is an intermediate-acting insulin with an onset of activity at 1–2 hours, peak activity around 6–12 hours, and a duration of action of between 18 and 26 hours in the dog. The times for peak activity and duration of action vary with the individual, but in some dogs, once-daily administration is adequate, although in the majority of cases, twice-daily administration is required to maintain good glycemic control. In the United States, clinicians also use NPH insulin, which has a shorter duration of action, and administer it to diabetic dogs in a divided twice-daily dosage.

Cats tend to metabolize insulin more quickly than dogs; therefore, a long-acting insulin such as protamine zinc insulin is often recommended if once-daily dosing is to be tried, although PZI is often administered twice daily as with other intermediate- to long-acting insulins. However, many clinicians use twice-daily dosing with lente insulin to gain good glycemic control. Insulin glargine, a long-acting insulin analog, has been used in cats with encouraging results (a dose of 0.25–0.5 U/kg q.24 h. or q.12 h. has been recommended). Insulin glargine forms microprecipitates at the site of injection from which small amounts of insulin are slowly released.

Lente insulin can be given as a single morning injection at the same time as or just before the first meal, with the second meal given 6–8 hours later to coincide with peak insulin activity. However, because of the frequency of hypoglycemia associated with once-daily treatment, the lente insulin can also be given in a divided twice-daily treatment protocol (see ahead given in the text). An initial dose of between 0.5 and 1.0 U/kg is used. Insulin is probably best dosed on body surface area rather than a simple weight basis. Thus, small dogs (<15 kg) tend to require 1.0 U/kg, and larger dogs (>25 kg) receive 0.5 U/kg. Although the subcutaneous route is ideal for long-term use, the intramuscular route may be used initially, especially in dehydrated or "healthy" ketotic animals because absorption from subcutaneous depots in these patients may be slow and erratic. Regular insulin can also be given by the intramuscular or intravenous route.

Insulin should be administered using specific 0.3, 0.5, or 1.0 mL syringes calibrated in units (100 U/mL or 40 U/mL depending on the concentration of the preparation). Insulin preparations should be stored in a refrigerator at 2–8°C (35.6–46.4°F) because they are adversely affected by heat or freezing. Preparations should be rolled gently to resuspend the particles before use. A diabetic patient will usually take 2–4 days to respond fully to a dose of insulin or a change in preparation. It is important to avoid increasing the dose too quickly before equilibration has occurred, as this can lead to a sudden and precipitous fall in blood glucose due to overdosage with insulin. In most cases, adjustments in the insulin dose should be made in small changes of 1–4 units per injection, depending on the size of the patient and the severity of the hyperglycemia. The type of preparation and frequency of administration may require alteration in those patients that prove difficult to stabilize with this standard routine. However, it is good for the clinician to become familiar with one type of insulin preparation and only change from that preparation if the insulin is the cause of the instability.

The standard routine for a dog would be:

8:00 a.m.: Give lente insulin injection SC
8:30 a.m.: Feed half of the measured daily ration
2:30 p.m.: Feed second half of the daily ration

for once-daily treatment (although administering the insulin in divided doses SC is recommended) and:

8:00 a.m.: Give lente insulin injection subcutaneously
8:30 a.m.: Feed half of the measured daily ration
8:00 p.m.: Give lente insulin injection subcutaneously
8:30 p.m.: Feed second half of the measured daily ration for twice-daily treatment

Keep the daily routine constant, including exercise; avoid titbits and scavenging.

Monitoring Therapy

Ideally, monitoring should consist of serial blood glucose concentrations, as tighter diabetic control can be gained than with urine glucose estimations. Initially, at least two blood glucose estimations should be made, one before insulin is administered and the second just before the second feed. Once the patient appears fairly stable, more frequent blood samples should be taken throughout the day to assess the degree of stabilization. An assessment of daily water intake can also provide useful information about the degree of diabetic control.

Blood glucose concentrations should ideally be maintained at between 5 and 9 mmol/L (90 and 162 mg/dL) (**Figure 12.86**). The blood glucose concentration will usually be highest in the morning before insulin is administered and lowest just before the second feed. A trace of glucose in the morning urine sample may be acceptable, but the urine should be negative at other times in the day. However, it is important to remember that urine glucose may not reflect the blood glucose concentration at the same point in time, and if the urine glucose is negative, the blood glucose concentration could

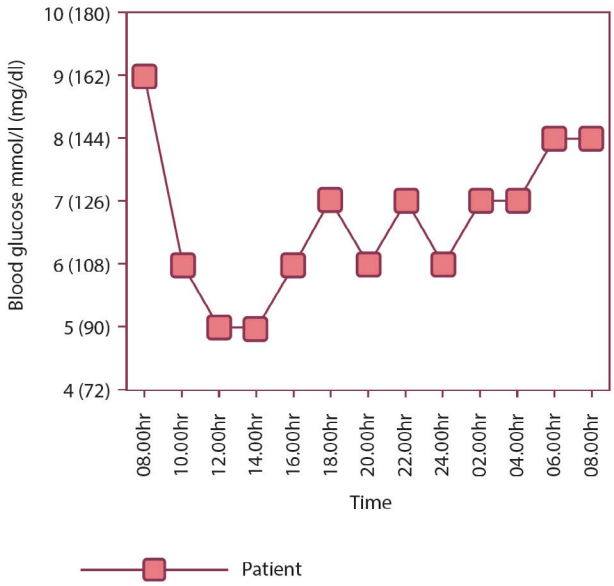

FIGURE 12.86 Ideal blood glucose curve.

be hypoglycemic (<3.0 mmol/L [<54 mg/dL]), normoglycemic, or hyperglycemic (>5.5 mmol/L [>99 mg/dL]). Although the author's clients monitor urine for glucose and ketones regularly, he does not advocate adjusting daily insulin dosages on the basis of morning urine glucose measurements. Instead, he prefers to continue with a fixed insulin dosage unless the patient remains unstable for more than several days.

Measurement of glycated proteins such as fructosamine and glycosylated Hgb are used increasingly in the dog and cat to monitor the response to treatment. The irreversible, nonenzymatic glycation process occurs throughout the life span of the protein, mainly albumin in the case of fructosamine, and is proportional to the glucose concentration over that time. These measurements reflect the average blood glucose concentration over the preceding 1–2 weeks in the case of serum fructosamine and 2–3 months in the case of glycosylated Hgb. Fructosamine concentrations <400 mmol/L indicate good glycemic control, whereas concentrations >500 mmol/L are found in newly diagnosed or poorly controlled diabetics. Glycosylated Hgb is less routinely available as an assay. Well-controlled diabetic dogs have between 4% and 6% glycosylated Hgb, whereas poorly controlled diabetics have concentrations >7%.

Diabetic records (Figure 12.87) should be kept by the owner for each patient, as alterations to stability can be assessed more easily over a period of time. Insulin requirements will be increased by infection, estrus (particularly the metestrus phase of the cycle), pregnancy, and ketoacidosis. It is, therefore, recommended that entire bitches should undergo ovariohysterectomy in order to avoid insulin resistance at subsequent seasons.

Investigation of Instability

If a patient appears to be poorly stabilized at home despite repeated attempts to provide adequate glycemic

Date	Urine exam	Insulin dose & time of injection	Food	Drink	Body weight	Blood results	Note
15 March	am glucose-ve ketones-ve	18 units lente insulin s.c. 8.00 am	3/4 tin Dogga 8.30 am 2.30 pm	0.9 L	24 kg	2.00 pm blood glucose 4.6 mmol/l	Bright and alert

FIGURE 12.87 Diabetic record.

control, the diabetic record should be checked, and the patient examined for signs of disease that could cause insulin resistance (e.g., infection, estrus, pregnancy, ketoacidosis, hyperadrenocorticism, or acromegaly). The daily routine should be discussed with the owner to make sure that the diet is constant and measured and that there is no access to titbits or scavenging. The insulin preparation should be checked for type, expiry date, and storage, as should the ability of the owner to administer the insulin (adequate mixing, correct dosage, and injection technique).

If an obvious cause cannot be determined, the patient should be hospitalized on its daily routine, and serial blood glucose determinations made every 1–2 hours throughout the day. Determinations made with glucose reagent strips and a glucose meter are simple, fast, and sufficiently accurate for this purpose. Some owners are prepared to record these measurements at home environment, which is useful as it provides a more realistic assessment of the patient in its own home environment. The use of a continuous glucose monitoring system or a flash glucose monitoring system has proved useful but is more expensive. The results should then be plotted on a graph against time, although it is important to realize that precise glucose curves may vary from day to day in any diabetic patient.

Three major causes of instability can be deduced from the graph of serial blood glucose determinations:

- The first is insulin-induced hyperglycemia, also called the Somogyi overswing, where excessive insulin dosage leads to paradoxical hyperglycemia (Figure 12.88). The blood glucose concentration is high in the morning before insulin is given but falls sharply to hypoglycemic concentrations (<3.5 mmol/L [<63.1 mg/dL]) after insulin administration. The hypoglycemic period is short in duration and is not associated with signs of hypoglycemia. In fact, the nadir can easily be missed if frequent sampling is not performed. The low blood glucose concentration stimulates the release of hormones antagonistic to insulin (e.g., glucagon, cortisol, and catecholamines), and these cause the glucose concentration to rebound quickly to high levels. If blood glucose and/or urine glucose concentrations were measured only before insulin and before the second feed, the concentrations would be high, and this could easily be misinterpreted as a reason for increasing the daily

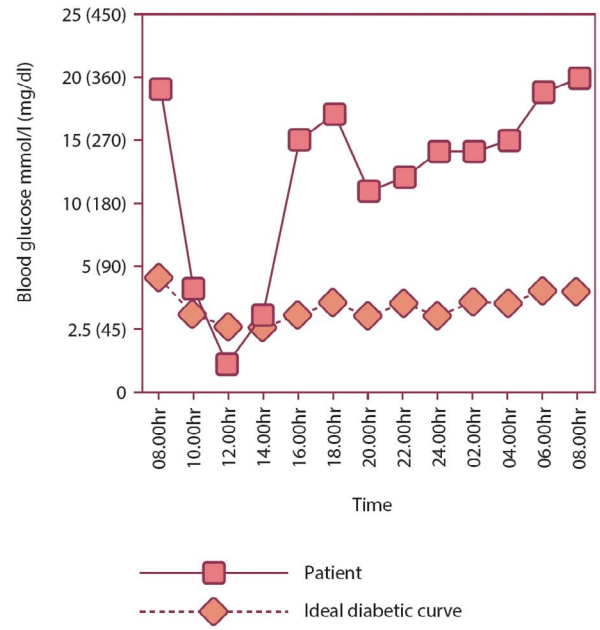

FIGURE 12.88 Insulin-induced hyperglycemia (Somogyi overswing).

insulin dose when, in fact, the patient is already being overdosed. The treatment for insulin-induced hyperglycemia is to reduce the daily dose of insulin in order to prevent the hypoglycemia that causes the dramatic swing in blood glucose concentrations.

- The second cause of instability is due to rapid metabolism of insulin, which means that an intermediate-acting insulin preparation does not last for a full 24 hours (Figure 12.89). In such cases, the blood glucose concentration is high in the morning before insulin is given but falls to normal levels for much of the day. However, after the second feed, the blood glucose concentration rises and remains high for the remainder of the day. This leads to a considerable period of hyperglycemia and results in glycosuria in the morning and often nocturnal polydipsia and polyuria. The treatment for rapid insulin metabolism is either to try a longer-acting insulin preparation (e.g., protamine zinc insulin or insulin glargine [Ultralente is no longer available in the United States]) or to administer two doses of lente insulin 12 hours apart, with two meals at the time of injection or four small meals given at approximately 6-hour intervals.

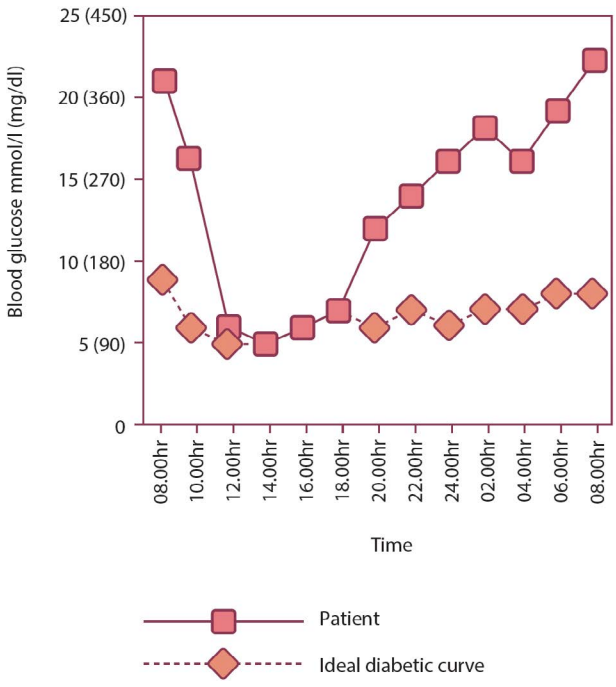

FIGURE 12.89 Rapid metabolism of insulin.

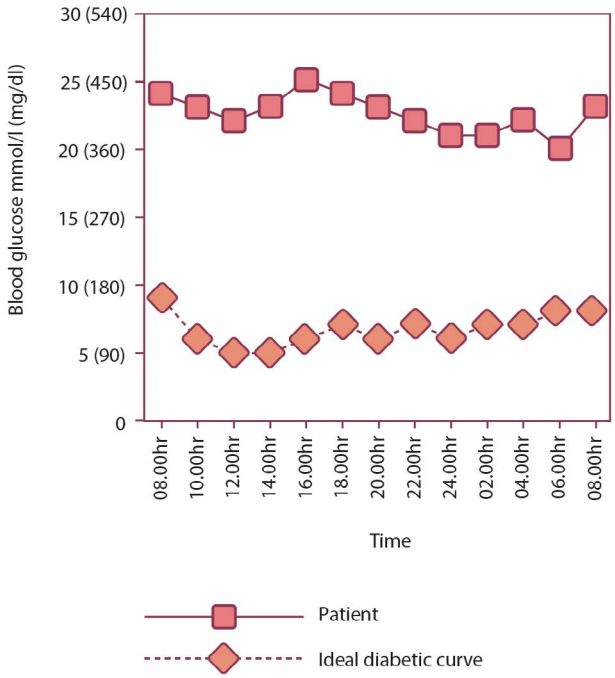

FIGURE 12.90 Insulin resistance.

- The third cause of instability is associated with insulin resistance. In these cases, the animal remains persistently hyperglycemic despite an insulin dosage of more than 2.2 U/kg per day (Figure 12.90). Although some patients can be stabilized satisfactorily at doses higher than this, peripheral antagonism to insulin activity is likely to be present. In cases where adequate stabilization is not possible, a thorough investigation of the patient is required to try and identify the precise cause of the insulin resistance. Some of the causes of insulin resistance are listed in Table 12.28. Correction or treatment of the underlying cause will usually enable the patient to be stabilized at a lower dose of insulin with improved glycemic control.

INSULINOMA

Definition/Overview

Functional islet cell tumors (insulinomas) are the most frequently occurring tumors of the endocrine pancreas

TABLE 12.28 Causes of insulin resistance

- Obesity
- Hyperadrenocorticism
- Exogenous glucocorticoid administration
- Metestrus phase of the estrous cycle
- Exogenous progestogen administration
- Acromegaly
- Hypothyroidism
- Hyperthyroidism
- Impaired absorption of insulin
- Excessive insulin antibody formation
- Pheochromocytoma
- Glucagonoma

in dogs. Most insulin-secreting tumors are malignant islet cell carcinomas that metastasize to regional lymph nodes and/or the liver. Early diagnosis is important, as dogs with metastases have significantly reduced survival times. Insulinomas are rare in cats.

Etiology

Causes of episodic weakness (Table 12.24), causes of hypoglycemia in adults (Table 12.29).

Pathophysiology

Insulinomas release insulin despite the presence of hypoglycemia. Hypoglycemia is normally the major inhibitory stimulus for insulin secretion. As a result of hyperinsulinism, tissue utilization of glucose continues, the hypoglycemia worsens, and ultimately clinical signs develop. The onset and severity of clinical signs are determined by the degree of hypoglycemia and the rate at which the plasma concentration of glucose falls. A rapid decline in plasma glucose concentration may occur with fasting, exercise, or excitement in dogs with insulinomas. The brain is an obligate consumer of glucose. Cerebral cells have limited stores of glycogen and a limited ability to utilize protein and amino acids for energy. These cells will be the first affected by hypoglycemia. Prolonged and profound hypoglycemia causes ischemic neuronal cell damage.

TABLE 12.29 Differential diagnosis of hypoglycemia in adult dogs and cats

- Incorrect anticoagulant/delayed separation of serum from red blood cells
- Functional islet cell tumor (insulinoma)
- Excessive insulin administration
- Extrapancreatic tumors, particularly hepatic tumors
- Liver disease (cirrhosis, hepatic necrosis)
- Septicemic or endotoxic shock
- Hypoadrenocorticism
- Idiopathic hypoglycemia in working dogs
- Xylitol toxicity in dogs
- Iatrogenic insulin overdosage
- Severe polycythemia

Hypoglycemia is a potent stimulus for the release of hormones that have an antagonistic action to insulin. These include glucagon, GH, glucocorticoids, catecholamines, and possibly thyroid hormones. These hormones act in concert to raise the plasma glucose concentration. Some of the clinical manifestations of hypoglycemia, such as muscle tremors, nervousness, restlessness, and hunger, may, in fact, result from stimulation of the sympathetic nervous system and increased levels of circulating catecholamines.

Clinical Presentation

Insulinomas usually occur in middle-aged to older dogs (mean age of 9 years) of any breed, although medium to large breeds appear to be predisposed. No sex predisposition has been reported. Insulinomas appear to be very rare in cats. A tentative diagnosis of hyperinsulinism is generally based on fulfilment of the criteria from Whipple's triad:

1. The presence of neurologic signs typical of hypoglycemia, which may be precipitated by exercise or excitement.
2. Hypoglycemia (plasma glucose <3 mmol/L [<54 mg/dL]) at the time of the clinical signs.
3. Resolution of clinical signs following feeding or administration of intravenous glucose.

Clinical signs associated with hypoglycemia include fatigue, generalized weakness, collapse, muscle tremors, altered behavior, confusion/disorientation, apparent blindness, ataxia, incoordination, stupor, and seizures. These signs are usually episodic in nature and may occur with fasting, exercise, or excitement in dogs with insulinomas. Provocative stimuli, such as IV administration of glucagon or glucose, result in excessive secretion of insulin from neoplastic beta cells. This response may be even greater if glucose is administered orally, as numerous intestinal hormones (glucagon, secretin, cholecystokinin, gastrin, and gastric inhibitory peptide) are secreted in response to oral glucose, and these in turn increase insulin secretion. It is by this mechanism that feeding has been reported to initiate clinical signs in dogs with insulinomas.

Seizure activity is one of the most common clinical manifestations of hypoglycemia. The seizures may be grand mal or focal in nature and are normally self-limiting, lasting between 30 seconds and 5 minutes. Peripheral neuropathy with nerve degeneration and demyelination has also been associated with canine insulinoma in a few cases. Insulinomas are generally small tumors and do not lead to malignant cachexia. Thus, weight loss is not a feature of this disease.

Diagnosis

Laboratory Findings

A presumptive diagnosis of insulinoma is based on the presence of typical clinical signs in association with

persistent hypoglycemia and an inappropriately high plasma insulin concentration. A fasting plasma glucose concentration of 3 mmol/L (54 mg/dL) or less is found in most cases. Some dogs with insulinoma show no clinical signs despite having extremely low blood glucose concentrations (<2 mmol/L [<36 mg/dL]) because they are able to adapt to these low concentrations over a prolonged period of time. Serum fructosamine concentrations are also reduced (<250 µmol/L), supporting substantial periods of hypoglycemia even in those patients with normal or low-normal fasting blood glucose concentrations.

Plasma insulin concentrations >20 mU/L in association with hypoglycemia are inappropriate, and an insulin-to-glucose ratio >4.2 is considered diagnostic.

In borderline cases, an IV glucose tolerance test using 0.5 g glucose/kg body weight has proved useful. Insulin-secreting tumors retain a degree of responsiveness to the glucose challenge; a glucose half-life of <20 minutes and/or a fractional clearance rate of more than 3%/minute is highly suggestive of insulinoma in the dog.

Although hypoalbuminemia, hypokalemia, and increases in serum ALP concentrations have occasionally been reported, these findings are not specific or helpful in achieving a definitive diagnosis.

Diagnostic Imaging

Abdominal ultrasonography using a high-quality diagnostic ultrasound machine has been used to examine the pancreas of dogs with suspected insulinomas. Most insulinomas are quite small (<2.5 cm) and are isoechoic to hypoechoic when compared with the surrounding pancreatic tissue. In one study, a pancreatic mass was identified as a spherical or lobular hypoechoic nodule in 75% of dogs with insulinomas (Figure 12.91). Tumors as small as 7 mm have been identified in the pancreas.

Cross-sectional imaging using CT or MRI has proved useful in identifying insulinomas in cases in which ultrasonography has failed to detect a lesion. The use of dual-phase (arterial and venous phases) or triple-phase (arterial, venous, and equilibrium phases) CT angiography for evaluation of insulinomas increases the chance that attenuation differences will improve visualization of a small mass. CT has also been shown to be more sensitive for the detection of lymph node and hepatic metastases.

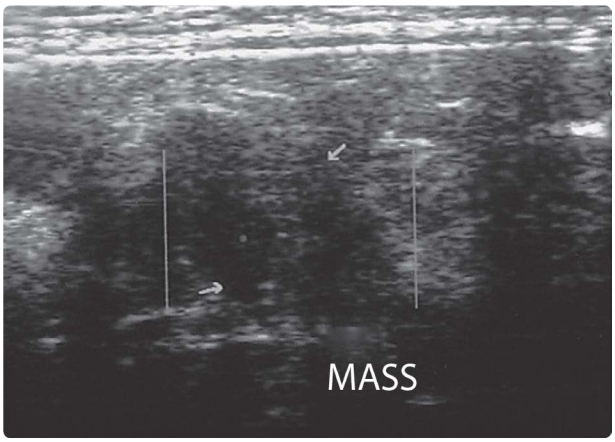

FIGURE 12.91 Ultrasonogram of the pancreas of a crossbred dog showing a hypoechoic mass, which proved to be an insulinoma on histology.

Management

Management of insulinomas should be directed at specific treatment of the tumor, reduction of insulin secretion, and correction of hypoglycemia. Sometimes, IV glucagon is needed to increase the blood glucose to desirably safe levels. The initial glucagon dose is 50.0 ng/kg as an IV bolus followed with a maintenance dose of 5–10 ng/kg per minute.

Surgical Management

Surgical resection of the pancreatic tumor and metastatic tumor masses should be the first approach to therapy (Figures 12.92–12.95). Most insulinomas are located in the left lobe of the pancreas, with masses in the right lobe or body occurring less frequently. Tumors are usually solitary, but multiple masses may occur. Rarely, there is a diffuse islet cell tumor with no discrete

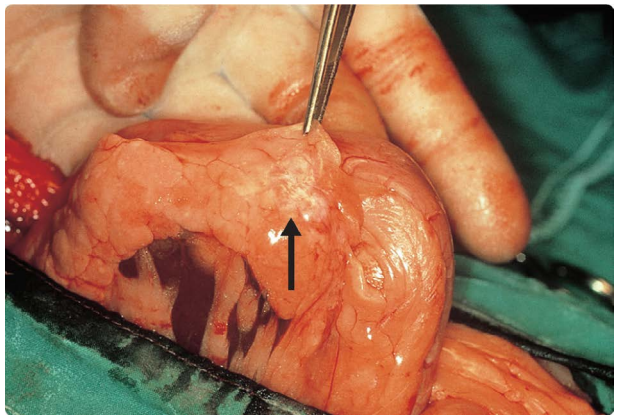

FIGURE 12.92 An insulinoma being pointed out at surgery (arrow).

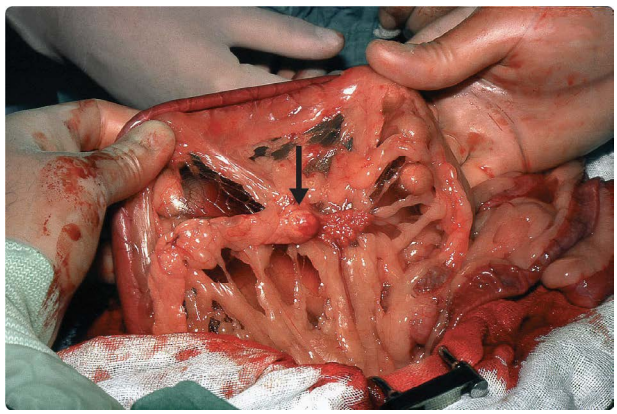

FIGURE 12.93 Surgical view of an insulinoma before (black arrow) ligation for removal. (*Courtesy of M. Schaer.*)

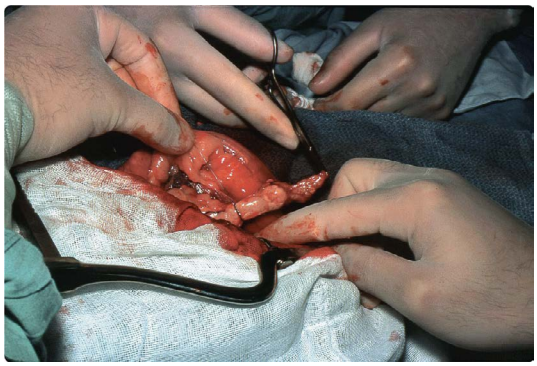

FIGURE 12.94 Surgical view of ligation of an insulinoma prior to removal. (*Courtesy of M. Schaer.*)

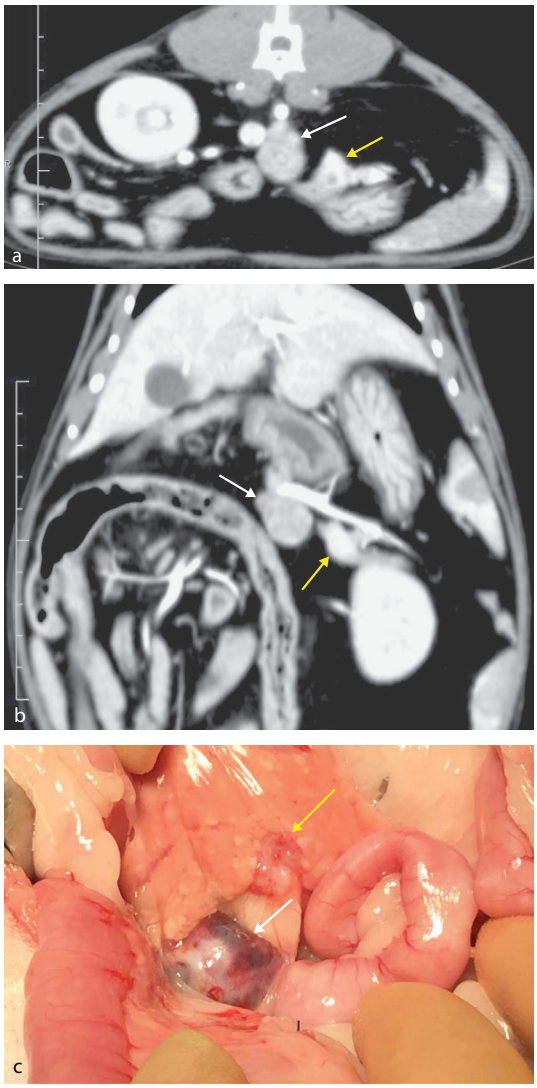

FIGURE 12.95 A 10-year-old Domestic Shorthair cat with hypoglycemia. The contrast CT shows an intensely contrast-enhancing mass in the left limb of the pancreas (yellow arrow) and a separate moderately contrast-enhancing lymph node (white arrow) on the **(a)** transverse and **(b)** dorsal reconstructed images. These lesions were confirmed at surgery **(c)** and histology confirmed an insulinoma with spread to the local lymph node.

nodule. There does not appear to be a difference in survival in relation to tumor location within the pancreas, but there is a suggestion that tumors with a high mitotic count carry a worse prognosis.

Postoperative recovery is routine in many cases, but complications, including pancreatitis, hyperglycemia, overt diabetes mellitus, and hypoglycemia, occur. In nearly all cases, hypoglycemia will recur eventually due to metastasis.

Medical Management

Medical management should be used if widespread metastasis is present or if hypoglycemia recurs after surgery. This should consist of dietary control (frequent small meals of a diet high in proteins, fats, and complex carbohydrates) and the use of prednisolone, which inhibits insulin and stimulates glycogenolysis, and diazoxide, a nondiuretic, benzothiadiazine antihypertensive drug that inhibits insulin secretion (Table 12.30). Octreotide, a somatostatin analog that inhibits insulin synthesis and secretion, has also been used and has been shown to be effective in some cases. Recently, the multireceptor tyrosine kinase inhibitor toceranib (Palladia), when used with prednisolone, has been shown to achieve long-term, improved survival in dogs with metastatic insulinoma.

The prognosis is guarded due to the malignant nature of the disease. However, many dogs do best with a combination of medical and surgical management. The median time to recurrence of clinical signs after surgery is 12 months (range 4–16 months), and the median postoperative survival time is 26 months (range 6–46 months).

TABLE 12.30 Management of hypoglycemia

- In acute hypoglycemic crisis, give 1 mL/kg of a 40%–50% glucose solution by slow IV injection, or, if the animal is still conscious, provide a meal containing glucose. Glucose administration is an emergency treatment and cannot be used for long-term control. If this proves ineffective in preventing severe hypoglycemia, glucagon should be used. The initial dose of glucagon is 50.0 ng/kg given as an IV bolus followed with a maintenance CRI dose of 5–10 ng/kg per minute.
- Management of chronic hypoglycemia requires a combination of therapies
  - *Diet:* Feed small meals high in protein and low in simple sugars 5–6 times daily
  - Exercise should be restricted
  - Diabetogenic drugs
- *Glucocorticoids:* Prednisolone (0.5–1 mg/kg daily in divided doses)
- Diazoxide, a nondiuretic benzothiadiazine antihypertensive drug that acts by suppressing insulin secretion (10 mg/kg in divided doses increasing up to 60 mg/kg daily if necessary)
- Octreotide, a long-acting somatostatin analog that inhibits insulin synthesis and secretion (10–20 µg SC q.12 h. or q.8 h.); only effective in some dogs, close monitoring required
- Streptozotocin and alloxan are nephrotoxic and not recommended

INTRODUCTION

The kidneys are responsible for maintaining the body's fluid and electrolyte balance, filtering metabolic waste, and performing hormonal functions. Reduced renal function manifests itself in several ways including increased blood levels nitrogenous compounds This is referred to as azotemia. Uremia is the constellation of clinical signs that results from azotemia and includes vomiting, lethargy, anorexia, diarrhea, oral ulcerations, and uremic breath.

Azotemia is categorized by its underlying cause. This is clinically important because not all azotemia is the result of kidney disease. Prerenal and postrenal factors can result in increased levels of nitrogenous compounds despite otherwise healthy kidneys.

Prerenal azotemia is the result of decreased kidney perfusion in the absence of actual kidney disease or injury. Decreased renal blood flow leads to a reduction in glomerular filtration and a compensatory activation of the renin–angiotensin–aldosterone system. The ensuing increase in tubular sodium reabsorption and antidiuretic hormone-induced water reabsorption leads to production of concentrated urine. This is important, as the hallmark of prerenal azotemia is mild-to-moderate azotemia with an increased urine specific gravity. Treatment of the underlying condition (Table 13.1) will often lead to resolution of clinical signs.

Postrenal azotemia can result from either an obstruction in urine outflow or leakage of urine into the abdomen. With a urinary obstruction, the blockage causes increased hydrostatic pressure in Bowman's capsule and decreased glomerular filtration. This is most commonly observed in urethral obstructions, since unilateral ureteral obstructions leave one kidney functioning normally; however, azotemia can occur with unilateral ureteral obstructions if a patient has pre-existing kidney disease.

TABLE 13.1 Causes of prerenal azotemia

Hypotension	– Anesthesia – Dehydration – Hypoadrenocorticism (Addison's disease)
Hypoperfusion	– Cardiac disease – Hemorrhage – Shock
Thrombosis	– Renal artery or vein occlusion

A rupture of the urinary tract results in the accumulation of fluid in the abdomen. Because urea is highly diffusible, it is quickly resorbed back into circulation along with some of the fluid. Creatinine, which is not diffusible, becomes trapped. Patients who experience a urinary tract rupture develop an accumulation of fluid that has a blood urea nitrogen (BUN) comparable to serum plasma but a creatinine that is elevated.

Renal azotemia is a direct result of renal parenchymal disease. Because of differing etiology, prognosis and treatment, primary renal disease is classified clinically into acute kidney injury (AKI) or chronic kidney disease (CKD) and histologically as glomerular or tubular disease.

Differentiation between AKI and CKD is important in determining etiology, prognosis, and treatment options (Table 13.2). Immediate intervention and aggressive therapy are more likely to produce clinical recovery in AKI,

PCV	Normal/increased	Anemia
Acidosis	Moderate/severe	Moderate
Serum potassium	Normal/increased	Normal to decreased
Osteodystrophy	None	Rare (e.g., rubber jaw)

since underlying causes may be identified and treated. In addition, surviving nephrons can undergo hypertrophy and compensate for ones that are lost to the renal insult. Lastly, some damaged nephrons may be capable of recovering if given sufficient time.

It is unlikely that a treatable cause of kidney disease will be identified in the CKD patient. Also, it is doubtful that remaining nephrons have additional compensatory capacity and there is little hope for nephron repair. Treatment in the CKD patient is directed toward supportive care. Although, differentiation between the two conditions is essential, there is no single test to discriminate between them. Diagnosis is made based on a combination of history, clinical signs, physical examination findings and diagnostic tests.

ACUTE KIDNEY INJURY

Definition/Overview

Acute kidney injury (AKI) is a condition characterized by a rapidly progressive impairment in the kidney's ability to filter metabolic waste, as well as maintain the body's fluid and electrolyte balance.

Etiology

Acute kidney injury is the result of damage that can be caused by ischemia, nephrotoxins, infectious agents, or systemic disease (Table 13.3). In companion animal medicine, AKI is most commonly the result of nephrotoxins and infectious agents.

Pathophysiology

There are many specific mechanisms by which the kidney can be injured. Some of the most common causes include infectious, nephrotoxins, ischemic, hypertension, and immune mediated. Many of the more common causes can be found in Table 13.4.

TABLE 13.3 Common causes of acute kidney injury

Nephrotoxins	– Aminoglycosides – Amphotericin B – Cisplatin and carboplatin – Cyclosporin – Ethylene glycol – Jerky treats – Melamine – NSAIDs – Toxic plants (e.g., cats: lilies, dogs: grapes) – Other
Infectious agents	– Babesiosis – Ehrlichiosis – Leishmania – Leptospirosis – Pyelonephritis – Rickettsiosis (e.g., *Rickettsia rickettsii*, Rocky Mountain spotted fever)
Systemic disease	– Heat stroke
Ischemia	– Severe hypotension (e.g., anesthetic induced)

Clinical Presentation

General

Clinical signs of AKI are somewhat dependent on the underlying cause, severity of the azotemia, and electrolyte imbalances. Signs that are often noted include depression, weakness, dehydration, anorexia, vomiting, diarrhea, uremic breath, oral ulcers, and hypothermia.

Ethylene Glycol

Specific

Ethylene glycol is an alcohol that does not become toxic until metabolized by the liver. Early clinical signs are due to the alcohol's effect on the central nervous system and include ataxia, proprioceptive deficits, muscle tremors, nausea, vomiting, and seizures. Polyuria and polydipsia are common because ethylene glycol and its metabolites exert a diuretic effect. Since it is potentially treatable in the early stages, ethylene glycol exposure should be considered in every dog with unexplained neurologic signs.

Differential Diagnosis

Prerenal azotemia, postrenal azotemia, Addison's disease, and CKD.

Diagnosis

Determining the likely underlying cause of the kidney injury is critical in assessing prognosis as well as developing an appropriate treatment plan. The importance of the client interview cannot be over emphasized. Questions should focus on possible exposure to environmental nephrotoxins (e.g., ethylene glycol, cholecalciferol-based

TABLE 13.4 Mechanism for common causes of acute kidney injury

Ethylene glycol	– Used as an antifreeze in cars (prohibited in some countries)
	– Toxic dose: 1.4 mL/kg in cats, 4.4 mL/kg in dogs
	– Ethylene glycol is broken down in the liver by a series of oxidative steps
	  – Several of the ethylene glycol metabolites are directly toxic to renal epithelial cells
	  – One of the metabolites, oxalate, leads to the formation of calcium oxalate crystals within the tubules

Leptospirosis	– Zoonotic disease
	  – Caused by a number of antigenically distinct serovars of the bacteria *Leptospira interrogans sensu lato*
	– Maintained in the wild by asymptomatic wild animals (hosts), which shed the bacteria in urine
	  – Infection occurs when leptospires penetrate mucous membranes or broken skin
	  – Renal tubular epithelial cells become colonized, resulting in interstitial lymphoplasmacytic inflammation

NSAIDs	– NSAIDs block the cyclooxygenase pathway preventing the formation of locally protective prostaglandins in the kidney – Activation of the renin–angiotensin system leads to vasoconstriction in the glomerular capillary bed – As the arterioles constrict, blood flowing out of the glomerulus and into peritubular capillaries decreases – If left unchecked, the resulting decreased blood flow to the medulla of the kidney leads to ischemic injury – Suppression of the renin–angiotensin system by IV fluid therapy can help prevent this vasoconstriction
Cholecalciferol-based rodenticides	– Cholecalciferol is metabolized to calcitriol, the active form of vitamin D – Calcitriol increases intestinal absorption, stimulates bone resorption, and encourages renal tubular reabsorption of calcium – This can lead to soft tissue (e.g., kidney) mineralization
***Lilium* and *Hemerocallis* (true lilies)**	– Lilies of the genera *Lilium* and *Hemerocallis* (i.e., Easter lilies, tiger lilies, etc.) are extraordinarily nephrotoxic; however, the mechanism of toxicity is not known – It is important to note that not all lilies are members of this group – Peruvian and peace lilies are examples of plants that are not toxic
Grapes/raisins	– The mechanism of toxicity is not known; however, it does not appear to be related to heavy metals, pesticides, or mycotoxins – Ingestion has been shown to causes acute tubular necrosis of the proximal tubule

rodenticides), household toxins (lilies, grape products), current medications (both human and pet), any medications or drugs that could have been consumed, and recent travel history. Often, travel will expose a patient to diseases not commonly encountered in the local environment.

Once the presence of azotemia (increased BUN, creatinine, and phosphorus) is confirmed, possible differential diagnoses (prerenal azotemia, postrenal azotemia, chronic kidney disease, Addison's disease) must be eliminated from consideration. A sodium-to-potassium ratio that is less than 29 should raise suspicion that the patient has hypoadrenocorticism, not kidney disease.

Urinalysis can be used to quickly differentiate between prerenal and renal azotemia. Isosthenuria is typical of acute kidney injury, while a urine specific gravity of greater than 1.025 in the dog and greater than 1.035 in the cat is typically associated with prerenal azotemia. The presence of glucosuria in the absence of hyperglycemia is suggestive of acute proximal tubule dysfunction but is also seen with Fanconi syndrome. The discovery of protein, in the absence of bacteria, white blood cells, or casts, may be suggestive of glomerular disease (see PLN). Only a urine protein-to-creatinine ratio can provide a quantitative assessment of urine protein concentration and should be performed on every proteinuric patient. Microscopic examination of the urine sediment allows detection of calcium oxalate monohydrate crystals, which are associated with ethylene glycol toxicity (Figure 13.1).

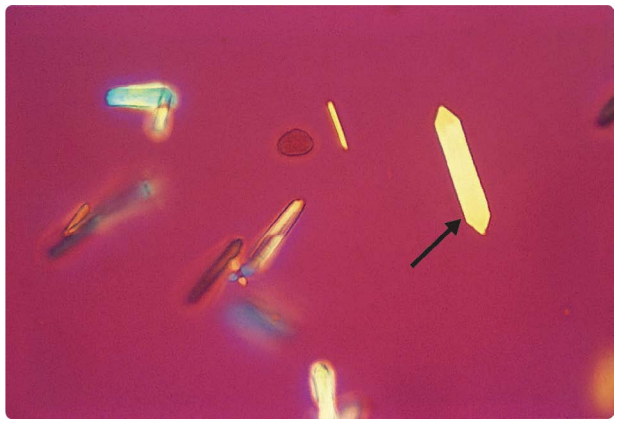

FIGURE 13.1 Calcium oxalate monohydrate crystals (arrow) typical of those observed in the urine sediment of animals with ethylene glycol intoxication. (*Courtesy of C.A. Osborne.*)

Bacteria may be seen in cases of pyelonephritis; however, the absence of bacteria and/or inflammatory cells does not eliminate pyelonephritis as a cause of AKI. Casts, often observed in AKI, can help determine the underlying cause (Figure 13.2 and Table 13.5).

Urine Culture

In cases in which pyelonephritis is suspected either due to pyelectasia or urinalysis findings, a urine culture and sensitivity should be performed.

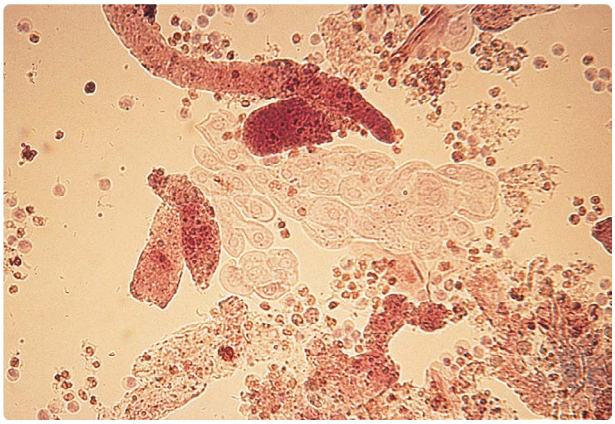

FIGURE 13.2 Granular casts in the urine sediment of a dog with acute kidney injury. (*Courtesy of D.F. Senior.*)

TABLE 13.5 Types of casts and associated conditions

Hyaline casts	Proteinuria—glomerulonephritis and amyloidosis
Granular casts	Degeneration of cells or precipitation of proteins – Associated with ischemic or toxic tubular injury
Fatty casts	Granular casts containing lipid – Associated with nephritic syndrome and diabetes
White cell casts	Pyelonephritis
Waxy casts	Final degeneration of granular cases – Associated with intrarenal stasis

Complete Blood Count

Changes in the complete blood count are often nonspecific; however, elevations in the white blood cell count can be associated with pyelonephritis and systemic infectious diseases. The absence of a stress leukogram (neutrophilia, lymphopenia, and eosinopenia) should raise the suspicion that the patient has hypoadrenocorticism.

Serum Chemistry

Acute kidney injury is accompanied by an elevation in BUN and creatinine. Elevations in phosphate usually parallel or exceed that of creatinine. Calcium is often mild to moderately elevated. Hypocalcemia is also associated with ethylene glycol toxicity. Serum bicarbonate decreases while potassium increases with the degree of renal dysfunction. Anion gap should always be calculated ($[Na^+ + K^+] - [Cl^- + HCO_3^-]$). Normal canine anion gaps range from 12 to 24 mEq/L, while normal feline values are 13–27 mEq/L. Increases are associated with metabolic acidosis caused by ketones, lactate, or uremia; however, significant increases in an AKI patient are suggestive of toxin ingestion. In veterinary medicine, the most common toxin is ethylene glycol, although methanol, ethanol, and salicylic acid should be considered as other potential toxins.

FIGURE 13.3 Ultrasound of a kidney of a CKD cat. The kidney is small, hyperechoic, and has poor corticomedullary definition. There is mild-to-moderate irregularity of the cortical borders.

Radiographs and Ultrasound

When available, ultrasound is the preferred imaging modality (Figure 13.3). Ultrasound can provide information about the renal architecture, outflow tract, and allows interrogation of the renal blood flow. Patients with AKI usually present with kidneys of normal to increased size while small, irregular-shaped kidneys are suggestive of chronic disease.

Infectious Disease Serology

In areas where leptospirosis is endemic, infection should be considered in any patients demonstrating signs of AKI. There are two commonly performed tests: Microscopic agglutination titer (MAT) and polymerase chain reaction (PCR). MAT measures antibodies to leptospirosis serovars, while the PCR probes for *Leptospira* DNA in urine or blood. Generally, a MAT >1:800 in the absence of recent vaccination suggests exposure, while a fourfold increase in paired titers 14 days apart indicates an active infection. The test can be negative in the early phase of the infection even when the animal is quite sick. The benefit of the PCR is that it can be positive before elevations in the MAT. Although laboratories can test urine or blood, the recommendation is to test both. Previous treatment with antibiotics can produce false negative results, and the test is not 100% specific. Enzyme-linked immunosorbent assays (ELISA) testing for *Leptospira*-specific antibodies are available; however, they are associated with significant problems with sensitivity and specificity. Studies have identified one cage side test, in particular WITNESS (Zoetis), as having reliable results. Other serologic testing (leishmaniasis, rickettsia, babesiosis, etc.) should be considered based on patient location and the relevant travel history.

Ethylene Glycol Test

Any patient with a severe metabolic acidosis, increased anion gap, calcium oxalate crystalluria, hypocalcemia,

or any combination of these signs should be tested for ethylene glycol ingestion. This should be done regardless of the patient's history, as most owners will underestimate exposure risk. It is important to note that some commercially available test kits may not be sensitive enough to detect ethylene glycol exposure in cats as the lethal serum concentration is below the threshold of the test; therefore, it is important to know the limitations of the test.

Management

Successful treatment of AKI is dependent on determining an underlying cause, correcting dehydration, establishing a brisk diuresis, and correcting life-threatening electrolyte imbalances. Often, treatment must begin before the cause can be established; however, the importance of accurate fluid therapy cannot be overemphasized. Studies in people and animal models clearly demonstrate that even imperceivable overhydration can be fatal in AKI patients.

Due to inappetence, vomiting, and an impaired ability to concentrate urine, dehydration is common in AKI patients. Initial fluid therapy must account for three factors: (1) Patient dehydration, (2) maintenance fluids, and (3) insensible losses. Although balanced electrolyte solutions contain small amounts of potassium, studies in people suggest these fluids are associated with a better outcome than 0.9% sodium chloride.

First, the patient's level of dehydration must be estimated (Table 13.6), and then the volume of fluids needed to correct dehydration can be calculated using the equation: Deficit in L = % dehydration × kg body weight. This deficit must be divided and administered over 12–24 hours in order to give time for fluids to equilibrate between the vascular, interstitial, and cellular compartments. Commonly available formulas for calculating "maintenance" fluids assume normally functioning kidneys and are of little use in formulating AKI fluid therapy plans; rather, an indwelling urinary catheter should be aseptically placed to measure urine output. Hourly urine production is then used as a surrogate for "maintenance" fluid rate. Finally, insensible losses can be estimated as 20 mL/kg per day plus any fluids lost to vomiting or diarrhea (See Example A).

Once dehydration has been corrected, fluid therapy should account only for maintenance fluids and insensible losses. Hourly urine production rate continues to be used as a surrogate for maintenance. Insensible losses are estimated as earlier (See Example B).

Our goal should be a brisk diuresis of at least 1 mL/kg/h. Well-hydrated animals producing less than 0.25 mL/kg/h of urine are considered to be oliguric, while anuric patients produce no urine. These conditions necessitate aggressive treatment. Occasionally, AKI patients will produce large volumes of urine once dehydration is corrected. Polyuric patients are probably either less severely affected or represent a later course of the disease process. These patients are generally easier to manage, as they are less likely to develop life-threatening electrolyte abnormalities and fluid overload; however, they still require careful monitoring. Significant azotemia and uremia can persist during this polyuric phase and is not considered a negative prognostic indicator.

TABLE 13.6 Signs used to determine degree of dehydration

Percent dehydration	Clinical signs
<5%	Not detectable
5%–6%	Subtle loss of skin elasticity
6%–8%	Delay in return of skin to normal position Slight increase in capillary refill time (CRT) Dry mucous membranes
10%–12%	Skin stands in place when tented Increase in CRT Eyes sunken Dry mucous membranes Shock—tachycardia, cold extremities, weak pulses
12%–15%	Death imminent

EXAMPLE A

10 kg male neutered Shih Tzu presents for signs consistent with AKI and on the basis of increased CRT, sunken eyes, and dry mucous membranes is determined to be 10% dehydrated. He is producing 5 mL/h urine. Total dehydration is determined to be 1 L (L = 10 kg × 0.10), which will be given over 12–24 hours. Thus:

Dehydration component of the fluid therapy = 83 mL/h (1,000 mL/12 h)

Maintenance fluids = patient's hourly urine production: 5 mL/h

There has been no vomiting or diarrhea, so the **insensible losses** = 8 mL/h [(20 mL/kg x10)/24]

Initial hourly fluid rate = 96 mL/h (83 mL/h + 5 mL/h + 8 mL/h)

Urine output per hour is monitored regularly and the maintenance fluid component of the formula adjusted.

EXAMPLE B

Our patient is now well hydrated and is producing 9 mL/h.

Maintenance fluids = patient's hourly urine production 9 mL/h

There has been no vomiting or diarrhea so **insensible losses** = 8 mL/h [(20 mL/kg x10 kg)/24h]

Hourly fluid rate = 17 mL/h (9 mL/h + 8 mL/h)

Urine output is monitored regularly and the maintenance component of the formula adjusted.

Mannitol is considered to be the initial treatment of choice for oliguric and anuric animals that are well hydrated and not fluid overloaded. Although clinical studies are lacking, experimental models suggest mannitol can increase renal blood flow, shrink swollen tubular cells, dislodge tubular obstructions, and scavenge free radicals. It is given as a 0.25–1.0 g/kg IV bolus over 30 minutes. If urine production improves, a CRI 1–2 mg/kg per minute can be started. Mannitol is contraindicated in patients with ethylene glycol intoxication because it can further exacerbate hyperosmolality. If there is no response to or the patient is overhydrated, furosemide therapy should be attempted.

Furosemide is a loop diuretic which has been associated with the induction of diuresis and resolution of tubular obstructions under experimental conditions. Furosemide is typically given as a bolus (2 mg/kg IV), and if urine production increases, it is continued as a CRI (0.25–1.0mg/kg/h). Aminoglycoside toxicity should not be treated with furosemide as it can potentiate further kidney injury. Studies in people have failed to demonstrate improved survival in AKI patients who received furosemide or mannitol; however, widespread access to advanced therapies such as dialysis makes it unclear if these studies are directly applicable to animals.

Small retrospective studies had suggested that fenoldopam, a peripheral dopamine D1 receptor agonist, and diltiazem, a calcium channel blocker, might be helpful in the treatment of AKI. More recent prospective studies have failed to demonstrate a benefit of either drug. Evidence suggests that use of diltiazem may actually be contraindicated depending on the AKI cause; therefore, use of these drugs is not recommended.

Patients that produce significant amounts of urine in response to rehydration or mannitol/furosemide therapy are less likely to require specific treatment for electrolyte and acid–base imbalances. Oliguric and anuric patients that do not respond to medical management can quickly develop fatal hyperkalemia and metabolic acidosis.

Hyperkalemia

The most common life-threatening electrolyte imbalance encountered in AKI is hyperkalemia. Restoring urine production is critical. Elevation in serum potassium causes a reduction of the transmembrane electrochemical gradient and changes nerve and muscle cell excitability. Clinically, signs of hyperkalemia include muscle weakness, reduced cardiac contractility, arrhythmias, and neurologic abnormalities. Classic ECG findings include bradycardia, disappearance of the P wave, spiking of the T wave, and widened QRS complexes (Figure 13.4). These changes begin to appear when potassium approaches 6.5 mEq/L. Cardiac arrest can occur at any time.

In the absence of adequate urine production, only dialysis can provide a long-term solution to hyperkalemia; however, there are several strategies for short-term management of this condition (Table 13.7).

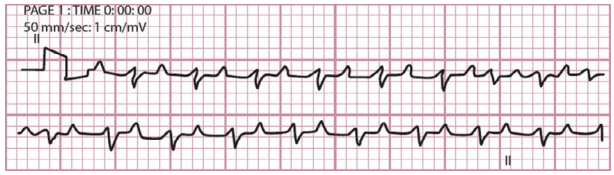

FIGURE 13.4 Example of an ECG of a patient with hyperkalemia (lead II).

TABLE 13.7 Strategies for the treatment of hyperkalemia

– Calcium gluconate (10% solution) 0.5–1.0 mL/kg can be given IV over 10–15 minutes – Protects against cardiac toxicity for approximately 30 minutes – Note: Calcium gluconate comes in several concentrations, this dose is only for 10%
– Albuterol sulfate (90 µg/actuation) 1–5 actuations delivered via "AeroDawg" chamber – Effect and duration may be dose dependent, with serum potassium decreases taking 30–60 minutes to reach maximal effect
– Regular insulin 0.1–0.25 u/kg and glucose 1–2 g per unit of insulin given – Potassium transported into cells with glucose, provides short-term correction – Note: It is important to periodically check blood glucose after administration and treat possible hypoglycemia
– Sodium bicarbonate 1–2 mEq/kg over 20 minutes – Corrects for acidosis allowing K+ back into cells, effect can last up to 1–2 hours – Note: Reserved for cases where serum bicarbonate <12 mEq/L and pH <7.2

Metabolic Acidosis

Metabolic acidosis is also common in AKI as the renal tubules are responsible for recapturing filtered bicarbonate as well as manufacturing new buffer. Generally, metabolic acidosis is not treated unless serum bicarbonate is less than 12 mEq/L and pH <7.2. A dose for bicarbonate can be calculated as (body weight in kg × 0.3) × (16 – measured bicarbonate mEq/L). Typically, only two-thirds of the dose is given with one-third given IV over 30 minutes, while another one-third can be given with IV over 4 hours. Acid–base status should be re-evaluated before additional bicarbonate is administered as needed.

Emesis

AKI patients commonly experience significant vomiting that can complicate treatment, worsen electrolyte abnormalities, and contribute to dehydration. The vomiting is likely due to both stimulation of the chemoreceptor trigger zone by uremic toxins and gastric irritation. Emesis should be addressed with a combination of antiemetic and gastric protectant medications (Table 13.8). Since there are antiemetics in at least three different class of drugs, multiple drugs can be used to control emesis. For example, it is not uncommon to combine a metoclopramide CRI with maropitant. Until emesis is controlled, these medications should be given IV.

TABLE 13.8 Protocols used in control emesis in acute kidney injury patients

Antiemetics	Medication	Class	Dose
	Metoclopramide (Reglan)	Dopamine inhibitor	0.01–0.02 mg/kg/h IV constant rate infusion or 0.2–0.5 mg/kg IV, p.o. q.8 h.
	Maropitant citrate (Cerenia)	NK1 inhibitor	1 mg/kg SC q.24 h. (dogs) 1 mg/kg SC or IV (cats)
	Ondansetron (Zofran)	5-HT3 inhibitor	0.1–1.0 mg/kg IV q.6–12 h.
	Dolasetron (Anzemet) 0.6–1.0 mg/kg IV q.24 h.	5-HT3 inhibitor	
Control of gastric irritation			
	Pantoprazole (Protonix)	Proton pump inhibitor	0.5–1 mg/kg IV q.24 h. given over 15 minutes
	Omeprazole (Prilosec)	Proton pump inhibitor	0.7 mg/kg p.o. q.24 h.
	Sucralfate (Carafate)	Gastric coating	0.5–1.0 mg/kg p.o. (dog) 0.25 mg/kg (cat)
	Famotidine (Pepcid)	H_2 receptor antagonist	0.5 mg/kg p.o., SQ, IV q.24 h.

Drug Dosage

Many drugs are excreted by the kidneys. In AKI, dosages of these drugs must be adjusted to reflect the reduced clearance. Although measuring serum drug levels and adjust dosages accordingly is ideal, it is rarely performed. A more common methodology is to give one standard dose and reduce subsequent dosages by multiplying them by 1/serum creatinine. This is based on the principle that increases in serum creatinine are inversely proportionate to the decrease in glomerular filtration rate (GFR). However, this approximation is only valid until serum creatinine approaches 4 mg/dL. Many will reduce the dosages based on serum creatinine until it rises above 4.0 and then use the calculation as a guide while empirically adjusting the dosage. Nephrotoxic drugs and renally excreted drugs with a narrow therapeutic index should be avoided in AKI patients.

Leptospirosis

Patients should be treated as outlined previously with special attention paid to fluid therapy. Patients who are oliguric or anuric benefit from advanced renal therapies such as dialysis/continuous renal replacement therapy (CRRT), and referral should be considered. Whenever possible, doxycycline should be used as the initial antimicrobial therapy as it treats both the leptospiremia and clears the carrier state; however, doxycycline is metabolized by the liver and excreted in the bile. In patients with evidence of liver impairment, antibiotics in the beta-lactam category (penicillin, ampicillin) should be used for 2 weeks to clear the leptospiremia. This is then followed with doxycycline to clear the carrier state.

Specific Toxin Ingestion

Ethylene Glycol

Exposure is always a medical emergency. Several cageside tests are available for ethylene glycol detection. These tests differ in their sensitivity as well as the complexity of the testing procedure. In the absence of an in-hospital diagnostic test, the treatment of ethylene glycol should begin whenever a combination of compatible laboratory findings (severe metabolic acidosis, increased anion gap, hypocalcemia, calcium oxalate monohydrate crystalluria) is seen in an animal demonstrating appropriate clinical signs. Because it is rapidly absorbed and likely to lead to emesis, vomiting should be not induced. Also, due to the risk of aspiration and the lack of efficacy, activated charcoal should not be administered. Initial serum chemistry should be obtained and repeated at 24 and 48 hours.

4-methylpyrazole (4-MP), an antidote, should be administered at once (Table 13.9). The first step in ethylene glycol's metabolism into toxic intermediaries takes place in the liver by alcohol dehydrogenase. Methylpyrazole binds to and inactivates alcohol dehydrogenase so that the ethylene glycol can leave the body unchanged through the kidneys. Ethanol can also be administered IV as alcohol dehydrogenase will preferentially metabolize the ethanol; however, 4-MP is safer and more efficacious. Aggressive IV fluid therapy should be started, and urine output monitored for at least 48 hours. If urine output decreases, follow AKI fluid therapy recommendations outlined previously.

In dogs, the greatest benefit of treatment is seen in the first 5–8 hours and cats within 3 hours of ingestion. In one study, those cats treated 3 hours or less after exposure with 4-MP had 100% survival while those that received ethanol had a 25% survival; however, 4 hours after ethylene glycol ingestion, there was 100% mortality regardless of treatment.

In 2015, the U.S. FDA withdrew approval for Antizol-Vet, making 4-MP unavailable to the American veterinary market. Compounded 4-MP is available but is not legal in some states. Check local laws before administering compounded 4-MP. In instances where 4-MP is unavailable, an ethanol solution can

TABLE 13.9 Treatment of ethylene glycol toxicity

Canine 4-MP treatment	4-MP (methylpyrazole 50 mg/mL) – 20 mg/kg IV first dose – 15 mg/kg at 12 hours – 15 mg/kg at 24 hours – 5 mg/kg at 36 hours
Feline 4-MP treatment	4-MP (methylpyrazole 50 mg/mL) – 126 mg/kg 4-MP (methylpyrazole 50 mg/mL) slow IV initial dose – 31.25 mg/kg IV at 12 hours – 31.25 mg/kg IV at 24 hours – 31.25 mg/kg IV at 36 hours
Ethanol treatment	Create 7% ethanol solution – Remove 175 mL from a 1 L bag of saline – Add 175 mL of 80-proof vodka Alternative – Remove 78 mL from a 1 L bag of saline – Add 78 mL of 190-proof grain alcohol (e.g., Everclear) Administer IV loading dose of – 8.6 mL/kg continued as a CRI of 1.43 mL/kg/h

be administered IV (Table 13.9). Ethanol can lead to significant central nervous system (CNS) depression, vomiting, and compound the clinical signs of ethylene glycol ingestion.

NSAID Toxicity

Nonsteroidal anti-inflammatory drugs (NSAIDs) are potent inhibitors of prostaglandin synthesis. Prostaglandins are important for maintaining normal renal blood flow, and their absence can lead to hypoxic kidney injury. Each NSAID has a different toxic dose, and whenever possible, poison control should be consulted. Rate of absorption from the GI can be affected by the formulation with gel caps being absorbed faster than tablets. Generally, if ingestion is discovered in the first 2–4 hours, vomiting should be induced. Due to extensive enterohepatic circulation, activated charcoal should be administered and repeated. Initial serum chemistry should be obtained and repeated at 24 and 48 hours. Aggressive IV fluid therapy should be started, and urine output monitored for at least 48 hours. Misoprostol, a synthetic prostaglandin E1 analog, can be given to dogs at a dose of 2.0–5.0 mcg/kg every 8 hours. Due to its long half-life, naproxen toxicities should be treated for at least 72 hours. Recently, significant NSAID toxicities have been successfully treated with therapeutic plasma exchange. These patients demonstrated little or no residual kidney injury. Owners who are interested should be referred as soon as possible, as treatment is time sensitive. Some NSAID toxicities may also be amenable to lipid therapy.

Cholecalciferol-based Rodenticides

Because of restrictions placed on traditional anticoagulant rodenticides, use of cholecalciferol-based products is becoming more common. If ingestion is discovered in the first 2 hours, vomiting should be induced and activated charcoal administered and repeated. Initial serum chemistry should be obtained and then repeated every 24 hours for 4 days. Aggressive IV fluid therapy should be started, and urine output monitored. Sodium chloride is the preferred fluid as it promotes calcium excretion. A combination of furosemide (2 mg/kg every 6 hours) and prednisone (2–3 mg/kg every 12 hours) should be administered to further increase calcium excretion. Phosphate binders (e.g., aluminum hydroxide) can be used as needed. If urine output decreases, follow AKI fluid therapy recommendations outlined previously. As treatment for cholecalciferol toxicity can last weeks, pamidronate 1.3–2.0 mg/kg given IV over 2 hours has become the preferred treatment of choice. Often only one dose is needed. Serum renal, calcium and phosphorus levels should be monitored for 6 weeks.

Grapes and Raisins

Ingestion of grapes and raisins as well as products containing them has been associated with development of AKI in dogs. The mechanism of toxicity is unknown. Interestingly, not all dogs are susceptible to the toxic effects. As it is an idiosyncratic reaction, there is no minimum dose that should be considered safe. Ingestion of anything more than palm-full should be considered toxic. Grapes delay gastric emptying; therefore, if ingestion is discovered in the first 6 hours, vomiting should be induced, and a single dose of activated charcoal administered. Initial serum chemistry should be obtained and then repeated at 24 hours. Aggressive IV fluid therapy should be started, and urine output monitored for at least 48 hours. If urine output decreases, follow AKI fluid therapy recommendations outlined previously. Dogs showing signs of AKI have a guarded prognosis. In one study, although about half of affected patients survived; 35% of survivors had had signs of CKD.

Lily Ingestion

True lily plants of the family *Liliaceae* (i.e. Easter lilies, tiger lilies, etc.) are extraordinarily nephrotoxic to cats, and even the smallest exposure should be considered potentially fatal. Simply drinking the water from a vase containing lilies can cause irreversible kidney damage. While the mechanism of the toxicity is not known, it causes severe acute proximal tubular necrosis. If ingestion is discovered in the first 2 hours, vomiting should be induced, and activated charcoal administered. Initial serum chemistry should be obtained and then repeated at 24 hours. Aggressive IV fluid therapy should be started, and urine output monitored for at least 48 hours. If urine output decreases, follow AKI fluid therapy recommendations outlined previously. Prognosis for cats presenting for lily ingestions is guarded. In one small study, cats that became oliguric or anuric died despite aggressive interventions.

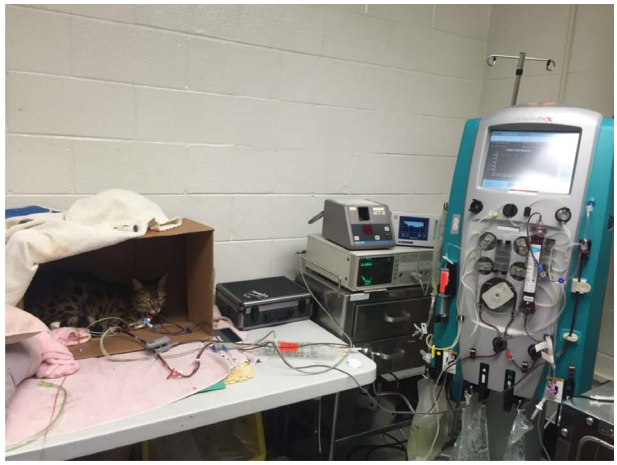

FIGURE 13.5 Patient receiving continuous renal replacement therapy. A box with towel over the front was set up to make the patient feel safe and more comfortable.

Advanced Renal Therapies

In recent years, the increasing availability of intermittent hemodialysis and continuous renal replacement therapy has made these modalities a viable option for patients with AKI (Figure 13.5). They should be considered whenever an AKI patient is experiencing azotemia, electrolyte imbalances, or fluid overload that does not respond to conventional therapy. In addition, many centers offer therapeutic plasma exchange which can help with protein bound toxins such as NSAIDS.

If an owner is interested in advanced therapies, a center should be consulted as soon as possible Chance of a successful treatment increases with earlier intervention. In addition, if there is any chance that a client may be interested in dialysis, the jugular veins should not be disturbed. In many patients, these are the only veins in which a dialysis catheter can be placed, and even a single blood draw can render a vein unusable. An up-to-date list of dialysis centers can be found at http://WWW.ASVNU.ORG.

Prognosis

Prognosis is completely dependent on the underlying cause. While leptospirosis patients may require advanced medical care including dialysis, most will do well. Those patients that are unfortunate enough to be exposed to ethylene glycol are much less fortunate. When an underlying case cannot be determined, it is generally accepted that the likelihood of recovery is 50%, although access to dialysis may improve outcome.

CHRONIC KIDNEY DISEASE

Definition/Overview

Chronic kidney disease (CKD) is characterized by a progressive decrease in the kidney's ability to concentrate urine, excrete nitrogenous waste, produce hormones, and maintain electrolyte balance. This deterioration in renal function is due to a gradual, irreversible loss of nephrons and is the most common type of kidney disease in companion animals. CKD is often divided into two categories based on the underlying etiology: Congenital and acquired.

TABLE 13.10 Congenital causes of chronic kidney disease in the dog and cat

Condition	Breed
Amyloidosis	Dog: Shar Pei, Beagle, English Foxhound Cat: Abyssinian, Siamese
Renal dysplasia	Dog: Shi Tzu, Lhasa Apso, Golden Retriever, Soft-coated Wheaten Terrier, others
Fanconi syndrome	Dog: Basenji
Polycystic kidney disease	Dog: Cairn Terrier, Bull Terrier Cat: Persian
Glomerulopathy	Dog: Bernese Mountain Dog, Brittany Spaniel, Rottweiler, Soft-coated Wheaten Terrier, English Cocker Spaniel, Samoyed, Dalmatian, Bull Terrier

In congenital kidney disease, the animal is either born with renal lesions (e.g., aplasia, dysplasia) or born with a condition that will lead to kidney disease in the future (e.g., Shar Pei fever). While many congenital renal diseases are thought to be inherited, the mode of transmission and pathogenesis is often unclear. The patient's condition usually becomes apparent early in life, often in the first year, and is progressive (Table 13.10).

Acquired CKD is the result of an insult to the renal parenchyma that causes nephron loss and precipitates a gradual decline in renal function. While in some cases it is possible to determine and treat the underlying cause of the renal disease (i.e., pyelonephritis), most cases are idiopathic. Regardless of the etiology, most cases of CKD have a similar clinical presentation, course, and treatment.

Pathophysiology

Although the exact pathophysiology of most CKD cases is not known, one possible explanation for the progressive nature of the condition is glomerular hyperfiltration. In glomerular hyperfiltration, an initial insult reduces the number of functioning nephrons (Figure 13.6). This could be a sequela of acute kidney injury, a congenital defect, or the result of a chronic disease process (e.g., hypertension). Remaining nephrons compensate by dilating glomerular arterioles, increased renal plasma flow, and increased single-nephron GFR. This process increased intraglomerular hydrostatic pressure, which eventually leads to mechanical disruption of the capillaries and protein loss through the glomerulus. Excess filtered protein is reabsorbed by the epithelial cells of the proximal convoluted tubule (PCT), broken down by cellular lysosomal mechanisms and re-enters the body as amino acids. This

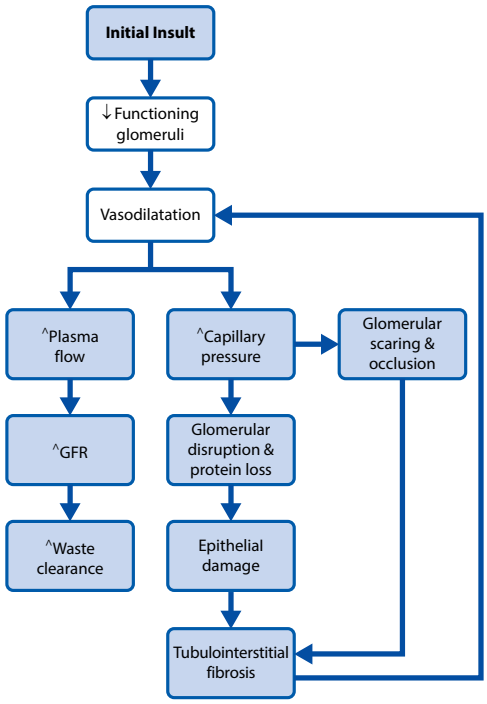

FIGURE 13.6 Pathway by which glomerular hyperfiltration leads to kidney damage.

process releases oxygen free radicals, which stimulate the release of inflammatory cytokines. The resulting inflammation damages epithelial cells. Increased glomerular pressure also results in scarring and eventual occlusion of the glomerular capillaries. Continued damage to tubular epithelial cells, combined with glomerular capillary injury, leads to tubulointerstitial fibrosis, which is the hallmark of CKD (Figures 13.7 and 13.8). Thus, what starts as a compensatory mechanism eventually perpetuates additional renal damage.

Differential Diagnosis

Prerenal, primary renal, or postrenal azotemia; acute renal injury

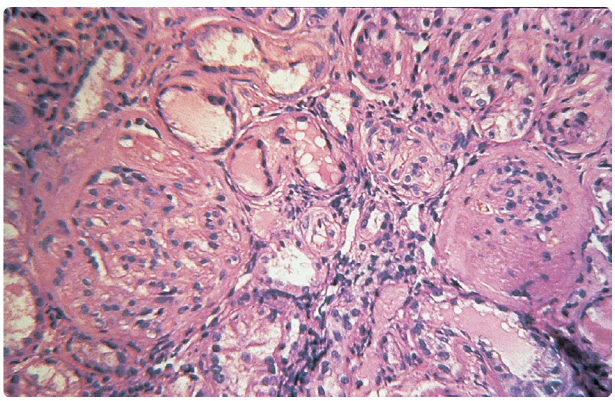

FIGURE 13.7 Histopathology of the kidney from a dog with chronic kidney disease. Glomerulosclerosis and a mononuclear interstitial infiltrate. (*Courtesy of D.F. Senior.*)

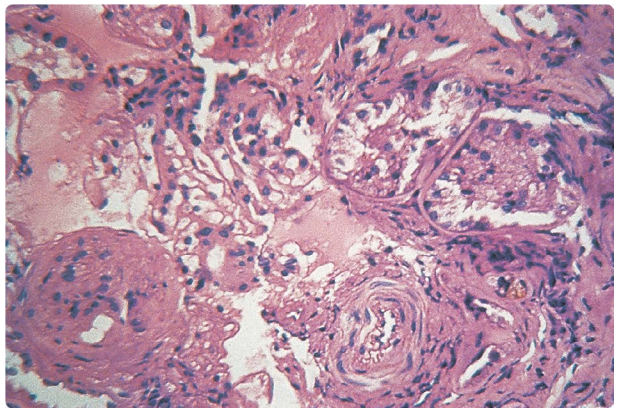

FIGURE 13.8 Histopathology of the kidney from a dog with chronic kidney disease. Tubular atrophy and interstitial fibrosis. (*Courtesy of D.F. Senior.*)

Clinical Presentation

Common clinical features of CKD include polyuria/polydipsia, weight loss, lethargy, anorexia, vomiting, dehydration, oral ulcers, and uremic breath. In cats, blindness secondary to hypertension is not uncommon and is often the primary reason that owners seek veterinary care.

Diagnosis

The diagnosis of CKD is made on the basis history, physical examination, and laboratory blood work. Once the presence of azotemia is confirmed, possible differential diagnosis (prerenal azotemia, postrenal azotemia, and AKI) must be eliminated from consideration. A complete blood count, serum chemistry, urinalysis with urine protein-to-creatinine ratio, and ultrasound should be performed on all CKD patients.

Serum Chemistry

Traditionally, the diagnosis of chronic kidney disease focused on elevations in BUN and creatinine. However, CKD patients are often muscle wasted, which can artificially decrease creatinine. In addition, BUN can be affected by many nonrenal factors (e.g., diet, hydration, GI bleeding), making it a somewhat unreliable indicator. Symmetric dimethylarginine (SDMA) is a newer and more consistent marker of kidney function. SDMA is product of protein modification and is produced in the cytoplasm of all nucleated cells. Because it is cleared exclusively by the kidneys, it is an excellent marker of kidney function. Elevations in SDMA have the ability to detect decreased kidney function up to 17 months before creatinine in cats and as much as 9 months in dogs. SDMA should be part of screening blood work in older pets and those with suspected renal impairment. It important to note that SDMA is essentially a measure of glomerular filtration and can be increased in dehydrated patients; therefore, accessing patient hydration status is essential.

Elevation of serum phosphate is common. Calcium is often mildly to moderately elevated as a result of secondary hyperparathyroidism. Serum bicarbonate

decreases with the degree of renal dysfunction and significant decreases may be associated with a worse long-term prognosis. Potassium levels are usually maintained in the normal range in dogs, but hypokalemia can be observed in cats.

Complete Blood Count

A normochromic, normocytic, nonregenerative anemia is the most common hematologic finding in patients with CKD. Elevations in the white blood cell count can be associated with chronic pyelonephritis or a systemic infectious disease; however, the white blood cell counts are usually unremarkable.

Urinalysis

The most common urinalysis finding in CKD is isosthenuria (specific gravity 1.007–1.015); however, some cats may be able to concentrate urine in the early phases of CKD. The finding of large amount of glucose in a normoglycemic patient is suggestive of proximal tubular dysfunction and can be seen in dogs with Fanconi syndrome (Figure 13.9). The detection of protein, in the absence of gross hematuria, bacteria, white blood cells, or casts in the urine sediment, may be the result of glomerular disease. A quantitative assessment of urine protein concentration requires that a urine protein-to-creatinine ratio (UPC) be performed (see section on Glomerular Disease). In cats, UPC may be prognostic even in the absence of overt proteinuria. Studies suggest that cats with CKD and a UPC <0.43 can be expected to live approximately 2 years from the time of diagnosis. Those with a UPC >0.43 live only about 9 months. Even in the absence of microscopically detected bacteria, a urine culture should be considered if pyelonephritis is suspected.

Blood Pressure Measurement

Hypertension is a common complication of CKD that eventually affects the majority of cats and dogs. Not only can hypertension have negative consequences for the eyes, heart, and nervous system, it can also potentiate further kidney damage; therefore, identifying and treating these patients is essential. Specific guidelines for measuring and treating hypertension can be found in the hypertension section.

Fanconi facts	Failure of proximal tubule transport Sodium, bicarbonate, potassium, glucose, amino acids not resorbed 10–16% of Basenjis affected, documented in other breeds
Diagnosis	Signs of CKD and glucosuria with normal blood glucose are suggestive Aminoaciduria is diagnostic
Treatment	Oral supplementation: Bicarbonate goal (serum >12 mmol/l [12 mEq/l]); potassium goal (serum 4–6 mmol/l [4–6 mEq/l]); calcium goal (serum 2.25–2.5 mmol/l [9–10 mg/dl]) Renal failure diet
Prognosis	Good with proper treatment

FIGURE 13.9 Fanconi syndrome characteristics.

Radiographs and Ultrasound

When available, ultrasound is the preferred imaging modality. It can provide an unparalleled view of the renal architecture and outflow tract; nevertheless, radiographs can be helpful is accessing kidney size and for looking for ureteral stones. Typically, CKD is characterized as bilateral loss of renal mass; however, certain disease processes, such as polycystic kidney disease, have a characteristic ultrasound appearance. Enlarged kidneys are suggestive of an underlying disease process (e.g., lymphoma, feline infectious peritonitis [FIP], hydronephrosis), primary renal neoplasia, or AKI. Mild dilatation of the renal pelvis (pyelectasia) can be seen with chronic kidney infections. Congenital renal dysplasia and aplasia are characterized by an abnormal renal architecture with loss of the delineation between the cortex and medulla.

Management

Staging

Patients with CKD should be staged according to the guidelines developed by the International Renal Interest Society (IRIS). These guidelines classify patients on the basis of renal function, proteinuria, and blood pressure (Table 13.11). For example, a 15-year-old cat with an SDMA of 37, creatinine of 3.0, UPC of 2.0, and blood pressure of 170 mmHg would be classified as a Stage 3, proteinuric, hypertensive patient. The IRIS scoring system not only allows for a common nomenclature for describing, discussing, and monitoring patients, it allows for best practice to be developed and promulgated for disease stage.

Fluid Therapy

Many patients with CKD present with some degree of dehydration. This can complicate management of CKD as dehydration leads to hypoperfusion and prerenal azotemia. Thus, proper rehydration can result in significant reductions in azotemia. Therefore, the degree of dehydration should be estimated, and, if significant, a regimen of replacement fluids should be calculated and administered intravenously over 12–24 hours (Table 13.6). In mildly dehydrated patients, subcutaneous fluids can be administered during the office visit. In either case, when patients have difficulty maintaining proper hydration, the daily administration of subcutaneous fluids at home can help prevent dehydration, reduce azotemia, and improve the patient's quality of life (Figure 13.10a, b) An alternative possibility is the placement of an esophagostomy tube (Figure 13.11a–h). These are easily inserted (with practice), can remain in position for extended periods of time, and can be used to provide the pet's fluid and nutritional needs. They also provide a route for medication administration.

TABLE 13.11 IRIS stages of CKD

		Stage 1	Stage 2	Stage 3	Stage 4
Creatinine* in mg/dL	Canine	<1.4 (125 µmol/L)	1.4–2.8 (125–250 µmol/L)	2.9–5.0 (251–440 µmol/L)	>5.0 (440 µmol/L)
	Feline	<1.6 (140 µmol/L)	1.6–2.8 (140–250 µmol/L)	2.9–5.0 (251–440 µmol/L)	>5.0 (440 µmol/L)
SDMA* in µg/dL	Canine	<18	– 18–35	– 36–54	– >54
	Feline	<18	18–25	26–38	>38

UPC ratio Canine	Nonproteinuric <0.2	Borderline proteinuric 0.2–0.5	Proteinuric >0.5
Feline	Nonproteinuric <0.2	Borderline proteinuric 0.2–0.4	Proteinuric >0.4

Systolic blood pressure in mmHg	Normotensive <140	Prehypertensive 140–159	Hypertensive 160–179	Severely hypertensive >180

* If the SDMA and creatinine are discordant, you should use the one that produces the higher stage.

Control of Acidosis

One of the primary functions of the kidney is to maintain acid–base balance. The renal tubules reabsorb filtered bicarbonate, generate new bicarbonate, and excrete acids. As CKD progresses, the ability of the kidneys to perform this function fails. Even when mild, chronic acidosis enhances protein catabolism, promotes bone demineralization, and contributes to the array of clinical signs. Because most feline maintenance diets are acidified, changing the patient to an appropriately buffered kidney disease diet helps prevent and correct metabolic acidosis. When the patient is being fed an appropriate diet, additional oral alkalization therapy is only indicated when total CO_2 is <18 mEq/L or serum bicarbonate is <17 mEq/L. Initially, sodium bicarbonate at a dose of 5–10 mg/kg q.8–12 h. or potassium citrate at 40–60 mg/kg q.8–12 h. can be given. The exact dose needs to be tailored to the individual patient.

Potassium

Hypokalemia is a common finding in cats with CKD and is associated with muscle weakness, muscle mass loss, ileus, and potentially cardiac arrhythmias; however, the most commonly observed manifestation is anorexia. This condition is not recognized in dogs. The mechanism by which cats develop hypokalemia is unknown; however, it is generally believed to be a combination of malnutrition and excessive renal losses. In one study, one-third of healthy cats fed a potassium restricted diet developed interstitial nephritis and fibrosis. This suggests that low potassium is not only an effect of kidney disease but can contribute to its progression. For this reason, feline kidney disease diets are potassium supplemented and, in most cases, will prevent hypokalemia. In patients that do not respond to diet therapy alone, oral supplementation with potassium citrate 20–30 mg/kg p.o. q.24 h. can be given (a convenient powder form is commercially available for the smaller-sized animal).

Hyperphosphatemia

Because of its role in muscle and nerve conduction, calcium is highly regulated within the body. Parathyroid hormone (PTH) is released by the parathyroid gland in response to decreases in circulating

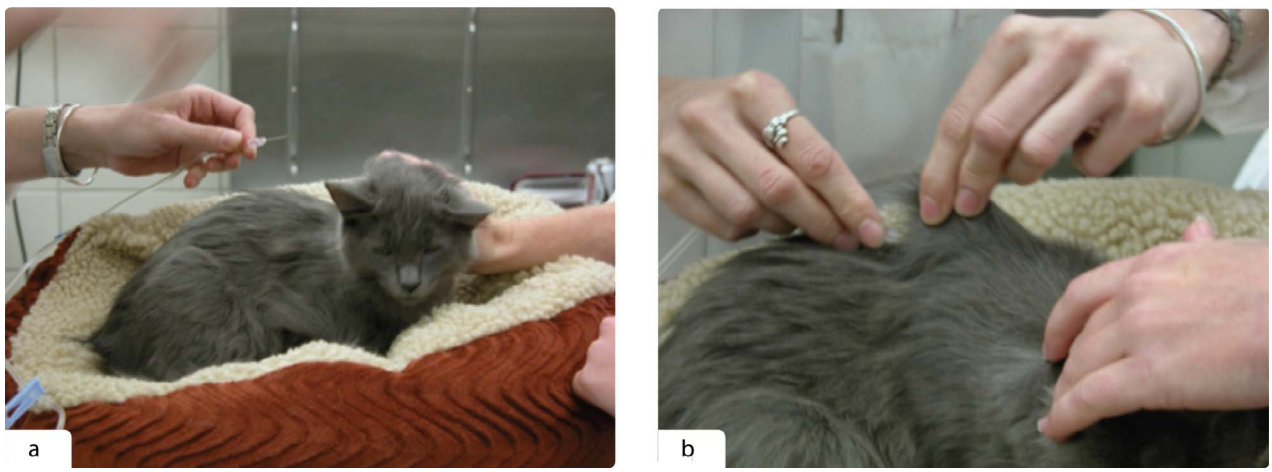

FIGURE 13.10 (a, b) Cat with chronic kidney disease receiving subcutaneous fluids.

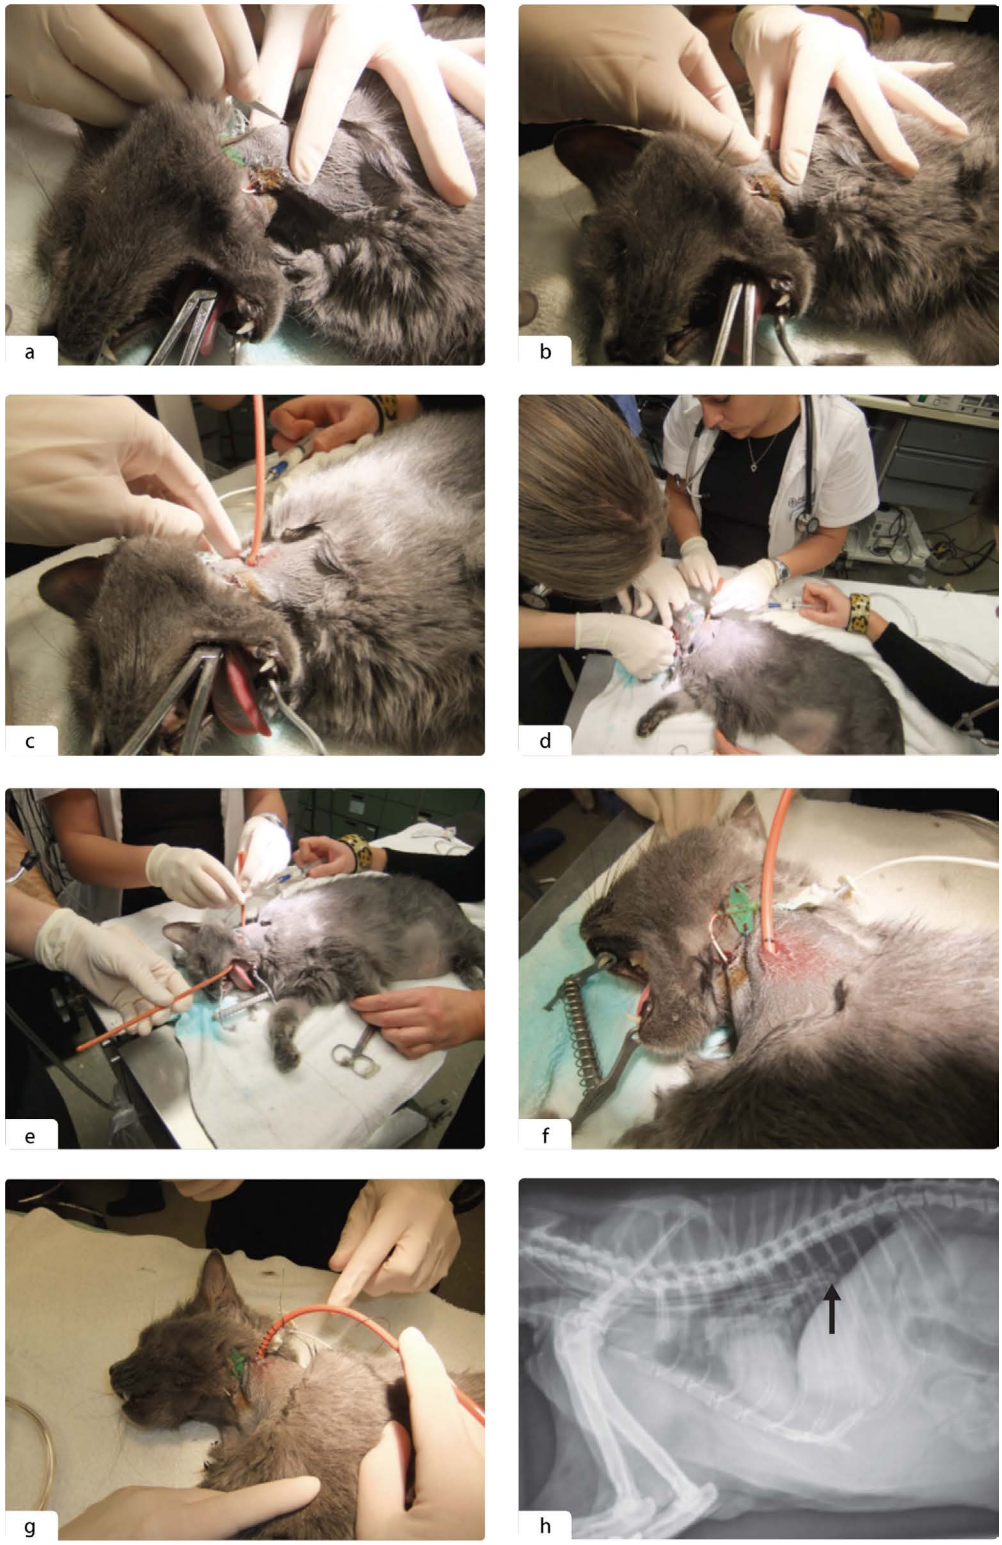

FIGURE 13.11 Esophagostomy tube placement. The patient is anesthetized and monitored. Although most tubes are placed on the left lateral cervical area, the right can be used as well. A red rubber or silicone tube is selected and marked so that the end of the tube will be located in the esophagus between the 6th and 9th intercostal spaces. The left lateral cervical area is clipped and scrubbed. The jugular vein is identified and isolated. **(a)** A pair of Mixter hemostats (tip forms a right angle) is inserted into the mouth and a small stab incision is made through the skin just over the tip of the hemostat. **(b)** The hemostat is seen poking through the skin. **(c)** A feeding tube is inserted into the open jaws of the hemostat. **(d)** The feeding tube is pulled into the esophagus and out of the mouth. **(e, f)** The tube is fed back into the mouth and down the esophagus. **(g)** A purse-string suture and a finger trap are placed to hold the tube in place. **(h)** Radiography confirms correct placement. Note the end of the tube is caudal to the heart and cranial to the lower esophageal sphincter (arrow).

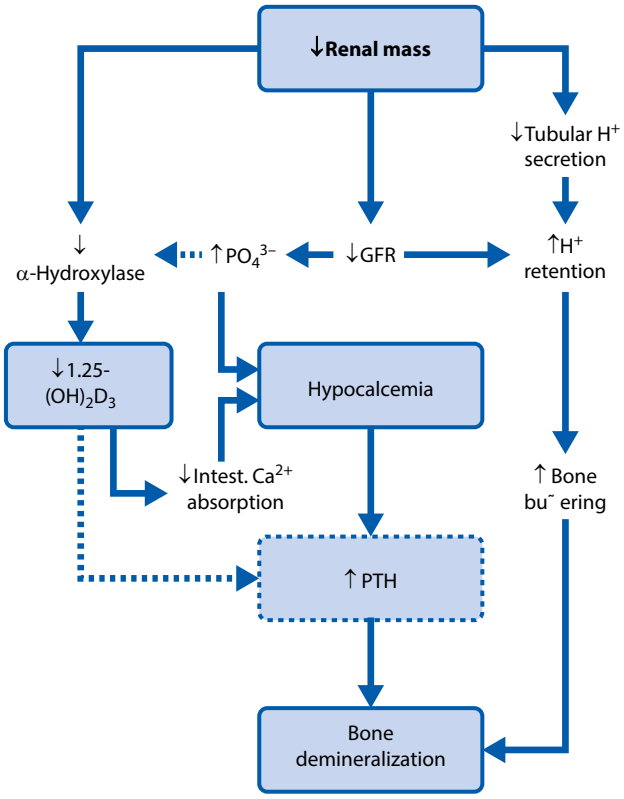

FIGURE 13.12 Pathogenesis of renal secondary hyperparathyroidism in chronic kidney disease. Renal production of calcitriol normally inhibits parathyroid hormone production and release by the parathyroid gland. Broken arrows indicate an inhibitory action.

calcium (Figure 13.12). PTH causes the release of stored calcium and simulates an enzyme in the renal tissue, alpha-1 hydroxylase, to convert calcidiol to calcitriol. Calcitriol, the active form of vitamin D3, stimulates absorption of calcium from the intestinal tract, enhances the activity of PTH, and provides the negative feedback for PTH release. Phosphate is normally absorbed from the diet, used for metabolic processes, and subsequently undergoes renal excretion. As renal mass decreases and GFR falls, excessive levels of phosphate accumulate in the blood. Phosphate acts to inhibit alpha-1 hydroxylase, thus preventing the formation of calcitriol and removing the negative feedback on PTH. Thus, hyperphosphatemia leads to loss of calcitriol, increased release of PTH, and further harvesting of calcium and phosphorus from bone. Soft tissue mineralization becomes a concern when serum calcium and phosphorus are elevated. In addition, PTH is believed to be a uremic toxin which is responsible for some the signs seen in CKD patients.

Lastly, calcitriol may also play a role in slowing the progression of renal disease. Therefore, controlling hyperphosphatemia is essential.

There is no medical treatment that will rapidly decrease serum phosphorus levels; however, fluid therapy can help in dehydrated patients. Since the primary source of serum phosphorus is dietary, the first step is to change the patient's diet to a low-phosphorus kidney disease diet. In some cases, this will adequately control serum phosphorous levels. If after 1–2 weeks hyperphosphatemia has not resolved, a phosphate-binding agent should be added. Aluminum hydroxide and aluminum carbonate are commonly used and effective in binding phosphorus in the intestine. These are dosed at 30–80 mg/kg q.24 h. divided and given with meals. Cats often find liquid phosphate binders to be unpalatable and may do better with powered forms. Lanthanum carbonate (Fosrenol) 30 mg/kg divided and given with meals is an alternative. It should be crushed and mixed well with food. Calcium acetate given at 60–90 mg/kg q.24 h. divided with meals may also be effective in binding phosphate but may contribute to hypercalcemia; therefore, monitoring of serum calcium is essential. Regardless of the binder selected, the medication should be started at the lowest dose and then adjusted as needed based on serum phosphorus levels. Two weeks should be given between rechecks. Several new phosphate binders have been introduced for use by human kidney disease patients. These new drugs are expensive and have not been shown to be more effective or safer in cats and dogs.

Since elevated PTH levels result from inhibition of calcitriol synthesis, supplementation with exogenous calcitriol has been proposed as a treatment for secondary hyperparathyroidism. Studies suggest that calcitriol therapy slows progression of CKD and improves survival in CKD dogs. Since studies have shown no such benefit in cats, calcitriol should not be used in this species. Prior to calcitriol use, calcium and phosphate serum levels should be within normal range. Calcitriol given at 2.0–2.5 ng/kg per day has been effective in normalizing serum PTH levels; however, dosages must be tailored to each patient. Ionized calcium and PTH must be monitored. The goal is to minimize PTH without inducing hypercalcemia. Since calcitriol can significantly increase intestinal calcium and phosphorus absorption, it must not be given with food. It is recommended that calcium and phosphate levels be monitored 1 week after starting therapy and monthly thereafter.

Proteinuria

Proteinuria can accelerate the progression of CKD, and steps to mitigate protein loss should be taken when the UPC exceeds 0.4 in the cat and 0.5 in the dog. Therapy usually involves feeding of a protein-restricted diet and administration of a renin–angiotensin–aldosterone system (RAAS) inhibitor. The goal of the therapy is to reduce the protein-to-creatinine ratio by at least 50% and preferably into the normal range. More treatment information is available in the PLN section.

Treatment of Anemia

The cause of anemia in CKD is multifactorial and includes decreased red blood cell (RBC) life span due to uremic toxins, nutritional deficiencies impairing RBC production, and intestinal bleeding; however, the most important cause of anemia is the loss of erythropoietin production by renal interstitial cells (Figure 13.13). Erythropoietin

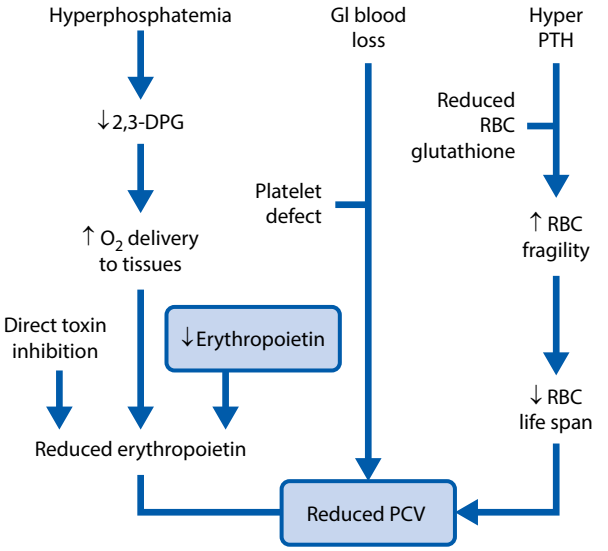

FIGURE 13.13 Pathogenesis of anemia in chronic kidney disease. The major cause of anemia is reduced renal production of erythropoietin.

is a glycoprotein that increases the number of committed stem cells in the bone marrow that will develop into erythrocytes. In the absence of erythropoietin, erythroid stem cells undergo apoptosis. Release of erythropoietin depends on oxygen sensors located on renal interstitial cell membranes. These sensors upregulate production of erythropoietin during hypoxia and downregulate production when blood oxygen levels are normal.

Patients who are symptomatic for their anemia or have a critically low packed cell volume (PCV) should immediately receive a compatible transfusion. Those patients with low PCVs that are not symptomatic should be started on a recombinant erythropoietin replacement therapy. Two options exist: Epoetin alfa (Epogen), and darbepoetin alfa (Aranesp®). Epoetin alfa is significantly less costly. Because it is a human recombinant protein, epoetin alfa simulates an immune response in 25%–30% of patients. This can inactivate the exogenous hormone as well as the endogenous erythropoietin. The resulting red cell aplasia can be difficult to treat and can leave the patient transfusion dependent. For this reason, epoetin alfa should be reserved only for patients with significant anemia and cost concerns. The induction dose is 50–150 units/kg SQ 3 times a week. Response time is variable, but increases in PCV are usually seen in 1–2 weeks, and target PCV should be obtained within a month. Once PCV has returned to 24%–28%, the dose is tapered down to the minimum needed to maintain efficacy. Often 50–100 units/kg SQ 1–2 times a week is sufficient. The PCV should be rechecked every 2 weeks during induction and then monthly. Failure of the PCV to rise despite increasing dosages of epoetin alfa is strongly suggestive of an immune response. The drug should be discontinued at once, and its use can be re-attempted in 3–4 weeks. As the immune response is likely to persist, these patients may never again respond appropriately to therapy. In addition, once an immune response develops to epoetin alfa, darbepoetin alfa is unlikely to be effective. Use of epoetin alfa has also been associated with hypertension, and, therefore, blood pressure should be checked regularly.

Although darbepoetin alfa is costlier, experience suggests that it is much less likely to stimulate an immune response. The induction dose is 0.45–1.5 mcg/kg subcutaneously (SC) every 7 days. This continues until the patient's PCV reaches the low end of the normal range. At this point, the patient is changed to every-other-week dosing. Initially, PCV should be checked weekly and then monthly once stable. Due to the high demand for iron needed for erythropoiesis, it is recommended that patients receiving either epoetin alfa or darbepoetin alfa receive iron supplementation (10 mg/kg intramuscularly (IM) every 3–4 weeks). Like Epogen, use of darbepoetin alfa has been associated with hypertension, requiring regular blood pressure evaluations.

Diet

The mainstay of CKD management is the correction of dehydration and nutritional support. Dietary formulations for patient with CKD have traditionally focused on protein restriction in hopes of slowing the progression of kidney disease. While protein restriction does help reduce uremia and can significantly improve the patient's quality of life, it is not clear that controlling protein alone can significantly change the disease course. Nevertheless, it is clear that patients with CKD who are fed a kidney disease diet live longer than those fed a maintenance formulation. Control of acidosis, hyperphosphatemia, and hypokalemia are helpful in treating these patients. Studies demonstrate that proper regulation of serum phosphorus alone can improve survival of CKD patients. The ratio of omega-3 to omega-6 fatty acids may also play an important role in slowing the progression of renal disease. Commercially available kidney disease diets are generously supplemented with omega-3 fatty acids.

Anorexia

Patients with CKD often suffer from anorexia. While the exact cause of inappetence is unknown, it is probably related to uremic toxins combined with irritation of the gastrointestinal tract. Due to their low protein, restricted phosphorus, and reduced sodium, kidney disease diets can be unpalatable. Owners should try several different brands and formulations in order to find one that their pet will eat. Some owners report good success with rotating several different diets. Many CKD pets will eat frequent small meals rather than one or two large ones; therefore, feeding schedules and amounts may need to be adjusted. Warming of wet food can also make a renal diet more palatable, especially to cats; however, when utilizing a microwave oven, care must be taken as nonuniform heating can lead to oral burns. Transdermal mirtazapine (Mirataz®) has been approved for use in the United States and the EU as an appetite simulant in cats. Recently, capromorelin (Elura®) was

approved in the United States as an appetite simulant for cats with CKD. Because hypergastrinemia can occur with CKD, many patients respond to H2-histamine receptor blockers such as famotidine 0.5 mg/kg IV, p.o. q.24 h. When present, nausea can usually be relieved with maropitant citrate (Cerenia®) or dolasetron mesylate (Anzemet®) (see Table 13.8).

Advanced Renal Therapies

Renal transplantation for cats with CKD is now being performed at select referral centers. In order to be a candidate, a patient must be documented to be free of infectious diseases such as feline leukemia virus, feline immunodeficiency virus, and toxoplasmosis. Recent thoracic radiographs and an abdominal ultrasound are required to show the absence of a malignancy. In addition, an echocardiogram may be required to demonstrate that the patient does not have on underlying cardiac condition. A good candidate would be a middle-aged cat that is suffering from increasing azotemia despite appropriate therapy and in good body condition. Six-month survival approaches 60% while 3-year survival is greater than 40%. While renal transplantation has been performed in dogs, the success rates have not been encouraging due to problems with tissue rejection. Centers performing renal transplantation can be found online at WWW.ASVNU.ORG.

Hemodialysis for the CKD patient is available at some centers. While technically feasible, cost, complications, and the need for frequent treatments has made this option impractical for most.

Prognosis

CKD is an insidious disease, and progression is inevitable; however, when properly managed, patients can do well for relatively long periods of time. In general, cats will do well for longer periods of time than dogs.

PROTEIN-LOSING NEPHROPATHY

Definition/Overview

Normally, the glomerulus provides an effective barrier against the loss of albumin and other large proteins. In protein-losing nephropathy, the barrier is disrupted, and excessive amounts of protein cross the glomerular filtration barrier into the tubules. As a result, tubules become damaged by inflammation and fibrosis. Thus, what starts as a localized disruption of the glomerulus leads to a generalized disease of the nephron and kidney.

Pathophysiology

The glomerular capillary bed is unique in that it can filter molecules based on the size and charge of a molecule. The wall of the glomerular capillary is composed of three distinct layers: Endothelial cells, glomerular basement membrane, and epithelial cells (Figure 13.14). The endothelial cells form the inner lining of the capillary

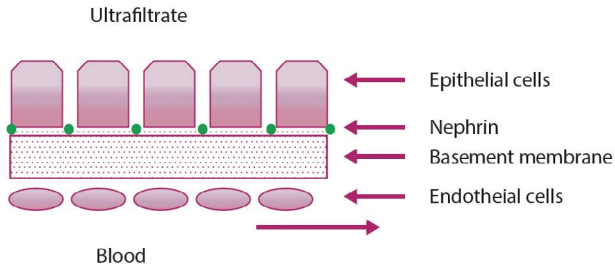

FIGURE 13.14 The components of the glomerular membrane.

tube. While the endothelial cells do not provide a significant filtration barrier, they do serve other important functions such as the inhibition of clot formation. The basement membrane, which provides the structural scaffold of the glomerulus, possesses a negative charge that helps establish glomerular charge selectivity. It is composed of type IV collagen, laminin, and heparan sulfate. Collagen is primarily responsible for the structural support, laminin is involved with cell adhesion, and heparan sulfate provides the basement membrane its negative charge. Epithelial cells, called podocytes, freely float in Bowman space. These cells give rise to an array of parallel projections called foot processes, which are attached to the basement membrane. The projections interdigitate to form slit pores. Proteins, such as nephrin, bridge slit pores and limit the size of molecules that can pass.

The degree to which a protein can pass across the glomerular capillary wall is a function of molecular size and charge (Figure 13.15). Selectivity is based primarily on podocyte slit pores and to a lesser extent the negative charge. Typically, small negatively charged proteins, such as inulin (5,200 MW) are freely filtered. Larger ones such as myoglobin (17,000 MW) are partially filtered, while albumin (69,000 MW) is minimally filtered. Under normal circumstances, most filtered proteins are

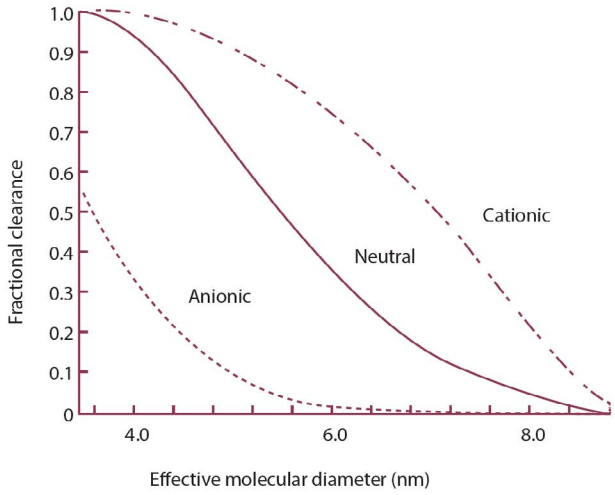

FIGURE 13.15 Charge selectivity of glomerulus demonstrated by fractional clearance of anionic and neutral molecules. The neutral molecule is more freely filtered because it is not repelled by the membrane's charge.

reabsorbed in the proximal convoluted tubule. Large proteins are taken into the tubular epithelial cells by carrier-mediated endocytosis and then catabolized in the lysosomes where they are broken down into amino acids. The process of breaking down large amounts of proteins into amino acids is thought to release oxygen free radicals and leads to the release of inflammatory cytokines. The resulting inflammation causes fibrosis and scarring of the tubules.

There are two broad disease categories associated with disruption of the normal filtration barrier of the glomerulus and the development of protein-losing nephropathy (PLN): Glomerulonephritis (GN) and amyloidosis. These cannot be distinguished from each other on the basis of clinical signs or laboratory data. Only a renal biopsy can differentiate the two conditions.

Amyloidosis

Amyloidosis is caused by an inappropriate deposition of fibrils into glomerulus. These fibrils are formed by the polymerization of protein subunits, which have a specific tertiary structure called a beta-pleated sheet. These subunits, such as serum amyloid A (SAA), are produced in the liver and are one of a number of acute-phase reactants manufactured in response to inflammation. The exact function of these proteins is unknown, but production appears to be simulated by interleukin-2 (IL-2), IL-6, and tumor necrosis factor (TNF), which are released by macrophages. Once polymerized, the amyloid fibrils cannot be degraded because the beta-pleated sheet conformation prevents enzymatic degradation. When deposited in the glomerulus, the fibrils act to disrupt normal function (Figure 13.16).

Glomerulonephritis

Glomerulonephritis (GN) results from the deposition of preformed circulating immune complexes or complexing of circulating antibodies with exogenous or endogenous antigens on the glomerular basement membrane. The presence of immune complexes leads to activation of complement, neutrophil chemotaxis, platelet aggregation, and activation of the coagulation system. This results in protein spilling across the glomerulus and into the proximal tubules. Eventually, the glomerulus responds to the immune response with cellular proliferation, thickening of the basement membrane, and eventually sclerosis.

GN can be divided into three categories based on histologic appearance: (1) Membranoproliferative glomerulonephritis, (2) membranous nephropathy, and (3) proliferative glomerulonephritis.

Membranoproliferative glomerulonephritis (MPGN) is the most common type of GN seen in the dog and accounts for up to 60% of all cases. While a familial form of the disease is seen with Bernese Mountain dogs, and a rapidly progressive form has been associated with *Borrelia burgdorferi* infection, the underlying cause of most cases is unknown. The classic histopathologic appearance is that of thickened capillary loops and mesangial hypercellularity (Figures 13.17–13.20).

Membranous nephropathy (MN) is the second most common type of GN lesions seen in the dog and is the most common in the cat (Figures 13.21–13.24). In this condition, the glomerular basement membrane becomes thickened due to the deposition of immune complexes in the subepithelial spaces and the resulting proliferation of the basement membrane. Proliferative glomerulonephritis accounts for as little as 2% of GN cases and is characterized by endocapillary or mesangial proliferation.

Clinical Presentation

Generally, PLN is a disease of middle-aged to older dogs. Clinical features of PLN are somewhat dependent on the stage at which the disease is diagnosed. While some dogs are azotemic and sick, many cases are detected on routine urinalysis in otherwise healthy patients.

Diagnosis

Urinalysis

The hallmark of PLN is the finding of inappropriate amounts of urine protein in the absence of bacteria, casts, or white blood cells. It is impossible to determine the significance of proteinuria detected on urinalysis or dipstick; therefore, the finding of proteinuria always warrants further investigation.

Normal renal protein excretion in dogs and cats is less than 20 mg/kg per day. A 24-hour urine collection is the gold standard for quantifying the magnitude of protein excretion; however, this is neither convenient nor practical in the clinical setting. Because the urine protein-to-creatinine ratio (UPC) has been shown to closely correlate with 24-hour protein excretion, this value is most commonly used. Healthy dogs and cats have been shown to have a UPC of less than 0.5 and 0.4, respectively. It is important to note that the presence of white blood cells, bacteria, epithelial cells, and casts can significantly increase the UPC; therefore, UPC should only be performed in tandem with a urine sediment examination. Interestingly, RBCs have a minimal effect on the UPC.

Studies have shown that there are day-to-day variations in the amount of protein that is lost through the glomerulus of PLN patients. For example, a patient with a UPC of 4.0 can expect as much as a 50% day-to-day variation in the UPC. This makes monitoring and treating these patients challenging, as 1.0–2.0 changes in the UPC could either be either be a response to treatment or just day-to-day variability. One way to avoid this is to have the owner collect and refrigerate free catch samples over 3–4 days and then submit a pooled sample of the urine. This minimizes the day-to-day variation and provides a more accurate assessment of protein loss. Providing the urine is properly refrigerated, the UPC is stable.

Serum Chemistry

Findings are dependent on the stage of the disease. In many otherwise healthy patients, the chemistry may be normal. In slightly more advanced cases, the patient may have hypoalbuminemia. Finally, patients presenting with signs of kidney disease usually have elevations in BUN, creatinine, phosphorus, and a decrease in bicarbonate.

Complete Blood Count

In all but the most advanced cases, the CBC will be normal. In patients with clinical signs of kidney disease, a normocytic, normochromic, nonregenerative anemia may present. Changes in the white blood can occur with specific infectious diseases.

Underlying Cause

As glomerulonephritis can be secondary to an identifiable underlying disease (Table 2.13.1), and amyloidosis is associated with inflammation, a thorough search for an inciting cause is essential. Infectious, neoplastic, endocrine, inflammatory, and drug-related causes must be considered (Figure 2.13.1).

Infectious Disease Serology

Serologic tests should be selected on the basis of the patient's geographic location and the relevant travel history.

Blood Pressure

Hypertension can be both a cause and a result of proteinuria hypertension; thus, evaluation of blood pressure is essential

Radiographs and Ultrasound

Imaging plays an important part in the diagnostic plan for PLN. Protein-losing nephropathy can be secondary to neoplastic processes, and ultrasound and radiographic studies in combination with a thorough physical examination are essential in elimination this as a possible underlying cause. Ultrasound can also provide information about the renal architecture. In addition, this modality can be used to obtain renal biopsies in a minimally invasive fashion.

If an underlying disease process is found, then therapy aimed at treating the primary condition should be initiated; otherwise, the condition is labeled as idiopathic. Prognosis may be better if the cause can be identified and treated.

Management

Amyloidosis versus Glomerulonephritis

The only way to differentiate amyloidosis from glomerulonephritis is by renal biopsy. There is no meaningful difference between the clinical pathology and physical exam findings in these two conditions. At a minimum, tissue samples should be stained with Congo red to determine if the patient has GN or amyloidosis (see Figure 13.16). In addition, several forms of GN are recognized and can only be differentiated on the bases on a renal biopsy sample examined by light, electron, and

immunofluorescence microscopy. As this requires special equipment and staining, there are a limited number of centers that perform this type of histopathological study. One such laboratory is International Veterinary Renal Pathology Service in the United States. Another is the European Veterinary Renal Pathology Service (EVRPS). Since different forms of protein-losing nephropathy have different treatment options and prognosis, these pathology services should be utilized whenever possible.

Amyloid-Specific Treatment

Colchicine, an inhibitor of microtubule assembly, has been shown to inhibit release of serum amyloid A from hepatocytes and may be of benefit before overt signs of kidney disease develop. It has been used in humans with familial Mediterranean fever to prevent onset of renal amyloidosis. The efficacy of this drug in treatment of renal amyloidosis in animals in not established. Colchicine has significant side effects, including vomiting, diarrhea, and nausea. In addition, there is no known benefit to starting treatment after azotemia develops. The currently recommended canine dose is 0.025–0.03 mg/kg p.o. q.24 h.

Although controversial, dimethyl sulfoxide (DMSO) has been advocated for the treatment of amyloidosis. Theoretical benefits include solubilization of amyloid fibrils, reduced serum concentration of SAA, as well as reduced renal inflammation. There are no studies to determine if DMSO is beneficial in the treatment of amyloidosis, but case reports suggest a benefit. The canine dose is 90 mg/kg diluted 1:4 with sterile saline given subcutaneously 3 times a week. Methylsulfonylmethane (MSM) is a derivative of DMSO that can be given orally. Theoretical benefits are the same as for DMSO, but it is considered more convenient since it can be given at home. It should be noted that there is no data or published case reports to support the use of MSM. Recommended canine dose is 88 mg/kg q.8 h.

GN Specific

Angiotensin-converting enzyme (ACE) inhibitors have been shown to decrease UPC and improve clinical outcome in patients with GN. The effect may be due to decreased glomerular hydrostatic pressure secondary to dilation of the efferent arteriole. There is also evidence that ACE inhibitors may inhibit cytokine production, thereby decreasing interstitial fibrosis. Although enalapril can be used, it is cleared exclusively through the kidney, while benazepril (0.25–0.5 mg/kg p.o. q.12–24 h.), which has renal and hepatic clearance, is preferred. There is some evidence that angiotensin receptor blockers (ARBs) may be as if not more effective than ACE inhibitors. Telmisartan 1.0–2.0 mg/kg p.o. q.24 h. has been shown to effectively decrease proteinuria in cats. This likely true in dogs as well.

Immunosuppression

When histopathologic evidence of an active immunologic basis for the PLN exists, immunosuppressive therapy is strongly recommended. Such evidence would include electron-dense deposits detected on electron microscopy and immunoglobulin or complement-associated immune complexes detected by immunofluorescent microscopy. In cases where the PLN is progressive and histopathology is unavailable, the use of immunosuppressive drugs could be considered providing the owner is aware of potential risks. In cases of progressive canine GN, mycophenolate 10 mg/kg p.o. q.12 h. has been recommended with or without cyclophosphamide 200–250 mg/m^2 every 3 weeks. Response to treatment can be measured by changes in the UPC. A complete response is defined as a UPC of <0.5, while a partial response is defined as a reduction of the UPC by 50% of the pretreatment value. In dogs that demonstrate no response to immunosuppressive therapy after 8 weeks, immunosuppression should be discontinued. In patients that do have a response to therapy, immunosuppressive therapy should continue for 12–16 weeks, after which the dose may be tapered while monitoring UPC and degree of azotemia.

COMMON AMYLOID AND GN THERAPIES

Diet Therapy

Patients with PLN should be fed a properly formulated kidney disease diet which is low in protein, high in omega-3 polyunsaturated fatty acids, and low in sodium. Studies in people with PLN have shown that feeding a high-protein diet is associated with increased glomerular protein loss, additional renal pathology, and higher mortality. Conversely, patients fed a low-protein diet lose less protein in their urine, experience less renal pathology, and live longer. The reason for this paradox is unclear but may involve damage caused by the increased protein being presented to the proximal tubule when a high-protein diet is consumed.

Thromboembolism

Thromboembolism is a known cause of death in patients with glomerular disease. Much of the blame has been placed on antithrombin III, which, because of its size, is lost through the damaged glomerulus at a rate comparable to albumin. However, not all animals with low albumin experience thromboembolic events, and, therefore, other factors are likely involved. Risk of thromboembolism appears to be greatest when antithrombin III is less than 75% of normal. This correlates with a serum albumin of approximately 2.0 g/dL. There are few studies upon which to base anticoagulation recommendations. Low-dose aspirin had been recommended to inhibit platelet aggregation and clot formation; however, recent research suggests that previously recommended doses may not be efficacious. A more effective option is clopidogrel 1.0–2.0 mg/kg q.24 h. in dogs and 18.75 mg/cat p.o. q.24 h. Clopidogrel is a platelet aggregation inhibitor which appears to be effective in decreasing the risk of thromboembolism.

Blood Pressure

The majority of patients with glomerular disease develop significant hypertension during the course of their disease. Hypertension can lead to ocular, cardiac, and cerebral damage and potentiate further kidney injury. Therefore, blood pressure should be checked periodically, and antihypertensive therapy administered as needed. See the Hypertension section of this chapter for more information.

Fluid Therapy

While fluid therapy is a cornerstone in the treatment of AKI and CKD, it should be used with great caution in PLN patients. These patients are extremely vulnerable to fluid overload and edema. In addition, colloids should not be routinely given to prevent or treat edema as the colloids themselves may further potentiate kidney injury. When necessary, only enough fluids to correct dehydration should be administered. This should be done over relatively long periods of time (i.e., 24 hours) and under close supervision. In patients where edema has already occurred, fluid therapy should be avoided.

Prognosis

Prognosis is variable and dependent on degree of proteinuria and response to treatment. In general, patients who are azotemic at the time of diagnosis will not respond as well as those that are asymptomatic.

HYPERTENSION

Definition/Overview

The definition of "normal" blood pressure and hypertension has recently undergone significant revision. Blood pressure is now categorized on the basis of how likely a range of pressures is to cause target organ damage (TOD). In addition, studies have shown that cats whose blood pressure falls in the range of 140–159 mmHg are likely to develop organ-damaging hypertension in the near future. It is thought that this may be true for dogs as well. This has given rise to a new category: Prehypertensive. On the basis of this criteria, canine and feline blood pressures are divided into the following four categories:

Normotensive—minimal TOD risk SBP <140 mm Hg
Prehypertensive—low TOD risk SBP 140–159 mm Hg
Hypertensive—moderate TOD risk SBP 160–179 mm Hg
Severely hypertensive—high TOD risk SBP ≥180 mm Hg

Etiology

Clinically, hypertension is divided into three categories: (1) Situational, (2) idiopathic, and (3) secondary. Situational hypertension is an elevation in blood pressure that is the consequence of stress in an otherwise normotensive animal (e.g., in-clinic experience). It is problematic as it can be mistaken for actual hypertension, resulting in unnecessary treatment. Idiopathic hypertension is the result of an imbalance between cardiac output, systemic vascular resistance, and the autonomic nervous system. Idiopathic (essential) hypertension accounts for more than 90% of all cases of elevated blood pressure in human patients; however, it is thought to be uncommon in dogs and accounts for only 13%–20% of hypertensive cats. Secondary hypertension occurs as a consequence of another disease or medication and accounts for the majority of small animal cases (Table 13.12). Clinically, this is important because it allows clinicians to focus their blood pressure screening efforts on specific "at-risk" populations.

Pathophysiology

Normal blood pressure is the result of a complex interaction between the heart, the kidneys, the autonomic nervous system, and the endothelial signaling mechanisms (Figure 13.25). These factors determine cardiac output and systemic vascular resistance, which are the ultimate blood pressure determinants (BP = CO × SVR). Although the relationship between renal disease and

TABLE 13.12 List of conditions and medications commonly associated with secondary hypertension in the dog and cat

Dogs	Chronic kidney disease	Cats	Chronic kidney disease
	Acute kidney disease		Acute kidney disease

	Glucocorticoids		
	Epogen/darbepoetin alfa		
	Phenylpropanolamine		

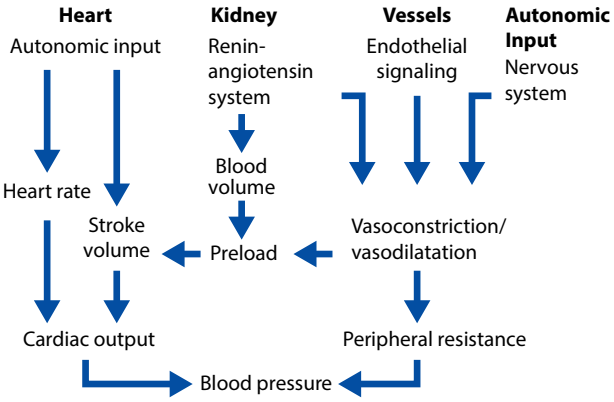

FIGURE 13.25 Complex interactions between heart, kidneys, vessels, nervous system, and endothelial signaling system, which determine blood pressure.

hypertension has been studied extensively, the connection between the two remains elusive. Recent data suggests that the cause is multifactorial.

Clinical Presentation

When increases in blood pressure are mild, the patient usually has no obvious clinical signs directly attributable to hypertension. As the elevations in systolic pressure increase, damage to the target organs, (eyes, heart, brain, and kidneys) starts to become apparent. Ocular damage is so common in CKD cats that loss of vision and not the underlying renal disease often initiates the initial office visit. Retinal edema, tortuous vessels, and hemorrhage characterize hypertensive retinopathy (Figure 13.26a, b), while choroidopathy results in ischemic necrosis of the choriocapillaris and the retinal pigmented epithelium. This presents clinically as blindness from retinal detachment.

The heart is a muscle, and as the pressure against which the heart must pump increases, cardiac changes occur. The most common change in dogs and cats is cardiomegaly associated with left ventricular concentric hypertrophy. This results in reduced diastolic ventricular internal diameter with decreased cardiac output as well as dilation of the proximal aorta. Clinically, these changes can present as a murmur, an arrhythmia, and, in cats, a gallop sound.

As systolic blood pressure exceeds the capacity of the autoregulatory mechanisms of the cerebral vasculature, hypertensive encephalopathy becomes apparent. Initially, this may present as vocalization and progress to ataxia, depression, disorientation, and seizures. This condition constitutes an emergency.

Differential Diagnosis

Situational hypertension, error in measurement

Diagnosis

Actual blood pressure is measured by placing a catheter in a suitable artery and connecting it to a transducer, which reports the pressure on a multifunction

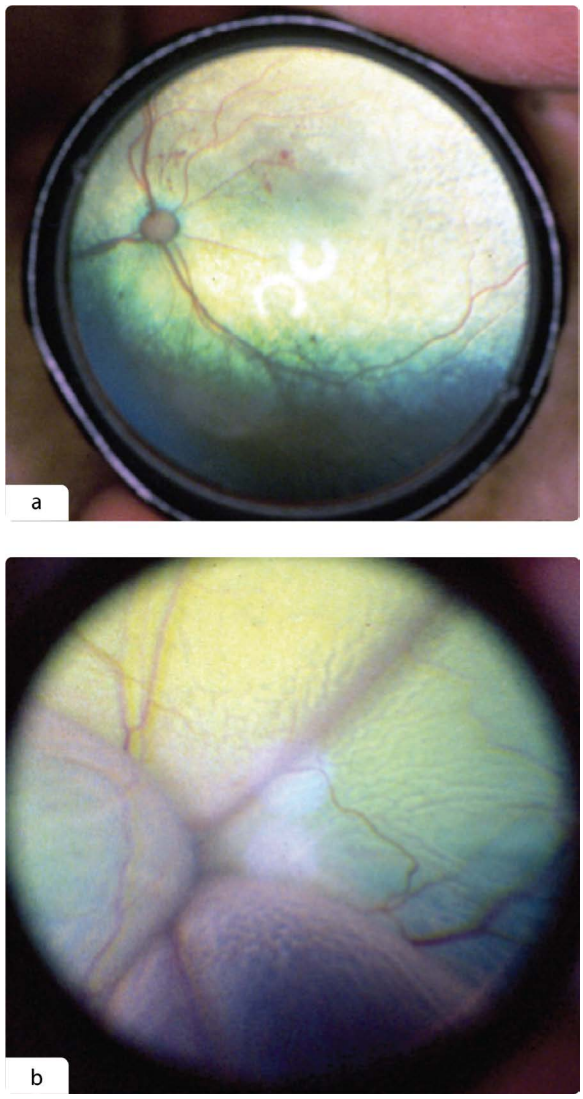

FIGURE 13.26 (a) Ocular changes consistent with hypertension. Note the tortuous vessels, hemorrhage, and edema. **(b)** Retinal detachment secondary to hypertension. (*Courtesy of P. Miller.*)

monitor (Figure 13.27a, b). While this is the most accurate way to measure blood pressure, it is invasive, painful, and neither convenient nor practical in the clinical setting. Indirect measurements of blood pressure using Doppler and oscillometric techniques are clinically most useful.

Oscillometric devices work by inflating a cuff around a distal extremity until arterial blood flow is occluded (Figure 13.28). The unit then slowly deflates the cuff while monitoring for pulsations created by arterial blood flow. These pulsations crescendo until they reach a point of maximal intensity, at which point they decrescendo. When plotted, this increase and decrease in pulse intensity forms an "oscillometric envelope" (Figures 13.29 and 13.30) The point of maximal intensity in the graph is the mean arterial pressure. These units then use proprietary algorithms to estimate systolic and diastolic pressures. Oscillometric units are

FIGURE 13.27 Direct blood pressure measurements are made by placing a catheter in an artery, connecting the catheter to a transducer, and displaying blood pressure on a monitor. **(a)** Patient with arterial catheter in a hind limb and the transducer at the level of the heart. **(b)** Multifunction monitor displaying blood pressure.

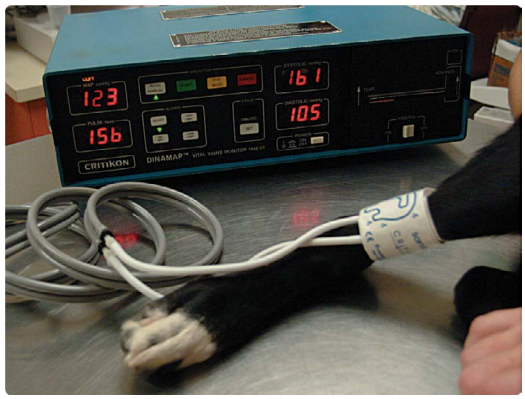

FIGURE 13.28 Oscillometric blood pressure measuring device.

FIGURE 13.29 Oscillometric envelope plotted against cuff pressure (red arrow). Notice that the arterial pulse intensity initially crescendos as cuff pressure decreases then begins to decrescendo. The point of maximal pulse intensity represents MAP.

popular in clinical practice because they are automated and provide systolic, diastolic, and mean arterial pressure. Nevertheless, these units can produce spurious results, especially if the oscillometric envelope is not correctly captured. For this reason, units that display the envelope for the user to evaluate may be preferred.

The Doppler flow detector is a commonly used blood pressure measuring device. The only equipment needed is the Doppler flow detector, a sphygmomanometer, and a selection of different sized cuffs (Figure 13.31). These

FIGURE 13.31 Feline patient having blood pressure measured with a Doppler device.

devices work by emitting an ultrasound wave and then comparing the frequency of the initial signal to the one that is reflected back to the probe. If the wave is reflected off the surface of a moving object, such as blood cells coursing through an artery, the frequency is shifted. The Doppler unit makes this change in frequency audible, and the operator hears this as a characteristic "swoosh" sound.

The first step in Doppler blood pressure measurement is to palpate an artery in the distal portion of an extremity (Figures 13.32–13.36). The hair over the artery is clipped, and a cuff with a width 30%–40% of the circumference of the limb is placed proximal to the clipped area. To ensure conduction, ultrasound gel is placed on the Doppler probe, which is then placed over the clipped area. The probe is then adjusted until the sound of arterial blood pulsations can be clearly heard. The cuff is inflated approximately 10–20 mmHg past the point at which blood flow can no longer be detected. Then, the cuff is gradually deflated while the operator observes the sphygmomanometer's display. The pressure at which the sound of blood flow first returns is the systolic pressure. Although the systolic blood pressure is easily obtained, determining diastolic pressure is often not possible.

FIGURE 13.32 Measuring blood pressure using the Doppler method. The artery is palpated.

FIGURE 13.33 Measuring blood pressure using the Doppler method. An area over the artery is clipped.

FIGURE 13.34 Measuring blood pressure using the Doppler method. A cuff, whose width is 30–40% the circumference of the limb, is selected.

FIGURE 13.35 Measuring blood pressure using the Doppler method. Ultrasound gel is placed on the probe to improve conduction.

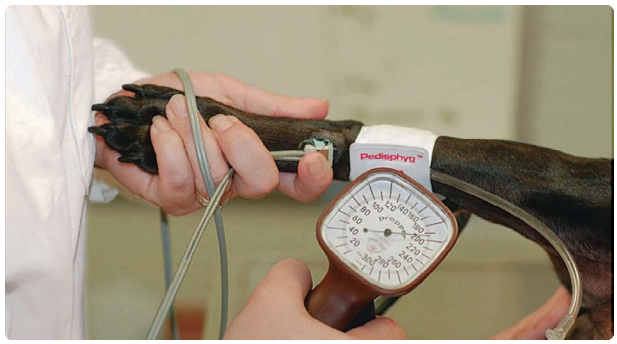

FIGURE 13.36 Measuring blood pressure using the Doppler method. The probe is placed over the artery and the sound of blood flowing is heard. The cuff is inflated to 20 mmHg greater than needed to occlude the blood flow and then the cuff is slowly deflated until the sound of blood flowing is heard again. This sound represents systolic blood pressure.

Principals of Accurate Measurement

Regardless which blood pressure measuring technology is used, four principles help to ensure accurate measurements: Acclimation to the patient, proper cuff size selection, consistency of personnel, and repeatability of results.

Perhaps the most important factor in attaining accurate and repeatable blood pressure measurements is proper acclimation of the patient. "Situational hypertension"

refers to elevations in blood pressure that are the result of stress or anxiety. An example might be the stress created by a visit to the veterinarian. While cats may display in a more obvious and dramatic response to an office visit, nervousness or excitement can profoundly affect canines as well. In order to minimize situational hypertension, blood pressure should always be measured in a quiet area away from other animals and before other procedures. The patient should be allowed to acclimate to its surroundings, and the owner should be present. Restraint should be kept to an absolute minimum. Some animals will demonstrate an effect whereby the blood pressure readings continue to decrease as the measurement process continues. This is the part of the acclimation process, and pressure measurements should continue until readings stabilize.

Proper cuff size selection is essential to accurate blood pressure measurement. Although some veterinary oscillometric devices come with an integrated cuff selection system, most devices require that the operator select an appropriately sized cuff. The width of the cuff should be 30%–40% of the circumference of the extremity where the cuff is being placed. A cuff that is too wide can underestimate blood pressure, while a cuff that is too small may artificially increase values.

Consistency of personnel and technique are an essential part of obtaining accurate blood pressure measurements. Whenever possible, the same team should be involved in the process, and they should utilize the same technique each time pressure is measured. The phenomenon by which this produces more accurate measurements is probably related to operator experience.

Individual blood pressure measurements can be inaccurate for a variety of reasons. Blood pressure measurements should be repeated 5–7 times and the individual measurements compared. If there is a significant variation (>10%) between the measurements, the readings should be discarded, and the process repeated. It is important to record the limb used, body position, cuff size, all measurements, and the staff involved so that all parameters are consistent between visits. Even something as innocuous as changing limbs can have an effect on measured pressures.

Management

It is important that cases of situation hypertension not be confused with and treated for actual blood pressure elevations. Therefore, elevations in blood pressure that are accompanied with obvious signs of TOD should be treated immediately, while other cases should be verified on three separate visits (Figure 13.37). In cases of moderate hypertension (systolic pressure <180 mmHg) these repeat measurements can be within 8 weeks; however, in severe hypertension, these visits should be sooner. When a patient's disposition makes accurate clinic blood pressures impossible, it may be possible to schedule a visit from a mobile veterinarian or teach the owner to use an oscillometric device at home.

As most small animals with elevated blood pressure suffer from secondary hypertension, the first step should be to identify and, when possible, treat the underlying condition. While this may decrease blood pressure and make hypertension more amenable to therapy, finding an underlying cause is not justification to withhold or delay treatment.

Dog-Specific Therapy

Angiotensin-converting enzyme (ACE) inhibitors are the initial drug of choice in treating canine hypertension (Table 13.13). ACE inhibitors exert their effect by

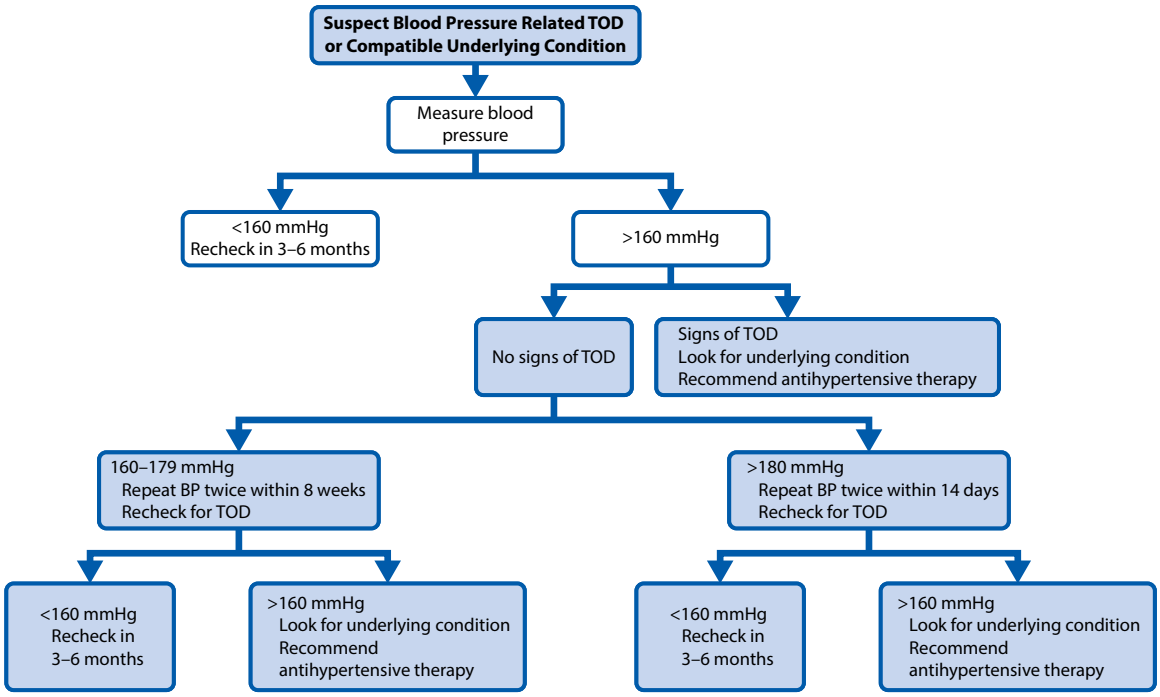

FIGURE 13.37 Recommended approach to the evaluation of a possibly hypertensive patient involves reliable measurements of blood pressure as well as the identification of possible target organ damage (TOD).

TABLE 13.13 Commonly used antihypertensive drugs in the dog and cat

Drug	Class	Canine dose	Feline dose
Enalapril	ACE inhibitor	0.5–1.0 mg/kg p.o. q.12–24 h.	0.25–0.5 mg/kg p.o. q.12–24 h.
Benazepril	ACE inhibitor	0.5–2.0 mg/kg p.o. q.12–24 h.	0.5 mg/kg p.o. q.12–24 h.
Telmisartan	ARBs	1 mg/kg p.o. q.24 h.	1.5 mg/kg p.o. q.12 h. x14 days, then 1.5 mg/kg p.o. q.24 h.
Amlodipine	Ca++ channel blocker	0.1–0.5 mg/kg p.o. q.24 h.	0.625–1.25 mg per cat p.o. q.24 h.
Atenolol	β Blocker	0.25–1.0 mg/kg p.o. q.12–24 h.	6.25–12.5 mg per cat p.o. q.12–24 h.
Propranolol	β Blocker	0.2–1 mg/kg p.o. q.8–12 h.	2.5–5 mg per cat p.o. q.8–12 h.
Spironolactone	Aldosterone inhibitors	1.0–2.0 mg/kg p.o. q.12 h.	1.0–2.0 mg/kg p.o. q.12 h.

blocking the conversion of angiotensin I to angiotensin II and help lower blood pressure in three ways. First, angiotensin II is a powerful vasoconstrictor, and inhibiting its synthesis leads to systemic vasodilatation. Secondly, angiotensin II directly promotes sodium absorption in the proximal tubule; this leads to intravascular volume expansion. Lastly, aldosterone release is stimulated by angiotensin II, and this further promotes sodium and water reabsorption in the kidney. The two most commonly used ACE inhibitors are enalapril and benazepril. Because enalapril is cleared exclusively by the kidneys, and its half-life can be significantly increased by renal disease, its use should be avoided in CKD patients. Instead, benazepril, which is cleared by the kidneys and liver, is preferred. In some CKD patients, ACE inhibitors have been associated with a worsening of azotemia; therefore, renal values should be checked 7–14 days after starting therapy in these patients. Although not as well studied in the dog as in cats, angiotensin receptor blockers (ARBs) are a reasonable alternative to ACE inhibitors in dogs.

ACE inhibitors and ARBs sometimes fail to produce the desired blood pressure decrease. In these patients, a calcium channel blocker can be added to the ACE inhibitor therapy. These agents exert their effects by blocking the influx of calcium needed to cause smooth muscle contraction and act to decrease systemic vascular resistance. Amlodipine besylate (Table 13.13) is the most widely used calcium channel blocker. Theoretically, calcium channel blockers have the potential to worsen renal disease despite lowering blood pressure. This effect is thought to be mediated by calcium channel blocker's preferential dilation of the glomerular afferent arteriole, paradoxically resulting in glomerular hypertension. Therefore, calcium channel blockers should not be used as a monotherapy agent in dogs. As ACE inhibitors and ARBs preferentially dilate the afferent arteriole, coadministration of these drugs with a calcium channel blocker results in a neutral effect on glomerular capillary hydrostatic pressures.

Cat-Specific Therapy

ACE inhibitors are less effective in treating feline hypertension. Studies have shown that as many as 50% of hypertensive cats fail to respond to enalapril. While benazepril has been shown to produce a statistically significant decrease in feline blood pressure, the actual reduction is relatively modest. For this reason, amlodipine besylate, a calcium channel blocker, has been the drug of choice in controlling feline hypertension. It is long acting, gradual in effect, and is often successful in controlling feline hypertension as a monotherapy agent. Decreases in blood pressure are somewhat dose dependent but can range from 30 to 70 mmHg. Although use of amlodipine as a monotherapy agent is discouraged in the dog, it does not appear to be problematic in cats.

ARBs are a newer class of drug that exerts their effect by directly blocking the angiotensin II type I receptors (Figure 13.38). Like ACE inhibitors, they are vasodilators. Several studies have demonstrated that telmisartan produces a predictable 23–25 mmHg decrease in feline blood pressure. In addition, because it affects only angiotensin II type I receptors, it has theoretical benefits over calcium channel blockers, including anti-inflammatory and antiproliferative effects. Telmisartan (Semintra®, Boehringer Ingelheim Vetmedica GmbH) is currently the only veterinary antihypertensive approved for use in cats by both the United States and Europe.

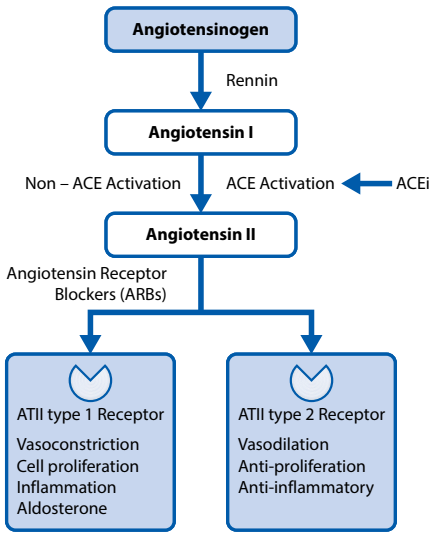

FIGURE 13.38 ACE inhibitors work by preventing the conversion of angiotensin I to angiotensin II; however, over time, this blockage becomes less effective. ARBs block the angiotensin II type 1 receptor, leaving the type 2 receptor unaffected. This has theoretical benefits, including anti-inflammatory and anti-proliferative effects.

Adjunctive Therapy

Beta-blockers are useful adjunctive therapy in dogs or cats where the initial antihypertensive agent has failed to produce the desired effect. Beta-adrenergic receptors are found in both the heart (beta-1) and lungs (beta-2). Blockade of the beta-1 receptors slow the heart and lower blood pressure, while blockade of the beta-2 receptors can trigger bronchial constriction. Therefore, only selective beta-1 antagonists (see Table 13.13) should be utilized.

It has long been known that aldosterone contributes to hypertension by stimulating sodium and water reabsorption in the kidney and thereby increasing intravascular volume. More recently, it has become apparent that aldosterone plays a role in the inflammation, fibrosis, and necrosis seen in TOD. Inhibiting aldosterone may have protective effects on target organs. Although more research is needed, hypertensive patients may benefit from the use of aldosterone antagonists such as spironolactone (see Table 13.13).

Goals and Monitoring

The goal of treating hypertensive patients is to gradually lower systolic pressure to less than 140 mmHg (Figure 13.39). It is important in the initial stages of treatment to monitor the patient regularly and avoid making rapid adjustments in medication. Changes in antihypertensive therapy should only be made every 1–2 weeks. Proteinuria is common in hypertensive patients and has been shown to be a negative prognostic indicator. Therefore, reducing proteinuria should be a secondary goal of therapy. Reductions in proteinuria can be achieved using a combination of ACE inhibitors and ARBs. Once the patient's blood pressure and proteinuria has been regulated, it should be rechecked every 3 months. Complete blood count and serum chemistry should be checked twice a year.

Prognosis

When diagnosed and treated before significant target organ damage, prognosis is generally good; however, hypertension is often secondary to an underlying condition, which may be life limiting.

INCONTINENCE

Definition/Overview

Incontinence refers to involuntary escape of urine during the storage phase of the urinary cycle. This can present in different ways; however, the most common presentation is an intermittent or continuous dribbling of urine combined with episodes of normal voiding.

Etiology

Causes of incontinence include urethral sphincter incompetence, anatomic abnormality in the termination of the ureters (ectopic ureters), an inability of the bladder to dilate, spasms of the bladder, or damage to the nerves controlling micturition (Table 13.14). Nevertheless, urethral sphincter mechanism incompetence and ectopic ureters are the most common causes and account for 85% of all incontinence cases.

Pathophysiology

The urinary cycle is divided into two phases: The filling phase, and the emptying phase (Figure 13.40). During the filling phase, the hypogastric nerve provides sympathetic stimulation of β-receptors in the body of the bladder, resulting in relaxation and stretching, while stimulation of α-receptors in the bladder's trigone region and proximal urethra causes constriction (Figure 13.41). Thus, the sympathetic branch of the autonomic nervous system dominates the filling phase of micturition by constricting the outflow of the bladder while allowing the body of the bladder to distend. Sympathetic stimulation also blocks parasympathetic transmission, thereby inhibiting urination.

As the bladder fills, sensory receptors embedded in the wall of the bladder become active, and signals travel

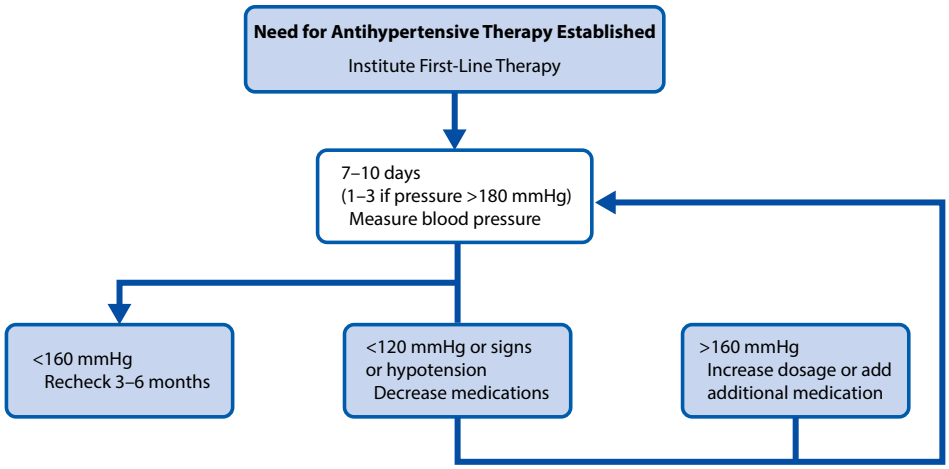

FIGURE 13.39 Stepwise approach for management of hypertension involves repeat blood pressure measurement and making medication adjustments.

TABLE 13.14 Causes of incontinence

Cause	Typical signalment	Clinical signs	Relative frequency
USMI	Post-spay female	Dribbling of urine when resting Previously normal urination	Frequent
Ectopic ureters	Young female	Continual urine dribbling Noted from early age	Common
Detrusor instability – Urge incontinence – Idiopathic instability	Middle-aged female	Pollakiuria, urgency	Less common
Neurologic disease	None	*Upper motor:* Erratic reflexive bladder emptying with a difficult-to-express bladder *Lower motor:* No attempts to urinate, easily expressed bladder	Less common
Pelvic entrapment of bladder	Adult large-breed female	Continual urine dribbling	Less common

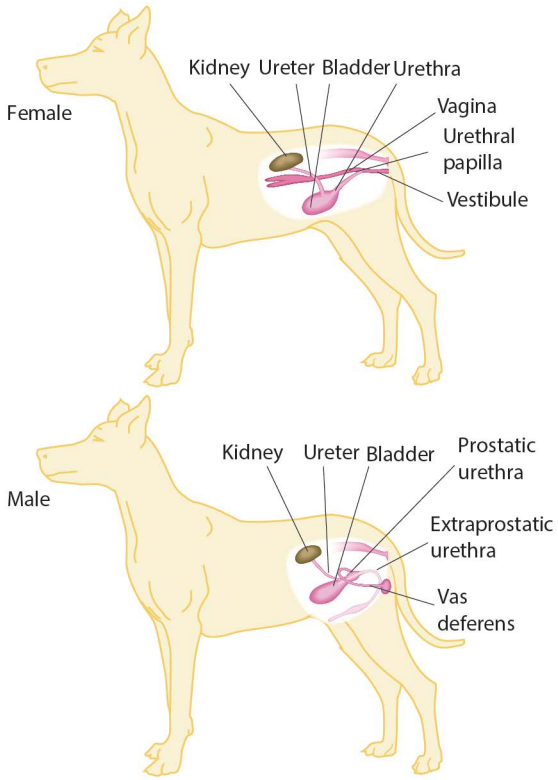

FIGURE 13.40 Functional components of the urinary tract. Urine is produced in the kidney, travels to the bladder via the ureter, and is stored in the bladder. The urethra acts as a valve and prevents the dribbling of urine and, when appropriate, directs urine out of the body.

via the pelvic nerve to the spinal cord. This information is relayed to the brainstem where these impulses are integrated with information from the forebrain. Once it is an appropriate time and place to void, the impulse to empty the bladder is carried down the spinal cord. Parasympathetic neurons located in the pelvic nerve transmit impulses to the parasympathetic ganglia in the bladder wall. Nerve fibers leave this nucleus and innervate smooth muscle fibers of the detrusor muscle, causing contraction of the bladder body and relaxation of the bladder neck. At the same time, reflex contraction of the striated muscle of the urethra mediated by the pudendal nerve is inhibited. The parasympathetic nervous system dominates the emptying phase of the urinary cycle by coordinating the contraction of the bladder as well as relaxation of the bladder neck, proximal urethra, and external sphincter.

Urethral sphincter mechanism incompetence (USMI) is the most common cause of canine urinary incontinence, affecting as many as 20% of all spayed dogs. The onset of incontinence is usually seen 2–3 years after an uneventful ovariohysterectomy but can occur any time after the procedure. Owners typically describe a dribbling of urine that is most noticeable when the animal is asleep. The exact mechanism by which removal of the ovaries leads to incontinence is unknown. Historically it had been thought that since estrogen upregulates urethral sphincter α-receptors, loss of estrogen decreased responsiveness of the urethra to sympathetic stimulation. More recently, elevations of gonadotropin-releasing hormone and luteinizing hormone resulting from loss of gonadal feedback have been implicated in decreased urethral contractility. In addition, spayed female dogs seem to have an increase concentration of collagen in their urine outflow tract, resulting in a less elastic urethra. Lastly, some cases of USMI seem to respond to surgical intervention. Taken together, the evidence suggests the cause of USMI is either multifactorial or that USMI is actually a collection of conditions with a common presentation.

Ectopic ureters (EU) are a congenital abnormality characterized by termination of one or both ureters at a point distal to the neck of the bladder. Affected animals typically leak urine from birth. Ectopic ureters are categorized as extramural or intramural based on their point of attachment and behavior. Intramural ectopic ureters attach to the bladder and tunnel below the submucosa and empty into urethra or vagina. Over 95% of EUs are reported to be intramural. Extramural ectopic ureters attach and empty directly into the urethra, the vagina, or the uterus. In cases of unilateral EU, normal urine voiding is reported as one ureter is properly emptying into the bladder. Normal urination may or may

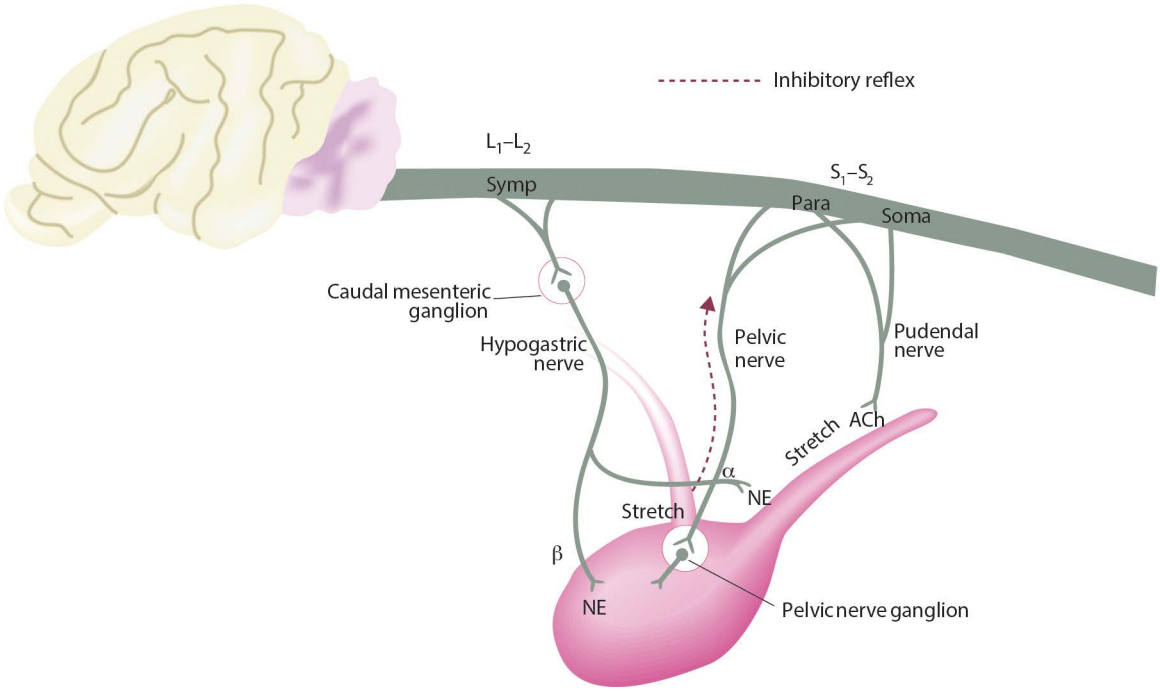

FIGURE 13.41 Schematic diagram representing the autonomic and somatic innervation of the bladder and urethra. Sympathetic (Symp) nerve fibers responsible for the storage phase of urination travel in the hypogastric nerve and stimulate receptors in the body and neck of the bladder. Beta receptors in the body of the bladder allow the detrusor muscle to relax and fill. Alpha receptors in the neck of the bladder and proximal urethra result in contraction and continence. Parasympathetic (Para) nerve fibers responsible for the voiding phase of the urinary cycle travel in the pelvic nerve. Sensory information travels from the bladder to the spinal cord via the pelvic nerve. Somatic (Soma) control of the external urethral sphincter travels in the pudendal nerve.

not occur in bilateral cases. Almost 90% of canine EU occurs in females, and depending on the study, 32%–91% of these are bilateral. Although ectopic ureters have been reported in cats, they are rarely diagnosed.

Detrusor instability is characterized by sudden urge to urinate and an involuntary bladder contraction (Figure 13.42). When this occurs secondary to infection, neoplasia, or urolithiasis, this condition is referred to urge incontinence. When an underlying condition is not diagnosed, the condition is called idiopathic detrusor instability.

Location of the bladder within the pelvis ("pelvic bladder") has also been associated with urinary incontinence. Although this condition is most often seen in large breed female dogs, it has also been reported in males. In most dogs, the bladder is positioned in the abdomen, while in affected animals, the bladder neck and some portion of the bladder body are located in the pelvic canal. The exact role that bladder position plays in dogs is not clear. In people, the bladder neck and proximal urethra are normally located within the abdomen. Increased abdominal pressure caused by normal activity is equally applied to the bladder body, neck, and proximal urethra. This uniform distribution of pressures helps maintains continence. In a patient with a pelvic bladder, the neck and proximal urethra are outside the abdomen, shielding it from these uniform pressures; however, at least 50% of dogs with a pelvic bladder are completely unaffected. This suggests that other factors are involved. It has been proposed that "pelvic bladder" in dogs is actually part of a syndrome characterized by shortened urethra, dysfunctional detrusor, and abnormal urethral musculature and not an issue of uniform distribution of pressures.

FIGURE 13.42 Dog with urge incontinence. The patient was later found to have a bladder mass.

Clinical Presentation

The most common presentation is an intermittent or continuous dribbling of urine combined with episode of normal voiding.

Differential Diagnosis

Nocturia, pollakiuria, and urgency.

Diagnosis

A detailed history that focuses on the timing, volume, possible trauma, and events surrounding the leakage of urine (e.g., sleeping, excitement) are essential. In addition, determining the quality and quantity of the purposeful urinations is important. Nocturia, pollakiuria, and urgency, which can all be confused with incontinence, can be eliminated on the basis of a thorough history.

A detailed inspection of the genitals should be performed. The area around the genitals should be checked for moisture, urine staining of the fur, and skin scalding. These are classic signs of incontinence, and if not seen, the clinician should consider alternative explanations. The external genitalia should be examined to be sure they are anatomically correct. In addition, observing the animal urinate is important in confirming normal micturition.

Laboratory data should include a complete blood count (CBC), serum chemistry panel, urinalysis, and diagnostic imaging. A urine culture should be considered. The CBC and chemistry panel help rule out systemic disease, while the urinalysis may implicate cystitis as a cause of the incontinence. Urine culture results can be difficult to interpret. Although urinary tract infections can lead to urge incontinence, infection can also be the result of anatomic abnormalities. Diagnostic imaging is essential to look for uroliths or other abnormalities (Figure 13.43).

A thorough neurological examination is a critical part of the incontinence workup. Disorders affecting the spinal cord above the fifth lumbar vertebra (upper motor neuron lesions) produce an involuntary, erratic, reflexive emptying of the bladder with increased resistance of the external urethral sphincter. Typically, these animals present with significant neurologic abnormalities that are easier to detect. Lesions of the sacral spinal cord (lower motor neuron lesions) prevent bladder sensation from traveling up the spinal cord, and as a result, the patient makes no attempts to urinate even as the bladder becomes overdistended. Sacral lesions also affect the pudendal nerve and result in the loss of external sphincter resistance. Typically, patients with sacral lesions have an easily expressed overdistended bladder and dribble urine.

FIGURE 13.43 Ultrasound of a bladder reveals a mass (between arrowheads). The mass was eventually determined to be a tissue reaction to suture material used in a previous cystotomy.

USMI

Due to its prevalence, typical presentation, and the relative safety of medical treatment, the diagnosis of USMI is often made empirically (Table 13.15). Definitive diagnosis requires that a urethral pressure profile (UPP) be performed. This test, which requires specialized equipment, is available only at select referral institutions; therefore, it reserved for atypical presentations (e.g., male dogs) or refractory cases. During a UPP, a pressure-measuring catheter is inserted into the bladder and withdrawn through the urethra. When finished, the computer generates a mapping of the pressures. This allows the clinician to determine if the pressure exerted by the urethral sphincter is adequate and if the functional length of the urethra is normal.

TABLE 13.15 Commonly utilized drugs for treating incontinence

Drug	Class	Dosages
Dicyclomine	Anticholinergic	Dogs: 5–10 mg per dog p.o. q.8 h.
Estriol	Hormone	Dogs: 2 mg p.o. q.24 h./14 days, then 1 mg q.24 h./14 days, then 0.5 mg q.24 h. or to lowest effective dose
Flavoxate	Anticholinergic	Dogs: 100–200 mg per dog p.o. q.12–24 h.
Oxybutynin	Anticholinergic	Dogs: 0.2 mg/kg p.o. q.8–12 h.
Phenylpropanolamine	Alpha agonist	Dogs: 1–1.5 mg/kg p.o. q.12–24 h. Cats: 1–1.5 mg/kg p.o. q.12–24 h.
Testosterone cypionate	Hormone	2.2 mg/kg IM every 4–6 weeks

Ectopic Ureters

Typically, ectopic ureters are suspected in young female dogs that have a history of dribbling urine since they were very young. Interestingly, because of the small volume of urine produced and the expectation that young puppies will have "accidents," this condition is often initially overlooked. The diagnosis of ectopic ureters has historically been made on the basis of excretory urography, retrograde vaginourethrography, or some combination of these radiographic procedures. Collectively, these tests have a sensitivity of only 70%–80%. The use of rigid cystoscopy has been shown to be 100% sensitive and specific. This combined with the ability to laser correct the EU in one minimally invasive procedure has made cystoscopy the diagnostic of choice.

Urge Incontinence/Idiopathic Detrusor Instability

The diagnosis of urge incontinence is made on the basis of finding an underlying cause for the bladder instability. As in all cases of incontinence, a thorough physical, neurologic examination, history, urinalysis with microscopic examination of the sediment, and culture are essential. Radiographs and ultrasound examination of the lower urinary are critical to look for neoplasia, urolithiasis, or structural abnormalities (Figure 13.43). Cystoscopic examination of the lower urinary tract should be considered in cases where an obvious cause is not found.

Diagnosis of idiopathic detrusor instability should only be considered once urge incontinence has been eliminated from consideration. Definitive diagnosis of idiopathic detrusor instability is diagnosed based on the results of a cystometrogram. During this test, a catheter is placed in the bladder, and it is slowly filled with saline. The normal canine bladder will allow uninterrupted filling until a threshold volume of 22 mL/kg is reached. At this point, involuntary bladder contractions begin. Dogs with idiopathic detrusor instability will experience involuntary bladder contractions at a greatly reduced volume. While simple in principle, the equipment to perform this test is complex and only available at a limited number of referral institutions.

Pelvic Bladder

Diagnosis of a pelvic bladder is made on the basis of contrast radiographs (Figures 13.44 and 13.45). Contrast radiographs show an abnormally shaped, caudally displaced bladder that fails to taper at the junction with the urethra. Since many dogs with pelvic bladder syndrome will often demonstrate a dysfunctional detrusor and an abnormal urethral musculature, a urethra pressure profile and cystometrogram may be indicated.

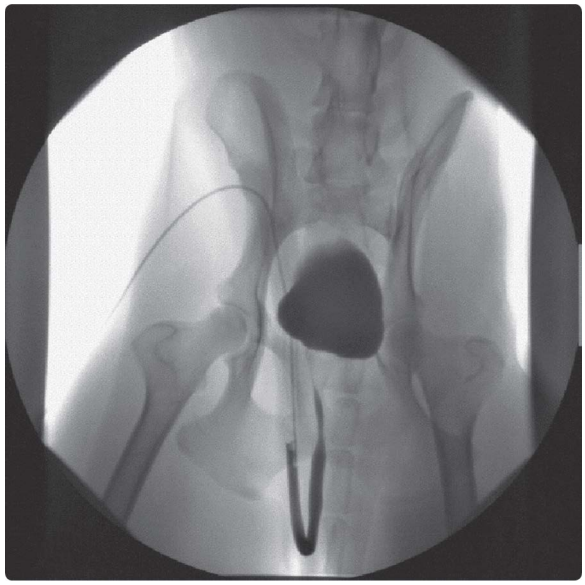

FIGURE 13.44 Pelvic bladders are usually seen in female dogs; however, this example is in a 2-year-old male Greyhound. Note the position of the bladder and its failure to taper at the junction with the urethra.

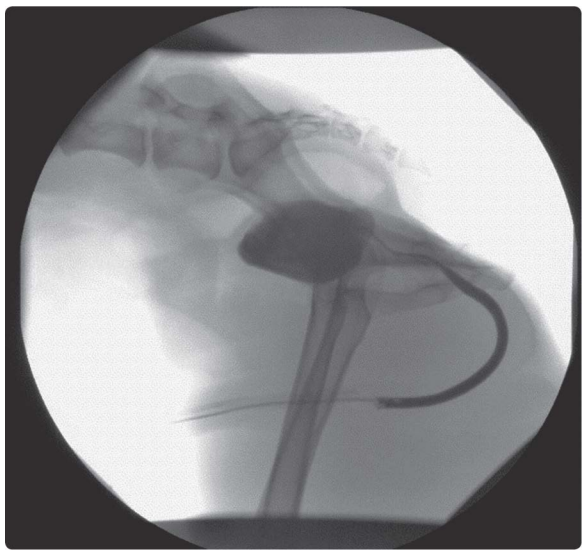

FIGURE 13.45 Pelvic bladders are usually seen in female dogs; however, this example is in a 2-year-old male Greyhound. A urethral pressure profile and cystometrogram revealed a nonresponsive detrusor muscle and incompetent urethra.

Management

Spay-Related Incontinence

Alpha-adrenergic agonists such as phenylpropanolamine have long been considered the mainstay for the treatment for USMI (see Table 13.15). Total resolution of urinary incontinence can be expected in 85% of cases while a significant improvement in clinical signs occurs in most dogs. Since the side effects of phenylpropanolamine include hypertension, tachycardia, increased intraocular pressure, and hepatic glycogenolysis, this drug should be avoided in patients with hypertension, glaucoma, or diabetes mellitus. Blood pressure should be measured prior to and shortly after starting phenylpropanolamine, as the drug can induce hypertension in otherwise normotensive dogs.

Estriol (Incurin®) is an estrogen-based treatment for USMI. Estrogens work by exerting a permissive effect on the α-receptors of the urethral sphincter, resulting in increasing responsiveness to the sympathetic nervous system and increased urethral tone. Common side effects include loss of appetite, vomiting, excessive water drinking, and a swollen vulva. For most patients, these seem to resolve quickly. Unlike previously available estrogen formulations, Estriol does not appear to be associated with bone marrow suppression.

For the small percentage of USMI patients that do not adequately respond to medical management, several procedural options exist. The first, urethral collagen injection, involves the endoscopic placement of collagen or extracellular matrix into the urethral submucosa. Approximately 68% of dogs treated with this method attained full urinary continence, and an additional 25% of owners reported a significant decrease in urine dribbling. These endoscopically placed injections result in bulging of the urethra into the lumen and significantly improved urethral closure. The primary limitation of this procedure is its temporary nature, as most dogs return to incontinence over time. While many of the dogs that relapse will respond to medical management, most will require additional injections within 2 years.

Another option is the surgical placement of a hydraulic urethral occluder. A hydraulic urethral occluder is an inflatable silicone cuff that is surgically placed around the proximal urethra (Figure 13.46a–d). The cuff is attached to an inflation port, which is secured subcutaneously to the abdominal wall. The occluder works by providing resistance to the proximal urethra. When the patient urinates, pressure in the bladder overcomes the resistance, and normal micturition occurs. The resistance provided by the occluder can be adjusted through the injection port.

Treatment of USMI in male dogs is similar but often less rewarding than their female counterparts. Only 44% of incontinent male dogs improve with administration of phenylpropanolamine. Testosterone alone or in combination with α-agonists may be attempted; however, only 38% of testosterone-treated dogs became completely continent, while 50% showed no response. In addition, use of testosterone may be associated with serious side effects. For male dogs that do not respond to medical management, injection of a bulking agent and hydraulic urethral occluders may be options.

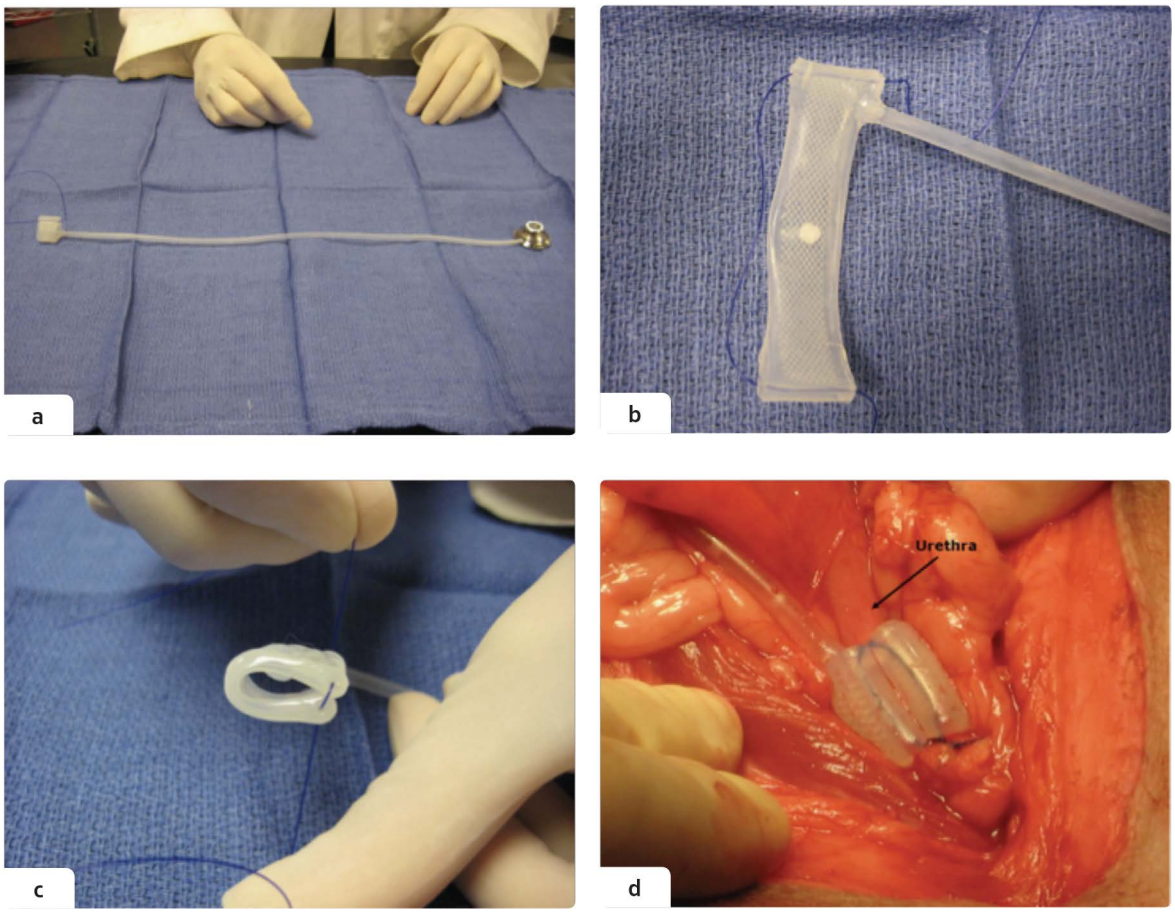

FIGURE 13.46 **(a)** Hydraulic urethral occlusion device. Note the cuff, which will be surgically placed around the urethra, and the inflation port, which will be secured subcutaneously to the abdominal wall. **(b, c)** Close-up of a cuff that will be placed around the neck of the bladder. **(d)** Cuff placed around the urethra. (*Courtesy of A. Berent.*)

Ectopic Ureters

Extramural ectopic ureters, which are rare, attach and directly empty into the urethra, the vagina, or the uterus. These must be surgically reimplanted. Intramural ectopic ureters attach to the bladder correctly and then tunnel below the submucosa and empty into urethra or vagina. These are amenable to correction by laser ablation, which is less invasive, more effective, and associated with fewer complications than surgical techniques (Figure 13.47a–f). In addition, the ectopic ureter is both diagnosed and corrected during the same anesthetic event. Nevertheless, some dogs will experience a degree of incontinence after correction. The reason for this is unclear; however, many will respond to medical therapy.

Some degree of hydronephrosis is common in dogs born with ectopic ureters (Figure 13.48a, b). An abdominal ultrasound should be performed to examine the architecture of the affected kidney. Although some kidneys may need to be removed, many will regain function once the abnormality is corrected. The decision to perform a nephrectomy should not be taken lightly.

Urge Incontinence/Idiopathic Detrusor Instability

Treatment of urge incontinence is based on the successful resolution of the underlying condition. Usually, no additional therapy is needed. Treatment for idiopathic detrusor instability relies on anticholinergic drugs that interfere with parasympathetic nervous system's stimulatory effect on the detrusor muscle. Commonly used drugs include flavoxate, oxybutynin, and dicyclomine (see Table 13.15).

Pelvic Bladder

Treatment of pelvic bladder syndrome is often unrewarding. Treatment with phenylpropanolamine may be helpful in some cases but likely to be ineffective (see Table 13.15). Some have recommended colposuspension; however, there is little evidence to support the use of this procedure.

Prognosis

Most common causes of incontinence are treatable, and, therefore, prognosis is good.

FELINE LOWER URINARY TRACT DISEASE

Definition/Overview

Feline lower urinary tract disease (FLUTD) is a term given to cats that exhibit clinical signs, including straining to urinate, hematuria, pollakiuria, and periuria. Feline lower urinary tract disease is quite common and accounts for nearly 5% of all cats presenting for veterinary care. The condition can be divided into two groups: (1) Cats that present with a urethra obstruction, and (2) cats that are displaying clinical signs but are not obstructed. While the former group is almost always male, the later can be either. A cat with an obstructed urethra is always a medical emergency.

Etiology

FLUTD can be the result of feline idiopathic cystitis (FIC), urethral plugs, uroliths, and other causes. Most cases fall into the category of idiopathic, although urethral plugs are common. Uroliths are less common, accounting for 10% or fewer of FLUTD cats. Despite common misconceptions, UTIs in young health cats are exceedingly rare and almost never the cause of FLUTD. Tumors are occasionally seen but are also very uncommon.

Pathophysiology

Idiopathic Cystitis

Most cases of FLUTD are idiopathic, making this a frustrating disease to diagnose and treat. It is thought that the clinical signs may be the result of urethral spasms which are secondary to stress or anxiety. When normal cats are subjected to stressful events, (e.g., introduction of a new housemate), there is an initial catecholamine release followed by period of acclimation and a return to baseline levels. Some cats with FIC have been shown to have an exaggerated and an extended catecholamine response, which is similar to some anxiety disorders. Besides generalized anxiety, this catecholamine release can also have an effect on specific organs.

Urethral Plugs

Urethral plugs are a mix of a proteinaceous matrix and struvite crystals that is likely related to idiopathic cystitis. In addition to having an abnormal response to stress, cats with FLUTD can have defects in the urinary tract glycosaminoglycan layer. This layer protects the bladder wall from noxious substances in urine. A defect in the glycosaminoglycans results in pain and inflammation of the bladder wall. Pain stimulates further release of catecholamines, which increases urothelium permeability, leading to leakage of serum constituents into the urine. This provides the proteins needed for matrix formation and increases urine pH, promoting the formation of massive numbers of struvite crystals. The protein matrix forms a web-like structure in the urethra that traps the struvite crystals, leading to the plug.

Urinary Tract Infections

Urine osmolality in young healthy cats is so high that it acts to inhibit bacterial growth. This combined with normal host defense mechanisms make urinary tract infections extremely rare in these patients. Any appearance of clinical improvement in a FLUTD cat after antibiotic administration is likely coincidental. In the absence of a urine culture obtained by cystocentesis, the use of antibiotics is not recommended.

Other

Uroliths and neoplasia can result in signs consistent with FLUTD; however, they are uncommon. These topics are covered elsewhere in this chapter.

Clinical Presentation

Obstructive

Urethral obstruction usually occurs in male cats between 1 and 8 years of age. Obstructed cats strain unproductively to urinate and may cry out. Owners may mistake these attempts for constipation. Licking of the genital region is also frequently observed. Patients often hide in a secluded area. Cats examined soon after obstruction may be fractious and resist examination. After more prolonged obstruction, patients become progressively more depressed. An enlarged firm bladder is felt on abdominal palpation.

Nonobstructive

Signs of nonobstructive FLUTD are variable but usually include stranguria, pollakiuria, hematuria, and dysuria. Affected cats may vocalize during urination and urinate in inappropriate places. The bladder of cats with nonobstructive FLUTD is usually small with a thickened wall. Attempts at collecting urine through cystocentesis are often unrewarding due to the frequent attempts at urination that occurs, especially when the patient is handled.

Differential Diagnosis

Inappropriate urination (behavioral), uroliths, urinary tract infection, neoplasia, anatomic defects.

Diagnosis

All cats presenting for FLUTD should have diagnostic imaging. This will allow for inspection of the urinary tract for uroliths, anatomic malformations, and neoplasia. As is true with many urinary tract conditions, ultrasound combined with radiographs is likely to yield more information than either alone. Nevertheless, treatment of an unstable obstructed patient should not be delayed. In these cases, radiographic studies should be performed once the obstruction is relieved.

Obstructive

Obstructive FLUTD is identified by palpation of an enlarged, firm bladder. Urinalysis can be performed on urine collected by cystocentesis, before urethral catheterization, or via the catheter after relief of the obstruction. Serum creatinine, BUN, and potassium allow assessment of the degree of prerenal azotemia; however, these are likely to resolve quickly once the obstruction is relieved. An electrocardiogram (ECG) tracing should always be performed to assess cardiotoxicity associated with hyperkalemia.

Nonobstructive

Along with diagnostic imaging, laboratory data should include a CBC, serum chemistry panel, and urinalysis. The CBC and chemistry panel help rule out systemic disease. Crystalluria is not an uncommon urinalysis finding and is unlikely to be the cause of the condition; rather, it is most likely a result of the inflammation. For this reason, the crystalluria is not usually considered a therapeutic target.

Management

The first step in assessing a cat that presents with FLUTD is to quickly recognize patients that are obstructed. These cats are almost always male and can be identified by the palpation of an enlarged, firm bladder. Affected cats may azotemic, hyperkalemic, acidotic, bradycardic, and have an ECG consistent with atrial standstill secondary to hyperkalemia (e.g., absence of P waves, prolonged QRS, spiked T waves) (Figure 13.49). Patients should have an IV catheter placed and be sedated. See Figure 13.50 for treatment algorithm.

Once the urinary catheter is placed, urine output should be monitored for at least 24–48 hours for

FIGURE 13.49 An ECG example of hyperkalemia causing atrial standstill. Note the characteristic absence of P waves, prolonged QRS, and spiked T waves.

Obstructive algorithm:

- Draw blood for possible serum chemistry and electrolytes.
- Place IV catheter and begin ˜uid s.
- Monitor ECG and treat hyperkalemia as needed (**Table 13.7**).
- Carefully attempt to catheterize with a sterile Slippery Sam™ or 3.5-French open-end tomcat catheter (**Figure 13.51a, b**).
- If obstruction cannot be relieved, attempt to dislodge by ˜ushing urethra with sterile saline or la ctated Ringer's solution.
- If bladder is extremely ÿrm, remove urine by cystocentesis. This decreases back-pressure and allows for aseptic collection of urine for analysis and culture.
- If obstruction will not dislodge, use retropulsion with the urethral oriÿce pinched o¸.
- A small amount of lidocaine gel may be infused into the catheter to decrease urethral spasm.

Once urethral patency is established:

- If a 'Slippery Sam' catheter was used to relieve obstruction, the catheter can be sutured in place.
- If a tomcat catheter was used:
  - Measure distance from prepuce to neck of bladder.
  - Note distance on a sterile 5-French polyvinyl catheter (soft red rubber) and insert into the urethra up to that point.
  - Place tape on external part of tube (as close to prepuce as possible) and suture tape to prepuce with two sutures.
  - Tape free end of tube to tail.
  - Attach extension set to urinary catheter and place sterile collection bag on the other end of the extension set.
- Place e-collar before the patient awakens.

FIGURE 13.50 Algorithm for treating obstructed cats.

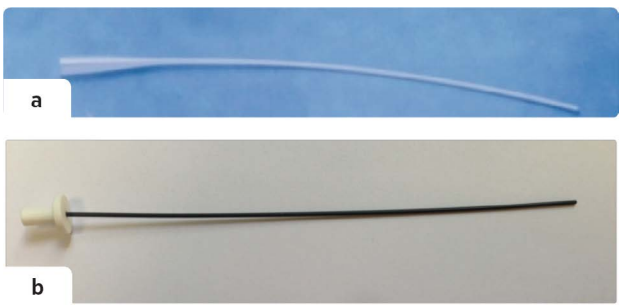

FIGURE 13.51 Examples of a tomcat catheter (a) and a Slippery Sam™ catheter (b).

evidence postobstructive diuresis. This is a high rate of urine output that occurs when an obstruction is relieved. The cause is unknown; however, significant amounts of dilute urine can be produced, leading to hypovolemia. Recommendations are to measure urine output every 2–4 hours and set the IV fluid rate so that it matches urine production. Fortunately, postobstructive diuresis is self-limiting and usually resolves in 24–48 hours. It is not clear if there is an optimal amount of time to leave the urinary catheter in place; however, it seems prudent to wait for postobstructive diuresis (if any) to resolve and the urine to be clear of gross blood contamination.

All Cats

A wide variety of empirical treatments have been claimed to be successful in the treatment of idiopathic cystitis and urethral plugs. The waxing-waning nature of the clinical signs makes evaluation of treatment modalities difficult. Compounding the problem is a lack of well-controlled clinical trials. Nevertheless, a multifaceted approach involving environmental enrichment, diet, pheromones, and pharmacology seems to alleviate signs and decrease recurrence in many cats.

Environment

Feline lower urinary tract disease may actually be a clinical manifestation of a physiologically inappropriate response to stress. This is similar to the colitis that some dogs experience when subjected to a stressful event such a boarding. As such, we must look for possible stressors in the cat's environment and ways to reduce them. Surveys that require the owner to answer detailed questions about the home environment have been developed. These surveys are helpful in extracting information from the owner in a systematic and concise way that may be difficult in a time limited clinic interaction (**Figure 13.52**).

In multicat households, the "cats +1" rule should be applied to all shared resources. If there are two cats in the household, then there should be three litter boxes, three food bowls, three water bowls, three scratching posts, etc. Litter boxes should be kept very clean and away from other pets. Having a dog interrupting private time in the box or rummaging through the litter looking for "treats" can be very stressful. Water bowls need to be kept clean and filled. Some cats seem reluctant to drink if their whiskers can touch the sides of the bowl; therefore, an extra-wide drinking bowl may be helpful. As with litter boxes, bowls should be out of the reach of curious children and hungry dogs. Cats also seem to prefer surveying the environment from elevated vantage points. This gives the cat a place where they can feel safe catnapping. Cat hammocks and window perches can provide them with the necessary comfort. Toys that encourage interaction between owners and their pets should be encouraged. When there is conflict between pets, steps must be taken to mitigate adverse interactions, even if it requires physical separation. Owners are encouraged to carefully observe the cat for signs of inter-pet conflict, as stressful interactions may be subtle to the casual observer.

Household Resource Checklist

The following questions ask about your cat's resources so we can learn more about the environment your cat(s) live in. Please ✓ **DK** if you don't know, **NA** if it does not apply, or **Yes** or **No** after each question. If you have more than one cat, please answer for **all** cats. Resources (food, water, litter, and resting areas) for each cat are assumed to be out of (cat) sight of each other, such as around a corner or in another room. If they are in sight of each other, please answer **No**.

Space		DK	NA	Yes	No
1	Each cat has its own resting area in a convenient location that provides some privacy.	☐	☐	☐	☐
2	Resting areas are located such that another animal cannot sneak up on the cat while it rests.	☐	☐	☐	☐
3	Resting areas are located away from appliances or air ducts that could come on unexpectedly (machinery) while the cat rests.	☐	☐	☐	☐
4	Perches are provided so each cat can look down on its surroundings.	☐	☐	☐	☐
5	Each cat can move about freely, explore, climb, stretch, and play if it chooses to.	☐	☐	☐	☐
6	Each cat has the opportunity to move to a warmer or cooler area if it chooses to.	☐	☐	☐	☐
7	A radio or TV is left playing when the cat is home alone.	☐	☐	☐	☐
Food and water					
8	Each cat has its own food bowl.	☐	☐	☐	☐
9	Each cat has its own water bowl	☐	☐	☐	☐
10	Bowls are located in a convenient location to provide privacy while the cat eats or drinks.	☐	☐	☐	☐
11	Bowls are located such that other animals cannot sneak up on the cat while it eats or drinks	☐	☐	☐	☐
12	Bowls are washed regularly (at least weekly) with a mild detergent.	☐	☐	☐	☐
13	Bowls are located away from machinery.	☐	☐	☐	☐
Litter boxes					
14	Each cat has its own box (one box per cat, plus 1).	☐	☐	☐	☐
15	Boxes are located in convenient, well-ventilated locations that still give each cat some privacy while using it.	☐	☐	☐	☐
16	Boxes are located on more than one level in multi-level houses.	☐	☐	☐	☐
17	Boxes are located so another animal cannot sneak up on the cat during use.	☐	☐	☐	☐
18	Boxes are located away from machinery that could come on unexpectedly during use.	☐	☐	☐	☐
19	The litter is scooped daily.	☐	☐	☐	☐
20	The litter is completely replaced weekly.	☐	☐	☐	☐
21	Boxes are washed regularly (at least monthly) with a mild detergent (like dishwashing liquid), rather than strongly scented cleaners.	☐	☐	☐	☐
22	Unscented clumping litter is used.	☐	☐	☐	☐
23	A different brand or type of litter is purchased infrequently (less than monthly).	☐	☐	☐	☐
24	If a different type of litter is provided, it is put in a separate box so the cat can choose to use it (or not) if it wants to	☐	☐	☐	☐
Social contact					
25	Each cat has the opportunity to play with other animals or the owner if it chooses to on a daily basis.	☐	☐	☐	☐
26	Each cat has the option to disengage from other animals or people in the household at all times.	☐	☐	☐	☐
27	Do any cats interact with outdoor cats through windows?	☐	☐	☐	☐

Comments: anything else your cat regularly does or does not do that you think might be helpful for us to know about?

FIGURE 13.52 (*Continued*)

Diet

The role of diet in controlling FIC and urethral plugs is somewhat controversial. Although many feline diets have been acidified and, in some cases, magnesium restricted "for urinary tract health," there is no proven benefit of this practice. Struvite crystals do not damage normal urinary tract epithelium, and their presence does not appear to be the cause of cystitis. Nevertheless, the

feeding of canned moist diet has been shown to lower incidences and recurrence of FIC. While it is clear that the ingestion of a wet food diet decreases urine osmolality and, therefore, concentration of noxious substances, other factors may be involved. The feeding of a wet food involves a different type of interaction between the owner and the pet. Bowls need to be washed, cans opened, food scooped and prepared, and finally, the cat is presented with its meal. This can be contrasted with scooping and "dumping" of a dry kibble. Whether it is the moisture content of the food, the ritual involved, or both, the feeding of a wet food diet is important in reducing recurrence of FLUTD.

It is important, not to "switch" diets, especially in cats accustomed to a dry kibble food. The stress associated with an abrupt diet change has the potential to trigger further episodes of cystitis or, worse, anorexia and hepatic lipidosis. Rather, the new diet should be offered alongside the cat's usual food, and the pet should be allowed to choose between them. Most cats will eventually choose the wet food. If the cat will only eat dry food, then a change should not be instituted.

The eating environment should be analyzed for potential stress. Many cats prefer to eat alone where they will not be disturbed by other animals, sudden movement, or unexpected noises. Other cats seem to be more social and may enjoy companionship during their meals. The goal is to minimize stress and maximize the pleasure of the dining experience for the individual cat.

Pheromones

Pheromones are chemical messengers that convey information between members of the same species. Cats release several pheromones from facial scent glands, and they deposit these pheromones by rubbing their heads on objects, including their human companions, when they feel safe. A synthetic analog (Feliway®, Ceva Santé Animale, France) is available as both a room diffuser and spray. While studies examining the use of this product in cats with cystitis are lacking, there is evidence that this product may decrease marking and scratching behavior in multicat households, as well as increase grooming and eating in hospitalized patients. It has been suggested that the spray can be applied to the area in which the cat is inappropriately urinating or that an entire room can be treated with a plug-in diffuser.

Drug Therapy

Amitriptyline (Elavil®), is a tricycle antidepressant drug with antianxiety, analgesic, and anti-inflammatory properties. Although some small studies have shown no benefit from the use of amitriptyline for the treatment of FLUTD, others have demonstrated a significant benefit from its use. In one study, 100% of obstructed cats which received no treatment other than amitriptyline recovered. Not only does amitriptyline decrease anxiety, provides analgesia both peripherally and in CNS, it has been shown to be a potent urethral relaxer. Recommended dosage is 1 mg/kg q.24 h. Like all oral medications for cats, compounding into a liquid should be considered if pills are problematic.

Prazosin (Minipress®) is an alpha-blocker that may decrease urethral spasms. At this time, there are no controlled studies to support or refute its usage; however, empirical observations suggest it may be helpful. It is dosed at 0.5 mg per cat (not kg) p.o. q.24 h.

As FLUTD is associated with significant discomfort, analgesics should be provided. Butorphanol, an opioid analgesic, appears to provide satisfactory pain relief. Robenacoxib (Onsior®), a nonsteroidal anti-inflammatory drug, may also be helpful in controlling discomfort. Some have had success with gabapentin (5 mg/kg p.o. q.24 h.).

While the exact cause of FLUTD is unknown, a multifaceted approach combining environmental enrichment, diet, pheromones, and pharmacology appears to give many patients relief. In cases in which symptoms cannot be controlled, a penile urethrostomy may be required. Because of the risk of incontinence, the required anatomic modification, and high lifelong risk of infection, this should only be considered when other possible alternatives have been exhausted.

Prognosis

While most cats will respond to a combination of environmental modifications, pheromones, and pharmacology, some may still require penile urethrostomy; however, surgery fails to address the underlying issue.

UROLITHIASIS

Definition/Overview

Common uroliths in dogs and cats include struvite and calcium oxalate, while ammonium urate and cystine are less common (Tables 13.16 and 13.17).

Etiology

Urine is a complex solution made up of dissolved substances, some of which have a tendency to precipitate out of solution, while others actively inhibit precipitation by increasing solubility. For example, as the concentration of calcium in urine increases, there is an increased risk of it binding to oxalate and forming crystals and stones; however, citrate in the urine binds to calcium and makes it unavailable. If we look at Figure 13.52, there is a region on the chart called the solubility product. If urine were only made up of substances that tend to precipitate out of solution, then this would be the maximum saturation that could be achieved. However, the presence of inhibitors like citrate allows urine to achieve a metastable supersaturated state. Under normal circumstances, there is a balance between precipitators and inhibitors, and urine exists in this metastable state; however, if there is an excess of precipitators or a shortage of inhibitors, crystals and uroliths can form. In some cases, urine pH can also directly impact the solubility of these solutes.

TABLE 13.16 Uroliths in dogs

* If less than 1 year old, usually due to urease-producing infection.
† Only rarely found.
†† In portosystemic shunts.
‡ Usually sterile.
‡‡ Associated with urease-producing infection.

Pathophysiology

Struvite

In dogs, the most common urolith is struvite (magnesium, ammonium, phosphate). These stones are associated with urease-producing bacteria (*Staphylococcus intermedius*, *Proteus mirabilis*, *Pseudomonas* spp., *Klebsiella* spp.). Urea is plentiful in the urine, and urease splits it to form

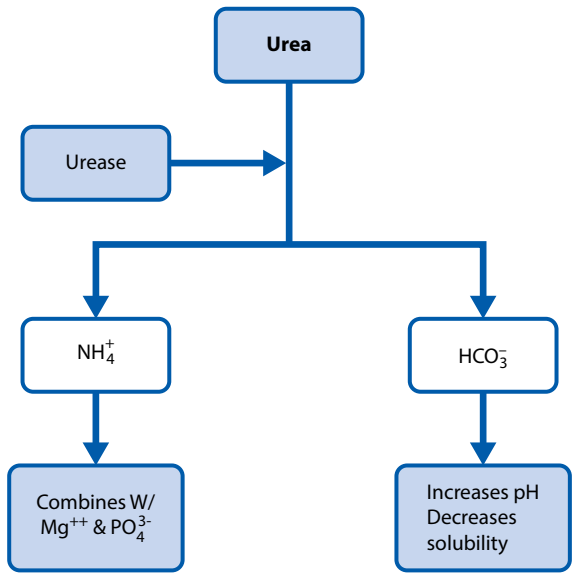

FIGURE 13.53 Bacterial urease splits urea, which is plentiful in urine, to form ammonium and bicarbonate. Ammonium combines with magnesium and phosphate while the bicarbonate raises the urine pH. The change in pH decreases the solubility of the ammonium–magnesium–phosphate complex, leading to the formation of struvite crystals and stones.

ammonium and bicarbonate (Figure 13.53). Ammonium combines with magnesium and phosphate, while the bicarbonate raises the urine pH. The change in pH decreases the solubility of the ammonium, magnesium, phosphate complex, leading to the formation of struvite crystals and stones. The anatomic configuration of the female makes urease-producing infections more common than in males.

In contrast to canines and people, struvite uroliths found in young, healthy cats are usually not associated with urinary tract infections. Although the exact pathophysiology is not well understood, diet, breed, sex, and urine pH all seem to play a role.

Calcium Oxalate

The second most common canine urolith is calcium oxalate. The formation of these stones can be the result of excessive calcium/oxalate excretion or an absence of precipitation inhibitors. Although most cases are idiopathic, possible causes of excessive calcium excretion into urine should be investigated. Increased calcium in the urine can be result of excessive kidney loss or increased renal excretion due to elevated blood calcium levels. Elevated blood levels can be secondary to (1) increased intestinal absorption, (2) hyperparathyroidism, (3) paraneoplastic syndromes, (4) granulomatous disease, or (5) calcitriol toxicosis. While it was once thought that urine pH had a great effect on calcium oxalate formation, it is now generally accepted that urine acidity plays only a minor role.

Serum ionized calcium levels should be measured in all patients who present with calcium oxalate uroliths or crystals. This information when combined with serum levels of calcitriol, PTH, and parathyroid hormone-related peptide (PTHrP) can be helpful in identifying the underlying cause of calcium oxalate formation (Table 13.18). For example, calcium oxalate uroliths occur in dogs secondary to hyperparathyroidism. In these patients, excessive PTH results in osteoclastic reclamation of bone and excessive formation of calcitriol (25-hydroxyvitamin D) by the kidney. Calcitriol increases intestinal absorption of calcium. These two actions result in elevations in blood calcium concentrations. In the kidney, excessive amounts of calcium are passed through the glomerulus. Although PTH simulates renal calcium reabsorption, the filtered calcium overwhelms the kidney's resorptive capacity, resulting in hypercalciuria and stone formation.

TABLE 13.18 Causes of canine hypercalcemia can often be determined by measuring calcium, parathyroid hormone (PTH), calcitriol, and parathyroid hormone-related peptide (PTHrP)

	Ca++	PTH	Calcitriol	PTHrP
Intestinal	E	L	L	O
Leakage	N	N	N	O
Hyperparathyroid	E	E	E	O
Paraneoplastic	E	L	E	E
Granulomatous	E	L	E	O
Calcipotriol	E	L	E	O

E, elevated; L, low; N, normal; O, zero.

TABLE 13.19 Causes of feline hypercalcemia can often be determined by measuring ionized calcium, parathyroid hormone, and parathyroid hormone-related peptide

	Ionized Ca++	PTH	PTHrP
Idiopathic	High	Normal/high	O
Cancer	High	Low	High
Primary	High	High*	O

Note: Since idiopathic hypercalcemia can present with only slightly increased total calcium, it is recommended that ionized calcium be used for screening.

* Primary hyperPTH can have PTH values ranging from normal to high. Any normal PTH with increased PTH concentrations is inappropriately elevated.

Leakage hypercalciuria is a failure of the renal tubules to resorb filtered calcium despite the presence of adequate PTH. As calcium is lost, PTH is released from the parathyroid gland, mobilizing calcium from bone, and stimulating formation of calcitriol. Although calcium is lost into the urine, serum levels are normal due to the actions of PTH and calcitriol. Even though leakage hypercalciuria can occur as a primary condition, it should be noted that hyperadrenocorticism (Cushing's disease) and steroids can both promote leakage hypercalciuria and urolith formation.

Although many cases of feline calcium oxalate are idiopathic, all patients should be screened for idiopathic hypercalcemia, malignancy hypercalcemia, and primary hyperparathyroidism. Since increases in total calcium can be underwhelming in some of these conditions, ionized calcium should be tested in all patients with calcium uroliths. If high, PTH and PTHrP levels should be measured. Based on these three parameters, the likely cause of the hypercalcemia can be determined (Table 13.19).

Cats with idiopathic hypercalcemia may have only slight elevations in total calcium, while ionized calcium can be dramatically affected. While at least half of affected cats will have no clinical signs, others will experience weight loss, signs of inflammatory bowel disease, constipation, anorexia, and oxalate stones. Besides removing the calcium oxalate stones, these patients should be fed a high-fiber, alkaline-urine-forming diet. While many will respond to high-dose prednisolone (5–10 mg per cat q.24 h.) bisphosphonates (e.g., alendronate) may be a better alternative. Alendronate can be given 10 mg per cat once a week. The dose then can be adjusted (5–20 mg per cat) based on ionized calcium rechecks at 8 weeks and then monthly. As alendronate can cause esophagitis, the pill should not be split or crushed and always followed with 5 mL of tap water.

Urate

Urate stones are the third most common urolith in dogs and account for 8% of canine urinary calculi. A genetic predisposition (autosomal recessive) has been

documented in Dalmatians and is suspected in English Bulldogs. Urate uroliths are observed in a number of other breeds. While the mechanism of urate stone formation in these dogs is unclear, Yorkshire Terrier, Shih Tzu, and Miniature Schnauzer appear to be overrepresented. Urate stone formation has also been associated with hepatic dysfunction, especially hepatic portal shunts.

In most dogs, dietary purines are metabolized in a series of steps to the highly soluble allantoin (Figure 13.54). This process, which takes place in the liver, involves converting purines to hypoxanthine. Through the action of xanthine oxidase, hypoxanthine is converted to xanthine and then uric acid. Uric acid, which is poorly soluble, is then converted to the highly soluble allantoin through the enzymatic action of uricase. Although Dalmatians possess all the necessary enzymes to convert purines to allantoin, it appears that a defective cell membrane transport system decreases hepatic metabolism of uric acid, and large amounts of uric acid are then presented to the kidney. The resulting hyperuricosuria may not completely explain the urolith formation, as not all Dalmatians with increased urate excretion are affected. It is likely that other factors, including urine pH and a decrease in the production of crystallization inhibitors, play a role. The fact that most Dalmatians that present for urate stones are male is likely due to anatomic differences (e.g., decreased urethral diameter) between the sexes.

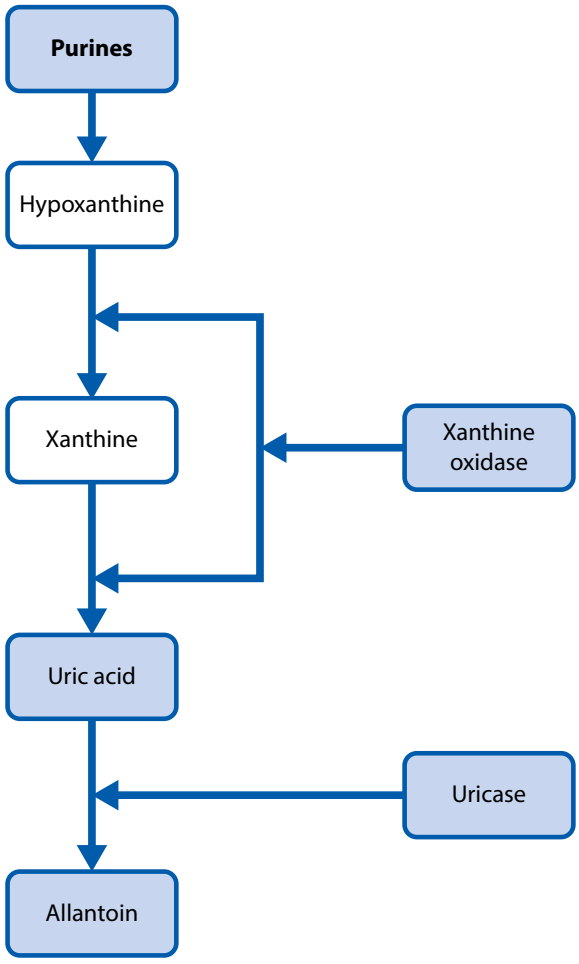

FIGURE 13.54 Dietary purines are metabolized in a series of oxidative steps to the highly water soluble allantoin. In some patients, the process is interrupted, leaving large amounts of the poorly soluble uric acid.

Urate uroliths have been observed in cats. There does not appear to be a breed predilection. Most urate uroliths occur in younger cats and may occur as a secondary to liver disease or portal vascular anomaly; however, most appear to be idiopathic.

Canine Cystine

In the United Sates, cystine urolithiasis is uncommon and accounts for only 1%–2% of all uroliths; however, the incidence may be higher elsewhere. Cystine uroliths have been reported in more than 100 different breeds of dogs, and more than 90% of these stones occur in male intact patients.

In the kidney, cystine is freely filtered by the glomerulus and then reabsorbed in the proximal convoluted tubule. In affected dogs, there is a defect in the proteins needed for cystine reabsorption, and excessive amounts of the poorly soluble amino acid are excreted in the urine. Four different genetic mutations have been identified affecting several different breeds. For example, in Newfoundland dogs, the condition is inherited as an autosomal recessive condition, while in Australian Cattle dogs, it is autosomal dominant. In most dogs (>90%), the condition appears to be testosterone responsive, and castration significantly reduces cystinuria. DNA testing is available to determining which form of the disease is affecting a patient (PennGen®).

Clinical Presentation

Clinical signs vary with the location of the uroliths. Nephroliths may cause sublumbar pain and hematuria, but they are often associated with no clinical signs. Bladder uroliths cause signs of lower urinary tract inflammation with hematuria, pollakiuria, and stranguria. Urethral uroliths in male dogs cause stranguria and intermittent incontinence with a full bladder. In both dogs and cats, they can cause complete urethral obstruction.

Differential Diagnosis

Lower urinary tract inflammation (hematuria and proteinuria), trauma, neoplasia, UTI, idiopathic cystitis (cats)

Diagnosis

Presence, number, size, and location of uroliths are usually determined by radiographic and/or ultrasound examination (Tables 13.16 and 13.17). As size and radiolucency can vary substantially, ultrasound has proven to be more diagnostically useful than radiographs.

Likely, mineral composition of uroliths can be predicted on the bias of clinical data, including the age, breed, sex, radiographic density and shape of the uroliths (Figure 13.55a, b), composition urine crystals (Figures 13.56–13.59), urine pH, and bacterial culture

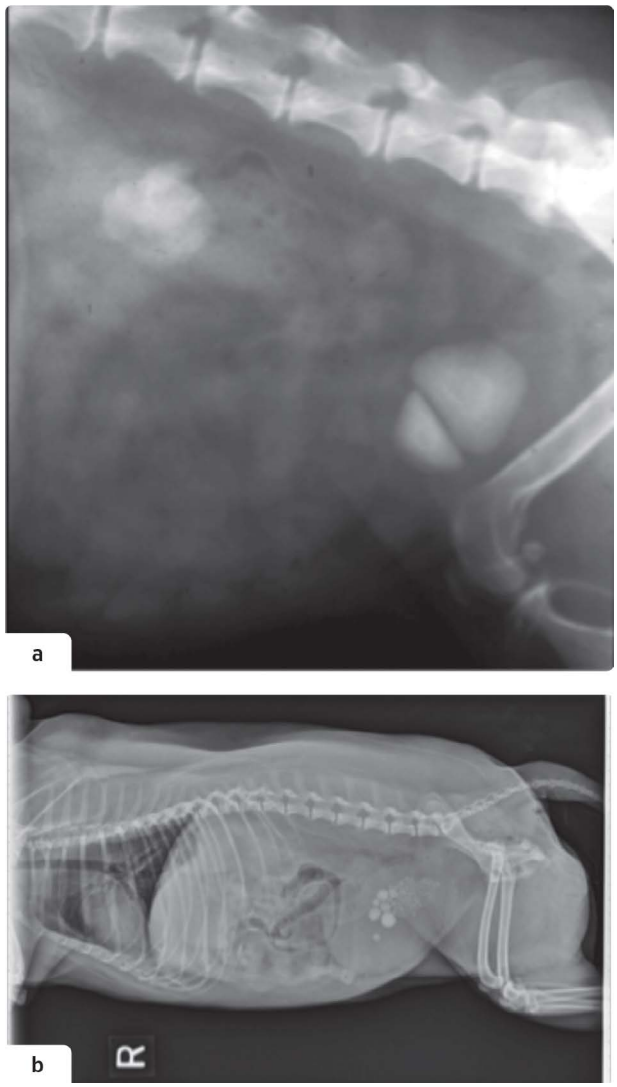

FIGURE 13.55 Although struvite uroliths are classically described as being large with flattened edges between the stones **(a)**, they can appear as many small stones **(b)**, making predicting the composition of the uroliths based on clinical data challenging. In addition, uroliths of a mixed composition are not uncommon; therefore, whenever possible, uroliths should be submitted for analysis.

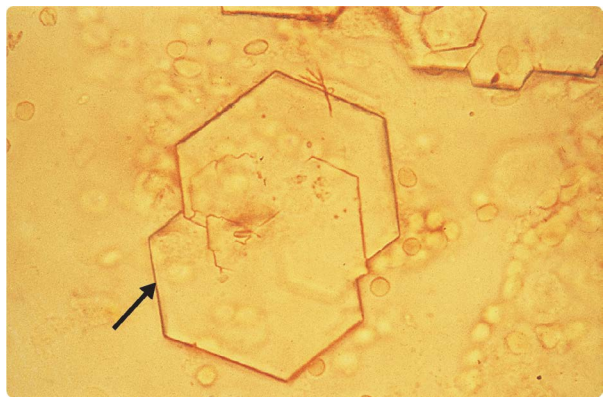

FIGURE 13.59 Appearance of crystals in urine corresponding to the common uroliths (arrow): cystine. (*Courtesy of D.F. Senior.*)

of the urine; however, actual mineral composition can only be determined by quantitative analysis of recovered uroliths. These tests, which include optical crystallography, x-ray diffraction, and infrared spectroscopy, are only performed at specialty laboratories and should be performed on every patient.

FIGURE 13.60 Lateral abdominal radiograph of a patient with a subcutaneous bypass (SUB). The proximal end of the device is in the kidney. The distal end is positioned within the urinary bladder. This restores the flow of urine from kidney to the bladder without addressing the obstructed ureter. The port, located in the ventral abdomen, allows for flushing and collecting of urine samples. These are typically placed using fluoroscopy.

Management

Depending on their location in the urinary tract, there are different ways to treat uroliths. Stones located in the kidney (nephroliths) are usually left untreated unless they obstruct the ureter, at which point most would require surgical intervention. Although an attempt can be made to dissolve nephroliths in dogs, only 20%–30% are composed of struvite. The rest are likely calcium oxalate. Virtually all feline nephroliths are calcium. Stones that become lodged in the ureter (ureterolith) represent a surgical emergency because in a matter of days they can lead to hydronephrosis and irreversible kidney damage. Traditionally, these have been surgically removed; however, today options such as ureteral stents and subcutaneous ureteral bypass devices (Figure 13.60) have become possible.

Struvite, urate, and cystine uroliths are all amenable to being dissolved (Figure 13.61); however, in male patients, these is always a risk of urethral obstruction. Removal of tiny stones can be attempted with catheter-assisted retrieval. Small stones may be removed with urohydropropulsion or endoscopically utilizing a stone basket (Figure 13.62). Larger stones can be fragmented with a laser and removed endoscopically. Once removed, all stones should be submitted for analysis. While diagnostic imaging and urinalysis can provide information about the possible composition of the stone (Tables 13.16 and 13.17 and Figures 13.56–13.59), only a proper stone analysis can provide definitive information regarding stone composition.

Preliminary: Urine obtained by cystocentesis submitted for culture and sensitivity.

Initiate therapy: Start oral antimicrobial drugs based on urine culture and sensitivity results and begin feeding commercially available struvite dissolving diet.
Antimicrobial therapy must continue for duration of dissolution therapy.

Every 30 days: Physical examination, urinalysis, abdominal radiographs. If pH is >7.0, suspect resistant infection and submit urine for culture and sensitivity. Adjust antimicrobial as indicated.

Continue protocol: Continue therapy for 30 days after the ÿrst follow-up radiographic examination that shows no evidence of uroliths.

FIGURE 13.61 Canine struvite uroliths dissolution flowchart.

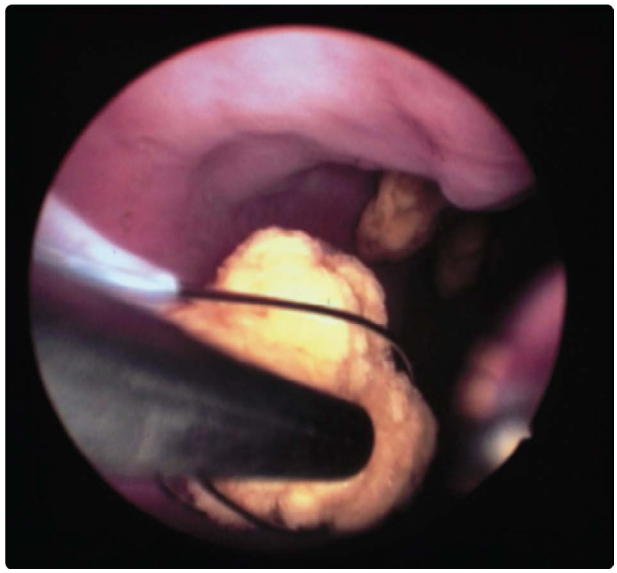

FIGURE 13.62 Urolith removed with a urethroscope and retrieval basket.

Canine Struvite Uroliths

Struvite uroliths can be dissolved over time; however, this carries the risk of urethral obstruction in males. A discussion with the owner about the relative risks and benefits of medical and surgical management should occur before deciding on a therapy. The owner should be made aware that in dogs the dissolving process takes many months.

Dissolution of struvite uroliths involves a combination of antimicrobial and dietary therapy. Appropriate antimicrobial selection can only be made on the basis of a urine culture and sensitivity. The urine must be obtained by cystocentesis and plated in a timely fashion. Since bacteria are often sequestered and protected in the layers of the stone, antibiotic therapy must be continued throughout the entire dissolution process. There are several commercially available struvite-dissolving diets. These diets tend to be low in protein and acidify the urine. At home, the owner should periodically test urine pH with a dipstick. If the pH is greater than 7.0, a resistant urinary tract infection should be suspected, and a urine sample, obtained by cystocentesis, should be submitted for culture. The patient's progress should be evaluated monthly by performing abdominal radiographs and a urinalysis.

Inhibition of struvite formation requires prevention of alkaline urine; therefore, the urinary tract must be free of infections. At-home monitoring can be performed by periodically measuring urine pH. The presence of

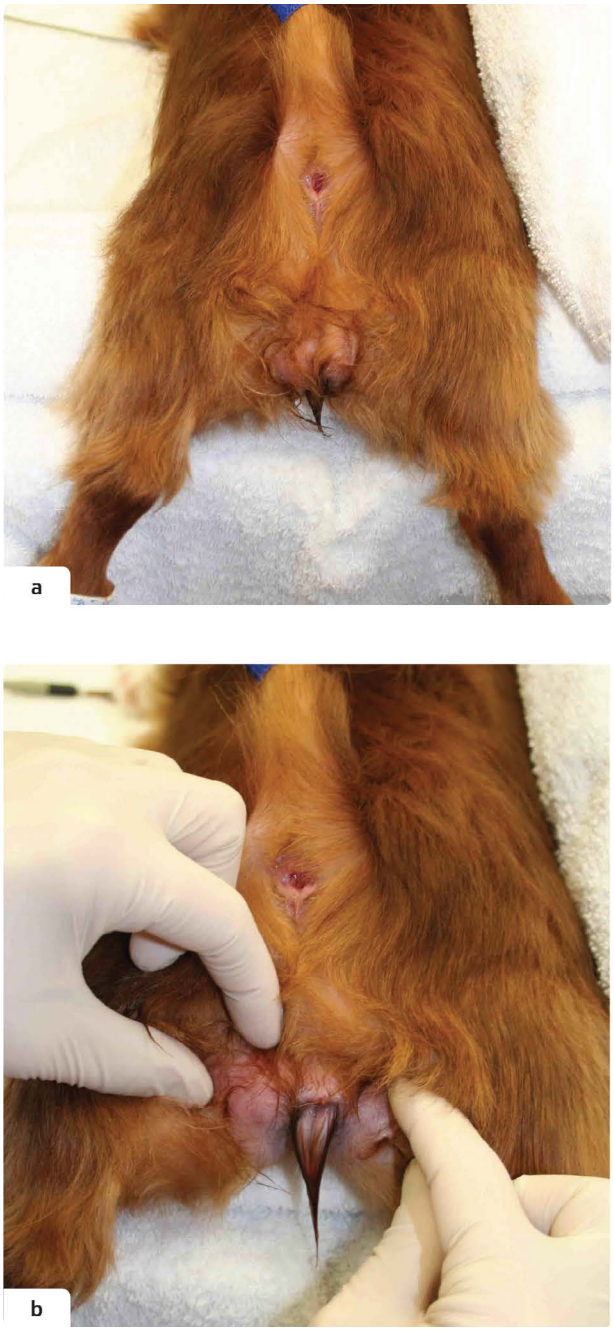

FIGURE 13.63 (a, b) Dog with an involuted vulva. Note how the extent of the involution is not apparent until a complete genital examination is performed.

alkaline urine indicates that a urine culture is necessary. Dogs with recurrent UTIs despite the resolution of uroliths should be evaluated for structural abnormalities that may predispose the patient to UTIs. We have found that most of these cases involve an involuted vulva (Figure 13.63a, b).

Feline Struvite Uroliths

Feline struvite uroliths can be dissolved by feeding a diet that is both restricted in magnesium, phosphorous, and protein and induces aciduria. There are several commercial diets which are formulated to accomplish struvite dissolution is cats. Unlike dogs, complete dissolution of stones can be often accomplished in just days to weeks. Although one might assume there is a high risk of urethral obstruction, this is actually quite rare. In cases where the composition of the stone is unknown, an attempt should always be made to dissolve the stone first.

Canine Calcium Oxalate

Calcium oxalate uroliths cannot be dissolved and must be removed using urohydropropulsion, a stone basket, surgery, or lithotripsy. One of the most important steps in preventing calcium oxalate crystals and uroliths is to increase water intake, which can be accomplished by feeding a canned diet. The optimum diet composition to prevent calcium oxalate urolith formation is unknown. Previously, it had been recommended that diets be low in protein and sodium restricted; however, recent epidemiologic studies have challenged this approach. Currently recommended diets include Royal Canin S/O, Hill's u/d, and Hills w/d. Despite appropriate diet therapy, as many as 50% of dogs will have recurrence within 3 years.

After calcium oxalate stone removal, the owner should purchase a refractometer and urine dipsticks. Urine should be checked weekly to be certain urine specific gravity remains less than 1.020 and pH is 7.0–7.5. Radiographs should be taken every 4 months so that stones can be detected while they are small enough to be removed by stone basket, catheter-assisted retrieval, or urohydropropulsion.

Thiazide diuretics have been shown to decrease urinary calcium excretion and should be considered in dogs with persistent calcium oxalate crystalluria or recurrence of uroliths despite appropriate diet therapy (hydrochlorothiazide 2 mg/kg p.o. q.12 h.). Citrate is a urolith inhibitor that forms complexes with calcium and increases its solubility. In people, oral potassium citrate ingestion increases urine pH and increases the amount of citrate in the urine; however, the benefit of potassium citrate supplementation in dogs is unclear. In dogs, oral potassium citrate does not result in a significant change in urine citrate concentration. Nevertheless, some still recommend supplementation (25–50 mg/kg p.o. q.12 h.).

Feline Calcium Oxalate

Cats with elevations in ionized calcium should be treated appropriately for any underlying condition. Once the hypercalcemia is addressed, the amount of calcium spilling into the urine will abate, and they should not continue to form uroliths. For idiopathic urolith-producing patients, there are two diets formulated for the prevention of these stones. These diets contain potassium citrate and induce a urine pH of approximately 7.0. Neither has been evaluated in actual calcium oxalate-forming cats; nevertheless, cats consuming c/d Multicare (Hill's Pet Nutrition) and SO (Royal Canin) do appear to have decreased urine calcium oxalate saturation.

Canine Urate

Although urate uroliths can be medically dissolved, there is a significant risk of urethral obstruction in male dogs. A discussion with the owner about the relative risks and benefits of medical and surgical management should occur before selecting a therapy. Dissolution should not be attempted in dogs with known liver disease.

The dissolution of urate uroliths involves dietary changes, medical intervention, and urine modification. Reduction of urate excretion can be achieved by restricting total protein and by replacing high-purine-content proteins (e.g., fish) with low-purine-content proteins (e.g., eggs). Feeding a protein-restricted diet can dilute urine by decreasing the urea available for the medullary concentration gradient of the kidney. A canned diet increases water intake and can further decrease urine concentration. Hills u/d, i/d Sensitive Canine and Purina HA Hydrolyzed have all be successfully employed. Allopurinol, a xanthine oxidase inhibitor, prevents the conversion of soluble xanthine to the insoluble uric acid (see **Figure 13.54**). Although a variety of adverse reactions have been reported in humans, the most commonly reported adverse effect in dogs is the formation of xanthine uroliths. This is usually seen when high-protein diets are consumed in conjunction with the medication. For this reason, long-term use is not advised.

Prevention of urate uroliths recurrence is best accomplished through a combination of low-protein diet and urine alkalinization. Prophylactic treatment with allopurinol is not recommended. Urate urolith formation is inhibited in alkaline urine as the concentration of ammonium ions needed for stone formation decreases. The target pH range is 7.0–7.4. Low-protein diets favor an alkaline pH; however, if further urine alkalinization is needed, potassium citrate (40–90 mg/kg p.o. q.12 h.) can be utilized. A urine pH of 7.5 or higher should be avoided, as this may favor the formation of calcium phosphate and struvite uroliths. Response to medical therapy can be evaluated by checking periodic monitoring of urine pH (7.0–7.4), specific gravity (<1.015), and serum BUN (<10 mg/dL).

Canine Cystine

Although cystine uroliths can be medically dissolved (1–3 months), there is a significant risk of urethral obstruction. For this reason, dissolving them should never be attempted in male dogs (>97% of cases). Since the majority of cases are likely testosterone responsive, the patient should be either DNA tested and then castrated or castrated with no further testing.

Prevention of cystine uroliths in non-testosterone-response dogs involves dietary changes, medical intervention, and urine modification. Reduction of cystine excretion can be achieved by restricting total protein. Feeding a protein-restricted diet can also dilute urine by decreasing the urea available for renal medulla. Further urine dilution can be achieved by feeding a canned diet. Thiol-containing drugs catalyze the conversion of the poorly soluble cystine to more soluble compounds. N-(2-mercaptopropionyl) glycine (Thiola®, Mission Pharmacal) 20 mg/kg p.o. q.12 h. is commonly used for this purpose. Side effects, including aggression, myopathy, proteinuria, anemia, and thrombocytopenia, may limit its use. Cystine urolith formation is inhibited in alkaline urine. The target pH range is 7.0–7.4. Low-protein diets favor an alkaline pH; however, sometimes further urine alkalinization is needed. Potassium citrate (40–90 mg/kg p.o. q.12 h.) can be utilized. A urine pH of 7.5 or higher should be avoided, as this may favor the formation of calcium phosphate and struvite uroliths. Response to medical therapy can be evaluated by periodic at home checking of urine pH (7.0–7.4) and specific gravity (<1.015).

TUMORS OF THE LOWER URINARY TRACT

Definition/Overview

Tumors of the lower urinary tract are relatively rare, representing less than 2% of all canine neoplasms and an even lower percentage of feline neoplasms. Most are malignant, and transitional cell carcinoma (TCC) is by far the most common. Other neoplasms seen less frequently include squamous cell carcinoma, adenocarcinoma, undifferentiated carcinoma, rhabdomyosarcoma, and fibroma.

Etiology

Scottish Terriers have an 18-fold increased risk of developing transitional cell carcinoma, while Shetland Sheepdogs and Beagles have a 4-fold increased risk. A link between lawn herbicide and pesticide exposure and the development of TCC has been established. In cats, the tumor types are more varied with different primary cell types involved. As many as 20% of bladder tumors in cats may be benign.

Pathophysiology

Transitional cell carcinomas spread by direct extension through the wall of the bladder or urethra to adjacent tissue and draining lymph nodes. At diagnosis, about 40% have undergone metastasis, most commonly to regional lymph nodes, the lungs, and ventral lumbar vertebrae; however, ureteral and urethral obstructions are the most common life-limiting complications. Secondary UTIs are common, a development that can intensify clinical signs.

Clinical Presentation

Affected animals present with signs of lower urinary tract inflammation, including pollakiuria, dysuria, stranguria, and hematuria. Urethral obstruction may be evident in patients with urethral involvement. On physical examination, the bladder wall may be thickened, and a mass may be palpable. For urethral tumors in dogs, a portion or all of the urethra may be thickened on rectal palpation.

FIGURE 13.64 Example of a retrograde urethrogram in a patient with urethral obstruction due to transitional cell carcinoma. The arrow indicates an area of filling defect.

Differential Diagnosis

Abnormal micturition: UTI, urolithiasis, behavioral disturbances, urethral stricture, granulomatous urethritis, neurologic disorders, cystitis.

Diagnosis

Historically, TCC has been diagnosed based on a combination of diagnostic imaging (Figure 13.64), urinalysis findings, and diagnostic catheterization (suction biopsies). Each of these has limitations. More recently, two genetic mutations associated with approximately 95% of TCC cases have been identified, and a test has been made commercially available (CADET® BRAF-PLUS). This test, which is both sensitive and specific, uses a specialized free-catch urine system which is totally noninvasive. Unlike earlier tests, it is not affected by other urinary tract conditions.

In cases where urinary tract neoplasia is suspected but the CADET test is negative, samples for histopathologic/cytologic examination can be obtained by either cystoscopy or diagnostic catheterization (Figure 13.65). Because of the risk of spreading the neoplasia, fine-needle aspirates should not be attempted. Diagnostic catheterization is performed by placing a side-hole catheter in the urethra while using rectal palpation or ultrasound to guide the catheter tip into the affected area. Suction is then applied using a syringe so that the catheter adheres to the urethral wall, and abnormal tissue is drawn inside the lumen of the side hole. Then, the catheter is forcibly removed while continuing to apply suction. When available, urethroscopy and cystoscopy can be rewarding procedures. Not only do they allow visual inspection of the urethra and bladder, but they also facilitate tissue biopsies.

FIGURE 13.65 Example of simple equipment needed for effective urethral suction biopsy. The patient is sedated and a catheter inserted into the urethra using rectal palpation to guide the catheter tip into the affected area. Suction is applied using the syringe and the catheter is forcibly removed.

Management

The success of surgical intervention is limited by the late stage at which the diagnosis of tumors of the lower urinary tract is generally made. The mainstay of therapy is composed of piroxicam (0.3 mg/kg p.o. q.24 h.) alone or in combination with chemotherapy. Urethral stenting may be utilized in patients presenting with or developing a urethral obstruction with this therapy.

Prognosis

Piroxicam has an 18% reported overall response rate and 35% when used in combination with chemotherapeutic agents. Commonly used drugs include doxorubicin, cyclophosphamide, mitoxantrone, cisplatin, and carboplatin. Radiation therapy has also been successfully employed.

Urethral and prostatic involvement is associated with a worse prognosis due to the likelihood of urinary obstruction. Urethral stenting can provide palliative relief of obstructed urethras (Figures 13.64 and 13.66). Control of concurrent UTI and treatment with an anticholinergic such as propantheline (7.5–15 mg p.o. q.8–12 h.) to reduce bladder spasm can alleviate some of the urge incontinence experienced by affected dogs.

CYSTIC DISEASE

Definition/Overview

Polycystic kidney disease (PKD) is a bilateral condition that has been reported in Persian cats, Cairn Terriers, West Highland White Terriers, and Australian Bull Terriers. Rare solitary renal cysts can be seen in otherwise normal cats and dogs. Perirenal pseudocysts have also been described in cats.

FIGURE 13.66 The patient after placement of a urethral stent.

Etiology

PKD has a genetic basis with autosomal-dominant inheritance in Persian cats and autosomal recessive inheritance in Cairn and West Highland White Terriers. As many as 40% of Persian cats are carriers.

Pathophysiology

The precise changes in the nephron wall that lead to PKD are not known. A prevailing theory is that a genetic mutation leads to apoptosis of the renal parenchyma. This allows cystic epithelial cells to proliferate, which creates multiple, often large cysts.

Persian cats can appear normal as kittens and only develop pronounced renomegaly and CKD as adults. In the single report of PKD in Cairn Terriers, dogs developed clinical renal disease as very young puppies. The cysts of PKD can become infected. The cause of perirenal pseudocysts in cats is unknown, and most affected animals are diagnosed in CKD.

Clinical Presentation

Animals with PKD or perirenal pseudocyst develop extreme bilateral renomegaly with concurrent signs of CKD. Affected Persian cats can be any age on initial presentation, but in Cairn and West Highland White Terriers, affected animals are usually very young. Solitary renal cysts are most often diagnosed as an incidental finding.

Differential Diagnosis

Renomegaly, neoplasia, hydronephrosis, amyloidosis, feline infectious peritonitis.

Diagnosis

In Persian cats, an ultrasound performed at 16 weeks has been reported to have a sensitivity of 75% and a specificity of 100%, while an ultrasound performed at 36 weeks of age has a sensitivity of 91% and a specificity of 100%. Cairn Terrier PKD is characterized by the presence of cysts in the liver and kidney, while West Highland White Terriers develop PKD as puppies.

Once bilateral renomegaly is recognized on physical examination, ultrasound examination can differentiate between PKD, solitary cysts, and perirenal pseudocysts. In PKD, the cysts are multiple, of variable size, and throughout the parenchyma of the kidney (**Figure 13.67a, b**), whereas in perirenal pseudocysts the renal capsule is extremely distended, completely surrounding the kidney with fluid (**Figure 13.68**).

Management

No specific treatment is available to manage cats with PKD or perirenal pseudocyst other than support for their concurrent CKD. Antibiotics to control secondary pyelonephritis may prevent some of the malaise suffered by cats with PKD.

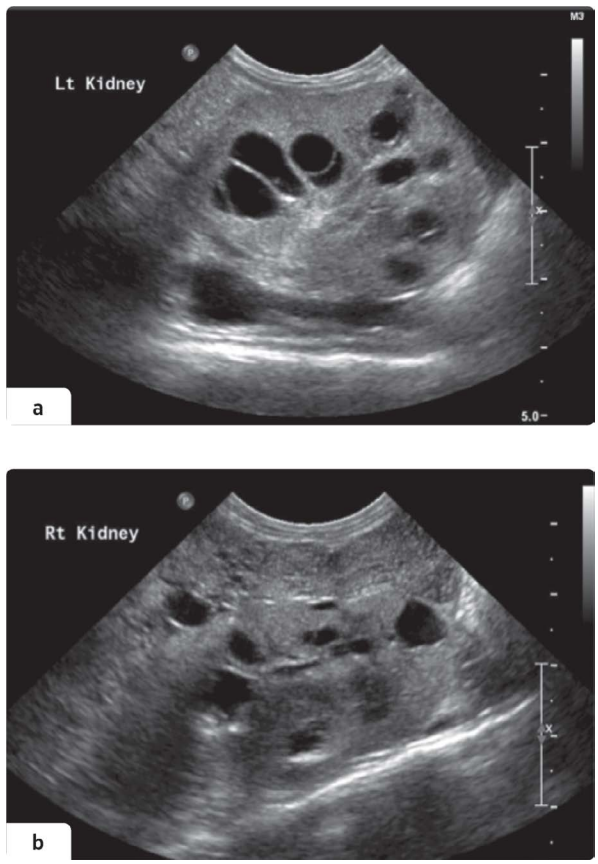

FIGURE 13.67 (a, b) Ultrasonograms of a Persian cat (age unknown) with polycystic kidney disease. (*Courtesy of R. Baumruck.*)

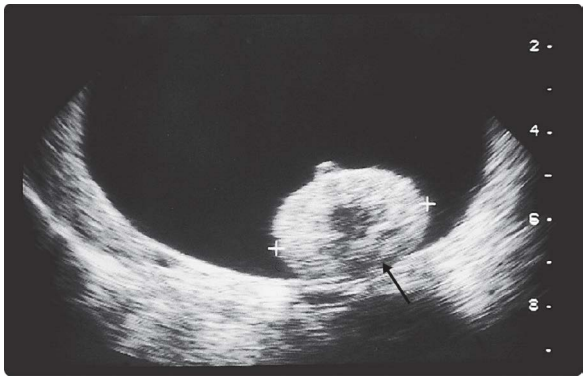

FIGURE 13.68 Ultrasonographic appearance of the kidney (arrow) and the surrounding cystic structure in a cat with a perirenal pseudocyst. (*Courtesy of AM Grooters; from* Compendium on Continuing Education for the Practicing Veterinarian*, 1997, 9:1226, with permission.*)

Prognosis

PKD is an insidious disease without effective treatment. Although clinical signs of CKD can be managed, long-term prognosis is poor.

RENAL TUMORS

Definition/Overview

Primary kidney tumors are rare and account for less than 2% of all canine cancer. Moreover, they are usually tumors that have metastasized from a remote site. The most common histologic types in dogs include renal tubular cell carcinoma, transitional cell carcinoma, and renal cell papilloma. Carcinoma, sarcoma, fibroma, hemangiosarcoma, lymphoma, and nephroblastoma have also been reported. In cats, lymphoma is the predominant renal neoplasia.

Etiology

The large renal blood supply results in the kidney being the site of distant metastases from primary tumors elsewhere in the body.

Pathophysiology

Tumors cause pain, hematuria, hydronephrosis (if they obstruct urine outflow), and displacement of normal renal tissue, which can lead to CKD. Early metastasis by the time of initial presentation is usual. Paraneoplastic syndromes have been described, including polycythemia and hypertrophic osteopathy. A hereditary multifocal renal cystadenocarcinoma of German Shepherd Dogs is accompanied by cutaneous nodules (dermatofibrosis).

Clinical Presentation

At presentation, affected animals usually exhibit anorexia and weight loss. Dogs and cats with nonlymphomatous renal tumors can present with red-brown urine that appears the same color both at the beginning and the end of urination. In addition, pollakiuria, stranguria, and urgency are not usually observed. Unilateral renal enlargement and pain may be evident on abdominal palpation. Unilateral tumors do not cause CKD.

In dogs with renal lymphoma, renal involvement can be diffuse, so both kidneys can be enlarged. Gross hematuria is not common, and evidence of the tumor can usually be detected involving other organs. In cats, lymphoma usually causes "lumpy" bilateral renomegaly. In both dogs and cats, the diffuse bilateral nature of renal lymphoma generally leads to CKD.

Differential Diagnosis

Renomegaly: Hydronephrosis, amyloidosis, feline infectious peritonitis, cystic disease.

Diagnosis

Abdominal radiographs show an irregularly enlarged kidney, and areas of mineralization may be visible. While an intravenous urogram can be used to find abnormal blood perfusion or distortion of the collection system, ultrasonographic imaging can readily detect the abnormal tissue (Figure 13.69). Cytologic evaluation of the urine has proven unreliable, so only a fine-needle aspirate or biopsy can provide a definitive diagnosis. Thoracic radiographs and an abdominal ultrasound should be performed to rule out metastasis of a renal tumor or a primary tumor in another organ.

Management

Treatment of discrete renal tumors is by surgical resection (Figure 13.70).

Prognosis is poor because of the late stage at which these tumors are generally diagnosed. However, nephroblastoma is less metastatic than other tumors, and nephrectomy can be curative. Usual treatments for lymphoma are indicated, and renal function can show some improvement if remission is achieved.

FIGURE 13.69 Renal mass in the right kidney later confirmed to be anaplastic carcinoma.

URINARY TRACT INFECTION

Definition/Overview

A urinary tract infection (UTI) is defined as the presence of bacteria in urine in a patient with related clinical signs. Such signs can include urgency, inappropriate urination, dysuria, pollakiuria, stranguria, and urinary incontinence. At one time, the simple presence of bacteria in the urine (subclinical bacteriuria) justified the use of antibiotics. In both people and animals, subclinical bacteriuria is no longer considered a pathologic state that requires treatment; therefore, proper antimicrobial stewardship dictates that we not treat these cases.

Etiology

UTIs develop when bacterial number and virulence are sufficient to overcome host defenses, or a disease state alters the host defense mechanisms.

Pathophysiology

The urinary tract and urine have a number of defense mechanisms, which prevent bacterial colonization. Urinary tract defenses include a tight sphincter, frequent forceful voiding, a long urethra, a glycosaminoglycan coating, regular shedding of epithelial cells, and urinary secretion of immunoglobulin and cytokines. Characteristics of urine that prevent bacterial colonization include an inhospitable pH, high urine osmolality (especially cats), and urinary inhibitors of bacterial adherence. When there is loss of normal defense mechanisms or an overwhelming inoculation of pathogenic bacteria, the urinary tract can become infected. If there is an inflammatory response to the bacteria, we can see clinical signs associated with a UTI. Rectal and genital bacteria are thought to serve as a reservoir for infection. Although more than 20 different species bacteria can be found colonizing this area, only seven account for the vast majority of UTIs (Table 13.20).

TABLE 13.20 Frequency of bacterial isolates from urinary tract infection in dogs (%)

Microorganism	%
Escherichia coli	26–67
Staphylococcus spp.	11–19
Proteus mirabilis	3–32
Enterococcus/Streptococcus spp.	3–22
Klebsiella pneumoniae	2–8
Pseudomonas aeruginosa	2–4
Enterobacter cloacae	2–6

Clinical Presentation

Clinical signs are dependent on whether the upper urinary tract, the lower urinary tract, or both are affected. Lower urinary tract infections can have any combination of urgency, hematuria, inappropriate urination, dysuria, pollakiuria, stranguria, and urinary incontinence. Most of these signs are due to inflammation of the bladder and/or urethra. It is important to note while infections involving the lower urinary tract can cause pollakiuria, they cannot cause polyuria. When the upper urinary tract is involved, signs consistent with acute kidney injury and septicemia may predominate.

Although a mucopurulent or bloody discharge is sometimes seen at the distal end of the penis or vulva, physical exam findings in patients with UTIs are usually unremarkable. Intact male dogs may exhibit pain on rectal palpation suggesting prostatic involvement. Patients with pyelonephritis may exhibit signs of back pain.

Differential Diagnosis

Lower urinary tract inflammation: Trauma, neoplasia, urolithiasis, idiopathic detrusor instability.

Diagnosis

Urinary tract infections can be divided into two general categories: (1) Uncomplicated, also called sporadic bacterial cystitis, and (2) complicated or recurrent bacterial cystitis. Uncomplicated cases are those first time UTIs in which no underlying predisposing condition can be identified. Complicated cases include those with a predisposing condition, a history of recurrent history of UTIs, and intact male dogs. Predisposing conditions include systemic diseases (e.g., renal disease, hyperadrenocorticism, diabetes mellitus, hyperthyroidism), structural abnormalities (e.g., vulvar malformations, uroliths, tumors, PKD, etc.), and immunosuppressive medications.

The incidental finding of bacteriuria in an asymptomatic patient should not trigger a diagnostic workup or treatment. Subclinical bacteriuria is not a pathologic condition requiring antimicrobials. Diagnostic workup for an uncomplicated UTI should include a thorough physical examination, urinalysis, and culture.

Diagnostics for complicated cases should focus on possible underlying conditions and include a thorough physical examination, diagnostic imaging, CBC, serum chemistry, urinalysis, and culture. While abdominal radiographs are commonly performed, ultrasound may have more diagnostic value as it is more sensitive and specific for finding uroliths, discovering structural abnormalities, and detecting pyelectasia.

The cornerstone of diagnosing and treating urinary tract infections is a urine culture. In addition, widespread antibiotic resistance makes antimicrobial susceptibility testing essential. Interestingly, as more than 50% of all urine samples submitted for culture fail to grow bacteria, clinical signs commonly associated with UTIs are not specific.

Urine should be collected aseptically by cystocentesis. Often, patients with UTIs will experience pollakiuria resulting in a small urinary bladder, making cystocentesis difficult. In these cases, ultrasound can be helpful in sample collection. When cystocentesis is not possible, urine may be collected by catheterization, although in female dogs and all cats, sedation would be required. Midstream urine collection as is performed in people is generally not acceptable because of the likelihood of sample contamination.

In most cases, urine collected for culture will need to be sent to a diagnostic laboratory. Although in-hospital culture kits exist, none provide reliable information on antimicrobial sensitivity, severely limiting their utility. Urine should be refrigerated immediately after collection, as samples left at room temperature can experience an exponential increase in bacterial growth, potentially amplifying contaminates and leading to death of pathogenic bacterial. Results from samples refrigerated more than 24 hours should be treated with skepticism as both false positive and false negative results are possible.

Antimicrobial susceptibility based on the minimum inhibitory concentration (MIC) provides essential information for selecting an appropriate antibiotic therapy. Results are often reported as (S)ensitive, (I)ntermediate, and (R)esistant. In the MIC test, isolates of the patient's uropathogen are incubated with different dilutions of an antibiotic. The minimum concentration of the antibiotic that will inhibit the growth of the bacteria represents the bacteriostatic dose. If the achievable urine concentration of the antibiotic can be expected to be four or more times the MIC, then this drug would be an acceptable choice.

Management

In uncomplicated cases, treatment with amoxicillin, or trimethoprim-sulfamethoxazole can be initiated while waiting for the results of susceptibility testing. Antibiotic therapy should be reevaluated once susceptibility results become available. While earlier recommendations called for administration of antimicrobials for 10–14 days, it is now generally recognized that shorter courses, such as 5 days, are just as efficacious. The use of NSAIDs to decrease lower urinary tract inflammation should be considered. In cases where a urine culture is unavailable or declined by owners, empirical treatment can be attempted with these same antibiotics. Other classes of antimicrobials such as fluoroquinolones should never be empirically used.

In complicated cases, it is important to address underlying conditions. Endocrine disorders such as hyperadrenocorticism, diabetes mellitus, and hyperthyroidism must be regulated in order for UTIs to be adequately controlled. A recessed vulva (see **Figure 13.63**) is a common malformation that contributes to many UTIs in female dogs. This can be surgically corrected. Immunosuppressive medications should be reduced to the lowest effect dose. Repeated courses of antibiotics without correcting the underlying problem are likely to result in multidrug-resistant infections.

In intact male dogs, UTIs can involve the prostate, and only certain antibiotics can penetrate this organ. If appropriate antibiotic therapy is not selected, the urinary tract can be repeatedly re-infected by sequestered bacteria. Antibiotic selection needs to be guided by the results of antimicrobial susceptibility testing as well as by considering which drugs are likely to penetrate the prostate. Macrolides, lincosamides, sulfonamides, chloramphenicol, and fluoroquinolones all seem to be reasonable choices.

Despite appropriate therapy and a failure to diagnosis a predisposing underlying cause, persistent and recurrent UTIs occur. One strategy to prevent reinfection is oral administration of methenamine hippurate (Urex®) (500 mg p.o. q.12 h. dog; 250 mg p.o. q.12 h. cat). In the presence of acidic urine (pH ≤5.5) methenamine is converted to formaldehyde. Ammonium chloride can be used to acidify the urine (65 mg/kg p.o. q.8 h. in dogs; 20 mg/kg p.o. q.12 h. in cats). Although controversial, long-term, low-dose antimicrobial treatment can also be used in the treatment of recurrent UTIs. Patients are given a full course of antimicrobial based on sensitivity test results for 3–4 weeks. Treatment is then continued for at least 6 months by giving 50% of the regular daily dose at night after the patient has voided.

Prognosis

Most UTIs are easily treated, and the prognosis is quite good.

DISORDERS OF THE BRAIN

Introduction

Diseases of the forebrain (cerebrum and thalamus) are very complex and may affect the whole of the central nervous system (CNS). In veterinary medicine, the clinical symptoms of brain dysfunction can be relatively mild despite being often associated with a severe lesion. Dogs and cats with forebrain dysfunction may exhibit clinical signs that include altered mental status (obtundation more likely than stupor or coma), behavioral changes, circling in a wide arc, head-pressing, visual impairment, focal and/or generalized seizure activity, and hemi-inattention (unilateral hemineglect) syndrome. Conscious proprioceptive deficits with a normal to near-normal gait are characteristic of forebrain dysfunction. Neck pain may be appreciable in some patients with structural brain lesions. Lesions from the midbrain (mesencephalon) through the medulla (myelencephalon) may lead to altered mental status (stupor or coma more likely than with forebrain lesions), proprioceptive and gait abnormalities, deficits in cranial nerves (CNs) III–XII, and central vestibular dysfunction.

Neurodiagnostic Investigation

Depending on the localization of the disease, appropriate diagnostic tests should be performed to rule in or out each disease on the differential diagnosis list. Sometimes the underlying disorder is evident, such as with cranial trauma; however, all too often animals with brain disease can present a diagnostic challenge. If the animal presents in a coma, emergency evaluation of airway patency and vital signs, including cardiac function and respiration, should be undertaken, as for animals with head trauma. The important aspects of the evaluation of animals with brain disease include:

- Response to noxious stimulation
- The presence of voluntary motor movement
- Posture (i.e., decerebrate rigidity)
- Pupillary reactivity to light
- Eye movements (physiologic nystagmus)
- Segmental spinal reflexes

This evaluation is very similar to that of the patient with severe head trauma, and in some respects, the modified Glasgow Coma Scale (GCS) system may be useful, although it has not been universally utilized or validated. Unless the diagnosis is established from the history (e.g., toxin ingestion), further testing is usually necessary:

- Routine laboratory analysis is essential—the minimal acceptable information should include packed cell volume (PCV), total protein concentration, blood urea nitrogen (BUN), electrolytes, and glucose concentrations.
- Urinalysis and urine production rate should be assessed, which may necessitate urethral catheterization.
- Liver function tests.
- Thoracic and abdominal radiographs may be useful to supplement physical examination findings.
- Cerebrospinal fluid (CSF) analysis is indicated primarily to confirm an inflammatory lesion. Although such analysis is rarely specific, when it is assessed in conjunction with the patient's signalment, history, neurologic signs, and the results of other diagnostic tests (such as serologic assays), it can help to better define the underlying etiology. If there is evidence or even a suspicion of increased intracranial pressure (ICP) (anisocoria, lack of pupil

DOI: 10.1201/9781003254591-33

response to light, reduced or absent physiologic nystagmus, decreased or absent response to noxious stimulation), diagnostic imaging should be performed prior to cisterna magna or lumbar puncture, which risks promoting further herniation. In these cases, reducing the ICP using mannitol (0.5–2.0 g/kg IV) should be considered.

- Advanced imaging studies such as computed tomography (CT) and magnetic resonance imaging (MRI) are strongly indicated to assess the integrity of the intracranial structures.
- An electroencephalogram (EEG) records the electrical activity associated with forebrain structures. An EEG is rarely specific, and with certain cerebral conditions, it also lacks sensitivity. Although rarely used as a diagnostic tool, electroencephalography can provide confirmation of brain death (flat or isoelectric EEG). However, other factors, such as patient body temperature, concurrent drug administration, and cardiac function, must be considered before brain death is diagnosed.

VASCULAR DISEASE

Definition/Overview

Cerebrovascular disease refers to any abnormality of the brain caused by a pathologic process compromising blood supply. Pathologic processes that may result in cerebrovascular disease include occlusion of the lumen by a thrombus or embolus, rupture of a blood vessel wall, a lesion or altered permeability of the vessel wall, and increased viscosity or other changes in the quality of the blood. Stroke or cerebrovascular accident (CVA) is the most common clinical presentation of cerebrovascular disease and is defined as a sudden onset of nonprogressive focal brain signs secondary to cerebrovascular disease. Cerebral microbleeds (CMBs) are small, well-defined, rounded, intraparenchymal hemorrhagic lesions with a maximum ≤5 mm diameter and no known history of head trauma.

Etiology

Vascular disturbances of the nervous system can arise due to a loss of adequate blood supply (ischemia/infarct) or hemorrhage into the nervous tissue. The initial process is focal in the majority of cases. However, it is possible with a disturbance in systemic perfusion that there is a multifocal, diffuse hemorrhagic process in the brain with a subsequent multifocal course. Vascular damage to the nervous system can be due to various different causes such as neoplasia, endocrine diseases, CNS infections, atherosclerosis, carcinogenic emboli, vasospasm, hematologic disturbances, vasculitis, hyperviscosity syndrome, hypertension, coagulopathy, disseminated intravascular coagulation, or sepsis. Hypertension, diabetes mellitus, hypothyroidism, and hyperadrenocorticism have been identified as concurrent systemic disorders in dogs with CMB. The majority of CMBs in dogs are found in the cerebral cortex.

Pathophysiology

Ischemia means the reduction of the blood flow to a level that is not compatible with normal function. An infarct is a large and continual reduction in the blood flow resulting in tissue necrosis. Hypoxia/ischemia initially particularly affects the most sensitive elements of the tissue and then subsequently disturbs all the tissue components. The main mechanism of cell damage found in an infarct is a reduced energy metabolism. Dogs with brain infarction are frequently (55%) detected with a comorbidity predisposing to CVA; chronic kidney disease (24%) and hyperadrenocorticism (18%) being most commonly encountered. Cats documented with ischemic brain infarcts have been affected by hypertrophic cardiomyopathy, neoplasia, and hyperthyroidism.

Spontaneous intracranial hemorrhage is caused by a bleed within the brain or in its immediate surroundings without accompanying trauma. A brain hemorrhage can be epidural, subarachnoidal, intraparenchymal, or intraventricular. Epidural or subdural hemorrhages are always associated with cranial trauma. Although not well documented, hypertension appears to play a role in the development of primary intraparenchymal hemorrhage in the dog and cat. Secondary intraparenchymal hemorrhages are associated with reperfusion disturbances after infarcts, congenital arteriovenous malformations, intracranial tumors, and coagulopathies. The damage to the brain is the result of compression or destruction of the surrounding brain tissue. In addition, reduced blood flow to the brain, increased ICP, and obstructive hydrocephalus can be the consequence of an intracranial hemorrhage. In cats with hemorrhagic brain infarcts, significant liver pathology and nephritis have been identified in 100% and 25% of cases, respectively. *Angiostrongylus vasorum* is a lungworm detected in much of Europe and Canada which can cause thrombocytopenia and/or dysfunction of coagulation factors, resembling chronic disseminated intravascular coagulation (DIC).

Clinical Presentation

Cavalier King Charles Spaniels and Greyhounds have been suggested to be breeds predisposed to CVA. Generally, cerebrovascular diseases start suddenly and have a nonprogressive course. The brain dysfunction due to an infarct is usually focal. The neurologic deficits depend on the size of the lesion and are usually asymmetrical. The forebrain symptoms are mainly seizures, possibly in clusters, with contralateral visual and proprioceptive deficits. Behavioral changes are common and involve compulsive pacing, disorientation, and sudden attacks of anxiety or aggression. Ipsilateral circling or head tilt can often be seen.

CMBs occur in up to 10% of dogs undergoing brain MRI, being more common in older (median age 13 years) and smaller (median weight 8.7 kg) dogs. Small (toy and miniature) Poodles and Shih Tzus are most frequently affected with CMBs. Dogs with CMBs appear to present more frequently for vestibular signs and more commonly have proteinuria.

Hypertensive encephalopathy has been reported in dogs and cats. It is associated with either an acute (>30 mmHg from resting level) or a sustained (>180 mmHg) elevation in systolic arterial blood pressure. The clinical signs reflect involvement of the prosencephalon and include seizures, altered mentation, loss of consciousness, and blindness. In addition, signs may also relate to dysfunction of the CNS structures of the caudal fossa and include altered mentation, vestibular or cerebellar ataxia, and abnormal nystagmus. Ocular changes suggestive of hypertension, such as retinal hemorrhage, retinal detachment, and hyphema, may also be observed.

Differential Diagnosis

Head trauma, neoplasia, CNS inflammation.

Diagnosis

Complete blood count (CBC), biochemistry profile, coagulation tests, and urinalysis are helpful in excluding renal disease, sepsis, hyperviscosity syndrome, or coagulopathy. Assessment of systemic blood pressure at several time points is vital. Endocrine evaluations may be necessary if an endocrine association is suspected based on clinical evaluation of the patient. Thoracic and abdominal imaging is important to rule out cavity neoplasia. Electrocardiography and an ultrasonographic investigation of the heart may be necessary to diagnose heart disease, although this is a rare association in veterinary medicine.

The most useful specific diagnostic methods are imaging techniques such as CT or MRI. Abnormal changes in patients with brain infarcts can be visualized with CT within a few hours. These changes depend on the age of the lesion and are normally shown as a slightly hypodense region. An increase in contrast can occur after a few days in the periphery of the lesion and reflects the capillary proliferation. CT is a sensitive method of imaging acute hemorrhages. These appear as hyperdense regions, which become more demarcated over the next 72 hours and attain a constant pattern after roughly 4 weeks.

In MRI, an infarct is hypointense in T1-weighted sequences and hyperintense in T2-weighted sequences (**Figure 14.1a–e**). These changes can already be seen an hour after the start of the infarct, meaning that MRI is more sensitive for the visualization of an infarct than CT. In comparison, the depiction of a hemorrhage with MRI is more complicated and depends on the age of the lesion. As infarct and hemorrhage can occur at the same time, CT is often preferred in the acute stages to differentiate between these two different types of disease.

Management

Treatment of dogs with ischemic events to the brain is largely supportive. The aim of the treatment is to ensure an adequate oxygen supply to the tissue to treat neurological problems and the causative disease.

Oxygen supplementation is often enough in many cases. Hypovolemia should be treated with fluids, although administration of large volumes of crystalloids should be avoided as this causes a worsening of cerebral edema and can increase the ICP. Diazepam (0.5–1.0 mg/kg IV) and barbiturates (phenobarbital 2–5 mg/kg p.o. q.12 h.) can be used to control seizure activity and reduce the brain metabolism.

The prognosis for dogs with focal brain infarcts is variable, but most have a guarded to fair prognosis for recovery of partial or full function. In a single study with a total of 22 dogs with presumed CVAs, 23% died within 30 days; however, those that survived this period had a median survival time of 505 days. The long-term prognosis in cats with CVAs is currently unknown.

ANOMALOUS/DEVELOPMENTAL DISORDERS

CONGENITAL HYDROCEPHALUS

Definition/Overview

Hydrocephalus is the term used to describe a condition of abnormal dilatation of the ventricular system within the brain. It can be further subdivided into obstructive and nonobstructive types. Ventricular dilatation occurs with some frequency in dogs and cats due to a variety of intracranial disease processes. Some breeds are predisposed to congenital hydrocephalus, including Chihuahuas, Pomeranians, Yorkshire Terriers, English Bulldogs, Lhasa Apsos, Toy Poodles, Cairn Terriers, Boston Terriers, Pugs, Pekingese, and Maltese.

Etiology

Hydrocephalus can result from:

- Obstruction (intraventricular or extraventricular) of the ventricular system (e.g., brain tumor)
- Increased size of the ventricles due to loss of brain parenchyma (hydrocephalus *ex vacuo*)
- No obvious cause (congenital)
- The overproduction of CSF associated with a choroid plexus tumor (rare)
- Obstruction of CSF flow in cats as a result of ependymitis and vasculitis associated with CNS infection with feline coronavirus (which causes feline infectious peritonitis [FIP])

Pathophysiology

Diffuse ventricular enlargement suggests congenital ventricular dilatation or obstruction at the level of the lateral apertures or foramen magnum. Focal ventricular enlargement suggests focal obstruction or loss of parenchymal cells. It is not uncommon to have asymmetrical bilateral lateral ventricle enlargement. Animals

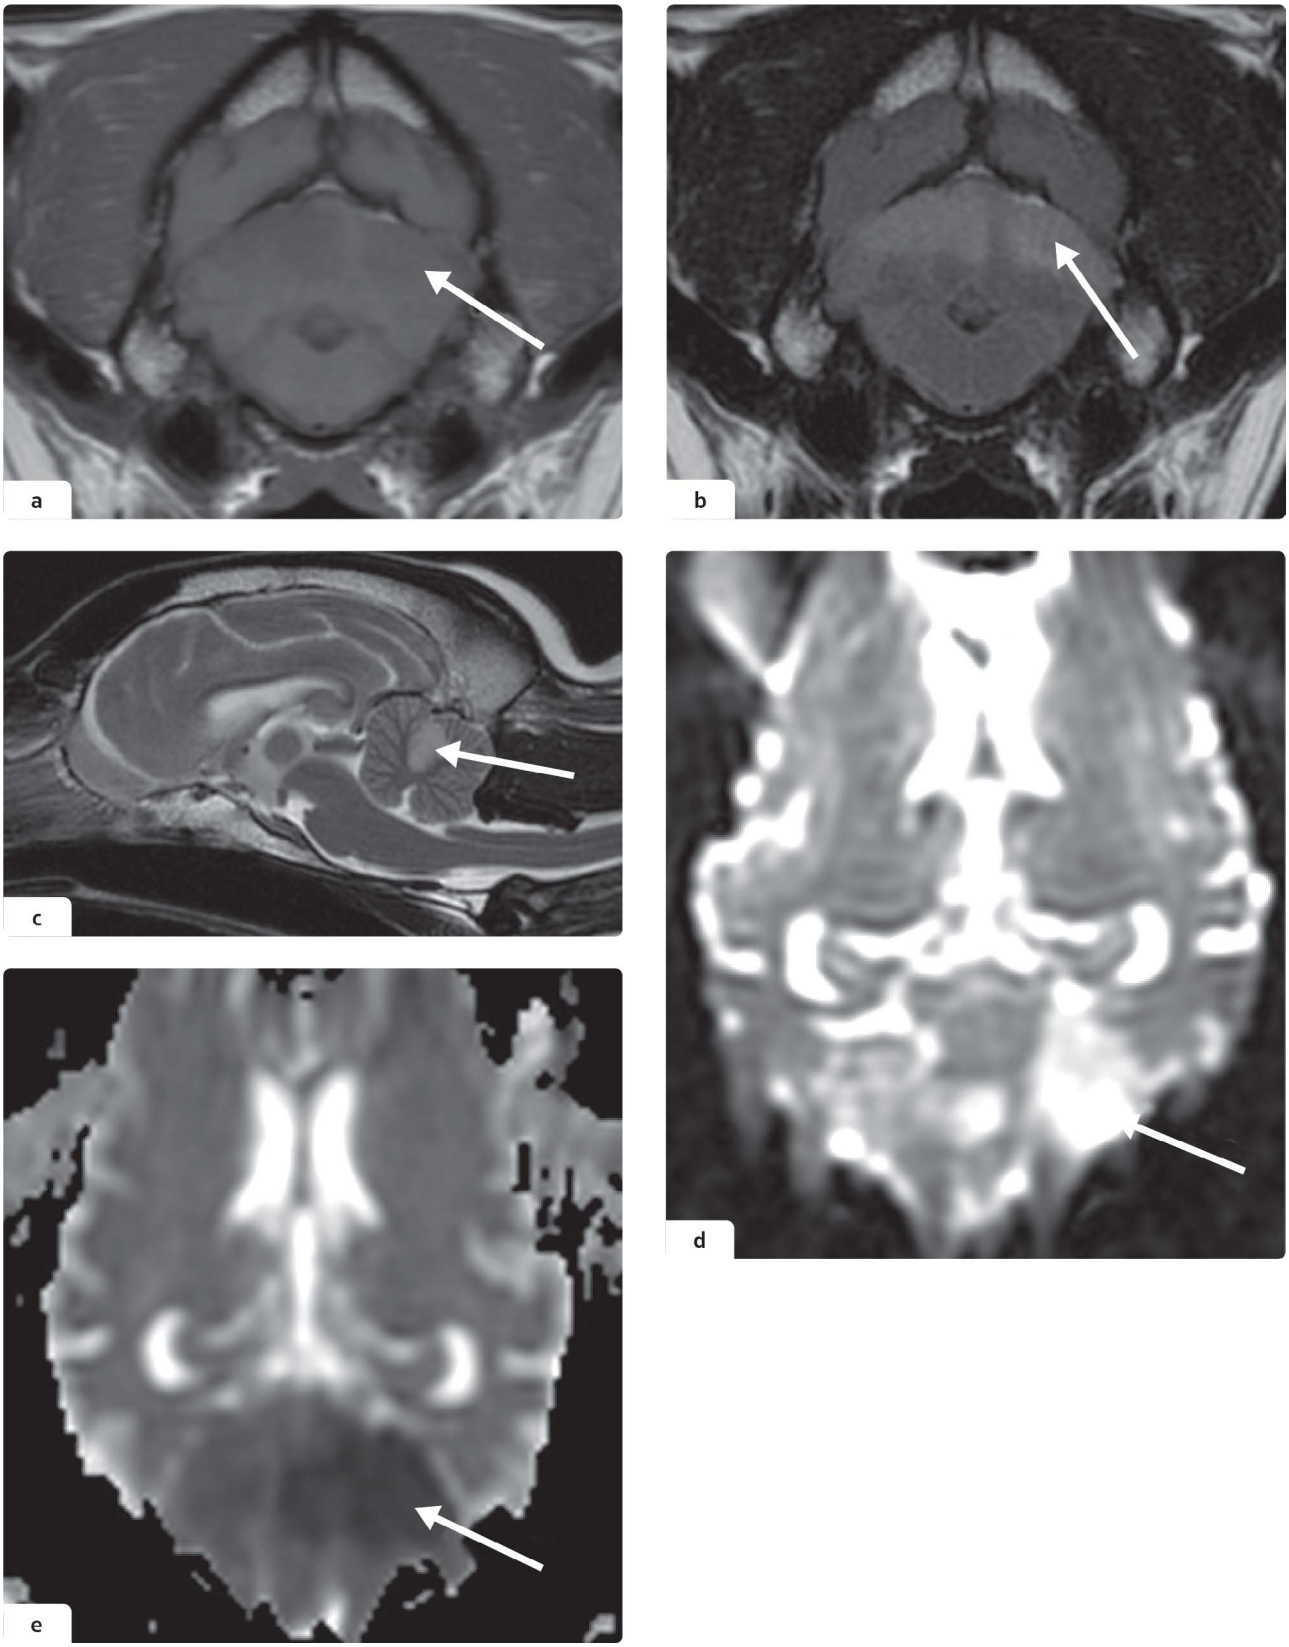

FIGURE 14.1 MR images of a 7-year-old mixed-breed dog with an ischemic stroke (arrows). **(a)** T1-weighted transverse image at the level of the cerebellum demonstrating a large hypointense lesion (arrow). **(b)** T2-weighted transverse image at the same level demonstrating the lesion as hyperintense. **(c)** Midline sagittal T2-weighted image demonstrating the well-demarcated hyperintense lesion within the cerebellum. **(d)** Dorsal plane diffusion-weighted image demonstrating the lesion as hyperintense. **(e)** At the same level, an apparent diffusion coefficient map demonstrates the lesion as a signal void.

with an asymmetrical appearance of the ventricles should be critically evaluated for focal obstruction of, or impingement on, the ventricular system due to mass effect. Elevation of ICP associated with hydrocephalus can occur in cases of acute severe obstruction to CSF flow or chronically enlarged ventricles with little cortical mantle remaining to absorb pressure.

Initial pathologic changes are found in the ependyma at the angles of the lateral ventricles. Loss of integrity of the ependymal surface allows water to leak into the periventricular white matter, causing edema. Further enlargement of the ventricles causes direct damage to the white matter due to compression. Treatment needs to be considered prior to damage affecting the cerebral cortex.

Clinical Presentation

Hydrocephalus can result in clinical signs due to loss of neurons or neuronal function and/or alterations in ICP and all of its consequences. Clinical signs of hydrocephalus can reflect the anatomic level of disease involvement or can represent a diffuse disease process. The severity of the clinical signs is not necessarily dependent on the degree of ventricular dilatation but rather on a host of concurrent abnormalities, including the underlying disease process, associated ICP changes, intraventricular hemorrhage, and the acuity of ventricular obstruction. In animals with severe hydrocephalus, the compressed layer of cortex is prone to tearing either spontaneously or with minor trauma, causing a sudden onset of focal signs of forebrain disease.

In young dogs prior to ossification of the cranial sutures, hydrocephalus may contribute to abnormalities of skull development such as a thinning of the bone structure, a dome-shaped or bossed appearance to the head (Figure 14.2), or a persistent fontanelle.

A ventral and/or lateral strabismus has been noted in humans and animals with hydrocephalus. This is sometimes referred to as the "setting sun sign." Confusion remains as to the underlying reason for this clinical finding. It has been suggested that this appearance is associated with skull deformity and distortion of the orbits. Others suggest that because this abnormality can be improved with shunting of the lateral and third ventricles, the strabismus is associated with pressure on the mesencephalic tegmentum.

As a result of the involvement of the forebrain and brainstem structures in hydrocephalus, alterations in awareness and cognition are common. Many congenitally affected animals may appear less intelligent than normal and be difficult to house train. In addition to alterations in consciousness, aggression, circling, and paresis may also be seen. Central visual dysfunction can occur with compression of the optic radiations and occipital cortex. Seizures have been reported to be a common clinical sign in dogs and cats with internal hydrocephalus due to various causes, affecting between 16% and 33% of cases. However, the prevalence of seizures as a clinical sign in dogs and cats with idiopathic internal hydrocephalus after ruling out additional brain diseases was 1.7% based on a study of 98 dogs and 23 cats.

Occasionally, when hydrocephalus is associated with fourth ventricle enlargement, there may be pronounced vestibular dysfunction.

Differential Diagnosis

Lissencephaly, hepatic (metabolic) encephalopathy.

Diagnosis

The diagnosis of hydrocephalus is aided by information obtained from a variety of imaging and electrophysiologic studies.

Ultrasonography can be used to diagnose hydrocephalus (Figure 14.3). This is most readily accomplished when a fontanelle is present, as it provides an acoustic window (ultrasound waves do not adequately penetrate the skull). In general, correlation between the degree of ventricular enlargement and clinical signs is poor. CT is often useful for defining ventricular size. The ventricular system is usually readily identifiable due to its relatively dark signal in comparison with the parenchyma. CT evaluation also affords the ability to examine the majority of the ventricular system as well as additional intracranial structures. MRI also affords evaluation of the ventricular system (Figure 14.4). It is

FIGURE 14.2 A 2-year-old Cavalier King Charles Spaniel with a domed skull due to its underlying hydrocephalus.

FIGURE 14.3 Ultrasound of the cerebral cavity reveals extensive ventricular volume as a hypoechoic (dark) signal within the more hyperechoic parenchyma.

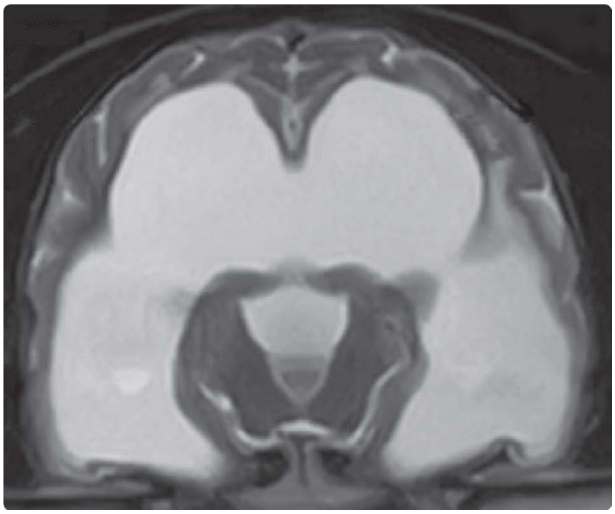

FIGURE 14.4 T2-weighted transverse MR image at the level of the brainstem depicts large lateral ventricles hyperintense to the surrounding parenchyma.

now recognized that many toy breeds that are predisposed to hydrocephalus also have anomalies such as Chiari-like malformations, which can potentially complicate their management and are only detected on MRI. Ventriculomegaly may be misdiagnosed as relevant internal hydrocephalus and interpreted to be the cause of clinical signs in dogs affected by other less conspicuous diseases. A ventricle–brain size ratio of above 0.6 calculated with MRI is used to determine whether there is clinically relevant internal hydrocephalus or asymptomatic ventricular enlargement (ventriculomegaly) in dogs, together with several other structural abnormalities. These other MR imaging findings associated with clinically relevant hydrocephalus include an elevation of the corpus callosum, dorsoventral flattening of the interthalamic adhesion, periventricular edema, dilation of the olfactory recesses, thinning of the cortical sulci and/or the subarachnoid space, and disruption of the internal capsule adjacent to the caudate nucleus.

Management

Although the prognosis for resolution of hydrocephalus is uncertain, there are several medical and surgical options that may be beneficial. The choice of treatment is generally dictated by physical status, age of the animal, and cause of the hydrocephalus. Medical treatment may include general supportive care and drugs to limit CSF production and reduce ICP. Surgical treatment is designed to provide drainage of CSF from the brain to another site for absorption. Glucocorticoids are often used for medical treatment. Prednisone may be given (0.25–0.5 mg/kg p.o. q.12 h., then gradually reduced at weekly intervals to 0.1 mg/kg p.o. q.48 h.). This dose is continued for at least 1 month, after which time it is discontinued, if possible. Some animals can be adequately managed with long-term glucocorticoid administration at low doses. If no clinical benefits are observed within 2 weeks, or if side effects develop, other forms of therapy should be tried. Acetazolamide (a carbonic anhydrase inhibitor) is thought to reduce CSF pressure by decreasing CSF production. Its effectiveness in treating hydrocephalus is inconsistent. Omeprazole has also been administered for the treatment of clinical signs related to hydrocephalus; however, positive outcomes are also inconsistent.

Surgery is generally required for those animals that do not improve within 2 weeks, if deterioration occurs during corticosteroid therapy, or if there is an obstructive cause such as a tumor that cannot be resected. As a successful outcome may be more likely in animals that have minimal clinical signs, surgery may be appropriate in animals with a VB (height of ventricle to height of brain) ratio >60%, although, few owners are willing to undergo the expense and risk of shunt placement if their dog appears healthy. Ventriculoperitoneal shunts are most commonly used in small animals. The shunts have not been proven to be more effective than medical management, but only surgical treatment offers the possibility of long-term control of the clinical signs. Complications of shunt placement occur in approximately 20% of cases and are most likely during the first 6 months after shunt placement.

CHIARI-LIKE MALFORMATION SYNDROME

Definition/Overview

Chiari-like malformation syndrome (CLMS) is the canine analog of Chiari type 1 malformation of people. Although only recently described in dogs, CLMS appears to be a very common neurologic disorder in this species. This disease is almost exclusive to small breed dogs, with the Cavalier King Charles Spaniel (CKCS) being the most overrepresented. Other breeds commonly encountered with CLMS include Brussels Griffon, Miniature/Toy Poodle, Yorkshire Terrier, Maltese, Pug, Pomeranian, and Pekingese. Brachycephalic cats, especially the Persian, can have CLMS.

Etiology

The disorder is a congenital malformation of the suboccipital bone, leading to overcrowding of the caudal fossa and compression of the cervicomedullary junction at the level of the foramen magnum. There is convincing evidence in the CKCS breed that CLMS is a heritable disease, although the exact mode of inheritance has not been determined.

Pathophysiology

Progressive alterations in pressure dynamics between the intracranial and spinal compartments are believed to be responsible for the development of clinical signs of CLMS. Although aberrant pressure dynamics due to obstruction of CSF pathways at the level of the foramen magnum are generally agreed to cause syringomyelia in CLMS, the exact mechanism of this development is

unknown, and there are multiple theories proposed to explain it. Newer theories suggest that the syringomyelia fluid is actually derived from extracellular fluid from the cord itself, either driven into the central canal via a pulse pressure wave from behind the foramen magnum obstruction and/or drawn into the central canal via a centrifugally directed hydrostatic pressure force within the spinal cord. Common to all theories of syrinx development in CLMS is the causative factor of obstruction of normal CSF flow at the foramen magnum. Pain related to CLMS is thought to relate to failure to equilibrate intracranial pressure due to obstruction of CSF pathways. Intracranial pressure is affected by the systolic pulse, venous drainage, the balance between CSF production and absorption, and microgravitational effects; for example, when being lifted rapidly or with head position. Classically in humans, pain in CM is exacerbated by Valsalva, a brief increase in intrathoracic pressure, for example when coughing or with abdominal straining.

The clinical sign of scratching activity is believed to be due to the syrinx interfering with spinothalamic tracts and/or dorsal horn neurons, resulting in abnormal sensations (dysesthesia/paresthesia). Scoliosis (torticollis) is most likely due to asymmetric syrinx damage to sensory proprioceptive neurons innervating cervical musculature. An alternative, less likely, hypothesis is syrinx damage to lower motor neurons (LMNs) innervating cervical musculature.

Clinical Presentation

Most dogs with CLMS are presented for evaluation as young adults between 3 and 6 years of age. However, the age range for this disorder is very broad, ranging from <6 months to more than 12 years of age. Dogs that are presented at <2 years of age often have more severe clinical signs than older dogs. Signs of canine CLMS include vocalization on posture change or on lifting, spinal pain, head and ear rubbing or scratching, aversion to touch, refusal or difficulty jumping or climbing stairs, exercise intolerance/reduced activity, sleep disruption, and behavioral change.

Scratching activity and neck discomfort are due to the presence of an associated syrinx in the cervical spinal cord and often are exacerbated by stress or excitement and physical contact with the neck/shoulder region (e.g., collar).

Diagnosis

Consistent findings on MR imaging indicative of CLMS are attenuation/obliteration of the dorsal subarachnoid space at the cervicomedullary junction and rostral displacement of the caudal cerebellum by the suboccipital bone (Figure 14.5). Other common MRI findings in CLMS include syringomyelia (usually C2 level caudally), herniation of the caudal cerebellum through the foramen magnum, and a "kinked" appearance of the caudal medulla. In the absence of concurrent disease processes, CSF analysis is usually normal; occasionally, a mild mononuclear pleocytosis may be apparent.

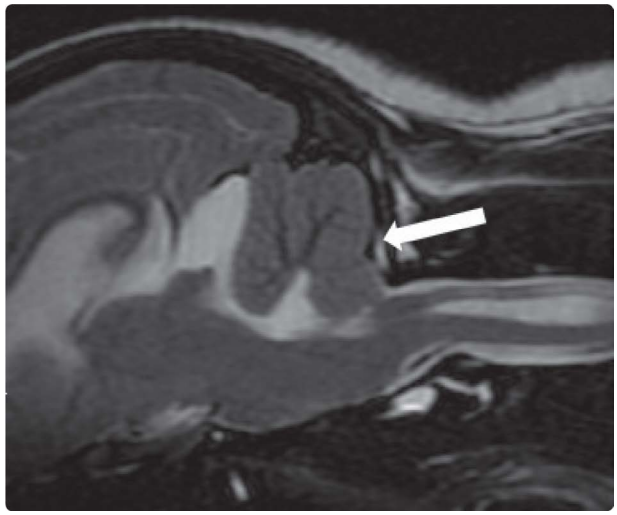

FIGURE 14.5 T2-weighted sagittal MR image of the brain and skull of a Brussels Griffon dog; the arrow points to a hypoplastic occipital bone, which is causing compression and herniation of the cerebellum through the foramen magnum, classic for Chiari-like malformation in dogs.

Management

Treatment of CLMS can be divided into medical and surgical therapy. Medical therapy generally falls into three categories: Analgesic drugs (implies relief of dysesthesia/paresthesia also), drugs that decrease CSF production, and corticosteroid therapy. By far, the most useful drug available for relief of the scratching activity associated with syringomyelia is pregabalin (2–4 mg/kg p.o. q.8–12 h.). There is poor evidence that pain associated with CLMS will improve with prescription of carprofen alone. There is some evidence of improvement with combination of carprofen and gabapentin. Orally administered opioid drugs are sometimes helpful in alleviating neck and head pain in CLMS dogs. A number of drugs aimed at decreasing CSF production have been used in CLMS patients in an effort to diminish the CSF pulse pressure. They include omeprazole (a proton pump inhibitor), acetazolamide (a carbonic anhydrase inhibitor), and furosemide (a loop diuretic). Corticosteroids are often used in medical management of CLMS. An initial anti-inflammatory prednisone dose of 0.5 mg/kg p.o. q.12 h. is often effective in controlling clinical signs. In most cases of CLMS, medical therapy will diminish the severity of clinical signs, but resolution is unlikely. The preferred surgical procedure for treatment of CLMS in dogs is foramen magnum decompression.

Prognosis

Clinical signs will progress in approximately 75% of dogs, and approximately 15% will be euthanized because of CLMS. However, despite progressive signs, many dogs with signs of pain and phantom scratching respond to medical management and are considered by their owners to have an acceptable quality of life.

Although syrinx width increases over time, the rate of increase is not constant. Many syringes appear to rapidly expand within months (or even days) and then can remain remarkably unchanged over years having achieved a hydrodynamic equilibrium.

INTRACRANIAL ARACHNOID CYST (DIVERTICULUM)

Definition and Overview

Intracranial arachnoid cyst (IAC) (also termed intra-arachnoid cyst) is a developmental brain disorder in which CSF is thought to accumulate within a split of the arachnoid membrane. All reported canine cases have been in the caudal fossa. Because IAC is typically associated with the quadrigeminal cistern in dogs, these accumulations of fluid are often called quadrigeminal cysts in this species. The vast majority of reported IAC cases in dogs have been small breeds, with a predominance of brachycephalic dogs.

Etiology

The cause of this developmental anomaly is unknown.

Pathophysiology

It is believed that some aberration of CSF flow from the choroid plexuses during development forces a separation within the forming arachnoid layer, eventually leading to the creation of an IAC. The mechanisms by which an IAC continues to expand with fluid are unknown. Fluid may be secreted by the arachnoid cells lining the cyst cavity.

Clinical Presentation

There is a wide age range at clinical presentation for dogs with IAC (2 months to 10 years), with an approximate average age of 4 years. The most common clinical signs seen with IAC are forebrain (including seizure activity) and/or central vestibular (cerebellovestibular) dysfunction. Dogs may also present with a primary complaint of neck pain. They can be incidental findings.

Differential Diagnosis

Hydrocephalus, congenital portosystemic shunt, hepatic encephalopathy, infectious CNS disease, toxicities.

Diagnosis

Diagnosis is typically made via CT or (preferably) MRI (Figure 14.6). IACs can also be visualized using ultrasound imaging (via foramen magnum, temporal window, and/or persistent bregmatic fontanelle), especially in younger dogs. The characteristic appearance of an IAC is a large, well-demarcated, fluid-filled structure, isointense with the CSF spaces and located between the caudal cerebrum and rostral cerebellum. Because IAC may be an incidental finding, it is important to rule out concurrent inflammatory disease (i.e., by using CSF examination).

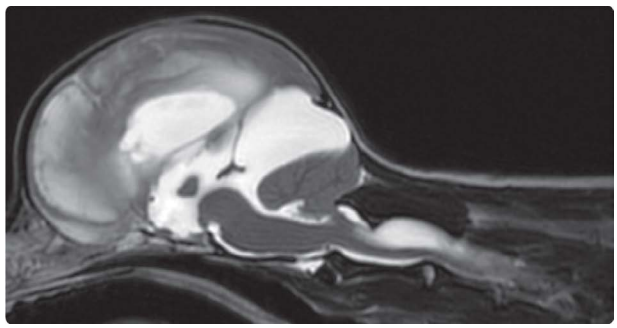

FIGURE 14.6 Sagittal T2-weighted midline brain MR image of a 2-year-old toy breed dog with a large cyst dorsal to and compressing the cerebellum and brainstem.

Management

Medical treatment for IAC is identical to that described for congenital hydrocephalus (see mentioned in the text earlier) (e.g., corticosteroids, diuretics, anticonvulsants if indicated). Dogs with an IAC tend to respond initially to medical therapy, but the response is often temporary. Surgical management of IACs is typically either achieved via cyst fenestration or cystoperitoneal shunt placement.

DEGENERATIVE DISEASES

INHERITED NEURODEGENERATIVE DISEASES

Definition/Overview

Neurodegenerative diseases can affect any part of the nervous system and commonly result in dysfunction of the brain. Examples include multisystem neuronal degeneration of Cocker Spaniels, spongiform degenerations in Labrador Retrievers, Samoyeds, Silky Terriers, Dalmatians (cavitating leukodystrophy), mixed-breed dogs and Egyptian Mau kittens, and multisystemic chromatolytic neuronal degeneration in Cairn Terriers.

Etiology

The likely etiology for many of these diseases is genetic, although it has not been elucidated in most of them.

Pathophysiology

Storage diseases are due to an inborn error of metabolism and the absence of a vital enzyme necessary to break down endogenous body substances. These substances then accumulate within the neuron or other cells associated with the nervous system and eventually cause cellular dysfunction (Figure 14.7). The numerous storage diseases of small animals have been reviewed in detail in other publications.

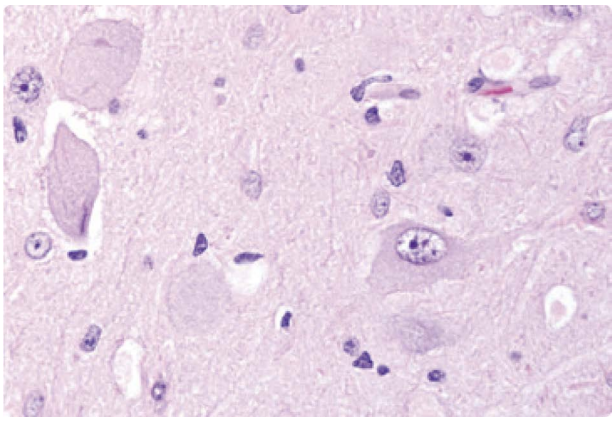

FIGURE 14.7 Intracytoplasmic storage material in the majority of the neurons of the trigeminal ganglion of a dog with GM2 storage disease. The tissue is stained with hematoxylin and eosin.

Clinical Presentation

The majority of degenerative diseases involving the nervous system result in clinical signs early in life, usually with an onset at <1 year of age. Many are breed related and presumed inherited. Clinical signs are slowly progressive with severe alterations in consciousness occurring relatively late in the disease course. Most diseases cause multifocal neurologic signs, and many affect the cerebellum.

Differential Diagnosis

Hydrocephalus, congenital portosystemic shunt, hepatic encephalopathy, infectious CNS disease, toxicities.

Diagnosis

Antemortem diagnosis requires biopsy of the affected tissue. Determination of the lysosomal enzyme activity within the brain and other cells may be helpful but is not universally clinically available.

Screening blood and urine for accumulation products indicative of inborn errors of metabolism may suggest the presence of a lysosomal storage disease and, in some cases, can be diagnostic. Depending on the disease, abnormal accumulations may be evident within cells (particularly macrophages) on buffy coat blood smears and in biopsy samples from the liver, spleen, lymph nodes, bone marrow, or nerves. Screening tests performed on fresh urine samples should include evaluation for the following analytes:

- *Urinary organic acids:* The accumulation of organic acids within the body fluids (particularly urine) is indicative of inborn errors of metabolism such as L-2-hydroxyglutaric aciduria in Staffordshire Bull Terriers.
- *Urinary oligosaccharides:* The accumulation of mannose-containing oligosaccharides in cats is indicative of mannosidosis. The accumulation of high-molecular-weight oligosaccharides in dogs and cats is indicative of GM1 and GM2 gangliosidosis, and of fucosidosis in English Springer Spaniels.
- *Urinary glycosaminoglycans:* The accumulation of dermatan sulfate is indicative of mucopolysaccharidosis (MPS) I, II, VI, and VII. The accumulation of heparin sulfate is indicative of MPS IIIA and IIIB.

Where the signalment and neurologic signs are suggestive of one or more lysosomal storage diseases, and where the underlying enzyme defect is known for those diseases, then an enzyme analysis can be performed against known normal control animals. A reduction in the level of enzyme activity is indicative of that particular lysosomal storage disease. Washed white blood cells or cultured skin fibroblasts are usually the most appropriate cell source and can be assayed either fresh or fresh-frozen.

Characteristic MRI changes may be apparent with some canine and feline genetic diseases, although the changes are rarely specific for a single disease. The lesions usually appear bilaterally symmetrical (e.g., as seen with L-2-hydroxyglutaric aciduria in Staffordshire Bull Terriers) and often result in a decrease in the apparent size of the cerebellum. Fucosidosis in English Springer Spaniels and some of the gangliosidoses can also result in notable MRI abnormalities.

Management

Currently, there is no effective treatment for degenerative diseases of the CNS. Symptomatic therapy, such as anticonvulsants and antianxiety drugs, can help alleviate clinical signs, but these diseases are inevitably progressive. Often, helping the owner decide when to elect euthanasia for a dog affected by a slowly progressive brain disease is the most challenging aspect of these diseases.

COGNITIVE DYSFUNCTION SYNDROME

Definition/Overview

Cognitive dysfunction syndrome (CDS) affects older dogs (>8 years of age) and cats which typically show chronic progressive behavioral abnormalities. The prevalence of CDS in dogs 11–12 years old is estimated to be approximately 28% and is 68% in dogs 15–16 years of age. In addition to advancing age, other reported risk factors for developing CDS include sex (females at highest risk, spayed/neutered at higher risk than intact dogs) and body size (smaller dogs at higher risk than larger dogs); however, some reports have not found associations between sex or body size and the likelihood of developing CDS. Idiopathic epilepsy (IE) has recently emerged as a risk factor for CDS in dogs.

Etiology

There is no specific etiology identified for this condition.

Pathophysiology

The normal aging brain progressively atrophies with increases in oxidative damage, inflammation, glutamate-mediated excitotoxic damage, and other types of neuropathology that ultimately result in neuronal dysfunction and cognitive decline. In dogs, the frontal lobe volume decreases, ventricular size increases, and there is evidence of meningeal calcification, demyelination, increased lipofuscin and apoptotic bodies, neuroaxonal degeneration, and a reduction in the number of neurons. Dogs between 13 and 15 years of age have approximately 30% less neurons in the hilus of the dentate gyrus when compared to 3- to 5-year-old dog, with other studies showing that there is reduced neurogenesis in the mature brain, and noradrenergic neurons in the locus coeruleus of cognitively impaired dogs and cats are significantly reduced.

Similar to the early stages of Alzheimer's disease (AD) in humans, diffuse beta-amyloid (Aβ) plaques may develop in the brain in aging dogs, but canines do not develop full-blown neurofibrillary tangles, which is the second neuropathologic characteristic of AD. Aged dogs do, however, show the accumulation of several phosphorylated tau epitopes that are consistent with AD in humans. Proteomic studies have revealed a significant increase of hyperphosphorylated tau in synaptosomes of CDS dogs compared with non-CDS dogs, suggesting that cognitive decline in dogs maybe related to the tau synaptic impairment and neuroinflammation. Tau phosphorylation is also seen in the aging cat brain and has been more frequently associated with the presence of seizures in this species.

In the dog, Aβ deposition occurs earliest in the prefrontal cortex and later in the temporal cortex, hippocampus, and occipital cortex. Beagles that show learning and memory impairments in a laboratory setting with systematic cognitive tests also show higher levels of Aβ plaques than those old dogs without cognitive impairments. Soluble forms of Aβ called Aβ oligomers have recently been identified in humans with AD and are considered highly toxic, impairing synaptic function, and strongly associated with cognitive dysfunction. Aβ is typically observed in cats older than 10 years, but Aβ deposition seems to be different from that of dogs and humans, as well as being poorly correlated with cognitive decline in this species.

Cerebrovascular amyloid angiopathy (CAA) is the deposition of Aβ in association with the cerebrovasculature. The occipital cortex seems to be particularly vulnerable to CAA in the aged dog brain, which may compromise the blood–brain barrier, disrupt vessel wall viability, and cause microhemorrhages. Aged dogs may also show lacunar infarcts of the caudate nucleus and thalamus, with most dogs showing no causative metabolic, endocrine, or hypertensive disease, and these lesions increase in number with advancing age.

Clinical Presentation

Classic signs of CDS are summarized by the acronym DISHAA, which refers to disorientation; alterations in interactions with owners, other pets, and the environment; sleep–wake cycle disturbances; house soiling; and changes in activity and anxiety levels. Although a decline in activity might be reported, laboratory studies suggest that increased locomotor activity and decreased immobile time are associated with greater cognitive impairment. In addition, signs of fear, phobias, and anxiety, which are commonly reported by owners of senior pets, might also be considered a component of CDS. Finally, memory deficits, which are some of the first recognizable signs of cognitive impairment in humans, have been identified early in the process of brain aging in both dogs and cats. Therefore, learning or memory deficits in aged dogs and cats would also be a sign of CDS.

Differential Diagnosis

Brain tumor, cerebrovascular disease, metabolic encephalopathy, hypertensive encephalopathy.

Diagnosis

Cognitive disorder is diagnosed by excluding other causes of the behavioral abnormalities. However, due to the nonspecific clinical signs associated with this clinical syndrome, it is difficult to make a definitive diagnosis. An extensive evaluation for other causes of intracranial signs in older dogs should be undertaken. Additionally, multitargeted approaches that combine owner-evaluated questionnaires with neuropsychological tests can be most effective in screening cognitively affected dogs from normally aging dogs.

Recent investigations have supported the use of MRI-assessed interthalamic adhesion thickness, interthalamic adhesion thickness/brain height ratio, and interthalamic adhesion thickness/brain height ratio/lateral ventricle to brain height ratio for quantifying brain atrophy in dogs with cognitive dysfunction. However, decreases in interthalamic adhesion size are not specific for cognitive dysfunction and have been reported sporadically in other disorders that can cause brain atrophy.

Leukoaraiosis, bilaterally symmetrical, periventricular T2, and fluid-attenuated inversion recovery (FLAIR) hyperintensities in white matter, has also been identified brains of elderly dogs in conjunction with signs of brain atrophy. The lesions are isointense on pre- and postcontrast T1W imaging and contiguous to the lateral ventricles, with a variable degree of extension into the adjacent subcortical white matter. The lesions are suspected to be caused by Wallerian degeneration, demyelination, and accompanying gliosis but may also represent a local degeneration of the regional blood–brain barrier (BBB).

Management

Recent work suggests that simple preventive measures against CDS may be generally advisable in pet dogs and cats as they near middle age rather than waiting until obvious clinical signs are present. Environmental enrichment can have positive effects on behavioral health and

quality of life in pets and is likely to improve cognitive function. Inconsistency in the management of the senior pet's environment (especially for cats) can cause stress and negatively impact health and behavioral well-being. As sensory, motor, and cognitive function decline, new odor, tactile, and/or sound cues may help the pet better cope with its environment. Canine studies have shown that mental stimulation is an essential component in maintaining quality of life and that continued enrichment in the form of training, play, exercise, and novel toys can help to maintain cognitive function.

Diets rich in antioxidants have been useful in slowing age-related behavioral changes. A nutrient blend consisting of antioxidants, B vitamins, fish oil and l-arginine has been shown to have cognition improving effects in dogs and retard aging-induced decline in learning, memory, and executive function. Similar positive results have also been seen in cats using this nutrient supplementation. Another strategy is a diet containing medium-chain triglycerides (MCTs), which are converted to ketone bodies by the liver. Since a decline in cerebral glucose metabolism and reduced energy metabolism are associated with cognitive decline, MCT-induced ketone bodies provide an alternate energy source that can be used by the brain.

Selegiline, also known as L-deprenyl, is a selective and irreversible inhibitor of monoamine oxidase B. It may enhance dopamine and other catecholamines in the cortex and hippocampus and has been shown to improve signs consistent with CDS in dogs. This drug also may be neuroprotective possibly by reducing free radical production and/or increasing enzymes that scavenge free radicals such as superoxide dismutase and catalase.

Antidepressant and antianxiety medications may be beneficial in the symptomatic management of some animals. Melatonin is best given to dogs 30 minutes before bedtime. Diphenhydramine, phenobarbital, or trazodone can also promote sedation. For the dog or cat that has difficulty settling at night but then sleeps well, situational use of anxiolytics can be helpful. Benzodiazepines have rapid onset, are generally short acting, and have sedative effects at the higher end of the recommended dosage range. Since pain may contribute to unsettled sleep or night waking, gabapentin or pregabalin can be added both as an adjunctive therapy for pain management and for its behavioral calming effects. For senior pets with generalized anxiety, noise phobias, or separation anxiety, buspirone or selective serotonin reuptake inhibitors like fluoxetine and sertraline may be considered because of their low risk of side effects. Recent evidence suggests that the anticonvulsant drug levetiracetam is effective in improving cognitive function and decreasing hyperexcitability.

METABOLIC DISEASES

Numerous metabolic abnormalities may alter cerebrocortical and brainstem function. Liver disease (hepatic encephalopathy), renal disease (renal encephalopathy), pancreatic disease (pancreatic encephalopathy), glucose abnormalities (hyperglycemia or hypoglycemia), electrolyte abnormalities (sodium, potassium, chloride, calcium, magnesium), cardiovascular diseases (resulting in ischemia and hypoxia), and acid–base abnormalities are examples of metabolic diseases. Endocrine abnormalities (thyroid hormones and cortisol) may also affect consciousness.

HEPATIC ENCEPHALOPATHY

Definition/Overview

When liver function is compromised due to organ failure, hepatic microvascular dysplasia, or portosystemic shunting, CNS signs quickly ensue.

Pathophysiology

Hepatic encephalopathy occurs when numerous putative neurotoxins reach the brain without being metabolized as a result of passing through an abnormally functioning liver. Suspected toxins include neurotransmitters (e.g., gamma-aminobutyric acid [GABA] and glutamate), aromatic amino acids, and ammonia.

Clinical Presentation

Animals with hepatic encephalopathy are most often admitted for seizures, ptyalism (especially in cats), and mentation changes, which range from behavioral abnormalities to coma. Signs of hepatic dysfunction, such as weight loss, polydipsia, anorexia, and vomiting, may be present. These animals are often sensitive to the administration of benzodiazepines and barbiturates, as both these types of drugs are metabolized by the liver. Overzealous administration of these drugs may result in stupor and coma due to CNS depression.

Differential Diagnosis

Hydrocephalus, inflammatory CNS diseases, toxicity, other metabolic encephalopathies.

Diagnosis

The diagnosis of hepatic encephalopathy (HE) is supported by abnormal liver function studies such as bile acid testing and resting ammonia levels. Other associated abnormalities may include microcytic red blood cells; low albumin, cholesterol, glucose, and urea concentrations; and elevated liver enzymes if there is parenchymal damage. The preferred imaging studies to confirm a diagnosis of portosystemic shunt include mesenteric portography, abdominal ultrasonography, and per rectal scintigraphy. Transcranial color-coded duplex ultrasonography and MRI have also been used to characterize the brain tissue of animals with hepatic encephalopathy. MRI examinations performed in animals with HE have revealed changes such as cortical atrophy and bilaterally symmetric T1-hyperintensities

within the lentiform nuclei, presumably due to manganese accumulation

Management

Treatment of hepatic encephalopathy aims to:

- Treat the underlying liver disease
- Treat any associated seizures
- Reduce the level of hematogenous neurotoxins (e.g., ammonia) or factors that can increase ammonia production (e.g., metabolic alkalosis, hypokalemia, gastrointestinal [GI] bleeding)

A diet of high-quality, low-quantity protein can help to minimize ammonia production in the gut. Lactulose (0.5–1.0 mL/kg p.o. q.8 h.) is frequently used to assist with this aim, as it reduces the amount of colonic ammonia produced and "traps" ammonia by creating an acidic environment within the gut. Lactulose can also be administered as an enema to comatose patients (1–2 mL/kg q.4–6 h. until loose stool is seen). In addition, neomycin (20 mg/kg p.o. q.8 h.), ampicillin (22 mg/kg p.o. q.8 h.), or metronidazole (7.5 mg/kg p.o. q.8 h.) can be given to reduce the number of urea-splitting bacteria in the colon. Potassium bromide can be used in these cases but requires load-dosing to rapidly attain steady-state levels. The ideal anticonvulsant to use is levetiracetam (p.o., IM, or IV). Seizures following surgical ligation of portosystemic shunts can be especially severe and difficult to effectively treat. Cautious use of a constant rate infusion of diazepam or midazolam may be used for status epilepticus in this situation; however, it can be difficult to dose due to the underlying alterations in liver function. Reduced dosages titrated to effect can be helpful but require vigilant patient monitoring and assessment.

HYPOGLYCEMIA

Definition/Overview

The neurons in the brain require glucose for energy metabolism. A decrease in the availability of glucose to the brain neurons can cause a constellation of clinical abnormalities.

Etiology

Decreases in the blood glucose level alter intracranial neuronal function.

Pathophysiology

Hypoglycemia can occur secondary to insulinoma, liver disease, hypoadrenocorticism, glycogen storage diseases, insulin overdose in diabetic animals, toxicity (e.g., xylitol), infectious diseases, and extrapancreatic neoplasia. Toy breeds and neonates may become hypoglycemic during times of stress. Some dogs that undertake significant exercise (e.g., hunting dogs) and young animals with metabolic stresses (such as caused by a parasitic infestation) are also at risk of developing hypoglycemia.

Clinical Presentation

Hypoglycemia can cause a variety of neurologic signs, including anxiety, a ravenous appetite, lethargy or depression, tremors, seizures, and coma. Exercise or fasting may precipitate signs. The speed with which the glucose concentration changes influences signs to a certain extent. A sudden drop in the blood glucose level causes a sympathetic discharge, hence anxiety and hunger, whereas a chronically low glucose concentration causes lethargy. Central blindness is a frequent finding in animals that present with hypoglycemic seizures. This can be a permanent residual deficit if severe damage has occurred.

Differential Diagnosis

Hydrocephalus, inflammatory CNS diseases, toxicity, other metabolic encephalopathies.

Diagnosis

Serum glucose concentrations <3.3 mmol/L (<60 mg/dL) accompanied by consistent neurologic signs are suggestive of significant hypoglycemia. If the glucose level decreases slowly, some animals can tolerate a lower concentration (<2 mmol/L; <35 mg/dL) without serious clinical problems. Imaging can be used to demonstrate the presence of a pancreatic mass, which may be one of several types of pathology, including insulinoma (beta cell carcinoma).

Management

Treatment depends on the underlying cause. Feeding multiple small meals can help dogs with insulinomas. Direct correction of hypoglycemia is indicated in emergency situations. Syrup can be applied to the gums when IV access is not available (e.g., by owners). It should be noted that if the suspected diagnosis is insulinoma, giving large amounts of glucose, either in the form of a large meal or IV, can sometimes cause a further increase in insulin release into the circulation and exacerbate the problem.

ELECTROLYTE DISTURBANCES

SODIUM ABNORMALITIES

Definition/Overview

Both hypernatremia and hyponatremia may affect the CNS and result in abnormalities of mentation.

Etiology

Any cause of an abnormal sodium concentration will result in neurologic dysfunction. Hypernatremia is most extreme in animals with abnormalities of thirst and drinking, which may also be associated with hypothalamic disease.

HYPERNATREMIA

Pathophysiology

Hypernatremia is synonymous with hyperosmolality and can lead to shrinkage of the brain parenchymal cells, which in turn can cause stretching of the small intracranial blood vessels and hemorrhage. After 2–3 days, the brain attempts to compensate for the altered extracellular sodium level by producing osmotically active intracellular substances (idiogenic osmoles). Thus, overly rapid correction of chronic hypernatremia can cause sudden swelling of the brain parenchyma and ultimately be fatal.

Clinical Presentation

The clinical signs of hypernatremia include lethargy and irritability progressing to ataxia, tremors, myoclonus, seizures, blindness, coma, and death.

Differential Diagnosis

Hydrocephalus, inflammatory CNS diseases, toxicity, other metabolic encephalopathies.

Diagnosis

Demonstration of an abnormal electrolyte level in the presence of an encephalopathy, which improves with appropriate correction, confirms the diagnosis.

Management

Guidelines for the treatment of sodium abnormalities have been suggested but are crude. Appropriate therapy is based on replacement of the water deficit (calculated using the following equation) in conjunction with addressing the underlying cause:

$$\text{Water deficit (l)} = 0.6 \times \text{bodyweight(kg)} \times (\text{patient's sodium concentration/normal sodium concentration} - 1)$$

However, calculations such as this are only used as a guide to begin therapy. With chronic serum sodium abnormalities, cautious fluid therapy with frequent monitoring for neurologic deterioration is imperative. In an animal with established hypernatremia, the water deficit should be corrected either orally or by fluid therapy administered conservatively over 2–3 days. An isotonic maintenance fluid (such as lactated Ringer's solution) should be used, initially at 1.5 times the normal maintenance rate. Serum sodium concentrations should be monitored every 4–6 hours and the rate of fluid therapy administration adjusted up or down accordingly. If the serum sodium concentration is lowered too rapidly, cerebral edema may result, with a clinical deterioration in consciousness. With slow-onset hypernatremia (occurs over 48 hours or more), the maximal daily decrease with treatment should not exceed 0.5 mEq/h or 8–12 mEq/L per 24 hours.

HYPONATREMIA

Pathophysiology

Hyponatremia is synonymous with hypo-osmolality and can result in swelling of the brain parenchymal cells with subsequent edema. After 2–3 days, the brain tries to compensate for this by actively extruding osmotically active intracellular components. As with hypernatremia, rapid correction of hyponatremia can be fatal.

Clinical Presentation

The clinical signs of hyponatremia include lethargy, nausea, and vomiting progressing to seizures, coma, and death.

Differential Diagnosis

Hydrocephalus, inflammatory CNS diseases, toxicity, other metabolic encephalopathies.

Diagnosis

Demonstration of an abnormal electrolyte level in the presence of an encephalopathy, which improves with appropriate correction, confirms the diagnosis. T2-weighted and FLAIR MR images of the thalamic area of the brain reveal characteristic bilateral hyperintense abnormalities. These abnormalities are often focal and oval.

Management

Appropriate therapy is based on correction of the sodium deficit (calculated using the following equation) in conjunction with addressing the underlying cause:

$$\text{Sodium deficit (mEq/l)} = 0.6 \times \text{bodyweight(kg)} \times (\text{normal sodium concentration} - \text{patient's sodium concentration})$$

As for hypernatremia, cautious fluid therapy and frequent monitoring are paramount. Too rapid correction of established hyponatremia can result in thalamic lesions. When hyponatremia has occurred over a period of >24 hours, treatment is adjusted so that the maximal increase does not exceed 0.5 mEq/L/h or 8–12 mEq/L per 24 hours.

NEOPLASTIC DISEASES

Definition/Overview

Brain tumors most commonly affect older dogs and cats. Brain tumors may arise primarily from the brain or surrounding tissues, extend into the brain from adjacent structures, or metastasize to the brain from another location in the body. Tumors result in clinical signs either through primary mechanical damage or as a

consequence of secondary pathophysiologic events such as edema and hemorrhage.

The median age of dogs diagnosed with a brain tumor is reported to be 9 years (range: 4–13 years). The most commonly affected breeds include Golden Retrievers, Labrador Retrievers, Boxers, Collies, Bulldogs, and Boston Terriers. The median age at the time of diagnosis of brain tumors in cats is reported to be 11.3 years (± 3.8 years).

Pathophysiology

Tumors of the intracranial space may be primary (arising from tissues in the intracranial space) or secondary (arising from tissues adjacent to the intracranial space or from metastasis). Primary intracranial tumors include:

- *Meningiomas:* The most common brain tumors in dogs and cats. These tumors arise from the arachnoid layer of the meninges, originating at the periphery of the brain parenchyma and expanding inwards.
- *Gliomas:* Arise from the supporting cells of the brain parenchyma. These include astrocytes and oligodendrocytes forming astrocytomas, oligodendrogliomas, and the extremely malignant glioblastoma multiforme. Brachycephalic breeds such as Boxers and Boston Terriers may be more often affected with these tumors.
- *Ependymomas:* Arise from the ependymal lining of the ventricular system.
- *Choroid plexus tumors (CPT):* Arise from areas where the choroid plexus is concentrated (the lateral, third, and fourth ventricles).
- *Pituitary gland tumors:* Macroadenomas may enlarge dorsally from the sella and compress the diencephalon. Neurologic impairment can be surprisingly minimal. The relative size of the tumor cannot be predicted from the endocrine test result.

Secondary intracranial lesions arise as a result of metastasis or direct extension from extraneural sites. Numerous tumors in older animals metastasize to the brain, including hemangiosarcomas, lymphomas, and mammary gland and other carcinomas.

Clinical Presentation

Most canine brain tumors affect the forebrain. The most common presenting complaint in these cases is seizures. Seizures are sometimes the only sign of a structural intracranial abnormality, with the remainder of the neurologic examination findings being normal. This is particularly true with more rostral and olfactory lobe lesions. Otherwise, the clinical signs associated with tumors affecting the brain depend on the location within the brain, brainstem, or cerebellum. Disorientation, circling, ataxia, depression, and CN signs can variably be seen.

Most feline intracranial neoplasia affects the forebrain. The most common neurologic signs include altered consciousness (depression, stupor, or coma), circling, seizures, ataxia, and behavioral changes.

Differential Diagnosis

CNS inflammatory diseases such as granulomatous meningoencephalomyelitis (GME) and those due to infections.

Diagnosis

Advanced imaging modalities, such as CT and MRI, are most commonly used to investigate cases of suspected neoplasia (Figure 14.8a–h).

Accurate presumptive diagnoses of the general tumor type (meningioma, glioma, or CPT) can be made extrapolated from MRI features in 70% of dogs with primary brain tumors.

CT-guided, freehand needle biopsy of brain tumors has been reported in dogs with intracranial lesions to obtain a histologic diagnosis prior to treatment. Although CT-guided, freehand needle biopsy is a relatively safe procedure, the diagnostic yield can be variable.

An MRI-compatible stereotactic brain biopsy system has recently been validated for use in dogs. This modified frameless stereotactic system has been shown to have acceptable precision for obtaining biopsy samples and has been used successfully in a clinical setting.

CSF analysis is often not helpful for the definitive diagnosis of a brain tumor and, in some instances, can even be misleading. Typically, CSF in dogs with a brain tumor contains an increased level of protein without a concurrent pleocytosis (albuminocytologic dissociation). However, in a significant proportion of these cases, cellular changes consistent with inflammation are present and, interpreted alone, may falsely suggest a primary inflammatory disease. Occasionally, CSF in a dog with a brain tumor is normal. The presence of neoplastic cells in the CSF is specific; however, it is a very rare finding.

Management

Treatment for brain tumors in dogs depends on tumor type, location, natural history of the tumor, associated morbidity/mortality with the treatment modality, and cost. While studies of brain tumor treatment in dogs and cats exist in the veterinary literature, many have incomplete diagnoses, nonstandardized treatment protocols, lack of a control population, and different tumor types being grouped together to increase overall case numbers. These problems make it difficult to make definitive statements regarding treatment efficacy.

Glucocorticoid therapy provides minimal supportive care for patients with brain tumors, although its use can often be necessary and helpful. The aims of glucocorticoid treatment are to control the secondary conditions of acquired hydrocephalus and peritumoral edema and to reduce ICP. Clinical signs in many patients improve following the initiation of steroid treatment, which may give some indication of tumor invasion and what could be achieved with surgery.

Surgery is ideal for superficially located, encapsulated, relatively small benign tumors, of which

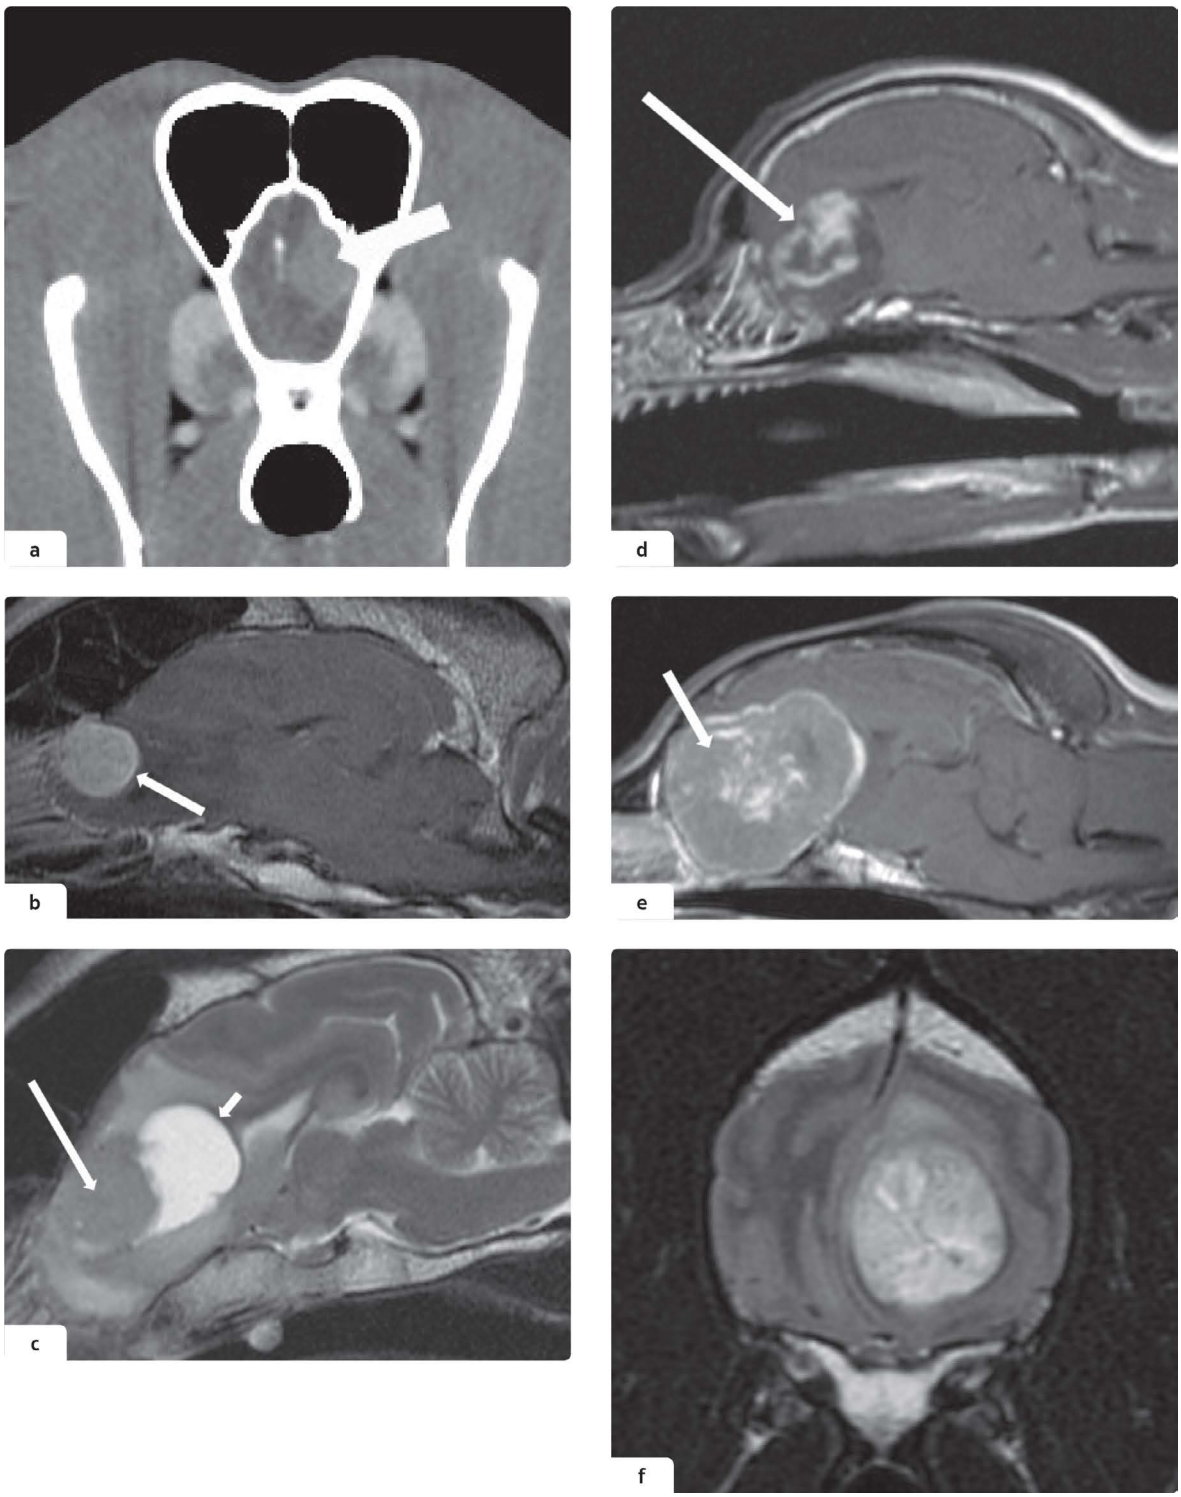

FIGURE 14.8 **(a)** Postcontrast transverse CT brain scan at the level of the olfactory bulbs and frontal sinuses. A well-defined, contrast-enhanced lesion can be identified (arrow), which was confirmed to be meningioma on histopathology following resection. **(b)** T1-weighted postcontrast midline sagittal brain MR image depicting a homogeneously enhancing lesion in the olfactory bulb (arrow), characteristic for a meningioma. **(c)** T2-weighted midline sagittal brain MR image depicting an isointense to hyperintense lesion in the olfactory bulb (long arrow), which is accompanied by a cystic component (short arrow), which is well described for meningiomas. **(d)** T1-weighted postcontrast midline sagittal brain image depicting a heterogeneously enhancing lesion in the frontal lobe characteristic for a glioma, which in this case was an astrocytoma. **(e)** T1-weighted postcontrast midline sagittal brain MR image depicting a heterogeneously enhancing lesion in the olfactory bulb and the frontal lobe. The lesion was a nasal adenocarcinoma extending caudally from the nasal cavity. **(f)** T2-weighted transverse brain MR image clearly showing a large well-demarcated, heterogeneously hyperintense lesion causing mass effect (midline shift of the brain). The lesion was confirmed as an oligodendroglioma. (*Continued*)

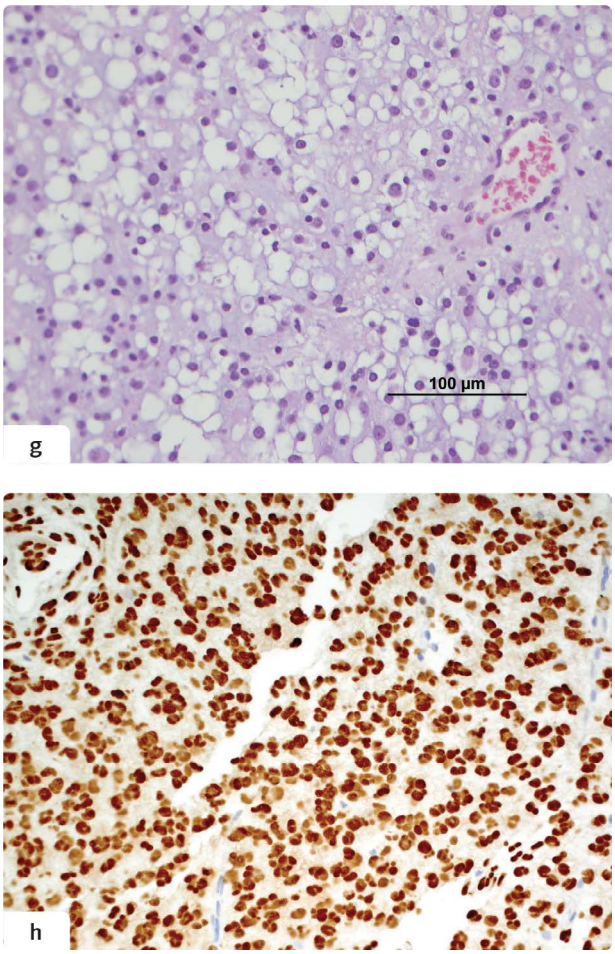

FIGURE 14.8 (*Continued*) (g) The oligodendroglioma shown in (f) is stained with hematoxylin and eosin. **(h)** The oligodendroglioma shown in (f) stains positively immunohistochemically with Olig2.

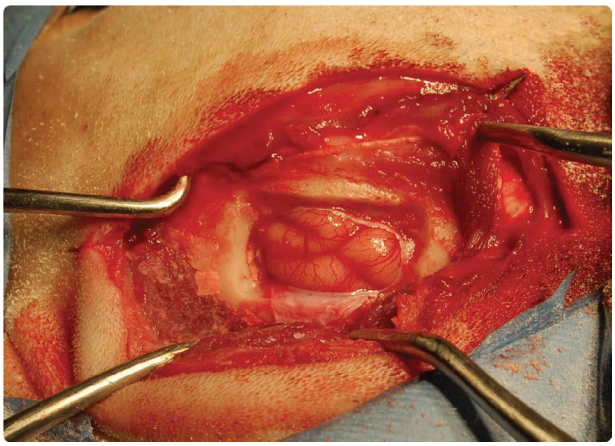

FIGURE 14.9 A lateral rostrotentorial craniectomy is used to approach the parietal lobe of the brain for the purposes of tumor resection.

meningiomas are the most common example (Figure 14.9). Early postoperative neurological deterioration has been reported in up to 45% of dogs, with 11% of dogs experiencing seizures, and non-neurological postoperative complications such as aspiration pneumonia reported in up to 18%. Median survival times reported in dogs following surgery for all types of brain tumor vary but tend to cluster around 140–150 days. For meningiomas, median survival times may be slightly longer (240 days), and there is evidence that improving surgical excision using ultrasonic aspiration or endoscopy does improve survival times. Surgical excision is more readily accomplished in cats, as meningiomas in this species tend to be well encapsulated and easily delineated from normal brain tissue. Studies have determined the median survival time in cats following meningioma resection to be between 22 and 27 months.

Conventional radiation therapy has been shown to be effective for brain tumors in dogs. The main goal of treatment is to administer the highest possible dose to the tumor while minimizing the dose to the surrounding normal tissue. Median survival time in dogs is around 150–350 days. Single fraction stereotactic radiation therapy (SRT) has resulted in a median survival time of over 17 months for dogs with intracranial meningiomas and so should be considered a viable alternative to the fractionated regimens. Stereotactic RT is also effective in prolonging survival in dogs with intracranial gliomas, with similar results to conventional hyperfractionated protocols. Additionally, it appears that patients can be safely treated with multiple rounds of SRT, resulting in improved survival times. Radiation therapy (RT) is effective to reduce pituitary size and the mass effect associated with pituitary tumors but does not appear to affect blood hormone concentrations, necessitating additional medical treatment against hypercortisolism. Radiation generally shrinks the tumor by 25%–50% and may not completely control the neurologic signs associated with a large tumor. Sixty percent of cats with pituitary tumors treated with RT improved, with 50%–60% no longer needing insulin or having improved insulin response and partial or complete remission of neurologic signs. Survival outcomes with stereotactic radiotherapy for dogs with pituitary tumors (MST = 10.3 months) are reportedly shorter than those reported with definitive radiation (MST = 32 months), especially for dogs with hyperadrenocorticism.

Chemotherapy is used as a primary therapy or as an adjunct to surgery in selected instances in animals with brain tumors. Carmustine and lomustine are alkylating agents that have some effectiveness against gliomas. Dogs with intraparenchymal mass lesions (presumptively diagnosed gliomas), dogs treated with lomustine (n = 17, MST 4.5 months) survived significantly longer than dogs receiving palliative care only (n = 23; MST 1 month). Hydroxyurea (30–45 mg/kg p.o. three times a week, with monitoring of the blood cell count for evidence of myelosuppression) is gaining popularity for treatment of meningiomas. There is little to no data available on the effectiveness of chemotherapy for canine or feline brain tumors.

INFLAMMATORY INFECTIOUS CNS DISEASES

Definition/Overview

Encephalitis and infectious diseases often exist concurrently in dogs and cats.

Etiology

Numerous infectious agents have been implicated:

- *Viral:* Distemper, parvovirus, parainfluenza, herpesvirus, feline coronavirus (which causes FIP), West Nile virus, pseudorabies, and rabies
- *Bacterial*
- *Rickettsial:* Rocky Mountain spotted fever and *Ehrlichia*
- *Fungal:* Blastomycosis, histoplasmosis, cryptococcosis, coccidioidomycosis, and aspergillosis
- *Protozoal:* Toxoplasmosis and neosporosis
- *Unclassified organisms:* Protothecosis

Pathophysiology

The specific pathophysiology of the aforementioned infectious diseases in the CNS is discussed in further sections. Inflammation of the structures of the brain (encephalitis) can coexist with inflammation of the meninges (meningitis) and, occasionally, with inflammation of the spinal cord (myelitis).

Clinical Presentation

As a general rule, inflammatory diseases tend to be acute in onset and progressive, with a multifocal or diffuse, often asymmetrical, distribution within the CNS. Neurologic manifestations are quite variable and reflect the location of the inflammatory foci within the nervous system. Central vestibular signs are commonly encountered and can be seen alone or in combination with other neurologic signs. Neck pain can also be present as a manifestation of meningeal inflammation. Animals with CNS infections frequently do not have evidence of systemic involvement. Therefore, the absence of fever, anorexia, and depression and the presence of a normal hemogram cannot be used to exclude the possibility of an infectious etiology in an animal with neurologic signs.

Differential Diagnosis

Sterile causes of CNS inflammatory disease, brain tumor, metabolic and toxic encephalopathies.

Diagnosis

A thorough ophthalmologic examination should be performed in every neurologic case to look for evidence of fundic changes or uveitis compatible with inflammatory disease. Definitive diagnosis of CNS inflammatory disease is typically based on finding an increased total nucleated cell count or an abnormal cell type distribution, with a concomitant increase in protein concentrations, on CSF analysis. In rare instances, normal CSF can be obtained from an animal with confirmed CNS inflammatory disease. This can occur if the inflammation does not involve the meninges or the ependymal lining of the ventricular system, or if the animal has been treated with corticosteroids prior to CSF collection. Elevations in protein concentration can result from breakdown of the blood–brain barrier or intrathecal antibody production. It is likely that both of these mechanisms contribute toward the elevated protein levels recognized with most CNS inflammatory disease. Cytologic evaluation of the fluid provides additional information as to possible causes (Figure 14.10).
