

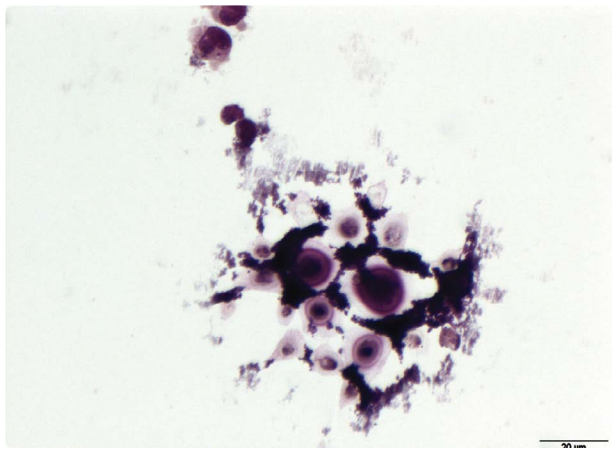

FIGURE 14.10 *Cryptococcus* organisms can be seen in this cytologic analysis from CSF of a dog with seizure episodes. (*Courtesy of R. Di Terlizzi.*)

Additional testing, based on the cytologic evaluation, is performed in an attempt to identify the infectious cause of the inflammation. These tests can include:

- CSF culture for bacterial or fungal organisms
- Serum and CSF antibody or antigen titers
- CSF polymerase chain reaction (PCR) analysis

However, despite extensive testing, an underlying cause for the inflammation is not determined in most cases.

Management

Treatment is aimed at the primary disease process. Treatment with clindamycin (10–15 mg/kg p.o. q.12 h.) and/or trimethoprim/sulfonamide (15 mg/kg p.o. q.12 h.) for potential protozoal infections can be initiated once a diagnosis of encephalomyelitis has been made based on CSF results, while additional test results are pending. If no infectious cause is discovered on additional testing, or the animal does not respond to initial antimicrobial therapy, treatment with corticosteroids should

be initiated. Anti-inflammatory doses are often effective at alleviating the clinical signs, but higher immunosuppressive doses may be required in some instances to appropriately manage the immune-mediated disease. Prognosis is variable and depends on both the cause of the inflammation and the extent and the severity of associated neurologic deficits. Some infections, especially those caused by protozoal and fungal agents, are difficult to eradicate and relapses are common. In addition, residual neurologic deficits can persist despite successful treatment of an infection due to irreversible damage caused by the inciting agent.

RABIES

Definition/Overview

Rabies is caused by an enveloped RNA neurotropic virus of the genus *Lyssavirus* in the family Rhabdoviridae. All warm-blooded animals are vulnerable to infection with rabies, but species susceptibility varies tremendously. Foxes, coyotes, jackals, and wolves are among the most susceptible animals, with skunks, raccoons, bats, and cattle also having a high susceptibility.

Pathophysiology

Infection most often occurs as a result of being bitten by an infected animal with rabies virus in its saliva. The incubation period is influenced by multiple factors, including patient age, bite site, the variant, and the amount of virus inoculated. After IM inoculation, the virus enters the neuromuscular junctions following a variable period (from days to 6 months) of replication in the local tissues. The virus rapidly spreads up the peripheral nerves and then the spinal cord to the forebrain, causing damage to the nervous tissue en route and resulting in progressive nervous system signs.

Clinical Presentation

There are several overlapping phases during the progression of the disease. In dogs, there is usually a prodromal phase (lasts for 2–3 days) during which clinical signs such as apprehension, nervousness, anxiety, and variable fever may be seen. Overall, a significant change in the normal behavior of the animal is noted by the owner. Affected animals can be seen to constantly lick the site of viral inoculation. Cats may also exhibit this prodromal phase, but it more commonly consists of erratic behavior for 1–2 days.

The furious or psychotic form of rabies usually lasts up to a week in dogs and is manifest by cerebral dysfunction with exaggerated responses to sound and touch. Affected animals can bite at imaginary objects or their cage and become extremely irritable. At this stage, they frequently exhibit generalized tonic–clonic seizure activity, during which they can die. Occasionally, dogs can exhibit a predeath paralyzed state. Cats typically develop the furious stage, resulting in unprovoked attacks and appearing "disconnected" from the environment.

The paralytic or dumb form of rabies is often seen within 2–4 days following the onset of clinical signs and is manifest by flaccid paralysis. In both dogs and cats, a bite to the neck or head may more commonly result in CN dysfunction. Dysphonia, dysphagia, excessive salivation, and a dropped jaw may be seen, and these clinical signs are also classed as part of the paralytic form. Coma and death usually follow these signs within 2–4 days.

Differential Diagnosis

Other infectious and sterile causes of CNS inflammatory disease, brain tumor, metabolic and toxic encephalopathies.

Diagnosis

Rabies should always be suspected in any animal presenting with neurologic dysfunction and living in an area known to have a virus reservoir in the local wildlife. Particular concern should be raised for animals that are known to be unvaccinated and that have exhibited clinical signs for <5 days.

There are no antemortem tests sensitive enough to be consistently reliable for confirming a diagnosis of rabies, and there are no hematologic or serum biochemical changes characteristic of the disease. CSF analysis may reveal elevated protein levels and white blood cell count with a lymphocytic predominance. Serologic tests are rarely performed because of the low percentage of animals that have time to develop antibodies. However, a serologic assay can be used to assess vaccine efficacy.

A direct fluorescent antibody assay test of the nervous tissue can be performed on thin touch impression smears and is rapid and sensitive for a definitive diagnosis. The most commonly affected areas on examination are the brainstem, hippocampus, cerebrum, and cerebellum (Figure 14.11). Reverse transcription PCR (RT-PCR) is a relatively new method for rabies diagnosis and is very useful when the sample size is small (e.g., CSF sample).

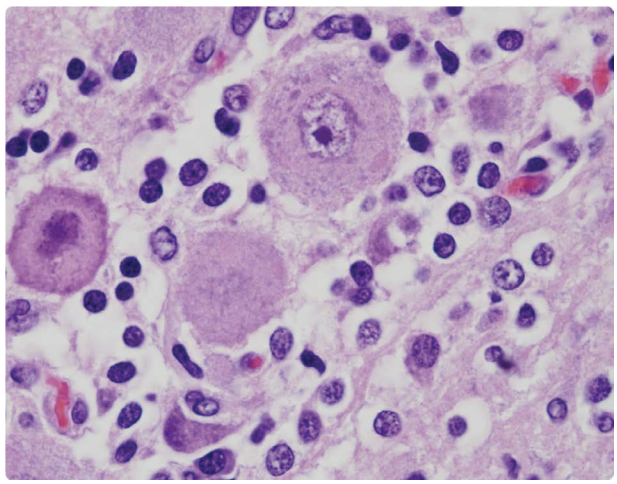

FIGURE 14.11 Intracytoplasmic (pink) inclusion bodies can be seen within the neuronal cells of a dog with rabies virus infection.

Management

There is no specific treatment for this fatal disease. A dog or cat suspected of contracting the disease should be quarantined as recommended by the local health authorities or euthanized and the brain submitted for examination. Exposure of all healthcare providers to the animal and/or its tissues should be restricted.

BACTERIAL MENINGOENCEPHALITIS

Definition/Overview

Bacterial infection is a relatively rare cause of encephalitis in dogs and cats when compared with other species.

Etiology

Bacterial infection of the CNS.

Pathophysiology

Bacterial infection of the brain is usually a consequence of direct extension of infection from the middle ear or sinuses or a penetrating injury to the skull (surgical or traumatic). Hematogenous spread can occur less commonly. Both aerobic and anaerobic infections have been reported. It is possible for the infection to be limited to the extradural or subarachnoid space, especially following bite wounds, in which case the infection can remain localized (intracranial empyema or abscess), and signs might not be so rapidly progressive. Clinical signs are largely the result of the inflammatory reaction that bacteria incite.

Clinical Presentation

Animals can exhibit a variety of signs, including vestibular dysfunction, seizures, cerebellar signs, paresis, cervical hyperesthesia, and coma. Fever is present in approximately 50% of cases at presentation. The signs are usually rapidly progressive and frequently fatal.

Differential Diagnosis

Other infectious and sterile causes of CNS inflammatory disease, brain tumor, metabolic and toxic encephalopathies.

Diagnosis

Routine blood work usually reflects an inflammatory process but can be normal. A urine sample should be cultured if bacterial encephalitis is suspected, and blood cultures are indicated in animals in which there is no obvious source of infection. Imaging of the brain (CT or MRI) is helpful to identify defects in the skull and otitis media/interna (OMI) and can be suggestive of an inflammatory process (Figure 14.12). CSF analysis is the most useful test. Typically, there is a marked elevation in the protein level and total nucleated cell count, and the majority of cells are degenerate neutrophils. Bacteria may be visible in the spinal fluid. However, CSF analysis can be unremarkable or show more nonspecific inflammatory changes. CSF should be cultured if it contains degenerate neutrophils, although it is common for the cultures to be negative.

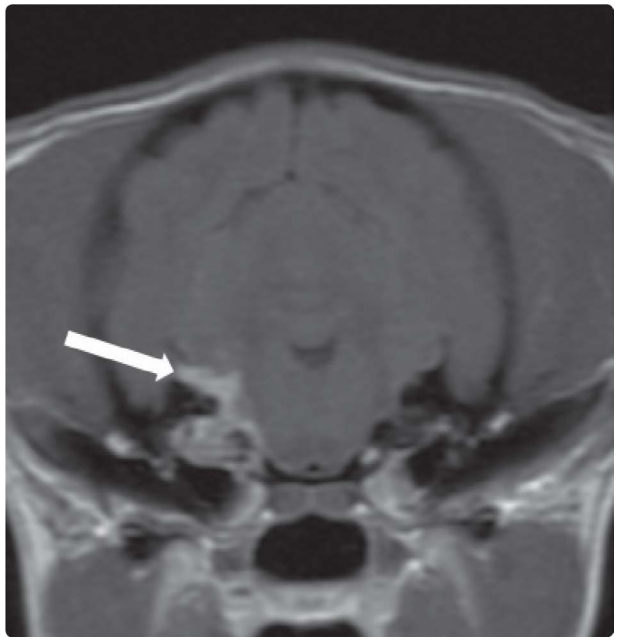

FIGURE 14.12 T1-weighted postcontrast transverse brain MR image at the level of the bullae reveals extension of otitis media/interna into the central nervous system (arrow) in an 8-year-old Yorkshire Terrier.

Management

Treatment with an antibacterial drug that penetrates the CNS should be initiated while waiting for culture results. The most common bacterial isolates are *Escherichia coli*, *Streptococcus*, and *Klebsiella*, but anaerobic infections can also occur. Appropriate drugs include fluoroquinolones and third-generation cephalosporins. Many patients are in a critical condition and need IV fluids and anti-inflammatory drugs. Mechanical ventilation might be necessary in comatose patients. Prognosis is poor in animals with rapidly progressing severe signs. Early appropriate treatment is vital to obtain a good outcome.

CANINE DISTEMPER VIRUS INFECTION

Definition/Overview

Canine distemper is a multisystemic viral disease that causes multifocal CNS dysfunction. It most commonly affects unvaccinated dogs.

Etiology

Canine distemper virus (CDV) is a paramyxovirus that commonly infects the CNS of dogs.

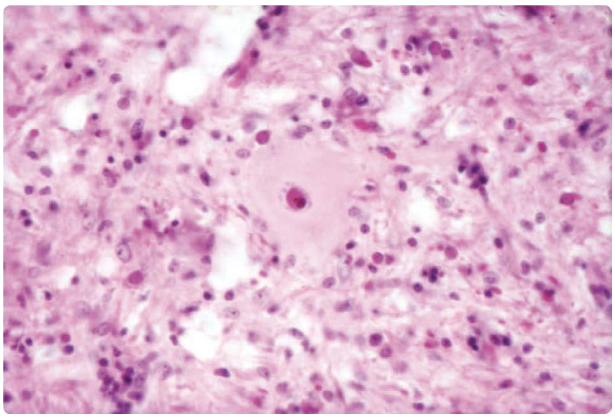

FIGURE 14.13 Intranuclear inclusion material in a neuron of a dog with distemper virus infection. The tissue is stained with hematoxylin and eosin.

Pathophysiology

The presence and severity of the neurologic signs depend on factors such as the age and immunocompetence of the host and the neurovirulence of the virus strain. Many dogs probably develop transient CNS infections without concurrent clinical signs. In the CNS, CDV initially replicates in the neurons and glial cells (Figure 14.13) and can cause both gray and white matter lesions, with one usually predominating. These early degenerative lesions are not characteristically inflammatory. A chronic course of CNS infection results from a late or insufficient immune response to CDV, with characteristic inflammatory demyelinating lesions. Polioencephalomyelopathy has been reported most frequently in immature dogs, while leukoencephalomyelopathy or a combination of both is more common in mature animals.

Clinical Presentation

Presentation can include seizures, visual deficits, vestibular dysfunction, cerebellar signs, paresis, and myoclonus. The presence of myoclonus is most commonly associated with CDV infection but is not pathognomonic, as it has been described with other inflammatory CNS disorders. Neurologic disease associated with CDV infection tends to have a progressive course. Disease can develop in well-vaccinated animals, so previous vaccination history does not exclude the possibility of CDV-associated disease. Systemic signs, such as respiratory and GI involvement, are reported to precede the neurologic signs by 2–3 weeks. However, many dogs have no previous history of disease prior to the onset of neurologic signs. Extraneural signs include conjunctivitis, rhinitis, fever, respiratory signs, GI signs, tonsillitis, cachexia, enamel hypoplasia, and hyperkeratosis of the footpads or nose. These signs are frequently mild. Fundic examination is recommended in all suspected cases, as many dogs have evidence of chorioretinitis.

Differential Diagnosis

Other infectious and sterile causes of CNS inflammatory disease, brain tumor, metabolic and toxic encephalopathies.

Diagnosis

An indirect fluorescent antibody test for viral antigen in conjunctival smears can be positive in many dogs with CNS distemper, regardless of whether the disease is acute or chronic. Viral antigen can also be demonstrated in tracheal washings and urine sediment. Results of CSF analysis are variable. During the acute stage of the disease, an inflammatory response is lacking, and thus, the cell count and protein levels can be normal. In the chronic stage of the disease, lymphocytic pleocytosis is more frequently identified. An elevated CSF titer of antibody against CDV relative to the serum titer is supportive of a diagnosis. Biopsy samples of haired skin from the dorsal neck can be used antemortem for immunohistochemical testing for acute CDV infection. PCR analysis of urine and CSF samples for CDV has proven most useful in the antemortem diagnosis of distemper-associated neurologic disease.

Management

There is no specific treatment for CDV-associated neurologic disease. Overall, the prognosis is poor, especially in cases with rapidly progressive signs. However, some dogs can survive with residual neurologic deficits. Seizures are reported to be an unfavorable prognostic sign as they are often difficult to control with antiepileptic drugs. Consequently, in cases where the neurologic signs are not severe, it is recommended that the animal is provided with supportive care, and the disease progression monitored over 1–2 weeks before considering euthanasia.

FELINE INFECTIOUS PERITONITIS

Definition/Overview

Feline infectious peritonitis (FIP) is a multisystemic viral disease that causes multifocal CNS dysfunction.

Etiology

Feline coronavirus is the causative agent of FIP, which is the most common cause of meningoencephalomyelitis in cats.

Pathophysiology

The disease occurs most commonly in cats <3 years old and from multiple cat households; however, cats as old as 15 years have been diagnosed with the disease. Neurologic involvement is most common with the noneffusive or "dry" form of the disease. Up to one-third of cats with the noneffusive form of the disease have been reported to have either primary neurologic FIP or neurologic signs as part of the overall disease presentation. FIP induces a

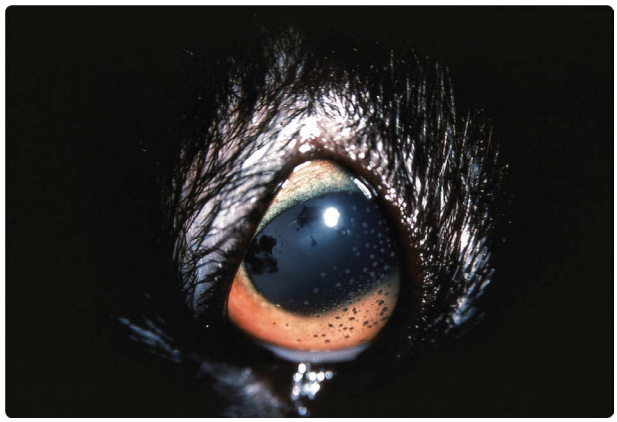

FIGURE 14.14 Ocular feline infectious peritonitis in a cat, showing keratic precipitates. (*Courtesy of Ophthalmology Service, University of Florida.*)

pyogranulomatous and immune complex-mediated vasculitis involving the meninges, ependymal lining, periventricular brain tissue, and choroid plexus of the CNS. Secondary hydrocephalus can be seen due to obstruction of the ventricular system by the inflammation.

Clinical Presentation

Neurologic signs include seizures, cerebellar signs, vestibular dysfunction, and paresis. The disease often has an insidious onset and can lack distinct clinical signs. Affected cats may have concurrent systemic signs, including anorexia and weight loss. Ocular lesions have also been identified, including anterior uveitis, iritis, keratic precipitates (Figure 14.14), retinitis, and anisocoria.

Differential Diagnosis

Other infectious and sterile causes of CNS inflammatory disease, brain tumor, metabolic and toxic encephalopathies.

Diagnosis

Hematological findings can include anemia, leukocytosis, and hyperglobulinemia; however, in some affected cats, no abnormalities are present. Serum tests for anticoronavirus antibodies are often positive, but they have low specificity. In addition, a negative serum titer (i.e., a complete absence of antibody) does not exclude the possibility of FIP-associated neurologic disease because soluble antibodies can form immune complexes and escape detection by standard tests. Advanced imaging of the brain often reveals the presence of ventricular dilatation, and periventricular contrast enhancement can be visible with MRI (Figure 14.15). Results of CSF analysis are variable. The characteristic finding is a marked neutrophilic to pyogranulomatous pleocytosis, with cell counts often in the hundreds, and an associated increase in protein concentration to >200 mg/dL. However, the CSF can be normal, show a mild mononuclear pleocytosis, or have a normal cell count with an elevated protein concentration. Positive CSF titers can be a useful

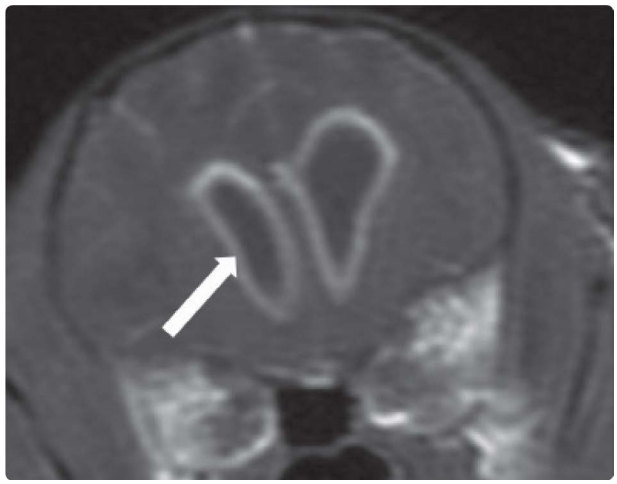

FIGURE 14.15 T1-weighted transverse brain MR image of a 3-year-old Domestic Shorthair cat with feline infectious peritonitis; marked enhancement of the lateral ventricular lining (arrow) is associated with the infection in this cat.

antemortem indicator of neurologic disease. However, positive antibody titers must be interpreted with respect to the integrity of the blood–brain barrier. PCR assays performed on CSF samples have not been shown to be reliable for confirming disease.

Management

Prognosis for cats with CNS FIP is poor. Definitive treatment is not available. The use of immunosuppressive drugs can slow the progression of disease. Recently, treatment with nucleoside analogs have shown clinical efficacy and may result in clearance and long-term resolution of neurological FIP. Treated cats demonstrated resolution of disease defined based on normalization of MRI and CSF findings.

Affected animals should be isolated from other cats to prevent the spread of infection.

TOXOPLASMOSIS AND NEOSPOROSIS

Definition/Overview

Toxoplasmosis and neosporosis are multifocal CNS diseases that are relatively uncommon following systemic infection with *Toxoplasma* or *Neospora*.

Etiology

Toxoplasma gondii is an intracellular protozoan parasite of humans and animals that can cause encephalitis in infected dogs and cats. *Neospora caninum* is a protozoan parasite that is known to cause neurologic disease in dogs but not cats.

Pathophysiology

Ingestion of tissue from infected intermediate hosts is the most common cause of *T. gondii* infection in dogs

and cats. In the case of *N. caninum* infection, dogs are commonly infected in utero, although they can also be infected by ingestion of intermediate host tissue.

Clinical Presentation

Signs of disease are seen most frequently in young or immunocompromised animals and can occur with concurrent CDV infection or FIP. Neurologic signs include seizures, behavioral changes, CN deficits, cerebellar signs, and diffuse neuromuscular disease. A progressive cerebellar ataxia has been described in adult dogs with neosporosis. A characteristic early sign of disease is progressive rigidity of one or more limbs as a result of myositis and neuritis. Concurrent ocular abnormalities can be identified on fundoscopic examination.

Differential Diagnosis

Other infectious and sterile causes of CNS inflammatory disease, brain tumor, metabolic and toxic encephalopathies.

Diagnosis

Imaging can reveal the presence of either solitary or multiple mass lesions in the brain of affected animals. CSF analysis typically demonstrates pleocytosis with a mixed population of neutrophils and the presence of small and large mononuclear cells. Eosinophils can also be seen. With toxoplasmosis, a presumptive diagnosis is based on positive antibody titers in the CSF. However, a positive titer can be seen in animals previously exposed to the organism following nonspecific immune stimulation and, therefore, is not definitive evidence of active disease. Serum and CSF anti-*Neospora* antibody titers are more reliable than serum titers alone. However, for both infections, evidence of a rising titer should be obtained. PCR assays performed on CSF samples can aid in the antemortem diagnosis of these protozoal infections.

Management

Clindamycin and/or trimethoprim/sulfonamide therapy for 3–4 weeks is recommended in animals with CNS protozoal infections. Trimethoprim/sulfonamide can be combined with pyrimethamine (0.5–1.0 mg/kg p.o. q.24 h. for 2 days, then 0.25 mg/kg p.o. q.24 h. for 2 weeks) and a folic acid supplement (5 mg per day p.o.) once the diagnosis has been confirmed. Neurologic signs typically improve with treatment but might not resolve because of permanent damage caused by the organism. In addition, relapses are possible.

CRYPTOCOCCOSIS

Definition/Overview

Cryptococcus neoformans is the most common fungal organism that affects the CNS. It occurs more commonly in cats than in dogs and causes multifocal signs.

Etiology

Cryptococcus is a saprophytic yeast with a worldwide distribution. The organism can be isolated from several sources, although its main reservoir is pigeon droppings.

Clinical Presentation

Nonspecific signs include anorexia, weight loss, lethargy, lymphadenopathy, and pyrexia. Respiratory signs include nasal discharge, sneezing, and coughing. Ocular disease (including anterior uveitis, chorioretinitis, and retinal detachment) can be seen in association with neurologic signs. Neurologic signs often reflect a diffuse or multifocal localization and frequently include altered mentation, CN deficits, and gait abnormalities.

Pathophysiology

Dogs and cats most frequently become infected following inhalation of the organism. Neurologic involvement results from hematogenous spread or local extension of an infection through the cribriform plate.

Differential Diagnosis

Other infectious and sterile causes of CNS inflammatory disease, brain tumor, metabolic and toxic encephalopathies.

Diagnosis

MRI findings are variable and include multifocal or solitary lesions with uniform or peripheral contrast enhancement (**Figure 14.16a, b**). Meningeal enhancement can also be observed. A hemogram can reveal the presence of monocytosis. In animals with extraneural disease, a definitive diagnosis can often be made based on cytology and/or culture of urine, nasal discharge, lymph node aspirates, or cutaneous masses. In addition, these animals often have positive CSF or serum titers for cryptococcal capsular antigen. Diagnosis of CNS cryptococcosis can often be made by cytologic evaluation of the CSF. Neutrophilic, mononuclear, or mixed pleocytosis can be seen, with neutrophilic pleocytosis most common in cats. Eosinophils are frequently present. The encapsulated organism can be seen in cytologic preparations in the majority of cases. The use of India ink, new methylene blue, or Gram stain allows the organisms to be identified more readily (**Figure 14.17**). In cases in which the organism is not observed on cytology, diagnosis can be made either by detecting cryptococcal capsular antigen in the CSF or by culturing CSF samples.

Management

Treatment with amphotericin, fluconazole, or itraconazole is recommended, although overall prognosis

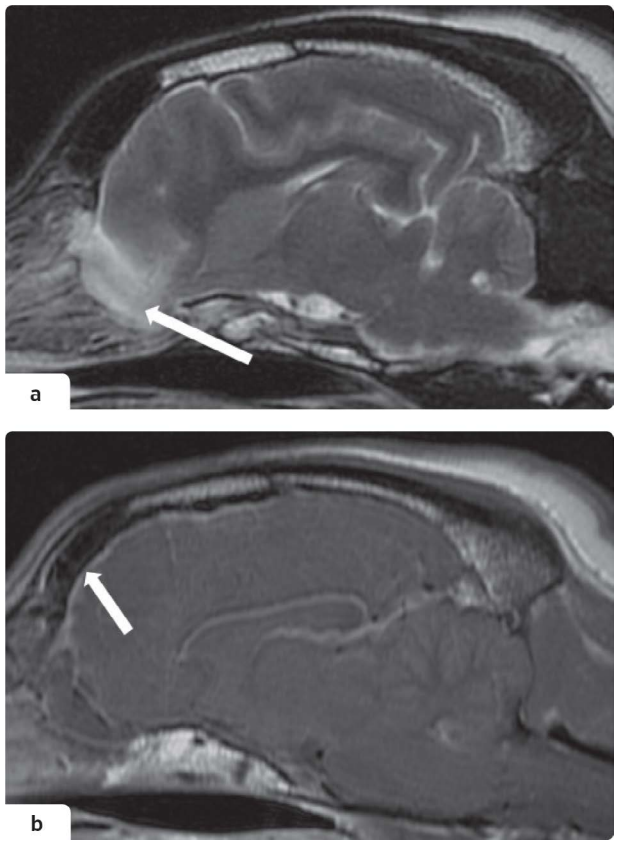

FIGURE 14.16 (a) Midline sagittal T2-weighted MR image of a dog's brain with *Cryptococcus* infection showing a granuloma adjacent to the cribriform plate in the olfactory bulb (arrow). **(b)** Midline sagittal T1-weighted MR image of the same dog reveals marked meningeal contrast enhancement (arrow) compatible with inflammation associated with the fungal infection.

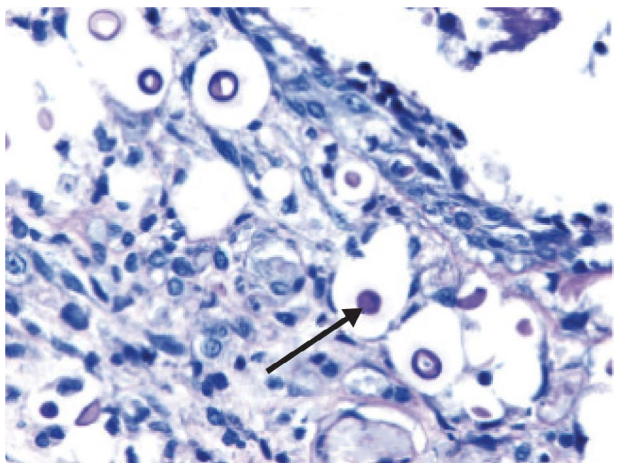

FIGURE 14.17 Brain tissue stained with periodic acid–Schiff to highlight the fungal bodies in purple (arrow), with the capsular area shown in white.

is fair to poor. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be administered when antifungal therapy is initiated to counteract the intense inflammatory reaction that accompanies the killing of *Cryptococcus*. Long-term treatment is required, ranging from several months to years. It is difficult to completely rid the body of the organism, and relapses are common. Treatment should be continued until serum cryptococcal titers are negative or for 2 months beyond the resolution of clinical signs.

INFLAMMATORY NONINFECTIOUS CNS DISEASES

Inflammatory, noninfectious causes of CNS dysfunction in dogs include such diseases as GME and necrotizing encephalitis. These diseases are often grouped together antemortem within the term meningoencephalitis of undetermined origin or MUO.

GRANULOMATOUS MENINGOENCEPHALOMYELITIS

Definition/Overview

GME is an inflammatory disease of unknown etiology that affects the CNS of dogs and, rarely, cats.

Etiology

The etiology is unknown, although infectious, autoimmune, and neoplastic causes have been proposed.

Pathophysiology

Although the cause of GME is unknown, characteristics of the lesion suggest a possible immunologic basis for the disease, and an immune-mediated pathogenesis is suspected.

Clinical Presentation

The disease is most common in middle-aged toy and small breed dogs, with a possible breed predisposition in Poodles and Terriers. Three clinicopathologic forms of the disease are described: (1) An ocular form, which manifests with acute onset of dilated, unresponsive pupils due to optic neuritis; (2) a focal form, which presents with clinical signs suggestive of a single space-occupying mass, with areas of predilection in the pontomedullary region and forebrain; and (3) a diffuse form, which presents with clinical signs suggestive of a multifocal CNS disorder, with the cerebrum, brainstem, cerebellum, and cervical spinal cord most commonly involved. Clinical signs are usually acute in onset and progressive.

Differential Diagnosis

Other infectious and sterile causes of CNS inflammatory disease, brain tumor, metabolic and toxic encephalopathies.

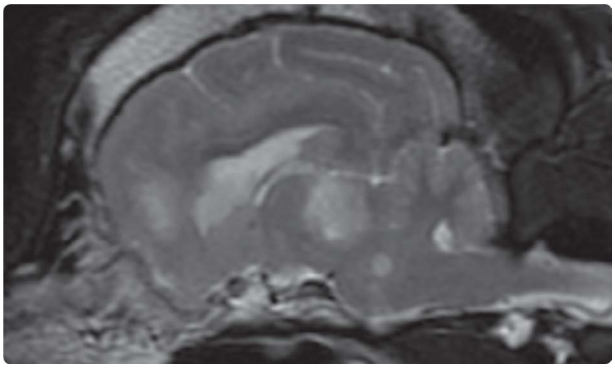

FIGURE 14.18 Sagittal paramedian T2-weighted brain MR image of a 2-year-old French Bulldog demonstrating multifocal hyperintensities confirmed to be GME on histopathology.

Diagnosis

CSF analysis typically reveals a mononuclear pleocytosis with an associated increase in protein concentration. However, both neutrophilic pleocytosis and normal CSF analysis have been reported. A mass lesion may be evident on imaging with the focal form of the disease, while the brain parenchyma can have a patchy, heterogeneous appearance with the diffuse form (Figure 14.18). A definitive diagnosis can only be made histologically on postmortem examination or by biopsy. Antemortem diagnosis is usually presumptive by exclusion of infectious etiologies.

Management

The most commonly prescribed treatment for GME consists of immunosuppressive doses of corticosteroids. Other immunomodulatory drugs are frequently used in combination with corticosteroids and include cytosine arabinoside, cyclosporine, mycophenolate, procarbazine, lomustine, and azathioprine. Radiation therapy has also been recommended as a treatment for dogs with the focal form of the disease. Overall, prognosis is poor, but survival times range from weeks to years. The diffuse form of the disease carries the worst prognosis, with a survival time of weeks to months.

NECROTIZING MENINGO(LEUKO) ENCEPHALITIS

Definition/Overview

Necrotizing meningo(leuko)encephalitis is a chronic progressive neurologic disorder reported in Pugs (Pug encephalitis), Yorkshire Terriers, Chihuahuas, and Maltese. There are also sporadic reports of similar findings in other small-breed dogs, such as the Chihuahua, Pekingese, and Shih Tzu.

Etiology

The etiology of the disease is unknown.

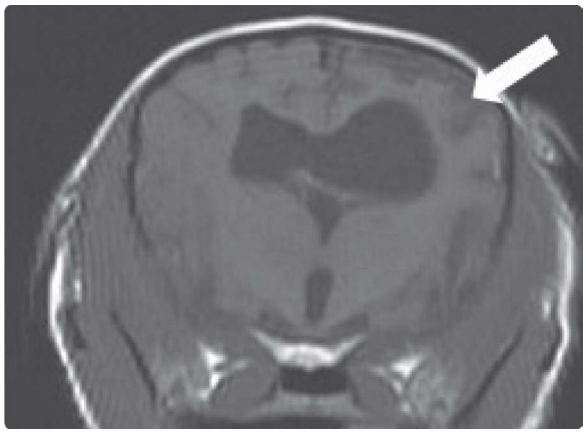

FIGURE 14.19 Transverse T1-weighted brain MR image depicting a loss of subcortical parenchyma (arrow) associated with necrotizing meningoencephalitis in a dog.

Pathophysiology

Infection with an alpha-type herpesvirus has been suggested based on histologic similarities with this type of infection in humans. However, attempts at viral isolation have been unsuccessful. The disease is associated with necrosis and a nonsuppurative meningoencephalitis, predominantly in the cortex. The subcortical white matter is frequently involved (Figure 14.19). Areas of necrosis can also be seen in the brainstem. Recent research suggests that genetics may play a role in disease susceptibility in Pugs.

Clinical Presentation

Pug encephalitis is most commonly seen in juvenile to young adults and causes seizures and other signs of forebrain dysfunction. The disease described in Maltese also has a predilection for the forebrain. The disease in Yorkshire Terriers causes signs of forebrain and brainstem involvement. Chihuahuas with necrotizing meningoencephalitis present with neurologic signs, which include seizures, blindness, mentation changes, and postural deficits. Multifocal loss or collapse of cortical gray/white matter demarcation is identified on MRI. Multifocal asymmetrical areas of necrosis or collapse in both gray and white matter of the cerebral hemispheres are seen on postmortem.

Differential Diagnosis

Other infectious and sterile causes of CNS inflammatory disease, brain tumor, metabolic and toxic encephalopathies.

Diagnosis

CT may reveal a focal hypodense area within the brain parenchyma relating to the area of necrosis. Multifocal, asymmetrical areas of high signal intensity in the brain can be seen on T2-weighted MR images, with variable contrast enhancement of the parenchyma and meninges visible on T1-weighted images. A lymphocytic

pleocytosis is most frequently recognized on CSF analysis. A definitive diagnosis is based on histopathology.

Management

Prognosis is poor, and the disease is typically fatal. Combined immunosuppressive protocols similar to those utilized for the treatment of GME are recommended. As with GME, there is limited information on the efficacy of such treatments in cases of histologically confirmed disease.

NUTRITIONAL DISEASES (THIAMINE DEFICIENCY)

Definition/Overview

Thiamine deficiency is a rare problem in dogs and cats that results in an acute progressive multifocal disease of the brain.

Etiology

Thiamine must be provided in the diet, as dogs and cats are unable to produce it endogenously. Fish is high in thiaminase and feeding an all-fish diet to cats can lead to thiamine deficiency. Overcooking canned food or meat, causing heat destruction of thiamine, has led to thiamine deficiency in dogs. Feeding meat preserved with sulfur dioxide to dogs and cats may also result in thiamine deficiency.

Pathophysiology

Thiamine (vitamin B1) is a necessary cofactor for normal carbohydrate oxidation, and its deficiency results in insufficient adenosine triphosphate (ATP) production in the brain with subsequent neuronal dysfunction and death (if not treated).

Clinical Presentation

Neurologic dysfunction due to thiamine deficiency tends to be acute and rapidly progressive. In both dogs and cats, signs of neurologic dysfunction due to thiamine deficiency typically include vestibular ataxia, decreased mentation (obtundation leading to coma, if not treated), ventroflexion of the head and neck, seizure activity, pupillary dilation with absent menace responses, and head tremors (Figure 14.20a, b). Left untreated, affected animals progress to a comatose state with opisthotonos (decerebrate posture) and ultimately death.

Differential Diagnosis

CNS inflammatory disease, cerebrovascular disease, toxicity.

Diagnosis

Antemortem diagnosis of thiamine deficiency is typically based on characteristic clinical signs of thiamine deficiency in a dog or cat receiving a thiamine-deficient diet. A positive response to thiamine administration also supports the diagnosis. Elevated blood pyruvate and lactate levels and decreased erythrocyte transketolase activity are supportive of the diagnosis, but these tests are rarely done. There are reports of MR imaging in dogs with thiamine deficiency. Similar to other metabolic encephalopathies, bilaterally symmetric brain lesions (hyperintense on T2-weighted images) were evident. In animals that die because of thiamine deficiency, characteristic bilaterally symmetric lesions (petechial hemorrhages) are appreciable throughout the brain at necropsy, especially in the caudal colliculi of the midbrain.

FIGURE 14.20 (a) A 7-year-old Domestic Shorthair cat exhibiting ventroflexion associated with its thiamine deficiency. **(b)** Transverse T2-weighted brain MR image of a dog with thiamine deficiency depicting bilateral hyperintensities associated with the colliculi (arrows).

Management

Treatment of suspected thiamine deficiency is with IM or SC thiamine hydrochloride. Rapid IV injection of thiamine can cause an acute anaphylactoid reaction; therefore, this route of administration is contraindicated. Anaphylactoid reactions are still possible, albeit

more unlikely, with the IM and SC routes. The dosage is 5–50 mg per day for dogs and 1–20 mg per day for cats. If recognized and treated early, prognosis for survival of thiamine deficiency is good. If not treated rapidly in the early period of neurologic dysfunction, prognosis for survival is guarded to poor.

HEAD TRAUMA

Definition/Overview

Severe head trauma is associated with high mortality in animals. The appropriate therapy for head trauma patients remains controversial in veterinary medicine due to a lack of objective information on the treatment of dogs and cats with head injuries. Treatment of affected animals must be immediate if the animal is to recover to a level that is both functional and acceptable to the owner. Many dogs and cats can recover from severe brain injuries if systemic and neurologic abnormalities that can be treated are identified early enough.

Etiology

Common causes of head injuries in cats and dogs include road traffic accidents, falls, kicks, gunshot or pellet wounds, and bites from larger animals. Traumatic injuries to the brain may result from blunt or penetrating insults. Most canine head trauma results from blunt vehicular trauma, while most feline head trauma is associated with crush injury.

Pathophysiology

Head trauma pathophysiology can be divided into primary and secondary injury. Primary injury to the brain cannot be reversed, occurs immediately, and describes the physical disruption of brain tissue. This includes contusions, hematomas, lacerations, and diffuse axonal injury leading to vasogenic edema. The underlying vascular and cellular pathophysiology of head trauma is similar to that described for spinal cord trauma but is complicated by elevations in ICP. This secondary injury is delayed and progressive, potentially providing targets for treatment. In addition to excitatory neurotransmitter release, ATP depletion resulting in cytotoxic edema, intracellular calcium accumulation causing activation of intracellular enzyme systems, and oxygen radical production resulting in lipid peroxidation occur. Traumatic brain injury is associated with a marked inflammatory response. The secondary injury "cascade" is exacerbated by systemic abnormalities present in the patient, which include hypotension, hypoxia, hypoglycemia or hyperglycemia, hypocapnia or hypercapnia, and hyperthermia.

After head trauma, the volume of the brain tissue compartment increases, usually due to edema or hemorrhage. As the brain tissue compartment increases, the CSF and the blood compartments must decrease, or ICP will increase. Compensation for increased brain tissue volume initially involves the translocation of CSF out of the skull. This is followed by decreased production of CSF and, eventually, decreased cerebral blood flow. These compensatory mechanisms prevent increases in ICP for an undetermined period. Once the ability for compensation is exhausted, a further small increase in intracranial volume will result in dramatic elevations of ICP, with the immediate onset of clinical signs. Increases in ICP are often responsible for clinical decline after head trauma. Marked increases in ICP lead to an elevation of mean arterial blood pressure (MABP) and reflex bradycardia (Cushing reflex). In addition to a drop in heart rate coupled with an elevated MABP, other clinical manifestations of ICP elevation include anisocoria, miosis, mydriasis, altered mentation, loss of motor function with the development of vertical nystagmus, and extensor rigidity toward the end stages.

Differential Diagnosis

Cerebrovascular disease, toxicities.

Diagnosis

Imaging of the patient's head is often indicated, especially in animals that fail to respond to aggressive medical therapy or deteriorate after initially responding. Skull radiographs are unlikely to reveal clinically useful information about brain injury but may occasionally reveal evidence of calvarial fractures (**Figure 14.21a–f**). CT is the preferred modality for imaging the head in cases of severe head injury associated with fractures. Even patients with "mild" head trauma can exhibit abnormalities on the CT scan and so the initial decision to image the patient's head should not be based on the neurologic examination alone. CT image acquisition time is faster and often less expensive than MRI, and CT also demonstrates bone detail better than MRI. Several classification methods based on the initial CT findings can be used for predicting prognosis. The recently reported Koret CT score (KCTS) was developed to address these differences. It considers lesions such as cranial vault fractures, areas of brain hyperdensity consistent with hemorrhage, midline shift, ventricular asymmetry, and lesions involving specifically the caudotentorial region, which are commonly identified in dogs following traumatic brain injury (TBI). Each of the mentioned abnormalities is given a score based on its presumed effect on prognosis:

CT parameter	Score assigned
Hemorrhage	1
Midline shift/lateral ventricle asymmetry	1
Cranial vault fracture	1
Any caudotentorial lesion (hypodensity, hemorrhage, fracture)	3
Depressed fracture	1
Sum score	0–7

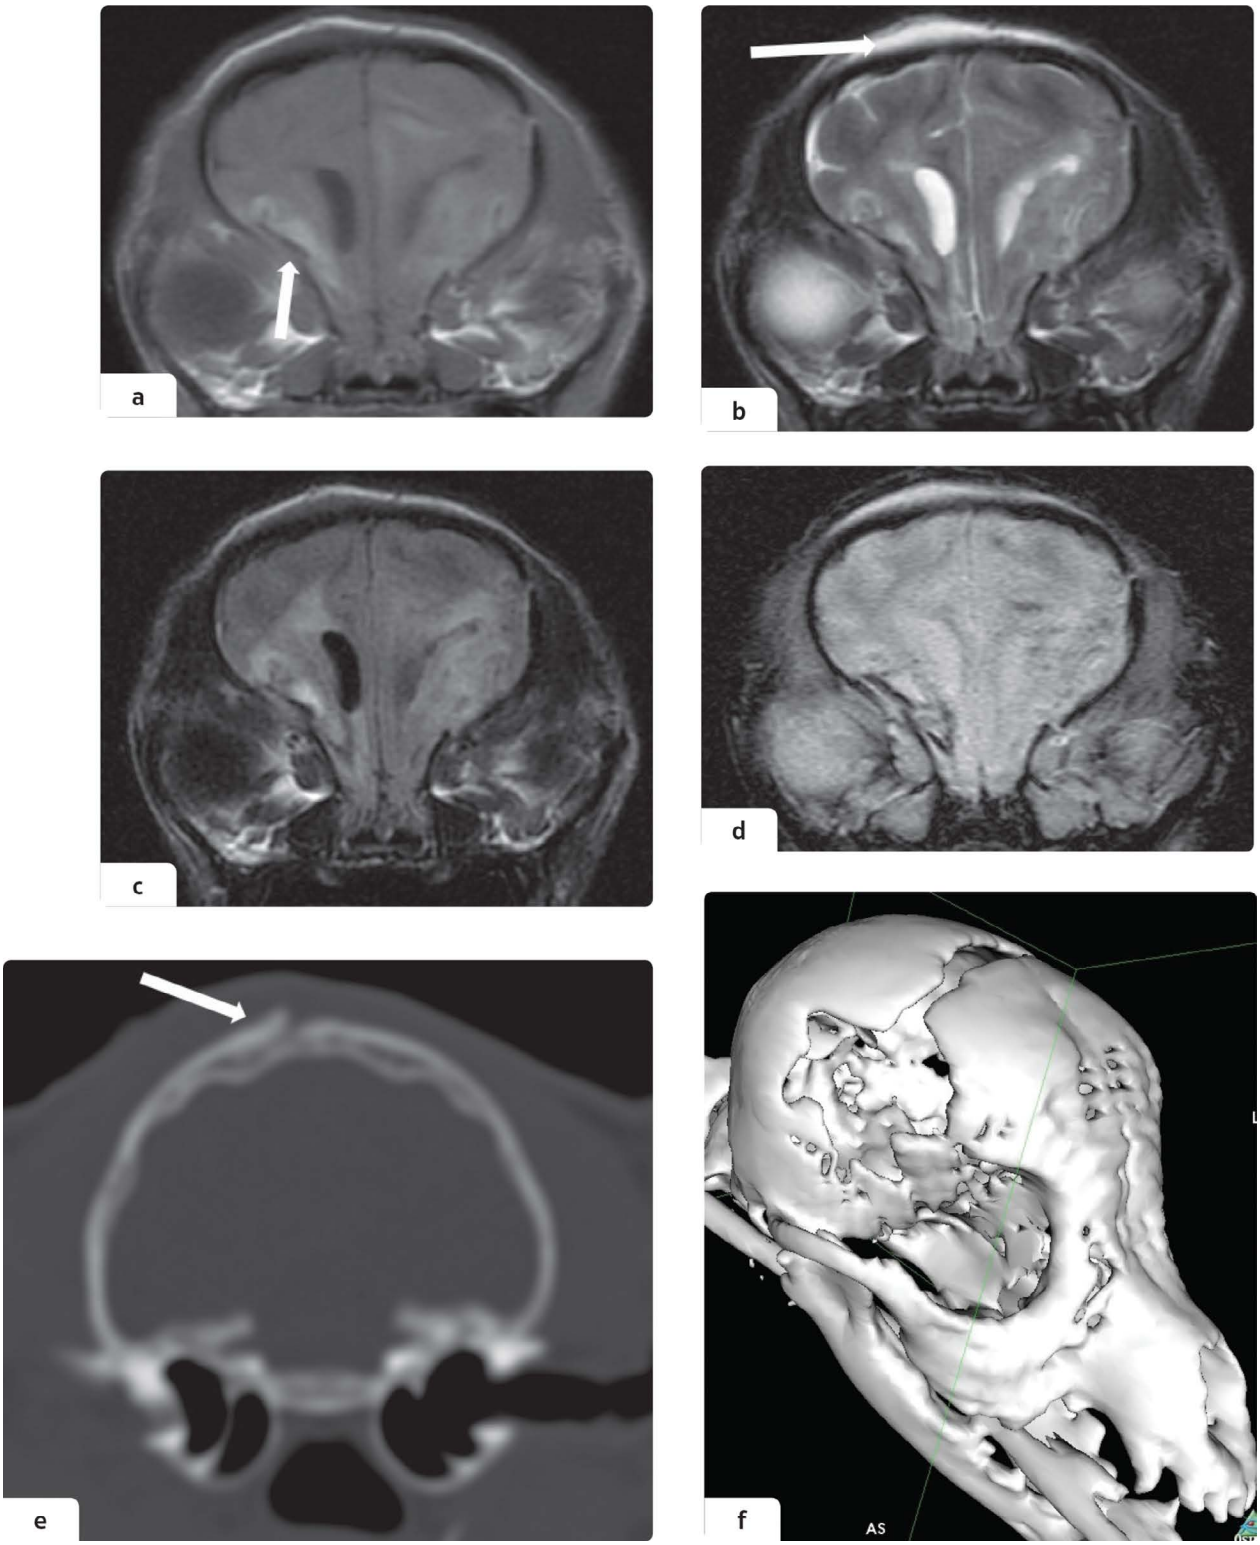

FIGURE 14.21 **(a)** T1-weighted transverse MR image of a dog 24 hours following a head trauma. A linear fracture of the skull associated with the orbit (arrow) can be seen. Multifocal areas of parenchymal damage can be identified within the frontal lobes. **(b)** T2-weighted transverse MR image of the dog in (a). In addition to the parenchymal damage, a focal area of soft tissue damage can be seen on the dorsum of the head as a hyperintensity (arrow). **(c)** T2-weighted FLAIR MR image suppressing free fluid seen on the T2-weighted image and highlighting pathologic hyperintensities alone. **(d)** Transverse gradient echo MR image detailing hemorrhage and bone as black, making both easier to determine in comparison with the other sequences. **(e)** Transverse skull CT scan of a cat following a bite on the head. A small, nondepressed fracture of the skull can be made out (arrow) with this modality, although underlying parenchymal damage is difficult to discern. **(f)** 3D reconstruction of a dog with a depressed skull fracture.

A study of 35 dogs with TBI found a significant negative association between the KCTS and survival for both short (10 days) and long (6 month) terms. A cutoff KCTS score of 3 yielded sensitivities and specificities of 85% and 100% for short-term survival and 83% and 89% for long-term survival, respectively.

MRI has been shown to provide key information relevant to the prognosis based on its ability to detect subtle parenchymal damage not evident on CT imaging. The detection of midline parenchymal shift and ventricular obliteration on MR images is associated with a poor prognosis for survival, based on a recent canine study. Furthermore, lesions of the intracranial structures that may benefit from surgical therapy, such as hematomas and pneumocephalus, can be accurately identified using advanced imaging.

MRI has been shown to provide key information relevant to the prognosis based upon its ability to detect subtle parenchymal damage not evident on CT (**Figure 14.21**). The detection of a midline parenchymal shift and ventricular obliteration on MR images are associated with a poor prognosis for survival

A modified MRI grading system score has been developed for use in veterinary medicine:

Grade 1: Normal brain parenchyma
Grade 2: Lesions only affect the cerebral hemisphere, cerebellar parenchyma, or both without median shift
Grade 3: Same as grade 2 but with median shift
Grade 4: Lesions affecting the corpus callosum, thalamus, or basal nuclei with or without lesions of a lower grade
Grade 5: Unilateral brain lesions in the brainstem with or without lesions of a lower grade
Grade 6: Bilateral brain lesions in the brainstem with or without lesions of a lower grade

A study of 50 dogs demonstrated that a greater area of affected brain parenchyma, a greater degree of midline shift, and a lower modified MRI grade was correlated with poorer clinical outcome follow-up scores and that the MGCS is lower in dogs with evidence of brain herniation. Also in this study, development of post-traumatic epilepsy in dogs was associated with a greater percentage area of brain parenchyma affected on the MR images. Another series of 18 dogs showed that dogs with parenchymal injury affecting the caudal cranial fossa had poorer outcomes (death, euthanasia, or severe persistent neurological deficits).

In cats, a poorer prognosis has been associated with a peripharyngeal pattern of injury and orbital trauma. Additionally, the frequency of bilateral or multifocal parenchymal lesions on T2-weighted imaging, and mass effect, particularly caudal transtentorial herniation, was statistically significantly higher in cats with a poorer outcome.

Cervical spinal radiographs are also advised at the time of any skull imaging to rule out concurrent spinal lesions. As for spinal trauma (see ahead given in the text), thoracic radiographs will help to evaluate for evidence of thoracic and cardiac trauma.

Management

A detailed assessment is important for determining the way in which treatment is tailored to the individual patient. Systemic and neurologic assessment must be undertaken rapidly and continually reassessed. In humans, traumatic brain injury is graded as mild, moderate, or severe on the basis of an objective scoring system (e.g., GCS). A modification of the GCS has been proposed for use in veterinary medicine. The modified scoring system incorporates three categories of the examination (level of consciousness; motor activity; brainstem reflexes), which are assigned a score from 1 to 6, providing a total score of 3–18, with the best prognosis being the higher score.

The most important consideration in head injury is maintenance of cerebral perfusion by treatment of hypotension and elevated ICP.

The basic goal of fluid management of head trauma cases is to maintain a normovolemic to slightly hypervolemic state to ensure an adequate cerebral perfusion pressure. Initial resuscitation usually involves IV administration of hypertonic saline and/or synthetic colloids. Use of these solutions allows rapid restoration of blood volume and pressure while limiting the volume of fluid administered. In contrast, crystalloids will extravasate into the interstitium within an hour of administration, and thus, larger volumes are required for restoration of blood volume. If isotonic crystalloids are chosen for administration (appropriate in mild head trauma), an aliquot of the shock dose (90 mL/kg in the dog and 60 mL/kg in the cat) can be given rapidly and repeated until improved tissue perfusion is achieved. Hypertonic saline administration (4–5 mL/kg over 2–5 minutes; 4 mL/kg of 7.5% or 5.3 mL/kg of 3%) draws fluid from the interstitial and intracellular spaces into the intravascular space, which improves blood pressure and cerebral blood pressure and flow, with a subsequent decrease in ICP. Colloid solutions can be administered after hypertonic saline is used to maintain the intravascular volume, possibly due to retention of fluids in the intravascular compartments, maintaining an intravascular oncotic gradient. The coadministration of hypertonic solutions and colloids is more effective at restoring blood volume than either alone. A dose of 4 mL/kg total of a 1:2 combination of 23.4% hypertonic saline with 6% hydroxyethyl starch (hetastarch) has been recommended.

Osmotic diuretics are very useful in the treatment of intracranial hypertension. Use of mannitol is recommended once vascular volume has been stabilized. Mannitol has an immediate plasma-expanding effect, which reduces blood viscosity, increasing cerebral blood flow and oxygen delivery. This results in vasoconstriction within a few minutes, causing an almost immediate decrease in ICP. The better-known osmotic effect of mannitol reverses the blood–brain osmotic gradient, thereby reducing extracellular fluid volume in both normal and damaged brain. Mannitol should be administered as a bolus over a 15-minute period, rather than as an infusion, in order to obtain the plasma-expanding

effect. Its effect on decreasing brain edema takes approximately 15–30 minutes to establish and lasts between 2 and 8 hours. Doses of 0.5–2.0 g/kg appear to be equally effective in lowering ICP, but the duration of effect is shorter with the lower doses.

Oxygen supplementation is recommended for most acutely brain injured animals. Supplemental oxygen should be administered initially via flow by, as oxygen cages are usually ineffective because constant monitoring of the patient does not allow for a closed system. As soon as possible, nasal oxygen catheters or transtracheal oxygen catheters should be used to supply a 40% inspired oxygen concentration with flow rates of 100 mL/kg per minute and 50 mL/kg per minute, respectively.

CRANIAL NERVE DISEASES

HEAD TILT AND NYSTAGMUS

Definition/Overview

Head tilt and nystagmus are relatively common presentations typically associated with vestibular disease (Figure 14.22). A thorough neurologic evaluation is critical to successful management. By determining the location of the disturbance within the vestibular system, a list of differential diagnoses and a diagnostic plan can be formulated.

FIGURE 14.22 An 8-year-old Domestic Shorthair cat with a left-sided head tilt.

Etiology

For peripheral vestibular disease, OMI, idiopathic vestibular disease, hypothyroidism, toxicity, trauma, and neoplasia should be considered. For central vestibular disease, CNS inflammation, cerebrovascular accident, neoplasia, hydrocephalus, trauma, metronidazole toxicity, thiamine deficiency, and lysosomal storage diseases should be considered.

Pathophysiology

The vestibular system functions to maintain an animal's balance and orientation with respect to gravity. The system detects linear acceleration and rotational movement of the head and is responsible for maintaining the position of the eyes, trunk, and limbs in reference to the position of the head. The sensory receptors for vestibular input are located in the membranous labyrinth of the inner ear. Input from the receptors enters the brain via the vestibular portion of CN VIII, where the majority of fibers terminate in one of four vestibular nuclei. The remaining axons terminate in the cerebellum. Pathways from the vestibular nuclei project to the nuclei of CNs III (oculomotor), IV (trochlear), and VI (abducent) to control eye movements, as well as to other brainstem centers and the cerebellum, cerebral cortex, and spinal cord. A head tilt results from the loss of antigravity muscle tone on one side of the neck. Jerk nystagmus develops from the dysfunction of the pathways responsible for integrating vestibular input with the extraocular eye muscles.

Clinical Presentation

Head tilt is described as a rotation of the head about the first cervical vertebra such that one of the ears is held lower than the other. Head tilt is indicative of vestibular disease and is the most consistent sign of a unilateral vestibular deficit. Nystagmus is a term used to denote the involuntary rhythmic oscillation of the eyeballs. The eye movements have a slow phase in one direction and a rapid recovery in the opposite direction, which can be horizontal, rotary, or vertical in character. Other clinical signs of vestibular dysfunction include ataxia, a wide-based stance, circling, leaning, falling or rolling toward the side of the head tilt, and positional strabismus, where the eye on the affected side deviates ventrally or ventrolaterally when the head is elevated. Animals with acute vestibular disease can present with anorexia or vomiting associated with the disequilibrium.

Differential Diagnosis

The differential diagnoses for an animal with vestibular disease vary considerably depending on whether the vestibular deficits are determined to be central or peripheral in origin. The two most common disease processes that cause central vestibular signs are neoplasia and infection/inflammation, while the two most common diagnoses in animals with peripheral vestibular signs are OMI and idiopathic vestibular disease.

Diagnosis

A CBC, blood chemistry, thyroid panel, and urinalysis should be performed in all animals presenting with vestibular signs. This can be useful for identifying potential inflammatory or metabolic disturbances that might be responsible for the clinical signs, in addition to serving as a general health screen, because further diagnostic testing usually requires anesthesia. Blood pressure measurements should also be obtained, as hypertension can manifest as vestibular dysfunction. An animal found to have peripheral vestibular disease should undergo a thorough otoscopic examination, performed under anesthesia, along with radiographs of the tympanic bullae to assess for OMI. It should be noted that normal radiographs do not rule out OMI. If there is evidence of OMI, a sample of fluid should be obtained via myringotomy and submitted for cytology and bacterial culture. CT and MRI of the tympanic bullae are the most sensitive means of identifying fluid within the middle ear and can be considered in cases posing a diagnostic challenge (Figure 14.23a–c). If the equipment is available, hearing can be assessed using a brainstem auditory evoked response to evaluate for involvement of the cochlear branch of CN VIII. Cats should undergo a thorough pharyngeal examination to check for possible inflammatory polyps. Diagnostic testing in an animal found to have central vestibular disease should include advanced imaging of the brain (preferably MRI) to identify any structural abnormalities. Analysis of CSF collected from the cerebellomedullary cistern can also be helpful. Serologic ± CSF testing for potential infectious agents is indicated where CSF testing shows inflammation.

Management

Treatment options for vestibular dysfunction are determined by the underlying etiology. Supportive care should consist of administering IV fluids to animals that are vomiting and confining the animal to a well-padded area in order to minimize self-trauma secondary to disorientation. Meclizine or maropitant can be given to treat nausea.

PERIPHERAL VESTIBULAR DISEASES

IDIOPATHIC VESTIBULAR DISEASE

Definition/Overview

Idiopathic vestibular disease is a common cause of vestibular disturbance in both dogs and cats.

Etiology

The cause of idiopathic vestibular disease is unknown.

Pathophysiology

Idiopathic vestibular disease is characterized by the acute or even peracute onset of nonprogressive peripheral vestibular signs, which has been associated with inflammation of the membranous labyrinth of the semicircular canals.

Clinical Presentation

The clinical signs most commonly reflect unilateral involvement of the peripheral vestibular system and can be quite severe and acute at onset. Occasionally, bilateral disease is seen, especially in cats. In contrast with many of the other diseases that affect the peripheral vestibular system, facial paresis and Horner's syndrome are not features of idiopathic vestibular disease.

Differential Diagnosis

OMI, ototoxicity, trauma, aural neoplasia, hypothyroidism, nasopharyngeal polyps.

Diagnosis

Diagnosis is based on the presence of a compatible history and physical examination findings and by the exclusion of other causes of peripheral vestibular disease, particularly OMI. Typically, improvement in clinical

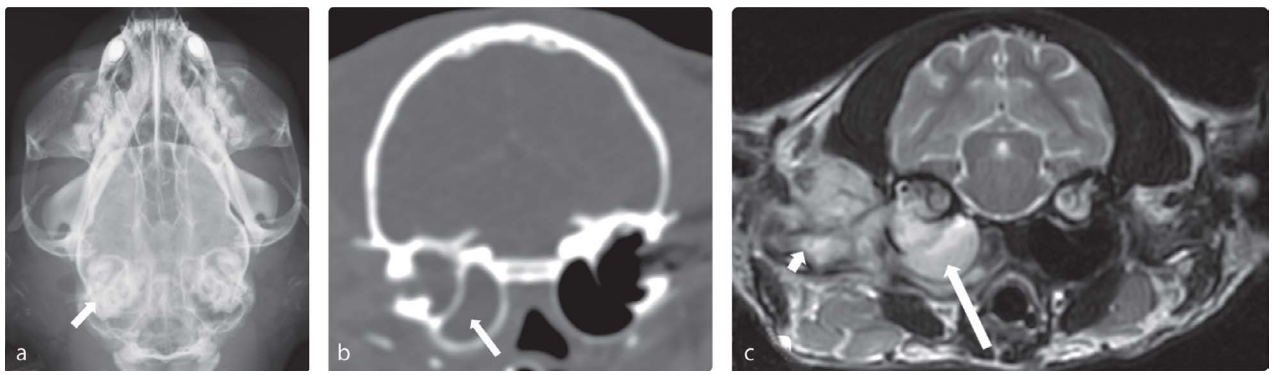

FIGURE 14.23 **(a)** Ventrodorsal radiograph of a cat with a right-sided head tilt. There is increased bone density associated with the osseous bulla on the right side (arrow), compatible with middle ear disease. **(b)** Transverse CT scan of the cat in (a) at the level of the osseous bullae. Soft tissue opacity (arrow) can be seen within both of the cat's middle ear cavities on the right side, accompanied by increased bone density. **(c)** Transverse T2-weighted MR image of the same cat at the level of the bullae confirming abnormal signal within the middle (arrow) and external ear cavities. The cat had a severe otitis media/interna, which had extended from the external ear canal and resulted in peripheral vestibular signs.

signs is seen within 2–3 days without specific treatment, and this can be used to help confirm the diagnosis.

Management

No treatment is recommended aside from supportive care, which consists of administering IV fluids to animals that are vomiting and confining the animal to a well-padded area in order to minimize self-trauma secondary to disorientation. Meclizine or maropitant can be given to treat nausea. Prognosis is good, as the condition resolves on its own within 2–4 weeks in dogs and 4–6 weeks in cats. A mild residual head tilt or ataxia can persist in some animals.

OTITIS MEDIA/INTERNA

Definition/Overview

Otitis media/interna (OMI) is one of the more commonly recognized causes of peripheral vestibular disease in both dogs and cats.

Etiology

OMI is caused by bacterial infection of the middle and inner ear.

Pathophysiology

OMI typically develops as an extension of otitis externa (OE), with common bacterial isolates, including *Staphylococcus intermedius* and *Pseudomonas* spp. OMI can occur in the absence of OE, in which case it is believed to be due to ascent of bacteria from the oral cavity through the auditory tube or hematogenous spread.

Clinical Presentation

Evidence of OE can be apparent on general physical examination. Facial nerve paralysis, neurogenic keratoconjunctivitis sicca, and/or Horner's syndrome can be seen in association with the vestibular signs due to the close association of CN VII and the sympathetic supply with the petrous temporal bone. Disease is most frequently unilateral, but bilateral disease can also occur.

Differential Diagnosis

Idiopathic vestibular disease, ototoxicity, trauma, aural neoplasia, hypothyroidism, nasopharyngeal polyps.

Diagnosis

Diagnosis is based on a thorough otoscopic examination and imaging of the tympanic bullae. Radiography of the tympanic bullae can reveal evidence of fluid density within, and sclerosis of, the bulla. However, radiographs can be normal in some cases, particularly early in the course of disease, and thus, additional imaging techniques such as CT or MRI might be required to provide more sensitive imaging of the bone and soft tissue in the affected area. Any exudate noted in the external ear canal should be removed by gentle saline irrigation to visualize the tympanic membrane. The tympanic membrane is frequently ruptured; if it is intact, it can appear to be bulging into the external ear canal. If fluid is visualized within the middle ear, an attempt should be made to obtain a sample via myringotomy. This can be performed under general anesthesia by inserting a 22-gauge spinal needle or tomcat catheter through the ventral aspect of the tympanic membrane, using an otoscope for guidance. The fluid present can then be gently aspirated into a syringe and submitted for cytology and bacterial culture.

Management

The treatment for bacterial OMI consists of a 4- to 6-week (at least) course of systemic antibacterial drugs. The choice of drugs should be based on the results of culture and sensitivity testing (if samples are successfully obtained via myringotomy). Otherwise, a drug that is effective against the most common causative organisms and penetrates the tympanic bullae (e.g., amoxicillin/clavulanate, a cephalosporin, or a fluoroquinolone) should be chosen. Otic cleansing products should not be used, particularly if the tympanic membrane initially cannot be visualized. If cleansing products escape into the middle ear, they can worsen the vestibular signs and cause deafness. Prognosis is good for resolution of the infection, although neurologic deficits can persist after effective medical therapy due to irreversible damage to the neural structures. Cases that are unresponsive to medical therapy might require surgical drainage and débridement via bulla osteotomy. Occasionally, an infection can extend into the cranial vault, causing central rather than peripheral vestibular signs to predominate. Aggressive management, including surgical drainage of the tympanic bulla and cranial vault via a bulla osteotomy and appropriate drug therapy, can result in a favorable outcome in such cases.

NASOPHARYNGEAL POLYPS

Definition/Overview

Nasopharyngeal (inflammatory) polyps comprise well-vascularized fibrous tissue lined by epithelium. Disease is identified most frequently in cats from 1 to 5 years of age but has been reported in dogs.

Etiology

These benign polyps are usually secondary to inflammation of the Eustachian tube.

Pathophysiology

Nasopharyngeal polyps originate in the auditory tube or the lining of the tympanic cavity and grow passively into the nasopharynx or middle ear of cats and, very

rarely, dogs. OMI can be a complication of auditory tube obstruction by the polyp.

Clinical Presentation

Polyps can cause signs of upper respiratory disease and dysphagia in addition to peripheral vestibular dysfunction. Evidence of otitis externa is often present.

Differential Diagnosis

Idiopathic vestibular disease, OMI, ototoxicity, trauma, aural neoplasia, hypothyroidism.

Diagnosis

Diagnosis is based on visualizing the polyp in the nasopharynx or external ear canal during a thorough pharyngeal and otoscopic examination performed under anesthesia. Radiography can reveal occlusion of the nasopharynx or sclerosis and soft tissue opacity within the tympanic bulla. Advanced imaging can provide additional information on the extent of soft tissue involvement associated with the polyp.

Management

Treatment involves removal of the polyp. Many polyps are attached to the auditory tube by a narrow stalk of tissue, and this can be successfully removed with simple traction. More extensive polyps may require surgical removal via ventral bulla osteotomy. Horner's syndrome is a common postoperative complication following ventral bulla osteotomy but tends to be transient. Overall, the prognosis is good. However, recurrence is possible, especially for polyps removed nonsurgically.

OTOTOXICITY

Definition/Overview

Peripheral vestibular dysfunction can occur secondary to administration of several systemic or topical medications.

Etiology

Systemic administration of aminoglycosides is most commonly associated with ototoxicity.

Pathophysiology

Prolonged therapy for >2 weeks with high doses of the drug are necessary to induce changes in normal animals; however, animals with renal impairment are more susceptible to developing toxicity. Of the aminoglycosides, streptomycin is most often associated with damage to the vestibular system. Due to the potential for ototoxicity, topical otic preparations should never be introduced into the ear when the tympanic membrane cannot be visualized or is found to be ruptured.

Clinical Presentation

Ototoxic agents can affect vestibular function, hearing, or both. Other agents can induce ototoxicity when used topically, the most notable of which are the iodophors and chlorhexidine.

Differential Diagnosis

Idiopathic vestibular disease, OMI, nasopharyngeal polyps, trauma, aural neoplasia, hypothyroidism.

Diagnosis

Diagnosis is based on the acute onset of compatible clinical signs in an animal that has recently been administered an ototoxic agent, in addition to the exclusion of other causes. Deafness can be confirmed with brainstem auditory evoked response testing.

Management

No definitive treatment is possible. Vestibular signs usually improve over time due to resolution of the damage or compensatory mechanisms, but deafness tends to be permanent.

CENTRAL VESTIBULAR DISEASES (SEE ALSO OTHER CAUSES OF BRAIN DISEASE)

METRONIDAZOLE TOXICITY

Definition/Overview

Central vestibular signs have been reported in dogs (and rarely in cats) following administration of metronidazole.

Etiology

Dogs reported to have developed metronidazole toxicity were typically treated with an oral dose of >60 mg/kg per day, although doses as low as 30 mg/kg per day have been incriminated. Metronidazole toxicity has also been reported in cats, but affected animals display signs of forebrain and cerebellar involvement rather than vestibular signs. Toxicity can be seen with lower doses than those reported for dogs.

Pathophysiology

The pathogenesis is poorly understood, but it is hypothesized to be related to the interaction of metronidazole with GABA receptors in the cerebellum and vestibular nuclei.

Clinical Presentation

Initial clinical signs include anorexia and vomiting and can progress rapidly to include bilateral central

vestibular signs with either a symmetrical or asymmetrical generalized ataxia and a positional vertical nystagmus. Head tilt and seizures are observed less frequently. The onset of clinical signs can occur as soon as 3 days after initiating treatment but can also be seen following chronic therapy.

Diagnosis

A history of metronidazole administration and compatible clinical signs should lead to a high suspicion for this disorder.

Management

Treatment consists of discontinuation of the drug and provision of nursing care. In addition, administration of diazepam (0.5 mg/kg IV followed by 0.5 mg/kg p.o. q.8 h. for 3 days has been recommended) has been shown to shorten recovery times in dogs. Recovery is typically seen within 1–3 days in dogs treated with diazepam and within 2–3 weeks in dogs, for which treatment only consists of drug discontinuation and supportive care. As with dogs, clinical signs in cats are reversible with discontinuation of the drug.

DROPPED JAW

Definition/Overview

Weakness of the jaw muscles may manifest as a reduction in voluntary movement of the jaw causing dysphagia or a complete loss of jaw muscle tone and inability to close the mouth (Figure 14.24).

Etiology

The cause of dropped jaw is a bilateral lesion affecting the motor component of CN V (trigeminal nerve). Most commonly this is due to idiopathic trigeminal nerve palsy, which is thought to be a neuritis of unknown cause. Lymphoma and immune-mediated inflammatory diseases are less common differentials that should be considered.

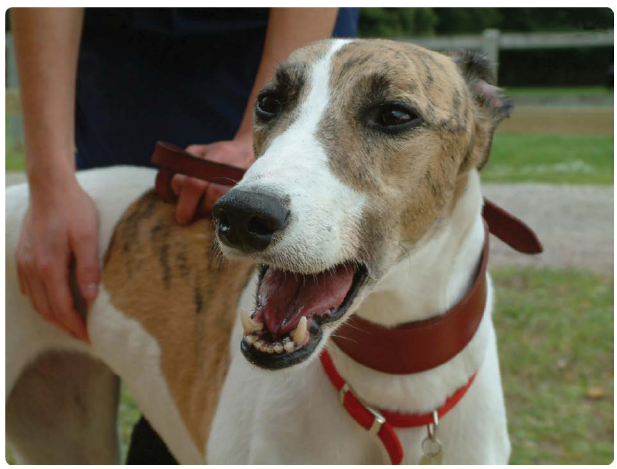

FIGURE 14.24 A 7-year-old Greyhound with an acute onset of dropped jaw.

Pathophysiology

The inability to close the mouth implies a bilateral lesion affecting the motor component of CN V, since a unilateral lesion does not cause sufficient weakness to prevent mouth closure. The bilateral nature of the trigeminal lesion strongly implies that it involves the peripheral nerves rather than the brainstem, since a lesion in the brainstem large enough to affect both trigeminal nuclei would likely be fatal. The motor neurons of CN V are located in the pons near the rostral cerebellar peduncles, and their axons are distributed to the muscles of mastication by the mandibular branch of CN V.

It is important to differentiate a lesion affecting only CN V from one affecting multiple CNs, since both may cause an animal to drool. This can be achieved by examining the animal's ability to use its tongue and swallow food when its mouth is held partially closed. These functions are mediated by CN XII (hypoglossal nerve) and CN IX (glossopharyngeal nerve), respectively, which are not affected by an isolated motor trigeminal neuropathy. Apparent inability to close the mouth must also be distinguished from an unwillingness to close the mouth, which can be caused by painful conditions of the head, such as masticatory muscle myositis, retrobulbar lesions, temporomandibular joint disease, or craniomandibular osteopathy.

Diagnosis

Diagnosis of idiopathic trigeminal neuritis is made largely through recognition of the typical pattern of clinical signs, absence of any other neurologic disease, and allowing a period of time to elapse in which recovery can occur. MRI and CSF can be helpful to rule out other causes.

Management

Treatment of idiopathic trigeminal neuritis is supportive: Helping the animal to eat by offering boluses of soft food and assisting with drinking or the placement of a temporary feeding tube. It has been suggested that holding the mouth partially closed with a muzzle facilitates eating and drinking during recovery. Most animals recover rapidly and are able to eat unassisted within 3 weeks.

ATROPHY OF THE MASTICATORY MUSCLES

Definition/Overview

Masticatory muscle atrophy can occur bilaterally or unilaterally (Figure 14.25). In spite of dramatic muscle atrophy, the ability to close the mouth usually appears

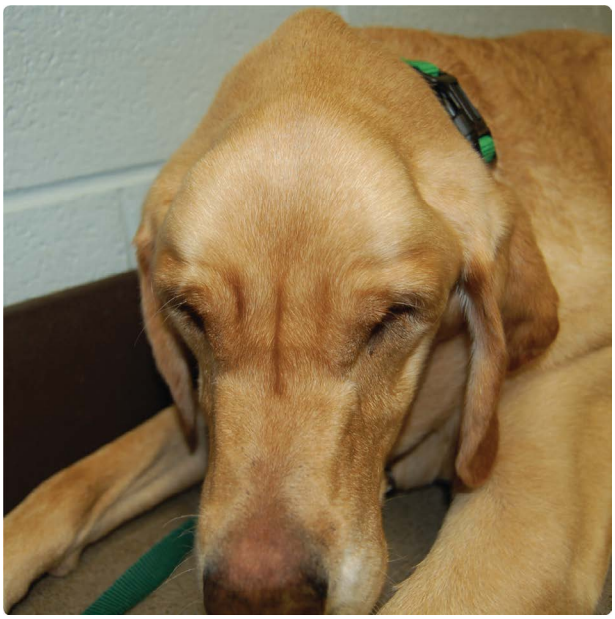

FIGURE 14.25 Bilateral temporal muscle atrophy is seen in this dog with generalized masticatory muscle atrophy.

unimpaired. However, opening the mouth may be very limited in cases in which there has been muscle inflammation and subsequent fibrosis.

Etiology

Masticatory muscle atrophy can result from impaired muscle innervation due to lesions of the motor branch of CN V, diseases of the muscles themselves, or systemic disorders such as cachexia or hyperadrenocorticism (or exogenous steroid administration). Unilateral loss of temporal muscle mass can occur in the absence of any sensory signs; it is recognized that nerve sheath tumors may be responsible. In a recent study of 63 dogs with unilateral masticatory muscle atrophy, presumptive trigeminal nerve sheath tumor (pTNST) was diagnosed in 30 dogs (47.6%); survival time varied from 1 day to 21 months (median, 5 months). Other extra-axial mass lesions were observed in 13 dogs (20.6%); survival time varied from 6 days to 25 months (median, 2.5 months). In 18 dogs (28.6%), no abnormalities were observed on MRI. Neurological signs only progressed in one dog.

Pathophysiology

Bilateral atrophy can be caused by many systemic diseases, most notably cachexia (associated with cancer) and hyperadrenocorticism (associated with exogenous or endogenous corticosteroids). However, bilateral atrophy most commonly occurs as a consequence of masticatory myositis due to the destruction of muscle fibers and scarring, which can occur rapidly. This is an immune-mediated disorder in which antibody-directed inflammation is targeted at the muscles of mastication, including the masseter, temporalis, and pterygoid muscles. The specific antigen is part of the unique myofiber (type 2M) contained within these muscles. There is no gender predisposition documented for masticatory myositis, and breeds noted to have a predisposition include the German Shepherd Dog, Hungarian Vizsla, and Cavalier King Charles Spaniel. Most affected dogs are of large breeds and are often young adults; cats are infrequently affected.

Clinical Presentation

Atrophy of the masticatory muscles can occur unilaterally or bilaterally. Bilateral atrophy is not associated with failure to close the mouth, but some individuals exhibit limited mouth opening (trismus). Third eyelid protrusion may follow severe temporal and masseter muscle atrophy, resulting in enophthalmos (due to loss of muscle support to the orbit), which may be sufficiently severe to impair vision. Swelling of the muscles of mastication can occur in the acute phase of masticatory myositis with trismus and exophthalmos. Palpation of the muscles or attempting to open the jaws may cause pain, and occasionally a "locked jaw" syndrome can result, in which animals are unable to either open or close their mouth. Exophthalmos in the absence of masticatory muscle swelling can result from myositis of the extraocular muscles. Young Golden Retrievers may be predisposed to this unusual disease.

Diagnosis

Detection of a significant concentration of anti-type 2M muscle fiber antibodies confirms masticatory myositis, although by the time the chronic phase is reached, the antibody response may well have subsided. Serum creatine kinase (CK) levels may also be elevated. Muscle biopsy may reveal an inflammatory infiltrate, myofiber necrosis, and phagocytosis. It may also specifically identify antibody localization to the type 2M myofibers. Electromyography often identifies spontaneous abnormalities and should always be performed to evaluate the rest of the musculature in cases where a more generalized myopathy is suspected. CT or MRI is required to diagnose nerve sheath tumors in cases with unilateral masticatory muscle atrophy (Figure 14.26).

Management

Masticatory muscle atrophy as a result of systemic disease does not appear to be reversible but does not often cause significant deficits. Masticatory myositis is treated with immunosuppressive doses of corticosteroids, but some cases of atrophy are too far advanced for this therapy to be effective. The recommended dose of prednisolone is 1–2 mg/kg p.o. q.12 h. for 3–4 weeks, after which the dosage is tapered slowly to achieve the lowest dosage q.48 h. that eliminates the clinical signs. Most dogs treated aggressively in the early stages show a good response to therapy, but relapses are possible. Some cases require the addition of a further immunosuppressive medication, such as

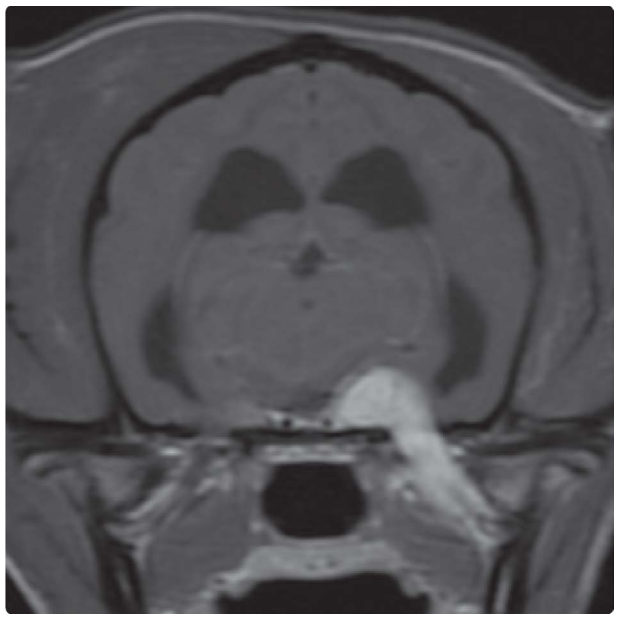

FIGURE 14.26 Transverse T1-weighted postcontrast brain MR image at the level of the brainstem; the hyperintense lesion compressing the brainstem and seen to exit the skull was confirmed to be a trigeminal nerve sheath tumor.

azathioprine. While cases that respond rapidly often have a favorable prognosis, chronic loss of muscle may lead to trismus and permanent dysphagia. Feeding regimens should be discussed with the owner, as even in the early stages of a responsive condition feeding tubes may be necessary, if only to reduce the potential for aspiration pneumonia. Additional therapy such as vigorous physiotherapy of the jaw muscles (by encouraging the dog to chew rawhides or play with tennis balls) is advisable.

FACIAL PARALYSIS

Definition/Overview

Dogs and less commonly cats can present with a drooping of the face due to reduced innervation of the muscles of facial expression. This is most commonly seen as a drooping lip but can also affect the eyelids (Figure 14.27).

Etiology

Facial nerve dysfunction may be due to disease of the peripheral facial nerve caused by OMI, trauma, hypothyroidism, neoplasia of the middle/inner ear, or polyneuropathies. Disease of the facial nerve nucleus in the medulla of the brainstem can result from any disease affecting the CNS. The most common cause of peripheral facial nerve paralysis has been reported to be idiopathic (75% of dogs and 25% of cats with facial paralysis). In addition, facial nerve palsy is sometimes observed in animals with more generalized peripheral neuropathies (e.g., those affecting multiple limbs).

FIGURE 14.27 A 6-year-old female Boxer with left-sided facial paresis.

Pathophysiology

Muscles that control facial expression and maintain the normal appearance of the palpebral fissures and mouth are innervated by the facial nerve. The neuron cell bodies are located in the facial nuclei of the rostral medulla, and axons leave the ventrolateral surface of the medulla ventral to CN VIII (vestibulocochlear nerve). CN VII (facial nerve) enters the petrosal bone through the internal acoustic meatus on the dorsal aspect of CN VIII and emerges from the skull through the stylomastoid foramen. Any disease affecting CN VII along its path can result in facial paresis, which is often seen as an acute-onset disease.

Clinical Presentation

Facial nerve paralysis or palsy may be unilateral or bilateral. Widening of the palpebral fissure and laxity of the facial muscles of expression may be seen. The lip may droop on the affected side, and food or saliva may fall from that side of the mouth. The nasal philtrum can be deviated to the normal side in the early stages, and drooping of the ears may be apparent in some breeds. There are some signs of CN VII dysfunction, for which pet owners may seek veterinary attention, that do not immediately suggest a facial nerve lesion. Owners may observe the third eyelid flicking over the eye. In these cases, the animal substitutes globe retraction (with concomitant third eyelid protrusion) for blinking with the paralyzed lids. Additionally, accumulation of food in cheeks that have poor muscle tone may lead to halitosis.

Loss of the palpebral and corneal reflexes predisposes the animal to exposure keratitis, which can occur subsequent to improper lubrication of the cornea, despite normal tear production. Clinical signs

are usually maximal within 7 days, and recovery can take 3–6 weeks, if it occurs at all. With chronicity, muscle contracture can lead to narrowing of the palpebral fissure, widening of the mouth, and, in unilateral cases, deviation of the nostrils towards the affected side.

Diagnosis

All possible causes of facial paresis and/or paralysis should be excluded before this specific diagnosis of idiopathic facial paresis can be made. A thorough investigation for ear disease should be undertaken in addition to blood tests for hypothyroidism and electromyography to rule out polyneuropathies. MRI may reveal contrast enhancement of the intratemporal facial nerve, which may suggest a poorer prognosis.

Management

There is no effective treatment for the underlying disease, but it is important to ensure that the cornea is adequately lubricated (either by endogenous production or eye drops). The prognosis for idiopathic facial palsy varies. Many animals make a gradual recovery (weeks to months), but some are left with permanent deficits. These deficits may progress to muscle contracture and deform the facial expression permanently. This can be mistakenly interpreted as hemifacial spasm, an uncommon syndrome in dogs and cats.

SPINAL DISORDERS

Clinical Signs of Spinal Cord Dysfunction

The clinical signs associated with spinal cord dysfunction depend on the location, size, and rate of development of the lesion. A small lesion on one side of the spinal cord without a great deal of associated cord swelling (e.g., a slowly growing tumor) will likely cause signs predominantly on the side of the lesion. However, a large lesion or a lesion associated with substantial cord swelling (e.g., an acute disc herniation in the thoracolumbar region) will likely result in bilateral signs of dysfunction. In most spinal cord disorders, bilateral deficits will be observed, but the deficits are often more pronounced on the side of the lesion. Proprioceptive and nociceptive information traveling toward the brain, as well as voluntary motor impulses traveling from the brain, can be affected with spinal cord disease. With progressive spinal cord disease, proprioception is usually the first deficit observed, followed by deficits in voluntary motor ability and finally deficits in the ability to perceive painful stimuli (nociception).

The clinical signs listed in further text for each of the anatomic subdivisions of the spinal cord represent all possible abnormalities that may be encountered with lesions in these respective areas. The clinician may, for example, encounter cases of cervical myelopathy in which severe neck pain is the only clinically detectable abnormality. Alternatively, cases may be encountered with more extensive lesions in the same anatomic location in which the patient is tetraplegic with minimal pain perception to the limbs and having respiratory difficulty. There is a spectrum of possible clinical presentations between these two extreme examples. A topic that is sometimes confusing to clinicians is that of upper motor neuron (UMN) fecal incontinence. Although it is apparently less common than with cauda equina lesions, fecal incontinence may result from cervical or thoracolumbar spinal cord lesions (particularly dorsal lesions, commonly of a cystic nature). This may be due to interruption of ascending information from the rectum to brainstem and cerebral centers responsible for a normal, coordinated defecation reflex, interruption of descending inhibitory influence from such centers on the local spinal cord sacral defecation reflex, or a combination of the two. Since fecal incontinence in these cases does not directly involve the LMNs innervating the anal sphincter musculature or the sensory neurons or nerves innervating the perineum, perineal sensation (in patients with intact pain sensation), as well as anal sphincter tone and perineal reflexes (e.g., anal reflex), are typically normal. The clinical information regarding UMN fecal incontinence in veterinary patients is limited, but it suggests that it may be more responsive to surgical intervention than LMN fecal incontinence. The cauda equina is defined as the nerve roots derived from the cord segments L7 and caudally. Damage to the spinal cord segments supplying the cauda equina will produce the same clinical signs of dysfunction as disruption of the respective nerve roots.

Clinical Signs Related to Disease of C1–C5 Spinal Cord Segments

- Cervical pain (hyperesthesia).
- Proprioceptive deficits ipsilateral to the lesion (forelimb and hindlimb) or all four limbs.
- Voluntary motor deficits ipsilateral to the lesion (forelimb and hindlimb) or all four limbs, varying from paresis to plegia. The paresis or plegia (hemiparesis, hemiplegia, tetraparesis, tetraplegia) is UMN in nature, with normal to hyperactive reflex activity in all limbs.
- Horner's syndrome ipsilateral to the lesion or bilaterally.
- Respiratory difficulty (severe lesions) involving both chest excursions and diaphragmatic movements.
- UMN bladder dysfunction.
- UMN fecal incontinence is possible.
- Nociceptive (pain perception) deficits are possible in all four limbs.

Clinical Signs Related to Disease of C6–T2 Spinal Cord Segments

- Cervical pain (hyperesthesia).
- Proprioceptive deficits ipsilateral to the lesion (forelimb and hindlimb) or all four limbs.
- Voluntary motor deficits ipsilateral to the lesion (forelimb and hindlimb) or all four limbs, varying from

paresis to plegia. The paresis or plegia is classically LMN in nature in the forelimbs (involvement of the gray matter of C6–T2 or the efferent axonal processes from that gray matter) and UMN in nature in the hindlimbs. In some instances (e.g., caudal cervical spondylomyelopathy), caudal cervical lesions may result in obvious signs of UMN paraparesis, with subtle or clinically inapparent forelimb deficits.
- Horner's syndrome ipsilateral to the lesion or bilaterally.
- Decreased or absent cutaneous trunci (panniculus) reflex ipsilateral to the lesion or bilaterally. The deficit is due to impairment of the efferent arm of the reflex arc.
- Respiratory difficulty with severe lesions. The respiratory pattern often differs from that seen with C1–C5 spinal cord lesions. Since the phrenic nerve arises from spinal cord segments C5–C7, there is usually enough phrenic nerve function to provide diaphragmatic movement, but impulses from the medullary respiratory centers cannot effectively traverse the damaged cord segments to stimulate the cell bodies of the intercostal nerves. This is the reason for the "abdominal breathing" pattern seen with severe caudal cervical myelopathies. The thoracic cage moves minimally, if at all, and the exaggerated activity of the diaphragm causes the abdominal contents to move passively.
- UMN bladder dysfunction.
- UMN fecal incontinence is possible.
- Nociceptive deficits are possible in all four limbs.

Clinical Signs Related to Disease of T3–L3 Spinal Cord Segments

- Thoracolumbar pain (hyperesthesia).
- Proprioceptive deficits in the hindlimb ipsilateral to the lesion or both hindlimbs.
- Voluntary motor deficits in the hindlimb ipsilateral to the lesion or both hindlimbs. The paresis or plegia (monoparesis, monoplegia, paraparesis, paraplegia) is UMN in nature, with normal to hyperactive reflex activity in the hindlimbs.
- The forelimbs are neurologically normal (normal proprioception, normal voluntary motor activity). Schiff–Sherrington posture may be seen in the forelimbs and should not be confused with a cervical spinal cord problem. Schiff–Sherrington posture is an anatomic phenomenon, not a prognostic indicator. Depending on the nature of the injury, spinal shock is also a possibility.
- Horner's syndrome is possible with very cranial lesions (T3 spinal cord level) but less likely in comparison with cervical lesions.
- Decreased or absent cutaneous trunci (panniculus) reflex, approximately one to four vertebral levels caudal to the spinal cord lesion. The deficit is due to impairment of the afferent arm of the reflex arc.
- UMN bladder dysfunction.
- UMN fecal incontinence is possible.
- Nociceptive deficits are possible in both hindlimbs.

Clinical Signs Related to Disease of L4–S3 Spinal Cord Segments

- Lumbar pain (hyperesthesia).
- Proprioceptive deficits in the hindlimb ipsilateral to the lesion or in both hindlimbs.
- Voluntary motor deficits in the hindlimb ipsilateral to the lesion or both hindlimbs. The paresis or plegia (monoparesis, monoplegia, paraparesis, paraplegia) is LMN in nature, with a decreased to absent patellar reflex ipsilateral to the lesion or bilaterally. The withdrawal and gastrocnemius reflexes may be normal or decreased, depending on the extent of damage to the L6 spinal segment (L6 contributes to the sciatic nerve).
- A decreased or absent panniculus (cutaneous trunci) reflex may or may not be appreciable one to four vertebral levels caudal to the lesion because the last three or four lumbar spinal nerves do not give off dorsal cutaneous branches.
- LMN bladder dysfunction.
- LMN fecal incontinence is possible. Decreased anal tone is possible.
- Nociceptive deficits are possible in both hindlimbs and the tail.

Neurodiagnostic Investigation

History and findings of physical and neurologic examinations will identify a neurologic problem and assist with neuroanatomic localization and consideration of differentials. The onset (acute or chronic), rate of progression (rapid or gradual), and temporal relation (intermittent and/or episodic, stable or insidious) can be established. A recommended diagnostic approach to spinal cord diseases is as follows:

- CBC, serum biochemistry profile, and urinalysis.
- Thoracic radiographs in animals >5 years of age and after trauma.
- Survey spinal radiographs can assist with recognition of obvious abnormalities such as discospondylitis, luxations, and bone neoplasia. If an abnormality is not seen, advanced imaging and CSF analysis are indicated.
- CSF collection, preferably from the cerebellomedullary cistern and caudal lumbar region (**Figure 14.28a, b**).
- Myelography and epidurography are useful for the detection and characterization of compressive spinal cord lesions (extradural, intradural, and intramedullary) and for determining the extent of the compression (**Figure 14.29**).
- CT is used as a primary method to evaluate the spine or assist with determining lesion extent after myelography.
- MRI is becoming more available to veterinarians in general and specialty practice and is considered the standard of care in the detection of lesions within the spinal cord.

Additional diagnostic procedures include electrodiagnostic evaluation (electromyography and nerve conduction studies), nerve and muscle biopsy, CSF protein electrophoresis, serology, PCR, and exploratory surgery.

FIGURE 14.28 (a) The skin over the caudal skull and cranial cervical column is shaved and prepared in a sterile fashion for a CSF tap at the cerebellomedullary cistern. **(b)** A spinal needle with a translucent hub is used to obtain CSF, and it is allowed to drip into a sterile polypropylene tube.

VASCULAR DISEASE

FIBROCARTILAGINOUS EMBOLIC MYELOPATHY

Definition/Overview

Fibrocartilaginous embolic myelopathy (FCEM) is characterized by acute spinal cord infarction caused by embolism of fibrocartilage identical to that of the nucleus pulposus of the intervertebral disc. Acute tetraparesis, paraparesis, monoparesis, or monoplegia can be seen based on the location of the ischemic injury to the cord. Most commonly, this affects large breed dogs. FCEM rarely affects cats.

Etiology

FCEM is caused by embolism of fibrocartilage identical to that of the nucleus pulposus of the intervertebral disc (IVD).

Pathophysiology

Many theories exist as to the pathophysiology for embolization. Entry of disc material into the vascular system and embolization from the point of entry to the arteries and veins of the spinal cord has yet to be elucidated. The gray matter is more severely affected because of its higher metabolic demand. Nonchondrodystrophoid breeds are predisposed, which may relate to the disc being more gelatinous and prone to cause microextrusion. FCEM is frequently recognized in large and giant breed dogs but also affects small- to medium-sized dogs. Purebred dogs that have been documented with FCEM include Miniature Schnauzers, German Shepherd Dogs, Staffordshire Bull Terriers, Labrador Retrievers, and Irish Wolfhounds. FCEM is rare in cats. In dogs, the male-to-female ratio varies in different studies, and the median age in most studies is 5 or 6 years with a wide age range. In cats, males and females are equally represented, with most cats older than 7 years. While FCEM is also described in cats, a separate pathophysiology can also be seen associated with a characteristic clinical presentation, termed "feline ischemic myelopathy" and described in more detail in further sections.

Clinical Presentation

Neuroanatomic localization often is associated with the spinal cord intumescences, but other spinal cord regions can be involved. Thoracolumbar signs are more common than cervicothoracic signs. Clinical signs usually are associated with trauma or exercise. Asymmetrical lesion distribution is a clinical feature due to the distribution of the blood vessels to the spinal cord parenchyma; however, the lesion can be symmetrical. Symmetrical lesions more often are associated with loss of nociception. Spinal hyperesthesia can be present initially but is absent after the onset of ischemia. Maximal neurologic deficits usually occur within the first 24 hours. Dogs

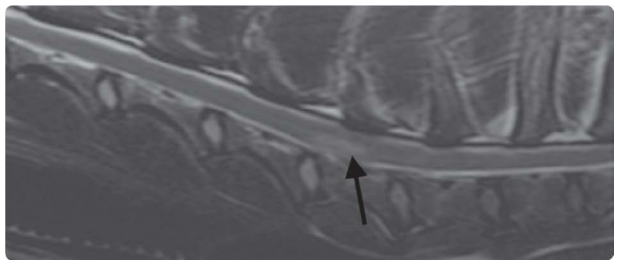

FIGURE 14.30 Sagittal T2-weighted cervical spinal MR image of a 6-year-old Labrador Retriever with a hyperintense lesion within the parenchyma of the spinal cord (arrow), confirmed histopathologically to be associated with a fibrocartilaginous embolus.

with lumbosacral intumescent involvement more often have loss of deep pain perception.

Diagnosis

Diagnosis is based on history, signalment, and clinical signs. Intramedullary spinal cord swelling provides early myelographic evidence of FCEM. MRI is the preferred diagnostic imaging modality for detection of intramedullary lesions and a presumptive diagnosis of FCEM. MRI findings include a focal, sharply demarcated, and often asymmetric intramedullary lesion, which predominantly affects the gray matter (**Figure 14.30**). CSF analysis may reveal abnormalities in severe cases. Dogs that are ambulatory on presentation are more likely to have normal MRI. The severity of neurologic signs has been associated with the extent of longitudinal and transverse lesions on MRI. Diagnosis of FCEM is confirmed by histopathology and documentation of nucleus pulposus in the spinal cord vasculature.

Management

Treatment is with supportive care. As for all spinal cord injuries, physical rehabilitation is important in the process of recovery.

As with other acute myelopathies, outcome is associated with the severity of neurological dysfunction, with a very guarded prognosis attached to dogs with plegia and absent deep pain perception of the affected limbs. It is also notable that persistent neurological deficits are seen in 50%–93% of dogs, with reduced urinary and fecal incontinence also reported in 2.5%–33% of dogs. Prognosis appears to be associated with the size of the spinal cord lesion, with an increased longitudinal and transverse extent of the intramedullary lesion on MRI shown to be associated with a poorer prognosis. Other factors, such as lower motor neuron signs and symmetrical lesions, have also been suggested as negative prognostic indicators. Dog size and severity of clinical signs may also contribute to owners electing for euthanasia, often early in the postinjury period. Although there is more limited data available regarding outcome in cats, the prognosis also appears good with positive outcomes, particularly in the presence of intact deep pain perception.

FELINE ISCHEMIC MYELOPATHY ASSOCIATED WITH HYALINE ARTERIOPATHY

Definition/Overview

This is a recently described condition in older cats, whereby an ischemic myelopathy in the cranial cervical region is thought to be related to hyaline arterial degeneration.

Etiology

The underlying etiology appears to be that of thrombosis secondary to hyaline degeneration of the ventral spinal artery or basilar artery in the region of the cranial cervical spinal cord.

Pathophysiology

Most cases involve an ischemic myelopathy occurring in the cranial cervical spinal cord, resulting from an infarction in the territory of the ventral spinal artery. Given the involvement of the basilar artery, affected cats can also demonstrate ischemic injuries in regions of the brainstem. Many cats are diagnosed with concurrent chronic systemic diseases, such as chronic kidney disease, hypertension, and hypertrophic cardiomyopathy, although the clinical relevance of these diagnoses is unknown.

Clinical Presentation

Clinical signs involve a peracute onset, nonprogressive cervical myelopathy in an older cat of any breed, occurring at an average age of around 14 years. The typical presentation is that of nonambulatory tetraparesis or tetraplegia, with affected cats also often demonstrating marked cervical ventroflexion. Spinal reflexes are usually intact in all four limbs, consistent with a localization to the C1–C5 spinal cord segments, with no spinal pain on examination. In contrast to most cases of FCEM (see mentioned in the text earlier), clinical signs of myelopathy typically affect both sides of the body symmetrically.

Diagnosis

Alongside a high index of suspicion based on the characteristic clinical presentation, a diagnosis is made on the basis of characteristic MRI features. A well-demarcated, intramedullary T2-weighted hyperintense spinal cord lesion is usually evident in the ventral cervical spinal cord, around the level of the C2 vertebra.

Management

As for other ischemic myelopathies such as FCEM, treatment is predominantly supportive with physical rehabilitation to facilitate recovery. The prognosis appears

to be good in most cases, with a return to ambulation in around 6 days on average. However, some cats may develop a chronic relapsing clinical course, so affected cats should be monitored for signs of recurrence in the future. Appropriate management of any concurrent systemic diseases is also an important treatment consideration in these cats.

AORTIC THROMBOSIS AND THROMBOEMBOLISM

Definition/Overview

Thrombosis or thromboembolism affects the terminal aorta and/or the iliac arteries in most dogs and cats, resulting in an acute or chronic onset of pelvic limb dysfunction. Thrombosis is the pathologic formation of a blood clot within a vessel, while an embolus occurs when a thrombus breaks off and obstructs blood flow in a distal location. Aortic thromboembolism, also known as saddle thrombus, often causes acute neurologic dysfunction affecting the hindlimbs, most commonly in cats, in addition to clinical signs of poor peripheral perfusion, such as nail bed cyanosis. The disease can occasionally affect dogs and may present more chronically as lameness or exercise intolerance affecting the hindlimbs.

Etiology

Cats with systemic thromboembolic disease have a thrombus that obstructs the terminal aorta. The most frequent underlying disease in cats with thromboembolism is hypertrophic cardiomyopathy but also other unclassified cardiomyopathies. In dogs, the disease is more commonly associated with steroid use, hyperadrenocorticism, and neoplasia.

Pathophysiology

Aortic thromboembolism is also known as saddle thrombus. Thrombi form in the left atrium, and dilation of the left atrium is one of the greatest risk factors for aortic thromboembolism. The three conditions that favor thrombus formation include blood stasis, hypercoagulability, and endothelial damage (Virchow's triad). Once the thrombus forms, it usually follows a path of least resistance and eventually lodges at the aortic trifurcation. Restriction of blood flow by the embolus and release of vasoactive substances cause ischemic injury to the nerves and muscles of the hindlimbs.

Clinical Presentation

The median age of onset in dogs is 10 years, but it has been seen in dogs from the age of 2 upward. Acute onset of clinical signs is extremely common in cats but is only seen in approximately 15%–47% of affected dogs. Clinical signs consist of acute onset of an asymmetrical hindlimb paresis and/or paralysis. Abyssinian, Birman, Ragdoll, and male cats were overrepresented in one study. The femoral pulse is weak or absent. The limbs are cold, and the nail beds are cyanotic and fail to bleed when cut. The hindlimbs are stiff, and the muscles are hard and painful on palpation. Typically, there is loss of hindlimb nociception distally. Tachypnea and hypothermia are frequently seen. Congestive heart failure and arrhythmias can each be seen in over 40% of cats. The more common chronic presentation in dogs is less likely to be painful, may be asymmetric, and many dogs are ambulatory, with over 40% of dogs having detectable femoral pulses. The term "claudication" has been proposed to describe cases with intermittent painful lameness, especially during exercise, and this is caused by anomalies of the peripheral blood flow to one or both pelvic limbs.

Diagnosis

Aortic thromboembolism is suspected based on clinical signs. Common biochemical abnormalities in these cats include hyperglycemia, hyperkalemia, azotemia, and a markedly elevated CK concentration soon after the embolic episode. A decrease in blood glucose of 17%–34% compared to unaffected limbs can be observed in dogs with arterial thrombosis, and absolute glucose cutoffs of 30 mg/dL and 16 mg/dL, in cats and dogs, respectively, corresponds to 100% sensitivity for the disease. Evidence of cardiac disease is further supported by physical examination findings, thoracic radiographs, and echocardiography. Doppler ultrasonography and/or CT of the aorta and its trifurcation can sometimes identify thrombotic disease (Figure 14.31).

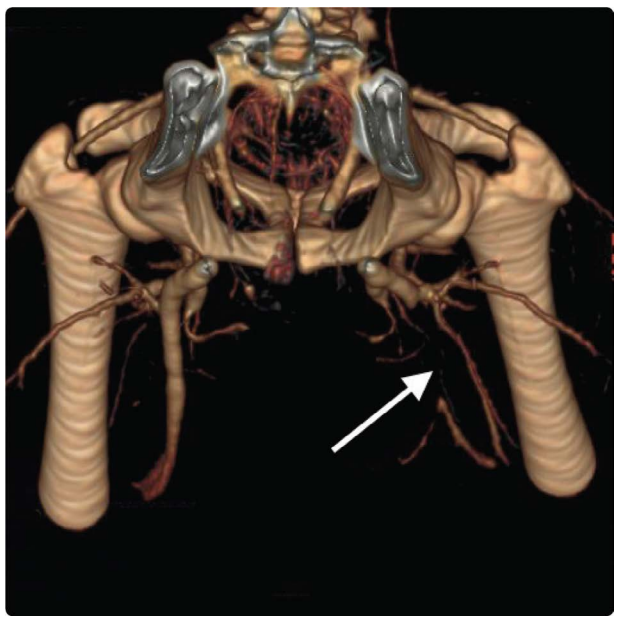

FIGURE 14.31 3D reconstructed CT scan of the pelvis and hindlimbs identifying a lack of vascular perfusion in the left femoral artery (arrow) secondary to an intravascular thrombus. (*Courtesy of Davies Veterinary Specialists.*)

Management

Initially, therapy involves management of the cardiac disease and supportive care.

Limiting the formation of further thrombi, controlling hypercoagulable states, and allowing normal thrombolysis to occur are the mainstay of current therapy for dogs and cats with aortic thrombosis or aortic thromboembolism. Medical management consists in treating the acute phase with:

1. Anticoagulants (e.g., unfractionated or low-molecular-weight heparins, warfarin, rivaroxaban, and apixaban). Rivaroxaban and apixaban are two of the newest group of anticoagulant medications, which include direct factor Xa inhibitors and direct thrombin inhibitors known as direct small molecule inhibitors.
2. Antithrombotics (e.g., clopidogrel, aspirin). Clopidogrel would be ideally recommended (2–4 mg/kg per day) due to evidence of improved platelet inhibition compared to aspirin, and clopidogrel administration has been associated with significantly reduced likelihood of recurrent arterial thromboembolism compared to aspirin with a longer median time to recurrence.
3. Thrombolysis (tissue plasminogen activator or TPA). Survival of TPA-treated cats was recently shown to be similar to those that just received pain medications and thromboprophylaxis. Complications are reportedly high in cats with administration of TPA, which include azotemia, cardiac arrhythmias, hyperkalemia, acidosis, and sudden death.
4. Heart failure therapy in cats when present.
5. Surgery can be considered to remove the thrombus if anesthesia can be administered.
6. Intense supportive and symptomatic therapy is warranted including pain relief.

The prognosis is guarded in dogs with 50%–60% survival to discharge and with 28% being alive at 100 days in one study. Ambulatory status and a chronic presentation are the only known positive predictors of outcome documented in dogs, with a median survival time of 293 days reported for dogs with a chronic progressive course. The prognosis for cats is typically poor, with 26%–66% of cats euthanized in the acute phase, a reported rate of survival to discharge of 0%–50%, and a 6-month recurrence rate of 45%–75%. Only 2% of 250 cats in one study survived over a year. Low rectal temperature, bradycardia, and multiple limb involvement have all been associated with decreased survival rate in cats.

TRAUMATIC DISEASES

FRACTURES AND LUXATIONS

Definition/Overview

Spinal fracture and luxation in dogs and cats are most commonly associated with severe external trauma, occurring in approximately 6% of cases as the cause of spinal cord dysfunction. The resulting clinical signs can vary from pain to paralysis with loss of nociception.

Etiology

Automobile-related injury is the most common cause of exogenous trauma to the spine.

Pathophysiology

The thoracolumbar junction is the most commonly injured site in dogs and cats. Fractures occur between T11 and L6 in 50%–60% of patients after blunt trauma. Fractures in the thoracic spine may have little displacement because of the protection provided by the ribs, ligamentous support, and epaxial musculature. Fractures and luxations of the thoracolumbar spine are often associated with other systemic injuries (e.g., pneumothorax, pulmonary contusions, orthopedic injuries, urogenital injuries, and diaphragmatic hernia). Approximately 20% of patients with thoracolumbar fractures have a second spinal column fracture. In the neck, the atlantoaxial junction is relatively unstable and, therefore, particularly at risk. The axis is the most commonly fractured cervical vertebra because it acts as a fulcrum between the caudal cervical spine and the so-called cervicocranium (the skull, atlas, dens, and body of the axis) (**Figure 14.32a–c**).

Primary mechanical injury to neural tissue can subsequently lead to secondary biochemical injury. The amount of neural tissue injury is related to the rapidity and severity of insult and the amount and duration of compression.

Clinical Presentation

The neurologic signs are determined by the level of any associated spinal cord damage. Schiff–Sherrington posture is a common finding associated with acute thoracolumbar injury but is not a prognostic indicator (**Figure 14.33**). Pain perception is carefully assessed in paraplegic animals to assist with determination of prognosis. Respiratory crises may be noted with acute cervical spinal cord injury.

Diagnosis

Results of the neurologic examination are used to determine neuroanatomic localization and severity of the spinal cord injury. It is important to perform the neurologic examination with care to prevent further injury and displacement of the spine. The neurologic examination findings are most important in establishing the prognosis, irrespective of radiographic findings. Plain radiography of the entire spine should be performed. Two views are used while minimizing patient movement by obtaining the ventrodorsal view using horizontal beam. Results of survey radiography are used to determine the precise lesion location(s) and extent, demonstrate multiple lesions, and guide appropriate management (**Figure 14.34**). Myelography or cross-sectional imaging is used when the radiographic findings do not

correlate with the neurologic examination, to evaluate spinal cord swelling in concussive injuries and further assess severity of spinal cord compression. CT or MRI is useful for further evaluating bone and spinal cord tissues, respectively, and provide a 3D configuration of the fracture/luxation extent for assessment of spinal stability (Figure 14.35a–d).

Management

The critical factor in determining whether conservative or surgical management of spinal fracture and luxation is appropriate depends on the presence of instability. Spinal stability is assessed using a three-compartment theory (Figure 14.36). Priority is placed on treatment of extraneural injuries, beginning with management of shock and hemorrhage. Management of an animal with spinal trauma focuses on the prevention of secondary injury to the spinal cord parenchyma. Indications for nonsurgical management include minimal neurologic deficits, minimal vertebral displacement, and lack of myelographic evidence of spinal cord compression. Principles of conservative management are appropriate confinement for 6–8 weeks and use of external coaptation. The aim of external support is to provide immobilization of the vertebral segments cranial and caudal to the damaged area. It is important to follow principles of bandage care when using methods of external support. The patient will need to be turned regularly and kept clean and dry to prevent urine scalding.

Surgical management often provides a better chance for more rapid and complete neurologic recovery.

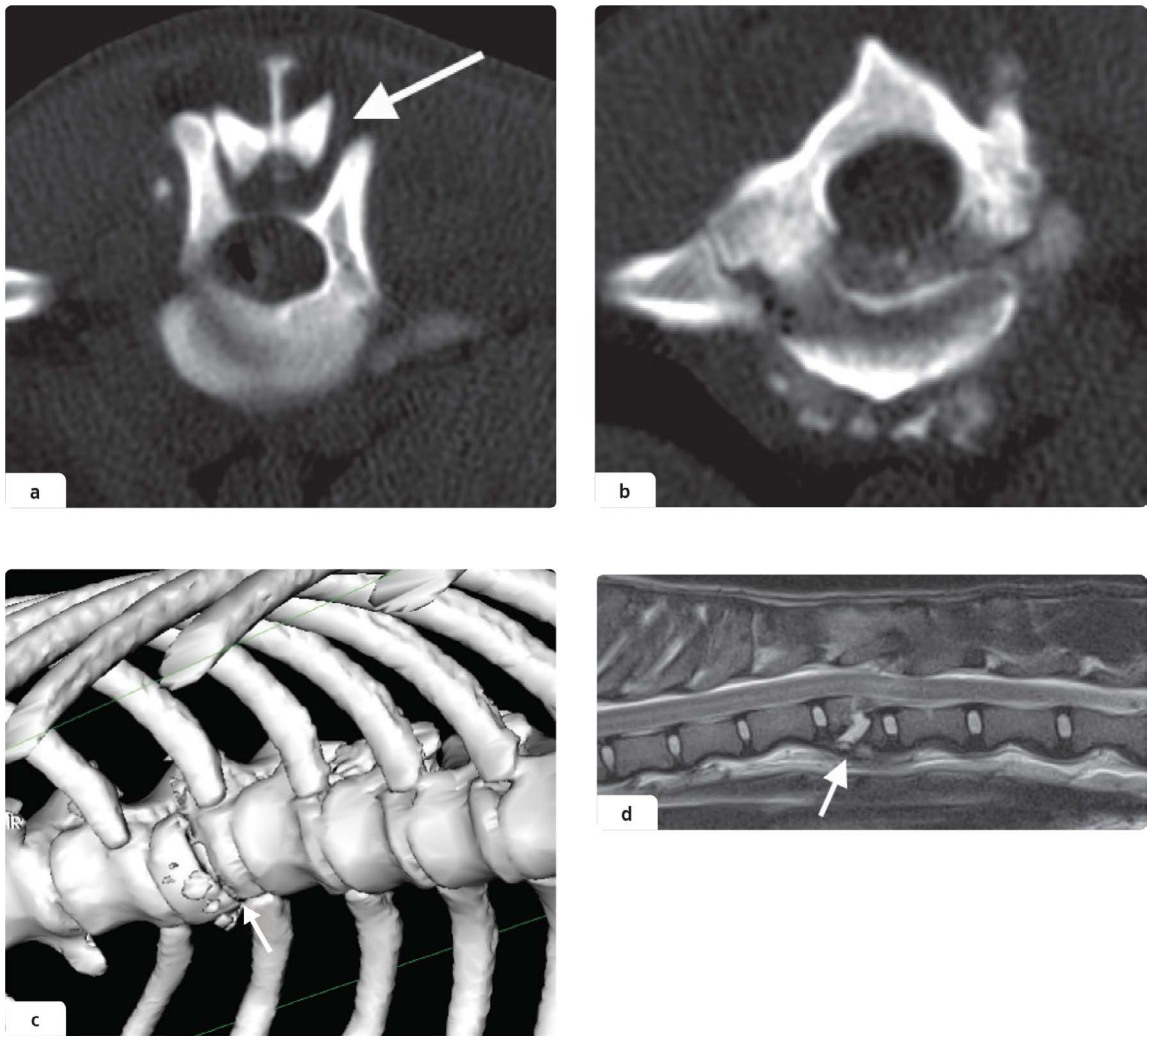

FIGURE 14.35 **(a)** Transverse T12 and T13 vertebral CT scan of the fracture depicted in **Figure 14.34**. Note the subluxation of the articular processes (arrow). **(b)** Transverse T12 vertebral body CT scan showing the fracture depicted in **Figure 14.34**. **(c)** 3D reconstructed CT scan of the thoracic vertebrae helps identify the ventral aspect of the T12 body fracture (arrow). **(d)** Sagittal T2-weighted MR image of the thoracic vertebrae is useful to visualize the effect of the T12 fracture (arrow) on the spinal cord.

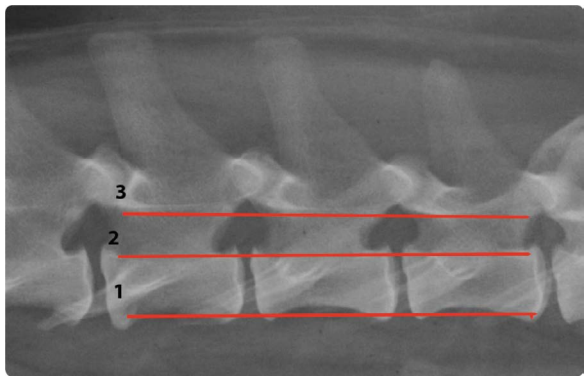

FIGURE 14.36 Three-compartment model of vertebral instability. Compartment one contains the ventral three-quarters of the vertebral body, the disc, and the ventral longitudinal ligament. The second compartment consists of the dorsal one-quarter of the vertebral body, the disc, and the dorsal longitudinal ligament. The third compartment includes the articular processes, lateral pedicles, dorsal laminae, interarcuate ligaments, and dorsal spinous processes.

However, the role of surgery for spinal trauma remains unclear. Indications include severe neurologic deficits and deteriorating neurologic status, imaging evidence of compression, and damage of two or more vertebral compartments. Timely surgical intervention is important to allow for maximal recovery. The objectives for surgical management of spinal trauma are decompression, realignment, and stabilization. The decompressive procedure should be conservative so as not to disrupt further the integrity of the vertebrae but large enough to allow for removal of compressive material. Successful outcome after surgical fixation depends on the type and strength of fixation, the surgeon's skill and knowledge of the spinal anatomy, and the accuracy of vertebral column alignment (**Figure 14.37**).

Careful attention to postoperative care is imperative for the wellbeing of the patient. Potential complications include urinary tract infections, decubital ulcers (**Figure 14.38a, b**), and implant failure. Physical rehabilitation is important in the recovery process.

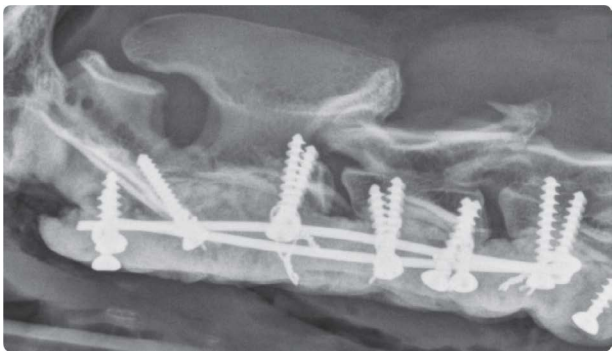

FIGURE 14.37 Lateral postspinal fixation radiograph of the dog with a C2 vertebral fracture illustrated in Figure 14.33.

Prognosis following vertebral fracture and luxation is largely dependent on the severity of neurological deficits. In the case of thoracolumbar spinal trauma, prognosis is considered poor in dogs presenting with paraplegia and absent deep pain perception. In one study, only 12% of dogs presenting with presenting with absent deep pain perception following thoracolumbar fracture/luxation recovered ambulation, and none regained deep pain perception regardless of surgical or medical management. As a result, careful consideration should be given to whether to go ahead with treatment in a dog or cat presenting with paraplegia absent deep pain perception following vertebral trauma. Referral or reassessment of deep pain perception after a short period (<24 hours) of supportive care and immobilization can be considered, at which point if deep pain perception is still absent, owners should be informed that functional recovery is unlikely to occur.

Although no prospective comparisons are available, outcome in dogs and cats with intact deep pain perception tends to be good with both surgical and medical management when the treatment option is selected according to individual patient factors. Retrospective studies suggest a 70%–95% recovery rate for medical management of vertebral fractures and luxation, suggesting a good outcome can be achieved in patients for which surgery is not deemed indicated.

While a similar functional recovery has been reported following cervical, thoracic, and lumbar vertebral fractures and luxation, surgical management of cervical fractures does appear to be associated with a higher risk of perioperative mortality, up to 36% in one study. This may reflect the need for ventilatory support in severely injured dogs with cervical fractures, particularly if the surgery is associated with further iatrogenic damage. Prompt identification and referral is recommended in cases of cervical vertebral trauma presenting with nonambulatory tetraparesis or tetraplegia.

BRACHIAL PLEXUS AVULSION

Definition/Overview

Traumatic injuries causing avulsion of the nerve roots of the brachial plexus are the most common cause of acute forelimb monoparesis or monoplegia in small animals.

Etiology

These injuries are usually a result of abduction and simultaneous caudal displacement of the forelimbs caused by road traffic accidents or falls from a height.

Pathophysiology

The site of root avulsion is usually intradural where the nerve roots arise from the spinal cord. At this point, nerve roots lack a well-defined perineurium and constitute the weakest structure between the spinal cord and the peripheral nervous system. If the avulsion is severe enough, it may place traction over the spinal cord and damage spinal cord pathways, causing ipsilateral hindlimb neurologic deficits. Both dorsal and ventral nerve roots can be affected, but the motor roots appear to be more susceptible to this type of trauma.

Clinical Presentation

Signs are peracute in onset following the traumatic incident. Depending on which nerve roots are affected, avulsions are divided into three types:

- Cranial avulsions (C6–C7 nerve roots)
- Caudal avulsions (C8–T2 nerve roots)
- Complete avulsions (C6–T2 nerve roots)

Cranial avulsions are rare and result in few clinical signs. The elbow extensor muscles are not affected, so the animal can bear weight on the affected limb. There is loss of shoulder movement and elbow flexion, and atrophy of supraspinatus and infraspinatus muscles usually develops.

Caudal and complete avulsions are more common and cause more severe clinical signs. They both cause paralysis of the triceps brachii muscle, so the animal cannot extend the elbow or bear weight on the affected limb. Affected animals drag the limb knuckled over (Figure 14.39). Forelimb muscles are hypotonic, and severe neurogenic atrophy starts about 1 week after the injury. Spinal reflexes and postural reactions are reduced. If the elbow flexor muscles are spared (caudal avulsions), the animal can carry the limb flexed at this level, avoiding contact with the floor.

Sensory signs are also common. The pattern of decreased or absent sensation in the affected limb allows better determination of the type of avulsion. Cutaneous sensation should be checked in the entire limb, but particular attention should be paid to nociception in the medial (radial and musculocutaneous) and lateral (radial and ulnar) digits, since it is essential in determining a prognosis.

FIGURE 14.39 Forelimb monoplegia and moderate proximal limb muscle atrophy are evident in this dog with a right-sided brachial plexus avulsion following a traumatic insult.

A high percentage of patients with brachial plexus avulsions show partial Horner's syndrome and/or loss of cutaneous trunci reflex ipsilateral to the side of the avulsion. Avulsion of the T1 ventral nerve root causes injury to the preganglionic sympathetic nerve fibers to the eye, causing ipsilateral miosis (partial Horner's syndrome). Loss of the cutaneous trunci reflex is caused by damage to the C8–T1 ventral spinal nerve roots that form the lateral thoracic nerve and innervate the cutaneous trunci muscle. The contralateral reflex is usually present after ipsilateral stimulation.

Diagnosis

A history of forelimb monoparesis after a traumatic incident should raise a high suspicion of brachial plexus avulsion. Every animal unable to use one forelimb after trauma should be examined carefully to detect orthopedic as well as neurologic abnormalities. MRI of the affected plexus may provide information on the degree of nerve and associated soft tissue trauma. Electromyography allows detection of spontaneous electrical activity in the denervated muscles 7–10 days after the injury. Nerve conduction velocity studies of the radial and ulnar nerves allow determination of the degree of injury. Since the radial nerve is commonly injured in brachial plexus avulsions, serial electrodiagnostic evaluations of this nerve may provide useful diagnostic and prognostic information.

Management

Unfortunately, there is no routinely effective treatment for this type of injury. The degree of recovery depends only on the severity of the nerve lesion at the time of injury.

If nociception is present in the medial and lateral digits, prognosis for recovery is good, and aggressive physiotherapy should be recommended to the owner. If nociception is absent, prognosis will depend on the severity of the axonal injury, being good for neurapraxic lesions but guarded to poor for axonotmetic (nerve injury to axon while sparing the myelin) and neurotmetic (disruption of axon, myelin sheaths, and connective tissue) lesions. Pure axonotmesis occurs rarely, so the potential for recovery, although present, is low and prognosis poor.

When the proximal branches of the radial and musculocutaneous nerves are spared so that the elbow flexor and extensor muscles are not denervated, corrective surgery can be used to provide carpal extension and prevent the distal part of the limb from collapsing. Tendon transplantation or carpal arthrodesis procedures can be performed.

Animals with caudal and complete brachial plexus avulsions have a poor-to-guarded prognosis if neurotmesis has occurred. Only those with neurapraxic

(temporary loss of sensory and motor function due to nerve injury) injuries show improvement and recover completely. However, most animals do not improve but go on to show severe limb atrophy, eventually developing serious complications such as trophic ulcers, joint contractures or self-mutilations from paresthesia, or abnormal sensation in the affected areas produced by regeneration of sensory nerves. In these cases, amputation of the limb is necessary. The best predictor of complete recovery seems to be nociception. Preservation of nociception is an indicator of a milder type of injury and should prompt the clinician to recommend supportive therapy while waiting for motor function to recover. However, if no improvement is seen during the first 2 months, recovery is unlikely to occur.

DEGENERATIVE DISEASES

DEGENERATIVE MYELOPATHY

Definition/Overview

Degenerative myelopathy (DM) is a slowly progressive nonpainful paresis and ataxia usually affecting large-breed dogs (especially the German Shepherd Dog).

Etiology

For many years the etiology of DM remained unknown. A mutation in the superoxide dismutase 1 (SOD1) gene is now associated with this disease.

Pathophysiology

The uniformity of clinical signs, histopathology, age, and breed predilections suggested an inherited basis for DM. Segregation of DM in families has been reported in the Siberian Husky, Pembroke Welsh Corgi, and Chesapeake Bay Retriever. Dogs testing homozygous for the mutation are at risk for developing DM. Some dogs are homozygous for the mutation but remain free of clinical signs, which suggests age-related incomplete penetrance. A different SOD1 mutation has been discovered in the Bernese Mountain dog; therefore, currently available DNA tests cannot be used to rule out a diagnosis of DM. Other sequence variants in the same gene or in a different gene might produce a similar disease phenotype. A progressive degeneration of the spinal cord, predominantly in the T3–L3 region, is responsible for the clinical signs.

Clinical Presentation

Dogs with DM show an insidious, progressive ataxia and paresis of the hindlimbs, ultimately leading to paraplegia and euthanasia. If hindlimb hyporeflexia is observed, reflecting nerve root involvement, the disease is sometimes termed canine degenerative radiculomyelopathy. Although the German Shepherd Dog is the most commonly affected breed, DM has been reported in many other pure and mixed breeds. There is no sex predilection. In most breeds, the mean age of onset of neurologic signs is 9 years.

Progressive, asymmetric UMN paraparesis, hindlimb ataxia, and lack of paraspinal hyperesthesia are key clinical features of DM. The clinical course of DM can vary after the presumptive diagnosis. Pet owners usually elect euthanasia when dogs can no longer support weight in their hindlimbs and need walking assistance (Figure 14.40a, b). Smaller breed dogs can be cared for by the pet owner over a longer time. The median disease duration in the Pembroke Welsh Corgi is 19 months. As a result of a longer survival time, affected Pembroke Welsh Corgis often have signs of forelimb paresis at the time of euthanasia. The earliest clinical signs of DM are general proprioceptive ataxia

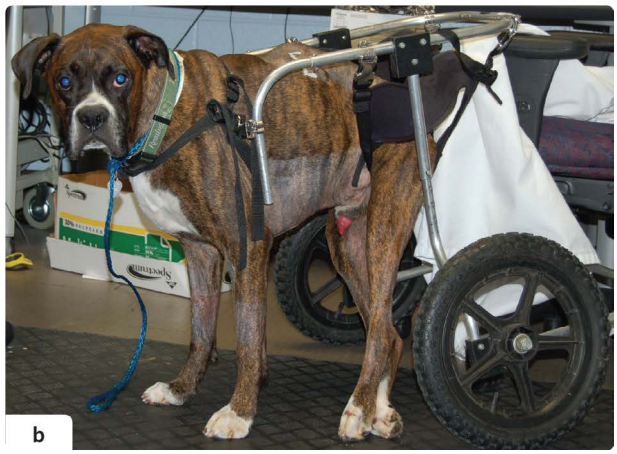

FIGURE 14.40 (a) A 9-year-old German Shepherd Dog with degenerative myelopathy demonstrates profound weakness of the hindlimbs. **(b)** Severe motor dysfunction of the hindlimbs can be assisted with the use of canine support carts, as shown in this photo.

and mild paresis in the hindlimbs. Worn nails and asymmetric hindlimb weakness are apparent on physical examination. Asymmetry of signs at disease onset is frequently reported. At disease onset, spinal reflex abnormalities are consistent with UMN paresis localized in the T3–L3 spinal cord segments. Patellar reflexes may be normal or exaggerated; however, hyporeflexia of the patellar reflex has also been described in dogs at a similar disease stage. Flexor reflexes may also be normal or show crossed extension (suggestive of chronic UMN dysfunction). Most large-breed dogs progress to nonambulatory paraparesis within 6–9 months from onset of clinical signs and are euthanized during this disease stage. If the dog is not euthanized early, clinical signs will progress to LMN paraplegia and ascend to affect the forelimbs. Flaccid tetraplegia ultimately occurs in dogs with advanced disease. The paresis becomes more symmetrical as the disease progresses. LMN signs emerge as hyporeflexia of the patellar and withdrawal reflexes, flaccid paralysis, and widespread muscle atrophy beginning in the hindlimbs as the dogs become nonambulatory. Widespread and severe loss of muscle mass occurs in the appendicular muscles in the late stage of DM.

Diagnosis

Tentative antemortem diagnosis is presently based on ruling out other diseases causing progressive myelopathy. Common differentials include intervertebral disc disease (IVDD), inflammatory disease, and spinal cord neoplasia. Hip dysplasia and degenerative lumbosacral stenosis often can be confused with the diagnosis of DM, although the neurologic findings are different if a careful examination is performed. It is not uncommon for DM affected dogs to have coexisting neurological and orthopedic diseases. Diagnostic testing is typically performed in the early disease stage. The lack of abnormal findings of electrodiagnostic testing and myelography or cross-sectional imaging (MRI, CT), along with characteristic disease pattern for progression of neurologic signs, support a presumptive diagnosis of DM. Definitive diagnosis of DM is determined postmortem by histopathologic examination of the spinal cord. A blood test is available to identify SOD1 mutations, but the results can only suggest the disease or help rule it out rather than confirm it.

Management

Treatment regimens have been empiric, with lack of evidence-based medicine approaches. Moreover, there exists no prophylactic or curative treatment for human DM. Aminocaproic acid, an antiprotease agent, has been advocated for long-term management of DM; however, there have been no published clinical data to support drug efficacy. While treatment of vitamin deficiencies can resolve neurologic disease in some animals, therapy with parenteral cyanocobalamin or oral alpha-tocopherol did not affect neurologic progression in a study of DM affected dogs. Physical rehabilitation regimens have been advocated for management of DM. Overall, long-term prognosis is considered poor.

HANSEN TYPE 1 INTERVERTEBRAL DISC DISEASE

See also Chapter 15, Musculoskeletal Disorders.

Definition/Overview

Herniation of degenerate nucleus pulposus can result in sudden onset of clinical signs, ranging from spinal pain to the loss of motor function and pain sensation. This is most common in the thoracolumbar spinal column but can affect the cervical spinal cord as well. While most reports in the veterinary literature relate to dogs, intervertebral disc extrusions are also reported in cats.

Etiology

Herniation of the nucleus pulposus through the annulus of the disc and extrusion of nuclear material into the spinal canal, resulting in concussion of the spinal cord and concurrent compression.

Pathophysiology

Hansen type 1 IVDD is herniation of the nucleus pulposus through the annular fibers and extrusion of nuclear material into the spinal canal. The condition is typically associated with chondroid disc degeneration. The disc extrudes through the dorsal annulus, causing ventral, ventrolateral, or circumferential compression of the spinal cord. Acute disc extrusion is characterized by the presence of soft disc material within the vertebral canal and extradural hemorrhage. Chronic disc extrusion is characterized by extradural fibrous adhesions around the herniated disc material, which has often become a hard mineralized mass. Hansen type 1 IVDD typically affects chondrodystrophic breeds and has an acute onset. However, large nonchondrodystrophic breeds of dog such as the Dobermann and Labrador Retriever may also be affected. The Dachshund has the highest incidence, but other frequently affected breeds include the French Bulldog, Pekingese, Welsh Corgi, Beagle, Lhasa Apso, and Miniature Poodle. In Dachshunds, severe disc degeneration denoted by presence of mineralization on spinal radiography is highly heritable. Genetic investigations have recently identified an FGF4 retrogene insertion on chromosome 12 associated with the development of Hansen type 1 intervertebral disc extrusions and chondrodystrophy across several dog breeds.

Hansen type 1 IVDD most commonly occurs within the thoracolumbar region of chondrodystrophic breeds. The thoracolumbar junction (T12–T13 to L1–L2) accounts for the highest incidence of all disc lesions. The incidence of thoracolumbar IVDD progressively decreases from T12–T13 caudally. The most common site for Hansen type 1 IVDD in large, nonchondrodystrophic breeds is the interspace between L1 and L2.

FIGURE 14.41 An arched back (kyphosis) is often indicative of thoracolumbar pain.

Clinical Presentation

Onset of neurologic signs may be peracute (<1 hour), acute (<24 hours), or gradual (>24 hours). Dogs presented with peracute or acute thoracolumbar disc extrusions may manifest clinical signs of spinal shock or Schiff–Sherrington postures. These indicate acute and severe spinal cord injury but do not determine prognosis. The degree of neurologic dysfunction is variable and affects prognosis. Clinical signs vary from spinal hyperesthesia only to paraplegia with or without nociception. Dogs with pain only are usually reluctant to walk and may show kyphosis (Figure 14.41); these dogs often have myelographic, CT, and MRI evidence of substantial spinal cord compression. Dogs with paraplegia and lack of nociception usually have undergone acute and severe disc extrusions (Figure 14.42).

Diagnosis

The initial diagnosis of IVDD is obtained from the signalment, history, and neurologic examination. Differential diagnoses to be considered include trauma, fibrocartilaginous embolism, discospondylitis, neoplasia, and meningomyelitis. Diagnosis of thoracolumbar

FIGURE 14.42 Typical posture adopted by dogs with paraplegia.

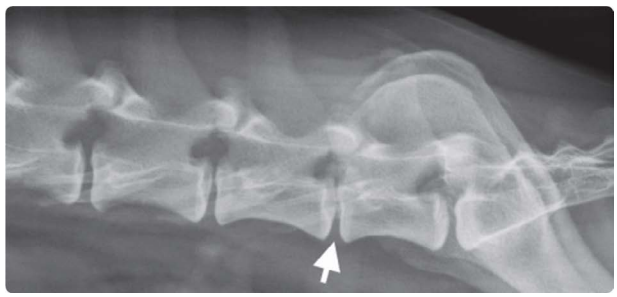

FIGURE 14.43 The radiographic characteristics of intervertebral disc disease are highlighted in this radiograph at L6–L7 (arrow).

disc extrusion and/or protrusion is confirmed by cross-sectional imaging and surgery.

Survey spinal radiography can help to determine the diagnosis and site of a thoracolumbar disc extrusion if radiographic signs are well defined and consistent with neuroanatomic localization. Radiographic findings signifying suspected IVD extrusion include the following (Figure 14.43):

- Narrowing of the IVD space
- Wedging of the disc space
- Narrowing of the intervertebral foramen
- Mineralized material in the spinal canal or superimposed over the intervertebral foramen

As survey radiographs identify the correct site of disc extrusion in only about 70% of cases, further imaging, such as myelography or cross-sectional imaging (CT, MRI), is strongly recommended prior to surgery.

CT or MRI is used alone or as an adjunct to myelography to delineate lateralization of extruded disc material and lesion extent. CT alone has been shown to be more accurate than myelography at identifying the major site of disc herniation and has the advantage of being a more rapid test with fewer side effects than myelography. Mineralized disc material and acute hemorrhage can be identified in the vertebral canal using noncontrast-enhanced CT (Figure 14.44). Acutely extruded disc material typically is recognized as a heterogeneous hyperattenuating extradural mass. The attenuation of the disc material increases with the degree of mineralization. Chronically extruded disc material has a more homogeneous hyperattenuating appearance.

MRI provides a more sensitive technique in recognition of spinal cord pathology (e.g., edema and hemorrhage) and 3D delineation of the spinal cord compression, allowing for an accurate surgical approach and determining the extent of surgical decompression required. MRI is considered the best method for early recognition of in situ disc degeneration and for determining localization and extent of extruded disc material within the epidural space (Figure 14.45). MRI may have diagnostic value in detecting myelomalacia. Findings from a recent study in dogs with IVD extrusion and lack of nociception suggested that an area of hyperintensity >7 times the length of L2 on T2-weighted

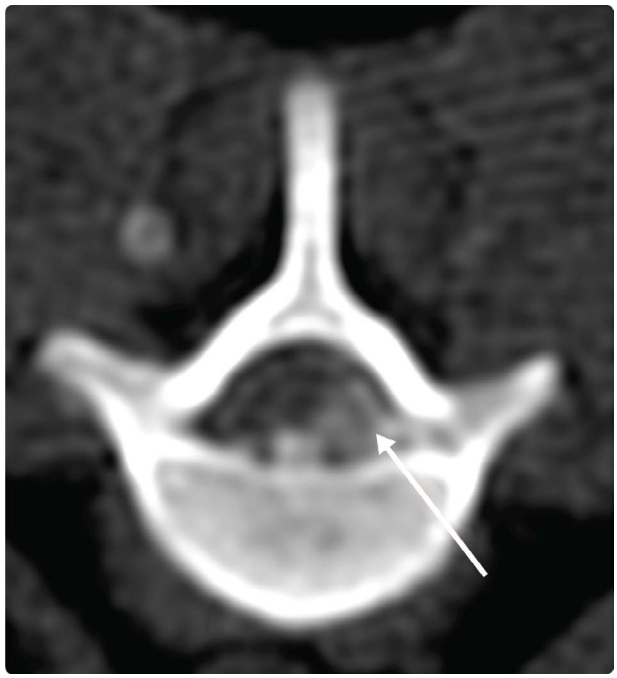

FIGURE 14.44 Transverse CT scan of the lumbar spinal column at the site of an acute mineralized intervertebral disc extrusion (arrow).

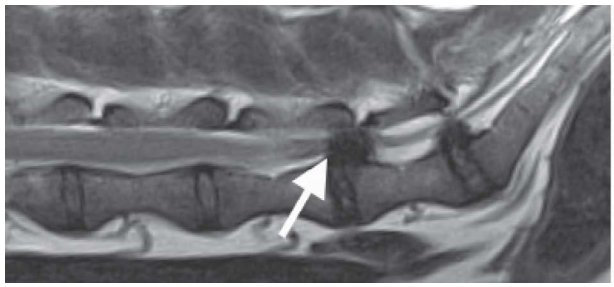

FIGURE 14.45 Sagittal T2-weighted MR image of the lumbar spine of the dog in **Figure 14.43**. An acute mineralized disc extrusion (arrow) is seen to compress neural tissue at L6/7.

sagittal images may allow for a presumptive diagnosis of myelomalacia.

Management

Indications for nonsurgical treatment of thoracolumbar IVDD include a first-time incident of spinal pain only, mild-to-moderate paraparesis, and the financial constraints of the client. The last is the only reason for nonsurgical treatment of a recumbent patient, which should always be considered a surgical candidate, if possible. Dogs can be managed with strict cage rest for 4–6 weeks combined with pain relief using anti-inflammatory drugs, opioids, and muscle relaxants. GI protectants also may be necessary with use of anti-inflammatory therapies. Never use NSAIDs in combination with corticosteroids, as gastric ulcers can result, and in some cases, these may lead to the death of the animal. Acupuncture also has been advocated as a treatment for pain management. Dogs should be monitored closely for deterioration of neurologic status. If pain persists or the neurologic status worsens, surgical management is recommended. Studies have shown that recovery rates in nonambulatory dogs are lower and recurrence rates higher following conservative rather than surgical treatment. Success rates for conservative management of ambulatory dogs with pain only or mild paresis range from 82% to 100%. More recent retrospective studies of conservatively managed dogs with thoracolumbar disc disease documented 30%–50% recurrence rates in dogs with minimally affected ambulatory status. Recurrence of spinal pain in dogs with thoracolumbar IVDD that are conservatively managed usually occurs within 6 months to 1 year from onset of the initial clinical signs. Methylprednisolone sodium succinate is not recommended for the treatment of this disease due to the lack of demonstrated efficacy and the side effects.

Indications for surgical management of thoracolumbar IVDD include spinal pain or paresis unresponsive to medical therapy, recurrence or progression of clinical signs, nonambulatory paraparesis or paraplegia with intact nociception, and paraplegia without nociception for <24–48 hours. Prolonged loss of nociception (>48 hours) carries a poor prognosis, and owners should be made aware of this prior to surgery. However, it is often difficult to know when nociception was lost; in addition, recovery has been observed in dogs that had surgery >5 days after the onset of paraplegia. There is currently no consensus regarding the impact of the duration of signs prior to treatment on outcome in dogs with thoracolumbar intervertebral disc extrusion, with variable findings among several studies. However, there is some recent evidence to suggest that an interval of >12 hours between onset of nonambulatory status and surgery might increase the risk of progressive myelomalacia in paraplegic dogs with absent deep pain perception. It has also been suggested that an overnight delay to performing decompressive surgery could increase the risk of clinically meaningful deterioration in nonambulatory dogs with thoracolumbar intervertebral disc extrusion. As a result, while even deep pain perception negative dogs can recover following a delay of >48 hours after losing ambulatory function, it is reasonable to suggest that prompt intervention should be sought in severely affected (nonambulatory) patients and that unnecessary delays should be avoided.

Surgery includes spinal cord decompression by removal of extruded disc material. Chronicity of disc extrusion at the time of surgery may influence the ease with which extruded disc material can be removed.

HYDRATED NUCLEUS PULPOSUS EXTRUSION (HNPE)

Definition/Overview

Included in the degenerative disease category due to the variable degree of degenerative change associated with the affected intervertebral disc, hydrated nucleus

pulposus extrusion (HNPE) is a relatively recent addition to the list of terms used to describe forms of intervertebral disc disease in dogs. To reflect the characteristic clinical and diagnostic imaging features of the condition, this condition is also sometimes referred to as "acute compressive HNPE."

Etiology

Acute compressive HNPE is associated with the presence of well-hydrated nucleus pulposus material in the vertebral canal, leading to a variable degree of spinal cord compression.

Pathophysiology

The underlying pathophysiology leading to the extrusion is not fully understood but differs from Hansen type 1 intervertebral disc extrusion in that the extruded material is typically only minimally to nondegenerated. It is possible that a small tear in the annulus fibrosus occurs acutely following sudden biomechanical changes, with a resulting extrusion of hydrated nuclear material into the vertebral canal ventral to the spinal cord. In contrast to acute noncompressive nucleus pulposus extrusion (ANNPE), the hydrated material then remains in the vertebral canal of sufficient volume to cause spinal cord compression.

Clinical Presentation

The vast majority of reported cases of HNPE occur in the cervical region (although it can also affect the thoracolumbar region), resulting in a characteristic clinical presentation of acute-onset tetraparesis or tetraplegia. The acute onset typically occurs spontaneously without an inciting traumatic event or exercise and is followed by a short period of progression over 24–48 hours in most cases. HNPE is most often associated with symmetrical neurological deficits, as opposed to the lateralization typically seen with ANNPE or ischemic myelopathies such as FCEM. In contrast to Hansen type 1 intervertebral disc extrusion, cervical HNPE typically presents without evidence spinal hyperesthesia but with more severe neurological deficits, leading to tetraplegia with reduced ventilation in some cases. HNPE is predominantly seen in middle-aged or older dogs without any specific breed predispositions, affecting both chondrodystrophic and nonchondrodystrophic breeds.

Diagnosis

The characteristic clinical presentation of an acute onset, symmetrical, nonpainful myelopathy localized to the cervical region (C1–C5 or C6–T2 spinal cord segments), with a short progressive phase, allows a high index of suspicion for a presumptive diagnosis of HNPE. However, advanced imaging is required to confirm the diagnosis and exclude differential diagnoses such as Hansen type 1 intervertebral disc extrusion, ANNPE, and fibrocartilaginous embolic myelopathy (FCEM). The diagnostic imaging modality of choice for diagnosing HNPE is MRI (Figure 14.46), with the following characteristic features reported:

- Ventral, midline extradural material overlying an intervertebral disc, with features of hydration (T2-weighted hyperintense, T1-weighted hypointense)
- A characteristic bilobed, or "seagull" shaped appearance to the extradural material
- Spinal cord compression at this level, with or without an adjacent focal intramedullary T2-weighted hyperintensity
- The affected intervertebral disc is narrowed with a reduced volume of T2-weighted hyperintense nucleus pulposus signal

Although a diagnosis of HNPE is typically made using these MRI features, a recent study has suggested

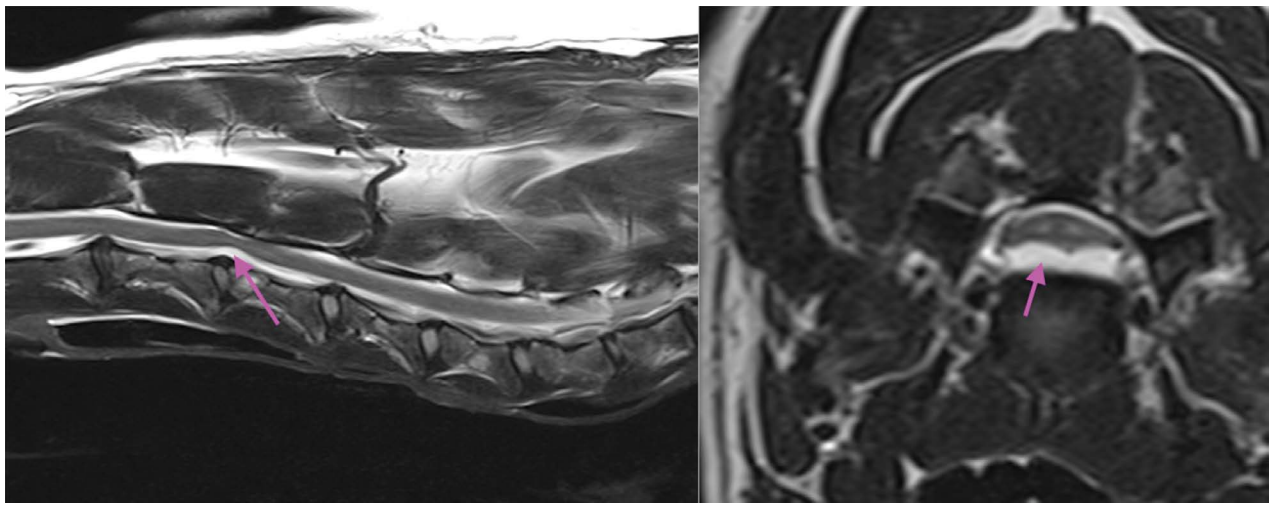

FIGURE 14.46 A T2W sagittal (left) and transverse (right) image of the cervical spinal cord of a dog with a peracute onset of tetraparesis. There is a ventral, midline extradural mass overlying the C3–C4 disc space with features of hydration (T2-weighted hyperintensity) which exhibits the characteristic bilobed, or "seagull" shaped appearance (arrow on right) of HNPE.

that contrast-enhanced CT is also a feasible means of reaching a diagnosis with a sensitivity of 91% and specificity of 100% reported. In that study, HNPE was characterized by the presence of compressive extradural hypodense material immediately dorsal to an intervertebral disc, with rim enhancement and narrowing of the affected disc.

Management

Both medical and surgical management options are described for HNPE in dogs. Recovery is typically rapid and complete regardless of treatment modality, with the majority of dogs returning to ambulatory function within 1 week. Unsuccessful outcomes are rare and typically involve complications in dogs presenting with tetraplegia and compromised ventilatory function. However, it should also be noted that recovery of ambulation has been reported even in these most severely affected dogs following surgery.

Medical management usually consists of restricted exercise in combination with appropriate nursing care, physical therapy, and rehabilitation according to the severity of neurological dysfunction. Dogs presenting with tetraplegia should be assessed for reduced respiratory function as they may require mechanical ventilation. Although typically a nonpainful condition, appropriate analgesia should be administered according to examination findings.

Surgical treatment typically involves performing a decompressive ventral slot procedure of the affected intervertebral disc. Although surgical management has often been recommended for cases with severe signs and obvious spinal cord compression, a recent retrospective study did not find a difference in outcome between dogs managed medically or surgically for cervical HNPE. However, since most unsuccessful outcomes or deaths following cervical HNPE have involved tetraplegic dogs with reduced respiratory function, it is possible that these most severely affected patients may benefit from surgical management.

ACUTE NONCOMPRESSIVE NUCLEUS PULPOSUS EXTRUSION

Definition/Overview

Various terms have been used to describe this type of intervertebral disc herniation, including high-velocity, low-volume disc extrusion; traumatic intervertebral disc extrusion; intervertebral disc explosion; missile discs; and Hansen type 3 intervertebral disc disease. Over time, most of these terms have fallen out of favor, and given that Hansen classification system did not describe a type 3, the use of Hansen type 3 in particular for this purpose has been discouraged. Most reports of this condition describe a peracute extrusion of nondegenerated (hydrated) nucleus pulposus that results in spinal cord contusion with minimal compression, typically occurring at exercise with or without external trauma. Based on these characteristics, the term acute noncompressive nucleus pulposus extrusion (ANNPE) has become widely adopted in the veterinary literature as the most appropriate and descriptive terminology for this condition in dogs and cats.

Etiology

A peracute extrusion of nondegenerated (hydrated) nucleus pulposus that results in spinal cord contusion with minimal compression, typically occurring at exercise with or without external trauma.

Pathophysiology

The normal (nondegenerated) intervertebral disc is comprised of a well-hydrated, gelatinous nucleus pulposus, surrounded by a dense, fibrous annulus fibrosus. As a result of the lamellar structure of the annulus fibrosus, the annulus fibrosus provides strength as well as mobility to the vertebral column. However, when the intervertebral disc is subjected to supraphysiological forces during moments of brief exertion (e.g., running, twisting, jumping to catch a ball) or external forces (e.g., blunt trauma), the annulus can suddenly rupture. In the nondegenerated disc, this can lead to a sudden extrusion of a relatively small volume of nuclear material at great force, which then impacts the spinal cord causing a primarily contusive injury. As a result of the well-hydrated nature of the extruded material, it can then dissipate and be resorbed, leaving minimal to no spinal cord compression. In some cases, the material can even penetrate the dura, recently referred to as an intradural/intramedullary intervertebral disc extrusion. Given the typically nonsurgical nature of the condition and good prognosis in most cases, histopathological descriptions of ANNPE are rare. However, postmortem findings in similar cases have historically revealed tears in the dorsal annulus fibrosus of affected dogs, with evidence of nondegenerated nucleus pulposus material present in the vertebral canal.

Clinical Presentation

In dogs, ANNPE typically presents with a very characteristic peracute onset myelopathy (ranging from ataxia and paresis to plegia of the limbs distal to the lesion) occurring during strenuous exercise or associated with external trauma (in which case it is sometimes referred to as traumatic intervertebral disc extrusion). Clinical signs are usually nonprogressive after the first 24 hours and often quite markedly lateralized, with asymmetrical deficits reported in up to 90% of dogs with ANNPE. Another characteristic feature associated with ANNPE is spontaneous vocalization at the onset of signs, which is often described in dogs, although clinical examination usually reveals only mild to no spinal hyperesthesia on palpation. The thoracolumbar junction is the most commonly affected region of the vertebral column, as seen with Hansen type 1 intervertebral disc extrusions,

although ANNPE can also occur in the cervical region. When ANNPE occurs in the thoracolumbar region, the peracute onset myelopathy may be associated with a Schiff–Sherrington posture, as well as signs of spinal shock in the affected limb(s). Although these signs do not have prognostic significance, they must be recognized on examination to ensure an accurate neuroanatomical localization. For example, reduced withdrawal reflex and limb tone in the affected limb(s), in the presence of an intact patella reflex, perineal reflex, and thoracolumbar cutaneous trunci cutoff, suggests a lesion affecting T3–L3 spinal cord segments with associated spinal shock. Based on this characteristic clinical presentation, important differential diagnoses for ANNPE in dogs and cats include other peracute lesions such as an ischemic myelopathy (e.g., fibrocartilaginous embolic myelopathy, FCEM) or vertebral fracture/luxation where there is a history of external trauma.

Although there are fewer descriptions of feline ANNPE in the literature, more cats have been reported to present with symmetrical clinical signs compared to dogs, and up to 75% of cats with ANNPE present following external trauma.

Diagnosis

Based on the particularly characteristic clinical presentation, a high index of clinical suspicion for ANNPE can typically be reached prior to performing diagnostic tests. The main differential diagnosis in dogs and cats with a peracute onset, nonprogressive, minimally painful (after initial onset), lateralized signs of spinal cord dysfunction is an ischemic myelopathy (typically caused by an FCE in dogs). If there is a history of trauma, vertebral fractures and luxations should be excluded as a priority. Plain spinal radiographs can be used as an initial step in such cases and may also reveal a narrowed intervertebral disc space, which can be seen with ANNPE. In cases where there remains a clinical index of suspicion for trauma despite unremarkable radiographs, advanced imaging such as CT should be considered to fully exclude fractures or luxations.

In order to make a more specific diagnosis, spinal MRI is typically required which can be used to differentiate between ANNPE and ischemic myelopathy using reported imaging criteria. The MRI features that can be used to make a diagnosis of ANNPE are outlined and demonstrated in Figure 14.47.

- Focal intramedullary T2-weighted hyperintensity of the spinal cord
- Spinal cord lesion located overlying an IVD
- Reduced volume of T2-weighted hyperintense nucleus pulposus signal in the affected IVD
- Mild narrowing of the affected IVD in midsagittal view
- Small volume extradural material (T2-weighted hyperintense, T1-weighted hypointense) dorsal to the IVD with minimal to no spinal cord compression

Management

As there is no significant spinal cord compression associated with ANNPE, treatment is focused on supportive medical management in order to aid functional recovery from the primarily contusive injury, and to minimize complications. Although there are currently no treatments with documented benefit in the management of secondary spinal cord injury in dogs, it is important to ensure that adequate systemic blood pressure and oxygenation are maintained to optimize spinal cord perfusion in cases with a concurrent history of trauma, for example. As around half of dogs with ANNPE present with spinal hyperesthesia on examination, nonsteroidal anti-inflammatory or opioid analgesia may be indicated. The mainstay of subsequent medical management involves supportive nursing care for recumbent patients (regular bladder expression if required, monitoring for skin abrasions and urine scald, nutritional support),

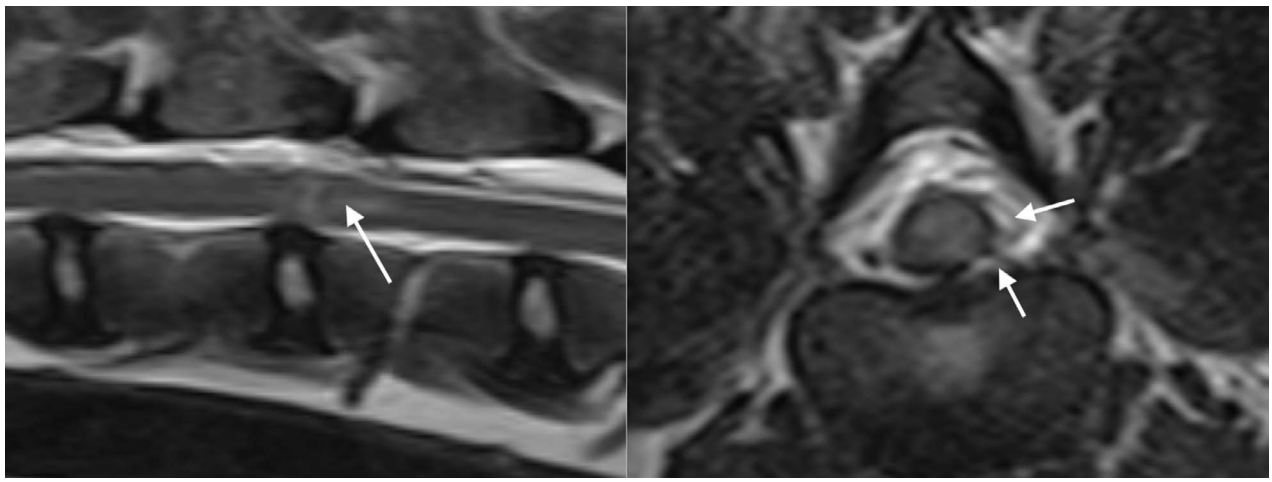

FIGURE 14.47 A T2W sagittal (left) and transverse (right) image of the thoracolumbar spinal cord of a dog with a peracute onset of paralysis due to an ANNPE. There is a focal intramedullary spinal cord T2-weighted hyperintensity overlying the L2–L3 disc space. The nucleus pulposus signal at this site has a reduced volume, and there is a small volume of extradural material around the cord (arrows on right) with minimal to no associated compression.

and physical therapy adapted according to the severity of associated neurological deficits.

As with other causes of acute spinal cord injury, outcome following ANNPE is largely dependent of the severity of neurological dysfunction on examination. While most dogs will return to ambulatory function, those presenting monoplegic, paraplegic, or tetraplegic will often retain gait abnormalities in the long term. Dogs that are paraplegic with absent deep pain perception due to ANNPE have a guarded prognosis, with few examples of recovery of ambulation in such dogs reported. Diagnostic imaging findings may also provide some prognostic information, with an increased intramedullary lesion size on MRI suggested to be associated with a poorer functional outcome. Variable degrees of urinary and fecal incontinence are also reported following thoracolumbar ANNPE, mainly in more severely affected dogs, with long-term urinary and fecal incontinence seen in 18% and 54% of paraplegic dogs with intact deep pain perception, respectively, in one study. Both severity of signs (paraplegia with or without deep pain perception) and MRI lesion size (>40% of spinal cord transverse cross-sectional area) were found to be associated with the subsequent development of long-term urinary and fecal incontinence.

Although there is limited number of cases in the literature on which to evaluate outcome following ANNPE in cats, a return to ambulatory function and continence was seen in most cases in a recent case series.

HANSEN TYPE 2 INTERVERTEBRAL DISC DISEASE

Definition/Overview

Herniation of the annulus fibrosus can result in slow, progressive clinical signs ranging from intermittent spinal pain through ataxia and paresis to the loss of motor function in the later stages. This is most common in the thoracolumbar spinal column but can affect the cervical and lumbosacral spinal cord as well, where it can be accompanied by degenerative changes of the vertebrae, creating a more dynamic/position-associated disease. (See Cervical Spondylomyelopathy and Degenerative Lumbosacral Syndrome.)

Etiology

Herniation of the annulus of the disc (protrusion) into the spinal canal resulting in spinal cord compression.

Pathophysiology

Hansen type 2 IVDD is annular protrusion caused by shifting of central nuclear material and is commonly associated with fibroid disc degeneration. The annulus fibrosus slowly protrudes into the spinal canal to cause spinal cord compression. The chronic compression can lead to focal ischemia and other microvascular derangements of the spinal cord. Type 2 IVDD usually occurs at the mobile points of the spinal column and is more common in older, nonchondrodystrophic breeds of dog. It is not uncommon to identify multiple affected disc spaces. Chronic spinal instability may be an underlying predisposition to type 2 IVDD.

Clinical Presentation

The clinical signs of Hansen type 2 IVDD include slowly progressive hindlimb ataxia, weakness, reluctance to rise or jump on furniture, and difficulty climbing stairs. Onset of clinical signs is considered chronic and progressive, although acute exacerbations of signs are not uncommon. Localization is focal with asymmetrical or symmetrical weakness. Paraspinal hyperesthesia may or may not be present.

Diagnosis

Diagnosis may be suspected on routine spinal radiographs that show the presence of degenerative changes in the spinal column, such as spondylosis. Myelography, CT myelography, or MRI is necessary to locate the spinal cord compression (Figure 14.48).

Management

Medical therapy is indicated in animals with early-onset type 2 IVDD and mild deficits. It also is indicated in those animals that are concurrently afflicted with suspected DM. Medical therapy involves administration of NSAIDs or corticosteroids. The use of a muscle relaxant such as diazepam or methocarbamol should be considered in patients with spinal hyperesthesia. Clinical signs do not always respond to medical therapy and often return after discontinuation of these therapies. Surgical decompression may offer a better long-term outcome.

The type of surgical decompression depends on the location of the lesion. A hemilaminectomy is performed for lesions in the thoracic spine and lumbar spine cranial to L5 (Figure 14.49a, b). A dorsal laminectomy is performed if the lesion is located in the lumbosacral area (Figure 14.50). Typically, type 2 disc protrusions require more spinal cord manipulation to relieve the compression from the annulus. The protrusion is usually excised; however, decompression by laminectomy alone may also be adequate in cases where the disc material is irretrievable. Lateral corpectomy is an alternative method for decompression of ventral and lateroventral

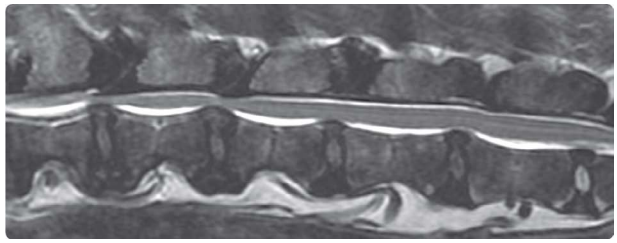

FIGURE 14.48 Sagittal T2-weighted MR image of the thoracolumbar spinal column in a dog with multiple type 2 intervertebral disc herniations.

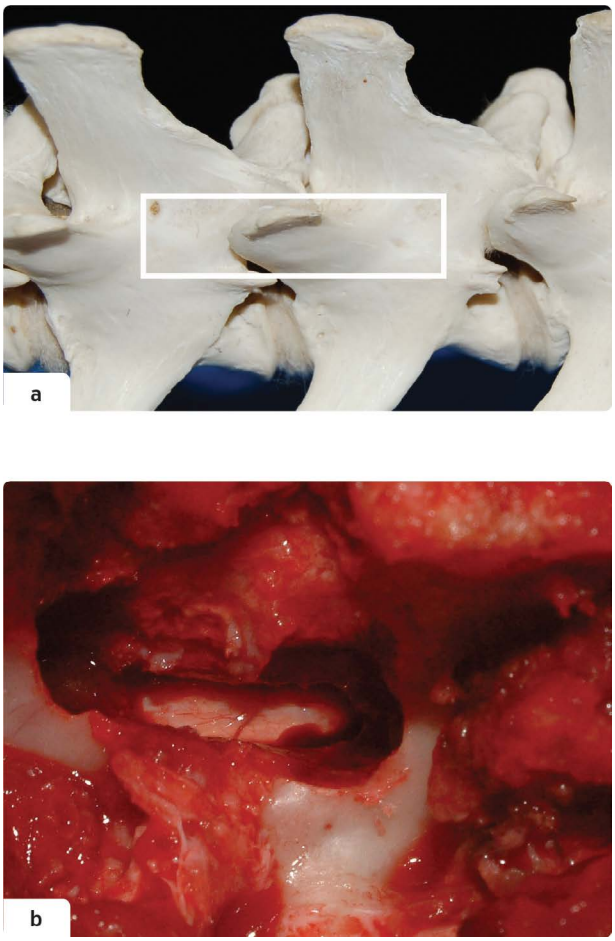

FIGURE 14.49 (a) The surgical "window" for a hemilaminectomy is illustrated on a spinal column model. (b) The spinal cord is visible through the hemilaminectomy window made in the vertebrae.

thoracolumbar disc disease. Often the neurologic status of the animal is worse after surgery, but this is usually temporary. Often dogs with chronic clinical signs have multiple IVDD herniations, which complicate surgical decision making.

If surgery is instituted early, prognosis is usually fair to good when patients are considered refractory to medical therapy. If the disease has coursed for several months and is associated with severe neurologic signs (i.e., paraplegia), the prognosis is considered guarded.

CERVICAL SPONDYLOMYELOPATHY (WOBBLER SYNDROME)

Definition/Overview

Cervical spondylomyelopathy describes a syndrome of compression of the cervical spinal cord as a result of degenerative and congenital changes in the cervical spine. There are many names for this syndrome, including wobbler syndrome, caudal cervical stenotic myelopathy, cervical malformation/malarticulation, and disc-associated wobbler syndrome (DAWS). Classically, this is thought of as a disease of large (e.g., Dobermann, Dalmatian) and giant breed (e.g., Great Dane, Mastiff breeds, Bernese Mountain dog) dogs, although identical changes also occur in toy and small breed dogs such as Chihuahuas and Yorkshire Terriers.

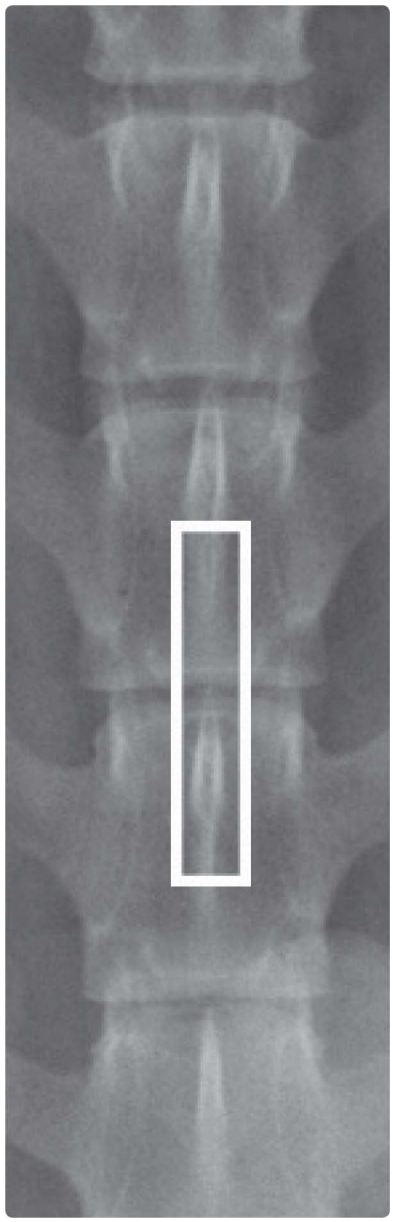

FIGURE 14.50 The surgical "window" for a dorsal laminectomy is illustrated in this lumbar vertebral radiograph.

Etiology

The etiology of these changes is most likely multifactorial. Genetic factors probably play a role, as the disease is seen in specific breeds of dog, although a pattern of inheritance has not been established in commonly affected breeds. Overnutrition and excess calcium supplementation in the first year of life has been implicated

in Great Danes, but correction of these feeding patterns has not prevented occurrence of the disease in this breed. It has also been postulated that conformation of the head and neck influences the development of lesions. However, a study on Dobermanns failed to find a correlation between various body dimensions and radiographic or neurologic signs. It is believed by many that the degenerative changes seen in this syndrome ultimately result from relative instability of the cervical spinal column.

Pathophysiology

Progressive spinal cord compression results from both congenital stenosis and degenerative changes in the vertebral column. The changes can be listed as:

- Hypertrophy and protrusion of the annulus fibrosus, often associated with "tipping" of vertebrae. This change is classically associated with DAWS in Dobermanns.
- Hypertrophy of the ligamentum flavum and dorsal longitudinal ligament. These changes are also common in DAWS.
- Hypertrophy of synovial membrane and formation of synovial cysts at the articular facets, occurring in giant breed stenotic myelopathy and associated with remodeling of the facets.
- Stenosis of the vertebral canal; historically, this has been described in giant breed stenotic myelopathy. However, there is evidence that Dobermanns also have a relative stenosis of their cervical vertebral canal.
- Degenerative joint disease and remodeling of the articular processes, commonly found in giant breed stenotic myelopathy.

Clinical Presentation

Clinical signs include progressive ataxia, tetraparesis, and, sometimes, neck pain (Figure 14.51). Signs in the hindlimbs are more severe than the forelimbs. Dogs with caudal cervical compression frequently have a short, stilted forelimb gait with a dysmetric, disconnected hindlimb gait. Nerve root entrapment can cause forelimb lameness and muscle atrophy; in particular, compression of the suprascapular nerve can produce marked atrophy of the supraspinatus and infraspinatus muscles, making the scapular spine easily palpable. Although this is typically a chronic progressive disease, acute onset of severe signs can occur.

FIGURE 14.51 An 8-year-old Dobermann with cervical vertebral spondylomyelopathy (Wobbler syndrome) presenting with neck pain.

Diagnosis

Survey radiographs of the cervical spine may show degenerative changes typical of this syndrome but cannot be used to identify sites of spinal cord compression. Stressed views should not be taken, as compression of the spinal cord can be exacerbated. Myelography combined with CT used to be the gold standard for diagnosis of cervical spondylomyelopathy and for surgical planning. Linear traction views of the myelogram are used to determine whether compression can be addressed by distraction and fusion of vertebrae (i.e., a dynamic lesion). However, MRI has largely replaced CT and myelography. The advantages of MRI include greater accuracy at detecting spinal cord compression and parenchymal disease in addition to decreased morbidity associated with this imaging modality (Figure 14.52a–d).

Management

Dogs with neurologic deficits should be treated surgically, as this is a chronic progressive disease. However, many owners cannot afford, or do not wish, to have surgery performed. Medical therapy can be considered in such cases and in dogs with mild deficits. Medical management includes treatment of pain with anti-inflammatory drugs and muscle relaxants and restriction of unmonitored activity combined with controlled exercise and physical therapy. Anti-inflammatory doses of corticosteroids have been used to reduce vasogenic edema but do not appear to influence the outcome. Acupuncture can be useful to control chronic pain in some dogs. Dogs managed in this way should be monitored weekly to biweekly to allow early recognition of deterioration and recommendation for surgical intervention.

The aims of surgery are to decompress and/or stabilize the cervical spine. Surgical strategies include the ventral slot (to remove disc material from the canal), distraction/stabilization techniques (to treat lesions responsive to traction) (Figure 14.53), and dorsal laminectomy (to remove dorsal compression or address multiple disc protrusions). Postoperative rehabilitation of patients is critical to their recovery, and owners need to be fully informed about the implications of rehabilitating a nonambulatory large or giant breed dog. Rehabilitation includes passive range-of-motion exercises and massage in the recumbent dog, hydrotherapy, and controlled exercise. Recovery of these dogs can be prolonged (6–12 weeks or more) due to the chronic nature of the disease.

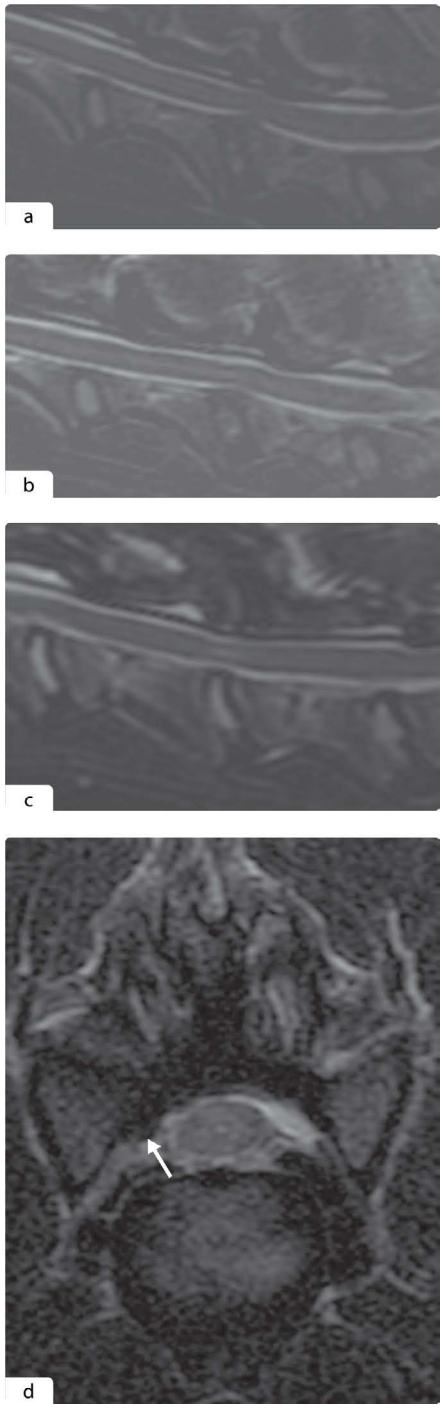

FIGURE 14.52 (a) T2-weighted sagittal caudal cervical MR image of the Dobermann in **Figure 14.51**. A ventrally compressive lesion is seen over the disc space of C6–C7. **(b)** Following mild traction applied to the neck, the MRI is repeated and shows a concurrent mild reduction in the degree of ventral compression, indicating a traction-responsive lesion. **(c)** T2-weighted sagittal caudal cervical MR image of a 1-year-old Great Dane with chronic, progressive tetraparesis. Mild compression of the cord can be seen, as can central cord hyperintensity related to the chronic compression. **(d)** T2-weighted transverse MR image at the level of the compression seen in (c), confirming that the compression is due to articular process malformation (arrow) and concurrent stenosis of the spinal canal.

DEGENERATIVE LUMBOSACRAL STENOSIS

Definition/Overview

Lumbosacral stenosis (cauda equina syndrome, lumbosacral malarticulation and malformation, lumbosacral instability, lumbosacral spondylopathy) is common in middle- to old-aged, large-breed dogs and represents a plethora of orthopedic abnormalities associated with the lumbosacral anatomy. Degenerative lumbosacral stenosis is also being recognized with increasing frequency in the cat.

Etiology

Neurologic abnormalities occur coincident with tissue (joint capsule, interarcuate ligament, disc, bone, fibrous adhesions) impingement on the cauda equina, the nerve roots at the level of the foramina, or the vascular supply. Transitional vertebrae have been identified as a predisposing cause of cauda equina syndrome in German Shepherd Dogs and other breeds.

Pathophysiology

The pathologic process begins with Hansen type 2 IVD degeneration followed by osteophyte formation of the L7–S1 endplates and articular processes. The syndrome is characterized by stenosis of the spinal canal from vertebral subluxation and/or stenotic intervertebral foramina. Concurrent with compressive disease, underlying instability may further accentuate the clinical signs, especially in active dogs.

Clinical Presentation

Neuroanatomic localization to the lumbosacral region is determined by the neurologic examination based on signs related to sensory, motor, and autonomic dysfunction. Nonspecific observations include reluctance to rise and hindlimb lameness. Neurologic signs commonly include pain and motor dysfunction as a result of LMN weakness (sciatic, pudendal, caudal nerves). Pain is the most consistent clinical sign and reflective of

FIGURE 14.54 A Labrador Retriever with degenerative lumbosacral disease exhibiting reduced tail tone, hindlimb muscle atrophy, and a weak stance.

compressive or inflammatory processes affecting pain-sensitive structures (nerve root, meninges, periosteum, and joints). It is the opinion of the author that the pain primarily originates from nerve root (radicular pain) compression (particularly L7). The affected patient often stands with the hindlimbs tucked under the caudal abdomen to flex the spine and lessen the nerve root compression (Figure 14.54). Motor dysfunction varies in severity. The patient may have mild-to-severe gait and postural reaction deficits. The gait is frequently short-strided or shuffled. Postural reaction deficits are often asymmetrical, depending on the degree of cauda equina involvement. Reflex dysfunction of the limbs commonly involves those muscles innervated by the sciatic nerve (L6–S1 nerve roots, but L7 and S1 provide the major contribution), particularly the flexor and extensor muscles of the hock. The patellar reflex may appear hyperreflexic due to loss of antagonism from the flexor muscles (pseudo-hyperreflexia). The cranial tibial and gastrocnemius reflexes may be hyporeflexic. The withdrawal reflexes are reduced in the stifle and hock joints. Less commonly, the pudendal and caudal nerves may be involved. The pudendal nerve (S1, S2, and S3) innervates the perineal region, including the external anal and urethral sphincters. The caudal nerves innervate the tail. Decreased tail tone is assessed on palpation and inability to wag. Other less common clinical signs include fecal and urinary incontinence. If micturition dysfunction is suspected, it is important to closely evaluate sensory perception of the perineal region and the anal reflex.

Diagnosis

A diagnosis of lumbosacral syndrome is suspected from the neurologic examination. Definitive diagnosis of degenerative lumbosacral stenosis is difficult because no one test has 100% specificity and sensitivity, leading to false-positive and false-negative results. Dynamic imaging is important to investigate mobility of the joint and concurrent changes in nervous tissue compression. Diagnostic procedures to test for degenerative lumbosacral stenosis include electrophysiology, survey and contrast radiography, CT, and MRI. Survey radiography is useful to rule out other causes of cauda equina syndrome. Abnormal findings associated with degenerative lumbosacral stenosis include osteochondrosis of the sacral endplate, transitional vertebrae, spondylosis, subluxation, sclerosis of the endplates, and bony proliferation of the articular processes.

Stress radiography (extension and flexion views) has been used to identify underlying "instability" of the lumbosacral junction; however, normal dogs might also have evidence of such "instability". MRI is superior to radiography for demonstrating dynamic compression of the neural tissues.

CT has the advantage of better soft tissue and bone resolution. Cross-sectional, dorsal, and sagittal images allow determination of lesion extent. The articular processes, IVDs, and foramina can be evaluated. CT imaging studies should be performed prior to injecting contrast medium into the vertebral canal or subarachnoid space. Abnormalities detected by CT include loss of epidural fat, increased soft tissue opacity in the intervertebral foramen, bulging of the IVD, thecal sac displacement, spondylosis, narrowed vertebral canal, thickened articular processes, and osteophyte formation on the articular processes in the intervertebral foramen.

MRI is superior to CT with regard to soft tissue definition (Figure 14.55). The spinal cord, CSF, IVDs, ligaments, and nerve roots can be directly visualized. MRI may allow early recognition of IVD degeneration and a more accurate assessment of epidural fat displacement, although this is open to overinterpretation.

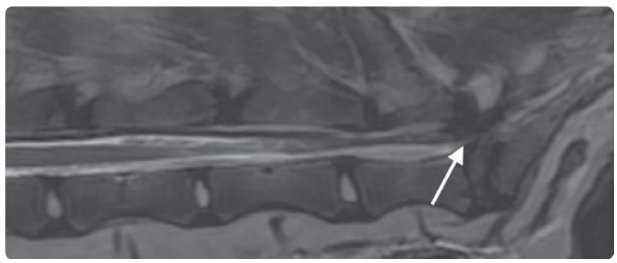

FIGURE 14.55 Sagittal T2-weighted caudal lumbar spinal MR image of the dog in Figure 14.54 confirming marked neural tissue compression at the L7–S1 intervertebral disc space (arrow).

Parasagittal and transverse views can provide evidence of stenosis within the L7–S1 intervertebral foramina. As with radiography, extension and flexion views of the lumbosacral spine can provide evidence of dynamic disease. Importantly, CT and MRI imaging findings may not correlate with the severity of the clinical signs and thus should not be used to predict surgical outcomes or determine the prognosis.

Management

Indications for medical management include the first episode of clinical signs or intermittent pain. Management consists of strict confinement for 8–14 weeks, anti-inflammatory medication using low-dose prednisolone or NSAIDs, and weight loss. The recovery rate with medical management is between 24% and 50%. A recent report described the use of methylprednisolone sodium acetate (40 mg/mL) injections into the lumbosacral epidural space at a dose of 1 mg/kg. The treatment resulted in clinical improvement in 79% and complete resolution of clinical signs in 53% of dogs mildly affected by degenerative lumbosacral stenosis. The protocol included injections at 0, 2, and 6 weeks, with additional injections as needed.

Indications for surgical management include failure of medical management, severe pain, and moderate-to-severe neurologic deficits (in particular incontinence). Surgical techniques include decompression and excision of the proliferative tissue and fixation and fusion of the lumbosacral junction. Surgical decompression is the most common treatment, although distraction–fusion techniques may also be used if indicated. The most crucial aspect of postoperative care is strict cage confinement for 8–12 weeks and a gradual return to fitness. It is important to institute-controlled exercise as part of the physical rehabilitation program. In addition, bladder management involves proper monitoring of bladder emptying to avoid urinary tract infections. If the clinical signs resolve with surgery, then the prognosis is fair to good. Dogs with severe neurologic deficits and urinary and fecal incontinence for more than a few weeks prior to surgery have a guarded to poor prognosis. Rates of postoperative improvement range from 41% to 95%.

SPONDYLOSIS DEFORMANS

Definition/Overview

Degenerative change associated with the vertebrae, most often the vertebral bodies, easily seen on radiographs but rarely a cause of clinical disease.

Etiology

Degenerative, often age-related change.

Pathophysiology

Spondylosis deformans is characterized by formation of bony growths and bridges at the intervertebral spaces.

FIGURE 14.56 Lateral radiograph of the lumbar vertebrae demonstrating ventral bridging spondylosis.

The condition is a common radiographic finding in older dogs along the thoracic and lumbar spine. Most likely spondylosis is associated with degeneration of the annulus fibrosus of the IVD. Presence of spondylosis deformans has been associated with type 2 IVDD and degenerative lumbosacral stenosis; however, these diagnoses are often made independent of the presence of spondylosis.

Clinical Presentation

Spondylosis rarely causes neurologic signs but is occasionally associated with back pain.

Diagnosis

The lesion is radiographically identifiable (Figure 14.56). The osteophyte formation usually does not compress the neural tissue or encroach within the vertebral canal.

Management

NSAIDs or steroids have been reported to lessen spinal discomfort in animals with severe ankylosing spondylosis. Spondylosis deformans is usually an incidental finding and is rarely associated with clinical signs; therefore, the prognosis is good.

SPINAL SYNOVIAL CYSTS

Definition/Overview

Spinal synovial cysts occur in the cervical spine of young large-breed dogs but more commonly involve the thoracolumbar region in older large-breed dogs.

Etiology

Cysts originate from synovial joint lining of vertebral joints.

Pathophysiology

Spinal extradural synovial cysts and ganglion cysts arise from the articular facets. Some authors have referred to both structures as intraspinal cysts due to the confusion of tissue origination. Pathogenesis of synovial cysts has been associated with degenerative disease and trauma. Increased mechanical stress and joint motion may predispose the thoracolumbar junction to osteoarthritis and synovial cyst formation. Histopathology of the cyst reveals fibrous connective tissue with a synovial cell lining.

Clinical Presentation

Clinical signs are consistent with a progressive myelopathy and include paraspinal hyperesthesia.

Diagnosis

Radiographic findings include degenerative changes and remodeling of the articular processes. Myelography demonstrates spinal cord compression, especially on the ventrodorsal view, with attenuation of the contrast column medial to the articular processes. Attenuation of the ventral and dorsal columns (giving an hourglass appearance) is also present on lateral projections. The lesion is better defined using CT myelography and MRI. Cysts will appear as hyperintense lesions on both T2-weighted and short tau inversion recovery (STIR) images (Figure 14.57). Albuminocytologic dissociation is a consistent finding on lumbar CSF analysis.

Management

The treatment often involves surgical decompression and excision of the cyst. Surgical intervention is indicated with severe neurologic deficits and refractory pain. A hemilaminectomy is often performed if one side is affected. The cyst and any protruding disc material are removed. Marked improvements in gait and neurologic deficits occur post surgery.

ANOMALOUS DISEASES

CHIARI-LIKE MALFORMATION SYNDROME AND SYRINGOMYELIA (SEE ALSO BRAIN DISEASE SECTION)

Overview/Definition

Chiari-like malformation syndrome (CLMS), also known as caudal occipital malformation syndrome, and syringomyelia (SM) often occur together, although both may occur independently of the other. SM is a condition characterized by the presence of a fluid-filled cavity (syrinx) or cavities within the parenchyma of the spinal cord. CLMS and SM are most common in toy and small breed dogs, best described in the CKCS and the Brussels Griffon. Less consistently affected breeds are French Bulldogs, Boston Terriers, and Pug dogs. Perhaps surprising, many toy breeds with extreme facial foreshortening, such as the Pekinese, Japanese Chin, and Shi Tzu, are not as predisposed, perhaps reflecting a different skull shape, brain size, and genetic heritage. Brachycephalic cats, especially the Persian, can have CM, but associated SM is not reported.

Etiology

In Cavalier King Charles Spaniels (CKCSs), CLMS/SM is a hereditary condition, possibly autosomal recessive with incomplete penetrance. CLMS is caused by congenital hypoplasia of the supraoccipital bone resulting in overcrowding of the structures within the caudal fossa; this finding is in line with human studies.

A consistent feature is neuroparenchyma disproportion with the "box" (skull and cranial cervical vertebrae) being too "short" for the contents (brain and cranial cervical spinal cord). The reduction in craniofacial bony tissue results in forebrain crowding—the rostral forebrain has a flattened appearance with reduced ventrally displaced olfactory bulbs. The caudal cranial fossa is reduced rostrally by the displaced forebrain and caudally by a short, straight supraoccipital bone (also known as caudal occipital malformation syndrome). Some predisposed breeds such as the CKCS have comparatively big brains. The cerebellum is flattened against the supraoccipital bone, resulting in vermal indentation and herniation of the vermis into or though the foramen magnum. Craniocervical junction overcrowding is compounded by craniocervical junction deformation, including change in angulation of the dens (cervical flexure) and increased proximity of the atlas to the skull and loss of the cerebellomedullary cistern (sometimes referred to as atlanto-occipital overlapping). Overcrowding of the

craniocervical junction results in kinking or elevation of the medulla. In some miniature toy breeds such as the Chihuahua and Pomeranian, cerebellar deformation is not as a prominent feature, especially if they have occipital dysplasia—failure of ossification of the membranous supraoccipital bone thought to be secondary to pressure of the cerebellum against the developing bone. In these breeds, the craniocervical junction abnormalities seem more important to development of clinical signs.

SM is secondary to abnormal CSF flow and is usually associated with CLMS, although it may be associated with other trauma, inflammation, and neoplasia. SM associated with CLMS is predisposed by two morphological phenotypes (or combination of), the first by more extreme brachycephaly and the second by more extreme craniocervical junction deformation. Other factors likely important in the development of SM are reduced CSF absorption through nasal lymphatics, reduced venous drainage, altered neuroparenchymal compliance and conformation of the spinal canal and cord. The pathogenesis of spinal cord fluid cavitation secondary to CSF channel obstruction is debated. The most accepted theory is that CSF in the subarachnoid space fluid enters the spinal perivascular space and then the spinal cord parenchyma because of a mismatch in timing between the arterial pulse peak pressure and CSF pulse peak pressure.

Pathophysiology

Pain in CLMS is thought to relate to failure to equilibrate intracranial pressure due to obstruction of CSF pathways. Intracranial pressure is affected by the systolic pulse, venous drainage, the balance between CSF production and absorption, and microgravitational effects; for example, when being lifted rapidly or with head position. Pain can be exacerbated by Valsalva, a brief increase in intrathoracic pressure, for example when coughing or with abdominal straining.

The pathogenesis of SM appears to be multifactorial (see Etiology), as its dorsoventral size and sagittal extent do not correlate well with a single morphologic abnormality. The location of the syrinx within the dorsal aspect of the spinal cord affecting the dorsal horn is thought to be one mechanism behind the development of pain, specifically neuropathic pain and scratching behavior. Neuropathic pain is secondary to disordered processing of sensory information within the nervous system and results in spontaneous pain, paresthesia, dysesthesia, allodynia, or hyperpathia.

Clinical Presentation

Onset of signs may be acute or chronic in dogs ranging from 6 months to 10 years of age, but no sex predisposition has been identified; most dogs with clinically relevant disease will show signs of CLMS or SM before 4 years of age.

Clinical signs can be seen in dogs with CLMS alone and are usually related to neuropathic pain syndromes. These include vocalization on posture change or on lifting, spinal pain, head and ear rubbing or scratching, aversion to touch, refusal or difficulty jumping or climbing stairs, exercise intolerance/reduced activity, sleep disruption, and behavioral change.

In the presence of SM, neuropathic pain syndromes and neurologic deficits related to spinal cord destruction can present variably. The most common sign of CLMS/SM is pain, predominately isolated to the cervical region, occurring in 35% of affected dogs. "Phantom scratching," where the dogs will attempt to scratch often without making contact with their skin, is the most notable manifestation of these neuropathic pain abnormalities and has been described in affected dogs, ranging from an infrequent to a near constant problem.

Other clinical signs include scoliosis and neurologic deficits relating to cervical spinal cord dysfunction. Tetraparesis, sensory ataxia, and abnormal proprioceptive positioning in all limbs have been noted in dogs with CLMS/SM. Intracranial signs, such as facial paresis and vestibular dysfunction, have also been reported. However, dogs may be completely asymptomatic for CLMS and/or SM.

Diagnosis

These structural abnormalities are best diagnosed with MRI, but they may be clinically silent; therefore, their significance must be carefully considered when such abnormalities are discovered. SM is seen as hyperintensity on T2-weighted MR images and as hypointensity on T1-weighted images; a prominent or dilated central canal can be seen in some dogs. The extent of SM is very variable, with some cases exhibiting a focal cyst-like structure most commonly in the dorsal cervical cord (predominantly gray matter) and others exhibiting multifocal, multiloculated lesions throughout the entire spinal cord (holocord syringomyelia) (Figure 14.58). Suggestive of a "presyrinx" is a local area of T2-weighted FLAIR hyperintensity associated with the central canal. It is important to rule out other concurrent diseases as being the cause of clinical signs, which can be difficult, but performing CSF analysis is important. As CLMS/SM occurs in toy breed and small dogs, it is essential to consider a CSF tap to investigate the possibility of an inflammatory disease and imaging to rule out disc disease. Evaluating the clinical significance of CLMS or SM MRI findings is difficult. In addition to the 2D measurements of skull and cerebellar sizes, it

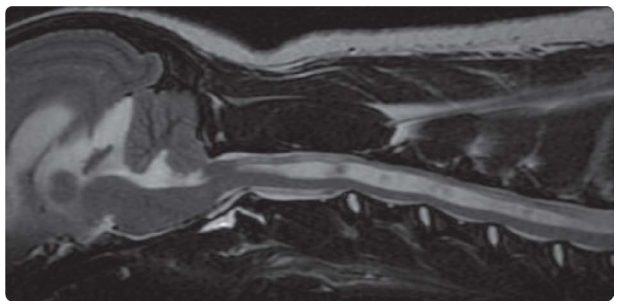

FIGURE 14.58 T2-weighted sagittal cervical spinal MR image. A large, centrally located, fluid-filled cavity can be seen within the spinal cord, representing syringomyelia.

has become apparent that volumetric ratios of the caudal fossa size can be useful in supporting an association with clinical signs.

Management

Treatment may not be necessary in asymptomatic dogs or dogs with mild nonprogressive signs. Dogs exhibiting pain, more severe neurologic deficits, or progressive signs can be treated either medically or surgically. Typically, medical therapy is pursued initially, involving the use of analgesics and drugs that reduce CSF formation. There is poor evidence that pain associated with CLMS will improve with prescription of carprofen alone. There is some evidence of improvement with combination of carprofen and gabapentin and good evidence of improvement with pregabalin.

Furosemide (1–2 mg/kg p.o. q.12 h.) and prednisone (0.5–1.0 mg/kg p.o. q.24 h., tapering dose) are frequently used together in an attempt to decrease CSF production. There is less evidence to support the clinical use of acetazolamide and omeprazole for this purpose, but these drugs are also options.

Clinical signs will progress in approximately 75% of dogs, and approximately 15% will be euthanized. However, despite progressive signs, many dogs with signs of pain and phantom scratching respond to medical management and are considered by their owners to have an acceptable quality of life. Although syrinx width increases over time, the rate of increase is not constant. Many syrinxes appear to rapidly expand within months (or even days) and then can remain remarkably unchanged over years, having achieved a hydrodynamic equilibrium. Dogs that are presented with SM before 3 years of age have a poorer prognosis and are more likely to develop severe weakness which is more difficult to manage. Cervicotorticollis can improve slowly despite persistence of the syrinx.

If medical therapy does not alleviate the clinical signs, surgical decompression of the foramen magnum has been suggested (suboccipital craniectomy) and is the treatment of choice in people. Foramen magnum decompression has been performed in dogs, with success rates reported at about 80%; however, recurrence is common in nearly half of cases in the long term, and neuropathic pain and the accompanying signs of scratching may persist, requiring continued medical therapy. Additionally, multiple surgeries may be necessary if scar tissue develops at the surgical site, obstructing CSF flow, although cranioplasty may reduce the likelihood of this complication. Improvement may not result in the reduction of syrinx size, which usually persists.

SUBARACHNOID DIVERTICULA (SAD) (SUBARACHNOID CYSTS)

Definition/Overview

Subarachnoid diverticula (SAD; also known as subarachnoid cysts, meningeal cysts, intra-arachnoid cysts, and leptomeningeal cysts) can cause compression of the cervical or thoracolumbar spinal cord.

Etiology

Congenital, inflammatory, traumatic.

Pathophysiology

Arachnoid diverticula occur in the intradural–extramedullary space. Although SADs can occur over the entire length of the vertebral column, they occur most commonly in the cranial cervical or thoracolumbar region. Cervical SADs have most commonly a C2–C3 localization and thoracolumbar SADs most commonly a T13–L1 localization. Large-breed dogs are most commonly affected by cervical and small breed dogs most commonly by thoracolumbar SADs. In Pugs, SADs are, however, also regularly seen in the cervical region, and one report described cervical SADs in seven related young Pugs. Most SADs are single lesions with a midline dorsal localization. They can also be multiple, multilobulated, or have ventral or lateralized localizations. Reports have indicated that Rottweilers are predisposed for SAD. Pugs and French Bulldogs are also significantly overrepresented. SAD have occasionally been reported in cats. So far, all reported feline SADs are considered to be acquired and secondary to other causes

Clinical Presentation

The nature of clinical signs is reflected by the location of the SAD. The clinical presentation is predominantly a slowly progressive, general proprioceptive ataxia and hypermetria. Obvious paresis is noted in <5% of affected cases. Although unusual for lesions located in the thoracolumbar region, approximately 20% of dogs with thoracolumbar SAD have urinary or fecal incontinence. It has been suggested that this upper motor neuron incontinence is related to the midline dorsal location of most SADs interfering with the sensory pathways for conscious urination and defecation. Spinal hyperesthesia is not common and occurs in approximately 20% of cases. Dogs with cervical SAD can demonstrate a stiff and floating gait of the thoracic limbs. Because of the multifactorial etiology of SAD, there is a wide variation in the age of onset of clinical signs. Dogue de Bordeaux with SAD are younger, while Pugs develop clinical signs later in life compared to other breeds with SAD

Diagnosis

Myelography is useful for detecting the diverticula within the intradural space. On MRI, the diverticula appear as focal, well-circumscribed lesions that are isointense to CSF on both T1-weighted and T2-weighted images (**Figure 14.59**). MRI is more sensitive than CT in detecting associated intramedullary lesions such as SM.

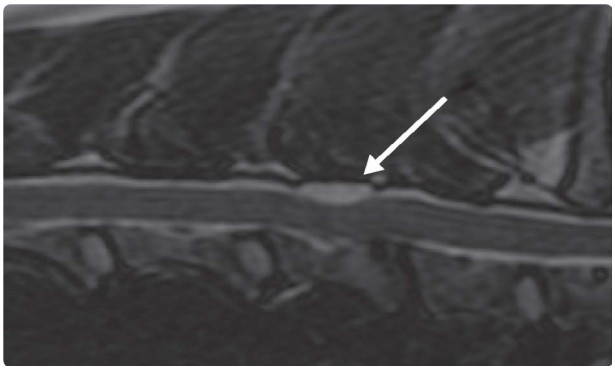

FIGURE 14.59 T2-weighted caudal cervical spinal MR image depicting a dorsal fluid-filled lesion (arrow) associated with the spinal cord and subarachnoid space. This is often referred to as a subarachnoid cyst or diverticulum.

Management

Medical and surgical treatment options have been reported for SAD. Medical treatment typically consists of administration of anti-inflammatory doses of prednisolone (0.5 mg/kg s.i.d. p.o.). The rationale for administering prednisolone is to ameliorate vasogenic edema and decrease the rate of CSF production. Several surgical techniques have been described, which include a durotomy, durectomy, or marsupialization with subsequent removal of present arachnoid adhesions. There is no clear evidence of superiority of one surgical technique over the others. Although transient early postoperative neurological deterioration is common, most dogs will experience long-term improvement. There is some evidence that surgery is associated with a better long-term outcome compared to medical management. The prognosis is good for young dogs if treated soon after development of clinical signs. Dogs older than 3 years of age and those with clinical signs for a duration of >4 months have a poor long-term outcome when treated with only fenestration of the cyst.

One study reported that 82% of dogs treated surgically experienced a long-term neurological improvement, while 3% remained stable and 16% deteriorated. After medical management, 30% experienced a long-term neurological improvement, while 30% remained stable and 40% deteriorated.

Although rare, late-onset recurrence of clinical signs is possible. The median time to recurrence of neurological signs is 20.5 months after surgery, and the reasons for these relapses include regrowth of the SAD, herniation of the spinal cord through the laminectomy membrane, and laminectomy membrane formation.

Although surgery has been associated with good outcomes in most dogs, it has been suggested that Pugs have a poor long-term prognosis after surgery for thoracolumbar SAD. One study demonstrated that although 80% of Pugs experienced a good short-term outcome after surgery, 85% of these dogs experienced late-onset recurrence of neurological signs. Although it is currently unclear why Pugs have a more unfavorable prognosis, it is possible that thoracolumbar SAD formation in this breed is associated with a multifactorial etiology and variety of pathological mechanisms.

VERTEBRAL COLUMN MALFORMATIONS

ATLANTOAXIAL INSTABILITY

Definition/Overview

Subluxation of the atlantoaxial junction is a relatively common problem in toy breed dogs and causes acute to chronic tetraparesis, ataxia, and pain.

Etiology

Trauma, congenital malformation.

Pathophysiology

The atlas (first cervical vertebra) and axis (second cervical vertebra) are held together by ligaments that run from the dens of the axis to the atlas and the skull, over the dens binding it to the floor of the atlas (the transverse ligament), and between the dorsal lamina of the atlas and the dorsal spinous process of the axis. The dens is a bony projection from the cranial aspect of the body of the axis and develops from a separate growth plate. The atlantoaxial and atlanto-occipital region is prone to congenital defects, which can predispose to this luxation:

- Aplasia, hypoplasia, or dorsal angulation of the dens (toy and small breeds of dog are predisposed to this condition)
- Congenital absence of the transverse ligament
- Incomplete ossification of the atlas

Clinical Presentation

Onset of signs in dogs with the congenital form of the disease usually occurs in young dogs (<2 years of age), although problems can develop at any age. Signs can develop acutely or gradually, and waxing and waning of signs is often reported, presumably a reflection of instability at the atlantoaxial junction causing repeated injury to the spinal cord. Signs include neck pain (variably present), ataxia, tetraparesis, and postural reaction and conscious proprioceptive deficits with normal-to-increased muscle tone and myotatic reflexes in all four legs. In severe cases, animals can present with tetraplegia and difficulty breathing, and they may die acutely as a result of respiratory failure. Some animals present with seizure-like episodes that involve sudden onset of opisthotonos and vocalization, presumably reflecting intermittent compression of the spinal cord and nerve roots, causing severe but transient pain and paresis.

Diagnosis

Atlantoaxial subluxation can be diagnosed from survey radiographs of the cervical spine, although extreme care must be taken when restraining and moving dogs in which this disease is suspected. If the animal is sedated or anesthetized, the head and neck should be supported in slight extension to avoid further spinal cord injury. On lateral radiographs, an increased space can be seen between the dorsal lamina of the atlas and the dorsal spinous process of the axis. In severe cases, malalignment of the bodies of the atlas and axis is clearly visible. The presence and size of the dens can be evaluated most accurately on ventrodorsal views. If there is no evidence of subluxation on the lateral views, the neck can be carefully flexed to see if there is instability (the space between the dorsal lamina of the atlas and the dorsal spinous process of the axis should be evaluated). It is preferable to do this with fluoroscopy so that the movement can be monitored to prevent accidental iatrogenic subluxation. Advanced imaging is commonly performed to aid in decision-making for surgery. CT allows clear identification of the bony components of the atlantoaxial region, facilitating surgical planning for implant placement. MRI highlights the spinal cord and brainstem parenchyma, allowing diagnosis of concurrent abnormalities such as CLMS or hydrocephalus, which might complicate recovery from surgery (Figure 14.60a, b).

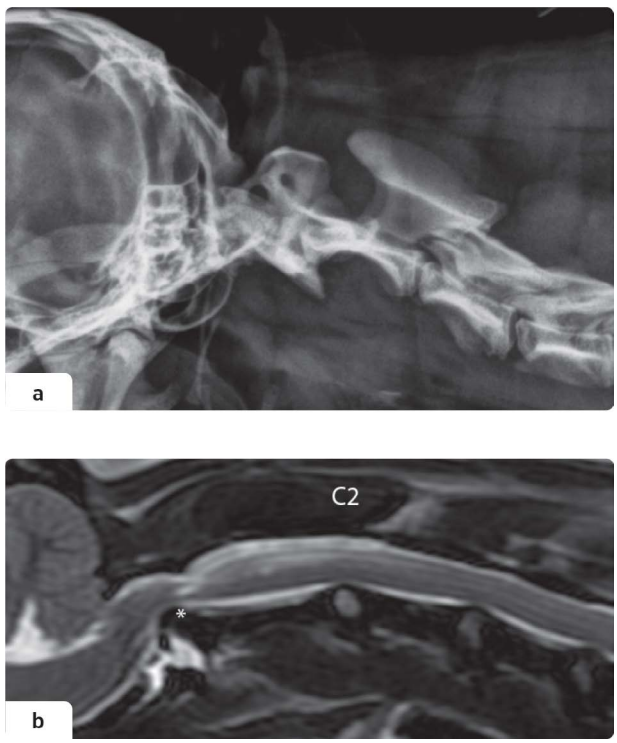

FIGURE 14.60 **(a)** Lateral radiograph of a Yorkshire Terrier with acute-onset neck pain. There is a notable space present between the dorsum of C1 and the dorsal arch of C2 compatible with atlantoaxial subluxation. **(b)** Sagittal T2-weighted MR image of the cranial cervical spine of the dog shown in (a). Marked cord compression can be seen associated with a subluxation of the dens (asterisk).

Management

Dogs with mild signs can be treated conservatively by placing an external splint for at least 6 weeks. The splint must immobilize the atlantoaxial junction and so must come over the head cranial to the ears and go back to the level of the chest. The aim is to stabilize the junction while the ligamentous structures heal. The dog and the splint should be checked daily by the owner for signs of decubital ulcers and checked weekly by the veterinarian, with regular bandage changes if necessary (Figure 14.61). Splint placement addresses instability and can produce an immediate improvement, although severe displacement of the atlantoaxial junction may not be adequately addressed. In one study, 6 of 16 dogs failed to improve following splint placement and were euthanized, while the remaining 10 dogs responded well and maintained a good outcome 1 year after splint removal. Surgery is recommended in dogs with neurologic deficits, although it can be associated with high perioperative morbidity and mortality (Figure 14.62). Dorsal and ventral approaches to the atlantoaxial junction have been described, but dorsal approaches, although requiring less dissection and retraction of important soft tissue structures such as the esophagus, pharynx, and larynx, are associated with a greater risk of causing spinal cord injury during surgery and a higher incidence of implant failure. A neck splint may be placed postoperatively while fusion occurs if transarticular screws alone are used. This is a problematic area to repair surgically. Bone quality is often poor, the bones are small, movement of the vertebrae may cause additional injury to the spinal cord, and the pharynx and larynx can be damaged during retraction. There is a risk of respiratory arrest and death in the perioperative period as a result of additional spinal cord injury or inflammation of the upper airways secondary to retraction. While this is a serious disease, dogs treated surgically have an excellent prognosis if they survive the 48-hour perioperative period. Although reported surgical success rates range from 50% to 90%, the majority report a mortality rate in the region of 20%, with the majority of deaths occurring either during or

FIGURE 14.61 External stabilization of the neck requires a ventral splint and bandaging, which needs to extend from the mandible to the midthorax.

FIGURE 14.62 Lateral postoperative radiograph of the dog in **Figure 14.60**. A ventral fixation approach using transarticular pins, screws, and polymethylmethacrylate cement has been used.

immediately after surgery. As with all spinal cord diseases, prognosis is worse in animals with severe and chronic neurologic deficits. It has also been shown that prognosis is better in young dogs (<24 months).

VERTEBRAL ANOMALIES

Definition/Overview

Vertebral anomalies (e.g., hemivertebra, butterfly vertebra, block vertebra, spina bifida, and caudal articular dysplasia) involve defects in formation of the vertebra and segmentation defects. Congenital anomalies of the vertebral column may be associated also with anomalies of the spinal cord (dysraphism) and/or other organ systems (e.g., cardiovascular and urogenital). Spina bifida is considered a form of spinal dysraphism and is characterized by failure of the vertebral arches to fuse, with or without protrusion of the spinal cord and meninges. Caudal articular process dysplasia (CAD) is characterized by a complete (aplasia) or partial (hypoplasia) absence of one or more caudal articular processes. Although every breed can be affected, this condition has been heavily associated with the Pug breed. The caudal articular processes of the caudal thoracic vertebrae, between T10 and T13, are most often affected in animals with neurological signs.

Etiology

Congenital.

Pathophysiology

Vertebral anomalies are common in the brachycephalic and "screw-tailed" breeds of dog such as Bulldogs and Boston Terriers and the "tailless" cat, the Manx. If they are associated with clinical signs, it can be due to associated osseous compression, disc disease, or associated soft tissue abnormalities (subarachnoid diverticula).

It has been proposed that CAD can lead to low-grade and repetitive vertebral instability, which can lead to a condition termed "constrictive myelopathy" or "meningeal fibrosis." This is characterized by the formation of a dense, circumferential band of fibrotic tissue causing intradural adhesions between the arachnoid and pia mater and constriction of the spinal cord. Although meningeal fibrosis has traditionally been associated with caudal articular process dysplasia, this condition has also been reported in Pugs without concurrent vertebral anomalies. The causative relationship between meningeal fibrosis and caudal articular process dysplasia is, therefore, unclear. Meningeal fibrosis in Pugs could potentially represent a multifactorial neurological syndrome or a disease entity in itself. Pathological and histopathological findings in Pugs with meningeal fibrosis include circumferential fibrosis with concomitant focal gliosis, syringomyelia, or hydromyelia. Lymphohistiocytic inflammation is also commonly present. Meningeal fibrosis has also been associated with spinal arachnoid diverticulum (see mentioned in the text earlier) formation in Pugs.

Clinical Presentation

Vertebral anomalies are often an incidental finding and usually cause no clinical signs. Malformations involving the spinal cord are more likely to cause neurologic deficits, the nature of which is determined by the location of the abnormality.

Caudal articular process dysplasia and meningeal fibrosis can cause a chronic onset of slowly progressive paraparesis and ataxia of the pelvic limbs. Urinary and especially fecal incontinence is common. Spinal hyperesthesia is typically not present. Clinical signs are not caused by the vertebral anomaly in itself but by the constrictive meningeal fibrosis. Affected animals develop clinical signs later in life, with one study reporting a median age around 7.5 years. This vertebral malformation occurs, however, commonly in neurologically normal small brachycephalic dogs. A study evaluating CT studies of dogs without spinal disease revealed that 70.4% of French Bulldogs, 84.1% of English Bulldogs, and 97% of Pugs showed evidence of caudal articular process dysplasia. Compared to the other two breeds, Pugs demonstrated a significantly higher prevalence of caudal articular process dysplasia with a higher prevalence of aplasia, a lower prevalence of hypoplasia, more affected vertebrae per dog, and more vertebrae with bilateral caudal articular process dysplasia. Pugs also demonstrated most often caudal articular process dysplasia between the vertebral levels of T10 and T13, while in French and English Bulldogs, this occurred most often in the more cranial thoracic vertebrae.

Diagnosis

Diagnosis is suspected based on clinical signs, signalment, and survey radiographic findings. Myelography and cross-sectional imaging are useful for determining the extent of compression, stenosis or other possible spinal cord and spinal column deformities. MRI is more sensitive for determining spinal cord involvement and associated defects of altered CSF flow (cyst, syrinx, edema).

Caudal articular process dysplasia can be readily visualized on survey radiographs and especially CT. Because this vertebral anomaly can occur in clinically normal dogs and occurs in the vast majority of neurologically normal Pugs, it is not sufficient to merely observe hypoplastic or aplastic caudal articular processes on diagnostic imaging studies. The imaging modality of choice to diagnose meningeal fibrosis is MRI. The MRI abnormalities associated with meningeal fibrosis include an irregular subarachnoid space, multiple linear hypointense bands that transverse from the arachnoid to the pia across the arachnoid space, spinal cord distortion and compression, cerebrospinal fluid to accumulation in multiple pockets, and bilateral V-shaped ventrolateral extradural lesion. An intraparenchymal hyperintensity is usually present at the site of spinal cord compression. An additional advantage of MRI is the possibility to detect concurrent spinal conditions such as intervertebral disc disease, spinal arachnoid diverticula, and syringomyelia. It is not uncommon for multiple spinal conditions to be present at the site of caudal articular process dysplasia. One study demonstrated compressive intervertebral disc protrusion in 56% and spinal arachnoid diverticula in 22% of Pugs with caudal articular process dysplasia at the same site. Although a causal relationship has been hypothesized, the relationship between caudal articular process dysplasia and other spinal conditions is currently unclear.

Management

If clinical signs are nonprogressive, conservative management is recommended. Decompressive surgery is recommended with clinical signs of compressive myelopathy. Likewise, spinal instability and malalignment require vertebral stabilization techniques. The prognosis is good for most vertebral anomalies because the majority of cases do not produce clinical signs. The prognosis is considered guarded if signs of spinal cord dysfunction are present. Multiple anomalies may exist concurrently.

Little is known about the natural progression or results of medical management associated with constrictive myelopathy and caudal articular process dysplasia. Surgical treatment consisting of decompressive surgery in combination with dissection of the pia–arachnoid adhesions has been associated with a poor outcome. Surgical treatment consisting of vertebral stabilization with or without additional decompression has been associated with neurological improvement in the majority of cases. Concurrent urinary or fecal incontinence is, however, expected to resolve in less than half of affected cases. Another study reported favorable outcomes after subarachnoid–subarachnoid shunt placement to bridge the site of cerebrospinal fluid flow obstruction in dogs with pia–arachnoid fibrosis. Objective comparison of outcome data is, however, challenging because of the variety of imaging findings, pathological abnormalities, and the substantial proportion of dogs with concurrent spinal disorders, such as intervertebral disc protrusion and spinal arachnoid diverticula.

SPINAL STENOSIS

Definition/Overview

Spinal stenosis indicates a malformation of the spine present at birth and occurs as a primary lesion or in association with other anomalies that predispose to stenosis.

Etiology

Congenital.

Pathophysiology

Relative stenosis refers to canal narrowing that does not cause compression of neural tissue, whereas absolute stenosis refers to a stenosis causing spinal cord compression. Dobermanns have a relative stenosis that most commonly involves the cranial thoracic vertebrae (T3–T6). There have also been reports of thoracic vertebral stenosis in Bull Mastiffs, Great Danes, Basset Hounds, Dogues de Bordeaux, and English Bulldogs.

Clinical Presentation

Neurologic signs reflect the neuroanatomic localization of the stenosis. Onset is usually insidious and progressive.

Diagnosis

Diagnosis is based on survey radiography that defines associated vertebral anomalies but requires myelography and/or cross-sectional imaging to determine the presence of stenosis. MRI of the spinal cord is recommended to further delineate associated neural tissue anomalies or abnormalities.

Management

Surgical decompression may relieve the compression; however, associated vertebral and spinal cord anomalies need to be considered. The prognosis is considered guarded due to chronicity and presence of other anomalies. The lack of information available with regard to surgical follow-up makes it difficult to give an accurate prognosis.

NEOPLASTIC DISEASES

SPINAL MENINGIOMAS

Definition/Overview

Tumors affecting the spinal cord are described based on their location as extradural, intradural–extramedullary, or intramedullary. Intradural–extramedullary tumors include meningioma and nerve sheath tumors. Meningiomas affecting the spinal cord are most common in the neck.

Etiology

Unknown.

Pathophysiology

Spinal meningiomas are the most common primary spinal cord tumor in cats older than 8 years of age. The mean age for spinal meningiomas in dogs is 9 years. Spinal meningiomas in dogs are most common in the cervical spinal cord but can occur in any region of the spinal cord.

Clinical Presentation

Meningiomas of the spinal cord in dogs and cats tend to present with a progressive paraparesis. The clinical signs represent the spinal cord region involved. Paraspinal pain may or may not be present.

Diagnosis

Myelography typically shows an intradural–extramedullary compressive lesion. With MRI, these tumors are isointense to hypointense on T1-weighted images, hyperintense on T2-weighted images, and demonstrate strong, uniform contrast enhancement (Figure 14.63).

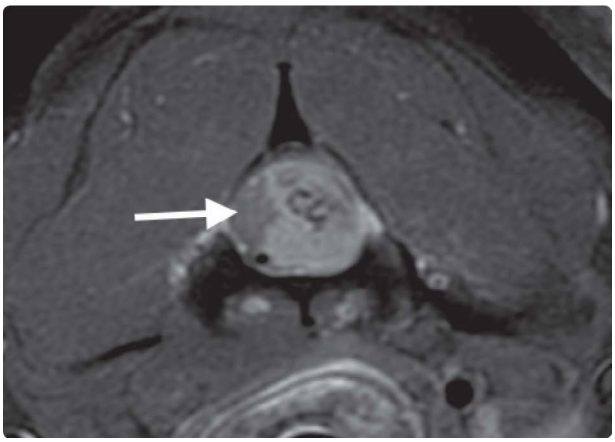

FIGURE 14.63 Transverse postcontrast T1-weighted MR image at the level of C2 showing a strongly enhancing lesion markedly compressing the cord (arrow) to a fraction of its normal size. Surgical resection of the lesion was performed and confirmed a meningioma.

Management

These lesions should be surgically explored because many meningiomas can be completely or partially removed and, therefore, may be associated with prolonged survival after surgery. Postoperative radiation therapy may be used adjunctively to prolong survival in dogs and cats with incompletely excised tumors. Treatment with surgery and radiation therapy can result in an improved outcome and prevent recurrence. Surgical results are guarded when meningiomas are associated with an intumescence, a ventral location, and invasion of the neural parenchyma.

NERVE SHEATH TUMORS

Definition/Overview

Peripheral nerve sheath tumors (PNSTs) are neoplasms that arise from cells surrounding the axons in peripheral nerves or nerve roots, and they are divided into benign and malignant variants. Most PNSTs in dogs are anaplastic, have a high mitotic index, and an aggressive biological behavior, so they are designated as malignant PNSTs. Malignant nerve sheath tumors are common in dogs but rare in cats. No sex or breed predilection has been demonstrated for PNSTs in dogs. Most affected animals are adults over 7 years of age, but younger animals may also be affected.

Etiology

Unknown.

Pathophysiology

Malignant PNSTs in dogs most commonly affect the caudal cervical (C6–C8) and the cranial thoracic (T1–T2) nerve roots, although nerve sheath tumors have also been described affecting the sciatic nerve and femoral nerve. These tumors may have their origin in the nerve roots or the brachial or lumbosacral plexi, or they may arise from more peripheral locations in the nerves. Usually, the tumor spreads slowly, both distally and proximally, and may invade the vertebral canal, causing spinal cord compression and associated neurologic deficits. As the tumors grow proximally, they spread to neighboring nerves in the plexus bundle, with a high percentage of dogs showing evidence of multiple nerve involvement at the time of diagnosis. PNSTs are highly invasive locally, but they rarely metastasize, although pulmonary metastasis in advanced cases has been described.

Clinical Presentation

Malignant PNSTs typically affect older dogs and have been described occasionally in cats. Slowly progressive forelimb lameness or paresis and muscle atrophy are the predominant clinical signs of malignant PNSTs (Figure 14.64). In addition, pain on palpation of the limb or

FIGURE 14.64 A Yorkshire Terrier demonstrating left forelimb root signature associated with a peripheral nerve sheath tumor.

axillary region may be encountered. A palpable axillary mass may be present in some cases, but it is not common. Enlargement of the affected limb has been described in one case. Clinical signs progress slowly, and orthopedic disease is often suspected before a definitive diagnosis is made. As the PNST spreads proximally and compresses the spinal cord, neurologic deficits may develop in the ipsilateral hindlimb, progressing to all four limbs. If the dorsal cervical nerve roots are affected, animals may also show cervical pain.

Unilateral, partial, or complete Horner's syndrome may appear if the cranial thoracic nerve roots are affected by the tumor itself or if there is cord compression at this point (Figure 14.65). Similarly, the ipsilateral cutaneous trunci reflex may be absent due to invasion of the C8–T1 ventral nerve roots or compression of these spinal cord segments.

FIGURE 14.65 Left-sided Horner's syndrome comprising ptosis, miosis, and third eyelid protrusion is seen in this adult cat.

Diagnosis

Orthopedic disease must be excluded by careful orthopedic examination and radiographs of the appropriate joints. Complete blood work (CBC, serum biochemistry panel), thoracic radiographs, and abdominal ultrasonography should be performed in any dog suspected of having a malignant PNST in order to rule out metastatic disease and assess general health status. Survey radiographs of the spine are often normal. Oblique views may reveal enlargement of the affected intervertebral foramen due to pressure atrophy, caused by the thickened nerve root. Occasionally, lysis of the affected vertebral bodies may be observed. CT imaging allows visualization of some malignant PNSTs, and masses as small as 1.0 cm can be identified on contrast-enhanced CT scans. Enhancement of the mass with iodinated contrast medium provides excellent views, helps differentiate vascular structures, and allows subtle differences in soft tissue opacity created by tumor vasculature to be seen. MRI evaluation of the brachial plexus or peripheral nerves provides excellent diagnostic images, but again, not all PNSTs can be detected using this imaging modality early in the course of the disease (Figure 14.66).

Ultrasound examination of the affected limb may allow visualization of large, hypoechogenic tubular masses that displace vessels and destroy normal architecture, and ultrasound-guided fine-needle aspirates of the masses may be useful to reach a final diagnosis in some cases. Electromyography reveals abnormal, spontaneous electrical activity in the affected limb muscles and is of great assistance in differentiating neurologic from orthopedic disease.

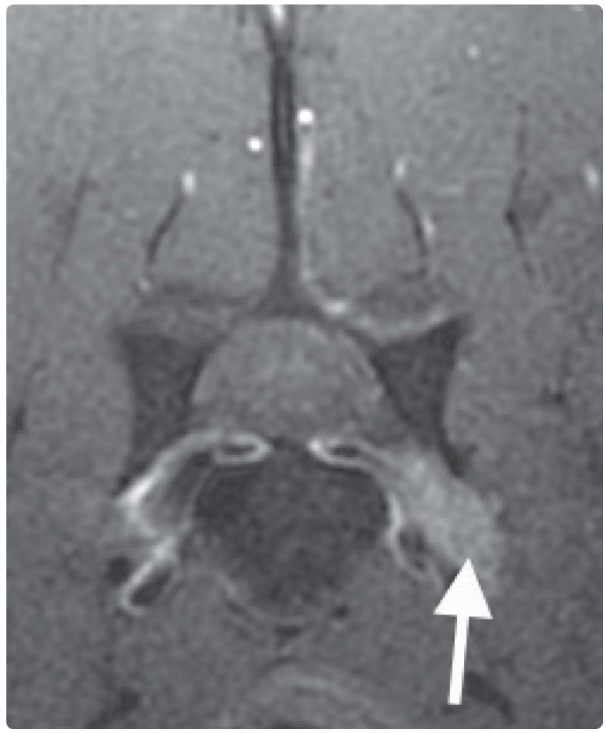

FIGURE 14.66 Nerve root enhancement (arrow) associated with a nerve sheath tumor is depicted on this transverse postcontrast T1-weighted MR image at the level of C7.

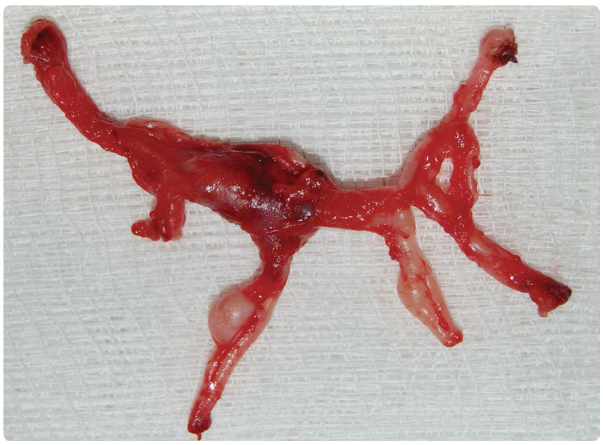

FIGURE 14.67 The lumbar plexus of a dog affected with an extensive malignant peripheral nerve sheath tumor.

Management

Unfortunately, there is usually no curative treatment for PNSTs. Complete surgical resection may be difficult due to the invasive behavior of these tumors and the late detection of the disease in most cases. Tumors within the brachial plexus or peripheral nerves are treated with local excision or amputation of the affected limb. Repeated surgeries may be needed as recurrences are common. In many instances, amputation of the limb is the only option. Early diagnosis and aggressive surgical intervention are recommended to maximize the possibility of complete tumor resection. Aggressive surgical resection at an early stage, if the tumor is peripheral, can be curative (Figure 14.67). Amputation is only advisable when the tumor is distal, and there is no invasion of the spinal canal. In addition, amputation is performed in some cases just to prevent or avoid self-mutilation and injuries to the limb in cases of loss of sensation or paresthesias. Surgery can be followed by a course of radiation therapy, but it is unclear whether this positively affects the prognosis, since these tumors are poorly responsive to radiation. Despite aggressive management, the overall prognosis is poor for most cases of malignant PNSTs. Recurrence rate after surgery is high. There is a tendency for dogs with more proximally located tumors to respond less favorably to surgery and to relapse earlier (1 month for nerve root tumors and 7.5 months for plexus tumors) than those with peripherally located tumors (>9 months after surgery). Incomplete resection is common, indicating that grossly visible margins at the time of surgery are frequently inaccurate indicators of tumor excision.

VERTEBRAL BODY TUMORS

Definition/Overview

Tumors affecting the spinal cord are described based on their location as extradural, intradural–extramedullary, or intramedullary. Extramedullary tumors are the most frequent and most commonly are primary vertebral tumors.

Etiology

Unknown.

Pathophysiology

Vertebral body tumors are primary or metastatic tumors most frequently reported in large and giant breed dogs. Commonly described tumors in dogs include osteosarcoma, fibrosarcoma, chondrosarcoma, hemangiosarcoma, plasma cell tumor, carcinoma, lymphoma, and liposarcoma. Small breed dogs have a higher rate of vertebral metastasis than large breed dogs. In cats, the most commonly described vertebral body tumor is osteosarcoma. Primary vertebral body tumors will cause a secondary myelopathy by compression or direct spinal cord invasion.

Clinical Presentation

Clinical signs may be focal or multifocal depending on the extension of the tumor. Signs include pain and paraparesis or paralysis. Pathologic fractures of the vertebral body result in an acute onset of neurologic deficits.

Diagnosis

Diagnosis is often based on survey radiographic findings, such as lysis and pathologic fractures secondary to tumor destruction of the bone. Other supportive diagnostic techniques, such as CT, MRI, and myelography, are used to determine lesion extent (Figure 14.68). MRI and scintigraphy can be used to detect multiple metastases. Fluoroscopic-guided needle aspiration or surgical biopsy can be used to obtain a definitive diagnosis.

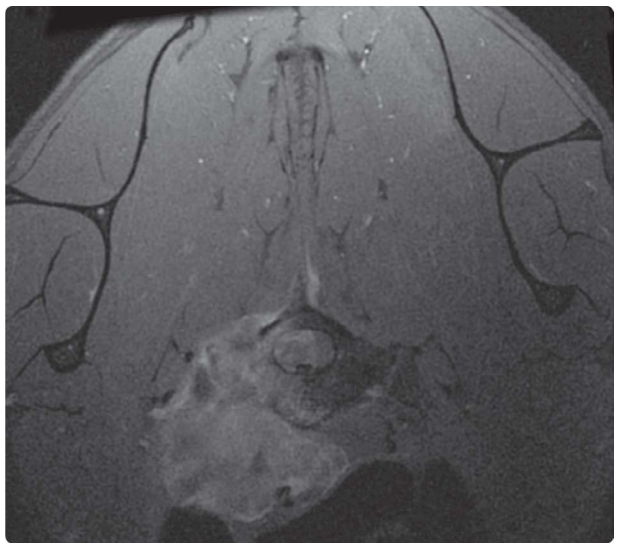

FIGURE 14.68 Transverse postcontrast T1-weighted MR image at the level of the T2 vertebra clearly demonstrating a large irregular lesion associated with the vertebral body and compressing the spinal cord. The lesion was confirmed to be a chondrosarcoma.

Management

Palliative treatment options include surgery, radiation therapy, chemotherapy, or various combinations of the three. A vertebrectomy with a bone allograft fusion has been used for the treatment of a primary vertebral neoplasm in a dog. Decompression or stabilization techniques are used in patients that are rapidly deteriorating. The overall prognosis is considered guarded for dogs and cats with vertebral neoplasia. Survival is not impacted greatly by various treatments but is often determined by the neurologic deficits at the time of diagnosis.

THORACOLUMBAR SPINAL TUMOR OF YOUNG DOGS (SPINAL NEPHROBLASTOMA)

Definition/Overview

Canine nephroblastoma is an intradural–extramedullary neoplasm in young dogs located between T10 and L2 in the spinal cord. Occasionally, this tumor is extradural or intramedullary.

Etiology

The origin of the tumor is unknown, but descriptions have included medulloepithelioma, embryonal nephroma, nephroblastoma, and Wilms tumor (Figure 14.69).

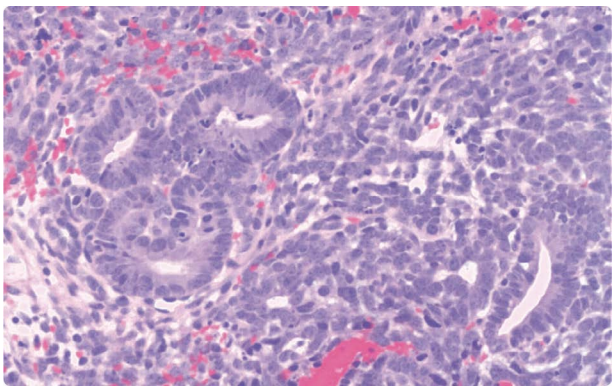

FIGURE 14.69 Histopathologic section of a nephroblastoma stained with hematoxylin and eosin.

Pathophysiology

Primary spinal nephroblastoma is thought to arise from embryonic tissue trapped within the dura during fetal development. Histologic appearance may vary. Usually, neuroepithelioma involves one kidney or the spinal cord but not both. Rarely, renal neuroepithelioma will secondarily metastasize to the spinal cord, bone marrow, and spinal canal.

Clinical Presentation

Clinical signs of spinal nephroblastoma are dependent on tumor location. The most common neurologic findings include progressive paraparesis and ataxia. Clinical signs of spinal neuroepitheliomas consist of a progressive asymmetrical T3–L3 myelopathy.

Diagnosis

Survey radiography of the spine shows no abnormalities. Myelography is useful for determining location and lesion extent. CT or MRI of the spine can better assess vertebral and spinal cord involvement (Figure 14.70a, b). Abdominal radiography and ultrasonography can assess for primary renal involvement if present. Immunohistochemistry is used to identify the mesenchymal or epithelial components of neuroepithelioma. Staining with Wilms tumor 1 (WT-1) antibody can support a diagnosis of nephroblastoma.

Management

If detected early, surgical excision can lead to long-term survival with limited morbidity. Adjunct irradiation is considered when total surgical resection is not possible and may provide a good functional outcome. Overall prognosis is uncertain because of the limited number of cases reported. Prognosis is considered guarded to poor because spinal cord involvement is often extensive by the time of diagnosis. Long-term prognosis is poor because of tumor recurrence.

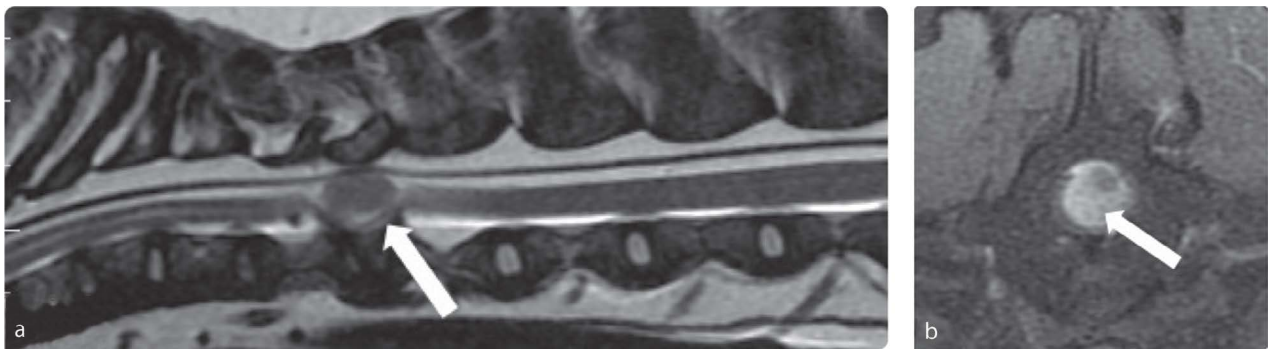

FIGURE 14.70 **(a)** Sagittal T2-weighted and **(b)** transverse postcontrast T1-weighted MR images of a nephroblastoma (arrows) compressing the spinal cord in the thoracic spine.

SPINAL LYMPHOMA

Definition/Overview

Extradural lymphoma is the most common tumor to induce spinal cord dysfunction in cats and occurs less commonly in dogs.

Etiology

Unknown.

Pathophysiology

Feline leukemia virus has been implicated and is an important factor associated with lymphoma in young cats. Feline spinal lymphoma has a predilection for the thoracic and lumbar spinal cord. Most affected cats are <2 years of age, but older animals may also be affected. Lymphoma in cats commonly is found in extraneural sites. Renal lymphoma is likely to relapse in the CNS. Lymphoma is the most commonly diagnosed malignant tumor in dogs, but involvement of the nervous system is relatively unusual. Involvement of the CNS is more common than the peripheral nervous system in both dogs and cats.

Clinical Presentation

Neurologic signs are related to the location of the lymphoma and are often insidious, but there can be an acute exacerbation with rapid deterioration. Often, cats with lymphoma have multifocal signs reflective of multiple lesions in the CNS. The most common initial clinical sign in cats is paraparesis, with pain and other nonspecific abnormalities such as anorexia, lethargy, weight loss, and respiratory tract infection.

Diagnosis

The safest and most reliable method of obtaining a diagnosis of lymphoma in the CNS may be by confirming the presence of lymphoma in other organ systems. The abdominal organs and bone marrow are commonly aspirated but may not be affected. CSF analysis may detect the presence of malignant lymphocytes, but lack of this finding cannot rule out CNS involvement (Figure 14.71). Survey spinal radiography may detect bone involvement. Myelography is useful for determining lesion extent and determining extradural, intradural–extramedullary, or intramedullary involvement. Spinal lymphoma is detected most commonly as an extradural lesion. MRI may detect intramedullary lesions (Figure 14.72). A definitive diagnosis can be determined from cytologic examination of the contents of fluoroscopic-guided fine-needle aspirations or a surgical biopsy.

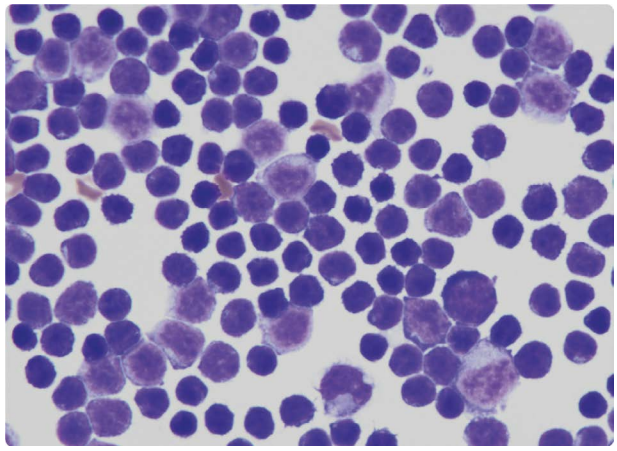

FIGURE 14.71 Cytologic analysis of CSF from a dog with a CNS lymphoma.

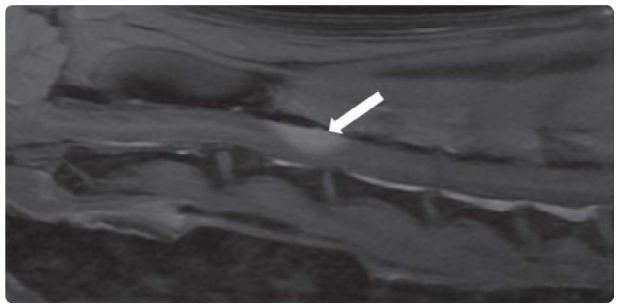

FIGURE 14.72 Sagittal postcontrast T1-weighted cervical spinal cord MR image of a dog with a spinal cord lymphoma (arrow).

Management

Therapies used in combination or alone include surgical resection, focal irradiation, and systemic chemotherapy (e.g., cytarabine or methotrexate and corticosteroids). A laminectomy procedure provides an accurate histologic diagnosis and adequate decompression. Surgical treatment is necessary for cats that fail to respond rapidly to chemotherapy. Duration and remission times vary among studies. Intramedullary lymphoma is difficult to treat because of poor penetration across the blood–brain barrier of some chemotherapeutic agents. Effectiveness of chemotherapy for lymphoma with neural involvement still remains to be determined. In general, the prognosis for hindlimb paresis or paralysis in cats is guarded to poor. The median duration of complete or partial remission in six cats with spinal lymphoma and severe neurologic deficits, treated with vincristine sulfate, cyclophosphamide, and prednisolone, has been reported as 14 weeks (range 5–28 weeks) and 6 weeks (range 4–10 weeks), respectively.

INFLAMMATORY DISEASES

DISCOSPONDYLITIS/OSTEOMYELITIS

Definition/Overview

Discospondylitis is due to infection of the intervertebral disc and adjacent vertebral endplates. If the infection is confined to the vertebral body, it is called vertebral

osteomyelitis or spondylitis. The sites most commonly affected are L7–S1, caudal cervical, midthoracic, and thoracolumbar spine. The infection is usually slowly progressive but can result in acute signs due to secondary pathologic vertebral fractures and IVDD. Its most common clinical sign is that of spinal pain, but neurologic signs are seen and related to the localization. An association with empyema has been documented in several dogs, which may represent an extension of the disease and should be considered when considering diagnostic tests and/or when dealing with a refractory case.

Etiology

Coagulase-positive *Staphylococcus* spp. (*S. intermedius* or *S. aureus*) are the most common etiologic agents associated with canine discospondylitis. Other less commonly identified organisms include *Streptococcus* spp., *E. coli*, *Actinomyces* spp., and *Brucella canis*, as well as *Aspergillus* spp. Young German Shepherd Dog bitches and Hungarian Vizslas seem to be predisposed to aspergillosis, whereas young American Basset Hounds contract discospondylitis due to systemic tuberculosis.

Pathophysiology

Hematogenous spread from distant foci of infection (urogenital tract, skin, dental disease), penetrating wounds, surgery, or plant material migration can cause direct infection of the disc space or vertebrae, the latter of which is usually seen at the level of L2–L4 at the insertion of the diaphragmatic crus. Immunosuppression due to factors such as hyperadrenocorticism is considered a predisposing cause. Infection causes osseous lysis, proliferation, and soft tissue reaction, which can cause neural compression.

Canine brucellosis (*Brucella canis*) accounts for a high percentage of discospondylitis cases in countries where it is endemic. It is also increasingly recognized in nonendemic countries where street dogs are imported from endemic countries for rehoming. *Brucella suis* is a notifiable disease that has recently emerged in dogs in New South Wales. Most cases occurred in dogs that participated in feral pig hunting (or were exposed to those dogs) or were fed raw feral pig meat. Other signs include orchitis, sacroiliitis, epididymitis, pyrexia, and lameness. Testing should be performed in countries in which brucellosis is not yet eradicated, especially if the dog is fed raw pig meat, is used for hunting, or kept on a farm. In Western Europe, Brucella testing should be performed in any dog presenting with spinal pain that was "rescued" and imported from countries with a large stray population, especially if from Eastern or Southern Europe. Canine brucellosis (*B. canis*) is not notifiable to WHO or EU, whereas *B. abortus*, *B. suis*, and *B. melitensis* are, even though it is an accepted zoonotic disease. In the United States, there is mandatory reporting of brucellosis in dogs to state health authorities and mandatory communication with veterinarians and dog owners to alert them of the zoonotic risk. One aspect of reducing the zoonotic potential is educating owners about options for managing *B. canis*–positive dogs, such as sterilization, antimicrobial drug therapy, and repeat testing, or euthanasia if those measures cannot be applied. Anyone who has contact with an infected dog should maintain good hygiene standards when handling its urine, feces, or reproductive products.

Clinical Presentation

Spinal pain is the most common initial clinical sign in this disease, which is most frequently seen in large intact male young to middle-aged dogs. With proliferation of inflammatory tissue, compression of neural tissue can lead to ataxia, paresis, and occasionally paralysis dependent on where the lesion is located. Although it can occur in any animal, the condition is less common in toy and chondrodystrophoid breeds of dog and rare in cats. Purebred dogs seem more commonly affected than mixed breeds. Approximately 30% of dogs have signs of systemic illness such as fever and weight loss.

Diagnosis

Hematological changes are usually not present unless there are concurrent conditions such as endocarditis. Serum C-reactive protein is elevated in cases of discospondylitis and may be clinically more useful to screen dogs with back pain than pyrexia or leukocytosis alone. Urine cytology may reveal bacterial or fungal agents. Blood and urine cultures should be performed in all suspected cases and are positive in up to 75% and 50% of cases, respectively. Ideally, these should be performed prior to initiating antibiotic therapy. Serology for brucellosis should also be performed, especially in view of its zoonotic potential; this has been reported to be positive in up to 10% of cases. The standard test for *B. canis* is culture. Commonly collected samples include blood, vaginal discharge, and semen. Of these, blood is the most commonly collected; however, because bacteremia can be intermittent, positive animals may be missed. The best time for culturing *Brucella* is 2–4 weeks after infection, after demonstration of reproductive failure, when bacteremia is the highest. Culture requires up to 9 days, increasing the risk for exposure of laboratory personnel if the cultures are not handled appropriately.

Definitive diagnosis is usually made with spinal radiographs, although radiographic change may not be evident in the first 2–4 weeks of infection (**Figure 14.73a–c**). The most commonly affected site is L7–S1, but other frequently affected sites include the caudal cervical/cranial thoracic vertebrae and the thoracolumbar junction. As this can be a multifocal disease, the entire spine should be radiographed. Radiographic evidence of disease includes narrowing of the disc space, accompanied by subtle irregularity of both endplates, through to gross lysis and osseous proliferation of the adjacent vertebral bone, and even pathological fractures. The radiographic appearance of discospondylitis can differ in dogs <6 months of age compared with adults. On initial radiographs in young dogs, there may

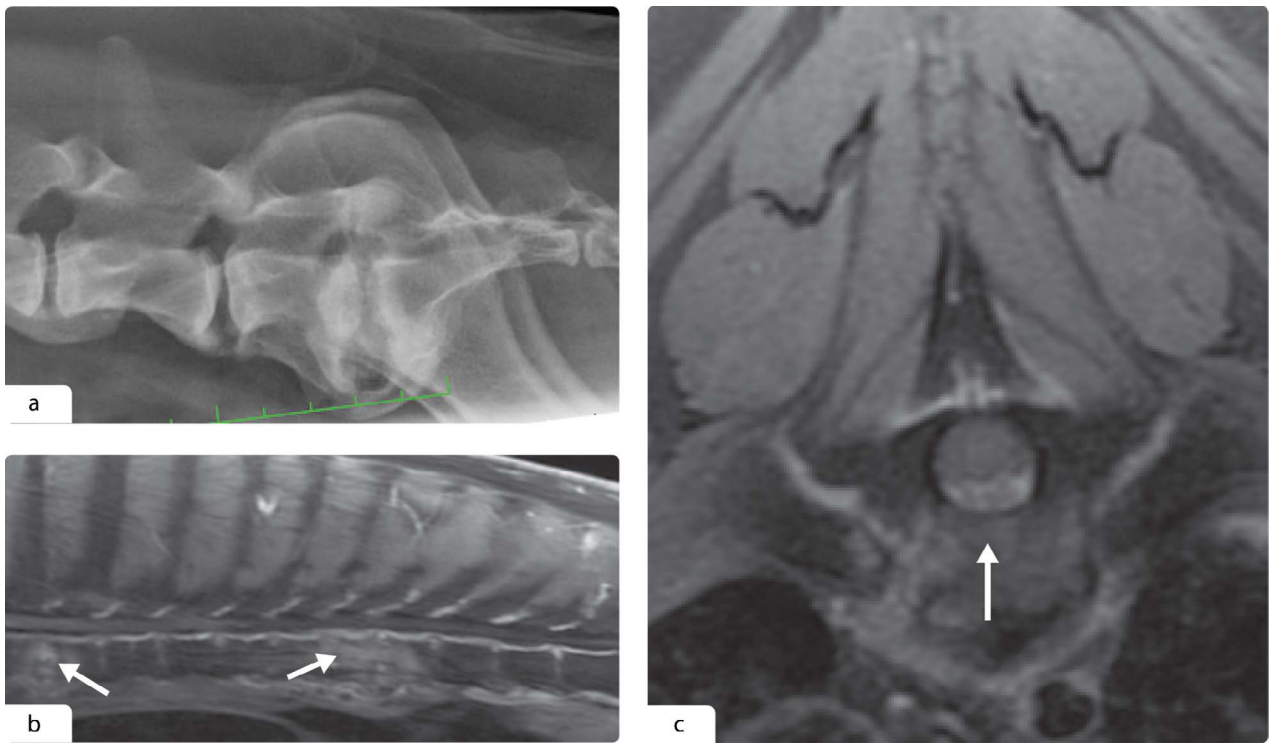

FIGURE 14.73 **(a)** Lateral radiograph of the lumbosacral joint of a dog with discospondylitis. Note the endplate sclerosis and lysis. **(b)** Sagittal and **(c)** transverse postcontrast T1-weighted MR images of the thoracic spinal column of a dog with multifocal discospondylitis illustrating the marked vertebral body uptake of contrast (arrows).

be intervertebral disc space narrowing without evidence of vertebral endplate osteolysis. Subtle osteolysis of the adjacent vertebral endplates can be seen on follow-up radiographs if performed. Over time, the majority of these dogs develop osteolysis of the vertebral metaphyses with an appearance similar to discospondylitis in adult dogs, and in one study, many with discospondylitis of the thoracolumbar vertebral column had a subluxation at the site on follow-up radiographs. Radiography can also be used to monitor the response to treatment or the progression of the disease, although clinical progression is equally important, as radiographic change can lag behind clinical improvement.

CT can identify subtle endplate erosion and paravertebral soft tissue swelling more readily than radiography. Postmyelogram CT clearly defines compression of the neural tissues by infected tissues, as does MRI. Discospondylitis appears to have increased signal intensity on T2-weighted images and decreased signal intensity on T1-weighted images, changes also seen in the paravertebral tissues in all cases. MRI can also highlight the inflammation in the surrounding muscles (Figure 14.73b, c).

If urine and blood culture and brucellosis serology have not identified an etiologic agent in cases of discospondylitis, percutaneous needle aspiration of the disc space can be a safe procedure to obtain tissue for bacterial and fungal cultures and cytology. However, this procedure requires general anesthesia, sterile surgical preparation, and fluoroscopic or CT guidance of the needle and is usually only performed in patients unresponsive to initial broad-spectrum antibiotics. The procedure has been documented to be up to 75% sensitive. Open biopsy of the vertebrae may be considered if needle aspiration is unrewarding. This has yielded positive cultures in approximately 80% of patients. In all cases, diagnostic investigation of potential systemic infectious foci should be considered. This should include abdominal ultrasonography for prostatic or renal disease, thoracic radiographs for pulmonary disease, and cardiac ultrasonography for endocardial disease.

Management

Once radiographic evidence of discospondylitis is present, treatment for the common potential pathogen *S. intermedius* infection may be started. Initial treatment of discospondylitis consists of antibiotics (potentiated amoxicillin or cephalexin), cage rest, and analgesics. Results of cultures may require alteration of this choice.

IV antibiotics should be considered if severe neurologic compromise or signs of sepsis are present; otherwise, oral antibiotics are acceptable. However quickly the patient improves, continuation of the antibiotics for 8–16 weeks is recommended. Resolution of clinical signs, such as pain and fever, should be expected within 5 days of initiating therapy; however, complete neurologic resolution may take 2–3 months. Residual deficits may remain, but persistent pain indicates an active disease, and these patients should be treated with an additional antibiotic and considered for further diagnostics, as they may have a potential fungal infection or surgical lesion.

Discospondylitis associated with *Aspergillus* spp. has been treated with itraconazole (5 mg/kg of body weight p.o. q.24 h.), although long-term reports of success are lacking, with the belief being that chronic recurrence and progression are likely. Treatment of *B. canis* and *B. suis* discospondylitis is controversial because infection is considered lifelong, and the dog will continue to shed bacteria intermittently. Transmission of *B. canis* from dogs to humans is possible; immunocompromised individuals are at greater risk. A 6-week course of a combination of doxycycline and rifampicin combined with surgical resection of infected tissues (castration after 2 weeks of preoperative antibiotics), taking into account zoonotic and recurrence risk, seems to be effective in dogs infected with *B. suis*. Rifampicin is hepatotoxic, and serum biochemistry should be monitored. No antibiotic therapy appears to eliminate *B. canis* completely from affected dogs.

Surgical decompression is rarely needed and should only be considered in refractory cases or those with severe neurologic deficits that show no sign of improvement within 3–5 days. Although internal fixation can be acceptable even at the site of an infection, it may be more appropriate to consider external skeletal fixation, as has been successfully described in dogs with lumbosacral discospondylitis.

The prognosis for this disease is generally very good unless the etiology is fungal or *B. canis*, there are multiple lesions, vertebral fracture or subluxation occurs, or there is endocarditis. The potential for recurrence should be considered, especially if brucellosis has been diagnosed or an underlying immunosuppressive condition is present. Residual neurologic deficits are possible, and in those cases that have severe neurologic deficits associated with the infection, the prognosis should initially be guarded.

STEROID-RESPONSIVE MENINGITIS–ARTERITIS

Definition/Overview

Steroid-responsive meningitis–arteritis (SRMA), also termed necrotizing vasculitis, juvenile polyarteritis syndrome, corticosteroid-responsive meningitis/meningomyelitis, aseptic suppurative meningitis, panarteritis, and pain syndrome, is a noninfectious inflammatory condition reported in Beagles, Bernese Mountain dogs, Border Collies, Boxers, German Short-haired Pointers, Nova Scotia Duck Tolling Retrievers, Golden Retrievers, Weimaraners, and Whippets but is noted and probably occurs in other medium-to-large dog breeds.

Etiology

An immunologic cause of this disease is suspected, resulting in a vasculitis. The etiopathogenesis is unknown, but an infectious cause has been suggested, although none as yet identified.

Pathophysiology

Notably, increased levels of CSF and serum IgA, increased CSF and blood B-cell/T-cell ratios, and CSF IL-8 levels are all thought to be compatible with immune system stimulation. High CD11a expression on polymorphonuclear cells appears to be an important factor in the pathogenesis of SRMA and may be involved in the enhanced passage of neutrophils into the subarachnoid space leading to meningitis and clinical signs. Matrix metalloproteinase-2 seems to also be involved in the neutrophilic invasion into the subarachnoid space. Involvement of such molecular markers provides a potential therapeutic target. Subsequent to neutrophilic invasion of the subarachnoid space, there is development of a fibrinoid arteritis and leptomeningeal inflammation in the spinal cord and, to a lesser degree, the brain. With chronic progression of the lesions, rupture and hemorrhage of the weakened vasculature may be present, accompanied by thickened leptomeninges with less severe inflammation.

The arteritis is systemic, and there may be other clinical or subclinical organ involvement, in particular the heart, glomerulonephritis, paraspinal muscle, and joints. Rarely, severe motor dysfunction may result from spontaneous bleeding into the subarachnoid space, spinal cord hematoma/hematomyelia, or subconjunctival hemorrhages. Some dogs with immune-mediated polyarthritis (up to 46% and especially Bernese Mountain dogs, Boxers, and Akitas) may show similar clinical signs to dogs with SRMA because of articular process involvement or concurrent meningitis.

Clinical Presentation

Affected dogs are often young adults (8–18 months old) but may be of any age and are usually febrile and hyperesthetic with cervical rigidity and anorexia (Figure 14.74). Neurologic deficits can be seen in the chronic form of

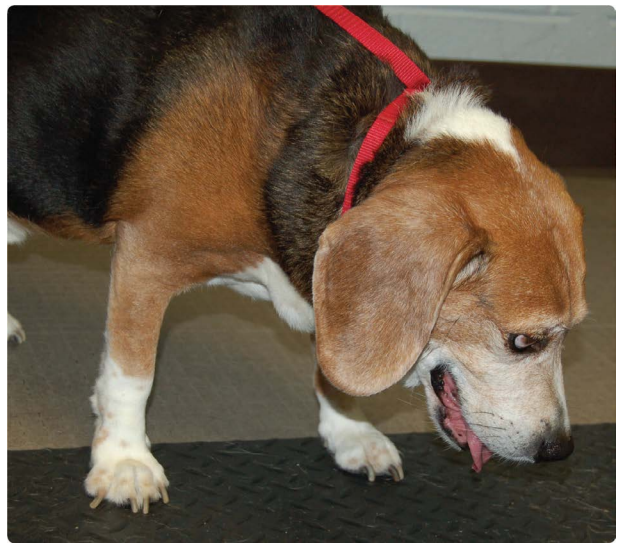

FIGURE 14.74 A Beagle with severe neck pain associated with its sterile meningitis.

this disease, and, rarely, severe motor dysfunction may result from spontaneous bleeding into the subarachnoid space. Some dogs (up to 46%) with immune-mediated polyarthritis, especially Bernese Mountain dogs, Boxers, and Akitas, may show similar clinical signs to dogs with SRMA and have concurrent meningitis. Some dogs may have concurrent glomerulonephritis.

Diagnosis

A marked peripheral neutrophilia with a left shift may be seen at the time of the clinical signs. C-reactive protein (CRP) is reported to be significantly higher in dogs with SRMA compared with dogs with other neurological diseases. However, this is a nonspecific test, as elevation can also occur in sepsis and other CNS inflammatory disease. CRP can also be used to monitor response to treatment. Serum CRP and other acute-phase proteins respond immediately to both the onset and resolution of inflammation and are consistently elevated in patients exhibiting signs suggesting SRMA relapse but with normal CSF and leukograms. CSF often reveals a marked neutrophilic pleocytosis and protein elevation; cell counts of >100 cells/μL are common. Neutrophils are nondegenerative, unlike bacterial meningitis. In the majority of dogs with either acute or chronic disease, there are elevations of IgA levels in the CSF and the serum, although this is not specific for this disease. IgA CSF concentrations are significantly higher in dogs with SRMA compared with other disease categories, with the exception of inflammatory CNS disease, and so are considered nonspecific.

Diagnostic imaging is not required for diagnosis of SRMA but is useful to eliminate other causes of cervical pain. In particular, spinal radiographs to rule out discospondylitis, an important differential for spinal pain and pyrexia in a juvenile dog. MRI of the cervical vertebral column is often normal but may reveal meningeal paramagnetic contrast enhancement, signal changes in the cervical paraspinal musculature (T2 or STIR hyperintensity or contrast enhancement) and multifocal ill-defined, T2-hyperintense lesions within the cervical spinal cord with variable contrast enhancement. MRI may also reveal changes consistent with hemorrhage within the subarachnoid space or spinal cord.

Arthrocentesis is indicated if joint pain is identified and is recommended if signalment is suggestive of SRMA, but CSF analysis is normal, as immune-mediated polyarthritis involving the articular processes can mimic SRMA.

Management

The prognosis can be good if dogs are treated early and aggressively with immunosuppressive doses of corticosteroids, with up to 80% of cases going into long-term remission. Infectious diseases should be ruled out before this treatment is initiated. The treatment is long term and has been reported to be required for over 2 years in some dogs; however, after this time, serum and CSF IgA levels were still elevated in some dogs, so are not considered valuable for disease monitoring. Monitoring of CSF cell count in dogs with this condition is a sensitive indicator of success of treatment. Serum CRP is more useful than CSF cell counts or serum and CSF IgA to guide tapering of therapy. However, normal serum CRP does not exclude future relapse.

In refractory cases or in patients with steroid-related adverse effects, alternative immunomodulation therapy such as mycophenolate, leflunomide, azathioprine, cyclosporin, or cytarabine should be considered. To reduce the adverse effects and reduction in quality of life associated with long-term, high-dose corticosteroids, a combination of mycophenolate and corticosteroids can be used in all cases of SRMA from the onset of the disease, adding leflunomide in refractory cases. This allows a reduction in the daily dose of corticosteroids. CRP, hematology, and ALT should be monitored every 1–2 months, and the mycophenolate is typically continued for 6 months. Successful treatment of SMRA with cytosine arabinoside and corticosteroids in a small cases series is reported. However, there was a high incidence of adverse events that required additional management. Successful treatment of SMRA with azathioprine and corticosteroids is also reported, with a reasonably low relapse rate found.

SPINAL EMPYEMA

Definition/Overview

Spinal empyema is defined as an extensive accumulation of purulent material in the epidural space of the vertebral canal. This is an uncommon condition.

Etiology

Direct extension of osteomyelitis or discospondylitis is the main cause of the infection in veterinary medicine. Infection could also be subsequent to surgery, foreign bodies, and trauma.

Pathophysiology

Extension or introduction of an infectious agent into the spinal canal can cause a purulent accumulation, which can result in compression of the spinal cord and systemic signs of an infectious disease.

Clinical Presentation

Characteristic clinical signs are a high fever, acute progressive spinal hyperesthesia, and progressive myelopathy.

Diagnosis

Hematology reveals an inflammatory leukogram. Blood cultures can be positive. *Staphylococcus* and *Streptococcus* spp. are commonly isolated. Radiography may reveal vertebral physitis or discospondylitis. Diagnosis is aided by myelography, CT, or MRI with

FIGURE 14.75 Epidural soft tissue material compressing the cord (arrow) and confirmed to be empyema can be seen on this sagittal postcontrast T1-weighted MR image of the caudal cervical spine.

identification of extradural compression that extends over multiple spinal cord segments. MRI is most sensitive for assessment of severity and extent of changes associated with infection of the paraspinal muscle and other soft tissue structures (Figure 14.75). Cross-sectional imaging can further help guide surgical therapy.

Management

Effective treatment is rapid institution of an appropriate antibiotic therapy and surgical drainage of the epidural fluid. Surgery is the treatment of choice because it allows for spinal cord decompression, drainage of the infected material, and direct culture of the organism. Dogs with spinal empyema have a good outcome when treated with surgery and the appropriate long-term antibiotic therapy based on culture and sensitivity.

CANINE DISTEMPER VIRAL MYELITIS

Definition/Overview

CDV is a *Morbillivirus* within the family Paramyxoviridae that can cause focal or diffuse lesions in both the gray and white matter of the CNS. Focal or diffuse demyelination can occur in the white matter of the spinal cord. Neurologic forms often occur as the only clinical manifestation in dogs with intermediate levels of viral immunity.

Etiology

CDV.

Pathophysiology

The type of lesion produced in the CNS depends on host immunity and the age and duration of infection. The type of lesion ranges from acute polioencephalomyelopathy with glial and neuronal necrosis in immature or immunodeficient dogs to more chronic leukoencephalomyelopathy with demyelination in older or immunosuppressed dogs. Demyelination is, therefore, a more prominent feature in the chronic stages of disease.

Clinical Presentation

Respiratory, enteric, neurologic, and ocular manifestations have been described in naturally occurring disease. Respiratory and enteric forms of the disease are more common in puppies or severely immunosuppressed adult dogs. Neurologic signs, whether acute or chronic, are usually progressive. Neurologic signs vary with the area of the CNS infected, but spinal cord signs can predominate. Clinical signs of CDV myelitis are focal or diffuse, with the T3–L3 spinal region more frequently involved. Paraspinal hyperesthesia can occur as a result of meningeal inflammation. Myoclonus (involuntary twitching of muscles) can present without other neurologic signs, but as the spinal cord disease progresses, there may be UMN signs in the affected limbs.

Diagnosis

Diagnosis of CDV infection is based on history and clinical signs. A definitive antemortem diagnosis of CDV is difficult to obtain. MRI may provide evidence of white matter involvement in the brain and spinal cord. Clinical laboratory findings and CSF analysis are often nonspecific. Immunofluorescent techniques for CDV antigen on conjunctival tissue, CSF, urine, skin, or blood can facilitate diagnosis but lack sensitivity. Multiple methods of detection increase diagnostic suspicion of CDV. PCR and analysis of CSF-specific IgG levels and determining the CSF-to-serum ratio can be used to detect chronic CDV infections.

Management

The treatment of CDV myelitis is often unsuccessful. Corticosteroid therapy of short duration may provide some remedy. Clinical signs typically wax and wane over time followed by a more rapid progression. The prognosis is considered poor for recovery.

FELINE INFECTIOUS PERITONITIS, MYELITIS, AND MENINGITIS

Definition/Overview

Feline infectious peritonitis (FIP) is a common viral disease in cats caused by the ubiquitous feline enteric coronavirus. FIP is an immune complex forming disease involving virus, antibodies, and complement, which results in multifocal inflammatory lesions affecting the nervous system. A T3–L3 myelopathy is one of three distinct clinical syndromes identified in cats with neurological FIP, which also includes central vestibular syndrome and multifocal CNS disease.

Etiology

Mutated feline coronavirus.

Pathophysiology

Histologic findings include granulomatous inflammation of the meninges, ependymal cells, and choroid plexus. FIP occurs in two forms: Noneffusive (dry) and effusive (wet). CNS involvement is seen most commonly with the dry form.

Clinical Presentation

Most cats infected are <2 years of age, but cats of any age can be infected. Clinical signs are often insidious and present with focal, diffuse, or multifocal distribution. Signs often are vague and reflect multiple organ system involvement. Keratic precipitates can be present on the corneas (see **Figure 14.14**). Systemic signs include pyrexia, weight loss, dullness, and anorexia. Commonly recognized spinal signs are hindlimb or generalized ataxia and paraspinal hyperesthesia. When the virus affects the spinal cord, the resulting pathology includes hydromyelia and myelitis. Other areas of the CNS such as the spinal cord can be involved but not as commonly as intracranial signs.

Diagnosis

Confirmation of FIP antemortem is very difficult. Biopsy confirmation of infected tissue is the only method to definitively diagnose FIP. CSF analysis is abnormal with an elevated total nucleated cell count and protein levels. The white blood cell differential often reflects a neutrophilic pleocytosis, but cellular distribution can be variable. CSF protein concentration can be extremely elevated (1,000–2,000 mg/dL). Results of serologic testing are difficult to interpret reliably. The most useful antemortem indicators of disease are a positive anti-coronavirus titer in CSF (>1:640), a high serum total protein concentration, and compatible findings on imaging. Magnetic resonance imaging abnormalities of cats with FIP myelopathy include meningeal contrast enhancement, ependymal contrast enhancement, and syringomyelia.

Management

FIP is an incurable disease, and clinical management involves supportive and palliative care. Use of corticosteroids and other immunosuppressive drugs may slow the progression of the disease. Various other drugs such as antiviral and immunomodulating (interferon) drugs have been used, but none have been shown to be effective. The prognosis for cats with FIP is poor, with median survival times of 14 days reported when the cats have CNS disease, although recent success has been achieved with the use of nucleoside analogues in cats with neurological FIP.

PROTOZOAL MYELITIS

Definition/Overview

Protozoal infection can cause a focal or disseminated myelopathy in dogs and cats, respectively. Meningoencephalomyelitis and myositis are common lesions associated with *Neospora caninum* infection. Rapid ascending myelitis is more common with *N. caninum* infection. Many previously reported cases of *Toxoplasma gondii* are now thought to be due to *N. caninum*.

Etiology

N. caninum and *T. gondii*.

Pathophysiology

Infection can occur in utero, by ingestion of oocysts (due to fecal contamination), or by ingestion of bradyzoites (in muscle). Although subclinical infection is common, clinically significant protozoal infections tend to occur in immunocompromised or young animals and can affect muscle, peripheral nerves, and the CNS.

Clinical Presentation

The neurologic signs of protozoal infection reflect disseminated or progressive multifocal disease. Dogs as young as 4 weeks of age may develop a progressive asymmetrical or symmetrical paraparesis from *T. gondii* or *N. caninum* infection. The organism infects the lumbosacral nerve roots and muscles and often causes a myelitis and/or meningitis. These dogs may have a "bunny-hopping" gait or present with severe rigid extension of the hindlimbs (**Figure 14.76**). The limbs are rigid because of muscle fibrosis and tendon contracture. The patellar and withdrawal reflexes are lost, and severe muscle atrophy often ensues. Rarely, the disease progresses rapidly to tetraparesis and respiratory paralysis.

Diagnosis

Diagnosis is suspected based on history and clinical signs. Electromyography shows diffuse fibrillation

FIGURE 14.76 A Labrador Retriever puppy exhibiting hindlimb hyperextension associated with a *Toxoplasma* infection of the local nerves and muscles.

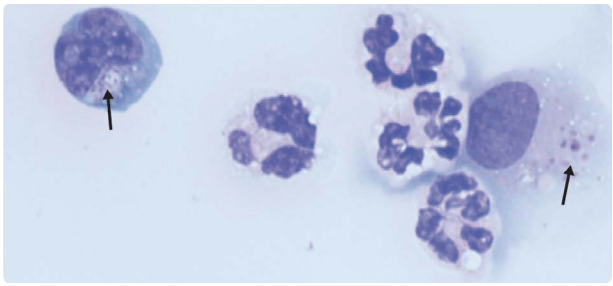

FIGURE 14.77 Cytologic analysis of CSF from a dog with *Toxoplasma gondii* infection revealed intracytoplasmic organisms in many cells (arrows).

potentials and sharp waves in the lumbar paravertebral and hindlimb musculature. CSF analysis shows a mixed cell or mononuclear pleocytosis and an elevated protein concentration, occasionally positive for organisms (Figure 14.77). Histology of the muscle and identification of the organism confirms the diagnosis. Serology for *T. gondii* and *N. caninum* is often positive, and PCR analysis of the CSF can confirm the diagnosis.

Management

Early treatment for 2–4 weeks with combinations of trimethoprim–sulfadiazine or ormetoprim sulfadimethoxine and clindamycin may improve clinical signs. Pyrimethamine may be added to the regimen but can cause bone marrow suppression in young animals. Early antibiotic treatment may improve clinical signs, but recovery is often incomplete. Poor prognostic indicators for resolution of clinical signs include rapidly progressive disease, signs of multifocal CNS disease, hindlimb hyperextension, and a long time interval between onset of clinical disease and treatment.

NEUROMUSCULAR DISORDERS

Clinical Signs

The classical clinical sign of neuromuscular disease is weakness. A paretic gait is usually manifested as a stilted stride that becomes progressively shorter with accompanying ventroflexion of the neck, reluctance to walk or run, lying down, and collapse. If ataxia is present, this suggests a UMN disorder or a sensory neuropathy. Following rest, muscle strength may greatly improve, but such a finding is not consistent. In between episodes, animals may be completely normal or clinical signs of weakness may persist.

Lesion Localization

A thorough history and physical and neurologic examination are essential to determine if weakness is a result of a neuromuscular disease or other systemic disorder. Metabolic and systemic diseases, cardiorespiratory disease, orthopedic, and central neurologic causes of weakness should be ruled out. It is important to approach the patient in a thorough and logical manner, excluding diseases by utilizing the least complex and least invasive tests first.

It is best to perform a standardized clinical examination so that a full physical and neurologic examination is consistently performed. A practical format used for the general examination includes inspection and palpation of muscles and nerves, passive motion of joints, percussion of muscles and tendons, sensory testing, and gait analysis.

Muscle atrophy or hypertrophy can be readily observed at rest, as can spontaneous muscle activity such as fasciculations or tremors. Weakness can often be observed at rest; however, it is easier to detect with moderate walking activity. Weakness of the paraspinal muscles can result in abnormal postures, including thoracic kyphosis and scoliosis. Extraocular, laryngeal, and pharyngeal muscles should also be examined at this time, particularly if the history is suggestive of dyspnea or dysphagia. A complete neurologic examination should be performed in all patients with a history of weakness, exercise intolerance, or collapse.

Gait disturbances can require close observation. An abnormal gait will result from weakness of any of the principal flexor or extensor muscles of the limbs, in addition to any structural abnormalities of the articular surfaces, joint capsules, or ligaments. A normal gait also requires coordination by the CNS, which stimulates or inhibits flexors, extensors, adductors, and abductors for counteracting gravity. In general, gait abnormalities result from (1) pain, (2) muscle weakness, (3) reduced range of joint motion, (4) weakness of UMN or LMN origin, (5) spasticity, (6) dystonia, (7) rigidity, and (8) ataxia. The gait should be observed from both sides as well as from front and back, with ample ambulating space. There are four phases of the gait that should be inspected: Palmar or plantar strike (as the foot meets the floor), midstance, push off, and midswing. The examiner should note the rhythm, symmetry, and strength of strides; the base width of the gait; and the duration of the phases. The base width is the distance between the feet during the strides. Assessment is subjective, but a base width larger than the width of the trunk can suggest sensory deficits causing the ataxia.

Exercise testing in muscle disorders provides the means to assess exercise capacity quantitatively, reproduce exercise-induced symptoms, and investigate the pathophysiology of exercise limitations. Exercise is a powerful tool for evaluating the integrity of the metabolic pathways that power muscular work and assessing the physiologic responses that are linked to the state of muscle energy metabolism. Thus, exercise testing is particularly useful in the investigation of disorders of muscle energy metabolism. In addition, exercise can be utilized to assess objectively the effectiveness of treatment in metabolic myopathies.

Neurodiagnostic Investigation

The diagnostic plan is dependent on the localization of signs, as well as their suspected underlying mechanism.

As some of these problems are episodic, their frequency must be taken into account, and it should be recognized that many of the tests will need to be performed at the time of an "episode." Most neuromuscular disorders, however, will result in continual signs, which may vary in severity based on the level of activity.

The following tests should be considered for all cases with weakness or collapse, particularly if a neuromuscular disorder is suspected.

Video Footage

If the episodes are so infrequent that they are not observed by the clinician, the owners should attempt to capture the event on videotape. Observation of the event is critical to the diagnosis. Without observation, the nature of the event must be surmised by listening to the "eyewitness" description offered by the owner.

Minimum Database

Comprehensive hematology, serum biochemistry (including CK, lactate, and electrolytes), urine analysis, a fecal examination, and a resting electrocardiogram, as well as thoracic and abdominal radiographs, should be considered the minimum essential database. A thyroid panel and an adrenocorticotropic hormone (ACTH) stimulation test should also be considered, as neuromuscular disease may be the first and only manifestation of endocrine disorders. Resting blood pressure assessments should also be performed if there is any concern about a cardiorespiratory disease, and peripheral vascular pulses should always be palpated to evaluate the potential of peripheral vascular compromise.

Serum Creatine Kinase

CK is a specific enzyme marker of myofiber damage and the one most frequently used in the diagnosis of muscle diseases. CK is often increased in necrotizing, inflammatory, and dystrophic myopathies and is usually normal in muscle diseases in which necrosis is not a feature (e.g., myotonia). The enzyme is very labile and so is nonspecific. As the half-life is only about 2 hours, the magnitude and persistence of increased CK activity is an indication of severity and activity of an underlying muscle disease. However, this enzyme can be elevated following IM injections, surgery, prolonged recumbency, and even anorexia in cats. Conversely, muscle disease should never be ruled out based on a normal CK level.

Cardiac Troponin I

Troponin is located in myofibrils and is the regulatory protein of contractile skeletal and cardiac muscle. Cardiac muscle can be affected by generalized myopathies, including muscular dystrophy, mitochondrial myopathies, and necrotizing myopathies. Although cardiac troponin concentrations are not affected by nonspecific types of skeletal muscle damage, a generalized disease of muscle affecting the myocardium could elevate this enzyme. This could be potentially helpful in the future as a prognostic marker based on extent of disease.

Myoglobin

Myoglobin present in the urine (myoglobinuria) usually indicates severe muscle damage, frequently rhabdomyolysis following trauma, toxins, infections, and malignant hyperthermia. However, a correlation does not exist between serum CK and myoglobinuria, and so it is considered an insensitive test. Recurrent myoglobinuria may be detected in inherited metabolic myopathies and in muscular dystrophy. Myoglobin is toxic to the renal tubules and can cause acute kidney injury.

Serology and PCR

Investigations of infectious diseases may require extensive serologic tests, and their interpretation may be difficult, but depending on the potential for exposure, serology should be performed on all possible infectious candidates (particularly *Toxoplasma gondii*, *Neospora caninum*, *Hepatozoon* spp. and *Leishmania* spp.) depending on geographic locale and travel history. Serology for autoimmune conditions such as rheumatoid arthritis, systemic lupus, and myasthenia gravis may be warranted if suspected. Antibodies against the acetylcholine receptor (AChR) should be measured in all dogs with acquired megaesophagus and dysphagia. Anti-GM2 ganglioside Abs have a diagnostic sensitivity of 60% and a specificity of 97% for acute canine polyradiculoneuritis and should be considered for patients with an acute onset of peripheral nerve disease.

Electrophysiology

Extensive electrophysiologic testing may be required to confirm the precise lesion localization of the disease if a neuromuscular abnormality is suspected. An abbreviated needle electromyography (EMG) test may be worthwhile in the initial investigations, as it can quickly aid identification of an axonal or muscular disease. This is particularly helpful in cases with obvious muscle hypertrophy or atrophy. Repetitive nerve stimulation and single-fiber EMG should be considered for neuromuscular junction assessment (**Figure 14.78**).

Advanced Imaging

Unless a CNS abnormality is suspected, it may not be necessary to consider spinal radiographs, CT, or MRI studies. Thoracic radiographs can assist with the diagnosis of megaesophagus and associated aspiration pneumonia. Fluoroscopy or contrast-enhanced radiography may be helpful to evaluate the function of the esophagus if enlargement is not obvious on plain survey radiographs and swallowing if dysphagia is present. Cardiac ultrasonography may be required if a cardiorespiratory condition is suspected.

MRI and CT scans have recently been utilized to document the presence of muscle pathology, particularly

FIGURE 14.78 Electrophysiologic assessment of the nerves in the forelimb. Stimulating needles are placed proximally in close association to a specific nerve, and recording electrodes are placed distally in the interosseous muscles to detect the resultant action potentials.

on postcontrast images. The location of the contrast uptake within the muscles detected on MRI or CT can assist with choosing suitable areas for a more high-yield biopsy, which is important in early-onset, localized, or patchy myopathies.

Cerebrospinal Fluid Analysis

A CSF tap may help to rule out CNS diseases as well as diffuse inflammatory conditions of the nerve roots, but rarely is it a specific test, and rarely will it be helpful in cases of neuromuscular collapse. Evaluation for infectious diseases can be achieved with serologic techniques or with PCR analysis of the CSF.

Muscle and Nerve Biopsy

If a neuromuscular disease is suspected, a muscle or nerve biopsy can provide a specific diagnosis of the underlying cause (Figure 14.79). Since a peripheral nerve can react in only a limited number of ways to a variety of insults, the biopsy in most instances just confirms the presence of axonal degeneration, demyelination, abnormalities of supporting structures, inflammation, or infiltrative neoplasia. However, a nerve biopsy can provide information on regeneration, remyelination, and degree of fiber depletion and fibrosis, which are important for prognosis. The muscle biopsy is of utmost importance in the diagnosis of most muscle diseases, particularly the inherited diseases.

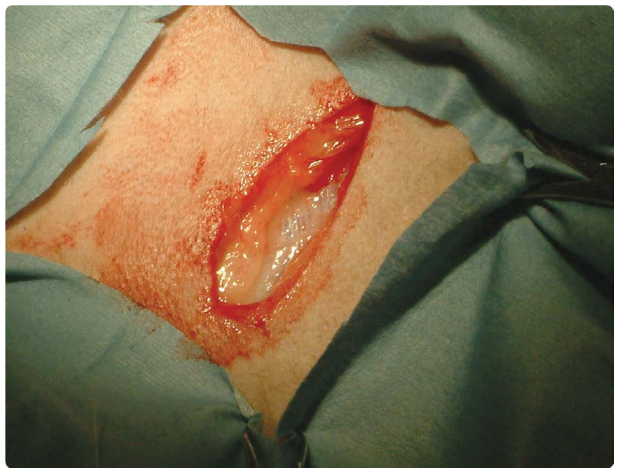

FIGURE 14.79 A linear skin incision exposes subcutaneous fat and shiny underlying muscle fascia. The fascia needs to be incised, which will allow a small piece of muscle to be sampled for histopathologic assessment.

NEUROPATHIES

BREED-RELATED NEUROPATHY

Definition/Overview

Inherited and breed-related neuropathies are rare diseases that usually affect young animals and can produce generalized motor, mixed motor and sensory, pure sensory, and/or autonomic deficits.

Etiology

Unknown, suspected genetic in many breeds.

Pathophysiology

Progressive, usually chronic degeneration of the myelin and/or the axons of sensory and/or motor fibers.

Clinical Presentation

Typically, progressive LMN paresis develops, often affecting the hindlimbs first but eventually involving the forelimbs. The concurrent development of laryngeal paralysis and megaesophagus is recognized as a syndrome called laryngeal paralysis polyneuropathy complex. This syndrome has been reported in young Rottweilers, Dalmatians, Leonbergers, white-coated German Shepherd Dogs, Miniature Schnauzers, Alaskan Malamutes, Black Russian Terriers, and Pyrenean Mountain Dogs among others. It is now recognized that older dogs with idiopathic laryngeal paralysis, in particular Labrador Retrievers, also suffer from a more generalized neuropathy that is likely hereditary. Sometimes referred to as geriatric-onset laryngeal paralysis and generalized polyneuropathy (GOLPP), late-onset laryngeal paralysis (LoLP), or idiopathic acquired laryngeal paralysis, it appears that the laryngeal paralysis is, in fact, part of a progressive generalized neuropathy. GOLPP is a common clinical condition affecting geriatric, large and giant-breed dogs, most commonly Labrador Retrievers, in which the laryngeal innervation degenerates over time. Owners of Labrador Retrievers with LoLP perceive it to be a life-limiting disease that negatively impacts their dog's quality of life. GOLPP

typically develops by 10–11 years of age. The condition appears to be a peripheral neuropathy, with degenerative changes present in peripheral nerves. It remains unknown whether the disease also affects the central nervous system. The underlying pathogenesis of GOLPP is not understood. It is currently unclear whether it is due to a single pathological mechanism or is a common clinical phenotype resulting from a variety of underlying pathologies.

Several different breeds of cat are also reported to have hereditary neuropathies, including the Siberian cat, the Snow-Show, the Bengal, and Birman. There are some general similarities between the reports in these breeds, giving rise to the idea that the breeds may be predisposed to the same disease rather than the disease truly being breed specific. Heterogenous motor polyneuropathies should be considered in young cats of any breed and sex that are presented with relapsing or progressive generalized neuromuscular disease. There is a suggestion that some of these breed-related and often self-limiting peripheral neuropathies may have an inflammatory component.

Familial sensory neuropathies are particularly unusual but have been reported in English Pointers, English Springer Spaniels, French Spaniels, Longhaired Dachshunds, Jack Russell Terriers, Border Collies, Miniature Pinschers, Fox Terriers, and German Shorthaired Pointers. The Border Collie breed is affected with a progressive proprioceptive ataxia with self-mutilation with an age of onset between 2 and 7 months. The neuropathy in this breed is classified as a sensory and autonomic neuropathy, and an inversion disrupting the FAM134B gene has been identified through whole genome sequencing. Dachshunds present with nociceptive deficits, mild ataxia, and loss of conscious proprioception. These dogs have been reported to self-mutilate their penis and dribble urine. The disease in English Pointers and French and English Spaniels is more severe and more specific to nociception. They lose nociception in their distal limbs around 3–8 months of age and as a result lick, chew, and even autoamputate their digits. These dogs do not have conscious proprioceptive deficits.

Diagnosis

Diagnosis is by recognition of typical breed, age of onset, presentation, and ruling out other disorders by electrophysiologic evaluation of nerve function and nerve biopsy. All dogs with laryngeal weakness should undergo investigation for a more extensive polyneuropathy with at least a neurological examination. Thyroid function and myasthenia gravis testing is encouraged. Esophageal function tests, including a swallowing study using barium contrast radiography or fluoroscopy, thoracic radiographs, or evaluation of swallowing reflexes/responses, should be considered in these dogs. In one study, all dogs (age range 7–15 years) with laryngeal paresis had abnormal esophageal function tests at the time of diagnosis, but only a third had clinical signs.

Management

Therapy is limited to symptomatic management of signs in most diseases. For cases with laryngeal paresis, treatment usually includes a unilateral surgical arytenoid lateralization, which is generally very successful and associated with an improved quality of life. The most common postoperative risk is aspiration pneumonia. Other surgical treatments include bilateral arytenoid lateralization, partial laryngectomy, and tracheostomy; however, these procedures are associated with a higher complication rate than unilateral arytenoid lateralization. There is no specific treatment for the progressive generalized polyneuropathy. Physical therapy is advised in many cases to maintain range of motion and muscle mass. It is important to recognize problems and diagnose the cause of signs in animals used for breeding.

ENDOCRINE NEUROPATHY

Definition/Overview

Endocrine diseases that are known or suspected to cause a peripheral neuropathy include diabetes mellitus, hypoglycemia (most commonly as a result of insulinoma in dogs), hypothyroidism, and hyperadrenocorticism. These diseases are associated with chronic progressive diffuse weakness with or without systemic signs of the specific endocrine disease.

Etiology

Diabetes mellitus, hypoglycemia (most commonly as a result of insulinoma in dogs), hypothyroidism, and hyperadrenocorticism.

Pathophysiology

Poorly controlled diabetes mellitus causes distal axonal degeneration, with the longest peripheral nerves affected first.

Clinical Presentation

The most common manifestation of diabetes mellitus is a sciatic neuropathy in cats causing a plantigrade stance in the hindlimbs at rest and when walking. Affected cats retain the ability to ambulate, but hock flexion is absent when the withdrawal reflex is tested. As the signs progress, they also develop a palmigrade stance. Although pathologic changes and sporadic cases of neuropathy have been detected in diabetic dogs, it is usually a subclinical problem in this species. However, when it does occur, it resembles a degenerative myelopathy, which will reverse with improved diabetic regulation. Hypothyroidism has been reported to be a cause of weakness in dogs as a result of a generalized peripheral neuropathy. In addition, idiopathic neuropathies such as facial or laryngeal paralysis, peripheral vestibular syndrome, and megaesophagus have been linked to hypothyroidism.

Diagnosis

Diagnosis of diabetic neuropathy is strongly suspected in animals with poorly controlled diabetes and classic neurologic findings. Definitive diagnosis is made by electrophysiologic studies and nerve biopsy. Although axonal degeneration can be present in severely affected animals, the most common findings are abnormalities in Schwann cells and myelin. Diagnosis of hypothyroidism is made by measurement of serum total and free T4 and thyroid-stimulating hormone levels.

Management

Prognosis for full recovery of peripheral nerve function associated with diabetes mellitus is good in most cases. Restoring normoglycemia prevents progression and, in most cases, may result in complete resolution of neurologic signs. Supplementation with thyroxine may reverse the signs of generalized peripheral neuropathy associated with hypothyroidism over 2–3 months, but laryngeal and esophageal abnormalities usually persist.

INSULINOMA

Definition/Overview

Chronic, severe hypoglycemia (<3 mmol/L [54 mg/dL]) is almost invariably associated with insulinomas in dogs and can result in a generalized neuropathy.

Etiology

Pancreatic beta cell tumor.

Clinical Presentation

The most common neurologic signs result from the effects of hypoglycemia on the CNS (seizures, weakness, exercise intolerance, and collapse). However, persistent hypoglycemia may also cause a distal peripheral neuropathy that manifests initially as a stiff gait, particularly in the hindlimbs, but progresses to more obvious signs of a generalized peripheral neuropathy with prominent sciatic deficits.

Diagnosis

Diagnosis is based on documentation of hypoglycemia with concurrent inappropriate hyperinsulinemia in the presence of the clinical signs and associated with a pancreatic mass, documented with ultrasound or MRI or surgical exploration (Figure 14.80) and histopathology following resection.

Management

Treatment of the insulinoma may improve the gait depending on the extent of the underlying disease.

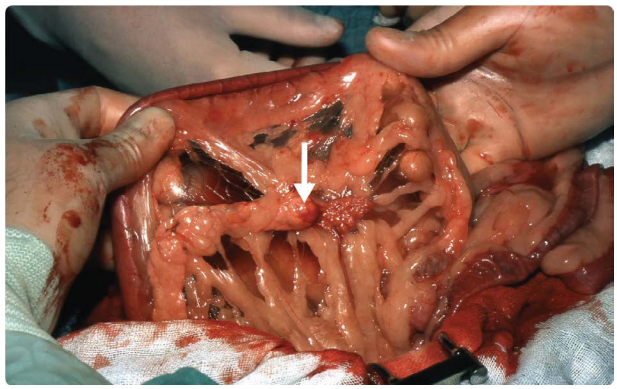

FIGURE 14.80 Insulinoma (arrow) as viewed at surgery in a dog. (*Courtesy of M. Schaer.*)

INFLAMMATORY DISEASES

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

Definition/Overview

Chronic inflammatory demyelinating polyneuropathy (CIDP) causes slowly progressive LMN tetraparesis in adult dogs and cats with no gender or breed bias.

Etiology

CIDP is an immune-mediated disease in which the inflammatory reaction is focused on peripheral nerve myelin sheaths. The etiology of the disease is unknown, but it appears to be similar to chronic inflammatory demyelinating polyneuropathy in humans, which is believed to be an immune-mediated disorder driven by cell-mediated and humoral responses against peripheral nerve antigens. CIDP in humans has been associated with many systemic disorders such as diabetes, hypoproteinemia, thyroid dysfunction, and neoplasia.

Pathophysiology

CIDP is an apparently immune-mediated disease in which the inflammatory reaction is focused on peripheral nerve myelin. The chronic presentation in dogs normally is manifested by demyelination and remyelination with onion bulb formation associated with prominent mononuclear inflammation. Some aspects of this lesion are manifested in other canine radiculoneuropathies, usually in association with wider involvement of peripheral nerves

Clinical Presentation

Signs can relapse intermittently and can progress from paraparesis to tetraplegia. Shifting lameness, a plantigrade stance, and ventroflexion of the neck have been described in cats, along with megaesophagus and regurgitation. Leg tremors and laryngeal and facial paralysis have been noted in dogs.

Diagnosis

Anti-GM2 ganglioside antibody titer evaluation should also be considered in these cases, although other antibodies directed against molecules of the nodal and paranodal organization may be involved. MRI may frequently not be considered for a polyneuropathy, but hypertrophy of the cervicothoracic nerve roots in a dog with CIDP has been reported. Notably, nerve roots not always are bilaterally or symmetrically affected. Definitive diagnosis is reached by a combination of electrophysiologic studies and nerve biopsy. Typically, motor nerve conduction velocity is reduced. There is multifocal paranodal demyelination in teased nerve fiber preparations, and thinly myelinated fibers are visible on semithin sections. Electron microscopy reveals macrophages stripping myelin and the presence of demyelinated and remyelinated fibers. There is also a mononuclear infiltrate.

Management

Treatment consists of immunosuppression with prednisone (initial dose of 2 mg/kg p.o. divided q.12 h. for 1–2 weeks followed by gradual tapering over a period of weeks). Most cases respond favorably to this regimen, although some eventually relapse and become steroid resistant.

ACUTE POLYRADICULONEURITIS

Definition/Overview

Acute polyradiculoneuritis (APN) (inflammation of peripheral nerves and nerve roots) is probably the most common peripheral neuropathy of dogs and young purebred cats.

Etiology

The disease can be subclassified according to cause as Coonhound paralysis, (seen in North America, with onset of signs 7–10 days after raccoon bites), idiopathic polyradiculoneuritis, and postvaccinal polyradiculoneuritis (extremely rare). Risk factors suspected (apart from inoculation of racoon saliva and vaccination), include upper respiratory and gastrointestinal infections. Jack Russell Terriers and West Highland White Terriers have a significantly greater odds of developing APN. An important association in man is concurrent infection with a specific serotype of *Campylobacter jejuni*. A similar relationship has been documented in dogs, with the most common *Campylobacter* species identified being *Campylobacter upsaliensis*. This is possibly associated with consumption of raw chicken found in dogs' diets. APN dogs also have significantly lower serum 25-hydroxyvitamin D3 concentration when compared to control dogs. However, the cause and clinical significance of the altered vitamin D status in dogs with acute polyradiculoneuritis is not yet clear. It has also been shown that dogs with idiopathic acute polyradiculoneuritis are more likely to have positive titers for *T. gondii* than control dogs.

Pathophysiology

Signs are caused by an inflammatory reaction to axons and myelin sheaths that is most intense at the level of the ventral nerve root, with minimal dorsal root involvement. Electrophysiological findings in dogs suggest that it is primarily a motor axonopathy. A recent study in dogs has demonstrated the presence of anti-GM2 ganglioside antibodies in sera from a high percentage of dogs with APN. Gangliosides are found in high concentrations in membranes of neural tissue. When antiganglioside antibodies bind to gangliosides, the complement cascade is activated, resulting in an attack to membrane complexes, pathologic changes, and dysfunction of the structures targeted.

Clinical Presentation

Affected dogs suffer from an acute ascending paralysis that progresses over 2–4 days to LMN tetraparesis or plegia. Spinal hyperesthesia has been noted in some dogs, and CNs can become involved, leading to dysphonia and facial weakness. Severe cases may suffer respiratory failure. Affected cats develop a rapidly ascending flaccid tetraparesis with severely decreased to absent spinal reflexes within 72 hours from the onset of clinical signs. Some cats develop respiratory paralysis leading to apnea and eventual euthanasia, whereas others can recover uneventfully in 4–6 weeks.

Diagnosis

The number of diseases that cause acute onset of LMN tetraparesis/tetraplegia is limited, and polyradiculoneuritis should always be suspected when this clinical picture occurs. Other diseases to consider include botulism and, in the United States and Australia, tick paralysis. Fecal culture and PCR from fecal samples can help to identify *Campylobacter* species. Anti-GM2 ganglioside antibodies were detected in 14 out of 25 APN dogs, and anti-GA1 antibodies in one further dog, providing a diagnostic sensitivity of 60% and a specificity of 97%.

EMG reveals spontaneous electrical activity consistent with denervation (fibrillation potentials and positive sharp waves). Nerve conduction velocities are dispersed and reduced, with nerve roots more severely affected than the distal nerve. Definitive diagnosis is established with a nerve biopsy.

Management

Treatment is focused on supportive care and rehabilitation. Corticosteroid administration is not beneficial. The pulmonary function of recumbent animals must be monitored closely. If hypoventilation is suspected, a blood gas analysis should be performed to document progressive increases in PCO_2 (>65 mmHg; reference value 35–45 mmHg) to determine whether mechanical ventilation is necessary. Animals should be turned,

and passive range-of-motion exercises and massage of limbs should be performed at least four times a day. If pulmonary function is unaffected, with adequate supportive care most animals will recover over a period of 3–6 weeks. However, the need for mechanical ventilation, the presence of aspiration pneumonia, and severe muscle atrophy with development of contractures all worsen the outcome. The median time to ambulation (>3 steps without support) from onset of the clinical signs is 50.7 days (range 10–110 days). The median time to reach a plateau (best clinical improvement) is 95 days (range 13–300 days). Prolonged courses (up to 3–4 months) and incomplete recoveries are possible in some dogs. Usually, the more severe the clinical signs are, the longer the recovery time is.

PROTOZOAL NEURITIS

Definition/Overview

Infection with the protozoal organisms *Toxoplasma gondii* and *Neospora caninum* can cause an intense polyradiculoneuritis in dogs, accompanied by a myositis.

Etiology

Protozoal infection.

Pathophysiology

Clinically significant protozoal infections affect young or immunocompromised dogs. Dogs are both definitive and intermediate hosts for *Neospora* spp., with cattle, sheep, goats, and other mammals also acting as intermediate hosts. Cats are the definitive host for *Toxoplasma* spp., with most mammals serving as intermediate hosts. Infection can occur transplacentally (common for *N. caninum*), by ingestion of protozoal cysts from infected secondary hosts, and by ingestion of oocysts shed in feces (common for toxoplasmosis).

Clinical Presentation

Clinical signs can be extremely variable as a result of infection of muscle, peripheral nerve, and the CNS. Typically, the hindlimbs are affected first, and the combination of myositis and neuritis causes rigid extension of the limbs, with severe muscle atrophy and contractures developing quickly. However, multifocal CNS signs can be present, and a cerebellar syndrome has also been reported.

Diagnosis

Definitive diagnosis can be made by identification of the organisms in muscle or nerve biopsies, combined with serology. Serology alone can be confusing with a high rate of false-positive titers, particularly in the case of toxoplasmosis. PCR analysis of CSF may provide a more specific diagnosis, but the sensitivity of this test is unknown.

Management

Treatment of protozoal infections can be attempted using clindamycin. However, a combination of trimethoprim/sulfadiazine and pyrimethamine is more effective at actually killing the organisms and penetrates the CNS well. Animals on this protocol can be supplemented with folic acid. Azithromycin can be added as it is effective at killing intracellular organisms. Prognosis depends on the severity of clinical signs and muscle contractures. Recovery of normal function is unlikely, although institution of treatment can prevent progression of signs. If treatment is initiated while signs are still mild, the prognosis is better, but relapses can occur.

TOXIN-ASSOCIATED DISEASES

BOTULISM

Definition/Overview

Botulism intoxication can result in an acute onset of rapidly progressive diffuse neuromuscular signs. Multiple dogs can be involved at the same time depending on the source and accessibility of the toxin.

Etiology

There are several forms of the botulinum toxin produced by *Clostridium botulinum*, but botulinum C is the only form associated with canine disease. Rare cases have been described in association with types B and D.

Pathophysiology

Botulism is caused by absorption of the botulinum toxin following ingestion of spoiled carrion or raw meat. The spores formed by bacteria, which are highly resistant to severe environmental conditions, will germinate in anaerobic conditions such as those provided by rotten carcasses of dead animals. Following cell or spore lysis, the toxin is released and binds with other protein complexes to form progenitor toxins. These progenitor toxins are extremely stable, particularly at low pH, and pass through the stomach into the small intestine where the toxin is released and absorbed. The toxin is absorbed from the small intestine by endocytosis and enters the lymphatic system and from there the bloodstream. The botulism toxin heavy chain then binds rapidly and with extremely high affinity to presynaptic peripheral nerve terminals, affecting the limb, trunk, and head muscles.

The botulinum toxin produced by *C. botulinum* is taken up at the neuromuscular junction and prevents synaptic release of acetylcholine at the neuromuscular junction of cholinergic nerves. Botulinum toxins, like tetanospasmin, are zinc endopeptidases, and botulinum C binds to the presynaptic protein SNAP 25.

Clinical Presentation

Botulism causes LMN tetraparesis that starts in the hindlimbs as mild weakness but progresses to tetraplegia in severe cases. CNs are often involved, producing facial paresis, dysphonia, megaesophagus, and regurgitation. Autonomic signs such as mydriasis and dry eye are variably present. Onset of signs usually occurs over 2–4 days and is often preceded by a history of dietary indiscretion (usually consuming spoiled meat) and vomiting or diarrhea. Botulism is extremely rare in cats.

Diagnosis

History and clinical signs are indicative of the disease. Electrophysiologic studies may be supportive of the diagnosis. Reduced motor nerve conduction velocity has been reported, suggesting that there is a concurrent neuropathy. Definitive diagnosis is difficult to establish. The presence of botulinum toxin in the serum, feces, or vomitus may be detected using a specific antitoxin to perform a neutralization test in mice, and use of an ELISA has been reported, demonstrating an increase in serum titers to botulinum neurotoxin type C, 3 weeks after onset of signs. Typically, the toxin is no longer detectable by the time neurologic signs are evident.

Management

Treatment is supportive and recovery occurs over a period of approximately 3 weeks. Recumbent dogs should be turned regularly, kept clean and dry, and their bladder expressed if necessary. Megaesophagus and regurgitation should be managed by intermittent suction of the esophagus by means of a nasoesophageal tube, antacids (e.g., famotidine) to decrease acidity of stomach contents (decreases esophagitis and effects of aspiration), and antibiotics for aspiration pneumonia if necessary. Ampicillin, aminoglycosides, erythromycin, ciprofloxacin, and imipenem interfere with neuromuscular conduction and should be avoided. If megaesophagus is present, the dog should be fed while held or propped with the head up and that position maintained for approximately 30 minutes after feeding. Arterial blood gas analysis should be performed to check for hypoventilation in tetraplegic animals and in animals that may have aspirated. Passive range-of-motion exercises and massage should be performed every 6 hours while the animal is recumbent. If pulmonary function is not adversely affected, dogs have a good prognosis with adequate nursing. If aspiration pneumonia or hypoventilation develops, the prognosis is grave, but recovery can occur if appropriate ventilatory support can be provided.

TETANUS

Definition/Overview

Tetanus is a toxicoinfectious disease resulting from bacterial infection by *Clostridium tetani*. The infection can spread from its origin to the CNS and cause local or generalized muscular rigidity before potentially spreading to the brain. Without intensive supportive care, many cases can be fatal.

Etiology

Tetanus is caused by absorption of tetanus toxin (tetanospasmin) produced by the anaerobic motile, Gram-positive, nonencapsulated, spore-forming, rod-shaped bacterium *Clostridium tetani*. The organism's resistant spores are ubiquitous, with a natural habitat in moist, fertile soil; however, they can survive indefinitely in dusty indoor environments. The source of the bacterium is usually a penetrating wound providing both contamination with *Clostridium* and the conditions suitable for its growth. Infection can follow teething, dental fractures, nailbed infections, parturition, or surgeries such as ovariohysterectomy.

Pathophysiology

The exotoxin tetanospasmin is absorbed into the bloodstream and from there is taken up by the nerves. In a similar fashion to botulinum toxin, tetanospasmin has zinc metalloproteinase activity and binds to and cleaves synaptobrevin (a SNARE protein that mediates fusion of synaptic vesicles with the presynaptic membrane), preventing the release of neurotransmitter and causing failure of synaptic transmission. However, in tetanus, the toxin is transported retrogradely up the motor neurons and from there to inhibitor interneurons (the Renshaw cells) where it blocks release of the inhibitory neurotransmitters glycine and gamma-aminobutyric acid (GABA).

Clinical Presentation

Tetanus most commonly affects young large-breed dogs and is rare in cats. Clinical signs can take up to 3 weeks to become apparent from the onset of infection, although most cases exhibit symptoms within 5–12 days. Owners most frequently report changes in the face and eyes as the first clinical signs that they notice.

A characteristic facial expression (risus sardonicus) is often seen as a result of increased facial muscle tone. The palpebral fissure is wider than usual, the pupils are miotic, the ears are rigid, the lips are drawn back, and the forehead is wrinkled. The third eyelid may be protruded, and there is often profuse salivation because the animal has difficulty swallowing. Involvement of the head can lead to spasms of the masticatory and pharyngeal muscles, causing trismus (lockjaw) and dysphagia. Trismus is not pathognomonic for tetanus on its own and must be differentiated from the other causes, which include temporomandibular joint disease or subluxation, masticatory myositis, and retrobulbar abscess.

At least 50% of dogs progress within a median of 4 days (range 0–14 days) to recumbency with severe muscle spasms (Figure 14.81). Visual and tactile stimuli and placing the animal on its side often results in a further increase in muscle tone, resulting in muscle spasms. As

FIGURE 14.81 A young Bull Terrier exhibits generalized signs of tetanus with limb rigidity, creating a "sawhorse" stance and facial muscle abnormalities compatible with "risus sardonicus."

signs progress, the animal may have difficulty breathing and can develop a hiatal hernia and megaesophagus as a result of increased diaphragmatic tone. Both bradycardia and tachycardia have been described in dogs with tetanus due to effects of the toxin on the autonomic nervous system, in addition to dysuria, urinary retention, and constipation.

A tetanus severity classification system has been proposed in dogs: Class I dogs have only facial signs of tetanus; class II dogs have generalized rigidity or dysphagia, with or without class I signs; class III dogs have class I or II signs and are recumbent or have seizures; and class IV dogs have class I, II, or III signs as well as abnormal heart rate, respiratory rate, or blood pressure measurements. Survival rate decreases with severity class.

Cats are more likely to present with a focal form of the disease with signs limited to the area of the infection (e.g., monoparesis following distal limb injury, although this has also been reported in dogs).

Diagnosis

The diagnosis is usually presumptive and based on the presence of classic clinical signs. The presence of a wound or history of recent surgery are supportive of the diagnosis. Attempts can be made to culture the organism but are frequently unsuccessful due to low organism numbers and the need for anaerobic conditions. An infectious process may be suggested by the results of the complete blood count. Muscle enzymes may be elevated in patients with tetanus because of the persistent muscle spasticity; high activities of creatine kinase (1,599–18,405 U/L [reference range 61–394 U/L]) have been documented in more than 50% of dogs. CSF analysis is unremarkable. Radiographs may be helpful to identify involvement of the esophagus, diaphragm, and secondary changes in the lungs resulting from aspiration pneumonia. Attempts to isolate *C. tetani* from wounds often fails because of the low concentration of organisms and the requirement for strict anaerobic culture conditions at 37° C for at least 2 weeks. A Gram stain of a smear from an open wound may identify Gram-positive rods and dark-staining spheric endospores, but the morphology of the bacterium is nonspecific and similar to that of many other bacteria.

Management

There are three treatment strategies for dogs and cats with tetanus: (1) Toxins present in the body outside of the CNS should be neutralized; (2) organisms present in the body should be destroyed to prevent further toxin release; and (3) the effects of the toxin already in the CNS should be minimized. Intensive care management of affected animals is essential.

- **Toxin neutralization**

  Antitoxin neutralizes any toxin that is unbound to the CNS. Therefore, the timing of administration in relation to the onset of the disease is essential to its effectiveness. The antitoxin used can be either antitetanus equine serum or human tetanus immune globulin. Antitoxin should be administered intravenously (100–500 IU/kg, although a wide range of doses is cited by different authors) to inactivate any circulating toxin. A test dose of 0.1 mL of a 1:10,000 solution should be given subcutaneously 20–30 minutes prior to the intravenous dose to check for adverse reactions. A wheal at the site of injection may indicate that an anaphylactic reaction will develop. Epinephrine (0.1 mL/kg IV of the 1:10,000 dilution), glucocorticoids, and an antihistamine (e.g., diphenhydramine) should be readily available in case of an adverse reaction (or the latter two even given on a prophylactic basis. There has been no significant benefit in survival, severity of clinical signs, or duration of clinical signs shown for dogs treated with antitoxin.
- **Antimicrobial therapy**

  If the source of infection can be identified, it should be treated by surgical debridement (if necessary), flushing with hydrogen peroxide. Antimicrobials are essential to kill vegetative *C. tetani* organisms in order to reduce the amount of circulating toxin. Classically, penicillin G has been the drug of choice, either intravenously as an aqueous potassium or sodium salt or intramuscularly as the procaine salt (20,000–100,000 U/kg q.6–12 h. for 10 days in cats and dogs). However, metronidazole (7–10 mg/kg p.o. or IV q.8–12 h. for 10 days) has been shown superior to penicillin G in clinical tetanus because it achieves bactericidal therapeutic concentrations in anaerobic tissues. Other options include clindamycin (10 mg/kg p.o., IV, or IM q.8–12 h.) and tetracycline (22 mg/kg p.o. or IV q.8 h.) or doxycycline (5–10 mg/kg p.o. or IV q.12 h.).
- **Supportive care**

  Intensive nursing care is essential for successful treatment of patients with tetanus. The dog or cat should be isolated in a dark and quiet environment, with cotton wool balls placed in the external ear canals. Minimal handling is optimal, and all treatments, therefore, should be coordinated to occur together at set

times through the day. Complications occurring during treatment include aspiration pneumonia, upper respiratory tract obstruction requiring tracheostomy, hiatal hernia, hyperthermia, and coxofemoral luxation. Pressure sores or decubital ulcers should be prevented with appropriate soft or padded bedding and frequent turning.

Extensor tone can be reduced with a number of different drugs. Phenobarbital, pentobarbital, acepromazine, chlorpromazine, diazepam, and methocarbamol have all been advocated. These drugs also help to reduce patient anxiety. With severe signs such as generalized tonic–clonic seizure activity, generalized body stiffness, and opisthotonos, a propofol infusion may be necessary, but cardiovascular parameters should be monitored closely, and careful consideration should be given to whether the patient should be intubated and placed on positive-pressure ventilation. The use of magnesium sulfate ($MgSO_4$) infusions or supraphysiologic magnesium therapy has been documented as a potential adjunct therapy in the management of spastic paralysis in dogs with tetanus. A dose of 70 mg/kg over 30 minutes followed by an initial CRI of 100 mg/kg per day has been recommended for dogs based on human literature. The goal of this treatment is to increase total serum magnesium to 2–4 mmol/L (4.86–9.73 mg/dL) based on a target therapeutic range derived from the human literature.

If unable to prehend and swallow food, the animal may need to have a gastrostomy tube placed, and in some instances, a tracheostomy tube may also be necessary. Percutaneous gastrostomy tube placement may prevent the complications associated with nasogastric tube feeding, particularly the stress that may be associated with an indwelling intranasal tube. Gastrostomy- or gastrojejunostomy-assisted tube feeding also can reduce the risk of aspiration pneumonia, a potential complication in dogs with severe forms of tetanus and those that are recumbent for a prolonged period. If airway obstruction develops because of laryngeal spasm or a buildup of saliva or tracheal secretions, intubation and mechanical ventilation may be necessary. A tracheostomy often is performed in these patients to decrease the need for continuous anesthesia. Urinary and fecal retention occur in some patients with hypertonic anal and urinary sphincters. An indwelling urinary catheter may be beneficial in these patients, although the urine should be analyzed regularly for evidence of nosocomial infection.

Recovery is slow, and signs may take up to 4 months to resolve completely, although most animals dramatically improve within a month of starting treatment. Reported outcomes of tetanus vary. Most dogs that recover (58%–82%) show some improvement within 5–12 days, although the presence of autonomic abnormalities is a poor prognostic indicator. Median length of hospitalization for dogs has been reported to be 13 days (range 6–42 days). Mortality is likely related to the severity of clinical signs. One study reveals that all dogs with class I or II clinical signs survived, and only 58% of class III or IV signs survived. However, actual mortality may be difficult to estimate given the fact that long-term intensive management of these cases is associated with a significant financial burden for the owners; therefore, many animals are euthanized humanely. A full recovery may not be possible in at least 15% of dogs that survive, but continued improvement may be seen for 3–5 months. Cats are reported to recover well from localized tetanus, with some residual deficits remaining several months later.

At least 46% of surviving dogs in one large study developed abnormal "dream enactment," clinically consistent with rapid eye movement (REM) sleep disorder. Twitching, running, and vocalization were new sleep behaviors in 53, 80, and 60% of affected dogs. Clinically, probable REM sleep disorder was described as violent or "nightmare"-like in 36% affected dogs and like an epileptic seizure in 40% affected dogs. When trialed, antiepileptic medications were ineffective. Onset occurred before discharge in 25% cases. For dogs that developed REM sleep disorder after discharge, onset occurred within 2 weeks of discharge in 77% dogs. The clinical events did not worsen in severity or frequency in any dog and spontaneously resolved within 6 months in 43% cases.

TICK PARALYSIS

Definition/Overview

Attachment of a tick is associated with an acute onset of progressive diffuse neuromuscular disease. It is encountered commonly in the United States, and more severe forms occur in Australia and Africa.

Etiology

The ticks most commonly associated with tick paralysis in North America are the Rocky Mountain wood tick (*Dermacentor andersoni*), the American dog tick (*Dermacentor variabilis*), the lone star tick (*Amblyomma americanum*) and the Gulf Coast tick (*Amblyomma maculatum*). In Australia, tick paralysis is a common problem affecting both dogs and cats living along the east and southeastern coast reportedly due to *Ixodes holocyclus* and *Ixodes coronatus*.

Pathophysiology

Certain species of female ticks contain a toxin within their saliva that causes presynaptic blockade of acetylcholine release and a flaccid tetraplegia. Signs appear after the tick has been attached for 3–5 days and progress over 1–3 days. They usually resolve within an equal period following removal of the tick, except in the case of the Australian tick, in which signs can progress following tick removal.

Clinical Presentation

Ascending lower motor neuron paralysis develops within 5–9 days of tick attachment. One tick is sufficient to cause paralysis; large numbers of ticks are associated with increased severity of clinical signs and rapidity of

onset. Early signs are hindlimb weakness and ataxia, which progresses to tetraplegia over 1–3 days. Tendon (stretch) reflexes, such as the patellar reflex, are usually lost before withdrawal reflexes. Cranial nerves are rarely affected, but some animals may show changes in voice, suggesting laryngeal involvement, or facial and masticatory muscle weakness. Sensory, urethral, and sphincter functions are unaffected in dogs with American tick paralysis. If ticks remain in situ, death from respiratory paralysis can occur in 1–5 days.

Diagnosis

Appropriate clinical signs and the presence of an engorged tick together with rapid improvement after tick removal are sufficient for diagnosis.

Management

Removal of entire tick, including mouth parts, is necessary for treatment. Repeated searching of the whole body for further ticks should be undertaken. Long hair should be clipped to improve the efficacy of tick searches. Application of topical insecticidal solution is effective against ticks. Noticeable improvement occurs within 24 hours of tick removal, and the majority of cases are fully recovered within 1–3 days if all ticks are removed. Supportive care for paralysis should be provided. Prognosis is good if all ticks are removed, and animals do not require ventilatory support.

MYASTHENIA GRAVIS

Definition/Overview

Immune-mediated myasthenia gravis (MG) is a relatively common neuromuscular disease affecting dogs and, occasionally, cats. Acquired MG has been observed in dogs older than 3 months of all breeds but particularly in German Shepherd Dogs, Golden Retrievers, and Labrador Retrievers. In one report, the relative risk of acquired MG in different breeds of dog was highest in Akitas. Newfoundlands and Great Danes may be predisposed to a familial form of acquired MG. A bimodal age of onset (<5 years and >7 years) has also been reported in affected dogs, and spayed females may have heightened risk. In cats, Abyssinians and the closely related Somalis seem to be overrepresented, and gender is not a risk factor in cats.

Etiology

MG is an immune-mediated or less frequently a congenital disease.

Pathophysiology

MG is characterized by failure of neuromuscular transmission due to a reduction in the number of functional nicotinic AChRs on the postsynaptic membrane of the neuromuscular junction. This deficiency of functional receptors reduces the sensitivity of the postsynaptic membrane to the neurotransmitter acetylcholine. Acquired canine MG is an immune-mediated disease caused by production of autoantibodies (predominantly IgG) directed against muscle AChRs at the neuromuscular junction. Based on experimental and human clinical studies, MG involves both B and T cells. Complement-mediated destruction of the postsynaptic membrane of the neuromuscular junction and antibody-induced blockade of AChR function occur.

Congenital myasthenic syndromes (CMSs) are defined in dogs and cats as a clinically heterogeneous group of genetic disorders causing aberrant neuromuscular transmission. Congenital myasthenic syndromes have an onset at 2–16 weeks of age and are infrequently seen in dogs and cats. Congenital myasthenia gravis is thought to be an autosomal recessive trait in Jack Russell Terriers, Smooth Fox Terriers, and Springer Spaniels. A reversible form of congenital myasthenia gravis has been identified in young Smooth-haired Miniature Dachshunds, in which the clinical signs spontaneously resolve by 6 months of age. Congenital myasthenia gravis has also been reported in several cats. Despite efforts to classify CMSs in dogs and cats, many suspected CMSs presently cannot be classified because of a lack of identification of an underlying genetic mutation. Among these suspected CMSs, many are suspected to be postsynaptic because of a lack of postsynaptic AChR.

Clinical Presentation

Several forms of MG have been described in dogs including:

- *Focal MG:* Defined as weakness in >1 focal skeletal muscle group that does not involve the appendicular skeletal muscles. These focal skeletal muscle groups are facial, esophageal, pharyngeal, and laryngeal skeletal muscles. The predominant clinical signs are regurgitation associated with megaesophagus (note that the caudal two-thirds of the esophagus in dogs contains striated muscles), and dysphagia. Less commonly, other signs encountered are facial muscle weakness, a weak jaw tone, a weak gag reflex, and laryngeal paralysis. The incidence ranges from 26% to 43% of all cases of myasthenia gravis.
- *Generalized MG:* Defined as appendicular skeletal muscle weakness associated with severe exercise intolerance. This can occur with or without megaesophagus, facial or laryngeal muscle weakness and is reported in up to 57% of dogs with myasthenia gravis (Figure 14.82).
- *Acute fulminant MG:* Associated with a rapid onset of paralysis and megaesophagus and possibly including diaphragm and intercostal muscle fatigue. This may just represent a severe presentation of the generalized form but can present acutely.

Up to 15% of cats and 43% of dogs with MG may not have clinically detectable limb muscle weakness. Approximately 7% of dogs and 30% of cats with MG have generalized weakness without esophageal or

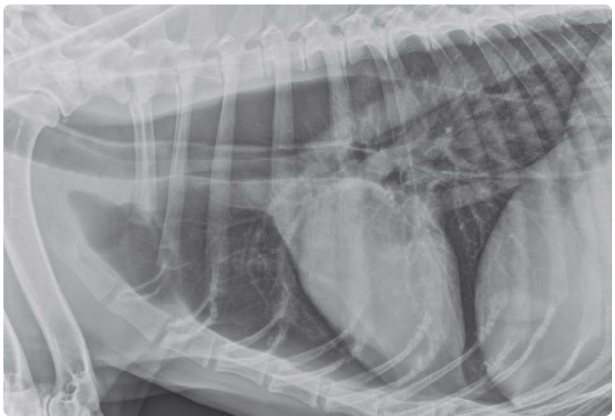

FIGURE 14.82 Lateral thoracic radiograph of a dog with megaesophagus.

pharyngeal dysfunction. Any one of the three forms of MG may be either nonthymoma associated or thymoma associated, which is considered a separate clinical form of the disease.[33,34] There is a greater incidence of mediastinal thymoma in cats with myasthenia gravis (15%–52%) than in dogs (3.4%).

While affected dogs may develop a stiff, choppy gait, in which the stride shortens until they crouch in sternal recumbency and rest their head on their forepaws, cats with MG are usually hypotonic, "floppy," and reluctant to walk. After rest, dogs walk normally for a short period before repeating the cycle. Many animals have facial weakness (repeated stimulation of the palpebral reflex causes it to diminish) and are unable to close their eyelids (accompanied by lack of menace and absent palpebral reflex). Third eyelids may be protruded. Neurologic examination may reveal normal sensation and intact tendon reflexes but diminished withdrawal reflexes, poor postural reactions, and proprioceptive deficits.

Diagnosis

A presumptive diagnosis of MG may be made by the resolution of muscle weakness following IV injection of edrophonium chloride (0.1 mg/kg in dogs, with a maximum 5 mg dose; 0.2–1.0 mg total dose in cats; Editors' Note: Drug currently unavailable). This test may be useful in diagnosing focal myasthenia if a decreased or absent palpebral reflex responds to edrophonium. A negative test does not rule out MG—either focal or generalized. Occasionally, this test causes a cholinergic crisis of bradycardia, profuse salivation, miosis, dyspnea, cyanosis, and limb tremors, which can be reversed with atropine (0.05 mg/kg IV). Electrodiagnostics in the form of repetitive stimulation and single-fiber EMG can assist in the diagnosis, although the tests lack sensitivity and specificity. However, lengthy anesthesia is necessary, and this may be contraindicated in a critical patient.

Diagnosis of MG is confirmed in both dogs and cats by the demonstration of circulating AChR antibodies in a serum sample. Reactive antibodies can usually be demonstrated in the sera of approximately 98% of dogs with acquired MG and in most affected cats. Antibody elevations in dogs and cats are specific for MG, whether it is acquired, paraneoplastic, or concurrent with another autoimmune disease. In the absence of immunosuppressive therapy, there is a good correlation in dogs between the clinical course of MG and the AChR antibody titer. Immunosuppressive therapy for longer than 7–10 days will lower antibody titers, so a thorough history is important to establish prior medication administration. Antibody titers may be negative early in the course of disease, and so retesting is suggested if clinical signs were recent in onset. Seronegative MG may occur if low-titer and high-affinity antibodies are bound to muscle AChRs in a range undetectable by the standard serum assay.

The diagnosis of CMSs is confirmed by the presence of exercise-related weakness in very young dogs for which muscle biopsy does not indicate a congenital muscle or peripheral nerve disease. The response to intravenous edrophonium is variable with an increase in muscle strength and a decremental response of the muscle action potential following repetitive nerve stimulation seen in animals with postsynaptic deficits, or no response seen in animals with presynaptic deficits and a deterioration of function seen following acetylcholinesterase inhibitors in synaptic CMSs. Biochemical quantification of acetylcholine receptor concentration in an external intercostal muscle specimen can be performed at a few research centers but is only useful in the postsynaptic CMSs. As this is not an immune-mediated disease, testing for acetylcholine receptor antibodies is not indicated. Genetic testing is available for most of the documented breeds affected.

Management

Treatment should begin with oral anticholinesterase drugs (pyridostigmine bromide 0.5–3 mg/kg q.12–8 h.). The drug dosage should be started at the low end to avoid cholinergic crisis and can then be modified based on response. As noted previously, cholinergic crisis manifests itself as a combination of bradycardia, profuse salivation, urination, diarrhea, dyspnea (bronchospasm, bronchosecretion), miosis, cyanosis, and limb tremors. If oral treatment is not possible due to severe regurgitation, injectable neostigmine can be given (0.04 mg/kg IM q.6 h.).

If limb muscle strength has not returned to normal following anticholinesterase treatment, or if intolerable side effects of cholinergic excess are noted, and if there is no evidence of aspiration pneumonia, alternate day low-dose corticosteroid therapy should be initiated (0.5 mg/kg p.o. q.48 h.) in the immune-mediated form of MG. Immunosuppressive dosages of corticosteroids should be avoided early in the disease, as this can exacerbate weakness, but the steroid dose can be increased every 2 weeks up to an immunosuppressive daily dose (2 mg/kg) if necessary. Once a state of clinical remission is achieved, the dose is reduced by 50% every 2–4 weeks while monitoring carefully for relapse. If there is no response to immunosuppressive doses of corticosteroids, azathioprine can be added to the regimen

(2 mg/kg p.o. q.24 h.). There are reports describing the successful short-term outcome in several dogs with severe myasthenia gravis treated with plasmapheresis.

Supportive care includes the elevation of food and water bowls or placement of a percutaneous endoscopic gastrostomy (PEG) tube. Many dogs can be fed with food presented as small balls; the animal is then kept in a vertical position for 10–20 minutes to assist with the passage of food into the stomach. Water must also be offered, in reduced quantities, on a more frequent basis and from an elevated position. Construction of a "vertical feeding" system (e.g., a Bailey chair) has been described by owners of dogs with myasthenia gravis. These maintain the dog in an upright position during and following eating. Famotidine administered orally or via a PEG tube (0.5–1.0 mg/kg q.12 h.) may reduce the nausea and gastrointestinal irritation caused by pyridostigmine. These side effects may also be prevented by diluting liquid pyridostigmine 50:50 with water. In addition, famotidine helps to reduce esophagitis due to acid reflux.

MYOPATHIES

NONINFLAMMATORY MYOPATHIES: ACQUIRED

ENDOCRINE MYOPATHIES

STEROID MYOPATHY

Definition/Overview

Chronic corticosteroid therapy may result in dramatic muscle atrophy and weakness, particularly in dogs. Steroid myopathy may be overlooked in patients receiving steroid treatment for disorders that produce weakness, such as inflammatory myopathies or CNS diseases.

Etiology

Chronic corticosteroid therapy.

Pathophysiology

The major actions of glucocorticoids are to increase muscle protein catabolism and inhibit synthesis of myofibrillar proteins. Protein synthesis is inhibited primarily in type 2 muscle fibers, and so net protein loss is greatest in these fibers. Inhibition of protein synthesis is dependent on the dose of steroids administered. Steroid myopathy is also associated with alterations in muscle carbohydrate metabolism, due in part to steroid-induced insulin resistance.

Clinical Presentation

Animals with steroid myopathy commonly have other clinical signs of glucocorticoid excess; skin and hair coat changes are typical. Patients rarely develop severe clinical weakness with <4 weeks of steroid administration. Muscle atrophy, particularly of the masticatory muscles, may occur within 2 weeks of steroid therapy (Figure 14.83). It has been reported that steroid myopathy is more common after administration of the fluorinated corticosteroids such as triamcinolone, betamethasone, and dexamethasone.

FIGURE 14.83 Marked hindlimb muscle atrophy is seen in this dog confirmed to have an underlying steroid myopathy.

Diagnosis

Diagnosis of steroid myopathy necessitates exclusion of other causes of generalized muscle disease, in addition to evidence of long-term steroid administration and muscle biopsy confirmation of disease. The typical pattern of type 2 fiber atrophy may be identified early in the course of steroid myopathy with muscle biopsy.

Management

The treatment of choice for iatrogenic steroid myopathy is steroid dose reduction. Obviously, this can only be achieved if the condition that warranted treatment with corticosteroids is safely controlled. Conversion to a nonfluorinated steroid preparation and alternate day treatment are recommended. Improvement may be seen but can take many weeks or longer. Because of the catabolic effect of corticosteroids, optimizing nutritional status is important. Protein supplementation in patients with a loss of muscle mass is recommended. Physical therapy or mild exercise may be useful in prevention and treatment of muscle weakness and wasting in patients receiving glucocorticoids. Androgens can partially antagonize the catabolic actions of glucocorticoids.

CUSHING'S MYOPATHY

Definition/Overview

A myopathy has been described in dogs with spontaneous hyperadrenocorticism. A pseudomyotonia is most often seen.

Etiology

Hyperadrenocorticism.

Pathophysiology

The myopathy found in Cushing's disease has been attributed to glucocorticoid excess, as described previously for steroid myopathy. It has been suggested that elevated levels of ACTH may also be myopathic.

Clinical Presentation

Most affected dogs are middle aged; females are predisposed. Poodles and the smaller breeds are also overrepresented. Affected dogs often, but not always, have characteristic signs of hyperadrenocorticism, in addition to generalized muscle atrophy, but with a stiff gait and hypertrophy of the proximal appendicular muscles. Of the cats that have been reported with Cushing's syndrome, the majority are middle aged or older (average 10–11 years) and are usually of mixed breed. Approximately 70% of the cats are female. No distinct myopathy has been reported in these cats, but muscle wasting is a prominent finding. Some dogs will have generalized muscle weakness and atrophy on presentation rather than generalized stiffness.

Diagnosis

Diagnosis necessitates exclusion of other causes of generalized muscle disease, in addition to biochemical confirmation of Cushing's disease and muscle biopsy evidence of type 2 myofiber atrophy. There may be mild serum CK elevation in some dogs. The pathologic changes have been described as dystrophic.

Management

Signs can resolve in some dogs over a period of months when they are treated for their primary disease, but deficits can persist. Improvement in motor function appears unlikely but may be inversely related to the duration of disease prior to therapy. Dietary and rehabilitation treatments should also be instituted, as for steroid myopathy.

HYPOTHYROID MYOPATHY

Definition/Overview

A myopathy occurs in dogs associated with spontaneous or experimentally induced hypothyroidism.

Etiology

Hypothyroidism.

Pathophysiology

In general, hypothyroidism affects carbohydrate, protein, and lipid metabolism within muscle. Muscle glycogenolysis is impaired, protein synthesis and degradation are decreased, causing net protein catabolism, and muscle uptake of triglycerides is reduced. Thyroid hormone imbalance has been determined to contribute to abnormalities of cellular energy generation in striated muscle through multiple carnitine-dependent mitochondrial biochemical pathways, supported in part by the fact that chronic hypothyroidism in dogs is associated with a marked reduction of skeletal muscle-free carnitine.

Clinical Presentation

Neuromuscular signs, including stiffness, weakness, reluctance to move, and muscle wasting, may be the first indication of an underlying endocrine disorder. Typical clinical signs of hypothyroidism, including lethargy, weight gain, seborrhea, and alopecia, may or may not be clinically evident.

Diagnosis

Serum CK concentrations may be normal, especially in the first 6 months of the disease, or significantly elevated. Aspartate aminotransferase and lactate dehydrogenase activities can also be elevated. Prominent histopathologic alterations include variation in muscle fiber size with type 2 fiber atrophy and an increased population of type 1 fibers, and multifocal nemaline rod inclusions.

Management

The only effective treatment is to restore the patient to a euthyroid state. Once this is achieved, the prognosis for recovery can be good and be achieved in a few weeks. It is reasonable to institute physical therapy to limit disuse atrophy and joint contractures. There is no evidence that dietary manipulation improves muscle function in this disease.

NONINFLAMMATORY MYOPATHIES: DYSTROPHIC

MUSCULAR DYSTROPHY

Definition/Overview

Muscular dystrophies are a heterogeneous group of inherited, degenerative, mostly noninflammatory disorders characterized by progressive muscle weakness, muscle atrophy or hypertrophy, gait abnormalities, and muscle contractures beginning in the first few months of life. While over 30 muscular dystrophies have been identified to date in humans, only a small number have been characterized in dogs and cats. The muscular dystrophies were originally characterized based on phenotypic features such as pattern of inheritance and the distribution of muscle involvement. With the advent of the molecular age, most have been shown to occur due to mutations of genes that code for proteins in the dystrophin–glycoprotein complex that spans the muscle cell membrane. Dystrophin and its associated glycoproteins

connect the contractile apparatus in the muscle to the sarcolemma, providing mechanical stability.

Etiology

Muscular dystrophy in dogs and cats is most commonly associated with dystrophin deficiency. In some cases, dystrophin is present but is abnormal.

Pathophysiology

Dystrophin links the myofiber cytoskeleton to the extracellular matrix and is crucial in stabilization of muscle fiber membranes during contraction. The dystrophin gene is located on the X chromosome; thus, dystrophin deficiency is an X-linked recessive trait transmitted by a female carrier. Females may be asymptomatic or expressing carriers or be homozygous for the disease, produced from mating carriers and affected males. Homozygous females have elevated CK levels and comparable histologic lesions to those seen in affected male dogs.

Clinical Presentation

Dystrophin deficiency has been documented in several breeds of dogs, including Golden Retriever, Rottweiler, German Short-haired Pointer, Irish Terrier, Groenendael Shepherd Dog, Japanese Spitz, Samoyed, Miniature Schnauzer, Brittany Spaniel, Rat Terrier, Old English Sheepdog, Pembroke Welsh Corgi, Cavalier King Charles Spaniel, Weimaraner, Labrador Retriever, Alaskan Malamute, Jack Russell Terrier, Lurcher, Australian Labradoodle, Border Collie, Miniature Poodle, Spanish Water Spaniel, Norfolk Terrier, and Labrador Retriever as well as in Domestic Shorthair cats. Clinical signs usually develop in the first 6 months of life and are rapidly progressive, although a slower disease course has been documented in some dogs. Affected dogs may demonstrate remarkable phenotypic variation, with some dogs dying within the first few days of life, and others living well into adulthood.

A deficiency of dystrophin in dogs manifests primarily in males, causing generally diffuse muscle atrophy and hypertrophy of certain muscle groups (cranial sartorius, semimembranosus, semitendinosus, and tongue muscles) and with generalized muscle hypertrophy or atrophy in cats (Figure 14.84). Affected animals can be weak at birth and ineffectual sucklers, necessitating nutritional supplementation. As affected animals age, they become more evidently exercise intolerant. Dogs have a characteristic plantigrade posture with the paws laterally rotated and tarsi held close together. While walking, they may advance the hindlimbs simultaneously (bunny hop) and abduct the forelimbs. Dysphagia, regurgitation, and dyspnea may occur as a result of hypertrophy of the lingual, pharyngeal, and esophageal musculature and the diaphragm. Cardiomyopathy may result in heart failure.

Diagnosis

A 6-minute walk test, defined as the distance an individual can walk in 6 minutes, is commonly used in muscular dystrophy clinical trials and has been employed in dogs to characterize cardiac and respiratory disease severity. The serum CK concentration is usually markedly elevated (10,000–100,000 IU/L). EMG reveals complex repetitive discharges. A dystrophic phenotype, characterized early in the course of disease by small group muscle fiber necrosis and regeneration, and more chronically by fibrosis and fatty deposition, is typically present on histopathology of muscle biopsy specimens. An absence of or decreased amount of dystrophin on immunohistochemistry and immunoblotting of muscle specimens confirms the diagnosis. Recently, MRI has been used to characterize the dystrophic muscle. Gene sequencing is routinely done in humans to identify specific mutations for the sake of genetic counseling and targeted therapies. However, mutations have been identified in only a few of the canine conditions.

FIGURE 14.84 Muscular dystrophy in a young cat showing excessive salivation associated with hypertrophy of its tongue. (*Courtesy of M. Schaer and F. Gaschen.*)

Management

There is no specific treatment. Prednisone (0.5 mg/kg q.24 h.) could have benefit in affected dogs. However, this has not been substantiated by clinical studies. If steroids are used, they should be combined with physical therapy. The prognosis is poor.

NONINFLAMMATORY MYOPATHIES: NONDYSTROPHIC CONGENITAL MYOPATHIES

The nondystrophic congenital myopathies are defined by distinctive morphologic abnormalities in skeletal muscle biopsies, including centronuclear and myotubular myopathies, the core myopathies, and protein accumulation myopathies, including nemaline rod and myofibrillar myopathies. The genetic basis for some of these myopathies is known in dogs.

CENTRONUCLEAR MYOPATHY (PREVIOUSLY KNOWN AS LABRADOR RETRIEVER MYOPATHY, TYPE 2 FIBER DEFICIENCY, AUTOSOMAL RECESSIVE MUSCULAR DYSTROPHY)

Definition/Overview

Centronuclear myopathies in humans are heterogeneous forms of inherited muscle disorders that share common clinical and histologic features. Hallmarks of the disease include generalized muscle weakness, ptosis, ophthalmoplegia externa, absence of the patellar reflex in Labrador Retrievers, muscular atrophy predominantly affecting type 1 myofibers, nuclei centralization, and pale central zones with variably staining granules.

Etiology

This is an autosomal recessively inherited myopathy. A short, interspersed repeat element (SINE) exonic insertion in the PTPLA gene leads to multiple splicing defects.

Pathophysiology

Historically, this disorder has been referred to as a polyneuropathy, muscular dystrophy, myotonia, and a hereditary myopathy. The precise etiology was unknown, and there was much debate about whether it represented a myopathy or a neuropathy, as characteristics of both were observed. Investigation of chronic pathologic changes in a group of Labrador Retrievers with a similar phenotype demonstrated that the muscle pathology became more obviously myopathic with time, and central nuclei were evident. The term centronuclear myopathy was proposed for this disease, as the majority of muscle fibers display centrally placed nuclei, with disorganized sarcoplasmic architecture over the long term.

Clinical Presentation

Yellow, chocolate, and black Labrador Retrievers from 8 weeks to 11 months of age exhibit a stiff "bunny-hopping" gait with an abnormal "low" head and neck posture and exercise intolerance. Tendon reflexes are absent or reduced. The signs are exacerbated by cold ambient temperature, exercise, or excitement but tend to stabilize at 1 year of age. Affected dogs often have reduced muscle mass and a poor conformation, and working strains of Labrador Retriever are overrepresented.

Diagnosis

Serum CK activity is normal or only mildly elevated. EMG reveals fibrillation potentials, positive sharp waves, and complex repetitive discharges. Nerve conduction studies are normal. Pathologic changes within muscle biopsy specimens are variable and can include both neuropathic and myopathic abnormalities. There is usually dramatic variation in myofiber size, with small and large group atrophy. A few fibers display centrally placed nuclei and this percentage increases over the long term. A type 2 fiber deficiency has been described. Genetic testing provides the definitive diagnosis, and a DNA-based test is now available for identification of affected dogs and carriers (http://www.labradorcnm.com).

Management

Supportive therapy and avoidance of cold are advised until the condition stabilizes. The disease itself is not lethal, and so the prognosis is fair, but dogs always have reduced exercise tolerance and will not be able to perform as working dogs. The condition tends to stabilize at approximately 1 year of age.

INHERITED MYOPATHY IN GREAT DANES (PREVIOUSLY NAMED CENTRAL CORE MYOPATHY, CORE-LIKE MYOPATHY)

Definition/Overview

A hereditary, noninflammatory myopathy with distinct histologic myopathic features has been described in young Great Dane dogs, affecting both sexes. While it was originally described as a "central core myopathy," the histochemical characteristics differ from this disease in humans. Now the disease is termed "inherited myopathy of Great Danes," potentially until an underlying cause has been identified.

Etiology

An autosomal recessive mode of inheritance is most likely. New unpublished studies have recently confirmed that this myopathy now belongs in the centronuclear/myotubular group of myopathies.

Clinical Presentation

Clinical dysfunction can be seen to affect both males and females from 6 to 19 months of age (median age of onset is 7 months), and consists of progressive muscle wasting, exercise intolerance, general body tremors, and collapse exacerbated by excitement or exercise. All affected dogs have fawn or brindle coat coloration. Affected dogs are usually stunted when compared to their littermates. The generalized muscle atrophy is usually mild to moderate and particularly affects the biceps femoris, quadriceps, temporalis, gluteal, supraspinatus, and infraspinatus muscles. The dogs "tuck" their legs under their abdomen and have an extended tail carriage. When they walk or run, they are short strided with a stiff hindlimb gait, beginning to "bunny hop" as they get faster. The tremors are present at rest and get worse with any movement or excitement. The neurologic examination is unremarkable, but some dogs have been described with reduced reflexes. Myalgia has not been described in any dogs.

Diagnosis

Serum CK activity has been noted to be normal to increased (up to 26-fold). EMG reveals fibrillations and positive sharp waves in all muscles. Diagnosis is easily made by examination of muscle biopsy specimens that show well-defined central cytoarchitectural changes that are highlighted by localization of oxidative enzyme activity.

Management

There is no known treatment at present, and the disease is usually progressive and fatal, although survival for up to 55 months has been described.

HYPOKALEMIC MYOPATHY

Definition/Overview

Hypokalemic myopathy is seen in cats and, very rarely, in dogs, resulting from one of the following: Reduced potassium intake, increased potassium entry into the cells, increased potassium loss from the body, familial disorder of electrolyte regulation (seen in Burmese kittens).

Etiology

Acute or chronic hypokalemia.

Pathophysiology

Hypokalemia significantly affects muscle membrane activity and, therefore, muscle function. The myocyte becomes increasingly refractory to depolarization in a hypokalemic environment. Eventually, the muscle cell membrane suddenly becomes permeable to sodium ions, and membrane hypopolarization occurs, inducing an acute onset of severe weakness. The familial disorder of electrolyte regulation (e.g., as seen in Burmese kittens) has been found to be due to a single nonsense mutation in the gene (WNK4) coding for lysine-deficient 4 protein kinase, an enzyme present primarily in the distal nephron. The underlying pathomechanism in affected cats is, therefore, likely to be a potassium-wasting nephropathy, as this enzyme is involved in complex sodium/potassium exchange mechanisms in the kidney.

Clinical Presentation

Clinical signs of muscle weakness in the cat become evident with any cause of potassium depletion and include generalized weakness and ventroflexion of the neck (Figures 14.85 and 14.86). The most severely affected patients exhibit profound exercise intolerance accompanied by collapse. The weakness can ultimately result in paralysis and is progressive until the potassium deficit is corrected. The neurologic examination is within normal limits.

FIGURE 14.85 Young kitten with hypokalemic myopathy showing its cervical muscular weakness. (*Courtesy of M. Schaer.*)

Diagnosis

The serum potassium level is often 1.5–3.5 mEq/L. Serum CK is often 500–10,000 IU/L. Chronic kidney disease and adrenocortical aldosteronomas in cats with urine loss of potassium should be ruled out with serum biochemistry and urine evaluations, as well as imaging assessments of the structure and function of the kidney and adrenal glands. The dietary potassium content should be investigated; diets should be at least 0.6% rich in potassium. Hyperthyroidism should also be ruled out. Electrophysiology may be normal or have areas of fibrillations and positive sharp waves. Histologic examination of muscle biopsies may be normal or show muscle fiber necrosis with little or no evidence of inflammation. It is worth mentioning that hypokalemia in Burmese cats is not always present concomitantly with the clinical signs, which are episodic, and this requires serial serum potassium measures. Fortunately, genetic testing for the mutation in the gene WNK4 is now available.

Management

Potassium gluconate (2–4 mEq p.o. q.12 h.) may be used in all animals. The dosage is adjusted until the serum

FIGURE 14.86 The same kitten 24 hours later after potassium supplementation. (*Courtesy of M. Schaer.*)

potassium levels are normal. Adequate diet may be enough if insufficient potassium was the initiating cause, but potassium supplementation may be needed for life in cats with renal disease. Spironolactone is helpful for treating aldosterone-secreting tumors and adrenocortical hyperplasia involving the zona glomerulosa. Adrenalectomy is a definitive treatment for the adrenal tumor unless metastasis has occurred. Severely affected cats may be treated with IV potassium chloride (0.2–0.4 mEq/kg/h diluted in IV fluids) with constant cardiac monitoring. Higher doses might even be required. Prognosis can be good if the potassium levels can be regulated or supplemented.

MYOTONIA CONGENITA

Definition/Overview

Myotonia is a clinical sign defined as prolonged contraction or delayed relaxation of a muscle after voluntary movement or after mechanical or electrical stimulation.

Etiology

Myotonia congenita is commonly due to diminished chloride conductance across the muscle membrane.

Pathophysiology

As the chloride channel contributes approximately two-thirds of the resting membrane conductance, a fall in chloride channel conductance significantly compromises the resting membrane potential. During normal muscle activation–depolarization, potassium ions accumulate in the sarcoplasmic reticulum and increase the probability of further depolarizations, which is "buffered" in the presence of normal high-chloride conductance. Loss of this conductance tips the balance toward potassium-induced after-depolarization bursts that manifest as myotonia. In some cases, this is due to genetic defects in skeletal muscle ion channels. Sodium, calcium, and potassium channel abnormalities have all been documented in people with similar muscle dysfunctions and likely exist in veterinary medicine.

Clinical Presentation

Myotonia is characterized by muscle stiffness without cramping and muscle dimpling after palpation. Congenital myotonia has been described in the Chow Chow (suspected autosomal recessive), Miniature Schnauzer (autosomal recessive), Australian Cattle Dog, Jack Russell Terrier, and in a series of related domestic kittens. Dental and craniofacial abnormalities were exhibited in affected Miniature Schnauzers. Single cases of congenital myotonia have been reported in a Great Dane, a Staffordshire Terrier, and a Cocker Spaniel. In dogs, clinical signs of muscle stiffness are evident at the time of first ambulation and are progressive; however, the signs can improve with exercise. Myotonia is accompanied by difficulty in rising, splaying of the limbs, a "bunny-hopping" gait, muscle hypertrophy, regurgitation, and stridor. Hypertrophied skeletal muscles are painless on palpation. Similar clinical signs have been documented in cats.

Diagnosis

Routine laboratory evaluations, including serum CK concentration, are usually normal. Electrophysiologic findings are characterized by waxing and waning myotonic discharges sounding like a "revving" motorcycle. Muscle biopsy evaluation may reveal muscle hypertrophy or a type 1 fiber predominance without inflammation. For detection of the mutant allele in affected and carrier Miniature Schnauzers, a DNA-based test on whole blood has been developed and is available at the University of Pennsylvania. A novel mutation of the CLCN1 gene associated with hereditary myotonia has also been identified in the Australian Cattle dog, and a DNA test is now available.

Management

Treatment is directed at decreasing the repetitive activity in the muscle by using antagonists to voltage-gated sodium channels. These drugs include extended-release procainamide (40–50 mg/kg p.o. q.8–12 h.), quinidine, phenytoin, and mexiletine (8.3 mg/kg p.o. q.8 h.). The treatment has been documented to improve but not normalize the condition; therefore, the prognosis depends on the severity of the clinical signs in the individual animal.

MISCELLANEOUS MYOPATHIES AND CAUSES OF COLLAPSE

EXERCISE-INDUCED COLLAPSE IN LABRADOR RETRIEVERS

Definition/Overview

A syndrome of exercise intolerance and collapse has been observed in young adult (often 7 months to 2 years old) Labrador Retrievers of either sex and any color, especially those used in field trials. This genetic condition has also been detected in Chesapeake Bay Retrievers, Curly-coated Retrievers, Boykin Spaniels, Pembroke Welsh Corgis, and mixed-breed dogs thought to be Labrador Retriever crosses A similar syndrome has been seen in working Border Collies, Golden Retrievers, and Australian Shepherd Dogs, although it is likely that a different genetic mutation is responsible.

Etiology

A genetic mutation identified in the dynamin 1 gene (DNM1) is responsible for this disorder in Labrador Retrievers.

Pathophysiology

Dynamin 1 is expressed almost exclusively in the brain and spinal cord where it plays a key role in synaptic

vesicle endocytosis at the presynaptic terminal membrane. The mutant protein results in a temperature dependent reversible loss of motor function. It appears that this is an autosomal recessive disease.

Clinical Signs

Affected dogs are normal at rest and with normal activity. They are usually very well muscled, athletic, and excitable. The earliest gait abnormalities seen in exercising dogs with exercise-induced collapse (EIC) usually include a "rocking" or forced gait, with a wide-based hindlimb stance. Dogs that can still walk after exercise exhibit a characteristic crouched hindlimb gait with long strides and a base-wide posture when turning. Ataxia is usually noted after 5–15 minutes of strenuous activity, often followed by an episode of collapse, panting, and distress. Patellar reflexes are lost during this time, and this finding may persist beyond recovery to a normal gait. The dogs usually return to normal after 10–20 minutes of rest, especially if passive cooling actions such as fans are used. A small percentage of dogs have died during the exercise period. Although dramatic elevations in body temperature after exercise (>41.5°C) have been reported, normal Labrador Retrievers demonstrate similar such elevations without collapse. Affected dogs are significantly more tachycardic and have more severe respiratory alkalosis after exercise compared with normal dogs. Although a few dogs with EIC have been documented with mild elevations in serum CK levels after exercise, they are not compatible with dystrophic or myonecrotic muscle. Muscle biopsy characteristics and sequential lactate and pyruvate concentrations are normal when evaluated.

Affected Border Collies develop abnormal mentation and/or an abnormal gait during evaluation. All dogs have postexercise elevations in rectal temperature, pulse rate, arterial blood pH, PaO2, and lactate and decreased $PaCO_2$ and bicarbonate, as expected with strenuous exercise, but there are no significant differences between affected dogs and normal dogs. Electrocardiography demonstrates sinus tachycardia in all dogs following exercise. Needle electromyography is normal, and evaluation of muscle biopsy cryosections using a standard panel of histochemical stains and reactions is normal. Genetic testing excludes the dynamin-1-related exercise-induced collapse mutation and the V547A malignant hyperthermia mutation as the cause of this syndrome. Although a genetic basis is suspected, the cause of collapse in this breed is not yet determined.

Diagnosis

Apart from severe alkalosis on arterial blood gas analysis, all clinicopathologic (including lactate-to-pyruvate ratios), electrophysiologic, and histopathologic tests are normal. A genetic test is now available for identification of affected and carrier dogs of the Labrador Retriever, Chesapeake Bay Retriever, and Curly-coated Retriever breeds (http://www.vdl.umn.edu/services-and-fees/canine-neuromuscular/index.htm).

Management

The condition is not progressive, and so a normal life span should be expected if the dogs are not heavily exercised. Exercise restriction is the only advice given at this time regarding treatment, especially when ambient temperatures are high. Hunting dogs may be less affected in cold weather. Genetic testing can be used to guide breeding programs.

FIBROTIC MYOPATHY

Definition/Overview

This acquired, usually nonpainful disorder associated with a fibrous band within a muscle has been reported sporadically in dogs affecting specific muscle groups, including the muscles of the medial thigh (gracilis, semimembranosus, or semitendinosus), sartorius, infraspinatus, and iliopsoas. It is most commonly seen in German Shepherd Dogs, usually male, with an age range from 8 months to 9 years. Similar disorders have been reported in the Dobermann, Rottweiler, St. Bernard, Boxer, and Old English Sheepdog. Fibrotic myopathy of the semitendinosus has been reported in a cat.

Etiology

Active dogs seem to be susceptible to this disorder, and recent studies in dogs suggest that fibrotic myopathy may be related to muscle injury from excessive activity, including jumping and sprinting.

Pathophysiology

Fibrotic myopathy has been called gracilis or semitendinosus myopathy, although any of the hamstring muscles can be affected, and a similar disease has been described affecting the infraspinatus, sartorius, and iliopsoas muscles. A fibrous band can be palpated within the affected muscle belly and can extend the length of the muscle. It is proposed that muscle strain causes inflammation, edema, and localized hemorrhage, which leads to fibrosis. Increased angulation (flexion) at the stifle in normal German Shepherd Dogs may predispose these dogs to increased hamstring stress during physical activity, explaining their overrepresentation.

Clinical Presentation

This may be a unilateral or bilateral disease, and signs depend on the muscle group involved. While onset in some dogs is acute, the gait deficit appears to be insidious in most dogs and is best seen when dogs are "trotting."

- *Gracilis myopathy:* In dogs with gracilis and/or semimembranosus or semitendinosus muscle involvement, the hindlimb gait is characterized by a shortened stride

with a rapid medial rotation of the paw, external rotation of the hock, and internal rotation of the stifle during the mid-to-late swing phase of the stride, resulting in the paw being slapped to the ground prematurely. The gait anomaly results from restricted abduction of the coxofemoral joint and reduced extension of the stifle and hock.

- *Iliopsoas fibrotic myopathy:* This has been associated with chronic progressive lameness, flexion contracture of the coxofemoral joints, severe pain, and decreased femoral reflexes.
- *Infraspinatus myopathy:* Fibrotic contracture of the infraspinatus muscle, a rare musculotendinous disorder mainly affecting hunting dogs, begins as an acute onset of a painful nonweight-bearing lameness. Following this onset, the initial pain and lameness improve over a period of 1–4 weeks, after which a characteristic circumducted gait abnormality develops in the forelimb accompanied by elbow adduction with external rotation of the distal part of both forelimbs.

Diagnosis

The gait is characteristic of the disease and neurologic examination is usually normal. Tight fibrous cords are palpable in affected muscles. Atrophy or swelling may be associated with this disease when affecting the infraspinatus muscles. Serum CK levels may be normal or moderately elevated in some animals. Absence of myoelectrical activity in the band during EMG evaluation is consistent with total replacement of muscle fibers by dense connective tissue. Ultrasonography, CT, and MRI can all be useful for diagnosing muscle fibrosis in the specific muscles affected by this disease.

Management

Prognosis is guarded to poor, since the condition in dogs tends to recur within several months following surgical resection of the fibrous band, or transection, partial excision, or complete resection of the affected muscle. However, tenectomy has been described to improve gait and provide pain relief associated with iliopsoas muscle contracture, as it has with bilateral infraspinatus contractures. Nonsurgical treatment (e.g., corticosteroids, NSAIDs, acupuncture) is usually ineffective. Nonsurgical rehabilitation, including therapeutic ultrasound and cross-fiber friction massage, resulted in mild improvement in several dogs (slight increase in range of motion of the stifle and less crossing-over of hindlimbs). However, gracilis and semitendinosus fibrosis does not appear to be painful and simply causes a gait deficit. Dogs can live with these diseases without a problem.

EXERTIONAL RHABDOMYOLYSIS, MALIGNANT HYPERTHERMIA, AND RHABDOMYOLYSIS

Definition/Overview

Rhabdomyolysis is a clinical syndrome consisting of acute muscle necrosis with swollen painful muscles causing weakness and collapse. With the exception of racing Greyhounds and sled dogs, exertional rhabdomyolysis (ER) is rare. Malignant hyperthermia (MH) has been reported in various breeds of immature and mature dogs: St. Bernards, Border Collies, Labrador Retrievers, Pointers, Spaniels, Greyhounds, and animals crossbred with Dobermanns.

Etiology

MH is a hereditary disorder of skeletal muscle, with collapsing episodes triggered by exposure to halothane, depolarizing muscle relaxants, and occasionally stress or exercise. Rhabdomyolysis may also occur sporadically in dogs as a complication of prolonged convulsive seizures (and extreme muscle exertion), infections including babesiosis and neosporosis, heat stroke, and MH. Rhabdomyolysis has also been reported following various intoxications and envenomations and as an idiopathic disorder in dogs.

Pathophysiology

In racing Greyhounds exhibiting ER, severe lactic acidosis leading to muscle cell swelling, local ischemia, muscle cell necrosis, and myoglobinuria (**Figure 14.84**) with nephropathy has been proposed as a likely sequence of events in the pathogenesis. The final common pathophysiologic mechanism resulting from direct injury to the sarcolemma or failure of energy supply to the muscle is an uncontrolled rise in free intracellular calcium concentration and activation of calcium-dependent proteases. These abnormalities result in destruction of myofibrils and lysosomal digestion of muscle fiber contents (myonecrosis). In MH, the underlying defect in calcium (Ca) homeostasis occurs at the level of the skeletal muscle sarcoplasmic reticulum, where there is hypersensitive and heightened ligand-gating of the calcium-release channel. Most variants of MH are known to be caused by a mutation in the gene on chromosome 1 encoding the skeletal muscle calcium release channel (ryanodine receptor 1: RYR1).

Clinical Presentation

Clinical signs of ER may occur during or within 24–48 hours of a race or trial and are characterized by extreme distress, hyperpnea, and generalized muscle pain, especially over the back and hindquarters, which may appear swollen and firm. Limbs may be rigidly tonic, and affected dogs may have a "hunchback" appearance and refuse to walk. Myoglobinuria and death within 48 hours are common in severe, acute cases. Typical manifestations of collapse associated with MH include a rapidly progressive elevation in body temperature, tachycardia, hypercarbia, and rhabdomyolysis.

Diagnosis

Clinical signs associated with an acute episode of exertion should prompt suspicion. Serum CK may be

FIGURE 14.87 A urine sample showing myoglobinuria. (*Courtesy of M. Schaer.*)

markedly elevated. Urinalysis should be performed to rule out subsequent myoglobinuria (Figure 14.87). EMG investigation will be normal in acute muscle disease. Muscle biopsy will confirm rhabdomyolysis, but as time is of the essence for the treatment of this disease, it is rarely advised.

Management

Treatment for rhabdomyolysis is mainly supportive, with intensive fluid therapy being necessary to maintain normal renal function. The systemic complications of rhabdomyolysis should be identified and individually addressed. Multimodal drug therapy, including dantrolene, analgesics, antibiotics, and mannitol, has been described with a beneficial effect. Frequent blood gas analyses, biochemistry, and urine analyses are advised to monitor systemic acid–base status as well as kidney function. The prognosis is guarded.

It is essential to remove triggering agents in the treatment of MH. This needs to be combined with symptomatic treatment. Stomach lavage with iced water, body surface cooling, and IV administration of cold isotonic saline solution may be beneficial. Dantrolene can prevent a MH crisis or reverse anesthetic-induced MH if given early enough (3–5 mg/kg IV). As for rhabdomyolysis, the prognosis is guarded.

INFLAMMATORY MYOPATHIES: INFECTIOUS

Definition/Overview

Infection can occasionally cause diffuse muscle and/or nerve disease and may be part of a systemic disease.

Etiology

Inflammatory myopathies have been associated with protozoal, viral, rickettsial, and, rarely, bacterial infections.

Pathophysiology

Infections causing myopathies in dogs and cats are usually multisystemic. Protozoal and viral infections often become clinical in young animals in situations of immune compromise. Older animals may have concurrent infections or neoplastic diseases affecting local immunocompetence.

Clinical Presentation

Signs seen in these patients are not specific but represent diffuse muscle disease. They include marked weight loss, weakness, exercise intolerance, generalized muscle atrophy, muscle pain (myalgia), and, in the late stages of disease, contractures, and recumbency.

Diagnosis

Diagnosis of an inflammatory myopathy necessitates muscle biopsy. Elevations of serum CK and abnormal needle EMG can be nonspecific findings. Definitive etiologic diagnosis may be difficult as it relies on the identification of organisms within the tissues, specifically with molecular or immunohistochemical methods; however, *Toxoplasma* and *Neospora* spp. are often seen within the muscle. The interpretation of serologic titers is particularly difficult in the acute stages of disease because a single positive result only implies exposure to the disease, rather than clinical infection.

Management

The prognosis for most infectious inflammatory myopathies is guarded, but partial function may remain if treatment is initiated early in the course of the disease. Clindamycin treatment is recommended for protozoal myositis, and this has been reported to be successful but may require months of administration. If CNS infection is suspected, additional antimicrobials should be considered such as the trimethoprim–sulfa drugs. If treatment is not initiated until the disease has reached a state of recumbency, it is unlikely that the patient will walk again. Intense physiotherapy may be needed in addition to specific antibiotics, especially in young patients that are continuing to grow in the face of severe muscle contractures caused by the infections.

INFLAMMATORY MYOPATHIES: IMMUNE-MEDIATED

IDIOPATHIC POLYMYOSITIS

Definition/Overview

Idiopathic polymyositis is a generalized inflammatory myopathy affecting dogs and, less commonly, cats that is not associated with any other systemic connective tissue disease or infectious cause.

Etiology

Immune-mediated dysfunction.

Pathophysiology

Tissue inflammation arises due to immune-mediated damage by CD8+ T lymphocytes. Several genes involved with innate and adaptive immunity are upregulated in this disease, as are those involved in proinflammatory and anti-inflammatory pathways. Circulating autoantibodies against an unidentified sarcolemmal antigen supporting a humoral immune component have been reported in Newfoundlands and Boxers. Autoantibodies to a 42-kDa molecule in striated muscle have been documented in Pembroke Welsh Corgis.

Clinical Presentation

Progressive exercise intolerance with acute exacerbation of weakness may occur, but the disease may initially be episodic; marked weight loss is often reported by the owner. A stiff, uncomfortable gait in all limbs is often accompanied by an arched thoracolumbar spine (kyphosis) and a ventroflexed neck. Commonly, multiple skeletal muscles are affected, but it can manifest as a focal disease affecting pharyngeal, laryngeal, esophageal, or, infrequently, tongue muscle groups, causing dysphagia, dysphonia, and stridor or regurgitation. Myalgia may be present, but this is not a consistent finding. Pyrexia may be a feature of the disease or a consequence of aspiration pneumonia. Any age and breed of dog and cat may be affected. However, breed-specific variants of polymyositis affect Newfoundlands, Boxers, Pembroke Welsh Corgis, and, recently, Hungarian Vizslas. The disease affecting Vizslas is marked by pharyngeal dysphagia, megaesophagus, and masticatory muscle atrophy, although exercise intolerance has also been described. Dysphagia and megaesophagus are more commonly seen in Newfoundlands with inflammatory myopathy when compared with other dogs. Corgis present with severe tongue atrophy, facial muscular atrophy, and occasional gait abnormalities.

Diagnosis

Diagnosis is based on identification of at least three of the following, including a confirmatory muscle biopsy:

- Appropriate clinical signs.
- Elevation of serum CK concentration (at least 5–10 times the upper reference range) (CK can be low in end-stage disease). CK is not always elevated during active muscle disease; this seems to depend on distribution of cellular infiltrates and degree of muscle damage.
- Compatible electrophysiologic findings.
- Negative infectious disease titers.
- Inflammatory muscle biopsy (critical for the diagnosis); demonstration of mononuclear cell infiltration into muscle and invasion of cells into apparently non-necrotic fibers.

Management

Early and aggressive institution of immunosuppressive therapy is essential for a good clinical outcome. The prognosis can be good unless there is concurrent megaesophagus or pharyngeal dysfunction, or if therapy is not initiated until after there has been severe myofiber loss or fibrosis. Robust muscle regeneration has been documented in the face of significant inflammation and fibrosis, suggesting that muscle can survive if treatment can be initiated prior to regenerative capacity of the muscle being exhausted. Long-term treatment is usually required. The serum CK concentration should be monitored, and immunosuppressive therapy continued until the CK returns to the reference range and clinical signs have resolved.

INTRODUCTION

These are exciting times in veterinary medicine, particularly for those with an interest in musculoskeletal disorders. As a result of an ever-expanding knowledge base, pets are living longer, and the human–animal bond has never been stronger. Senior dogs are becoming recognized as a group with special needs, and multimodal pain management has become a foundation of our practice ethics. The continued understanding of cyclooxygenase-1 and cyclooxygenase-2 has led to development of numerous nonsteroidal anti-inflammatory drugs (NSAIDs), which have become the cornerstone in the treatment of pain and inflammation. Nutritional management, exercise, and physical therapy, long ignored in veterinary medicine, are now recognized as very important treatment adjuncts. Disease processes are being recognized as more complex than previously appreciated, and it follows that treatment must embrace similar complexity. The quest for greater understanding must always be a driving force for the practitioner.

History

Making a clinical diagnosis is often assisted by noting the correlation of clinical signs to a time course (Figure 15.1). This can only be done by recording an accurate history. Whereas traumatic injuries present with an acute severity that rapidly diminishes, autoimmune diseases are often episodic in clinical presentation, and neoplasia generally presents with vague signs that become progressively worse with time.

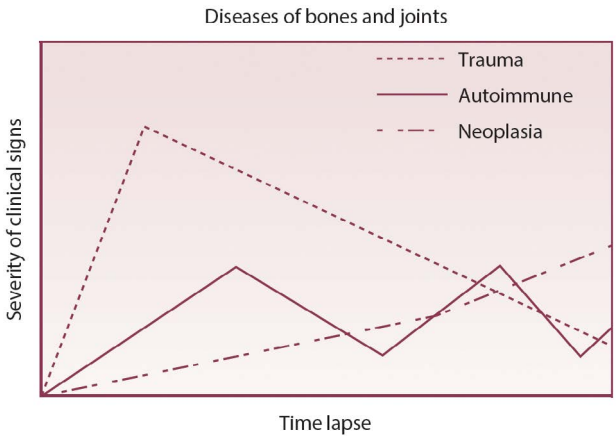

FIGURE 15.1 The correlation between clinical signs and a time course.

Examination

Dogs and cats with skeletal diseases most often present with lameness, swelling, or a combination of the two. After recording a thorough history and conducting a comprehensive physical examination, diagnostic imaging is often the next step in diagnostic aid. While radiography is often the most informative diagnostic aid, musculoskeletal ultrasound has been gaining in popularity in complementing radiography in the diagnosis of various orthopedic conditions. To determine the most probable cause of the underlying problem, the clinician must identify the pathophysiologic disease mechanisms involved that are associated with the clinical presentation and, thereafter, derive a diagnosis. Trying to

DOI: 10.1201/9781003254591-34

determine a cause of the problem without identifying the pathophysiologic disease mechanisms involved leads to an overdependence on diagnosis by previous experience, thereby restricting the capacity to diagnose disease processes never personally encountered.

The problem-oriented medical record is designed for a logical approach to problem solving. Additionally, to avoid overlooking possible differential diagnoses, many find it helpful to screen for disease processes using the DAMNIT acronym of pathophysiology:

- Degenerative disorders
- Anomalies
- Metabolic disorders
- Neoplasia, nutritional disorders
- Inflammation (infectious or noninfectious), immune disorders, iatrogenic disorders, idiopathic
- Toxicity (endogenous or exogenous), trauma (internal or external)

The following conditions should be considered under the heading of musculoskeletal disorders:

- *Degenerative and developmental disorders:* Degenerative joint disease (DJD), canine hip dysplasia, intervertebral disc disease, cauda equina syndrome, cranial cruciate disease, medial patella luxation (MPL), elbow dysplasia (ununited anconeal process, fragmented coronoid process)
- *Anomalies:* Agenesis, luxation, ectrodactyly, osteochondrodysplasia, growth arrests, growth plate disorders, retained cartilage core
- *Metabolic disorders:* Hyperparathyroidism, hyperadrenocorticism
- *Neoplasia:* Osteosarcoma, chondrosarcoma, hemangiosarcoma, fibrosarcoma, synovial cell sarcoma
- *Nutritional disorders:* Nutritional hyperthyroidism, hypervitaminosis A, hypovitaminosis D
- *Infection/inflammation:* Osteomyelitis, discospondylitis, septic/suppurative arthritis
- *Immune disorders:* Immune-mediated polyarthritis, erosive and nonerosive arthritis, systemic lupus erythematosus (SLE)
- *Iatrogenic disorders:* Synostosis, sequestra
- *Idiopathic:* Avascular necrosis of the femoral head (Legg–Calvé–Perthes disease), hypertrophic osteopathy, bone cyst, multiple cartilaginous exostoses, osteochondrosis, panosteitis, craniomandibular osteopathy, hypertrophic osteodystrophy, idiopathic polyarthritis
- *Toxicity:* Lead poisoning
- *Trauma:* Fracture, muscle, tendon, and ligament injuries:
  - Common calcaneal tendinopathy, biceps tendinopathy, collateral ligament injury (stifle, tarsus)

Many skeletal diseases are predisposed to specific areas of long bones, which makes disease rule outs logical by region of bone affected (Figure 15.2). Bone diseases that affect the epiphysis include infectious arthritis (with

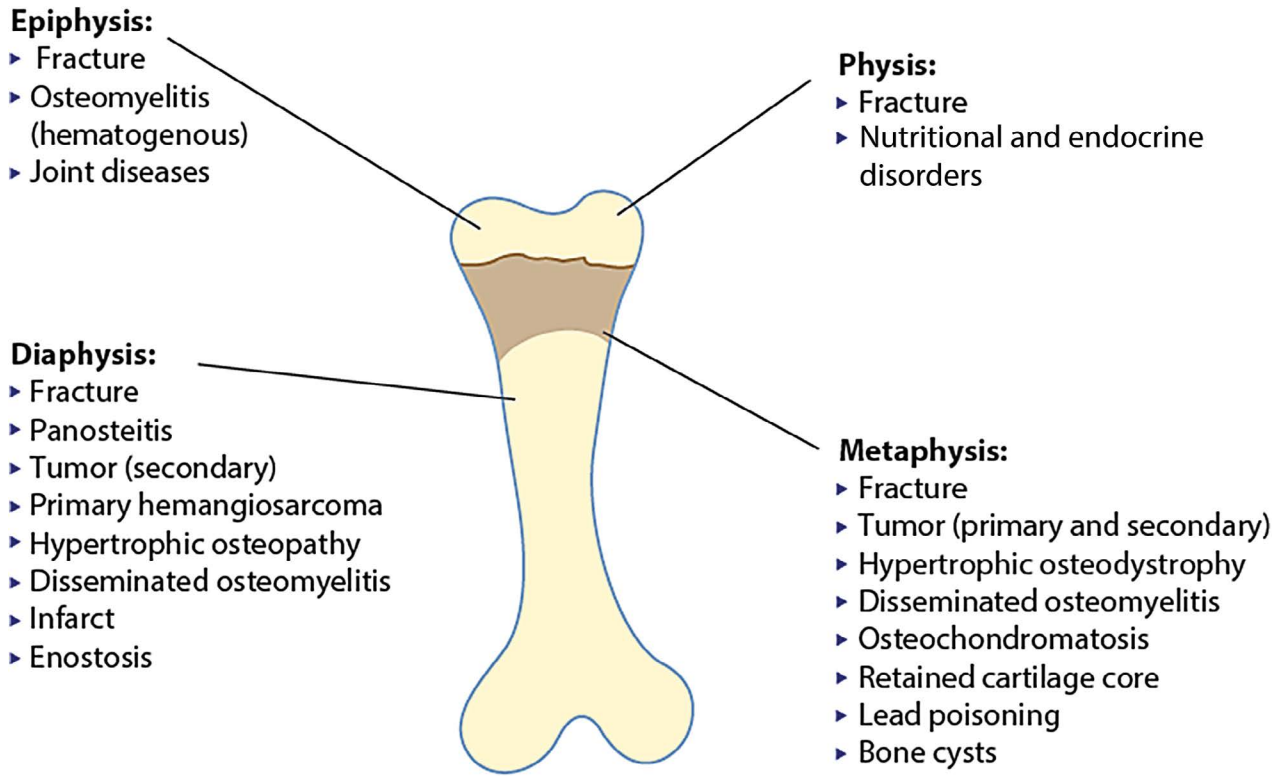

FIGURE 15.2 Bone diseases affecting long bones.

extension to subchondral bone), joint tumors (fibrosarcoma, synovial sarcoma [with extension to adjacent bone]), osteochondrosis (proximal humerus, medial humeral condyle, lateral or medial trochlear ridges, lateral femoral condyle, distal ulnar epiphysis "retained cartilage core"), osteoarthrosis (with subchondral bone sclerosis and/or epiphyseal "cysts"), primary bone tumors (with extension to the epiphysis), and erosive polyarthritis (rheumatoid [with periarticular and subchondral bone lysis]). Alterations of the physis may be seen with traumatic injury or fracture, hematogenous dissemination of infection, and nutritional or endocrine disorders. Diseases that may affect the metaphysis include primary bone tumors (osteogenic sarcoma, chondrosarcoma, and fibrosarcoma), primary hemangiosarcoma of bone, disseminated osteomyelitis, metastatic tumors, and hypertrophic osteodystrophy. Lesions of the diaphysis can result from canine panosteitis, metastatic tumors, bone infarction, disseminated osteomyelitis, primary hemangiosarcoma of bone, and hypertrophic osteopathy (hypertrophic pulmonary osteoarthropathy). It must be appreciated that some skeletal diseases are characterized by unpredictable anatomic location and variable distribution.

DEGENERATIVE DISORDERS

DEGENERATIVE JOINT DISEASE

Definition/Overview

DJD is a total joint disease with joint cartilage degeneration. Surface fibrillation and fissures ultimately result from an initial increase in cartilage swelling followed by dehydration and reduction in concentration of matrix proteoglycan. This leads to deformation under loading, with less elastic return and, consequently, more contact pressure on subchondral bone (Figure 15.3).

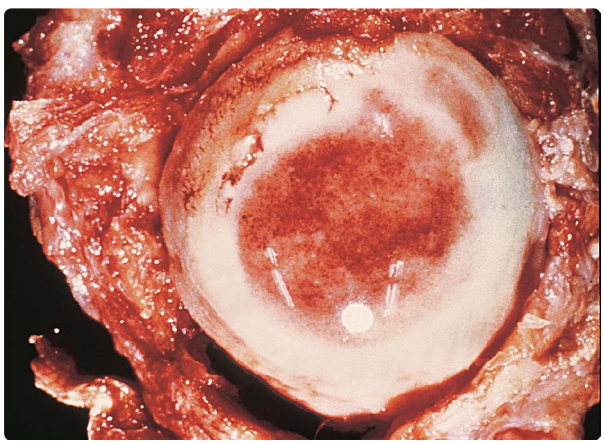

FIGURE 15.3 Eburnation of the femoral head resulting from DJD. Chondromalacia attributed to a decrease in sulfated mucopolysaccharide content is the earliest sign of degeneration, followed by fibrillation exposure of the collagen framework through the loss of ground substance. Fibrillation progresses to eburnation as subchondral bone becomes sclerotic from mechanical pressure and/or the effect of the synovial fluid.

Pathophysiology

Autoimmunity and the phagocytosis of immune complexes, leading to the release of substances deleterious to the affected joint, play an important role in the pathogenesis of DJD, although the exact role of specific immune responses is not known.

Clinical Presentation

Affected animals usually present with lameness or gait change. Once the affected joints are identified and examined, radiographs are taken to support the diagnosis.

Diagnosis

Characteristic radiographic features of DJD include subchondral bony sclerosis, subchondral cyst formation, joint space narrowing, and intra-articular or periarticular osteophyte formation. Arthroscopy can be both diagnostic and a treatment option. Arthroscopically observed morphologic changes give the clinician an appreciation for early treatment of these disorders.

Management

Treatment goals are to alleviate discomfort, retard the development of further deterioration, and, ideally, restore affected joints to as near normal as possible. Optimal management is with implementation of a multimodal regimen (Figure 15.4), which is best approached through the six points of two overlapping triangles, one representing nonmedical treatment and the other medical treatment (Figures 15.5a, b and 15.6). Surgical intervention may be appropriate, especially in correcting conditions of instability.

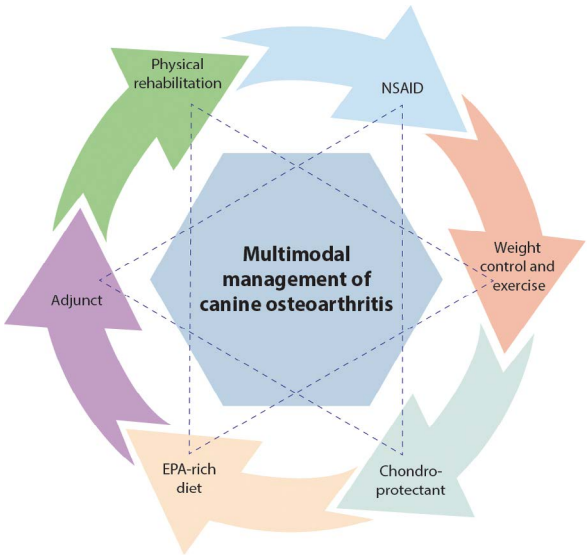

FIGURE 15.4 The multimodal management of canine osteoarthritis integrates six different elements: NSAIDs, weight control and exercise, a chondroprotectant, an eicosapentaenoic acid-rich diet, an adjunct, and physical rehabilitation. (*From Fox SM (2013).* Pain Management in Small Animal Medicine. *CRC Press, Boca Raton.*)

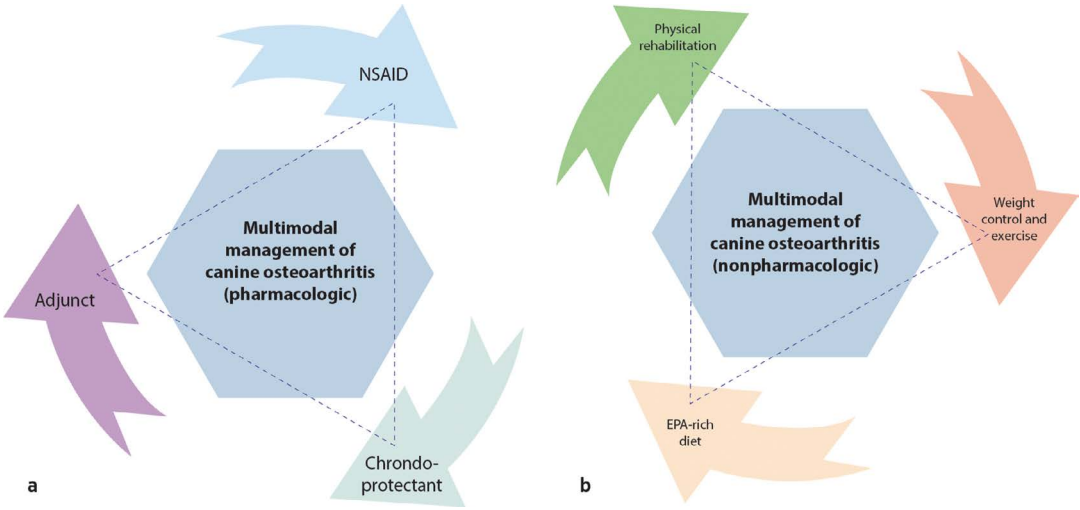

FIGURE 15.5 **(a)** The pharmacologic (medical) management of osteoarthritis is achieved with a NSAID, a chondroprotectant, and analgesic adjuncts. **(b)** The nonpharmaceutical management of osteoarthritis comprises weight control/exercise, an eicosapentaenoic acid-rich diet, and physical rehabilitation. (*From Fox SM (2013).* Pain Management in Small Animal Medicine. *CRC Press, Boca Raton.*)

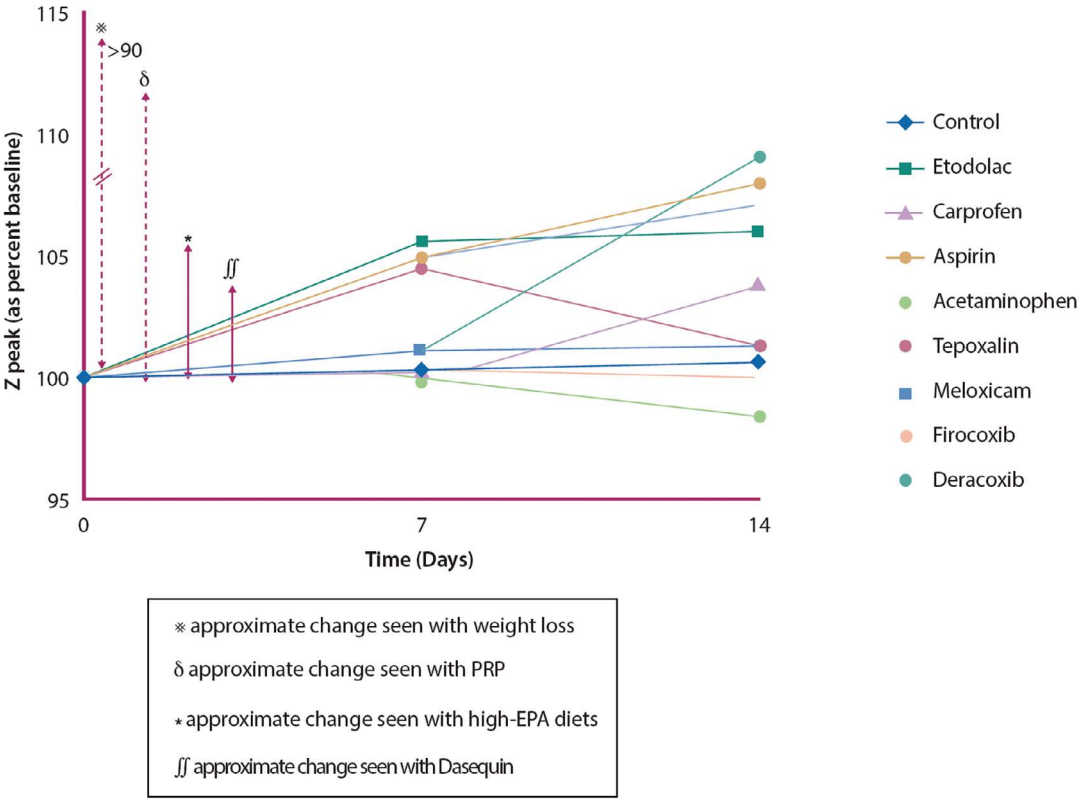

FIGURE 15.6 Relative efficacy of several contemporary NSAIDs used in veterinary medicine to treat osteoarthritis as assessed by force plate gait analysis (FPGA). Every dog in this study responded to a NSAID, but not every dog responded to each NSAID. Comparative responses from different treatment modalities (different studies) are further superimposed on this NSAID response graphic. All the studies used FPGA for assessment. Millis DL (2006). ∬ Millis DL (2010). Dasuquin's efficacy may be similar to that of NSAIDs in dogs. Joint Health: A roundtable discussion. Supplement. *Vet Med* 105(11):10.

Two recent additions to the adjunct modality in consideration for management of canine DJD are implementation of a piprant-class drug and radiosynoviorthesis. In 2013, the World Health Organization defined a newly recognized class of drug that acts as a prostaglandin receptor antagonist. The prototypic drug grapiprant is an analgesic, anti-inflammatory agent that acts as an EP4 prostaglandin receptor antagonist. Radiosynoviorthesis is an intra-articular radionuclide therapy, for which Sn-117m is showing promise for its therapeutic effects in animal models of inflammatory arthritis.

HIP DYSPLASIA

Definition/Overview

Hip dysplasia, a developmental and progressively degenerative disorder characterized by hip laxity, pain, and development of osteoarthritis. It is more common in large breeds of dogs, but small breed dogs as well as cats can also be severely affected. Nongenetic risk factors include nutrition, growth rate, body size, exercise, and muscle mass.

Etiology

Although the cause of hip dysplasia is unknown, it has a hereditary basis. It is considered to be a polygenic trait, with expression determined by both genetic and environmental factors.

Pathophysiology

At birth, the hip is normal. With development, increased laxity and/or changes to the congruity of the femoral head and the acetabulum result in increased amounts of synovial fluid and hypertrophy of the round ligament of the head of the femur. Articular cartilage deteriorates, synovitis ensues, and the joint capsule thickens. With further progression of joint incongruity, bone changes occur, and osteophytes form surrounding the joint (Figure 15.7). Discomfort in the early stages of the disease is associated with stretching or tearing of fibers in the joint capsule and the round ligament, while that in advanced disease is from osteoarthritis (Figures 15.8 and 15.9).

Clinical Presentation

Signs of decreased activity and various degrees of joint discomfort are seen at two stages of the afflicted dog's life, between 4 and 12 months of age, and over 5 years. Affected dogs will often bunny hop (run with both hindlimbs moving together), prefer to sit rather than stand, demonstrate decreased mobility and range of motion, posture abnormally to defecate or urinate, and may show changes in eating trends and behavior.

Differential Diagnosis

Degenerative myelopathy, lumbosacral disease, stifle instability, fracture, luxation, iliopsoas muscle strain.

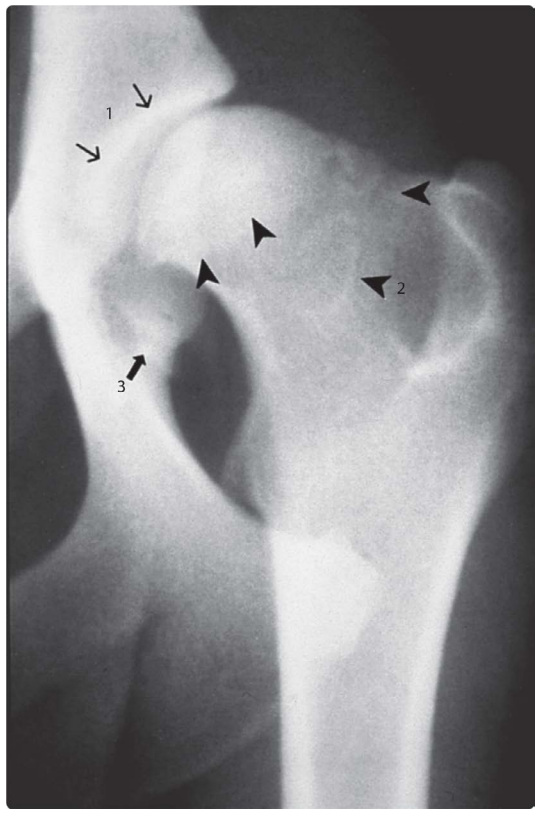

FIGURE 15.7 Moderate hip dysplasia. Less than 40% dorsal rim acetabular cover of the femoral head and secondary changes: (1) Sclerosis of the cranial acetabular margin; (2) osteophyte buildup at femoral neck capsule attachment (Morgan's line or caudolateral curvilinear osteophyte); and (3) caudal acetabular rim osteophyte deposition.

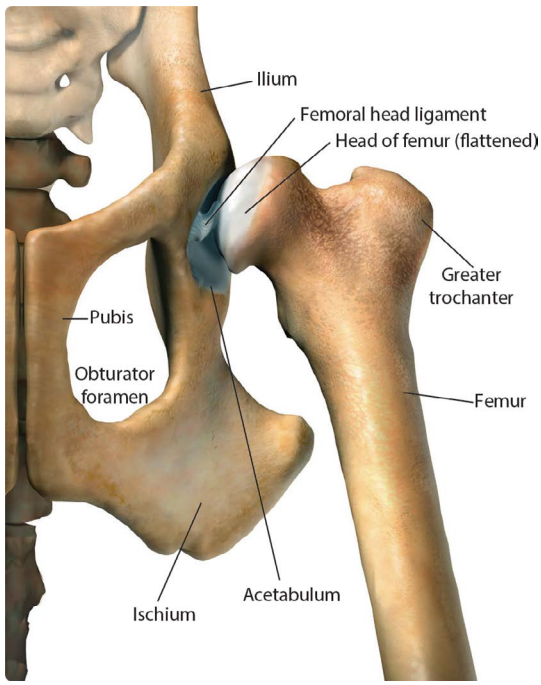

FIGURE 15.8 Illustration of hip dysplasia showing femoral head luxation, shallow acetabulum, and femoral head conformation change.

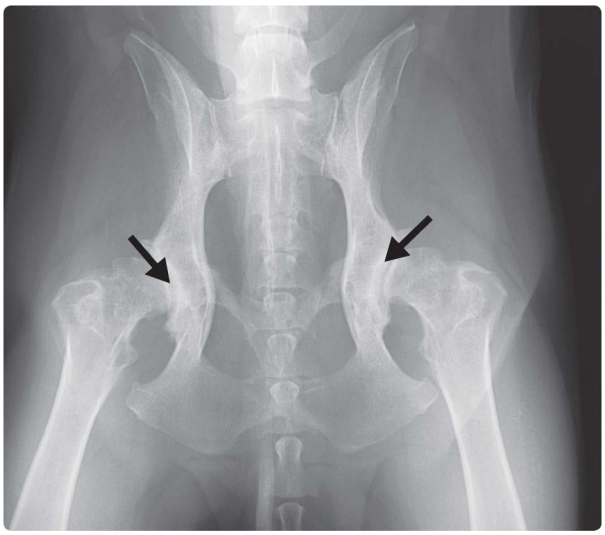

FIGURE 15.9 Radiograph of hip dysplasia showing poor acetabular cover to the femoral head (arrows).

Diagnosis

Diagnosis is made by physical (Figures 15.10 and 15.11) and radiographic examination. Comparing a lame limb with the contralateral limb and observing the dog ambulate at different gaits and on different surfaces, as well as on steps, can be helpful during the physical examination. It should be noted that often patient sedation is required to best evaluate for presence of an Ortolani sign.

Management

Available treatments (conservative or surgical) vary widely depending on the age of the animal, the pathologic condition of the joint, the expectation of function, the surgical skill of the clinician, and the financial resources of the owner. Conservative management consists of weight loss, formulated exercises, EPA-rich diets, and judicious use of analgesics and NSAIDs. Nutraceuticals have gained popularity as adjunct therapy for DJD; however, their evidence base remains indecisive.

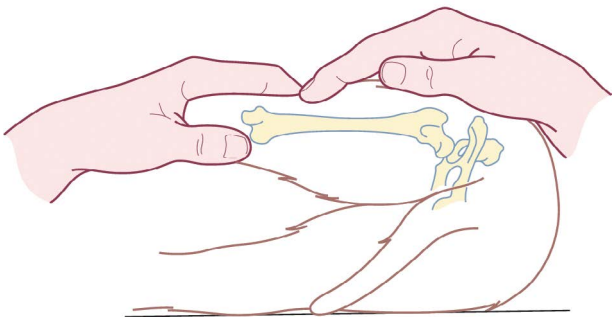

FIGURE 15.10 Physical examination for the Ortolani sign. The coxofemoral joint is subluxated by driving the femoral shaft dorsal to the long axis of the spine. (*Adapted from Fox SM (1987). A symposium on hip dysplasia.* Veterinary Medicine *82(7):683–716.*)

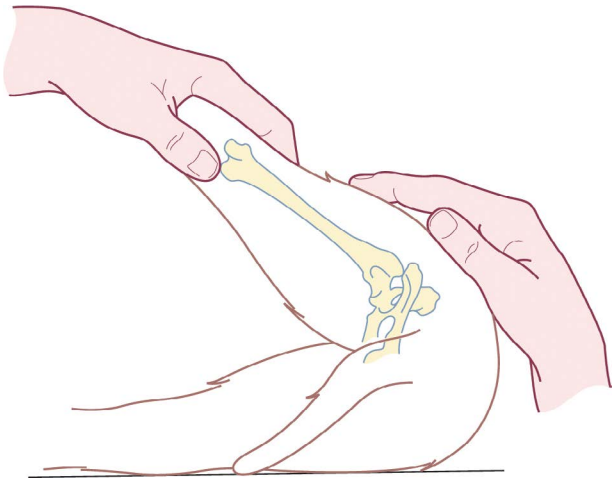

FIGURE 15.11 Physical examination for the Ortolani sign, with the coxofemoral joint subluxated, the femur is abducted until the femoral head "clunks" back into the acetabulum. The palpable (and often audible) clunk is considered a positive Ortolani sign. (*Adapted from Fox SM (1987). A symposium on hip dysplasia.* Veterinary Medicine *82(7):683–716.*)

For the immature animal, pectineal myectomy, pubic symphysiodesis, pelvic osteotomy, and femoral osteotomy are procedures frequently performed, while femoral head and neck excision and total hip replacement are most often performed in the mature animal. With the exception of pectineal myectomy and femoral head and neck excision, these surgeries require both special equipment and training.

ELBOW DYSPLASIA: UNUNITED ANCONEAL PROCESS/FRAGMENTED CORONOID PROCESS

Definition/Overview

The term general term elbow dysplasia is applied to several developmental conditions of the elbow that may occur individually or in combination. Conditions encompassing elbow dysplasia include ununited anconeal process (UAP), fragmented coronoid process (FCP), osteochondrosis of the humeral condyle, and elbow incongruity (Figure 15.12).

Etiology

Because these two diseases, together with osteochondritis dissecans (OCD) of the medial humeral condyle, overlap, a common etiology of osteochondrosis has been proposed. Skeletally immature large and giant breed dogs are affected, and the condition is often bilateral. The etiology of UAP and FCP is most often accepted to be incongruous growth of the radius and ulna. Incongruent development between the semilunar notch of the ulnar and humeral condyle may also contribute to the development of conditions of elbow dysplasia. The

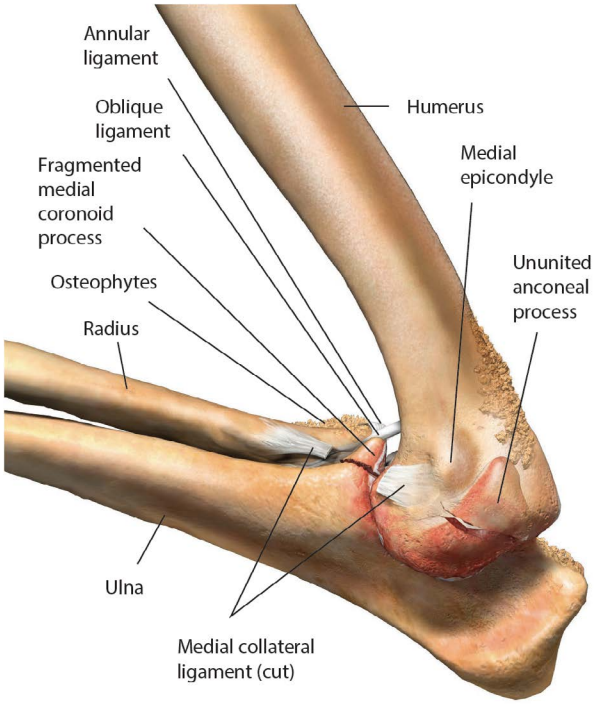

FIGURE 15.12 Elbow dysplasia is often a manifestation of FCP and/or UAP.

anconeus develops from a separate ossification center only in large dogs and will normally come to union with the parent ulna by 20 weeks of age. If this union has not occurred by this time, it is considered ununited.

Pathophysiology

It is proposed that if the radius grows faster than the ulna in large breed dogs, it places abnormal distractive forces on the anconeus through the distal end of the humerus, destabilizing the cartilaginous attachment of the anconeus to the ulna and, therefore, preventing its normal ossification. Similarly, a narrow semilunar notch would put abnormal strain on either the anconeal process or coronoid process (or both) during weight bearing, potentially resulting in development of FCP or UAP.

In contrast, if the ulna grows faster than the radius, more weight than normal is placed on the medial ulnar coronoid. Normally, the coronoid processes together with the radial head bear the compressive forces from the distal humerus. With asynchronous growth, the lateral aspect of the medial ulnar coronoid suffers damage and can become fragmented.

Clinical Presentation

Both UAP and FCP lead to forelimb lameness with an abnormal gait. Affected dogs tend to stand with the elbow abducted and feet pointed inwards but can also occasionally stand with elbow adducted with feet pointed outward. Joint effusion may be present, and the dog resents deep elbow palpation and elbow manipulation, especially hyperextension and pronation of the antebrachium.

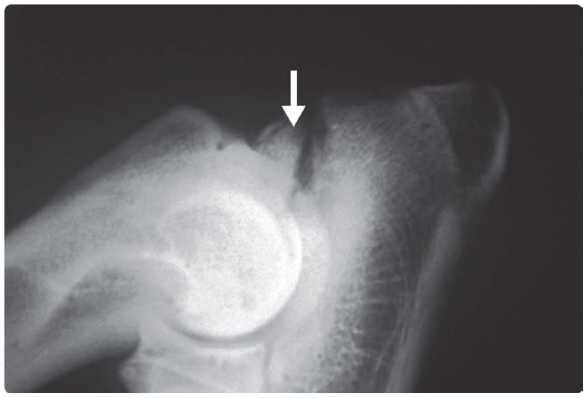

FIGURE 15.13 Ununited anconeal process (arrow) is best demonstrated in a hyperflexed lateral radiograph, which avoids the overlapping density of the medial humeral epicondyle. A diagnosis is made when the anconeus has not fused by 5 months of age.

Differential Diagnosis

Luxation/subluxation, OCD (humeral head), biceps brachii muscle/tendon disease, panosteitis.

Diagnosis

UAP is diagnosed radiographically by a hyperflexed lateral radiograph of the elbow revealing failure of the anconeal process to fuse with the proximal ulna in a dog older than 5 months of age (Figure 15.13).

Primary lesions associated with a fragmented medial coronoid process are extremely difficult to see radiographically (Figures 15.14 and 15.15). Blunting of the coronoid process and secondary changes such as osteophyte deposition proximal to the anconeal process, caudal to the distal humeral condyle, and anterior to the radial head are radiographic findings consistent with a fragmented medial coronoid process of long standing (Figure 15.16). Due to overlapping bones of the elbow combined with low sensitivity for mild changes in the elbow, survey radiographs can be very insensitive in detecting FCP or elbow incongruity. Therefore, a presumptive diagnosis of fragmented medial coronoid process is often made based on breed,

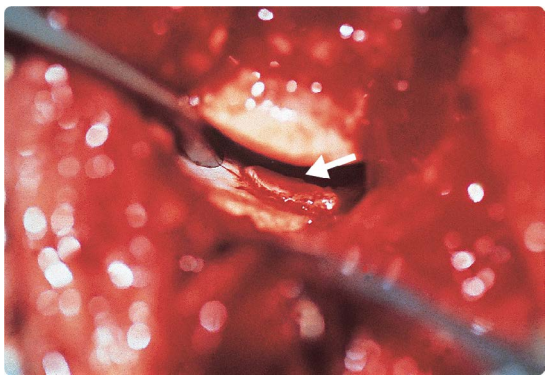

FIGURE 15.14 The separate coronoid fragment is rarely identified because it usually occurs on the lateral aspect of the medial coronoid process. An intraoperative view (arrow).

FIGURE 15.15 The separate coronoid fragment is rarely identified because it usually occurs on the lateral aspect of the medial coronoid process. Sequential views made along an arc around the elbow joint demonstrate the difficulty with radiographic identification of the coronoid lesion, as other bony structures always silhouette this area. The presence of secondary joint disease may be the only radiographic evidence of the fragmented coronoid. Periarticular osteophytes may be observed on the proximal margin of the anconeal process, coronoid process, medial humeral epicondyle, or cranial proximal radius. Sclerosis of the subchondral bone of the ulnar trochlear notch, a widened humeral–ulnar trochlear notch, and a widened humeral–ulnar joint space may be observed. Comparison radiographs of both elbows are extremely helpful because the lesions are often subtle.

FIGURE 15.16 Radiographic signs of elbow dysplasia include osteophyte deposition within the anconeal process, at the leading edge of the radial head, and on the medial humeral condyle, as well as sclerosis of the trochlear notch of the ulna.

age, history, clinical signs, and physical examination. CT imaging is required for a more definitive diagnosis of elbow dysplasia due to its increased sensitivity and multiplanar imaging capability. When CT imaging is unavailable, the diagnosis of FCP is often one of exclusion. Although CT can give detailed imaging of the bones of the elbow, arthroscopy is the gold standard to determine cartilage status and degree of severity of progression of degeneration in dogs with elbow dysplasia. More recently, nanoscopes have been developed, which can be used as a bedside diagnostic imaging tool for the identification of a FCP. Patients typically only require sedation as these scopes are typically the diameter of a 16- to 18-gauge needle.

Management

Treatment for UAP is surgical, either removal or attachment of the process. Surgery to include fragment removal and lesion curettage is the treatment of choice for FCP. Distal and proximal ulnar osteotomies are also performed in certain situations in addition to arthroscopy and UAP removal (**Figure 15.17a, b**). Prognosis for both

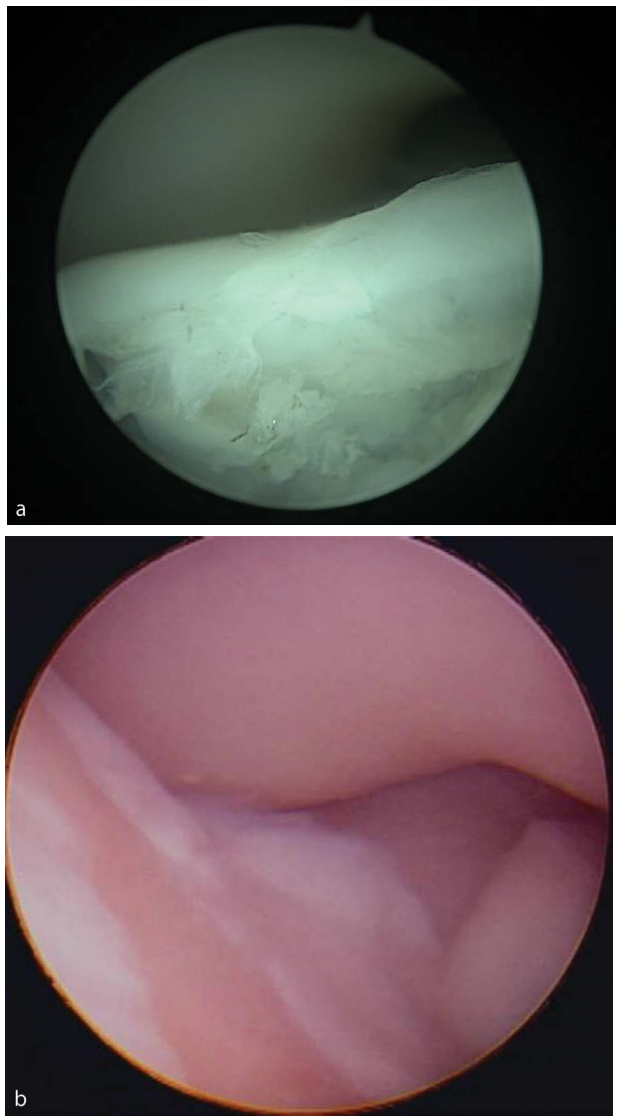

FIGURE 15.17 Arthroscopic images of different left elbows. **(a)** Fragment is in foreground, and humeral condyle is seen in the background. **(b)** The fragmented coronoid is seen in the lower right. Full-thickness cartilage erosion is noted on the ulna in the foreground.

conditions is dependent on the severity of secondary changes at the time of treatment. Total and partial elbow replacement procedures are available and are proving to be viable options for treating end-stage elbow arthritis.

Conservative management consists of weight loss, exercise modification, NSAIDs and analgesics such as gabapentin. Chondroprotectants are also used, often in combination with NSAIDs.

Intra-articular therapies have also been used with moderate success. Intra-articular therapies include hyaluronic acid, platelet-rich plasma, autologous stem cells, and corticosteroids. These therapies may reduce the use of daily NSAIDs therapy but require sedation and ability to perform arthrocentesis. Joint cytology is recommended to accompany joint injections to monitor progression of disease process.

OSTEOCHONDROSIS

Definition/Overview

Osteochondrosis is an endochondral ossification defect, the term denoting a dissecting lesion between articular cartilage and underlying bone. Once articular cartilage dissects free from the underlying calcified tissue, the lesion of OCD has formed.

Etiology

The etiology of the disease is multifactorial, with genetic, nutritional, and environmental contributions.

Pathophysiology

Osteochondrosis is the culmination of the failure of normal endochondral ossification. Failure of the ossification process leads to thickened area of cartilage. The process is thought to begin secondary to disruption of normal blood supply to the cartilage anlage. The abnormally thick cartilage results in poor nutrient diffusion to the chondrocytes and eventual chondrocyte death. The thickened area of cartilage is susceptible to damage caused by normal weight-bearing forces. Fissures may form leading to separation of the cartilage from the subchondral done. Osteochondritis dissecans (OCD) is the term used once the cartilaginous flap has formed with the resultant joint inflammation and lameness.

Clinical Presentation

Clinical signs of lameness appear between 4 and 12 months of age, mostly in large and giant breeds of dogs. Bones affected include the humeral head, medial humeral condyle, femoral condyles, and talus.

Differential Diagnosis

Intra-articular (osteochondral) fractures, elbow dysplasia, panosteitis, periarticular ligamentous injury, cranial cruciate injury, biceps tenosynovitis.

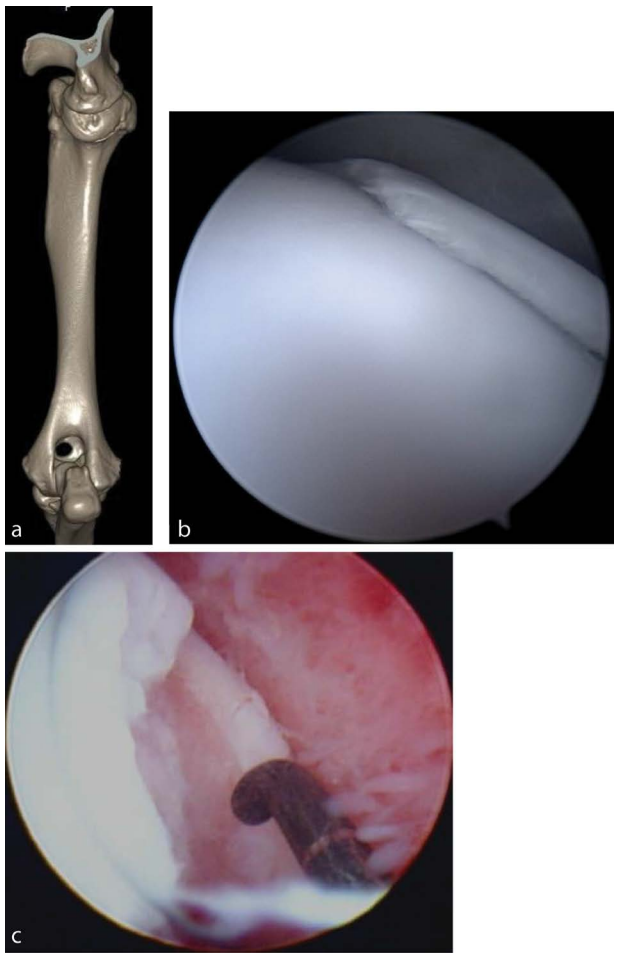

FIGURE 15.18 Arthroscopic images of a shoulder OCD lesion. **(a)** 3D reconstruction from CT imaging of a humeral head OCD lesion in the caudal central region. **(b)** Lesion as it is initially seen. **(c)** The OCD flap is being lifted by an arthroscopic probe prior to removal.

Diagnosis

The typical lesion appears radiographically as a flattened or concave radiolucent defect in the subchondral bone immediately beneath the articular cartilage (Figure 15.18a–c). Free-floating, mineralized cartilage fragments ("joint mice") may also be present within the affected joint (Figures 15.19 and 15.20).

Management

Treatment is surgical. Pain and lameness in a dog with radiographic evidence of osteochondrosis are an indication for surgical exploration. All loose cartilage fragments, including joint mice, are removed from the joint, and the lesion is curettaged to stimulate the articular surface defect to heal by fibrocartilage formation. Although clinical severity is not correlated with radiographic findings, the prognosis is based on secondary changes. Shoulder and stifle lesions typically yield a better prognosis than elbow and tarsus lesions. Resurfacing techniques using allografts, autografts, and synthetic grafts are also used to fill in the defect. Although not

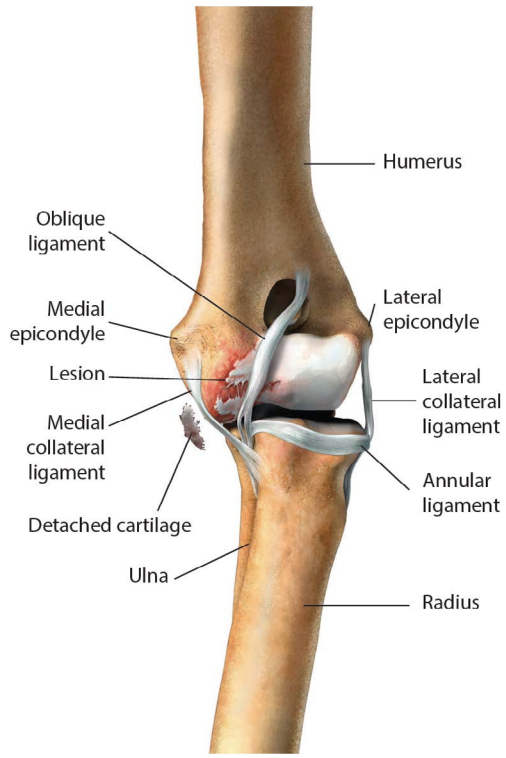

FIGURE 15.19 Osteochondrosis lesion of the humeral condyle. Lesion is typically found on the trochlea of the humerus.

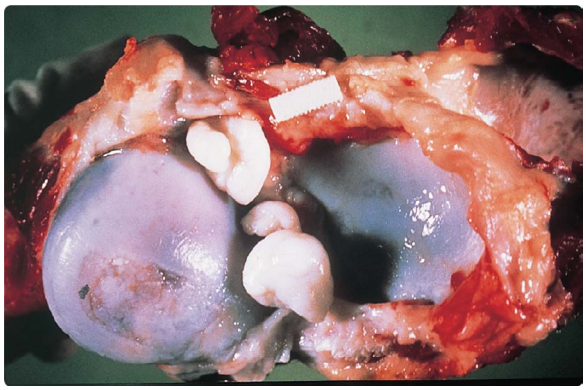

FIGURE 15.20 Humeral head osteochondrosis appears grossly with fibrillation and eburnation and may include joint mice, as seen in this case. Also note the thickened joint capsule, which might manifest clinically as restricted range of motion.

curative, NSAIDs are useful to treat symptomatically the pain associated with DJD.

RETAINED ENDOCHONDRAL CARTILAGE CORE

Definition/Overview

Retained endochondral cartilage core occurs in the distal ulnar metaphysis of immature large and giant breed dogs, appearing as a radiolucent inverted cone.

Etiology

The etiology of the disorder is not well understood but is thought to be similar to disruption of endochondral ossification (osteochondrosis) of the physis instead of the more typical development of osteochondrosis of the epiphysis. The core is a result of improper mineralization (Figure 15.21). Fortunately, most cases of retained endochondral cartilage core do not persist long enough to produce a deformity. This same condition may be seen in the lateral femoral condyle, leading to genu valgum, a predisposition to "knock-knees" and lateral patellar luxation.

Pathophysiology

In Great Dane pups, formation of cartilage core in the distal ulnar and tibial metaphyses has been associated with feeding excess calcium.

Clinical Presentation

The condition is often self-resolving and an incidental radiographic finding; however, it may be associated with varying degrees of growth retardation after 5 months of age.

FIGURE 15.21 Histologically, retained cartilage core, as seen here, is a failure of normal endochondral ossification within the distal ulna. Radiographically, an inverted radiolucent cone may be observed extending proximally from the distal ulnar physis into the metaphysis. This condition may lead to deformation of the carpus as is seen in the condition radius curvus.

Diagnosis

Radiography of the distal ulna. A radiolucent core of cartilage 5–10 mm wide and 2–6 cm long extending from the distal ulnar physis into metaphyseal bone is pathognomonic.

Management

Corrective/reconstructive surgery is the treatment of choice for deformities resulting from retained endochondral cartilage core.

CRANIAL CRUCIATE LIGAMENT RUPTURE

Definition/Overview

Rupture of the cranial cruciate ligament (Figure 15.22) is frequently associated with hindlimb lameness in dogs (especially large breeds of older, overweight females), contributing to its recognition as the major cause of stifle joint DJD. Injury leaves the animal with partial to complete instability of the joint (Figure 15.23).

Etiology

The history varies from dogs presenting with acute signs of hindlimb lameness to patients with a chronic course of intermittent lameness, often culminating in a more acute exacerbation. Degeneration of the ligament is poorly understood but may be affected by age, breed, sex hormones, body weight, conformational abnormalities, immune-mediated processes, and limb immobilization or loss of tone due to irregular use. There is also speculation that excessive (>35°) tibial plateau angle is an etiologic factor.

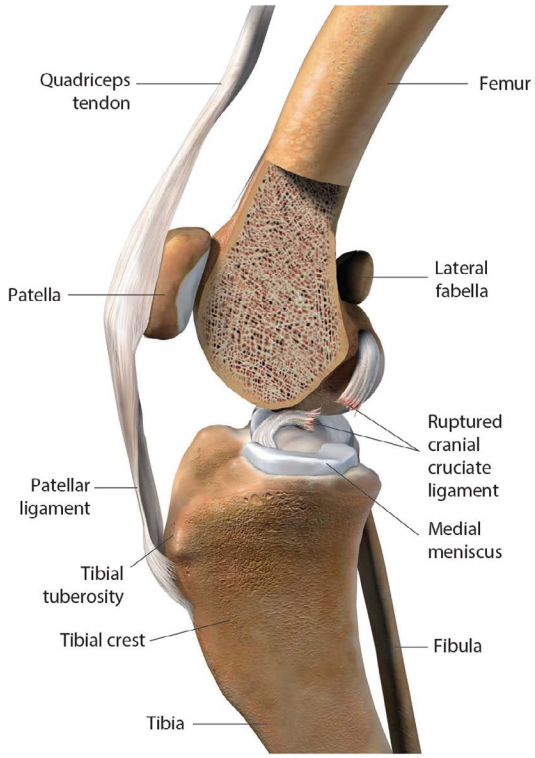

FIGURE 15.22 Illustration depicting a torn cranial cruciate ligament.

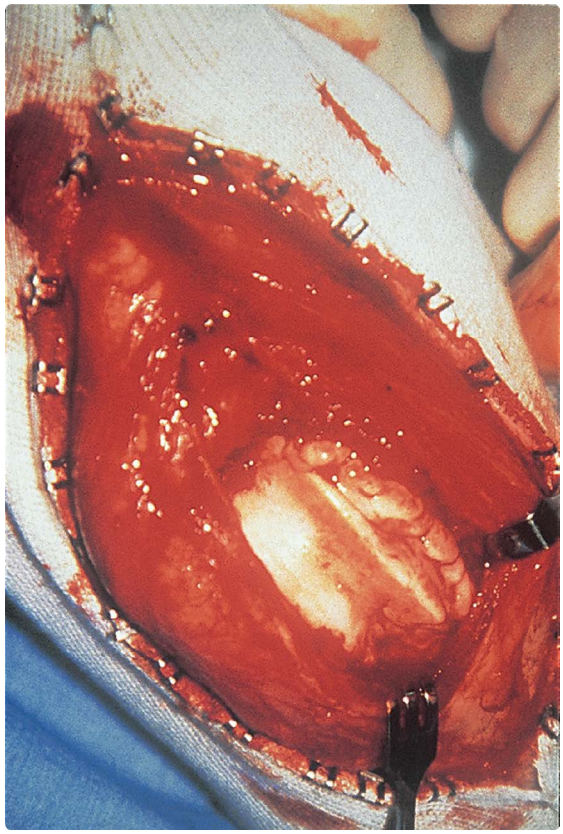

FIGURE 15.23 Cranial cruciate ligament rupture is a common presentation in clinical practice. In larger breeds of dog, surgical stabilization is important in order to minimize the progression of degenerative joint disease, demonstrated by osteophyte deposition on the lateral aspect of this femoral condyle. (*Courtesy of the late M.S. Bloomberg.*)

Pathophysiology

Immune-mediated arthritis, lymphocytic–plasmacytic synovitis, and septic arthritis may predispose the ligament to rupture. Cranial cruciate ligament strength deteriorates with aging, correlating with loss of fiber bundle organization and metaplastic changes of cellular elements. Tears may occur in total or in part (approximately 30% of patients with stifle lameness), and osteoarthritis soon follows. Cranial cruciate ligament compromise results in additional stress on the menisci, which frequently tear (>50% of patients), thus further contributing to joint osteoarthritis.

Clinical Presentation

A common presenting sign is lameness of the hindlimb. Acute traumatic ligament rupture is accompanied by severe lameness and occasional non-weight-bearing.

FIGURE 15.24 Osteochondritis dissecans of the femoral condyle is a differential diagnosis for stifle lameness; however, the condition does not present with cranial drawer motion.

Lameness subsides in 3–5 weeks as muscle atrophy progresses. In contrast, dogs with chronic disease have a more insidious history of lameness, often intermittent and exacerbated by exercise. Joint effusion is characteristic. Subtle weight shifts during standing and difficulty rising can also suggest cruciate disease.

Differential Diagnosis

Patellar luxation, meniscal injury, collateral ligament compromise, hip dysplasia, skeletally immature dog (have some degree of drawer sign), osteochondrosis of the femoral condyle (Figure 15.24), neoplasia (synovial cell sarcoma).

Diagnosis

High-quality radiographs can be suggestive for cranial cruciate ligament compromise and often demonstrate joint effusion and early signs of DJD (Figures 15.25–15.28). Joint effusion may cause cranial displacement of the infrapatellar fat pad, and osteophyte deposition is commonly observed on the distal pole of the patella in more chronic cases. A bow-legged conformation, internal rotation of the tibia, or straight stifle increases suspicion of cruciate disease. Thickening of the medial joint capsule (medial buttress) is characteristic of long-standing disease. The most consistent physical exam finding is pain on hyperextension of the stifle. Cranial drawer

FIGURE 15.25 Radiograph showing the relative displacement of the fat pad in mild cranial cruciate ligament rupture. (*Courtesy of B. Poteet.*)

FIGURE 15.26 Radiograph showing the relative displacement of the fat pad in moderate cranial cruciate ligament rupture. (*Courtesy of B. Poteet.*)

FIGURE 15.27 Radiograph showing the relative displacement of the fat pad in severe cranial cruciate ligament rupture. (*Courtesy of B. Poteet.*)

FIGURE 15.28 Radiograph showing the normal joint. (*Courtesy of B. Poteet.*)

motion is one of the hallmarks of cruciate compromise and may be detected by the cranial drawer test in either flexion or extension. The tibial compression test is also diagnostic and very sensitive. Partial tears of the craniomedial band of the ligament are identified by palpation when cranial tibial displacement is prevented by extension, but abnormal cranial drawer motion is evident in flexion. Due to periarticular fibrosis, cranial drawer motion may be difficult to elicit in dogs with chronic cruciate disease. In young, growing dogs, "puppy drawer" may be found. This drawer is differentiated by lack of stifle effusion or pain and is due to normal laxity in the ligament until skeletal maturity is reached. This drawer sign has a distinct endpoint since the ligament is intact.

Management

Treatment options are influenced by the animal's weight, age, intended use, concurrent medical problems, economic considerations, and veterinary surgical training. Dogs >15 kg body weight clearly benefit from surgical therapy. Smaller dogs and cats respond favorably to surgical interventions similar to larger dogs but may clinically appear to do well with conservative management as long as they have unilateral disease.

Conservative therapy includes weight loss/management, activity modification, nutritional joint supplements, and careful use of NSAID analgesics. Leash walking, swimming rehabilitation are appropriate exercise activities. The objectives of surgery are joint stabilization, early return to function and minimizing secondary DJD.

A myriad of surgical methods for joint stabilization have been described, suggesting that no one method is ideal. At present, extracapsular stabilization, tibial plateau leveling osteotomy (TPLO) techniques, and tibial tuberosity advancement are in favor. Recent studies have shown some long-term clinical advantages with the TPLO procedure with regard to range of motion

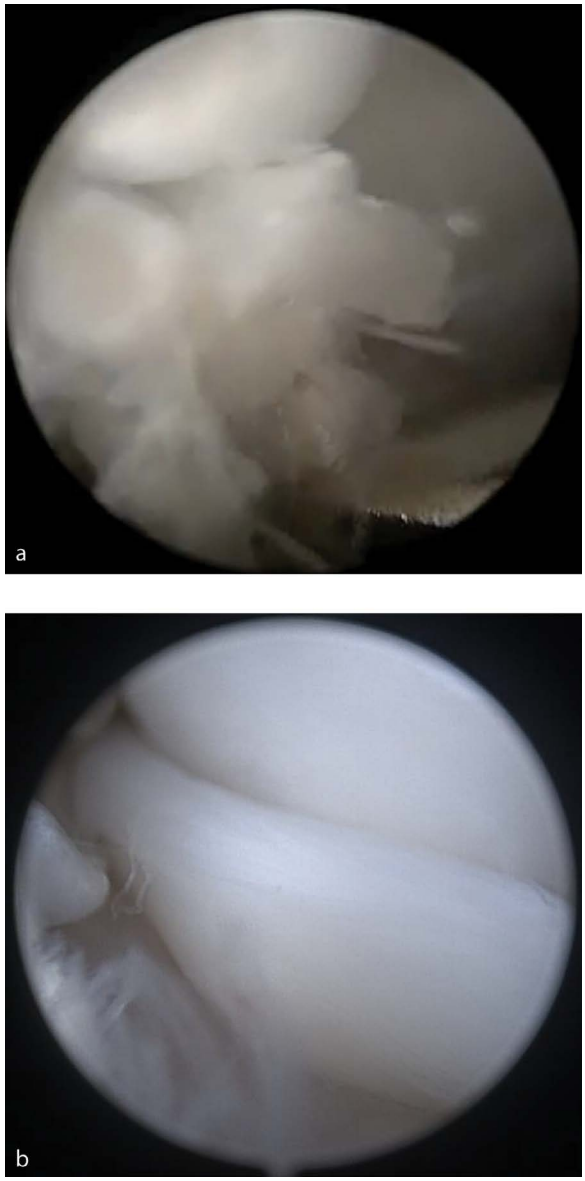

FIGURE 15.29 Images taken during stifle arthroscopy showing torn cruciate fibers **(a)** and **(b)** a cranially displaced bucket handle tear of the medial meniscus.

and overall function. Irrespective of the technique for stabilization, the joint must be inspected for meniscal damage either by an arthrotomy or arthroscopy. The frequency of meniscal damage (**Figure 15.29a, b**) increases with chronicity and is as great as 80% in dogs with complete tears.

DEVELOPMENTAL LUXATIONS

Definition/Overview

Most joint luxations are traumatic, although congenital/developmental luxations (**Figure 15.30**) do occur in both dogs and cats. Femoropatellar luxation is frequently diagnosed in small dogs and occasionally in

FIGURE 15.30 Congenital joint luxations, such as this elbow, often accompany other anomalies and are best treated by "salvage" procedures.

large dogs and cats (Figures 15.31 and 15.32). The condition varies from complete, irreducible luxation of the patella and severe lameness to mild instability without

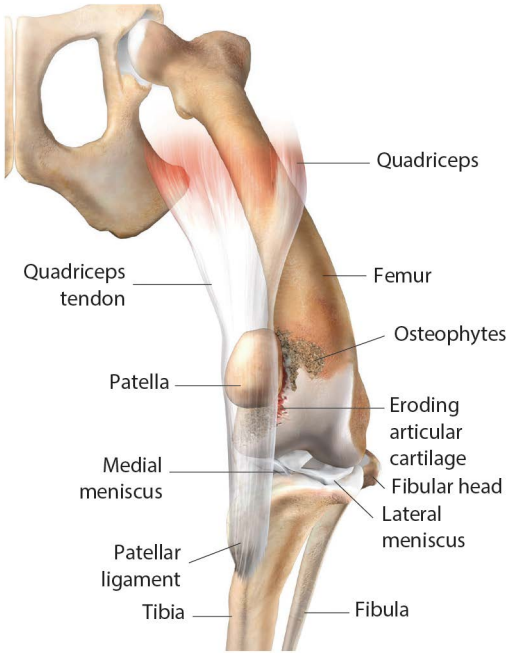

FIGURE 15.31 Illustration of medial patella luxation, a common developmental anomaly in small breed dogs.

FIGURE 15.32 Radiograph of medial patella luxation, a common developmental anomaly in small breed dogs.

associated clinical signs. Grading is made from 1 to 4 based on the severity of the condition and clinical signs.

Etiology

In dogs, the smaller breeds are more commonly affected with luxations owing to disruption of supporting joint structures or anatomic developmental failures. The changes noted during development are difficult to attribute causation. For instance, with the development of a shallow or concave trochlear groove in small dogs, it is unclear if the lack of a groove contributes to patella luxation or if the development of patella luxation results in abnormal groove formation.

Pathophysiology

Multifactorial developmental abnormalities can contribute to development of patella luxation. Abnormal growth of the distal femur (femoral varus), underdeveloped trochlear groove, medially directed growth of the tibial tuberosity, soft tissue restrictions (contracted musculature or medially displaced origin of the rectus femoris), and lack of supporting joint structures (such as the fabellopatellar ligament) have all been found to be responsible, individually or more commonly in combination, for development of patella luxation. In doing so, the patella rides over the trochlear ridge (with medial more common than lateral). Articular cartilage of both the ridge and the articular surface of the patella may become eburnated down to subchondral bone. Ultimately, DJD leads to chronic osteoarthritis. In grades 3 and 4, severe bony deformities may be present, including marked internal tibial rotation and an S-shaped curve of the distal femur and proximal tibia.

Clinical Presentation

Grade 1 luxations are often incidental findings during physical examination, where the patella can be manually luxated but spontaneously reduces back into the groove. Grade 2 luxations typically present with a history of intermittent lameness, resolving spontaneously with patella reduction. Owners often report that the dog suddenly skips and carries the limb without apparent pain, flexes and extends the joint several times, and is then able to bear weight normally thereafter. In this case, the animal is allowing the patella to pop back into place by forcing the limb into extension. With a grade 3 luxation, the patella remains outside the trochlear groove but during examination can be replaced into the groove; however, it immediately re-luxates once manipulation is ceased. The owner frequently reports that the dog shows a "crouched" gait, since the dog often uses the limb in a semiflexed, internally rotated position. Grade 4 is a nonreducible luxation of the patella. The tibia is often rotated internally from 60 to 90 degrees relative to the sagittal plane, and limb disfiguration often accompanies abnormal gait. Patella luxation often occurs bilaterally.

Differential Diagnosis

Premature physeal closure, cranial cruciate ligament rupture, collateral ligament disruption, tibial tubercle avulsion fracture, patellar tendon rupture.

Diagnosis

Diagnosis is most often apparent on physical examination, and it can be confirmed radiographically. Acute lameness in a dog with chronic luxation is usually caused by rupture of the cranial cruciate ligament, as cranial stifle support from the straight patella ligament is lacking. Every small-breed dog should be examined for patella luxation.

Radiographic images should be obtained to assess for abnormal bone morphology or the occurrence of comorbidities such as hip dysplasia or cranial cruciate disease. True craniocaudal images of the femur are necessary to accurately assess femoral varus. These images are obtained via horizontal beam imaging or positioning the patient such that the femur is parallel to the radiographic imaging table.

Management

Surgical correction for developmental luxations in growing animals is often disappointing due to the rapid anatomic changes in the growing dog and inevitable DJD. Once past the rapid growth phase, or after skeletal maturity, surgical correction of patella luxation is often rewarding. Surgical methods include sulcoplasty, block or wedge recession trochleoplasty, tibial tuberosity transposition, and antirotational techniques. For severe patella luxations, corrective osteotomies of the distal femur or proximal tibia maybe needed as well. Uncomplicated traumatic luxations most often carry a favorable prognosis if treated promptly.

CHRONIC DEGENERATIVE TENDINOPATHIES

Definition/Overview

Degenerative tendinopathies typically have an insidious onset that may go unnoticed until severe changes have occurred or an intermittent occurrence with inability to localize source of lameness or showed improvement with rest and anti-inflammatory medications. The two most common chronic tendinopathies occur in the common calcaneal tendon and the proximal biceps tendon.

Etiology

The etiology of degenerative tendinopathy is poorly understood but is suspected to most commonly be secondary to repetitive use injury. Chronic strain may cause microfiber damage due to the innate low density of tendon vascularity. This results in poor reparative response leading to increased parenchymal damage and worsening of tendon injury. Tendon pathology typically leads to tendon thickening, with or without accompanying inflammation. These changes lead to decreased compliance and increased stiffness of the tendon resulting in pain and lameness. With time, chronic inflammation can lead to increased vascularity and mineralization (**Figures 15.33–15.35**).

Pathophysiology

Chronic tendinopathies are commonly thought to be due to repetitive use/overuse. These injuries often have an insidious onset and can be quite advanced at the time of presentation, evidenced by the significant changes found at the time of diagnosis, including tendon thickening and mineralization along with changes at the bony insertion of the tendon as well as enthesophyte formation.

Clinical Presentation

Weight bearing lameness of the affected limb is common. For a common calcaneal tendon injury, a "dropped hock" with or without excessive digit flexion may be noted during weight bearing. With an affected but still intact tendon, plantigrade stance may not be noted; however, the distance from calcaneus to the ground will be less than the contralateral side (if unaffected).

For biceps tenosynovitis, pain is commonly elicited upon shoulder flexion with elbow extension. Because the biceps muscle crosses the shoulder and elbow, this positioning is essential to cause appropriate stretch of the effected muscle and tendon. Reduction in shoulder extension may be noted. This is likely due to concurrent joint inflammation, since the bicipital tendon of origin is within the joint capsule. Conversely, primary arthritides of the shoulder joint can secondarily affect the biceps tendon, giving a positive examination finding for biceps pain due to inflammation without true tendon injury.

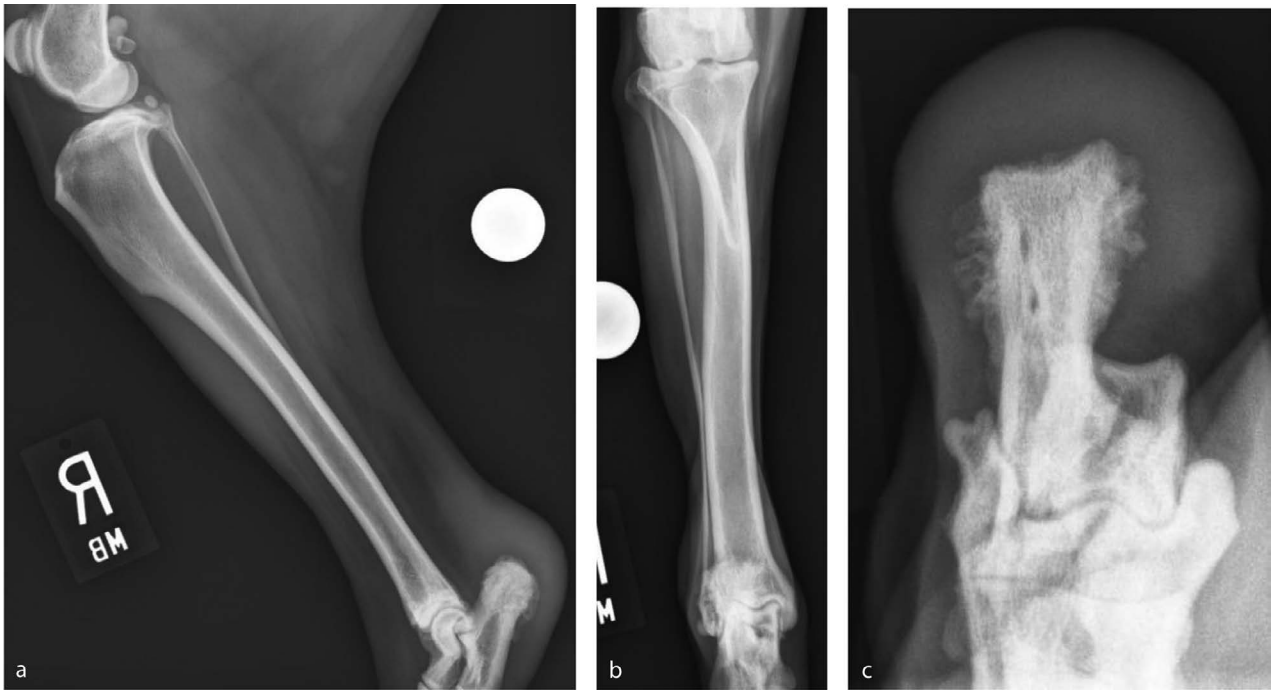

FIGURE 15.33 (a, b) Lateral and craniocaudal radiographic projections of a dog with chronic common calcaneal tendinopathy revealing marked soft tissue swelling in the region of the calcaneus extending proximally. **(c)** A skyline projection of the calcaneus highlighting the extensive soft tissue thickening and periosteal reaction in the region of tendon insertion on the calcaneus.

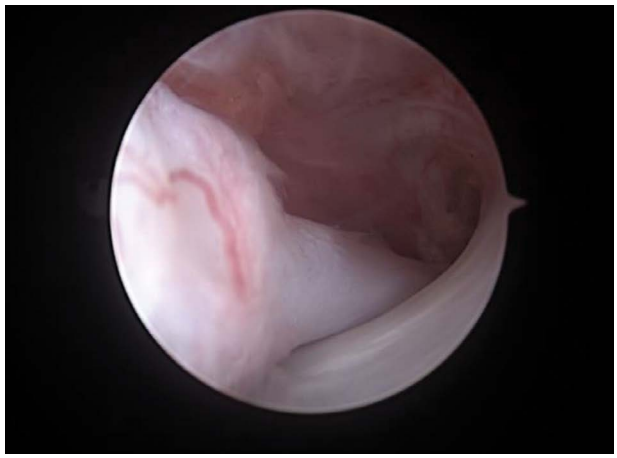

FIGURE 15.34 Arthroscopic image of partially torn biceps tendons. Image of acute tear with a majority of the tendon still intact.

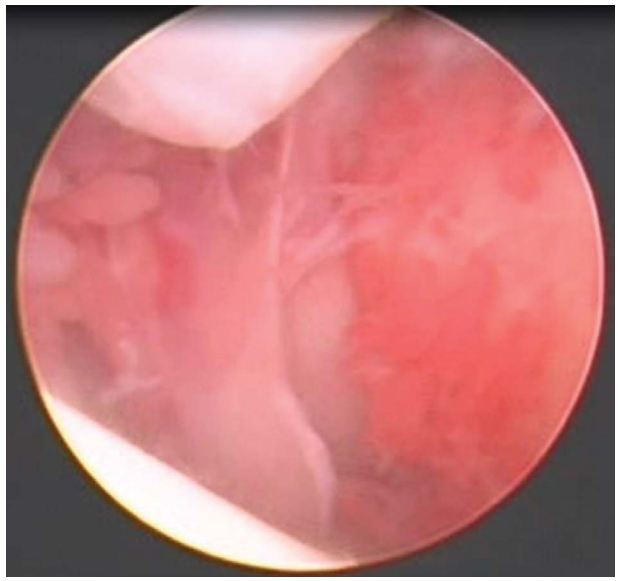

FIGURE 15.35 Arthroscopic image of partially torn biceps tendons. Image shows a more chronic biceps tendon with a near complete rupture of the tendon.

Differential Diagnosis

Common calcaneal tendon: Acute tendon rupture, calcaneal fracture, superficial digital tendon luxation
Biceps tenosynovitis: OCD, medial shoulder instability, neoplasia, primary shoulder arthritides (septic joint, severe DJD)

Diagnosis

Diagnosis of chronic tendinopathy is generally achieved via a combination of physical examination findings along with confirmatory diagnostic imaging, typically musculoskeletal ultrasound. Physical examination findings include tendon thickening, pain with direct palpation of the tendon, and reduced range of motion. The calcaneal tendon develops thickening at its insertion on the calcaneus. The thickening extends proximally, generally corresponding the degree of severity of injury to

the tendon. While the biceps tendon may develop thickening, it is generally not to the extent that is palpable upon examination. Pain on tendon stretch is due to the loss of compliance in the tendon. For the common calcaneal tendon, this is accomplished with the stifle kept in extension while attempting to flex the tarsus. For the biceps tendon, this is accomplished by keeping the elbow in extension while flexing the shoulder.

Management

Chronic tendinopathies can often be resolved with conservative management. Successful treatment of chronic tendinopathies typically involves joint immobilization to reduce tendon strain along with activity modification. Additional therapies are utilized to improve healing within the tendon, including PRP injection, shockwave therapy, therapeutic ultrasound, and/or cross-frictional massage.

Joint immobilization is initially done in cases of common calcaneal tendinopathy. Immobilization doesn't completely eliminate tendon strain because the gastrocnemius muscle can still contract creating tension in the tendon; however, immobilization does maintain the joint in extension, placing the muscle in the contracted position that limits the amount of tension that can be generated. Following 2-4 weeks of immobilization, controlled range of motion is initiated either via an orthotic device with a controlled range-of-motion hinge design. Alternatively, splinting with progressive flexion at the tarsus and periodic sedated range of motion has been utilized.

ANOMALIES

ECTRODACTYLY

Definition/Overview

Skeletal growth disorders that are apparent at birth or manifest later in young animals are of two main types: Generalized dysplasias and localized malformations of individual bones. Ectrodactyly (Gr. ectro = congenital absence) (split hand or lobster claw deformity) is an abnormal limb development with metacarpal bone separation (Figure 15.36), digit contracture, digit aplasia, metacarpal hypoplasia, and metacarpal fusions. The condition is usually unilateral.

Etiology

In the cat, ectrodactyly is caused by a dominant gene with variable expression.

Pathophysiology

The cleft between metacarpal bones may terminate just below the carpus or extend proximally through the carpus, separating the radius and ulna entirely.

FIGURE 15.36 A number of congenital anomalies may affect the digits. Here, a syndactyly of digits 2, 3 and 4, 5 is seen, as metacarpals 3 and 4 are separated at the level of the metacarpal heads. (*Courtesy of the late M.S. Bloomberg.*)

Clinical Presentation

Ectrodactyly presents as absence of the central digit or incomplete fusion of three digits. There are many variations of this condition, but typically, the third digit and metacarpal bone are absent, which produces a deep cleft dividing the paw into ulnar and radial parts. Concomitant congenital elbow luxation is common.

Differential Diagnosis

Congenital amputation.

Diagnosis

Diagnosis is made by physical examination and supporting radiographs.

Management

Reconstructive surgery or arthrodesis can improve function.

OSTEOCHONDRODYSPLASIA

Definition/Overview

Osteochondrodysplasia is an abnormality of cartilage or bone growth and development. In achondroplasia, endochondral ossification of all long bones is retarded, resulting in shortened and deformed limbs. Hypochondroplasia is similar to achondroplasia; however, the condition is less severe. The Bulldog, Boston Terrier, Pug, Pekingese, Japanese Spaniel, and Shih Tzu are achondroplastic, while the Dachshund, Basset Hound, Beagle, Welsh Corgi, Dandi Dinmont Terrier, Scottish Terrier, and Skye Terrier are hypochondroplastic.

Etiology

In most osteochondrodysplasias, there is a known or suspected genetic basis, and autosomal recessive inheritance is common.

Pathophysiology

There are several syndromes of chondrodystrophia fetalis in animals, some of them inherited, and all of them result in disproportionate dwarfism. Dwarfism of chondrodystrophia fetalis is differentiated from primordial dwarfism by disproportionate body form. As a result of an endochondral ossification defect, one or more long bones grows in retardation.

Clinical Presentation

Animals may exhibit dwarfism, and there may be reduced limb length relative to the trunk because of the discrepant development of the axial and appendicular skeleton.

Differential Diagnosis

When the condition affects one or more limbs, particularly the forelimbs, bilateral premature closure of the physes (radial/ulnar) can be a differential diagnosis of concern. Genetic anomalies tend to be symmetrical. Premature physeal closure can be bilateral, and closure of the distal ulnar physis is more sensitive to insult than the radial physis.

Diagnosis

Serial radiography of the long bone physes during the rapid growth phase is often diagnostic for premature physeal closure as a differential.

Management

Corrective osteotomies and bone-lengthening procedures can yield good outcomes; however, correction of severe deformities is often best addressed with staged procedures to maintain associated joint congruities until growth rate is diminished. Once growth is diminished, final correction can be attempted. If severe and not addressed early, the results are often unrewarding.

GROWTH DEFORMITIES

Definition/Overview

Chondrodysplasia is responsible for most growth deformities in dogs. Trauma is the most common origin of acquired growth deformities due to the exuberant nature of puppies. Unilateral growth deformities are most commonly secondary to trauma, whereas bilateral deformities are more likely to be congenital/developmental.

Etiology

Long bones grow in length through the process of endochondral ossification, which occurs at the growth plate or physis. Alterations in this normal process can lead to growth deformities, which are most frequently seen in the antebrachium. The most common cause of premature growth cessation is trauma to the distal ulnar physeal growth plate. Large and giant breeds are most commonly affected.

Pes varus is a growth abnormality of the distal tibia and fibula most commonly seen in Dachshunds. It can be unilateral or bilateral and is thought to be secondary to asymmetrical premature closure of the distal tibial physis. Trauma is potentially a cause in non-Dachshund breed but is generally believed to be a genetic condition in Dachshunds.

Pathophysiology

Following trauma, asymmetric growth of the physis leads to valgus (Figure 15.37) or varus (Figure 15.38) deformation of the limb. The severity of disfigurement is dependent on the growth potential remaining after the physeal trauma. The antebrachium is predisposed to growth deformity because of the two-bone system and the architecture of the distal ulnar physis.

FIGURE 15.37 Valgus deformation of the carpus resulting from premature closure of the distal ulnar physes.

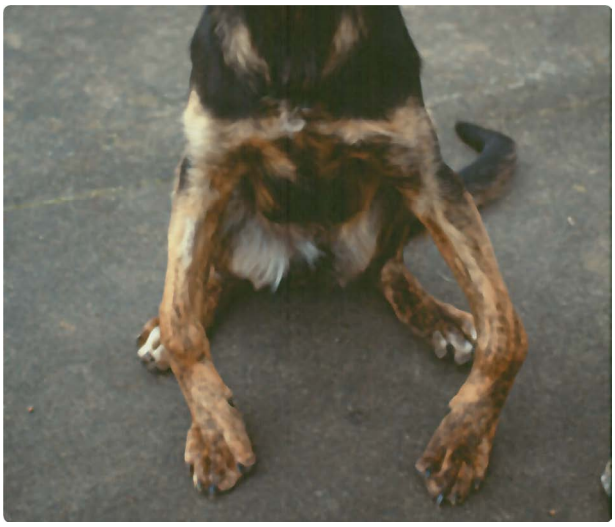

FIGURE 15.38 Young dog with varus deformation of the carpal joints resulting from premature closure of the distal radial physes.

Clinical Presentation

Three deformities of the radius result from premature closure of the distal ulnar physis: Lateral deviation (valgus), cranial bowing (curvus) (Figure 15.39), and external rotation (supination). Caudolateral subluxation of the radial carpal joint results, with stretching of the medial soft tissue supporting structures. The radial head may also luxate the humeral condyles from the trochlear notch of the ulna. Abnormal articulations resulting in irreversible degenerative osteoarthritis in the carpal and elbow joints may be sequelae. In the severe condition, the patient appears to be walking on its mediopalmar metacarpals. Elbow luxation can be very painful for the patients.

As the name implies, pes varus results in a varus deviation of the distal tibia and fibula. Additionally, internal rotation of the distal tibia is commonly seen. Fortunately, abnormalities of the proximal tibia and fibula do not accompany this condition.

Differential Diagnosis

Congenital deformity, ligamentous trauma, luxation, fracture.

Diagnosis

For the antebrachium, diagnosis is by radiography of the carpal and elbow joints (Figures 15.40 and 15.41), comparing them with the contralateral limb if that limb is normal. The condition is predictable when closure of the distal ulnar physis precedes that of the distal radial physis and significant growth remains before skeletal maturation.

For hindlimb, orthogonal images of the tibia and fibula to include the tarsus are compared to those of the contralateral limb. Closure of the medial distal tibia

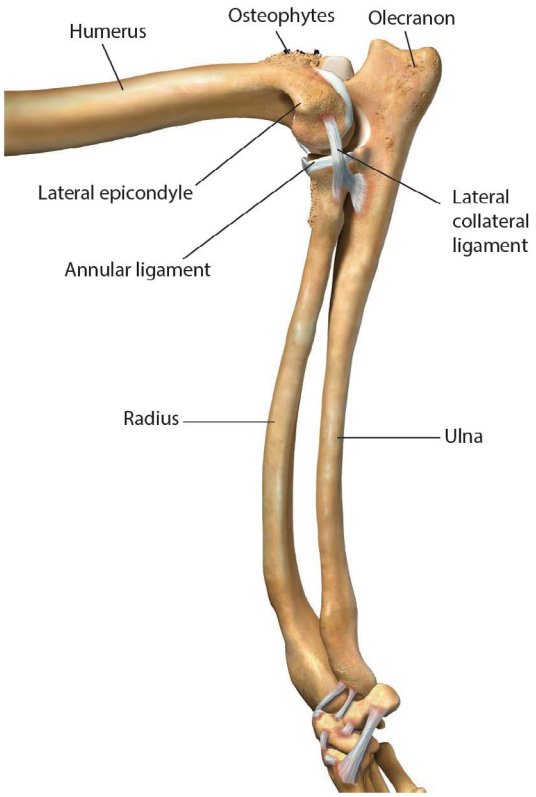

FIGURE 15.39 Radius curvus can lead to disfigurement of the entire antebrachium, including the elbow and the carpus.

FIGURE 15.40 Craniocaudal projection showing some of the radiographic changes commonly seen with premature closure of the distal ulnar growth plate: Valgus deviation of the distal radius, external rotation of the distal antebrachium, mild elbow incongruity, and mild radiocarpal subluxation.

FIGURE 15.41 Medial lateral projection showing some of the radiographic changes commonly seen with premature closure of the distal ulnar growth plate: Valgus deviation of the distal radius, external rotation of the distal antebrachium, mild elbow incongruity, and mild radiocarpal subluxation.

epiphysis may be noted on craniocaudal images but more commonly is presumed based on the pattern of growth abnormality.

Management

ADVANCED SURGICAL RECONSTRUCTION

Early identification and intervention with distal ulnar ostectomy to "uncouple" the distal radial growth have significant positive benefit to limiting elbow incongruity and irreversible degenerative changes. Distal ulnar ostectomy may or may not positively benefit the remaining growth of the distal radius. A secondary corrective procedure may be required after growth potential has subsided.

Pes varus does not commonly result in the same debilitating sequela of the antebrachial growth disturbances. Pes varus can be addressed once growth has subsided but also requires advanced reconstructive interventions.

METABOLIC DISORDERS

PANOSTEITIS

Definition/Overview

Panosteitis is a disease of the fatty bone marrow, with secondary involvement of bone.

Etiology

The cause is poorly understood; some authors have implicated a viral role.

Pathophysiology

Medullary endostosis and occasional subperiosteal new bone formation are characteristic of this self-limiting disease in young, large, or giant breeds of dogs, which may last up to 18 months. Pain may be due to disturbance of endosteal and periosteal elements, vascular congestion, or high intramedullary pressure. German Shepherd Dogs are most commonly affected.

Clinical Presentation

Clinical signs of lameness usually appear in immature dogs, with a prevalence in males, but onset has been documented as late as 5 years of age. Episodic lameness lasts 2–3 weeks, with bouts persisting for 2–9 months. Lameness may range from mild to severe, involve one or more bones, and be persistent or intermittent. Other signs include anorexia, lethargy, pyrexia, and weight loss. The ulna is most commonly affected, although the radius, humerus, femur, and tibia may also show involvement.

Clinical signs are usually associated with pain, which can be elicited with deep palpation of the affected bone and often self-resolves by the time the dog reaches 18–20 months of age. Mild depression, inappetence, and weight loss may occur in severely affected patients.

Differential Diagnosis

Osteochondrosis, elbow dysplasia, fractures, ligamentous injury, immune-mediated arthritides, Lyme disease, bacterial endocarditis.

Diagnosis

The earliest radiographic abnormality seen is an increase in intramedullary density (Figures 15.42–15.45). Initially unifocal with indistinct margins, lesions coalesce as the disease progresses. There is no correlation between radiographic signs, degree of lameness, and amount of pain elicited on deep palpation of the limb. Often, radiographic signs lag behind clinical signs by weeks.

Management

Treatment with analgesics (NSAIDs) and supportive care yields excellent results, although the course of treatment may be prolonged.

CRANIOMANDIBULAR OSTEOPATHY

Definition/Overview

Craniomandibular osteopathy is a proliferative nonneoplastic disease of the flat bones in the skull, where

FIGURE 15.42 Radiographic findings of panosteitis center around the nutrient foramina. The early phase begins with an increase in endosteal and medullary density, with blurring of the normal trabecular pattern. In the second phase, the densities tend to coalesce, become patchy and mottled, and fill the medullary canal. After 4–6 weeks, the medullary canal regains a normal or decreased density, and cortical thickening may persist. A differential diagnosis list should include bone neoplasm and hematogenous osteomyelitis.

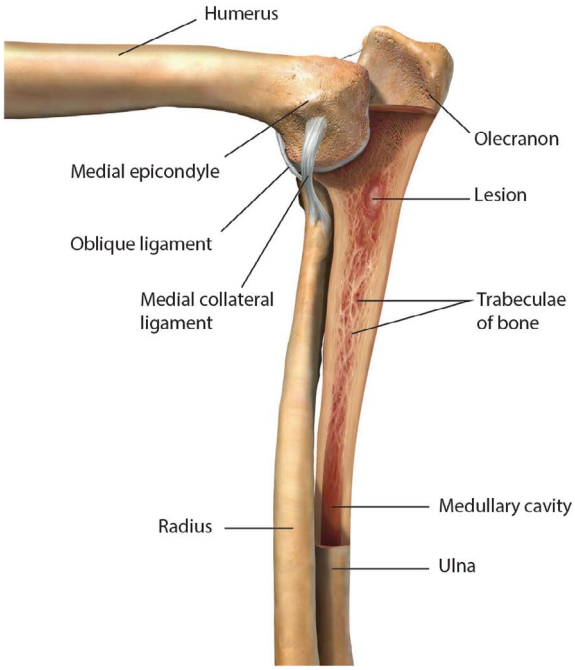

FIGURE 15.43 A schematic drawing of panosteitis showing increased density of the ulnar medullary canal.

FIGURE 15.44 A lateral radiograph of an ulna affected with panosteitis showing areas of increased density within the medullary canal. The disease is most commonly seen in long bones such as the tibia and ulna.

FIGURE 15.45 A craniocaudal radiograph of an ulna affected with panosteitis showing areas of increased density within the medullary canal. The disease is most commonly seen in long bones such as the tibia and ulna.

mandibular lamellar bone is resorbed, and juvenile bone is produced. Scottish Terriers and West Highland White Terriers between 3 and 6 months of age are most commonly affected (Figure 15.46).

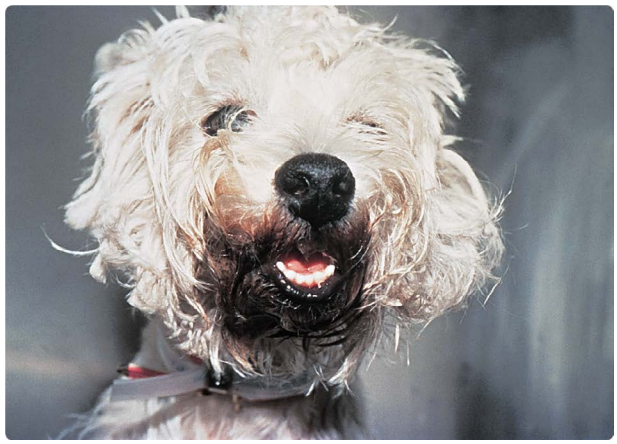

FIGURE 15.46 This young West Highland White Terrier has severe osteoproliferative pathology involving the mandible and temporomandibular joint. (*Courtesy of M. Schaer.*)

Etiology

The condition is inherited in West Highland White Terriers, and there may be a genetic predisposition in Scottish Terriers. However, as the condition occurs sporadically in other breeds, there may be several causes.

Pathophysiology

The disease is characterized by resorption of existing lamellae, vascular fibrous stroma in place of marrow spaces, proliferation of coarse trabecular bone beyond normal periosteal boundaries, and infiltration by inflammatory cells at the periphery of new bone. New primitive bone shows a mosaic pattern of cement lines.

Clinical Presentation

Animals are usually presented because of pain on opening the mouth, although lethargy, anorexia, pyrexia, excess salivation, prehension difficulties, lymphadenopathy, temporal muscle atrophy, weight loss, and dehydration may also be seen. The clinical course may fluctuate, with periods of remission and exacerbation.

Differential Diagnosis

Osteomyelitis, traumatic periostitis, temporomandibular joint ankyloses, neoplasia.

Diagnosis

Skull radiographs demonstrate bilaterally symmetrical periosteal lesions involving the mandible and temporal bones. Osseous proliferation of the mandible or tympanic bulla and periosteal new bone formation may be seen around the temporomandibular junction (Figure 15.47).

Management

Craniomandibular osteopathy is a self-limiting disease for which treatment is directed at supporting the animal (including analgesic therapy) until the condition regresses. In severely affected nonresolving cases, resection of the condyloid process of the mandible or a partial hemimandibulectomy may be considered. NSAID treatment can reduce pain and discomfort. The poorest prognosis is associated with deposition of bone surrounding the temporomandibular joint. Prolonged glucocorticoid therapy can slow disease progression and totally restore normalcy, if started early.

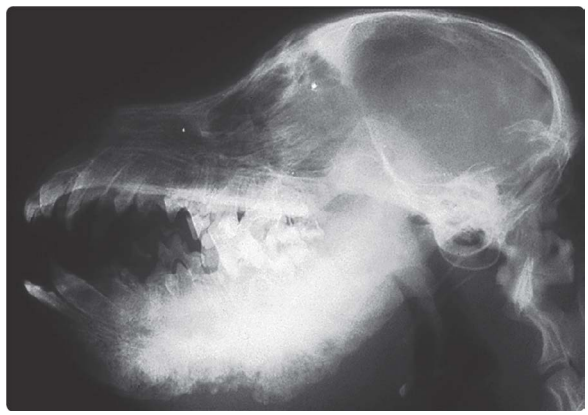

FIGURE 15.47 Lateral radiograph showing pronounced mandibular periosteal proliferation. (*Courtesy of M. Schaer.*)

HYPERTROPHIC OSTEODYSTROPHY

Definition/Overview

Hypertrophic osteodystrophy (HOD; metaphyseal osteopathy) is a metaphyseal bone disease of immature large and giant breeds of dogs. Although all bones are susceptible, the distal radius and ulna are most commonly affected. Metaphyses are widened due to perimetaphyseal swelling and bone deposition.

Etiology

The cause of the disease is unknown. Hypotheses, including the influence of hypovitaminosis C, dietary oversupplementation, and infectious organisms, have not been validated. HOD has been diagnosed in several different dog breeds. Weimaraners appear to have a strong heritable predisposition, and an immune mechanism is likely involved.

Pathophysiology

The pathogenesis is obscure; however, a disturbance of the metaphyseal blood supply leads to a failure or delay in ossification of the hypertrophic zone of the metaphyseal growth plate. The disease is usually bilaterally symmetrical and episodic. Some cases recover within a few days, but others have one or more relapses over several weeks before recovery.

Clinical Presentation

Presenting signs involve some degree of lameness where the metaphyseal region of the long bones may be

FIGURE 15.48 This approximately 2- to 3-month-old Weimaraner puppy suffered from severe debilitating effects of hypertrophic osteodystrophy. (*Courtesy of M. Schaer.*)

swollen, warm, and painful on palpation (Figure 15.48). The disease may be accompanied by depression, inappetence, and variable pyrexia.

Differential Diagnosis

Panosteitis, elbow dysplasia, OCD, polyarthritis, septic metaphysitis, retained cartilage core, canine osteochondrodysplasia.

Diagnosis

Necrosis and resorption of the metaphyseal trabeculae may be seen radiographically as an irregular radiolucent line in the metaphyses adjacent to the growth plates (Figure 15.49). Subperiosteal new bone formation (likely hematoma mineralization) may be mild or extensive in the area of the metaphyseal growth plate.

Management

Treatment is largely supportive with rest, analgesics, anti-inflammatory drugs, and attention to a proper diet. Vitamin C supplementation has no efficacy. Antibiotics may be indicated for treatment of secondary infection, if identified. Animals with mild lesions have a good-to-excellent prognosis, while the severely affected carry a guarded prognosis (death and euthanasia are not uncommon). There is no specific treatment for the disease, although anti-inflammatory analgesia (NSAIDs) can be palliative and physical rehabilitation activities may be beneficial. In one study of Weimaraners, treatment with corticosteroids was superior to treatment with NSAIDs, suggesting that the immune suppressive action of corticosteroids may be preferential for achieving remission.

HYPERADRENOCORTICISM

See also Chapter 12.

Definition/Overview

Hyperadrenocorticism is found in the presence of Cushing's disease or with chronic excessive administration of glucocorticoids.

FIGURE 15.49 This approximately 2- to 3-month-old Weimaraner puppy from Figure 15.48 suffered from severe debilitating effects of hypertrophic osteodystrophy. Note the marked radiographic swelling of the carpal metaphyseal region. Bacterial physitis with sepsis was also present. (*Courtesy of M. Schaer.*)

Etiology

There are several recognized causes of hyperadrenocorticism: A pituitary tumor, which synthesizes and secretes excess adrenocorticotrophic hormone (pituitary-dependent hyperadrenocorticism [PDH]); adrenocortical tumors, which randomly secrete excessive cortisol independently of the pituitary (adrenocortical dependent); and administration of excessive glucocorticoids (e.g., drugs for skin, ear, and eye conditions [iatrogenic]).

Pathophysiology

Osteoporosis of the spine and long bones can be associated with this disease in dogs, as calcium absorption from the gut, urinary excretion of calcium, normal production of bone matrix, and fibroblast as well as osteoblast proliferation and differentiation are affected.

Clinical Presentation

Poodles, Dachshunds, Boston Terriers, Boxers, and Beagles have been reported to be at higher risk than other breeds. In general, endogenous hyperadrenocorticism affects middle-aged to old animals; however, the iatrogenic form can be seen in young dogs. Severity of

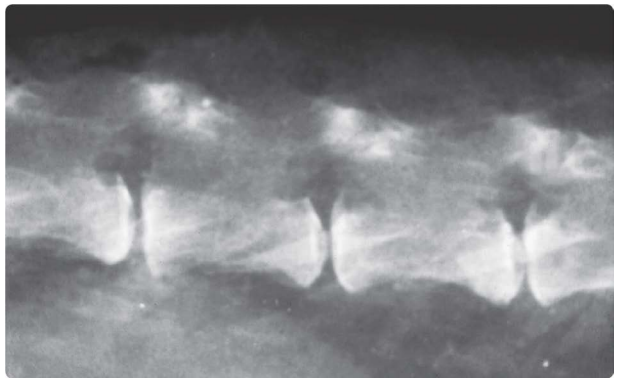

FIGURE 15.50 Lumbar vertebrae showing osteopenia. (*Courtesy of M. Schaer.*)

signs varies depending on the duration and degree of cortisol excess. The most apparent signs are polyuria, polydipsia, polyphagia, and a pendulous abdomen. Lethargy, muscle weakness, muscle atrophy, panting, obesity, hyperpigmentation, calcinosis cutis, and facial nerve palsy can also occur. Cats show similar signs and are commonly poorly controlled diabetics as well.

Differential Diagnosis

Hypothyroidism, acromegaly, renal disease, hepatopathy, diabetes mellitus, ligament rupture.

Diagnosis

Radiography will reveal the extent of bone involvement (Figure 15.50). A urine cortisol-to-creatinine ratio is a very practical screening test. A diagnosis of hyperadrenocorticism is made by dexamethasone suppression testing or ACTH response testing. Abdominal radiography, ultrasonography, CT, and MRI are all useful in differentiating PDH from adrenal tumors.

Management

Surgery is usually not an option for PDH. Medical management for treating both PDH and adrenal tumors in dogs is with o, p'-DDD. Trilostane is now used commonly for treating PDH in dogs and cats; it can also be used to treat functional adrenocortical tumors in cats.

NEOPLASIA

Bone neoplasms may arise from bone tissue elements, or they may invade bone by local extension or distant metastasis. Most primary bone tumors are malignant. While the most frequent clinical signs in dogs and cats with appendicular bone tumors are pain or lameness referable to the primary tumor, signs of axial skeletal neoplasms reflect the tumor location. Radiographic findings such as periosteal new bone formation and bone destruction may support a diagnosis of neoplasia, but a definitive diagnosis is made histologically from a bone biopsy. Primary bone tumors and bone metastases are infrequent in cats.

PRIMARY BONE TUMORS

The most common primary bone tumors among dogs and cats include osteosarcoma, parosteal osteosarcoma in the cat, chondrosarcoma, and fibrosarcoma. Clinical signs and physical exam findings are usually quite similar among these tumor types.

Definition/Overview of Primary Bone Tumors

Osteosarcoma is the most frequently reported (70%–80%) primary bone tumor in cats. Solitary osteolytic metaphyseal long bone lesions in older cats are considered osteosarcoma until proven otherwise; these lesions tend to be less aggressive than canine osteosarcoma.

Osteosarcoma is the most common (85%) bone tumor in the dog. At greatest risk are the Saint Bernard, Great Dane, Golden Retriever, Irish Setter, Dobermann, and German Shepherd Dog.

Parosteal osteosarcoma is the second most common bone tumor in the cat.

Chondrosarcoma is the second most common bone tumor in dogs (Figure 15.51). Lesions can originate in the ribs (most common primary rib tumor), long bones, extraskeletal sites, nasal cavity, vertebrae, facial bones, pelvis, digits, and os penis. The nasal cavity is commonly affected. This tumor is uncommon in cats.

Primary fibrosarcoma of bone originates from the fibrous components of the medulla and is the third most common primary bone neoplasm in dogs. Primary fibrosarcoma of bone is rare in cats. Parosteal or soft tissue

FIGURE 15.51 Chondrosarcoma of the proximal scapula characterized by both destruction and proliferation. (*Courtesy of I.A. Robertson.*)

origin is more common, and axial skeleton sites are more common than appendicular sites. This neoplasm tends to be locally invasive but late to metastasize.

Etiology

The cause of primary bone tumors is generally unknown. The association of osteosarcoma with metaphyseal bone, however, suggests that neoplastic transformation may result from aberrant bone growth or differentiation. Some dogs may be genetically predisposed, as mutation and inactivation of the p53 tumor suppressor gene have been found. Chondrosarcoma lesions can occur in cases of multiple cartilaginous exostosis.

Pathophysiology

No specific pathophysiologic pathways have been identified in primary bone tumors; however, each of them do have some differences in respect to tumor development location and destruction of bone. Osteosarcomas have been reported at locations where metallic implants have been used for fracture fixation, as well as at previous fracture sites or where there is chronic inflammation. In parosteal osteosarcomas, typically, the lesions appear as a mixed proliferative or lytic pattern in the metaphyseal region of the affected bone. The formation of periosteal bone in adjacent tissue leads to the development of a Codman triangle, comprising proliferation of the periosteum and mild destruction of cortical tissue.

Chondrosarcomas develop anaplastic cartilage cells between and within the tumors that show various stages of differentiation and maturation. Metastasis may occur in any tissue but most commonly affects lung tissue.

Fibrosarcomas are fibroblastic tumors that produce bundles of collagenous fibers but no neoplastic bone, osteoid, or cartilage either in the primary tumor or its metastases. It is often difficult to determine if the tumor is primarily a bone neoplasm or a soft tissue neoplasm invading bone. Fibrosarcomas produce bone lysis with minimal reactive bone response.

Clinical Presentation

Typical presentation for primary bone tumors is lameness or pain over the affected bone. Often a firm swelling is noted in locations with sufficient muscular tissue. The ability to detect the tumor on palpation may be challenging, only becoming apparent after chronic muscle wasting or after pathologic fracture has occurred.

Most osteosarcomas originate in the metaphyses of long bones, with a higher frequency in the forelimbs. Tumors are most prevalent away from the elbow and around the stifle. Animals usually present with swelling and lameness of the affected limb. Swelling may or may not involve soft tissue. The tumor is seen arising on the outer surface of the cortex of the humerus, femur, frontal bones, and ramus of the mandible. Although osteosarcomas generally do not cross articular cartilage, adjacent bones can be affected but generally through periarticular soft tissue or if the tumor is a telangiectatic osteosarcoma. Owing to the sudden onset of swelling and pain, a nonneoplastic orthopedic problem can be mistakenly assumed.

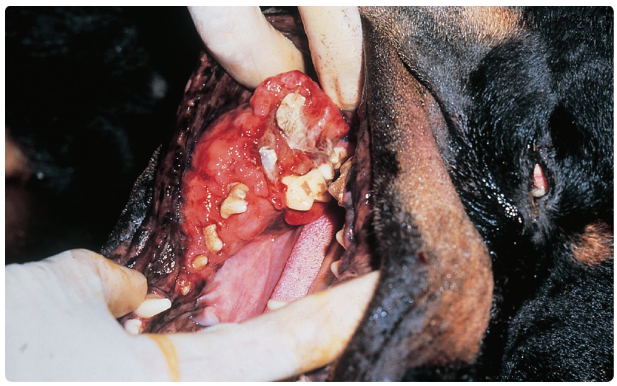

FIGURE 15.52 Mandibular fibrosarcoma in an 8-year-old Rottweiler.

Parosteal osteosarcoma the lesions are slow growing, but affected sites can elicit pain.

Chondrosarcoma occurs commonly in ribs, nasal bones, and the pelvis. Pain on palpation of the lesion is common, and swelling may occur at the tumor site. Intrathoracic extension of tumors may give rise to pleural effusion.

Animals with oral fibrosarcoma lesions (Figure 15.52) usually present with fleshy, pink, firm, sessile masses in the palate or gingiva, which deeply infiltrate soft tissue and bone. Long bones may have swelling, typically at a metaphyseal site, and the site is often painful to palpation.

Differential Diagnosis

Metastatic lesion, other primary bone tumor, osteomyelitis. Osteosarcoma should be ruled out in any large-breed dog presenting with sudden lameness.

Diagnosis

For any suspected bone tumor, the definitive diagnosis is made by a bone biopsy. In some cases, with a primary lytic appearance, the diagnosis may be made by fine-needle aspirate and cytology. For osteosarcoma, a presumptive diagnosis can be made by radiography, which may reveal a Codman's triangle and the proliferative or lytic pattern of the metaphyseal bone region (Figure 15.53). Pain is often elicited with deep palpation over the site. If treatment is considered, the extent of disease metastasis should be determined by a radiographic survey of the thorax or skeleton. A small percentage (5%–10%) of affected animals have detectable lung lesions.

Radiographically, parosteal tumors appear less aggressive than periosteal tumors. The lesions are moderately well circumscribed, and lysis of the cortex is usually mild. Biopsy specimens must be evaluated carefully for areas of tumor cells, as lesions may be misdiagnosed as reactive bone, chondroma, or osteoma.

FIGURE 15.53 Osteosarcomas may produce a localized soft tissue swelling containing mineralized foci. In this case, the carpus was swollen. There is extensive bony destruction, with the cortex eroded at several sites.

For suspected fibrosarcomas, biopsy specimens should be carefully examined, as it is difficult to distinguish fibroblastic osteosarcoma from fibrosarcoma.

Management

Wide surgical excision or amputation is the treatment of choice for most primary bone tumors. In the case of parosteal osteosarcomas, amputation may be curative due to their slow growth and do not tend to metastasize early. Most primary bone tumors grow rapidly, and treatment is often unrewarding. Cisplatin is the chemotherapy of choice for treatment of osteosarcoma in dogs (toxic to cats). However, microscopic metastasis is common by the time of diagnosis. Survival is <6 months with limb amputation and <18 months if there is additional chemotherapy. Osteosarcoma in cats is less aggressive, and amputation alone yields a median survival of >4 years. Since osteosarcoma is often associated with considerable pain, management with NSAIDs may be appropriate for dogs. Furthermore, there is some speculation that COX-2-specific NSAIDs manifest antitumor mechanisms. Adjunctive analgesics such as opioids, N-methyl-d-aspartate antagonists, and ion-channel regulators may be necessary to control the pain.

For chondrosarcomas, the prognosis is guarded to good if complete excision of the tumor is accomplished. Chemotherapy with cisplatin is appropriate for nonresectable tumors; however, response of chondrosarcomas to radiation and chemotherapy is poor. Regarding fibrosarcomas, the best treatment is wide surgical excision with an overall guarded prognosis. There is no suggestion that chemotherapy may be advantageous.

VASCULAR TUMORS OF BONE

Definition/Overview

Primary vascular tumors of bone are infrequently encountered, but they are virtually all malignant. Any bone may be affected, but the axial skeleton is more frequently affected than the appendicular skeleton. Hemangiosarcoma of the bone is more common in the dog than in the cat, and the German Shepherd Dog is most frequently at risk.

Etiology

Hemangiosarcoma is a malignancy of vascular endothelial cells or their precursors.

Pathophysiology

These tumors rapidly metastasize via hematogenous routes to the liver and lungs. They can rupture, leading to acute hemorrhage and sudden death.

Clinical Presentation

History and presenting signs are similar to those for osteosarcoma. Osteolysis is the dominant radiographic feature.

Differential Diagnosis

Telangiectatic osteosarcoma (Figures 15.54–15.56).

FIGURE 15.54 This dog was lame on her right hindlimb for several weeks before she had a sudden onset of hemorrhagic swelling in the thigh muscle region. Radiographs (not shown) showed considerable osteolysis of the femur. The primary differential diagnosis included a hemangiosarcoma. (*Courtesy of M. Schaer.*)

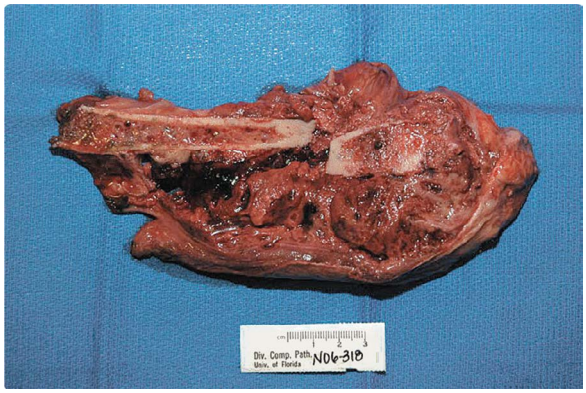

FIGURE 15.55 Gross necropsy of the same dog in **Figure 15.54** showed the lesion to be a telangiectatic osteosarcoma. (*Courtesy of M. Schaer.*)

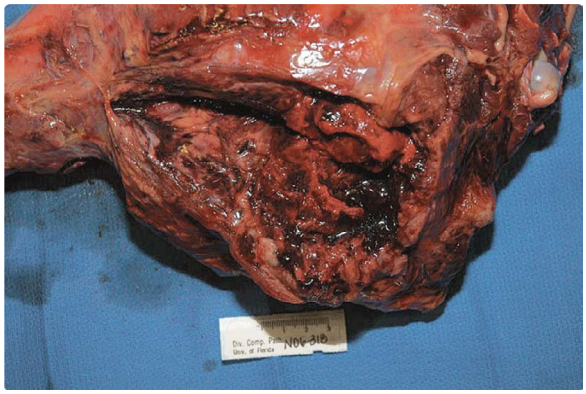

FIGURE 15.56 There was considerable hemorrhage into the thigh muscles. (*Courtesy of M. Schaer.*)

FIGURE 15.57 Pelvic hemangiosarcoma. This lesion is characterized by soft tissue swelling and periosteal proliferation.

Diagnosis

Radiographically, hemangiosarcomas show massive destruction, often involving one-half or more of the entire bone shaft. Destruction tends to remain confined within the medullary cavity with both proximal and distal expansion. Marked periosteal new bone formation is not characteristic but may be seen (**Figure 15.57**), and pathologic fractures may occur. Hemangiosarcomas often have vascular spaces, and biopsy for diagnosis may be nondiagnostic. Therefore, it is prudent to biopsy at the periphery of the tumor to obtain distinct cores of tissue.

Management

Affected dogs must be thoroughly staged with thoracic and abdominal radiography, bone scintigraphy, or bone survey radiography. Prognosis is poor irrespective of surgical excision and adjunct chemotherapy.

SYNOVIAL CELL SARCOMA

Definition/Overview

Synovial cell sarcoma is the most frequent tumor of soft tissue that involves adjacent bones.

Etiology

This tumor may arise from precursor mesenchymal cells outside the synovial membrane of articular structures.

Pathophysiology

The biological behavior of this tumor is variable. Synovial cell sarcoma is a disease of middle-aged to older dogs and is rarely reported in cats. Joints most commonly involved are the stifle, elbow, carpus, tibiotarsal, and phalangeal joints. Nearly half of affected patients ultimately develop metastasis involving the lungs or regional lymph nodes.

Clinical Presentation

Examination of the affected joint may reveal swelling, pain, and a decreased range of motion. Joint swelling typically involves both sides of the joint.

Differential Diagnosis

Primary bone tumor, osteoarthritis, osteomyelitis, villonodular synovitis.

FIGURE 15.58 Synovial cell sarcoma with soft tissue swelling of the elbow and erosion of the olecranon (proximal ulna) (arrow). Synovial cell sarcoma is most often seen in the elbow and stifle. The tumor usually crosses the joint space. The lesion is predominantly osteolytic, periosteal proliferation is minimal, and soft tissue mineralization is rare. (*Courtesy of A.M. Walker.*)

Diagnosis

Radiographic evidence of a destructive lesion involving bones on both sides of a joint suggests synovial sarcoma, and both the stifle and the elbow are sites of predilection (Figures 15.58–15.61). A biopsy of both the soft tissue lesion and associated bone is diagnostic. Regional lymph node cytology may also be diagnostic.

FIGURE 15.59 Cranial-caudal radiographic lesions diagnosed as synovial cell sarcoma of the tarsometatarsal joint. (*Courtesy of B. Poteet.*)

FIGURE 15.60 Lateral radiographic lesions diagnosed as synovial cell sarcoma of the tarsometatarsal joint. (*Courtesy of B. Poteet.*)

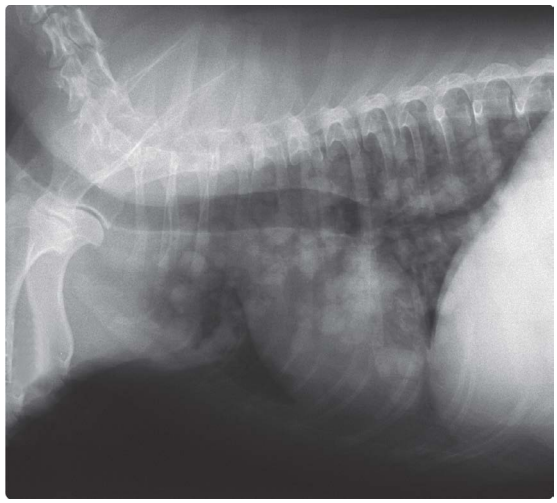

FIGURE 15.61 A lateral thoracic radiograph of the same dog from Figures 15.59 and 15.60 showing metastatic lesions in the thorax. (*Courtesy of B. Poteet.*)

Management

The prognosis after surgery is variable, with recurrence being not uncommon. Survival after excisional biopsy and combination chemotherapy has been reported; however, metastasis occurs in up to 50% of cases.

SQUAMOUS CELL CARCINOMA

Definition/Overview

Squamous cell carcinoma (SCC) is a common tumor involving the skin in both the dog and cat, and it is a common feline neoplasm involving bone. SCCs are usually found in nonpigmented or lightly pigmented skin.

Etiology

Primary lesions occur on the skin and may arise de novo or from overexposure to sunlight. Cats are predisposed to this type of cancer because of a lack of skin pigmentation and a desire to seek sunlight. The lesions are highly erosive and deeply infiltrative and, although late to metastasize, may spread to bone. SCC in cats occurs frequently in the oral cavity and less frequently involves the digits.

Pathophysiology

Unknown; however, SCC can metastasize almost anywhere.

Clinical Presentation

The most common cutaneous locations for SCC in the dog are the toes, scrotum, nose, limbs, and anus, while the nose, eyelids, lips, and pinnae are common locations in the cat. Lesions vary from a red firm plaque to a cauliflower-like ulceration, and they may appear as sequelae to crusts, ulcers, or masses that may have been present for months and been unresponsive to conservative treatment. SCC located deep to teeth can be a reason for premature tooth loosening.

Differential Diagnosis

Draining abscessation, nail bed infection/osteomyelitis, eosinophilic granuloma, mast cell tumor, cutaneous lymphosarcoma.

Diagnosis

Biopsy or cytology.

Management

Superficial tumors are treated by surgery, cryosurgery, or irradiation. Digits with tumor involvement should be amputated. Adjunct chemotherapy or radiation therapy has provided remission (generally only for a short duration) where surgical excision is incomplete, the mass is nonresectable, or the patient has metastasis. When lesions are advanced and bone involvement is present, the prognosis is guarded.

NUTRITIONAL DISORDERS

RICKETS/OSTEOMALACIA

Definition/Overview

Inadequate supplies of cholecalciferol or vitamin D result in rickets or osteomalacia (adult equivalent), diseases affecting the hypertrophic zone of metaphyseal growth plates.

Etiology

Likely causes include dietary deficiency (hypovitaminosis D), impaired absorption or an inadequate concentration of minerals from the diet, and an inborn error in the metabolism of vitamin D. Dogs and cats are mainly dependent on vitamin D from their diet due to an inability to synthesize cholecalciferol in skin exposed to ultraviolet light.

Pathophysiology

There is a failure of mineralization of cartilage and osteoid. The costochondral junctions and metaphyses may be enlarged so that the joints appear swollen.

Clinical Presentation

Immature animals with rickets or mature animals with osteomalacia may be presented with lameness, difficulty rising, a stiff gait, limb bowing, pathologic fractures, or sudden paralysis.

Differential Diagnosis

Hyperparathyroidism.

Diagnosis

Radiographic signs may be similar to hyperparathyroidism and commonly include radiolucent cortical bone due to poor mineralization, thin cortices, bowed diaphyses, and a loss of lamina dura dentes.

Management

Treatment consists of proper dietary supplementation with adequate but not excessive amounts of calcium, phosphorus, and vitamin D and repair of any pathologic fractures.

HYPERVITAMINOSIS A

Definition/Overview

Hypervitaminosis A is a disease of cats that consume large amounts of raw liver.

Etiology

Excessive and prolonged intake of vitamin A either from supplements or liver-rich diets.

Pathophysiology

The condition is characterized by cervical and thoracic bridging exostoses and limb joint periarticular ankylosis, especially in the elbow.

Clinical Presentation

Animals may present with irritability, poor grooming, lethargy, depression, gingivitis, and lameness. In the

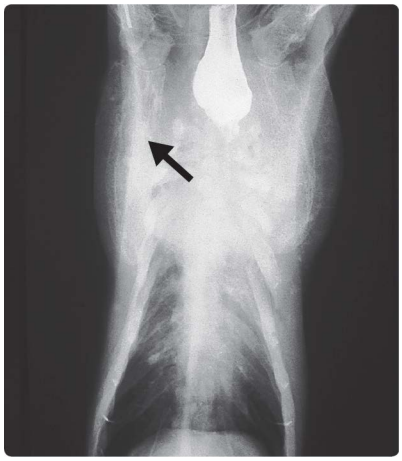

FIGURE 15.62 Thoracic rhabdomyosarcoma and long-standing hypervitaminosis A. The tumor caused esophageal obstruction, as shown on this barium esophagram. The hypervitaminosis A causes the bony proliferation, as shown by the arrow. (*Courtesy of M. Schaer.*)

early stages, the lesions are painful, and they may ankylose, leading to abnormal posture and neck stiffness.

Differential Diagnosis

Nutritional secondary hyperparathyroidism, hypovitaminosis D.

Diagnosis

Radiographically, there is evidence of exostoses and enthesophytes in the cranial and thoracic vertebrae, particularly in older affected animals (Figures 15.62–15.64). There may also be enthesophytes around limb joints (e.g., the elbow or shoulder).

Management

Treatment is aimed at avoidance of excess vitamin A. In elderly cats, despite bone remodeling, there may be

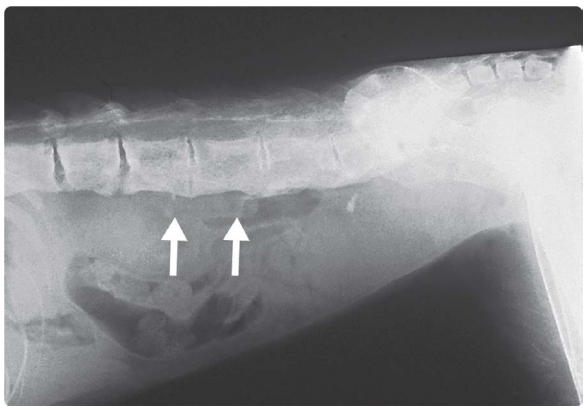

FIGURE 15.63 Radiograph from an aged cat with thoracic rhabdomyosarcoma and long-standing hypervitaminosis A. Note the characteristic hypervitaminosis A-induced bone thickening involving the lumbar vertebrae and pelvis. (*Courtesy of M. Schaer.*)

FIGURE 15.64 Postmortem specimen from an aged cat with thoracic rhabdomyosarcoma and long-standing hypervitaminosis A. Note the characteristic bone thickening involving the scapulae (arrows). (*Courtesy of M. Schaer.*)

rigidity from ankylosis. In young animals, bone growth may be permanently affected.

INFECTION/INFLAMMATION

SUPPURATIVE OSTEOMYELITIS

Definition/Overview

Suppurative osteomyelitis is a bacterial (rarely fungal) contamination of bone leading to the formation of purulent discharge.

Etiology

About half of infections are caused by *Staphylococcus aureus*, whereas polymicrobial infections can be caused by *Streptococcus* spp. and Gram-negative bacteria such as *Pseudomonas* spp., *Klebsiella* spp., *Escherichia coli*, and *Proteus* spp. Sometimes, anaerobic bacteria are involved. Bone is relatively resistant to infection unless there is a concurrent soft tissue injury, bone necrosis, sequestration, fracture instability, implanted foreign material, altered host defenses, or some combination.

Pathophysiology

Associated soft tissue changes can be observed as early as 24 hours. These changes include swelling and loss of fascial planes, and a fistulous tract may eventually develop as a consequence. Bone changes, bony lysis, areas of periosteal new bone formation, or presence of a sequestrum do not become apparent until 10–14 days after introduction of the infection.

Clinical Presentation

In acute conditions, animals may present with signs of systemic illness, including inappetence, dullness, weight loss, and pyrexia. Affected periosteum and surrounding

FIGURE 15.65 A postoperative lateral view of osteomyelitis involving the ulna.

muscle may appear swollen, painful, and feel hot. In chronic conditions, animals may present with fibrosis, muscle atrophy, lymphadenopathy, and contracture.

Differential Diagnosis

Neoplasia, bone cysts, HOD, medullary bone infarction.

Diagnosis

Diagnosis is usually determined from the history, physical examination, microbiology, and radiology. In acute cases, radiography reveals swelling of soft tissue (Figures 15.65 and 15.66) but no osseous changes, whereas in chronic cases, there is evidence of formation of periosteal new bone, which appears as radially oriented, spiculated, and extensive growth. Bone resorption leads to lysis of the medulla, rounding of the ends of fractured bones, and thinning of the cortex. Osteomyelitis can virtually be diagnosed by the presence of sequestra. Bacterial culture should confirm the diagnosis and dictate antibacterial selection.

FIGURE 15.66 The same dog as Figure 15.65 on a cranial-caudal projection.

Management

Drugs that readily cross the capillary membrane of bone and are widely distributed in interstitial fluid include beta-lactams (cephalosporins, penicillins), aminoglycosides, and quinolones. Acute osteomyelitis is usually cured after 4–6 weeks of antibacterial treatment, whereas such treatment is pointless in chronic cases without débridement and surgical removal of sequestra and/or associated implants. Antibiotic-impregnated, absorbable or nonabsorbable beads, or delayed release gels have been used in both acute and chronic cases. Recurrence of infection may require repeated sequestrectomy, débridement, microbiologic culturing, drainage, fracture stabilization, or bone grafting.

INFLAMMATORY ARTHRITIDES

Definition/Overview

Suppurative arthritis is an inflammatory disease of the joints characterized by cellular infiltrates and inflammatory changes in the synovial membrane and synovial fluid. Bacterial infective arthritis is the most common manifestation of septic arthritis; however, fungal agents have also been implicated. Clinical manifestations are due to both persistent inflammatory reactions resulting from deposition and phagocytosis of immune complexes and release of damaging lysosomal enzymes within the joint. The cause and source of immune complexes are unknown.

Noninfective inflammatory arthropathies, including the immune-mediated arthritides, are subdivided as erosive and nonerosive. Erosive arthritides include canine rheumatoid arthritis (RA) and erosive polyarthritis of Greyhounds. Canine rheumatoid arthritis (RA) is a progressive inflammatory polyarthropathy characterized by erosion and destructive changes in the joint that involves both cellular and immune interactions. Characteristic signs are generalized stiffness and shifting limb lameness accompanying systemic signs such as fever, lethargy, and inappetence. The most severely affected joints are the carpal, tarsal, and interphalangeal joints, although the stifle, elbow, and hip are also commonly affected.

Erosive polyarthritis is a specific disease entity in the young Greyhound (Figures 15.67 and 15.68) and mature cats. Chronic progressive polyarthritis of cats is etiologically linked to feline syncytium-forming virus, a common retrovirus infection, and all cats with this disease are serologically and virologically positive for this infection (high incidence of false-positive tests). Cats can also acquire a calicivirus-associated arthritis from natural infection and by vaccination.

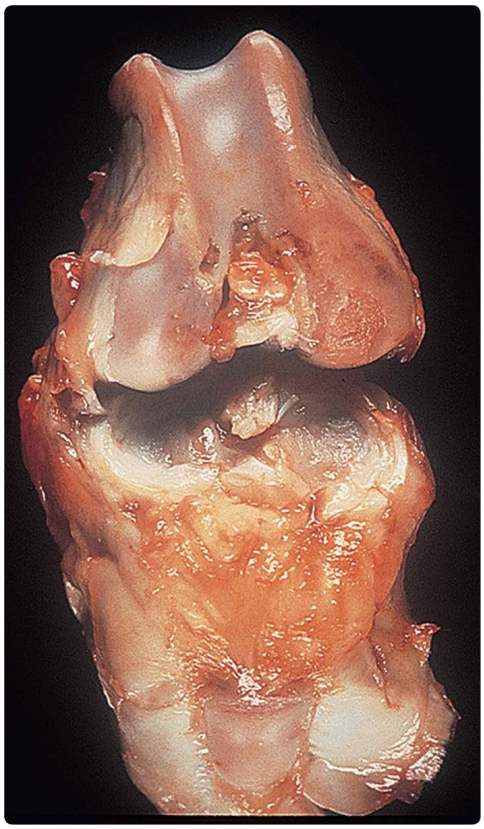

FIGURE 15.67 Gross specimen from a Greyhound with erosive polyarthritis. The cartilage of the trochlear groove has a rough surface, and the red and blue caste to the cartilage identifies the subchondral bone beneath thin, translucent cartilage. The synovium is hypertrophic. (*Courtesy of the late M.S. Bloomberg.*)

Nonerosive arthritides can be further subdivided as follows:

- Systemic lupus erythematosus
- Plasmacytic–lymphocytic synovitis
- Polyarthritis / polymyositis syndrome
- Idiopathic polyarthritis

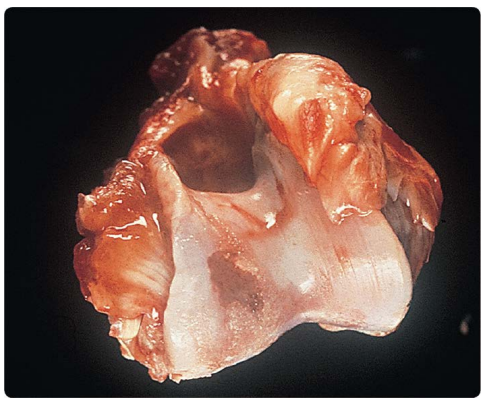

FIGURE 15.68 Gross specimen from a Greyhound with erosive polyarthritis. The distal humerus has a granular, rough cartilaginous surface with linear score marks, cartilage cracks, and a deep erosion. (*Courtesy of the late M.S. Bloomberg.*)

- Drug-induced arthritis
- Hepatopathic arthritis
- Enteropathic arthritis
- Arthritis associated with malignant neoplasia

SLE is a multisystem autoimmune disease characterized by the formation of autoantibodies against a wide array of self-antigens and circulating immune complexes. Although polyarthritis is a frequent feature of SLE in both dogs and cats, it is more likely to be a predominant clinical disease in dogs, whereas cats tend to manifest other systemic signs.

Etiology

Septic Arthritis

Joints are common destinations for blood-borne microbial pathogens because the synovium and the subchondral bone are highly perfused. Additionally, the synovium is a highly phagocytic organ and is, therefore, a common site for trapping blood-borne microbes and immune complexes. In contrast to dogs, infectious arthritis is less common in cats due to infrequent urinary tract and skin infections. Organisms commonly involved in joint infections in dogs include *Staphylococcus* spp., *Streptococcus* spp., *Erysipelothrix* spp., *Corynebacterium* spp., coliforms, *Pasteurella* spp., *Salmonella* spp., and, occasionally, *B. canis*. In cats, the usual offending organisms are *Pasteurella multocida* and hemolytic strains of *E. coli*.

Erosive Arthritis

In RA, immune complexes in the synovium and synovial fluid probably initiate the inflammatory reaction.

Nonerosive Arthritis

Etiologically diverse, nonerosive, noninfectious arthritis occurs in both dogs and cats. Immune complexes in the synovial membrane (resulting in a type 3 immune reaction) are believed to result in joint disease. In idiopathic nondeforming arthritis, the origin and nature of the antigens in the complexes are unknown. The antigens in SLE are of nuclear origin. The antigens in enteropathic arthritis probably originate from the inflamed bowel, and antigens in arthritis secondary to chronic infectious disease or neoplasia originate from the offending microorganisms or from the tumor cells. The cause of SLE is unknown.

Polyarthritis may be a manifestation of drug-induced vasculitis. Fever and stiffness may be seen from the time of first administration or as late as 3 weeks after drug initiation. Skin rash may or may not occur concurrently. Intolerance to trimethoprim–sulfa, penicillins, erythromycin, lincomycin, and cephalosporins is most common. Drug withdrawal yields rapid resolution of signs.

Pathophysiology

Septic Arthritis

Damaged joints, such as joints with chronic degenerative joint disease, are more likely to accommodate

blood-borne pathogens. Larger dogs, older dogs, and proximal rather than distal joints are more commonly affected by degenerative joint disease. Prostatitis, cystitis, pyelonephritis, pyodermas, and oral infections can all be accompanied by septicemia, leading to septic arthritis. Complications include osteomyelitis, fibrous or bony ankylosis, and secondary joint disease.

Erosive Arthritis

Canine RA is more severe in the carpal and tarsal joints. In the early stages, the disease is often accompanied by fever, malaise, anorexia, and lymphadenopathy, while renal amyloidosis can be a complication of long-standing disease. In the central region of the joint, pannus arising from granulation tissue in the underlying marrow cavity causes cartilage destruction. Ankylosis in advanced lesions is common in the intercarpal and intertarsal joints.

Nonerosive Arthritis

This joint disease tends to be cyclic, affecting one or more joints. Biopsy of the synovial membranes shows a nonvillous hyperplasia, sparse mononuclear cell infiltrates, moderate neutrophil infiltrate, and fibrin exudation.

In SLE, the production of autoantibodies to nonorgan-specific nuclear and cytoplasmic antigens and to cell- and organ-specific antigens results from an immunoregulatory defect. Resultant immune complexes are deposited in the glomerular basement membrane, synovial membrane, skin, blood vessels, and other sites. Complement is activated by the immune complexes, leading to tissue injury and inflammation. Furthermore, a direct cytotoxic effect of autoantibodies against membrane-bound antigens contributes to tissue damage.

Clinical Presentation

Septic Arthritis

Animals with septic arthritis are usually painful upon palpation and have significant lameness often severe enough to be nonweight-bearing. Redness and swelling may be observed in the overlying skin and soft tissue. Fever is common. Pointing abscessation and draining tracts may also be present (Figure 15.69).

Erosive Arthritis

Canine RA is a disease of mainly small dogs, manifesting initially as a shifting lameness with soft tissue swelling around involved joints. The disease is often accompanied by fever, malaise, anorexia, and lymphadenopathy in the early stages, while renal amyloidosis can complicate long-standing disease. Excessive amounts of synovial fluid may be present, which is generally discolored and turbid and yields a typically poor and friable mucin clot.

Nonerosive Arthritis

The clinical and radiographic findings of polyarthritis demonstrate the inflammatory nature of the disease and simulate those of RA (narrowed joint space, periarticular osteophytes, subchondral sclerosis, and capsular swelling). The history is one of cyclic fever, including anorexia, lameness, stiffness, and malaise. Muscle atrophy may also be noted.

FIGURE 15.69 This patient had been treated with high doses of prednisone for an earlier diagnosis of pemphigus vulgaris. The immunosuppressive doses of this drug very likely predisposed this patient to a monoarticular *Salmonella* spp. joint infection that responded well to aspiration and intensive antimicrobial treatment. (*Courtesy of M. Schaer.*)

Differential Diagnosis

Septic Arthritis

Lyme disease (*Borrelia burgdorferi*), mycoplasmosis (often associated with immunocompromise), rickettsiosis (polyarthritis is a prominent feature), ehrlichiosis (nonerosive polyarthritis, always thrombocytopenia, triad of thrombocytopenia, fever, and lymphadenopathy).

Erosive Arthritis

Neoplasia, immunologic cause.

Nonerosive Arthritis

Neoplasia, infectious disease, trauma.

Diagnosis

Septic Arthritis

Synovial fluid from septic joints is often bloody, and the presence of toxic, ruptured, and degranulated neutrophils should suggest a bacterial infection. Although slight periosteal proliferation of bone adjacent to the joint space may be seen in late-stage arthritis, early stages are characterized by thickened synovial membrane, distended joint capsule with displacement of adjacent fascial planes, and widening of the joint space from joint effusion. Aspiration of the joint is necessary for a diagnosis by cytology and culture. Positive bacterial culture is low, with only 30% cases resulting in positive culture, even in cases that have bacteria noted

FIGURE 15.70 A cranial-caudal radiographic projection of the carpus of a 7-year-old male Whippet showing erosive polyarthritis. Radiographic investigations of patients with polyarthritis often reveal slightly large joints with soft tissue swelling, periarticular osteophytes, osteolysis of the distal portion of the radius and radial carpal bone, and loss of joint space. (*Courtesy of A.M. Walker.*)

on cytologic examination. Joint cytology supportive of a septic cause should be treated as such despite negative bacteria culture results unless proven otherwise by other diagnostic testing.

Erosive Arthritis

No single test can diagnose canine RA, including the presence of rheumatoid factors in the blood. A prominent radiographic lesion is the progressive destruction of subchondral bone in the more central areas and at the area of synovium attachment (Figures 15.70 and 15.71). A characteristic finding in canine RA is the presence in synovial fluid of mononuclear cells containing IgG.

FIGURE 15.71 The same dog as Figure 15.70 on lateral projection. (*Courtesy of A.M. Walker.*)

Nonerosive Arthritis

Diagnosis is complicated by the cyclic nature of the disease; therefore, consideration must be made of a clinical history with antibiotic-nonresponsive cyclic fever, malaise, anorexia, and lameness. Joint fluid with a neutrophilia of 5,000–100,000 cells/μL yet sterile for bacteria, viruses, *Mycoplasma*, and *Chlamydia* is diagnostic. Diagnosis of SLE is based on a positive ANA or lupus erythematosus test, or both, and two major signs of polyarthritis, proteinuria, dermatitis, hemolytic anemia, leukopenia, thrombocytopenia, or polymyositis.

Management

Septic Arthritis

Treatment of bacterial arthritis is dictated by identification of the causative organism and determination of antibiotic sensitivities. Concurrent cultures of joint fluid, serum, and urine may optimize isolation of the pathogen(s). In the absence of positive bacteria culture, empiric antibiotic therapy is chosen and response to therapy gauged. Generally, continued administration of appropriate antibiotics for 2 weeks or more after the resolution of clinical signs is curative. Drainage of the suppurative exudate helps prevent lysosomal-caused joint damage. Most cases of bacterial arthritis are monoarticular.

Erosive Arthritis

Treatment of RA with corticosteroids, anti-inflammatories, and gold salts has been used, but the effect is merely palliative. If the condition is identified in the early stages, it can be arrested with combination immunosuppressive drug therapy, whereas in advanced conditions, adjunctive joint arthrodesis may be necessary.

Nonerosive Arthritis

Glucocorticoids alone or in combination with immunosuppressive drugs provide remission; however, recurrence of illness is common when therapy is discontinued. Treatment of SLE is directed at controlling the abnormal immune response and reducing the inflammation. Corticosteroids are the foundation of treatment with adjunctive cytotoxic immunosuppressive drugs for additional improvement or when the patient is steroid intolerant.

The most commonly encountered immune disorders affecting the skeletal system are SLE and immune-mediated polyarthropathy. When there is doubt as to whether an arthritis is due to a tick-borne or immune etiology, it is rational to first treat with tetracycline or doxycycline for at least 5 days before initiating treatment with immunosuppressive therapy. A favorable response is expected in 2–4 days if the arthritis is due to spirochetes or rickettsiae.

IATROGENIC DISORDERS

SYNOSTOSIS

Definition/Overview

Synostosis of the radius and ulna is not a developmental disease but rather a sequela following fracture of the mid to proximal radius and ulna. This condition can be of clinical significance in growing animals.

Etiology

A restriction in the relative growth of the proximal ulna is usually associated with a callus spanning the radius and the ulna. This can occur following inadequate or delayed stabilization of a fracture; however, it can also occur despite satisfactory stabilization of a diaphyseal radius/ulna fracture, especially in young dogs with prolific bone healing potential.

Pathophysiology

Synostosis can be associated with a bridging callus following inadequate reduction of radial or ulnar fractures. The condition may also be caused by transfixation of both bones with pins or screws during internal fixation before skeletal maturity. Where considerable growth follows transfixation, the normal growth of the proximal radius is not matched by the proximal ulna, resulting in the radial head continuing the lengthen resulting in elbow incongruity with proximal displacement of the humeral condyles and trochlear notch deformation.

Clinical Presentation

Synostosis presents as an antebrachial deformity that may also include luxation or subluxation of the elbow joint.

Differential Diagnosis

Traumatic premature physeal closure.

Diagnosis

Radiographic finding is of bone bridging two synchronously growing bones, such as the radius and ulna in a growing animal (Figure 15.72).

Management

Treatment of synostosis is based on the degree of malformation and the potential for further bone growth. Surgery consists of removal of the growth constraint and realignment of the elbow joint if appropriate. Bridging callus can be resected, and the defect filled with autogenous fat graft to prevent reformation.

FIGURE 15.72 Synostosis of the radius and ulna in a young German Shepherd Dog. The synostosis (within the diaphysis) resulted in elbow incongruity and a UAP due to disproportionate growth of the proximal portion of the radius ("long radius") relative to the ulna. (*Courtesy of the late M.S. Bloomberg.*)

IDIOPATHIC DISORDERS

LEGG–CALVÉ–PERTHES DISEASE

Definition/Overview

Legg–Calvé–Perthes disease (aseptic necrosis of the femoral head) is a disease of small, immature dogs seen most commonly in Cairn Terriers, West Highland White Terriers, Manchester Terriers, Miniature Pinschers, and Poodles. Spontaneous degeneration of the femoral head and neck (Figure 15.73) is followed by collapse of the coxofemoral joint and osteoarthritis.

Etiology

The cause of Perthes disease is unknown, although in the Manchester Terrier, a multifactorial inheritance pattern with a high degree of heritability has been identified.

Pathophysiology

A major part of the blood supply to the capital epiphysis of the femur becomes compromised, and the ischemic portion becomes necrotic. Necrosis of subchondral bone leads to collapse and deformation of the femoral head under normal weight bearing.

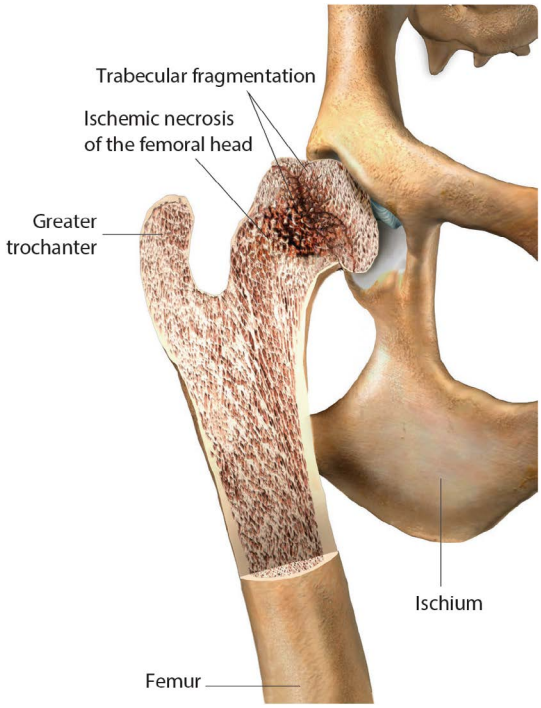

FIGURE 15.73 Illustration of Legg–Calvé–Perthes disease depicting collapse of the femoral head and neck areas.

Clinical Presentation

Perthes disease is usually unilateral and associated with thigh muscle atrophy and pain in the hip.

Differential Diagnosis

Luxating patella, coxofemoral luxation, capital physeal fracture.

Diagnosis

Diagnosis is confirmed by radiographic findings that include radiolucent areas of the proximal femoral epiphysis (Figure 15.74), epiphyseal deformity, thickening of the femoral neck, and increased width of the hip joint space.

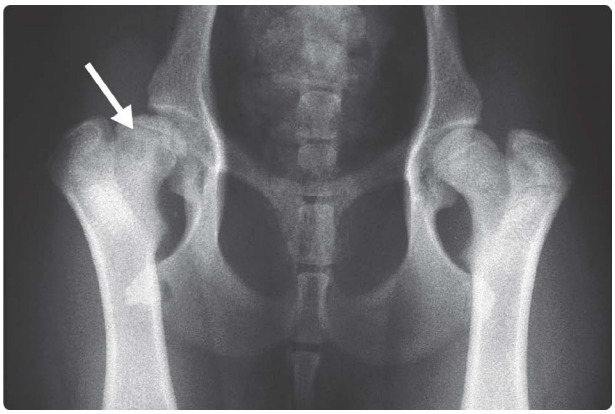

FIGURE 15.74 Unilateral Perthes disease in a 6-month-old female Fox Terrier presented for right hindlimb lameness. This radiograph shows lysis of the femoral head (arrow).

Management

Pathology is usually advanced by the time dogs are presented with clinical signs. The surgical procedure of femoral head and neck ostectomy is recommended as a salvage procedure. Micro total hip prosthesis may be available for clients interested in this option. Total hip arthroplasty is also considered a salvage procedure.

BONE CYSTS

Definition/Overview

Simple bone cysts are benign bone lesions occurring only in large breed dogs. The distal radius and/or ulna is affected most often.

Etiology

The etiology is unknown but may involve intramedullary metaphyseal hemorrhage or local disturbance of bone growth.

Pathophysiology

Lesions occur in metaphyses and adjacent diaphyses of long bones. They are lined by thin membranes and contain serosanguineous fluid.

Clinical Presentation

Affected dogs either have no clinical signs referable to the lesion or have an associated lameness. Pain, swelling, and joint stiffness may be evident in the area of the bone cyst, and the cyst may predispose to a pathologic fracture.

Differential Diagnosis

Atypical bone neoplasia, fibrous dysplasia of bone, aneurysmal bone cyst.

Diagnosis

Radiographically, bone cysts appear as radiolucent defects with cortical thinning (Figures 15.75 and 15.76). Periosteal reaction is absent, and the lesion may consist of several chambers. Fine needle aspiration biopsy and cytologic examination may prove diagnostic.

Management

Drainage, curettage, autogenous grafting, and drilling with multiple holes have all been used to treat bone cysts. Left untreated, bone cysts have the potential for inciting a pathologic fracture.

FIGURE 15.75 A lateral radiograph showing an aneurysmal bone cyst in the distal tibia of a mature male Sheltie. This is a rare neoplasm and has produced bony lysis with minimal cortical or periosteal reaction. The bone has expanded with a thin cortex, and a pathologic fracture may ensue. (*Courtesy of S. Newell.*)

FIGURE 15.76 The same dog as **Figure 15.75** on cranial-caudal projection. (*Courtesy of S. Newell.*)

SECONDARY HYPERTROPHIC OSTEOPATHY

Definition/Overview

Hypertrophic osteopathy (pulmonary osteoarthropathy, hypertrophic pulmonary osteoarthropathy, hypertrophic pulmonary osteopathy) is a secondary pathologic disease frequently associated with some form of pulmonary disease and characterized by bilateral symmetrical swellings in the distal extremities of all four limbs. It is a disease of older dogs, and the majority of bones in the limb may show a diffuse periosteal reaction. Bone changes usually begin distally and spread proximally.

Etiology

The cause is unknown, and the disease is not restricted to primary thoracic neoplasia.

Pathophysiology

This disease involves increased blood flow to the distal extremities, then overgrowth of connective tissue and subsequent osteoneogenesis. It is proposed that a neural reflex originating in the thorax affects connective tissue and periosteum of the limbs.

Clinical Presentation

Diseased patients are stiff and reluctant to move. Limbs are often painful, warm, and swollen (**Figure 15.77**). Primary thoracic disease may manifest with cough, abnormal lung sounds, dyspnea, or cardiac displacement.

Differential Diagnosis

Osteomyelitis, metastatic neoplasia.

Diagnosis

Radiographic examination reveals early involvement of the metacarpal and metatarsal bones (**Figure 15.78**), with subsequent progression of periosteal reaction recognized in more proximal long bones and joints. Radiographic studies should include films of the thoracic and abdominal cavities to rule out pulmonary or abdominal (e.g., bladder rhabdomyosarcoma or liver adenocarcinoma) disease. Skeletal recognition of hypertrophic osteopathy signals other disease processes; therefore, interrogative diagnostics should follow if hypertrophic osteopathy is suspected.

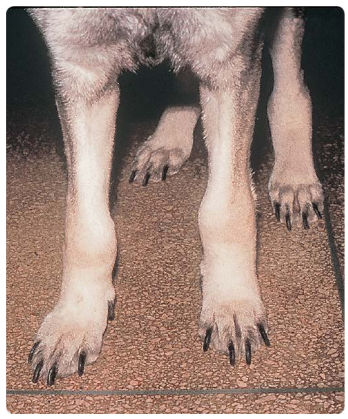

FIGURE 15.77 This 11-year-old female spayed German Shepherd Dog has hypertrophic osteopathy as a result of renal carcinoma metastasizing to its chest. Note the distal appendageal swellings. (*Courtesy of M. Schaer.*)

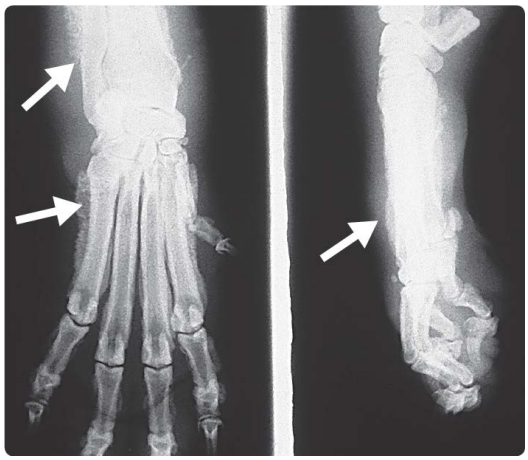

FIGURE 15.78 Hypertrophic osteopathy was diagnosed in this 11-year-old female spayed German Shepherd Dog. All four distal extremities were involved. The radiograph shows the periosteal proliferation involving the distal foreleg (arrows). (*Courtesy of M. Schaer.*)

Management

Clinical signs typically resolve within 1–2 weeks of successful treatment for the primary cause, although resolution of the bony lesions may take months. Relief of lameness may be gained with intrathoracic vagotomy on the ipsilateral side to the bony lesion(s).

MULTIPLE CARTILAGINOUS EXOSTOSES

Definition/Overview

Multiple cartilaginous exostoses (osteochondromatosis, diaphyseal aclasis, hereditary multiple exostoses), reported in both dogs and cats, is a disease manifestation of endochondral ossification where partially ossified protrusions arise from the cortical surfaces of bones. The vertebrae, ribs, and long bones are most frequently affected in dogs.

Etiology

The condition may be inherited as an autosomal dominant trait in dogs. Differentiation to cartilage and bone of chondrocytes displaced from the metaphyseal growth plate is believed to be the cause, and growth of the exostoses usually ceases with skeletal maturation. In the cat, feline leukemia virus has been associated with osteochondromas. Transformation of cartilaginous exostoses into osteosarcoma and chondrosarcoma has been reported.

Pathophysiology

Protuberances consist of cancellous bone covered by a surface of hyaline cartilage; they arise in the metaphyseal region of bones by endochondral ossification. As growth continues, exostoses may finally become located in the diaphysis.

Clinical Presentation

Clinical signs may include paresis due to spinal cord compression or pain from exostoses touching adjacent tissue. Superficial exostoses may be palpated.

Differential Diagnosis

Neoplasia, fracture callus.

Diagnosis

Radiographs reveal bony masses with a smooth, thin shell arising from the cortical surfaces of the appendicular or axial skeleton (Figures 15.79 and 15.80a–d). The expanding exostoses may lead to skeletal deformation. Periodic radiographic evaluation is advised, with the consideration that chronic lesions may transform to bone neoplasia.

Management

The extent of the lesion dictates treatment, and surgical excision may be indicated if the lesion interferes with function.

FIGURE 15.79 Cartilaginous exostoses observed on the medial aspect of the distal radial metaphysis.

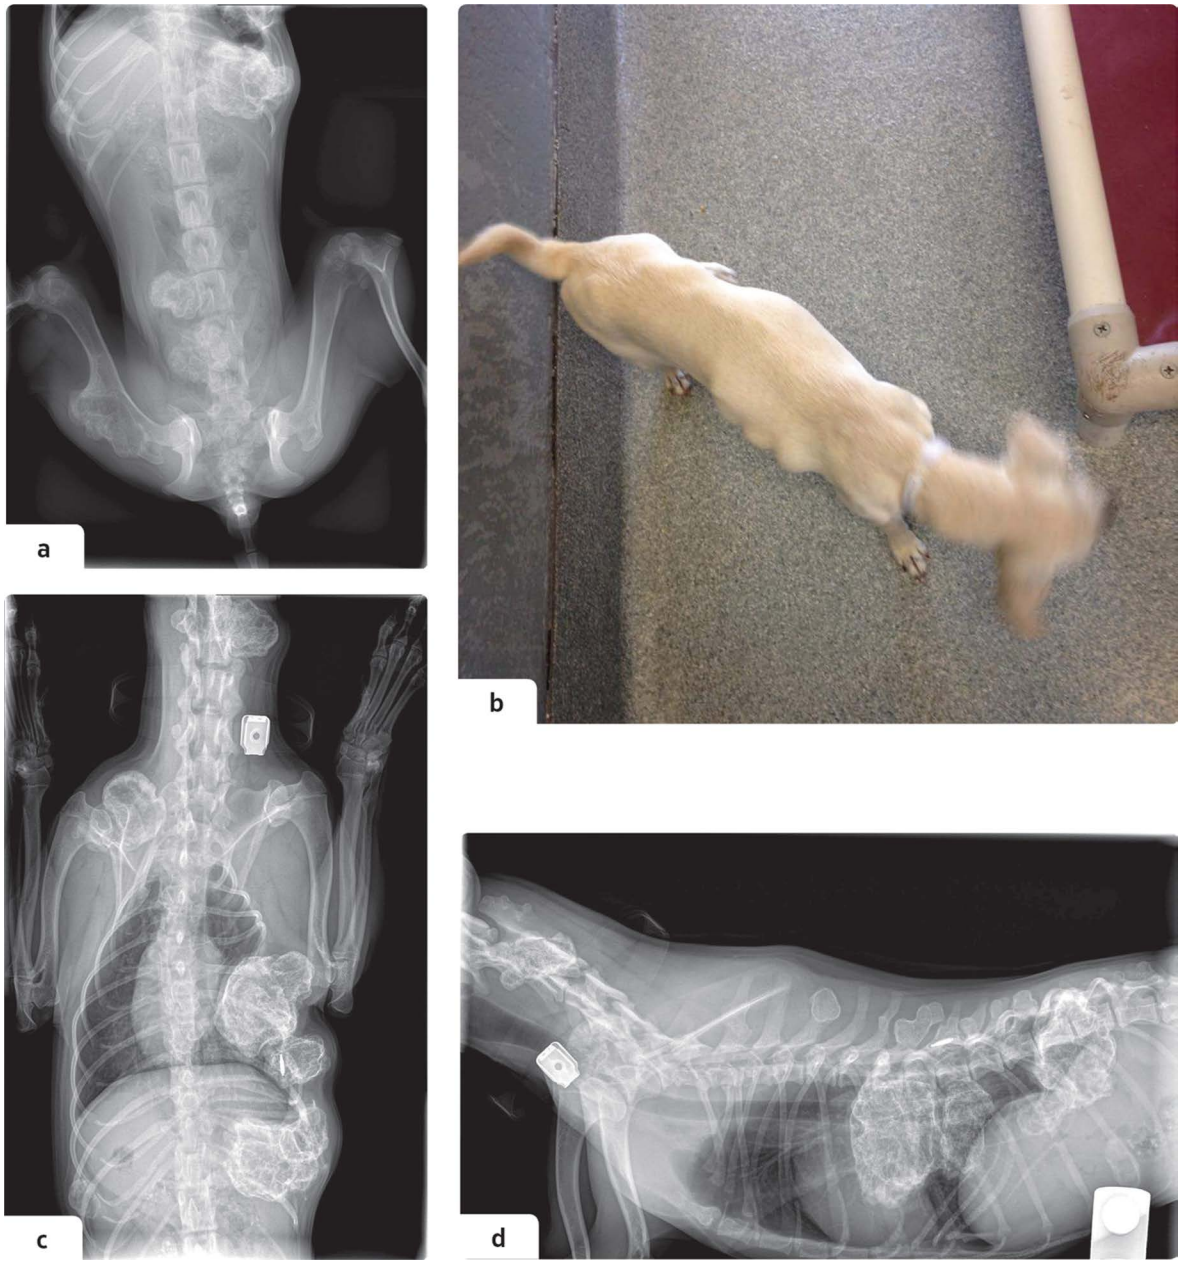

FIGURE 15.80 (a–d) These images depict a young mixed-breed dog with diffuse cartilaginous exostoses showing the external masses and their radiographic appearance at various costochondral sites. (*Courtesy of H. Campbell and A. Alvarez.*)

TOXICITY AND TRAUMA

LEAD POISONING

Definition/Overview

Skeletal signs are usually absent with lead poisoning, but in some affected young dogs, radiography reveals "lead lines" in the bones.

Etiology

Plumbism is a disease caused by the ingestion of lead-containing materials, mainly paint.

Pathophysiology

Lead toxicity may result in gastrointestinal, neurologic, and hematologic abnormalities. Radiographic "lead lines" result from accumulation of thick, mineralized trabeculae at the metaphyseal sites because of impaired osteoclastic activity.

Clinical Presentation

Gastrointestinal signs of vomiting, diarrhea, anorexia, and abdominal pain tend to predominate over central nervous system (CNS) signs of lethargy, hysteria, seizures, and blindness.

FIGURE 15.81 "Lead lines" seen in the metaphysis of an immature dog. (*Courtesy of B.R. Jones.*)

Differential Diagnosis

Hypervitaminosis D, hyperphosphatemia, bismuth toxicity.

Diagnosis

Radiographically, dense sclerotic "lead lines" may be seen in the metaphysis of long bones of immature dogs (Figure 15.81). They are most apparent in the distal radius and ulna. Chronic toxicity of vitamin D, phosphorus, or bismuth can cause a similar radiographic lesion.

Management

Skeletal signs may persist following treatment for toxicity.

TRAUMATIC LUXATIONS

Definition/Overview

Hip—craniodorsal displacement of the femoral head is the most common presentation. This injury causes significant trauma in a normal hip. Dogs with mild dysplasia are at risk with even minor traumatic incidents. Caudoventral luxations occur more frequently in small-breed dogs with low-intensity traumatic events such as slipping on floors with limb abduction. It is important to differentiate direction of luxation as treatment recommendations are different. Closed reductions are potentially effective in dogs with no underlying hip dysplasia,

Elbow—requires significant force to cause elbow luxation in dogs without underlying elbow disease process and may accompany periarticular fractures. Luxations that result in damage to annular ligament separating the radial head from the ulna are less likely to resolve with closed reduction and conservative management.

Etiology

Craniodorsal luxation is likely secondary to increased force directed along the weight-bearing access, resulting in failure of the round ligament of the femoral head and subsequent luxation. In contrast, a caudoventral luxation is thought to be secondary to an excessive abducting force resulting in failure of the ventral acetabular ligament with or without rupture of the round ligament of the femoral head.

Elbow luxation most commonly is the result of a medially or laterally applied force to the forelimb during weight bearing.

Pathophysiology

Regardless of direction of luxation, traumatic luxation will result in reduced or altered range of motion of the joint. Depending on relative location of displaced bone, there may or may not be crepitus present during range of motion. Pain on manipulation is often, but not always, present during examination.

Clinical Presentation

Hip

Dogs with craniodorsal luxation typically present with a non or partially weight-bearing lameness. The affected limb is often observed to be held in slight abduction with external rotation of the limb. Manipulation of the affected joint is typically noted to have reduced range of motion in extension and possible bony conflict with extension. Palpation of the local anatomic landmarks reveals dorsal displacement of the greater trochanter, resulting in alignment of ischial tuberosity, greater trochanter, and wing of the ilium. Caudoventral luxations are more likely to be non-weight bearing. The limb is most often held in a flexed position with possible adduction and internal rotation.

Differential Diagnosis

Periarticular fracture, neoplasia.

Diagnosis

The diagnosis is usually highly suspected following history and physical examination. Definitive diagnosis

usually requires radiographic imaging (Figure 15.82a–d). Additionally, imaging also helps to determine if any periarticular comorbidities are present, and in the case of hip luxation, the presence of underlying hip dysplasia greatly affect the prognosis and recommended course of treatment.

Management

Traumatic luxation of the hip can be managed with closed or open reduction. Closed reduction is recommended; up to 50% of closed reductions do not reluxate and can recover without surgical intervention.

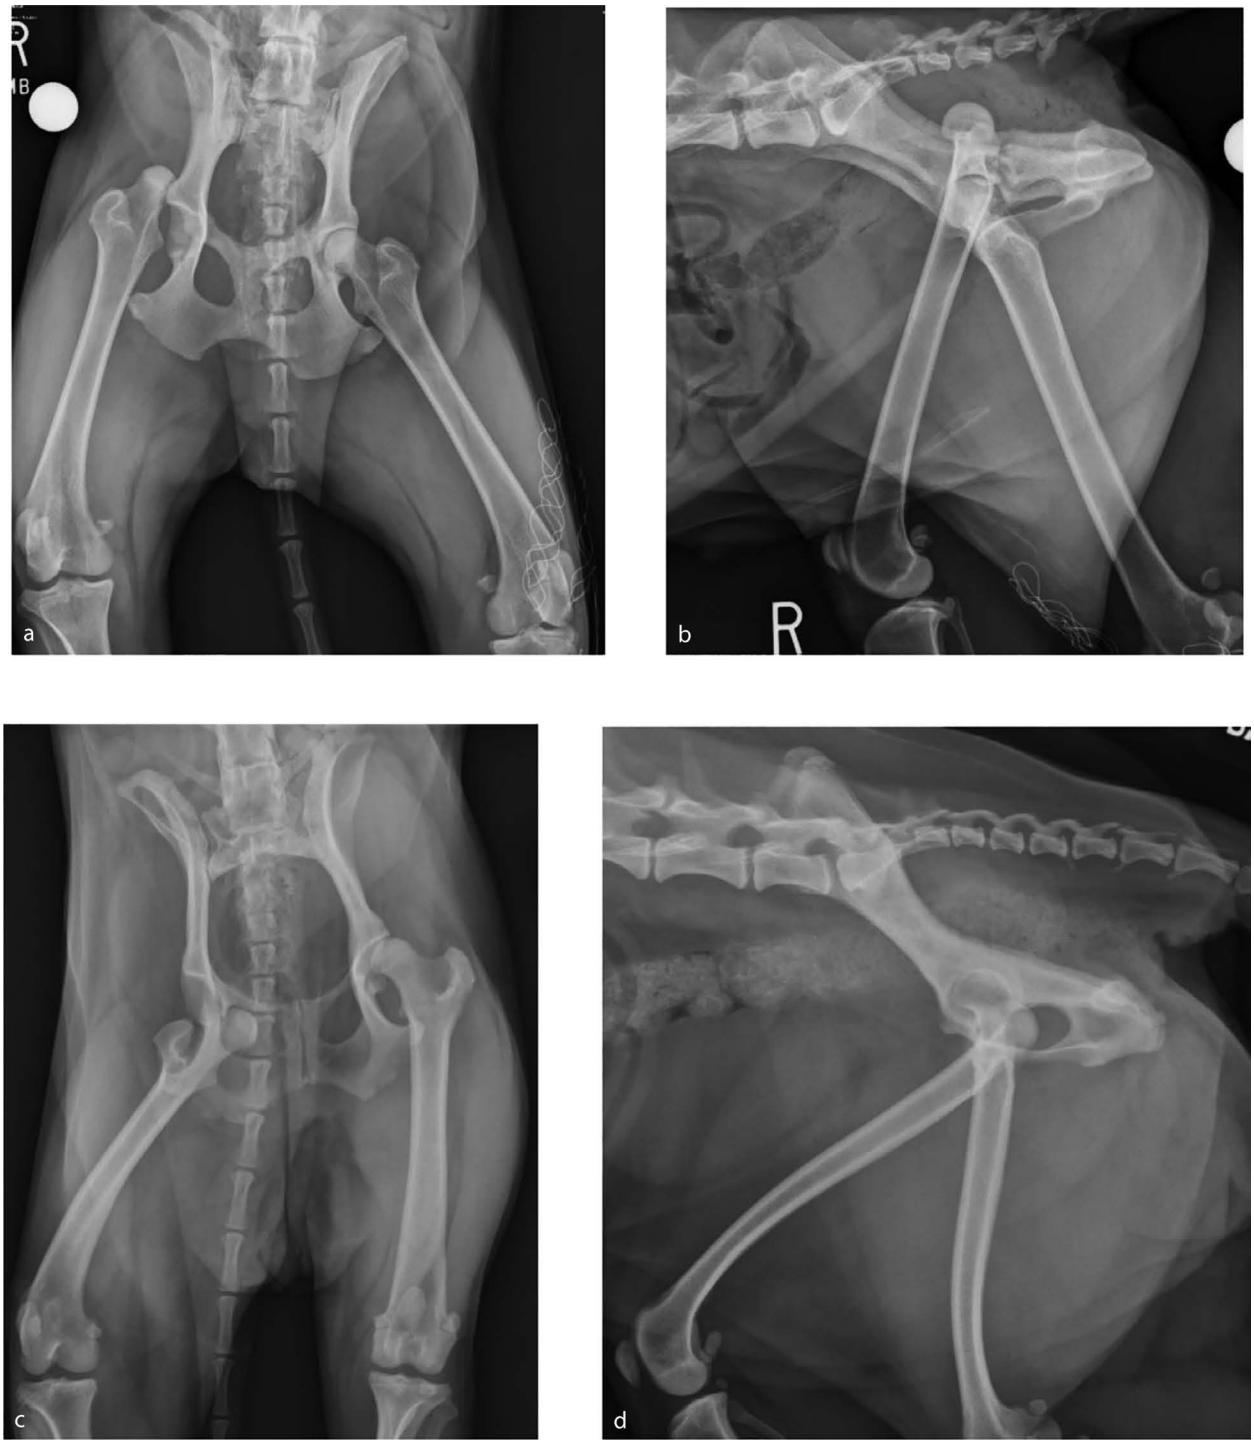

FIGURE 15.82 (a, b) Orthogonal projections of a traumatic craniodorsal luxation in a dog. In this dog, the femoral ligament remained intact. Luxation resulted from a slab fracture of the ventral femoral head. Careful examination of the image shows flattening of the ventral femoral head and a small bone fragment within the acetabular region on the ventrodorsal projection. **(c, d)** Orthogonal projections of a caudoventral luxation in a Cavalier King Charles' Spaniel that occurred following a slip in the house.

Open surgical reduction is accomplished with a toggle and suture technique to recreate the ligament of the head of the femur and imbrication of the joint capsule. If left untreated and managed conservatively, some smaller dogs and cats will have fair function as they form a false arthrosis dorsal to the acetabulum. However, most will have muscle atrophy, chronic pain, and reduced range of motion (ROM) to the hindlimb.

Correction of traumatic elbow luxations via either open or closed reduction is recommended, as these patients do not respond favorably to conservative management. The elbow is inherently stable, if closed reduction is successful, with continued treatment of immobilization for 4–6 weeks followed by gradual reintroduction of range of motion.

COLLATERAL LIGAMENT RUPTURE/INJURY

Definition/Overview

Collateral ligaments play an important role in joint stability for most hinged-type joints. Partial injuries such as partial ligament rupture or stretching of the ligament may not result in joint instability such that nonsurgical interventions may be effective. The tarsus, stifle, and phalanges are more often affected (Figure 15.83a–c).

Etiology

Collateral ligamentous disruption is generally secondary to a medial/lateral force with a fixed distal limb (i.e., weight bearing). The ligamentous injury can be midsubstance or occur as a result of an avulsion with or without a bone segment accompanying the detached ligament.

FIGURE 15.83 Radiographic images for a dog with suspected collateral ligament injury. **(a, b)** Standard radiographic imaging with only mild-to-moderate stifle effusion. Dog was limping following a traumatic event. PE revealed a positive cranial drawer. However, the stifle appeared more lax than usual. **(c)** A lateral stress view was requested revealing lateral collateral incompetence.

FIGURE 15.84 (a–c) Orthogonal radiographic projections of the tarsus in a dog following a road traffic accident. A severe shearing injury was sustained medially. Medial instability was apparent on examination and manipulation of the tarsus. Radiographic images were taken to document extent of injury. Stressed views at the time of presentation can aid in assessment of stability following intervention—surgical or conservative management—in serial assessments during recovery.

Pathophysiology

Ligamentous injury can occur at the bone ligament interface (origin or insertion) or can be within the ligament substance. If the injury occurs at the bone interface, resulting in a sufficiently large bone fragment (avulsion) included with the ligament, there is a better chance for bone-to-bone healing with intervention. Midsubstance tears rarely heal, and successful healing with coaptation alone has a very low chance for successful resolution. In cases such as Figure 15.84a–c with extensive soft tissue injury, sufficient fibrous healing may occur periarticularly to provide sufficient stability to the joint. In these cases, a significant loss of range of motion can be expected. Isolated collateral ligament injury in the absence of other regional soft tissue injury is unlikely to heal, and, in many cases, primary ligament repair via surgical intervention is not possible. Prosthetic ligament repair is typically performed.

Clinical Presentation

Most collateral ligament injuries occur with a traumatic event and may have other more serious comorbidities that require immediate care. Collateral ligament injuries can often initially be managed with coaptation while other injuries are addressed first.

Collateral ligament injury is suspected after a thorough orthopedic examination. Collateral ligament injury may accompany joint luxations; however, it often presents without joint luxation. In acute cases, patients are often non-weight bearing. Some patients with isolated collateral ligament injury may be willing to attempt weight bearing but often are unable to support their weight. During weight bearing, the limb may be observed to angulate in an abnormal manner at the joint.

Differential Diagnosis

Periarticular fracture.

Diagnosis

Physical exam findings, radiographic confirmation with additional stress views challenging stability of suspected collateral ligament injury.

Management

For large avulsion segments, the bone component can be reattached with cross pins and a tension band or with a cortical screw. Prosthetic ligament repair can be performed for most collateral ligaments from the tarsus/carpus and proximal. Prosthetic ligament repair is usually accomplished with large-gauge monofilament suture (nylon, Prolene, or similar) or braided suture (ultra-high-molecular-weight polyethylene or similar). Suture material may be attached to bone via anchors or through bone tunnels.

In some cases, collateral ligament injury accompanies other sever joint injuries such that arthrodesis may be the best option for continued comfortable limb use long term.

Regardless of the technique used to re-establish primary joint stability, secondary support will be needed via splint or cast immobilization or in some cases with transarticular external fixation. For tarsal instability with extensive soft tissue injury, no difference in clinical outcome was shown regardless of the technique chosen. All three (coaptation, prosthetic ligament reconstruction, or arthrodesis) options resulted in similar frequency of complications and similar ultimate limb use and client satisfaction.

Coaptation is initially indicated for phalangeal injuries and tarsal injuries with significant soft tissue wounds. The stifle joint can initially be coapted but will require reconstruction for optimal return to function.

Anatomic reconstruction, partial or pantarsal arthrodesis is effective for persistent tarsal instability. Phalangeal injuries are typically treated with conservative management.

ADVANCED DIAGNOSTIC TECHNIQUES

Increasingly sophisticated tests for the diagnosis of musculoskeletal disorders have become available over recent years. Patient history and physical examination continue to be the mainstay; however, arthroscopy, CT, and MRI are becoming more integrated into our diagnostic offerings. In addition, nuclear scintigraphy, ultrasonography, and gait analysis are diagnostics for special interests.

Magnetic Resonance Imaging

MRI offers excellent contrast and resolution, providing the ability to differentiate between adjacent joint structures.

Indications

Any soft tissue structure that can be placed within the magnetic field. Common uses include:

- CNS diseases of the brain and spinal cord; peripheral nerve root diseases
- Orthopedic conditions of tendons, ligaments, joint capsule, connective tissue, and bone marrow
- Nasal, oral, and auditory diseases

Contraindication

Cases precluding general anesthesia.

Advantages

- Helpful in early disease detection
- Assists in chemotherapy and radiation therapy planning
- Noninvasive
- Higher contrast makes MR image quality superior to that of reconstructed CT images
- Chemically maps body tissues
- Excellent detection of tissue hemorrhage and edema
- Allows image acquisition in any anatomic plane
- Paramagnetic contrast medium is very safe
- Allows detection of discospondylitis before radiographic detection
- More accurate detection of tumor invasion to adjacent structures
- Absence of ionizing radiation
- High sensitivity in detecting abnormal bone marrow

Disadvantages

- Highly motion sensitive
- Resolution inferior to that of CT images
- Cannot image body areas containing metal
- Limited availability
- Costly to purchase and maintain

Computed Tomography

The newest CT technology is spiral or helical scanning. In CT, the patient continuously moves through a gantry on a motorized couch, while the x-ray tube rotates continually during the patient transit. This gives a volumetric representation of the resulting pixels that allows for 3D reconstruction. Multiple slices (1–64) are taken per rotation. The technique is very fast, requiring approximately 10 seconds to do an entire canine thorax.

Indications

- Any body part can be assessed, provided it can fit within the gantry.
- Skull and CNS lesions are most often assessed in veterinary patients.

Contraindications

Relative contraindication: The patient could not be anesthetized for CT; therefore, instead of general anesthesia,

CT is performed under sedation. Often CT imaging can be accomplished with sedation, and for severely affected animals (moribund), sedation may not be needed to obtain diagnostic imaging.

Advantages

- Excellent resolution (down to 0.1 mm diameter) and detail and speed of image acquisition
- Excellent image contrast, with 2,000 shades of gray
- Any areas of mineral and gas are detectable, where they are unseen in conventional radiographs
- Noninvasive

Disadvantages

- General anesthesia may be required for some studies
- Limited availability
- Larger doses of ionizing radiation compared to conventional radiography
- Limited gantry size
- Expense

Arthroscopy

Arthroscopy has revolutionized orthopedic surgery since its veterinary acceptance in the 1970s. In the equine species, arthroscopy has replaced many arthrotomies. A characteristic value of arthroscopy is that this procedure can simultaneously serve as both a diagnostic and therapeutic. The technique is implemented as an adjunct to a thorough orthopedic and radiographic examination.

Advantages

- Is routinely available at surgical referral centers
- Offers a minimally invasive technique, with few complications
- Provides a detailed view and magnification of intra-articular structures and lesions

Disadvantages

- Requires a substantial financial investment and long learning curve.
- Has more limited application in the smaller breeds.
- While associated with a low frequency of complications, the most common is perhaps iatrogenic cartilage damage associated with instrument insertion and manipulation.

CHAPTER 16

Hematologic Disorders

Katie M. Boes, Claire M. Cannon, and Julien R.S. Dandrieux

Introduction 647
Erythrocyte Disorders (Nonneoplastic) 647
Case Examples 712
Recommended Further Readings 716

INTRODUCTION

Blood disorders occur commonly in dogs and cats, often secondary to systemic disease or injury. History, physical examination, and laboratory diagnostic tests, including a complete blood count (CBC), are crucial for recognition and complete characterization of these disorders. Once a baseline is obtained, further workup can be planned to include imaging, sampling of abnormal organs, and bone marrow evaluation as indicated.

ERYTHROCYTE DISORDERS (NONNEOPLASTIC)

GENERAL APPROACH TO ANEMIA

Definition/Overview

Anemia is one of the most frequent hematologic abnormalities encountered in practice. It is not a disease but rather the reflection of a disease state.

Etiology

The three general causes of anemia are erythrocyte loss (hemorrhage), lysis (hemolysis), and decreased production in the bone marrow (atrophy, hypoplasia, or aplasia). Anemia is classified as preregenerative, regenerative, or post-regenerative. **Figure 16.1** lists the main causes of anemia.

Pathophysiology

A decreased red blood cell (RBC) mass leads to insufficient oxygen delivery to vital organs and subsequent decreased aerobic metabolism, energy production, and tissue function. Cellular and tissue injury can occur with more severe or prolonged anemia.

Clinical Presentation and Physical Examination Findings

Common historical signs of anemia include lethargy, depression, weakness, exercise intolerance, pica, and hyporexia. Recumbency, seizures, syncope, and coma may occur with severe anemia.

Pale mucous membranes are a common physical examination finding (**Figure 16.2a, b**). Pallor can be due to hypoperfusion, hypoxemia, or anemia. Animals with hypoperfusion have typically no or only mild decrease in their packed cell volume (PCV) and have an increased capillary refill time (CRT). In contrast, cats and dogs that develop pallor secondary to anemia have a moderate-to-severe reduction in their PCV and are typically hyperkinetic (normal-to-decreased CRT and hyperkinetic pulses). A PCV should always be measured in the pale animal, but the CRT cannot always be evaluated due to the lack of contrast with pallor. If pallor is present, thorough examination for evidence of petechiae, ecchymosis, or bleeding is indicated.

With moderate-to-severe anemia, heart murmur, tachycardia, tachypnea, and dyspnea may be appreciated. Icterus (**Figure 16.3**) may occur with hemolytic anemia or internal hemorrhage, whereas intravascular hemolytic anemia can cause hemolysis (**Figure 16.4**) and hemoglobinuria in addition to icterus (see also Chapter 2.8). Hemorrhage into the thoracic and abdominal cavities may cause dyspnea and abdominal enlargement, respectively. Occasionally, anemia may be discovered during routine blood evaluation in an apparently clinically normal animal. Sedentary animals, especially cats, often have a moderate anemia that goes unnoticed for long periods of time. Splenomegaly and hepatomegaly frequently occur due to increased extravascular hemolysis or extramedullary hematopoiesis. Lymph nodes should be carefully palpated as lymphadenomegaly can suggest underlying diseases such as infectious or neoplastic processes. The

animal should also be evaluated for trauma or surgery and sites of blood loss. A fundic exam is helpful as a first screen for an underlying infectious disease.

Clinical signs depend on the severity of the anemia and the onset of anemia. An animal with slow progressive anemia will develop compensatory mechanisms (see ahead given in the text), and obvious clinical signs will only develop with moderate-to-severe anemia. In comparison, an animal with acute hemolysis will develop marked clinical signs with a comparatively mild anemia.

History

If not previously obtained, a complete history is required in addition to a thorough physical examination. Table 16.1 lists some of the pertinent questions, and Table 16.2 lists the drugs and toxins that have been reported as a cause of anemia in dogs and cats. The clinician also needs to obtain information about concurrent disease and duration of disease.

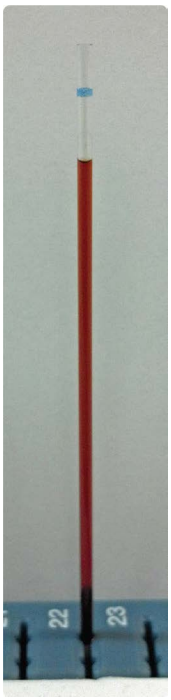

FIGURE 16.4 Red plasma and PCV of 0.14 L/L (14%) in an animal with intravascular hemolysis. The pink supernate characterizes hemolysis.

Differential Diagnosis

Refer to each specific disease.

Diagnosis

Diagnosis include laboratory testing (starting with a CBC), including infectious agent testing according to the animal history, diagnostic imaging, and sampling for cytology or histology as indicated. When this is insufficient to reach a diagnosis, bone marrow sampling may be required. In the emergency setting, the clinician should ideally take the samples prior treating and at a minimum an ethylenediaminetetraacetic acid (EDTA) sample for PCV/total protein (TP)/hematology/polymerase chain reaction (PCR)/Coombs as indicated and serum for biochemistry and serology. A citrate sample is also indicated if a hemostasis problem is suspected.

Complete Blood Count

Anemia is identified by a decreased PCV, hematocrit (Hct), RBC count, or hemoglobin (Hgb) concentration. The PCV is the most accurate and least expensive method of documenting anemia. It is performed by centrifuging a microhematocrit tube filled with anticoagulated whole blood for 5 minutes at 12,000–15,000 g and then measuring the RBC volume as a percentage of the total blood volume. See Table 16.3 for causes of erroneous PCV.

The plasma of the spun microhematocrit tube should be evaluated for lipemia, hemolysis, or icterus, since this may help identify the cause of the anemia, disease states, or potential biochemical interferences (Figure 16.4). The plasma protein or total solid concentration should be determined by refractometer.

The Hct may be calculated from the mean cell volume (MCV) and RBC by a hematology analyzer (see Table 16.3 for equations and artifacts), or it may be measured by conductivity by some blood gas instruments. The Hct is similar to the PCV, except the PCV is typically higher by 1–3 percentage units due to trapped plasma between RBCs in the microhematocrit tube.

Hgb concentration is typically determined using a spectrophotometer by the cyanmethemoglobin method or a cyanide-free method.

TABLE 16.1 Specific questions to ask owners of a pet with anemia

Questions	Reasons
Bloody or dark tarry stools?	Intestinal bleeding (e.g., ulcerated mass) Potential for iron deficiency
Change in urine coloration?	Either due to bilirubinuria, hematuria, or hemoglobinuria (intravascular hemolysis)
Fleas noted?	Severe flea infestation can be a cause of anemia
Ticks noted?	Possible tick-borne disease such as ehrlichiosis (bone marrow) or babesiosis (hemolysis)
Worming status?	Severe hookworm infestation may cause anemia, especially in young animals
Any current treatment or possible access to toxins?	See Table 16.2 for some of the drugs and toxins reported as cause for anemia in dogs and cats
FeLV/FIV status?	Retroviral infection can lead to anemia through different mechanisms
Dog fight (Pitbull), kennels (Greyhound)	*Babesia gibsoni* may be transmitted by bites from Pitbulls
Female pet used for reproduction or pet has received a blood transfusion	Requirements for crossmatching if blood transfusion is likely to be required

TABLE 16.2 Examples of common drugs and toxins that can cause anemia in dogs and cats (this is not an exhaustive list, as any drug has the potential to trigger an idiosyncratic reaction)

Drug*	Species
Acetaminophen/paracetamol†	C > D
Nonsteroidal anti-inflammatories (NSAID)	C, D
Benzocaine	C
Chemotherapeutic agents	C, D
Chloramphenicol	C, D
Gold salts	C, D
Griseofulvin	C, D
Methimazole	C
Methionine	C
Methylene blue†	C > D
Metronidazole	D
Penicillins and cephalosporins	D > C
Phenobarbital	D
Phenothiazines	C, D
Propylthiouracil	C
Propylene glycol	C
Sulfa derivatives	D > C
Zinc	C, D

* Different mechanisms can lead to anemia (e.g., thrombocytopenia, IMHA, bone marrow suppression).

† Drug is not recommended for cats.

The RBC count is usually performed by an automated cell counter or, less commonly, by a hemocytometer.

The mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) are calculated RBC indices (Table 16.3 for equations and artifacts) that help classify the type of anemia as normochromic (normal MCH and MCHC) or hypochromic (decreased MCH and MCHC). When these values are discrepant, MCHC is the preferred index for interpretation.

MCV may be determined directly by automated cell counters or calculated (Table 16.3). MCV reflects RBC size and may be categorized as macrocytic (increased MCV), microcytic (decreased MCV), or normocytic (normal MCV). An increased MCV may occur with RBC regeneration, feline leukemia virus (FeLV) infection, or breed variation (Toy and Miniature Poodle dogs). Decreased MCVs are observed with iron deficiency, liver disease, portosystemic shunts, breed variation (Akita and Shiba dogs), or young animals.

Blood smear evaluation of RBCs involves qualification of changes in size (anisocytosis), shape (poikilocytosis), and color (chromasia). The presence of abnormal red cells (e.g., nucleated precursors, basophilic stippling, infectious parasites, and Heinz bodies) or red cell arrangement (e.g., agglutination and rouleaux) should be noted.

Reticulocyte Counts

Reticulocytes are young RBCs that contain more ribonucleic acid (RNA) and less Hgb than mature RBCs. Most reticulocytes develop into mature RBCs in the bone marrow and are subsequently released into peripheral circulation. However, low numbers of reticulocytes are present in blood under normal hematologic conditions. Increased numbers of reticulocytes in blood (reticulocytosis) are seen with tissue hypoxia, and the presence or absence of reticulocytosis classifies the anemia as regenerative or nonregenerative, respectively. Once initiated in the bone marrow, regeneration may take at least 3 days before reticulocytes appear in circulation. For this reason, a preregenerative anemia can be seen during the first 3 days after the development of acute anemia. If the animal is stable, a repeat reticulocyte count 3 days after the first one can be used to confirm that an anemia is nonregenerative.

Reticulocyte counts may be determined by automated hematology analyzers or by manual methods. For manual reticulocyte count quantification, equal volumes of blood and 0.5% new methylene blue stain are incubated together for 15–20 minutes at room temperature. Then, a routine blood smear is made and allowed to dry. The numbers of aggregated (dogs and cats) and punctate (cats) forms per 1,000 erythrocytes are counted to determine the reticulocyte percentage (retic%) (Figures 16.5 and 16.6). The absolute reticulocyte count (retic#) is the more accurate reflection of RBC regeneration and is calculated from the retic% and RBC count (Table 16.3).

Dogs normally have 0%–1% reticulocytes (0–80,000/μL) in blood. In normal cats, aggregated reticulocytes range from 0% to 0.4% (0–30,000/μL), and punctate reticulocytes are <5% (<500,000/μL). Aggregated reticulocytes represent the most active or recent form of regeneration in the dog and cat and are identified as polychromatophils in Romanowsky-stained smears. Punctate reticulocytes in cats do not stain as polychromatophilic cells, and they represent past regeneration that occurred in the prior 2–4 weeks.

Note that the absolute reticulocyte count is the best method to identify regeneration. In the absence of a reticulocyte count, increased polychromasia on a Romanowsky-stained blood smear is the only RBC morphology that is specific for regeneration. Within the monolayer, dogs normally have 0–1 polychromatophils/100× objective field, and cats have no to rare polychromatophils/100× objective field. Greater numbers reflect regeneration.

When the RBC count is not available, the PCV may be used to calculate the corrected reticulocyte percentage (Table 16.3). A corrected reticulocyte percentage (CRP) value >1% indicates increased RBC regeneration.

Some hematology analyzers also provide reticulocyte indices, which characterize the size and hemoglobin content of reticulocytes. Causes for abnormal reticulocyte

TABLE 16.3 Hematologic parameter abnormalities

Parameter and method	Increased patient result	Decreased patient result
Packed cell volume (PCV) Directly measured	– Dehydration – Excitement (epinephrine) – Breed (Greyhound, Whippet) – Chronic hypoxia – Neoplasia – Artifact: Inadequate mixing or centrifugation	– Anemia – Overhydration – Artifact: Excessive EDTA, in vitro hemolysis, inadequate mixing
Hematocrit (Hct) Hct (%) = MCV (fL) × RBC ($x10^6$/μL) ÷ 10	– See increased PCV (except artifact) – Artifact: Falsely increased MCV or RBC, inadequate mixing	– See decreased PCV (except artifact) – Artifact: Excessive EDTA, falsely decreased MCV or RBC, in vitro hemolysis, inadequate mixing
Hemoglobin (Hgb) Directly measured	– See increased PCV (except artifact) – Artifact: Excessive Heinz bodies, hemolysis, lipemia, some gammopathies	– See decreased PCV (except artifact)
Red blood cell concentration (RBC) Directly measured	– See increased PCV (except artifact) – Artifact: Inadequate mixing, marked thrombocytosis	– See decreased PCV (except artifact) – Artifact: Clotted sample, in vitro hemolysis, inadequate mixing, RBC agglutination
Mean cell volume (MCV) Directly measured	– Reticulocytosis – Breed (some Poodles) – FeLV – Folate/cobalamin deficiency – Artifact: Hypernatremia, RBC agglutination, sample storage	– Young animals using adult RIs – Breed (Asian dog breeds) – Iron deficiency – Portosystemic shunt – Artifact: Excess EDTA, hyponatremia
Mean corpuscular hemoglobin (MCH) MCH (pg) = Hgb (g/dL) × 10 ÷ RBC ($x10^6$/μL)	– See increased MCV (except artifact) – Artifact: Falsely increased Hgb, falsely decreased RBC	– See decreased MCV (except artifact) – Artifact: Falsely decreased Hgb, falsely increased RBC
Mean corpuscular hemoglobin concentration (MCHC) MCHC (g/dL) = Hgb (g/dL) × 100 ÷ Hct (%)	– Artifact: Falsely increased Hgb, falsely decreased Hct	– Reticulocytosis – Iron deficiency – Portosystemic shunt – Lead poisoning – Artifact: Falsely decreased Hgb, falsely increased Hct
Absolute reticulocyte count (retic#) Retic# ($x10^3$/μL) = Retic% (%) × RBC ($x10^6$/μL) × 10	– Marrow erythroid hyperplasia – Artifact: Babesiosis, inadequate mixing, leukemia	– Marrow erythroid atrophy – Artifact: Clotted sample, in vitro hemolysis, inadequate mixing, reticulocyte agglutination
Corrected reticulocyte percentage (CRP) Dog: CRP (%) = Retic% (%) × Patient's Hct (%) ÷ 45% Cat: CRP (%) = Retic% (%) × Patient's Hct (%) ÷ 35%	– See increased retic#	– See decreased retic#

Retic%, percent reticulocyte count; RI, reference interval.

hemoglobin content (CHr) and reticulocyte mean corpuscular volume (rMCV) are similar to those of abnormal MCHC and MCV, respectively. In particular, low CHr and rMCV may detect iron deficiency earlier than erythrocyte indices.

Biochemical Profiles

Biochemical profiles may reveal disease that can affect the ability to regenerate erythrocytes, especially diseases of the liver and kidney. Other changes can be suggestive of endocrine disease, and a discrepancy in urea increase compared to creatinine can suggest gastrointestinal blood loss. A low albumin and total protein are more likely with blood loss than hemolysis in an animal with normal liver function. Icterus can develop secondary to hemolysis, especially in dogs, and can also be present with internal bleeding resorption.

Fecal Examination and Urinalysis

These tests are performed to determine sources of blood loss in the gastrointestinal (GI) tract or urinary tract, respectively.

Fecal occult blood test consists of smearing feces on a test pad to detect bleeding that is not apparent grossly. The animal should ideally not be fed red meat for 3 days prior to testing to reduce the risk of a false-positive result. The sample should be run 2–3 days after application to reduce the risk of false-positive result from

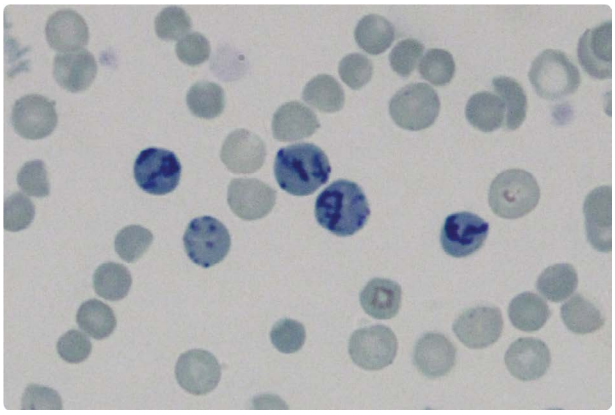

FIGURE 16.5 New methylene blue–stained blood smear from a dog, showing five aggregated reticulocytes.

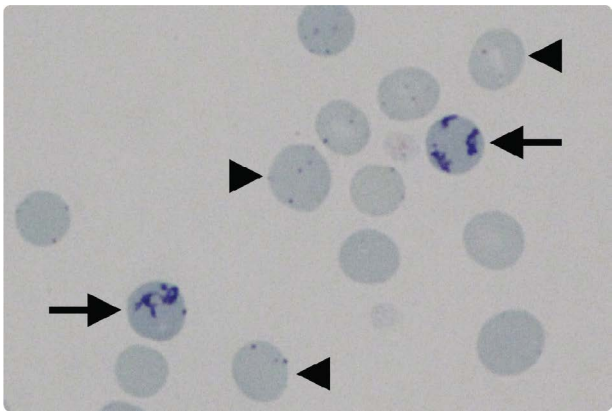

FIGURE 16.6 Feline aggregated (arrows) and punctate (arrowheads) reticulocytes demonstrated by new methylene blue stain.

plant-derived peroxidases. Vitamin C supplementation can falsely decrease the result.

Dipstick can be used to detect microscopic hematuria and confirm ongoing hematuria. Comparison of a free catch and cystocentesis urine sample can be useful to differentiate significant hematuria proximal or caudal to the bladder neck (e.g., distal urethra or uterine pathology).

Laboratory Testing for Infectious Etiologies

The clinician needs to be aware of the travel history of the pet and potential infectious agents that are relevant in their region. Testing modalities include direct visualization (e.g., *Babesia* on a smear), serology (e.g., FIV antibody test to identify viral exposure), and antigenic testing (e.g., FeLV antigen test). See Chapter 11.

Diagnostic Imaging

Diagnostic imaging is often required in the workup of the anemic animal. It can be especially useful to assess the origin of bleeding in the absence of obvious source. In the emergency setting, this includes abdominal and thoracic-focused assessment with sonography for trauma, triage, and tracking (AFAST and TFAST).

Similarly, imaging is useful to rule out triggers for hemolysis (e.g., abdominal radiographs to exclude a foreign body containing zinc) or in an animal with suspected associative immune-mediated hemolytic anemia (e.g., neoplasia with secondary immune-mediated hemolytic anemia [IMHA]).

Endoscopy

Endoscopy might be indicated to further assess and sample sources of GI, respiratory, or urinary bleeding. See specific diseases for more information.

Cytology and Histopathology

If abnormalities are detected during the workup that are potentially relevant as a cause for the anemia, sampling should be considered to reach a final diagnosis, help with prognosis, and guide treatment. Platelet count and coagulation profile should be considered in an anemic animal prior to sampling if a primary or secondary hemostasis disorder is suspected.

Sampling of enlarged organs (e.g., lymphadenomegaly, splenomegaly, and hepatomegaly) may reveal primary pathology (e.g., bleeding tumor) or secondary pathology (e.g., extramedullary hematopoiesis, reactive lymphoid hyperplasia).

Bone Marrow Evaluation

Bone marrow evaluation (Table 16.4) is best performed when both aspirate and core biopsies are taken together, since each provides different information. Results must always be compared with a recent CBC (within 24 hours) to determine the current status of regeneration. Indications for bone marrow evaluation include persistent cytopenia(s) of unknown etiology, diagnosing leukemia, and infectious myelitis. The procedure is typically performed if the disease etiology has not been identified with previous workup, including sampling of abnormalities such as lymphadenopathy, diagnostic imaging, and laboratory testing (e.g., tick-borne disease). This is a sterile procedure, and usually, sedation with or without local anesthesia (ilium, sternum) or general anesthesia (humeral sampling) is recommended as pain is expected.

Sites frequently used in dogs include the dorsal ilium, humerus (best for obese animals), and femur (small dogs or puppies). Aspirate from the sternum has also been described and is used in some institutions routinely for monitoring purposes. Sites frequently used in cats include the humerus, femur, and dorsal ilium by transilial or perpendicular approach (Figures 16.7–16.9). Specialized needles are preferred for the collection process, and the procedures are well established.

Classifying the General Cause of Anemia

The previous tests help classify the cause of anemia as hemorrhage, hemolysis, or decreased RBC production (Table 16.5).

TABLE 16.4 Bone marrow aspiration and core biopsy procedures for the dog and cat

Aspiration biopsy	Core biopsy
Equipment – Illinois sternal disposable needle, 15–18 G, 2.5–5 cm (1–2 inches) long (Cardinal Health, Dublin, OH) Procedure – Pass the needle with its stylet a few millimeters into the bone until it is firmly embedded – Place a 12 mL syringe coated with 5% EDTA solution onto the biopsy needle and collect 1–2 mL of bloody material – Place the marrow material into a plastic Petri dish and pick up the glistening particles with a pipette – Gently express this material out of the tube onto a glass slide – Make a squash preparation by laying a second slide on the first and pulling them horizontally apart	Equipment – Jamshidi aspiration/biopsy disposable needle, 11–13 G, 5–10 cm (2–4 inches) long (Cardinal Health, Dublin, OH) Procedure – Pass the needle with stylet through the skin and subcutaneous tissues – Remove the stylet while advancing the needle 0.5–1.5 cm into the bone, depending on the size of the animal – Twist the instrument sharply to cut the sample and withdraw the needle slowly – Remove the core sample and roll it onto a glass slide for cytologic examination; following this, place sample in 10% buffered formalin for histologic fixation

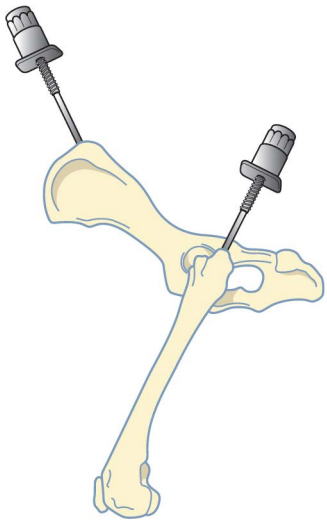

FIGURE 16.7 Bone marrow sites for aspiration and core biopsy using the dorsal crest of the ilium and the proximal femur. The parallel approach to the ilium is best for aspiration biopsy in medium- or large-sized breeds having an easily palpable crest protuberance.

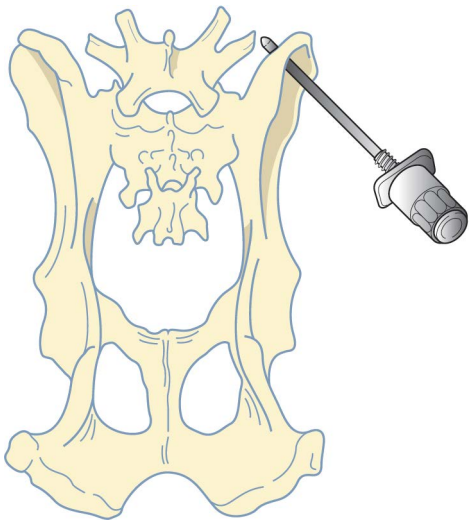

FIGURE 16.8 Bone marrow site for the transilial approach for core biopsy in a cat or small dog.

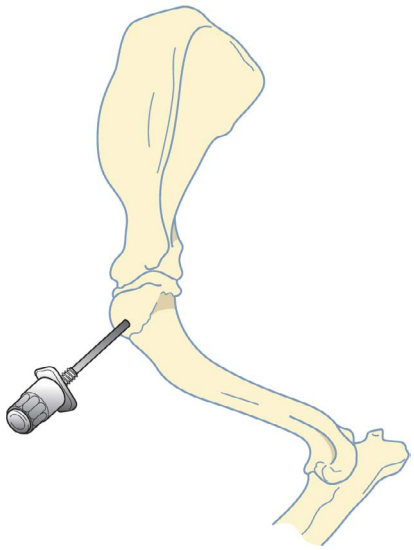

FIGURE 16.9 Bone marrow site for aspiration and core biopsy using the anterior lateral side of the proximal humerus. This site is especially helpful in obese animals.

Historical and physical support for hemorrhage includes a history of trauma or surgery or the observation of bleeding wounds, petechiae, ecchymoses, heavy external or intestinal parasitism, epistaxis, hemoptysis, melena, hematochezia, hemorrhagic effusions, or hematuria. Hemorrhage typically causes regenerative anemia, but nonregenerative anemia may occur with peracute hemorrhage prior to the release of reticulocytes from the bone marrow (preregenerative anemia, first 3 days), or with chronic external blood loss leading to iron deficiency. Proportionate decreases in albumin and globulin concentrations, termed *panhypoproteinemia*, support hemorrhage as the cause of anemia, since proteins are also lost with extravasation of whole blood. An increased serum urea nitrogen concentration relative to creatinine concentration can occur with excessive intestinal absorption of protein due to gastric or small intestinal hemorrhage.

External bleeding such as melena or hematuria might be obvious for the owner but can also easily be missed. For example, hematuria might only be noticed when the pet urinates in snow or might not be macroscopically

TABLE 16.5 Indicators of general categories of anemia

	Blood loss	Hemolysis	Decreased production
Clinical	Hemorrhage (internal or external), petechiae, ecchymosis, trauma	Icteric plasma and mucous membranes	Petechiae (if also decreased platelet production)
CBC	Reticulocytosis; increased polychromasia, decreased plasma proteins	Reticulocytosis, increased polychromasia, increased MCHC, red plasma	No reticulocytosis, no polychromasia, other cytopenias
Chemistry	Increased BUN versus creatinine (GI bleeding), panhypoproteinemia, hyperbilirubinemia (internal hemorrhage)	Hyperbilirubinemia	
Urinalysis	Hematuria (if urine loss is the cause), bilirubinuria (internal hemorrhage)	Golden-orange urine, pigmenturia without hematuria, bilirubinuria	

apparent as the amount of blood loss is too small. Long-term external bleeding will lead to iron deficiency with the typical nonregenerative, microcytic, hypochromic anemia. However, in the early stage, the anemia will be strongly regenerative, and for this reason, the primary cause might be missed. Changes in hematological indices over time can be useful in these cases to identify the primary cause.

Excessive destruction of mature RBCs results in regenerative anemia unless the hemolysis is peracute and, therefore, preregenerative. Support for hemolysis as the cause of anemia includes yellow plasma or mucous membranes (icterus), red plasma (hemolysis), and hemoglobin in the urine (hemoglobinuria). Since icterus may occur with other disease processes (e.g., liver disease or cholestasis), it is not pathognomonic for hemolysis. Panhypoproteinemia is not an expected finding of hemolysis.

Decreased RBC production causes nonregenerative anemia. Therefore, reticulocyte counts are typically within normal limits or decreased. Icterus or hemolysis does not typically occur, but both can occasionally be seen with precursor immune-mediated anemia or if there is concurrent liver or cholestatic disease. Nonregenerative anemia is not directly linked with panhypoproteinemia. The main causes of nonregenerative anemia include anemia of endocrine disease, anemia of inflammatory or chronic disease, anemia of chronic kidney disease (CKD), bone marrow disease, and late-stage iron-deficiency anemia.

The severity of the anemia can also allude to the cause, as marked anemia is typically seen with hemolysis or with bone marrow disorders. Although it can also be seen in animals with CKD due to a lack of erythropoietin production, this is only expected in animals with advanced disease (see ahead given in the text). For this reason, further investigation is required in an animal with marked anemia and early-stage kidney disease.

The combination of the severity of the anemia and clinical signs is also useful to categorize the type of anemia. A dog or a cat with moderate-to-severe anemia without clinical signs, such as tachycardia, tachypnea, change in appetite, or lethargy, is likely to have chronic anemia. Signs will be more pronounced in an animal with acute anemia or with decompensation of end-stage chronic anemia.

Management

Principles of Transfusion Therapy

Blood transfusion depends on the etiology, severity, and chronicity of the anemia. Whole blood contains both red blood cells and clotting factors. Whole blood can be centrifuged and separated into packed RBCs (pRBCs, RBCs without plasma) that can be stored up to 5 weeks at –4°C and fresh frozen plasma (FFP) that can be stored for at least a year at –20°C. Less readily available products include platelet-rich plasma or platelet concentrates.

A patient that is anemic secondary to significant blood loss will benefit from whole blood transfusion to replenish RBCs and plasma that have been lost (hypovolemic anemia). If not available, the animal will benefit from pRBC to improve the oxygen-carrier capacity and fluid therapy as required.

If coagulopathy is causing blood loss and anemia, then FFP or whole blood should be given to correct the underlying problem, if warranted (see Chapter 17). If the amount of blood loss is significant, whole blood transfusion or pRBC will also be needed.

If the origin of the anemia is hemolysis or bone marrow disorder (isovolemic anemia), then pRBC is the product of choice. Although pRBC might also be beneficial in marked anemia of renal disease, treatment of the primary cause (erythropoietin deficiency) is likely to be more useful long term with iron supplementation (see Chapter 13).

Whole blood should not be used to replenish platelets in a thrombocytopenic animal, but platelet products should be used, if available. Animals with significant bleeding will need RBCs as required until the platelet count has improved. Similarly, albumin cannot be significantly replenished with blood products.

Rapid decreases in RBC mass can cause more severe clinical signs and patient outcomes, since physiologic compensation mechanisms are more easily overwhelmed. However, slow daily decreases in PCV of 0.01–0.03 L/L (1%–3%) may not cause clinical signs. Generally, replacement therapy in chronic anemia may not be warranted until the PCV drops below 0.20–0.25 L/L (20%–25%), since compensatory mechanisms begin to fail at lower RBC masses. When the PCV reaches 0.12–0.15 L/L

(12%–15%), transfusion therapy is usually strongly recommended, especially if sedation or anesthesia is required for workup (e.g., bone marrow sampling).

There is not a single trigger to determine when a specific animal requires a transfusion, and the clinician needs to take an educated guess accounting for the breed normal hematocrit (e.g., Greyhounds have a higher normal PCV and might require a transfusion earlier than other breeds), the clinical signs (lethargy, tachycardia) at rest, hyperlactatemia, and other signs.

Pretransfusion testing should be performed to ensure efficacy of treatment and patient safety. The clinician should consider running these tests in advance if the animal is likely to require a transfusion urgently to save time if not cost prohibitive. Pretransfusion compatibility testing includes blood typing and cross-matching. Blood typing detects RBC antigens, while cross-matching detects the presence of anti-RBC antibodies in plasma or serum.

Dogs do not have naturally occurring RBC alloantibodies. Therefore, dogs develop alloimmune RBC antibodies when they are exposed to foreign RBCs during pregnancy, parturition, or blood transfusion. At least 12 dog erythrocyte antigens (DEAs) have been identified, but DEAs 1.1, 1.2, 4, 7, and Dal are most likely to induce alloantibody formation. Blood typing is not essential prior to a nonparous patient's first blood transfusion, but administering DEA 1.1-positive blood to a DEA 1.1-negative dog will reduce the blood donor pool if subsequent blood transfusions are needed. Cross-matching is also not essential for a transfusion in a naïve dog but is recommended if repeated transfusion is required after 4 days from the first one, as alloantibodies develop in this time frame.

Cats have three major RBC types: Type A, type B, and type AB. Type A is the most prevalent blood type in the United States, with type B cats more commonly identified in Europe and Australia; type AB cats are rare. Exotic breeds of cats, including Abyssinians, Birmans, Persians, Himalayans, and Rexes, have an increased prevalence of type B blood. RBC alloantibodies occur naturally in cats except in type AB cats, which do not produce A or B alloantibodies. At a minimum, all cats should be blood typed prior to their first blood transfusion to ensure they receive appropriate type A or type B blood. However, only typing for A and B antigens carries a slight risk of not identifying other natural occurring alloantibodies, such as the Mik antigen. If blood typing is not available, a cross-match should be performed. Similar to dogs, cross-matching should be performed if blood is administered 4 or more days after the first transfusion.

During cross-match testing, incompatibility between patient and donor manifests itself as hemolysis and/or agglutination in either the major or minor cross-matches (Table 16.6). If the donor autocontrol displays either hemolysis or agglutination, it is best not to use it. If the donor autocontrol displays these changes, the major and minor cross-match results will be difficult, if not impossible, to interpret. A major cross-match incompatibility indicates that the donor's blood may not be used. However, incompatibility in the minor cross-match may not prevent use of the donor's packed RBCs if a better match cannot be found. The decision is up to the clinician, and the blood transfusion should be carefully monitored.

TABLE 16.6 Standard cross-matching procedures used to detect transfusion incompatibility

- Collect from each patient and donor, 1 tube for serum (red top) and 1 tube for cells (purple top)
- Wash cells 3 times in 0.9% saline
- Add 4.8 mL saline to 0.2 mL RBCs to make a 4% cell suspension
- Red cells and serum mixtures
  - *Major cross-match:* Donor RBCs (0.1 mL or 2 drops) + patient serum (0.1 mL or 2 drops)
  - *Minor cross-match:* Patient RBCs (0.1 mL or 2 drops) + donor serum (0.1 mL or 2 drops)
  - *Donor control:* Donor cells (0.1 mL or 2 drops) + donor serum (0.1 mL or 2 drops)
  - *Patient control:* Patient cells (0.1 ml or 2 drops) + patient serum (0.1 ml or 2 drops)
- Incubate each mixture in a glass tube for 15 minutes at 37°C (98.6°F) to evaluate compatibility; additional incubations at room temperature and 4°C (39.2°F) may be performed to identify cold agglutinins and hemolysins
- Centrifuge tubes at 280 g for 1 minute
- Examine the supernatant for hemolysis in all cross-matches, including autocontrols; report the presence of hemolysis relative to autocontrols
- Examine cell suspension for gross and microscopic agglutination in all cross-matches, including autocontrols (agglutination is defined as the collection of three or more RBCs), report the presence of agglutination relative to autocontrols

Blood Transfusion

The goal of transfusion therapy is to provide the anemic patient with sufficient oxygen-carrying particles (RBCs) to alleviate clinical signs of hypoxia but with as little product as necessary so as to reduce the likelihood of transfusion reactions and volume overload. Smaller dosages may be needed in chronic anemias due to the presence of physiologic compensation and internal blood loss anemia, since hemorrhaged RBCs will reenter the circulation (approximately 50% over 24 hours). Discussion on fluid type, rate, and monitoring for resuscitation of severe hemorrhage is discussed in depth in Chapter 23. In these cases, the patient should be monitored for hypocalcemia and hypomagnesemia secondary to citrate anticoagulant administration.

In general, the optimal component for normovolemic patients (e.g., normovolemic blood loss anemia, hemolysis, bone marrow disorder) is packed RBCs with the aim to increase the oxygen-carrying capacity. Hypovolemic blood loss anemia is best treated with packed RBCs and fluids (e.g., crystalloid or colloid solutions) in separate lines and into different veins or alternatively whole blood transfusion. Product availability often dictates which component will be administered.

The blood product is typically administrated via a peripheral or jugular vein, although intraosseous access

can be used in neonates. Initial dosages are typically 6–10 mL packed RBCs/kg or 10–20 mL whole blood/kg. Dosage as low as 5 mL/kg/day might be needed in animals with heart disease. Animals with preexisting heart disease, that are normovolemic but transfused with whole blood, should be carefully monitored for fluid overload, especially cats.

Appropriate filters and administration sets must be used to retain clotted blood or debris. The blood does not need to be warmed prior to administration. For the first 30 minutes, the initial rate of administration should be kept slow (e.g., up to 0.5 mL/kg/h) in order to observe any incompatibility reactions (see ahead given in the text). After initial transfusion, normovolemic patients can receive rates of 10–20 mL/kg/h, but hypovolemic patients with acute anemia may require higher rates depending on the individual needs. Slow transfusion rates are recommended for patients with cardiac disease, but any transfusion should be given within 4–6 hours of initiating treatment. The blood product should be considered contaminated after this time frame. An estimate is that 2.2 mL/kg of whole blood will increase the recipient hematocrit by about 1%.

Transfusion reactions can be divided in acute (within the first 48 hours) and delayed as well as immunological versus nonimmunological. Examples of nonimmunological reaction include fever, citrate intoxication (with high transfusion rate or significant liver impairment), fluid overload, and disease transmission. Immune-mediated hemolysis can be acute (within minutes) with signs such as tremor, fever, or vomiting. Delayed hemolysis is characterized by rapid decline of the RBCs with concurrent hemoglobinemia and hyperbilirubinemia starting a few days after the transfusion. It can be difficult to differentiate between ongoing immune-mediated destruction of the animal's own red cells versus a delayed transfusion reaction. A common complication in people is a transfusion-related acute lung injury (TRALI) that seems to be infrequent in dogs (3.7% of cases in one study).

In view of the potential life-threatening complications and rapid onset, it is important to closely monitor animals receiving blood products prior and during transfusion. An example of protocol is to acquire a baseline prior transfusion on a monitoring sheet (body temperature, heart rate, respiratory rate, and blood pressure). The transfusion is started at a slow rate, and any signs of vomiting, pruritus, or change in the baseline are monitored every 5–10 minutes for the first 30 minutes. If the transfusion is tolerated, the rate can be increased to the desired flow, and monitoring continues every 30 minutes thereafter. The transfusion should be discontinued if severe signs are noted (e.g., urticaria, vomiting, diarrhea, or collapse). If the animal develops a fever, the transfusion should be stopped, and the animal monitored for 15–30 minutes prior to deciding to continue the transfusion at the same or a lower rate. Overall efficacy of the blood transfusion is assessed by measuring the Hct, PCV, or Hgb prior to and after the administration of whole blood or packed RBCs If not initially hemolyzed, transfused RBCs have a half-life of approximately 21–35 days but shorter if there is ongoing destruction.

Xenotransfusion

Xenotransfusion from dogs to cats has been reported. Although, the literature on the subject is sparse, there is one recent large case series of 49 cats receiving xenotransfusion. No severe acute adverse reaction has been reported in different studies, but delayed hemolytic transfusion reaction within 2 days was noted in 64% of cats (25 out of 39 cats) surviving the first 24 hours in the largest study. Reasons to consider xenotransfusion include lack of adequate feline blood products, life-threatening emergencies, and financial constraints. For this reason, despite the low risk of severe acute adverse reaction, a delayed hemolytic transfusion is likely. Xenotransfusion might be successful if the anemia is expected to become regenerative timely and can be quickly controlled (e.g., such as acute blood loss during surgery or after trauma).

REGENERATIVE ANEMIA

Regenerative anemia is anemia with increased numbers of reticulocytes in the blood. It identifies the cause of the anemia as RBC loss from blood vessels or RBC destruction. Depending on the severity of hemorrhage or hemolysis, the regenerative response may be mild to strong. In some cases, the anemia may occur so rapidly that the animal may have too little time to mount a regenerative response by the time the condition is recognized. A period of 2–3 days is necessary for RBC maturation once the stimulation from hypoxia has occurred. Therefore, anemia due to hemorrhage or hemolysis may appear nonregenerative during this preregenerative phase. In a stable animal with mild-to-moderate anemia, sequential CBCs over 3 days can help differentiate preregenerative anemia from nonregenerative anemia.

ACUTE BLOOD LOSS

Definition/Overview

Whole blood is lost from the blood vessels. Hemorrhage may be internal (e.g., abdominal, thoracic, or pericardial cavities) or external (e.g., GI tract, urinary tract, respiratory tract, or open wounds).

Etiology

Common causes of blood loss include trauma, surgery, intracavitary bleeding lesion (mass, organ rupture such as spleen), external and internal parasitism, gastric ulcers, tumors of the GI and urinary systems, and phlebotomy (Table 16.7). Repeat phlebotomy can be a significant cause of blood loss in hospitalized small dogs and cats.

TABLE 16.7 Common causes of blood loss

- Trauma
- Surgery
- External and internal parasitism
- Gastric or intestinal ulcers
- Tumors of gastrointestinal and urinary systems
- Splenic rupture
- Coagulation abnormalities
- Thrombocytopenia
- Iatrogenic (repeat phlebotomy in a small dog or cat)

Pathophysiology

Large volumes of blood must be lost before appreciable changes occur in the number of erythrocytes or PCV. The immediate loss of blood results in little or no change to the PCV, owing to the concurrent and proportional loss of RBCs and plasma. To increase blood volume and pressure, the body redistributes fluid from the extravascular space to the intravascular space over the course of several hours to days. This results in a lowered PCV and plasma protein concentration. Physiologic alterations to acute blood loss include preservation of perfusion of the brain, heart, and viscera by restricting blood flow to less essential tissues (e.g., skin). Table 16.8 lists differences in findings that can help the clinician to differentiate an animal with blood loss versus hemolysis (immune mediated or not).

Clinical Presentation

Animals with acute blood loss (>20% of normal blood volume) will present with abnormal perfusion that can be assessed with mucous membrane (MM) color, CRT, heart rate, and pulse quality. This is the result of several hemodynamic mechanisms directing blood away from less essential tissue to preserve the perfusion of important organs such as the brain and heart. An animal with mild hypovolemia will have normal/pink MM, normal CRT (<1s), mild tachycardia with increased pulse amplitude. If hypovolemia progresses, the animal will develop pale pink MM with a normal CRT and decreased pulse amplitude. With severe hypovolemia and decompensated shock, the MM become white or muddy, the CRT is prolonged to not measurable, and the pulse amplitude is severely decreased. Such animals develop hypotension and might also be profoundly lethargic with cold extremities and skin and be hyperlactemic. Blood losses of >50% normal blood volume cause shock and death within hours.

Differential Diagnosis

Bleeding secondary to disorders of primary (marked thrombocytopenia) or secondary hemostasis, hemolytic conditions.

Diagnosis

Physical examination for external wounds, obvious parasites load, including rectal examination for melena. TFAST and AFAST to assess a source of bleeding. As mentioned before, a PCV/TP and CBC are recommended to assess the animal including platelet count but will be normal in an acute setting. Serial measurements of PCV/TP will be helpful to confirm a decrease with time and fluid therapy.

Other diagnostic tests include buccal mucosal bleeding time and coagulation testing to rule out hemostasis disorders. If no obvious cause is determined, further considerations include thorough abdominal and thoracic

TABLE 16.8 Changes in findings between blood loss, immune-mediated hemolysis, and nonimmune-mediated hemolysis

	Blood loss	Hemolysis (immune-mediated)	Hemolysis (not immune-mediated)
Source of bleeding	Often evident†	None	None
Icterus	Rare‡	Often	Often
Hepatomegaly/splenomegaly	Rare	Often	Often
Plasma or serum protein concentration	Normal to low	Normal to high	Normal to high
PCV	Normal to low§	Low	Low
Hemoglobinemia/Hemoglobinuria	No	Often / Often	Yes / Yes
Autoagglutination	No	Possible	Possible*
Spherocytosis	No	Likely	Rare*
Direct Coombs test	Negative	Likely positive	Rarely positive*
RBC changes	Signs of regeneration	See Table 16.3	See Table 16.3

* Hemolysis secondary to an infectious process can have an immune-mediated component, and for this reason, infectious diseases need to be ruled out from history and specific testing. No autoagglutination or spherocytosis would be expected from oxidant-induced hemolysis.

† If the bleeding is in the gastrointestinal tract or urinary tract and in small amount, detection can be difficult.

‡ Icterus is possible with significant internal bleeding; however, the source is likely to be evident from physical examination and diagnostic imaging.

§ PCV will be normal with an acute blood loss until fluid shift has occurred.

imaging, urinalysis for hematuria, fecal floatation, and fecal occult blood. If present and safe (adequate hemostasis), sampling of body cavity fluid or abnormal findings for cytology is indicated. Blood sampled from a cavity will not clot as platelets have been consumed; therefore, a sample can be placed in a tube without additive for a few minutes to confirm the absence of clotting and ensure that the spleen or the liver was not inadvertently sampled during the procedure.

If there is a strong suspicion for significant GI bleeding, endoscopy can be used to assess the stomach and proximal duodenum as well as distal ileum. However, the lesion can be out of reach in which case capsule endoscopy (such as ALICAM®) or explorative laparotomy might be indicated if there is strong evidence of GI bleeding. Limitation to the use of an endocapsule include failure to enter the duodenum before the battery dies and inability to obtain biopsies. In rare cases, significant bleeding from the respiratory tract is ingested by the animal, and thoracic imaging +/– bronchoscopy will be required to achieve a diagnosis.

Management

See Chapter 21 for treatment of hypovolemic shock and blood transfusion. Blood products should be considered when acute hemorrhage causes the PCV to drop to 0.2–0.25 L/L (20%–25%) in the dog or cat during stabilization.

HEMOLYTIC ANEMIA

Hemolytic anemia is most commonly a result of immune-mediated destruction, RBC parasites, oxidant-induced injury, or mechanical fragmentation (micro-angiopathy). Blood smear evaluation has a critical role in differentiating the causes of hemolysis (Table 16.9) and, therefore, the appropriate disease treatment. Other differences between blood loss versus hemolytic process are listed in Table 16.8.

PRIMARY (NONASSOCIATIVE OR IDIOPATHIC) IMMUNE-MEDIATED HEMOLYTIC ANEMIA

Definition/Overview

IMHA is antibody- and complement-mediated RBC destruction. It is subclassified into primary or nonassociative IMHA and secondary or associative IMHA. Both terminologies will be used synonymously for the remainder of this section. The nonassociative form is characterized by a dysregulated immune system that produces antibodies against unaltered RBC surface antigens in the absence of an identifiable cause (truly idiopathic or unrecognized trigger). Associative or secondary IMHA may occur as a sequela to infection, drugs, or neoplasms that typically alter RBC surface antigens. In some instances, it is impossible to determine if the comorbidity is the cause for the IMHA (secondary) or coincidental; therefore, the term associative has been suggested. Associative or primary IMHA is the most common form of IMHA in dogs. Although previous reports in cats suggested that feline IMHA was more frequently associative, especially with concurrent FeLV infection, more recent studies suggest that primary IMHA is more common in cats as well.

Etiology

The etiology of nonassociative IMHA is unknown, but regulatory T-lymphocyte dysfunction, defects in central or peripheral tolerance, cross-reactivity with self- and foreign antigens, and exposure of hidden antigens have been implicated. It may be associated with systemic lupus erythematosus (SLE) or other autoimmune disease.

TABLE 16.9 Potential erythrocyte abnormalities with main causes of hemolysis

Abnormality	Immune-mediated	Infectious	Oxidant-induced	Micro-angiopathy
Ghost cells	✔	✔	✔	
Agglutination	✔	✔		
Spherocytes*	✔	✔		
RBC parasites		✔		
Heinz bodies†			✔	
Eccentrocytes			✔	
Methemoglobinemia			✔	
Schistocytes				✔
Acanthocytes				✔
Keratocytes				✔

* Spherocytes are difficult to identify in cats since their red cells normally lack central pallor.

† Up to 15% of feline RBCs may normally contain Heinz bodies. In addition to oxidative toxicosis, increased Heinz bodies in cats may occur with hyperthyroidism, diabetes mellitus, and lymphoma.

Pathophysiology

Antibodies of the IgG subclass are most commonly implicated in canine IMHA, but IgM antibodies and complement may also contribute to disease. The variable fragment of the antibody binds the RBC surface antigen, marking it for removal by the monocyte–macrophage system or activating the classical complement pathway. Splenic macrophages, and to a lesser degree hepatic macrophage (Kupffer cells), bind the constant fragment of the RBC-bound antibody. The macrophages either completely phagocytize the RBC and remove it from circulation or only phagocytize a part of the RBC membrane. Completely phagocytized RBCs are digested, and the hemoglobin is converted to bilirubin, which results in clinical icterus and hyperbilirubinemia. The partially phagocytized RBC remains in circulation but with an abnormal RBC morphology (spherocyte). Therefore, spherocytes on a blood smear indicate RBC lysis by macrophages (extravascular hemolysis). Activation of the classical complement pathway can lead to membrane attack complex formation and subsequent RBC lysis within the blood vessel (intravascular hemolysis). The lysed RBC releases its intracellular contents into the plasma, which results in hemoglobinemia and subsequent hemoglobinuria if the haptoglobin savage system is overwhelmed. The lysed RBC membranes can be visualized on a blood smear as ghost cells. In vivo agglutination of RBCs occurs when IgM or high titers of IgG molecules cause bridging of RBCs.

Common causes of death in canine IMHA are tissue hypoxia due to anemia, and thromboembolic disease, including disseminated intravascular coagulation (DIC) and pulmonary thromboembolism.

Clinical Presentation

Primary IMHA may occur in dogs of any signalment, but young adult to middle-aged dogs, females, and several breeds (American Cocker Spaniel, Bichon Frise, Collie, English Springer Spaniel, Finnish Spitz, Miniature Pinscher, Miniature Schnauzer, Old English Sheepdog, and Poodle) have an increased risk of disease. In dogs, the mean age is 5–6 years, with a reported range of 1–13 years. In feline IMHA, cats less than 6-year-old are overrepresented. Although males have been reported to be more frequently represented, this was not the case in a larger study with inclusion of a control group.

Clinical signs vary with the severity and duration of onset of the anemia but often include lethargy, depression, weakness, and anorexia. Collapse, vomiting, diarrhea, tachypnea, and polydipsia are less common. Multisystemic hemorrhages may occur secondary to DIC, whereas pigmenturia may occur with intravascular hemolysis.

Pale mucous membranes are the most common physical examination finding, but patients may also exhibit tachycardia, tachypnea, icterus, and fever. A systolic heart murmur may occur from increased turbulences due to low red blood cell content. Due to extravascular phagocytosis, splenomegaly and/or hepatomegaly may

FIGURE 16.10 Cold agglutinin disease demonstrating necrotic ear tips. (*Courtesy of J. Thompson.*)

be detected. If the patient's autoantibodies are primarily active below normal core body temperatures (cold agglutinins), then clinical signs may be most prominent at the cooler extremities, particularly necrosis of the tail, ear tips, nose, and nail bed (Figure 16.10).

Differential Diagnosis

Other causes of hemolysis, including infectious hemolytic anemia, oxidant-induced hemolytic anemia, congenital erythrocyte defects, hypophosphatemia, envenomation, mechanical fragmentation, and hemophagocytic histiocytic sarcoma. Hemorrhage.

Diagnosis

CBC often reveals severe to moderate (0.05–0.3 L/L [5%–30%]) anemia with evidence of regeneration (reticulocytosis and polychromasia) and support for regeneration (increased MCV, decreased MCHC, anisocytosis, nucleated RBCs in circulation [metarubricytosis, rubricytosis, or normoblastemia], Howell–Jolly bodies, basophilic stippling, and siderocytes). Identification of agglutination or spherocytes confirms an immune-mediated etiology for the anemia (Figures 16.11–16.13);

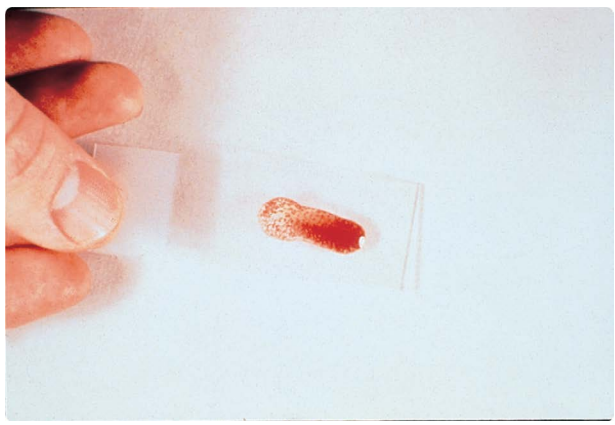

FIGURE 16.11 Gross appearance of macroscopic agglutination. (*Courtesy of J. Thompson.*)

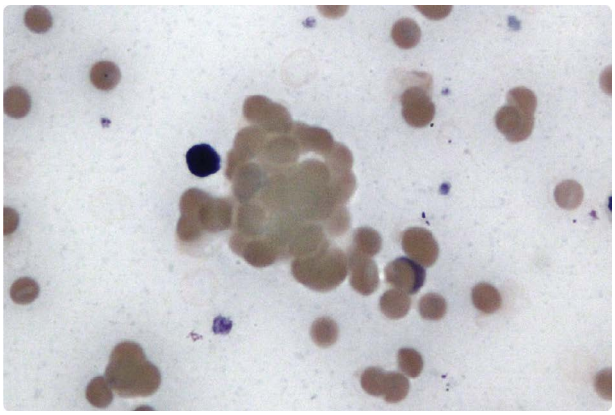

FIGURE 16.12 Microscopic RBC agglutination on a Romanowsky-stained blood smear.

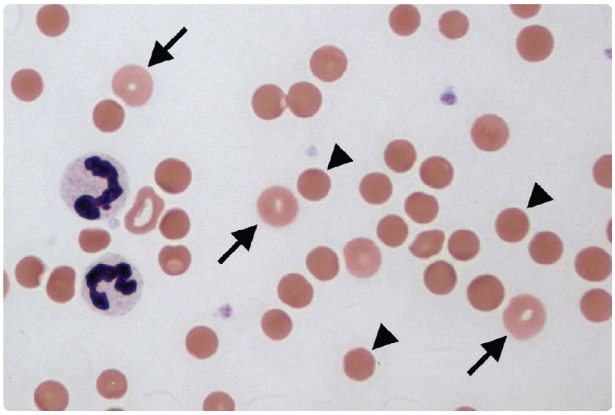

FIGURE 16.13 Compared with normal RBCs (arrows), spherocytes (arrowheads) are more eosinophilic, appear smaller, and lack central pallor.

FIGURE 16.14 Rouleaux formation in a wet mount of blood before the addition of saline to dilute or reduce cell adherence. (*Courtesy of J. Thompson*.)

FIGURE 16.15 Wet mount of blood demonstrating tight red cell clusters following addition of saline, indicating true agglutination. (*Courtesy of J. Thompson*.)

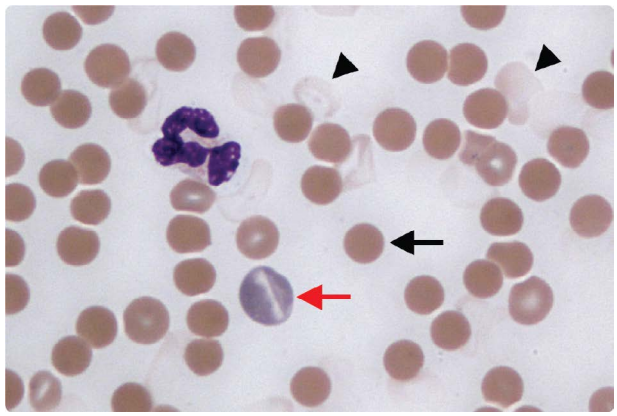

FIGURE 16.16 Blood smear from a dog with immune-mediated hemolytic anemia shows spherocytes (black arrow), ghost cells (arrowheads), and one polychromatophil (red arrow).

however, agglutination can be seen with some infectious etiologies, and spherocytes are difficult to appreciate in cats, since their RBCs normally lack central pallor. The saline test is helpful in distinguishing agglutination from rouleaux. A drop of physiologic saline is mixed with a drop of blood and then examined as a wet mount. The dilution will reduce rouleau formation, but agglutinated RBCs remain in tight clusters (Figures 16.14 and 16.15). Ghost cells may be seen with intravascular hemolysis (Figure 16.16). The leukogram is often inflammatory and is characterized by moderate-to-marked neutrophilia with increased band neutrophils (left shift), variable lymphocyte counts, and monocytosis. Neutrophil toxicity is usually absent or mild. Despite the marked neutrophilia, there is no active infectious trigger in nonassociative IMHA, hence antibiotic treatment is not required. Neutrophils may contain hemosiderin, and monocytes may exhibit erythrophagocytosis. Thrombocytopenia is present in 25%–70% of dogs with IMHA and may be due to concurrent immune-mediated platelet destruction (Evans syndrome) or DIC. Although many cats are not regenerative at presentation, regeneration will occur in a large proportion within 5 days. Cats also have frequently a lymphocytosis at presentation. Cats with nonassociative anemia have been reported to have higher albumin and lymphocyte count than cats with associative anemia.

However, this is of limited use clinically as there is a large overlap between both populations.

Serum biochemistry findings may include hyperbilirubinemia due to enhanced RBC destruction, and elevations in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activities with hypoxic liver injury. Alkaline phosphatase (ALP) activity may be increased with cholestasis and, in the dog, stress.

Urine may be golden or orange due to bilirubinuria or red due to hemoglobinuria (intravascular hemolysis). Proteinuria may be attributed to hemoglobinuria or renal injury secondary to immune complex deposition, hypoxia, or hemoglobin nephropathy. Cylindruria may present as Hgb or granular casts.

A direct antiglobulin test or Coombs test identifies antibody and complement on the surface of RBCs and is used to diagnose IMHA in the absence of spherocytosis and agglutination. The Coombs test may be positive in up to 75% of animals with IMHA. For this test, the patient's washed RBCs are combined with antiglobulin reagent. This reagent contains species-specific antibodies that bind complement and the Fc portion of the patient's antibodies. When the patient's complement and antibodies are bound to the patient's RBCs, the antiglobulin reagent creates antibody bridges and induces RBC agglutination. Agglutination, when observed, is diagnostic for the presence of antibody-coated erythrocytes. A positive Coombs test may also occur with secondary hemolytic anemias, lymphoproliferative disorders, and immune-mediated thrombocytopenia. False-negative results may occur with the recent use of corticosteroids or low levels of antibody present on the red cell surface. Flow cytometry is another valuable tool to detect the presence of antibody on the surface of erythrocytes.

Figure 16.17 describes an approach to determine if an animal is likely to have immune-mediated hemolysis. After confirming the anemia, the first step is to assess the animal for signs of RBC immune-mediated destruction, and the second step is to determine if there are signs of hemolysis.

Once an IMHA is suspected or confirmed, then additional tests such as diagnostic imaging and testing for blood-borne infectious agents should be pursued to rule out causes of associative IMHA that are relevant for the animal. In the absence of other relevant causes, a diagnostic of nonassociative IMHA is reached.

Management

Specific recommendations for IMHA treatment remain challenging, as there is a paucity of well-designed studies to compare treatment options as recently reviewed (recommended further reading: ACVIM statements). Treatment considerations for nonassociative IMHA

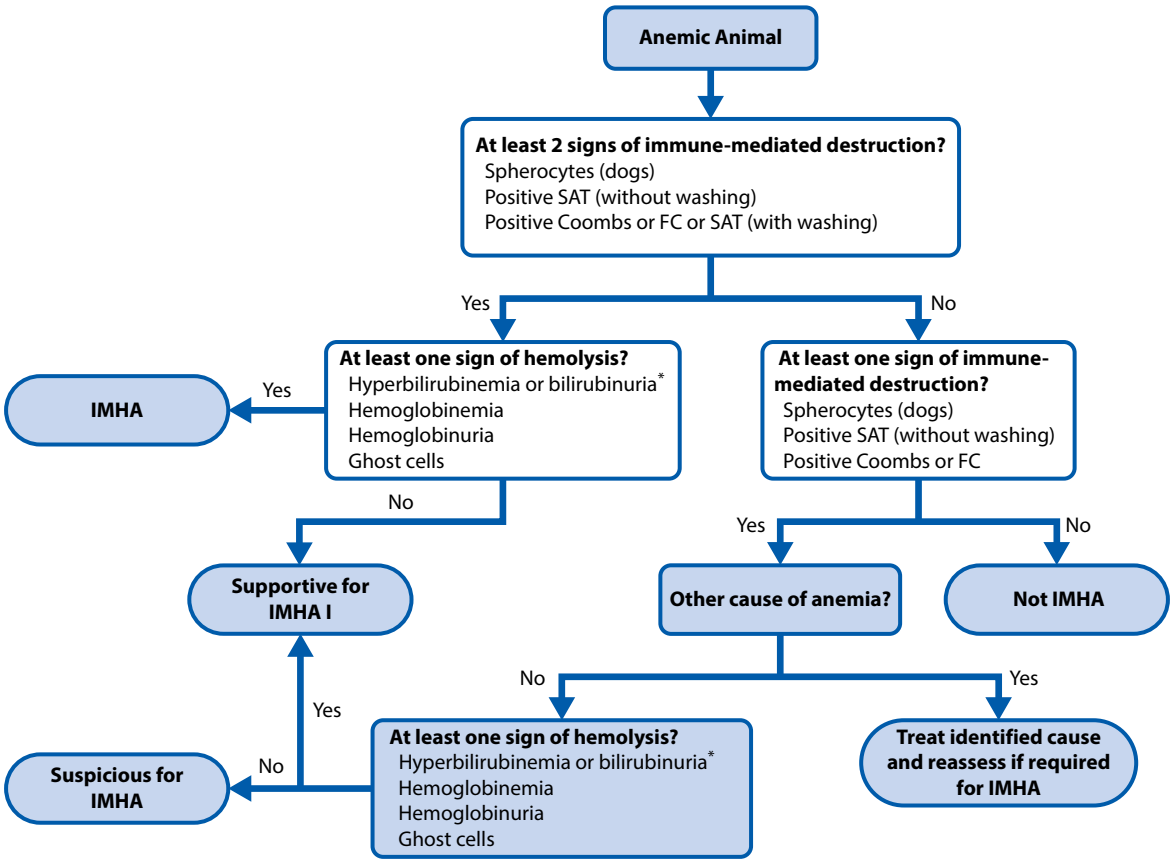

FIGURE 16.17 Flow chart to determine the likelihood of an animal to have primary or secondary IMHA. FC, flow cytometry; SAT, saline-agglutination test. *In the absence of hepatic or posthepatic cause. Clinically, icterus confirms the presence of hyperbilirubinemia.

include blood transfusion (as required), immunosuppression, and thromboprophylaxis, as thromboembolism is a frequent complicating factor.

Steroids are the mainstay treatment of IMHA as they are cheap, have a rapid onset of action, and several mechanisms of action such as inhibition of phagocytes, decreased complement and antibody bindings to the erythrocytes, and suppression of Ig production (over a few weeks). Severity of clinical signs and presence of negative prognostic factors such as intravascular hemolysis, increased bilirubin or urea might warrant more aggressive treatment. The use of some modalities is limited by the cost and availability (e.g., intravenous immunoglobulins [IVIG], plasmapheresis). For this reason, the clinician needs to make treatment decisions according to the animal, comorbidities, financial and emotional status of the owners without a fit-all answer.

An example of a decision tree to start immunosuppressant treatment is outlined in Figure 16.18. The owners need to be warned that the treatment will last for several months (typically >4–6 months) with a reduction of steroid side effects during tapering. Considerations for a second-line immunosuppressant include severe or life-threatening disease, no response to prednisolone monotherapy within 1–2 weeks, expected marked steroids side effects (dogs >25 kg or known side effects from previous treatment), and relapse early with steroids tapering. Common drugs, dosages, and monitoring are summarized in Table 16.10.

Starting dose for oral prednisone or prednisolone is 2 mg/kg pertuzumab day for 1–2 weeks. There is evidence that large dogs have increased prednisolone plasma concentration at the same dosage as small dogs. Consequently, side effects are worse without increased immunosuppression, and life quality of the animal can become unacceptable for owners (e.g., incontinent dog too weak to go outside to urinate), leading to euthanasia due to side effects rather than lack of control of the IMHA. For this reason, the recommendation for large dogs is to dose by body surface rather than weight (40–50 mg/m^2 q.24 h.). Parenterally administered dexamethasone (0.1–0.2 mg/kg IV q.12 h.) can be used initially if the patient is unable to receive oral medications.

If the initial dosage of prednisolone is higher than 2 mg/kg/day, the clinician should aim to reduce it to less than 2 mg/kg/day 1–2 weeks after starting treatment. If the disease is not controlled after this time, then the addition of a second-line immunosuppressant should be considered.

There is currently no clear evidence to help the clinician choose the best second-line treatment, and several options are available (Table 16.10). Azathioprine and cyclosporine have been used historically as second-line treatment and more recently mycophenolate mofetil (MMF), whereas only little information is available for leflunomide. Cyclosporine has the advantage of not being bone marrow suppressive. In cats, chlorambucil is used instead of azathioprine. The use of cyclophosphamide is not recommended, as there is evidence suggesting a worse prognosis with it.

Cyclosporine is a very potent immunosuppressant. Microemulsified cyclosporine is recommended, and the clinician needs to be aware that compounded cyclosporine might be differently absorbed than commercial

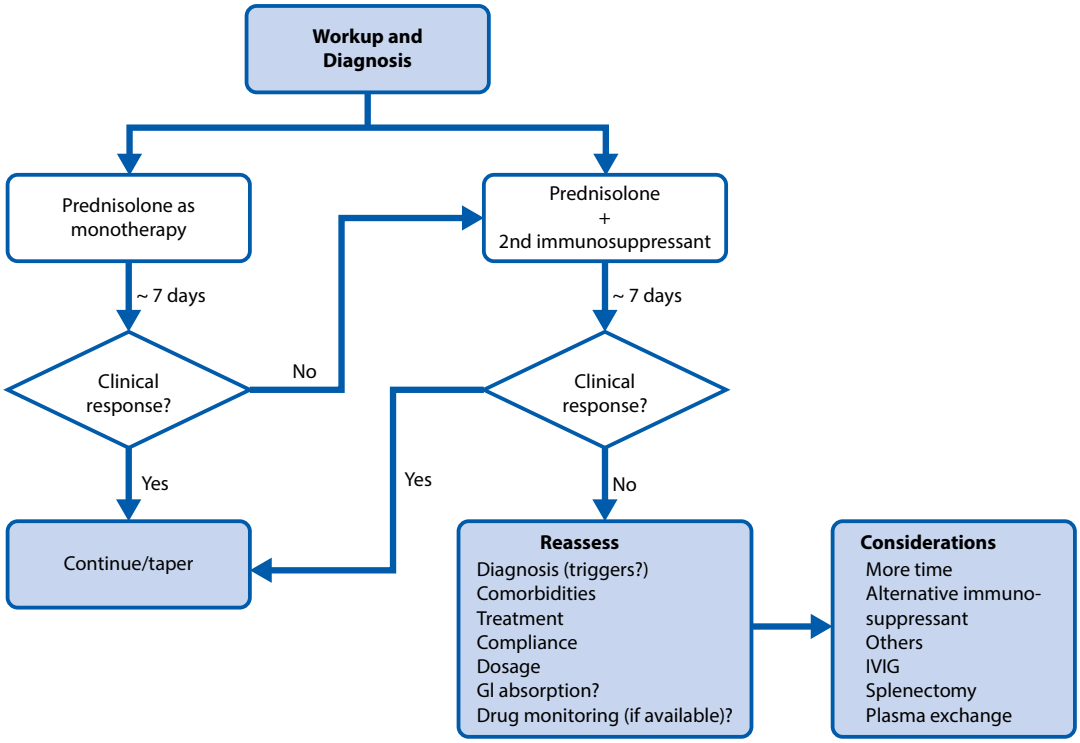

FIGURE 16.18 Decision tree for treatment of dogs diagnosed with nonassociative (primary) IMHA. GI, gastrointestinal; IVIG, intravenous immunoglobulin.

TABLE 16.10 Immunosuppressant dosages, common adverse effects, and suggested monitoring

Drug	Dog	Cat	Adverse effects	Monitoring suggestion*
Prednisolone	<25 kg: 2 mg/kg q.24 h. >25 kg: 40–50 mg/m^2 q.24 h.[2†]	2 mg/kg q.24 h.	– PU/PD, polyphagia, panting, (D) urinary incontinence, muscle loss and weakness, lethargy, diabetes	– CBC, biochemistry every month for 3 months, then every 2–3 months – Cats: Every month for the first 3 months
Cyclosporine	10 mg/kg p.o. q.24 h. (or divided q.12 h.)	3–4 mg/kg p.o. q.12 h. 5–7 mg/kg p.o. q. 24 h.	– Nausea, anorexia, vomiting, diarrhea – Gingival hyperplasia	– CBC, biochemistry every month for 3 months, then every 3–6 months – Consider therapeutic drug monitoring
Azathioprine	2 mg/kg p.o. q.24 h. for 2 weeks, then q.48 h.	Not recommended	– Nausea, anorexia, vomiting, diarrhea – *Less frequently:* Hepatotoxicity, myelosuppression	– CBC, ALT/ALP every 2 weeks for the first 8 weeks, every 1–3 months after
Chlorambucil	2–4 mg/m^2 p.o. q.24 h.	1.5–4 mg/m^2 p.o. q.24 h. or 15 mg/m^2 p.o. q.24 h. for 4 days every 3 weeks or 20 mg/m^2 p.o. every 2 weeks	– Vomiting, diarrhea – Anemia, leukopenia, thrombocytopenia – Neurotoxicity – Fanconi syndrome (C)	– Repeat CBC after 1 month, thereafter every 2–3 months – Biochemistry and urinalysis (inc. UPC every 3 months)
Mycophenolate mofetil	8–12 mg/kg p.o. q.12 h.	10 mg/kg p.o. q.12 h.	– Diarrhea (dose related), hyporexia	– GI side effects – CBC every 2 weeks for the first 4 weeks, every 2–3 months until discontinued
Leflunomide	2 mg/kg p.o. q.24 h.	2 mg/kg p.o. q.24 h. for 48 hours, then 2 mg/kg p.o. q.48 h.	– Diarrhea, inappetence, lethargy, unexplained hemorrhage, thrombocytopenia	– CBC, ALT/ALP every month for 3 months, then every 2–3 months – Consider TDM

* A baseline is recommended including CBC, biochemistry, and urinalysis. Urine protein-to-creatinine ratio is also recommended in cats treated with chlorambucil. Cats develop diabetes secondary to steroid treatment usually within the first 3 months of treatment.

† The author typically uses 40 mg/m^2 in dogs ≥5 kg. For example, a 40 kg dog (1.18 m^2) will receive 50 mg daily rather than 80 mg. Cats have poor hepatic methylation, and for this reason, prednisolone rather than prednisone should be used to achieve a more reliable effect.

Azathioprine: Hepatotoxicity usually develops in first 2–4 weeks, more common in GSD. Myelosuppression can occur much later in the treatment.

Mycophenolate: Hepatotoxicity reported in people but not dogs. As not commonly used, consider monitoring liver enzymes.

TDM, therapeutic drug monitoring.

cyclosporine. Therapeutic drug monitoring (TDM) is available for cyclosporine. Pharmacokinetic monitoring consists in measuring cyclosporine trough concentration (i.e., prior next dose), whereas pharmacodynamic monitoring consists in measuring inhibition of IL-2 transcription (i.e., direct effect of cyclosporine, currently only available for dogs). Pharmacokinetic or pharmacodynamic monitoring can be performed after a week of treatment and should be considered in dogs not responding to treatment, where drug interaction might affect cyclosporine pharmacokinetics (i.e., concurrent treatment with ketoconazole), or excessive immunosuppression is suspected due to secondary infections. Specific targets should be discussed with the laboratory. Cyclosporine side effects include vomiting, gingival hyperplasia, hair loss, and papilloma-like skin lesions. The gastrointestinal signs might be controlled by giving the treatment with food or freezing the capsules prior treatment.

Azathioprine is a thiopurine that inhibits purine synthesis with a complex metabolism involving the enzyme thiopurine methyltransferase (TPMT). Cats are at high risk of myelotoxicity due to low TPMT activity, and for this reason, the drug is not recommended in this species. As the drug can cause bone marrow toxicity, it is ideally avoided if the animal is neutropenic (<2,000/µL) or thrombocytopenic (<80,000/µL); however, it might be used if the cause for the bicytopenia or pancytopenia is immune mediated. Although side effects of azathioprine therapy are infrequent, they may include GI signs, hepatotoxicosis, and bone marrow toxicosis. It might also be linked to acute pancreatitis. The tablet should not be split, and the owner should handle with gloves. Chlorambucil is an alkylating agent that can be used instead of azathioprine in cats. Variable dosages have been reported (Table 16.10), and the animal needs to be monitored for immunosuppression.

MMF, as azathioprine, is also a purine inhibitor. For this reason, both drugs should not be used concurrently. The main side effect is delayed, dose-related GI signs.

There is very little information on the use of leflunomide, a pyrimidine inhibitor, and dosage frequency in cats is less than in dogs. Some rare cases of unexplained hemorrhage have been reported in dogs with the use of this drug.

If an animal requires more than two immunosuppressive drugs to control the disease, there is a high risk of secondary infection, especially if cyclosporine is one of the immunosuppressant used.

IVIG has also been used in dogs with nonassociative IMHA. The literature available does not suggest that IVIG is superior to other immunosuppressive treatment but supports quick onset of action and faster response. Other therapies, such as plasmapheresis, is likely to play a more important role in the future for severe IMHA, but there is limited information and accessibility currently.

Thromboembolism has been recognized as an important cause of morbidity and mortality in dogs with IMHA. This is particularly relevant for dogs with autoagglutination, intravascular hemolysis, and treated with high-dose prednisolone or IVIG. As thrombosis in IMHA is mostly venous (lungs, spleen, and portal vein), thromboprophylaxis with anticoagulants or anticoagulants and platelets inhibition is favored over platelet inhibition alone. Thromboprophylaxis is recommended in all dogs with IMHA except if marked thrombocytopenia is present. An arbitrary cut-off of platelets less than 30,000 x10^9/L has been suggested, which is likely to reflect destructive rather than consumptive thrombocytopenia. Recommended dosages are listed in Table 16.11, and the reader is referred to the CURATIVE and ACVIM statements for more in-depth reading. Options include unfractionated heparin or low-molecular-weight heparin (dalteparin or enoxaparin) with individual dose adjustment using anti-Xa assay. The latter is a limitation as the assay is not widely available. An alternative is to use rivaroxaban, an oral Xa inhibitor. Options for antiplatelet drugs include clopidogrel and aspirin. There is some evidence that suggest that clopidogrel is more efficacious. Thromboprophylaxis should be administered for at least 2 weeks (highest risk of thromboembolism event) but ideally until the dog is in remission.

Splenectomy has been reported as treatment for relapsing or refractory IMHA; however, there is limited information and no studies with a control population. If this treatment is considered, the clinician should exclude a vector-borne disease as much as possible, and treatment adjusted prior surgery (especially antithrombotic treatment). Cats seem to be less prone to develop thrombi than dogs.

Treatment Response Monitoring and Tapering Regime

Treatment response is characterized by increase in the PCV, normalization of the bilirubin, and resolution of the autoagglutination and spherocytosis if present. If this is achieved 2 weeks after starting treatment and the PCV is ideally ≥30%, then slow reduction of the prednisolone (up to 25%) can start. It will take time for some of the abnormalities noted at diagnosis to resolve (for example small number of spherocytes remains), but the overall picture needs to suggest treatment response. If the animal is treated with an additional immunosuppressant, more rapid reduction of the steroid can be considered (25%–50%).

The authors taper prednisolone every 2–3 weeks until the dosage is <1 mg/kg q.24 h., and every 4–6 weeks thereafter. If the animal receives a second-line immunosuppressant, alternate tapering with prednisolone can be considered once the prednisolone dosage is <1 mg/kg q.24 h. if the second-line treatment is tolerated and affordable until then. Some clinicians prefer to stop prednisolone first and then the second-line treatment 4–8 weeks later without tapering.

It is important to note that dogs may remain mildly anemic, despite control of the disease, until complete weaning of prednisolone. For this reason, a mild anemia without evidence of hemolysis should not be interpreted as a lack of response. At a minimum, PCV should be monitored prior to each reduction and 1–2 weeks after.

If there is a relapse during tapering, prednisolone should be restarted (if stopped) or increased to the last effective dose. If the animal was treated with prednisolone alone, a second-line immunosuppressant should be considered. The animal should be reassessed for possible triggers and if none is found tapering as previously described but with longer intervals between tapers once the disease is controlled again. If there is a third relapse, long-term immunosuppressive treatment might be required.

Prognosis

In general, there is guarded to poor prognosis for long-term survival in dogs. While 50%–88% of dogs with IMHA are discharged from the hospital, most die or are

TABLE 16.11 Thromboprophylaxis treatment available in dogs

Drug	Route	Dosage	Mechanism of action
Unfractionated heparin	IV SC	100 U/kg bolus, then 900 U/kg/24 h. 150–300 U/kg q.6 h.	Anticoagulant
Dalteparin	SC	150–175 U/kg q.8 h.	Anticoagulant
Enoxaparin	SC	0.8–1/0 mg/kg q.6–8 h.	Anticoagulant
Rivaroxaban	p.o.	1–2 mg/kg q.24 h.	Anticoagulant
Clopidogrel	p.o.	1.1–4.0 mg/kg q.24 h.	Antiplatelet
Aspirin	p.o.	1–2 mg/kg q.24 h.	Antiplatelet

euthanized within the subsequent 2 months. Negative prognostic indicators are the presence of severe disease (liver, kidney), thrombocytopenia, SLE, intravascular hemolysis, RBC agglutination, prolonged coagulation times (PT and aPTT), increased band neutrophils (left shift), marked leukocytosis, and increased urea and bilirubin.

Primary feline IMHA has a better prognosis with 24%–32% mortality rate, and relapse occurs in 16%–19% of cases. Negative prognostic factors include higher bilirubinemia and age, and positive prognostic factors are higher lymphocyte count and globulin concentration. In the largest study, 59.3% of cats with nonassociative IMHA were still alive at 6 months compared to 25.8% of cats with associative IMHA.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

Definition/Overview

Red cell destruction is secondary to an adverse or idiosyncratic drug reaction.

Etiology

Substances known to induce immune hemolytic anemia include levamisole, carprofen, cephalosporin antibiotics, griseofulvin, propylthiouracil, and methimazole.

Pathophysiology

Drug-induced immune hemolytic anemia (DIIHA) may be drug dependent or drug independent. Drug-dependent IHA occurs only in the presence of the inciting drug. In these cases, the immune reaction is directed at the drug, which is bound to RBC surface antigens. Drug-independent IHA may occur in the absence of the inciting drug and is likely secondary to immune system stimulation.

Clinical Presentation

See nonassociative IMHA.

Differential Diagnosis

See nonassociative IMHA.

Diagnosis

Diagnosis is based on a history of administering a drug known to induce IMHA, the presence of laboratory findings consistent with IMHA, and the absence of other causes of associative IMHA (e.g., erythrocytic parasites). Rechallenging is not recommended because of the potential for morbidity and mortality.

Management

Drugs known to cause associative IMHA should be discontinued. Immunosuppressive and supportive therapy as described for nonassociative IMHA.

ALLOIMMUNE HEMOLYSIS

Definition/Overview

Alloimmune hemolysis is immune-mediated destruction of RBCs that express foreign antigens. The most common forms of alloimmune hemolysis in small animal medicine are hemolytic transfusion reactions and neonatal isoerythrolysis (NI).

Etiology

See principles of transfusion medicine.

Pathophysiology

In dogs, sensitization occurs at least 4 days after initial antigen exposure. A major hemolytic transfusion reaction occurs when a blood recipient receives a blood product containing a DEA to which the recipient has been sensitized, causing hemolysis of the donated RBCs. NI rarely occurs in dogs but most commonly involves a DEA 1.1-positive puppy ingesting colostrum that contains DEA 1.1-antibodies from a previously sensitized DEA 1.1-negative bitch.

Since RBC alloantibodies occur naturally in cats, transfusion reactions may occur on the initial exposure to blood. The naturally occurring anti-B antibodies in type A cats are weak hemolysins and agglutinins, reducing the donated RBC half-life to 2.1 days. However, type B cats produce anti-A antibodies that are strong hemolysins and agglutinins, which can induce severe and life-threatening hemolytic transfusion reactions. NI is most commonly seen in kittens, wherein type A or type AB kittens ingest colostrum that contains type A antibodies from a type B queen.

Clinical Presentation

See nonassociative IMHA, except for the additional historical findings of receiving a blood transfusion or nursing from the dam. Clinical signs can occur within minutes to days of receiving a blood product or hours to days after ingesting colostrum. In NI, puppies and kittens are born healthy and nurse normally, then become pale and weak within 1–2 days after birth; reluctance to nurse, failure to thrive, dyspnea, hemoglobinuria, icterus, tail tip necrosis, and death may also occur.

Differential Diagnosis

See primary IMHA.

Diagnosis

The blood product recipient's temperature, heart rate, respiratory rate, blood pressure, and PCV should be monitored during the transfusion for signs of an adverse reaction. Evidence of hemolytic transfusion reaction includes hemolyzed plasma and red urine. Blood typing and cross-matching, if not already performed, can help confirm a hemolytic transfusion reaction. Clinical signs of nonhemolytic transfusion reactions, such as

vomiting, diarrhea, abdominal pain, or facial swelling, should also be monitored.

NI should be suspected in pale, icteric 1- to 2-day-old kittens and puppies. For a definitive diagnosis of NI, the dam's serum or colostrum can be cross-matched against the sire's or neonate's washed RBCs or by blood typing the queen and tom or kitten.

Management

Blood transfusion reactions can be avoided or reduced by blood typing and cross-matching prior to blood product administration. Starting the transfusion at a slower rate can help lessen the severity of the reaction if a reaction were to occur. The blood transfusion may be stopped once clinical signs of a reaction have been identified, or the transfusion may be slowed if the reaction is mild.

If NI is identified, puppies and kittens should not be allowed to nurse from their dam and should be fed a milk replacement formula. Blood typing queens and toms prior to breeding can prevent disease.

HEMOPLASMOSIS

See also Chapter 21.

Definition/Overview

Hemotropic mycoplasmosis (hemoplasmosis, formerly hemobartonellosis) is an infectious hemolytic disease of mammals caused by small, pleomorphic bacteria that parasitize the surface of RBCs. Acute hemolytic anemia is most common in cats, whereas dogs typically require immunosuppression, splenectomy, or splenic pathology to manifest clinical signs of disease.

Etiology

Carrier animals are the source of infection. The hemoplasmas of feline erythrocytes are *Mycoplasma haemofelis*, *Candidatus Mycoplasma haemominutum*, and *Candidatus Mycoplasma turicensis*. Dogs may be infected by *Mycoplasma haemocanis* or *Candidatus Mycoplasma haematoparvum*. See Chapter 21.

Pathophysiology

Hemoplasmas cause hemolysis by inducing secondary IMHA, the "innocent bystander effect," and direct RBC lysis.

Clinical Presentation

Clinical signs include those generally observed with hemolytic anemia (see primary IMHA and Chapter 21). Canine hemoplasmosis and the small form of feline hemoplasmosis are often not associated with clinical disease unless other conditions exist.

Differential Diagnosis

Similar differential diagnoses to primary IMHA.

Diagnosis

CBC, biochemical, and urinalysis abnormalities are almost identical to primary IMHA, except that *Mycoplasma* organisms may be observed on the surface of RBCs or in the background of the smear if there is a delay between sample collection and blood smear preparation. However, bacteremia is cyclical during the acute phase, so absence of visible organisms does not rule out infection. Organisms are rare or inapparent during preparasitemic, recovery, and carrier phases. Blood films should be well stained without precipitate to minimize any confusion in identifying the parasite. Cats often have coccoid or ring shapes, whereas dogs mostly have linear chain forms (**Figure 16.19a** and **b**). Polymerase chain reaction (PCR)–based tests are more sensitive than blood smear review. A PCR that is species specific is more useful as infections with *Candidatus M. haemominutum* or *Candidatus M. turicensis* should not be a cause for marked anemia without concurrent diseases. A positive Coombs test may be observed. Bacterial consumption of glucose in a blood sample may cause in-vitro hypoglycemia with heavy bacterial loads. Splenomegaly is often noted in cats.

Management

See Chapter 21.

Prognosis

See Chapter 21.

BABESIOSIS

See also Chapter 21.

Definition/Overview

Babesiosis is a tick-borne protozoal disease affecting erythrocytes of dogs (*Babesia canis*, *Babesia gibsoni*). There are three subspecies of *B. canis*, *B. canis vogeli* endemic in Africa, Asia, Australia, Europe, and North and South America, whereas *Babesia canis canis* is endemic in Europe and Africa and *Babesia canis rossi* only in Africa. More recently, *Babesia vulpes* has been reported in European and in North America, mostly as a coinfection. *Babesia conradae* has been detected in dogs from southern California. *Babesia felis* has not been reported in North American cats but is reported in Africa and southern Asia.

Etiology

Ixodid ticks are the major vectors of *Babesia* spp., although there have been cases of infection through blood transfusion and transplacental transmission. Sporozoites are transmitted through the tick's saliva during a blood meal, but the parasite needs to feed for at least 2 days before transmission occurs. Infection is also thought to occur through dog fighting.

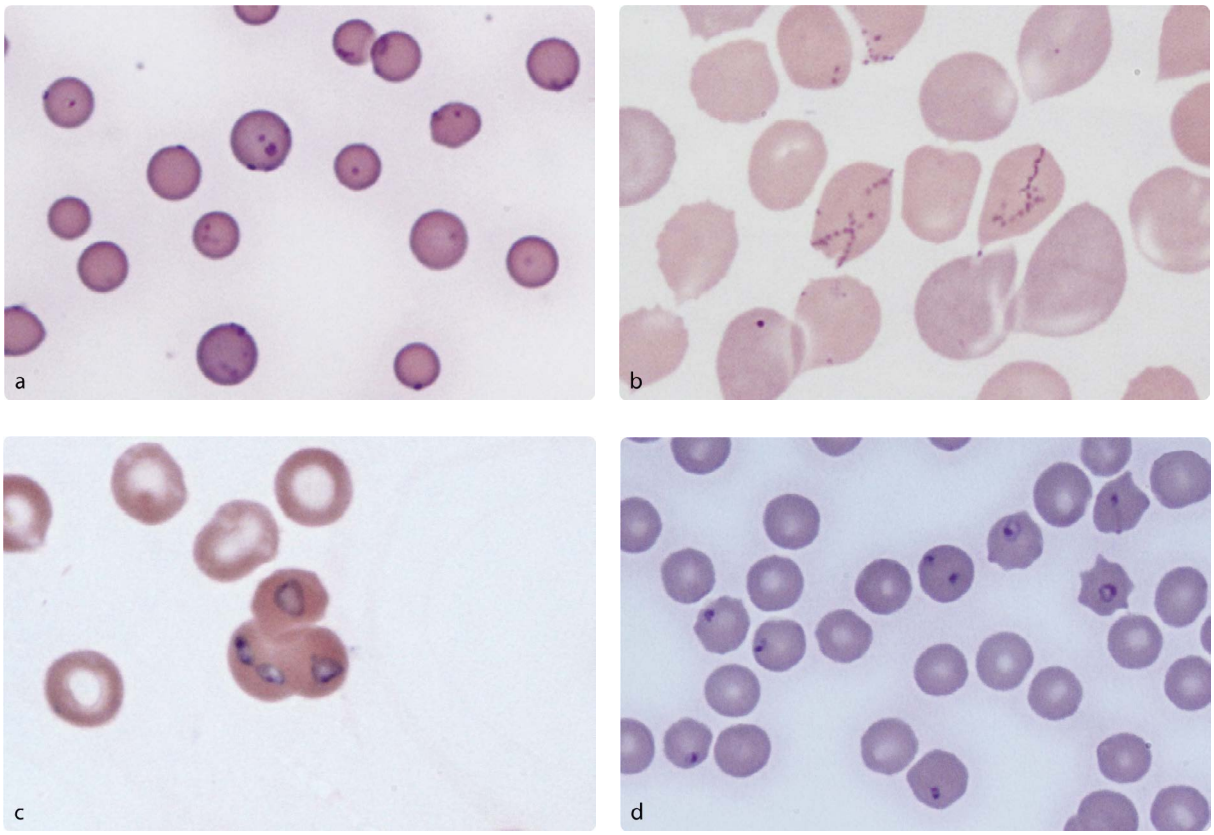

FIGURE 16.19 Erythrocytes parasites in cats and dogs. **(a)** Blood smear from cat with coccoid and ring forms of *M. haemofelis*. **(b)** *M. haemocanis* forms chains on the surface of dog erythrocytes. **(c)** Singular or paired tear-drop-shaped organisms of *B. canis* in three agglutinated erythrocytes. **(d)** Blood smear with multiple organisms from a cat infected with *C. felis*. (*Courtesy of N. Weinstein*.)

Pathophysiology

Babesia organisms become engulfed by erythrocytes, in which the parasites multiply to merozoites capable of infecting other erythrocytes. The incubation period is 10–12 days. Hosts are usually able to mount an effective immune response at this stage. If not, infected animals may develop a severe hemolytic anemia, hypotensive shock, and multiple organ dysfunction syndrome. Direct RBC lysis and secondary IMHA contribute to anemia. Thrombocytopenia might occur secondary to destruction or consumption. Animals may relapse following therapy, and affected dogs often remain carriers.

Clinical Presentation

See Chapter 21.

Differential Diagnosis

See nonassociative IMHA.

Diagnosis

CBC, biochemical, and urinalysis abnormalities are almost identical to primary IMHA, including anemia and thrombocytopenia, except that *Babesia* organisms may be observed within RBCs as clear, teardrop-shaped organisms, sometimes in pairs. *B. canis* is often large (Figure 16.19c), while *B. gibsoni* is much smaller. An indirect fluorescent antibody (IFA) serum test is available, which, when titers are high, indicates current infection. The most sensitive and specific test for genus, species, and subspecies is the PCR-based assay. Concurrent infections with *Ehrlichia canis* and hemotropic *Mycoplasma* spp. may occur. A Coombs test may be positive, as in IMHA. In severe cases, DIC may be present.

Management

See Chapter 21.

Prognosis

See Chapter 21.

CYTAUXZOONOSIS

Definition/Overview

Cytauxzoonosis, caused by *Cytauxzoon felis*, is a highly fatal protozoal disease of wild and domestic cats in the southern United States and mid-Atlantic states. It is a tick-borne disease whose natural reservoir host is the bobcat and possibly Florida panthers.

Etiology

C. felis is transmitted by *Dermacentor variabilis* and *Amblyomma americanum* ticks. The organism is a piroplasm hemoparasite of the family Theileriidae.

Pathophysiology

Macrophages infected with schizonts, a large membrane-bound structure containing numerous merozoites, line and occlude blood vessels throughout the body. This leads to tissue ischemia and hypoxia, hemorrhage, organ dysfunction, and DIC. Schizonts release merozoites, which infect erythrocytes and cause hemolysis. Infection may also cause bone marrow suppression and decreased RBC production.

Clinical Presentation

See Chapter 21.

Differential Diagnosis

Other infectious agents, neoplasia, organ failure, DIC.

Diagnosis

Cytology can be diagnostic, and commercial PCR is also available. Diagnosis is generally made postmortem by histologic identification of large schizonts in macrophages lining the sinusoids and veins of many tissues. Terminally, blood films may contain small (1–2 mm in diameter) ring or "safety pin" structures within erythrocytes (**Figure 16.19d**).

Management

See Chapter 21.

Prognosis

See Chapter 21.

OXIDANT-INDUCED HEMOLYTIC ANEMIA

Definition/Overview

Irreversible damage occurs to erythrocytes when the normal protective antioxidant mechanisms are exceeded, resulting in the formation of methemoglobin, Heinz bodies, and/or eccentrocytes.

Etiology

Oxidative agents that cause precipitation of Hgb and fusion of RBC membranes produce Heinz bodies and eccentrocytes, respectively. Causes of oxidant-induced hemolytic anemia include onions, garlic, Chinese chives, zinc (e.g., pennies, toys, zippers, galvanized wire, and zinc phosphide rodenticides), acetaminophen (paracetamol), methylene blue (in old urinary antiseptics), vitamin K3, methionine, topical benzocaine, propofol, mothball ingestion, propylene glycol, and skunk spray. Heinz body formation in cats has also been associated with diabetic ketoacidosis, hyperthyroidism, and lymphoma.

Pathophysiology

Accelerated red cell destruction involves intravascular fragmentation and extravascular phagocytosis by the spleen. Feline RBCs are predisposed to oxidant damage because of their Hgb structure. Oxidation of iron converts hemoglobin with Fe^{2+} to methemoglobin with Fe^{3+}, which cannot bind and transport oxygen.

Clinical Presentation

Clinical signs are similar to those with acute primary IMHA.

Differential Diagnosis

Similar differential diagnoses to primary IMHA.

Diagnosis

Diagnosis is made by the observation of methemoglobinemia and hemolytic anemia (regenerative anemia, icterus, hemolysis, hemoglobinuria, and/or ghost cells) with many Heinz bodies and/or eccentrocytes on a blood smear. On Romanowsky-stained blood smears, Heinz bodies are large, pale-staining areas in erythrocytes, or blunt projections from the membrane surface (**Figure 16.20**); there is only one Heinz body per RBC. On new methylene blue–stained wet mounts or dried blood smears, Heinz bodies are dark blue spots within RBCs (**Figure 16.21**). Eccentrocytes are RBCs with densely packed Hgb on one side of the cell and a thin colorless portion, or hemighost, on the opposite side (**Figure 16.22**). When the hemighost fragments off from the RBC, the remaining RBC is termed a *pyknocyte*. At moderate-to-higher concentrations, methemoglobinemia results in chocolate brown mucous membranes and blood. With zinc toxicosis, abdominal radiographs may reveal the ingestion of a metal object.

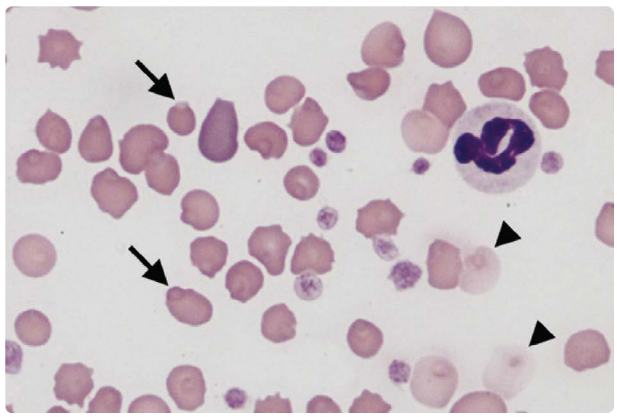

FIGURE 16.20 Heinz bodies in intact erythrocytes (arrows) and ghost cells (arrowheads) in a cat with oxidant-induced hemolytic anemia.

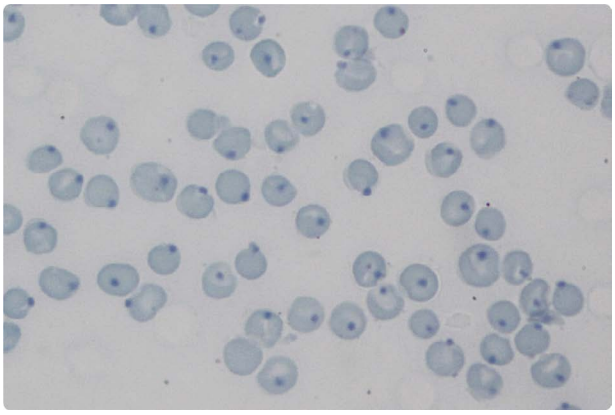

FIGURE 16.21 Heinz bodies are basophilic round structures with new methylene blue stain.

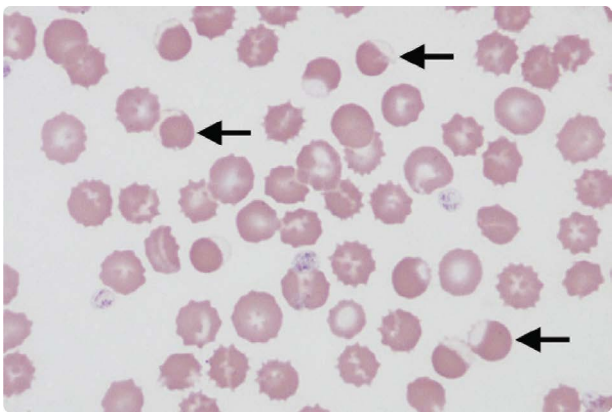

FIGURE 16.22 Eccentrocytes (arrows) in a dog receiving a continuous rate infusion of propofol.

Management

Treatment primarily involves removal of the source of oxidant. Emetics can be used if recent ingestion has occurred or endoscopic/surgical removal of a zinc foreign body. Blood transfusions or other forms of supportive care should be given as indicated. Acetylcysteine (Mucomyst®) (140 mg/kg of a 5% solution diluted with saline IV initially, then give 70 mg/kg [of a 5% solution] q.4–6 h. for 3–5 treatments) should be given to treat acetaminophen-induced toxicity.

MICROANGIOPATHIC HEMOLYTIC ANEMIA

Definition/Overview

Microangiopathic hemolytic anemia is due to mechanical fragmentation of normal RBCs in an abnormal vasculature system.

Etiology

Diseases that cause intravascular deposition of fibrin, turbulent blood flow, or abnormal blood vessel morphology can cause mechanical fragmentation of normal RBCs.

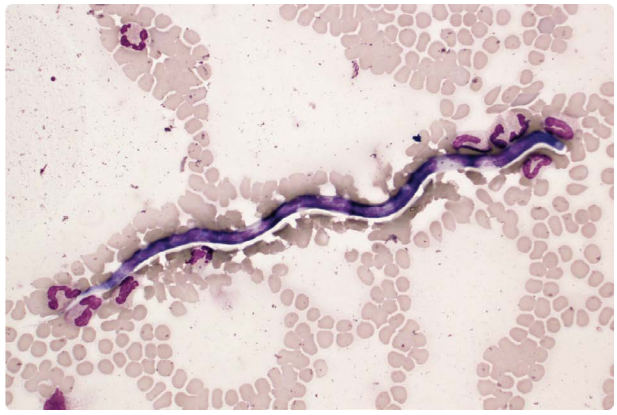

FIGURE 16.23 Microfilaria in a dog with *D. immitis* infection.

These diseases include DIC, vasculitis, hemangiosarcoma, heart valvular defects, dirofilariasis (Figure 16.23), splenic disease, hepatic disease, glomerulonephritis, myelofibrosis, and intravascular lymphoma.

Pathophysiology

Fibrin strands or abnormal rheologic forces cause shearing or lysis or RBCs. The RBC fragments, including schistocytes, acanthocytes, and keratocytes, are removed from circulation by the monocyte–macrophage system.

Differential Diagnosis

Blood loss, IMHA, oxidant-induced hemolysis, infectious hemolytic anemia, liver disease, disorders of lipid metabolism.

Clinical Presentation

The clinical presentation varies depending on the cause of the RBC fragmentation.

Diagnosis

Microangiopathic hemolytic anemia is typically a regenerative anemia with evidence of RBC fragmentation on blood smear evaluation (e.g., schistocytes, acanthocytes, keratocytes) (Figure 16.24). The degree of anemia is typically mild but may be moderate to rarely severe. Marrow erythropoiesis may be able to compensate for the degree of hemolysis, so RBC regeneration and/or anemia may not be present. Diagnosis of the underlying disease may include CBC with blood smear evaluation, heartworm antigen test, serum biochemical and urine analysis, coagulation panel, abdominal and thoracic imaging, and bone marrow biopsy.

Management

Management is directed at resolving the underlying cause of the microangiopathy.

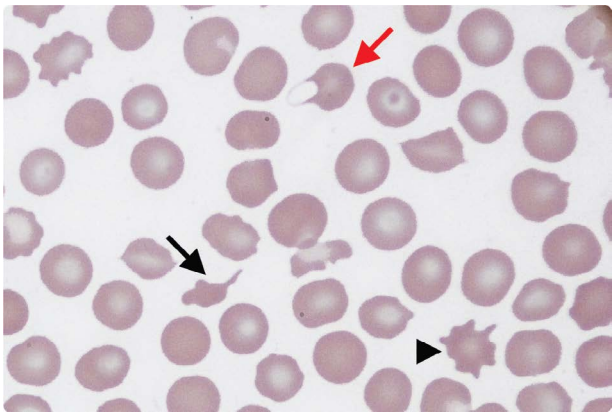

FIGURE 16.24 This dog with disseminated intravascular coagulation has circulating schistocytes (black arrow), acanthocytes (arrowhead), and keratocytes (red arrow).

PYRUVATE KINASE DEFICIENCY

Definition/Overview

Pyruvate kinase (PK) deficiency is a congenital deficiency in glycolytic enzymes. The condition has been documented in dogs (Basenji, Beagle, West Highland White Terrier, Cairn Terrier, American Eskimo Dog, Miniature Poodle, Chihuahua, and Pug) and cats (Abyssinian, Somali, Bengal, Maine Coon, and Domestic Shorthair cats).

Etiology

PK deficiency is an autosomal recessive trait due to a variety of mutations in the erythrocyte PK gene.

Pathophysiology

PK is an enzyme in the glycolytic pathway that is necessary for the anaerobic production of adenosine triphosphate (ATP). Therefore, energy metabolism is markedly impaired in PK-deficient RBCs, leading to shortened RBC life spans and hemolytic anemia. Persistent anemia causes increased intestinal absorption of iron and subsequent hepatic (hemosiderosis, hemochromatosis, cirrhosis, and failure) and bone marrow (myelofibrosis and osteosclerosis) injury.

Clinical Presentation

Heterozygotes show no clinical signs. Homozygotes often present in their youth with pale mucous membranes, exercise intolerance, tachycardia, and splenomegaly. Cats may not present until they are at an advanced age or with intermittent hemolytic anemia.

Differential Diagnosis

Phosphofructokinase deficiency, IMHA, oxidant-induced hemolysis, mycoplasmosis, and babesiosis.

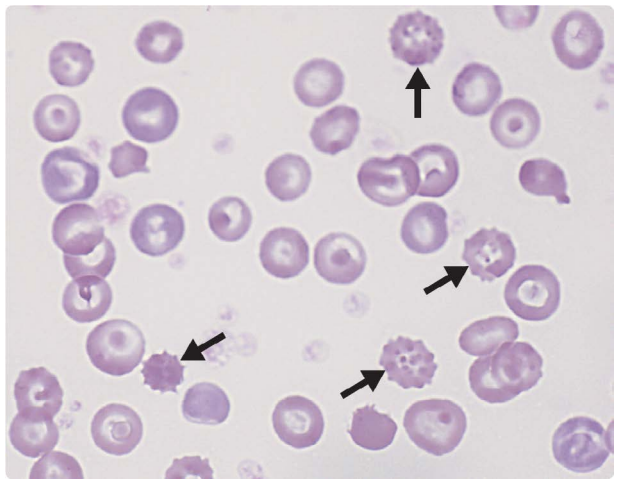

FIGURE 16.25 Pyruvate kinase deficiency in a dog showing polychromasia and several echinocytes (arrows).

Diagnosis

Diagnosis is suggested by the presence of hemolytic anemia with an intense reticulocytosis (15%–50%) and frequent nucleated red cells in a young dog (Figure 16.25). Splenectomy results in marked poikilocytosis with schistocytes and acanthocytes. Dogs may also show biochemical signs of liver injury or failure, as well as hematologic evidence of marrow failure (e.g., neutropenia and thrombocytopenia). PCR-based tests are available for the Basenji, West Highland White Terrier, Beagle, Dachshund, Toy Eskimo, and Cairn Terrier dog breeds, as well as Abyssinian and Somali cats. Definitive diagnosis for other breeds requires PK isoenzyme characterization.

Management

There is no specific treatment.

Prognosis

Dogs usually die between 1 and 5 years of age.

PHOSPHOFRUCTOKINASE DEFICIENCY

Definition/Overview

Phosphofructokinase (PFK) deficiency is a congenital deficiency in glycolytic enzymes. It has been identified in English Springer Spaniels, American Cocker Spaniels, Whippets, Wachtelhund, and mixed-breed dogs.

Etiology

A nonsense mutation of the muscle-type PFK gene leads to truncation of M-type PFK enzyme, which is structurally unstable and rapidly degrades.

Pathophysiology

Decreased PFK in RBCs leads to decreased glycolysis and anaerobic ATP generation, as well as decreased

concentrations of 2,3-diphosphoglycerate (2,3-DPG). Energy metabolism is impaired in PFK-deficient RBCs, leading to a shortened RBC life span and hemolytic anemia. The 2,3-DPG deficiency causes an increase in intracellular pH, and RBCs are especially fragile under alkaline conditions, such as hyperventilation-induced alkalemia.

Clinical Presentation

Heterozygote dogs show no clinical signs. Homozygote dogs have persistent compensated hemolytic anemia with sporadic episodes of intravascular hemolysis. Animals between episodes of hemolytic crises appear clinically normal or may have a decreased muscle mass; Hct is typically 30%–45%. Clinical signs during hemolytic crises include lethargy, pale or icteric mucous membranes, hemoglobinemia, hemoglobinuria, hepatosplenomegaly, and fever. Persistent reticulocytosis (10%–30%) and metarubricytosis are often noted (Figure 16.26).

Differential Diagnosis

PK deficiency, IMHA, oxidant-induced hemolysis, mycoplasmosis, and babesiosis.

Diagnosis

A PCR-based test differentiates normal, heterozygote, and homozygote animals of any age. Homozygotes can also be identified after 3 months of age by measuring erythrocyte PFK activity.

Management

Management is directed at avoiding situations that could lead to hyperventilation, such as excessive exercise, excitement, or high temperatures.

Prognosis

Dogs may have a normal life span if properly managed.

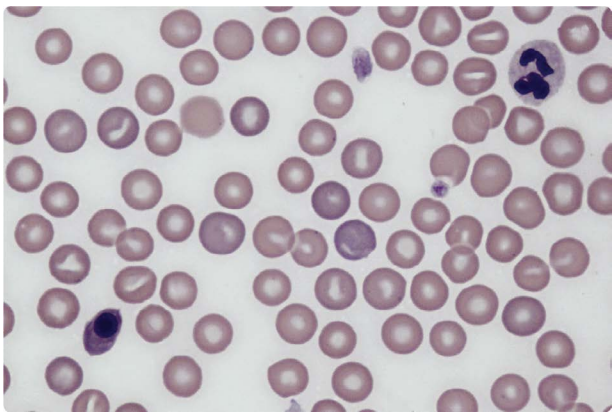

FIGURE 16.26 Polychromasia and metarubricytosis in a dog with phosphofructokinase deficiency. (*Courtesy of H. Tvedten.*)

OTHER CAUSES OF HEMOLYTIC ANEMIA

Other rare congenital hemolytic anemias have been documented. Feline erythropoietic porphyria has been reported in a family of Siamese cats that had hemolytic anemia, photosensitivity, and renal disease. A hereditary nonspherocytic hemolytic anemia has been identified in three related Beagles that exhibited persistent regenerative mild anemia (Hct, 30%–39%). Idiopathic hemolytic anemia has been documented in 13 Abyssinian and five Somali cats with regenerative moderate to marked anemias (Hct, 5%–25%).

Uncommon to rare causes of acquired hemolytic anemia include snake envenomation, hypophosphatemia, hemophagocytic histiocytic sarcoma, L-sorbose intoxication, and hypo-osmolality. Hematologic changes also noted with snakebites include spherocyte formation, echinocytosis, and coagulation abnormalities. Marked hypophosphatemia, typically ≤1.0–1.5 mg/dL, may cause intracellular ATP depletion, loss of RBC membrane integrity, and subsequent hemolysis. Severe hypophosphatemia has been associated with insulin administration in dogs and cats with diabetes mellitus, feline idiopathic hepatic lipidosis, and enteral alimentation in dogs and cats.

Hemophagocytic histiocytic sarcoma is a malignant proliferation of macrophages that exhibit marked erythrophagocytic activity. The neoplasm occurs with high incidence in Bernese Mountain Dogs, Golden Retrievers, Rottweilers, and Labrador Retrievers; it is rare in cats. Affected animals often present with Coombs-negative regenerative anemia, thrombocytopenia, hypoalbuminemia, hypocholesterolemia, and diffuse splenomegaly. Oral ingestion of L-sorbose, a sugar substitute, by dogs may cause intravascular hemolytic anemia secondary to glycolysis inhibition and decreased production of ATP within erythrocytes. Dogs with inherited high Na-K-ATPase activity in their RBCs (e.g., Japanese Akitas and Japanese Shibas) are resistant to hemolysis. Hypo-osmolar hemolysis may occur with rapid IV infusion of hypotonic fluids.

NONREGENERATIVE ANEMIA

A poorly regenerative or nonregenerative anemia is generally due to decreased RBC production in the bone marrow. Causes of regenerative anemia (hemorrhage and hemolysis) appear initially nonregenerative since the bone marrow requires at least 3–4 days to undergo erythroid hyperplasia and release greater numbers of reticulocytes. The main causes of nonregenerative include anemia of inflammatory or chronic disease (AID), anemia of endocrine disease (AED), anemia of renal disease (ARD), bone marrow disease (including precursor immune-mediated anemia, [PIMA]), and end-stage iron-deficiency anemia (IDA). A mild chronic nonregenerative anemia is more likely to be secondary to AID, AED, or ARD. ARD, IDA, or bone marrow disease are the likely differentials with moderate-to-severe chronic nonregenerative anemia. As mentioned earlier,

IDA will progress over time with a highly regenerative anemia early in the process, progressing to a poorly regenerative anemia with ongoing iron loss, and finally to the typical microcytic hypochromic nonregenerative anemia in end-stage disease.

SELECTIVE ERYTHROID ATROPHY, HYPOPLASIA, OR APLASIA

Atrophy is a reduction in the size of an organ or tissue, whereas hypoplasia and aplasia result from defective growth. Selective erythroid atrophy, hypoplasia, or aplasia is decreased or absent RBC production in the bone marrow without decreased production of other hematopoietic cells. Therefore, neutropenia and thrombocytopenia due to decreased production are not present.

ANEMIA OF INFLAMMATORY OR CHRONIC DISEASE

Definition/Overview

Anemia of inflammatory disease (AID) is the most frequent cause of nonregenerative anemia and is seen with chronic diseases. The anemia is usually mild to moderate in severity (i.e., typically PCV > 20%). Once recognized, it is of little clinical significance.

Etiology

Almost any inflammatory or chronic disorder can initiate AID, including infectious diseases, immune-mediated diseases (not targeting red cells), toxicities, and neoplasms.

Pathophysiology

The mechanism may involve decreased erythropoiesis, relatively reduced iron availability through sequestration in macrophages, and decreased RBC survival. This type of anemia is inflammatory in origin and studies have shown that cytokines, such as tumor necrosis factor (TNF), interferon-gamma, and interleukin (IL)-1, inhibit erythropoietin synthesis and decrease the responsiveness of progenitor cells to growth factors.

Clinical Presentation

Affected animals may present with prolonged anorexia, weight loss, and weakness. Other clinical signs reflect the actual source of inflammation or organ systems affected.

Differential Diagnosis

AED, ARD, IDA, bone marrow disease, preregenerative anemia.

Diagnosis

Laboratory findings often indicate a mild-to-moderate, normocytic, normochromic, nonregenerative anemia with or without an inflammatory leukogram in the face of an identifiable underlying disease. The MCV may be normal to slightly decreased. A serum iron profile may show low serum iron, low total iron-binding capacity, and increased serum ferritin, but there may be considerable overlap within the normal reference interval. The bone marrow has variable cellularity, with a normal to increased myeloid-to-erythroid ratio and normal-to-increased iron stores.

Management

Treatment is directed at the underlying disease and not the anemia. Iron supplementation does not effectively reverse this form of anemia.

ANEMIA OF CHRONIC KIDNEY DISEASE

See also Chapter 13.

Definition/Overview

The peritubular interstitial cells in the renal cortex produce erythropoietin (EPO) at a rate inversely proportional to the oxygen content (and therefore RBC mass) of blood. The anemia of chronic kidney disease (ACKD) is progressive and also mild to start with. It can become severe in advanced stages.

Etiology

Decreased EPO production is the major cause of ACKD, with minor contributions from decreased marrow responsiveness to EPO, poor nutrition, and decreased RBC survival. Concurrent GI hemorrhage caused by uremia may contribute to anemia.

Pathophysiology

Inadequate EPO and reduced response to EPO lead to decreased erythropoiesis. Uremic toxins may damage RBCs and decrease the RBC life span.

Clinical Presentation

See Chapter 13 for CKD and the International Renal Interest Society (IRIS), IRIS website for further discussion of presentation, staging, and treatment of CKD (http://www.iris-kidney.com/index.html).

If anemia is present in an animal with early CKD (IRIS stage 1 and 2), the cause of anemia is unlikely to be decreased EPO production, and the clinician should look for another cause.

Differential Diagnosis

AID, AED, GI blood loss, chronic liver disease, and IDA.

Diagnosis

See Chapter 13 for diagnosis of CKD. The major hematologic abnormality is normocytic, normochromic,

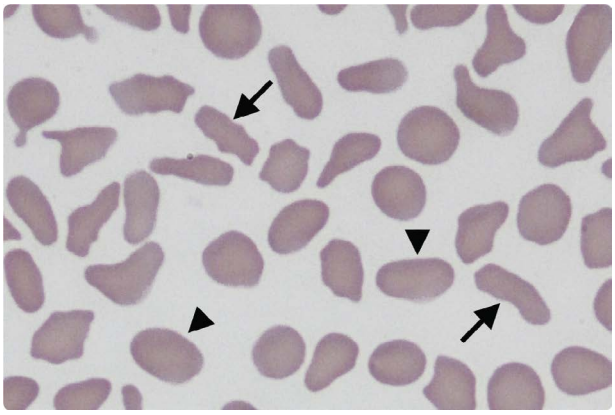

FIGURE 16.27 Burr cells (arrows) and ovalocytes (arrowheads) are elongate erythrocytes with and without ruffled borders, respectively.

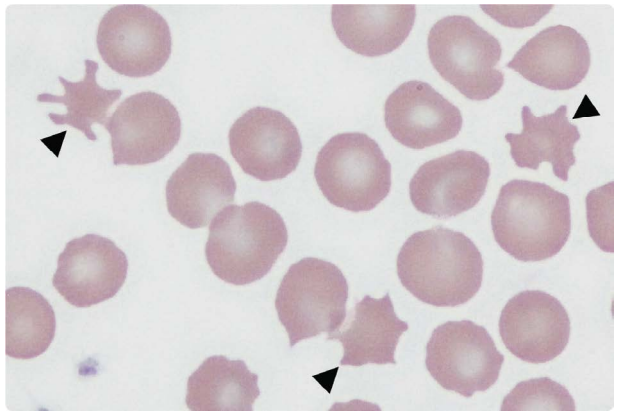

FIGURE 16.28 Three acanthocytes (arrowheads) with multiple irregularly shaped cytoplasmic projections.

nonregenerative anemia. Abnormal RBCs called burr cells (**Figure 16.27**) are associated with chronic kidney disease.

Management

See Chapter 21.

ANEMIA OF LIVER DISEASE

See also Chapter 10.

Definition/Overview

Decreased liver functional mass may influence red cell production, survival, or loss.

Etiology

Chronic-onset liver failure or portosystemic shunts may cause a significantly decreased liver functional mass. The liver produces the plasma iron transport protein, transferrin, and a small percentage of EPO. Clinical signs are usually primarily due to liver disease rather than anemia.

Pathophysiology

Mechanisms for nonregenerative anemia may include AID, decreased RBC life span due to defective protein and lipid metabolism, iron sequestration due to decreased production of transferrin, and EPO deficiency. Iron sequestration may cause microcytosis. Concurrent blood loss secondary to decreased liver production of clotting factors may contribute to the anemia.

Clinical Presentation

See Chapter 10.

Differential Diagnosis

Chronic kidney disease, nonhepatic AID, neoplasia, iron deficiency.

Diagnosis

The anemia is typically mild to moderate, normocytic, and normochromic; microcytosis is occasionally noted. Blood smears often reveal acanthocytes (**Figure 16.28**) or budding fragmentation. See Chapter 10.

Management

Treatment is directed at the underlying liver disease and not anemia.

ANEMIA OF ENDOCRINE DISORDERS

See also Chapter 12.

Definition/Overview

Hypothyroidism and hypoadrenocorticism may cause mild-to-moderate nonregenerative anemia in dogs. Anemia due to hyperestrogenism is discussed elsewhere (see generalized marrow atrophy, hypoplasia, or aplasia). The anemia is usually mild and not the cause for the clinical signs, except if significant GI bleeding occurs secondary to hypoadrenocorticism (regenerative to poorly regenerative anemia).

Etiology

Anemia is secondary to hypothyroidism or hypoadrenocorticism.

Pathophysiology

In hypothyroidism, low levels of thyroid hormone cause a decreased metabolic rate and thus reduced oxygen requirement by the tissues. This decreases EPO production and then erythropoiesis. Glucocorticoids have a stimulatory effect on erythropoiesis; therefore, glucocorticoid deficiency is expected to reduce erythropoiesis. GI hemorrhage due to glucocorticoid deficiency may contribute to anemia.

Clinical Presentation

See Chapter 12. The clinician should remember that dogs with only glucocorticoid deficiency (atypical Addison's) will present with chronic GI signs and lethargy but will not have the typical electrolytes abnormalities.

Differential Diagnosis

For nonregenerative anemia, AID, ACKD, IDA. See Chapter 11 for differential diagnoses for the patient's presentation.

Diagnosis

See Chapter 12.

Management

See Chapter 12. Except for severe GI bleeding requiring blood treatment, the degree of anemia is generally mild and expected to resolve with control of the primary disease.

FIGURE 16.29 Typical appearance of melena: Tarry black feces after digestion of blood. (*Courtesy of J. Dandrieux.*)

IRON-DEFICIENCY ANEMIA

Definition/Overview

Iron-deficiency anemia (IDA) occurs most commonly with chronic external blood loss and rarely with inadequate dietary iron intake and is due to deficient Hgb synthesis. After a preregenerative phase that is typically not noticed clinically except if the bleeding is important, the animal will develop first a strongly regenerative anemia. With ongoing iron loss, the anemia will progress to poorly regenerative anemia and finally to a nonregenerative anemia. End-stage IDA is characterized by nonregenerative, microcytic, and hypochromic anemia.

Etiology

Etiologies include chronic GI hemorrhage (neoplasia, intestinal parasites, or ulcerative diseases), chronic cutaneous blood loss (fleas, ticks, or bleeding tumors), urinary loss, and repeated phlebotomy (small animals hospitalized, blood donor animals). The owner might notice melena, black tarry feces, if the bleeding is important (**Figure 16.29**).

Pathophysiology

Hemoglobin synthesis is dependent on iron availability, and RBC maturation is dependent on adequate intracytoplasmic concentrations of hemoglobin. During times of iron deficiency, RBCs undergo additional mitoses to form smaller cells (microcytes) in an attempt to reach optimal intracytoplasmic concentrations of hemoglobin. With continued iron unavailability, the microcytes are no longer able to obtain optimal intracytoplasmic hemoglobin concentrations, thereby forming hypochromic cells. RBCs formed during times of iron deficiency are more fragile and less deformable and, therefore, lyse easily in circulation. This leads to decreased RBC life spans and the formation of keratocytes, acanthocytes, and schistocytes.

Clinical Presentation

Clinical signs of IDA are nonspecific and include insidious fatigue and exercise intolerance that develop over weeks to months. Owners may report pica as the animal licks or chews at unusual substances to try to compensate for the iron loss. Physical examination may reveal a systolic murmur, gallop rhythm, pale mucous membranes, and bounding pulses. Melena or hematochezia might be present, whereas heavy parasitism is less common. However, if there is an ongoing small amount of blood loss, it might be unnoticed.

Differential Diagnosis

Internal blood loss, hemolysis (especially early in the disease), AID, AED, ACKD, and bone marrow disease.

Diagnosis

Diagnosis is based on history and the presence of a microcytic, hypochromic anemia that is nonregenerative or poorly regenerative for the degree of anemia. However, the anemia will be strongly regenerative to start with without typical hematological changes until the iron storage has decreased sufficiently. For this reason, monitoring trends in MCV, MCHC, and reticulocytes count is very valuable to diagnose IDA. The MCV usually decreases prior to the MCHC, and so the MCHC may be within normal limits at the time of presentation. Erythrocytes in blood smears may appear

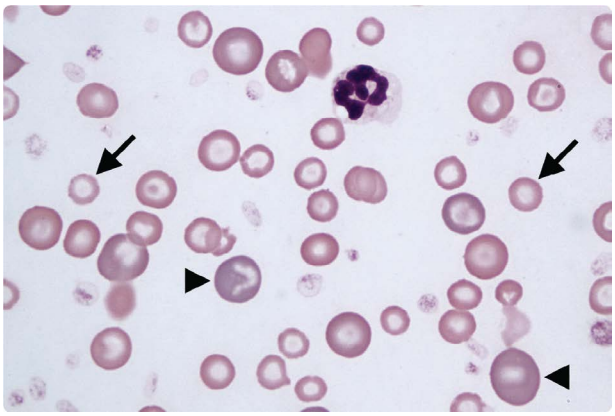

FIGURE 16.30 Iron-deficient erythrocytes are small with increased central pallor (arrows). Regeneration is present in early stages of iron-deficiency anemia (arrowheads).

small (microcytes) with increased central pallor (hypochromasia) (Figure 16.30). Microcytes and hypochromasia are observed in blood prior to changes in the MCV and MCHC, since the latter represent average cell values. Poikilocytosis may be prominent in the form of schistocytes, acanthocytes, keratocytes, codocytes, and elliptocytes (Figure 16.31). Thrombocytosis occurs in 50% of canine cases. Iron profiles have a decreased serum iron level (in cats <10.7 µmol/L [60 µg/dL]; in dogs <14.3 µmol/L [80 µg/dL]), normal-to-increased level of transferrin (measured as total iron-binding capacity), and decreased serum ferritin concentration. Percent saturation of transferrin in iron deficient animals is often <19% (normal is about 33%). Bone marrow examination shows decreased iron stores in the dog and marked erythroid proliferation. Absence of bone marrow iron stores is a normal finding in the cat.

Other changes suggestive of GI blood loss is a disproportionate increase in urea compared to creatinine due to the digestion of a high protein meal (the blood). A urinalysis is also recommended, if the source of external blood loss is not evident to rule out hematuria.

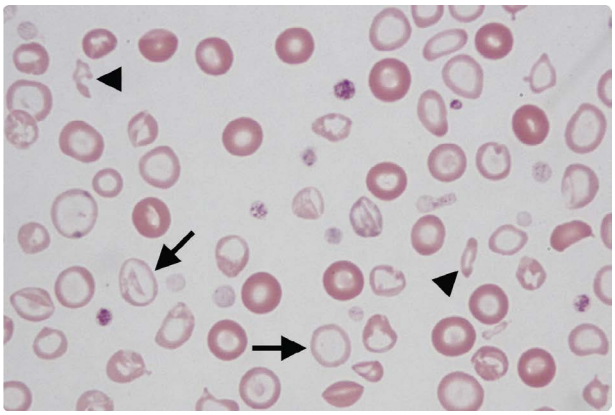

FIGURE 16.31 Late-stage iron-deficiency anemia with marked hypochromasia (arrows) and no polychromatophils. Iron-deficient erythrocytes are fragile and prone to fragmentation (arrowheads).

Management

Treatment involves correction of the inciting cause for the blood loss and iron supplementation either orally or parenterally. Parenteral supplementation is often preferred to start with as absorption is more reliable.

Ferrous sulfate is given orally at a rate of 100–300 mg ferrous sulfate (not elemental iron) in dogs and 50–100 mg in cats orally in divided doses. The main adverse effect with nontoxic dose is mild GI upset. This can be reduced by dividing the dose over the day or giving the iron with food, although the latter might reduce absorption. Antiacid may reduce iron absorption, and ferrous sulfate will decrease absorption of fluoroquinolone and thyroxine. Care in dosing is important as overdoses can be life-threatening.

Iron dextran is given IM (not IV or SC). Pain at injection site can be noted and rarely anaphylaxis. A drug interaction with reduced efficacy of mycophenolate mofetil is possible. In dogs, 50–300 mg IM (10–20 mg/kg, maximum 300 mg) is recommended with ongoing oral supplementation or repeat IM injections after a month. A dose of 50 mg (~10 mg/kg) IM is used in cats that can be repeated monthly. Therapy is continued for several weeks to months until the PCV and MCV return to normal.

The pet should be monitored for an anaphylactic reaction for 15–20 minutes after administration.

PRECURSOR-TARGETED IMMUNE-MEDIATED ANEMIA

Definition/Overview

Precursor targeted immune-mediated anemia (PIMA, nonregenerative immune-mediated hemolytic anemia) is characterized by immune-mediated destruction of erythroid precursors within the bone marrow, resulting in moderate-to-marked anemia without reticulocytosis. The bone marrow may reveal a near complete absence of erythroid precursors (pure red cell aplasia [PRCA]) or erythroid hyperplasia with maturation arrest (ineffective erythropoiesis) depending on the stage of maturation that is targeted.

Etiology

Similar to the more common regenerative IMHA, PIMA may be nonassociative or associative. Nonassociative PIMA is more common in dogs. Potential causes of associative PRCA include vaccination of dogs with a modified live parvovirus vaccine and FeLV infection in cats. Administration of recombinant human EPO may induce the development of anti-EPO antibodies, leading to an absence of EPO.

Pathophysiology

Immune-mediated destruction of erythroid cells may occur at any level of maturation. If hemolysis is directed at erythroid stem cells, there is PRCA. If hemolysis is directed at later erythroid precursors, there is marked

proliferation of stages prior to the targeted developmental stage and near absence of those after. This is termed "maturation arrest," and is indicative of either ineffective erythropoiesis or an early marrow response to anemia (preregenerative anemia). Therefore, preregenerative anemia should be ruled out prior to diagnosing ineffective erythropoiesis. Since mature RBCs in blood are not the target of immune destruction, RBCs in blood survive for their expected circulating lifespans (approximately 3 months in the dog and 2 months in the cat) prior to physiologic removal by splenic macrophages. This results in a gradual reduction in the PCV over weeks to months and allows for the development of physiologic compensation. PCV at time of admission is typically moderately to markedly decreased. Transport and utilization of oxygen and anaerobic metabolism are optimized, often resulting in mild clinical signs relative to the severity of anemia. Some dogs have evidence of bone marrow and peripheral destruction (presence of spherocytes, agglutination, or positive Coombs test).

Clinical Presentation

History and physical examination findings are similar to those seen in animals with regenerative nonassociative IMHA, except that chronic onset is more common, red plasma and urine are not expected, and icterus is less frequent.

Differential Diagnosis

Iron-deficiency anemia, drug toxicosis, other bone marrow diseases.

Diagnosis

Hematologic findings include moderate-to-severe normocytic, normochromic, nonregenerative anemia (Hct, 5%–26%). Spherocytes and agglutination are present in 15%–54% and 0%–5% of cases, respectively. Mature and band neutrophils are often increased, but neutrophils may be within the reference interval or decreased. Platelets may be increased, decreased, or within the reference interval. A direct Coombs test is often positive. Bone marrow findings are dependent on the RBC stage that is being destroyed and may reveal erythroid atrophy (including pure red cell aplasia) or erythroid hyperplasia with maturation arrest (ineffective erythropoiesis). Increased numbers of lymphocytes and plasma cells are common and may compose up to 60% and 33% of the total marrow cells, respectively. Serum ALT activity is commonly increased due to hypoxia-induced liver injury, but the total serum bilirubin concentration is only increased in less than 25% of cases. Concurrent immune-mediated disorders, such as polyarthritis, positive antinuclear antibody titers, and the presence of anti-megakaryocyte antibodies, support immune-mediated etiology.

Management

See regenerative nonassociative IMHA. Although less frequent, there is also a risk of thromboembolism.

Prognosis

More than 70% of dogs and cats are expected to recover. However, response to treatment takes typically longer than for a peripheral IMHA (take weeks to months). It is not unusual that animals are euthanized due to the need of costly transfusion until regeneration occurs. In a large study of 66 dogs, the presence of myelofibrosis did not impact on survival, although the study might have been underpowered. In any case, presence of myelofibrosis should not be a reason to preclude treatment.

FOLATE OR COBALAMIN DEFICIENCY

Definition/Overview

Folate (vitamin B9) and cobalamin (vitamin B12) are acquired through the diet and intestinally absorbed. Both are needed for DNA synthesis. Unlike most other tissues, bone marrow is particularly susceptible to the inhibition of DNA synthesis, as hematopoietic cells are constantly produced.

Etiology

Folate deficiency has been experimentally produced in cats fed a folate-deficient diet. However, dogs are highly resistant to folate deficiency. Congenital cobalamin deficiency (Imerslund-Gräsbeck syndrome, IGS) is an autosomal recessive trait in Giant Schnauzer dogs due to a cobalamin receptor complex defect. The genetic defect has also been documented in a Beagle, Border Collie, and in Australian Shepherd Dogs. Drug-induced folate deficiency is associated with anticonvulsants (phenobarbital, primidone), sulfonamides (sulfasalazine, trimethoprim–sulfadiazine), and antineoplastic agents by impairing its absorption or production. Serum folate and/or cobalamin levels may be decreased in dogs and cats with various GI and hepatic diseases and/or exocrine pancreatic insufficiency, but this very rarely results in anemia. Breeds reported with an increased frequency of hypocobalaminemia in the United Kingdom and North America include Chinese Shar-Pei and German Shepherd Dogs, whereas Staffordshire Bull Terriers were only reported in the United Kingdom.

Pathophysiology

Folate and cobalamin are required for DNA synthesis. Deficiencies in folate and/or cobalamin impair hematopoiesis, especially erythrocyte and neutrophil production. Nonregenerative anemia with erythroid dysplasia is typical of folate deficiency; concurrent neutropenia and myeloid dysplasia often occur. Cobalamin is also a cofactor for methylmalonyl coenzyme A. Reduced activity of this enzyme causes accumulation of methylmalonic acid (MMA), which is excreted in the urine and may indirectly impair urea cycle function.

Clinical Presentation

Patients of appropriate breeds with IGS are often presented at less than a year of age for lethargy, inappetence,

neurological signs, or failure to thrive. The signs are due to the systemic effect of folate and cobalamin deficiency rather than the anemia

Differential Diagnosis

Myelodysplastic syndrome, drug-induced dysplasias.

Diagnosis

Erythrocyte changes with congenital cobalamin deficiency include normocytic, normochromic anemia (Hct, 21%–36%), anisocytosis, poikilocytes, and nucleated erythrocytes with fully hemoglobinized cytoplasm and immature nuclei (erythroid dysplasia; megaloblasts). Neutropenia with hypersegmented neutrophils is frequently present, but neutrophilia may occur. Platelet concentrations are typically normal, and giant platelets may be present. The megaloblastic anemia described in people is not seen in dogs. In bone marrow, both erythroid hypoplasia and hyperplasia have been documented, but erythroid and myeloid dysplasia is a consistent finding. Specific tests include measurement of serum folate and cobalamin concentrations, as well as urine MMA concentrations.

Management

Dogs with congenital cobalamin deficiency have been successfully treated with parenteral or oral cobalamin supplementation. Protocols have not been rigorously validated and are guidelines only. Dogs with IGS require life-long supplementation. If an underlying cause is found, supplementation is required until the primary disease is controlled. Parenteral supplementation consists of injection of 250–1,000 µg SC weekly for 4–6 weeks before reassessing vitamin B12 concentration to ensure adequate supplementation. Alternatively, oral supplementation with 250 µg in cats and 250–1,000 µg in dogs daily for 12 weeks with recheck of cobalamin concentration can be used.

Prognosis

Dogs with congenital cobalamin deficiency have a good prognosis for recovery.

OTHER CAUSES OF SELECTIVE ERYTHROID HYPOPLASIA OR APLASIA

Dyserythropoiesis in English Springer Spaniels is characterized by microcytic normochromic nonregenerative anemia with polymyopathy, megaesophagus, and cardiomegaly.

GENERALIZED MARROW ATROPHY, HYPOPLASIA, OR APLASIA

Generalized marrow atrophy, hypoplasia, or aplasia results in decreased production of all hematopoietic lineages that arise from bone marrow. The typical finding is nonregenerative anemia with neutropenia and/or thrombocytopenia. Bicytopenia indicates that two cell lines are affected and pancytopenia all three cell lines. Blood lymphocyte concentrations should not be used to document bicytopenia or pancytopenia, since secondary lymphoid tissue is the primary site for lymphocyte production in adult dogs and cats. Blood monocyte, eosinophil, or basophil concentrations should also not be used, since these cells are normally present in low concentrations in peripheral blood, and it is difficult to reliably document decreased blood concentrations of these cells.

APLASTIC ANEMIA

Definition/Overview

The marrow consists of adipose and is nearly void of all nonlymphoid hematopoietic cells. Contradictory to the name, aplastic anemia is commonly acquired (atrophy) versus failed development of the bone marrow (aplasia), and it commonly causes bicytopenia (including red blood cells) or pancytopenia.

Etiology

A variety of etiologies have been implicated, including infectious agents (e.g., canine parvovirus, feline panleukopenia virus, canine distemper virus [CDV], *E. canis*, FeLV, and feline immunodeficiency virus [FIV]), drugs (e.g., trimethoprim–sulfadiazine, antineoplastic drugs, estradiol, phenylbutazone, fenbendazole, quinidine, cephalosporins, and griseofulvin), hyperestrogenism (e.g., Sertoli cell and granulosa cell tumors), whole body irradiation, and nonassociative immune-mediated stem cell destruction.

Pathophysiology

Stem cells or progenitor cells are targeted and destroyed, leading to decreased production of all hematopoietic precursors (granulocytic, erythroid, and megakaryocytic) with subsequent pancytopenia.

Clinical Presentation

The clinical presentation is partially dependent on the cause of aplastic anemia. Specifically, animals with hyperestrogenism may exhibit alopecia, feminization, or cryptorchidism. Clinical signs attributable to cytopenias include those associated with anemia (e.g., lethargy, weakness, pale mucous membranes), neutropenia (e.g., fever, infection, sepsis), and thrombocytopenia (e.g., petechial hemorrhages, epistaxis).

Differential Diagnosis

Nonassociative myelofibrosis, myelophthisic neoplasia, infectious myelitis, FeLV infection.

Diagnosis

Minimal diagnostics include CBC, bone marrow aspirate, and core biopsies. The diagnosis of aplastic anemia is based on the presence of nonregenerative anemia with concurrent marked hematopoietic atrophy/hypoplasia/aplasia in the bone marrow, which is nearly replaced with adipose tissue. The nonregenerative anemia is often accompanied by neutropenia and/or thrombocytopenia, but isolated anemia less commonly occurs. The cytopenias are often moderate to severe. In CDV infections, erythrocytes or leukocytes may contain one or more pale blue spots in the cytoplasm when stained with methanolic Romanowsky-type stains. However, these inclusions stain a deep purple color with an aqueous Romanowsky stain such as Diff-Quik® (Figure 16.32a–d). Other diagnostics should be directed at finding the underlying cause for aplastic anemia and include historical inquires of drug, radiation, or toxin exposure, testing for specific infectious agents, and evaluation for estrogen-secreting neoplasms.

Management

Specific treatment is directed at the underlying cause of the aplastic anemia, and includes cessation of myelotoxic drug administration, toxin removal, antiviral therapy, doxycycline administration for chronic *E. canis* infection, and surgical removal of estrogen-secreting neoplasms. Immune suppression may be attempted for nonassociative aplastic anemia. Supportive therapy may include blood transfusions for anemia or DIC, broad-spectrum antibiotics for neutropenia-induced bacterial infections, and bone marrow stimulants. Supportive treatment is likely to be required for an extended period of time.

Prognosis

The prognosis is guarded to poor, but complete clinical recovery is possible.

INFILTRATIVE BONE MARROW DISEASE (MYELOPHTHISIS)

Definition/Overview

The replacement of normal hematopoietic tissue in the bone marrow is termed *myelophthisis*.

Etiology

The marrow may be replaced by collagen (myelofibrosis), inflammatory cells (e.g., infectious myelitis due to histoplasmosis, other fungal infections, or toxoplasmosis), or neoplastic cells (e.g., hematopoietic or metastatic neoplasms).

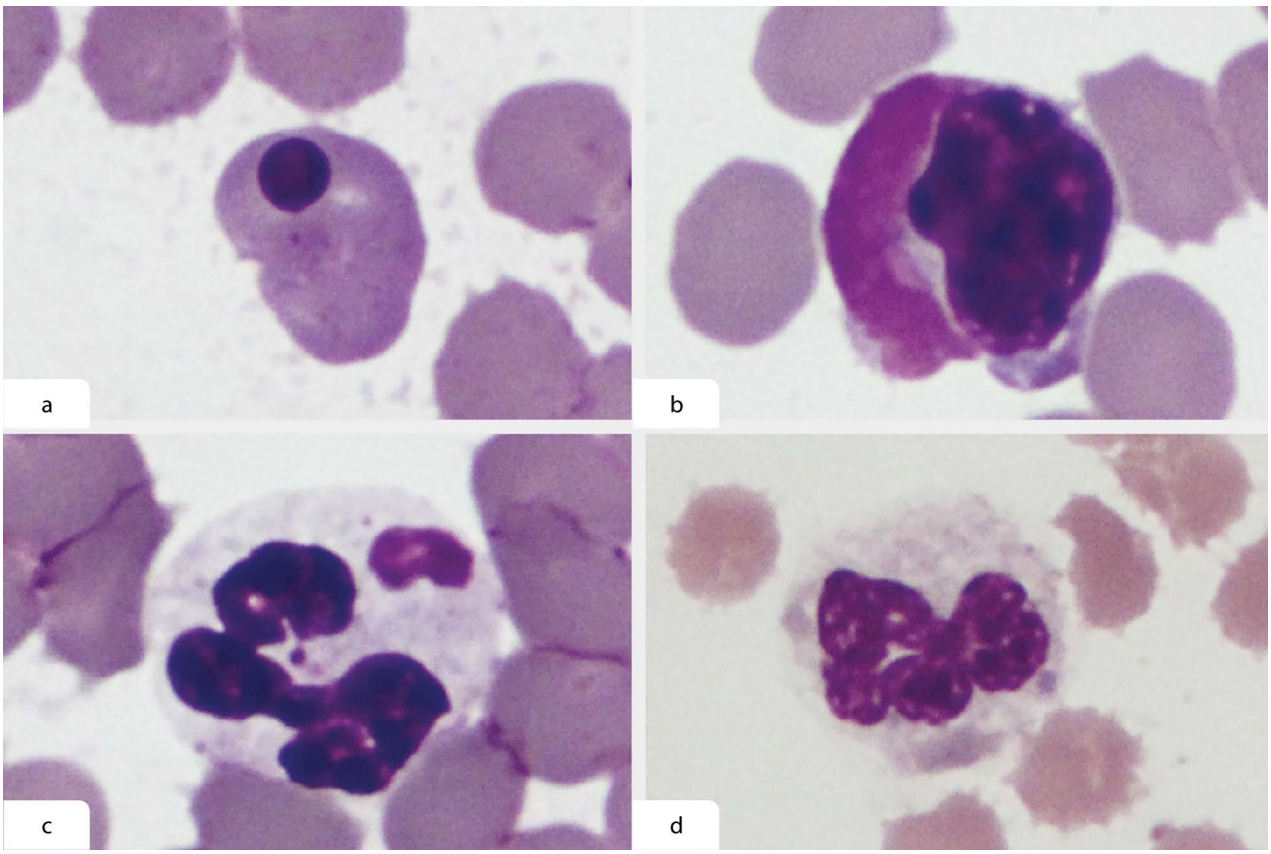

FIGURE 16.32 Canine distemper viral inclusions in an erythrocyte **(a)**, lymphocyte **(b)**, and neutrophils **(c and d)**. Vibrant magenta staining occurs with aqueous Romanowsky staining **(a–c)**, but methanolic Romanowsky stains impart a light pink–blue appearance **(d)**.

Pathophysiology

Mild infiltrates or focal lesions within the bone marrow produce minimal peripheral blood changes. Cytopenia occurs if involvement is diffuse and severe. Myelofibrosis usually occurs because of marrow damage produced by inflammation, necrosis, neoplasia, and toxic agents and may be seen in the terminal stages of chronic hemolytic anemia. Myelofibrosis is also associated with myelodysplastic syndrome and acute myelogenous leukemia in cats or with chronic myeloid neoplasia in dogs and cats.

Clinical Presentation

Animals are often presented with pale mucous membranes, fever, and bleeding, occasionally accompanied by hepatomegaly, splenomegaly, and lymphadenopathy.

Differential Diagnosis

Drug toxicosis, myelodysplastic syndrome, hematolymphatic neoplasia, and endogenous hyperestrogenism.

Diagnosis

Myelophthisis is likely if there is bicytopenia or pancytopenia with circulating neoplastic cells or evidence of systemic infection (e.g., fungal or protozoal organisms seen in blood smears or in tissue biopsies). Dacryocytes may be seen on blood smears (Figure 16.33). However, the definitive diagnosis of an infiltrative process requires bone marrow examination by both aspirate and core biopsies. Bone marrow aspiration attempts on fibrotic marrow usually produce "dry taps" (i.e., blood alone, without marrow particles). In such cases, bone marrow core biopsy is diagnostic (Figure 16.34).

Management

Treatment is directed at the underlying cause of cytopenia and may include immunosuppressive, antibiotic/antifungal, or antineoplastic therapy for nonassociative myelofibrosis, infectious myelitis, or neoplasia, respectively. Supportive care, including antibiotics, blood transfusions, anabolic steroids, and glucocorticoids, is often needed in severe cases. The condition may be reversible.

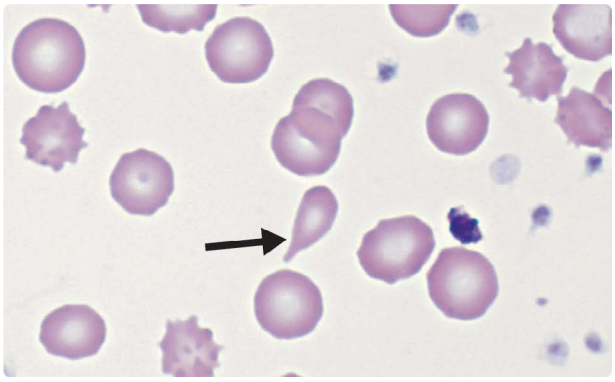

FIGURE 16.33 Dacryocyte (arrow) from the blood of a dog with myelofibrosis.

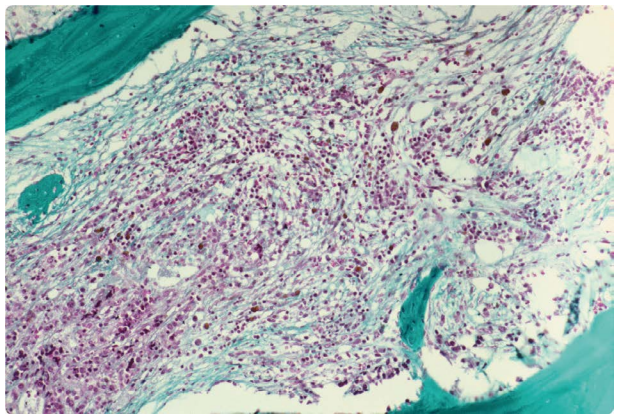

FIGURE 16.34 Bone marrow core section with trichrome stain for collagen (in green). Note the tight fibrillar arrangement of connective tissue, demonstrating myelofibrosis.

FELINE LEUKEMIA VIRUS-ASSOCIATED ANEMIA

Definition/Overview

Anemia is a major nonneoplastic complication of FeLV infection in cats. The anemia is variable in severity and regenerative status and is dependent on the underlying mechanism.

Etiology

FeLV infects hematopoietic stem cells and the supporting marrow stromal cells.

Pathophysiology

Most FeLV-associated anemias are nonregenerative. Mild-to-moderate nonregenerative anemia may occur secondary to AID. More severe nonregenerative anemia is expected with selective erythrocyte atrophy, PRCA, erythroid leukemia, or neoplastic myelophthisis. PRCA is associated with FeLV-C infection. When the virus infects erythroid precursors, it may cause either selective erythroid precursor damage (erythroid atrophy or PRCA) or neoplastic transformation of erythroid precursors. Erythroid neoplastic transformation leads to the proliferation of abnormal erythroid cells with defective metabolism, function, and maturation. These dysfunctional neoplastic cells fail to mature or prematurely die within the marrow, resulting in ineffective erythropoiesis in the marrow and anemia in the peripheral blood. Defective mitosis may cause macrocytic RBCs. Approximately 10% of FeLV-associated anemias are regenerative. Virus-induced immune suppression may allow secondary hemoplasmosis and infectious hemolytic anemia. FeLV may induce the expression of foreign antigens on erythrocyte surfaces, thereby inciting IMHA. Hemorrhage may occur secondary to

thrombocytopathia (i.e., platelet dysfunction) or suppressed platelet production causing marked thrombocytopenia (<50,000 platelets/μL).

Clinical Presentation

Clinical presentation is dependent on the severity and cause of anemia. Affected cats with moderate-to-marked nonregenerative anemia often show chronic wasting disease characterized by pale mucous membranes, lethargy, and anorexia.

Differential Diagnosis

Lymphoma, systemic mycoses, or other chronic inflammatory conditions, other viral infections, chronic kidney disease.

Diagnosis

Most FeLV-associated anemias are mild to severe, normocytic to macrocytic, normochromic, and nonregenerative or poorly regenerative. Nucleated erythrocytes in circulation with inadequate RBC regeneration (inappropriate metarubricytosis) or nucleated erythrocytes with asynchronous maturation (megaloblasts) may be noted. Concurrent neutropenia and thrombocytopenia occur with aplastic anemia, leukemia, or myelophthisis. Bone marrow findings vary from PRCA to erythroid hypoplasia to erythroid neoplasia (myelodysplastic syndrome or acute myeloid leukemia-M6). Concurrent findings with regenerative anemia may include hemotropic mycoplasma infection or marked thrombocytopenia. A definitive FeLV association is diagnosed with positive ELISA, PCR, or IFA tests.

Management

Treatment will vary depending on the presence of concurrent conditions such as neoplasia, hemoplasmosis, FIV infection, or FIP. Hematologic abnormalities due to defective production are mostly irreversible. However, marrow hypoplasia may be cyclical, so temporary life support may be considered during times of cytopenias. See Chapter 21.

Prognosis

Cats with PRCA often relapse with cessation of treatment, while those with aplastic anemia typically do not respond to treatment. Regardless of the cause, regenerative FeLV-associated anemias tend to respond favorably to treatment.

ERYTHROID DYSPLASIA

BONE MARROW DYSCRASIA OF POODLES

Definition/Overview

Bone marrow dyscrasia is a hereditary disorder of Toy and Miniature Poodles characterized by erythrocyte macrocytosis without anemia or reticulocytosis.

Etiology

The underlying etiology is unknown.

Pathophysiology

Measurements of folate or vitamin B12 are normal, and there is no response to therapeutic doses of vitamin B12. The abnormality appears to originate from bone marrow, as precursors are dysplastic.

Clinical Presentation

There are no associated clinical signs (incidental finding).

Differential Diagnosis

Myelodysplastic syndrome, drug-induced dysplasia, vitamin deficiency dysplasia, causes of regenerative anemia.

Diagnosis

Diagnosis is based on the breed and hematologic findings of normal PCV and reticulocyte results, macrocytosis (MCV >80 fL), inappropriate metarubricytosis with megaloblasts, Howell–Jolly bodies, and neutrophil hypersegmentation and gigantism (**Figure 16.35**).

Management

Treatment is not needed.

Prognosis

No negative clinical effects.

LEAD POISONING

See also Chapter 20.

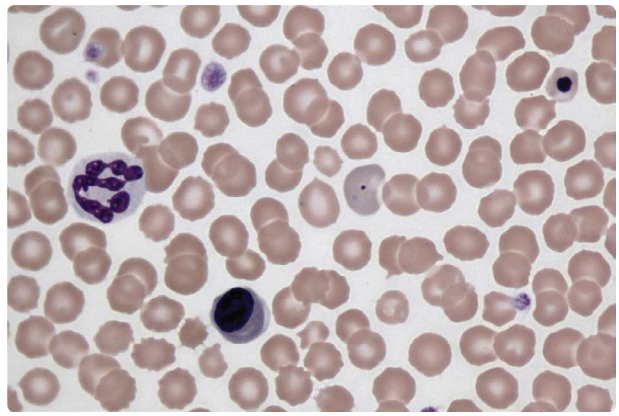

FIGURE 16.35 Blood from a Poodle with marrow dyscrasia demonstrating a hypersegmented neutrophil, inappropriate metarubricytosis, and nuclear fragments within erythrocytes. The MCV was 99.1 fL (reference range 66.4–77.4) without reticulocytosis.

Definition/Overview

Young animals are particularly susceptible to lead poisoning because it is absorbed quickly and may cross the blood–brain barrier in larger amounts than in older animals. Dietary calcium may increase lead absorption.

Etiology

Causes of lead poisoning include lead shot, especially if it is embedded in tissue in or near joints, and ingestion of lead-containing paint, linoleum, plumbing solder, and window caulking.

Pathophysiology

This condition causes mild anemia in some cases, possibly due to increased RBC fragility and abnormal erythropoiesis. Lead primarily affects heme synthesis, causing defective maturation.

Clinical Presentation

See Chapter 20. The anemia is usually not the reason for presentation.

Differential Diagnosis

Iron deficiency, FeLV infection, drug toxicosis, neurologic disorders, GI disorders, splenic neoplasia (e.g., hemangiosarcoma).

Diagnosis

Diagnosis is often based on a history of exposure to lead and increased lead concentrations in heparinized blood. The most consistent hematologic findings are nucleated RBCs with normal or slightly decreased PCV and no RBC regeneration (54% of cases have inappropriate metarubricytosis). When present, the anemia is often normocytic and normochromic but may be microcytic and hypochromic. Basophilic stippling is present in 25% of dogs with lead poisoning (Figure 16.36). Bone marrow aspirates or core biopsies are characterized by maturation arrest at the metarubricyte stage.

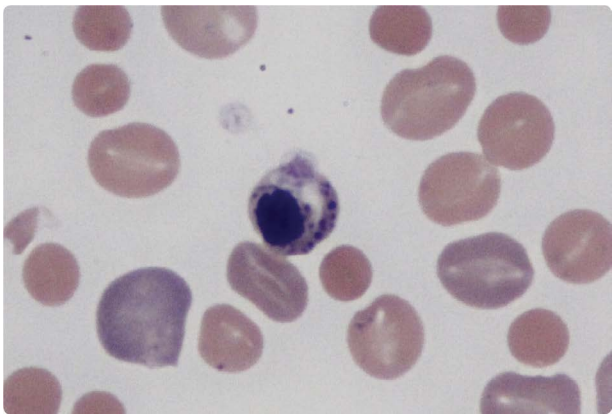

FIGURE 16.36 Basophilic stippling in a nucleated erythrocyte from a dog with lead poisoning.

Management

See Chapter 20.

Prognosis

See Chapter 20.

ERYTHROCYTOSIS

Erythrocytosis is an increased RBC concentration in peripheral blood that is detected by an increased PCV, Hct, RBC count, or Hgb concentration. Erythrocytosis may be relative (i.e., there is hemoconcentration or redistribution of RBCs in circulation) or absolute (increased RBC mass due to increased RBC production). Absolute erythrocytosis is further classified as primary or secondary. If erythroid proliferation is independent of EPO concentration, then absolute erythrocytosis is primary or erythroid neoplasia. Secondary erythrocytosis is either appropriate or inappropriate (Figure 16.37). If the RBC hyperplasia is secondary to systemic hypoxemia (arterial O_2 <92%, e.g., underlying cardiopulmonary disease), it is considered appropriate. Secondary inappropriate erythrocytosis develops with EPO-producing tumors or local renal hypoxemia secondary to renal disease with increased EPO production (neoplastic or pyelonephritis). Polycythemia is sometimes used interchangeably with erythrocytosis but is also used to mean absolute erythrocytosis. Polycythemia vera (PV) is a neoplastic proliferation of hematopoietic cells that produce mature erythrocytes.

RELATIVE ERYTHROCYTOSIS

Definition/Overview

The increased RBC concentration is due to redistribution of fluid or RBCs.

Etiology

Etiologies include dehydration, excitement, and endotoxic shock.

Pathophysiology

Fluid loss from the blood vessels causes a relative increase in the proportion of RBCs. Fluid may be lost from the body with dehydration or shifted into the interstitial tissues with endotoxic shock. The spleen contracts during an excitement/physiologic response to epinephrine, releasing erythrocytes from the splenic sinusoids into peripheral circulation.

Clinical Presentation

Dehydrated patients may be presented with tacky mucous membranes, prolonged CRTs, and skin tents. Animals with epinephrine-induced physiologic responses are often young, healthy animals that are easily excited.

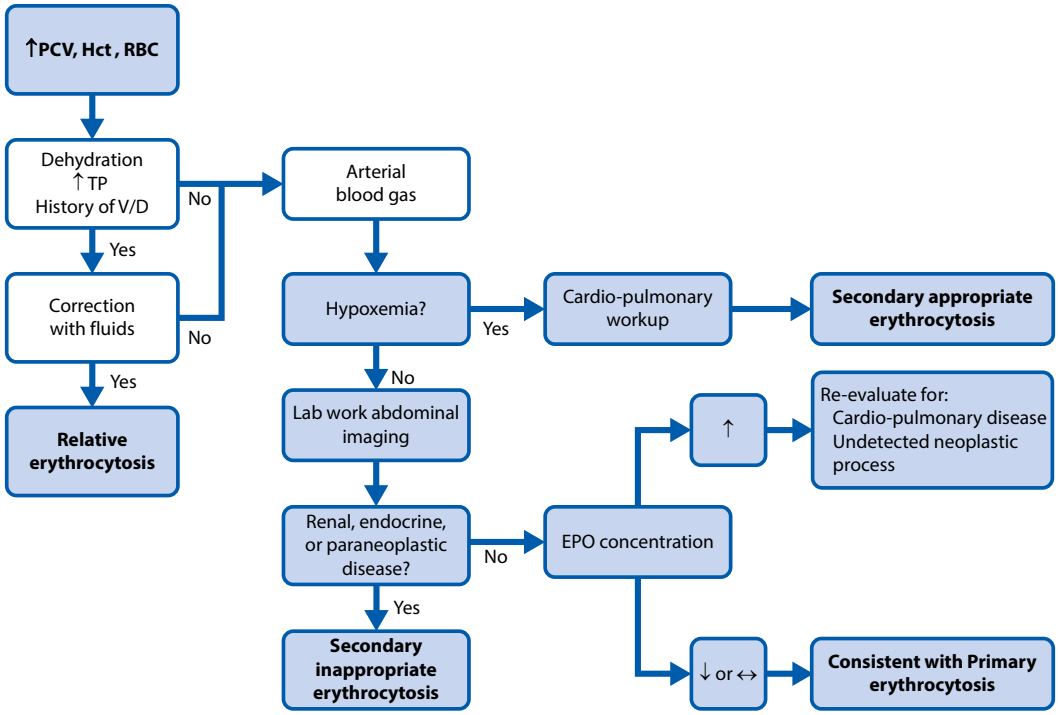

FIGURE 16.37 Workup considerations for the animal with erythrocytosis.

Differential Diagnosis

Causes of absolute erythrocytosis (heart disease, chronic pulmonary disease, hyperthyroidism, renal neoplasms, nonrenal neoplasms, PV, and acute erythroid leukemia).

Diagnosis

The diagnosis is based on the CBC, history, and physical examination. The hemogram indicates a red cell mass (PCV, Hct, Hgb, and/or RBC) that exceeds the normal reference interval for that species or breed. Greyhounds and Dachshunds normally have a high PCV of 0.6 L/L (60%), which should not be misinterpreted as erythrocytosis. Highly concentrated urine, azotemia, and concurrent increases in serum total protein, sodium, and chloride concentrations may be present with dehydration. Epinephrine release may also cause an excitement leukogram (mild neutrophilia and lymphocytosis without a left shift), thrombocytosis, and hyperglycemia.

Management

Dehydrated patients may need fluid therapy. Treatment is not necessary for excitement-induced erythrocytosis, as the response often normalizes within 30 minutes. If the erythrocytosis resolves with rehydration and does not recur, then the diagnosis is confirmed.

SECONDARY ABSOLUTE ERYTHROCYTOSIS

Definition/Overview

Secondary erythrocytosis involves overproduction of EPO or an EPO-like substance. The erythrocytosis is appropriate if it is in response to hypoxia but inappropriate if oxygen transport and tissue use are normal.

Etiology

Causes of secondary appropriate erythrocytosis include hypoxia (e.g., high altitude, chronic pulmonary disease, cardiac disease with right-to-left shunting, hyperthyroidism, or chronic methemoglobinemia). Secondary inappropriate erythrocytosis is caused by tumors that produce erythropoietin (e.g., renal lymphoma, renal carcinoma, and renal fibrosarcoma) and renal disease (e.g., pyelonephritis, local hypoxemia).

Pathophysiology

As a physiologically appropriate response to hypoxia, EPO production is stimulated by cardiopulmonary disorders. When the hypoxic stimulation is absent, an inappropriate production of EPO or EPO-like substance occurs related to tumor development or renal disease. Marked erythrocytosis can cause blood hyperviscosity and then poor tissue perfusion.

Clinical Presentation

Signs may be acute despite the chronic nature of the disorder. Initial findings are dependent on the initiating disease and the presence of hyperviscosity. Findings directly resulting from the erythrocytosis may include erythema, splenomegaly, and bright red mucous membranes. Clinical signs associated with hyperviscosity include functional abnormalities of the CNS and hemorrhage (epistaxis, hyphema, or GI bleeding).

Differential Diagnosis

PV and relative erythrocytosis.

Diagnosis

An arterial blood gas enables the clinician to determine if hypoxemia is present (Figure 16.37). If O_2 <92%, then workup for cardiopulmonary disease is indicated (thoracic radiographs, echocardiography, EKG, and BP). If there is no hypoxemia, laboratory workup (hematology, biochemistry including TT4, urinalysis, and culture) and abdominal diagnostic imaging is indicated to identify the underlying cause such as significant renal pathology, hyperthyroidism, or a paraneoplastic process. If no underlying disease is identified, EPO concentration can be measured (species-specific test). A low or normal EPO concentration is consistent with primary erythrocytosis. An elevated EPO suggest that an underlying disease has been missed, and the animal should be reassessed for cardiopulmonary disease or undetected neoplastic process. Serum EPO levels are currently measured by radioimmunoassay and ELISA methods.

Management

Treatment of secondary erythrocytosis often involves removal of the inciting cause (e.g., nephrectomy). Phlebotomy is indicated if there are signs of hyperviscosity.

METHEMOGLOBINEMIA

Definition/Overview

Methemoglobin may be produced in amounts that exceed normal protective antioxidant mechanisms. This form of Hgb is unable to bind and carry oxygen. Normal amounts of methemoglobin are <1% of total Hgb.

Etiology

Methemoglobinemia occurs most commonly from exposure to oxidative agents mentioned under Heinz body formation (p. 668). Rarely, a hereditary deficiency of methemoglobin reductase (cytochrome-b5 reductase) may cause methemoglobinemia. The latter has been documented in several dog breeds and a DSH cat.

Pathophysiology

The erythrocyte antioxidant pathways are overwhelmed, which results in heme oxidation from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Hemoglobin within the ferric state is termed methemoglobin and is unable to bind oxygen, producing a state of hypoxia.

Clinical Presentation

Clinically, the mucous membranes appear blue–gray or cyanotic (Figure 16.38) if methemoglobin levels exceed 0.2 L/L (20%). The patient is often dyspneic, weak, and ataxic when the methemoglobin content exceeds 0.5 L/L (50%).

FIGURE 16.38 This cat with methemoglobinemia as a result of acetaminophen toxicity has blue–gray gums. (*Courtesy of S. Ford.*)

Differential Diagnosis

Causes of multisystemic hypoxia without anemia (e.g., pulmonary disease, right-to-left cardiac shunts), causes of hemolytic anemia (e.g., IMHA, hemoplasmosis, babesiosis).

Diagnosis

The appearance of dark red or chocolate-colored blood, even after exposure to air, is diagnostic for the condition and is readily visible by a spot test on filter paper. When normal blood is exposed to air it becomes bright red, while the blood of affected animals stays dark red if the methemoglobin content exceeds 10% (Figure 16.39). Methemoglobin content is measured by spectrophotometry by a CO-oximeter or at specialized laboratories;

FIGURE 16.39 Two tubes of blood recently exposed to air. The tube on the left remains a dark color compared with normal blood in the right tube, indicating methemoglobinemia. (*Courtesy of J. Harvey.*)

the pulse oximeter cannot detect methemoglobinemia. Other erythrocyte changes may include mild secondary polycythemia in animals with methemoglobin reductase deficiency or regenerative anemia, Heinz bodies, and eccentrocytes in animals with oxidant-induced hemolytic anemia.

Management

Treatment is similar to that for Heinz body anemia. The source of oxidant should be removed with emetics if recent ingestion has occurred. For acetaminophen (paracetamol)-induced toxicity, acetylcysteine (Mucomyst®) is given initially IV at 140 mg/kg of a 5% solution diluted with saline and then 70 mg/kg (of a 5% solution) q.4 h. for 3–5 treatments. In addition, sodium ascorbate (vitamin C) may further reduce methemoglobin levels. A dose of 100–500 mg/day IV is recommended for dogs, and a dose of 100 mg/day IV is recommended for cats (see Chapter 20). Therapy is usually not required for animals with the reductase enzyme deficiency.

LEUKOCYTE DISORDERS (NONNEOPLASTIC)

LEUKOCYTOSIS

Leukocytosis is an increased concentration of the collective white blood cell (WBC) concentration above its reference interval. It does not distinguish which leukocyte type is increased.

Note that some hematology analyzers (e.g., impedance analyzers) cannot distinguish nucleated RBCs (NRBCs) from WBCs. Therefore, the automated WBC count is the sum of WBCs and NRBCs and should be considered the total nucleated cell count (TNCC) in these cases. If a metarubricytosis is present, the corrected WBC (CWBC) count can be calculated using the TNCC and a blood smear quantification of NRBCs (NRBCs/100 WBCs):

$$CWBC = TNCC \times 100/(100 + NRBCs/100\ WBCs)$$

NEUTROPHILIA

Neutrophilia is defined as a neutrophil concentration above the upper reference interval, which is generally >11,500/µL in the dog and >12,500/µL in the cat. Common causes of neutrophilia are excitement, stress, and inflammation, whereas uncommon to rare causes include paraneoplastic syndromes, myeloid leukemia, and canine leukocyte adhesion deficiency (CLAD).

Neutrophilia is further classified as "mature" or "left shifted" based on the absence or presence of immature neutrophils in blood, respectively. Mature neutrophils have condensed and dark chromatin with indentations or pinches in the nucleus that creates alternating segments of wide and narrow nuclear diameters. Mature neutrophils are, therefore, termed, "segmented neutrophils." Immature neutrophils lack segments and include band neutrophils (parallel nuclear walls), metamyelocytes (kidney bean-shaped nuclei), myelocytes (round or oval nuclei), promyelocytes (round or oval nuclei with pink cytoplasmic granules), and myeloblasts (round or oval nuclei with a nucleolus). In blood, segmented neutrophils predominate with no or rare band neutrophils. An increased concentration of immature neutrophils in blood is termed "left shift" and indicates increased demand for neutrophils during inflammation or inappropriate release of neutrophils in the absence of inflammation (e.g., leukemia). When immature neutrophils are released into blood during inflammation, the most mature neutrophil is released first, and earlier stages are released when more mature stages are depleted. Consequently, band neutrophils are first released during inflammation and are the most common immature neutrophil seen in blood. When attempting to distinguish the cause of the neutrophilia as inflammation or noninflammatory (excitement or stress), the presence of one or more of the following observations supports an inflammatory etiology: Neutrophilia >2–3 times the upper reference limit, presence of left shift, or neutrophil toxicity.

PHYSIOLOGIC AND CORTICOSTEROID-INDUCED NEUTROPHILIA AND MONOCYTOSIS

Definition/Overview

Physiologic (excitement or shift) neutrophilia and monocytosis are a transiently increased neutrophil and monocyte concentrations associated with epinephrine release during a fight or flight response. See **Table 16.12**.

CORTICOSTEROID-INDUCED NEUTROPHILIA AND MONOCYTOSIS

Definition/Overview

Neutrophilia and monocytosis (the latter especially in dogs) may be related to exogenous administration or endogenous release of glucocorticoids or ACTH. See **Table 16.12**.

Signs will reflect the underlying condition. See Chapter 11 for hyperadrenocorticism.

INFLAMMATORY NEUTROPHILIA

Definition/Overview

Inflammation causes increased mobilization of neutrophils from the bone marrow to the site of tissue inflammation (**Table 16.12**). The main indicators of inflammation are increased numbers of immature neutrophils in the blood, termed a left shift, and neutrophil toxicity.

TABLE 16.12 Common neutrophilia patterns and mechanisms of leukocyte concentration change*

Peripheral leukocyte	Physiologic leukogram (epinephrine)†	Stress leukogram (glucocorticoids)‡	Acute inflammatory leukogram	Chronic inflammatory leukogram
Segmented Neutrophils	↑ Marginal to circulating	↑ Marginal to circulating	↑–↑↑↑ Marginal to circulating Storage to circulating	↑–↑↑↑ Marrow hyperplasia
Band Neutrophils	N	N	±↑–↑↑ Maturation to circulating	±↑–↑↑ Marrow hyperplasia
Lymphocytes	±↑ Marginal to circulating Lymphatics to circulating	↓ "Homing" to lymph nodes Lympholysis	↓ "Homing" to lymph nodes	±↑ Lymphoid hyperplasia
Monocytes	N	±↑ Marginal to circulating	±↑ Marginal to circulating	±↑ Marrow hyperplasia
Eosinophils	N	±↓ Sequestered in marrow	±↓ Sequestered in marrow	±↑ Marrow hyperplasia

* Increased concentrations of nonlymphoid leukocytes in the blood circulating pool (free-flowing cells sampled during phlebotomy) may occur by (1) release of the bone marrow storage pool of mature cells into blood, (2) release of immature cells from the bone marrow maturation pool into blood, (3) or shifting from the blood marginal pool (leukocytes reversibly adhered to endothelium) to the blood circulating pool. Altered concentrations of lymphocytes in the blood circulating pool may occur with lymphocytes moving between the blood marginal pool, blood circulating pool, and secondary lymphoid tissues, such as lymph nodes. In dogs, there are equal numbers of blood marginal and circulating neutrophils, while cats have three times more neutrophils in the marginal pool compared to the circulating pool. Therefore, shifting of neutrophils from the marginal pool to the circulating pool may be greater in cats, in which a threefold increase in neutrophils may occur compared with a twofold increase in dogs.

† Transient increase due to epinephrine release during times of physiologic excitement or flight-fight response. Concurrent abnormalities include relative erythrocytosis, thrombocytosis, and hyperglycemia. Resolution is expected within 30 minutes.

‡ Secondary to stress, hyperadrenocorticism (Cushing's syndrome), or exogenous administration of glucocorticoids or ACTH. Resolution is expected within 24 hours after a single dose of prednisolone. At higher glucocorticoid concentrations, lymphocyte cell death (lympholysis) may occur.

A marked inflammatory neutrophilia that exceeds 50,000 neutrophils/μL is called a leukemoid response.

Etiology

The etiology can involve infectious or noninfectious sources. Infectious agents include bacteria, fungi, protozoa, or rickettsiae. Noninfectious conditions involve tissue necrosis such as necrotizing pancreatitis, neoplasia, immune-mediated disease, severe GI disease, thrombosis, and thermal burns. A leukemoid response may be associated with IMHA, pancreatitis, pyelonephritis, pyometra, peritonitis, pneumonia, hepatozoonosis, and malignant neoplasms with necrotic centers, especially carcinomas.

Pathophysiology

Inflammatory conditions produce cytokines, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte/macrophage colony-stimulating factor (GM-CSF), which promote release of neutrophils from the bone marrow and stimulate granulopoiesis.

Clinical Presentation

Sites of inflammation may be apparent from physical examination or diagnostic procedures. Signs will reflect the underlying condition. Pyrexia is often present.

Differential Diagnosis

Physiologic neutrophilia, corticosteroid-induced neutrophilia, hematopoietic leukemia.

Diagnosis

Diagnosis of inflammatory neutrophilia is based on a careful history and CBC evaluation. The most specific hematologic indicators of inflammation are the presence of a left shift or neutrophil toxicity.

Management

Treatment will depend on the inciting cause.

OTHER CAUSES OF NEUTROPHILIA

Paraneoplastic neutrophilia is caused by production of G-CSF by neoplasms, such as rectal adenomatous polyp, renal tubular carcinoma, and fibrosarcoma. CLAD is a genetic disorder characterized by marked neutrophilia and recurrent, life-threatening infections due to the inability of neutrophils to exit blood vessels and enter tissues. Both paraneoplastic neutrophilia and CLAD tend to produce neutrophilia that exceed 50,000/μL. Canine granulocytopathy syndrome is a rare condition of Irish Setter dogs characterized by recurrent life-threatening bacterial infections, pyrexia, and leukemoid response with impaired neutrophil bactericidal activity.

EOSINOPHILIA

Eosinophils are identified by pink–orange cytoplasmic granules that are round and variably sized in dogs and small and rod-shaped in cats (Figure 16.40). In some Greyhounds, Golden Retrievers, and Shetland Sheepdogs,

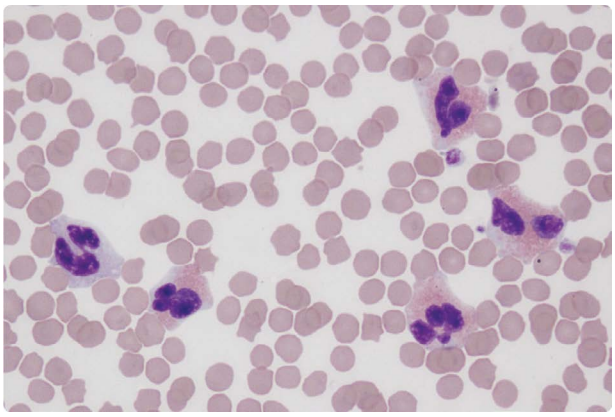

FIGURE 16.40 Blood from a cat with hypereosinophilic syndrome. Note the four eosinophils and one neutrophil (far left). These have the usual pink-staining cytoplasmic granules typical of eosinophils.

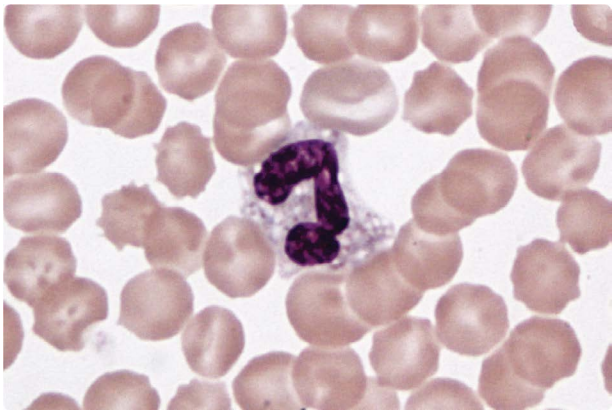

FIGURE 16.41 Canine eosinophil with poorly staining granules (gray eosinophil).

and, rarely, cats, eosinophils may have granules that do not stain with Romanowsky stains and are termed gray eosinophils (Figure 16.41). *Eosinophilia* is defined as an eosinophil concentration above the upper reference interval, which is generally >1,250/µL in the dog and >1,500/µL in the cat. Nonneoplastic eosinophilia is due to inflammation, fungal disease, parasitic disease, hypoadrenocorticism, or paraneoplastic response.

INFLAMMATORY EOSINOPHILIA

Definition/Overview

Eosinophilia may be seen with tissue parasitism or allergic (hypersensitivity) disorders.

Etiology

Peripheral eosinophilia may result from infiltration of the skin, respiratory tract, and alimentary tract by such parasites as *Ancylostoma* spp., *Trichuris vulpis*, *Toxocara canis*, *Dirofilaria immitis* (Figure 16.23), *Acanthocheilonema* (formerly *Dipetalonema*) *reconditum*, *Aelurostrongylus abstrusus*, *Eucoleus* (formerly *Capillaria*) spp., *Filaroides* spp., and *Paragonimus kellicotti*. Hypersensitivity reactions can occur from the effects of fleas, food, grasses, and nonspecific allergens. Many idiopathic eosinophilic conditions are thought to be hypersensitivity reactions, including feline eosinophilic granuloma complex and canine degranulation eosinophilic bronchopneumopathy.

Pathophysiology

T cell–dependent eosinophils are associated with parasitic infections and hypersensitivities. This type of eosinophilia is mediated by soluble factors, especially IL-5 and GM-CSF.

Clinical Presentation

Signs reflect the organ systems affected, such as skin rashes, diarrhea, coughing, and scratching.

Differential Diagnosis

Hypoadrenocorticism, paraneoplastic eosinophilia, hypereosinophilic syndrome, and leukemia.

Diagnosis

Diagnosis of parasitism or hypersensitivities includes history, physical examination, food trials, skin tests, laboratory testing (e.g., heartworm antigen test), and evaluations of blood smears for microfilaria (Figure 16.23), fecal floats and sediment, tracheobronchial washes, and cytologic or histologic biopsies.

Management

Treatment is aimed at the underlying cause.

HYPOADRENOCORTICISM (ADDISON'S DISEASE)

See also Chapter 12.

Definition/Overview

Glucocorticoids (e.g., cortisol) and mineralocorticoids (e.g., aldosterone) are hormones produced by the adrenal cortex. Deficient production of these hormones leads to hypoadrenocorticism. Eosinophilia is present in 20% of dogs with hypoadrenocorticism.

Etiology

Hypoadrenocorticism in dogs is typically a result of immune-mediated destruction of the adrenal cortex. Pituitary disease-causing ACTH deficiency is uncommon.

Pathophysiology

The pathophysiology of eosinophilia is not completely known but probably involves cortisol deficiency.

Clinical Presentation

See Chapter 12. The anemia is usually not the primary cause of presentation.

Differential Diagnosis

Inflammation, paraneoplastic eosinophilia, hypereosinophilic syndrome, and leukemia.

Diagnosis

Diagnosis is often based on history, physical examination findings, and blood tests for electrolytes and serum basal and post-ACTH cortisol levels. The most consistent hematologic abnormality is lack of a stress leukogram in a clinically ill animal. Less frequently, lymphocytosis and eosinophilia are seen.

Management

See Chapter 12.

PARANEOPLASTIC EOSINOPHILIA

Definition/Overview

Paraneoplastic syndromes are disorders caused by neoplasms but are not a direct result of the physical presence of the tumor in the organ or tissue.

Etiology

Tumor-associated eosinophilia has been reported in dogs with fibrosarcoma, anaplastic mammary carcinoma, T-cell lymphoma, or mast cell tumors, as well as in cats with mast cell tumors or lymphoma.

Pathophysiology

Tumor production and release of GM-CSF, IL-5, histamine, or chemotactic mediators enhance eosinophil production.

Clinical Presentation

Signs reflect the organ systems affected by the neoplasm and often involve one or more tissue masses in the skin, lymphatic system, or urogenital system.

Differential Diagnosis

Inflammation, hypoadrenocorticism, hypereosinophilic syndrome, and leukemia.

Diagnosis

Diagnosis of a paraneoplastic eosinophilia requires normalization or reduction of the eosinophil concentration in response to cancer remission.

Management

Treatment will reflect the underlying disease and may include surgery, radiation therapy, or chemotherapy.

HYPEREOSINOPHILIC SYNDROME

Definition/Overview

Hypereosinophilic syndrome is an uncommon form of peripheral eosinophilia in cats and has also been reported in dogs, mostly Rottweilers. The disease is accompanied by severe infiltration of eosinophils into many organs, often including the GI tract, liver, spleen, lymph nodes, and lung. It is difficult to differentiate from chronic eosinophilic leukemia, and at least in human medicine, it is now considered a form of chronic leukemia.

Etiology

The etiology is unknown.

Pathophysiology

There is often evidence of intestinal thickening and involvement of the bone marrow that resembles leukemia of well-differentiated eosinophils. Counts have been reported to exceed 50,000/μL (**Figure 16.40**). It is usually a multisystemic disease with involvement of other organs, especially the GI tract.

Clinical Presentation

Clinical signs reflect organ involvement and may include anorexia, weight loss, fever, vomiting, diarrhea, and lymphadenopathy. Death results from organ dysfunction caused by tissue infiltration.

Differential Diagnosis

Inflammation, paraneoplastic eosinophilia, and eosinophilic leukemia.

Diagnosis

Diagnosis is based on history, physical examination, presence of multisystemic involvement, and ruling out other causes of eosinophilia with fecal examination, heartworm testing, and diagnostic imaging with sampling as indicated. Bone marrow evaluation establishes the number of eosinophil precursor cells and the degree of marrow involvement. Needle and tissue biopsies show eosinophilic infiltrates.

Management

Prednisolone (1–3 mg/kg p.o. q.12 h.), with or without hydroxyurea (7.5 mg/kg p.o. q.12 h.), has been used to reduce eosinophil numbers and clinical signs. Other considerations include cyclosporine and one report of the use of a tyrosine kinase inhibitor.

Prognosis

Cats often respond poorly to chemotherapy for long-term control. Long-term response or remission has been reported in some dogs and some Rottweilers going into remission without specific immunosuppressive treatment.

BASOPHILIA

Basophilia is defined as an increased blood basophil concentration above the upper reference interval, generally >200/μL in the dog and cat (Figure 16.69). With the exception of hypoadrenocorticism and hypereosinophilic syndrome, nonneoplastic causes of basophilia are similar to those for eosinophilia—inflammation due to parasitic infections or hypersensitivities and paraneoplastic basophilia due to mast cell neoplasia or other malignancies. Marked basophilia with atypical leukocytes in the circulation or bone marrow should suggest basophilic leukemia, which is a rare presentation.

It is important to note that basophil granules in dogs and cats stain poorly. In these cases, the cells may be mistaken for toxic neutrophils in dogs or faded eosinophils in cats. In addition, basophilia must be distinguished from circulating mast cells in the dog.

LYMPHOCYTOSIS

Lymphocytosis is an increased concentration of lymphocytes in blood, usually >4,800/μL in the dog and >7,000/μL in the cat. Young animals within the first year of life typically have physiologically higher lymphocyte concentrations relative to adults, so appropriate reference intervals should be used.

Note that the general classifications of lymphocytosis are reactive (physiologic, chronic inflammation, hypoadrenocorticism) and neoplastic. Reactive lymphocytosis tends to be mild to moderate in severity (e.g., <15,000/μL in dogs and <20,000/μL in cats), consists of lymphocytes of varying morphology, and normalizes when the underlying disorder is appropriately treated. Neoplastic lymphocytosis has varying presentations but may be mild to marked in severity, consists of a single lymphocyte morphology, and persists without immunosuppressive or chemotherapy.

PHYSIOLOGIC LYMPHOCYTOSIS

See physiologic neutrophilia and lymphocytosis.

CHRONIC INFLAMMATORY LYMPHOCYTOSIS

Definition/Overview

Chronic antigenic or cytokine stimulation results in lymphoid hyperplasia.

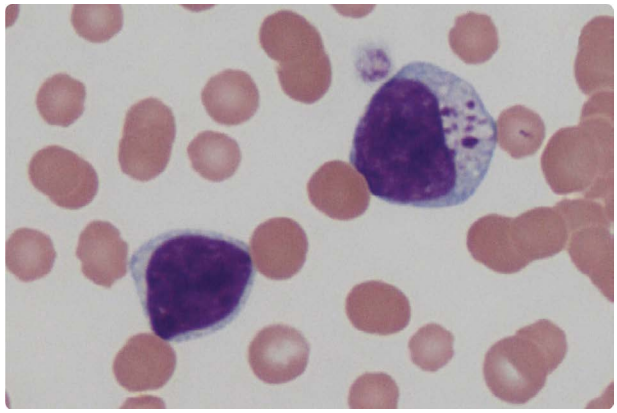

FIGURE 16.42 Compared with a small lymphocyte (left), a large granular lymphocyte (right) has a moderate amount of basophilic cytoplasm containing several coarse pink–purple granules.

Etiology

Chronic inflammation of an infectious or noninfectious etiology can cause lymphoid hyperplasia and subsequent lymphocytosis. In particular, lymphocytosis involving intermediate-sized granular lymphocytes (Figure 16.42) has been associated with *E. canis* infection in dogs. Modified live vaccines may also produce lymphocytosis about 1-week post immunization.

Pathophysiology

Antigen-presenting cells, such as macrophages and dendritic cells, process and present inciting antigens to T lymphocytes. B-cell development often requires costimulatory signals from T-helper cells, along with cytokines, for activation and differentiation into plasma cells that produce antibodies against the inciting antigen.

Clinical Presentation

Signs reflect the underlying inflammatory condition.

Differential Diagnosis

Excitement, hypoadrenocorticism, and lymphoid neoplasia.

Diagnosis

There is typically a mixed lymphoid population of small and large lymphocytes of varying morphology. Slightly enlarged lymphocytes with deeply basophilic cytoplasm (reactive lymphocytes) may be noted (Figure 16.43). Hyperglobulinemia due to a polyclonal gammopathy and plasma cell infiltration of tissues may also occur (Figure 16.44). The presence of intermediate-sized lymphocytes characterized by abundant pale blue cytoplasm with or without granules suggests T-cell stimulation (Figure 16.45). Maximum lymphocytosis in extreme immune reactions is usually <15,000/μL in dogs and <20,000/μL in cats.

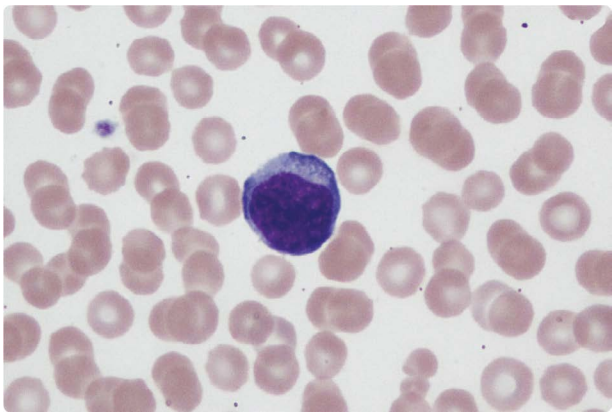

FIGURE 16.43 A reactive lymphocyte with a moderate amount of deeply basophilic cytoplasm and a perinuclear pale zone (Golgi apparatus).

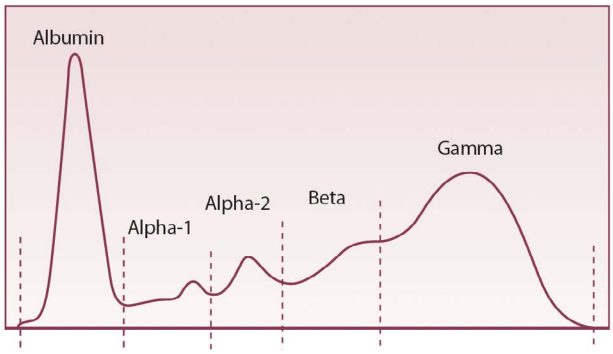

FIGURE 16.44 Serum protein electrophoretic tracing with a broad peak in the gamma region, indicating the presence of a polyclonal gammopathy in a case of canine ehrlichiosis.

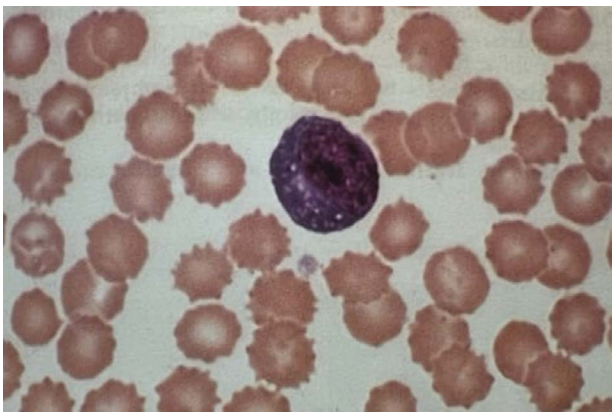

FIGURE 16.45 Intermediate-size lymphocytes.

Management

Treatment should be aimed at the underlying cause.

HYPOADRENOCORTICISM

See also Chapter 12.

Definition/Overview

Glucocorticoids (e.g., cortisol) and mineralocorticoids (e.g., aldosterone) are hormones produced by the adrenal cortex. Deficient production of these hormones leads to hypoadrenocorticism. Lymphocytosis is present in 10%–20% of dogs with hypoadrenocorticism.

Etiology

Hypoadrenocorticism in dogs is typically a result of immune-mediated destruction of the adrenal cortex. Pituitary disease causing ACTH deficiency is uncommon.

Pathophysiology

Corticosteroids cause lymphocytes to leave the circulation and enter lymphoid tissues. A lack of glucocorticoids inhibits this redistribution and allows lymphocyte numbers to increase in the circulation.

Clinical Presentation

See Chapter 11.

Differential Diagnosis

Physiologic lymphocytosis, chronic inflammation, and lymphoid leukemia.

Diagnosis

Lack of a stress leukogram in a visibly ill dog is the most consistent hematologic abnormality. See Chapter 11 for diagnosis.

Management

See Chapter 11.

MONOCYTOSIS

Monocytosis is defined as a blood monocyte concentration above the upper reference interval, generally >1,350/µL in the dog and >850/µL in the cat. It most frequently results from an increased demand for monocytes and tissue macrophages, which function in the defense against infectious agents, phagocytosis of damaged cells and debris, and secretion of many important biologically active molecules. Monocytes are not stored in the bone marrow during production but are immediately released. However, they may marginate in blood vessels for short periods of time or enter tissues from the circulating pool. Monocytes entering the tissues differentiate into macrophages, which can persist for days to months. Myeloid leukemia should be considered when monocyte counts exceed 15,000/µL or immature monocytoid forms are predominant.

CORTICOSTEROID-INDUCED MONOCYTOSIS

See corticosteroid-induced neutrophilia and monocytosis.

CHRONIC INFLAMMATORY MONOCYTOSIS

Definition/Overview

Monocytosis may occur with acute or chronic inflammation. However, the monocytosis associated with acute conditions is secondary to stress, whereas chronic inflammatory monocytosis results from monocytic hyperplasia.

Etiology

Inflammatory diseases that cause a high demand for tissue macrophages may produce monocytosis. These include immune-mediated disorders, tissue necrosis, foreign body reactions, and mycobacterial or fungal infections.

Pathophysiology

Inflammatory conditions produce cytokines, such as GM-CSF, macrophage colony-stimulating factor, and IL-3, which stimulates marrow production of monocytes.

Clinical Presentation

Signs will reflect the underlying inflammatory condition.

Differential Diagnosis

Corticosteroid-induced monocytosis, myeloid leukemia.

Diagnosis

Other hematologic abnormalities with chronic inflammation may include neutrophilia, neutrophil left shifting, toxic neutrophils, and lymphocytosis.

Management

Treatment is aimed at the inciting cause.

MASTOCYTEMIA

Mast cell precursors are produced in the bone marrow as nongranular mononuclear cells. They travel through peripheral blood to complete their maturation in solid tissues. As such, mast cell precursors cannot be distinguished from other mononuclear cells in blood. Mastocytemia is, therefore, defined as the presence of mast cells in peripheral blood, since the observance of any mast cells in blood is abnormal. Hematology analyzers cannot identify mast cells, so blood smear evaluation is imperative to identify mastocytemia. Mast cells are identified by the presence of purple cytoplasmic granules and a round nucleus (Figure 16.46) and should be distinguished from basophils, which have segmented nuclei. Methanolic Romanowsky stains are preferable to aqueous Romanowsky stains for identification of mast cells, since their granules are soluble in the latter stains and may not be visible. Mastocytemia typically indicates disseminated mast cell neoplasia (systemic mastocytosis) in cats, but most dogs with mastocytemia have disease other than mast cell neoplasia. Feline mast cell neoplasms often exhibit erythrophagocytosis.

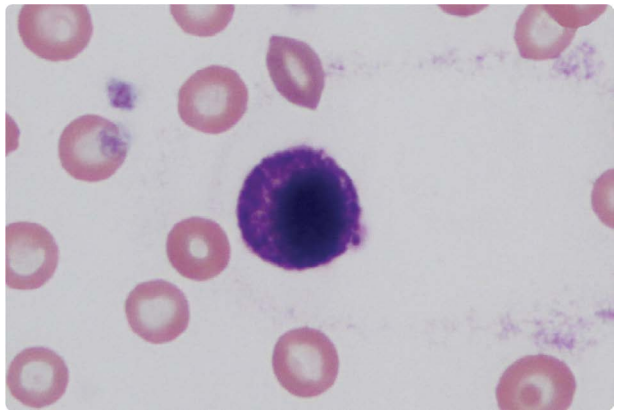

FIGURE 16.46 Mast cells are identified by dark purple cytoplasmic granules and a round nucleus.

Note that when present, mast cells tend to localize within the feathered edge of the blood smear.

REACTIVE MASTOCYTEMIA

Definition/Overview

Nonneoplastic conditions that present with mast cells in blood are termed mastocytemia.

Etiology

Mastocytemia in dogs is associated with inflammatory disease (parvovirus enteritis, hypersensitivities, and acute pancreatitis), regenerative anemia, neoplasms other than mast cell tumors, and trauma.

Pathophysiology

It is suggested that inflamed tissues, such as the GI tract or skin, may release these mast cells more readily than normal.

Clinical Presentation

Signs are dependent on the underlying disorder.

Differential Diagnosis

Mast cell neoplasia.

Diagnosis

History, physical examination, diagnostic imaging, and tissue biopsies are necessary to rule out mast cell neoplasia.

TABLE 16.13 Causes of lymphopenia

Lymphopenia
Corticosteroids – Stress – Cushing's syndrome – Glucocorticoid administration
Acute inflammation
Lymph loss – Gastrointestinal disease – Repeated drainage of chylous effusion
Lymphoid atrophy, hypoplasia, or aplasia – Immunosuppressive drugs – Generalized lymphadenopathy – Viruses (CDV, FeLV, FIV, parvoviruses) – Whole body irradiation – Severe combined immunodeficiency

Management

Treatment will reflect the underlying condition.

LEUKOPENIA

Leukopenia is a decreased concentration of all WBCs combined. Leukopenia may be due to decreases in neutrophils or lymphocytes. Because of their normally low concentrations in blood, decreases in monocytes, eosinophils, or basophils tend not to cause leukopenia. Monocytopenia and basopenia are not clinically significant in dogs and cats. Causes of eosinopenia and lymphopenia are listed in Tables 16.12 and 16.13.

NEUTROPENIA

Neutropenia is decreased blood neutrophils, often <3,000/μL in the dog and <2,500/μL in the cat. It may result from excessive tissue demands, redistribution within the vasculature, peripheral destruction, or decreased production (e.g., chemotherapy). Some breeds, such as Greyhound, have a lower neutrophil count, and breed-specific interval is required to interpret their CBC.

Note that patients with neutrophil concentrations <1,000/μL are at risk for secondary, life-threatening infection, termed neutropenic sepsis. Prophylactic administration of broad-spectrum antibiotics should be considered in these cases.

INFLAMMATORY NEUTROPENIA

Definition/Overview

Tissue utilization of neutrophils exceeds bone marrow production of neutrophils during times of severe inflammation.

Etiology

Causes of severe inflammation are typically infectious and include Gram-negative septicemia, severe enteritis, systemic mycoses, and systemic protozoal infections.

Pathophysiology

Neutrophil migration into inflamed tissues exceeds the release of neutrophils from the bone marrow.

Clinical Presentation

Signs are often indicative of infectious disease, including anorexia, pyrexia, and lethargy. Additional signs are dependent on the affected tissues or organs. If the neutropenia is severe, pyrexia might not be present.

Differential Diagnosis

Myelosuppression, endotoxemia, immune-mediated neutropenia, hemophagocytic syndrome, and cyclic hematopoiesis.

Diagnosis

Diagnosis is based on history, complete physical examination, and tests for infectious diseases. The presence of a left shift or neutrophil toxicity supports inflammation, but a mild left shift or slight toxicity may be seen with other causes of neutropenia. Sequential evaluation of the leukogram should exclude cyclic or transient neutropenia. If the neutropenia is persistent or bone marrow pathology is of concern, then cytology or histopathology of bone marrow should be considered.

Management

Treatment is directed at the inciting cause.

REDISTRIBUTION NEUTROPENIA

Definition/Overview

Increased margination of circulating neutrophils can result in neutropenia.

Etiology

Endotoxins from Gram-negative sepsis produce a transient neutropenia.

Pathophysiology

After a single exposure to endotoxin, neutrophils rapidly shift from the circulating pool to the marginal pool for 1–3 hours. The neutropenia is short lived since endotoxins also stimulate release of neutrophils from the bone marrow and neutropoiesis within the bone marrow.

Clinical Presentation

Signs of Gram-negative infection include pyrexia, anorexia, and lethargy. However, given the peracute time frame for the neutropenia, redistribution neutropenia is often no longer present on presentation of the animal.

Differential Diagnosis

Myelosuppression, severe inflammation, immune-mediated neutropenia, hemophagocytic syndrome, and cyclic hematopoiesis.

Diagnosis

Diagnosis is based on history, complete physical examination, tests for infectious diseases, and cytology or histopathology of bone marrow. Sequential evaluation of the leukogram may reveal a normal or increased neutrophil concentration with or without signs of inflammation (e.g., left shift, neutrophil toxicity).

Management

Treatment for sepsis involves appropriate antibiotics.

PERIPHERAL DESTRUCTION NEUTROPENIA

Definition/Overview

Neutropenia may be due to immune targeting of neutrophil antigens (immune-mediated neutropenia) or nonspecific destruction of hematopoietic cells by dysregulated phagocytes (hemophagocytic syndrome).

Etiology

Drugs responsible for suspected immune-mediated neutropenia include antithyroid drugs (e.g., thiouracil, methimazole) and cephalosporins. Hemophagocytic syndrome is caused by inappropriate activation of normal macrophages secondary to infectious (canine parvovirus, bacterial sepsis, ehrlichiosis, blastomycosis, and Lyme disease), neoplastic (lymphoid neoplasia and myelodysplastic syndrome), or immune-mediated (SLE) disease. Idiopathic hemophagocytic syndrome has also been described.

Pathophysiology

The disorder may involve antibody directed against surface antigens on the cell itself or antibody directed toward drug antigens attached to the neutrophil as an "innocent bystander." Autoantibodies may also produce defects in neutrophil function.

Clinical Presentation

Signs may reflect those of immune-mediated, infectious, or neoplastic diseases.

Differential Diagnosis

Other immune-mediated hematologic disorders, SLE, immune-mediated arthritis, neoplasia, drug-induced myelosuppression, severe systemic inflammation, endotoxemia, hypersplenism, cyclic hematopoiesis, and myelophthisis.

Diagnosis

Diagnosis of immune-mediated neutropenia requires detection of antineutrophil antibodies on the cells or in serum. However, such assays are not widely available and are not specific for immune-mediated neutropenia. Immune-mediated neutropenia is more commonly diagnosed by excluding other causes of neutropenia and demonstrating improvement with appropriate therapy. Hemophagocytic syndrome may cause bicytopenia or pancytopenia. Cytologic or histologic tissue biopsies reveal many phagocytic macrophages. An underlying disease may be identified with a complete diagnostic workup, including physical examination, thoracic and abdominal imaging, and fluid and tissue biopsies.

Management

Immune-mediated neutropenia may be resolved by stopping administration of the inciting drug and commencing immunosuppressive therapy. Treatment for hemophagocytic syndrome is directed at the inciting disease.

DECREASED PRODUCTION NEUTROPENIA

Definition/Overview

Decreased neutrophil production may occur with certain drugs, infectious agents, myelophthisis, and irradiation that affect the bone marrow. Trapped neutrophil syndrome (TNS) is an autosomal recessive disease reported in Border Collies that causes neutropenia.

Etiology

Drugs that cause neutropenia due to myelotoxicity include estrogen, chloramphenicol, trimethoprim–sulfadiazine, griseofulvin, and chemotherapeutic agents. Antineoplastic agents that can cause neutropenia include cyclophosphamide, chlorambucil, busulfan, melphalan, cisplatin, cytosine arabinoside, methotrexate, mitoxantrone, doxorubicin, and hydroxyurea. Cephalosporins and certain nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with myelotoxicity. Reduced granulopoiesis may be associated with such viruses as FeLV, FIP virus, feline panleukopenia virus, and canine parvovirus. *E. canis* infection, when severe, may also cause bone marrow atrophy. Leukemia, myelitis (e.g., systemic histoplasmosis), or idiopathic myelofibrosis may cause myelophthisis. TNS is caused by a mutation in the gene VPS 13B.

Pathophysiology

Normal hematopoietic precursors may be crowded out with myelophthisis. Irradiation, drugs, and infectious agents destroy rapidly dividing precursor cells. Aplastic anemia and myelofibrosis may be nonassociative.

Note that if there is generalized marrow injury, cells with short circulating life spans decrease prior to those with longer life spans. Neutrophils circulate for hours, platelets circulate for days to weeks, and erythrocytes circulate for months. Therefore, neutropenia often precedes other cytopenias, but moderate-to-marked anemia is appreciated for months after the initial insult.

Clinical Presentation

Signs may include those due to severe neutropenia (severe bacterial infections or sepsis) with or without signs of marked thrombocytopenia (petechiae and hemorrhage) and nonregenerative anemia (lethargy, pale mucous membranes). Other signs reflect the animal's underlying condition. Border Collies with TNS often present with pyrexia and joint effusion. They also have a ferret-like skull (narrow and elongated).

Differential Diagnosis

Cyclic hematopoiesis, severe systemic inflammation, endotoxemia, hemophagocytic syndrome, and immune-mediated neutropenia.

Diagnosis

Diagnosis of the underlying disorder may require a thorough history and physical examination, blood tests for viral disease and organ health (CBC, serum chemistry, and urinalysis), diagnostic imaging, tissue biopsy, bone marrow evaluation, and bacterial culture. Genetic testing is available for TNS. Evaluation of the bone marrow reveals myeloid hyperplasia.

Management

Treatment requires cessation of myelotoxic drugs and supportive care, particularly antibiotics. The use of recombinant canine G-CSF (5 µg/kg SC q.24 h.) has shown promise in reducing the severity of drug-induced myelosuppression in the dog and the cat. Specific treatment is dependent upon the underlying disorder. Dog with TNS often respond initially to antibiotic and prednisolone, but relapses are common.

CYCLIC HEMATOPOIESIS

Definition/Overview

Congenital cyclic hematopoiesis is an inherited autosomal recessive disorder of gray Collies characterized by periodic fluctuations in neutrophils and, to a lesser extent, in monocytes, platelets, and reticulocytes. Nonhereditary cyclic hematopoiesis may involve other breeds of dogs. Cyclic neutropenia in cats has been associated with FeLV infection.

Etiology

The molecular basis of the genetic defect in dogs is unknown but seems to be associated with a defect in the intracellular trafficking of neutrophil elastase. FeLV infection is associated with cyclic neutropenia in cats.

Pathophysiology

In gray Collies, cyclic differentiation of stem cells toward committed lineages results in 11- to 14-day cycles of erythrocyte, neutrophil, monocyte, and platelet production. Decreases in blood neutrophil concentrations are most prevalent given their shorter circulating life spans. Dogs with nonhereditary cyclic hematopoiesis have variable cycle lengths from 10 to 29 days. Cats infected with FeLV have neutrophil cycle lengths reported to range from 8 to 16 days.

Clinical Presentation

Clinical signs during neutropenic episodes include lethargy, pyrexia, anorexia, arthritis, keratitis, diarrhea, and respiratory infections. Affected Collies present with other distinctive features such as abnormal hair pigmentation, bilateral scleral ectasia, enteropathy, and gonadal hypoplasia.

Differential Diagnosis

Severe systemic inflammation, noncyclic myelosuppression from drugs, infections, or irradiation, immune-mediated neutropenia, hemophagocytic syndrome, and endotoxemia.

Diagnosis

Diagnosis is based on history, signalment, clinical signs, and cyclic decreases in cell counts. Carrier animals can be determined only by test mating. All affected dogs have a diluted coat color. Amyloidosis is commonly found in many tissues.

Management

Antibiotics and supportive care are necessary during neutropenic cycles. Experimental treatment for dogs with the "gray Collie syndrome" involves bone marrow transplantation and administration of lithium carbonate (21–26 mg/kg/day) or recombinant canine G-CSF (5 µg/kg/day). Cyclic neutropenia in FeLV-infected cats can respond to prednisolone.

Prognosis

Most affected dogs die within 6 months following chronic recurrent infection.

SEVERE COMBINED IMMUNODEFICIENCY

Definition/Overview

Congenital defects in lymphocyte development result in lymphoid hypoplasia or aplasia and subsequent marked lymphopenia and hypoglobulinemia. The disease is rare but has been documented in Basset Hounds, Cardigan Welsh Corgis, Jack Russell Terriers, and Frisian Water Dogs.

Etiology

The deficiency in Basset Hounds and Cardigan Welsh Corgis is X-linked due to separate mutations in an IL receptor. An autosomal recessive mode of inheritance occurs in Jack Russell Terriers due to mutated

DNA-dependent protein kinase. Frisian Water Dogs have a mutation of RAG1.

Pathophysiology

Defective lymphocyte development results in immune incompetence, which becomes fatal when maternal antibodies wane. There is depressed T-cell function, low IgG and IgA concentrations, and variable IgM concentrations. Affected animals usually die from infectious disease.

Clinical Presentation

Puppies may be small, thin, and inactive. Signs of recurrent infections occur as bacterial pyoderma and otitis externa within the first 6 weeks of life. Mucopurulent ocular and nasal discharges are common. Lymphadenopathy is not present. Death may occur within 50 hours of administering a modified live vaccine.

Differential Diagnosis

Systemic infections, PLE, and exogenous corticosteroids.

Diagnosis

Diagnosis is based on the history of high morbidity and mortality in puppies from the same breeding pair of dogs. Affected puppies have lymphopenia, hypoglobulinemia, and depressed T-lymphocyte function. Necropsy reveals profound lymphoid hypoplasia.

Management

Antibiotics may be administered, but death due to infectious disease is expected. Bone marrow transplantation is the only means to regain immune competence. Carrier animals should not be bred.

Prognosis

Mortality occurs when maternal antibodies wane at 8–14 weeks of age.

ABNORMAL NUCLEAR MORPHOLOGY

INFLAMMATORY LEFT SHIFT

Definition/Overview

A left shift is defined as an increase in immature neutrophils over the reference interval. Immature neutrophils include band neutrophils (bands), metamyelocytes, myelocytes, and promyelocytes. Left shifts are further classified as "regenerative" if there is neutrophilia and segmented neutrophils outnumber immature neutrophils or "degenerative" if immature neutrophils outnumber segmented neutrophils or if there is a decreased neutrophil concentration (neutropenia) with a left shift. Regenerative left shifts are a proper marrow response during inflammation, but degenerative left shifts often indicate more severe inflammatory states, such as sepsis.

Etiology

A left shift is usually caused by a systemic inflammatory lesion, such as in pyometra, pneumonia, large neoplasm, or immune-mediated disorders (e.g., IMHA). A degenerative left shift is typically a result of severe infectious disease.

Pathophysiology

Inflammatory cytokines (e.g., IL-1, IL-6, IL-8, GM-CSF, and G-CSF) enhance neutrophil release from the bone marrow into blood. Release is sequential in that bands enter the blood before metamyelocytes and earlier stages. With continued inflammation, cytokines stimulate neutrophil production, taking 5–7 days for a myeloblast to mature into a segmented form. A left shift may accompany acute or chronic inflammation.

Clinical Presentation

Signs reflect the affected organ system.

Differential Diagnosis

Pelger–Huët anomaly, myelodysplastic syndrome, granulocytic leukemia.

Diagnosis

Blood smear evaluation shows increased numbers of immature neutrophils, particularly band neutrophils (Figure 16.47). Sites of inflammation can be determined by history, physical examination, biochemical profile, urinalysis, diagnostic imaging, and sampling.

Management

Treatment is directed toward the underlying cause.

Prognosis

Animals with degenerative left shifts tend to have poorer outcomes relative to those with regenerative left

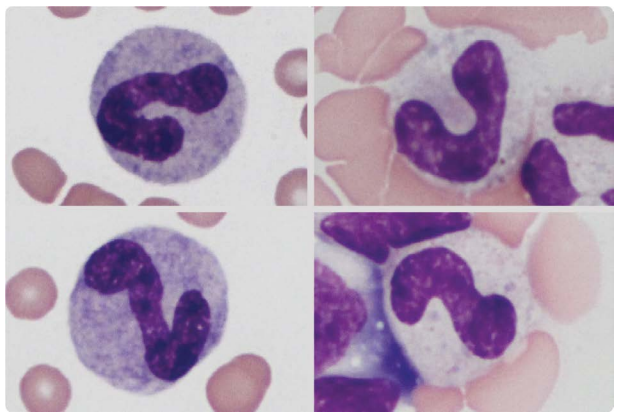

FIGURE 16.47 Band neutrophils from a cat (left) and dog (right) lack nuclear segments and have slightly open chromatin. The two feline neutrophils display cytoplasmic basophilia (toxicity).

shifts. Worsening of the left shift is a negative prognostic indicator, whereas dampening or resolution of a left shift indicates clinical improvement.

PELGER–HUËT ANOMALY

Definition/Overview

This nonneoplastic developmental abnormality is an inherited disorder in dogs and cats involving all granulocytes.

Etiology

Pelger–Huët anomaly is inherited in an autosomal dominant manner due to a mutated lamin B receptor. Affected dog breeds include, but are not exclusive to, Australian Heelers, Australian Shepherd Dogs, Basenjis, Border Collies, Cocker Spaniels, Coonhounds, German Shepherd Dogs, and Samoyeds. It has been reported in one family of Domestic Shorthair cats.

Pathophysiology

This condition is suggested to be a stem cell defect, since megakaryocytes may also appear hyposegmented.

Clinical Presentation

Chondrodysplasia has been recognized in a stillborn homozygous kitten. Heterozygote kittens may be stillborn or viable. Heterozygote dogs do not present with signs of infection.

Differential Diagnosis

Inflammatory left shift, myelodysplastic syndrome, and granulocytic leukemia.

Diagnosis

Diagnosis is based on the appearance of blood leukocytes that have mature chromatin (condensed, coarse, and patchy) and nuclear shapes that reflect immaturity (band, indented, or round) (Figure 16.48). The cytoplasm undergoes normal maturation. Pelger–Huët anomaly is frequently found during routine preoperative screening.

Note that the significance in diagnosing Pelger–Huët anomaly is that it is not misinterpreted as a degenerative left shift due to severe inflammation.

Management/Prognosis

No treatment is necessary. No leukocyte dysfunction.

Prognosis

Dogs: No leukocyte dysfunction. Cats: The homozygous condition is lethal and may be associated with increased susceptibility to infection.

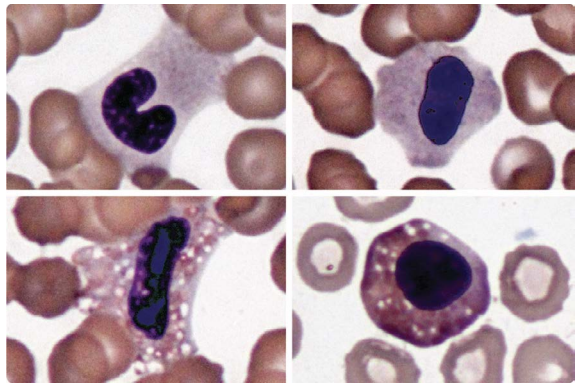

FIGURE 16.48 Nuclei of neutrophils (top) and eosinophils (bottom) fail to segment with Pelger–Huët anomaly. However, the chromatin pattern is dense, indicating nuclear maturity.

HYPERSEGMENTATION

Definition/Overview

Hypersegmentation is defined as a neutrophil with more than five nuclear segments, and it indicates aging or dysplasia.

Etiology

Hypersegmentation is seen with delayed sample analysis, glucocorticoid administration, hyperadrenocorticism, hyperthermia (e.g., heatstroke, malignant hyperthermia), CLAD, dysplastic processes (e.g., Poodle macrocytosis, vitamin B12 deficiency), and myeloid leukemias.

Pathophysiology

Hypersegmentation occurs as part of the normal aging process and reflects a prolonged transit time in blood. Dysplastic and neoplastic processes are due to abnormal neutrophil maturation.

Clinical Presentation

Signs reflect the underlying condition.

Differential Diagnosis

Hyperadrenocorticism, exogenous glucocorticoids, heatstroke, malignant hyperthermia, CLAD, Poodle macrocytosis, vitamin B12 (cobalamin) deficiency, myeloid leukemia.

Diagnosis

Affected neutrophils present with five or more distinct nuclear lobes on blood smears (Figure 16.49). Blood smears should be made at the time of sample acquisition to prevent in-vitro neutrophil aging and hypersegmentation.

Management

Treatment is directed toward the underlying cause.

FIGURE 16.49 Hypersegmented neutrophils in a dog with canine leukocyte adhesion deficiency.

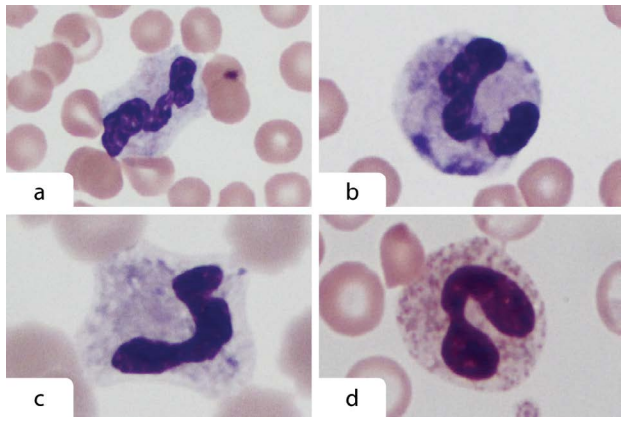

FIGURE 16.50 Signs of neutrophil toxic change include diffuse cytoplasmic basophilia **(a–c)**, cytoplasmic aggregates of basophilia termed Döhle bodies **(b, c)**, foamy cytoplasm **(b, c)**, and prominent pink primary granules or toxic granulation **(d)**.

ABNORMAL CYTOPLASMIC MORPHOLOGY

NEUTROPHIL TOXICITY

Definition/Overview

In addition to a left shift, neutrophils may exhibit toxic change during times of inflammation.

Etiology

Antibiotic responsiveness suggests a bacterial cause, but toxic change may also be found in cases of sterile inflammation or drug toxicity.

Pathophysiology

Toxic change is a result of a shortened maturation time or direct toxic injury to developing neutrophils. Döhle bodies represent lamellar aggregates of rough endoplasmic reticulum. Persistent ribosomes cause diffuse cytoplasmic basophilia. Foamy cytoplasmic vacuolation occurs with dispersed organelles. Enhanced primary granule staining contributes to the fine red granules known as *toxic granulation*.

Clinical Presentation

Signs reflect the site of inflammation or underlying condition.

Differential Diagnosis

EDTA storage artifact, lysosomal storage disease, granulation syndrome in Birman cats, Chédiak–Higashi syndrome in cats.

Diagnosis

Neutrophil toxicity is diagnosed via blood smear evaluation (Figure 16.50a–d). Tests for specific infectious agents and immune-mediated disorders may be indicated.

Management

Treatment is directed toward the underlying illness.

Prognosis

Reduction of toxic changes implies a favorable prognostic indicator.

LYSOSOMAL STORAGE DISEASES

Definition/Overview

Lysosomal storage diseases are a group of inheritable disorders caused by enzyme deficiencies that result in intralysosomal accumulations of undigested molecules. All these diseases are rare in dogs and cats.

Etiology

Lysosomal storage diseases produce granules or vacuoles in leukocytes include fucosidosis, GM1 gangliosidosis, GM2 gangliosidosis, alpha-mannosidosis, mucopolysaccharidosis (MPS) I, MPS IIIB, MPS VI, and MPS VII.

Pathophysiology

As lysosomes become engorged with degradation material, they compress surrounding organelles and impair cellular respiration and function. Waste products build up and damage the cell.

Clinical Presentation

Signs will vary with the type of enzyme deficiency but may include failure to thrive, growth retardation, seizures, ataxia, corneal clouding, hepatosplenomegaly, cardiac murmurs, renal dysfunction, and skeletal abnormalities.

Differential Diagnosis

EDTA storage artifact, toxic granulation, granulation syndrome in Birman cats, Chédiak–Higashi syndrome in cats.

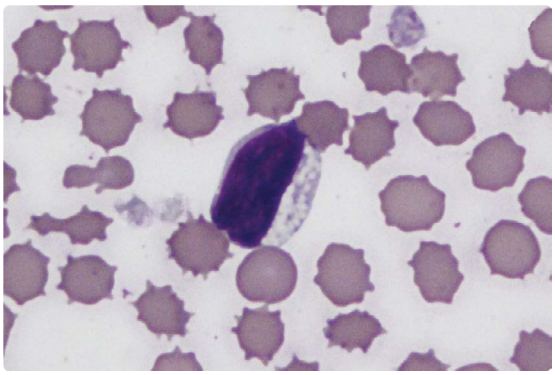

FIGURE 16.51 Vacuolated lymphocyte from a cat with lysosomal storage disease, consistent with mannosidosis.

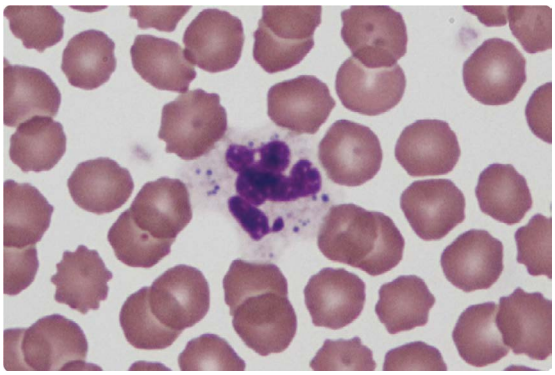

FIGURE 16.52 Granulated neutrophils in a dog with mucopolysaccharidosis I.

Diagnosis

Cytoplasmic granules or vacuoles are present in leukocytes depending on the type of enzyme deficiency (Figures 16.51 and 16.52). A urine spot test is used to screen for glycosaminoglycans, while a cell enzyme activity test is diagnostic. DNA-based tests are available for some diseases with known mutations.

Management

Experimentally, bone marrow transplantation has been used to treat some of these disorders. Affected animals should not be bred.

Prognosis

Without bone marrow transplantation, these diseases are progressive and fatal.

ABNORMAL NEUTROPHIL GRANULATION IN BIRMAN CATS

Definition/Overview

Abnormal neutrophil granulation is a genetic anomaly recognized in some Birman cats without associated clinical disease.

Etiology

Autosomal recessive disorder.

Pathophysiology

Neutrophil ultrastructure and function are normal.

Clinical Presentation

No clinical signs.

Differential Diagnosis

Toxic granulation, lysosomal storage disease.

Diagnosis

Diagnosis is based on the presence of fine, pink granules within the cytoplasm of neutrophils (Figure 16.53).

Management and Prognosis

No treatment is required.

FELINE CHÉDIAK–HIGASHI SYNDROME

Definition/Overview

Feline Chédiak–Higashi syndrome is a rare, inherited disorder of blue-smoke Persian cats with yellow eye color.

Etiology

The disorder is inherited as an autosomal recessive trait and caused by a mutant lysosomal docking protein, LYST.

Pathophysiology

Granule defects are present in leukocytes, melanocytes, and platelets, leading to abnormal and enlarged lysosomal granules in leukocytes, decreased neutrophil chemotaxis, bleeding diathesis, and oculocutaneous color dilution.

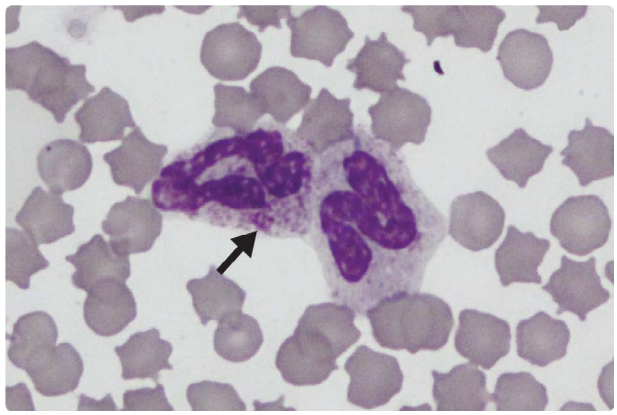

FIGURE 16.53 Fine pink granules (arrow) in a neutrophil from a Birman cat.

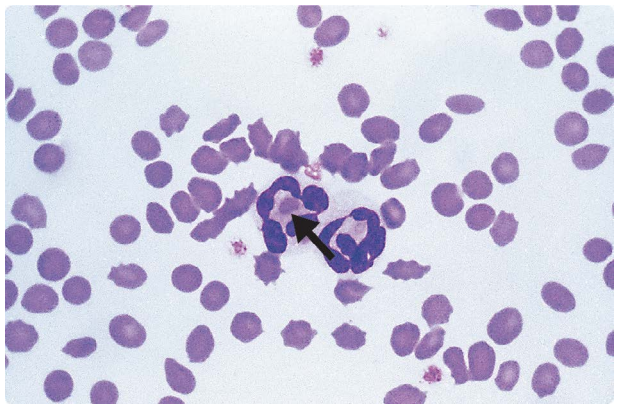

FIGURE 16.54 Feline Chédiak–Higashi syndrome presenting as large lavender cytoplasmic structures (arrow) within granulocytes. (*Courtesy of J. Harvey*.)

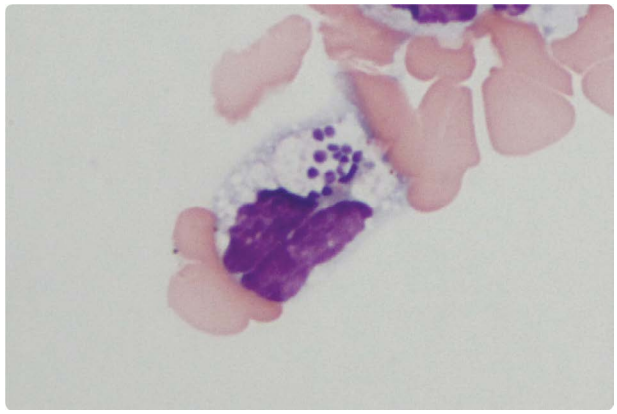

FIGURE 16.55 Blood smear from a dog with sepsis showing bacteria within a toxic neutrophil. Culture of the blood, liver, and lungs grew *Salmonella choleraesuis* subspecies *arizonae*.

Clinical Presentation

Affected cats may be photophobic with cataract formation. There is increased bleeding time due to platelet granule defects.

Differential Diagnosis

Cytoplasmic toxicity, lysosomal storage disease.

Diagnosis

Diagnosis is based on signalment, physical examination, and characteristic large, pink to magenta neutrophil granules (Figure 16.54) that are positive with peroxidase and Sudan black B stains. Neutropenia may also be present.

Management

Supportive therapy (e.g., blood transfusions, antibiotics) as needed. Neutrophil chemotaxis has been reported to improve following administration of canine G-CSF in cats. Neutrophil and platelet function can be restored with bone marrow transplantation.

Prognosis

Life expectancy can exceed 10 years.

INFECTIOUS AGENTS

See also Chapter 21.

A variety of infectious agents may be found within leukocytes during examination of the blood or bone marrow. These include bacterial (Figure 16.55), rickettsial, protozoal, and fungal organisms (Figure 16.56a–f), or canine distemper virus (CDV) inclusions (Figure 16.32). See further section for description of common findings on blood smear review. The reader is referred to Chapter 21 for further details.

EHRLICHIOSIS

Acute disease in dogs and cats most consistently causes thrombocytopenia and mild nonregenerative anemia. With chronic canine infection, hyperglobulinemia, pancytopenia, or granular lymphocytosis (Figure 16.42) is possible. The gammopathy is typically polyclonal but is rarely monoclonal (Figure 16.44). Blood smear evaluation may show intracytoplasmic bacterial colonies (morulae) in mononuclear cells (*E. canis* and *E. chaffeensis*) or granulocytes (*E. ewingii* or *A. phagocytophilum*) during acute infection (Figure 16.56c).

HEPATOZOONOSIS

Hepatozoon canis is classically diagnosed by blood smear evaluation, as gamonts are plentiful within blood neutrophils (Figure 16.56d). Blood PCR tests are also available. *Hepatozoon americanum* should be suspected based on clinical signs, marked neutrophilia (leukemoid response). In contrast to *H. canis*, only rare gamonts are present in the blood (<0.1% of WBCs).

LEISHMANIASIS

Characteristic organisms are present in macrophages of the bone marrow, lymph nodes, spleen, liver, kidney, and skin (Figure 16.56e). Amastigotes are recognized by the presence of a small purple nucleus and a perpendicular rod-shaped kinetoplast in Romanowsky-stained smears.

HISTOPLASMOSIS

Routine laboratory tests are not specific for histoplasmosis but may reflect the extent of systemic involvement. Some cats may develop pancytopenia due to marrow infection. Hypercalcemia associated with granulomatous disease is infrequent. Yeast forms are found within monocytes/

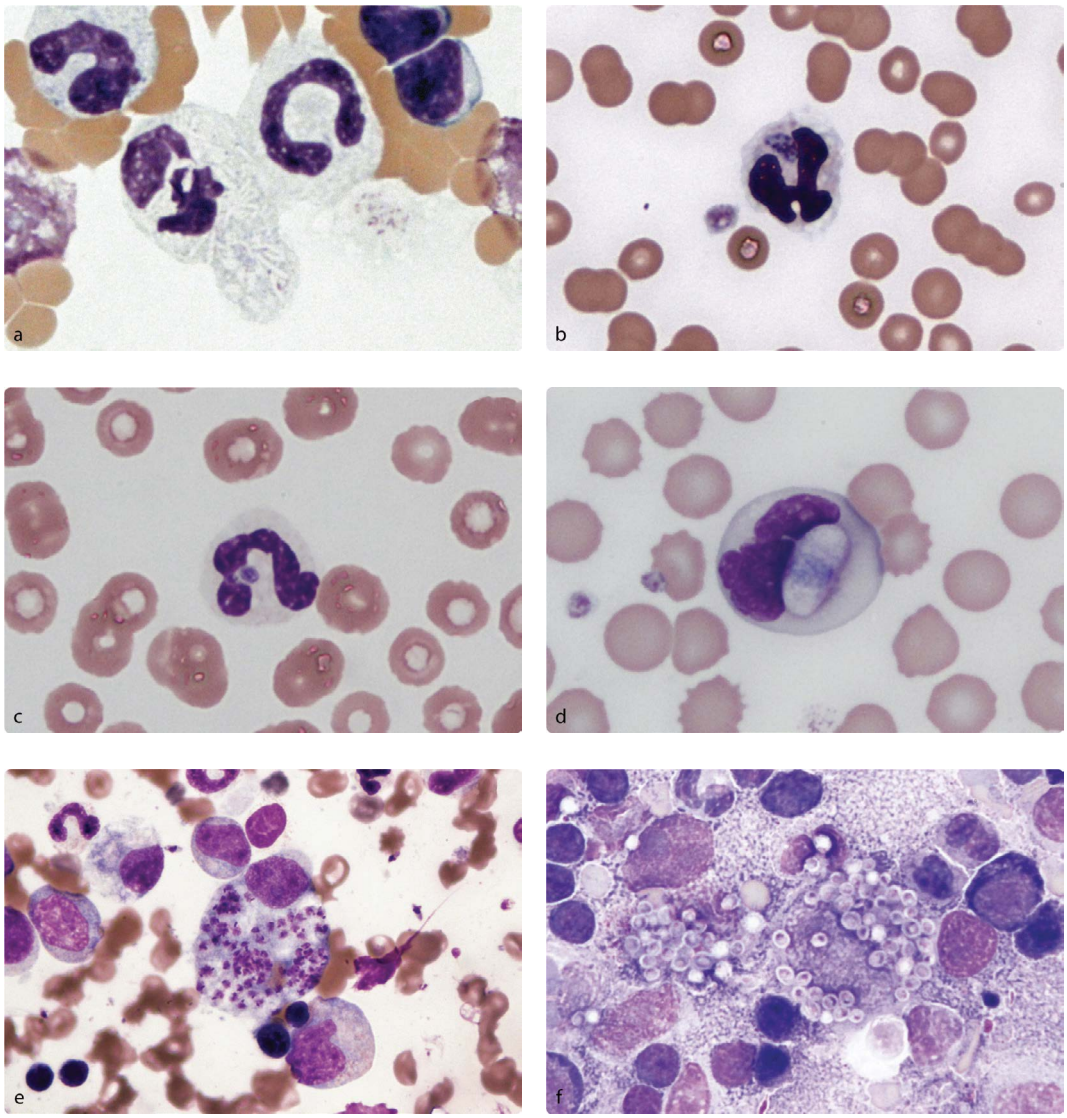

FIGURE 16.56 Leukocyte parasites in cats and dogs. **(a)** Circulating feline neutrophils with multiple intracytoplasmic nonstaining linear shapes identified as *Mycobacterium* spp. **(b)** Blood neutrophil containing a tachyzoite in a cat with toxoplasmosis. **(c)** *Ehrlichia ewingii* morula in a canine neutrophil. **(d)** A large, ovoid, nonstaining *H. canis* gamont within a neutrophil. **(e)** *Leishmania* amastigotes within a bone marrow macrophage from a dog. **(f)** Bone marrow smear from a cat with systemic histoplasmosis. There are numerous small, round to ovoid yeasts within two macrophages.

macrophages of the blood, bone marrow, lung, lymph node, liver, rectal scrapings, spleen, effusions, tracheal or bronchoalveolar washes, and, rarely, within cerebrospinal fluid (Figure 16.56e). The organism may also be found within neutrophils and, rarely, in eosinophils. They are oval structures measuring 2–4 microns and having a thin clear space or halo around them.

PLATELET DISORDERS (NONNEOPLASTIC)

Platelets are anucleate cells produced in the bone marrow from the cytoplasmic shearing of megakaryocytes. Platelets are a critical component of hemostasis and will, therefore, primarily be presented in the next chapter (Chapter 17). However, causes of nonneoplastic thrombocytosis and dysplasia are offered here.

REACTIVE THROMBOCYTOSIS

Definition/Overview

A nonneoplastic thrombocytosis is termed *reactive thrombocytosis*.

Etiology

Etiologies include exercise and epinephrine, inflammation, iron deficiency, recovery from thrombocytopenia, blood loss, nonhemic neoplasia, vincristine, vinblastine, splenectomy, and hyperadrenocorticism.

Pathophysiology

Exercise and epinephrine cause splenic smooth muscle contraction and increased blood flow, which leads to redistribution of platelets from the spleen and lungs into circulating blood. Other etiologies cause enhanced platelet production. For example, inflammatory cytokines, especially IL-6, stimulate thrombopoietin production and, subsequently, thrombopoiesis.

Clinical Presentation

Signs are dependent on the underlying disorder.

Differential Diagnosis

Essential thrombocythemia, primary myelofibrosis, PV.

Diagnosis

Diagnosis is based on an increased platelet concentration in the presence of an underlying cause for reactive thrombocytosis. Epinephrine release also causes erythrocytosis, neutrophilia, lymphocytosis, and hyperglycemia. Moderate-to-marked neutrophilia, a left shift, or the observation of toxic neutrophils supports inflammation. Blood loss is identified by anemia and decreases in albumin and globulin concentrations. Microcytic hypochromic nonregenerative or poorly regenerative anemia suggests iron deficiency. History and physical examination findings are also helpful. Persistent, marked thrombocytosis without an underlying etiology should raise concern for leukemia.

Management

Treatment is directed at the underlying cause.

MACROTHROMBOCYTOPENIA

Definition/Overview

Macrothrombocytopenia (thrombocytopenia with giant platelets) is an inherited disorder of Cavalier King Charles Spaniels, as well as Norfolk and Cairn Terriers, and in other breeds without hemorrhage or clinical signs. The giant platelets have diameters greater than those of RBCs.

Etiology

The disorder is caused by a mutant beta1-tubulin gene.

Pathophysiology

The mutant beta1-tubulin forms unstable dimers, which results in altered platelet formation and the release of large platelets. Small numbers of giant platelets result in a normal or near-normal total platelet mass in the blood.

Clinical Presentation

Macrothrombocytopenia is typically an incidental finding when the patient presents for routine evaluation or for other disease.

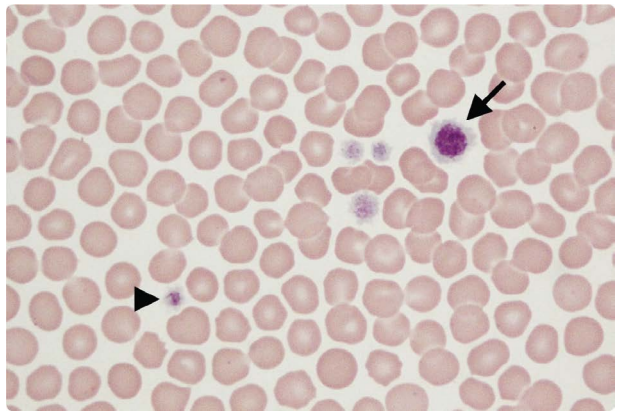

FIGURE 16.57 The platelets of Cavalier King Charles Spaniel dogs with macrothrombocytopenia range from normal (arrowhead) to giant (arrow) in size.

Differential Diagnosis

Immune-mediated thrombocytopenia, DIC, megakaryocytic leukemia.

Diagnosis

Diagnosis is based on the presence of thrombocytopenia and giant platelets in affected dogs (Figure 16.57). Median measurements in one study of platelets in Cavalier King Charles Spaniels compared with other breeds were 2.5–3.75 µm and 1.25–2.5 µm, respectively. The reduced platelet count is partially related to giant platelets being missed by automated hematology analyzers with small platelet size thresholds. Platelet counts measured by platelet mass (e.g., QBC hematology analyzer) better reflect the true platelet concentration. Studies indicate that male dogs have significantly lower platelet counts than females of the breed. A genetic test is available to confirm the diagnosis.

Management

Treatment is not warranted.

Prognosis

The disorder is not known to affect hemostasis.

DYSPLASTIC DISORDERS

Dysplastic disorders are characterized by developmental changes within the erythrocytes, granulocytes, and platelets. The etiology may be related to inheritable, infectious, drug-induced, and nutritional conditions. While dysplastic disorders often affect multiple hematopoietic lineages, abnormal growth of one cell line typically results in the patient's clinical manifestations. For this reason, select dysplastic disorders are included with the cell lineage that is chiefly deregulated. Disorders that primarily present as erythroid dysplasia include iron-deficiency anemia, FeLV infection, Poodle marrow dyscrasia, folate or cobalamin (vitamin B12)

deficiency, and lead poisoning. Manifestations of leukocyte dysplasias are Pelger–Huët anomaly, cyclic hematopoiesis of gray Collies, and leukocyte granule abnormalities. The most common platelet dysplastic disorders are macrothrombocytopenia of Cavalier King Charles Spaniels and vincristine-associated macrothrombocytes. Previously considered a preleukemic dysplasia, myelodysplastic syndrome is now considered a form of myeloid neoplasia and will be addressed in the corresponding section.

DRUG-INDUCED DYSPLASIA

Definition/Overview

Antibiotics and antineoplastic agents can produce reversible morphologic changes in blood cells.

Etiology

Drugs implicated are azathioprine, cyclophosphamide, cytosine arabinoside, vincristine, and chloramphenicol.

Pathophysiology

The drugs disrupt the normal production of erythroid cells within hours to days following administration. The mechanism is not related to folate deficiency.

Clinical Presentation

Signs will reflect the underlying conditions.

Differential Diagnosis

Myelodysplastic syndrome, acute myeloid leukemia, and nutrition-related dysplasia.

Diagnosis

Diagnosis is based on blood and bone marrow samples taken during routine post-treatment hematologic evaluations. Morphologic changes involve dyserythropoiesis characterized by macrocytosis, megaloblastoid changes, nuclear fragmentation, sideroblastosis, and siderocytosis. Folate concentrations are within normal limits.

Management

Normal morphology of hematopoietic cells occurs several days after cessation of drug therapy.

HEMATOPOIETIC MALIGNANCIES

Hematopoietic malignancies include neoplasms of lymphoid cells (lymphocytes and plasma cells), myeloid cells (erythrocytes, nonlymphoid leukocytes, and megakaryocytes), and uncommitted stem cells. Lymphoid neoplasms are more common than those of myeloid origin.

LYMPHOID NEOPLASIA

Lymphoid malignancies may originate from in any tissue. The most common sites include the lymph nodes, liver, spleen, bone marrow, alimentary tract, thymus, and skin. The term leukemia is used when neoplastic cells appear in blood or bone marrow and lymphoma when lymphoid neoplasia arises from other sites. However, this distinction can be challenging as lymphoma frequently involves the blood and bone marrow, and involvement of lymph nodes or other tissues is common in lymphoid leukemias. Lymphoid leukemia is further classified based on the maturity of the neoplastic cells. In acute lymphoid leukemia, immature (blast) cells predominate, whereas small mature lymphocytes predominate in chronic lymphocytic leukemia. A neoplasm of plasma cells arising from the bone marrow is called myeloma, whereas those in nonmarrow sites are referred to as plasmacytomas. The term myeloma-related disorder is sometimes used to refer to any plasma cell malignancy, especially in cats, as the clinical presentation in this species can vary from what is typically seen in dogs and people, and extramedullary origin is common. Lymphoid neoplasms, in descending frequency of occurrence, are lymphoma, plasmacytoma, myeloma, chronic lymphocytic leukemia, and acute lymphoblastic leukemia.

LYMPHOMA

Definition/Overview

Lymphoma (the preferred term over lymphosarcoma) is the most common hematopoietic tumor of dogs and cats. Multicentric disease is the most common presentation in dogs and usually involves the peripheral lymph nodes, spleen, and liver. Other sites of canine lymphoma include the alimentary tract, thymus, skin, and other extranodal locations in decreasing frequency. The most common anatomic location for lymphoma in cats is the alimentary tract. Thymic lymphoma is most common in young, FeLV-positive cats, while alimentary lymphoma is more common in older cats. Cats may also develop multicentric, renal, intranasal, laryngeal/tracheal, CNS, ocular, and cutaneous lymphoma.

Classification of Lymphoma

Lymphoma in dogs can be classified based on anatomic location, histologic subtype, and immunophenotype. Anatomic location has been discussed previously, though some specific sites warrant separate discussion. Primary hepatic and hepatosplenic lymphoma in dogs generally have a poor prognosis. Primary splenic lymphoma can have a better prognosis, but this may depend on the histologic subtype. Although rectal lymphoma in dogs is most often large cell/high grade, prognosis can be good with chemotherapy and appears much better than for other locations of high-grade/large-cell alimentary lymphoma.

TABLE 16.14 Most common canine lymphomas in decreasing frequency using the REAL/WHO system

REAL/WHO system
– Diffuse large B-cell lymphoma
– Peripheral T-cell lymphoma not otherwise specified
– T-zone lymphoma
– T-cell lymphoblastic lymphoma
– Marginal zone lymphoma

There are several histologic classification systems that have been applied to lymphoma in domestic animals. Using the Revised European American Lymphoma/World Health Organization (REAL/WHO) system, each subtype is classified as a distinct disease entity (Table 16.14). The National Cancer Institute Working Formulation (WF) and the Kiel systems categorize lymphomas by grade (low, intermediate, or high) and other features rather than specific diseases. Low-grade lymphomas are generally composed of small cells, have a low mitotic rate, and indolent progression. High-grade lymphomas have a high mitotic rate, usually are composed of intermediate to large cells, and progress rapidly.

In clinical practice, full REAL/WHO subtyping may not be performed in every case, and strong evidence to recommend different treatment for specific subtypes in many cases does not exist. However, determining whether lymphoma in a dog is likely to be aggressive or indolent based on factors such as cytology and/or histopathology, immunophenotype, and anatomic location is imperative in determining the most appropriate treatment.

In cats, different anatomic locations of lymphoma are often associated with certain histologies and immunophenotype, and to some degree biological behavior can be predicted based on the location. For example, nasal lymphoma tends to be quite treatment responsive and has a fair-to-good prognosis with treatment, whereas renal lymphoma is often aggressive with a poor prognosis. The effect of histologic features and immunophenotype on prognosis differs with different anatomic locations. For example, the prognosis of nasal lymphoma is not influenced by histologic grade, but in alimentary lymphoma, the most common low-grade, small-cell, T-cell form has a much better prognosis than the intermediate- to large-cell, high-grade forms.

Etiology

Prior to widespread FeLV testing and vaccination programs, about 60%–80% of feline cases were associated with FeLV infection. However, positive FeLV antigenemia is only identified in 10%–20% of contemporary cases. A possible breed predisposition to lymphoma has been identified in Siamese, especially young, FeLV negative cats with thymic/mediastinal lymphoma. Strong evidence for a retroviral etiology in dogs does not exist. Environmental exposures are considered possible etiologies. Overrepresented breeds include Boxer, Bulldog, Bull Mastiff, Dobermann, Golden Retriever, Labrador Retriever, Basset Hound, St. Bernard, Scottish Terrier, Airedale, Irish Setter, Rottweiler, and Briard. Breeds at risk are also geographical dependent (see Recommended Further Readings).

Pathophysiology

Lymphoma originates in peripheral lymphoid tissues, which causes local tissue injury and dysfunction. Over time, neoplastic cells will infiltrate widely into a variety of sites, which often include multiple lymph nodes, spleen, liver, and bone marrow.

Clinical Presentation

Clinical signs depend on the anatomic location of disease. In dogs with multicentric lymphoma, the most common presentation is nonpainful swellings of superficial lymph nodes. Splenomegaly or hepatomegaly may be present, along with internal lymphadenomegaly. Weight loss, vomiting, and inappetence often suggest an advanced stage with worse prognosis. Animals with alimentary lymphoma typically present with nonspecific gastrointestinal signs which may be acute or chronic and vary in severity depending on the nature of the disease (low grade/small cell versus high grade/large cell). Mediastinal or thymic masses can produce dyspnea due to the mass itself or associated pleural effusion. Cutaneous lesions can arise as a mild eczematous pruritic plaque and progress to a nodular lesion. Paraneoplastic hypercalcemia can cause clinical signs such as polydipsia and polyuria.

Differential Diagnosis

Differential diagnoses for dogs and cats with lymphoma vary depending on the anatomic form and clinical presentation. For generalized lymphadenopathy: Disseminated infections, immune-mediated disorders, and other hematopoietic tumors (e.g., advanced leukemia). For alimentary disease, lymphoplasmacytic enteritis, other neoplasms, granulomatous bowel disease, and hypereosinophilic syndrome should be considered. For cutaneous disease, pyoderma, other infectious or immune-mediated disease, parasitic infestation, and other neoplasms should be considered. For nasal lymphoma: Other nasal tumors, fungal rhinitis, lymphoplasmacytic rhinitis, and foreign body.

Diagnosis

The diagnostic approach to an animal with suspected lymphoma will vary depending on the clinical presentation.

Large- or intermediate-cell lymphoma is frequently diagnosed from fine-needle aspirates of affected tissues or fluids; these usually disclose a homogeneous population of lymphoblasts (Figures 16.58 and 16.59). Lymphoma of large granular lymphocytes has characteristic pink

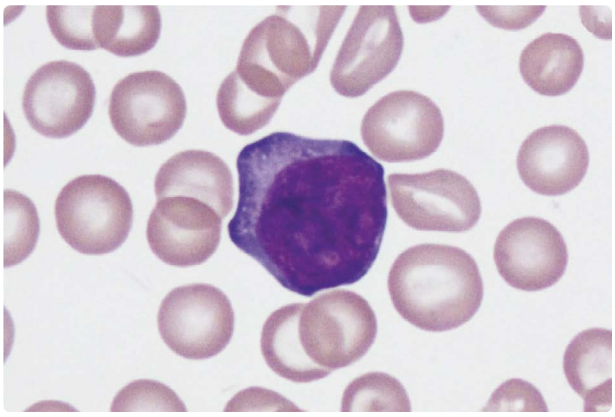

FIGURE 16.58 A lymphoblast in a dog with stage V lymphoma. Note the cell's large size, immature chromatin, and nucleoli.

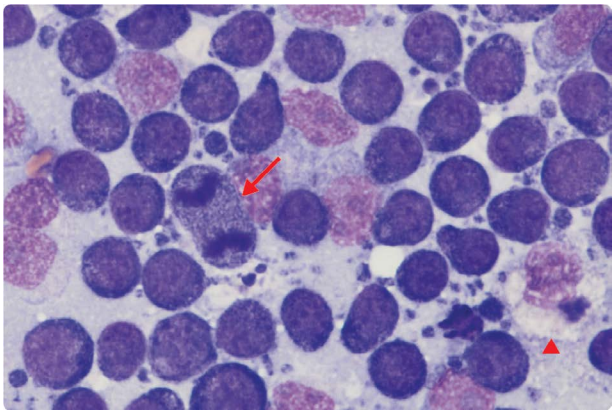

FIGURE 16.59 Cytologic preparation of large-cell lymphoma in a dog. The neoplastic lymphocytes are large with open chromatin and prominent nucleoli. Mitotic figures (arrow) and macrophages (arrowhead).

granules (Figure 16.60) and is most associated with splenic origin. If cytology is equivocal in distinguishing lymphoid hyperplasia from early lymphoma, a surgical biopsy may provide a definitive diagnosis based on changes in normal follicular architecture. In nodal small-cell lymphoma, cytology is typically not diagnostic. A homogenous population of monomorphic small lymphocytes can increase the index of suspicion, but for these and other cases where cytology is not definitive, then histopathology and immunohistochemistry, flow cytometry, and PCR for antigenic rearrangement (PARR) can be rewarding.

For an animal with a definitive diagnosis of lymphoma, determining immunophenotype via immunohistochemistry, immunocytochemistry, or flow cytometry may be prognostic in some clinical situations, including the most common canine presentation of multicentric lymphoma.

Hematology often reveals anemia of chronic disease, but a full CBC with blood smear evaluation is recommended to assess for concurrent blood loss or hemolysis, FeLV-associated macrocytosis, myelophthisis-associated cytopenias, and circulating atypical lymphocytes

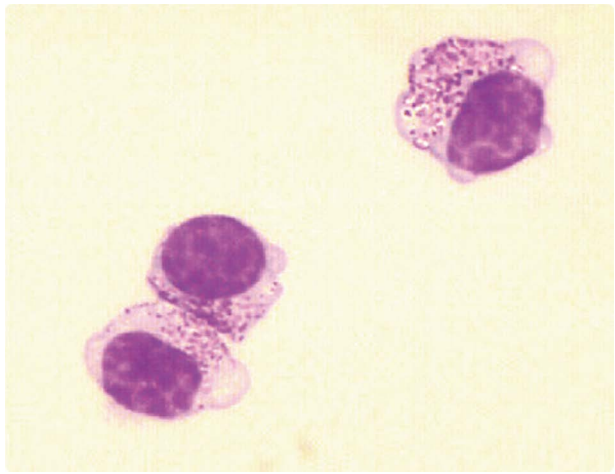

FIGURE 16.60 Cells from a cat with large granular lymphoma containing abundant magenta coarse cytoplasmic granules. Methanolic Romanowsky stain.

suggestive of stage V disease (Figure 16.60). Bone marrow aspiration can be performed for staging, prognosis, and in cases in which lymphoma is suspected but otherwise not proven.

Serum biochemical abnormalities include hypercalcemia in 15% of dogs with lymphoma (especially T-cell lymphoma) due to parathyroid hormone-related peptide production by neoplastic cells, azotemia with renal infiltration or secondary to hypercalcemia, elevated liver enzyme activity due to hepatic involvement, or hyperglobulinemia and monoclonal gammopathy with some B-cell lymphomas and plasma cell neoplasms. Cats should be screened for retrovirus (FeLV and FIV) infection for diagnostic, prognostic, and husbandry purposes.

Imaging, including radiographs, ultrasound, and CT, may be important for diagnosis, clinical staging, and monitoring response to treatment. However, in dogs with multicentric lymphoma, stage has not been a repeatable prognostic factor, and so full staging is not considered mandatory.

Management

In general, lymphoma requires systemic therapy. CHOP-based protocols involve combination chemotherapies of cyclophosphamide (C), doxorubicin (hydroxydaunorubicin [H]), vincristine (Oncovin [O]), and prednisone (P). The University of Wisconsin-Madison CHOP protocols are commonly recommended (see Recommended Further Readings). Prior to administering any potentially myelotoxic drug, a CBC should be performed to assess neutrophil and platelet concentrations. Cases of solitary lymphoma may be treated with surgery or radiation therapy. Nasal lymphoma in cats is often localized and responds well to radiation therapy.

Protocols utilizing a single cytotoxic agent such as doxorubicin or lomustine, usually in combination with prednisolone, can be effective in cases where the combination CHOP protocol is not desirable; however,

response rates and remission durations are typically less than for CHOP-based protocols. Doxorubicin and vincristine, as well as some other chemotherapy drugs, are P-glycoprotein substrates. Breeds at risk for mutations in ABCB1 (MDR1), which causes decreased P-glycoprotein function and increased toxicity of substrate drugs, should undergo ABCB1/MDR1 gene mutation analysis prior to chemotherapy. The most affected breed worldwide is the Collie, but multiple other breeds are reported, including the Australian Shepherd, Shetland Sheepdog, and Long-haired Whippet. Up to 5% of mixed-breed dogs overall and 10% of herding breed crosses may have the mutation.

After remission is achieved, relapse eventually occurs in most cases. If the duration of remission is judged to be good in patients that have completed their initial protocol, repeat treatment with the same protocol is often undertaken. Response rates are generally good. Duration of second remission in these cases is generally approximately half that of the first. In cases where lymphoma is refractory, or there is progressive disease during chemotherapy, rescue therapy may be pursued. Many protocols have been reported, and the complexity and toxicity of the chemotherapies often requires consultation with a veterinary oncologist.

Small-cell or indolent lymphoma is usually treated with a combination of oral chlorambucil and prednisolone, but in some cases, such as indolent nodal lymphoma in dogs, treatment is not initiated unless there are clinical signs associated with the disease or rapid disease progression.

Prognosis

Prognosis varies significantly depending on lymphoma classification. In general, for nonindolent lymphomas, progression and death within weeks is expected.

For dogs with nonindolent, multicentric lymphoma treated with combination or single-agent doxorubicin protocols, response rates vary from approximately 60% to over 90%, with combination protocols likely to have improved response rates. Median remission duration with these protocols ranges from approximately 4 to 11 months. Factors that influence prognosis in these dogs include WHO substage and lymphoma immunophenotype. Dogs showing no clinical signs of disease (i.e., WHO substage a) and B-cell lymphoma phenotype have better prognoses. Heavy bone marrow involvement may be associated with a poorer prognosis, but the effect of WHO stage on prognosis in these dogs requires further investigation. Prior steroid treatment is associated with shortened response durations.

In cats with nonindolent lymphoma treated with chemotherapy, usually CHOP- or COP-based, the overall response rates range from approximately 30% to 70%. Overall prognosis varies depending on the anatomic location, but in general, cats having a complete response to chemotherapy have a better prognosis, and approximately 25% of cats live longer than 2 years. Cats with a partial response generally have progressive disease within a few months.

In both dogs and cats with an indolent form of lymphoma, typically low grade/small cell, prognosis is better than for nonindolent forms, and survival times of several years are common.

CHRONIC LYMPHOCYTIC LEUKEMIA

Definition/Overview

Chronic lymphocytic leukemia (CLL) has a slow and protracted course of months to years. It occurs mostly in middle-aged or older dogs (mean 10 years). This form of leukemia occurs infrequently in cats but also appears to affect older individuals. The one case series reported in cats describes a 2:1 male-to-female distribution.

Etiology

An etiology has not been proven. Possible breed associations have been reported including German Shepherd Dogs, Golden Retrievers, and small-breed dogs in general. A syndrome of polyclonal expansion of small B cells has been described in English Bulldogs, which may have been previously misdiagnosed as CLL.

Pathophysiology

Phenotypically mature lymphocytes proliferate, and there is an increase in the stem cell compartment. In dogs, about 70% are of T-cell origin (CD8+, CD4+), with the remainder B cells or null cells. CLL arises from mature cells, but one form with granular morphology has been shown to develop initially from the spleen. Generally, liver, spleen, and lymph nodes become involved late in the disease. Cases of B-cell origin may present with hyperviscosity owing to increased gamma globulins, though this appears to be rare.

Clinical Presentation

Dogs with CLL are often asymptomatic, and lymphocytosis is detected incidentally on routine hematology. Lethargy and inappetence may be reported in advanced disease. More severe clinical signs are rare. On physical examination, lymphadenomegaly and splenomegaly may be detected. These are generally mild but may be marked in advanced disease. Cats similarly may have no clinical signs or mild, nonspecific signs, such as weight loss, inappetence, lethargy, vomiting or diarrhea.

Differential Diagnosis

Canine ehrlichiosis, other infectious diseases, postvaccinal responses in young dogs, polyclonal lymphocytosis in English Bulldogs.

Diagnosis

There is marked lymphocytosis of mature, small lymphocytes with condensed chromatin (**Figure 16.61**). Cell counts range from just above the normal reference interval to 300,000 cells/μL or more. A subset of CLL

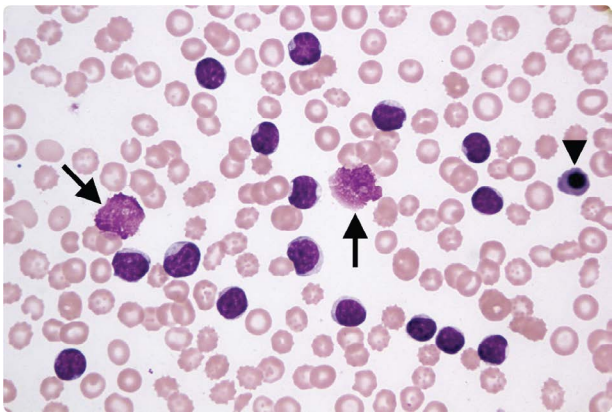

FIGURE 16.61 Chronic lymphocytic leukemia in a dog with a lymphocytosis of 183,000 cells/μL. The lymphocytes are small (i.e., ≤1.5 times the diameter of an RBC) with mature, dense chromatin. There are also two lysed cells (arrows) and one metarubricyte (arrowhead).

has granular lymphocyte morphology with an increased amount of pale blue cytoplasm and fine-to-coarse cytoplasmic pink granules. In dogs, lymphocyte counts exceeding 25,000/μL in blood or greater than 15% in bone marrow strongly suggest a malignant process. Mild normocytic, normochromic nonregenerative anemia is common. Neutropenia and thrombocytopenia occur late in disease with myelophthisis. Histopathology may better document the infiltration into nodal tissues by neoplastic lymphocytes, with loss of tissue architecture, though this is not generally required for diagnosis. Causes of chronic systemic disease (e.g., ehrlichiosis, leishmaniasis) should be ruled out.

Immunophenotyping is considered important both to assist with definitive diagnosis and for prognosis. However, flow cytometric features alone may not be sufficient to confirm leukemia, as the recently described syndrome in English Bulldogs demonstrates. These dogs have an expansion of small B cells on flow cytometry but on PCR for antigen receptor rearrangement have polyclonal or restricted polyclonal gene rearrangements, suggesting nonmalignant disease. These dogs often have hyperglobulinemia, which is an uncommon finding in dogs with CLL generally.

Management

When CLL is an incidental diagnosis, monitoring with regular physical examination and CBCs is generally recommended rather than immediate treatment initiation. There is no consensus on when treatment should commence. In general, if there are clinical signs or significant hematologic abnormalities beyond mild anemia, treatment is warranted. Excessive lymphocytosis may be considered a cue to start treatment, but there is no consensus on what constitutes this. The most common treatment is a combination of chlorambucil with prednisolone. Chlorambucil doses in dogs often start at 0.2 mg/kg or 6 mg/m^2 daily for 1–2 weeks then reduced to 0.1 mg/kg or 3 mg/m^2 daily and tapered further depending on response.

Prognosis

Most dogs and cats treated with chlorambucil and prednisolone have reduction or normalization of their lymphocytosis. Survival times in dogs and cats range from approximately 1–3 years. Progression to high-grade lymphoid malignancy, known as Richter's syndrome, is uncommonly described, and prognosis after this occurs is poor. Prognostic factors for CLL in dogs are not well established, but T-cell CLL may be associated with an improved prognosis compared with B cell or atypical CLL.

ACUTE LYMPHOBLASTIC LEUKEMIA

Definition/Overview

Acute lymphoblastic leukemia is a rapidly progressive disorder that occurs mostly in middle-aged dogs (mean 6 years). In cats, with the overall reduced incidence and prevalence of FeLV infection, ALL has become less common.

Etiology

Viral agents (FeLV) or environmental exposure are possible causes.

Pathophysiology

Bone marrow or peripheral blood contains morphologically immature precursor cells or lymphoblasts. Acute lymphoblastic leukemia is thought to arise from the bone marrow and later involves the liver, spleen, and other tissues.

Clinical Presentation

Clinical signs in dogs include lethargy, anorexia, vomiting, weight loss, and diarrhea for several weeks. On physical examination, splenomegaly is common, and hepatomegaly and lymphadenomegaly may also be present. Signs associated with cytopenias, such as bleeding due to thrombocytopenia or fever and infection due to neutropenia, may be present.

Differential Diagnosis

Stage V lymphoma, acute myeloid leukemia without maturation, acute undifferentiated leukemia.

Diagnosis

Hematologic abnormalities include increased numbers of immature lymphoid cells in the blood or bone marrow (Figure 16.62), nonregenerative anemia, neutropenia, thrombocytopenia, and an occasional monoclonal gammopathy. Flow cytometry may be useful to confirm an acute leukemia phenotype (CD34+), as well as lymphoid origin, since acute myeloid leukemia appears morphologically similar. Approximately 10% of cases are confined to the bone marrow without detectable blood involvement (aleukemic leukemia). Bone

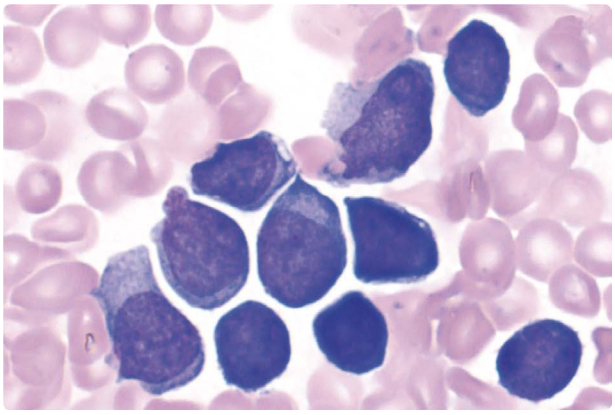

FIGURE 16.62 Acute lymphoblastic leukemia from a dog bone marrow. Note the large (i.e., ≥2.5–3 times the diameter of an RBC) immature cells with high nuclear-to-cytoplasmic ratio, finely stippled chromatin, and round-to-ovoid nuclei that contain multiple prominent nucleoli.

marrow evaluation is warranted in these cases and in cases with low numbers of circulating blasts (subleukemic leukemia). PCR tests for B- or T-cell antigen receptor rearrangement are available for difficult to diagnose cases.

Management

Treatment most often involves the same combination chemotherapy used for lymphoma. The prognosis is poor, with median survival (untreated or treated) being less than 3 months.

MULTIPLE MYELOMA

Definition/Overview

Multiple myeloma (MM, plasma cell myeloma) is a malignant disease of plasma cells. In dogs, bone marrow is primarily affected. In cats, widespread abdominal organ involvement without significant bone marrow involvement has been described. It affects older dogs (mean 9–10 years) and cats (median 12–14 years).

Etiology

The etiology is unknown.

Pathophysiology

Malignant plasma cells produce a clonal or, rarely, biclonal population of immunoglobulins (M proteins or paraproteins), light chains (Bence–Jones proteins), or heavy chains (heavy chain disease). These proteins may inhibit platelet function, causing bleeding diathesis, or result in hyperviscosity syndrome, renal failure, amyloidosis, or cryoglobulinemia. Infiltration into bone marrow by neoplastic plasma cells produces hematologic cytopenias. The destruction of bone by osteoclast-activating factors released by tumor cells causes lytic lesions and hypercalcemia. Bone pain and pathologic fractures are common sequelae. Plasma cell dysfunction can lead to immunodeficiency and increased susceptibility to infection.

Clinical Presentation

Clinical signs may be vague and variable, with lethargy and anorexia the most commonly reported signs in both dogs and cats. Lameness is reported in approximately 35% of dogs but is less common in cats. Other signs, such as paresis, blindness, bleeding from mucous membranes, vomiting and diarrhea, neurologic signs, or polydipsia and polyuria, can occur.

Differential Diagnosis

- *Causes of monoclonal gammopathy:* Ehrlichiosis, lymphoma, Leishmaniasis.
- *Causes of hepatosplenomegaly in cats:* Mast cell tumor, myelogenous leukemia, lymphoma, inflammatory, infectious.
- *Causes of bone lesions:* Primary or metastatic bone tumors, osteomyelitis.

Diagnosis

In dogs, identification of a monoclonal gammopathy detected in serum or urine (Bence–Jones proteinuria), radiographic or advanced imaging detection of osteolytic lesions, and bone marrow plasmacytosis with a cutoff of >20% are sufficient for a diagnosis of multiple myeloma (Figure 16.63). Urine protein reagent strips will not detect light chain proteinuria. In cats, monoclonal gammopathy and bone marrow plasmacytosis (>10% and/or atypical morphology) or visceral organ infiltration are suggested as diagnostic criteria.

Hematologic abnormalities in dogs and cats with multiple myeloma include nonregenerative anemia in 50%–80%, thrombocytopenia in approximately 40%–50%, neutropenia in approximately 25%–40%, and plasma cell leukemia in 5%–25% of cases. Hypoalbuminemia is common, azotemia is reported in

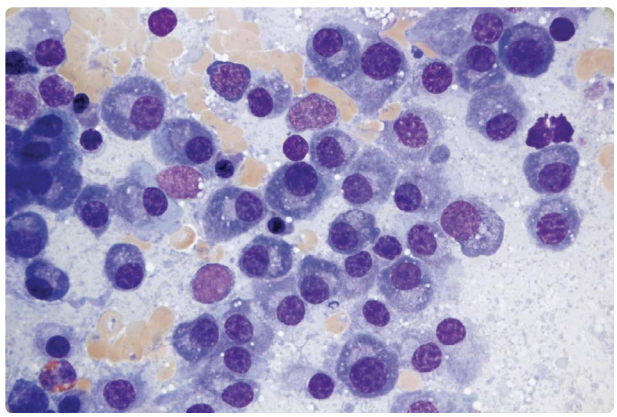

FIGURE 16.63 Aspirate preparation from a lytic bone lesion in a dog with multiple myeloma showing many plasma cells with abundant basophilic cytoplasm, prominent perinuclear pale zones, and peripherally placed nuclei with clumped chromatin.

approximately one-third, and hypercalcemia in approximately one-quarter of cases.

Management

Combination therapy with melphalan and prednisolone is considered standard of care in the dog. Melphalan may be given as a continuous dose starting at 0.1 mg/kg p.o. q.24 h. for 10 days, then 0.5 mg/kg q.24 h., or as a pulse dose of 7 mg/m^2 once daily for 5 consecutive days every 3 weeks. Prednisolone is initiated at 0.5 mg/kg once daily for 10 days then reduced to 0.5 mg/kg every other day. Discontinuation of prednisolone should be considered depending on the response.

In cats, melphalan appears to be myelosuppressive at doses generally tolerated by dogs. Cyclophosphamide and prednisolone have been suggested as an alternative either as 250 mg/m^2 every 2–3 weeks or 25 mg per cat twice weekly.

With either melphalan or cyclophosphamide, therapy is generally continued for as long as there is clinical benefit and no unacceptable toxicity. Patients should be monitored for myelosuppression with regular CBCs, the frequency of which will vary depending on the drug and protocol chosen, but at least monthly in the initial phase of treatment. Depending on which complications of MM are present, additional therapy may include plasmapheresis for hyperviscosity, fluid therapy for renal failure, orthopedic stabilization of pathologic fractures, and antibiotics for immunodeficiency.

Prognosis

While complete elimination of disease is rarely achieved, chemotherapy is effective at reducing tumor burden, improving clinical signs, and reducing serum globulins concentration. Assessment of response is based on clinical signs, serum globulins, and ideally repeat M component assessment. Dogs with normalization of hyperglobulinemia can have persistent paraproteinemia. Repeat bone marrow assessment may be required, especially in animals with cytopenias during chemotherapy treatment, where toxicity must be differentiated from progressive disease. In dogs treated with melphalan and prednisone, greater than 80% respond, and median survival times are approximately 1.5–2.5 years. Extensive bone lesions, light chain proteinuria, hypercalcemia, and azotemia have been identified as possible negative prognostic factors. Treatment and response data is scarcer in cats, but approximately 50%–80% will respond to chemotherapy, and although earlier reports suggested a poor prognosis with median survival time of approximately 4 months, better outcomes with median survival times of 8–13 months have been reported.

EXTRAMEDULLARY PLASMACYTOMA

Definition/Overview

Extramedullary plasmacytoma is a neoplastic proliferation of plasma cells that arises from tissues other than the bone marrow. The cells may be benign or malignant.

Etiology

The etiology is unknown.

Pathophysiology

Neoplastic plasma cells proliferate in the tissues. Malignant neoplasms may cause local and systemic tissue injury. Monoclonal gammopathies are less common than with MM.

Clinical Presentation

Clinical signs depend on the anatomic location, with skin being the most common location. Cutaneous plasmacytomas in dogs and cats are typically solitary, small, raised, alopecic, dermal nodules affecting the digits and pinnae more often than other sites. A syndrome of cutaneous plasmacytosis is described in dogs, where multiple lesions are present at the time of diagnosis. Oral plasmacytomas are also typically solitary but may become ulcerated and interfere with eating and drinking. Alimentary plasmacytomas can cause nonspecific gastrointestinal signs such as tenesmus and hematochezia in colorectal plasmacytomas and vomiting with gastric plasmacytomas. Solitary osseous plasmacytomas present with lameness or other signs depending on location, such as paresis in the case of vertebral lesions.

Differential Diagnosis

Cutaneous plasmacytoma: Other cutaneous neoplasms, especially mast cell tumor and histiocytoma, lymphoplasmacytic hyperplasia or inflammation, abscesses.

Alimentary plasmacytoma: Other alimentary neoplasia, inflammatory polyp, granuloma.

Solitary osseous plasmacytoma: Other primary bone tumor, multiple myeloma, secondary bone tumor, fungal or bacterial osteomyelitis.

Diagnosis

Diagnosis requires cytologic or histopathologic biopsy. For noncutaneous plasmacytomas, additional diagnostics (survey radiographs, bone marrow aspirate, serum electrophoresis) are important to ensure the lesion is solitary. Identification of a monoclonal gammopathy is occasionally described in cases with apparently solitary lesions, and so for confirmation of systemic disease, other criteria as used to diagnose multiple myeloma should be applied. Progression from solitary plasmacytoma to systemic plasma cell neoplasia has been reported and appears to be more common with those affecting sites other than the skin and oral cavity.

Management

Solitary plasma cell tumors are usually successfully treated with surgical excision and/or external beam radiotherapy. Cutaneous plasmacytosis in dogs is an aggressive disease, which does not typically lend itself to local therapy due to the diffuse nature at the time of diagnosis. Treatment as for multiple myeloma is recommended.

Prognosis

Canine cutaneous and oral plasmacytomas tend to be benign. Progression from solitary plasmacytoma to systemic plasma cell neoplasia has been reported and appears to be more common with those affecting sites other than the skin and oral cavity.

MYELOID (NONLYMPHOID) NEOPLASMS

Myeloid leukemias are clonal proliferations of erythroid, granulocytic, monocytic, and megakaryocytic cells. The 2008 WHO Classification of Tumors of Hematopoietic and Lymphoid Tissues, revised in 2016, includes myelodysplastic syndrome (MDS), myeloproliferative neoplasm (MPN), and acute myeloid leukemia (AML). These categories have been applied in animals. There are also categories of myeloid/lymphoid neoplasms, which is composed of diseases with specific gene rearrangements, and myelodysplastic/myeloproliferative neoplasms such as atypical chronic myeloid leukemia, which are not defined in veterinary species. A consensus classification system for canine and feline myeloid neoplasms has not been established.

MYELODYSPLASTIC SYNDROME

Definition/Overview

MDS is characterized by persistent peripheral cytopenia(s), normocellular to hypercellular marrow, dysplasia in one or more cell lines, and <20% blast cells in the marrow. In people, MDS is categorized based on the major cytopenia and morphological changes in cells. These subtypes have been described in animals, but the effect on subtype on biological behavior and prognosis is not defined.

Etiology

A possible role for FeLV infection in cats with MDS has been proposed, but no other etiologies have been described.

Pathophysiology

MDS often precedes acute leukemia by several weeks to months. Increased apoptosis is considered the mechanism for cytopenias in the face of marrow proliferation.

Clinical Presentation

Clinical signs are related to cytopenias and can include fever due to secondary infection from neutropenia, lethargy due to anemia, and hemorrhage due to thrombocytopenia.

Differential Diagnosis

Immune-mediated nonregenerative anemia, drug-induced dysplasia, and nutrition-related dysplasia.

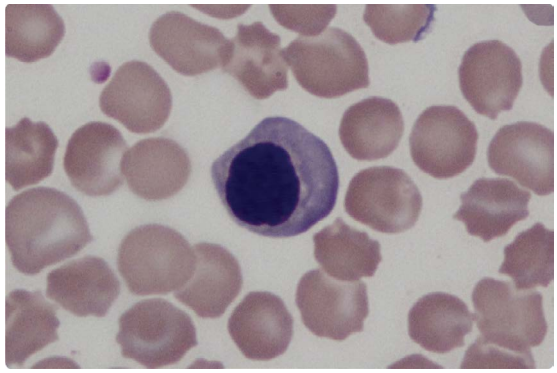

FIGURE 16.64 Inappropriate metarubricytosis and a dysplastic erythroid cell (megaloblast) in blood from a dog with myelodysplastic syndrome.

Diagnosis

Concurrent CBC and bone marrow cytology with or without histopathology are required for diagnosis. Other causes of dysplasia (e.g., drugs, breed-associated) should be excluded. Diagnosis requires detection of one or more cytopenias, normocellular to hypercellular marrow, <20% marrow myeloblasts, and myelodysplasia. Dysplastic changes in the blood or bone marrow include macrocytosis, megaloblastosis (Figure 16.64), nuclear fragmentation, abnormal cytoplasmic granulation, neutrophil hypersegmentation (Figure 16.65) or hyposegmentation, micromegakaryocytes or macrothrombocyte formation, and cell gigantism.

Management

As the condition may persist for long periods of time without major clinical disease, treatment is usually supportive and includes antibiotics and blood transfusions as needed. Dyserythropoiesis in the dog may respond to recombinant human EPO, but clinicians should bear in mind the risk of anti-EPO antibodies developing.

Prognosis

The prognosis is not well defined. Progression to AML can occur.

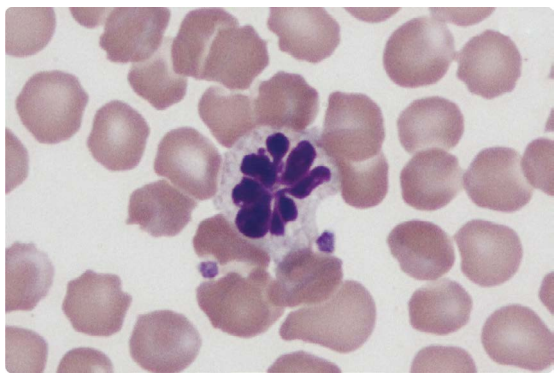

FIGURE 16.65 Dysplastic hypersegmented neutrophil from a dog with myelodysplastic syndrome.

MYELOPROLIFERATIVE NEOPLASMS

Definition/Overview

MPNs, previously known as chronic leukemias, consist of persistent, unexplained increases in one or more myeloid lineages with a predominance of morphologically mature neoplastic cells. MPNs in small animals include chronic granulocytic leukemia, essential thrombocythemia, polycythemia vera, and chronic myelomonocytic leukemia, and all are uncommon conditions. Primary myelofibrosis is an MPN described in humans which has been very rarely diagnosed in dogs and cats and is poorly defined.

Etiology

Feline MPN may be associated with FeLV infection.

Pathophysiology

Genetic mutations lead to cell proliferation and prolonged cell survival. BCR-ABL translocations have been documented in dogs with chronic monocytic and myelomonocytic leukemias. The leukemia slowly effaces the marrow, leading to a chronic disease course and cytopenias of other cell lines later in disease. Hyperviscosity syndrome is a potential complication of PV.

Clinical Presentation

Animals with leukocyte proliferations often have no clinical signs until late-stage disease. Therefore, diagnosis may be made with routine health screens. Late-stage disease consists of organ and marrow effacement, resulting in abdominal organomegaly, pallor if anemia is present, sepsis due to neutropenia or nonfunctional neutrophils, and hemorrhage from thrombocytopenia. Clinical signs in patients with PV relate to increased RBC mass and blood hyperviscosity. Mucous membranes may be dark red (Figure 16.66) because of PCVs of 0.65–0.82 L/L (65%–82%). Splenomegaly is usually not present. Polyuria, polydipsia, hemorrhage, and neurologic disorders occur in 50% of canine cases. Clinical signs of essential thrombocythemia include splenomegaly and platelet function abnormalities such as spontaneous bleeding and thromboembolism.

Differential Diagnosis

For PV: Causes of relative, appropriate absolute and inappropriate absolute erythrocytosis. For proliferations of neutrophils and monocytes: Causes of leukemoid response. For proliferations of eosinophils and basophils: Hypersensitivity reactions, parasitic infections, and hypereosinophilic syndrome. For essential thrombocythemia: Causes of reactive thrombocytosis.

Diagnosis

Since routine genetic testing is not available in veterinary medicine, these leukemias are diagnoses of exclusion. General features for all MPNs are persistent (>3 months) unexplained increases in one or more cell lines and relatively few blast cells in the bone marrow (<20% of all nucleated cells).

The subclassification is dependent on which cell lines are increased. Proliferations of neutrophils and/or monocytes include chronic myelogenous leukemia, chronic myelomonocytic leukemia, and chronic monocytic leukemia (Figure 16.67). Leukocyte counts are often markedly elevated (40,000–200,000/µL), and monocyte counts often exceed 4,000/µL (Figure 16.68). Neutrophilic leukemia must be differentiated from causes of a leukemoid inflammation, such as pyometra and pyelonephritis. Chronic eosinophilic leukemia is characterized by a high eosinophil count (often >50,000/µL) with a shift towards immaturity. It may be difficult to differentiate this malignancy from reactive hypereosinophilic conditions (e.g., allergies, parasitism, eosinophilic inflammatory diseases, paraneoplastic conditions). Chronic basophilic leukemia is mostly reported in dogs. It has been associated with thrombocytosis and anemia. Cytochemical staining with omega-exonuclease is helpful in identifying basophil precursors when cytoplasmic granulation is not apparent. Mature and immature basophils are increased in blood or bone marrow, and tissue infiltration may occur.

FIGURE 16.66 Brick red gums in a dog with polycythemia vera. (*Courtesy of J. Harvey.*)

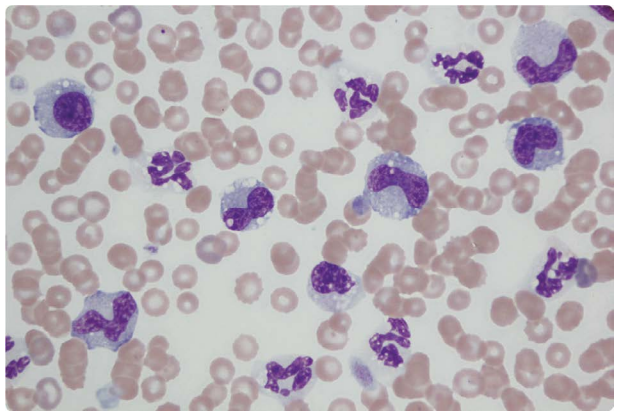

FIGURE 16.67 Chronic myelomonocytic leukemia in a dog with 116,491 neutrophils/µL and 26,277 monocytes/µL.

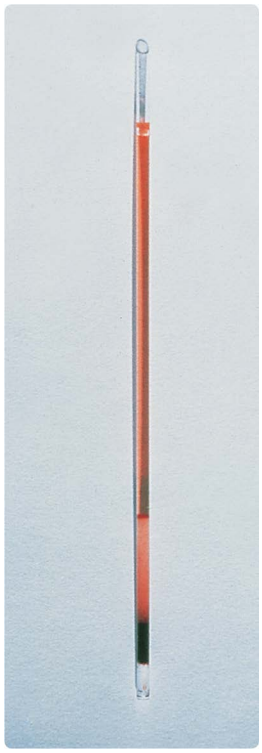

FIGURE 16.68 Large buffy coat present in a cat with acute myeloblastic leukemia displaying marked leukocytosis. (*Courtesy of J. Harvey.*)

Basophilic leukemia must be differentiated from mast cell leukemia.

PV, a proliferation of erythrocytes (primary erythrocytosis), occurs infrequently in dogs and cats. Diagnosis requires ruling out other causes of erythrocytosis. Arterial blood gas evaluations are normal with no evidence of hypoxemia. Erythropoietin levels are absent or reduced when measured at specialist laboratories. Leukocyte and platelet counts are normal to mildly elevated, and in a few cases, basophilia has been noted (Figure 16.69). Bone marrow examination indicates erythroid proliferation with normal morphology and maturation.

Essential thrombocythemia (primary thrombocythemia) is a rare neoplastic proliferation of megakaryocytes with subsequent thrombocytosis. Platelet counts are persistently above 600,000/μL (usually >1,000,000/μL), and platelet morphologic abnormalities may be present (Figure 16.57). Neutrophilia or basophilia may also be observed.

Management

For polycythemia vera, phlebotomy to remove 15–20 mL per kilogram of body weight with fluid replacement is indicated for immediate relief of clinical signs in many patients. Hydroxyurea is commonly used and is given in dogs at an initial dose of 30 mg/kg daily for 10 days, then reduced to 15 mg/kg daily and ultimately tapered to the lowest effective dose, with the goal of treatment being maintain the PCV as close to normal as possible. Repeated phlebotomies in combination with drug therapy may be required. Cats may be more prone to myelotoxicity from hydroxyurea and may require lower doses and more frequent monitoring.

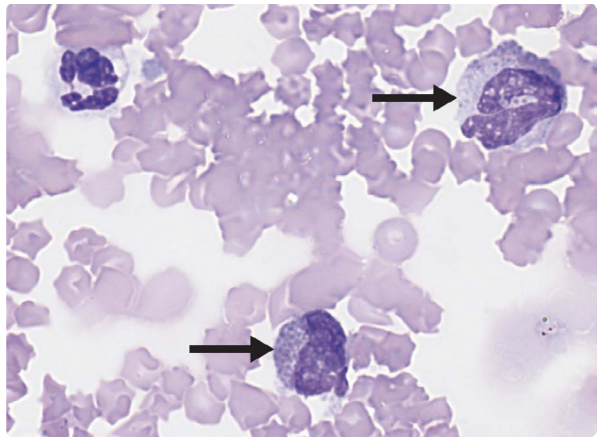

FIGURE 16.69 Feline blood with high hematocrit (0.64 L/L [64%]) and basophils (arrows) in a case of polycythemia vera.

For chronic myelogenous leukemia, hydroxyurea is also described and tapered to the lowest effective dose. Use of tyrosine kinase inhibitors such as imatinib and toceranib has been more recently described in dogs with CML due to the potential for them to have a BCR-ABL translocation similar to that responsible for a majority of CML in people.

There is little information on treatment for essential thrombocythemia (ET) in animals, but combination chemotherapy has been described in a dog, and in people, hydroxyurea is used in cases where clinical signs are present.

Supportive care (e.g., antibiotics, blood transfusions, and fluids) should be given when indicated.

Prognosis

Survival of months to years is expected, but eventual drug refractoriness or blast transformation is possible.

ACUTE MYELOID LEUKEMIA

Definition/Overview

AML is a proliferation of immature nonlymphoid hematopoietic cells that often results in myelophthisis and poor prognosis. In people, subtypes of AML are defined based on the identification of specific genetic abnormality or cell line. Genetic abnormalities including BCR-ABL translocation have been detected in dogs with AML, but their relevance is unknown. In dogs and cats, a uniform classification system has not been developed. However, utilizing morphology and immunophenotype, categories of AML without differentiation, AML with neutrophilic differentiation, AML with monocytic differentiation, AML with myelomonocytic differentiation, AML with megakaryoblastic differentiation, and AML with erythroid differentiation are described.

Etiology

FeLV is associated with feline AML.

Pathophysiology

Immature myeloid cells proliferate rapidly and efface the bone marrow, resulting in life-threatening cytopenia. Neoplastic cells often infiltrate tissues, causing widespread organ injury and dysfunction.

Clinical Presentation

Clinical signs are nonspecific with lethargy, weight loss, and hyporexia commonly reported. Clinical signs related to cytopenias may include fever due to secondary infection from neutropenia and bleeding due to thrombocytopenia. On physical examination, lymphadenopathy and hepatosplenomegaly are common.

Differential Diagnosis

Acute lymphoid leukemia, recovery following viral, toxin, or drug-induced leukopenia resulting in increased blasts in bone marrow.

For aleukemic cases: Other causes of cytopenia including immune-mediated (associative or nonassociative), drug toxicity, and myelodysplastic syndrome.

Diagnosis

Diagnosis is often made on a CBC and blood smear review. Peripheral blood findings often include immature myeloid cells and blast cells, as well as decreases in one or more cell lines due to myelophthisis. Thrombocytopenia-induced hemorrhage may also contribute to anemia. Bone marrow evaluation may be performed in cases with low or no circulating blasts or when AML subtype classification is desired. Flow cytometry or other special diagnostic techniques (e.g., cytochemistry on the blood or bone marrow) are often required to differentiate AML from ALL, as morphology alone is not definitive in most cases.

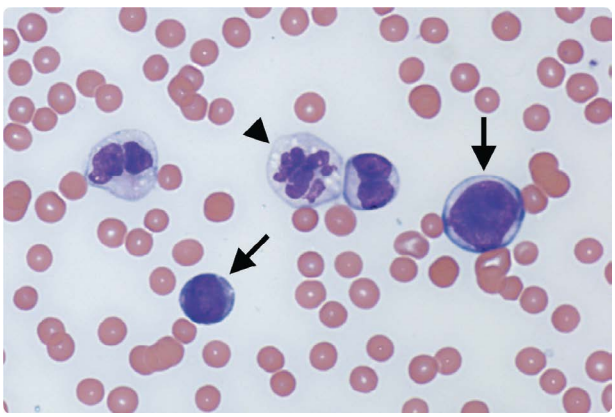

FIGURE 16.70 Blood from a dog with acute myelomonocytic leukemia with arrows indicating immature myeloid cells (myeloblasts) and an atypical segmented cell (arrowhead).

Within the marrow, there is hypercellular marrow, ≥20% blast cells, and variable proportions of myeloid cells. AML can be of myeloid, monocytic (Figure 16.70), erythroid, or megakaryocytic origin. When rebounding from neutropenia, such as following feline panleukopenia infection, the blood may appear neoplastic owing to the presence of large numbers of myeloblasts in the bone marrow. Persistent hematologic abnormalities must occur to confirm leukemia. Regenerative attempts following leukopenia are generally evident after 7–10 days for nonleukemic conditions.

Management

In general, AML is poorly responsive to chemotherapy, and consultation with an oncologist is recommended.

Prognosis

The prognosis is poor, as short-term responses are common but are not durable, in the order of weeks.

HISTIOCYTIC SARCOMA

Definition/Overview

Histiocytic sarcoma (HS) is a malignancy of histiocytes, which can be of dendritic cell or macrophage origin, and can manifest in a variety of ways. Localized HS is typically of dendritic cell origin and arises initially in one organ, though metastasis is common. Disseminated HS (previously known as malignant histiocytosis) is widespread at the time of diagnosis, commonly involving abdominal viscera (especially spleen and liver) and lungs, without an obvious primary site. Hemophagocytic HS arises from macrophages and affects the spleen, with widespread dissemination being common at diagnosis. Management and prognosis differ for the different manifestations.

Etiology

In dogs, several breed associations for HS have been identified, including Bernese Mountain Dogs, Flat-coated Retrievers, and Miniature Schnauzers, and an inherited predisposition with possible genetic drivers has been investigated in Bernese Mountain Dogs. An association between prior joint disease and periarticular HS has been found in Bernese Mountain Dogs and other breeds, though in other breeds this is largely related to cruciate ligament disease. There are some breed differences in clinical manifestation, with disseminated HS being more common in Bernese Mountain Dogs and localized HS being more common in Flat-coated Retrievers. No specific risk factors have been identified in cats, which are more likely to present with disseminated than localized HS.

Pathophysiology

Possible genetic drivers of HS have been identified in dogs, including gain-of-function mutations in PTPN11

and copy number alterations in tumor suppressor genes. Proliferation of malignant histiocytes in various tissues leads to clinical signs dependent on the organs involved. In hemophagocytic HS, malignant histiocytes of macrophage origin exhibit phagocytosis of red blood cells and other hematopoietic cells, and the animals often develop hypoalbuminemia.

Clinical Presentation

Clinical signs vary with sites of tumor involvement. Disseminated or visceral HS typically presents with vague clinical signs, including lethargy and inappetence. More common sites for localized HS include periarticular (presenting with lameness), pulmonary (presenting with coughing or other respiratory signs), or subcutaneous, often presenting with a mass without other clinical signs. Lymphadenomegaly (peripheral or internal) is common with disseminated or metastatic HS. Animals with hemophagocytic HS often present with clinical signs related to anemia or thrombocytopenia.

Differential Diagnosis

The most common neoplastic differential for HS is lymphoma, especially in disseminated or visceral HS. Anaplastic sarcoma is another common differential. Differentials for localized HS include:

- *Periarticular:* Primary or metastatic bone tumor, synovial sarcoma, myxoma, fungal osteomyelitis, primary orthopedic disease, hematoma
- *Pulmonary:* Other primary lung tumors, fungal granuloma, eosinophilic bronchopneumopathy
- *Hemophagocytic HS:* Immune-mediated hemolytic anemia, hemangiosarcoma, hemophagocytic syndrome, immune-mediated thrombocytopenia, immune-mediated neutropenia; primary protein-losing enteropathy is sometimes suspected in early cases presented with diarrhea and hypoalbuminemia

Diagnosis

Definitive diagnosis of HS on cytology or histopathology can be challenging due to the pleomorphic nature of the tumor cells. Immunocytochemistry or immunohistochemistry may be required, and antibodies to CD18, CD204, and Iba1 have been helpful. Fresh or frozen tissue evaluation of CD1 and CD11 subunits can further confirm the diagnosis or subclassify the cell of origin.

Full staging with thoracic and abdominal imaging is recommended for any case of HS, as metastasis of apparently localized disease is common. Bone marrow evaluation is recommended in animals with cytopenias not attributed to splenic hemophagocytic HS.

Management

For localized HS without evidence of metastasis at diagnosis, surgery or radiation therapy to the primary tumor and adjuvant chemotherapy is recommended where possible. For disseminated or metastatic disease, chemotherapy can be of benefit. CCNU (lomustine) appears to be the most effective drug against canine HS, with doxorubicin, epirubicin, and dacarbazine also having evidence of efficacy. In dogs with measurable disease, reported response rates to chemotherapy (single agent or combination) range from approximately 30%–60%. Treatment of feline HS is not well studied, though there are case reports of responses to therapies including CCNU.

Prognosis

Survival times for dogs with localized HS and no metastasis treated with adequate local control plus adjuvant chemotherapy can be very good, especially in dogs with periarticular HS in which a median survival time of approximately 2 years has been reported. However, development of metastatic disease is still common, and long-term outcome is guarded. Despite responses to chemotherapy, long-term prognosis for disseminated or metastatic HS is poor, with median survival times of approximately 6–9 months in those that respond to chemotherapy. Hemophagocytic HS appears to have an aggressive clinical course even with therapy, with most patients dying in days to weeks.

CASE EXAMPLES

Case 16.1: Systemic Histoplasmosis – Katie M. Boes, Julien R.S. Dandrieux, and Claire M. Cannon

Signalment/History

A 2-year-old indoor/outdoor spayed female Domestic Shorthair cat is presented for a 3-week history of weight loss and lethargy.

Clinical Examination

The cat is quiet, alert, responsive, and mentally dull with normal vital signs. There are general signs of ill thrift, including dull hair coat, poor BCS (2/9), and mild muscle atrophy of the hindlimbs. Mucous membranes are pale, and the cat is estimated to be 8% dehydrated. A grade 2/6 systolic heart murmur is auscultated.

Provisional Hematologic Abnormalities

Pale mucous membranes suggest anemia. Since icterus is not observed, hemolytic anemia is less likely. There is no evidence of external hemorrhage (e.g., trauma, external parasitism), internal hemorrhage (e.g., distended abdomen), or GI hemorrhage (e.g., perineal blood). Therefore, likely causes for the anemia are decreased RBC production and occult GI hemorrhage. The murmur is likely secondary to the anemia.

Differential Diagnosis

Causes of chronic disease, ill thrift, and anemia in a young cat include viral (FeLV, FIV, feline panleukopenia virus) infection; intestinal parasites; systemic fungal infection; lymphoma; mycoplasmosis; chronic or congenital kidney disease.

(Continued)

Laboratory Tests

A FeLV/FIV SNAP test was negative. A serum chemistry panel was consistent with stress (glucose = 184 mg/dL; RI 71–165), inflammation (albumin = 2.8 g/dL [RI 3.0–4.0]; globulins = 5.4 g/dL [RI 3.0–5.2]), and minimal cholestasis (GGT = 2 U/L [RI 0–1]; total bilirubin = 1.3 mg/dL [RI 0.0–0.4]). A CBC (**Table 16.15**) and blood smear review (**Figure 16.71**) were also performed.

TABLE 16.15 Hemogram results

Test	Result	Reference interval (from author's lab)
RBC	3.70 × 10^6/μL	7.28–11.36
Hemoglobin	5.3 g/dL	12.1–6.7
Hematocrit	17.1%	33.7–47.5
MCV	46.2 fL	38.4–49.2
MCHC	31.0 g/dL	34.1–37.0
Reticulocytes	15,400/μL	13,050–71,570
NRBCs	6/100 WBCs	0–1
WBCs	5,302/μL	4,250–11,360
Segmented neutrophils	3,287/μL	2,272–9,639
Band neutrophils	212/μL	0–0
Lymphocytes	1,750/μL	804–9,240
Monocytes	53/μL	0–952
Platelets	97,000/μL	148,700–531,600

FIGURE 16.71 Three small, ovoid yeasts (arrows) in the cytoplasm of a monocyte.

Blood smear review: Few schistocytes and acanthocytes; NRBCs are metarubricytes; many neutrophils with Döhle bodies and foamy cytoplasm; rare small ovoid yeast forms within monocytes.

Interpretation

The moderate-to-marked normocytic hypochromic anemia is primarily due to decreased production since it is nonregenerative. There is other evidence of hematopoietic hypoplasia (thrombocytopenia), and bone marrow injury is suspected (inappropriate metarubricytosis). Anemia of chronic disease may be contributing to the anemia but is not expected to cause this severity of anemia by itself. The schistocytes, acanthocytes, and thrombocytopenia raise concern for concurrent microangiopathic hemolysis and platelet consumption secondary to DIC. There is no evidence of blood loss anemia, such as increased BUN relative to creatinine or panhypoproteinemia. The left shift and toxic neutrophils (Döhle bodies and foamy cytoplasm) denote inflammation. The cause for the hematologic changes is present on the blood smear as intracytoplasmic yeast consistent with *Histoplasma capsulatum*.

Clinical Diagnosis

The diagnosis is systemic histoplasmosis with probable bone marrow infection and DIC.

Case Outcome

The cat was given a guarded prognosis for recovery, and the owners elected to euthanize the cat. A necropsy was not performed, but the owners authorized aspiration of the bone marrow after euthanasia. Cytologic evaluation of the bone marrow confirmed granulomatous fungal myelitis resulting in erythroid hypoplasia, myeloid hyperplasia, and megakaryocytic hypoplasia.

Treatment options include azole antifungal drugs such as itraconazole or fluconazole. Ketoconazole should be avoided as less effective and more likely to cause toxicity. In people, itraconazole is more effective than fluconazole, and although this might be the case as well in cats, there are reports of successful treatment with fluconazole monotherapy. If there is CNS involvement, treatment with amphotericin B should be used as first line with transition to itraconazole once the disease is better controlled. Treatment is typically long (6 months or more), and discontinuation can be considered when the lesions have resolved and potentially resolution of *H. capsulatum* antigen excretion.

Case 16.2: Gastrointestinal Stromal Tumor – Julien R.S. Dandrieux, Katie M. Boes, and Claire M. Cannon

Signalment/History

A 10-year 6-month-old spayed female Labradoodle is presented for a 2-week history of lethargy (worsening) and hyporexia. Previous history includes degenerative joint disease treated with pentosan polysulfate injections and a recent 4-week course of carprofen. The owner has noted increased defecation frequency since started carprofen and one episode of diarrhea. The owner has rat bait at home but in a closed cupboard, making exposure unlikely.

Clinical Examination

The dog is quiet, alert, and responsive. She is overweight (body condition score 6/9), and her mucous

(Continued)

membrane are pale with a normal capillary refilling time. The dog is tachycardic and tachypneic with tall and narrow pulses. Thoracic and cardiac auscultations are unremarkable. Abdominal palpation is unremarkable. Small amount of feces is present on rectal examination without evidence of fresh blood or melena. No obvious organomegaly or ascites is noted on AFAST and no pleural effusion on TFAST.

Provisional Hematologic Abnormalities

Pale mucous membranes and cardiovascular status suggest anemia. The absence of icterus makes hemolytic anemia less likely. There is no evidence of external blood loss reported by the owner and no evidence of internal hemorrhage; however, the dog has been treated with an NSAID and can potentially have secondary GI bleeding. GI bleeding in small amount cannot be excluded. Physical examination findings suggest marked anemia, and for this reason, anemia of inflammatory disease or endocrine disease are considered unlikely. The progressing lethargy, tachycardia, and tachypnea suggest that the dog would benefit from a blood transfusion.

Differential Diagnosis

Likely causes for the suspected marked anemia include either decreased RBC production or occult hemorrhage (GI or urinary) secondary to treatment (NSAID) or other pathology. Hemolytic anemia is less likely in the absence of icterus. Chronic renal disease is deemed unlikely in the absence of other suggestive clinical signs.

Laboratory Tests

A serum chemistry panel revealed mild panhypoproteinemia (42g/L [RI 52–82]) with mild hypoalbuminemia (21g/L [RI 22–39]) and hypoglobulinemia (21g/L [RI 25–45]). The rest of the serum chemistry results, including urea and bilirubin, were within normal limits.

A CBC (**Table 16.16**) and blood smear review (**Figure 16.72**) were also performed.

The blood smear review: The erythrocytes show moderate anisocytosis reflecting both macrocytosis and microcytosis, and many of the microcytes show prominent central pallor suggesting iron deficiency should be considered. Rare smaller cells show no central pallor, which mimic spherocyte morphology. Mild rouleau is present, but there is no agglutination.

Other testing included PT, aPTT (within RI), Coombs test (negative), and typing (DEA1- positive) in view of blood transfusion.

Interpretation

Although the anemia is strongly regenerative, there is some evidence of iron deficiency on blood smear with presence of microcytes with central pallor. The MCV would be expected to be higher with the degree of regeneration and reflects the combine presence of microcytes and reticulocytes. Although end-stage iron deficiency is characterized by nonregenerative to poorly regenerative microcytic, hypochromic anemia, earlier stages will still be strongly regenerative and should not be misinterpreted for a hemolytic process. The absence of agglutination and negative Coombs test together with normal bilirubin further suggest that hemolysis is unlikely.

TABLE 16.16 Hemogram results

Test	Result	Reference interval (from author's lab)
RBC	1.6 × 10^6/μL	5.5–8.5
Hemoglobin	2.9 g/dL	12.0–18.0
Hematocrit	12.0 %	37.0–55.0
MCV	65 fL	60–75
MCHC	252 g/L	320–380
Reticulocytes	350 x10^9/L	10–110
NRBCs	1/100 WBCs	0–1
WBCs	13,500/μL	6,000–17,000
Segmented neutrophils	11,500/μL	3,000–11,500
Band neutrophils	200/μL	0–300
Lymphocytes	1,100/μL	1,000–4,800
Monocytes	700/μL	200–1,400
Platelets	759,000/μL	200,000–500,00

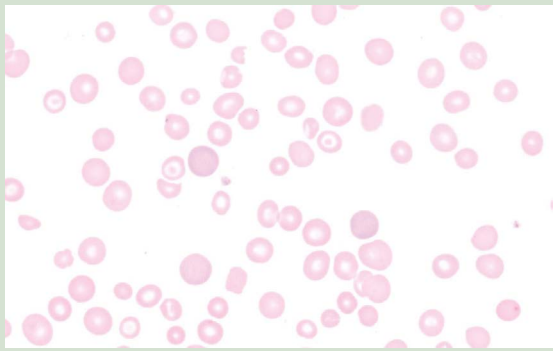

FIGURE 16.72 Blood smear. This blood smear shows a combination of polychromasia, anisocytosis, and occasional spherocytes.

Clinical Diagnosis

Iron-deficiency anemia.

Case Outcome

The dog was stabilized with packed red cell transfusion prior to further workup. Abdominal ultrasound revealed the presence of 4 cm diameter mass in the jejunum consistent with a mesenchymal cell proliferation on cytology. No evidence of metastasis was noted in the abdomen or on thoracic radiographs. The dog underwent surgery to remove the mass, and a final diagnosis of gastrointestinal stromal tumor (GIST) was obtained with immunohistochemistry.

(Continued)

The dog recovered well, and the GIST was fully excised. In dogs, that survive the perioperative period and have no visible metastasis, outcomes with GISTs can be very good, and adjuvant chemotherapy is not generally recommended. Tyrosine kinase inhibitors of c-Kit can be used in cases of unresectable or metastatic disease. The dog was euthanized 30 months later for an unrelated disease without recurrence of the GIST.

Case 16.3: Nonassociative Immune-Mediated Hemolytic Anemia – Julien R.S. Dandrieux and Katie M. Boes

Signalment/History

A 6-year-old spayed female German Shepherd Dog is presented for a 1-day history of decreased appetite and progressive lethargy. She also had a self-limiting episode of vomiting 4 days prior to presentation.

Clinical and Laboratory Examination

The dog is quiet, alert, responsive, and in a good body condition score (5/9, 28.5 kg). Her sclerae are mildly icteric. Her mucous membranes are pale with a normal capillary refilling time. Her heart rate is 132 beats/min with normodynamic pulses, and her respiratory rate 34 breaths/min with normal respiratory pattern. Thoracic and cardiac auscultation are within normal limits. There is some discomfort on cranial abdominal palpation but no masses noted.

Selected laboratory results are listed in **Table 16.17** and the blood smear is shown in **Figure 16.73**.

The anemia is marked, and there is marked agglutination on the smear that is confirmed with a saline agglutination test. Apart from the hyperbilirubinemia, the rest of the biochemistry panel is within reference interval, including the albumin and globulins concentrations. The urine was clear with negative dipstick and sediment.

Interpretation of Hematologic Abnormalities and Differential Diagnosis

Although the anemia is marked, and there is evidence of immune-mediated erythrocyte targeting (agglutination), the red cell regeneration is inadequate. This may occur with reticulocyte agglutination causing a falsely decreased reticulocyte count, peracute onset of the immune-mediated anemia (i.e., preregenerative anemia), or concurrent immune targeting of mature erythrocytes in peripheral blood and erythrocyte precursors in the bone marrow (i.e., nonregenerative anemia). The platelet count remains adequate, and the neutrophil count is usually expected to be higher with an immune-mediated hemolytic anemia. The albumin is normal, which does not support blood loss. Nonimmune-mediated hemolysis is deemed unlikely in view of the agglutination.

In view of these results, the dog is suspected to have immune-mediated hemolytic anemia, and further workup is required to determine if it is nonassociative or associative (i.e., primary or secondary). There is no history of recent drug administration, and the dog lives in a nonendemic area for arthropod-borne disease with no travel history. Further pertinent history in regard to blood transfusion requirement includes that the dog has not had a previous blood transfusion and never had a litter.

TABLE 16.17 Selected hemogram and chemistry panel results

Test	Result	Reference interval (from author's lab)
Red blood cell*	1.4 × 10^6/μL	5.5–8.5
Hemoglobin	57 g/L	120–180
Hematocrit*	0.10 L/L	0.35–0.53
PCV	0.16 L/L	0.37–0.55
MCV*	68 fL	60–75
MCHC	356 g/L	320–380
Reticulocytes*	93,000/μL	10,000–110,000
WBCs	13,500/μL	6,000–17,000
Segmented neutrophils	11,900/μL	3,000–11,500
Band neutrophils	0/μL	0–0
Lymphocytes	800/μL	1,000–4,800
Monocytes	700/μL	200–1,400
Platelets	302,000/μL	200,000–500,000
Bilirubin	25 μmol/L	0–20
Albumin	37 g/L	31–44
Globulins	37 g/L	14–37

* These results may be affected by agglutination and not be accurate in this instance.

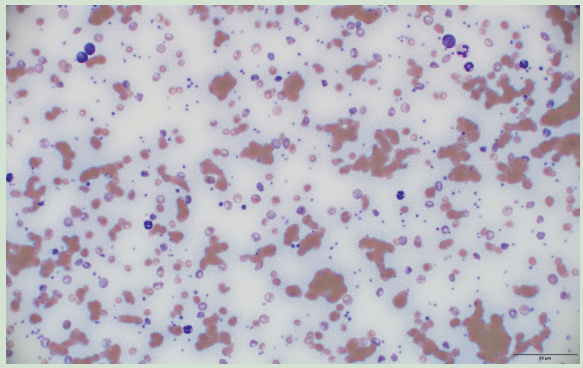

FIGURE 16.73 The body of the blood smear shows clustering of erythrocytes (agglutination) and linear arrays of erythrocytes (rouleaux). 50× objective field, Wright-Giemsa.

(Continued)

Other Diagnostic Procedures

The dog canine blood group was DEA 1-positive. In view of the agglutination, a Coombs test is not indicated.

Thoracic radiographs (including cranial abdomen) and abdominal ultrasound did not reveal any abnormalities.

The dog was stabilized with packed red blood cells and started on treatment with prednisolone for the suspected immune-mediated disease and clopidogrel to reduce the thromboembolic risk. However, the dog's PCV dropped rapidly over the following 5 days, and there was a lack of regenerative response. For this reason, a bone marrow aspiration was performed that showed ineffective hematopoiesis (i.e., lack of late-stage red cell precursors) and presence of frequent macrophages phagocytizing erythrocytes, reticulocytes, and metarubricytes. There were no dysplastic changes noted and no evidence of a neoplastic process in the bone marrow.

Clinical Diagnosis

In view of these results, the dog was diagnosed with a nonassociative or idiopathic immune-mediated hemolytic anemia targeting the peripheral red cells (agglutination) as well as the red cell precursors in the bone marrow (erythrophagia).

Case Outcome

The dog's prednisolone dosage was adjusted for her weight of 28.5 kg or 0.94 m^2 body surface area. She was treated with 40 mg/m^2, i.e., a total of 40 mg p.o. daily, rather than 60 mg (2 mg/kg daily) to reduce the risk of adverse effects as the treatment was expected to last several months.

In addition, she was treated with cyclosporine 5 mg/kg p.o. twice a day, as dogs with bone marrow involvement tend to respond more slowly, and no response was seen with 5 days of prednisolone monotherapy.

Although an anticoagulant such as rivaroxaban should be preferred, only clopidogrel was used in this instance to reduce the risk of thromboembolism.

The dog required an additional blood transfusion to stabilize her, but her anemia became regenerative 2 weeks after initiating treatment. Six months later, she remained clinically well with resolution of the IMHA, and her prednisolone had been tapered off. Her cyclosporine is currently being tapered off with the aim to discontinue all treatment within another 2 months.

NORMAL HEMOSTASIS

Hemostasis represents a balance between prothrombotic (clotting) and antithrombotic (bleeding) tendencies. An antithrombotic tendency is necessary for blood to circulate as a fluid. This is achieved by an intact endothelium separating prothrombotic substances in the blood (i.e., platelets, clotting factors) from those in the perivascular tissues (e.g., subendothelial collagen, tissue factor, von Willebrand factor [VWF]). Several endogenous antithrombotics are also synthesized and released by endothelial cells. These include endogenous platelet inhibitors (e.g., nitric oxide) and inhibitors of clotting factors (anticoagulants) (e.g., antithrombin). In the event of blood vessel injury, there is a rapid switch to a prothrombotic tendency. Initially, a reflex autonomic vasoconstriction increases the probability of intraluminal and perivascular prothrombotic substances interacting with each other. These interactions ultimately lead to the formation of a blood clot (thrombus) preventing blood loss from the damaged vessel. The steps leading to thrombus formation are traditionally separated into primary and secondary hemostasis, although the cell-based model of hemostasis may represent a better representation of in vivo events.

PRIMARY HEMOSTASIS

Primary hemostasis is determined by platelet number and function. Platelets are simple anucleate disc-shaped cells that circulate in the blood for about a week in dogs and cats. Thrombopoiesis refers to the formation of platelets in the bone marrow from progenitor stem cells through to the megakaryocyte, the immediate precursor to mature platelets. Thrombopoietin, a hormone mainly synthesized by the liver, is the major regulator of the process. Despite their structural simplicity, platelets are capable of diverse biological functions related to an abundance of cell surface receptors and intracellular granules containing a myriad of biologically active substances. Platelet surface receptors fall into two major types: Adhesion receptors (facilitating tethering of platelets to the site of vessel injury) or agonist receptors (involved in platelet activation).

The first step in primary hemostasis involves platelet adhesion to the site of vessel injury (**Figure 17.1**). Adhesion is quite weak initially, associated with adhesion receptors engaging with subendothelial prothrombotic substances (e.g., VWF and glycoprotein Ib-IX-V [GPIb-IX-V] receptor, collagen and glycoprotein VI [GPVI] receptor). The specific interactions differ between arteries and veins based upon the vessel shear stress. Platelet adhesion triggers intracellular signaling pathways involved in platelet activation. Platelet activation also occurs when specific activators bind to agonist receptors. Numerous platelet activators exist but vary in terms of their potency and clinical importance. Thrombin (factor IIa) is considered the most important activator of platelets. Other substances of note include adenosine diphosphate (ADP), thromboxane, serotonin, collagen, and epinephrine. Three key events occur during platelet activation: (1) Membrane flipping (i.e., changes in platelet cell membrane structure to promote a prothrombotic cell surface), (2) shape change (i.e., disc-shaped platelets become star shaped), and (3) platelet degranulation (i.e., release of substances from the intracellular granules). Activated platelets are then capable of forming platelet-to-platelet interactions (aggregation), largely mediated through fibrinogen binding to GP IIb/IIIa receptors.

DOI: 10.1201/9781003254591-36

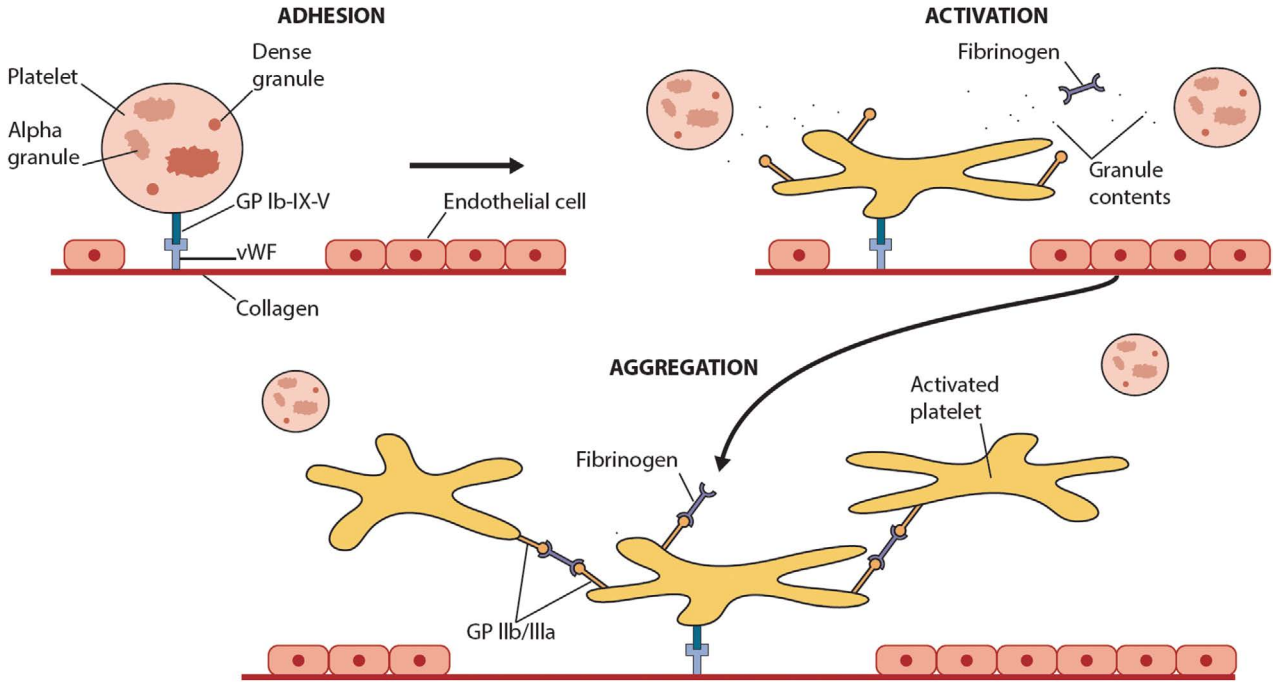

FIGURE 17.1 Platelet adhesion, activation, and aggregation. During adhesion, platelets bind to perivascular prothrombotic substances (e.g., subendothelial collagen). Platelet activation is characterized by plasma membrane flipping, shape change, and degranulation. Platelet aggregation (platelet-to-platelet interactions) mediated via fibrinogen binding to GP IIb/IIIa leads to the formation of the initial platelet plug. (*Courtesy of Bobbi Conner.*)

Aggregated platelets are the basis of the unstable platelet plug that forms as the initial defense against blood loss.

SECONDARY HEMOSTASIS

Secondary hemostasis is determined by the number and function of clotting factors, culminating in the formation of fibrin. Clotting factors are enzymes (serine proteases) that are released in their inactive form (zymogens). Similar to other enzymes, clotting factors work best within specific biological limits (e.g., temperature, pH). Clotting factors also must assemble on a phospholipid layer (e.g., cell membrane) to function appropriately, and some need cofactors (e.g., calcium, vitamin K). The clotting cascade describes the sequential activation of clotting factors, such that the preceding activated clotting factor activates the subsequent clotting factor (Figure 17.2). The nomenclature of clotting factors is somewhat confusing, since Roman numerals (e.g., factor X), names (e.g., fibrinogen), or a combination of both (e.g., thrombin and factor II) may be used to describe them. Activated clotting factors are indicated by the addition of a lowercase "a" (e.g., activated clotting factor X is FXa).

The clotting cascade is conventionally separated into extrinsic and intrinsic pathways that converge on the common pathway. The clotting factors are not numbered sequentially because individual factors were discovered prior to describing these pathways. For the clinician, distinguishing the extrinsic from the intrinsic pathway is useful when interpreting diagnostic tests.

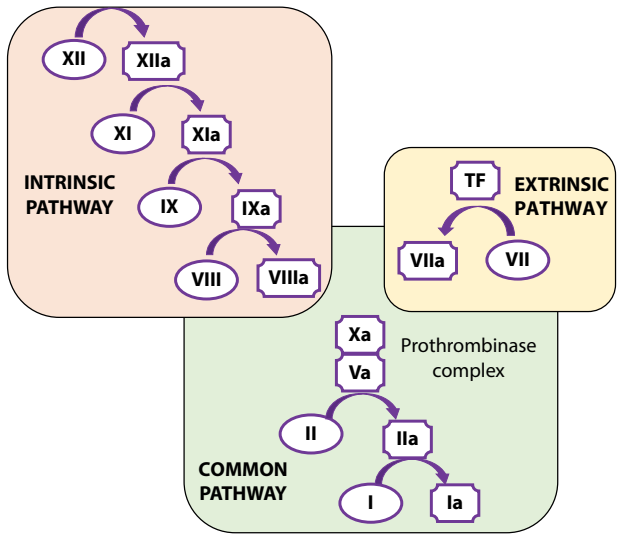

FIGURE 17.2 Depiction of the clotting cascade of serine proteases, separated into intrinsic and extrinsic pathways, converging on the common pathway culminating in fibrin formation. Activated clotting factors are denoted by "a." I, fibrinogen; Ia, fibrin; II, prothrombin; IIa, thrombin.

The extrinsic pathway, which is initiated by blood vessel injury, comprises tissue factor and FVII. Some FVII circulates in the activated form (FVIIa), making tissue factor–FVIIa interactions powerful and efficient initiators of thrombosis. In contrast, cross talk between inflammation and hemostasis is the major initiator of the intrinsic pathway (FXII, FXI, FVIII, FIX). The extrinsic and

intrinsic pathways converge on the common pathway culminating in fibrin formation. Initially, the prothrombinase complex (an enzyme complex composed of FVa–FXa) catalyzes the conversion of prothrombin (FII) to thrombin (FIIa), which in turn catalyzes the conversion of fibrinogen (FI) to fibrin (FIa). Polymerized fibrin cements the platelet plug formed at the end of primary hemostasis. Of all clotting factors, thrombin (FIIa) has greatest significance on hemostasis, since it has roles in primary and secondary hemostasis, as well as slowing clot degradation via thrombin activatable fibrinolysis inhibitor (TAFI).

CELL-BASED MODEL OF HEMOSTASIS

The cell-based model of hemostasis (Figure 17.3) provides an alternative description of the events leading to thrombus formation. The model incorporates three overlapping phases: Initiation, amplification, and propagation. Tissue factor-bearing cells (e.g., perivascular fibroblasts, macrophages, microparticles) are the major initiators of hemostasis, bearing resemblance to the events described in the extrinsic pathway. The initiation phase leads to the generation of a small amount of thrombin, which supports platelet activation during the amplification phase. The amplification phase is analogous to primary hemostasis. Finally, the propagation phase, which most closely resembles the intrinsic and common pathways, leads to the assembly of enzyme complexes (e.g., prothrombinase complex) on the surface of platelets. The propagation phase supports massive thrombin generation and effective thrombus formation.

FIBRINOLYSIS

Fibrin blood clots removal (fibrinolysis) occurs after blood vessel repair has occurred, restoring blood vessel patency. Clot breakdown is mediated by plasmin (Figure 17.4). The precursor to plasmin is plasminogen, which binds to lysine residues on the fibrin clot. Once clot bound, it is converted to plasmin under the influence of tissue plasminogen activator (tPA). Plasmin degrades the clot into fibrin degradation products (FDPs). A subset of FDPs, termed D-dimers, represent cross-linked subfractions of fibrin that were previously contained with blood clots. The fibrinolytic system is kept in check by inhibitors of tPA (i.e., plasminogen activator inhibitor-1), as well as endogenous inhibitors of plasmin (i.e., α2-antiplasmin).

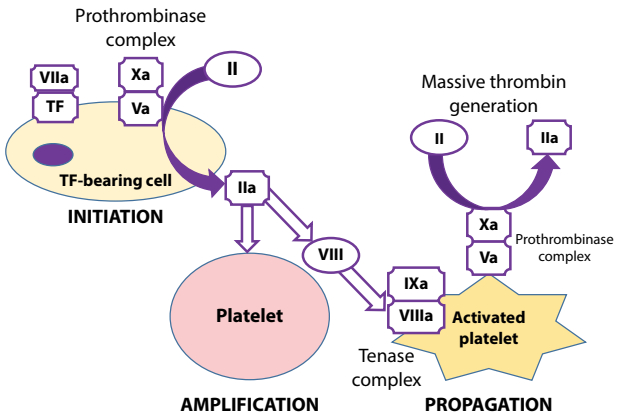

FIGURE 17.3 Depiction of the cell-based model of coagulation, consisting of initiation (on tissue factor-bearing cell surface), amplification (on nonactivated platelet surface), and propagation (on activated platelet surface) phases. Activated clotting factors are denoted by "a." TF, tissue factor.

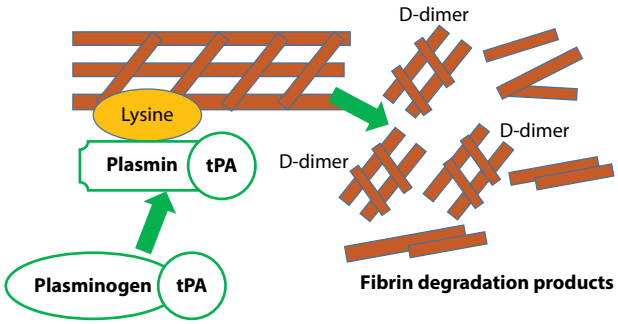

FIGURE 17.4 Plasminogen combines with tissue plasminogen activator (tPA) and is converted to plasmin. Plasmin binds to lysine residues on the surface of the fibrin clot, inducing fibrinolysis and formation of fibrin degradation products. Cross-linked fibrin degradation products are called D-dimers.

HEMOSTATIC DISORDERS

Dogs and cats with several primary diseases may develop abnormal hemostatic function. These animals may present with signs of dysfunction (i.e., bleeding or thrombosis) or be considered at increased risk of developing dysfunction in the future. Some patients can also suffer from complex hemostatic disorders, such as disseminated intravascular coagulation (DIC) that have features of both bleeding and thrombosis.

BLEEDING DISORDERS

Bleeding disorders (hypocoagulability) develop as a consequence of disordered primary hemostasis, secondary hemostasis, or fibrinolysis (Table 17.1). Primary hemostatic disorders occur with decreased platelet number (thrombocytopenia) or function (thrombocytopathia). Thrombocytopenia is most likely and must be ruled out first before considering platelet dysfunction. The hallmarks of primary hemostatic dysfunction (spontaneous small and superficial hemorrhages [petechia and ecchymoses]) contrast with the larger volume hemorrhages (e.g., body cavitary hemorrhage) more commonly seen with secondary hemostatic and hyperfibrinolytic disorders.

Table 17.1 represents the comparison of disorders of primary hemostasis, secondary hemostasis, and hyperfibrinolysis.

TABLE 17.1 Summary of the clinical features of bleeding disorders associated with primary hemostatic, secondary hemostatic, and hyperfibrinolytic disorders

	System components	Clinical signs	Diagnostic tests
Primary hemostasis	– Platelet number – Platelet function (intrinsic) – Platelet function (extrinsic)	– Spontaneous bleeding—petechiation, ecchymoses, mucosal bleeding, epistaxis, melena – Surgical/procedural/traumatic bleeding—variable but potentially severe, oozing	– Platelet count – Platelet indices – BMBT – Closure time – Aggregometry – Flow cytometry – Viscoelastic testing – Platelet mapping – VWF:Ag
Secondary hemostasis	– Clotting factor number – Clotting factor function	– Spontaneous bleeding—large volume, cavitary hemorrhage, hemarthrosis, SC bleeding, intramuscular bleeding – Surgical/procedural/traumatic bleeding	– PT – aPTT – ACT – Viscoelastic testing – Individual factor analysis – Thrombin generation
Hyperfibrinolysis	– Plasmin – Plasminogen activators – Plasminogen inhibitors	– Spontaneous bleeding—large volume, cavitary hemorrhage, hemarthrosis, SC bleeding, intramuscular bleeding – Surgical/procedural/traumatic bleeding	– FDPs – D-dimers – Viscoelastic testing

ACT, activated clotting time; aPTT, activated partial thromboplastin time; BMBT, buccal mucosal bleeding time; FDPs, fibrin degradation products; VWF:Ag, von Willebrand factor antigen.

THROMBOCYTOPENIA

Low platelet counts can be recognized by using an automated hematology analyzer and/or by reviewing blood smears. Automated platelet counts should be verified by blood smear, especially in cats, since platelet aggregation may cause falsely low numbers (pseudothrombocytopenia). Thrombocytopenia may also be seen as a normal variant in some breeds of dogs, most notably the Cavalier King Charles Spaniel. In this instance, there are a low number of larger platelets (macrothrombocytes) but without increased risk of bleeding (**Figure 17.5a, b**). It is helpful for the clinician to think about potential causes for true thrombocytopenia in terms of increased peripheral destruction, increased consumption, decreased production, or sequestration.

DESTRUCTION

Definition/Overview

Immune-mediated platelet destruction (immune-mediated thrombocytopenia [ITP]) is commonly seen in dogs but rarely seen in cats.

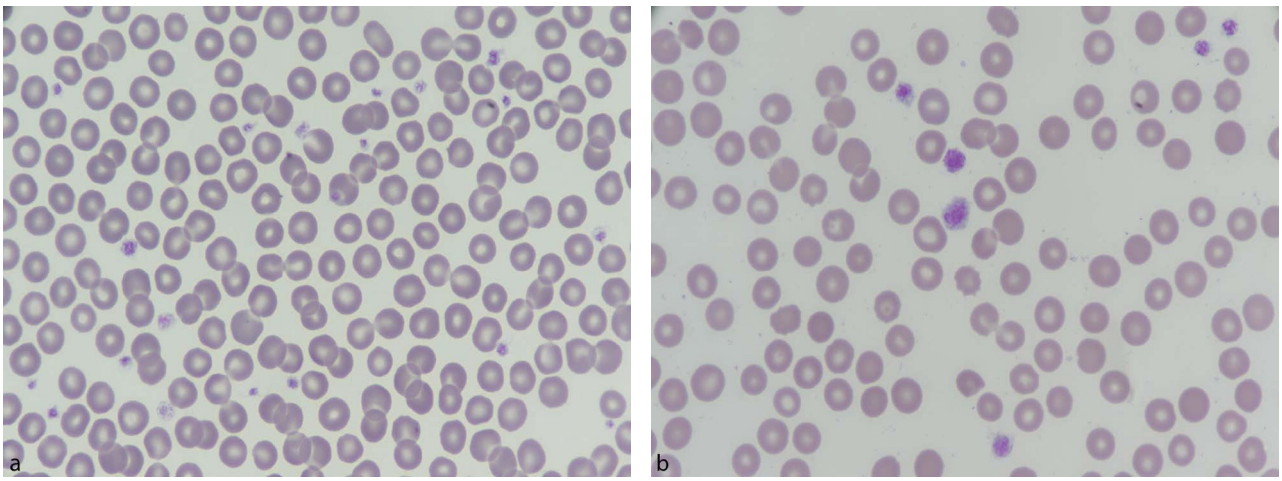

FIGURE 17.5 Comparison of **(a)** normal platelet number and platelet size in a dog with **(b)** macrothrombocytopenia in a Cavalier King Charles Spaniel. Note in the normal dog, platelets are consistently about a third to one-half the size of a red blood cell, while macrothrombocytes are about three-quarters the size of a red blood cell. (*Courtesy of Devorah Marks Stoew, DVM, DACVP.*)

Etiology

Both primary (idiopathic) and secondary forms of ITP occur. Possible triggers for secondary ITP include infections, drug or vaccine administration, neoplasia, and other immune-mediated disorders.

Pathophysiology

Antibodies directed toward glycoproteins on the platelet surface trigger a type 2 hypersensitivity reaction and subsequent platelet destruction. Spontaneous bleeding (petechiation and ecchymoses) occurs when platelets are unable to maintain normal endothelial intercellular junctions.

Clinical Presentation

Animals with ITP usually have evidence of spontaneous bleeding. Small surface bleeding (e.g., skin, conjunctiva) and mucosal bleeding (e.g., epistaxis, hematemesis, melena, gingival hemorrhage) are most common (Figure 17.6a–d), while frank hematuria can also occur. More severe bleeding may occur if trauma, surgery, or provocative procedures (e.g., biopsies) are performed. Some animals have subtle bleeding, but the systemic consequences of anemia may be more obvious (e.g., lethargy, dysrexia). Additional clinical symptoms referable to an underlying primary disease may be appreciated in patients with secondary ITP.

Differential Diagnosis

ITP typically results in severe thrombocytopenia, with alternative rule outs being bone marrow disease (e.g., neoplasia, myelofibrosis), Ehrlichiosis, destruction of platelet precursors (e.g., amegakaryocytic thrombocytopenia), and DIC.

Diagnosis

ITP leads to severe thrombocytopenia (<20,000 platelets/μL), although platelet counts <5,000/μL are most typical. Detection of antiplatelet antibodies, proving immune-mediated destruction, is uncommonly available, and more invasive tests (e.g., bone marrow sampling) to rule out other causes of severe thrombocytopenia are seldom done. Consequently, ITP is usually a diagnosis of exclusion. A diagnostic workup to assess for concurrent disease is recommended, although its extent will be

FIGURE 17.6 Classic signs of primary hemostatic dysfunction in dogs with immune-mediated thrombocytopenia. **(a)** Buccal mucosal petechiation, **(b)** ecchymoses on the trunk, **(c)** gross hematemesis in vomitus, **(d)** dark tarry stool melena in the perianal region.

determined by patient stability and owner finances. At a minimum, complete blood count, serum biochemistry, urinalysis, thoracic and abdominal imaging, and infectious disease testing endemic to your area are reasonable. A careful history to include recent drug exposure, recent vaccination, and any travel is also important.

Management

Therapeutic strategies for ITP are focused on three major aims: (1) Preventing further platelet destruction, (2) increasing platelet number, and (3) addressing the systemic consequences of thrombocytopenia. Preventing further platelet destruction involves immunosuppression and measures to combat any underlying inciting disease (e.g., doxycycline for vector-borne disease). Initial immunosuppression should involve oral prednisone in dogs (prednisolone in cats), but injectable dexamethasone sodium phosphate may be given initially in the hospital. Platelet recovery takes up to 7 days in most dogs with ITP treated with prednisone alone. It is noteworthy that spontaneous bleeding appears uncommon once platelet counts >40,000/μL are achieved. Prednisone plus another immunosuppressive drug may be considered, but there is no compelling evidence that two immunosuppressive drugs achieve faster remission than prednisone alone. Prednisone is typically tapered slowly (e.g., 3–6 months), since rapid discontinuation may lead to clinical relapse. A multitude of side effects may occur when long-term prednisone is used, however (e.g., polyuria, polydipsia, polyphagia, iatrogenic hypercortisolemia). A second immunosuppressive agent may enable faster tapering of prednisone with a lower chance of relapse. Several second-line immunosuppressive drugs could be considered (e.g., azathioprine, cyclosporine, mycophenolate, and leflunomide), and the decision is likely based on clinician preference. During the initial treatment of ITP in dogs, human intravenous immunoglobulin (IVIG) plus prednisone has been associated with faster recovery of platelet count compared to prednisone alone. The antineoplastic drug vincristine may also be considered to accelerate platelet recovery. Vincristine is thought to increase fragmentation of megakaryocytes and may also slow platelet destruction. Platelet recovery time is about 48 hours faster when dogs are managed with IVIG/prednisone or vincristine/prednisone compared to prednisone alone. Some dogs with systemic signs of anemia (e.g., weakness, tachycardia, tachypnea) may benefit from red blood cell transfusions. Hemostatic competence may also improve when red cells are administered, associated with improved platelet margination in blood vessels. Platelet containing blood products are not typically recommended in dogs with ITP, since transfused platelets are also destroyed rapidly. Platelet administration may be needed in the event of life-threatening bleeding (e.g., brain or lung hemorrhages). Gastroprotectants (e.g., antacids, sucralfate) are not likely to help gastrointestinal bleeding in dogs with ITP, since the bleeding is driven by their thrombocytopenia rather than gastric ulceration.

Prognosis

Up to 85% of dogs with ITP respond to treatment, but less information is available in cats since the disease is so rare. Worse outcome has been reported in dogs with ITP that have evidence of melena or high blood urea nitrogen (BUN) at presentation. Relapses may occur, especially if immunosuppressive therapies are discontinued quickly, and overall outcome may be worse if severe comorbidities are present.

CONSUMPTION

Consumptive thrombocytopenia is commonly seen in dogs and cats. Platelet extravasation leads to a low circulating platelet count. This may occur secondary to bleeding (e.g., hemangiosarcoma, trauma, DIC), sepsis (i.e., extravasation of neutrophil–platelet aggregates), thrombosis, endocarditis, pit viper envenomation, and vasculitis (Figure 17.7). Consumptive thrombocytopenia typically results in a platelet count in the region of 50,000–100,000/μL and should be considered less likely if a patient has a platelet count <20,000/μL. Consumptive thrombocytopenia is usually incidentally identified during the workup of different symptoms, since spontaneous bleeding is unlikely to occur. Hemostatic competence is generally preserved in these patients, such that dogs with splenic masses usually do not bleed during surgery even in the face of thrombocytopenia (Figure 17.8). It is wise to exert some caution, however, in thrombocytopenic animals, and specific risk should be considered on a case-by-case basis. In general, treatment of consumptive thrombocytopenia is usually directed at the primary disease process rather than the thrombocytopenia itself.

LACK OF PRODUCTION

Failure to generate new platelets most commonly occurs with bone marrow disease but could be a component of hepatic disease due to thrombopoietin deficiency.

FIGURE 17.7 Dog with sepsis secondary to infected bite wounds with a platelet count of 80,000/μL.

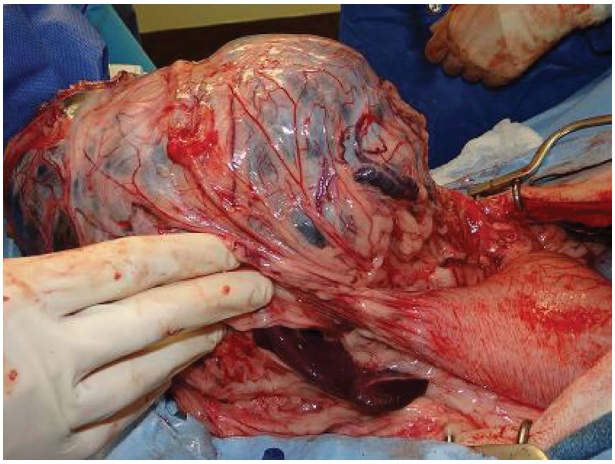

FIGURE 17.8 Splenic mass in a dog that was incidentally found in a dog with a platelet count of 107,000/μL identified on routine wellness blood work.

Severe thrombocytopenia is likely to occur with bone marrow disease and so can easily be confused with ITP. Bone marrow sampling would be necessary to confirm a diagnosis. Bone marrow sampling is uncommonly performed in severely thrombocytopenic dogs unless there is concern for deficiencies in other cell lines. A complete blood count is recommended in all animals with thrombocytopenia, therefore, since identifying bicytopenia or pancytopenia makes bone marrow disease more likely than ITP. Bone marrow sampling may also be recommended in some dogs with severe thrombocytopenia, once they have failed to respond to standard therapy. The nature of the underlying bone marrow disease can be variable (e.g., neoplastic, infectious, toxic, fibrosis).

SEQUESTRATION

Sequestration is the least common form of thrombocytopenia seen in dogs and cats. It occurs when platelets are effectively trapped and cannot circulate appropriately. This most likely occurs in splenic disease, particularly splenic torsion, but could also occur with severe hypothermia.

THROMBOCYTOPATHIA

Definition/Overview

Thrombocytopathia should be considered in patients with signs of primary hemostatic dysfunction that have normal platelet counts. Increased bleeding tendency may be appreciated after excessive bleeding following invasive procedures (e.g., cystocentesis, surgery).

Etiology

Thrombocytopathia may reflect an inherited or acquired problem, as well as an intrinsic or extrinsic dysfunction. Inherited intrinsic platelet disorders are uncommon but have identified in several dog and cat breeds. In contrast, von Willebrand disease (VWD) is a relatively common inherited extrinsic platelet disorder in dogs. Acquired platelet dysfunction may occur after administration of certain drugs and in some disease states. For example, clopidogrel and aspirin are commonly used to intentionally inhibit platelet dysfunction for treatment or prevention of thrombosis. Dose-dependent dysfunction may occur in animals receiving high doses of synthetic colloids. Several disease states may also lead to acquired thrombocytopathia, including, but not limited to, uremia, pit viper envenomation, babesiosis, heat stroke, and trauma-induced coagulopathy.

Pathophysiology

Clotting factors need to assemble on activated platelets in order to support thrombin generation. Intrinsic dysfunction represents an inherent issue with the platelet itself (e.g., failure to activate or aggregate). Inherited intrinsic platelet dysfunctions may represent diverse issues, including platelet receptor deficiency (e.g., Glanzmann thrombasthenia in Great Pyrenees dogs) and abnormal membrane flipping (e.g., Scott syndrome in German Shepherd Dogs). In contrast, extrinsic platelet dysfunction represents a failure of adhesion of otherwise normal platelets and is seen with VWD. Three variants of VWD are recognized (types 1, 2, and 3) based on the type and number of missing VWF multimers. Type 1 is the most common type seen, especially in Dobermanns. Affected patients have reduced numbers of both large and small multimers. Type 2 VWD has been described in German Shorthaired and Wirehaired Pointers and is characterized by fewer large multimers. Type 3 VWD is rarely seen but has been described in dog breeds, including Scottish Terriers and Shetland Sheepdogs. Type 3 affected dogs lack all multimers, and severe bleeding can occur. Most dogs with VWD do not experience spontaneous bleeding, but severe hemorrhage may occur after surgery or trauma.

Clinical Presentation

Depending on the disorder in question, spontaneous bleeding may or may not be noted, and the first hint of dysfunction may be related to abnormal bleeding after trauma, surgery, or other invasive procedures (Figure 17.9). In the latter scenario, severe and large-volume bleeding may be noted, which contrasts the superficial small bleeds typical of thrombocytopenia. It is also possible that the practitioner is faced with an animal known to have an issue or to be at risk of thrombocytopathia (e.g., Dobermann presented for elective surgery without known VWD status).

Differential Diagnosis

Thrombocytopenia; VWD also may resemble disordered secondary hemostatic disorders and hyperfibrinolysis.

FIGURE 17.9 Dog with heatstroke that developed marked epistaxis following placement of a nasogastric tube. The dog had a platelet count of 90,000/µL and normal PT and aPTT, suggesting the presence of thrombocytopathia as a cause for bleeding.

Diagnosis

As mentioned previously, verification of an accurate platelet count is important before performing any tests of platelet function. If an accurate count cannot be obtained due to excessive clumping, the possibility of significant intrinsic platelet dysfunction appears less likely, since aggregation has effectively been observed, but VWD cannot be excluded. It is also common for clinicians to perform tests of secondary hemostasis (PT, aPTT, ACT) and/or viscoelastic tests at this juncture to characterize hemostatic status as much as possible. For most clinicians, the first and most available insight into platelet function is the buccal mucosal bleeding time (BMBT) (Figure 17.10). This test is crude and subject to interoperator variation but provides good insight into primary hemostatic competence and is easily performed. Depending on patient tolerance, at least light sedation is usually necessary. The animal is restrained in lateral recumbency, and the upper lip is pulled upwards in order to expose the buccal mucosa. A proprietary lancet is used to make a uniform incision into the mucosa, avoiding obvious superficial blood vessels, and filter paper is placed close to the incision. The filter paper is used to soak up dripping blood, but care must be taken not to disturb the clot as it forms. Cats are expected to stop bleeding within 2.5 minutes, and most dogs stop between 3 and 4 minutes. Prolonged bleeding times suggest platelet dysfunction provided platelet counts are normal. An alternative strategy providing similar information to the BMBT is measuring the platelet closure time using an automated machine (PFA-100, PFA-200). If an abnormal BMBT or platelet closure time is identified, further tests to characterize the reason for this dysfunction may be pursued (e.g., VWD testing). This requires measurement of VWF antigen at a specialist laboratory on blood collected prior to significant bleeding or transfusion of plasma products. The VWF antigen is expressed as percentage between 0% and 180%, with VWF antigen <50% representing dogs that are abnormal carriers of VWD and at higher risk of bleeding. Animals with VWF antigen >70% are unlikely to be VWD carriers or to be at risk of bleeding. In situations where intrinsic platelet pathology is suspected, other tests (e.g., aggregometry, flow cytometry) may be used but are usually available at specialist centers only. Platelet function may also be assessed in animals receiving antiplatelet drugs for therapeutic monitoring. This may be considered to ensure an antiplatelet effect has been achieved or to assess bleeding risk. The latter may be needed in animals receiving antiplatelet drugs that require an invasive procedure (e.g., dental extractions, feeding tube placement). Monitoring options include modified viscoelastic tests (thromboelastography (TEG) platelet mapping) and platelet aggregometry. Ideally, the patient's platelet function will be compared relative to their own baseline function, with reasonable therapeutic goals of >80%–90% platelet inhibition.

FIGURE 17.10 A proprietary lancet used to perform a buccal mucosal bleeding time.

Management

Specific interventions are dictated by whether bleeding is present. If bleeding is present, then transfusion products may be necessary. The exact type of blood product is situation specific but could include fresh whole blood (containing platelets, red cells, and clotting factors) in animals with acute hemorrhage and anemia, while nonanemic patients may benefit from the transfusion of platelets and/or coagulation proteins without red blood cells. For animals with acquired dysfunction without active bleeding, recommendations may consist entirely of avoiding invasive procedures and treating underlying disease. Pre-emptive administration of blood products may be used in animals with platelet dysfunction without active bleeding undergoing elective procedures. For example, a Dobermann with type 1 VWD undergoing routine ovariohysterectomy would benefit from pre-emptive administration of VWF via cryoprecipitate (1 unit per 10 kg), fresh frozen plasma (10 mL per 10kg), or fresh whole blood (1 unit per 15 kg). Desmopressin, a synthetic analog of vasopressin, is also commonly used

FIGURE 17.11 Nasal formulation of desmopressin that can be administered subcutaneously to augment hemostatic function via release of stored von Willebrand factor in the endothelium.

for dogs with VWD. Desmopressin activates vasopressin receptors on the endothelium, leading to release of stored VWF. In practice, this requires subcutaneous injection of the intranasal desmopressin product typically used for the management of diabetes insipidus. A previously unopened desmopressin product should be used at a dose of 1–4 µg/kg about 30 minutes before the elective procedure (Figure 17.11). Desmopressin could also be used in patients with active bleeding associated with platelet dysfunction, although it can only be given once or twice given the finite VWF stores in the endothelium. Desmopressin can also be administered to dogs prior to donating blood to boost the amount of VWF in the collected unit before administration.

Prognosis

Prognosis is mainly determined by the presence or absence of bleeding, as well as any underlying disease processes present. Bleeding can be severe, especially in the postoperative setting, and blood products are the key to successful management.

CLOTTING FACTOR DEFICIENCY OR DYSFUNCTION

Definition/Overview

Secondary hemostatic disorders are associated with reduced numbers or activity of clotting factors. These conditions may result in overt bleeding but may also be considered in certain situations prior to bleeding (e.g., liver disease).

Etiology

Several inherited clotting factor deficiencies have been described in dogs and cats, although they vary in terms of their prevalence. Hemophilia A (FVIII deficiency) is the most common inherited clotting factor disorder in dogs. Acquired secondary hemostatic deficiencies can occur associated with several underlying diseases, including DIC, vitamin K antagonism (e.g., anticoagulant rodenticide toxicity), severe liver disease, neoplasia, heatstroke, angiostrongylosis, and severe trauma. Iatrogenic coagulopathy may be appreciated secondary to anticoagulant overdosing, excessive synthetic fluid administration leading to dilution, severe acidemia, and severe hypothermia.

Pathophysiology

Although specifics may vary between individual diseases, thrombus formation is prevented if clotting factors or cofactors are absent. Clotting factor deficiency underpins the bleeding noted in animals with inherited disorders, as well as synthetic liver disease. In the case of Coumadin-derived vitamin K antagonist anticoagulant rodenticide toxicity, clotting factor numbers are initially preserved, but activation is impaired. These rodenticides inhibit the enzyme vitamin K epoxide reductase, preventing vitamin K recycling. In its absence, vitamin K dependent clotting factors (FII, FVII, FIX, FX) remain inactive and cannot exert their biological activity.

Clinical Presentation

Animals may present with symptomatic bleeding as outlined in Table 17.1. Historical clues (e.g., patient age) may be helpful in prioritizing certain differentials, for example dogs with hemophilia A (FVIIIa deficiency) may develop overt bleeding when deciduous teeth are lost or after initial vaccinations. Older animals with signs of secondary hemostatic dysfunction would be more likely to have rodenticide toxicity, liver disease, and neoplasia. Some animals may be seen that are currently asymptomatic but with an increased risk of bleeding. This includes that have recently ingested anticoagulant rodenticides, since evidence of bleeding usually occurs 3–5 days later. Dogs with severe hepatopathy also tend not to exhibit spontaneous bleeding even in the face of abnormal hemostatic tests but can bleed considerably after biopsy.

Differential Diagnosis

Hyperfibrinolysis, VWD.

Diagnosis

In symptomatic animals, an initial diagnostic step would be to perform the traditional hemostatic tests PT and aPTT. The PT gives insight into the extrinsic (FVII) and common pathways, while the aPTT provides insight into intrinsic (FXII, FXI, FIX, FVIII) and common pathways. Interpreting PT and aPTT together provides useful insight into the specific issues at play in an individual animal. For example, a patient with an extrinsic pathway defect will have prolonged PT relative to aPTT, while aPTT prolongation in the face of normal or minimally prolonged PT is suggestive of intrinsic

pathway dysfunction. The most common reason for extrinsic pathway abnormalities is vitamin K antagonism, since FVII has the shortest half-life of the vitamin K dependent factors. Anticoagulant rodenticide toxicity is the most common reason for vitamin K antagonism but may also occur in severe hepatic disease and malabsorptive conditions (e.g., severe inflammatory bowel disease). Intrinsic pathway defects, characterized by aPTT prolongation in excess of PT, can be a helpful clue toward hereditary factor deficiencies (e.g., hemophilia A [FVIII], hemophilia B [FIX]). This pattern is also appreciated in cases of consumption, as well as in proinflammatory states (e.g., immune-mediated hemolytic anemia [IMHA]). If inherited factor deficiencies are suspected, individual factor analysis can be performed at specialist laboratories but should be performed prior to administration of plasma products. The clinician should be mindful of the potential pitfalls of PT/aPTT measurement, especially if point-of-care devices are used, since they are more prone to error than specialist laboratory tests (**Figure 17.12a, b**). The activated clotting time (ACT) is a whole blood alternative to aPTT. While the ACT will provide similar information to the aPTT, it can be affected by anemia and thrombocytopenia. It has particular utility in situations where the effects of high concentrations of heparin are being monitored (e.g., dialysis circuits). Viscoelastic indicators of clot strength (e.g., maximum amplitude on TEG) are largely determined by fibrinogen content and, therefore, could be utilized in understanding hemostatic competence of dogs with secondary hemostatic dysfunction but would do little to help identify the reason for bleeding

Management

Therapeutic strategies will be based on (1) clotting factor replacement, (2) cofactor administration, and/or (3) pharmacological hemostatic agents. Clotting factor replacement involves transfusion of plasma containing blood products. Labile clotting factors (FV, FVIII) persist for a shorter period of time than others. Fresh frozen plasma refers to a plasma product collected from a dog, promptly spun and separated, and stored for up to 12 months. Beyond 12 months, the product is termed frozen plasma since the labile factor activities are decreased. If the clinician intends to transfuse FVIII to a dog with hemophilia A, for example, it will be necessary to transfuse either fresh whole blood, fresh frozen plasma, or cryoprecipitate. In contrast, a dog that has vitamin K antagonism secondary to rodenticide toxicity in need of FII, FVII, FIX, and FX could be administered fresh whole blood, fresh frozen plasma, or frozen plasma.

Cofactor administration most commonly consists of providing vitamin K in situations of suspected or confirmed vitamin K antagonism. Injectable vitamin K is usually given subcutaneously in symptomatic patients with bleeding or if there is concern for malabsorptive disease. Intravenous injection of vitamin K has been associated with anaphylaxis, and intramuscular injection could lead to intramuscular bleeding. Once stabilized, oral vitamin K can be administered instead. The dose and duration of therapy will vary depending on the disease state in question. For example, physiological doses of vitamin K (1 mg/kg per day) are usually given to animals with hepatopathy undergoing liver biopsy for 1–2 days prior to surgery and for 1–2 days postoperatively. In contrast, animals that were symptomatic for anticoagulant rodenticide intoxication are given higher doses (5 mg/kg per day) for 30 days given the persistence of toxicant. It is then typical for PT to be rechecked 48 hours after cessation of vitamin K to verify no residual coagulopathy is present. An alternative approach is employed when dealing with animals that have just ingested rodenticide that are not yet symptomatic. Prompt gastrointestinal decontamination (emesis and activated charcoal) should be employed, and then two options exist for management. Given the success of decontamination, vitamin K can be held initially, and a PT is checked 48 hours later. If the PT is normal, then no further treatment is needed, while vitamin K (5 mg/kg per day for 30 days) is instituted as for symptomatic cases if the PT is prolonged.

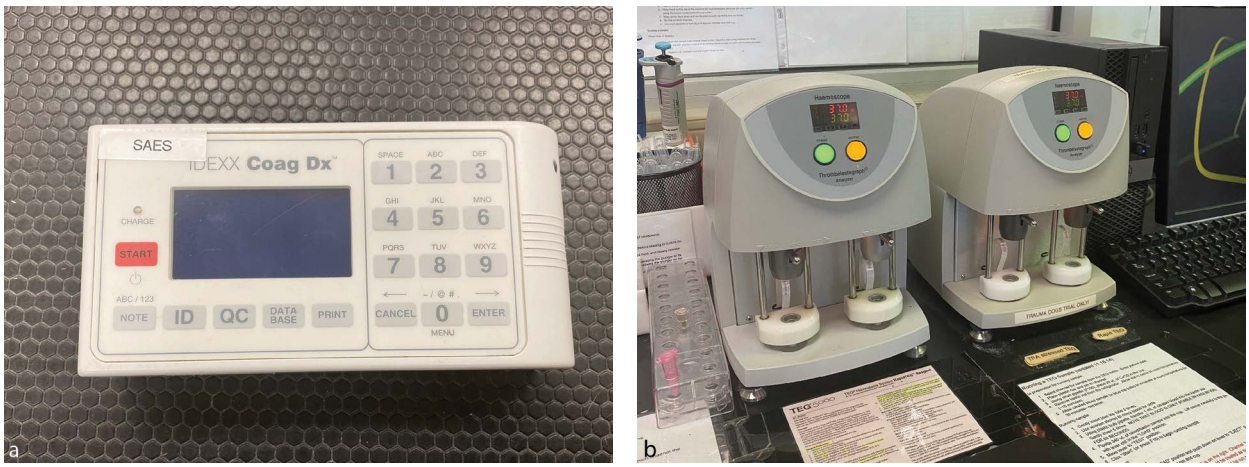

FIGURE 17.12 (a) Point-of-care device for patient-side measurement of prothrombin time and activated partial thromboplastin time and **(b)** thromboelastography machines.

Alternatively, vitamin K could be started after decontamination and given for 30 days, then rechecking PT 48 hours after cessation as for asymptomatic cases.

Finally, protamine is a specific antidote used in cases of iatrogenic bleeding secondary to heparin overdose but can prove difficult to dose effectively. Gene therapies are also emerging as potential therapeutic strategies for certain hereditary coagulopathies. Nonspecific hemostatic drugs (e.g., antifibrinolytics) may be considered for their adjunctive hemostatic effects.

Prognosis

Prognosis will be heavily influenced by the presence or absence of bleeding, as well as the reason for bleeding. Prompt and appropriate therapies for rodenticide toxicity, for example, are associated with excellent clinical outcomes, while hemostatic dysfunction secondary to severe underlying diseases (e.g., liver disease, heatstroke) will be determined by the severity of that issue. Animals with hereditary coagulopathies that receive repeated transfusions in light of bleeding events can survive long term, but this can prove to be both financially and emotionally taxing for owners.

HYPERFIBRINOLYSIS

Definition/Overview

Hyperfibrinolytic disorders describe enhanced plasmin-mediated clot breakdown.

Etiology

Hyperfibrinolysis is thought to occur in some Greyhounds that experience delayed postoperative hemorrhage secondary to decreased alpha-2 antiplasmin. Fibrinolytic disorders have also been identified as a secondary component of some hereditary coagulopathies in people (e.g., hemophilia A), but this has not been reported in dogs. Acquired hyperfibrinolysis has been reported in the setting of acute hemorrhage and shock (e.g., severe trauma, spontaneous hemoperitoneum), as well as acute liver disease and angiostrongylosis.

Pathophysiology

Simplistically, enhanced plasmin-mediated clot removal risks excessive blood loss, which could, in fact, lead to a consumptive coagulopathy through platelet and clotting factor use. The exact mechanisms at play in individual dogs have not been well characterized. Primary (hereditary) disorders represent abnormal regulation of fibrinolysis, while secondary (acquired) disorders describe increased activity of fibrinolysis. Hyperfibrinolysis associated with severe trauma and shock is well characterized in people and is thought to reflect the downstream effects of endothelial dysfunction (e.g., massive tPA release, inhibition of plasminogen activator inhibitor 1).

Clinical Presentation

Hyperfibrinolytic disorders should be considered in patients with acute, severe, large-volume hemorrhage, especially if shock or trauma is concurrently present. It is possible for hyperfibrinolysis to occur in conjunction with signs of other indicators consumptive coagulopathy (e.g., moderate thrombocytopenia, moderate PT, and aPTT prolongation).

Differential Diagnosis

Secondary hemostatic disorders, VWD.

Diagnosis

Until recently, D-dimers provided the best insight into fibrinolytic function in an individual patient. The more widespread availability of viscoelastic testing has provided an increased opportunity to identify hyperfibrinolysis (recognized as increased clot lysis) in dogs. The ability to recognize hyperfibrinolysis may be optimized by adding tPA to the TEG (tPA stressed TEG) (Figure 17.13).

Management

Antifibrinolytic drugs are a specific option for managing hyperfibrinolysis. Lysine analogs, including tranexamic acid and epsilon aminocaproic acid, are used for this purpose. Lysine analogs prevent the binding of plasminogen to lysine residues on the fibrin clot, thereby preventing plasmin-mediated clot removal (Figure 17.14). Management of hypoperfusion, especially if resuscitation is performed with plasma rather than large volumes of synthetic fluids, may play an important role in correcting hyperfibrinolysis in patients with states of shock.

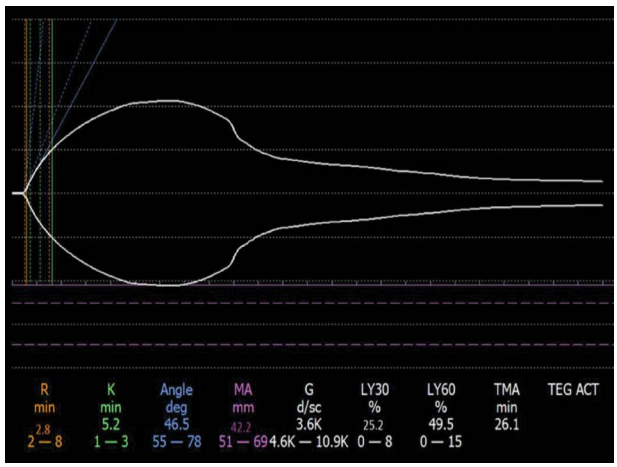

FIGURE 17.13 Thromboelastogram from a dog that sustained severe hemorrhage and hypovolemia following a thoracic stick impalement. The tracing is narrowed, consistent with hypocoagulability, and collapses prematurely, consistent with hyperfibrinolysis.

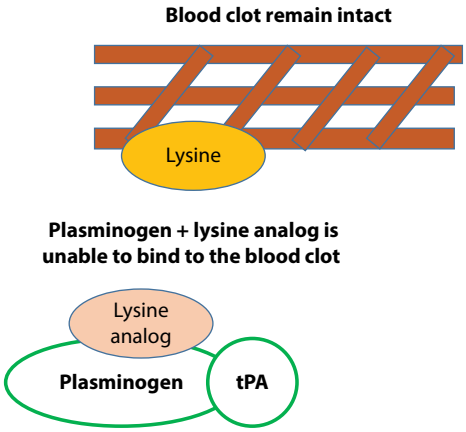

FIGURE 17.14 Lysine analogs prevent plasminogen binding to lysine residues on the surface of the fibrin clot, therefore supporting clot persistence.

Prognosis

Prognosis will be determined by the extent and severity of bleeding, especially in animals that suffered serious traumatic injuries. Bleeding in Greyhounds is unlikely to impact mortality but can be associated with longer hospitalization and more expensive treatments (e.g., blood product administration).

THROMBOTIC DISORDERS

Clinicians may be faced with animals that have (1) overt evidence of thrombosis, (2) a high suspicion of thrombosis not confirmed definitively, or (3) a disease associated with increased risk of thrombosis. Thrombosis can contribute to significant morbidity and mortality in affected animals. Thrombosis is used to describe blood clots that are localized to their blood vessel of origin, whereas thromboembolism describes the movement of a blood clot from its original location to a distant site. Risk factors for thrombosis development are described by Virchow's triad: (1) Hypercoagulability, (2) blood stasis, and (3) endothelial dysfunction. It is likely that several components of the triad must be present in order for thrombosis to occur. Hypercoagulability is the most readily investigated aspect of the triad. Viscoelastic tests provide a clinical correlate to hypercoagulability (e.g., increased maximum amplitude on thromboelastography). Hypercoagulability can occur associated with prothrombotic factor excess (e.g., increased fibrinogen, platelet hyperactivity) or antithrombotic factor deficiency (e.g., antithrombin loss). Blood stasis is harder to assess in individual patients, but ultrasound can be used to assess blood flow. Lastly, endothelial dysfunction is most difficult to assess and, therefore, is hard to assess its importance in individual patients. Patients tend to have either arterial thrombosis or venous thrombosis, suggesting different risk factors likely exist for their development, and will be considered separately in further sections.

ARTERIAL THROMBOSIS

Definition/Overview

Blood clots in the terminal aorta are common in cats (aortic thromboembolism [ATE]) and occasionally seen in dogs (aortic thrombosis). Other arteries may be affected leading to variable symptoms (e.g., cerebellar artery in a dog with acute cerebellar ataxia, main pulmonary artery thrombosis in a dog with pulmonary hypertension).

Etiology

ATE is most commonly seen in cats with cardiomyopathy (Figure 17.15) but may also occur secondary to lung (Figure 17.16a, b) tumors. Aortic thrombosis is less common in dogs but can occur due to a variety of diseases (e.g., protein-losing nephropathy, neoplasia, steroid administration, endocrinopathies, infections). No apparent cause is identified in some dogs with AT, however, despite extensive workup (i.e., cryptogenic disease).

Pathophysiology

Virchow's triad can be applied to understand the mechanisms underpinning arterial thrombosis. All aspects of the triad are potentially abnormal in cats with cardiomyopathy, for example. These cats are known to have prothrombotic factor excess, evidence of blood stasis when there is left atrial enlargement (evidenced by spontaneous echocardiographic contrast [smoke] and reduced atrial flow), and evidence of endothelial dysfunction on necropsy. Hypercoagulability may be recognized in other patients with arterial thrombosis (e.g., hypercoagulability on TEG, antithrombin deficiency), but blood stasis and endothelial dysfunction are harder to assess. Blood clots identified in arteries may represent true thrombosis or thromboembolism. Blood clots forming in the left ventricle (Figure 17.16c), for example, in cats with ATE break off then travel to the distal aorta, leading to significantly compromised blood flow to distal tissues.

FIGURE 17.15 Distal aortic ("saddle") thrombus in a cat with hypertrophic cardiomyopathy. (*Courtesy of M. Schaer.*)

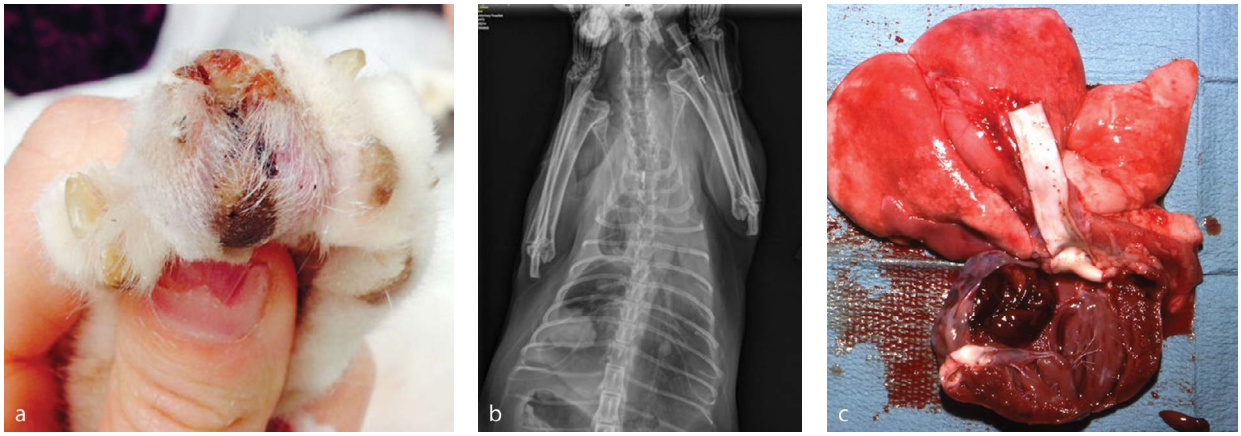

FIGURE 17.16 (a) A cat's paw showing the effects of a lung tumor thromboembolus; **(b)** ventral-dorsal radiograph of the same cat from (a) showing lung tumors with a prominent lesion in the right caudal lung lobe; **(c)** a postmortem view of a cat with cardiomyopathy and a large left atrial mural thrombus.

Clinical Presentation

Cats with ATE often present with an acute onset of bilateral pelvic limb paresis or plegia, with associated pain and distress recognized by marked tachypnea and vocalizing. Some cats may present with thoracic limb involvement and/or one pelvic limb instead. For cats with bilateral pelvic limb involvement, physical examination usually fulfils the five Ps: Paresis/plegia, pain, pallor, pulse absence, and poikilothermia (cold limbs) (Figure 17.17a). ATE may be the first indication of heart disease in some cats since there is often a long preclinical asymptomatic phase. The stress of the acute ATE event may push cats into congestive heart failure, so pulmonary edema and hypoxemia may also be identified. A similar presentation may be noted in dogs with aortic thrombosis, but more chronic and less dramatic presentations are also appreciated. Signs of arterial thrombosis will vary if other tissues are affected. Large blood clots in the pulmonary artery (Figure 17.17b) may lead to an acute onset of respiratory distress and hypoxemia or cardiovascular dysfunction. In the latter scenario, obstruction of blood flow from the right side of the heart will translate into poor left-sided cardiac output and signs of hypoperfusion.

Differential Diagnosis

Varies depending on the clinical presentation, for example, differential diagnoses for paresis include spinal cord injury, neoplasia, and muscle injury.

Diagnosis

Blood clots may be visualized with diagnostic imaging (e.g., ultrasound, computed tomography) but do require specialized equipment. For cats with ATE, a glucose and lactate differential can be considered. A blood sample obtained from an affected limb would be expected to have lower glucose and higher lactate compared to a sample obtained from an unaffected limb or jugular blood sample due to differences in perfusion. In many instances, confirmation of a blood clot with imaging or performing a glucose-lactate differential are not needed, since the presenting clinical signs are so compelling. For cats with signs of ATE, diagnostic workup should

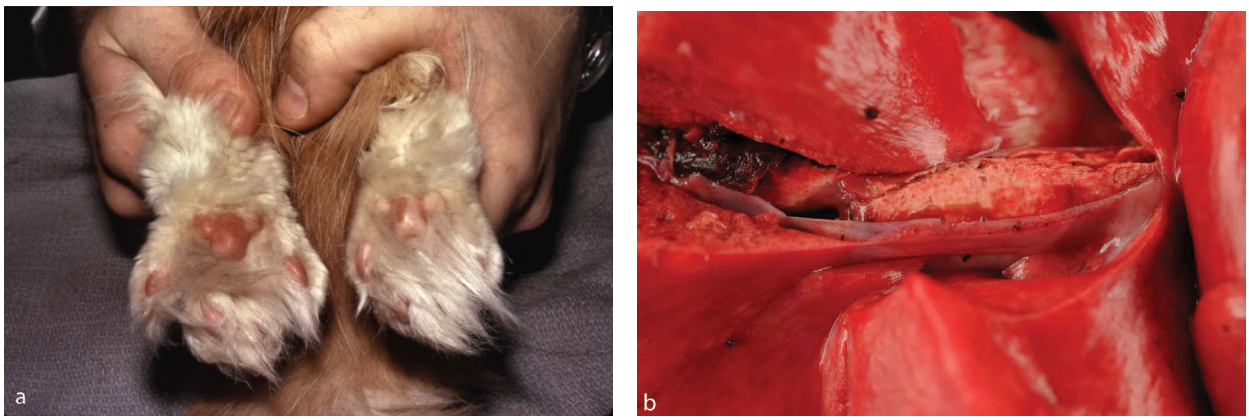

FIGURE 17.17 (a) Paw pads from a cat with aortic thromboembolism. Note the difference in color between the pads, the pad on the right showing acrocyanosis compared with the pad on the left. **(b)** A postmortem view of a Cushing's dog that formed a large thrombus in the pulmonary artery. (*Courtesy of M. Schaer.*)

consist of thoracic radiographs (to check for pulmonary edema and rule out lung masses) and ideally would involve characterization of underlying heart disease (e.g., echocardiography). For dogs with arterial thrombosis, a minimum diagnostic workup to include complete blood count, serum biochemistry, urinalysis, thoracic and abdominal imaging, and blood pressure measurement would be reasonable. Based on initial results, additional diagnostic testing may be considered (e.g., endocrine testing, advanced imaging). It is also noteworthy for the clinician that submits a pet with suspected blood clots for postmortem examination that blood clots may lyse quickly after death and, therefore, not be seen.

Management

Clinical management may encompass specific antithrombotic medications, as well as supportive measurements (e.g., analgesia, care of the recumbent animal) and treatment of underlying disease (e.g., heart failure management). Antithrombotic drugs refer to any drug that prevents blood clot formation. Antiplatelet drugs interfere with platelet function specifically, while anticoagulants interfere with clotting factors. The two situations when these drugs are used are preventing existing blood clots from getting bigger (i.e., treatment) or preventing new blood clots from forming (i.e., prevention or thromboprophylaxis). Histologically, arterial clots are platelet rich, and, therefore, antiplatelet drugs are often considered as the go-to option. The drug options most commonly used are aspirin and clopidogrel. Aspirin is a nonselective COX inhibitor that prevents the synthesis of thromboxane within the platelet. Thromboxane is, therefore, unable to bind to its specific platelet agonist receptor (TXA_2 receptor) and leads to irreversible platelet inhibition. Clopidogrel, in contrast, competes with ADP and prevents it binding to the specific ADP agonist receptor (P2Y12). Clopidogrel is considered to be superior to aspirin and is used more often in dogs and cats. Anticoagulant drugs (e.g., heparin, rivaroxaban) (Table 17.2) are still used with some frequency in animals with arterial thrombosis, since thrombin generation involves the assembly of clotting factors on the surface of activated platelets. For cats with cardiomyopathy, clopidogrel is often started if left atrial enlargement is noted prior to the onset of overt thrombosis, while dual therapy with clopidogrel and anticoagulants tend to be used after an acute crisis (Figure 17.18). If the patient stabilizes, anticoagulants are generally stopped after a few weeks, with clopidogrel maintained for the life of the patient. Thrombolytic drugs (e.g., tPA) may be considered in cases of acute thrombosis, since they accelerate

TABLE 17.2 Summary of anticoagulants

Drug category	Specific examples	Mechanism of action	Route of admin	Notes
Vitamin K_1 antagonist	Warfarin	– Inhibits the enzyme vitamin K epoxide reductase – Prevents vitamin K recycling needed for the activation of the clotting factors IIa, VIIa, IXa, and Xa – Also prevents activation of the anticoagulants protein C and protein S	p.o.	– Rarely used now – Cheap – Requires frequent therapeutic monitoring – Monitoring test = PT – Takes ≅ 3 days to take effect – Must give heparin during the first 3 days to prevent risk of thrombosis due to inhibition of protein C and protein S

Heparins	Unfractionated heparin	– Composed of a mixture of heparin chain lengths
		– Indirect anticoagulant
		  – Increases the activity of the endogenous anticoagulant antithrombin
		  – Antithrombin inhibits the effects of factors IIa and factors Xa
			IV
			SC
				– Cheap
				– Given by intermittent injection or as constant rate infusion
				– Frequent therapeutic monitoring is recommended
				– Monitoring tests: Anti-Xa activity, aPTT, activated clotting time (ACT), rapid-TEG
				– Avoid in patients with antithrombin deficiency

Low-molecular-weight heparins	Dalteparin (Fragmin®) Enoxaparin (Lovenox®)	– Standardized product containing short-chain lengths – Indirect anticoagulant – Different interaction with antithrombin compared to unfractionated heparin, meaning anticoagulant activity arises predominantly from inhibition of factor Xa	SC	– Expensive – Given by intermittent injection – Therapeutic monitoring is uncommonly available – Monitoring test–Anti-Xa activity – Avoid in patients with antithrombin deficiency
Direct oral anticoagulants	Rivaroxaban	– Direct inhibition of factor Xa – Does not rely on antithrombin to achieve effect	p.o.	– Expensive – Therapeutic monitoring is uncommonly available – Monitoring test–Anti-Xa activity, maybe PT

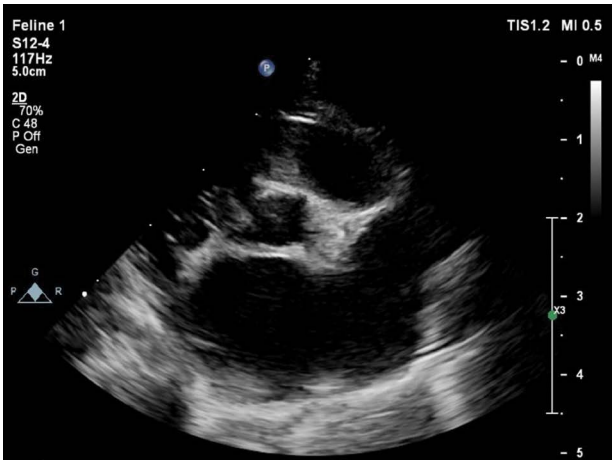

FIGURE 17.18 Right parasternal short-axis echocardiographic view of a cat with asymptomatic hypertrophic cardiomyopathy showing signs of left atrial enlargement for which prophylactic clopidogrel would be recommended.

plasmin-mediated clot breakdown and could be used alongside antithrombotic drugs. The use of thrombolytic drugs in the management of ATE in cats is controversial, however, since serious adverse effects have been encountered (bleeding, reperfusion injury), and outcome is not clearly improved with their usage.

Prognosis

Prognosis for cats with ATE is guarded, since about two-thirds of cats affected will not survive the acute crisis, and survivors have a high risk of recurrent episodes. Another challenge of acute arterial thrombosis is reperfusion injury, where severe metabolic derangements (e.g., electrolyte and acid–base abnormalities, acute azotemia) may occur when perfusion is restored. The prognosis for dogs with aortic thrombosis is largely governed by their ambulatory status at presentation, with nonambulatory dogs being more likely to die or be euthanized. The prognosis for other anatomical sites is variable (e.g., central nervous system signs are often short lived and nonprogressive).

VENOUS THROMBOSIS

Definition/Overview

Blood clots that form in veins are commonly seen in dogs and to a lesser extent in cats.

Etiology

Venous clots are associated with several diseases in dogs, leading to disturbances in Virchow's triad and pathological thrombosis. Associated diseases vary in importance depending on the location of the clot and include, but are not limited to, immune-mediated hemolytic anemia and heartworm disease (pulmonary thromboembolism), hepatobiliary disease and splenectomy (portal vein thrombosis), and central venous catheters (femoral vein, jugular vein). Venous clots are seen less often in cats.

Pathophysiology

Virchow's triad can again be applied to understand the mechanisms underpinning venous thrombosis. Hypercoagulability is most easily identified. Prothrombotic factor excess (e.g., hyperfibrinogenemia) may be observed in animals with systemic inflammatory diseases (e.g., IMHA, sepsis, acute necrotizing pancreatitis). Other mechanisms that may be implicated include abnormal tissue factor expression on cells (e.g., neoplastic cells) triggering the initiation phase of the cell-based model of hemostasis. In IMHA, hemolysis leads to the circulation of free hemoglobin that scavenges nitric oxide. Nitric oxide is a platelet inhibitor released by the endothelium; therefore, dogs with IMHA may also have uninhibited platelet activation. Immobility and recumbency is an important risk factor for venous thrombosis in people (e.g., long-haul flights, immobility after surgery) but is less well described in animals. Endothelial dysfunction may contribute to thrombosis also (e.g., central venous catheters) but are harder to investigate.

Clinical Presentation

The clinical consequences of venous thrombosis will depend on the tissues affected, the amount of vessel occlusion, and the chronicity of the problem. Acute thrombosis can lead to a rapid onset of severe, potentially devastating symptoms. For example, recent splenectomy has been associated with acute portal vein thrombosis that leads to a devastating syndrome of acute-onset hypovolemia secondary to massive gastrointestinal fluid losses and hemorrhage, widespread intestinal ischemia, gastrointestinal edema, and acute abdominal effusion (Figure 17.19). Other situations may risk morbidity but less likely to be associated with mortality (e.g., catheter-associated thrombosis).

FIGURE 17.19 Postmortem image of a dog with massive mesenteric ischemia secondary to an acute portal vein thrombus following splenectomy.

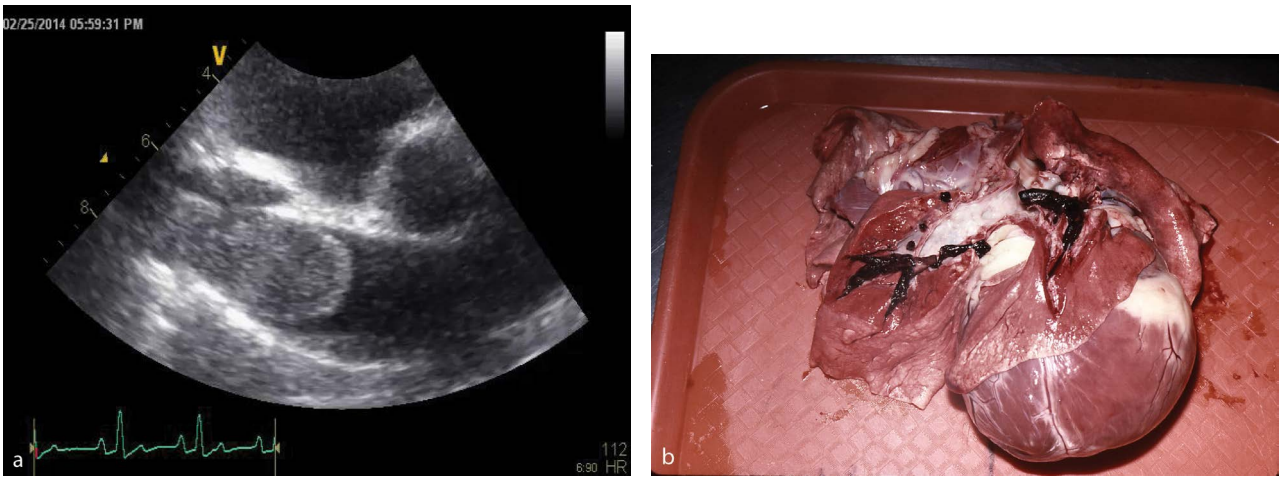

FIGURE 17.20 **(a)** Echocardiographic image of a dog with glomerulonephritis that developed acute tachypnea. A large thrombus is seen in the main pulmonary artery. **(b)** Postmortem lung dissection from a dog with immune-mediated hemolytic anemia that formed many pulmonary thrombi. (b, *Courtesy of M. Schaer.*)

Diagnosis

Similar to arterial clots, diagnostic imaging may allow visualization of venous thrombosis (e.g., ultrasound, computed tomography) (Figure 17.20a). Whether imaging is successful in identifying clots may be influenced by the skill of the operator. Patient stability may prevent imaging from being done, and a presumptive diagnosis may be made instead (e.g., acute onset of tachypnea and hypoxemia in a dog with IMHA suggestive of pulmonary thromboembolism; Figure 17.20b). Venous clots may also be recognized incidentally and may reflect the presence of disease rather than driving the process. As for arterial clots, a systemic diagnostic workup to include complete blood count, serum biochemistry, urinalysis, and thoracic and abdominal imaging would be reasonable. Venous clots may also be lysed prior to visualization in animals undergoing postmortem examination as for arterial thrombosis (Figure 17.21).

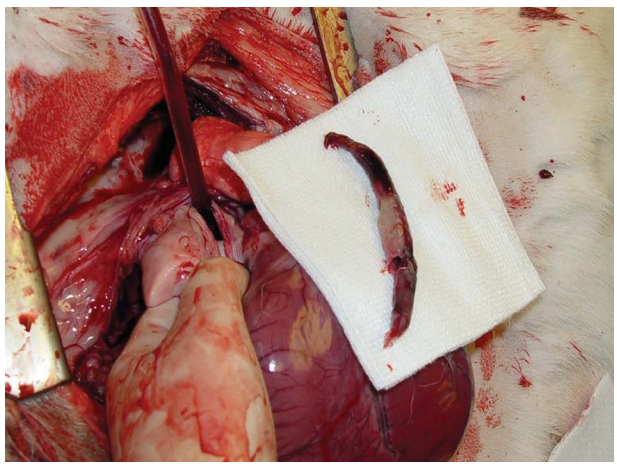

FIGURE 17.21 Large pulmonary artery clot identified during a postmortem examination.

Differential Diagnosis

Differential diagnosis will depend on clinical presentation, for example, acute onset of tachypnea and hypoxemia in a dog with IMHA could be secondary to pulmonary thromboembolism, but alternative differential diagnoses would include aspiration pneumonia, acute respiratory distress syndrome, volume overload, or heart failure.

Management

Clinical management will again encompass specific antithrombotic medications, as well as supportive measurements (e.g., supplemental oxygen) and situation-specific recommendations (e.g., removal of central venous catheter). Antithrombotic drugs will again be considered for the treatment or prevention of thrombosis. Histologically, venous clots are fibrin rich, and anticoagulant drugs interfering with fibrin formation are usually preferred. Several anticoagulant options are available (Table 17.2). Heparin drugs are commonly used, but there is growing interest in rivaroxaban. Several factors should be considered when choosing an anticoagulant drug. These include the cost of the drug, the frequency of dosing, the route of administration, and the requirement for therapeutic monitoring. For example, unfractionated heparin is a cheap drug given by injection multiple times per day, which benefits from therapeutic monitoring. In contrast, rivaroxaban is an expensive drug given orally once per day for which therapeutic monitoring may not be needed. As for arterial thrombosis, dual therapy (antithrombotic and antiplatelet drug) is often considered based on the cell-based model of hemostasis. The duration of therapy is often disease specific. For example, anticoagulants are likely used for a short period only in dogs with central venous catheter-related thrombosis yet may be considered for longer in dogs with IMHA. Thrombolytic drugs are used quite uncommonly for venous thrombosis and

are not suited for incidentally identified or chronic thrombosis.

Prognosis

Prognosis is variable, since a better prognosis is associated with incidentally identified thrombosis, while acute thrombosis can be devastating. Antithrombotic drugs have been associated with an improved outcome in certain disease states (e.g., IMHA). Consequently, thromboprophylaxis is recommended for animals with diseases associated with thrombosis.

COMPLEX HEMOSTATIC DISORDERS

Some animals acquire hemostatic dysfunction that has features of both hypercoagulability and hypocoagulability. These complex disorders are challenging both from a diagnostic and therapeutic perspective and are associated with a guarded or grave prognosis.

DISSEMINATED INTRAVASCULAR COAGULATION

Definition/Overview

Disseminated intravascular coagulation (DIC) is characterized by widespread thrombosis within blood vessels, which may lead to overt hemorrhage.

Etiology

DIC occurs secondary to an underlying disease process. Several disease states have been implicated in DIC, including systemic inflammation, sepsis, pancreatitis, neoplasia, heatstroke, and envenomation.

Pathophysiology

The precipitating trigger incites systemic activation of coagulation, resulting in massive thrombin generation and widespread clot formation. Extensive thrombosis has two major detrimental effects. First, microthrombosis may lead to tissue hypoperfusion and resultant tissue dysfunction. Second, massive thrombosis leads to clotting factor consumption and fibrinolysis activation, leading to a bleeding tendency.

Clinical Presentation

Obvious signs of bleeding develop later in the syndrome. In the nonovert, prothrombotic phase, signs of organ failure may be noted. This could include hypoxemia, arrhythmia, acute azotemia, icterus, and neurological deficits. One first helpful clue in hospitalized animals would be the appreciation of petechiation or ecchymoses and excessive bruising around venipuncture and IV catheter insertion sites (Figure 17.22).

FIGURE 17.22 Hospitalized dog with multicentric lymphoma and aspiration pneumonia that developed extensive ecchymoses on the trunk. Multiple hemostatic disorders were noted suggestive of disseminated intravascular coagulopathy.

Differential Diagnosis

Multiple organ dysfunction syndrome, hepatic failure.

Diagnosis

Clinical confirmation of DIC may be challenging, since clinical signs and laboratory changes identified in individual patients can vary. Early in the disease course, hypercoagulability and DIC will be asymptomatic (nonovert) and may be missed by conventional laboratory diagnostic tests. At this point, potential laboratory abnormalities would include increased maximum amplitude on TEG, moderate thrombocytopenia, possibly shortened PT and aPTT, increased D-dimers, and increased thrombin–antithrombin complexes. As consumption continues, a bleeding tendency may develop (overt DIC). The bleeding characteristics may have features of both primary and secondary hemostatic dysfunction. No absolute definition for DIC in dogs and cats exists. Generally, several abnormal diagnostic results in animals with compatible clinical signs is necessary. Potential hemostatic abnormalities in overt DIC include thrombocytopenia, prolongation of PT and aPTT, hypofibrinogenemia, elevated D-dimers, and reduced antithrombin activity.

Management

Management is very challenging, since in theory antithrombotic medications would be indicated in the early stages of DIC, while anticoagulant replenishment through provision of plasma transfusions would be helpful during overt DIC. Since most animals with DIC are recognized once bleeding is evident, it is most likely that blood products will form the mainstay of therapy. Antifibrinolytic drugs (e.g., aminocaproic acid, tranexamic acid) are contraindicated in DIC, since blood clot persistence could lead to worsening consumption of clotting factors and platelets.

Prognosis

Prognosis is often considered guarded to grave, but a greater chance of success would be expected if the underlying disease process triggering DIC is managed effectively, along with intensive care supportive care.

HEPATOBILIARY DISEASE

Definition/Overview

Intrinsic liver disease, biliary tract disease, and portovascular diseases have been associated with variable hemostatic profiles.

Etiology

Severe intrinsic liver diseases can be either acute or chronic in nature. A variety of diseases could be encountered, including inflammatory, infectious, toxic, and neoplastic insults. Biliary tract disorders encompass inflammatory, infectious, neoplastic, and obstructive pathologies. Portovascular conditions include congenital and acquired portosystemic shunts.

Pathophysiology

The liver has influence on primary hemostatic function via thrombopoietin production by hepatocytes. The liver is the major site of procoagulant and anticoagulant protein synthesis; therefore, advanced synthetic liver failure can lead to disruption of several important proteins. The cross talk between inflammation and coagulation may also impart the overall hemostatic status of an individual patient.

Clinical Presentation

Spontaneous hemorrhage is rarely seen in animals with liver disease, although tolerance for invasive procedures (e.g., biopsy) may be lower, and bleeding could result (Figure 17.23a, b). Thrombosis may occur in advanced liver disease, which may lead to additional symptoms depending on the location of the thrombus (e.g., portal vein thrombus leading to ascites). Dogs with congenital portosystemic shunts that had evidence of hepatic encephalopathy are more likely to be hypercoagulable.

Differential Diagnosis

DIC.

Diagnosis

Since variable hemostatic profiles can be encountered, it is reasonable to obtain a platelet count and PT/aPTT at the bare minimum. More comprehensive characterization of hemostasis, for example by measuring fibrinogen, D-dimers, and viscoelastic testing, may provide greater insight into the status of an individual patient. Hyperfibrinolysis may be appreciated in some patients with acute hepatopathy.

Management

The therapeutic approach will vary between patients. Patients with hypocoagulability are treated in the event of bleeding occurring. That said, pretreatment with vitamin K_1 and/or clotting factor administration may be provided to animals undergoing invasive procedures. For animals with thrombosis, anticoagulation is recommended, although the exact duration of therapy can vary and should be determined by clinical progress (e.g., resolution of ascites, ultrasound evidence of clot resolution).

Prognosis

Prognosis will depend on the extent of the primary disease and if complications occur associated with invasive procedures.

PART 1: A PRACTICAL APPROACH TO THE DERMATOLOGICAL WORKUP

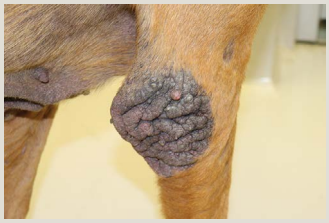
INTRODUCTION

Different dermatological diseases can have similar clinical features, which makes obtaining a definitive diagnosis challenging. This chapter will focus on the practical approach to any dermatological disorder as well as review some of the more common dermatological diseases. Use of a systematic approach to every dermatology case will aid in obtaining an accurate and timely diagnosis.

HISTORY

Obtaining a thorough and detailed medical history will be imperative when considering possible differential diagnoses contributing to the dermatosis. Many skin conditions are multifactorial with a complicated pathogenesis, so determining the overall health status of the animal is important as well.

When obtaining a history, important information includes signalment, age of onset, environmental and



DOI: 10.1201/9781003254591-37

lifestyle exposure, exposure to other animals, onset and distribution of clinical lesions, severity and distribution of pruritus, response to previous therapies, skin lesions present on other pets/people in the household, seasonal trends in disease occurrence, dietary history, and current medications and supplements. General demeanor, activity level, appetite, thirst level, urinary/defecation habits, body weight fluctuations, and changes in neurological status may all be necessary to understand the severity of disease and consider nonallergic causes such as endocrinopathies.

PHYSICAL EXAMINATION

The skin is an external and easily accessible organ for examination; however, the value of a complete physical exam cannot be overlooked. The particular types of skin pathology are illustrated and described in Table 18.1. Some dermatoses are a manifestation of systemic diseases, and evaluation of every body system will aid in making the correct diagnosis (Table 18.2). This includes thorough evaluation of the eyes and oral cavity, thoracic auscultation, abdominal palpation, lymph

TABLE 18.1 Common secondary skin lesions

Alopecia		Partial or complete loss of hair
Callus		Thickening and hardening of the skin with alopecia and hyperpigmentation, commonly located over a bone prominence such as an elbow or tarsus
Comedone		Dilated hair follicles filled with keratinous and sebaceous material creating small white and black raised lesions on the dorsum
Crust		Dried accumulations of scale, cells, blood, wound exudate, and medications on the skin surface
Epidermal collarette		Annual rim of scale representing the remnants of a pustule, vesicle, or bulla

(*Continued*)

TABLE 18.1 Common secondary skin lesions (*Continued*)

Erosion		Partial epidermal loss or defect that does not cross the basement membrane
Fissure		Cracking or linear cleavage of the epidermis that may cross into the dermis
Follicle casts		Excessive scale (keratin) and hair fragments accumulating around hair shafts
Hemorrhagic vesicle		Small, circumscribed, elevated lesion filled with fluid (blood) measuring <1 cm in size
Lichenification		Thickening and hardening of skin as a response to chronic dermatitis
Macule		Circumscribed, flat skin color change measuring <1 cm in size

(*Continued*)

TABLE 18.1 Common secondary skin lesions (*Continued*)

Necrosis		Ischemia or toxin-induced skin death
Nodule		Circumscribed, raised, firm elevation measuring >1 cm in size
Papule		Small, firm mass <1 cm in size
Patch		Circumscribed, flat skin color change measuring >1 cm in size
Pigment abnormalities		Changes in pigmentation (increased or decreased) of skin or hair in response to inflammation
Plaque		Large, flat-topped, raised lesion >1 cm in size (representing coalescing papules)

(*Continued*)

TABLE 18.1 Common secondary skin lesions (*Continued*)

Pustule		Small, circumscribed, elevated lesion filled with purulent exudate
Scale		Accumulation of loose stratum corneum appearing as fine, white material
Scar		Alopecic, depigmented fibrous tissue
Ulcer		Complete defect in the epidermis that crosses the basement membrane
Wheals		Rapidly developing and resolving circumscribed, elevated, edematous lesion

node palpation, rectal evaluation, complete neurological evaluation, and assessment of vital signs.

There are several goals to keep in mind when examining the skin, ears, claws, mucocutaneous regions, and appendages. The distribution of dermatological lesions provides information about the cause of the lesions. Typically, immune-mediated diseases cause a symmetrical pattern of lesion distribution, whereas infectious and neoplastic diseases cause asymmetrical patterns. Additionally, some immune-mediated conditions have consistent distribution patterns. For example, flea allergy dermatitis typically presents on the caudodorsal lumbar region, and discoid lupus erythematosus typically presents on the rostral muzzle and nose. Knowledge and recognition of distribution patterns can quickly narrow the differential diagnosis list.

When evaluating the skin, take note of the types of dermatological lesions present, as this can indicate the type of disease. Lesion are classified as primary and secondary. Primary lesions are present at the onset of disease and develop as a direct (de novo) cause of the pathogenesis, making them the most characteristic of the disease process. These include macules, papules, pustules, vesicles, bullae, wheals, and nodules. Contrarily, secondary lesions develop as the disease progresses over time and result from the primary lesions or from self-trauma. These include erosions, ulcers, fistulae, crusts, scale, lichenification, and alopecia (Table 18.2).

TABLE 18.2 Common skin conditions: Disease, etiology, clinical signs, diagnosis, and treatment

Common neoplastic and nonneoplastic skin tumors

Tumor	Characteristic lesion	Location	Diagnosis	Treatment
Apocrine gland tumors of the anal sac	Nodule, fistula, or ulceration	Perianal area	Histopathology, cytology	C, Ch, L, R, Sx
Basal cell tumor / carcinoma	Nodule, ulcer, cyst	Head, pinnae, neck, extremities for basal cell tumor, any for carcinoma	Histopathology, cytology	C, Ch, L, R, Sx
Collagenous nevus	Nodule, plaque, polyp	Extremities, head, neck, trunk, ventrum	Histopathology	None, C, L, Sx
Cutaneous T-cell lymphoma	Depigmentation, erosion, ulceration, papule, nodule, plaque, gingivitis, crusts	Nose, oral cavity, periocular, footpads, trunk	Histopathology	CCS, CHOP, Is, Lo, Le, R, Sx
Dermatofibromas, multiple	Nodule, mass	Any	Histopathology, abdominal ultrasound to assess kidney tumor	None
Fibropruritic nodule	Nodule	Rump	Histopathology	Flea eradication, CCS
Epidermal hamartoma	Hyperpigmented papule, nodule, plaque with linear orientation	Any	Histopathology	C, Is, L, Sx
Cutaneous hemangioma	Erythematous to black macules or papules	Ventral abdomen, trunk, extremities	Histopathology	C, L, Sx
Hair follicle tumors	Nodule, mass, cyst	Head, trunk, any	Histopathology	C, L, Is, Sx Ch for malignant forms
Histiocytoma	Nodule	Face, paw, trunk	Histopathology, cytology	None, C, L, Sx
Bowenoid in situ carcinoma (Bowen disease)	Pigmented plaque, scale	Trunk	Histopathology	C, Im, L, PDT, R, Sx
Keratoacanthoma	Nodule, cyst, cutaneous horn	Dorsum, tail, extremities, any	Histopathology	C, Is, L, Sx
Mast cell tumor	Nodule, papule, edema	Any, especially limbs, abdomen, chest	Histopathology, cytology	C, CCS, Ch, H1, H2, R, Sx
Melanoma	Hyperpigmented to nonpigmented nodule, mass, macule	Digit, claw bed, extremities, head, abdomen, scrotum	Histopathology, cytology	C, L, Sx R, Ch, and vaccine with malignant melanoma
Papilloma	Papule, nodule, wart-like	Face, lip margins, oral mucosa, paws, footpads, extremities, ventral abdomen	Histopathology, cytology	None, A, C, In, L, Sx
Plasmacytoma	Nodule	Head, pinnae, perioral, extremities	Histopathology, cytology	C, L, Sx R and Ch for multiple tumors
Perianal gland adenoma	Nodule	Perianal region	Histopathology, cytology	C, L, R, Sx, neuter
Sebaceous adenoma	Nodule (wart-like)	Trunk, head, extremities	Histopathology	None, C, L, Sx, vit A

(*Continued*)

TABLE 18.2 Common skin conditions: Disease, etiology, clinical signs, diagnosis, and treatment (*Continued*)

Common neoplastic and nonneoplastic skin tumors

Tumor	Characteristic lesion	Location	Diagnosis	Treatment
Squamous cell carcinoma	Erosion, ulceration, erythema, nodule, plaque	Pinnae, external ear canal, periocular, nose, trunk, claw bed, ventral abdomen	Histopathology	C, Ch, Im, L, R, Sx

A, azithromycin; C, cryosurgery; CCS, corticosteroids; Ch, chemotherapy; CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; H1, H1 blocker; H2, H2 blocker; Im, imiquimod; In, interferon; Is, isotretinoin; L, CO2 laser ablation; Le, leflunomide; Lo, lomustine; PDT, photodynamic therapy; R, radiation; Sx, surgical excision; vit A, vitamin A.

Common keratinization disorders

Disease	Etiology	Dermatologic signs	Diagnosis	Treatment
Canine ear margin dermatosis	Unknown, Dachshunds overrepresented	Scaling, crusting, follicular casts, alopecia, and lichenification of ear margins Fissures in chronic cases	Clinical appearance, histopathology	Antiseborrheic topical agents: Sulfur, salicylic acid, benzoyl peroxide, petroleum Moisturizers
Nasodigital hyperkeratosis	*Unknown:* Idiopathic, senile change, hereditary (e.g., Labrador Retriever), anatomical (e.g., Boxer, Bulldog), or secondary to other disease	Irregular, fine, papillated keratinous fronds on dorsal nasal planum and paw pads	Clinical appearance, histopathology, rule out other diseases	Filing/trimming excessive growth Topical moisturizers Topical antiseborrheic agents
Feline acne	Idiopathic, secondary to allergic dermatitis	Alopecia, erythema, papules, nodules, comedones, crusts of ventral rostral mandible	Clinical appearance, histopathology	Topical antiseptics, antibiotics, and/or antiseborrheics Systemic antibiotics Systemic steroids
Zinc-responsive dermatosis	*Syndrome I:* Defective intestinal absorption of zinc (e.g., Siberian Husky, Alaskan Malamute) *Syndrome II:* Rapidly growing animals fed zinc-deficient diet	Crusting and alopecia of pinnae, pressure points, periocular and perioral areas, muzzle, and ventral mandible	Clinical appearance, histopathology confirmatory	*Syndrome I:* Zinc supplementation *Syndrome II:* Zinc supplementation and dietary modification

Common metabolic disorders

Disease	Etiology	Dermatologic signs	Diagnosis	Treatment
Necrolytic migratory erythema / superficial necrolytic dermatitis / metabolic epidermal necrosis / hepatocutaneous syndrome	Liver failure or hepatopathy, pancreatic neoplasia, diabetes	Erythema, alopecia, crusts, erosions, ulcerations of rostral muzzle, perioral and perianal areas, axillae and inguinal areas, pinnae, elbows, and hocks Severe crusting of paw pads	Histopathology, abdominal ultrasound, serum chemistry	Grave prognosis (supportive care) IV amino acid supplementation Dietary amino acid, zinc, and essential fatty acid supplementation Antibiotics Topical antiseptics

(*Continued*)

TABLE 18.2 Common skin conditions: Disease, etiology, clinical signs, diagnosis, and treatment (*Continued*)

Common metabolic disorders				
Disease	**Etiology**	**Dermatologic signs**	**Diagnosis**	**Treatment**
Canine hypothyroidism	Lymphocytic thyroiditis (most commonly)	Myxedema (tragic face), symmetrical truncal alopecia, alopecia dorsal muzzle and tail, seborrhea, hyperpigmentation, secondary bacterial and yeast infection	Canine thyroid panel TSH (normal to high), total T4 (low), and fT4 (low) Hypercholesterolemia, mild nonregenerative anemia	Levothyroxine supplementation
Feline hyperthyroidism	Functional thyroid hyperplasia Thyroid adenoma	Palpable thyroid slip, excessive shedding, truncal alopecia, unkept/matted haircoat, seborrhea sicca, skin atrophy, increased nail growth	Total T4 (normal to high), fT4 (high) Ultrasound, radioactive thyroid scintigraphy	Iodine-restricted diet, methimazole, carbimazole, surgical removal, radioactive iodine therapy
Canine hyperadrenocorticism	Pituitary adenoma (80%) Adrenal neoplasia (15%–20%) Iatrogenic	Truncal alopecia, skin atrophy, seborrhea sicca, secondary infections, comedones, calcinosis cutis, hyperpigmentation, bruising	Physical exam, stress leukogram, elevated alkaline phosphatase, urine cortisol-to-creatinine ratio, ultrasound, ACTH stimulation test, resting ACTH, low-dose dexamethasone suppression test	Trilostane, mitotane, surgery Ketoconazole, selegiline, cabergoline
Feline hyperadrenocorticism	Pituitary adenoma (80%) Adrenal neoplasia (15%–20%) Iatrogenic	Truncal alopecia, skin atrophy, seborrhea sicca, secondary infections, comedones, calcinosis cutis, hyperpigmentation, skin fragility, bruising	Physical exam, stress leukogram, hyperglycemia, urine cortisol-to-creatinine ratio, ultrasound, ACTH stimulation test, resting ACTH, low-dose dexamethasone suppression test	Trilostane, surgery Metyrapone, radiation therapy
Alopecia X	Unknown Many proposed mechanisms, including sex hormone imbalance Chow Chow, Pomeranian, Poodle, and Keeshond overrepresented	Bilaterally symmetrical alopecia sparing head and legs Hyperpigmentation	Rule out other causes of alopecia Histopathology	None Microneedling, trilostane
Hyperestrogenism	Exogenous exposure from owners or other supplementation Intact female: Ovarian cyst Intact male: Sertoli cell tumor	Non inflammatory alopecia spreading from perineal area diffusely, gynecomastia, estrus behavior, pendulous prepuce, linear preputial erythema, comedones	Elevated estrogen levels, ultrasound, history	Remove exogenous exposure Ovariohysterectomy Castration
Xanthoma	Abnormal lipid metabolism (hyperlipoproteinemia) High-fat diets Megestrol acetate use in cats-induced diabetes mellitus	White-yellow papules, nodules or plaques, ulcer, erythema on head, extremities, paw, or bony prominences	Histopathology	Correct underlying cause and will spontaneously resolve Surgical removal

(*Continued*)

TABLE 18.2 Common skin conditions: Disease, etiology, clinical signs, diagnosis, and treatment (*Continued*)

Miscellaneous dermatological disorders				
Disease	**Etiology**	**Clinical signs**	**Diagnosis**	**Treatment**
Canine acral lick dermatitis/granuloma	Allergic dermatitis, osteoarthritis, neuropathy, behavioral	Well-demarcated alopecia, erythema, exudate, erosion, ulcer, crust, lichenification	Clinical appearance, histopathology	Barrier (e.g., E-collar, wrap), topical antiseptics, topical steroids, pain medications, systemic antibiotics, systemic anti-inflammatory drugs, gabapentin +/– amantadine, anxiolytics, address the underlying cause
Canine actinic (solar) dermatitis	Excessive UV radiation exposure	Alopecia, erythema, papule, nodules, crusts, ulcers, hemorrhagic bullae on sun-exposed skin	Clinical appearance and history Histopathology	UV radiation avoidance, protective clothing, firocoxib, retinoids (topical, systemic), vitamin A, carotenoids with glucocorticoids, topical diclofenac, topical imiquimod, sunscreen
Canine calcinosis cutis	Dystrophic calcification usually secondary to excessive cortisol levels (e.g., glucocorticoid use or hyperadrenocorticism)	Alopecic, firm, erythematous to salmon color papules and plaques Head, preauricular, dorsum, ventrum, perianal, or frictional areas	Clinical appearance, histopathology	Treat underlying cause of excessive cortisol, topical antiseptics to prevent infection, topical DMSO gel to resorb calcium, surgical removal focal lesions
Feline idiopathic ulcerative dermatitis	Unknown	Crusted ulcers with alopecia, lichenification, and variable pain and pruritus Localized to dorsal neck and shoulder area	Histopathology	Systemic glucocorticoids, topical antiseptics, surgical removal
Feline plasma cell pododermatitis	Unknown	Soft, flaccid, swollen paw pads with erythema, scaling, scaling striae, fissure, depigmentation, and ulcer	Histopathology	Doxycycline, cyclosporine, glucocorticoids
Canine dermatomyositis/ ischemic dermatopathy	Hereditary—Collie, Shetland Sheepdog, Beauceron Shepherd, Belgian Tervuren, Portuguese Water Dog, and others	Early-age onset (6 months) Lesions on areas with mechanical trauma or friction (face, muzzle, paws, extremities) Alopecia, erythema, scaling, crusting, ulceration	Histopathology, EMG	None; vitamin E, pentoxifylline
Postrabies vaccine vasculitis +/- panniculitis	Idiopathic with Poodle, Yorkshire Terrier, and Silky Terrier overrepresented	Well-demarcated, annular area of alopecia, erythema, hyperpigmentation, scaling, ulcer, and scarring at injection site	Histopathology	None, pentoxifylline, avoid vaccination in future

(*Continued*)

TABLE 18.2 Common skin conditions: Disease, etiology, clinical signs, diagnosis, and treatment (*Continued*)

Miscellaneous dermatological disorders				
Disease	**Etiology**	**Clinical signs**	**Diagnosis**	**Treatment**
Cutaneous adverse drug reaction	Idiosyncratic (unpredictable—any medication, supplement, vaccination, or antiparasitic treatment possible)	Variable clinical lesions and severity Erythema, alopecia, scaling, crusting, erosion, ulceration, hyperpigmentation, and tissue necrosis	Drug history, histopathology, response to drug withdrawal (drug provocation not recommended)	Supportive care
Common alopecia dermatoses				
Disease	**Etiology**	**Clinical signs**	**Diagnosis**	**Treatment**
Canine pattern alopecia/ baldness	Unknown with breed predilection (Boston Terrier, Boxer, Chihuahua, Dachshund, Italian Greyhound, Manchester Terrier, Miniature Pinscher, Whippet)	Noninflammatory, nonpruritic follicular miniaturization and alopecia of pinnae, dorsal head, ventral neck, ventral trunk, caudomedial pelvic limbs	Clinical presentation	None
Color dilution alopecia	Mutation in MLPH gene resulting in abnormal melanin deposition within hair shaft	Alopecia, papules, crusts, scaling, broken hairs, dull haircoat starting along dorsum and extending diffusely	Histopathology and clinical appearance	None
Anagen/telogen effluvium/ defluxion	Stress, disease, or drug-induced hair cycle arrest	Abrupt hair cycle arrest and rapid, noninflammatory alopecia diffusely occurring with days (anagen) or months (telogen) after inducing event	History, trichogram	None
Postclipping alopecia	Unknown—plush-coated breeds high risk	Lack of hair regrowth months after close clipping of hair	History	None Rule out other causes, melatonin
Canine recurrent/seasonal flank alopecia	Unknown cyclical follicular dysplasia Boxer, English Bulldog, Airedale Terrier, Schnauzer overrepresented	Cyclic well-demarcated, noninflammatory alopecia and hyperpigmentation on lateral trunk	History, histopathology	None Melatonin, microneedling
Feline paraneoplastic alopecia	Unknown pathophysiology Associated with pancreatic and hepatic neoplasms	Rapidly developing complete, noninflammatory alopecia of ventrum and extremities Shiny skin	History, histopathology, abdominal ultrasound, necropsy	None Grave prognosis
Common pigmentary dermatoses				
Disease	**Etiology**	**Clinical Signs**	**Diagnosis**	**Treatment**
Lentigo	Unknown Hereditary in Pugs and orange cats	Well-demarcated, flat, hyperpigmented macules Cats—mucocutaneous areas Dogs—diffusely on ventrum	Clinical appearance, histopathology	None Differentiate from pigmented viral plaques, pigmented nevi, and melanoma (these are raised lesions)
Vitiligo	Acquired melanocyte destruction Hereditary in Belgian Tervuren dogs, Rottweilers, and Old English Sheepdogs Idiopathic cases reported in Collie, Dobermann Pinscher, Giant Schnauzer, Bullmastiff, Newfoundland, German Shepherd Dog, Dachshund, and Siamese cat	Symmetrical macular depigmentation, leukoderma, and leukotrichia of nose, lips, buccal mucosa, face, footpads, claws May spread diffusely Periocular leukotrichia in Siamese cat	Clinical appearance, histopathology	None May spontaneously improve Attempted therapies include calcineurin inhibitors, vitamin D, antioxidants, narrow-band UVB light, L-phenylalanine

OTOSCOPY

Thorough evaluation of the ears includes evaluation of the periauricular skin, pinnae, and ear canals. Palpation of the ear canals is an important tool capable of indicating the severity of ear disease. Normal, noninflamed ear canals are pliable on palpation. Ear canals with severe inflammation are larger and firmer on palpation with decreased pliability (Figures 18.1 and 18.2a).

To access the ear canal with ease, first locate the tragus. This is the plateau-like outermost piece of cartilage at the ear canal opening. Find the intertragic incisure just caudal to the tragus, and gently insert the otoscope cone into this space with the otoscope cone pointed ventral and slightly rostral while gently lifting the ear pinna dorsally. Maneuvering the ear pinna will help to straighten out the vertical ear canal. Once at the proximal portion of the vertical ear canal, turn the otoscope cone medially while maneuvering the ear pinna lateroventrally. This will allow access to the horizontal ear canal for visualization of the tympanic membrane.

While evaluating the ear canal, observe for changes in wall thickness, erosions/ulcerations, masses, foreign body, otic debris, hair, and the tympanic membrane. Be mindful of the patient's comfort level during this process and use sedation if the animal is moderately painful. Assess the tympanic membrane for normal structures and position. Changes in architecture or presence of fluid/masses behind the tympanic membrane may cause bulging or rupture. Sometimes a tear or complete loss of the tympanic membrane is present.

Video otoscopy is another tool sometimes available for use during awake or sedated ear examination. Benefits of this equipment include image and video capture software, enhanced magnification and visualization of the ear canal, and access for otic procedures, including deep ear flush, myringotomy, and tissue extraction (Figure 18.2b, c).

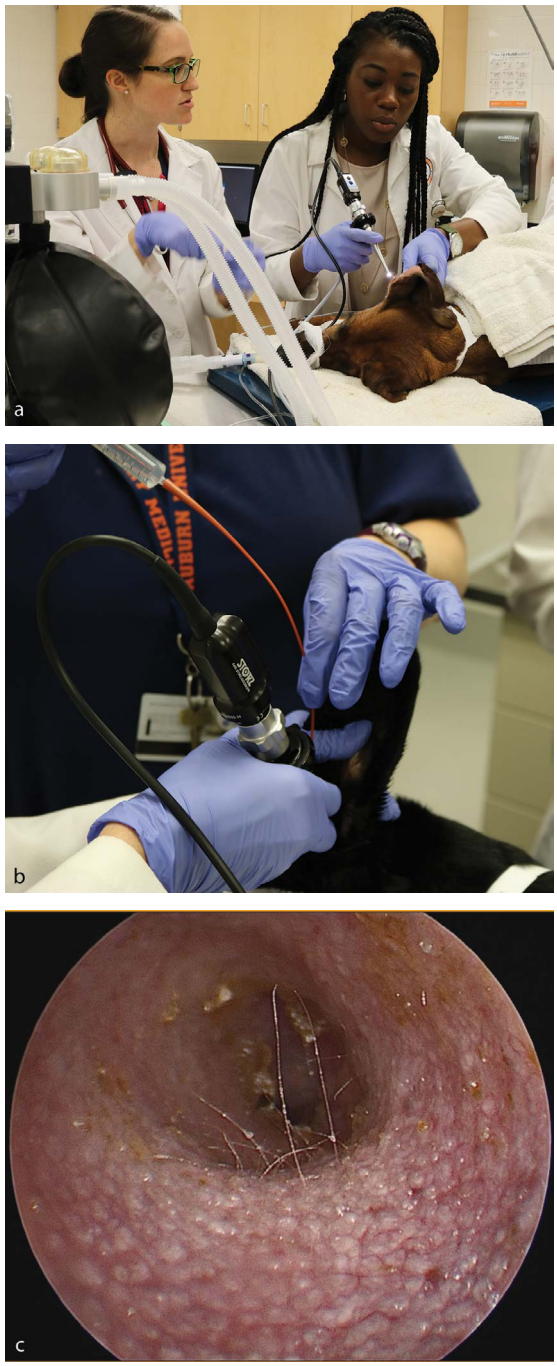


FIGURE 18.2 (a) Storz video otoscope is used to evaluate the external ear canal. (b) A red rubber catheter is passed through the instrument port to perform deep ear flushing with saline. (c) Severe glandular hyperplasia of vertical and horizontal external ear canal in a Cocker Spaniel with severe, chronic otitis externa.

CYTOLOGY

Cytology is a quick and easy diagnostic to perform in the clinic. Diff-Quik® is used to stain cytology slides for evaluation (Figure 18.3a, b) using a 40× or 100× oil objective for bacteria, yeast, inflammatory cells, acantholytic keratinocytes, and neoplastic cells.

The collection technique for cytology is dependent on the nature of the lesion. For exudative lesions, use direct impression smear of the exudate by placing a glass slide directly over the lesion and gently rotating in a circular

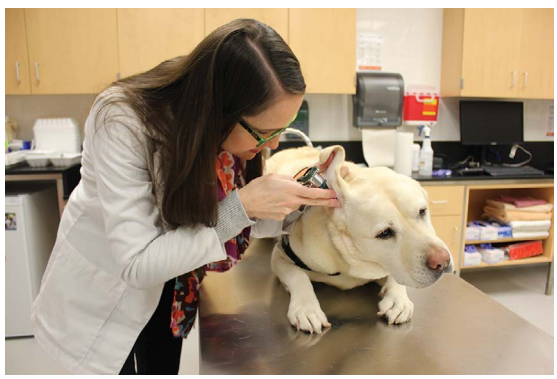

FIGURE 18.1 A handheld otoscope with ear cone.

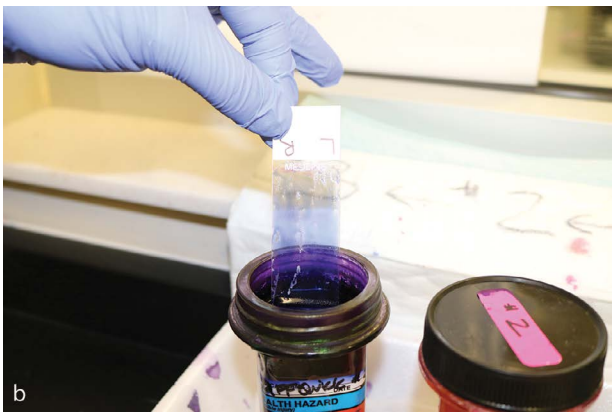

FIGURE 18.3 (a) Diff-Quik stain is a modified Romanowsky stain that includes a fixative (light blue), eosinophilic (red), and basophilic (dark blue) stain. **(b)** The slide is tinctured into each stain 5–10 times in each stain before rinsing with distilled water and air drying.

motion (Figure 18.4). Sampling from under a crust, along the edge of an epidermal collarette, or rupturing a pustule improves the diagnostic accuracy of the sample.

Direct impression provides reliable results from less exudative lesions as well; however, acetate tape cytology is helpful in areas that are difficult to fit a glass slide (e.g., interdigital skin) (Figure 18.5). One challenge of acetate tape cytology is the amount of sample obtained, which makes it difficult to see organisms present in low numbers (Figure 18.6).

FIGURE 18.4 Direct impression cytology of a skin lesion on the ventral abdomen of a dog.

FIGURE 18.5 Tape cytology of a skin lesion on the medial stifle of a dog.

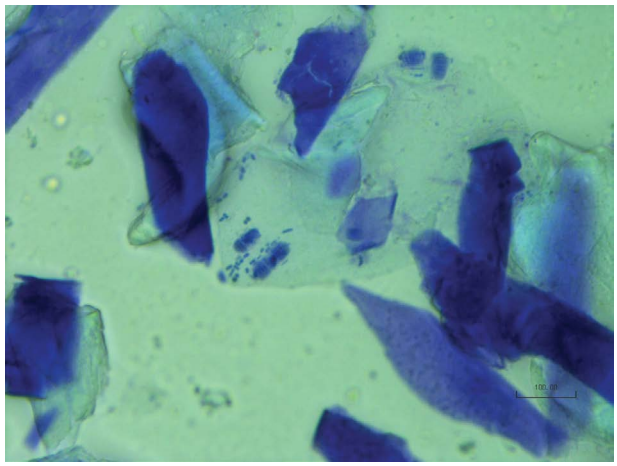

FIGURE 18.6 Tape cytology identifies large scrolls of corneocytes along with *Conchiformibius* spp. bacteria (oral contaminant), as well as cocci- and rod-shaped bacteria.

Sample claw bed debris using a blunt metal spatula or wooden tip of a cotton-tipped applicator. Roll or touch the sample to a glass slide for evaluation (Figure 18.7a, b).

For nodular lesions, especially nondraining nodules, fine-needle aspirate of the lesion using a 22- to 25-gauge needle (Figure 18.8) and 5 mL syringe to express contents onto a glass slide is more accurate than surface cytology alone.

Obtain otic cytology swab samples from both external ear canals using cotton-tipped applicators in cases of otitis. Roll the samples gently onto a glass slide, heat fix using a match or lighter, and then stain using Diff-Quik and/or Gram stain (Figure 18.9a–d). Evaluate otic samples for parasites by placing the otic debris into mineral oil on a glass slide, then apply a glass coverslip. Lower the microscope light source (condenser) and the light power when evaluating for parasites with the less powerful objectives (4× or 10×) (Figure 18.10a, b). Mites and other parasites are much larger than bacteria and yeast, so less power is required. Also, these organisms may be very translucent, so use of less light power enhances visualization of these parasites.

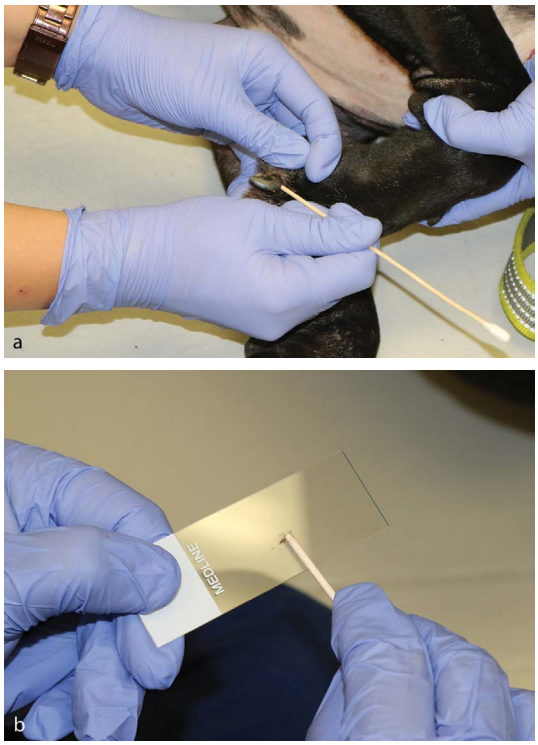

FIGURE 18.7 Claw bed cytology. **(a)** The blunt end of a metal spatula or cotton-tipped applicator is used to pull keratinous debris away from claw bed. **(b)** Sample is rolled onto center of glass slide, heat fixed, and stained for microscopic evaluation.

FIGURE 18.8 Fine-needle aspiration of digital mass on digital paw pad of a Great Dane.

SKIN SCRAPING

Skin scraping allows for visualization of parasites in the superficial and deep layers of the skin, and the technique varies slightly depending on the parasite of interest. In animals with pruritic dermatoses suspected to be caused by *Sarcoptes* spp. mites, superficial skin scraping over larger areas of the ventrum, elbows, hocks, and pinnae margins is preferred. Scrape the skin superficially without creating bleeding using wide swipes and a #10 scalpel blade or blunt metal spatula. Apply mineral oil to the blade/spatula or directly to the skin during scraping (Figure 18.11a, b). Deep skin scraping technique allows

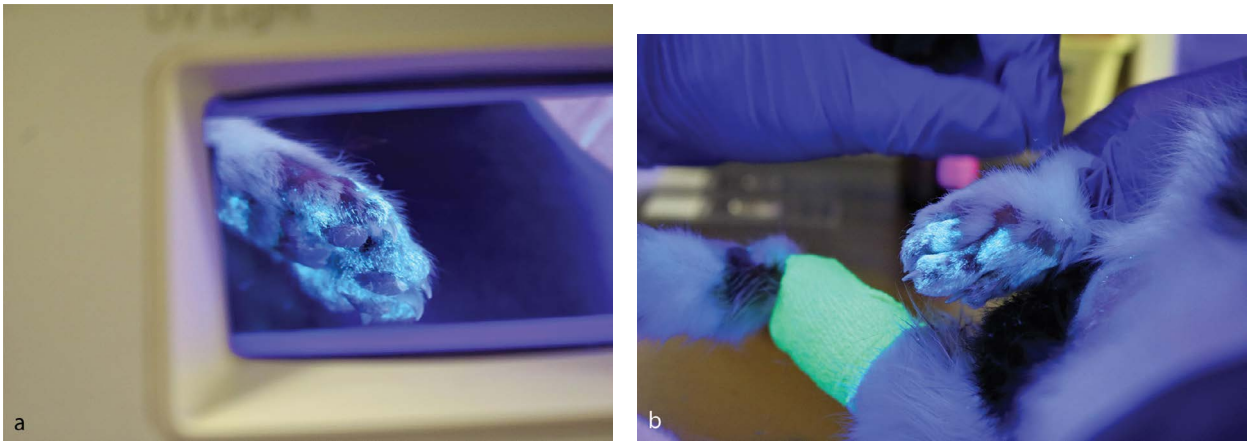

FIGURE 18.12 **(a)** Wood's lamp demonstrates green fluorescence of hairs on a cat paw with and **(b)** without magnification.

for visualization of *Demodex* spp. mites that live deeper in the hair follicle, and for this reason, a light squeezing of the skin to facilitate the extrusion of the mites may be indicated. Use the same instruments and mineral oil; however, select several focal areas of dermatitis and scrape repeatedly over the area until bleeding occurs (Figure 18.11c–e). Place a glass coverslip over the sample and evaluate as described earlier for otic parasites (Figure 18.11f).

WOOD'S LAMP

This is a screening test for dermatophytosis. Some species of dermatophyte fluoresce an apple-green/yellow-green color. The major dermatophyte positive to Wood's lamp is *Microsporum canis* (50%–80% of isolates); however, other less common fungi (*M. distortum*, *M. audouinii*, and *Trichophyton schoenleinii*) can also fluoresce (Figure 18.12a, b). The fluorescence is caused by a water-soluble chemical metabolite (pteridine) within the cortex or medulla of the hair. Keep in mind that other things can fluoresce to create a false-positive result, including medications, bacteria, scale/crust, soaps, petroleum, and fabric fibers. Wood's lamp is very helpful to make a diagnosis of dermatophytosis and select the best hairs to sample for culture or polymerase chain reaction (PCR). However, lack of fluorescence does not rule out dermatophytosis, so perform fungal culture or PCR to obtain a definitive diagnosis.

TRICHOGRAPHY

Microscopic evaluation of hairs (trichography) can be helpful to look for changes in the normal anatomy of hair shafts, evaluate for self-trauma (overgrooming/hair plucking), screen for parasites, and observe invasion of fungal hyphae or spores. Potassium hydroxide (KOH) 10%–20% with heat helps to dissolve keratinous buildup around hair shafts to improve visibility for trichography; however, it is not required to properly evaluate most animal hairs for changes. Pluck hairs from characteristic lesions, place in mineral oil, apply a coverslip, and evaluate at low and high power (Figure 18.13a, b).

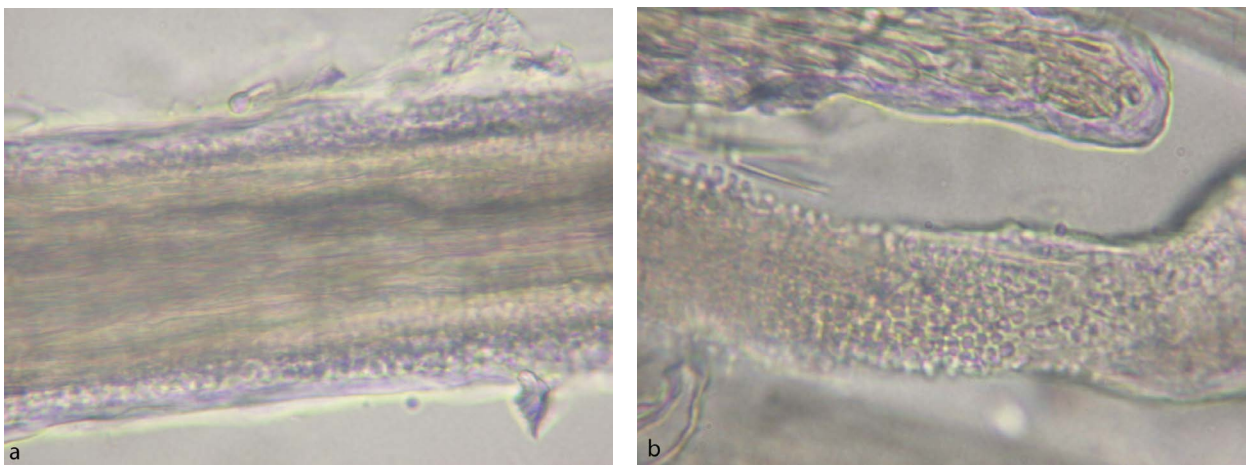

FIGURE 18.13 Hair shaft affected by dermatophytosis. **(a)** Note multiple hyphae running into the cortex of the hair shaft surrounded by arthrospores. **(b)** Note the large amount of arthrospores evident outside the hair shaft at the level of the bulb.

CULTURE

Fungal Culture

There are many fungal culture media available on the market. However, the most common used ones include the dermatophyte test medium (DTM) and Sabouraud-based media (Figure 18.14). The dermatophyte test medium is a specialized agar for culturing dermatophytes from hair and skin samples collected from peripheral lesion margins. The DTM is the most commonly used medium. Several types of fungal media exist with variable additives for rapid fungal sporulation or inhibition of saprophytic and bacterial overgrowth; however, many DTMs contain phenol red as a pH indicator. When dermatophytes consume protein in the media and release alkaline metabolites, the pH increases and causes a color change from yellow to red. After dermatophytes have consumed all of the protein, they will use the remaining carbohydrates, producing acid metabolites that cause the medium to change color from red back to yellow. The majority of other fungi (nondermatophytic) consume carbohydrate metabolites first so that no red color change occurs initially if they are the only fungal organisms present; however, after about 10–14 days, red color change occurs as they begin to utilize the remaining proteins. Ideally, evaluate DTMs daily for concurrent colony growth and color change. Examine growing colonies microscopically to confirm the most likely organism(s) present by evaluating the morphology of fungal reproductive structures. Macroscopic colony features, including color and texture, can aid in fungal identification as well. When growing the in-house DTMs, keep in mind that dermatophytes prefer to grow in the dark at 30°C with 30% humidity. False-negative growth may occur if culture environments are suboptimal.

Bacterial Culture Technique

Swab technique is a cheap and easy technique to perform; however, proper technique is important to prevent overgrowth of contaminants in culture. Reserve swab culture technique for aerobic bacteria collected from superficial skin lesions, including papules, pustules, crusts, and epidermal collarettes. Do not collect samples near mucocutaneous junctions due to the abundant flora at these sites. Avoid collecting samples from draining tracts and ventral paws due to the high risk for contamination of environmental organisms. This technique is not feasible for nodular lesions, so perform biopsy for tissue culture for nodular dermatitis (Figure 18.15a–e).

FIGURE 18.14 An example of dermatophyte testing medium (right side, lighter/clear) and rapid sporulating medium (left side, darker/opaque) dual plate (Derm-Duet II) for dermatophyte culture.

Macerated Tissue Culture

This technique is the gold standard for sample collection for all types of culture; however, it is more invasive and expensive than swab technique because it requires biopsy. Additionally, some animals may require sedation when collecting samples from the face, pinnae, paws, or perineal area, especially if they are overly fractious, stressed, or painful. This is the preferred collection technique for deep, nodular dermatitis, which may be caused by aerobic bacteria, anaerobic bacteria, opportunistic environmental bacteria (*Nocardia* spp., *Mycobacteria* spp.), dermatophyte, and opportunistic fungi.

Avoid performing a biopsy through a draining tract if possible (choose an intact nodule, papule, or pustule). Clean the area with chlorhexidine to remove any surface contaminants. Use 2% lidocaine injected beneath and/or around the lesion to be biopsied. Next, use a punch biopsy tool or scalpel blade to remove a tissue sample. When working up a nodular dermatoses case, include enough tissue for bacterial, fungal, and *Mycobacteria* spp. cultures to rule out infectious causes. You may need to take up to 4–5 punch biopsy samples when submitting several cultures (along with histopathology). Place samples in culture transport medium and submit to the laboratory as soon as possible (Figure 18.15a–e). Refrigeration preserves most bacteria and fungi in transit; however, some fungal and fungal-like organisms (e.g., *Pythium* spp., *Lagenidium* spp., *Paralagenidium* spp., *Aspergillus* spp., and Zygomycetes) die at cold temperatures. If you are not familiar with the handling of the specimen, it is always recommended to consult the laboratory submission guidelines or speak with a laboratory personnel for further guidance.

HISTOPATHOLOGY

Histopathology is helpful to evaluate changes in normal skin architecture induced by acute and chronic dermatoses. This technique provides a definitive diagnosis for autoimmune and neoplastic conditions, and it is useful to diagnose some inflammatory and infectious diseases. Biopsy selection site is critical when making an accurate diagnosis. Select primary lesions when possible, and

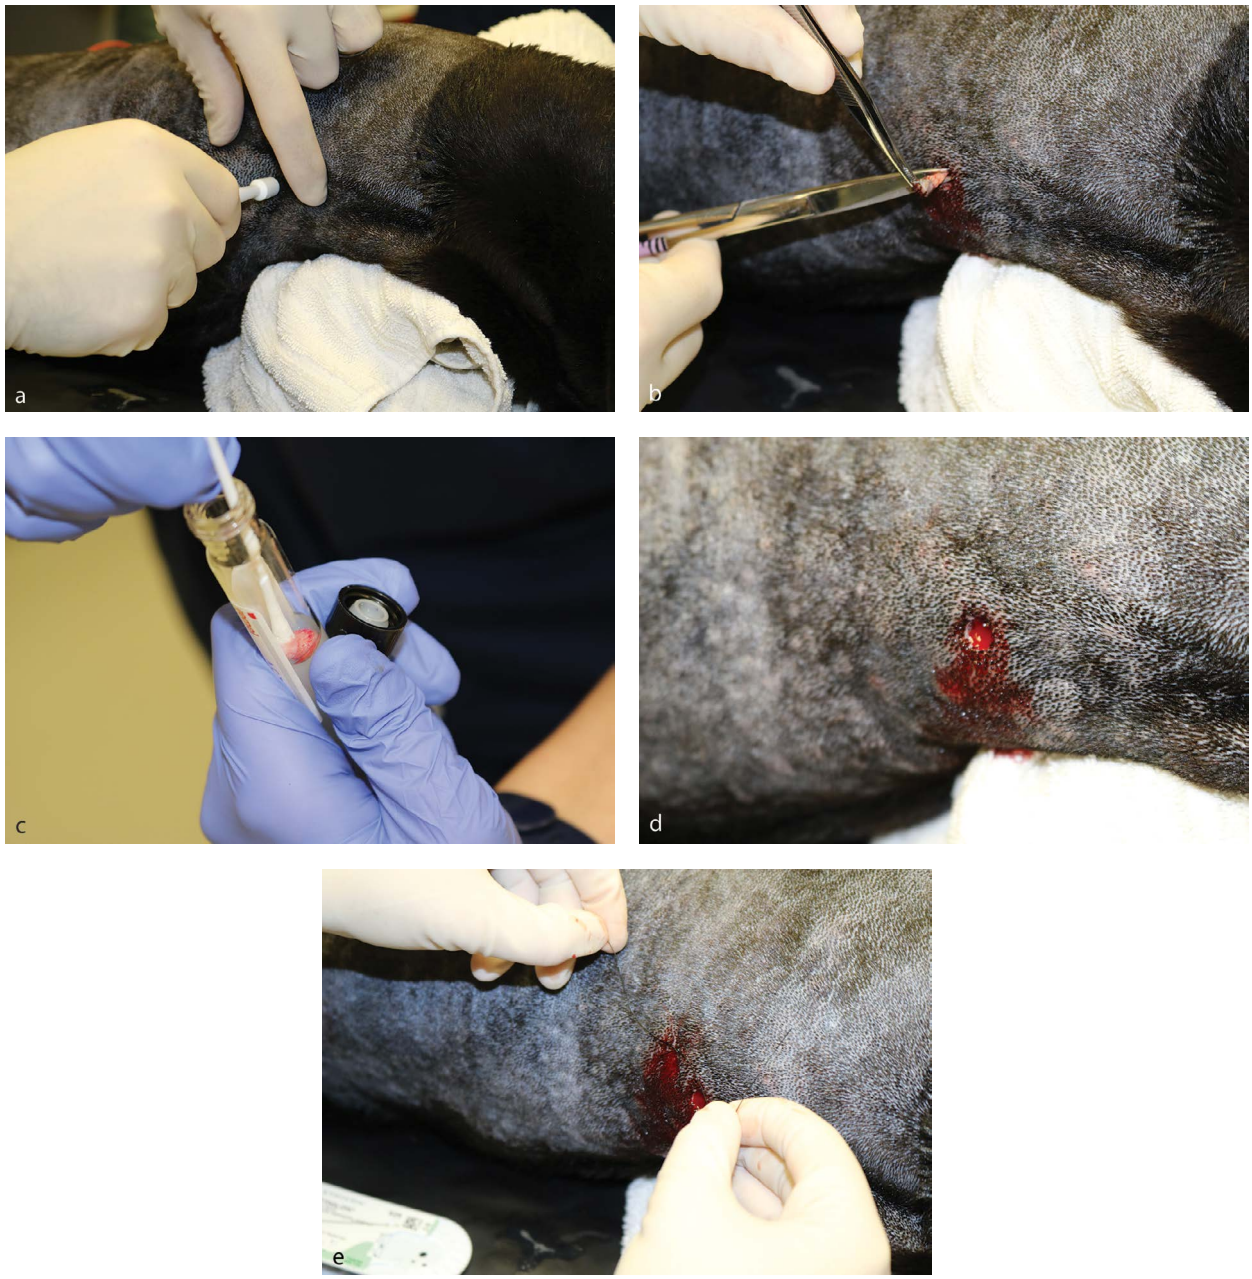

FIGURE 18.15 **(a)** Skin is injected with 2% lidocaine, and then an 8 mm punch biopsy tool is used to biopsy a representative sample. **(b)** The skin plug is removed with sterile scissors. **(c)** A punch biopsy sample is pressed deep into the culture media using a sterile swab prior to processing. **(d)** The biopsy site will hemorrhage slightly until **(e)** sutured using a single cruciate pattern.

always submit two to four pieces of tissue to improve diagnostic ability for the pathologist.

Preparation of the biopsy sites is different from that for tissue culture. The surface of skin collected for histopathology usually is not surgically prepared to avoid removing essential components necessary for making the diagnosis. Biopsy is performed as described earlier. Special stains provide better visualization of infectious organisms and include Gomori methenamine silver (GMS), periodic acid-Schiff (PAS), and acid-fast stains. Immunohistochemical stains may be helpful for identifying infectious and neoplastic cells.

ADVANCED IMAGING

Radiographs and advanced imagining modalities provide additional information about changes in deep soft tissues and bone. Radiographs of distal extremities provide evidence of chronic osteoarthritis, foreign body, or osteomyelitis as contributing factors to a dermatosis. Visualization of the tympanic cavity to assess for fluid, osteomyelitis, or neoplasms is preferred via advanced imaging modalities such as computed tomography (CT) or magnetic resonance imaging (MRI) studies; however, these modalities are limited to referral centers.

IMMUNODIAGNOSTICS

With the growing accessibility to research and commercial laboratories, immunodiagnostic testing options are expanding. Numerous PCR, enzyme-linked immunosorbent assay (ELISA), immunohistochemical stains, flow cytometry, deoxyribonucleic acid (DNA) profiling, and even whole genomic sequencing testing options are now available for purchase. In particular, PCR is a modality growing in popularity for making a rapid diagnosis using a small sample size. PCR to confirm the presence of an infectious organism in tissue is performed from fresh or formalin-fixed paraffin-embedded tissue samples. This technique is very sensitive to pick up organism DNA in a sample; however, positive test results do not prove the organism is the cause of disease or that it is even alive! For example, nonviable dermatophyte DNA may reside on the haircoat of the animal, and some animals may be asymptomatic carriers of dermatophyte. The same is true for *Mycobacteria* spp. and numerous saprophytic fungi, so it is important to pair PCR results with histopathology to confirm the presence of the organism within tissue proving infection instead of contamination of the sample.

BACTERIAL DERMATITIS

INTRODUCTION

Bacterial skin infections occur commonly in veterinary dermatology and are most often secondary to some other disease process. Common primary causes include allergic dermatitis, parasites, endocrinopathies (e.g., hypothyroidism, hyperadrenocorticism, and sex hormone imbalances), autoimmune dermatoses, adverse drug reactions, immunosuppression, and neoplasia. Identifying and controlling these primary conditions is necessary in order to adequately treat and prevent recurrence of the bacterial infection. This is especially important when considering that repeated infections and repeated use of antibiotics will contribute to antibiotic resistance.

The term "pyoderma" means "pus in skin," and it most commonly refers to bacterial dermatitis in veterinary dermatology. Pyoderma can be classified into surface, superficial, and deep pyoderma based on the cutaneous layers involved in the infection. Bacterial pyoderma is common in dogs and less common in cats. The most common etiologic agent involved is *Staphylococcus pseudintermedius*, though other causative bacteria include other normal flora bacteria such as *S. schleiferi*, *S. delphini*, *S. epidermidis*, *Streptococcus canis*, *Escherichia coli*, *Pseudomonas* spp., *Bacillus* spp., *Corynebacterium* spp., *Micrococcus* spp., and *Proteus mirabilis* to name a few.

Clinical presentations of bacterial dermatitis vary, but the diagnostic workup and treatment approach is similar. This section will focus on a few common presentations of bacterial dermatitis. Treatment of bacterial infections involves topical antimicrobial therapy and, occasionally, antibiotic therapy. Common active ingredients present in topical products effective against Gram-positive and Gram-negative bacteria include chlorhexidine, benzoyl peroxide, malic and acetic acids, lime sulfur, ethyl lactate, diluted sodium hypochlorite (bleach), superoxidized hypochlorous solution (modified bleach solution), povidone iodine (betadine), and accelerated hydrogen peroxide. Specific recommendations for preferred antibiotics and their doses for canine pyoderma are provided in open-access guidelines provided by the International Society for Companion Animal Infectious Diseases (https://iscaid.org/).

SKIN FOLD PYODERMA—INTERTRIGO

Definition/Overview

Intertrigo is a type of surface inflammation and infection in areas where the skin is folded upon itself (e.g., facial and caudal folds in brachycephalic dogs).

Etiology

Bacteria typically colonize warm, humid areas of the skin, including places where the skin is folded or wrinkled. Examples include naso-ocular skin folds, lip folds, interdigital webbing, axillae, inguinal area, neck folds, vulvar folds, and tail folds. Because the bacterial load may be higher in these areas, the skin is more prone to develop bacterial overgrowth and subsequent dermatitis.

Pathophysiology

Factors contributing to bacterial overgrowth at these sites include frictional forces (skin rubbing), poor ventilation, trapping of tears/saliva/urine/feces, and abundant surface secretions. The bacteria and yeast living in these skin folds overgrow, and secondary inflammation develops. Certain breeds are more prone to anatomical variations causing excessive skin folds, including English Bulldog, Boston Terrier, French Bulldog, Shar Pei, and Mastiff. Obesity may also be a contributing factor to acquired skin fold dermatitis.

Clinical Presentation

The most common clinical signs include malodor, erythema, alopecia, exudate, keratinous debris, and crusting within skin folds (**Figure 18.16**). Be sure to carefully examine areas by lifting skin folds; otherwise, the lesions are missed easily.

Differential Diagnoses

Yeast (*Malassezia* spp.) and *Demodex* spp. mites commonly complicate inflammation along with bacteria. Occasionally, dermatophyte may complicate these lesions.

FIGURE 18.16 Erythema, lichenification, alopecia, and papules within the perivulvar and intramammary skin folds of a dog.

Allergic dermatoses (atopic dermatitis, adverse food reaction) exacerbate inflammation of skin. Obesity contributes to the depth of skin folds. Urine and/or fecal incontinence contribute to bacterial overgrowth within skin folds.

Diagnosis

Cytology using direct impression smear technique or using a cotton-tipped applicator to collect the sample and roll it onto the slide will reveal cocci- and/or rod-shaped bacteria along with neutrophils. Occasionally, yeast may be found as well. Skin scraping and fungal culture to rule out infection with *Demodex* spp. and dermatophytes, respectively, may be indicated.

Management

Treatment centers on controlling the bacterial overgrowth and inflammation, reducing the exudate, and reducing friction, especially considering intertrigo is a life-long issue. Topical agents containing chlorhexidine aid in reducing overgrowth of bacteria and yeast, malic acid or acetic acid reduce excess moisture and act in an antimicrobial fashion, and corticosteroids help to reduce inflammation. Wipes, shampoos, mousses, and creams are commonly used formulations. If the infection is severe or in an area difficult to apply topical therapy, such as the naso-ocular or tail folds, then systemic antibacterial therapy may be required. Cosmetic surgery to remove excessive skin folds and weight loss help to reduce continued frictional damage of the skin.

PYOTRAUMATIC DERMATITIS—ACUTE MOIST DERMATITIS—HOT SPOT

Definition/Overview

Pyotraumatic dermatitis is a type of surface pyoderma characterized by an acute onset of self-induced inflammation and infection of skin due to excessive licking, chewing, or scratching in an effort to relieve either pain or pruritus of the skin.

Etiology

Pyotraumatic dermatitis occurs commonly in dogs with allergic dermatitis, particularly flea bite hypersensitivity and atopic dermatitis, but also food allergy. Lesions may be more common in these dogs during warm, humid seasons and in dogs with dense haircoats. Other underlying diseases associated with this dermatosis include ectoparasites, contact hypersensitivity, anal sacculitis, otitis externa, poor hygiene, osteoarthritis, peripheral neuropathy, and psychological disorders.

Pathophysiology

The original pruritic or painful stimulus causes the dog to overgroom an area of skin. The excessive licking, chewing, and/or scratching creates trauma to the skin leading to erythema, excoriation, inflammation, and secondary infections. Lesions spread rapidly circumferentially from the initial site, especially with ongoing self-induced trauma.

Clinical Presentation

Lesions present as well-demarcated areas of erythema, hair loss, excoriation, and exudate. With chronicity, lesions may develop crusts, scales, papules, and pustules. Lesions tend to be much larger than they appear, so shaving the haircoat to assess the severity of dermatitis is important, especially in long-haired dogs (Figure 18.17). Lesions tend to spread rapidly if not treated.

FIGURE 18.17 Multifocal erythematous and exudative plaques and papules with lichenification and crusting on left thoracic limb of a dog.

Differential Diagnoses

Determining the underlying cause is important and includes allergic dermatitis (atopic dermatitis, flea bite hypersensitivity, food allergy, and contact allergy), thermal or chemical injury, clipper blade-induced injury, osteoarthritis, or other musculoskeletal disorder, ectoparasites, dermatophytosis, bacterial dermatitis, *Malassezia* spp. dermatitis, otitis externa, anal sacculitis, peripheral neuropathy, and psychological disorders.

Diagnosis

History of an acute-onset exudative dermatitis along with owner-observed pruritic behaviors, dermatological lesion appearance, and cytological evaluation provide a rapid diagnosis. Histopathology may help to confirm the diagnosis if needed.

Management

Haircoat must be clipped in order to assess the extent of the dermatitis, and improve the efficacy of the topical treatment. If the lesion is localized to a focal area, then topical antibacterial and anti-inflammatory therapy alone is effective. If the lesion is more extensive, and/or the patient is significantly immunocompromised, then systemic antibiotic therapy may be needed. Antipruritic and anti-inflammatory therapy may include topical or systemic glucocorticoids, oclacitinib (Apoquel) or lokivetmab (Cytopoint). An Elizabethan collar or other barrier devices prevent ongoing self-induced trauma to lesions. Another important component of management is the identification and treatment of the primary cause of the pain and/or pruritus.

SUPERFICIAL BACTERIAL DERMATITIS

Definition/Overview

Bacterial infection and inflammation involving the epidermis and the superficial follicular epithelium.

Etiology

The most common causative agent in the dog and cat is *S. pseudintermedius*; however, other normal flora bacteria may contribute as well (see the introduction section). There are many causes for colonization with bacteria, including trauma/traumatic inoculation, allergic dermatitis (atopic dermatitis, food allergy, flea bite hypersensitivity, and contact allergy), endocrinopathies (e.g., hypothyroidism, hyperadrenocorticism, and sex hormone imbalances), autoimmune dermatoses, neoplasia, ectoparasites, and thermal/chemical injury.

Pathophysiology

Bacteria may either be traumatically inoculated through scratching, biting, or other forms of trauma, or bacteria may act in an opportunistic fashion to colonize epidermal and follicular epithelium in immunocompromised hosts. Recognition of bacterial colonization by the host immune systemic leads to neutrophilic and granulomatous inflammatory infiltrates into the skin and hair follicle creating inflammation, and clinical lesions develop. Animals with bacterial infections of the skin and hair follicle have variable pruritus.

Clinical Presentation

Clinical lesions may develop in any skin location, and sometimes the distribution of lesions may be helpful when determining the primary cause of infection. For example, atopic dermatitis causes lesions to develop on the face, pinnae, paws, axillae, ventral abdomen, perineum, and other frictional areas, whereas flea bite hypersensitivity causes lesions to develop near and around the tail base, ventral abdomen, and distal extremities. Lesions consistent of erythematous papules, pustules, epidermal collarettes, crusting, scaling, and alopecia (Figure 18.18a, b). Hair shafts may be observed protruding through the center of papular and pustular lesions. Lesions may coalesce to form plaques and large epidermal collarettes and may be widespread in chronic infections.

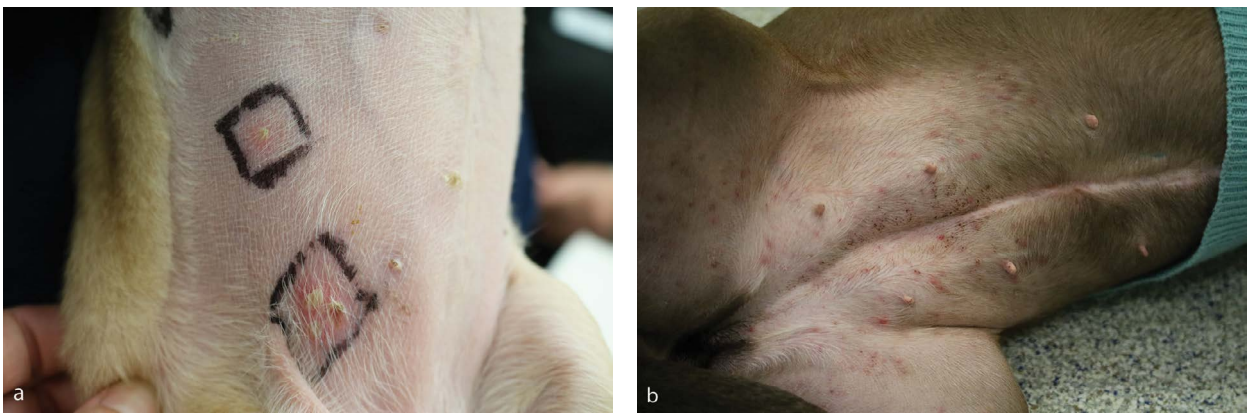

FIGURE 18.18 (a) Multifocal panfollicular pustules with circumferential erythema on ventral abdomen of a dog on chronic oral glucocorticoid therapy. (b) Numerous erythematous papules, epidermal collarettes, comedones, crusts, and alopecia on the ventral abdomen of an atopic dog.

Differential Diagnoses

The most likely differentials for superficial folliculitis include demodicosis and dermatophytosis. In fact, most of the clinical lesions are identical, which explains why superficial bacterial folliculitis is misdiagnosed as one of these diseases. Cytology, skin scrapings, Wood's lamp, trichography, and fungal culture can easily distinguish between these three differentials. Other differentials to consider include pemphigus foliaceus, dermatophilosis, *Malassezia* dermatitis, and epitheliotropic lymphoma.

Diagnosis

Clinical lesions combined with cytological evaluation is confirmatory for the majority of cases. Cytology collected from pustular contents, along the rim of an epidermal collarettes, or under a crust is most rewarding. Finding cocci-shaped bacteria inside of neutrophils in conjunction with examination findings is a confirmed diagnosis. Occasionally, bacterial load is low, and cytology does not yield a diagnostic sample. However, if highly degenerated neutrophils are present, these are highly suggestive of an active pyoderma. Swab or tissue aerobic culture and susceptibility testing is a more sensitive technique when bacterial folliculitis is suspected, but no bacteria are observed on cytological evaluation. Be sure to collect the sample from a pustule, under a crust, or along/under the rim of epidermal collarettes. Avoid culturing areas with high contamination, including perioral, paws, and perineal regions. Always perform aerobic culture and susceptibility testing when there is a suspicion of antibacterial resistance including animals/housemates with a history of antibiotic resistance, 50% reduction of skin lesions within 2 weeks of therapy, active lesions developing within the first 2 weeks of therapy, intracellular cocci after 6 weeks of therapy, and anytime there are rod-shaped bacteria on cytology.

Management

Topical therapy has the great advantage of preventing the formation of antibiotic resistance, since most topical therapies are antiseptics, not antibiotics. Current guidelines (https://iscaid.org/) suggest that topical therapy alone should be selected whenever possible. Treatment with topical therapy alone is sufficient to cure most cases of superficial bacterial folliculitis; however, owner and patient compliance will determine therapy success. If topical therapy is selected, daily to every-other-day application of sprays or mousses and weekly to biweekly (every 3 days) shampoo therapy is most effective to resolve the infection, especially with widespread lesions. Localized lesions can resolve with once- to twice-daily application of topical therapy using gel, cream, ointment, lotion, or wipe formulations. Owners need to understand the proper application techniques and contact times for improved therapy success. For example, dips, wipes, sprays, crèmes, and mousse products are applied without rinsing, whereas shampoos are applied for 10 minutes prior to rinsing. Topical therapy should be continued for 1 week beyond clinical and cytological resolution of lesions.

Systemic antibiotic therapy is indicated when topical therapy proves unsuccessful, owner/patient compliance is a known issue, a large body surface area is affected, or the patient is significantly immunocompromised. Consideration of the drug availability, safety, cost, and geographic antimicrobial resistance patterns is needed when selecting an antibiotic. Empirical selection of a first-tier antibiotic (e.g., cephalexin, amoxicillin/clavulanate, cefpodoxime, cefovecin, trimethoprim/ormetoprim-potentiated sulfonamides, or clindamycin) is recommended when culture and susceptibility results are not available. However, culture and susceptibility testing is needed anytime antibiotics from the second tier are selected (e.g., doxycycline/minocycline, chloramphenicol, fluoroquinolones, rifampin, or amikacin). Any other antibiotics would fall into the third-tier category and are not recommended for treating superficial bacterial folliculitis. Antibiotic treatment should continue 1 week beyond clinical and cytological resolution of lesions. Whenever possible, topical therapy should be used in conjunction with systemic antibiotic therapy.

Determining the primary cause of folliculitis as discussed previously is mandatory for treating and preventing recurrence of the folliculitis.

IMPETIGO—PUPPY PYODERMA

Definition/Overview

Impetigo is a form of superficial bacterial dermatitis characterized by nonfollicular subcorneal pustules affecting skin with little hair including the ventral abdomen, groin, axillae, and head.

Etiology

The most commonly isolated causative agent is *S. pseudintermedius*.

Pathophysiology

Impetigo is a noncontagious condition affecting young, peripubescent dogs. Causes include ectoparasites, viral infections, inadequate nutrition, filthy living environment, or idiopathic. It is observed rarely in adult dogs secondary to other diseases (e.g., hypothyroidism, hyperadrenocorticism, etc.). A similar condition occurs in kittens and is postulated to occur from overzealous grooming by the queen. Subsequently, bacteria involved include *Pasteurella multocida* and β–hemolytic streptococci.

Clinical Presentation

Small, nonfollicular pustules found on the glabrous skin of the groin, axillae, and ventral abdomen (**Figure 18.19**). Lesions are nonpainful, variably pruritic, and rupture easily creating a yellow-colored crust or epidermal collarettes.

FIGURE 18.19 Few large pustules on the abdomen of a puppy typical of puppy pyoderma. (*Courtesy of Dr. Schaer.*)

Differential Diagnoses

Contact allergic, irritant contact dermatitis, demodicosis, dermatophytosis, and adverse food reaction are all valuable differentials. In very severe cases, puppy strangles may also be considered.

Diagnosis

The presence and ventral distribution of nonfollicular pustules in a puppy, along with the presence of intracellular cocci confirms the diagnosis.

Management

Impetigo is a self-limiting disease for most puppies, especially if a primary cause is identified and corrected (e.g., poor nutrition, dirty living environments). Topical chlorhexidine therapy is the preferred treatment approach; however, systemic antibiotics are used when topical therapy fails to improve the condition, the lesions are severe/widespread, or when the condition recurs. Continue topical therapy for 1 week beyond clinical and cytological resolution of lesions.

Consideration of any underlying conditions leading to the development of these lesions should be identified and corrected.

MUCOCUTANEOUS PYODERMA

Definition/Overview

This is a superficial bacterial infection and inflammation of the haired skin and mucosal membranes of the eyelids, lips, nares, prepuce, vulva, and anus.

Etiology

The etiology is unknown, although bacterial overgrowth and infections contribute to the developing skin lesions, especially considering lesions improve with the use of systemic and topical antibacterial therapies and recur once these are discontinued.

Pathophysiology

The mechanisms by which skin lesions develop is unknown; however, some dogs have other underlying diseases including allergic dermatitis and endocrinopathies, which may contribute to the development of lesions. Genetic predispositions are thought to occur as German Shepherd Dogs and their crosses have an increased risk, though dogs of any age, breed, or sex may be affected.

Clinical Presentation

The disease has a striking symmetrical distribution to the mucocutaneous areas primarily, including the commissures of the lips and perioral skin (Figure 18.20); however, lesions may extend to the eyelids, nares, prepuce, vulva, and anus. Lesions consist of swelling, erythema, exudate, erosion, ulceration, depigmentation, and crusting. Lesions are painful.

Differential Diagnoses

Differential diagnoses include lip fold dermatitis or intertrigo, cutaneous lupus erythematosus, pemphigus foliaceus, pemphigus erythematosus, zinc-responsive dermatosis, cutaneous adverse drug reaction, demodicosis, dermatophytosis, allergic dermatitis (e.g., atopic dermatitis, food allergy, and contact allergy), irritant contact dermatitis, chemical burns, and epitheliotropic lymphoma.

Diagnosis

Physical exam findings, cytological evaluation, and response to antibacterial therapies provide a diagnosis

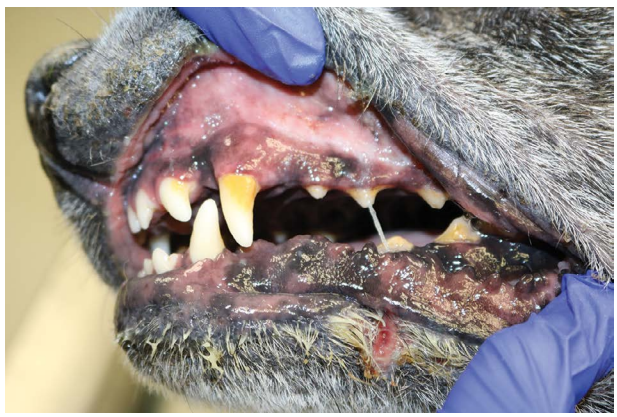

FIGURE 18.20 Alopecia, crusting, purulent exudate, and ulceration of the periorbital haired skin with depigmentation of oral mucosa and lips in a dog with mucocutaneous pyoderma.

in the majority of cases; however, histopathology and bacterial cultures may be beneficial in complicated cases.

Management

This disease is a lifelong condition and relapses occur commonly. Topical antibacterial therapy is the preferred treatment approach; however, systemic antibiotics are used when topical therapy fails to improve the condition, the lesions are severe/widespread, or when the condition recurs. Continue topical therapy for 1 week beyond clinical and cytological resolution of lesions. Clip the hair around the affected areas to improve penetration of the topical agents. One effective topical therapy approach is cleaning with an antiseptic solution (e.g., chlorhexidine, benzoyl peroxide). Consider implementation of a topical therapy routine in cases where relapses are ongoing.

DEEP PYODERMA AND FURUNCULOSIS

Definition/Overview

Deep pyoderma is a bacterial infection and inflammation extending into the dermis or subcutis. Furunculosis is a specific type of deep pyoderma developing as a consequence of follicular epithelium rupture into the dermis.

Etiology

Deep pyoderma may occur as a consequence of traumatic inoculation of bacteria, spread from another body site, or rupture of hair follicle epithelium (furunculosis). Furunculosis is a common cause of deep pyoderma and results in free hair shafts and keratin in the dermis. This stimulates a strong host pyogranulomatous "foreign body" reaction to the free keratin. Underlying causes of deep pyoderma include allergic dermatitis (e.g., atopic dermatitis, food allergy, flea bite hypersensitivity, and contact allergy), demodicosis, dermatophytosis, endocrinopathies, obesity, abnormal weight distribution or ambulation, short/stubby haircoat, calluses, trauma, solar dermatitis, or idiopathic.

Pathophysiology

Once a pyogranulomatous reaction occurs, lesions will progress from nodules to hemorrhagic bullae that fistulate and heal via scarring. With more severe lesions, cellulitis may develop. Fibrosis formation may trap bacteria and free keratin in the dermis, which contributes to recurrence of lesions at the same site.

Clinical Presentation

Lesions consist of painful to pruritic nodules, papules, fistulae, hemorrhagic bullae, and alopecia (Figure 18.21a–d). Fistulated lesions become covered in crusts as exudate dehydrates. Furunculosis lesions occur commonly in areas of friction, including the chin, paws, sternum, and over bony prominences. Lesions typically are multifocal but may be localized in cases of traumatic inoculation of an organism. Peripheral lymphadenopathy is common, and some dogs may experience fever, inappetence, and lameness in more severe cases.

A unique form of furunculosis occurs in dogs after grooming (also known as postgrooming folliculitis and furunculosis) with contaminated shampoos or grooming equipment. Numerous bacteria have been implicated in these infections, including *S. pseudintermedius, P. aeruginosa, Serratia* spp., and *Burkholderia* spp. Affected dogs usually are short to medium-coated, and lesions tend to be distributed along the dorsum. Lesions are painful.

Differential Diagnoses

Differential diagnoses to consider include demodicosis, dermatophytosis, foreign body, opportunistic environmental fungal or bacterial infections, sterile nodular panniculitis, nodular sebaceous adenitis, sterile granuloma pyogranuloma syndrome, and neoplasia.

Diagnosis

Clinical lesions and cytological evaluation are good starting places for achieving a diagnosis. Fine-needle aspirate from an intact furuncle or nodule reveals pyogranulomatous inflammation with intracellular bacteria, though very few bacteria may be observed. The most sensitive diagnostics include aerobic bacterial tissue culture and susceptibility testing and histopathology.

Management

Deep infections require more long-term antibacterial therapy to achieve complete resolution. Additionally, systemic antibiotics are required to adequately achieve drug penetration to the site of infection. Antibiotics ideally are selected based on culture and susceptibility testing, especially given the long-term therapy needed. For example, most deep bacterial infections and furunculosis require an average of 6–8 weeks of therapy, and therapy is continued 2 weeks beyond a clinical and cytological cure. If an inadequate antibiotic is empirically selected, this may significantly affect antimicrobial susceptibility patterns and future antibiotic options. Lesions tend to relapse if antibiotics are stopped too early. Topical therapy is helpful to assist with resolution of the superficial components of the infection, and topical glucocorticoids may serve as a safe alternative to systemic therapy for inflammation. Pain medications usually are required as most animals exhibit lameness and sensitivity on manipulation of the skin lesions. This disease is a lifelong problem. Consideration of any underlying conditions leading to the development of these lesions should be

FIGURE 18.21 **(a)** Severe lichenification, hyperpigmentation, alopecia, ulcers, erosions, and fistulation of the right lateral antebrachium in a German Shepherd Dog with deep pyoderma. **(b)** Numerous papules, pustules, erosions, ulcers, and fistula in a Labrador Retriever with postgrooming folliculitis and furunculosis. **(c)** Papule, crusts, and nodules with draining tracts and purulent exudate on the ventral mandible of a cat with chin acne. **(d)** Severe lichenification, erythema, and fistulae with hemorrhagic to purulent exudate of the interdigital skin of an English Bulldog with atopic dermatitis.

identified and corrected (e.g., obesity, allergic dermatitis, endocrinopathies, musculoskeletal disease, etc.). Long-term management with topical antimicrobial and anti-inflammatory agents helps to reduce flareups. When significant fibrosis occurs and serves as a nidus of lesion recurrence, the areas can be removed surgically (e.g., excisional biopsy, CO_2 laser ablation, or cryotherapy).

In some cases, lesions are sterile, and therapy aimed at reducing systemic inflammation may include glucocorticoids, modified cyclosporine (Atopica), oclacitinib (Apoquel), and tacrolimus (Protopic).

ABSCESSES AND CELLULITIS

Definition/Overview

An abscess is a well-organized, localized accumulation of purulent exudate in the dermis, subcutis, or deeper fascial layers. Cellulitis is an acute, unorganized, disseminated accumulation of purulent exudate extending from the dermis into the subcutis, fascial planes, musculature, and occasionally lymphatics.

Etiology

Most commonly, abscesses and cellulitis develop in response to bacterial infection, specifically *S. pseudintermedius*; however, any normal oral or cutaneous flora bacteria may cause infection, especially in the case of animal bites. The most common canine oral bacteria causing infection include *S.* pseudintermedius and *E. coli*, whereas feline oral bacteria typically include *P. multocida*, β-hemolytic streptococci, *Porphyromonas* spp., and *Fusobacterium* spp. Other causes include opportunistic bacteria such as *Mycobacteria* spp. or *Nocardia* spp. Occasionally, demodicosis and tooth root abscess may result in cellulitis.

Pathophysiology

Infection occurs when bacteria are traumatically inoculated in the skin as a result of the extension of a superficial infection into deeper layers of the skin, or

FIGURE 18.22 Large subcutaneous abscess with erythema and bruising on the ventral abdomen of a Yorkshire Terrier on glucocorticoids and mycophenolate for treatment of immune-mediated thrombocytopenia. Culture revealed *Clostridium* spp.

dissemination from another body location. Breaks in skin from animal bites or scratches, insect bites, chemical/thermal burns, surgical incisions, and intravenous catheters all serve as entry points into the deeper layers of skin. Dissemination is more likely to occur in immunosuppressed animals. Abscesses occur when bacteria are trapped deep in the skin, and the wound is sealed. This usually occurs 2–4 days after injury in the case of an animal bite or traumatic inoculation.

Clinical Presentation

A few days after inoculation, a firm, erythematous, painful, nodule to mass (abscess) develops in the deep layers of skin (Figure 18.22). In the case of cellulitis, tissue swelling is poorly demarcated and takes on a diffuse, erythematous, edematous, exudative dermatitis that is painful and hot to the touch. Fistulae may develop over time along with crusting. Fever, pain, lethargy, and decreased appetite may develop. Lesions are most common in areas prone to bites, including head, pinnae, neck, extremities, tail, and caudal dorsum. Sexually intact animals may be overrepresented.

Differential Diagnoses

Other causes of abscess and cellulitis include severe demodicosis, dermatophytic kerions and pseudomycetomas, opportunistic fungal and oomycotic infection, opportunistic bacterial infection, foreign body, surgical implants, sterile nodular panniculitis, sterile granuloma pyogranuloma syndrome, and neoplasia.

Diagnosis

History may provide evidence of a recent animal fight or other injury prior to the onset of clinical lesions. Clinical evaluation and cytology are useful initial diagnostic tools. Fine-needle aspirate of an abscess reveals purulent to pyogranulomatous inflammation with intracellular bacteria. Cellulitis may be more difficult to collect a sample for cytological examination. In both cases, tissue culture and susceptibility testing along with histopathology are important to confirm the diagnosis and implement appropriate antibiotic options. In the case of abscess and cellulitis, tissue cultures include aerobic, anaerobic, fungal, and mycobacterial cultures.

Management

Treatment is multifactorial. For abscesses, surgery to open the lesion to allow for draining as well as thorough cleaning using sterile saline lavage is helpful to reduce the bacterial load and improve penetration of systemic antibiotics at the site of infection. Remember to select antibiotics based on results of culture and susceptibility testing.

Treatment for cellulitis involves warm water Epsom salt soaks to reduce tissue swelling, deep tissue massage, and passive range-of-motion exercise to improve lymphatic flow, appropriate antibiotic selection, osmotic bandages to remove excessive fluid from tissue, and improved skin hygiene to prevent recurrence. If empirical antibiotic selection is chosen for initial therapy but the patient fails to improve, then tissue culture is paramount as the risk for an opportunistic bacterial (e.g., *Mycobacteria* spp., *Nocardia* spp.) or fungal (dimorphic fungi, pigmented and nonpigmented molds, oomycetes) organism(s) increases.

FUNGAL DERMATITIS

INTRODUCTION

There are over 100,000 types of fungi in the environment. Some of these are important pathogens in veterinary dermatology; however, most fungi do not cause disease in animals unless they are significantly immunocompromised (e.g., phaeohyphomycosis, hyalohyphomycosis, oomycosis, zygomycosis, etc.). This section will focus on the two most common types of fungal dermatoses in small animals (dermatophytosis and malasseziosis).

DERMATOPHYTOSIS

Definition/Overview

Dermatophytosis is an often overdiagnosed fungal infection of the skin, hair shaft, or claw by a keratin-loving (keratinophilic) fungal organism (termed dermatophyte). Dermatophytosis is a contagious and zoonotic disease.

Etiology

There are many species of dermatophytes that cause infection in dogs and cats. The three most common

are *Microsporum canis, Microsporum gypseum,* and *Trichophyton mentagrophytes*. The reservoir for *M. canis* is a cat, the reservoir for *M. gypseum* is soil, and the reservoir for *T. mentagrophytes* is a rodent.

Pathophysiology

Infection occurs most commonly by inoculation (e.g., clipper blades) or via entry through a compromised skin barrier (e.g., self-excoriation, abrasions, insect bites). Dermatophyte also produce fungal enzymes (proteases) that allow for further tissue penetration. The arthrospore is the infectious stage, and these are shed from infected animals into the environment where they are viable for greater than 12 months. Once the dermatophyte gains entry, hyphal invasion of skin, hair shafts, and claws leads to the development of clinical lesions. This is a self-limiting disease for most animals once the appropriate cell-mediated and humoral immune response is initiated. In cases of immunocompromised animals, the infection may persist. Rarely, some cats (e.g., Persian cats) may develop a unique form of disease (dermatophytic pseudomycetoma) characterized by nodular fungal dermatitis in the deep dermis and subcutis.

Clinical Presentation

Dermatophytosis has no age, breed, or sex predilection; however, young, debilitated, and chronically ill animals maybe be more likely to contract infection. Also, animals with an abnormal skin barrier (e.g., atopic dermatitis) may have an increased risk of infection. The most common clinical signs of infection include alopecia, crusting, scaling, broken hairs, and erythema (**Figure 18.23a, b**). Papules and pustules may be present. Occasionally, kerions (or localized, erythematous, raised nodules with ulceration) may develop when the immune response to the fungi is robust, and the fungi invade the dermis. Persian cats may develop a unique clinical presentation characterized by deep dermal/subcutaneous nodules (dermatophytic pseudomycetoma). Pain and pruritus are variable. This is a contagious disease, so other animals may be affected in the household. Keep in mind that many animals may serve as asymptomatic carriers, so in case of a positive animals, all in contact animals should be tested for dermatophytosis. This is a zoonotic disease, so people may become infected as well. Lesions present in an asymmetrical fashion. Lesions may be more common the face and thoracic limbs for *M. gypseum* and *T. mentagrophytes*

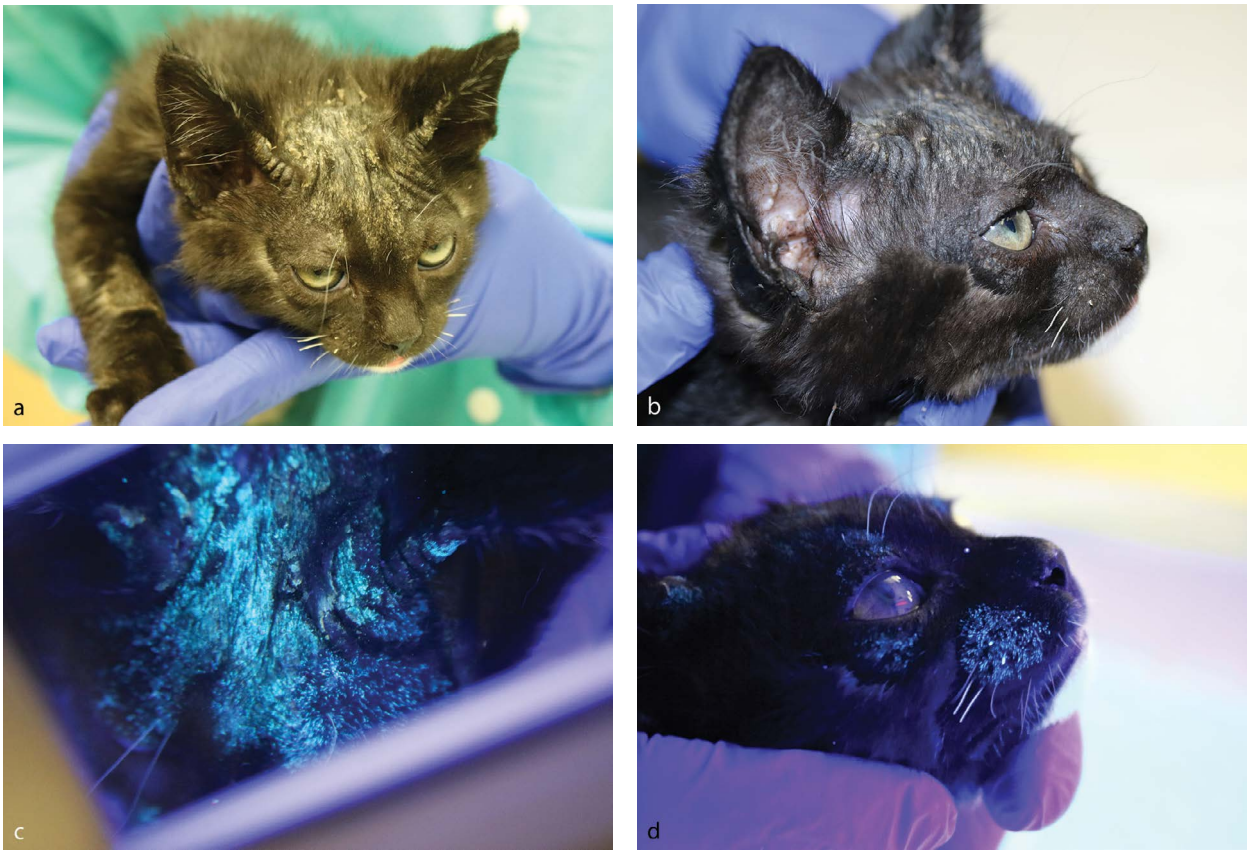

FIGURE 18.23 **(a)** Kitten with dermatophytosis characterized by alopecia, lichenification, scaling, and crusting of the dorsal head and pinnae. **(b)** Note the broken whiskers and hyperpigmentation of affected skin. **(c)** Scale and infected hairs demonstrating apple green fluorescence consistent with *Microsporum canis* infection. **(d)** Fluorescing hairs are the best to sample for dermatophyte culture and/or PCR testing.

due to the expected contact when digging in the soil or chasing rodents, respectively.

Differential Diagnoses

Other causes of folliculitis to consider include bacteria and *Demodex* spp. infections. For focal lesions, other differential diagnoses include abscess, injection site reaction, and ectoparasites. For widespread lesions, other differential diagnoses include allergic dermatitis (e.g., flea bite hypersensitivity, atopic dermatitis, adverse food reaction), telogen/anagen defluxion, psychogenic alopecia, autoimmune dermatoses (e.g., pemphigus foliaceus), or deep opportunistic bacterial/fungal dermatitis.

Diagnosis

There are several diagnostic tools that can be useful. Historical evidence of multiple in-contact animals with identical clinical lesions increases the suspicion of an infectious disease. Additionally, when owners develop similar crusting or erythematous lesions, the suspicion of dermatophytosis increases. Dermatophytosis is commonly overdiagnosed based on clinical lesions alone, so additional testing is required.

- *Wood's lamp:* Most *M. canis* isolates produce a metabolite that fluoresces bright green. Be sure the hair shaft, and not just the skin, is glowing (**Figure 18.23c, d**). Crusting, scaling, cloth fibers, medications, soaps, petroleum, and bacteria can glow (white to yellow) and cause a false-positive result.
- *Fungal culture:* Specialized fungal agars (e.g., DTM) for growing dermatophytes that contain phenol red are commonly used. This is a pH indicator that causes a red discoloration when dermatophytes grow and release alkaline metabolites. Other components of the culture are Sabouraud dextrose agar with added cycloheximide, gentamicin, and chlortetracycline to inhibit secondary growth of other fungi and bacteria. The interpretation of DTM cultures can be tricky if not constantly monitored. False-positive color change is possible, so perform cytological evaluation of all growing colonies to identify the dermatophyte species.
- Surface cytology from lesions usually reveals neutrophils and some macrophages. Occasionally, arthrospores are identified in heavily infected animals. Fine-needle aspirate of kerion or dermal nodules reveals pyogranulomatous inflammation and occasionally fungal hyphae and/or arthrospores.
- Trichography to evaluate for fungal hyphae within hair shaft and accumulation of arthrospores along or within hair shafts.
- Macerated tissue fungal culture is preferred for kerions or dermal nodular lesions.
- Dermatophyte PCR is a very sensitive and rapid technique for the identification of fungal DNA within or on hair shafts. This test does not prove fungi are living/viable, so be sure to pair this with a DTM culture for confirmation. Dermatophyte PCR is best used to make an initial, rapid diagnosis or to rule out dermatophytosis, while fungal cultures are more reliable for monitoring response to treatment and confirm the diagnosis.
- Histopathology is useful for kerions or dermal nodular forms of disease; however, they can aid in making the diagnosis of folliculocentric disease as well.

Management

While this is considered a self-limiting disease for most animals, treatment is pursued in most cases due to the zoonotic potential, with the main goal to reduce the amount of spores shed in the environment. Infected animals should be confined away from nonlesional, culture-negative housemates. A combination of topical and systemic therapy is useful to expedite time to improvement. Topical therapy helps limit transmission to people and other animals in the household by removing infectious arthrospores and hairs from the animal. Antifungal ingredients in topical therapies include lime sulfur, miconazole, ketoconazole, and enilconazole. Topical therapy can be applied as a dip or shampoo at least twice weekly and as a mousse, spray, or cream once to twice daily during active infection. Topical therapy is a safer alternative for young animals than systemic antifungal therapy. Systemic options include itraconazole, ketoconazole, fluconazole, terbinafine, and griseofulvin. Treatment is continued until two negative consecutive fungal cultures within 1 month from each other are achieved. Environmental decontamination to remove infected hairs is important to prevent transmission to other people or pets at home and prevent recurrence of infection. Daily vacuuming, steam cleaning, Swiffer dust wipes, accelerated hydrogen peroxide, bleach, and enilconazole are effective decontamination measures.

Dermatophytosis carries a good prognosis for cure; however, treatment can be frustrating in multianimal households. It is important to look for underlying causes of infection and initiate treatment if the disease is ongoing (e.g., allergies, stress, immunocompromise, etc.).

MALASSEZIA spp. DERMATITIS

Definition/Overview

This is a fungal skin infection due to an overgrowth of the yeast *Malassezia* spp. There are several species of *Malassezia* affecting dogs and cats, though the most common is *Malassezia pachydermatis*. Infections may cause intense pruritus due to hypersensitivity.

Etiology

Malassezia spp. yeast are normal commensals of the skin and ear canal. They prefer warm, dark, humid living conditions. As such, common locations include lip folds, interdigital skin, claw folds, ear canals, axillae, groin, perineal, and intertriginous skin. Diseases that alter normal skin conditions may make the skin more favorable for overgrowth of yeasts, including allergic

dermatitis (atopic dermatitis, food allergy, flea bite hypersensitivity), endocrinopathies (e.g., hypothyroidism, hyperadrenocorticism), and seborrheic dermatitis. Some dog breeds are overrepresented, including Basset Hound, Terriers, Poodles, American Cocker Spaniel, Shih Tzu, Dachshund, and English Setter.

Malassezia spp. overgrowth is less common in cats unless significant immunosuppression exists (e.g., FeLV/FIV positive cats, chronic glucocorticoid administration, and pemphigus foliaceus) or in case of allergic dermatoses.

Pathophysiology

The cause of *Malassezia* spp. overgrowth is unclear, though conditions that alter the normal skin environment causing increased lipid accumulation, temperature, or humidity may propagate overgrowth. Immunosuppression may contribute to loss of normal flora homeostasis.

Clinical Presentation

Malassezia spp. reside on the surface of the skin, and the most common clinical signs include pruritus, erythema, scaling, crusting, exudate, malodor, lichenification, and hyperpigmentation (Figure 18.24). Lesions occur more commonly in areas where *Malassezia* spp. reside (e.g., lip folds, ears, paws, claw beds, axillae, groin, tail folds, vulvar folds, etc.); however, lesions may be widespread in some cases.

Differential Diagnoses

Other causes of pruritus and erythematous dermatitis include allergic dermatitis (atopic dermatitis, flea bite hypersensitivity, food allergy), dermatophytosis, demodicosis, cutaneous adverse drug reaction, epitheliotropic lymphoma, sarcoptic and demodectic mange, ectoparasites, endocrinopathy (e.g., hypothyroidism), and idiopathic keratinization defects.

FIGURE 18.24 Epidermal dysplasia in a West Highland White Terrier characterized by severely lichenified and dysplastic skin with hyperpigmentation, erythema, alopecia, and crusting. Skin is greasy to the touch (seborrhea oleosa), and abundant *Malassezia* spp. organisms are present on skin cytology.

Diagnosis

Diagnosis is achieved easily through cytological evaluation of the affected skin for the peanut-shaped yeast. In some animals thought to be hypersensitive to *Malassezia* spp., very few yeast present on cytology could represent a significant clinical finding warranting treatment.

Management

The organisms live on the surface of the skin, so topical therapy is an important management tool. Antifungal ingredients in topical therapies include lime sulfur, miconazole, ketoconazole, terbinafine, and enilconazole. Topical therapy can be applied as a dip or shampoo at least twice weekly and as a mousse, spray, or cream once to twice daily during active infection. Systemic therapy may be needed in widespread, severe infections or in animals with suspected *Malassezia* spp. hypersensitivity. Systemic antifungal options include itraconazole, ketoconazole, fluconazole, and terbinafine.

Malassezia spp. dermatitis is a secondary dermatosis, so identification and management of the primary disease process is important to maintain treatment success.

PARASITIC DERMATOSES

Parasitic skin diseases are quite common in companion animals. Along with allergies and some infections, ectoparasites are the most common cause of pruritus in dogs and cats. Many parasitic dermatoses are seen in clinical practice; however, for brevity, the following will be discussed in this chapter: Canine and feline demodicosis, canine scabies, otoacariasis, cheyletiellosis and trombiculosis.

CANINE DEMODICOSIS

Definition/Overview

Canine demodicosis is one of the most common cutaneous parasitic diseases affecting young dogs. Canine demodicosis can be juvenile or adult onset, and it can be localized or generalized. The ability to differentiate the various forms is important when considering treatment options and prognosis. If untreated, the generalized form can become a very serious dermatological disease. For this reason, an early diagnosis is essential for successful treatment. A genetic predisposition for disease severity is suspect, so affected dogs should not be used for breeding purposes.

Etiology

Canine demodicosis is caused by species-specific demodectic mites living in the hair follicles or sebaceous glands of mammals. In dogs, demodicosis is due to two mites: *Demodex canis* and *D. injai*. *D. injai* is double

the length of *D. canis*. A hereditary "mite-specific" immune defect has been reported in affected dogs.

Pathophysiology

The exact pathogenesis of canine demodicosis is not clear. However, it is hypothesized, and in part demonstrated, that a defect in CD4+ T cells associated with an increase in oxidative stress contributes to the development of juvenile-onset demodicosis. Adult-onset demodicosis can be associated with systemic immunosuppression, either iatrogenic or associated to systemic diseases (e.g., neoplasia, Cushing's disease, etc.).

Clinical Presentation

The clinical presentation of canine demodicosis is extremely variable and is based on which mite is present: *D. canis* or *D. injai*. The typical presentation of demodicosis includes the presence of scales, erythema, well-demarcated alopecia, and folliculitis (Figure 18.25a, b). With time, it progresses to furunculosis with draining tracts, crusts, diffuse alopecia, and pruritus (Figure 18.25c, d). This latter sign is present mainly because of the presence of secondary bacterial infections. Lesions may appear anywhere on the body; however, face, ventrum, and extremities are the most common. Canine demodicosis caused by *D. injai* can include clinical differences like seborrhea oleosa on the dorsal midline and pruritus.

The differentiation in localized versus generalized forms is somehow arbitrary. In accordance to recently published guidelines, the localized form of demodicosis includes the presence of no more than five affected areas with a diameter less than 2.5 cm. If an entire body region (e.g., head, trunk, extremities) or more than one paw is affected, the demodicosis is classified as generalized. In juvenile onset, about 90% of the localized forms will disappear spontaneously, whereas 10% will progress to the generalized form. Canine demodicosis can also be classified as juvenile and adult onset. This distinction is based on the age of onset: Juvenile (18–24 months and adult >24 months.

FIGURE 18.25 **(a)** Shih Tzu with atopic dermatitis that received numerous long-acting steroid injections developed adult-onset generalized demodicosis localized to the ventral thorax and all four paws. Note the matting of the haircoat within purulent exudate, crusts, erythema, and hemorrhage. **(b)** The haircoat is shaved to reveal numerous erythematous to hemorrhagic papules and pustules with fistulation and ulceration of the skin. **(c)** Adult *Demodex canis* mite observed on skin scrapings from the ventral thorax. **(d)** Two weeks into treatment with topical antibacterial shampoo, systemic antibiotics, and oral isoxazoline treatment for the demodicosis.

Differential Diagnoses

Demodicosis is pleomorphic and can resemble many skin diseases. Bacterial (superficial pyoderma) and fungal (dermatophytosis) folliculitis are the most important differentials. Other differentials may include autoimmune diseases (e.g., pemphigus foliaceus, alopecia areata, sebaceous adenitis, rabies vaccine vasculopathy, cutaneous adverse drug reactions, sterile granuloma/pyogranuloma syndrome, etc.), and neoplasia (cutaneous T-cell lymphoma). When associated with secondary infections, allergies should also be considered, specifically when *D. injai* is isolated.

Diagnosis

The gold standard for a diagnosis of canine demodicosis is the presence of mites. This can be achieved in a variety of ways. The most effective test is deep skin scraping (**Figure 18.11a–e**), followed by trichography (hair plucking and evaluation) and histopathology. If correctly performed, deep skin scraping is able to rule out or rule in canine demodicosis. Trichography is less sensitive but equally effective if furunculosis and draining tracts are present. In addition, trichography is the recommended and safest test to sample sensitive areas (e.g., periocular, perilabial, interdigital). Histopathology should be reserved for granulomatous demodicosis and situations when skin scraping/trichography would not be as effective (e.g., severely lichenified skin, mucinotic skin of the Shar Pei).

Cytological evaluation of skin scrapings and hair plucks promotes identification of the different mite life stages. In addition, the differentiation among the life stages is essential to monitor treatment success (presence of immature forms [eggs and larvae] is indicative of an active disease; only adults may be indicative of a less active disease).

Management

Nowadays, many treatment options are available to treat canine demodicosis. However, very few of them are labeled for such disease. The oldest and only treatment labeled for canine demodicosis in the United States is amitraz. This is applied topically as a dip or sponged onto the skin weekly. In Europe, along with amitraz, weekly application of topical moxidectin (Advocate/Advantage Multi) is also labeled for demodicosis. Other equally effective, although not approved, treatments for demodicosis include daily oral ivermectin, daily oral moxidectin, and daily oral milbemycin. More practical treatment options include monthly administration of oral afoxolaner, sarolaner, and lotilaner as well as bimonthly or biquarterly administration of fluralaner.

Regardless of the therapy selected, the treatment for canine demodicosis should continue until obtaining two negative skin scrapings 1 month apart (or three negative skin scrapings 2 weeks apart). After that, the patients should be monitored for relapse via skin scrapings for 1 year (e.g., at 1, 3, 6, and 12 months post second negative scraping). Long-term treatment success is dependent on identification and correction of any immunosuppressive underlying cause. Secondary bacterial infections should also be properly treated when present.

Corticosteroids and oclacitinib are contraindicated in cases of canine demodicosis or in dogs with a history of demodicosis.

FELINE DEMODICOSIS

Definition/Overview

Feline demodicosis is an uncommon parasitic disease. Similar to canine demodicosis, it is caused by mites belonging to the genus *Demodex*. *Demodex gatoi* has a moderate geographic distribution, with most cases of feline demodicosis reported in Texas and the southeastern United States. *Demodex cati* is a very uncommon skin disease.

Etiology

Three morphologically different *Demodex* mites have been associated with feline demodicosis: *Demodex cati*, *D. gatoi*, and *Demodex* spp. (unnamed). The first one, *D. cati*, is a follicular mite very similar to *D. canis* in dogs, whereas *D. gatoi* is much shorter than *D. cati*. The third species, still unnamed but genetically different from the other two, is morphologically in between *D. cati* and *D. gatoi*.

Pathophysiology

Very little information is available on the pathogenesis of feline demodicosis. In particular, *D. cati* is quite uncommon, and it is generally associated with systemic immunosuppression. In particular, coinfections with FIV and FeLV are commonly reported. On the opposite, immunosuppression has not been associated with *D. gatoi*.

Clinical Presentation

Feline demodicosis can vary in clinical presentation based on the mite inducing the disease. For example, feline demodicosis caused by *D. cati* is very subtle and characterized by well-demarcated alopecia and erythema around the eyes, lips, nares, and ear tips (**Figure 18.26a, b**). Sometimes alopecia can be seen on the front limbs. On the contrary, *D. gatoi* is mainly associated with poorly demarcated alopecia and pruritus of the trunk and ventrum, and it is highly contagious between cats.

Differential Diagnoses

Differential diagnoses may include pruritic and nonpruritic skin diseases depending on which mite is present. For *D. gatoi*, allergies and other parasitic diseases (e.g., *Cheyletiella* spp., *Notoedres cati*, *Otodectes*

FIGURE 18.26 (a) Crusting and alopecia of the dorsal rostral muzzle in a cat receiving inhalant steroids for feline asthma. **(b)** Complete alopecia of the pinnae in the same cat. **(c)** *Demodex* spp. mites observed on skin scrapings and trichogram from the muzzle and pinnae.

cynotis) should be highly suspected. For *D. cati*, bacterial and fungal (dermatophytosis) folliculitis should be prioritized.

Diagnosis

Skin scraping is the gold standard for diagnosis feline demodicosis (Figure 18.26c). Skin scraping should be superficial for *D. gatoi* and deep for *D. cati*. In addition, hair plucking (trichography) can be used for diagnosing *D. cati*, whereas tape can be used instead of superficial skin scraping for *D. gatoi*. Fecal flotation can also be used to evaluate the parasite when cats are excessively licking. Because of the highly contagious nature of *D. gatoi*, other cats in the household should be tested, as they can serve as asymptomatic carriers.

Management

The management also differs based on which mite is found on skin scrapings. For *D. gatoi*, the gold standard treatment is weekly application of 2% lime sulfur for 6–8 consecutive weeks. However, recently the use of a topical application containing moxidectin/imidacloprid or fluralaner has been shown to be equally effective. All the cats in the household should be treated given the high percentage of transmission and the potential for asymptomatic carriers.

For *D. cati*, the treatment is very similar to canine demodicosis. Oral avermectins as well as topical moxidectin can be used. Amitraz can also been used, although it can be associated with severe side effects in cats and for this reason should be used as last option. Oral fluralaner was reported effective for treating generalized demodicosis caused by *D. cati* in a single case report.

CANINE SCABIES

Definition/Overview

Canine scabies (sarcoptic mange) is a very contagious species-specific parasitic disease. Sarcoptic mange is mainly reported in dogs; however, cats and wildlife canids can also be affected. This parasitic skin disease is one of the most pruritic skin diseases affecting dogs.

Etiology

The main parasite causing canine scabies is *Sarcoptes scabiei* var. *canis*.

Pathophysiology

The clinical presentation is due to a severe hypersensitivity reaction to the mites and mite feces. The pruritus is also associated with the actual presence of the mite burrowing in the epidermis. Because of the presence of a hypersensitivity reaction, most dogs are severely affected; however, some asymptomatic carriers with none or minimal pruritus can be observed. A cross-reactivity with other mites (e.g., house dust mites) has also been reported.

Clinical Presentation

Canine scabies is mainly characterized by an extreme pruritus distributed on the ventral aspect of the body. Other commonly affected areas include the ear margins, elbows, hocks, and paws (Figure 18.27a–c). Common clinical lesions observed include excoriations, scales, poorly demarcated alopecia, and yellow crusts. A pinnal-pedal reflex can be elucidated in 25%–90% of the affected dogs. It is important to remember that the pinnal-pedal reflex is not pathognomonic for scabies and can be elicited with other pruritic skin diseases.

FIGURE 18.27 **(a)** Stray puppy with severe pruritus demonstrating classic distribution pattern for canine scabies. Note the alopecia, lichenification, erythema, hyperpigmentation, scaling, crusting, and ulceration of the muzzle, pinnae, lateral elbows, lateral hocks, and distal extremities. **(b)** Magnified image of the hock of the same puppy. **(c)** *Sarcoptes* spp. mites observed on superficial skin scrapings.

Differential Diagnoses

Differentials should include other parasitic diseases (e.g., *Otodectes cynotis*, *Cheyletiella* spp., *Pelodera strongyloides*), allergies, and secondary pyoderma or *Malassezia* dermatitis.

Diagnosis

The gold standard for the diagnosis of sarcoptic mange is the evidence of the parasite, or part of it, on a superficial skin scraping. However, this is a poorly sensitive test considering a positive skin scraping is only present in up to 50% of the affected dogs. For this reason, the ultimate diagnosis occurs after treatment with appropriate miticidal medications followed by a resolution of the clinical signs. An ELISA serology test is also available, although more validation of this methodology is needed.

Management

A variety of topical and systemic treatment options are available for this parasitic disease. Topical 2% lime sulfur and systemic (or topical) avermectins are the most effective and commonly used products. More recently, the use of fluralaner, afoxolaner, sarolaner, and lotilaner demonstrate equally efficacy after a single dose. Despite the treatment implemented, an effective protocol dictates the use of a miticidal medication for at least 6 weeks. All in-contact animals should be treated because this is a contagious disease, and some animals may be asymptomatic carriers.

OTODECTES spp. ACARIASIS

Definition/Overview

Otodectes spp. acariasis (otoacariasis) is a fairly common parasitic skin disease affecting cats; however, dogs can also be affected. It is found mainly in young or shelter animals. The disease is very contagious and has zoonotic potential.

Etiology

Otodectes spp. acariasis is caused by a psoroptid mite, *Otodectes cynotis* (ear mites) (Figure 18.28a). These mites are mainly harbored in the external ear canal; however, extra-auricular localization has been reported.

Pathophysiology

Ear mites live in the external ear canal feeding on cellular debris and tissue fluid. The presence of the mites

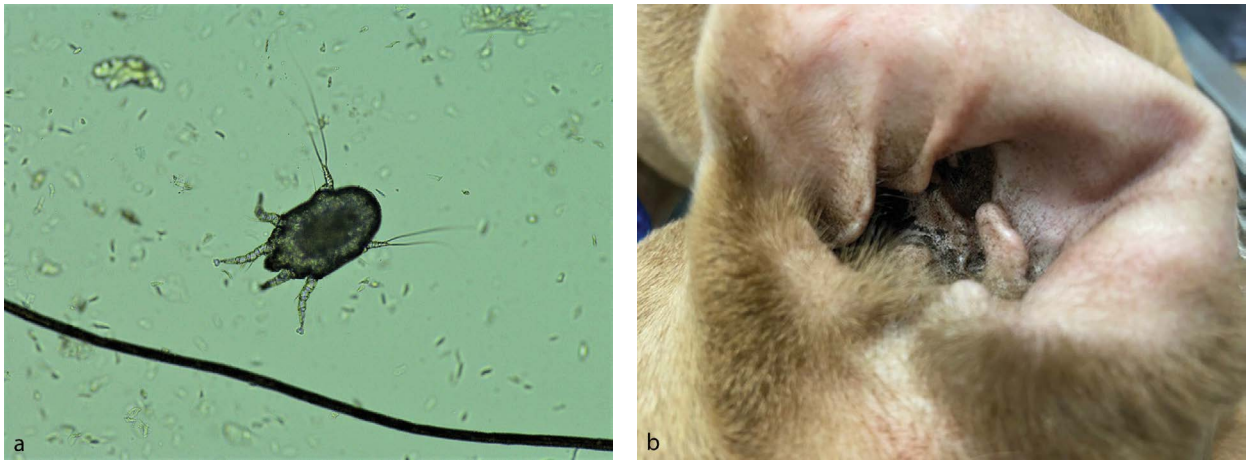

FIGURE 18.28 (a) *Otodectes* spp. mite identified from otic debris at 10× magnification. **(b)** Classic "coffee grounds" dry debris in the entrance of the external ear canal of a dog affected by *Otodectes* spp. (*Courtesy of Dr. Schaer*.)

feeding on the epidermis induces irritation and inflammation, leading to an overproduction of cerumen.

Clinical Presentation

The clinical presentation of *O. cynotis* is very characteristic. In fact, otoacariasis is associated with variable ear pruritus and head shaking. In addition, the presence of a black, dark brown, dry cerumen (coffee grounds) is very characteristic (Figure 18.28b). Because of the extra-auricular location of the mites, pruritus, papules, excoriations, and crusts can be observed in other locations as well (e.g., limbs, tail, and perianal).

Differential Diagnoses

Differentials should include any other cause of acute otitis externa, allergies, and secondary bacterial and yeast otitis/dermatitis. Dermatophytosis should also been considered in cases of extra-auricular localization.

Diagnosis

The diagnosis of otoacariasis is made by visualization of the mites on a skin scrapings or ear swabbing. This latter should be collected via a cotton-tipped applicator or a curette, and the material diluted in mineral oil. Ear mites are generally easily visualized; however, they may be difficult to see in the presence of an abundant inflammatory response.

Management

Systemic miticidal (e.g., avermectins) should be preferred to topical (aural) (e.g., thiabendazole) medications because of the potential extra-aural localization of the mites. Treatment should be performed for at least 6 weeks. Although not tested, fluralaner, afoxolaner, sarolaner, and lotilaner may potentially be useful treatment options as well. Because of the contagious nature of the disease, all in-contact animals should also be treated.

CHEYLETIELLOSIS

Definition/Overview

Cheyletiellosis ("walking dandruff") is a relatively common, pruritic skin disease mainly present in geographic areas where there is decreased use of flea prevention. Both dogs and cats are equally affected. A zoonotic potential is present for this mite.

Etiology

Cheyletiellosis is caused by multiple species of the genus *Cheyletiella* with minimal species specificity (Figure 18.29a). The most common species include *Cheyletiella yasguri* (dogs), *C. blakei* (cats), and *C. parasitovorax* (rabbits).

Pathophysiology

Cheyletiella mites live in the very superficial layers of the epidermis, feeding on epidermal debris and occasionally on tissue fluid or lymph. Eggs are laid and glued to the hairs.

Clinical Presentation

Symptoms are variable and can be associated with intermittent pruritus and alopecia. In addition, mild-to-severe scaling (Figure 18.29b), papules, and crusts can be present as well. Such lesions are mainly localized to the dorsal and ventral trunk, although other body regions can be affected.

Differential Diagnoses

Differentials should include other parasitic diseases (e.g., demodicosis, otoacariasis, and pediculosis), allergies, or infections (dermatophytes).

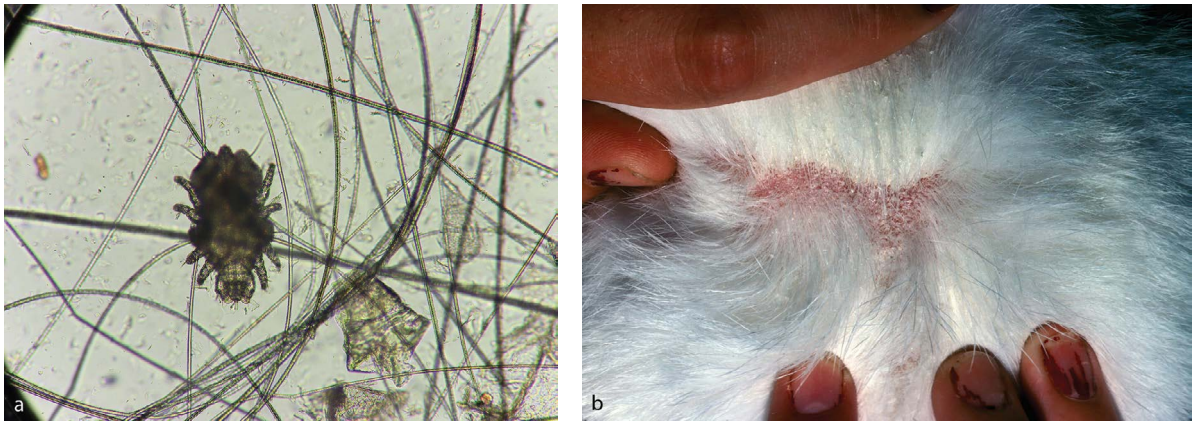

FIGURE 18.29 **(a)** *Cheyletiella* spp. mite identified on tape. **(b)** The separated fur on this rabbit illustrates the excess scaling typical of *Cheyletiella* spp. (b, *Courtesy of M. Schaer.*)

Diagnosis

The definitive diagnosis is based on direct observation of the mites or the eggs. This can be done with the naked eye by placing the "scales" on a dark paper and observing the mites moving ("walking dandruff"). An alternative is the visualization of the mites under the microscope by placing the scales in mineral oil. Importantly, a negative test does not rule out cheyletiellosis.

Management

Because of the ability for these mites to be transmitted via fomites, it is imperative to treat bedding and fomites with pyrethroid-based products. All affected and in-contact animals should also be treated. Most of the commercially available flea preventatives will be effective against *Cheyletiella* spp. However, topical 2% lime sulfur and systemic avermectins can also be used. The treatment should be implemented for 6–8 weeks.

TROMBICULOSIS

Definition/Overview

Trombiculosis is an uncommon pruritic skin disease affecting dogs and cats. It is caused by immature larvae of mites of the family Trombiculidae. Different species have been reported in Europe and in the United States. They are commonly knowns as "chiggers."

Etiology

Trombiculosis is caused by the six-legged larval stage of mites *Neotrombicula autumnalis* (European chigger), *Eutrombicula alfreddugesi* (North American chigger), *Walchia americana*, *Leptotrombidium subquadratum* (South Africa), and *Straelensia cynotis*.

Pathophysiology

The adult mites live in decaying plant material, whereas the larvae feed on animals.

Clinical Presentation

Chiggers can be extremely irritating and induce the rapid development of papules, crusts, and variable pruritus. Larvae are visible with the naked eye as red-orange dots adhering to the skin. The most commonly affected areas are the head (periaural), paws, and ventrum.

Differential Diagnoses

The presence of the red-orange larvae is quite characteristic. However, other causes of pruritus, including ectoparasites and allergies, should be considered. When papules and crusts occur, secondary infections should also be considered as viable differentials.

Diagnosis

The visualization of the red-orange larvae is diagnostic. However, they can be confirmed via microscopic examination to better identify the six-legged larvae.

Management

The use of most commercially available flea preventatives is effective to treat chiggers. In cases of extreme pruritus, a short course of corticosteroid may be indicated. For long-term management and prevention, the routine application of flea preventative is recommended.

ALLERGIES

Cutaneous hypersensitivity disorders (allergies) are very common in dogs and cats. Among others, flea-bite hypersensitivity, atopic diseases, and food allergy represent the majority of the hypersensitivity disorders seen in small animal practice. The pathogenesis of such disorders is not completely understood; however, the clinical signs are associated with a re-exposure to allergens to which the pet has been previously sensitized.

CANINE ATOPIC DERMATITIS

Definition/Overview

Canine atopic dermatitis (AD) is a genetically inherited inflammatory skin disease characterized by pruritus. AD generally is associated with an increase in allergen-specific IgE. However, cases with identical clinical signs but not associated with IgE also are present (canine atopic-like dermatitis). In temperate geographic regions, AD represents the second most common allergy in dogs, second only to fleabite hypersensitivity. Because of the strong genetic component, dogs with AD should not be used for breeding purposes.

Etiology

Canine AD is a multifaceted skin disease characterized by a defect of the skin barrier as well as an abnormal immune response to otherwise innocuous environmental allergens. Among others, the most common allergen for canine AD is house dust mite (*Dermatophagoides farinae* and *D. pteronyssinus*).

Pathophysiology

The pathophysiology of canine AD is not completely clear. However, in human AD, the most accredited theory hypothesizes the presence of a genetically predetermined defect in the skin barrier allowing the penetration of environmental allergens. Once in the skin, allergens stimulate the local immune response via the activation of dendritic cells (Langerhans cells and dermal dendritic cells), which trigger an immune response associated with T-helper type (Th) 2 lymphocytes. These produce specific cytokines, like interleukin (IL)-4 and IL-13, that inhibit the production of Th1 and regulatory cytokines such as IL-10 and transforming growth factor beta. This abnormal immune response leads to the activation and degranulation of cutaneous mast cells and other inflammatory cells with an increase in skin barrier damage initiating a vicious cycle of increased allergen penetration and pro-inflammatory immunological response. In chronic cases of AD, the local immune response switches from a predominantly Th2 to a Th1 milieu, which perpetuates the skin inflammation determining the clinical signs. Type 1 and 4 hypersensitivity reactions are associated with AD.

Clinical Presentation

Canine AD is a chronic skin disease that affects young to adult dogs with an average age of 1–3 years. However, cases as early as 6 months and as late as 6 years have been reported. A strong breed predisposition has been reported in Terriers and Retrievers. Canine AD is characterized by mild-to-severe pruritus mainly localized to head, ventrum, and extremities. Clinical signs of AD can be seasonal or nonseasonal depending upon the causing allergen(s); however, most seasonal presentations of disease gradually progress to nonseasonal. The most common clinical signs include pruritus, erythema, papules, and excoriations (Figure 18.30a–c). Chronic disease is

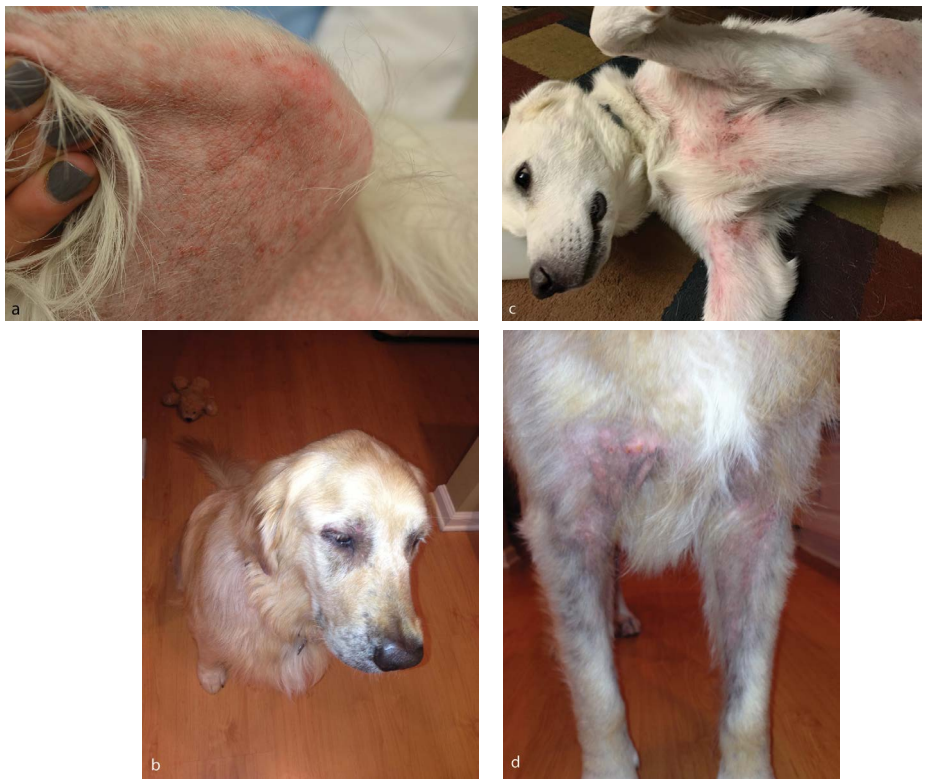

FIGURE 18.30 Classic lesions of atopic dermatitis in a dog. **(a)** Erythema, non-well-demarcated alopecia, papules, crusts, and hyperpigmentation on the flexor surface of the elbow both antebrachia, **(b)** periocular region, **(c)** medial aspect of the chest, **(d)** and thigh.

associated with lichenification and hyperpigmentation with alopecia (Figure 18.30d). The most common complications associated with AD include pyoderma, otitis externa, and *Malassezia* spp. dermatitis, with related clinical signs. Furthermore, association with other hypersensitivities (e.g., fleabite and food hypersensitivity) is common and expected.

Differential Diagnoses

Any other pruritic disease should be included in the differential list for canine AD. Among others, sarcoptic and demodectic mange, other parasitoses (e.g., cheyletiellosis, pediculosis), other allergies (food, contact, and fleabite), *Malassezia* spp. Dermatitis/otitis, bacterial pyoderma/otitis, and, occasionally, autoimmune dermatoses (e.g., pemphigus foliaceus, drug eruption) and epitheliotropic lymphoma.

Diagnosis

The diagnosis of canine AD is based on compatible history and clinical signs and after excluding any other pruritic skin disease. Secondary skin and ear infections are extremely common and should be considered as exacerbating factors for pruritus and inflammation.

Management

The best treatment for AD is allergen avoidance; however, this is impractical and extremely difficult to achieve. There are several potential treatment options to manage AD in dogs, although none of these can completely resolve (cure) the disease.

Allergen-specific immunotherapy (ASIT) is the most recommended long-term treatment by dermatologists for AD in dogs. ASIT consist of a mixture of allergens, relevant to the specific pet, that are administered either subcutaneously or sublingually. This is a lifelong treatment and can take up to 9–12 months before reaching full efficacy. In fact, when discontinued, AD relapses in most of the treated dogs. The formulation of ASIT is determined by allergy testing results via intradermal or serology testing. By themselves, positive results to either test are not considered diagnostic. An overall success rate, defined as the ability to decrease other symptomatic medications, of 65%–70% have been reported for ASIT.

A common alternative to ASIT is symptomatic therapy, which commonly is used concurrently with ASIT for more successful management of the disease. The main symptomatic therapy medications include corticosteroids, modified microemulsified cyclosporine, oclacitinib, and lokivetmab. Furthermore, less effective but commonly used as adjuvant medications are antihistamines (e.g., cetirizine, hydroxyzine, diphenhydramine, etc.), fatty acids, and pentoxifylline.

Fundamental for successful treatment is the use of topical anti-inflammatory/antipruritic, antimicrobial, and moisturizing agents. Frequent baths are essential not only to remove environmental allergens from the skin but also to rehydrate the skin, remove microorganisms, and restore the skin barrier.

FELINE ATOPIC SKIN SYNDROME

Definition/Overview

Feline atopic skin syndrome (FASS) is the feline counterpart of canine AD. Although extremely common, much less is known about FASS when compared to canine AD. Similar to canine AD, FASS is an inherited skin disease associated with an exaggerated immune response to otherwise innocuous environmental allergens.

Etiology

The etiology of FASS is very similar to canine AD.

Pathophysiology

Although much less is known about the pathophysiology of FASS, the most accredited theories hypothesize similar defects present in canine AD. Similar to canine AD, type 1 and 4 hypersensitivity reactions have been hypothesized for FASS.

Clinical Presentation

Likewise to canine AD, FASS is a chronic skin disease that affects young to adult cats with an average age of 1–3 years. A strong breed predisposition has not been determined, although domestic short-haired and long-haired cats, along with Abyssinians, are overrepresented. The clinical presentation of FASS is highly variable. Most of the affected cats express pruritus as main clinical sign (licking, pulling hair, chewing, rubbing); however, cats with mild to no pruritus are present. Clinical manifestations unique to cats with hypersensitivities (not only FASS) include eosinophilic plaques, indolent/rodent ulcer, linear and oral granulomas (Figure 18.31a, b). These presentations altogether form the eosinophilic granuloma complex. Other clinical manifestations include head and neck pruritus, self-inflicted alopecia, and military dermatitis. Furthermore, indicative of pruritus is the frequently observed presence of hairballs.

Clinical signs of FASS can be seasonal or nonseasonal depending upon the causing allergen(s); however, when starting as a seasonal disease, it gradually progresses to nonseasonal. The most common complications associated with FASS include pyoderma and *Malassezia* spp. dermatitis, with related clinical signs. Furthermore, association with other hypersensitivities (e.g., flea bite and food hypersensitivity) are common and expected.

Differential Diagnoses

Differentials for FASS vary based on the clinical signs. In general, other allergies should be included in the differential list. In addition, parasitic diseases, like feline

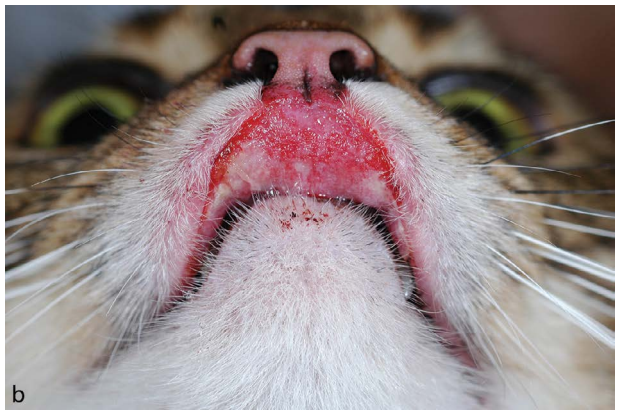

FIGURE 18.31 (a) Alopecic, eroded, erythematous plaques on the later thorax of a cat with eosinophilic granuloma complex (eosinophilic plaques). **(b)** Large ulcer on the dorsal aspect of the lip in a cat with eosinophilic granuloma complex (indolent ulcer).

sarcoptic (*Notoedres cati*) and demodectic (*Demodex gatoi*) mange, as well as otoacariasis (*Otodectes cynotis*) and cheyletiellosis should also been considered. Finally, dermatophytosis, skin infections (bacterial and *Malassezia*), viral dermatoses, and autoimmune diseases (e.g., pemphigus foliaceus) should also been included as potential differentials.

Diagnosis

As in canine AD, the diagnosis of FASS is based on compatible history and clinical signs after ruling out any other differential diagnosis listed previously.

Management

As in dogs, the best treatment for FASS is allergen avoidance. However, this is impractical and extremely difficult to achieve. Treatment options for FASS are available, although less in number.

ASIT is recommended as best potential long-term treatment for FASS. Similar to dogs, ASIT can be administered either subcutaneously or sublingually, although this latter option is much less utilized because of limitations due to the species (ability to administer it directly into the mouth). This is a lifelong treatment and can take up to 9–12 months before reaching full efficacy. As in dogs, the formulation of ASIT is based on allergy testing. These can be administered via intradermal or percutaneous test and via serology. By themselves, positive results to either test are not considered diagnostic.

Symptomatic therapy is the most used treatment option for FASS. The main symptomatic therapy medications include corticosteroids and cyclosporine. Although not labeled for cats, pharmacokinetic and safety studies for oclacitinib in cats have been published recently. Furthermore, less effective but commonly used medications include antihistamines (e.g., cetirizine, hydroxyzine, diphenhydramine, etc.), fatty acids, and pentoxifylline.

Fundamental for successful treatment is the use of topical anti-inflammatory/antipruritic, antimicrobials, and moisturizing agents. Because of the limitations intrinsic to the species, baths may not be feasible in some cats; thus, the use of leave-on mousse and sprays are used more commonly.

FLEABITE HYPERSENSITIVITY

Definition/Overview

Fleabite hypersensitivity is the most common allergy in dogs and cats living in temperate areas. However, it is quite uncommon in arid and high-altitude regions. Clinical signs are associated with an intermittent but constant exposure to flea bites. The re-exposure to minimal amounts of flea saliva (few bites) is enough to trigger severe clinical signs in dogs and cats.

Etiology

Fleabite hypersensitivity is associated with the exposure to flea saliva. Multiple allergens of different molecular weights have been identified in affected dogs and cats. The most common flea associated with this type of hypersensitivity is *Ctenocephalides felis felis*.

Pathophysiology

As in AD, the pathophysiology of flea bite hypersensitivity is complex and involves multiple cell types. A hypersensitivity reaction type 1 and 4 is associated with flea bite hypersensitivity. A large involvement of eosinophils and mast cells has been demonstrated in the first few days after exposure. An increase in total and allergen-specific IgE is also evident in affected dogs. A mixed inflammatory response, involving cytokines of both Th1 and Th2 response, have been detected in the blood of allergic dogs, although a clear predominance of Th2 cytokines was seen. Detailed pathophysiological information on flea bite hypersensitivity in cats is lacking; however, strong similarities are hypothesized between dogs and cats.

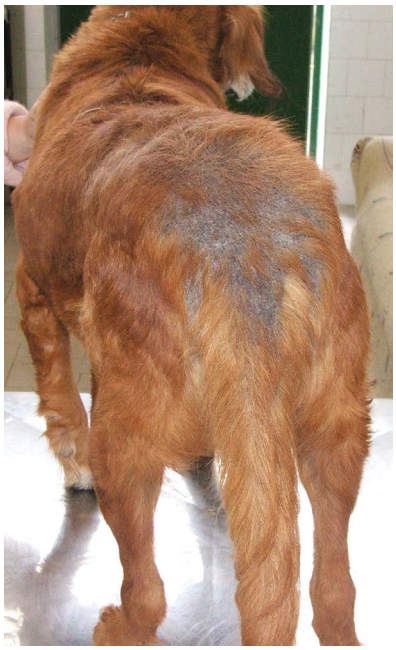

FIGURE 18.32 Alopecia, non-well-demarcated alopecia, erythema, and hyperpigmentation on the rump of a dog with flea allergy dermatitis.

Clinical Presentation

Fleabite hypersensitivity can occur in dogs and cats of any age and breed. Fleabite hypersensitivity is characterized generally by a lack of seasonality, although seasonal exacerbations, mainly in the warmer seasons, can occur. The classic clinical presentation of flea bite hypersensitivity in dogs is highly characteristic. This includes the presence of papules, erythema, alopecia, and pruritus mainly localized to the rump and base of the tail areas (Figure 18.32). With chronicity, lichenification and hyperpigmentation occur, and the lesions tend to extend to the whole back half of the body (Figure 18.32). In some cases, it is evident the presence of highly pruritic nodules in those areas as well. Generalized pruritus can occur in more chronic or severe cases.

In cats, this type of hypersensitivity is clinically almost indistinguishable from the others. The presence of military dermatitis is generally more evident in flea bite hypersensitivity than other allergies, but its presence cannot rule out other hypersensitivity reactions. Cats are generally presented for excessive grooming, pruritus, manifestations of the eosinophilic granuloma complex, excoriations, alopecia, and erythema. The most affected areas of the body include rump, abdomen, and neck. The frequent occurrence of hairballs suggests a highly pruritic cat.

As in other hypersensitivities, the insurgence of skin infections (bacterial and/or *Malassezia*) is present in affected dogs and cats.

Differential Diagnoses

Although in dogs the classic clinical presentation is highly suggestive of fleabite hypersensitivity, other allergies and parasites need to be ruled out in chronic and generalized cases. In cats, because of the high similarity of the clinical signs among allergies, FASS, food allergy, and parasites need to be excluded. Diseases like cheyletiellosis, pediculosis, sarcoptic and demodectic mange, trombiculosis, ear mites, and dermatophytosis have to be considered as likely differentials in dogs and cats affected by flea bite hypersensitivity.

Diagnosis

The diagnosis of fleabite hypersensitivity is mainly based on historical and clinical findings. However, the ultimate diagnosis occurs with resolution of the clinical signs after flea eradication. This can take up to 9–12 weeks before occurring. The presence of fleas or flea feces as well as the presence of *Dipylidium caninum* are highly supportive of a fleabite hypersensitivity. However, their absence is not enough to rule out this hypersensitivity. Allergy testing (intradermal or serology) can be used as valid aids to support the diagnosis but are not enough to make a definitive diagnosis by themselves.

Management

The management of fleabite hypersensitivity can be long and frustrating for pet owners. In the environment, fleas are extremely common. To achieve successful management, it is important to not only control the adult population of fleas but also the immature life stages in the environment. Nowadays, many insecticides are available on the market, and most of those are very effective and safe for dogs and cats. The use of adulticides along with insect growth regulators is mandatory to achieve full control of the disease. In some cases, an increased frequency of the applications (e.g., every 2 weeks) is also recommended in affected pets. If a repellent can be used, it should be implemented in affected pets. Furthermore, it is fundamental to ensure that all the pets in the household are on an effective flea preventative.

In the cases with the presence of secondary skin infections, this should be properly treated. In addition, the use of anti-inflammatory and/or antipruritic medications are highly recommended to manage the pruritus and inflammation.

FOOD ALLERGY

Definition/Overview

Food allergy is less common than flea bite hypersensitivity and AD/FASS. It is nonseasonal and associated with hypersensitivity to dietary substances. Food hypersensitivity is virtually identical to food intolerance, with the only difference being a lack of an immune response in the latter. A genetic component, although not confirmed, is highly suspected.

Etiology

Food allergy is associated with an abnormal immune response to ingested food ingredients. The most common allergens include proteins and glycoproteins. The natural protein conformation is essential in triggering the immune response. For this reason, reactions to raw ingredients may change once proteins are cooked. The most common allergens include protein from meat, milk, soy, and fish. Immune reaction to carbohydrates is much less common.

Pathophysiology

Compared with AD, much less is known about food allergy in dogs and cats. However, alterations of the gastrointestinal mucosal barrier, local immune system, oral tolerance, and structure of the allergens play a significant role in the sensitization process. In healthy pets, ingested allergenic substances are generally water soluble and degraded by the normal digestive process. In affected pets, allergenic proteins remain intact and are absorbed and recognized as foreign from the local immune system. A hypersensitivity reaction type 1, 3, and 4 is suspected to be associated with food allergy.

Clinical Presentation

Food allergy can affect any breed, although Terriers and Retrievers are overrepresented. Most commonly affected pets are less than 1 year of age or are elder pets. Clinical signs are indistinguishable from AD/FASS. In fact, a complete overlap of lesions and body distribution is present in the two diseases; it is not uncommon to even have AD/FASS (and/or fleabite hypersensitivity) and food allergy concurrently. One of the few differences with AD/FASS is the less common presence of gastrointestinal signs (e.g., flatulence, vomiting, diarrhea, soft stools, borborygmi, etc.) as with food allergy. Another difference is the possible absence of pruritus in food allergy as well as the high incidence of otitis and/or recurrent pyoderma as the only clinical signs. As in other types of allergy, the incidence of secondary skin and ear infections is very high.

Differential Diagnoses

As in AD/FASS, the most common differentials for food allergy include other allergies, parasitosis, and infections (bacterial and *Malassezia*). In particular, sarcoptic and demodectic mange, otoacariasis, and cheyletiellosis need to be included in the differential list. In cats, dermatophytosis, viral dermatoses, and autoimmune diseases (e.g., pemphigus foliaceus) should also been included as potential differentials.

Diagnosis

The diagnosis can only be achieved via a strict elimination diet trial. In fact, allergy tests (intradermal, epicutaneous, and serological) are not reliable in identifying the causative allergen(s). However, a high-negative predictive value (the likelihood that an ingredient is NOT associated with a reaction) has been associated with such tests. The elimination diet is performed using novel ingredients for the specific pet. Thus, it is fundamental to record a detailed feeding history to accurately select an elimination diet. The diet can be homemade or commercially available. The former can be more expensive and time consuming, although more targeted and selective. The most reliable commercially available diets are generally prescription diets, which guarantee the lack of or minimal food contamination between products. Diets useful for the trial include novel ingredients (e.g., kangaroo, rabbit, alligator, etc.) or hydrolyzed diets. Both options have pros and cons, and the choice of the diet should be based on the individual patient. Regardless of the diet chosen, the trial should be carried out for 8–10 weeks based on the resolution of the clinical signs. If anti-inflammatory, antipruritic, and antimicrobial medications are used, clinical signs may resolve faster, so the duration of the food trial can be decreased. It is important to avoid any flavored supplements or medications during the trial. Similarly, it is important to avoid contamination from food fed to other pets present in the household. Once there is a significant reduction in the severity of the clinical signs, a provocation test using the previous diet for up to 14 days should be performed to confirm the diagnosis. If medications were used to alleviate the clinical signs, it is important to discontinue those for at least 14 days before performing the provocation test. Once the diagnosis is confirmed, single ingredients, including treats/supplements, can be tested individually to identify the triggering ingredients.

Management

The best management is avoiding the triggering allergen. Most of the hypoallergenic prescription diets are fully balanced and represent a viable lifelong option for affected pets. However, if a relapse of the clinical signs occurs because of accidental ingestion of the incriminated allergens, the use of anti-inflammatory, antipruritic, and/or antimicrobial medications is highly recommended.

CONTACT ALLERGY

Definition/Overview

Contact allergy in an uncommon skin disease in dogs and cats. It is more common in tropical/subtropical climates where strongly allergenic plants (e.g., *Commelinaceae* spp.) proliferate. However, hypersensitivity reactions to different allergens have been described in dogs and cats. Recently contact allergy has been described as "an immune-mediated, antigen-specific inflammatory skin reaction following contact with a specific allergenic substance (sensitizer)" (e.g., poison ivy). As in food allergy/intolerance, the presence of a targeted immune reaction makes the distinction between contact allergy and irritant contact dermatitis.

Etiology

Contact allergy is generally due to an allergic reaction to plants or drugs. However, carpet deodorizers/cleaners, detergents, plastic dishes, synthetic carpet, etc., have been identified as potential culprits in dogs and cats.

Pathophysiology

The pathogenesis of contact allergy is still not completely understood. However, a delayed hypersensitivity reaction with the participation of CD8+ T cells is involved after percutaneous absorption of haptens. Contact allergy is characterized by a sensitization phase followed by a specific immune response to the allergen upon re-exposure. After sensitization, the immunological reaction can occur within 24 hours to several days after re-exposure. Once activated, cytotoxic T cells will be attracted to the skin and potentially induce apoptosis of the keratinocytes.

Clinical Presentation

The characteristic clinical signs of contact allergy include the presence of localized erythematous papules or macules with minimal to no erythroderma (diffuse erythema and scaling of skin; Figure 18.33). The lesions are commonly associated with variable pruritus and localized on the muzzle and glabrous areas (axillae, ventral aspect of the interdigital spaces, groin, perineum, pinnae). After the initial acute phase, secondary bacterial and/or *Malassezia* infections are expected.

Differential Diagnoses

The main differential diagnosis to consider is irritant contact dermatitis. However, other allergy (AD/FASS, food, flea bite, and insect) should be considered as well. Furthermore, parasitic skin diseases (sarcoptic and demodectic mange, hookworm dermatitis, *Pelodera* dermatitis) should also been included in the differential list.

FIGURE 18.33 Dog with contact allergy to *Commelina* spp. plants. Note the small erythematous papules on a normal-looking skin on the abdomen.

Diagnosis

The diagnosis is based on compatible history, clinical signs, and exclusion of other pruritic skin diseases. A patch test, open or closed, can be used as a valid and reliable aid to confirm the diagnosis and identify the offending allergen. The histopathological examination can also be highly suggestive of contact allergy and supplements the clinical diagnosis.

Management

The optimum treatment option is avoidance. When this is not completely possible, symptomatic treatments are available. Among others, pentoxifylline can be useful as preventative medication. Corticosteroids, cyclosporine, and oclacitinib have also been used as potential treatments. Topical and systemic antimicrobials should also be prescribed when necessary.

MOSQUITO BITE HYPERSENSITIVITY

Definition/Overview

Mosquito bite hypersensitivity is a relatively common cutaneous hypersensitivity affecting cats in temperate areas. The severity of the clinical signs varies from cat to cat and can be very mild to extremely severe.

Etiology

Mosquito bite hypersensitivity is directly associated with the exposure to mosquito bites.

Pathophysiology

The pathogenesis is not completely understood; however, similarities with flea bite hypersensitivity have been identified. A hypersensitivity reaction type 1 and 4 is associated with mosquito bite hypersensitivity. Once the allergen has been injected, it triggers a diffuse and severe eosinophilic and neutrophilic dermatitis of the affected areas.

Clinical Presentation

Mosquito bite hypersensitivity can occur in any breed at any age. The lesions tend to stay localized to areas directly affected by the bites. These include the tip of the ear, pinnae, and the bridge of the nose (Figure 18.34a, b). Lesions on the foot pads, lateral aspect of the elbows, and on the face (periorbital and perilabial areas) can also occur. The classic clinical presentation includes alopecia, erosions, ulcers, and variable pruritus. Eosinophilic granulomas and plaques have also been reported in affected cats. Outdoor cats living in temperate and tropical/subtropical regions are commonly affected. However, indoor cats can also be affected.

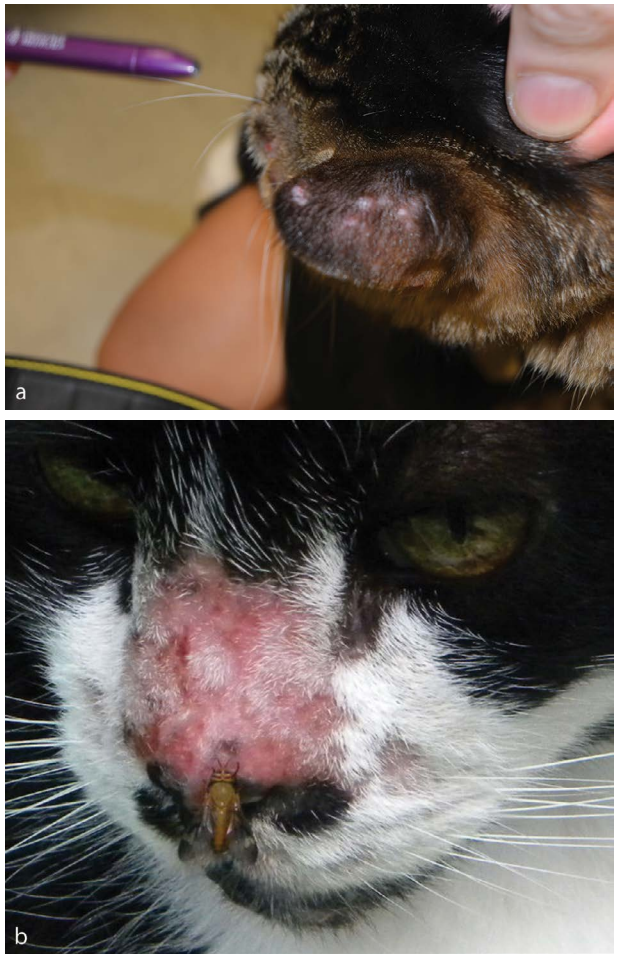

FIGURE 18.34 Alopecic and erythematous papules on the dorsal aspect of the convex surface of the ear pinna **(a)** and nose **(b)** in a cat with mosquito or other insect bite hypersensitivity.

Differential Diagnoses

In cats, because of the high similarity of the clinical signs among hypersensitivities, FASS, food and flea bite allergy should be excluded. Diseases like sarcoptic and demodectic mange, trombiculosis, ear mites, and dermatophytosis have to be considered as likely differentials in affected cats. Finally, viral dermatoses (e.g., herpesvirus and poxvirus), autoimmune diseases (e.g., pemphigus foliaceus), neoplastic diseases (e.g., squamous cell carcinoma and mast cell tumor), and infectious diseases (e.g., subcutaneous and systemic mycosis) should be included in the differential list.

Diagnosis

The diagnosis is based on compatible history (mosquito season), clinical findings, and confirmed by cytological and histopathological examination.

Management

The key in a successful management of mosquito bite hypersensitivity is avoiding the exposure to mosquitos. The use of repellants would be ideal. Unfortunately, few repellents are safe in cats. Neem oil as liquid spray or as spot-on solution is a popular repellant. Environmental control through the elimination of mosquito breeding habitats (e.g., standing water) and repellant sprays should be considered. The use of anti-inflammatory or antipruritic medications are also recommended. Topical and/or systemic antimicrobials should be prescribed when necessary.

AUTOIMMUNE SKIN DISEASES

Autoimmune skin diseases are rare in dogs and cats. They represent a subtype of the immune-mediated skin diseases. The major difference between autoimmune and immune-mediated is the identification of a self-antigen as the major target for the immune system in the former. Many autoimmune and immune-mediated skin diseases have been described in dogs and cats. However, in this chapter, only pemphigus foliaceus and sebaceous adenitis will be discussed. In addition, although the self-antigen has not been identified, diseases classically included in the group of autoimmune skin diseases like cutaneous lupus, vasculitis, lupoid onychitis, canine juvenile cellulitis/juvenile sterile granulomatous dermatitis, and lymphadenitis (puppy strangles) will also be discussed.

PEMPHIGUS FOLIACEUS

Definition/Overview

Although its prevalence is not known, pemphigus foliaceus is considered the most common autoimmune skin disease affecting dogs and cats. Pemphigus foliaceus is characterized by a pustular eruption due to loss of cohesion between keratinocytes. The major target for pemphigus foliaceus in dogs is desmocollin-1. A specific breed overrepresentation is seen in dogs (Akita, Newfoundland, Schipperke, Dobermann Pinscher, Finish Spitz, Dachshunds, English Cocker Spaniel, Chow Chow, Shar Pei, Collie, and Border Collie) and cats (Domestic Shorthaired, Siamese, Persians, and Ragdoll). The disease is exacerbated by exposure to UV light.

Etiology

Pemphigus foliaceus is associated with the production of autoantibodies directed toward the keratinocyte's adhesion molecule, desmocollin-1.

Pathophysiology

The pathogenesis of pemphigus foliaceus is not completely known; however, the disease seems to be multifactorial in origin. Genetic and environmental factors along with exposure to drugs seem to be highly involved in the development of the disease in dogs. Chronic antigenic stimulation (e.g., allergies) has also been hypothesized as potential trigger.

Pemphigus foliaceus is characterized by the presence of autoantibodies directed toward desmocollin-1 (in dogs) and desmoglein-1 (in people), weakening the desmosomal structures. Once these bonds between cells are weakened, neutrophils further disrupt the bonds creating loss of adhesion and formation of rafts of individual keratinocytes (acantholytic keratinocytes). This process leads to the formation of pustules characteristic of this disease.

Clinical Presentation

The clinical presentation of pemphigus foliaceus is quite diverse; however, lesions typically develop symmetrically on the body. Clinically, crusts, erythema, alopecia, erosions and ulcers characterize PF (Figures 18.35–18.37), although transient pustular eruption represents the primary lesion. The lesions generally progress caudally from the head, often starting from the nasal planum, which is the most commonly affected location. Pustules on the concave surface of the ear pinnae (dogs and cats) and nailbed (cats) are characteristic of pemphigus foliaceus. In same case, general malaise and fever can be observed.

FIGURE 18.35 Dorsal aspect of the bridge of the nose of a dog with pemphigus foliaceus. Note the large number of crusts, erosions, and alopecia symmetrically distributed.

FIGURE 18.36 Pustules on the abdomen of a dog with pemphigus foliaceus.

FIGURE 18.37 Cat with pemphigus foliaceus. Note the large amount of scales, alopecia, confluent papules forming erythematous plaques, yellow crust, and broken pustules.

Differential Diagnoses

The diagnosis of pemphigus foliaceus is not always straightforward. The list of top differential diagnoses should include superficial pyoderma, demodicosis, and dermatophytosis. Other autoimmune (e.g., lupus and dermatomyositis), neoplasia (cutaneous lymphoma), metabolic (necrolytic migratory erythema), and infectious (leishmaniasis) diseases should also be considered.

Diagnosis

History, clinical signs (distribution and type of lesions), skin cytology, and biopsies for histopathology are necessary to reach a definitive diagnosis. Fungal culture may also be required to rule out dermatophytosis. The characteristic cytological finding includes the presence of acantholytic keratinocytes. It is important to remember that acantholytic keratinocytes are not pathognomonic for pemphigus foliaceus, as superficial pyoderma and dermatophytosis can be associated with this finding. Because of the clinical similarities between pemphigus foliaceus and superficial pyoderma, a course of antibiotic is generally recommended before performing a skin biopsy for histopathology.

Management

The main goal of treatment is immunosuppressing the animal. To do so, drugs like corticosteroids (e.g., prednisone, prednisolone, triamcinolone, methylprednisolone, or dexamethasone), azathioprine, cyclosporine, chlorambucil, mycophenolate, and leflunomide are generally used at immunosuppressive dosages. Cats are much more responsive to treatment and carry a better prognosis than dogs. It is mandatory to monitor systemic organ function during treatment to avoid serious to life-threating side effects from the medications. In case of relapse, it is generally harder to control the disease without using highly immunosuppressive medications/

dosages. The treatment is generally lifelong except in cases of drug-induced pemphigus foliaceus.

CUTANEOUS (DISCOID) LUPUS ERYTHEMATOSUS

Definition/Overview

Cutaneous lupus erythematosus is a relatively common immune-mediated skin disease in dogs. It is considered a benign variant of systemic lupus with which it only shares the histopathological findings. A progression to systemic lupus has not been reported.

Etiology

The etiology of cutaneous lupus is unknown. A self-antigen is suspected but has not yet been identified. Similar to pemphigus foliaceus, cutaneous lupus is exacerbated by exposure to UV light.

Pathophysiology

The pathogenesis is not completely understood. However, the production of antibodies directed toward the keratinocytes and the basal membrane structures is hypothesized based on the histological findings. Once the antibodies have bounded to their target, the complement cascade and cytotoxic T cells are activated.

Clinical Presentation

Clinical signs are mainly localized to the nose (nasal planum and bridge of the nose) (Figure 18.38) extending to the periocular and perioral regions, ear pinnae, and eyelids. Uncommonly, lesions on the distal limbs, footpads, and perianal area have been reported. The severity of the lesions varies tremendously from mild discoloration (gray to bluish color change) of the nasal planum to erosions and severe ulceration with depigmentation and loss of cobblestone appearance of the nasal planum.

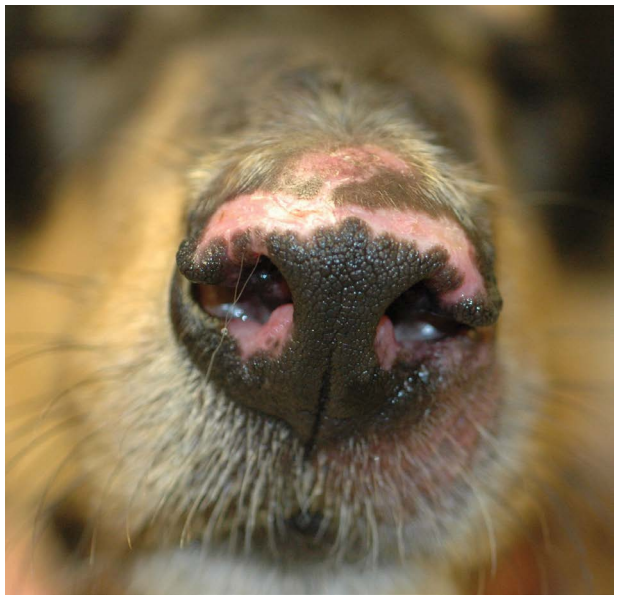

FIGURE 18.38 Nasal planum of a dog affected by cutaneous lupus erythematosus. Note the diffuse depigmentation of the nasal planum and loss of cobblestone appearance (atrophy) of the dorsal aspect of the nasal planum.

Differential Diagnoses

Differential diagnoses should include other immune-mediated/autoimmune diseases like pemphigus foliaceus, mucocutaneous pyoderma, pemphigus erythematosus, uveodermatologic syndrome, and systemic lupus. Cutaneous lymphoma, vitiligo, and contact dermatitis should also be considered.

Diagnosis

The diagnosis is mainly based on history, clinical signs, and confirmed by histopathological examination. The latter should be performed on nonulcerated areas. As in pemphigus foliaceus, sometimes a course of antibiotic prior to skin biopsy can help reduce the confounding alterations due to bacterial infections. Antinuclear antibody (ANA) test is generally negative (in contrast to systemic lupus).

Management

Due to the benign behavior of this disease, the most common treatments options include topical corticosteroids or calcineurin inhibitors (tacrolimus) and high sun protection factor (SPF) sunscreen creams. In more severe cases, the use of doxycycline and niacinamide combination, systemic corticosteroids (anti-inflammatory or immunosuppressive doses), or cyclosporine may be required. Administration of vitamin E and essential fatty acids have also been reported as an effective treatment in mild cases of cutaneous lupus.

LUPOID ONYCHITIS

Definition/Overview

Lupoid onychitis is a relatively common disease affecting the claws in dogs. A genetic predisposition has been identified in specific breeds like Bearded Collies. Lupoid onychitis can affect all breeds; however, Labrador Retrievers, Greyhounds, German Shepherd Dogs, Bearded Collies, and Rottweilers are overrepresented. Lupoid onychitis is unrelated to cutaneous or systemic lupus erythematous.

Etiology

The etiology is unknown.

Pathophysiology

Lupoid onychitis is associated with a severe inflammatory response at the level of the claw bed.

FIGURE 18.39 Onychodystrophy and onychomadesis in a dog with lupoid onychitis.

Clinical Presentation

Clinically, lupoid onychitis is associated with moderate to severe discomfort and pain. Claws show onychorrhexis, onychomadesis, subungual hemorrhage, and onychodystrophy (Figure 18.39). Paronychia can also be present with secondary bacterial infections.

Differential Diagnoses

Main differential diagnoses should include other causes of onychitis like bacterial or fungal onychitis, as well as trauma and neoplasia.

Diagnosis

The diagnosis is based on the characteristic clinical signs. Biopsy of the claw bed or phalanx three amputation may confirm the diagnosis, but it is not generally necessary. Bacterial and fungal culture may be required to definitely rule out bacterial and fungal onychitis. In some cases, a strict food trial has been suggested to rule out the potential involvement of food allergy.

Management

The main treatment options include the use of oral essential fatty acids (omega-3/omega-6) alone or in combination with doxycycline and niacinamide. Other treatment options may include systemic corticosteroids, vitamin E, and pentoxifylline. Pain control may be required in cases of severe pain and discomfort. In some cases, an elimination diet has been useful to control the clinical signs. Treatment should be continued until new claw growth is evident, although lifelong treatment is generally required to avoid relapses.

SEBACEOUS ADENITIS

Definition/Overview

Sebaceous adenitis is an uncommon inflammatory skin disease targeting the sebaceous glands. In chronic cases, the inflammatory response leads to complete destruction of the sebaceous glands.

Etiology

The etiology is unknown; however, an autosomal recessive mode of inheritance has been suggested in Poodles and Akitas. Affected dogs should not be used for breeding purposes.

Pathophysiology

Along with the genetic predisposition, immunological abnormalities have been suggested. In particular, a lymphocytic inflammatory pattern is observed in affected dogs. Lymphocytes mainly target sebaceous glands until complete destruction of the sebaceous glands is observed.

Clinical Presentation

The clinical presentation varies based on the hair coat length. In long-haired breeds, sebaceous adenitis is characterized by well-demarcated alopecia, scales, and follicular casts (Figure 18.40a–c). Lesions most commonly start on the head and progress caudally. On the contrary, short-haired breeds tend to present with well-demarcated alopecia, scales, nodules, and plaques. Secondary bacterial folliculitis is commonly observed in both forms. Pruritus can be present in cases with secondary infection.

Differential Diagnoses

Common causes of folliculitis (bacterial, fungal, and parasitic) should be considered. Other differentials may include hypothyroidism, primary seborrhea, ichthyosis, and follicular dysplasia.

Diagnosis

History, signalment, and clinical signs can be highly suggestive of sebaceous adenitis. Skin biopsy for histopathological examination is mandatory to confirm the diagnosis of sebaceous adenitis.

Management

Multiple treatment options are available to manage sebaceous adenitis. The most commonly used treatment is oral cyclosporine. This treatment can induce partial gland regeneration in cases in which complete glandular destruction has not occurred. Other treatments include the use of topical fatty acids, humectants, and propylene glycol. Oral or topical retinoids have also been used with success. In most cases, lifelong treatment is required, although systemic treatments may be reduced or discontinued overtime.

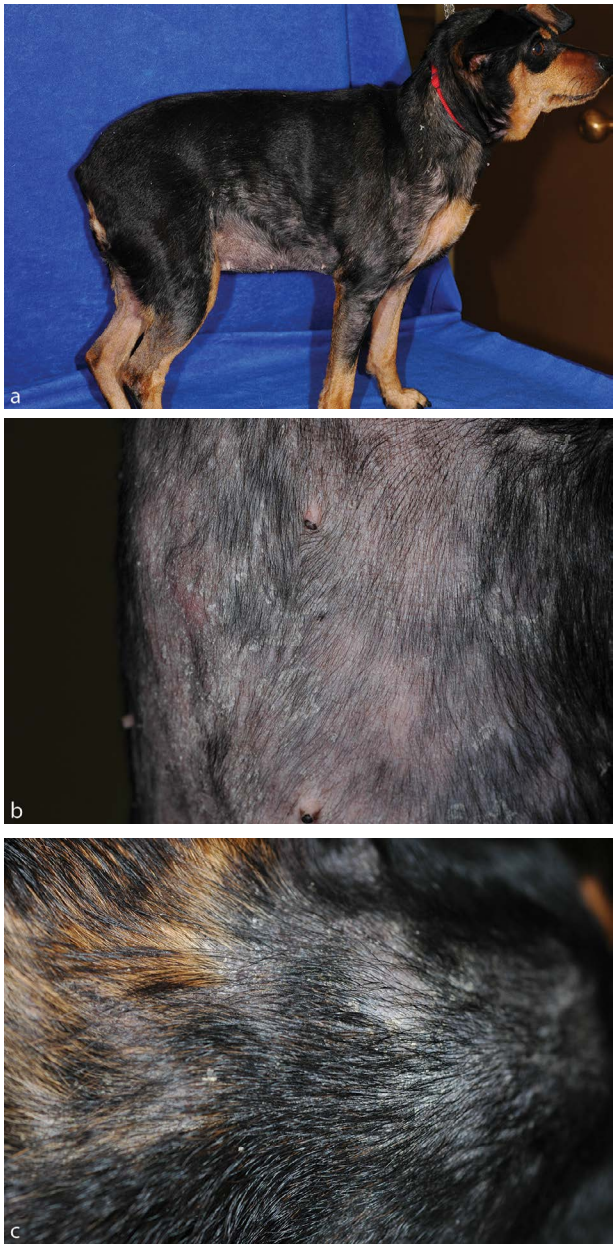

FIGURE 18.40 Dog with generalized sebaceous adenitis. Note the large scaling affecting the entire body but mainly focused on the cranial part of the body (a). A closeup image of the large scaling and alopecia affecting the abdomen (b). Alopecia and follicular casts affecting the head (c).

CANINE JUVENILE CELLULITIS/ JUVENILE STERILE GRANULOMATOUS DERMATITIS AND LYMPHADENITIS (PUPPY STRANGLES)

Definition/Overview

Canine juvenile cellulitis is an uncommon sterile granulomatous skin disease affecting the head. Lymphadenomegaly of lymph nodes in the head and neck, particularly the mandibular lymph nodes, and otitis are also commonly reported.

Etiology

The etiology of canine juvenile cellulitis is unknown. An abnormal immunological response to an unknown antigen is suggested. A potential hereditary component has also been hypothesized.

Pathophysiology

An underlying abnormal lymphocytic response has been suggested. A sterile suppurative response to an antigenic stimulation results in the observed clinical signs.

Clinical Presentation

Young dogs between 3 and 16 weeks of age are generally affected. The clinical presentation includes moderate-to-severe edema, pustules, crusts, and draining tracts mainly affecting the face (lips, muzzle, eyelids, and pinnae; Figure 18.41a); however, lesions on the abdomen (groin and prepuce) and perineal area have also been reported (Figure 18.41b). Lymphadenopathy, fever, polyarthropathy, and general malaise are also present.

Differential Diagnoses

Demodicosis, bacterial folliculitis/furunculosis, sterile granuloma/pyogranuloma syndrome, angioedema, insect bite, adverse drug/vaccine reaction, and dermatophytosis should be considered. Other differentials may include pemphigus foliaceus and otitis externa.

Diagnosis

The clinical picture is extremely suggestive of canine juvenile cellulitis. However, deep skin scraping and bacterial/fungal culture should be performed to rule out infectious organisms. Cytological and histopathological examination is essential to confirm the diagnosis.

Management

The use of immunosuppressive doses of corticosteroids is generally the first line of treatment. Once the clinical signs subside, the dose of corticosteroid is slowly tapered. In most cases, no relapse is observed; however, it is possible after discontinuation of the treatment. Cyclosporine is effective in refractory and/or relapsing cases. Secondary bacterial infections can also occur and need to be properly treated. Lesions may lead to permanent scarring.

NODULAR DERMATOSES

Nodules and masses are quite common in veterinary dermatology. When encountering such lesions, a

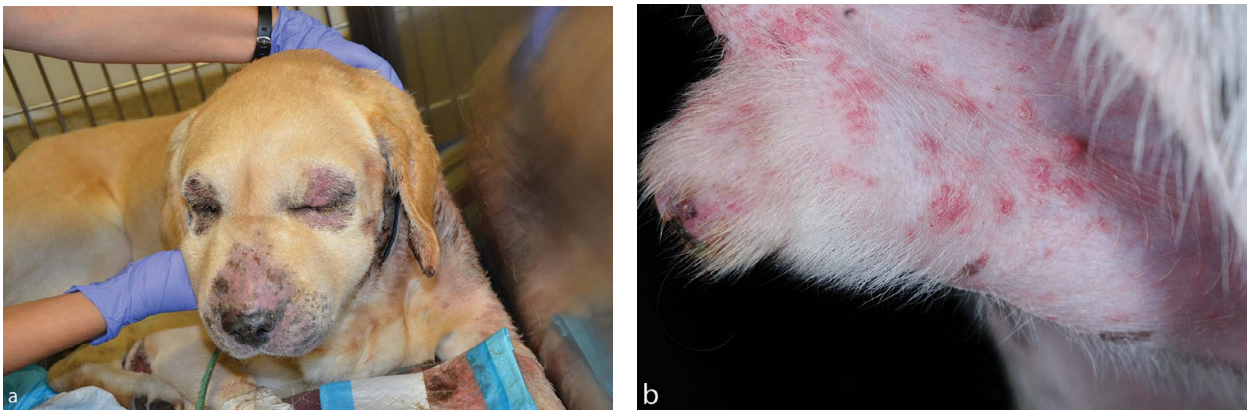

FIGURE 18.41 (a) Erythema, alopecia, crusting, and swelling of the face of a puppy typical of the canine juvenile cellulitis/juvenile sterile granulomatous dermatitis and lymphadenitis. **(b)** Pustules and papules in the groin of a dog affected by canine juvenile cellulitis/juvenile sterile granulomatous dermatitis and lymphadenitis. (a, *Courtesy of Dr. Schaer.*)

clinician needs to think about a variety of skin diseases. Based on the etiology, such lesions can be inflammatory (granulomas) or neoplastic in origin. Infectious (bacterial, fungal, oomycosis; Figure 18.42a), parasitic (Figure 18.42 b, c), or sterile diseases would be included in the first group. Inflammatory nodules are quite common in dogs and cats, and because of the variety of etiological agents involved, it is fundamental to proceed stepwise in order to reach an accurate diagnosis.

When a dog or a cat presents with cutaneous nodules/masses, it is imperative to collect an accurate history and perform a detailed physical and dermatological examination. This is followed by skin cytology (fine-needle aspirate of the lesions or impression from exudative/ulcerated lesions) to verify the nature of the process. This test is extremely informative to direct the clinician toward an inflammatory or a neoplastic process. Once neoplasia is excluded, the cytology should be followed by bacterial and fungal tissue cultures to rule out potential infectious organisms. Among others, mycobacteria and oomycetes need to be included in the differential diagnoses and properly ruled out using specialized test media. Along with the cultures, molecular diagnostics (PCR) can be extremely useful to rule out fastidious microorganisms (e.g., actinomycetes and mycobacteria), oomycetes, or protozoa (e.g., *Leishmania* spp.). Finally, skin histopathology collected using deep biopsy technique should always be performed to obtain the final diagnosis and definitely rule out (or confirm) a neoplastic process. Additionally, visualization of organisms within the skin confirms that growth in culture is true infection instead of contamination of the skin surface. In certain cases, the use of special staining (e.g., mycobacteria, fungi, oomycetes) or immunohistochemistry (e.g., leishmaniosis) is also essential to confirm the suspicion of infectious organisms.

Because of the diversity of treatments available for the various diseases (e.g., chemotherapy versus antimicrobials), it is of extreme importance to be able to reach a diagnosis before starting a systemic treatment. In fact, the use of an inappropriate treatment (e.g., immunosuppression) for an infectious disease may lead to catastrophic consequences for the animal's health.

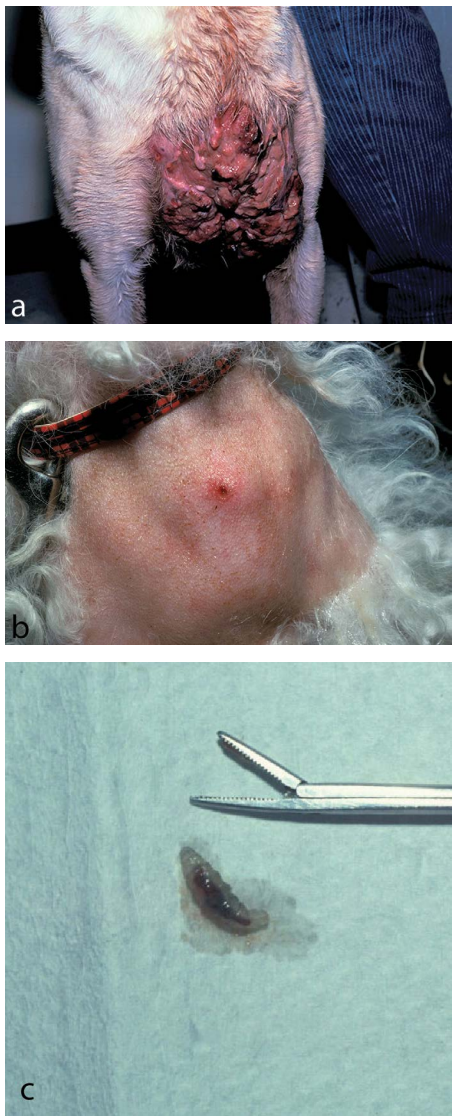

FIGURE 18.42 (a) Severe nodular dermatitis with draining tracts and serosanguineous discharge in a dog affected with cutaneous pythiosis. **(b)** A "blow-hole" caused by *Cuterebra* in a Maltese dog, and **(c)** the extracted worm larva. (*Courtesy of Dr. Schaer.*)

RAPID-GROWING MYCOBACTERIOSIS

Definition/Overview

The incidence of mycobacteriosis in dogs and cats is highly variable. It depends on the type of mycobacteria and the geographic locations. Based on the etiological agents, mycobacteriosis can be classified as rapid-growing and slow-growing mycobacteriosis. The former is more common than the latter. For slow-growing mycobacteria, a molecular diagnostic is necessary to isolate the organism (most do not grow in culture).

Etiology

Many different mycobacteria belong to this group of organisms. Among others, *M. fortuitum* group, *M. chelonae* group, and *M. smegmatis* group are the most commonly isolated rapid-growing microorganisms.

Pathophysiology

In order for the mycobacteria to initiate a disease process, a breach in the skin integrity is essential. Mycobacteria can be injected via bites or fomites (e.g., thorn or piece of wood). Once in the skin, the microorganisms stimulate a Th1 or Th2-type immune response leading to resolution or exacerbation of the process, respectively.

Clinical Presentation

The clinical presentation of mycobacteriosis varies based on the host and the organism. Most dogs and cats present with a single or multiple nodule(s), generally localized on the abdomen (adipose tissue) (Figure 18.43) or in other areas of the body (e.g., dorsum; Figure 18.44). The nodules can be individual or coalescing in larger masses or plaques. They can be ulcerated and create draining tracts oozing clear yellow exudate. Pruritus is generally not present to mild.

FIGURE 18.43 Cat with mycobacterial panniculitis. Note the extensive inflammation beside a previous attempt for surgical excision. This continuing spread of involvement is typical. (*Courtesy of Dr. Schaer.*)

FIGURE 18.44 Dog with mycobacteriosis. Note the large ulcerated and draining subcutaneous mass affecting the dorsum of this dog. (*Courtesy of Dr. Schaer.*)

Differential Diagnoses

The main noninfectious differential diagnoses include foreign body reaction, follicular/sebaceous cysts, sterile nodular panniculitis, sterile granuloma/pyogranuloma syndrome, histiocytosis, juvenile sterile granulomatous dermatitis and lymphadenitis, cutaneous xanthoma, and canine sarcoidosis. Among the infectious diseases, protozoa (e.g., *Leishmania* spp. and *Neospora* spp.), fungi (dermatophytosis, dimorphic, and opportunistic), algae, and oomycetes should be considered. Neoplastic skin diseases should also be included in the differential list.

Diagnosis

The diagnosis of mycobacteriosis can be frustrating. The definitive diagnosis is achieved via mycobacterial culture, although skin cytology may be indicative and, in some cases, diagnostic for mycobacteriosis. To increase the chances of success, a tissue biopsy is preferred to a swab. In addition, mycobacterial PCR can be a rapid and effective way to diagnose and speciate mycobacteria. When possible, an antimicrobial sensitivity panel should be requested.

Management

The treatment of mycobacteriosis varies based on the species of mycobacteria isolated. In cases of isolated nodules/masses, surgical removal maybe curative. In cases of large masses, medical treatment can be combined with surgical debulking to decrease the duration of the treatment. Generally, a combination of fluoroquinolones and macrolides is necessary, although the use of doxycycline may suffice. The appropriate antibiotic should be chosen based on sensitivity (preferred) or based on literature review. The treatment is generally implemented for several months after the clinical resolution.

CANINE LEISHMANIOSIS

Definition/Overview

Canine leishmaniosis (CL) is a protozoal systemic disease endemic in the Mediterranean basin, Middle East, and South America. However, the cases of canine leishmaniosis have increased in the past decades in North America. Most of those cases have a history of traveling to endemic areas. The clinical features are quite variable; however, they are frequently characterized by the presence of skin lesions and systemic clinical signs. This is a zoonotic disease.

Etiology

Canine leishmaniosis is caused by the protozoa of the genus *Leishmania*. Many species have been associated with CL; however, the most common organism is *L. infantum chagasi*. The parasite is transmitted by sand flies of the genus *Phlebotomus* and *Lutzomyia*.

Pathophysiology

CL is characterized by a Th2-predominant immunological response, which makes the host unable to eliminate infection. Once the parasite is injected (promastigote stage) into the skin by the sandfly, it is phagocytized by macrophages in which it changes to the amastigote stage. This latter stage is not killed by the macrophage, and the organism replicates until it induces rupture of the macrophage and diffusion of the parasite to other macrophages. Amastigotes multiply in the skin as well as in the reticuloendothelial system (liver, spleen, lymph nodes, and bone marrow), which induces organ enlargement and dysfunction.

Clinical Presentation

Canine leishmaniosis is a polymorphic disease. The most common clinical signs include lymphadenomegaly, anemia, weight loss, splenomegaly, and skin lesions (Figure 18.45a, b). The latter may include a diffuse exfoliative dermatitis, depigmentation of the nasal planum, vasculitis, nasal hyperkeratosis, alopecia, papular eruption, nodules, and ulcers. In addition, ocular lesions (from keratitis to panophthalmitis), muscle atrophy, lethargy, epistaxis, arthropathies, pyrexia, and renal failure also occur commonly.

Differential Diagnoses

The main noninfectious differential diagnoses include foreign body reaction, follicular/sebaceous cysts, sterile nodular panniculitis, sterile granuloma/pyogranuloma syndrome, histiocytosis, juvenile sterile granulomatous dermatitis and lymphadenitis, cutaneous xanthoma, and canine sarcoidosis. Among the infectious diseases, mycobacteria, fungi (dermatophytosis, dimorphic, and opportunistic), algae, and oomycetes should be considered. Neoplastic skin diseases, demodicosis, tick-borne diseases (e.g., ehrlichiosis, Rocky Mountain spotted fever, Lyme disease), and autoimmune diseases should also be included.

Diagnosis

The diagnosis of CL includes the presence of a suggestive history (e.g., traveling to endemic areas), compatible clinical signs, and diagnostics (blood work, circulating protein electrophoresis). The definite diagnosis is based on the visualization of the parasite on cytological samples

FIGURE 18.45 Dogs with leishmaniasis. Note the severe cachexia **(a)**, onychogryphosis, erosions, alopecia, hyperpigmentation, and crusts on both front limbs **(b)**, *Leishmania* spp. organisms within a macrophage of an infected dog; neutrophils and red blood cells are also present on this microscopic view **(c)**.

(Figure 18.45c) (lymph nodes, bone marrow, spleen, skin) or histopathology. However, serology and PCR are highly sensitive methods for the diagnosis of CL.

Management

Canine leishmaniosis is most commonly incurable but can be managed. The most common and effective treatment includes the combination of meglumine antimoniate and allopurinol. The former is administered in cycles of 30 days, whereas the allopurinol is administered daily for at least 6–12 months (sometimes for life). In the past decade, this combination has been partially substituted by the combination of miltefosine and allopurinol because of the better tolerability of the miltefosine. Other possible treatment options include aminosidine, amphotericin B, metronidazole/spiramycin, ketoconazole, and metronidazole/enrofloxacin. Because most dogs cannot be cured of this disease, the prevention of the transmission of the parasite is extremely important. Thus, the use of repellents containing permethrin or deltamethrin are essential. Recently, the use of vaccines has also been investigated as prevention or treatment of CL.

STERILE PYOGRANULOMATOUS DERMATITIS AND PANNICULITIS

Definition/Overview

Sterile pyogranulomatous dermatitis and panniculitis (sterile nodular panniculitis, SNP) is an uncommon skin disease mainly affecting young adult dogs. Many breeds seem to be predisposed to this syndrome. These include Dachshunds, Collies, Dobermann Pinscher, Golden Retriever, Boxer, and Poodles.

Etiology

The etiology is currently unknown.

Pathophysiology

The pathophysiology of sterile nodular panniculitis is not completely clear.

Clinical Presentation

Most dogs and cats affected by sterile pyogranulomatous dermatitis and panniculitis present with a single or multiple nodule(s), generally localized on the trunk (Figure 18.46a, b). The nodules can be individual or coalescing in larger masses or plaques. They can become ulcerated and create draining tracts oozing clear yellow viscous exudate. Pruritus is generally not present unless a secondary infection is present. In some cases, lethargy, fever, cutaneous pain, polyarthritis, hyporexia, and general malaise are significant clinical signs. Rarely, some dogs have a history of recent or active pancreatitis, but the association of this disease and SNP is unclear.

Differential Diagnoses

The main noninfectious differential diagnoses include foreign body reaction, follicular/sebaceous cysts, sterile granuloma/pyogranuloma syndrome, histiocytosis, juvenile sterile granulomatous dermatitis and lymphadenitis, cutaneous xanthoma, and canine sarcoidosis. Among the infectious diseases, protozoa (e.g., *Leishmania* spp. and *Neospora* spp.), fungi (dermatophytosis, dimorphic, and opportunistic), mycobacteria, algae, and oomycetes should be considered. Neoplastic skin diseases should also be included in the differential list.

Diagnosis

The diagnosis of sterile pyogranulomatous dermatitis and panniculitis can be very laborious at times, mainly when a secondary infection is present. The definitive diagnosis is achieved by ruling out any infectious disease able to mimic the same clinical presentation. Among others, mycobacterial, fungal, and oomycete infections have to be ruled out. To do so, specific tissue cultures and/or PCR should be performed along with histopathology of the skin.

FIGURE 18.46 Dog with sterile nodular panniculitis. Note the ulceration oozing sanguineous material associated with multiple nodules, crusts, scales, and alopecia on the dorsum (a) as well as on the muzzle (b).

Management

The main treatment of sterile pyogranulomatous dermatitis and panniculitis includes the use of immunomodulatory drugs with systemic corticosteroids as the first line of treatment. Noncorticosteroid immunomodulatory options include cyclosporine and doxycycline/niacinamide combination therapy. Mycophenolate mofetil and azathioprine are generally reserved for unresponsive cases.

CASE EXAMPLE

Case 18.1: Canine Demodicosis

Case Information

Signalment: A 3-year-old intact female Labrador Retriever

Presenting complaint: Multifocal, nonpruritic crusting and alopecia

History: One week prior to presentation, owners initially noticed a focal area of erythema and crusting with alopecia develop dorsal to the right eye. The area is not pruritic, and this dog has never had dermatological problems in the past. The lesion has continued to enlarge and become raised above the skin surface, and similar lesions are developing around the left eye. Owners noticed recently that the dog was holding her left eye more closed. This dog is a competition field trial dog that competes often and was artificially inseminated 3 weeks ago.

Physical examination: There was an approximately 3 cm × 2 cm erythematous, alopecic, crusted nodule dorsal to the right eye (**Figure 18.47**). Beneath the hemorrhagic crust was purulent exudate with ulceration (**Figure 18.48**). The lesion was mildly painful on palpation. There were numerous erythematous, alopecic, and exudative nodules present around the left eye, most notably on the dorsolateral aspect OS with mild blepharospasm (**Figure 18.49a, b**).

FIGURE 18.47 Approximately 3 cm × 2 cm erythematous, alopecic, crusted nodule dorsal to the right eye.

FIGURE 18.48 Approximately 3 cm × 2 cm erythematous, alopecic, crusted nodule dorsal to the right eye. The hemorrhagic crusts is lifted and reveals purulent, hemorrhagic exudate.

Assessment: The *problem list* included: (1) Multifocal nodular dermatitis, (2) blepharospasm, and (3) unknown pregnancy status. *Differential diagnoses* for problem #1 included deep bacterial infection, deep fungal infection, foreign body, demodicosis, insect bite hypersensitivity (eosinophilic folliculitis and furunculosis), cyst, or neoplasia. The lifestyle of the dog made infectious dermatitis or foreign body the most likely differentials, followed by demodicosis and, less likely, neoplasia. The most likely differential diagnosis for problem #2 was corneal erosion/ulceration secondary to trichiasis from periocular swelling or self-trauma from scratching. Confirmation of pregnancy was needed to resolve problem #3.

Diagnostic Plan

Cytology: Numerous neutrophils and cocci bacteria (**Figure 18.50**)

Deep skin scrapings: Numerous live *Demodex canis* mites—adults, nymphs, larvae, and eggs (**Figures 18.51–18.54**)

- DTM: Negative for growth
- Abdominal ultrasound: Normal uterus with no fetuses observed; Conclusion: Not pregnant
- Fluorescein staining OU: No uptake
- Schirmer's tear test OU: 22 OS, 19 OD

Diagnosis: Adult-onset demodicosis with secondary bacterial dermatitis. The stress of estrus and artificial insemination were presumed to be the cause of demodicosis in this case.

(Continued)

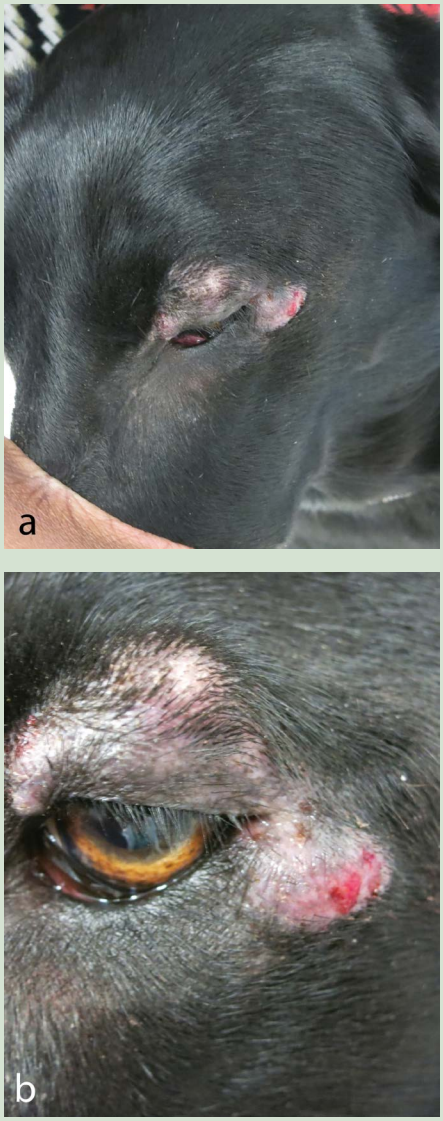

FIGURE 18.49 (a) Multinodular, erythematous, alopecic, and exudative periocular dermatitis OS. **(b)** Closeup: Multinodular, erythematous, alopecic, and exudative periocular dermatitis OS.

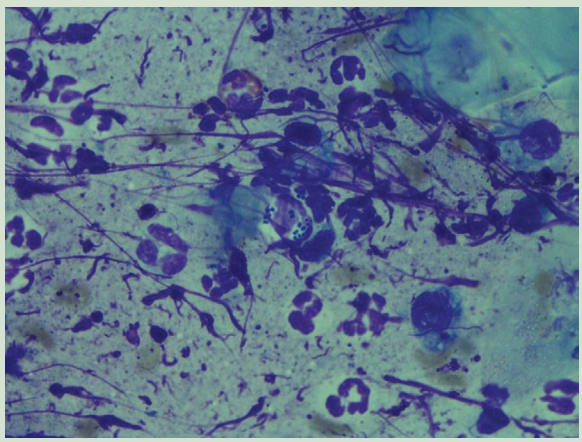

FIGURE 18.50 Neutrophils with intracellular cocci.

FIGURE 18.51 *D. canis* adult.

FIGURE 18.52 *D. canis* nymph.

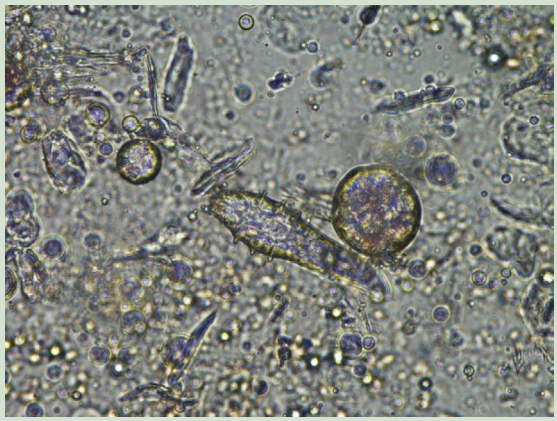

FIGURE 18.53 *D. canis* larva.

Treatment: Oral sarolaner once every 30 days to treat demodicosis; topical chlorhexidine 3% followed by topical mupirocin 2% ointment every 12 hours.

Rationale: Isoxazoline parasiticide therapies have proven highly efficacious in the treatment of canine demodicosis. Additionally, they have a wide safety profile because the therapeutic dose for the treatment of demodicosis is equivalent to the labeled dose for flea and tick prevention. Given the localized nature of the

(Continued)

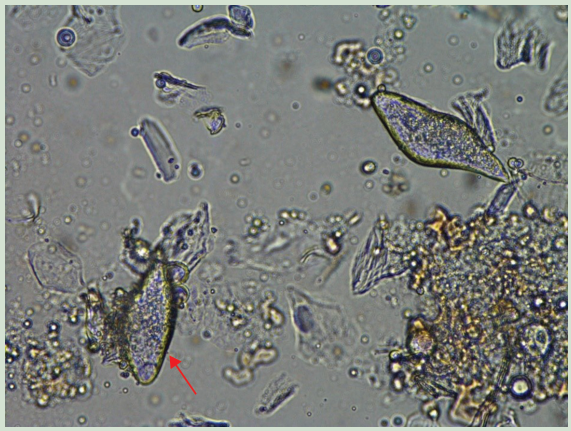

FIGURE 18.54 *D. canis* egg.

bacterial dermatitis, topical therapy was preferred. Topical chlorhexidine is effective against bacteria and yeast; however, care should be taken to avoid contact with the eyes. A wipe formulation was selected for this reason. Mupirocin ointment is effective against Gram-positive organisms such as *Staphylococcus pseudintermedius*.

Follow-up (3 weeks): Complete resolution of bacterial dermatitis with signification reduction of nodular appearance of lesions. Only alopecia remained. Skin cytology revealed no bacteria. Skin scrapings and trichography from affected areas revealed very few, dead *Demodex canis* mites. Mupirocin and topical chlorhexidine were discontinued after 1 additional week, and sarolaner was continued once monthly.

Follow-up (8 weeks): Complete resolution of nodular skin lesions with near-complete hair regrowth. No mites observed on skin scrapings or trichography from the previously affected area. Sarolaner was continued once monthly.

Follow-up (12 weeks): Complete resolution of dermatitis with complete hair regrowth. No mites observed on skin scrapings or trichography from the previously affected areas. Sarolaner was continued once monthly indefinitely.

Follow-up (6, 9, and 12 months): No recurrence of infection.

Discussion: The inciting cause of demodicosis in this dog was presumed to be stress-induced immunocompromise. The two postulated sources of profound stress included either estrus with artificial insemination and/or frequent participation in field competitions. Owners were counseled that relapse of demodicosis may occur at the time of estrus, pregnancy, and/or parturition in the future. Because the dog was performing in field competitions with the same frequency for the past 18 months, stress induced by these events was considered less likely. However, the combined stress of estrus and high physical performance could have been the cause. Because it was confirmed the dog was not pregnant at the time of diagnosis of demodicosis, this eliminated the concern for using isoxazolines for treatment. If demodicosis did relapse during a viable pregnancy, treatment options would be limited. Owners were advised to monitor closely for signs of recurrence, though risk of occurrence would be less likely if the dog continued on once monthly isoxazoline for flea and tick prevention.

INTRODUCTION

Ophthalmic manifestations of systemic disease (OMSD) can be seen in almost every periocular and ocular tissue, depending on the species and the disease process. As the globe, periocular, and orbital tissues have a limited response to disease processes, the clinical signs of an OMSD are often similar for many diseases. A complete ophthalmic examination of dogs and cats with confirmed or suspected OMSD remains, however, a critical diagnostic tool that can assist the clinician in the diagnosis, prognosis, and response to treatment of systemic disease processes. Infectious, neoplastic, autoimmune, immune-mediated, nutritional, toxic, and metabolic diseases may have ocular manifestations that can occur acutely and/or chronically. Current visual status and/or visual prognosis may also be an important deciding factor as owners determine how aggressively they may wish to pursue potential diagnostic and therapeutic options. The most common cause of uveitis in dogs and cats is idiopathic. Depending on the source read, the most common causes of uveitis in dogs are idiopathic (60%–70%), followed by infectious (18%–25%) and neoplastic (5%–25%). For cats, the most common causes of uveitis are idiopathic (40%) followed by infectious (30%) and neoplastic (5%). Determination of the exact cause of an OMSD can be challenging to the clinician and a source of frustration for the owner. With that said, the globe, periocular tissues and orbital tissues can provide important clues to assist in the diagnosis and treatment of numerous OMSDs.

BACTERIAL INFECTIONS

See also Chapter 21.

BACTEREMIA

Definition/Overview

Bacteremia from any source may result in seeding of the iris, ciliary body, or choroid with bacteria. This seeding of bacteria can cause anterior or posterior uveitis, endophthalmitis, chorioretinitis, and optic neuritis. Bacterial embolization may occur in pyometra, prostatitis, pancreatitis, bacterial endocarditis, periodontal disease, and salmonellosis or as an immune-mediated phenomenon associated with circulating antigen–antibody complexes (chronic inflammatory disease processes). Bacterial meningitis can be associated with signs of direct ocular involvement or with ocular signs that are related to the area of the brain affected.

LEPTOSPIROSIS

Definition/Overview

Leptospirosis is caused by a spirochete, which is a filamentous bacterium within the genus *Leptospira*. Organisms can be transmitted through contact with infected urine or contaminated water, bites, or

DOI: 10.1201/9781003254591-38

ingestion of infected material. After infection, bacteremia can result in vasculitis and endotheliitis. Dogs with leptospirosis may demonstrate conjunctivitis, anterior uveitis, and scleritis. Leptospirosis does not commonly cause ophthalmic signs in cats. It is considered a zoonotic disease, and appropriate precautions should be taken when handling affected animals or contaminated materials. The penicillin class of drugs (specifically ampicillin and amoxicillin) and doxycycline effectively treat this condition.

BRUCELLOSIS

Definition/Overview

Brucella canis is an aerobic, Gram-negative coccobacillus that can penetrate the mucous membranes of the conjunctiva, oropharynx, and genital tract. Ocular signs occur in about 14% of dogs, including recurrent corneal edema, anterior uveitis, hyphema, chorioretinitis, optic neuritis, endophthalmitis, and secondary glaucoma. Brucellosis should be considered in any dog that has chronic or recurrent uveitis, particularly in animals that are intact. The organism can be cultured from aqueous and vitreous, and titers detected in serum and aqueous humor. It is a zoonotic disease diagnosed by bacteriologic culturing. Systemic therapy with oral tetracycline and intramuscular streptomycin has been reported to be effective in over 90% of treated cases. A combination therapy of systemic streptomycin, rifampin, ciprofloxacin, and doxycycline has been shown to effectively treat ocular brucellosis. With any treatment regimen, relapses can occur.

LYME DISEASE

Definition/Overview

Borreliosis (Lyme disease), caused by the spirochete *Borrelia burgdorferi*, is a tick-borne disease transmitted by ticks of the *Ixodes* species, but transmission has also been associated with *Amblyomma americanum*. The primary reservoirs borreliosis are small rodents and birds. Transmission of the disease is related directly to contact time of the infected onto the host. The organism then spreads by moving through connective tissue but can, rarely, spread hematogenously. Prevention of borreliosis is most commonly achieved by vaccination and tick control. Ocular lesions in dogs include conjunctivitis, corneal edema, anterior uveitis, retinal petechiae, chorioretinitis, retinal detachment (RD), and orbital disease. Diagnosis by antibody testing remains challenging as vaccination may result in false-positive results, and high antibody titers for IgM may persist for months in naturally infected dogs. Systemic doxycycline remains the antibiotic of choice for borreliosis and generally requires chronic treatment of at least one month.

CLOSTRIDIAL DISEASE

Definition/Overview

Tetanus is caused by the bacterium *Clostridium tetani*. This organism is a motile, nonencapsulated, anaerobic, Gram-positive, rod-shaped, spore-forming bacterium. Spores of *Clostridium tetani* infect skin wounds or enter through a surgical procure. These spores then become vegetative and produce a potent neurotoxin, tetanospasmin, that migrates along axons to the central nervous system. This toxin causes the typical clinical signs by preventing inhibitory neurotransmission to motor neurons. Clinical signs can be localized or generalized. Ocular signs in dogs and cats are associated with third eyelid elevation and enophthalmos secondary to retraction of the globe due to contraction of the extraocular muscles. Contraction of the facial muscles also occurs. Dogs and cats are not as easily infected as other species such as horses and humans. Diagnosis is generally made by clinical signs, but the organism can be cultured, and antibodies to tetanospasmin can be measured to assist or confirm the diagnosis. Treatment is through administration of tetanus antitoxin. Penicillin-G and metronidazole may also be utilized to eliminate any remaining bacteria and prevent the binding of unbound tetanospasmin.

BARTONELLOSIS

Definition/Overview

Bartonella henselae is the causative agent for human "cat scratch disease" and is a zoonotic disease. *Bartonella* species are fastidious, hemotropic, Gram-negative, pleomorphic bacteria. *Bartonella vinsonii (berkhoffii)*, *B. clarridgeiae*, and *B. elizabethae* cause naturally occurring disease in dogs. *Bartonella henselae*, *B. clarridgeiae*, *B. koehlerae*, *B. elizabethae*, *B. weissii*, *B. quintana*, and *B. bovis* have all been associated with infection in cats, but infection with species other than *B. henselae* and *B. clarridgeiae* is rare. Tick transmission is likely the most common mode of transmission in dogs. While flea transmission is likely, the most common mode of transmission in cats, ticks can act as vectors for cat-to-cat or cat-to-human transmission. Because cats are a reservoir for *B. henselae* and most carrier cats do not have clinical disease, it is difficult to associate clinical disease with this organism in cats. Seropositivity in cats ranges from 5% to 90%, so serum antibody testing may be most useful in identifying seronegative cats in an attempt to rule out bartonellosis as a potential cause for uveitis. For sick cats, serum antibody titers with blood culture or polymerase chain reaction (PCR) testing may assist in confirming a diagnosis. Aqueous humor can also be harvested and submitted for PCR and antibody testing to calculate a Goldmann-Witmer coefficient (C value). A C value greater than 3 is suggestive of local antibody within the globe. Numerous studies have evaluated the efficacy of diagnostic testing in cats utilizing serology, PCR, aqueous humor

and/or blood culture in cats. Unfortunately, more recent studies demonstrated that it is not possible to associate ocular or systemic signs of disease with positive diagnostic testing due to the facts that this infectious agent is widespread within the general cat population, and so few cats are affected with clinical signs. In dogs, ocular signs include anterior uveitis, hyphema, chorioretinitis, and RD (due to systemic hypertension). In cats, 5%–10% of infected cats have ocular signs, including blepharitis, conjunctivitis, keratitis, uveitis (Figures 19.1 and 19.2), and chorioretinitis. Treatment of systemic bartonellosis in dogs and cats involves the use of systemic antibiotics such as azithromycin, enrofloxacin, or doxycycline for several weeks.

FIGURE 19.2 Fibrin in the anterior chamber obscures the pupil in this cat with bartonellosis.

MYCOPLASMA

Definition/Overview

Mycoplasma spp. are the smallest free-living organisms and are classified as prokaryotes. The organism has been isolated from cats affected with conjunctivitis as well as from healthy cats.

Etiology

Mycoplasma felis, *M. gatae*, *M. arginine*, *M. canadense*, *M. cynos*, *M. lipophilum*, and *M. hypopharyngis* have all been isolated for the conjunctiva of both sick and healthy cats. Experimentally, *M. felis* has caused conjunctivitis in some kittens but not in other kittens or in adult cats. As such, the role of *Mycoplasma* spp. in conjunctivitis in cats is unknown, and it is considered a rare cause of conjunctivitis. The disease is not self-limiting in all cases.

Pathophysiology

It is likely that *Mycoplasma* spp. are most able to establish infection in the conjunctiva of a cat already infected by another pathogen such as feline herpesvirus or *Chlamydophila felis*. An altered or immature immune system may also allow the establishment of infection.

Clinical Presentation

Initially, conjunctivitis may be unilateral, with the opposite eye usually becoming affected in 7–14 days. Early in the disease, the ocular discharge is serous with chemosis, hyperemia, and blepharospasm also present. Over time, the exudate increases, becoming mucopurulent and the chemosis more severe. The thick exudate may adhere to the conjunctiva and appear as a pseudomembrane. The nictitans may become hyperemic, swollen, and protrude. Papillary hypertrophy of the conjunctiva may occur. Conjunctival cytology reveals a predominantly neutrophilic response. *Mycoplasma* organisms are coccoid or coccobacillary, basophilic clusters found within the cytoplasm of infected conjunctival epithelial cells. Once the ocular discharge becomes more mucopurulent, the identification of organisms is much more challenging.

Differential Diagnosis

Conjunctivitis and/or conjunctival hyperemia is an extremely common clinical finding in numerous ocular diseases. It may be infectious (herpesvirus, calicivirus, *Mycoplasma*, and *Chlamydophila* in cats) or noninfectious with noninfectious being much more common. It may be primary or be secondary to ulcerative keratitis, eyelid disease (entropion, ectropion, blepharitis), orbital cellulitis, nasolacrimal duct obstruction, keratoconjunctivitis sicca (KCS), atopy, environmental irritation, and neoplasia (lymphoma). Episcleral injection also causes the white part of the globe to be red and is associated

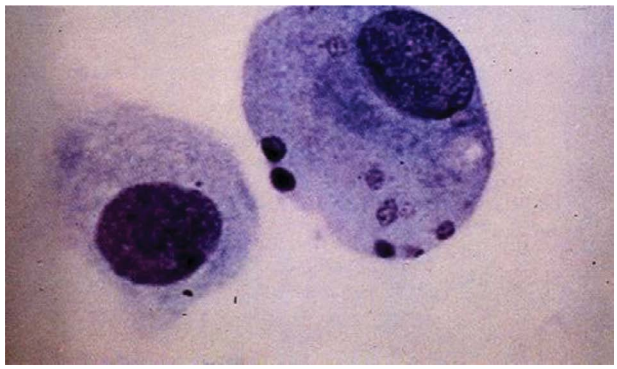

FIGURE 19.3 Conjunctival epithelial cell containing multiple, small basophilic inclusion bodies suggesting mycoplasma infection. Mycoplasma was identified in cultures from this eye. Giemsa stain.

with scleral or intraocular diseases such as episcleritis, anterior uveitis, glaucoma, and intraocular neoplasia.

Diagnosis

The diagnosis of mycoplasmosis can be confirmed by the culture of the organism on special media or by the cytologic identification of the characteristic coccoid or coccobacillary, basophilic clusters found within the cytoplasm of infected conjunctival epithelial cells (Figure 19.3).

Management

Treatment of conjunctivitis due to *M. felis* consists of application of topical antibiotics for 3 weeks. Effective topical antibiotics include tetracycline or erythromycin. Oral doxycycline has also been used to treat affected patients, but most cases should respond to topical therapy.

VIRAL INFECTIONS

See also Chapter 21.

FELINE CALICIVIRUS

Definition/Overview

Feline calicivirus (FCV) is a nonenveloped, single-stranded RNA picornavirus. It is primarily a respiratory pathogen but has also been associated with oral ulceration and polyarthritis. Compared with feline herpesvirus, FCV has low pathogenicity to infect the conjunctiva of cats. Calicivirus conjunctivitis is suspected when conjunctivitis accompanies oral ulceration in cats. Most cats spontaneously recover from FCV infection, but cats may remain chronically infected and asymptomatically shed the virus. The diagnosis of FCV can be made through virus isolation (VI), immunofluorescence assay (IFA), and polymerase chain reaction (PCR) assay. Specific topical antiviral preparations are not effective against a ribonucleic acid (RNA) virus.

RABIES

Definition/Overview

Rabies remains an important zoonotic disease across the world. Transmission occurs through the bite of an infected animal to any warm-blooded animal. Along with the known systemic effects, dogs and cats may show pupillary dilation, uveitis, slowed palpebral and corneal reflexes, and photophobia due to neurologic dysfunction.

CANINE HERPESVIRUS

Definition/Overview

Canine herpesvirus (CHV) is an enveloped, double-stranded deoxyribonucleic acid (DNA) virus and can be infective in all canids. The presence of ocular lesions is dependent on the age and immune status of the dog. Ocular lesions can occur in primary or recurrent infections. Ocular lesions in adult dogs are generally limited to blepharitis, conjunctivitis, ulcerative keratitis, and nonulcerative keratitis. The presence of conjunctival petechia and/or dendritic corneal ulceration are suggestive of CHV infection. In adult dogs with normal immune systems, CHV infection is generally mild and self-limiting. Puppies infected with CHV generally have much more dramatic ocular signs, including keratitis, panuveitis, synechia, cataracts, retinal necrosis, retinal dysplasia, retinal atrophy, optic neuritis, and optic nerve atrophy. Infection is generally fatal in puppies. Diagnosis is generally through the documentation of clinical signs but can be confirmed with VI, PCR, or identification of virus by transmission electron microscopy. Therapy is generally supportive, but topical antiviral medications such as cidofovir 0.5%, idoxuridine, and trifluridine 1% have been utilized along with topical antibiotics as well as topical and systemic pain control for dogs with corneal ulcers.

CANINE DISTEMPER VIRUS

Definition/Overview

Ocular signs have been observed in animals with acute and chronic infection with canine distemper virus (CDV).

Etiology

Canine distemper is caused by an enveloped, single-stranded RNA morbillivirus. The virus is spread mainly by inhalation of aerosolized respiratory viral particles

or other infected secretions such as urine. Widespread vaccination of dogs has markedly decreased the incidence of canine distemper.

Clinical Presentation

Clinical signs of CDV infection can vary with patient age, immune status of the dog, and the strain of the virus. CDV infection has systemic features ranging from mild-to-severe coughing, dyspnea, lethargy, anorexia, vomiting, diarrhea, and central nervous system (CNS) signs. Ocular signs include serous to mucopurulent bilateral ocular discharge, chorioretinitis, retinal detachment (RD), KCS (Figures 19.4–19.7) (which may last 4–8 weeks or be permanent), corneal ulcers, optic neuritis (sudden blindness), and cortical blindness. Chronic retinochoroidopathies can be seen as areas of increased tapetal reflectivity ("gold medallion lesions") and altered pigmentation in tapetal and nontapetal fundic areas but

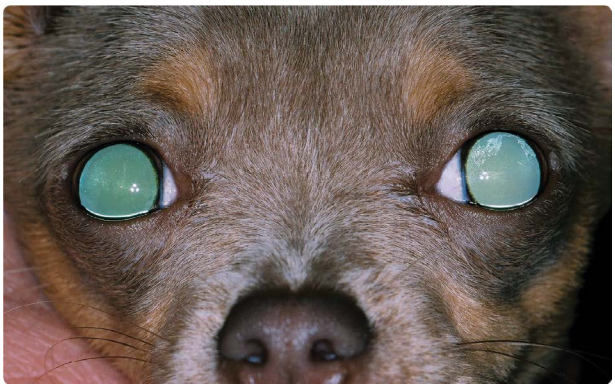

FIGURE 19.4 Dog with bilateral optic neuritis from canine distemper. Note the dilated pupils.

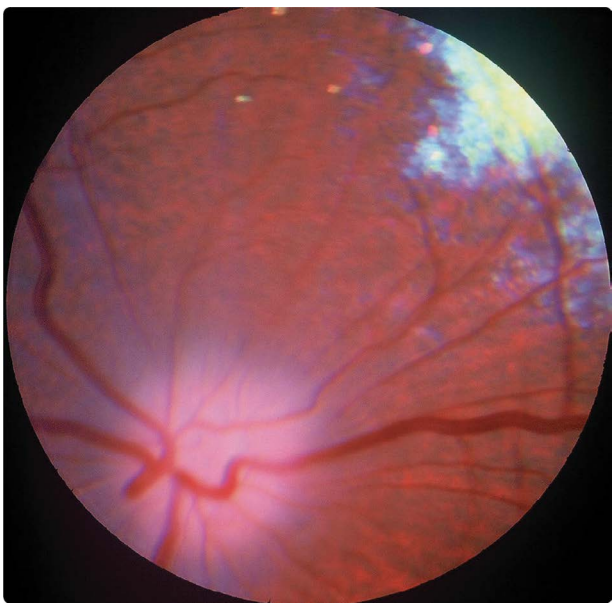

FIGURE 19.5 The optic nerve swelling, blurred edges (peripapillary edema and retinal detachment), and hyperemia of the optic disc indicate active optic neuritis.

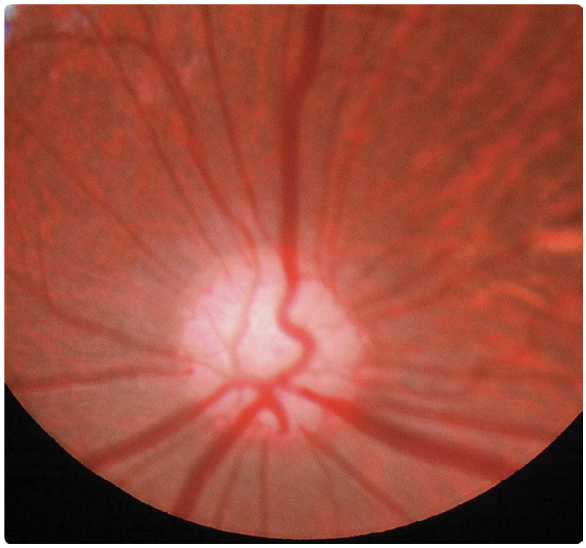

FIGURE 19.6 Mild optic nerve atrophy is present 2 months later.

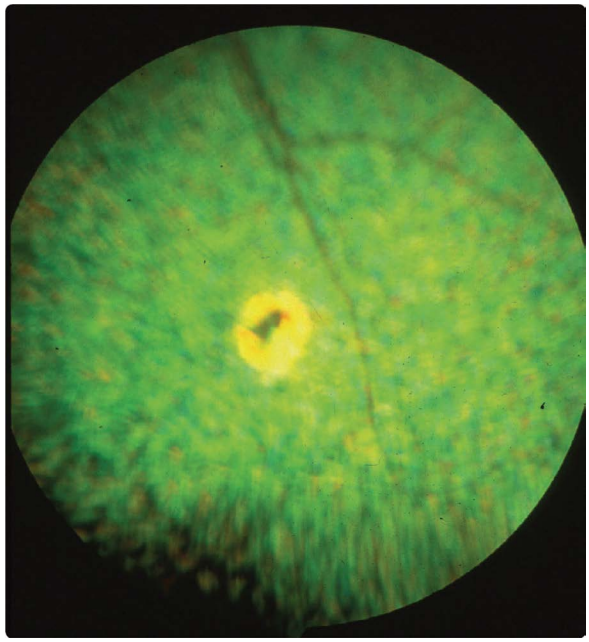

FIGURE 19.7 A focal area of healed chorioretinitis from distemper is found in this dog. The remaining chorioretinal scar is hyperreflective with a hyperpigmented center. In the past, these have been referred to as "gold medallion" lesions and were considered associated with CDV; however, any inflammatory and/or infectious lesion can result in a similar scar.

similar lesion may occur with any chorioretinal scar. The most profound and vision-threatening ocular lesion is optic neuritis resulting in mydriasis and vision loss. If the lesion affects the optic disc, then optic nerve swelling, hyperemia, hemorrhage, and peripapillary retinal edema may be present. If the inflammation is behind the globe, then additional diagnostic testing such as electroretinography and advanced imaging may be required to diagnose retrobulbar optic neuritis.

Differential Diagnosis

See Table 19.1.

Diagnosis

Conjunctival scrapings reveal mononuclear leukocytes and giant cells initially, then neutrophils. Intracellular inclusion bodies in conjunctival epithelial cells may be noted but are challenging to find if the patient does not have active conjunctival inflammation. Immunofluorescence of conjunctival smears may be positive 5–10 days post infection, although the virus disappears 21–28 days post infection. Reverse-transcriptase polymerase chain reaction (PCR) assays have been shown to be both sensitive and specific for detection of CDV.

Management

Treatment is aimed at controlling secondary infections, although ribavirin inhibits CDV replication in vitro. Acute optic neuritis is generally treated with systemic anti-inflammatory and/or immunomodulatory agents. Supportive treatment improves the chance for recovery and quality of life. Vaccination is the key to preventing CDV infection, as the prognosis for dogs with neurologic disease is considered guarded to poor.

INFECTIOUS CANINE HEPATITIS

Definition/Overview

Canine adenovirus 1 (CAV-1) may cause ocular signs, including anterior uveitis and corneal edema in naturally infected dogs and in dogs vaccinated with the modified live canine adenovirus type 1 vaccine. Keratouveitis occurs as after vaccination in about 0.4% of dogs. Due to the potential reaction to CAV-1, newer vaccines contain CAV type 2 to minimize the incidence of this condition.

Etiology

CAV-1 is a nonenveloped, double-stranded DNA adenovirus.

Pathophysiology

The corneal edema is a result of an Arthus-type hypersensitivity reaction in the corneal endothelium rather than direct viral replication. Classically, clinical signs develop 14–21 days post vaccination or 10–21 days following natural infection.

Clinical Presentation

Dogs generally present with severe, generally unilateral anterior uveitis with aqueous flare, hypotony, and corneal edema ("blue eye") appears in affected eyes (Figure 19.8). The clinical signs are bilateral in about 30% of cases. The anterior uveitis generally resolves

over a 2- to 3-week period, although persistent corneal edema can occur. Ocular complications include bullous keratopathy, keratoconus/keratoglobus, phthisis bulbi, and secondary glaucoma.

Differential Diagnosis

See Table 19.1.

Diagnosis

Diagnosis is generally based on the clinical history and signs and can be confirmed with immunohistochemistry for CAV-1 and detection of viral DNA using PCR in infected ocular tissue.

Management

Therapy is symptomatic and includes topically administered corticosteroids, hyperosmotics, atropine, and nonsteroidal anti-inflammatory drugs.

FELINE HERPESVIRUS (RHINOTRACHEITIS)

Definition/Overview

FHV-1 is a double-stranded DNA virus that is highly species specific. FHV-1 has marked tropism for the conjunctival epithelium and less so for the corneal epithelium. The virus is spread from cat to cat through fomites, aerosolization, or direct contact.

Etiology

Herpesvirus is the major cause of respiratory disease and associated conjunctivitis in cats. It is estimated that >90% of cats are seropositive to the virus, with as many as 80% of infected cats remaining latently infected on a life-long basis. Approximately 45% of these latently infected cats shed virus throughout their life. Cats with chronic herpetic conjunctivitis may also be feline immunodeficiency virus (FIV) positive.

Pathophysiology

FHV-1 infects the epithelial surfaces of the respiratory tract, conjunctiva, and, with less frequency, the cornea. The virus then ascends by axons of sensory neurons to the trigeminal ganglion to establish life-long latency with a potential for recrudescence. Cytolytic pathology and immune-mediated disease are associated with FHV-1 infection. FHV-1 was isolated from the conjunctiva, cornea, uveal tract, retina, optic nerve, ciliary ganglion, pterygopalatine ganglion, trigeminal ganglion, brainstem, visual cortex, cerebellum, and olfactory bulb of infected cats during the acute phase. Trigeminal and cranial cervical ganglia harbor latent virus in the latent phase.

Clinical Presentation

Early signs of herpesvirus conjunctivitis include a bilateral serous ocular discharge that becomes mucopurulent (neutrophilic) with time. Secondary bacterial infections enhance the mucopurulent exudate. Unilateral or bilateral conjunctivitis is likely the most common ocular clinical sign in cats with or without concurrent upper respiratory signs (Figures 19.9 and 19.10). Dendritic corneal and/or conjunctival ulcers from viral-induced cytolysis and larger geographic, immune-mediated stromal ulcers can be associated with FHV (Figures 19.11 and 19.12). Dendritic corneal ulcerations are the hallmark sign of FHV infection, but simple, geographic corneal ulceration remains a far more common clinical sign. Corneal ulcers may heal rapidly or become chronic. Stromal keratitis may occur as a secondary, immune-mediated reaction to the virus. Stromal keratitis results in inflammatory cell infiltrates and deep

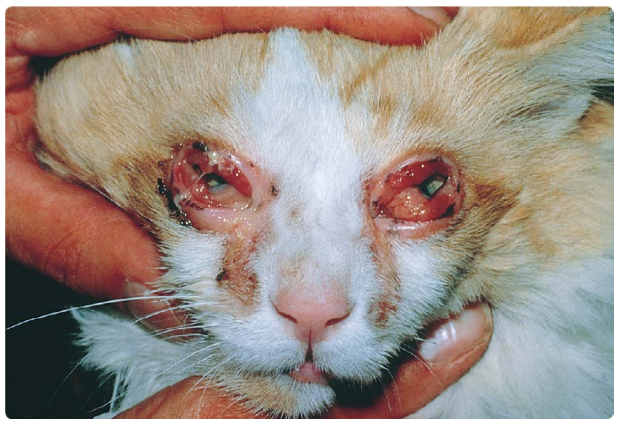

FIGURE 19.9 Bilateral blepharitis, conjunctival chemosis, hyperemia, and a mucoid discharge are found in this cat with herpesvirus.

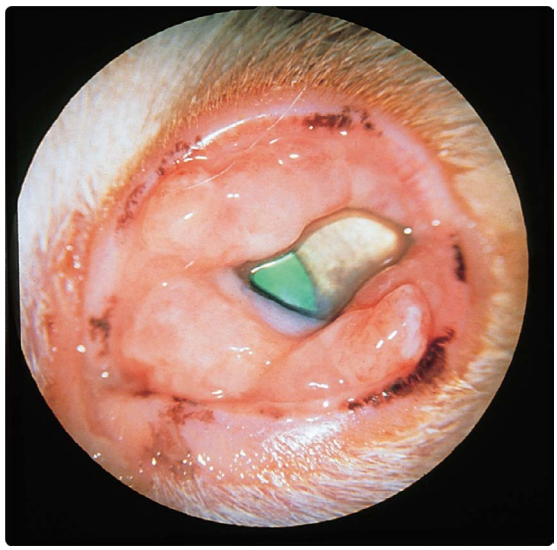

FIGURE 19.10 Chemosis is so severe in this cat with herpesvirus that the cornea can be barely seen. The cat also has diffuse, mild conjunctivitis.

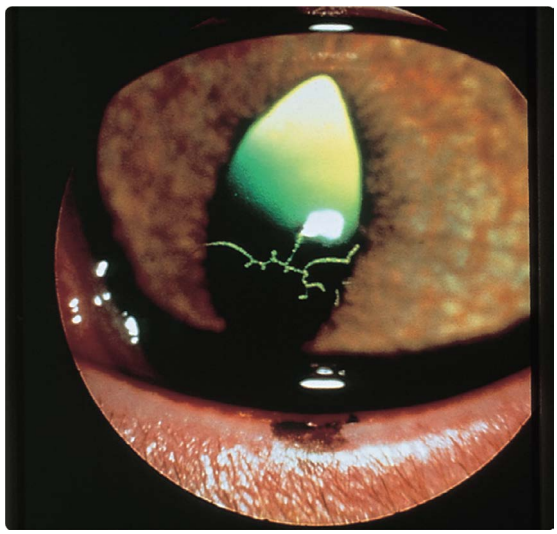

FIGURE 19.11 Linear, dendritic corneal ulcers are unique to herpesvirus.

FIGURE 19.12 Dendritic rose Bengal-positive lesions of the third eyelid conjunctiva are present in this cat with herpesvirus.

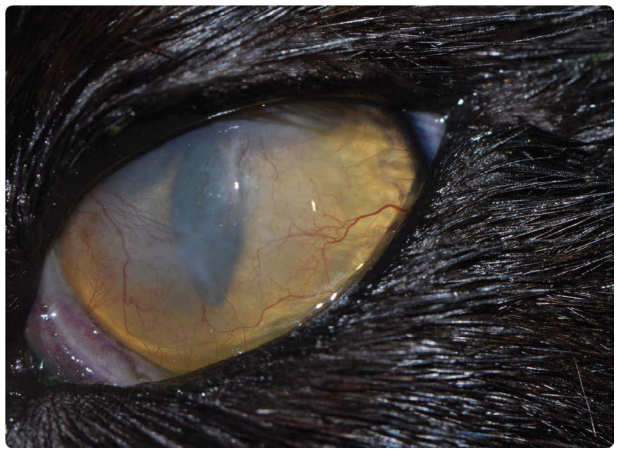

FIGURE 19.13 Generalized stromal keratitis is caused by FHV-1 in this cat.

FIGURE 19.14 Symblepharon (adhesions of conjunctiva to cornea or another conjunctival surface) from herpesvirus is present in this cat.

stromal vascularization (Figure 19.13). Symblepharon, secondary to conjunctival and corneal ulceration, is more common during a more acute primary infection (Figure 19.14). Neonatal ophthalmia can result from FHV infection during birth or within the perinatal period. Anterior uveitis may also be noted in some infected cats. KCS, while uncommon, may develop over time. Corneal sequestration and eosinophilic keratitis are also associated with FHV infection in cats (Figures 19.15 and 19.16).

Differential Diagnosis

Conjunctivitis is found in many types of eye diseases. It may be infectious (herpesvirus, calicivirus, *Mycoplasma*, and *Chlamydia* in cats) or noninfectious. Conjunctivitis may be primary or be secondary to ulcerative keratitis, eyelid disease, orbital cellulitis, nasolacrimal duct obstruction, KCS, atopy, environmental irritation, and neoplasia (lymphoma). Episcleral injection also causes the white part of the globe to be red and is associated with scleral or intraocular diseases such as episcleritis, anterior uveitis, glaucoma, and intraocular neoplasia.

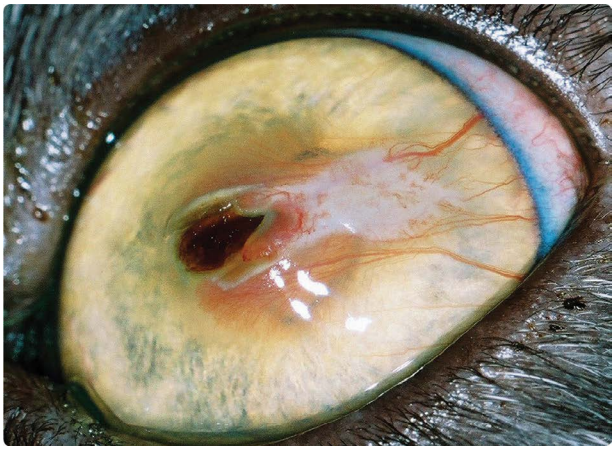

FIGURE 19.15 The dark corneal lesion with corneal fibrosis and vascularization is a corneal sequestrum and are clinically associated with chronic feline herpesvirus.

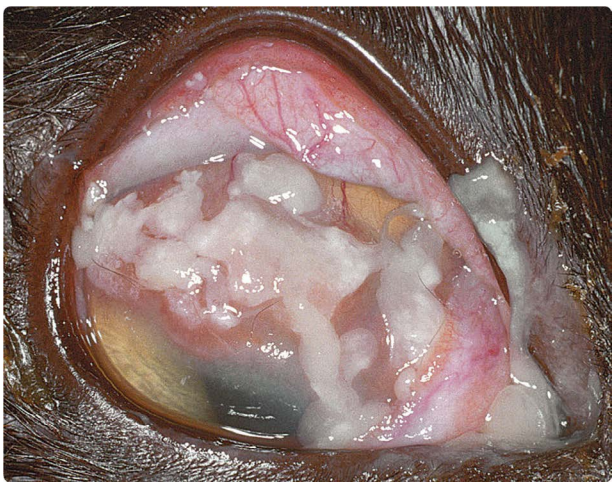

FIGURE 19.16 Eosinophilic keratitis is associated with feline herpesvirus in this cat. Note the white, proliferative, plaque lesions on the corneal surface.

Diagnosis

Due to the widespread presence of virus in normal and potentially infected cats, diagnostic confirmation of FHV infection remains challenging. While immunofluorescent antibody (IFA) and VI testing of conjunctival or corneal scrapings for herpesvirus is widely available, both are relatively insensitive in chronically infected cats. Serum antibody testing is only useful in nonvaccinated cats. Because it is an IFA test, prior fluorescein staining may yield false positives, so scrapings should be taken before staining. PCR and reverse-transcriptase PCR testing are more sensitive than the IFA tests. Although the extreme sensitivity (and specificity) of PCR has improved detection of virus, it has also confirmed that virus can be demonstrated in up to 31% of apparently normal cats. Conjunctival and/or corneal cytology is indicated in any cat with clinical signs of FHV infection. Lymphocytes generally predominate early, and large mononuclear cells are not uncommon. Neutrophils and giant epithelial cells are seen with chronic or secondary infection. Intranuclear inclusion bodies are seen very rarely, if ever, in clinical cases. Cytology can also be useful to assess for other cause of conjunctivitis such a *C. felis* or to rule out associated diseases like eosinophilic conjunctivitis or keratitis. Clinically, keratoconjunctivitis with dendritic branching corneal ulcers is generally assumed to be diagnostic of herpesvirus infection (**Figures 19.11** and **19.12**). Herpetic keratitis in the cat may or may not be associated with upper respiratory disease, particularly in more chronic cases.

Management

Therapy for herpesvirus remains challenging as a wide variety of both topical and systemic treatments have been utilized, each with varying degrees of success. In general, conjunctivitis and ulcerative keratitis are treated with topical antiviral preparations and broad-spectrum antibiotics to control any secondary bacterial infection. The efficacy of the antiviral medication in controlling the herpesvirus conjunctivitis (without corneal involvement) is variable. Herpesvirus vaccines are available for cats; however, herpesvirus conjunctivitis can occur in vaccinated cats. Recurrent herpesvirus may be associated with the immunosuppression by FIV/FeLV.

Antiviral agents should be prescribed when ocular signs are severe, persistent, or recurrent or when there is corneal ulceration. Of all the many topical antiviral agents that have been utilized and/or tested for the treatment of FHV, topical cidofovir (0.5%–1%) appears to be the most effective and has the added benefit of only needing to be given twice daily. Oral famciclovir (40 mg/kg p.o. q.8 h.) for 3 weeks can improve ocular, periocular, and systemic FHV disease. Oral treatment with L-lysine remains safe but controversial. While it has been documented to reduce clinical signs and viral shedding, it has not been confirmed to shorten clinical disease or reduce recurrence. Some owners feel, however, that chronic treatment with oral lysine is effective. The recommended dose of oral lysine is 500 mg q.12 h. in adult cats and 250 mg q.12 h. in kittens. Systemic interferon may be beneficial in cats that are refractory to other therapies. Treatment with topical steroids is more likely to result in corneal ulceration and also more likely to result in the development of stromal keratitis. If conjunctivitis or keratitis remains after antiviral treatment, then the addition of topical diclofenac (0.1%) or topical cyclosporine (0.2%) while maintaining antiviral therapy may be beneficial. Client education to establish clear goals of treatment is important. Regardless of any therapy or combination of therapies, many cats will continue to have clinical signs and recurrence of disease. It may also be beneficial to try different treatments for different cats, even those that have similar clinical signs, as different cats appear to respond to different therapy. Reduction and/or avoidance of stress can be beneficial to reduce recurrences. Recurrent and chronic herpes infections may suggest systemic immunosuppression, so cats should be evaluated for FeLV and FIV.

FELINE INFECTIOUS PERITONITIS

Definition/Overview

Effusive (wet) and noneffusive (dry) forms of feline infectious peritonitis (FIP) are known. The dry (noneffusive or parenchymatous) form of FIP is associated with the most ocular changes. There is increased risk of development of disease in young cats, sexually intact cats, and in certain breeds (Abyssinians, Bengals, Birmans, Himalayans, Ragdolls, and Rexes).

Etiology

FIP is caused by a coronavirus. Infection with feline coronavirus may result in no clinical disease, enteric disease, or FIP.

Pathophysiology

FIP replicates within macrophages and results in deposition of virus-laden macrophages within the endothelium of small blood vessels, which leads to pyogranulomatous lesions in a variety of tissues. Granulomatous lesions in the dry form are often found outside the abdomen and thorax, especially in the eye and the CNS. A fatal Arthus-type immune reaction of cats is associated with infection with the FIP virus.

Clinical Presentation

Ocular signs may occur without concurrent systemic signs or may be prodromal to systemic signs. The ocular signs are often bilateral but can be unilateral, even in patients with concurrent systemic disease. The most common ocular manifestation is bilateral, granulomatous anterior uveitis (Figures 19.17 and 19.18). Clinical signs include pyogranulomatous anterior and posterior uveitis, aqueous flare, "mutton-fat" keratic precipitates (Figure 19.19), hypopyon, synechiae, secondary glaucoma, exudative RD, choroiditis (Figure 19.20), retinal hemorrhages, vasculitis with pyogranulomatous sheathing or cuffing of retinal vessels (Figure 19.21), and optic neuritis. There have been several cases of remission in cats with ocular signs only and high FIP antibody titers.

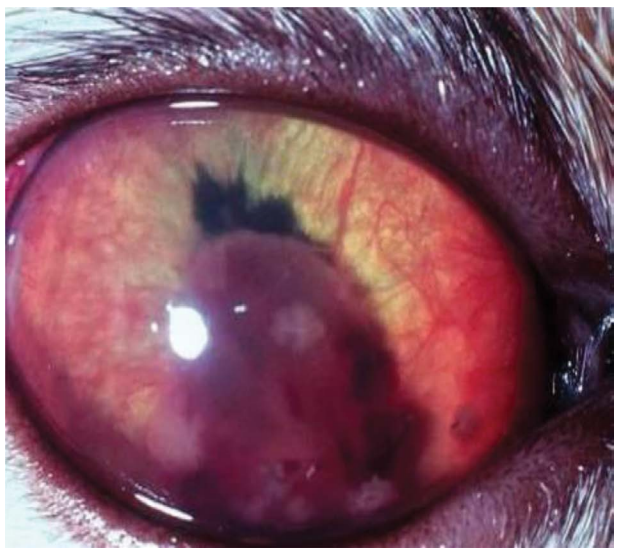

FIGURE 19.17 Fibrin clot, hypopyon, hyphema, iritis, iris neovascularization, miosis, and posterior synechia are found in this cat with FIP.

FIGURE 19.18 This is the same cat as in **Figure 19.17** 2 weeks after initial diagnosis. The cat has now developed iris bombe and secondary glaucoma.

Differential Diagnosis

See Table 19.1.

Diagnosis

Antemortem diagnostic confirmation of FIP remains particularly challenging, if not impossible. Serology can only be used as a guide to indicate current or previous infection. In general, a cat's history, clinical signs, and suggestive laboratory findings lead to a presumptive diagnosis. A presumptive diagnosis may be aided by clinical pathologic alterations, with the total plasma protein frequently very elevated, a polyclonal gammopathy, and elevated serum fibrinogen present. Anterior chamber

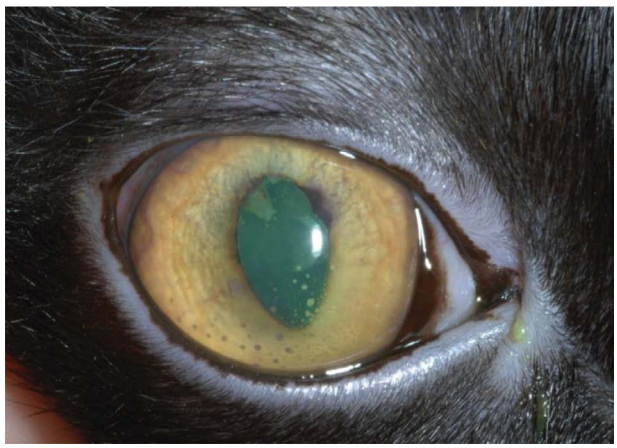

FIGURE 19.19 This cat with FIP has keratic precipitates.

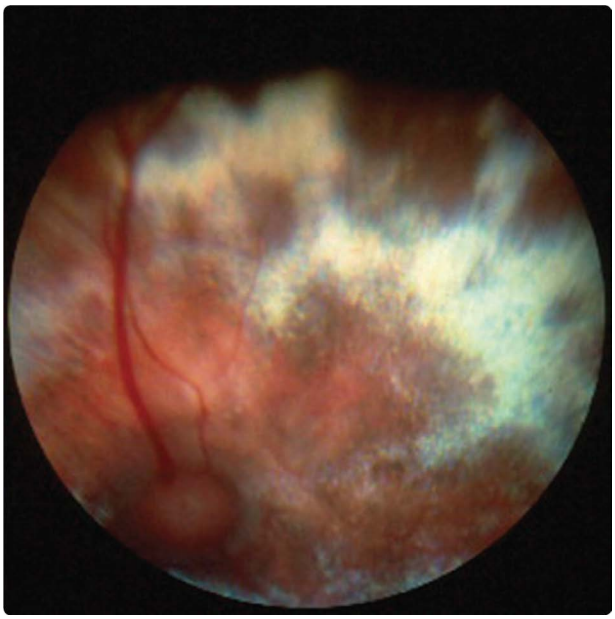

FIGURE 19.20 Focal regions of granulomatous and pigmented chorioretinitis are noticed in this cat with FIP.

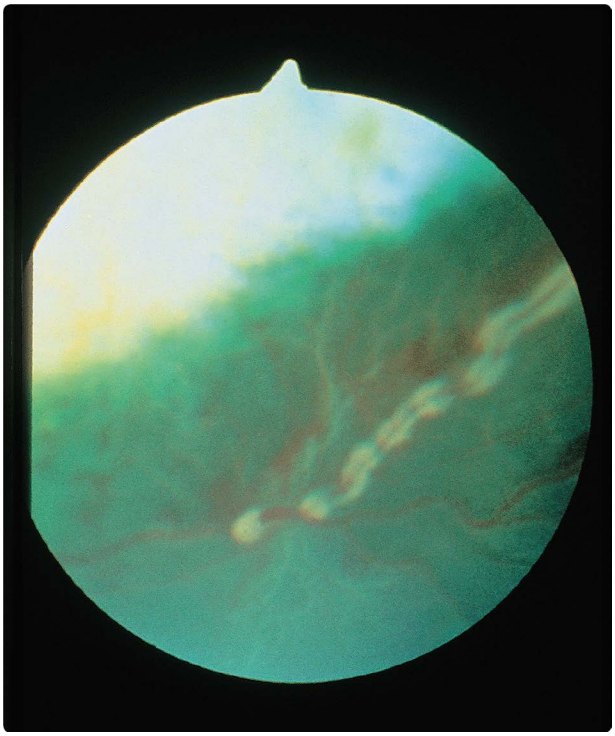

FIGURE 19.21 Perivascular cuffing, retinal edema, and retinal hemorrhage are noticed in the retina of a cat with FIP. (*Courtesy of B. Spiess.*)

paracentesis reveals protein, fibrin, neutrophils, erythrocytes, and mononuclear cells, but this is not specific to FIP cases. Recently, the sensitivity and specificity of an immunocytochemical assay in aqueous humor of cats suspected of having FIP was evaluated and not found to be clinically useful. No antemortem test, including histopathology, has proven to be diagnostic.

Management

There is no known effective treatment for FIP. Therapy for ocular manifestations of FIP is symptomatic for the anterior uveitis and generally includes topical steroids, topical atropine (if secondary glaucoma is not present), and systemic steroids. Response to therapy is generally temporary as the disease progresses.

FELINE LEUKEMIA VIRUS

Definition/Overview

FeLV can cause anterior uveitis (one or both eyes), retinitis, irregular or asymmetrical pupils, and secondary glaucoma.

Etiology

FeLV is a retrovirus whose genetic material is transmitted from host to host as RNA.

Pathophysiology

Infection with FeLV itself causes minimal ocular disease with the exception of its role in lymphosarcoma. The uveal tract is a common site for metastasis of leukemic lymphocytes. Cats with ocular lymphosarcoma may present initially with signs of mild uveitis, including miosis, aqueous flare and keratic precipitates, or subtle iridal masses. As the disease progresses, the iris becomes greatly thickened and distorted with the infiltration of tumor cells. Glaucoma is a common sequela as lymphoma cells infiltrate the iridocorneal angle.

Clinical Presentation

Ocular and periocular clinical signs include orbital masses, eyelid masses, conjunctival and third eyelid masses, anterior uveal masses, anterior uveitis, hypopyon, secondary glaucoma, chorioretinitis, choroidal masses, retinal hemorrhage, retinal detachments, and optic neuritis. Retinal changes include hemorrhages (Figure 19.22), pale retinal vessels (anemia), leukemic infiltrates appearing as multifocal gray opacities, and RDs. Corneal changes are uncommon but include keratitis, edema, and a keratopathy appearing as a wide opaque band of neoplastic stromal lymphoid cells. Conjunctivitis with proliferation of lymph follicles may be noted. Horner syndrome associated with mediastinal lymphosarcoma in FeLV-positive cats has been reported. Isolated iridal tumor formation may occur. Anisocoria, dyscoria, and abnormal pupillary light reflexes ("feline spastic pupil syndrome") have also been associated with FeLV infection of the ciliary ganglia and short ciliary nerves. The prognosis for cats affected with feline spastic pupil syndrome is poor.

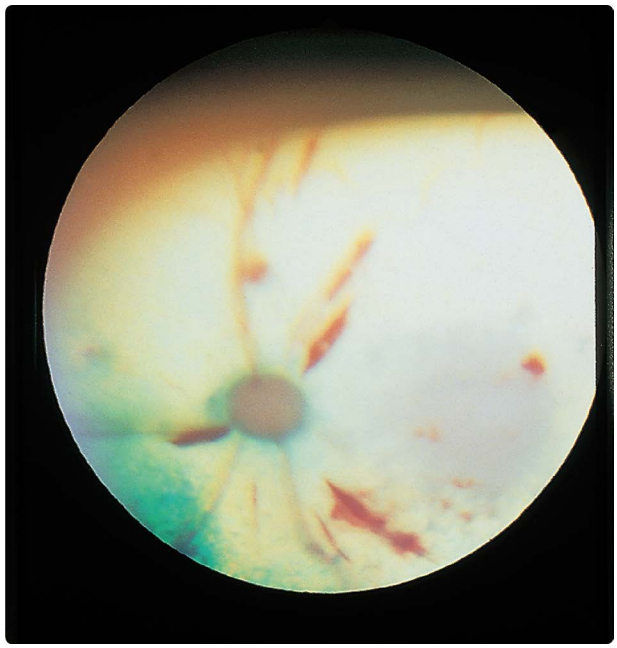

FIGURE 19.22 Linear flame hemorrhages of the nerve fiber layer and a focal exudative retinal detachment are noticed in this FeLV-positive cat.

Differential Diagnosis

See Table 19.1.

Diagnosis

Anterior chamber or vitreal paracentesis may reveal neoplastic cells in cases of lymphosarcoma but is usually nonspecific as to the etiology. A serum enzyme-linked immunosorbent assay (ELISA) antigen test is a good initial test for screening. If positive, indirect IFA testing can be performed on a peripheral blood smear of ELISA-positive cats. Indirect FA, ELISA, or PCR on bone marrow aspirates, lymph node biopsies, or biopsies of intraocular masses may also be useful. FeLV antigens and proviral DNA have been found in normal corneal tissue, and all potential donors should be screened prior to corneal transplantation.

Management

Therapy for FeLV includes management of opportunistic infections and supportive therapy that is directed toward the ocular and systemic clinical signs of each patient. Cats with an increased risk of exposure to FeLV should be vaccinated regularly.

FELINE PANLEUKOPENIA VIRUS

Definition/Overview

Feline panleukopenia virus is a parvovirus known to cause cerebellar hypoplasia and retinal dysplasia, with retinal rosette formation, loss of normal retinal layered architecture, and reduced thickness of the neural retina in kittens. Focal retinal dysplasia appears as sharply defined hyperreflective areas in the tapetal fundus and depigmented areas in the nontapetal fundus. Optic nerve hypoplasia may also occur with the feline panleukopenia virus.

FELINE IMMUNODEFICIENCY VIRUS

Definition/Overview

Feline immunodeficiency virus (FIV) is a lentivirus. FIV infection results in progressive loss of $CD4^+$ T-helper cells early in the infection, followed by depletion of $CD8^+$ T cells in the advanced stages of the disease. Anterior uveitis, lens luxation, pars planitis, and conjunctivitis are reported with FIV. Anterior uveitis and chorioretinitis are the most common ocular findings in cats coinfected with both FIV and *Toxoplasma gondii*. Currently marketed PCR assays for the detection of FIV lack sensitivity and vary significantly in accuracy, as false-positive results are higher in FIV-vaccinated cats than in unvaccinated cats. Positive serum antibody titers for toxoplasmosis are more common in FIV-positive cats. When testing for toxoplasmosis in these cases, it is important to test for both IgM and IgG, as up to 43% of coinfected cats can be positive for IgM but not for IgG.

FELINE SARCOMA VIRUS

Definition/Overview

Feline sarcoma virus is a naturally occurring, replication-defective, acute, transforming FeLV that has incorporated one of several cellular oncogenes. Under experimental conditions, it has been associated with uveal melanoma and anterior uveitis in cats. It is unknown if it plays any role in naturally occurring uveitis in cats.

PROTOZOAL INFECTION

LEISHMANIASIS

Definition/Overview

Leishmaniasis is of major public health significance in Central and South America, the Mediterranean region, Africa, and Asia. The visceral and cutaneous forms are associated with blepharitis, conjunctivitis, keratitis, KCS, anterior uveitis, rubeosis iridis, and severe panuveitis. Dogs are more commonly affected than cats.

Etiology

Leishmania spp. are diphasic protozoan parasites. Dogs are considered important primary reservoirs of *Leishmania* spp., and sandflies (*Phlebotomus* or

Lutzomyia spp.) are the vectors. *Leishmania donovani* has been reported as the cause of leishmaniasis of dogs within the United States and Canada. Naturally occurring leishmaniasis has been increasingly reported in cats in the last few years. Feline leishmaniasis is generally caused by *L. mexicana* in Texas, *L. major* in Egypt, and *L. (Viannia) panamensis* in Brazil. *L. infantum*, a causative agent of feline leishmaniasis in southern France and Italy, also causes leishmaniasis in dogs.

Pathophysiology

Transmission to vertebrates is via bites from infected sandflies, and sandflies are infected by reservoir hosts. The incubation period may be a few months to between 3 and 4 years. Over 90% of infected dogs develop clinical disease, and 81% of infected dogs will develop ocular lesions that are typically bilateral. The inflammation is mononuclear with the organism found in histiocytes.

Clinical Presentation

Cutaneous lesions begin on the head and can result in alopecia, scaliness, and vesicular lesions that may appear similar to pemphigus complex. Focal granulomatous blepharitis and conjunctivitis may occur. Scleritis, superficial or deep keratitis, KCS, anterior uveitis, and secondary glaucoma are also reported with *Leishmania* infections (**Figure 19.23**) in dogs, but the choroid and retina are usually spared. Documented lesions also occur in intraocular, extraocular, and adnexal muscles as well as the optic nerve of dogs. In cats, ocular lesions include ulcerative keratitis, panuveitis, and secondary glaucoma.

Differential Diagnosis

See Table 19.1.

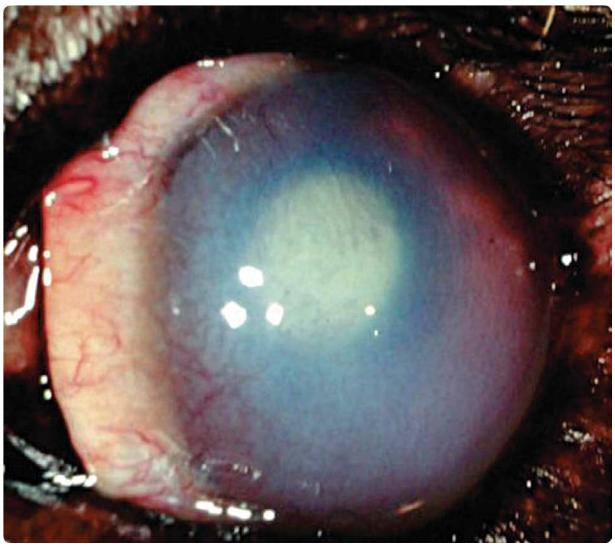

FIGURE 19.23 Leishmaniasis is causing keratouveitis in this dog from Italy. (*Courtesy of A. Guandalini.*)

Diagnosis

The *Leishmania* organism can be diagnosed with histopathologic or immunoperoxidase evaluation of cutaneous or ocular biopsy specimens, PCR of anticoagulated blood, or isolation of the organism from the subcutaneous tissue, bone marrow, lymph node aspirates, or skin impression smears. Serologic tests are available that use ELISA and indirect IFA testing.

Management

Elimination of the organism is difficult, and recurrence is common, so the prognosis is guarded. Allopurinol combined with meglumine antimoniate has been recommended for treatment. Allopurinol combined with sodium stibogluconate has been shown to be successful in the treatment of canine leishmaniasis without recurrence for over 24 months. Symptomatic therapy is used for the ocular lesions such as topical anti-inflammatory agents.

TOXOPLASMOSIS

See also Chapter 21.

Definition/Overview

Ocular signs of toxoplasmosis are more common in cats than dogs. Cats are both the definitive and the intermediate hosts of toxoplasmosis.

Etiology

Toxoplasmosis is an infection caused by the obligate intracellular coccidian parasite *Toxoplasma gondii*.

Pathophysiology

As cats are the definitive hosts, only they can shed oocysts that can be infective to other species. Cats can shed oocysts for about 7 days, beginning 3–5 days after infection. Oral ingestion of tissue cysts or oocysts results in spread of *Toxoplasma* tachyzoites to extraintestinal organs via the blood or lymph. Focal necrosis of the heart, eye, and brain results due to proliferation of *T. gondii*. Uveitis secondary to toxoplasmosis may result from rapid replication of tachyzoites within ocular tissue or from deposition of immune complexes within uveal tissue. Intraocular production of antibodies specific for *T. gondii* has been reported, and the organism has been identified within the uveal tract by histopathology and in the aqueous humor by PCR.

Clinical Presentation

Toxoplasmosis in cats occurs with ocular signs alone, or it can occur with generalized systemic involvement of the liver, heart, lungs, and meninges. The uveitis in cats is most frequently documented as multiple foci of retinitis or retinochoroiditis (**Figure 19.24**) with varying

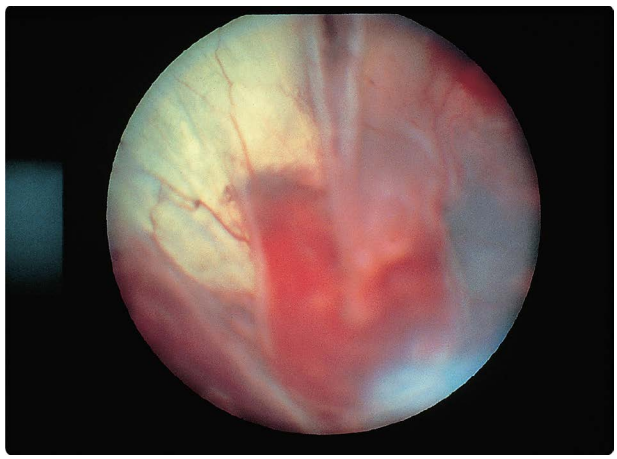

FIGURE 19.24 Extensive retinal hemorrhage and detachment are associated with intraocular toxoplasmosis in this cat.

degrees of anterior uveitis. Clinical signs in dogs (in decreasing order of frequency) are anterior uveitis, retinitis, choroiditis, extraocular myositis, scleritis, optic neuritis, and keratoconjunctivitis.

Differential Diagnosis

See Table 19.1.

Diagnosis

The definitive diagnosis of toxoplasmosis remains challenging. The presumptive diagnosis of toxoplasmosis can be made in cats with signs of uveitis and a positive serum titer IgM and/or IgG titer. Cats coinfected with FIV may never seroconvert from an IgM titer to an IgG titer. ELISA tests for detection of IgM antibodies and toxoplasma antigen have been developed for diagnosis of toxoplasmosis. Levels of the IgM class of antibody rise and fall over approximately 3–4 months after infection, whereas those of the IgG class of antibody may rise more slowly and remain elevated in cats for years after exposure to *T. gondii*. Detection of antibodies in the serum and aqueous humor can be compared through the calculation of a Goldmann-Witmer coefficient (C value). A C value of 3 or greater is consistent with local production of antibody within the globe. Histologic demonstration of the parasite is the sole definitive means of confirmation. Fecal examination for *Toxoplasma* oocysts can be useful to determine if the cat is shedding and potentially infectious for other animals or humans.

Management

Toxoplasmosis is a zoonotic disease. Owners should be instructed in basic hygiene rules to prevent toxoplasmosis, including daily cleaning of the litterbox, restriction of hunting (keep cats indoors), and do not feed cats raw or undercooked meat. Treatment for toxoplasmosis is most commonly done with oral clindamycin for 3–4 weeks along with topical and systemic corticosteroids and topical atropine. In cats with confirmed titers, uveitis may be chronic and require chronic therapy to control the uveitis.

FUNGAL DISEASES

See also Chapter 21.

Ocular manifestations of disseminated mycotic infections are relatively common in endemic areas. Systemic mycotic infections that commonly involve the eyes include cryptococcosis, histoplasmosis, blastomycosis, and coccidioidomycosis. Medium- to large-breed dogs are most commonly affected as their exposure to the organism is greater than small dogs. Inhalation is believed to be the primary route of infection, with hematogenous spread to the eye. Diagnosis is based on clinical and ocular signs, organism identification from ocular or other tissues, fungal culture, histopathology, serological testing (urine or serum), and imaging (thoracic and abdominal). The typical histopathologic lesion for systemic mycoses is granulomatous or pyogranulomatous inflammation with identification of organisms enhanced by special stains. Less common fungi/yeasts that may cause ocular signs (including conjunctivitis, endophthalmitis, keratitis, and/or chorioretinitis) are *Candida* spp., *Geotrichum* spp., *Aspergillus* spp., *Sporotrichum* spp., and *Paecilomyces* spp. *Candida* has caused corneal ulcers in cats.

CRYPTOCOCCOSIS

Definition/Overview

Cryptococcosis is an opportunistic systemic fungal infection. It is not a contagious disease. It is considered to be the most common feline systemic fungal infection. Birds such as pigeons are considered to be significant vectors of *Cryptococcus* spp.

Etiology

Cryptococcosis is caused by the saprophytic yeast-like organism *Cryptococcus neoformans* or *Cryptococcus gatii*. *C. neoformans* is associated with soil enriched with avian feces containing high levels of nitrogen. *C. neoformans* is yeast-like organism (3.5–7 microns) with a thick capsule.

Pathophysiology

The organism is most commonly inhaled from the environment. Cryptococcosis may infect the eye by hematogenous means or by extension from the nose or CNS. The organisms may be found in the ocular tissues, including the vitreous.

Clinical Presentation

Clinical signs in dogs are mainly associated with the CNS but ocular, upper respiratory, or cutaneous lesions

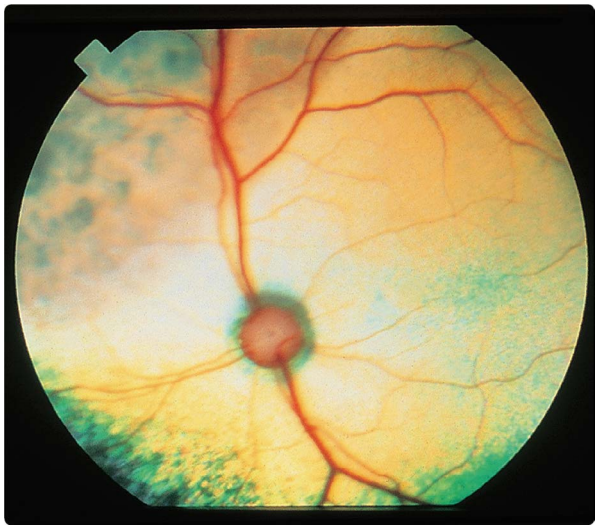

FIGURE 19.25 A large, focal, granulomatous lesion with hyperpigmented regions caused by cryptococcosis in a cat.

are also regularly found. Ocular or periorbital lesions are found in 20%–40% of dogs. In cats, clinical signs are primarily associated with the nasal passages, cutaneous lesions, or the CNS. Common ocular lesions in cats include chorioretinitis, RDs, anterior uveitis, exophthalmos, and optic neuritis (Figures 19.25 and 19.26).

Differential Diagnosis

See Table 19.1.

Diagnosis

Diagnosis is based on identification or culture of the organism by cytology of tissue aspirates, histology, or serologic testing. Organisms may be identified in subretinal or vitreal aspirates or cerebrospinal fluid (CSF) tap. A latex agglutination test against capsular antigens is available, and the titers appear to correlate with disease severity and response to treatment.

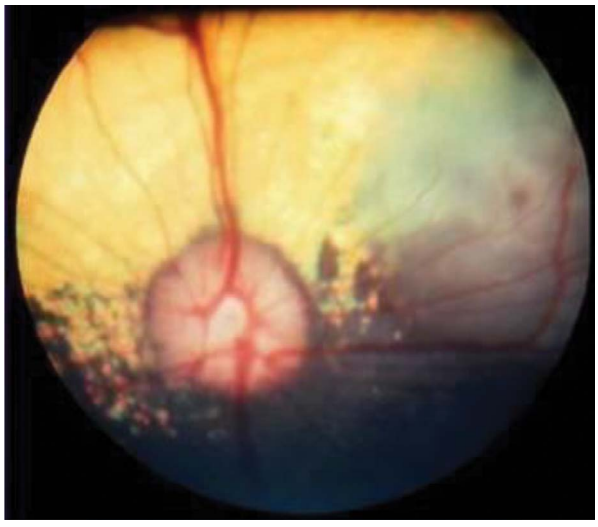

FIGURE 19.26 A large, focal, granulomatous lesion with hyperpigmented regions caused by cryptococcosis in a dog.

Management

Cryptococcosis has been successfully treated in cats with itraconazole and fluconazole, which may have fewer side effects than ketoconazole and amphotericin B. Numerous systemic antifungal agents, used either alone or in combination, have shown efficacy in dogs, including itraconazole, amphotericin B, flucytosine, ketoconazole, and fluconazole. Therapy is symptomatic for the anterior uveitis and generally includes topical steroids and topical atropine (if secondary glaucoma is not present).

COCCIDIOIDOMYCOSIS

Definition/Overview

Coccidioidomycosis is a systemic fungal infection found in dogs and rarely in cats. It is not a contagious disease. It appears to be a posterior segment disease, which can extend to the anterior segment.

Etiology

Coccidioidomycosis is caused by a dimorphic fungus *Coccidioides immitis*, found in the alkaline soil of the dry climate of the Southwestern United States, Western Mexico, and Central America.

Pathophysiology

Infection is through inhalation of arthrospores from the environment. Hematogenous and lymphatic dissemination of endospores causes disseminated disease. The eye is one of several organs that are most commonly affected.

Clinical Presentation

Systems commonly affected in dogs and cats include the bones, joints, respiratory tract, CNS, heart, lymph nodes, and eyes. Ocular signs may appear first and consist of granulomatous panuveitis, anterior uveitis, secondary glaucoma, orbital cellulitis, keratitis, retinitis, and RDs (Figure 19.27). Cats may also have subpalpebral, subconjunctival, and periocular swelling. Between 30% and 50% of cases in dogs have ocular signs.

Differential Diagnosis

See Table 19.1.

Diagnosis

Diagnosis is based on identification of the organism by cytology of tissue aspirates, histology, or serologic testing. Vitreous or subretinal aspiration may reveal endospores. Serologic tests (precipitin and complement

FIGURE 19.27 A large chorioretinal granuloma caused by *C. immitis* is present in the nontapetum of this dog.

fixation) are available. Histopathologically, a granulomatous uveitis, either unilateral or bilateral, is most common. The cornea, iridocorneal angle, ciliary body, retina, and choroid are affected. Hyphema and vitreal hemorrhage may be present.

Management

Oral ketoconazole, fluconazole, itraconazole, and amphotericin B have been used in dogs. Long-term use of ketoconazole in dogs has been found to be associated with the development of cataracts. Cats have been successfully treated with fluconazole. Therapy is symptomatic for the anterior uveitis and generally includes topical steroids and topical atropine (if secondary glaucoma is not present).

HISTOPLASMOSIS

Definition/Overview

Histoplasmosis is a systemic fungal infection of dogs and cats. It is a primary respiratory disease with dissemination to liver, spleen, intestine, lymph nodes, CNS, and bone. Histoplasmosis is widespread in alkaline soils of North and South America but particularly in the Ohio, Mississippi, and Missouri River valleys. Young hunting breeds of dogs may have an increased risk.

Etiology

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum*. *H. capsulatum* organisms are 2–4 microns, round to oval, and typically found within macrophages.

Pathophysiology

Infective conidia are either inhaled or ingested. Dissemination is hematogenous or via the lymphatics to the lungs, GI tract, liver, bone marrow, and eyes, resulting in a granulomatous inflammatory response. The choroid appears to be a preferred target region in the eye.

Clinical Presentation

Experimentally, ocular signs were identified in about 60% of eyes in dogs. Ocular signs in dogs and cats include granulomatous chorioretinitis (Figure 19.28), optic neuritis, RD, anterior uveitis, blepharitis, and conjunctivitis. Cats can also be affected with mass lesions of the conjunctiva and third eyelid (Figure 19.29).

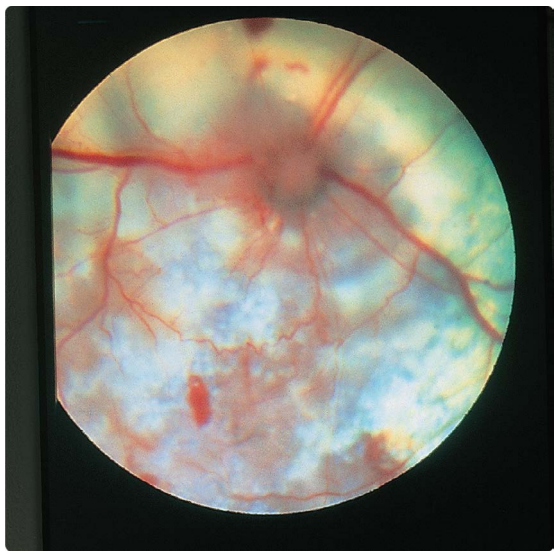

FIGURE 19.28 Retinal hemorrhage, peripapillary retinal edema, and flat retinal detachment due to histoplasmosis-induced chorioretinitis in a cat.

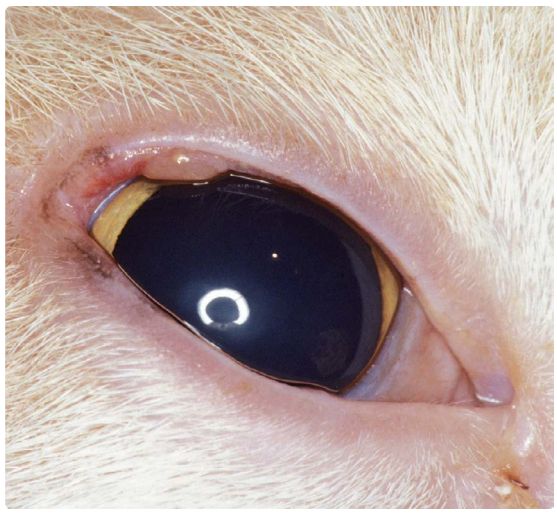

FIGURE 19.29 Histoplasmosis is present as a lump in the upper eyelid of this cat.

Differential Diagnosis

See Table 19.1.

Diagnosis

Diagnosis is based on identification or culture of the organism by cytology of tissue aspirates, histology, or serologic testing. Normocytic, normochromic, nonregenerative anemia is the most common hematologic abnormality. The organism may occasionally be seen in circulating mononuclear cells and eosinophils. Cats and dogs with disseminated histoplasmosis may have negative serologic tests. In dogs, serologic diagnosis with an agar gel immunodiffusion (AGID) test is 80% sensitive and 100% specific.

Management

Cases may respond to itraconazole or fluconazole alone. Combined treatment with amphotericin B and itraconazole may be more efficacious in patients with severe or fulminating disease. Cats have been successfully treated with itraconazole and fluconazole. In both dogs and cats, long-term therapy is generally required, and recurrence is common. Therapy is symptomatic for the anterior uveitis and generally includes topical steroids and topical atropine (if secondary glaucoma is not present).

BLASTOMYCOSIS

Definition/Overview

Blastomycosis is a systemic fungal infection that usually originates in the lungs and then disseminates to other organ systems. All systems of the body may be infected. The disease affects dogs more than cats. Bluetick Coonhounds, Treeing-walker Coonhounds, Pointers, and Weimaraners have been reported to have the highest risk of *Blastomyces dermatitidis* infection.

Etiology

Blastomycosis is caused by the dimorphic fungus *B. dermatitidis*. Water and soil contamination play an important role in the spread of blastomycosis. The budding yeast found in tissue is 5–20 microns with a thick, double-contoured wall.

Pathophysiology

Infection usually occurs by inhalation of infective conidiophores from the environment. Alveolar macrophages phagocytize the conidia. These cells may be transported into the pulmonary interstitium from where they gain access to the vascular system and lymphatics. Hematogenous and lymphatic dissemination leads to pyogranulomatous disease. The eyes are commonly affected in both dogs and cats.

Clinical Presentation

Ocular signs include conjunctivitis, corneal edema, corneal vascularization, anisocoria, anterior uveitis (Figure 19.30), secondary glaucoma, exophthalmos (retrobulbar inflammation), granulomatous chorioretinitis (Figures 19.31 and 19.32), RD, and optic neuritis (Figure 19.33).

Differential Diagnosis

See Table 19.1.

Diagnosis

Diagnosis is based on identification or culture of the organism by cytology of tissue aspirates, histology, or serologic testing. Detection of antigen in the urine is the

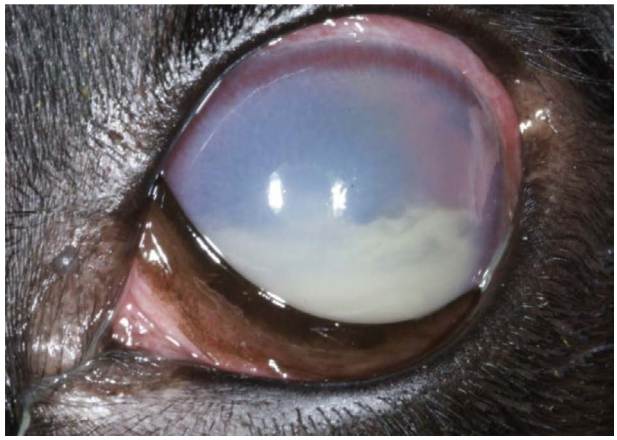

FIGURE 19.30 Scleral injection, deep perilimbal neovascularization, diffuse corneal edema, and hypopyon secondary to severe anterior uveitis in a dog with blastomycosis.

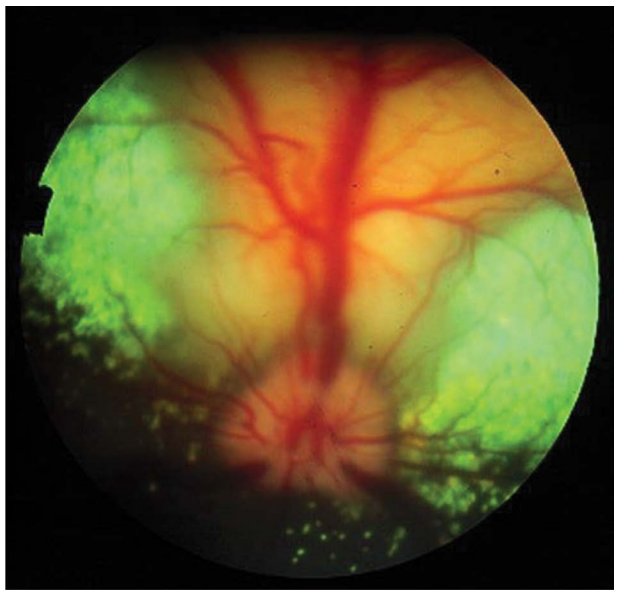

FIGURE 19.31 Large, subretinal granuloma in the central tapetum of a dog with blastomycosis.

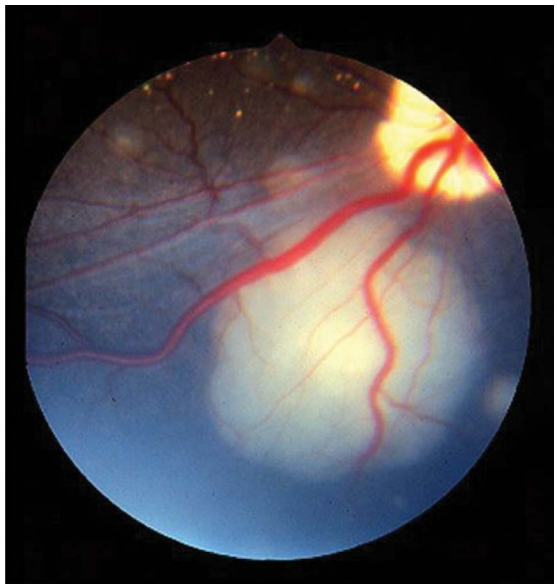

FIGURE 19.32 A subretinal granuloma in the nontapetum is present in this dog due to blastomycosis.

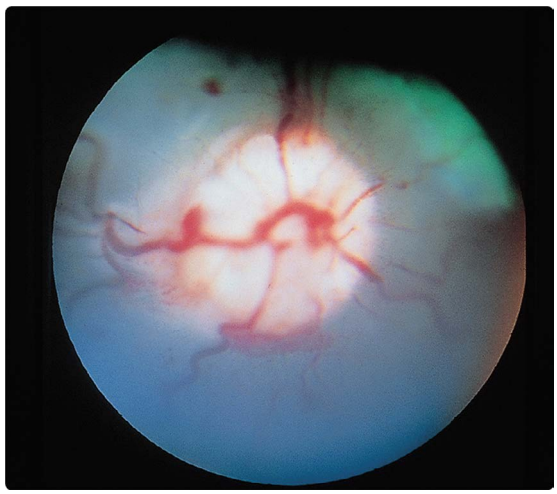

FIGURE 19.33 Optic neuritis, peripapillary retinal edema, and retinal hemorrhages in a dog with blastomycosis.

preferred method of diagnosis if the organism cannot be found of cytology or culture. The sensitivity of the urine antigen test is 93%.

Management

Itraconazole, ketoconazole, fluconazole, and amphotericin B are effective in treating some cases of canine blastomycosis, with itraconazole being the most commonly utilized. Itraconazole and itraconazole/amphotericin B can be used to treat blastomycosis in the cat. Therapy is symptomatic for the anterior uveitis and generally includes topical steroids and topical atropine (if secondary glaucoma is not present). The use of systemic anti-inflammatory agents will improve the prognosis for chorioretinal lesions, particularly the use of anti-inflammatory dose of steroids, but not all clinicians are

FIGURE 19.34 Severe granulomatous chorioretinitis with subretinal granuloma and retinal detachment caused by aspergillosis in a dog.

comfortable with this treatment regimen and will recommend systemic nonsteroidal agents instead.

ASPERGILLOSIS

Definition/Overview

Aspergillosis is caused by the filamentous fungus *Aspergillus* spp. Animals are infected opportunistically after inhaling *Aspergillus* spores. Disseminated aspergillosis has been reported to cause panuveitis, chorioretinitis, exudative RDs, and endophthalmitis (Figure 19.34). Recently, histopathologic evaluation of the eye of two different dogs demonstrated lens capsular rupture and intralenticular invasion of organism. German Shepherd Dogs are at increased risk. Diagnosis is made based on identification and culture of urine sediment, serum, synovial fluid, vitreous, lymph node, or intervertebral disc fine-needle aspirate biopsy specimens. Treatment is directed at eliminating the organism by administering amphotericin B, itraconazole, or fluconazole. Long-term therapy is required. Regardless, the prognosis for recovery from disseminated aspergillosis is poor.

ALGAE

PROTOTHECOSIS

Definition/Overview

Protothecosis is a rare and often fatal algal disease in the dog. The disseminated disease is most common in large-breed dogs and may be more common in females and Boxer dogs.

Etiology

Protothecosis is caused by two species of green algae, *Prototheca zopfii* (causes disseminated disease) and *P. wickerhamii* (associated with skin disease). These organisms are found in animal wastes and sewage. They are transmitted by ingestion of contaminated food, soil, or water.

Clinical Presentation

Systemic features in dogs include intermittent or protracted bloody diarrhea, CNS signs, skin lesions, lymphadenopathy, respiratory signs, and renal signs. Cats are reported to have skin lesions only. Ophthalmic signs are severe in >50% of the reported cases in dogs and include focal, diffuse, granulomatous chorioretinitis (Figures 19.35 and 19.36), vitreal exudate, RDs and degeneration, retinal hemorrhage, and panuveitis. The ocular signs may be the initial clinical abnormality and are usually bilateral.

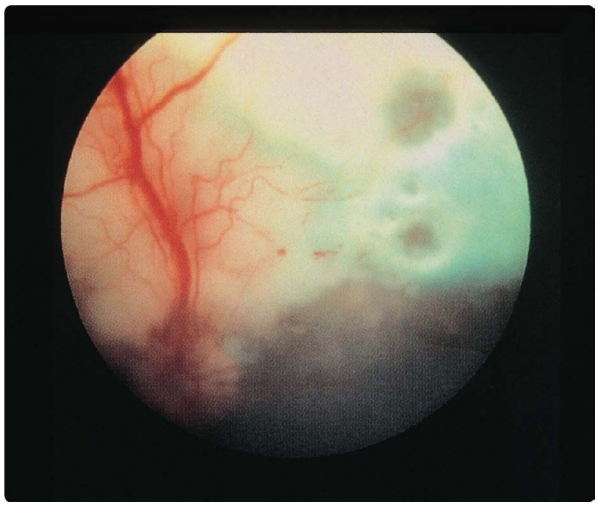

FIGURE 19.35 A subretinal granuloma elevates the retinal vessels dorsal to the optic disc. Focal hyperpigmented areas of chorioretinitis are also found in this dog with protothecosis.

FIGURE 19.36 Note the posterior synechia and vitreal opacification from protothecosis in the dog in Figure 19.35.

Differential Diagnosis

See Table 19.1.

Diagnosis

Diagnosis is by clinical signs, tissue aspiration, cytologic and histologic examination, and culture. Because colitis is one of the more common systemic signs associated with protothecosis, any dog with a history of hemorrhagic diarrhea and ocular lesions should be considered to be a candidate for this diagnosis.

Management

Amphotericin B and itraconazole have been shown to be initially effective, but most systemic infections are difficult to control, and the prognosis is grave. Therapy is symptomatic for the anterior uveitis and generally includes topical steroids and topical atropine (if secondary glaucoma is not present).

RICKETTSIA

EHRLICHIA CANIS

See also Chapter 21.

Definition/Overview

Ehrlichiosis is a tick-borne systemic disease known to be caused by a variety of rickettsial species. Several species of *Ehrlichia* are known to infect the dog, although *E. canis* is the most common. *E. canis* infection is associated with acute, subclinical, and chronic phases.

Etiology

E. canis is a small pleomorphic rickettsial organism that infects circulating mononuclear cells. The brown dog tick, *Rhipicephalus sanguineus*, is the arthropod vector of *E. canis*.

Pathophysiology

The prevalence of ocular lesions in canine ehrlichiosis has been reported as 10%–37%, and they are typically bilateral. Ocular lesions result from vasculitis, a platelet deficiency, and/or hyperviscosity. Chronic disease occurs in those dogs unable to mount an effective immune response to the organism. Neurologic signs consistent with meningoencephalitis are typical of dogs with disease manifestations that develop during chronic infection.

Clinical Presentation

Systemic features include lymphadenopathy, fever, nasal discharge, thrombocytopenia, and pancytopenia with an underlying vasculitis. Ocular signs are most commonly bilateral and may occur in both the acute and

chronic forms. Anterior uveitis and exudative retinal detachments are the most common ocular signs (Figures 19.37 and 19.38). Other ophthalmic signs include conjunctival and iridal petechia, panuveitis, retinitis, vasculitis, and tortuous retinal vessels with gray perivascular circular retinal foci in the early stages. Chorioretinitis and retinal vasculitis appearing as dark gray spots with surrounding hyperreflectivity in the tapetal fundus, subretinal hemorrhages, RD, optic neuritis, and papilledema are found in the later stages. Iridal petechiae, hyphema, and keratic precipitates may also be prominent (Figure 19.39).

Differential Diagnosis

See Tables 19.1 and 19.2.

FIGURE 19.37 Mild, diffuse corneal edema, fibrin clot, hyphema, and iritis in a dog with ehrlichiosis.

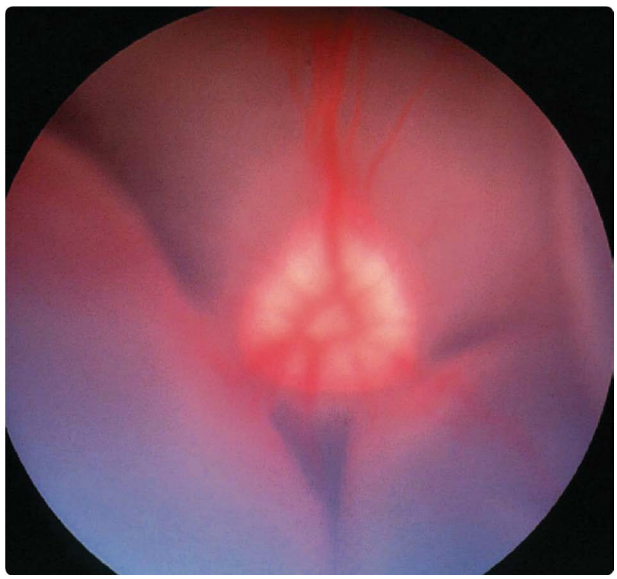

FIGURE 19.38 Retinal detachment with vasculitis and mild subretinal exudate involves nearly the entire retina in this dog with ehrlichiosis.

FIGURE 19.39 A blood clot is attached to the anterior lens capsule in this dog with ehrlichiosis. This dog has mild episcleral injection, perilimbal edema, and a blood clot in the anterior chamber secondary to anterior uveitis due to ehrlichiosis.

TABLE 19.2 Etiologies of hyphema and retinal hemorrhage associated with ophthalmic manifestations of systemic disease in dogs and cats

- Blood parasites
- Coagulopathies
- Hypertension (common cause of retinal hemorrhage)
- Hyperviscosity syndromes
- Intraocular neoplasia
- Retinal detachment
- Trauma (penetrating wounds of globe and, possibly, blunt trauma to head or globe)
- Uveitis associated with bacterial/fungal/viral/parasitic/immune-mediated diseases

Etiologies are listed in alphabetical order, not in order of importance.

Diagnosis

A diagnosis of ehrlichiosis is usually made on the basis of clinical signs, hematologic abnormalities, and serology. Nonregenerative anemia and thrombocytopenia are the predominant hematologic findings. Diagnosis of ehrlichiosis also involves direct visualization of morulae in peripheral blood smears, detection of *E. canis* antibodies, or PCR amplification of *Ehrlichia* spp. DNA.

Management

Tetracycline and doxycycline are used for systemic therapy. Anti-inflammatory doses of oral steroids may also improve res olution of ocular signs. Therapy is symptomatic for the anterior uveitis and generally includes topical steroids and topical atropine (if secondary glaucoma is not present).

ROCKY MOUNTAIN SPOTTED FEVER

Definition/Overview

Rocky Mountain spotted fever (RMSF) is a rickettsial disease of several vertebrate species that is transmitted by numerous ticks of the genus *Dermacentor*, *Amblyomma*, and *Rhicephalus*. Rodents and other small mammals serve a reservoirs for *Rickettsia rickettsii*.

Etiology

RMSF is caused by *Rickettsia rickettsii*, which is a small coccobacillary, Gram-negative obligate intracellular bacterium.

Pathophysiology

After entering the circulatory system, the rickettsiae replicate in the endothelial cells of capillaries and small blood vessels. Direct damage to the endothelial cells leads to vasculitis, necrosis, and increased vascular permeability. This process results in extravasation of fluid and blood cells into the extravascular fluid space. Varying degrees of damage are shown by the extent of ocular abnormalities.

Clinical Presentation

RMSF has ocular signs, including petechia of the conjunctiva and iris, scleral injection/edema, anterior uveitis, hyphema, retinal edema, and focal retinal petechiae associated with a mucopurulent oculonasal discharge, cough, lymphadenopathy, muscle and joint pain, vasculitis, splenomegaly, and thrombocytopenia (Figures 19.40 and 19.41).

Differential Diagnosis

See Tables 19.1 and 19.2.

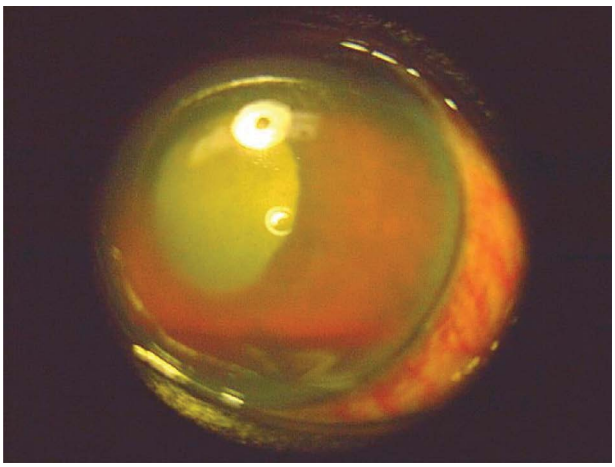

FIGURE 19.40 Episcleral injection, perilimbal corneal edema, hyphema, and iritis secondary to Rocky Mountain spotted fever in a dog.

FIGURE 19.41 Multiple, focal, deep retinal hemorrhages are present in this dog with Rocky Mountain spotted fever.

Diagnosis

Diagnosis is based consistent history, bloodwork, and on direct immunofluorescent testing for the organism, serologic testing, PCR, or rickettsial culture.

Management

Doxycycline is used for systemic therapy. Therapy is symptomatic for the anterior uveitis and generally includes topical steroids and topical atropine (if secondary glaucoma is not present).

CHLAMYDIA

Definition/Overview

Chlamydia felis produces a mild conjunctivitis in cats and is considered a zoonotic disease. C. *felis* is endemic in cats worldwide and may also infect the respiratory tract causing rhinitis and respiratory disease.

Etiology

C. *felis* is an obligate intracellular bacterium that contains both DNA and RNA.

Pathophysiology

Chlamydophilosis in transmitted by direct contact with other cats, aerosols, or fomites. Ocular disease results from host cell lysis that occurs during the release of elementary bodies. If untreated, infection with C. *felis* can produce chronic conjunctivitis. Asymptomatic carrier states can exist and are likely significant in spreading the organism within a population. Chlamydophilosis

may be complicated by coinfection with other microorganisms including *Mycoplasma* spp., *Bordetella bronchiseptica*, feline calicivirus, FHV-1, and FIV.

Clinical Presentation

Initially, the disease is unilateral, becoming bilateral in 7–14 days. Early in the disease, the conjunctiva is chemotic, hyperemic, and the ocular discharge is serous. Mild nasal discharge and sneezing may occur. As the disease progresses, the discharge becomes mucoid and then mucopurulent, the chemosis decreases, and the conjunctiva becomes hyperemic and thickened. Follicular conjunctivitis occurs in chronic untreated cases.

Differential Diagnosis

Conjunctivitis is found in many types of eye diseases. It may be infectious (herpesvirus, calicivirus, *Mycoplasma* and *Chlamydia* in cats) or noninfectious.

Diagnosis

Diagnosis of chlamydophilosis has been established by using a variety of ELISAs or using cell culture. Demonstration of the characteristic inclusion body within the conjunctival epithelial cell cytoplasm on cytologic examination of Giemsa-stained conjunctival smears may be helpful in lending support for a diagnosis of chlamydophilosis (Figure 19.42). However, inclusions are typically only detectable during early infection and in some cases not at all. PCR assays have become available for the diagnosis of *C. felis*.

Management

Treatment of chlamydial conjunctivitis consists of topical tetracycline, erythromycin, rifampin, fluoroquinolones, or azithromycin for several weeks. Generally, topical tetracycline q.8 h. for 3 weeks is effective. Systemic therapy with oral doxycycline may also be necessary. Oral azithromycin appears to be ineffective in clearing infection. Therapy should be continued for several weeks after clinical signs subside. Recurrence of disease is common in catteries and research colonies due to the short immunity to *C. felis*. *C. felis* may cause disease in humans; therefore, owners and technicians are advised to exercise care and observe strict hygiene when handling or treating infected cats. Vaccination may be necessary to prevent reoccurrence, particularly in catteries.

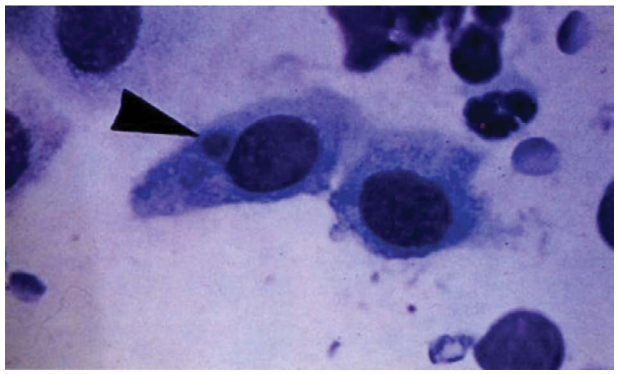

FIGURE 19.42 Chlamydial inclusion body (arrowhead) in epithelial cell from a kitten with acute conjunctivitis. Giemsa stain.

NEMATODIASIS

Dirofilariasis, caused by *Dirofilaria immitis*, is the most commonly reported intraocular nematode of dogs in North America. Ocular filariasis is associated with aberrant migration of immature (fourth-stage) canine heartworm larvae in the anterior chamber or vitreous with development into immature adults or fifth-stage larvae. Signs of anterior uveitis are evident, and the photophobic filarial larva may move from the anterior to posterior chamber. The immature heartworm must be surgically removed to be curative, and surgical removal has about a 90% success rate in removal and preservation of vision. The most commonly reported ocular complication is persistent corneal edema. Angiostrongylosis (French heartworm) caused by *Angiostrongylus vasorum* has been reported in dog and wild canids and may cause similar ocular signs as *Dirofilaria immitis*. Ocular larval migrans (*Toxocara canis* and *Baylisascaris procyonis*) causes anterior uveitis and focal chorioretinitis. Visual impairment is generally mild. Diagnosis is by serologic testing and larval identification. Onchocerciasis, caused by *Onchocerca lupi*, has been reported in dogs and cats. Affected animals may develop conjunctival, scleral, or periorbital masses but may also develop significant panuveitis and secondary glaucoma. Surgical removal may be curative, but chronic medical therapy may also be necessary, including oral steroids, oral doxycycline, oral ivermectin or selamectin, and oral melarsomine or emodepside. Microfilaria were recently identified in the corneal biopsies of seven dogs from Brazil with varying degrees of chronic vascular keratitis with corneal degeneration. The species of microfilaria was not identified, but case responded to oral doxycycline and ivermectin.

MISCELLANEOUS SYSTEMIC DISEASES

Ocular manifestations of hypercalcemia from hyperparathyroidism, neoplasia, renal failure, and hypoadrenocorticism may be associated with white, perilimbal calcium crystals on the conjunctiva, corneal calcification, corneal degeneration, and cataracts. Sustained hypocalcemia due to primary hypoparathyroidism, postparturient hypocalcemia, acute kidney injury or chronic kidney disease, acute pancreatitis, and intestinal malabsorption can cause focal punctate to linear cataracts to form in the anterior and posterior cortices of the lens of dogs and cats.

HYPERVISCOSITY SYNDROME

Definition/Overview

Hyperviscosity syndrome results from abnormal microcirculatory changes due to increased serum viscosity. The severity of hyperviscosity syndrome is linked to the size, shape, type, and concentration of large molecules (e.g., immunoglobulins [IgG and IgM]) in the bloodstream.

Etiology

The underlying cause is generally a malignancy but can also be due to infectious disease. Hyperviscosity may be caused by monoclonal gammopathy (multiple myeloma, macroglobulinemia, lymphocytic leukemia), polycythemia, renal disease, hepatic tumors, and infectious disease.

Pathophysiology

The hyperviscosity results in thromboembolism, sludging of plasma, and hemorrhages in the CNS and eye. Dilated and tortuous retinal vessels, retinal hemorrhages, and RD may be a result of sludging of blood in small vessels, hypertension, thrombocytopenia, coagulation abnormalities, and poor delivery of oxygen and nutrients.

Clinical Presentation

Ocular changes are noticed very early in disease and include retinal hemorrhage (Figure 19.43), retinal venous dilatation and segmentation, retinal vascular tortuosity, "boxcarring" of retinal vessels, microaneurysms of the retina, subretinal hemorrhage, RD (Figures 19.44–19.46), perivascular retinal folding, and papilledema. Anterior uveitis and secondary glaucoma may also be present.

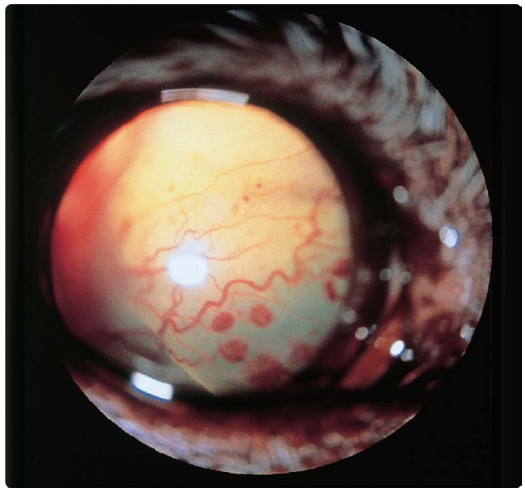

FIGURE 19.44 Dog with macroglobulinemia and hyperviscosity syndrome. Note the undulating retinal detachment with retinal hemorrhages in the dilated pupil.

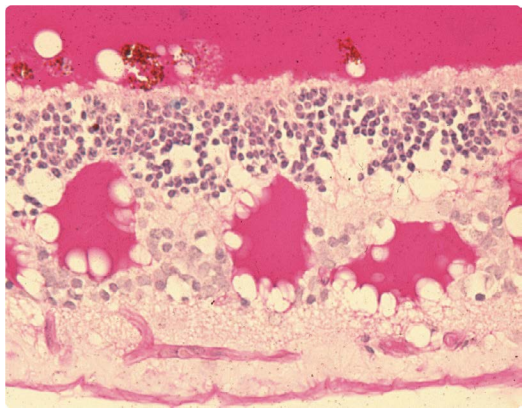

FIGURE 19.45 Histology. The right retina is detached with a large amount of PAS-positive subretinal fluid present. Intraretinal PAS-positive deposits, retinal vessel dilatation, and retinal pigment epithelium hyperplasia are noted (×250).

FIGURE 19.43 Multiple focal retinal hemorrhages and a small, peripheral, serous retinal detachment in an 18-year-old Siamese cat with hyperviscosity syndrome.

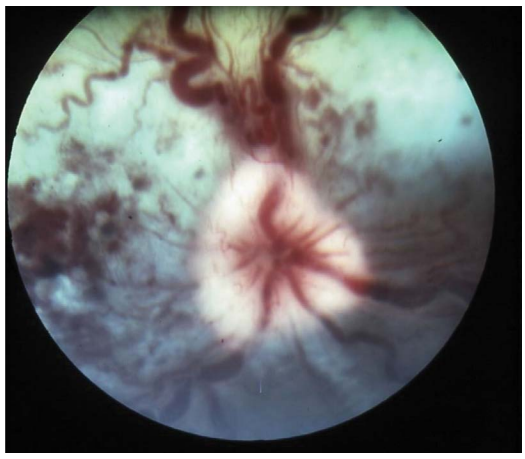

FIGURE 19.46 This dog has macroglobulinemia secondary to Waldenstrom macroglobulinemia. Note the thickened retinal vessels with sacculations as well as scattered retinal hemorrhages. (*Courtesy of M. Schaer.*)

Differential Diagnosis

See Tables 19.1 and 19.2.

Diagnosis

The diagnosis is made by demonstration of hyperproteinemia combined with serum and urine protein electrophoresis and immunoelectrophoresis. A coagulation assessment (platelet count, partial thromboplastin time, prothrombin time), serum protein electrophoresis, and serum viscosity measurements should be undertaken. Systemically affected animals should undergo a thorough anterior segment and funduscopic examinations.

Management

Plasmapheresis may be used to treat the hyperviscosity. Specific therapy directed at the diagnosed neoplastic or infectious disease is also indicated.

HYPERLIPIDEMIA

Definition/Overview

Hyperlipidemia is an increase in plasma concentration of triglycerides and/or cholesterol. Hyperlipidemia represents an abnormal finding in fasted dogs and cats and, when present, is indicative of either increased production or reduced degradation of lipoproteins. Hypothyroidism, diabetes mellitus, hyperadrenocorticism, pancreatitis, and renal (e.g., nephrotic syndrome) as well as hepatic (e.g., cholestasis) diseases can be associated with hyperlipidemia. Both primary and secondary hyperlipidemias may show ocular signs. Dogs and cats are commonly affected.

Etiology

Hyperlipidemia in dogs may be primary as an idiopathic hyperlipoproteinemia in the Beagle, Briard, Collie, Miniature Schnauzer, and Shetland Sheepdog or be secondary to diabetes mellitus, hypothyroidism, pancreatitis, lipoprotein lipase deficiency, renal and liver disease, or Cushing disease. Hyperlipidemia can occur in cats for several reasons, including postprandial hyperlipidemia, diabetes mellitus, exogenous corticosteroid administration, megestrol acetate administration, nephrotic syndrome, lipoprotein lipase deficiency, idiopathic hyperchylomicronemia, and familial hyperchylomicronemia.

Pathophysiology

Altered lipid metabolism may lead to lipemia of ocular blood vessels, corneal opacities, and lipemic aqueous. The term lipemia retinalis describes excess lipid within the retinal vessels, thus giving them a pale appearance. In both cats and dogs, it is the large, triglyceride-rich lipoproteins (e.g., low-density lipoproteins) that produce a visible lipemia. Hyperlipidemia may also manifest with lipids in the anterior chamber (lipemic aqueous). A prerequisite for gaining access to the anterior chamber by the large, lipid-laden molecules is breakdown of the blood–aqueous barrier secondary to pre-existing uveitis. Lipemic aqueous is commonly associated with systemic diseased that may cause hypertriglyceridemia as 95% of dog with lipemic aqueous have increased triglyceride levels.

Clinical Presentation

Increased triglycerides may result in brain dysfunction, acute pancreatitis, lipid-laden aqueous humor with anterior uveitis (Figure 19.47), and lipemia retinalis (Figure 19.48). Increased serum cholesterol has been

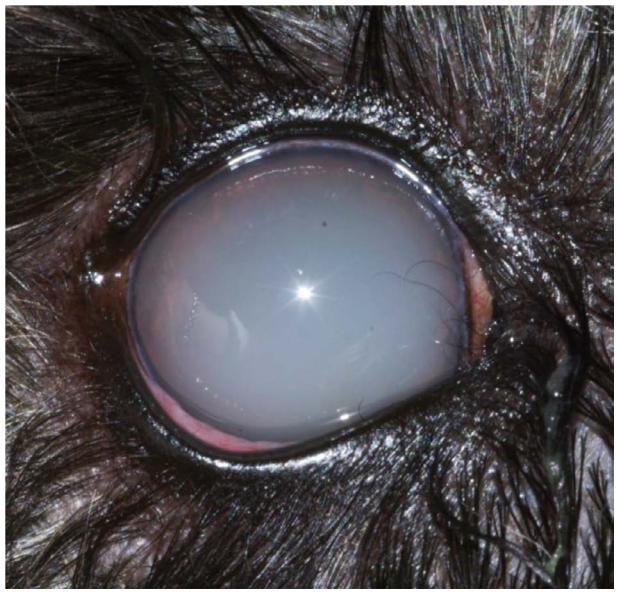

FIGURE 19.47 Lipemic aqueous in a lipemic dog with anterior uveitis. In more mild cases such as this, the lesion needs to be differentiated from diffuse corneal edema. As the lipemic aqueous worsens, it becomes more yellow in color.

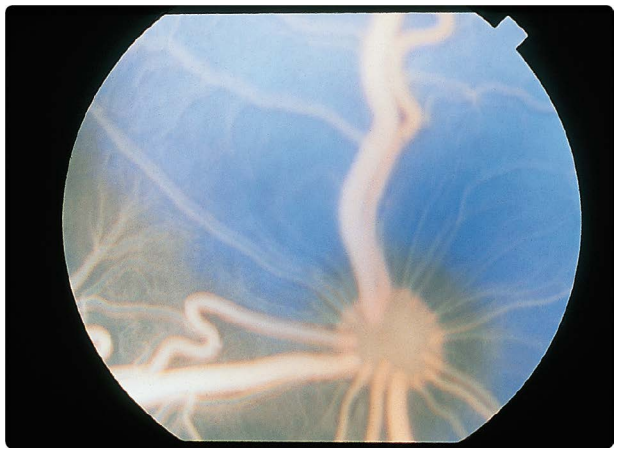

FIGURE 19.48 Lipemia retinalis in a kitten with a lipoprotein lipase deficiency. (*Courtesy of D. Brooks.*)

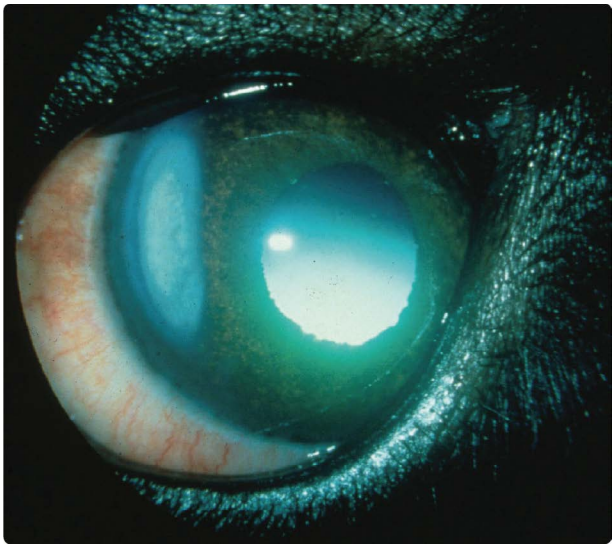

FIGURE 19.49 Lipidosis of the cornea in a hypercholesterolemic Dobermann.

suggested as a cause of lipid keratopathy, but most patients with increased cholesterol do not manifest with lipid keratopathy (Figure 19.49).

Differential Diagnosis

Other causes of corneal opacity, including corneal dystrophy, corneal ulcers, corneal scars, and inflammatory cellular infiltrates, must also be ruled out. It is reasonable to assess the lipid metabolism status of any patient presenting with lipemic aqueous, lipemia retinalis, or lipid keratopathy.

Diagnosis

Diagnosis is based on measurement of specific serum lipoproteins by electrophoresis or ultracentrifugation.

Management

Lipid-laden aqueous and lipemia retinalis resolve with resolution of the primary disorder and dietary modifications (low-fat diet), if necessary. Iridocyclitis should be treated if present. Untreated or severe uveitis may result in chronic inflammation and secondary glaucoma. Corneal lipid accumulation may not resolve. Only a limited number of lipid-lowering drugs have been used in dogs, with varying degrees of success for persistent hyperlipidemia. These include gemfibrozil, fish oils, cholestyramine, and lovastatin.

SYSTEMIC VASCULAR DISEASE

RDs associated with systemic hypertension due to chronic kidney disease are common in older cats and noticed in dogs (Figure 19.50). Complete RDs result in blindness, but vision may return if the hypertension responds to medical treatment and dietary adjustment.

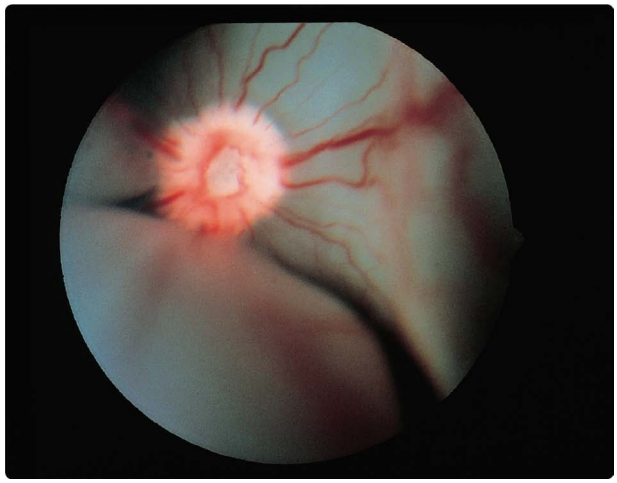

FIGURE 19.50 Exudative retinal detachment in a dog with nephrotic syndrome.

ANEMIA

Definition/Overview

Ocular manifestations of severe anemia in cats and dogs include conjunctival pallor, pale attenuated retinal vasculature, varying degrees of retinal hemorrhage, and subtle changes in tapetal reflectivity. Retinal hemorrhages are more likely to be observed, however, and are more dramatic if accompanied by thrombocytopenia (Figure 19.51). It has been suggested that anemia, alone is not a likely cause of retinal hemorrhage, but it is the diseases causing the anemia that result in retinal hemorrhage. It is postulated that the lack of red blood cells may render vascular endothelial cells hypoxic, thereby

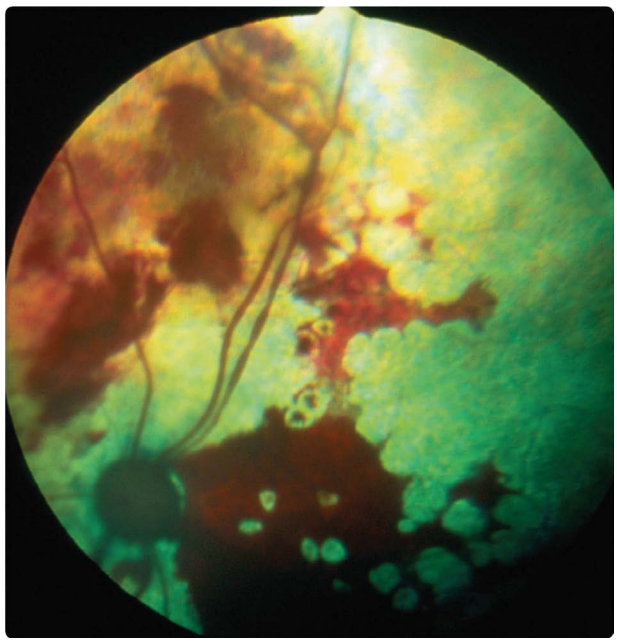

FIGURE 19.51 Vitreal and retinal hemorrhages in a cat with immune-mediated thrombocytopenia.

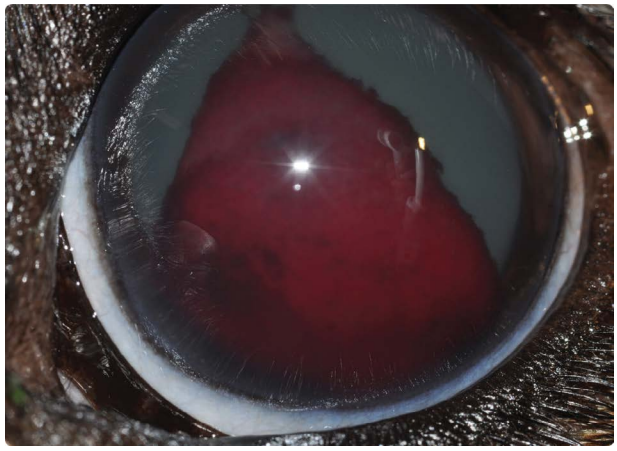

FIGURE 19.52 Hyphema shown in one of both eyes from a dog with immune-mediated hemolytic anemia and thrombocytopenia.

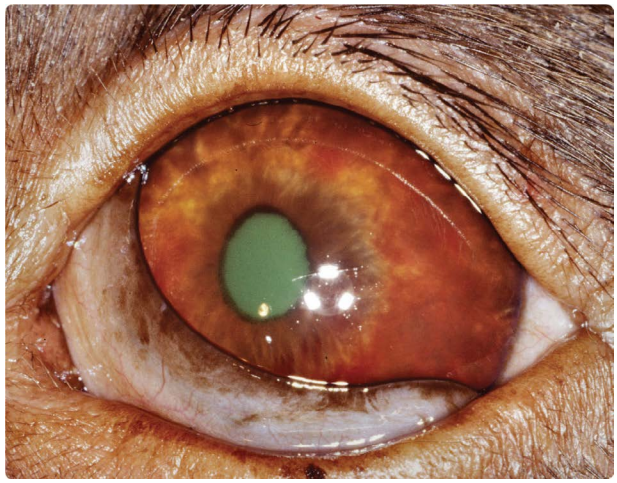

FIGURE 19.53 Iritis and iridal hemorrhage secondary to thrombocytopenia in a dog.

increasing vascular fragility and allowing retinal hemorrhages to occur in cats and dogs. The tapetal reflection is generally normal, which differentiates the retinal vessel attenuation from anemia from the attenuation found with retinal degeneration. Thrombocytopenia is more likely to cause ocular lesions such as hyphema and anterior uveitis in dogs (Figures 19.52 and 19.53).

SYSTEMIC ARTERIAL HYPERTENSION

See also Chapter 13.

Definition/Overview

Repeatable measurements of systolic pressure exceeding 160 mmHg and/or diastolic blood pressure measurements >100 mmHg are considered to indicate arterial hypertension. As any clinician knows, however, it can be challenging to accurately measure indirect blood pressure in both dogs and cats. Blindness is one of the most common presenting complaints with this disorder, as the eye is particularly sensitive to the effects of high blood pressure. Hypertensive retinopathy in many cats is a slow, insidious process. Vision may be spared if the process is identified and controlled before severe ocular disease develops. Consequently, old cats with diseases such as chronic kidney disease and hyperthyroidism should be screened for systemic hypertension. Old dogs with any systemic disease that is commonly associated with systemic hypertension should also be screened for systemic hypertension.

Etiology

Arterial hypertension in dogs and cats has been associated with old age, chronic anemia, hypercholesterolemia, atherosclerosis/arteriosclerosis, high-salt diets, obesity, and idiopathic essential hypertension. Secondary hypertension in dogs is now recognized as being a common complication of renal disease (60%–80% of cases), hyperadrenocorticism (59%–86% of cases), pheochromocytoma (>50% of cases), diabetes mellitus, primary hyperaldosteronism, hypothyroidism, and hyperthyroidism.

Hypertensive cats have been shown to have a greater prevalence of retinal lesions (48%) compared with normotensive cats (3%). In addition, cats with retinopathies had higher blood pressure (262 ± 34 mmHg) than hypertensive cats without retinal lesions (221 ± 34 mmHg). Cats over 8 years of age with chronic renal disease and with hyperthyroidism should have their fundi examined for lesions related to hypertension.

Pathophysiology

Renal pathology causes an increase in renin–angiotensin–aldosterone activity, which, in combination with increased plasma levels of norepinephrine, causes peripheral vasoconstriction. Incoming arterial and capillary blood at high pressure causes vasospasm, tissue hypoxia of the capillary beds allowing changes in vessel permeability, and exudation of fluid, plasma, or blood, resulting in development of infarcts and end-organ damage. The consequence of ocular vascular hypertensive changes is an initial vascular constriction in the retinal arterioles in response to increased blood pressure, which when sustained results in occlusion and ischemic necrosis of the vessel walls with resultant increased vascular permeability. The ocular circulation is not tolerant of such changes in its microcirculation.

Clinical Presentation

Ocular features in cats and dogs with hypertension include retinal arteriolar tortuosity, preretinal hemorrhage, retinal edema, perivasculitis, anterior uveitis, vitreal and anterior chamber hemorrhage, serous RDs, and retinal atrophy (Figures 19.54–19.66). In severe cases, irreversible blindness occurs. The severity of the lesions in cats has been correlated with the degree of systemic hypertension. In any dog or cat presenting with serous

FIGURE 19.56 Hyphema is present in this cat with systemic hypertension.

FIGURE 19.55 Extensive, serous retinal detachment with hemorrhages of the retinal and optic nerve vessels in a dog with systemic hypertension. The large, bright-white lesion in the lower left is a flash artifact.

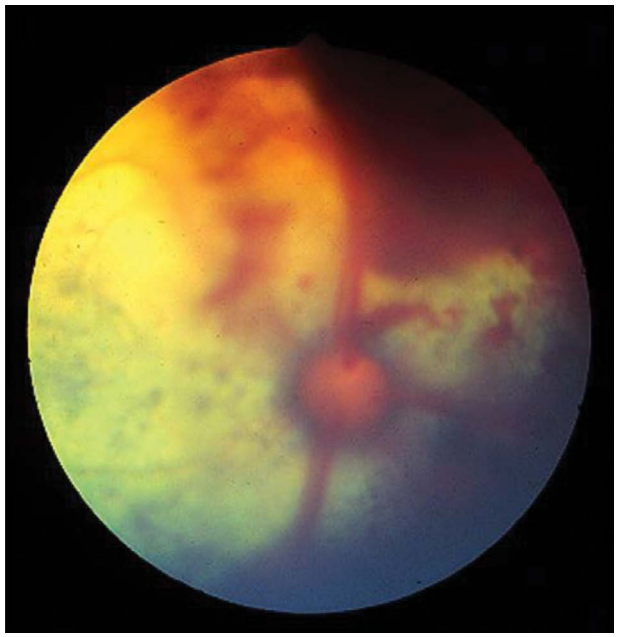

FIGURE 19.57 Hypertensive retinopathy manifested by dorsal vitreal hemorrhage, intraretinal hemorrhage, and retinal edema in a cat.

RDs and retinal or vitreal hemorrhage, systemic hypertension is the first syndrome that must be ruled out.

Differential Diagnosis

See Tables 19.1 and 19.2.

Diagnosis

Diagnosis is based on serial measurements of blood pressure along with typical clinical signs. A complete blood count (CBC), urinalysis, and serum biochemical profiles should be undertaken in all patients. All

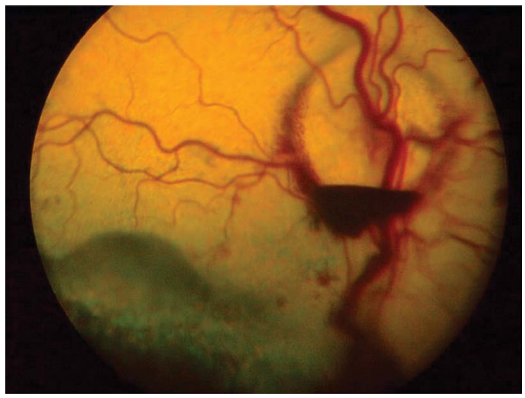

FIGURE 19.58 Preretinal "keel boat" hemorrhage in a dog with hypertensive retinopathy. An undulating, serous retinal detachment is noted in the lower left aspect of this image.

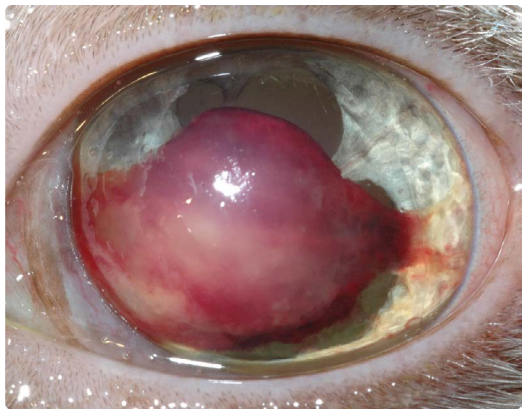

FIGURE 19.62 Hyphema is present in a dog with systemic hypertension.

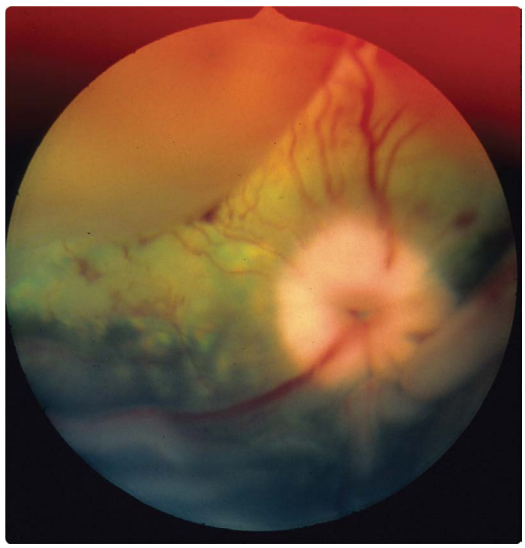

FIGURE 19.63 Retinal detachment and retinal hemorrhages in a dog with systemic hypertension.

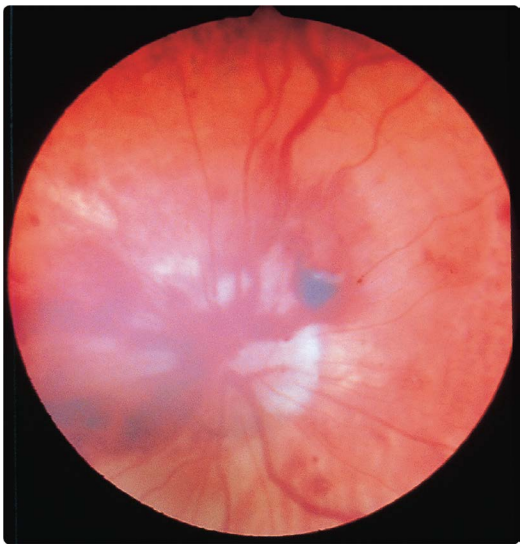

FIGURE 19.64 Vitreal and retinal hemorrhage obscure part of the optic disc in a dog with systemic hypertension.

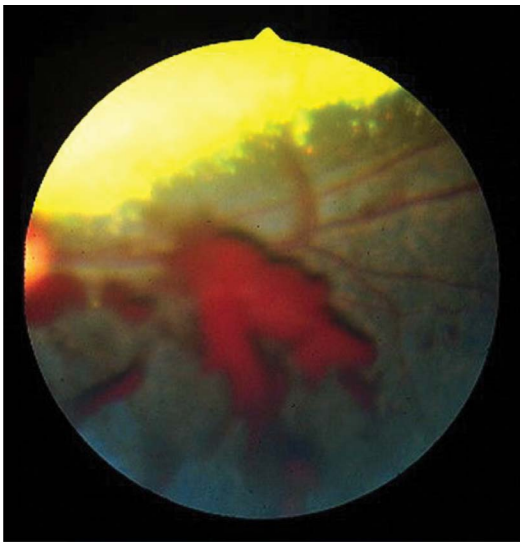

FIGURE 19.65 Preretinal hemorrhage in a dog with systemic hypertension.

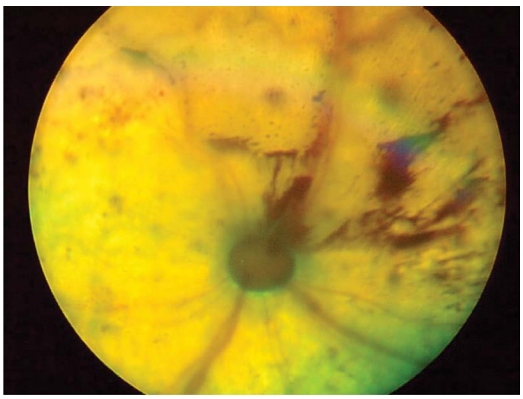

FIGURE 19.66 Multifocal retinal hemorrhages with serous retinal detachment in a cat with systemic hypertension.

affected patients should also have a complete physical examination and any other diagnostic tests as indicated in an attempt to rule in or rule out other systemic diseases associated with systemic hypertension.

Management

Treatment is based on the disease or diseases associated with the systemic hypertension. Unless these diseases are treated, the ocular lesions will not resolve and will worsen. The choice of antihypertensive drugs is left to the individual clinician as well as the other disease states for each patient. Patients with RDs and blindness may regain vision, particularly if the inciting cause and the concurrent systemic hypertension can be effectively treated or managed. The sooner the RDs are diagnosed and treated, the more likely it is that vision can be returned or spared. Chronic, complete RDs may never regain vision, even after treatment and retinal reattachment. In any patient diagnosed with systemic hypertension that has ocular lesions, serial ocular examination can be an effective tool to determine response to therapy. For example, if a patient's ocular signs are improving with treatment, but the indirect blood pressure measurements are still elevated, the improvement in ocular signs is strongly suggestive that the patient is on the correct therapy.

HORNER SYNDROME

Definition/Overview

Horner syndrome (sympathetic denervation) in the dog and cat is characterized by elevation of the third eyelid, ptosis, miosis (causing anisocoria), and enophthalmos.

Etiology

Sympathetic denervation to the eye can occur at the hypothalamus, brainstem/cervical cord, T1–T3 spinal cord segments, vagosympathetic trunk, cranial cervical ganglion, middle ear, ophthalmic branch of cranial nerve V, long ciliary nerve, and iris dilator muscle. The most common cause of Horner syndrome in the dog is secondary to an idiopathic, postganglionic lesion. Other causes of Horner syndrome include anterior mediastinal neoplasia, brachial plexus injury, otitis media, and cervical trauma.

Pathophysiology

Loss of sympathetic innervation causes a lack of tone in the orbital smooth muscle so that the eye retracts slightly, producing enophthalmos. Loss of innervation to the muscle of the upper eyelid (Muller's muscle) and sympathetically innervated tissue in the lower eyelid results in narrowing of the palpebral fissure and incomplete elevation of the upper eyelid or ptosis. Lack of sympathetic tone and enophthalmos results in elevation of the third eyelid. Reduction of normal sympathetic tone to the iris dilator muscle results miosis in the affected eye (Figure 19.67).

FIGURE 19.67 Miosis, third eyelid elevation, enophthalmos, and ptosis are found on the right side of a cat with Horner syndrome.

Clinical Presentation

The Horner miotic pupil is not pinpoint in room light. Constriction still occurs, and partial dilation in dark light occurs but not as much dilation as a normal pupil. The causative lesion can occur anywhere along the sympathetic chain. Intraocular pressure is normal, and vision is present.

Differential Diagnosis

Uveitis can cause miosis and elevation of the third eyelid. Painful eyes, such as an eye with corneal ulceration, can present with enophthalmos and blepharospasm that can be confused with Horner syndrome.

Diagnosis

Diagnosis is based on a complete physical examination and neurologic, otoscopic, and ophthalmologic examinations. Topically administered adrenergics such as 2.5% phenylephrine will restore the pupil to normal size, reposition the nictitans, and minimize the ptosis within about 20 minutes if the sympathetic lesion is postganglionic. If the patient has any other systemic signs, particularly additional neurologic abnormalities, evaluation by a neurologist is indicated.

Management

Idiopathic, postganglionic lesions may spontaneously resolve in some patients.

FELINE DYSAUTONOMIA OR FELINE DILATED PUPIL SYNDROME

Definition/Overview

Feline dysautonomia or feline dilated pupil syndrome (Key–Gaskell syndrome or feline autonomic neuropathy) is much more common in Europe than the United States. A similar syndrome is found in young, large-breed dogs living in rural areas of the Midwestern United States. Affected patients have widespread dysfunction of the autonomic nervous system.

Etiology

The cause is unknown, although lesions in the autonomic ganglia are consistent with a toxic cause. The bacterium *Clostridium botulinum* may be associated with the pathogenesis of feline dysautonomia.

Pathophysiology

Parasympathetic and sympathetic ganglia are equally affected. There is depletion of neuronal cell bodies, with many remaining neurons showing an atypical homogeneous cytoplasm, eccentric pyknotic nuclei, and dissolution of Nissl substance. Autonomic nerves show axonal degeneration, but peripheral nerves are comparatively spared. Ultrastructural changes include derangement of the rough endoplasmic reticulum, with cisternae lacking ribosomes and distended with flocculent material. Stacks of smooth membranous profiles are evident but no normal Golgi bodies.

Clinical Presentation

Ocular clinical signs include dilated, nonresponsive pupils, decreased tear production, and elevation of the third eyelid, but vision is not affected. Common systemic signs include dehydration, dysphagia, decreased appetite or anorexia, vomiting or regurgitation, xerostomia, constipation, bradycardia, and dysuria. Ataxia and poor proprioception may also occur.

Differential Diagnosis

Dilated pupils can be associated with glaucoma as well as retinal and optic nerve diseases. Significant iris atrophy may cause pupils (or one of the pupils) to appear dilated and nonresponsive to light.

Diagnosis

Diagnosis should be suspected from the characteristic clinical signs, and a definitive diagnosis can only be confirmed by the presence of lesions in the autonomic ganglia by histopathology. Urinary catecholamines are reduced. Pharmacologic testing can support the diagnosis. Pilocarpine (0.1%) topically constricts the pupil in affected cats, while topical echothiophate iodide (0.06%) and physostigmine (0.25%) will cause miosis in normal cats but not dysautonomic cats. Epinephrine at a concentration of 1:10,000 will induce retraction of the prolapsed third eyelid.

Management

Treatment includes supportive therapy with fluids, laxatives, and dietary management. Topical parasympathomimetics may be beneficial. The prognosis in affected patients is guarded to poor.

CANINE UVEODERMATOLOGIC SYNDROME

Definition/Overview

Ocular manifestations of canine uveodermatologic syndrome (UDS) are reported most often in "Arctic Circle" breeds such as Siberian Husky and Samoyed. Other breeds reported to be affected include the Australian Shepherd Dog, Beagle, Fila, Chow, Dachshund, Golden Retriever, Irish Setter, Old English Sheepdog, Saint Bernard, and Shetland Sheepdog. UDS appears to primarily affect young adult dogs, and ocular lesions generally precede dermatologic lesions.

Etiology

This is an autoimmune condition directed against melanin of neural crest (skin, hair, anterior uvea) and neuroectodermal (retina) origin.

Pathophysiology

This syndrome is considered to be an immune-mediated reaction to melanin that affects various organs containing melanocytes. It is similar to Vogt–Koyanagi–Harada (VKH) syndrome in people, although neurologic signs are rare in dogs as dogs' meninges are nonpigmented. Skin lesions are the result of a Th1-mediated inflammatory response, while ocular lesions are the result of a Th2-mediated inflammatory response. The role of certain dog leukocyte antigen class II gene alleles may be important regarding the pathogenesis of VKH-like syndrome in Akitas.

Clinical Presentation

Severe, bilateral panuveitis (Figures 19.68 and 19.69) and hypotony with secondary cataracts, glaucoma, RDs, and blindness are common. Iris and retinal depigmentation, poliosis/vitiligo, and ulceration of the face and muzzle are noticed (Figures 19.70 and 19.71). Dermal and hair depigmentation (vitiligo and poliosis, respectively) develop either gradually or rapidly, and they may be ulcerative in nature. The lesions are usually restricted to the mucocutaneous junctions of the face, involving the eyelids, nasal planum, and lips, but the scrotum and footpads are other areas of possible dermal involvement.

Differential Diagnosis

See Table 19.1.

Diagnosis

There is no specific diagnostic test for uveodermatologic syndrome. The diagnosis is made on the basis of clinical signs and histopathologic examination of skin biopsies. Skin biopsy specimens have lichenoid, interface dermatitis, histiocytes, and small mononuclear cells as well as

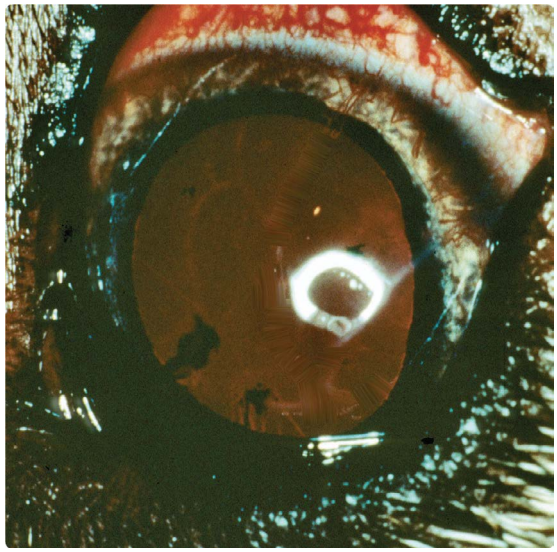

FIGURE 19.68 Husky dog with uveodermatologic syndrome (UDS). Anterior uveitis noted by scleral injection, iritis, and posterior synechia.

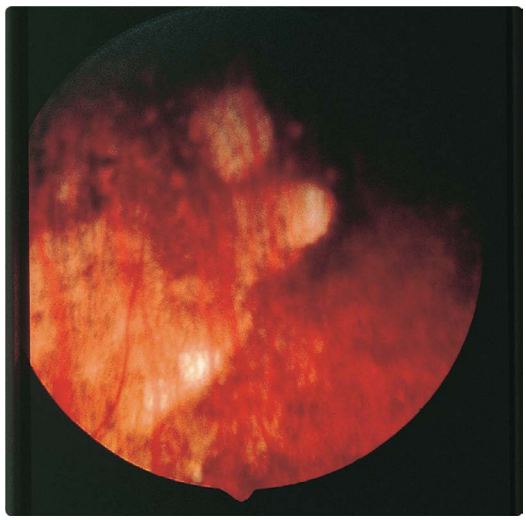

FIGURE 19.69 Focal depigmentation of the nontapetum due to previous chorioretinitis.

FIGURE 19.70 Dog with uveodermatologic syndrome prior to therapy. Note the depigmented and ulcerated lesions of the eyelid margins, nose, and lips.

FIGURE 19.71 Same dog with uveodermatologic syndrome as in Figure 19.70 after therapy.

giant cell infiltrations. The level of melanin in the epidermis and hair follicles is decreased. Special stains should be requested in the presence of granulomatous infiltrates in an attempt to identify microorganisms. Routine laboratory tests are typically normal. Skin biopsy should help to rule out other ulcerative skin diseases.

Management

Short-term success with systemically administered corticosteroids or azathioprine is good, but recurrence is common, particularly without chronic immunomodulatory therapy. Patients being treated with azathioprine must have bloodwork monitored, both acutely and chronically, to monitor for side effects in the liver and/or bone marrow. Other systemic immunomodulatory drugs such as cyclosporine may be beneficial in dogs that do not tolerate chronic azathioprine. Topical treatment of the uveitis with steroids is required.

GRANULOMATOUS MENINGOENCEPHALITIS AND MENINGOENCEPHALITIS OF UNKNOWN ETIOLOGY

See also Chapter 14.

Definition/Overview

Meningoencephalitis of unknown etiology (MUE) is a condition in which advanced diagnostic imaging and cerebrospinal fluid (CSF) analysis suggest an inflammatory, noninfectious disease process, but definitive histopathologic diagnosis is lacking. Granulomatous meningoencephalitis (GME) is diagnosed when the cause has been confirmed via histopathology, generally on postmortem examination. MUE/GME can be seen alone as a primary ocular disease or, more commonly, in conjunction with CNS disease. It is probably the most common inflammatory disease of the canine nervous system. The ocular signs may occur before CNS signs. The disease is typically seen in female, small-breed, middle-aged dogs, although any breed or age of dog may be affected.

Etiology

MUE/GME is an idiopathic, nonsuppurative inflammatory disease.

Pathophysiology

MUE/GME is characterized by the proliferation of reticuloendothelial elements and lymphoplastic infiltration of blood vessels of the CNS, the ciliary body, and the choroid. Perivascular infiltrates are composed of a heterogeneous population of major histocompatibility complex class II antigen-positive macrophages and mainly CD3 antigen-positive lymphocytes, supporting a hypothesis of T-cell-mediated, delayed-type hypersensitivity or an autoimmune disease.

Clinical Presentation

Ocular features include acute, unilateral, or bilateral blindness with a widely dilated, nonresponsive pupil in the affected eyes (Figure 19.72). Uveitis, optic neuritis (hyperemic, swollen, elevated optic disc, disc hemorrhage, peripapillary engorged vessels), retinal inflammation (white perivascular cuffs and yellow–white patches), and peripapillary RD are common (Figures 19.73 and 19.74). The optic disc may appear normal if the optic nerve involvement is posterior to the globe.

Differential Diagnosis

See Table 19.1. Any other infectious disease that can cause optic neuritis.

FIGURE 19.72 Dilated, nonresponsive pupils are present in a Miniature Pinscher with bilateral optic neuritis from granulomatous meningoencephalitis.

FIGURE 19.73 A swollen and hyperemic optic disc indicating optic neuritis that was associated with granulomatous meningoencephalitis.

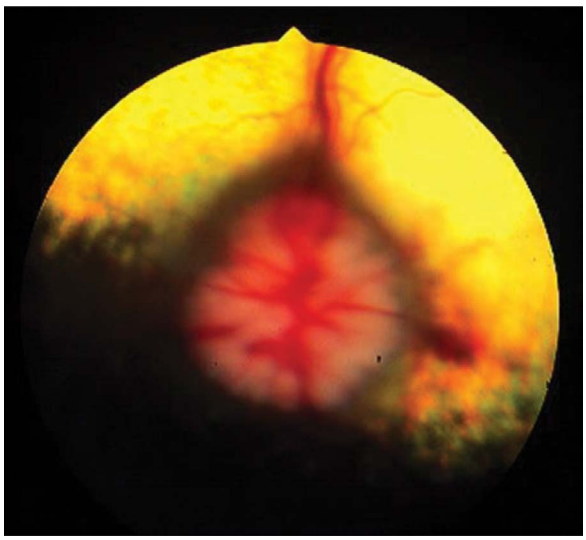

FIGURE 19.74 Swollen, hyperemic optic disc with peripapillary hemorrhages and peripapillary retinal detachment in a dog with meningoencephalitis of unknown etiology.

Diagnosis

Diagnosis of GME can only be confirmed at necropsy or by brain biopsy. MRI and analysis of CSF (increased CSF protein and pleocytosis) may enable a tentative diagnosis to be made (MUE).

Management

Treatment involves aggressive use of immunosuppressive corticosteroids often with added immunosuppression using cytosine arabinoside, azathioprine, leflunomide, or cyclosporine A. Gradual improvement and temporary remission are possible in about 30% of cases. Clinical signs tend to be progressive, and most dogs eventually lose vision permanently.

LYMPHOSARCOMA

Definition/Overview

Lymphosarcoma is the most common intraocular tumor of dogs and cats. It is usually a secondary ocular tumor and is usually bilateral. Presumed solitary ocular lymphoma (PSOL) has been reported in both dogs and cats. PSOL may be as common as systemic lymphoma in cats and is reported to have double the survival time compared to cats with systemic lymphoma. PSOL may also be more common that systemic lymphoma in dogs and is reported to have seven times the survival time compared to dogs with systemic lymphoma.

Etiology

This is generally a metastatic neoplastic disease to the eye and its adnexa. Cats may be positive for FeLV.

Pathophysiology

Systemic involvement generally precedes or accompanies ocular lymphosarcoma. Lymphosarcoma with secondary ocular involvement equates to advanced disease and translates to a shorter survival period for the patient.

Clinical Presentation

Lymphosarcoma in dogs and cats (Figures 19.75–19.82) may manifest as corneal edema, centrally migrating white bands of neoplastic cells, stromal hemorrhage, corneal vascularization, anterior uveitis with hyphema, hypopyon, keratic precipitates, secondary glaucoma, tortuous retinal vessels, retinal hemorrhages, perivascular sheathing, RD, or retinal tissue infiltration by tumor cells. Invasion of retinal tissue alone is very rare in dogs and cats but can occur. Cats more commonly have cranial nerve dysfunction. Exophthalmos secondary to orbital lymphoma may also occur.

Differential Diagnosis

See Table 19.1.

FIGURE 19.75 Miosis and diffuse iritis secondary to intraocular lymphosarcoma in a cat.

FIGURE 19.76 Focal and diffuse iritis and fibrin in a dog with lymphosarcoma.

FIGURE 19.77 Conjunctival lymphosarcoma in the right eye of this cat. An unrelated cataract is present in the left eye.

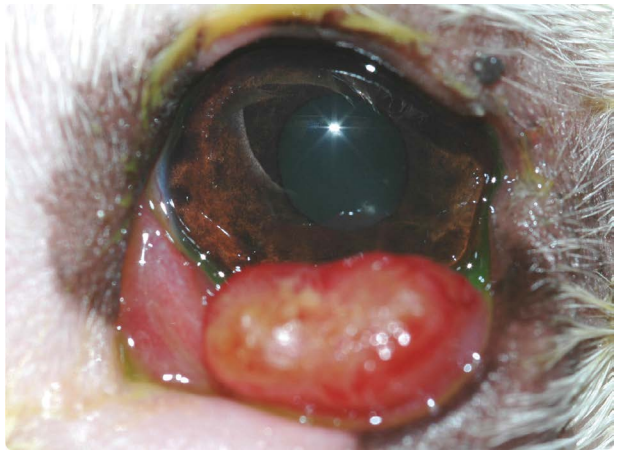

FIGURE 19.78 This mass on the third eyelid in a dog is lymphoma.

FIGURE 19.79 Lymphoma has effaced the entire anterior uveal tract of this cat.

FIGURE 19.80 Lymphosarcoma invasion of the choroid causes a focal retinal detachment in this cat.

FIGURE 19.81 Orbital lymphoma pressing on the globe indents the eye and distorts the ventral optic disc and nontapetal area of this dog's fundus.

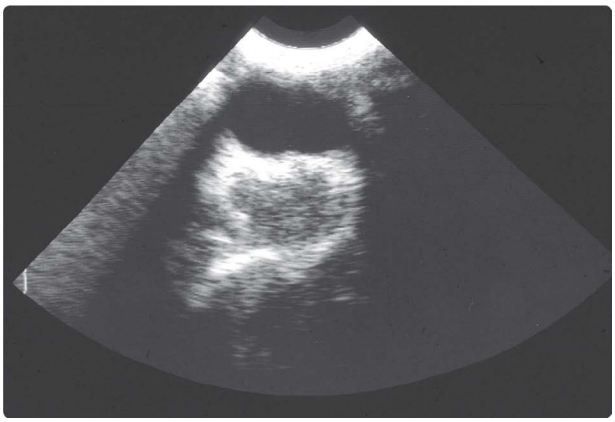

FIGURE 19.82 Ultrasound demonstrates the tumor presence behind the globe in the dog in Figure 19.81.

Diagnosis

Lymphadenopathy combined with bilateral anterior uveitis or intraocular hemorrhages should cause suspicion of lymphoma. Enlarged lymph nodes should be investigated by fine-needle aspiration.

Management

Anterior uveitis and hyphema should be treated by topical corticosteroids and atropine (if secondary glaucoma is not present). Medical protocols for treatment of lymphosarcoma should be instituted and are associated with the most rapid resolution of clinical signs.

DIABETES MELLITUS

See also Chapter 12.

Definition/Overview

There is a high incidence of cataracts in diabetic dogs, with many cataracts apparently developing rapidly over days to weeks. Most diabetic dogs form cataracts within 12–16 months after diagnosis.

Etiology

In dogs, inciting factors include obesity, immune-mediated insulitis, pancreatitis, infection, genetic predisposition, and insulin-antagonistic diseases. In cats, obesity-induced carbohydrate intolerance and amyloid deposition in islet cells are potential factors.

Clinical Presentation

The most common ocular manifestation of diabetes mellitus in small animals is acute formation of cataracts, often associated with sudden blindness (Figure 19.83). Diabetic cataracts in dogs begin at the lens equator and manifest as vacuoles that are best seen after pharmacologic dilation (Figure 19.84). Diabetic cataracts in cats are rare. Diabetic dogs may have KCS, reduced corneal sensitivity, and reduced tear film breakup times.

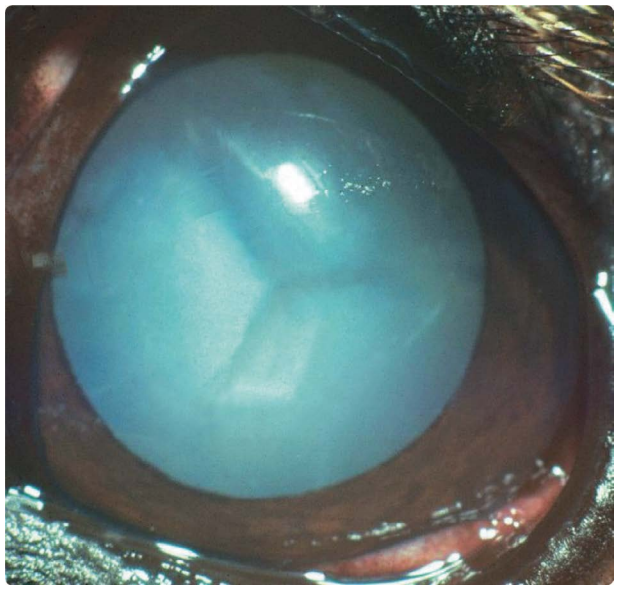

FIGURE 19.83 A mature cataract with prominent lens Y-suture involvement caused by diabetes mellitus in this dog.

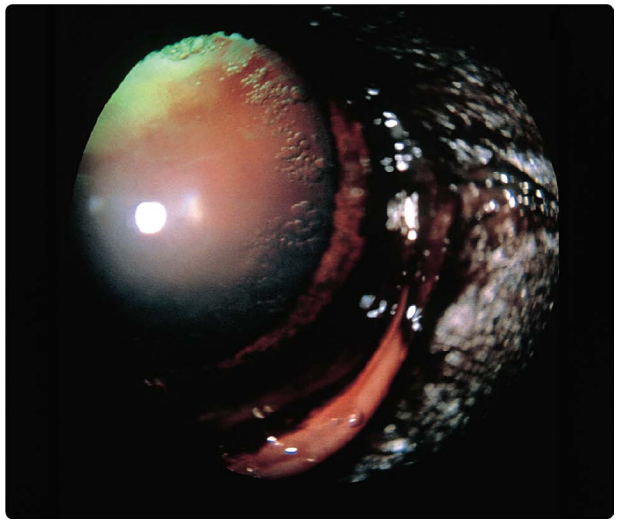

FIGURE 19.84 Lens fibers in the equatorial lens cortex swell and appear as vacuoles or bubbles at the equator of the lens in this dog with diabetes mellitus.

Pathophysiology

The cataracts form during periods of hyperglycemia when glucose enters the lens and is converted by the enzyme aldose reductase (AR) to sorbitol as the glycolytic enzyme hexokinase is saturated. Lens sorbitol dehydrogenase (SD) activity is also reduced, which allows sorbitol to accumulate in the lens. The sorbitol osmotically draws water into the lens, and the lens fibers swell and rupture to result in cataracts.

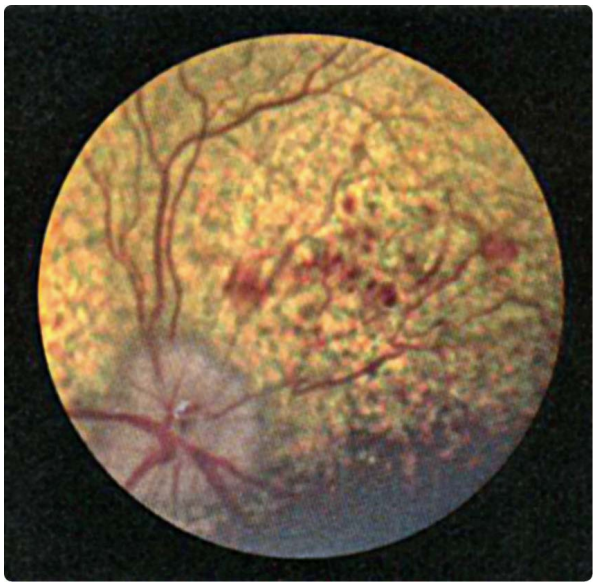

FIGURE 19.85 Retinal hemorrhages are present in this dog with diabetic retinopathy.

The cat lens generally has less age-matched activity of both AR and SD than that present in the lens of dogs, but the ratio of AR to SD is higher in the cat lens than the dog. Sorbitol should thus accumulate more quickly in diabetic cat lenses than in dogs, but the incidence of diabetic cataracts is actually lower clinically in diabetic cats than diabetic dogs. This may be a result of diabetes being primarily a disease of cats >7 years of age who have little AR activity in their aging lens. AR lens activity is highest in young cats (<4 years).

Ischemic changes in the retina of chronically diabetic dogs and cats can result in retinal vessel aneurysms and retinal hemorrhages (Figure 19.85). These changes may be masked by the rapid cataract formation.

Differential Diagnosis

Cataracts may be a hereditary condition in specific breeds. They may also be caused by aging, advanced retinal degeneration, anterior uveitis, diseases causing hypocalcemia, and radiation therapy.

Diagnosis

Early cataractous changes appear as vacuoles in the subepithelial equatorial cortex, which progress to mature, intumescent cataractous lenses with prominent Y-suture clefting. Anterior uveitis is also found in some canine diabetics. Diabetic retinopathy is slow to develop in diabetic dogs and cats.

Management

Surgery is necessary to treat the cataracts of controlled diabetic patients and is very successful at restoring sight. Topical aldose reductase inhibitors have shown promise to slow the development and advancement of diabetic cataract in dogs but are still experimental at this time.

LACRIMAL SYSTEM MANIFESTATIONS OF SYSTEMIC DISEASE

ACUTE AND CHRONIC KERATOCONJUNCTIVITIS SICCA

Definition/Overview

Keratoconjunctivitis sicca (KCS) is a disease associated with reduced aqueous secretions from the lacrimal and third eyelid glands. Most cases of chronic conjunctivitis in dogs are caused by KCS.

Etiology

The most common cause of KCS is immune-mediated dacryoadenitis. KCS in dogs may be associated with canine distemper, trauma, irradiation, and drug toxicity. Canine immune-mediated KCS has also been associated with atopy, hypothyroidism, hyperadrenocorticism, systemic lupus erythematosus (SLE), rheumatoid arthritis, diabetes mellitus, chronic active hepatitis, and pemphigoid disorders. FHV infection is associated with KCS in cats.

Pathophysiology

The trilayered precorneal tear film is critical for maintaining optical clarity and providing nutrition to the cornea. Lack of tears results in chronic and painful conjunctival and corneal degeneration. Left untreated, KCS may result in blindness.

Clinical Presentation

Blepharospasm, conjunctivitis, chemosis, mucoid to mucopurulent ocular discharge, superficial corneal pigmentation and vascularization, and corneal ulcers can be present (Figure 19.86). Cats seem less affected by low tear levels than dogs.

Differential Diagnosis

KCS is often confused with bacterial conjunctivitis. While it does occur, bacterial conjunctivitis in dogs in not common.

Diagnosis

Decreased Schirmer tear test levels (<10 mm per minute), along with appropriate clinical signs, are diagnostic. The presence of concurrent corneal ulcers should be identified and treated aggressively to prevent infection and/or collagenolysis.

Management

Topically administered cyclosporine A, tacrolimus, pimecrolimus, artificial tears, and antibiotics are effective

FIGURE 19.86 Chronic KCS in a dog. Note the mucoid ocular discharge, diffuse conjunctivitis, superficial vascularization, and superficial pigmentary keratitis.

at controlling KCS in up to 80% of dogs. If medical therapy is not working, adjunctive surgical options, including parotid duct transposition and canthoplasty, can be beneficial in that management of KCS.

SJÖGREN'S-LIKE SYNDROME

Definition/Overview

Sjögren's syndrome is a systemic autoimmune disease directed against glandular tissues. It is characterized by KCS, xerostomia, lymphoplasmacytic dacryoadenitis, and lymphocytic sialadenitis.

Etiology

Sjögren's syndrome is frequently associated with human autoimmune disease (rheumatoid arthritis, SLE, thyroiditis). A similar syndrome to Sjögren's syndrome has recently been recognized in dogs (KCS associated with SLE, hypothyroidism, diabetes mellitus, other immune disorders, and xerostomia) and cats.

Pathophysiology

There is immune-mediated destruction of the lacrimal and salivary glands.

Clinical Presentation

Sjögren's syndrome is characterized by KCS (xerophthalmia) and xerostomia (dry mouth).

Differential Diagnosis

Any chronic keratitis or keratoconjunctivitis.

Diagnosis

Clinical signs (KCS, keratitis, conjunctivitis), presence of other immune-mediated systemic diseases (e.g., pemphigus) associated with salivary signs, positive ANA test.

Management

Treatment is the same as for KCS with additional identification and management of concurrent autoimmune diseases.

SYSTEMIC DISEASE ASSOCIATED WITH INFLAMMATORY MYOPATHY

MASTICATORY MUSCLE MYOSITIS

See also Chapter 9.

Definition/Overview

Eosinophilic masticatory muscle myositis is an inflammatory disorder involving the muscles of mastication. Masticatory myositis typically affects young to middle-aged adult dogs and predominantly medium- to large-breeds dogs.

Etiology

The cause is unknown, but an immune-mediated reaction is possible. Neutrophils and eosinophils infiltrate the temporalis and pterygoid muscles to cause pronounced masticatory muscle fiber swelling and subsequent fibrosis.

Pathophysiology

The 2M muscle fibers in the masticatory muscles contain a unique type of myosin, which is specifically involved in immune-mediated reactions. The pathogenesis is not understood, although autoantibodies against type 2M muscle fibers are present in the circulation and tissue. Bacteria containing antigens similar to type 2M muscle fibers may initiate the myositis. Exophthalmos results from inflammatory swelling of the muscles of mastication forcing orbital fat and the globe anteriorly to cause the exophthalmos.

Clinical Presentation

Ocular lesions are present in about 45% of cases (Figure 19.87). Masticatory muscle myositis of the masseter,

FIGURE 19.87 Bilateral exophthalmos and third eyelid elevation secondary to masticatory muscle myositis in a Shetland Sheepdog.

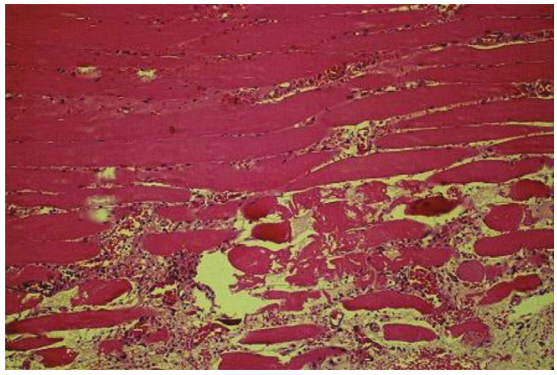

FIGURE 19.88 Histopathology of a muscle biopsy of the same dog in Figure 19.87 demonstrating muscle necrosis, inflammatory cells, and mild fibrosis.

pterygoid, and temporalis muscles may cause acute, painful exophthalmos that is followed by chronic muscle atrophy with enophthalmos and third eyelid elevation. Pain is elicited when opening the mouth. Most dogs present with anorexia and depression, although tonsillitis, submandibular and prescapular lymphadenopathy, and pyrexia may occur.

Differential Diagnosis

Orbital cellulitis and orbital neoplasia.

Diagnosis

Diagnosis is based on electromyography (which reveals abnormal spontaneous pathologic activity in the temporal and masseter muscles), peripheral eosinophilia, elevated serum creatine kinase, temporalis muscle biopsy, and the demonstration of serum 2M autoantibodies. MRI detects widespread, symmetrical, and in homogeneously hyperintense areas in the masticatory muscle. Histopathologic findings found are cellular infiltration of affected muscles with varying degrees of lymphocytes and/or macrophages and/or eosinophils; muscle atrophy, necrosis, and fibrosis; presence of fibrosis in chronic cases; and immune complexes bound to type 2M muscle fibers (Figure 19.88).

Management

Systemically administered corticosteroids are indicated in acute disorders. Uncontrolled myositis leads to painful masticatory muscle atrophy. Therapy may be life-long.

EXTRAOCULAR MUSCLE MYOSITIS

Definition/Overview

Extraocular muscle myositis is common in young, large-breed dogs such as Golden Retrievers.

Etiology

The specific cause of this focal inflammatory myositis is unknown at present.

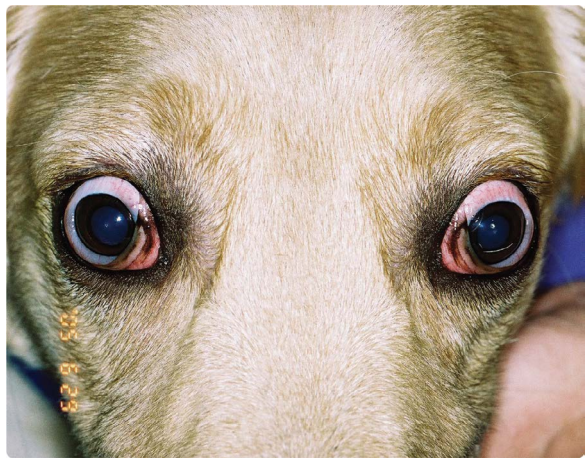

FIGURE 19.89 Young Golden Retriever with extraocular muscle myositis. Bilateral exophthalmos due to the extraocular muscle myositis.

Pathophysiology

Extraocular muscle myositis is an immune-mediated disease directed against the type 1 myofibers of the extraocular muscles. The pressure on the optic nerve from the swollen extraocular muscles can severely reduce optic nerve axoplasmic flow and cause visual deficit.

Clinical Presentation

The clinical signs are bilateral in most dogs, and most dogs are not painful. A generally nonpainful chemosis precedes exophthalmos in 81% of cases, and optic nerve impingement with optic neuritis may occur to cause blindness (Figures 19.89–19.92). Chronic inflammation may result in restrictive strabismus.

Differential Diagnosis

Orbital cellulitis and orbital neoplasia.

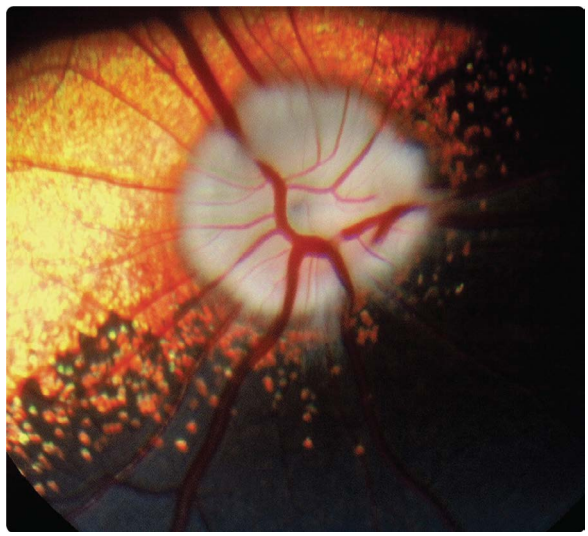

FIGURE 19.90 Same Golden Retriever as Figure 19.89. The optic disc is slightly swollen.

FIGURE 19.91 Same dog as Figure 19.89. MRI shows bilateral extraocular muscle swelling (arrowheads).

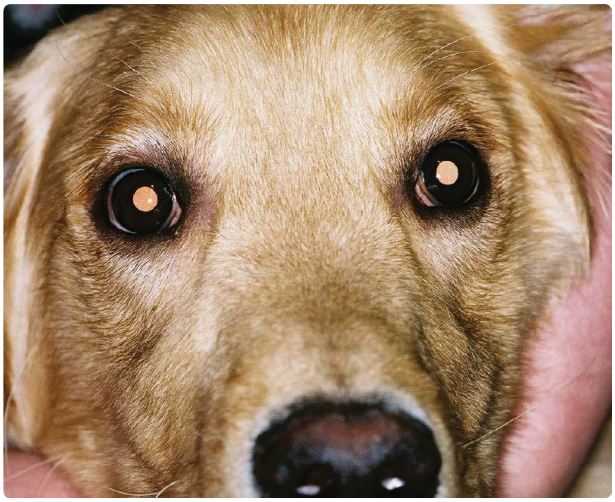

FIGURE 19.92 Same dog as Figure 19.89 4 months later. Therapy for the extraocular myositis has reduced the exophthalmos.

Diagnosis

Diagnosis is by serum and muscle biopsy for detection of type 1 myofiber antibodies.

Management

Treatment is the same as for masticatory muscle myositis.

NEOPLASIA OF THE ORBIT

Definition/Overview

Both primary and secondary neoplasia of the orbit occur in dogs and cats.

Etiology

Reports differ whether most orbital tumors are primary or secondary. Most orbital tumors are malignant in dogs and cats.

Pathophysiology

As the orbit contains almost all tissue types found in the body, a wide variety of tumors are reported involving all of those tissue types present within the orbit. Malignant cell types predominate with any widely metastatic tumor potentially involving the orbit.

Clinical Presentation

Progressive, usually nonpainful, slow exophthalmos with varying amounts of strabismus and exposure keratitis are the most common clinical signs (Figures 19.93 and 19.94). Acute-onset exophthalmos is most commonly associated with orbital inflammatory diseases such as retrobulbar abscesses/cellulitis. Exophthalmos with pain on attempting to open the mouth usually indicates a retrobulbar abscess or cellulitis, with swelling

FIGURE 19.93 A retrobulbar lipoma causing exophthalmos, third eyelid elevation, and dorsolateral displacement of the left globe within the orbit of this dog.

FIGURE 19.94 Bilateral third eyelid elevation, exophthalmos, and globe deviation in a dog with a brain tumor.

behind the last upper molar on the affected side also often observed. Dogs with orbital tumors undergoing necrosis can have the same clinical signs as dogs with orbital abscesses/cellulitis.

Differential Diagnosis

Orbital abscesses/cellulitis, masticatory myositis, salivary gland mucoceles, orbital varices.

Diagnosis

Cytologic examination and culture of discharge or aspirates from the orbit, biopsy of masses, exploration of fistulous tracts, ultrasonography, MRI, and CT are very valuable in evaluating orbital diseases (Figures 19.95–19.97). Of these, advanced imaging with CT or MRI followed by biopsy is the best way to establish a tissue diagnosis as well as to determine the potential invasiveness of the neoplasia. Histopathology is superior to cytology to determine a definitive diagnosis. Ultrasound-guided core biopsies are a safe and effective method to collect histopathologic samples. Affected patients should also undergo complete staging with CBC, serum biochemistry, urinalysis and imaging of the orbit, chest, and abdomen to check for evidence of potential metastasis.

Management

Early diagnosis and intervention may allow treatment along with salvage of the globe (Figures 19.98 and 19.99). In advanced or chronic cases, orbital exenteration (removal of the mass and the globe) is generally the therapy of choice unless the orbital tumor is well circumscribed. The prognosis for affected dogs and cats with orbital neoplasia is dependent on the type of tumor and when the tumor is diagnosed. Unfortunately, many cases are advanced prior to clinical signs and diagnosis.

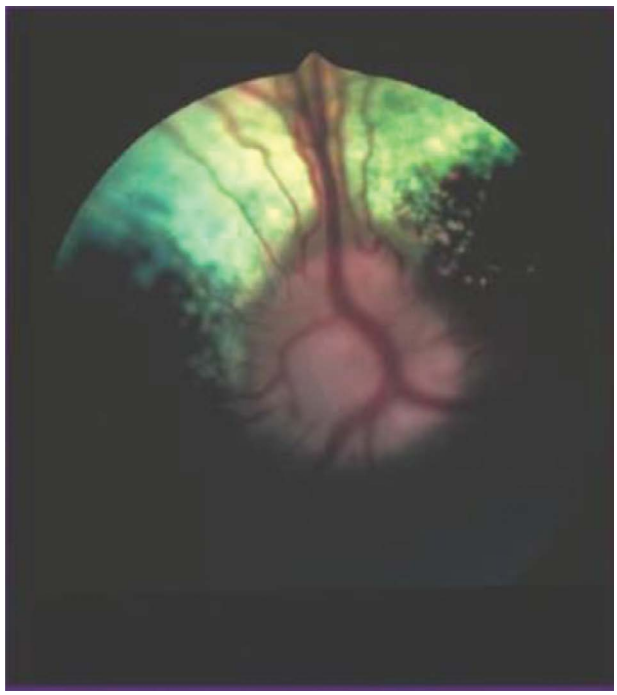

FIGURE 19.95 An optic nerve meningioma in the orbit has caused papilledema and scleral indentation of the optic disc in a mixed-breed dog.

FIGURE 19.96 Ocular and orbital ultrasound of the same dog in Figures 19.95 and 19.97. Note the circular mass indenting the globe.

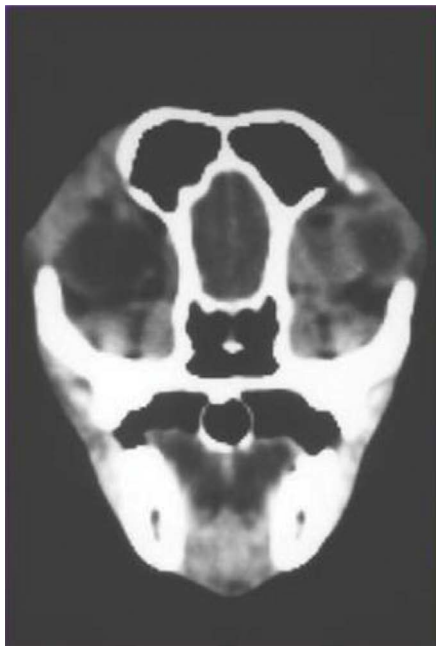

FIGURE 19.97 Orbital CT scan of the same dog in Figures 19.95 and 19.96. Note the mass behind the globe that is indenting the globe and has pushed the globe forward.

FIGURE 19.98 Exophthalmos, strabismus, and subconjunctival hemorrhage on the left side of this dog with lobular orbital adenoma.

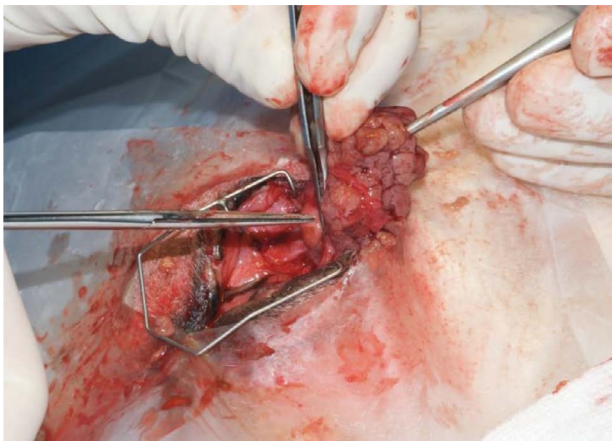

FIGURE 19.99 Surgical exploration and debulking of the retrobulbar lobular adenoma in the dog in **Figure 19.98**. The dog was visual before and after surgery.

The patient should be evaluated carefully for the ability to completely close the lids over the globe. Many patients with exophthalmos develop secondary exposure keratitis from lagophthalmos. Corneal ulceration may occur in patients with lagophthalmos. All patients with exophthalmos should be evaluated carefully for the presence of a corneal ulceration. If corneal ulceration is present, it should be treated like any other corneal ulcer. In addition, topical lubricating ointments should be applied every 2–6 hours to prevent desiccation of the ocular surface. A temporary tarsorrhaphy may be necessary if the exophthalmos is severe or prolonged.

CELLULITIS/ABSCESSATION OF THE ORBIT

Definition/Overview

Orbital cellulitis/abscessation occurs when there is infectious, inflammatory, traumatic, and potentially neoplastic disease within the orbit.

Etiology

The causes of orbital cellulitis include trauma, penetrating foreign body, extension of tooth root abscess or sinonasal disease, and hematogenous dissemination of infection or neoplasia. In some cases, an underlying cause may not be identifiable.

Pathophysiology

The canine and feline orbit lacks a bony floor, which leaves it vulnerable to penetrating injury or puncture if the patient chews a bone or a stick. Foreign bodies often are implicated as the cause of orbital cellulitis but rarely are identified definitively.

Clinical Presentation

The onset of clinical signs generally is rapid. These signs may include exophthalmos, periorbital swelling, chemosis, conjunctivitis, third eyelid elevation, fever, and pain upon opening the mouth (**Figure 19.100**). A soft, fluctuant swelling, hyperemia, or drainage may be present caudal to the last molar on the same side as the exophthalmos (**Figures 19.101** and **19.102**). Tooth root abscesses of the fourth premolar can erupt through the skin causing a draining tract ventral to the orbit.

Differential Diagnosis

Masticatory myositis, salivary gland mucoceles, orbital varices, orbital neoplasia with an inflammatory focus, or extraocular polymyositis.

Diagnosis

Diagnostic evaluation for orbital cellulitis or abscess should include a complete physical examination, a complete blood count, and a thorough oral examination. Due to the pain upon opening the mouth, most dogs will require heavy sedation or general anesthesia for a thorough evaluation and diagnostic sampling. Dental radiography may be indicated to rule out dental disease.

FIGURE 19.100 This dog has orbital and retrobulbar cellulitis. This patient has dramatic, severe conjunctivitis and chemosis, subconjunctival hemorrhage, third eyelid elevation, and significant periorbital swelling. (*Courtesy of M. Schaer.*)

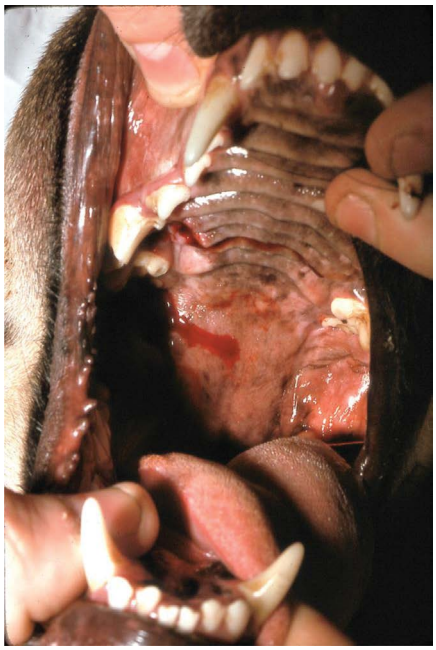

FIGURE 19.101 This is the same dog as in **Figure 19.100**. Note the hemorrhage coming from a draining tract behind the last upper molar on the right side. There is also a wound more rostrally on the soft palate, suggesting that the cause of the orbital cellulitis may have been from the dog chewing on a stick or other foreign material. (*Courtesy of M. Schaer.*)

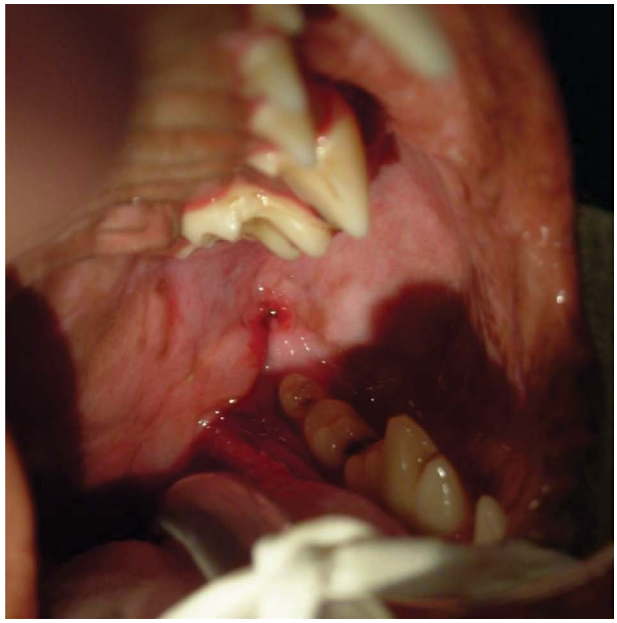

FIGURE 19.102 This dog with orbital cellulitis also has a small draining tract behind the last upper molar. (*Courtesy of M. Schaer.*)

Skull radiographs may demonstrate radiodense foreign bodies, show evidence of extension of inflammation from adjacent sinuses, or reveal orbital fractures. Orbital ultrasonography may demonstrate diffuse hyperechogenicity posterior to the globe or a discrete hypoechoic mass. Ultrasonography of the fellow normal orbit may be useful for comparison and aid in the identification of subtle lesions. Advanced imaging (including magnetic resonance imaging MRI and computed tomography CT) provides the most detailed and accurate images of the orbit and retrobulbar tissue. Fine-needle aspirates for cytologic evaluation and culture and sensitivity testing may be obtained from the retrobulbar space through the conjunctiva, skin, or oral cavity. Ultrasonographic, CT, or MRI guidance may be useful to improve localization when aspiration is performed. CT has not been shown to be an effective imaging modality to differentiate inflammatory versus neoplastic orbital disease, particularly when dealing with soft tissue lesions.

Management

In appropriate cases, therapy consists of establishing surgical drainage under general anesthesia, performing gentle, local irrigation, and administering systemic antibiotics. Before any of these procedures is performed, the operator should ensure that the cuff of the endotracheal tube is well inflated to prevent aspiration of any exudates. The mucosa may be incised behind the last upper molar using a #10 or #15 Bard-Parker scalpel blade, and a closed blunt mosquito hemostat should be inserted to enlarge the opening. The closed hemostat then should be opened gently to create a tract to allow drainage. Purulent material may not be immediately evident after establishment of a drainage tract. Samples should be procured for aerobic and anaerobic culture and sensitivity testing if purulent material is obtained. The tract then may be flushed gently with sterile saline solution. Systemic antibiotics should be administered after drainage has been established or when drainage cannot be established. Mixed aerobic and anaerobic bacterial infections occur most commonly in the dog and cat, and cephalosporins, extended-spectrum penicillins, potentiated penicillins, and carbapenems are recommended for initial antimicrobial treatment of orbital abscesses in dogs and cats. A recent study demonstrated that no bacteria cultured from dogs with orbital cellulitis/abscessation was susceptible to cefovecin, so this medication should not be utilized for treatment of canine orbital cellulitis/abscessation. Administration of systemic nonsteroidal anti-inflammatories and analgesics, including oral opioids such as tramadol hydrochloride, also is recommended until clinical signs resolve. Anti-inflammatory dosages of oral corticosteroids may also be effective; however, immunosuppressive dosages should be avoided. The patient should be evaluated carefully for the ability to completely close the lids over the globe. Many patients with exophthalmos develop secondary exposure keratitis from lagophthalmos. Corneal ulceration may occur in patients with lagophthalmos. All patients with exophthalmos should be evaluated carefully for the presence of a corneal ulceration. If corneal ulceration is present, it should be treated like any other corneal ulcer. In addition, topical lubricating ointments should be applied every 2–6 hours to prevent desiccation of the ocular surface. A temporary tarsorrhaphy may be necessary if the exophthalmos is severe or prolonged.

CONJUNCTIVAL MANIFESTATIONS OF SYSTEMIC DISEASE

Definition/Overview

Many systemic diseases of dogs and cats have nonspecific conjunctival manifestations. Mild hypoxia in cardiovascular disorders is manifested as conjunctivitis with dilation and darkening of conjunctival vessels. Conjunctival petechiation may be seen in any patient with a coagulopathy. Conjunctival venous engorgement may be noticed with congestive heart failure. Anemia may be seen as pallor or hemorrhage of the conjunctiva. Hyperviscosity syndromes are associated with conjunctival congestion. Icterus of the conjunctiva can be seen with any disease syndrome that causes icterus. Systemic tumors such as lymphoma may initially masquerade as conjunctivitis.

LIPID KERATOPATHY

Definition/Overview

Lipid keratopathy may be induced in hypercholesterolemic states by corneal trauma, ulcers, and surgery. Corneal lipidosis is reported in Shelties, Collies, German Shepherd Dogs, and Dobermanns.

Etiology

Lipid keratopathy in the dog is associated with hyperlipidemia, hypothyroidism, pancreatitis, diabetes mellitus, and spontaneous hyperlipidemia but can occur in the absence of any of these disease processes.

Pathophysiology

Lipid keratopathy is characterized by peripheral and central crystalline corneal stromal opacities (Figure 19.103). Corneal lipidosis generally does not completely regress.

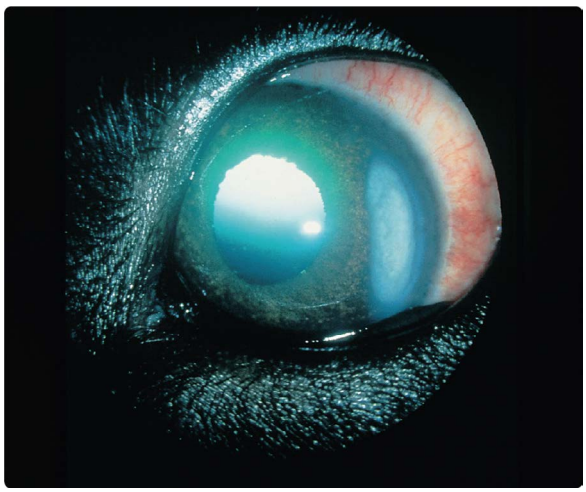

FIGURE 19.103 A limbal infiltrate of lipids accompanies elevated serum triglycerides in this dog with hypothyroidism.

Clinical Presentation

Lipid keratopathy appears as a bilateral, silver or blue–gray, complete ring at the limbus. The central cornea may be affected in advanced cases. Vascularization of the cornea may speed lipid deposition.

Differential Diagnosis

Rule out causes of corneal opacity, including corneal ulcers, edema, scars, and inflammatory cellular infiltrates from inflammatory, infectious, or neoplastic disease.

Diagnosis

Dogs with lipid keratopathy should have a serum lipid profile performed and be screened for thyroid function, pancreatitis, and diabetes mellitus. However, most affected dogs have normal lipid profiles.

Management

Low-fat diets may be beneficial in reducing the corneal opacity. If any inflammation is associated with the lesion, topical immunomodulators such as cyclosporine may be beneficial. Keratectomy may be utilized if vision is significantly affected by the opacification.

EYELID MANIFESTATIONS OF SYSTEMIC DISEASE

Definition/Overview

Chronic blepharitis may be associated with systemic endocrine imbalances such as hypothyroidism. Bacterial, fungal, parasitic, allergic, and neoplastic (lymphoma and mast cell tumors) diseases may affect the eyelids (Figures 19.104–19.108). Atopy, exposure to contact allergens, and autoimmune conditions are reported. Juvenile pyoderma can affect the lids of puppies. Predisposed breeds include the Dachshund, Golden Retriever, Labrador Retriever, Gordon Setter, and Lhasa

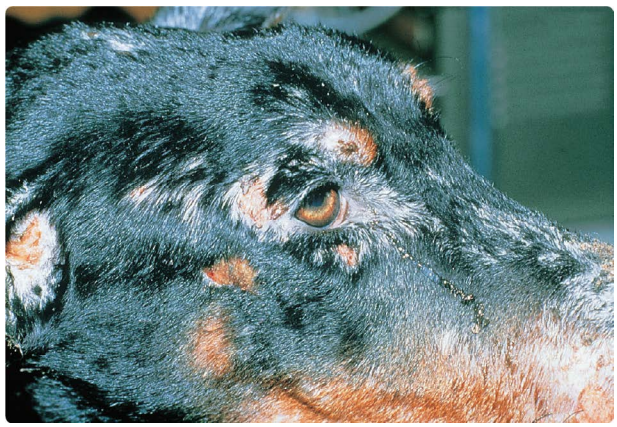

FIGURE 19.104 Alopecia and crustiness of the face and eyelids in a dog with systemic lupus erythematosus.

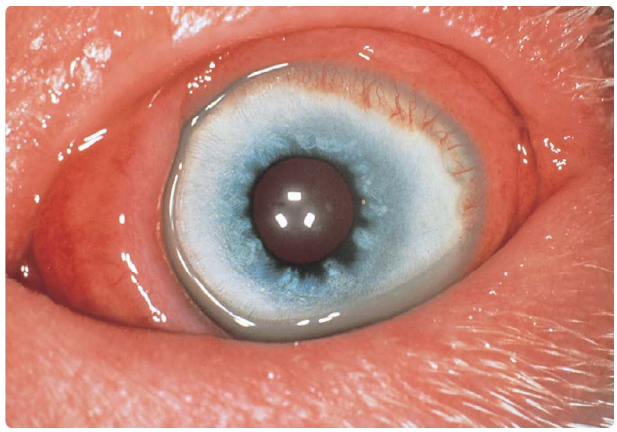

FIGURE 19.105 Blepharoconjunctivitis in a dog with demodicosis.

FIGURE 19.106 Blepharitis in a cat due to *Demodex* spp. infestation. (*Courtesy of K. Gelatt.*)

FIGURE 19.107 Zinc-responsive dermatosis in a Husky dog with bilateral blepharitis.

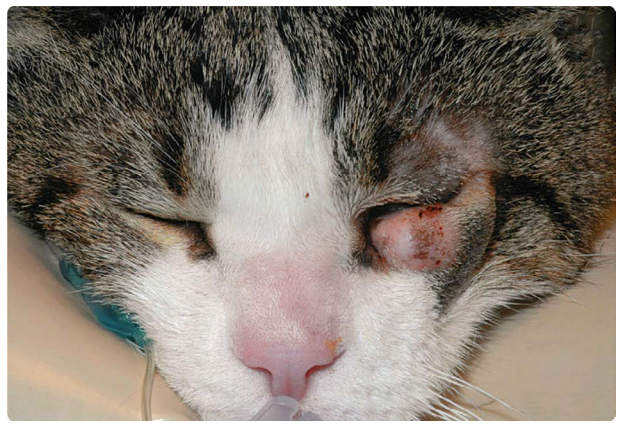

FIGURE 19.108 This mast cell tumor of the left lower lid of a cat was responsive to strontium radiation.

Apso. Papillomatous eyelid growths in young dogs may be associated with oral papillomatosis. Demodicosis causing deep lid pyoderma is reported in dogs and cats.

Bilateral and symmetrical hyperkeratotic "crustiness" of the lids is found in Huskies and Malamutes with zinc-responsive keratosis. An inherited inability to absorb zinc from the intestines causes the problem. Oral and parenteral elemental zinc supplementation is beneficial and will be required for the life of the patient.

Ocular manifestations of Ehlers–Danlos syndrome reported in the dog and the cat have been linked to excessive laxity of the eyelid skin and include entropion with secondary blepharospasm and keratoconjunctivitis (Figure 19.109). Cataract and lens luxation have been reported in the dog. The mode of inheritance in the dog and the cat is considered to be autosomal dominant.

Pemphigus foliaceus is the most common immune-mediated dermatologic condition affecting the feline eyelid and is also found in dogs. Pemphigus foliaceus,

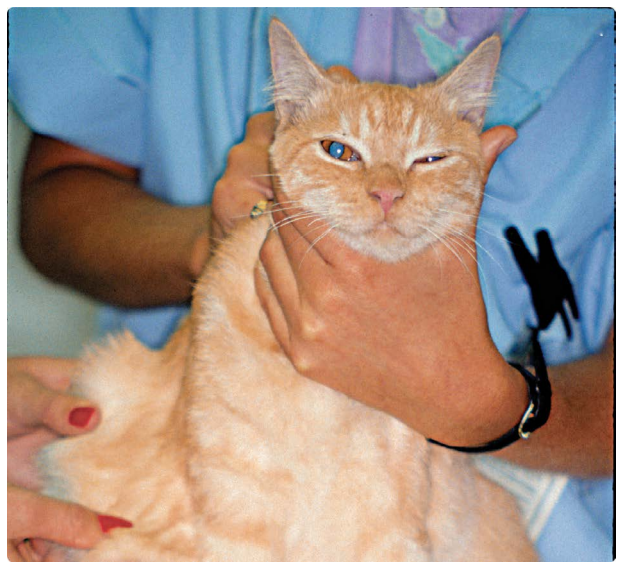

FIGURE 19.109 This cat has left-sided blepharospasm and Ehlers–Danlos-associated cataracts.

pemphigus erythematosus, pemphigus vulgaris, food hypersensitivity, and atopy may also affect the lids of cats and dogs.

UVEAL MANIFESTATIONS OF SYSTEMIC DISEASES

INFLAMMATION OF THE ANTERIOR UVEA

Definition/Overview

Inflammation of the anterior uvea (iris and ciliary body) is termed anterior uveitis or iridocyclitis. Inflammation of the posterior uvea or choroid is termed choroiditis. It is often useful to discuss inflammation of the anterior uvea as a distinct entity from the choroid, but inflammation of one region is generally associated with some degree of inflammation of the other region. Panuveitis is inflammation of the entire uveal tract, with endophthalmitis also involving the anterior chamber and vitreous. Anterior and posterior uveitis disrupt the protective blood–ocular barrier and allow blood and blood-derived compounds access to transparent nonvascular regions of the eye such that vision can be compromised.

Etiology

The most common cause of uveitis in dogs and cats is idiopathic. Patients with idiopathic uveitis are more likely to respond to therapy than patients diagnosed with infectious or neoplastic uveitis. Infectious and noninfectious neoplastic, immune-mediated, and metabolic systemic diseases can cause uveitis. Uveitis in cats is caused by systemic diseases such as FIP, FHV, FeLV-associated disorders, FIV, feline sarcoma virus (FeSV), toxoplasmosis, systemic mycotic infections, and neoplasms. Other causes for feline uveitis include bacteria (tuberculosis) and hypersensitivity reactions. Uveitis in dogs is caused by algae, bacteria, fungi, immune-mediated diseases, metabolic diseases, parasites (Figure 19.110), neoplasms, viruses, and rickettsiae.

Pathophysiology

Inflammatory mediators are released that disrupt the blood–ocular barrier and also cause the pupillary sphincter muscles and ciliary muscles to constrict.

Clinical Presentation

Miosis, conjunctival hyperemia, corneal edema, hypotony, hyphema, hypopyon, iris color change, iridal swelling, keratic precipitates (adherence of clusters of mononuclear inflammatory cells to the corneal endothelium), and pain may be found with anterior uveitis. Cataracts, deep corneal stromal vascularization, endophthalmitis, lens luxation, rubeosis iridis, iris bombé, and secondary glaucoma are adverse sequelae.

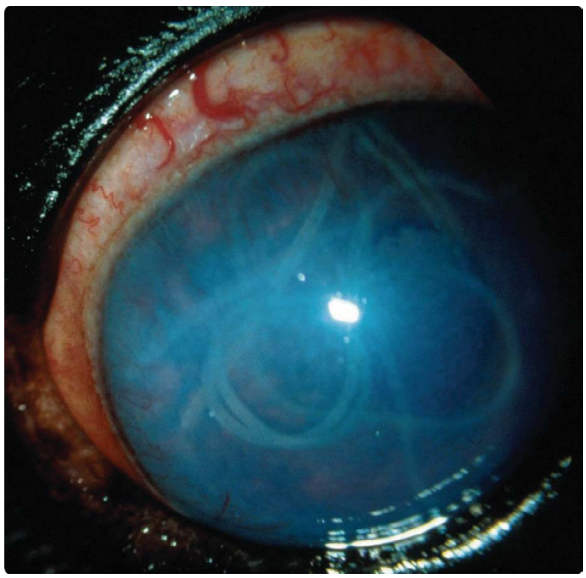

FIGURE 19.110 Heartworm larvae are motile and causing uveitis in this dog.

Choroiditis is associated with decreased vision, choroidal effusion, choroidal granulomas, optic neuritis, exudative RD, retinal hemorrhage, and vitreal opacification (Figures 19.111–19.115).

FIGURE 19.111 Keratic precipitates and hyphema in a cat with anterior uveitis from FIP.

FIGURE 19.112 Iridal neovascularization in a cat with thrombocytopenia.

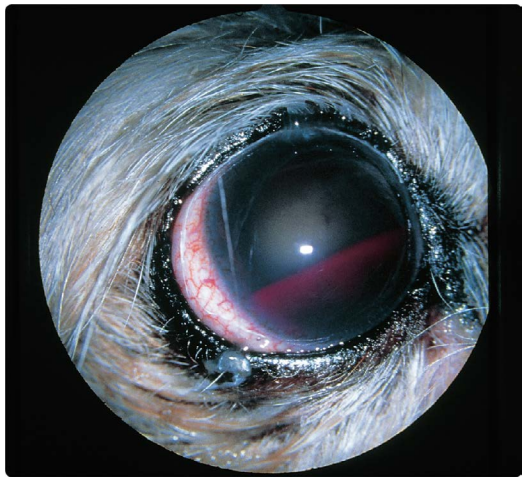

FIGURE 19.113 Hyphema due to renal hypertension indicates anterior uveitis in this dog.

FIGURE 19.114 An iris color change from blue to brown in the right eye of this cat is caused by anterior uveitis as the inflammatory or neoplastic cells infiltrate the iris stroma along with iridal neovascularization.

FIGURE 19.115 Cataracts may occur secondary to uveitis, or they may induce uveitis.

Differential Diagnosis

See Table 19.1.

Diagnosis

Complete physical and ocular examinations are important in animals with uveitis since they may provide diagnostic clues to the etiology. Other diagnostic considerations are a CBC, blood chemistries, serologic tests, and aqueous humor analysis. Cytologic evaluation and bacterial culture of aqueous and vitreous aspirates may help characterize the etiology of the uveitis. The uveitis may be unilateral or bilateral in multiple system diseases.

Management

Acute unilateral uveitis can be treated empirically. Bilateral or chronic uveitis, particularly posterior uveitis, is more likely due to infection and should be treated accordingly.

RETINAL AND OPTIC NERVE MANIFESTATIONS OF SYSTEMIC DISEASES

Definition/Overview

Neuronal ceroid lipofuscinosis (Batten disease) is reported in the English Setter, Tibetan Terrier, American Bulldog, American Cocker Spaniel, Australian Blue Heeler, Border Collie, Chihuahua, Dachshund, Dalmatian, Miniature Schnauzer, Polish Owczarek Nizinny, and Saluki. Ceroid is deposited in neurons of the CNS and in the retina and retinal pigment epithelium. Blindness and neurologic signs occur concurrently. Ophthalmoscopic lesions have not been noted in the English Setter and Tibetan Terrier, but mild tapetal hyperreflectivity, mild retinal vascular attenuation, and optic disc pallor have been noted as early as 2.5 years of age in affected Miniature Schnauzers.

Fucosidosis is an autosomal recessive glycoproteinosis occurring in the English Springer Spaniel. The disease is produced by a deficiency of the lysosomal enzyme α-L-fucosidase. While retinal ganglion cells are vacuolated from the accumulation of substrate, ophthalmoscopic lesions have not been reported with the visual impairment in the affected English Springer Spaniels.

The retinal dystrophy of the Briard dog is caused by a defect in polyunsaturated fatty acid metabolism. Plasma arachidonic acid levels are elevated to twice normal levels in American Briards with this congenital night blindness.

CHORIORETINITIS

Definition/Overview

Posterior uveitis involves the choroid and cannot be clinically distinguished from retinitis. It is therefore usually described as chorioretinitis.

Etiology

Chorioretinitis in the cat is frequently caused by toxoplasmosis, FIP, cryptococcosis, histoplasmosis, and blastomycosis. Toxoplasmosis and cryptococcosis commonly involve only the posterior segment, although anterior and

posterior uveitis may occur. Granulomatous choroiditis in cats can also be associated with several *Mycobacterium* species. Chorioretinitis in dogs is caused by distemper, leptospirosis, brucellosis, Rocky Mountain spotted fever, aspergillosis, blastomycosis, coccidioidomycosis, histoplasmosis, protothecosis, toxoplasmosis, leishmaniasis, and primary and secondary neoplasia. Potentially toxic drugs such as ivermectin can also cause chorioretinitis.

Clinical Presentation

The signs of retinal or chorioretinal inflammation include edema, infiltration with inflammatory cells and granuloma formation, hemorrhage, and possible exudative detachment (Figure 19.116). In dogs, retinal exudates, hemorrhage, and RD are a sequelae to chorioretinitis (Figure 19.117).

FIGURE 19.116 Focal areas of chorioretinitis in a cat.

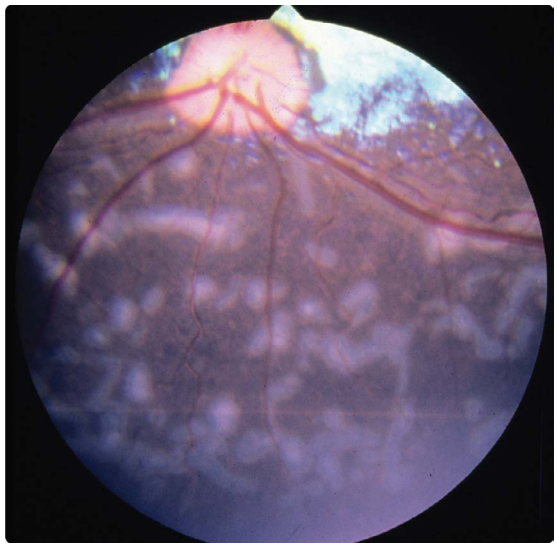

FIGURE 19.117 Chorioretinitis post ivermectin ingestion is present in this Border Collie.

Differential Diagnosis

See Table 19.1.

Diagnosis

Active chorioretinitis causes hyporeflective lesions in the tapetal region. Chorioretinal scars, characterized by hyperreflective areas in the tapetal region or depigmented areas in the nontapetal region, may be observed in normal healthy cats and dogs and are an indication of a previous subclinical inflammatory process (Figures 19.118 and 19.119). If the interior of the globe cannot be visualized due to clinical signs such as fibrin, hypopyon, hyphema, and/or secondary cataract, an ocular ultrasound may be

FIGURE 19.118 Inactive chorioretinitis is manifested with two areas of hyperreflectivity of the retina (more bright yellow areas) over the green tapetum of this dog.

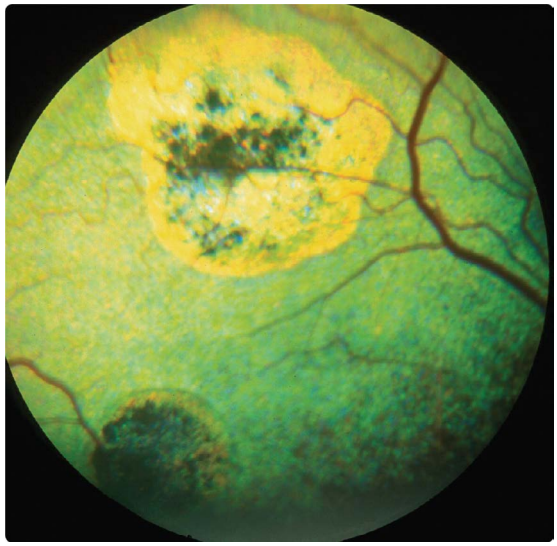

FIGURE 19.119 Hyperreflective areas of retinal atrophy with pigmentation from inactive chorioretinitis in a cat.

beneficial to diagnose a mass lesion or a retinal detachment with subretinal exudate.

Management

Treatment is determined by the inciting cause. Systemic therapy is necessary for treatment of retinal diseases.

UVEAL AND CHORIORETINAL MANIFESTATIONS OF SECONDARY NEOPLASIA

Definition/Overview

Secondary neoplasia may have similar ocular manifestations as both idiopathic or infectious uveitis. It may also present as a more solitary mass rather than diffuse uveitis. Neoplastic uveitis of the dog has been reported to occur in between 4% and 24% of cases. In a recent retrospective study, neoplasia was the cause of the uveitis in 5% of cats.

Etiology

The most common secondary neoplasm to affect both dogs and cats is lymphosarcoma. Numerous other secondary neoplasms have been reported in the dog, including hemangiosarcoma, malignant melanoma, osteosarcoma, mastocytoma, malignant histiocytosis, seminoma, transmissible venereal tumor, transitional cell carcinoma, neurogenic sarcoma, rhabdomyosarcoma, anaplastic fibrosarcoma, pheochromocytoma, and adenocarcinoma of the mammary gland, thyroid gland, parotid salivary gland, adrenal gland, sweat gland or renal, nasal, pancreatic, and pulmonary origin. Other systemic neoplasms reported in the cat include adenocarcinoma of lung, mammary or uterine origin, pulmonary carcinoma, soft-tissue fibrosarcoma, plasmacytoma, and multiple myeloma.

Pathophysiology

As many secondary neoplasms spreads hematogenously, the uveal tract is a site of predilection. The uveal tract is also an area where this hematogenous spread can often be visualized with a complete ophthalmic examination.

Clinical Presentation

Secondary neoplasms tend to have similar clinical signs and mimic anterior uveitis, posterior uveitis, and/or panuveitis secondary to idiopathic or infectious diseases (Figures 19.120 and 19.121). It is more likely for clinical signs of a secondary neoplasm to present bilaterally versus unilaterally, but this is not always the case. Secondary neoplasms often present with clinical signs affecting the choroid, but lymphosarcoma is most commonly associated with signs of anterior uveitis. Patients may have systemic disease related to that specific neoplasm, or the signs may be initially limited to the globe.

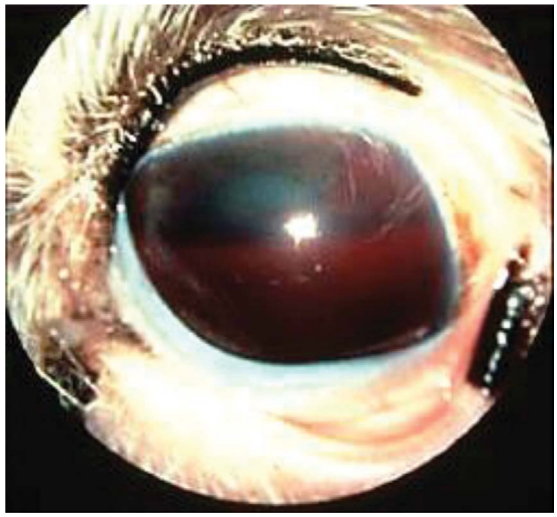

FIGURE 19.120 Hyphema in a dog with metastatic hemangiosarcoma.

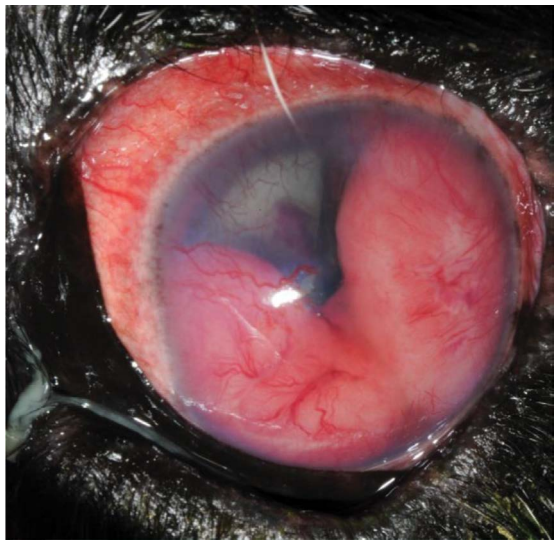

FIGURE 19.121 Scleral injection and iridal masses in a dog with histiocytic sarcoma.

Differential Diagnosis

See Tables 19.1 and 19.2.

Diagnosis

If systemic neoplasia is suspected, it is recommended to perform complete staging of the patient, including physical examination, CBC, serum chemistry panel, urinalysis, thoracic imaging (radiographs or CT), and abdominal imaging (ultrasound or CT). If the interior of the globe cannot be visualized due to clinical signs such as fibrin, hypopyon, hyphema, and/or secondary cataract, an ocular ultrasound may be beneficial to diagnose a mass lesion or a retinal detachment with subretinal exudate. It is also possible for inflammatory or infectious disease to also show similar lesions on ocular ultrasound. Aspirates of masses or mass lesions can

be attempted but may result in exacerbation of anterior uveitis. In most cases, histopathology is the best way to diagnose the secondary neoplasm, and the globe may be the simplest organ to obtain tissue.

Management

The treatment of systemic neoplasia affecting the globe is based on the diagnosis and generally directed at systemic treatment for that specific neoplasm. The treatment of the uveitis is based on the clinical signs present and is similar to uveitis of idiopathic or infectious etiologies.

RETINAL DETACHMENT

Definition/Overview

Retinal detachment (RD) occurs with separation of the inner nine layers of the neurosensory retina from the single outer retinal pigment epithelium (RPE).

Etiology

Bilateral RD suggests a systemic problem. Optic nerve colobomas, severe retinal dysplasia, systemic hypertension due to renal or cardiac failure, intraocular neoplasia, and chorioretinitis may cause RD. Infectious disease and neoplasia generally are associated with exudative retinal detachments. Hypertension can lead to serous retinal detachments with retinal and vitreal hemorrhage. Vitreoretinal dysplasia occurs in certain breeds (Jack Russell Terriers and Shih Tzus) that may lead to spontaneous, rhegmatogenous retinal detachment.

Pathophysiology

The neurosensory retina may be pushed away from the RPE by accumulation of chorioretinal inflammatory or neoplastic exudate in the subretinal space (exudative RD), or the retinal tissue may be torn, with retinal holes forming, and the retina can be pulled away from the RPE by vitreal traction from vitreal inflammation or hemorrhage (rhegmatogenous RD).

Clinical Presentation

The pupils are fixed and dilated if the RD is complete. Small detachments are not associated with blindness, but total RD is a serious problem with a poor visual outcome in most cases.

Differential Diagnosis

See Tables 19.1 and 19.2.

Diagnosis

Ophthalmic examination reveals dilated pupils (if bilateral), visible blood vessels behind the lens, leukocoria, vitreous degeneration and/or hemorrhage, and an opaque, folded retina. Ocular ultrasound is diagnostic of RD in eyes with cataracts or other opacity of the anterior segment that precludes direct visualization of the retina.

Management

The inciting systemic cause of the RD must be identified and treated. Systemic medical therapy may be curative in RD of short duration (e.g., cats with systemic hypertension-induced RD). Rhegmatogenous RD requires advanced microsurgery.

OPHTHALMOMYIASIS

Definition/Overview

Ophthalmomyiasis interna refers to the presence of dipteran fly larva in the eye.

Etiology

Ophthalmomyiasis is caused by the sheep nasal botfly (*Oestrus ovis*), warble fly (*Cuterebra* spp.), or the cattle warble fly (*Hypoderma bovis*). Larvae gain access to the eye via the blood or via direct migration through the tissues of the eye.

Pathophysiology

Larval migration and/or death incite mild-to-severe inflammation of the ocular tissues.

Clinical Presentation

Anterior uveitis and RDs may also occur with ophthalmomyiasis. Cats are more commonly affected than dogs. The presence of arcuate or linear areas of depigmentation in the tapetal and nontapetal fundus may be due to traumatic, degenerative, or inflammatory disease of the retina, RPE, and choroid (Figure 19.122). Clinical findings of ophthalmomyiasis are usually incidental.

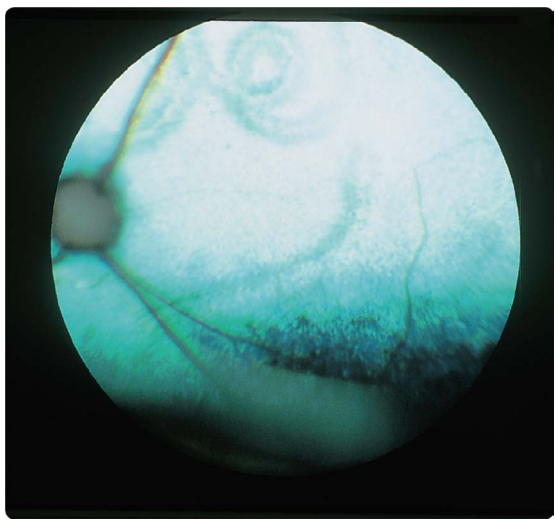

FIGURE 19.122 Curvilinear tracks due to ophthalmomyiasis in a cat.

Differential Diagnosis

See Table 19.1.

Diagnosis

Ophthalmomyiasis is evident as curvilinear tracks of retinal degeneration and retinal hemorrhage in dogs and cats. Larvae may be noticed floating in the vitreous or actively migrating in the retina.

Management

Most cases are incidental findings and require no therapy. Surgical removal of vitreal larvae can be done to remove a source of inflammation.

FELINE NUTRITIONAL RETINAL DEGENERATION OR TAURINE RETINOPATHY

Definition/Overview

Diets deficient in the amino acid taurine cause retinal degeneration and dilated cardiomyopathy in cats.

Etiology

Feline nutritional retinal degeneration occurs in cats that are fed commercial dog food or special diets formulated for dogs. Improperly formulated vegetarian cat diets can result in blindness in cats.

Pathophysiology

Taurine is an essential amino acid for cats with long-term deficiency causing severe retinal lesions. A taurine intake of 110 mg/kg body weight per day is needed to maintain normal retinal structure and function.

Clinical Presentation

Early lesions appear as bilateral, focal, hyperreflective regions in the area centralis. If taurine continues to be deficient in the diet, the retinal lesions progress to symmetrical, horizontal, band-shaped hyperreflective areas dorsal to the optic disc (Figures 19.123–19.126), with advanced stages appearing as diffuse generalized retinal atrophy and complete blindness.

Differential Diagnosis

Any inflammatory or infectious disease can leave a scar, but the location and orientation of the lesions in this disease are rather pathognomonic. Similar lesions can be found in cats that are reported to have only been fed diets with appropriate taurine levels, so it is possible that another syndrome/disease causes similar lesions, but this has not been documented.

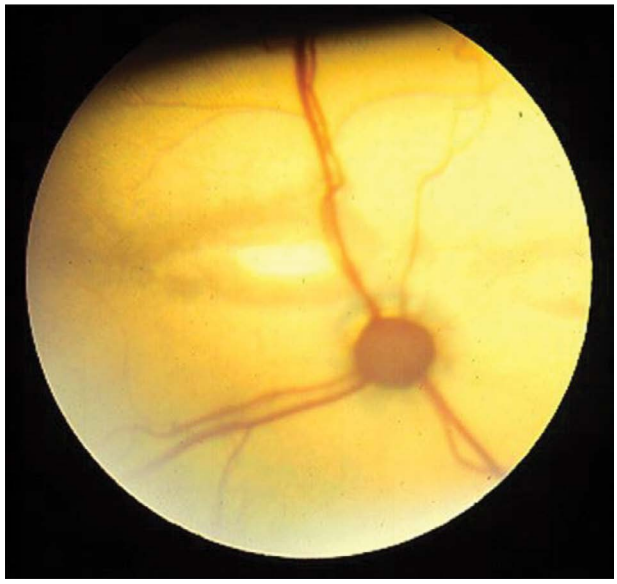

FIGURE 19.123 An oval area of tapetal hyperreflectivity over the area centralis of this cat with taurine retinopathy. This cat appeared to have normal vision.

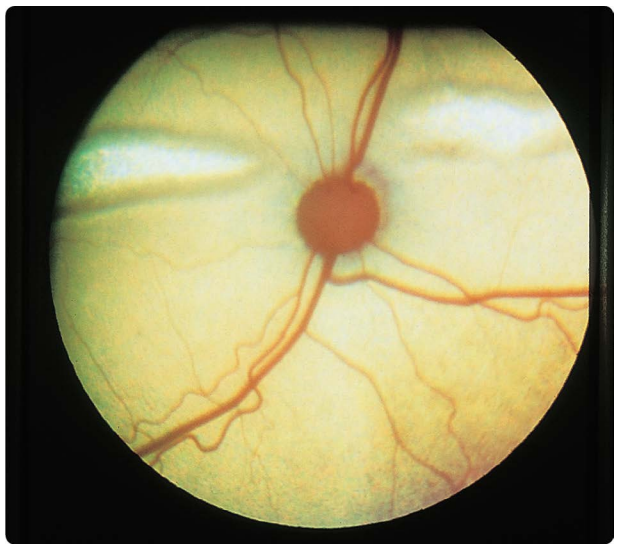

FIGURE 19.124 Two separate areas of hyperreflectivity dorsal to the optic disc in a cat with more advanced taurine retinopathy than the cat in Figure 19.123. This cat appeared to have normal vision.

Diagnosis

Measurement of plasma taurine levels is necessary to determine if taurine deficiency is present (a level less than 20 nmol/mL is critically low). Similar lesions can be found incidentally in cats that are fed appropriate diets and are not taurine deficient.

Management

Restoration of vision with taurine supplement is dependent on the degree of damage. The degeneration in early cases can be arrested if adequate amounts of taurine are

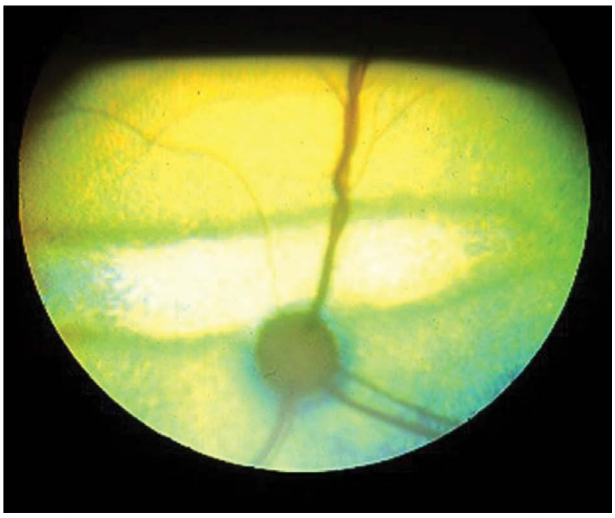

FIGURE 19.125 A complete band of hyperreflectivity dorsal to the optic disc in a cat with more advanced taurine retinopathy than the cat in **Figure 19.124**. This cat appeared to have normal vision.

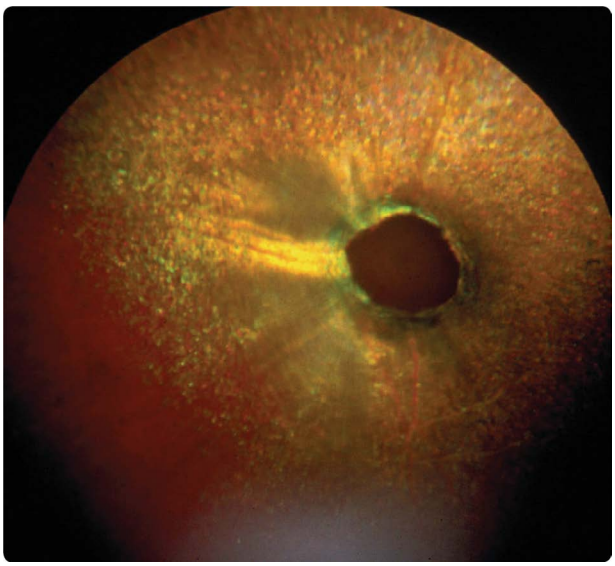

FIGURE 19.126 Diffuse retinal and optic nerve atrophy secondary to chronic taurine deficiency in a cat. This cat will be permanently nonvisual.

included in the diet. However, taurine supplementation is of no value restoring vision in eyes with advanced retinal degeneration and blindness.

ENROFLOXACIN RETINOPATHY

Definition/Overview

Enrofloxacin, a fluoroquinolone antibiotic, has been associated with a rare adverse ophthalmic reaction causing an acute, irreversible, retinal degeneration in cats. Pupils are fixed and dilated, and the retina demonstrates diffuse, severe retinal degeneration. The tapetum is diffusely hyperreflective, and there is significant vascular attenuation. Vision loss is acute and follows enrofloxacin administration. The reported estimated incidence of this adverse reaction is 1 in 122,414 treated cats, or 0.0008%. Toxicity more commonly occurs with parenteral administration. Adherence to the manufacturer's current recommendation for enrofloxacin dosage in cats is advisable but may still be too high for some cats.

OPTIC NEURITIS

Definition/Overview

Optic neuritis is inflammation of the intraocular or intraorbital optic nerve. It may be a manifestation of systemic illness. Optic neuritis is seen more commonly in male, middle-aged, and medium-to-large breeds of dogs. See previous section in this chapter on GME and MUE.

Etiology

Causes include idiopathic, immune-mediated, infectious, inflammatory, and neoplastic disorders.

Pathophysiology

Optic neuritis is more of a clinical syndrome than a single disease. Inflammation of the nerve or adjacent tissue causes damage to the optic nerve axons, vision loss, and optic nerve atrophy.

Clinical Presentation

The optic disc, when affected, appears swollen, with the peripapillary retina displaying evidence of RD. Retinal and optic disc hemorrhages and a vitreal haze may be present. The pupil is fixed and dilated, and vision is absent.

Differential Diagnosis

Intraorbital or retrobulbar optic neuritis must be differentiated from glaucoma, RD, cataracts, and sudden acquired retinal degeneration (SARD), a retinal disease associated with sudden blindness and a normal-appearing retina early in the disease process.

Diagnosis

Diagnosis is based on elimination of possible causes, a CBC, serum chemistry profile, urinalysis, screening for infectious diseases, heartworm antigen test, thoracic radiography, and analysis of CSF. An electroretinogram (ERG) can differentiate acute retinal disease, such as SARD, from intraorbital or retrobulbar optic neuritis. With SARD, the ERG will be flatline, but with intraorbital or retrobulbar optic neuritis, the ERG will be within normal limits.

Management

Oral corticosteroids are the drugs of choice in idiopathic cases. Other immunosuppressive agents, such as cytosine

arabinoside, azathioprine, leflunomide, or cyclosporine A, are also utilized. Many cases, however, relapse.

PAPILLEDEMA

Definition/Overview

Papilledema is noninflammatory swelling of the optic nerve head. Papilledema can result in optic nerve atrophy and blindness if the inciting condition cannot be eliminated.

Etiology

Papilledema is caused by partial obstruction of axoplasmic flow associated with increased intracranial pressure and is not commonly reported in dogs. Vision is present, particularly early in the disease process. Papilledema is seen in dogs with compression of the optic nerve by retrobulbar tumors and in dogs with elevated intraocular pressure in early glaucoma.

Pathophysiology

Sustained mechanical trauma to the optic nerve axons or ischemia to any part of the optic nerve can reduce axoplasmic flow. Axoplasmic flow of both fast and slow components becomes reduced at the lamina cribrosa in papilledema.

Clinical Presentation

Dilated pupils and optic nerve head swelling are present, but vision is maintained.

Differential Diagnosis

Must be differentiated from any cause of optic neuritis.

Diagnosis

Elevation/swelling of the optic disc, blurring of the disc margin, filling in of the optic cup, and protrusion of the disc into the vitreous are found ophthalmoscopically with papilledema. In contrast to optic neuritis, the optic disc is not usually hyperemic, and there are not associated peripapillary and retinal hemorrhages, inflammatory exudates, or peripapillary RD.

Management

Resolution of the elevated intracranial pressure can aid animals with papilledema.

LYSOSOMAL STORAGE DISEASES

Definition/Overview

Several lysosomal storage diseases have been identified in cats and dogs. Storage diseases are characterized by an accumulation of metabolic by-products within lysosomes, the cellular organelles that degrade complex macromolecules. Specific lysosomal storage diseases are normally named according to the specific accumulated product. Because this excess material is a normal cellular component, the histopathologic changes result from physical distortion of affected cells rather than from a toxic effect. Most lysosomal storage diseases with known modes of inheritance are inherited as an autosomal recessive trait.

ALPHA-MANNOSIDOSIS

Definition/Overview

Alpha-mannosidosis is a member of the inherited oligosaccharidoses described in Persian, Domestic Shorthair, and Domestic Longhair cats that results from a deficiency in acidic alpha-mannosidase. Ocular abnormalities described in affected cats include progressive corneal and lenticular opacification and resting nystagmus.

GLOBOID CELL LEUKODYSTROPHY

Definition/Overview

Globoid cell leukodystrophy, or Krabbe disease, is a member of the inherited sphingolipidoses described in the cat that result from a deficiency in galactocerebrosidase activity. The substrate galactocerebroside (i.e., galactosylceramide), a constituent of myelin, and another metabolite of myelin turnover, psychosine (galactosylsphingosine), accumulate. Ocular manifestations of this disease in cats include lack of vestibular ocular reflexes and signs associated with visual deficits, including diminished pupillary light reflexes and reduced menace responses. Galactocerebrosidosis is an autosomal recessive trait in West Highland White and Cairn Terriers. Clinical signs of globoid cell leukodystrophy in dogs are generally rapidly progressive and develop at a young age (2–6 months). Visual deficits and blindness may result late in the course of disease, but ophthalmoscopic lesions have not been observed.

GM1-GANGLIOSIDOSIS

Definition/Overview

GM1-gangliosidosis is caused by a deficiency of a lysosomal hydrolase, beta-galactosidase, which produces an accumulation of GM1-ganglioside in the cerebral cortex and visceral organs. Ganglion cell swelling is the main ocular sign in cats. With respect to dogs, GM1-gangliosidosis is an autosomal recessive condition seen in Alaskan Huskies, English Springer Spaniels, mixed-breed Beagles, Portuguese Water Dogs, and Shiba Inus. Abnormal ocular findings in dogs with this disease are limited to: (1) Central corneal clouding, as

has been observed in Shiba Inus and Portuguese Water Dogs; (2) vision disturbances, as seen in Shiba Inus and Portuguese Water Dogs; (3) strabismus, as has been observed in mixed-breed Beagles and Huskies; and (4) nystagmus, as has been observed in English Springer Spaniels, Portuguese Water Dogs, and Huskies.

GM2-GANGLIOSIDOSIS

Definition/Overview

GM2-gangliosidosis is caused by a deficiency of hexosaminidase. Clinical signs include ataxia, immobility, blindness, dysphagia, and finally seizures or generalized myoclonus (5 months of age), quadriplegia (6 months of age), and death prior to 8 months of age in cats. Variant forms of GM-2 gangliosidosis have been reported in the Japanese Spaniel, the German Shorthair Pointer, and the Golden Retriever.

MUCOLIPIDOSIS II

Definition/Overview

Mucolipidosis II, or inclusion cell disease, is caused by deficient activity of the enzyme N-acetylglucosamine-1-phosphotransferase. Ocular abnormalities detected in cats affected with mucolipidosis II include early-to-late lesions, absent menace response, diminished pupillary light reflexes, and dilated pupils by 4 months of age. Initially, retinal development appears normal until 2.5 months of age, at which time dorsal retinal degeneration develops followed by progressive end-stage generalized retinal degeneration and blindness by 3.5 months of age.

MUCOPOLYSACCHARIDOSES

Definition/Overview

The mucopolysaccharidoses (MPS) are a group of diseases characterized by defective metabolism of mucopolysaccharides (glycosaminoglycans). Three types of MPS have been identified in cats (MPS I, VI, and VII). Corneal clouding is the most debilitating ocular manifestation. Five types of MPS have been identified in dogs (MPS I, II, III, VI, and VII). Corneal opacities are also seen with these conditions in dogs.

This chapter will begin with the methods of decontamination followed by a discussion of intoxicants that affect specific organ systems in the body.

DECONTAMINATION

Decontamination is the cornerstone of treating toxicoses. With decontamination, we can change the kinetics of the toxin by reducing absorption and increasing excretion. Decontamination is performed in the asymptomatic patient. It is important that the ABCs (airway, breathing, circulation) are assessed before treating any toxicosis.

Decontamination of ocular exposures includes flushing the eyes with tepid water or saline solution for 20–30 minutes. The severity of ocular exposure can range from mild irritation to corrosion of the ocular tissues depending on the substance, concentration, and contact time.

Dermal exposures can occur to a large variety of substances. Damage to the skin can range from mild irritation to severe burns. Bathing with a mild liquid hand dishwashing detergent and warm water is recommended.

Oral ingestion is the most common route of toxicant exposure in pets. Dilution with milk or water is recommended for irritants and corrosives. Emetics can be used to evacuate the stomach if there are no contraindications. Contraindications include ingestion of corrosives or hydrocarbons, uncontrolled seizure disorders, cardiac failure, significant clinical signs, and previous vomiting. Emetics generally empty 40%–60% of the stomach contents. Potential complications from emesis induction may include aspiration, gastritis, and transient bradycardia (due to vagal stimulation). Emesis is most productive if performed within 1–2 hours post ingestion. Chocolate, grain-based rodenticides, and plant material can stay in the stomach longer (**Figure 20.1**). Feeding a small meal prior to inducing vomiting can increase chances of an adequate emesis. Apomorphine a centrally acting emetic agent is the emetic of choice in the dog. It can be given IV or conjunctivally. It works by antagonizing dopamine in the chemoreceptor trigger zone (CRTZ) quickly (i.e., within 5–10 minutes), resulting in vomiting. Potential adverse effects include

DOI: 10.1201/9781003254591-40

FIGURE 20.1 Chocolate emesis, several hours after ingestion. (*Courtesy of Mike Lucroy*.)

central nervous system (CNS) and respiratory depression and protracted vomiting. Naloxone can be used to reverse the CNS and respiratory depression. Naloxone will not block the emetic effect. If the toxicant affects the CRTZ, a locally acting emetic such as 3% hydrogen peroxide can be used in dogs. The dosage is 2 mL/kg (1 teaspoon/5 pounds) body weight, not to exceed 45 mL (3 tablespoons). Vomiting usually occurs within 10–15 minutes, and the dose can be repeated once if not initially successful. Overdosing with hydrogen peroxide should be avoided, as it may result in severe hemorrhagic gastritis. Recently, the Food and Drug Administration (FDA) approved the use of a new emetic, Clevor (ropinirole 30 mg/mL ophthalmic solution), which specifically antagonizes dopamine D2-type receptors in the CRTZ causing emesis.

The CRTZ in cats is regulated by alpha receptors and xylazine or dexmedetomidine can be used as an emetic. Yohimbine or atipamezole are used to reverse the CNS and cardiovascular (CV) signs.

Activated charcoal adsorbs toxicants in the gastrointestinal (GI) tract and facilitates excretion via the feces. Xenobiotics that are not effectively adsorbed by activated charcoal include ethanol, methanol, fertilizer, fluoride, petroleum distillates, heavy metals, iodides, nitrates, nitrites, sodium chloride, and chlorates. The recommended dose of activated charcoal for all species is 1–2 g/kg body weight.

Cathartics enhance elimination of substances bound to activated charcoal by moving them through the gastrointestinal tract. Cathartics are not to be used if the animal has diarrhea or is dehydrated. Osmotic cathartics, like sorbitol, pull electrolyte-free water into the gastrointestinal tract. Excessive dosing can lead to hypernatremia (see Sodium Toxicosis).

In situations where emesis cannot be performed, enemas can be helpful to eliminate toxicants from the lower gastrointestinal tract. Plain warm water or soapy warm water (10 mL/kg) is preferred.

Gastric lavage can also be used in mammals to remove recently ingested toxicants. Lavage is contraindicated with caustic substances or hydrocarbons. Gastric lavage is generally considered to be less effective than emesis in removing toxicants from the stomach. Patients are anesthetized and intubated with a cuffed endotracheal tube to protect the airway. Water used at body temperature (5–10 mL/kg) is instilled through a large-bore fenestrated gastric tube. Multiple lavages are performed until the lavage fluid becomes clear. Drainage of the lavage fluid is facilitated by the gravity method, with the patient's head being kept lower than the chest for fluid recovery. Recovered lavage fluid is collected and examined for evidence of ingested toxic substance(s).

Gastrotomy or endoscopy may be indicated for agents that will not readily pass through the gastrointestinal tract (coins, metal objects, expandable polyurethane glues, large amounts of toxic plant material, etc.).

Intravenous lipid emulsions are used to treat lipid soluble toxicants. The mechanism of action is unknown, but the working theory is the "lipid sink/lipid shuttle" theory. Lipophilic drugs are bound in the expanded plasma lipid volume, decreasing free (active) drug. The lipid emulsion of choice for treating lipid soluble toxicosis is the 20% solution and may be given through a peripheral catheter. Veterinary dosing guidelines have been extrapolated from human literature and are considered extra-label. Dosing is at 1.5 mL/kg initial IV bolus, followed by a constant rate infusion (CRI) of 0.25 mL/kg/min for 30–60 minutes. This can be repeated in 4–6 hours if no lipemia is present and the animal is still symptomatic. Uncommon adverse effects of lipids include allergic reactions, lipemia, hypertriglyceridemia, hemolysis (oxidative damage), and elevated liver and pancreatic values. Fat overload syndrome is caused by excessive lipid volumes overwhelming the endogenous lipid clearance mechanisms. Another deleterious side effect is that lipids can also bind antidotes or other therapies being used to treat the patient, resulting in a worsening of the clinical condition. Lipid therapy should be considered when traditional therapies have failed if the toxin is lipid soluble. Intravenous lipid emulsion therapy has been used successfully in the treatment of lidocaine, permethrins, baclofen, ivermectin, diltiazem, and ibuprofen intoxications among others.

Cholestyramine is an anion exchange resin used to lower cholesterol in humans who have not responded to normal therapies. It binds with bile acids in the intestine, preventing their reabsorption and stopping enterohepatic recirculation. This increases the excretion of the toxicant. Cholestyramine has been used in the treatment (off label) of several toxicity is both humans and animals. These include amiodarone, digitoxin, methotrexate, piroxicam, vitamin D, warfarin, blue-green algae, indomethacin, naproxen, and sago palm. The dose is 300 mg/kg p.o. t.i.d. with duration depending on the toxin ingested. For veterinary patients, the powder should be given with or mixed in canned food.

Advanced therapies such as hemodialysis, hemoperfusion, and therapeutic plasma exchange may be available. These procedures should be chosen based on the toxicant (molecule size, distribution, protein binding) and the size of the patient.

NERVOUS SYSTEM

The nervous system can be affected by various toxins, and clinical signs will vary depending on the dose and route of exposure. While the blood–brain barrier and blood–cerebrospinal fluid barrier help protect the brain from toxins, it is still susceptible to injury as it receives a high percentage of cardiac output (20%–25%) and requires a continuously high level of oxygen and nutrients. Refer to Table 20.1 for a list of selected toxicants.

ALCOHOLS (METHANOL, ETHANOL, ISOPROPYL)

Definition/Overview

Alcohols include ethanol (alcoholic beverages [Figure 20.10] liquid medications, hand sanitizers, yeast bread dough), methanol (wood alcohol, windshield washer fluid [Figure 20.11]), and isopropyl alcohol (isopropanol; flea sprays, rubbing alcohol [Figure 20.12]).

Pathophysiology

Alcohols are CNS depressants that act by enhancing the inhibitory effects of neurotransmitters in the CNS. Alcohols are rapidly absorbed orally, and some have dermal absorption (isopropyl).

TABLE 20.1 Selected toxicants and organ system(s) affected

Toxicant	Organ system(s)	Comments
Acetaminophen (paracetamol)	Hepatic, hematologic	See chapter for details
Acids	Dermal, GI	See chapter for details
Aflatoxins	Hepatic	Acute hepatic necrosis
Albuterol	Cardiovascular	See chapter for details
Alcohols (methanol, ethanol, isopropyl)	CNS	See chapter for details
Alkalis	Dermal, GI	See chapter for details
Allium spp. (onions, garlic)	Hematologic	See chapter for details
Alpha-lipoic acid (thioctic acid)	CNS, hepatic, renal	Hypoglycemia and organ failure
Amitraz	CNS, cardiovascular	Atipamezole is antidotal
Amatoxins (mushrooms)	Hepatic	See chapter for details
Aminoglycosides	Renal	Renal tubular necrosis
Amphetamines	CNS, cardiovascular	See chapter for details
Anatoxin-a (blue–green algae)	CNS	Respiratory paralysis
Anatoxin-a(s) (blue–green algae)	CNS	Naturally occurring organophosphate
Anticholinergic insecticides (organophosphates, carbamates)	CNS, PNS	See chapter for details
Anticoagulant rodenticides	Hematologic	See chapter for details
Antihistamines (diphenhydramine)	CNS	Sedation at low doses, stimulation at high doses
Arsenic, arsenical anthelmintics	Gastrointestinal	Hemorrhagic gastroenteritis, hypovolemic shock
Avermectins (ivermectin, moxidectin, selamectin, milbemycin)	CNS	See chapter for details
Baclofen	Musculoskeletal	Centrally acting skeletal muscle relaxant, death from respiratory paralysis
Barbiturates (phenobarbital, pentobarbital)	CNS	Treat with lipids
Benzodiazepines (diazepam, alprazolam)	CNS, hepatic (cats)	Flumazenil is antidotal
Bleach	Gastrointestinal	Vomiting, ulcers with concentrated products
Bromethalin	CNS	See chapter for details

(*Continued*)

TABLE 20.1 Selected toxicants and organ system(s) affected (*Continued*)

Toxicant	Organ system(s)	Comments
Bromide	CNS, gastrointestinal	Vomiting and CNS depression; sodium is antidotal
Brunfelsia spp. (yesterday, today, and tomorrow)	CNS	Tremors can last for weeks
Cannabis spp. (marijuana)	CNS	See chapter for details
Calcium channel blockers (diltiazem, verapamil)	Cardiovascular	Severe hypotension, bradycardia, treat with lipids
Carbon dioxide	Respiratory	Asphyxiation
Carbon monoxide	Respiratory	See chapter for details
Cardiac glycosides – *Nerium* spp. (oleander [**Figure 20.2**]) – *Digitalis* spp. (foxglove [**Figure 20.3**]), kalanchoe, *Convallaria majalis* (lily of the valley [**Figure 20.4**]), digoxin, toads, fireflies	Cardiac	Arrhythmias, digoxin FAB fragments are antidotal
Cholecalciferol rodenticides, calcipotriene and related vitamin D compounds	Renal	See chapter for details
Cyanide (cyanogenic glycosides—apple, cherry, peach, cassava, bamboo shoots, etc.)	Respiratory	– Stops oxygen utilization, cherry red blood (smell of almonds) – Rare in monogastrics
Cycad palm, sago palm (**Figure 20.5**) (*Cycas* spp., *Zamia* spp.)	Hepatic	Hepatic necrosis
DEET	CNS	Seizures
Detergents (nonionic, anionic, cationic)	Dermal, gastrointestinal	– Cationic—chemical burns – Nonionic, anionic—mild GI
Elapids (coral snakes)	PNS	Ascending paralysis
Essential oils	CNS, hepatic	Signs will vary depending on concentration and type of oil
Estrogens	Hematopoietic	Aplastic anemia
Ethylene glycol	Renal, CNS	See chapter for details
5-fluorouracil	CNS, gastrointestinal, hematopoietic	Chemotherapeutic agent—seizures are hard to control
5-hydroxytryptophan (5-HTP)	CNS	See serotoninergic medications for details
Fluoride	Gastrointestinal	Hemorrhagic gastritis
Gold salts	Renal	Glomerulopathy
Grayanotoxin-containing plants – Rhododendrons, azaleas (*Rhododendron* spp.), Laurels (*Kalmia* spp.) – Japanese pieris (*Pieris* spp.)	Cardiac, gastrointestinal	Arrhythmias GI signs are most common in nonruminants
Humulus lupulus (hops)	CNS, musculoskeletal	Severe hyperthermia, dantrolene is antidotal (dogs only)
Hydrogen sulfide	Respiratory	Paralyzes respiratory center
Imidazoline decongestants (oxymetazoline, xylometazoline, tetrahydrozoline, naphazoline)	Cardiovascular	Atipamezole is antidotal
Ionophores	PNS	Paralysis (dogs), neuropathy (cats)
Insoluble calcium oxalates	Gastrointestinal	See chapter for details
Iron	Gastrointestinal, hepatic	Deferoxamine is antidotal
Isocyanates (polyurethane glue)	Gastrointestinal	Foreign body
Isoniazid	CNS	Pyridoxine is antidotal
Isoxazole mushrooms	CNS	Alternating agitation and sedation
Ketoconazole	Hepatic	Cats (rare)

(*Continued*)

TABLE 20.1 Selected toxicants and organ system(s) affected (*Continued*)

Toxicant	Organ system(s)	Comments
Latrodectus spp. (widow spiders)	PNS	Painful muscle cramping
Lead	CNS, PNS, gastrointestinal	See chapter for details
Lectin plants – *Abrus precatorius* (Rosary pea) – *Ricinus communis* (castor bean [Figure 20.6]) – *Robinia* spp. (black locust)	Gastrointestinal, liver, renal	Vomiting most common, can see multiorgan failure
Lilium and *Hemerocallis* spp.	Renal	See chapter for details
Local anesthetics (benzocaine, lidocaine)	Cardiac, CNS, hematologic	Arrhythmias, seizures, methemoglobinemia (esp. cats)
Loxosceles spp. (recluse spiders)	Dermal, hematologic	Necrotic lesions (dogs rarely affected), slow to heal, hemolysis (rare)
Macadamia nuts	Musculoskeletal	Tremors, weakness (only dogs)
Metaldehyde	CNS	Molluscicide, tremors, seizures
Methionine	CNS	Hepatic encephalopathy-type signs
Methylene blue	Hematologic	– For treating methemoglobinemia – Can cause Heinz body anemia (cats)
Methylxanthines (chocolate, caffeine, coffee)	Gastrointestinal, CNS, cardiac	See chapter for details
Metronidazole	CNS	Most common with chronic large doses
Microcystins (blue–green algae)	Hepatic	Hepatic necrosis, hypovolemic and hemorrhagic shock
Minoxidil	Gastrointestinal, cardiac	Vomiting, hypotension, pulmonary edema, death
MAOIs (monoamine oxidase inhibitors)	CNS	Serotonin syndrome—see chapter for details
Muscarinic mushrooms (*Amanita muscaria*)	PNS	SLUDDE signs
Naphthalene	Hematologic	Hemolysis
Nicotine	CNS, gastrointestinal	See chapter for details
NSAIDs	Gastrointestinal, renal, CNS (some), liver (rare)	See chapter for details
Ochratoxin	Renal	Mycotoxin (rare)
Opioids, opiates	CNS	See chapter for details
Paraquat	Respiratory	Herbicide, pulmonary fibrosis
Petroleum distillates, hydrocarbons (gasoline, paint thinner, mineral spirits, oil, wax) (Figure 20.7)	Respiratory, CNS, dermal	Aspiration risk, defatting of skin, light hydrocarbons have CNS effects
Phenazopyridine	Hepatic, hematologic	Converted to acetaminophen, see chapter for details
Phenylpropanolamine (PPA)	Cardiovascular	See chapter for details
Pit vipers	Hematologic, vasculotoxic	Coagulopathy, rarely neurologic (Mojave A-toxin)
Propylene glycol	CNS, renal, hematologic	CNS depression, Heinz body anemia (chronic ingestion)
Pseudoephedrine (Figure 20.8)	CNS, cardiac	See amphetamines for details
Psilocybin mushrooms	CNS	See serotoninergic medications for details
Pyrethrins, pyrethroids	CNS	See chapter for details
Salicylates (aspirin)	Gastrointestinal, hepatic, hematopoietic, CNS	See chapter for details

(*Continued*)

TABLE 20.1 Selected toxicants and organ system(s) affected (*Continued*)

Toxicant	Organ system(s)	Comments
SSRIs (selective serotonin reuptake inhibitors)	CNS	See serotoninergic medications for details
SNRIs (serotonin and norepinephrine reuptake inhibitors)	CNS	See serotoninergic medications for details
Sodium	CNS	See chapter for details
Sodium fluoroacetate (1080)	CNS	Seizures
Spinosad	CNS, gastrointestinal	Makes animals susceptible to ivermectin toxicosis (even when used at appropriate dose)
Strychnine	CNS	Seizures, death from inability to expand chest
Sulfonamides	Hepatic, renal, hematologic	
Tacrolimus	Gastrointestinal	Vomiting, intussusception (up to day 6)
Taxus spp. (yew) (**Figure 20.9**)	Cardiovascular	Arrhythmias, death
Thiaminase (raw fish)	CNS	Cats Thiamine is antidotal
Tremorgenic mycotoxins (penitrem A, roquefortine)	CNS	See chapter for details
Tricyclic antidepressants (TCAs) (amitriptyline, clomipramine)	CNS	See serotoninergic medications for details
Turpentine	CNS, respiratory	Depression, aspiration
Vitis spp. (grapes, raisins)	Renal	See chapter for details
Xylitol	CNS, liver	See chapter for details
Zinc	Hematologic, renal (secondary)	See chapter for details
Zinc phosphide	CNS, respiratory	– Rodenticide, releases phosphine gas – Dangerous to veterinary personnel

FIGURE 20.2 *Nerium oleander*—Oleander.

FIGURE 20.3 *Digitalis* spp.—Foxglove. (*Courtesy of Laura Stern.*)

FIGURE 20.4 *Convallaria majalis*—Lily of the Valley. (*Courtesy of Laura Stern*.)

FIGURE 20.5 *Cycas* spp.—Sago or cycad palm.

FIGURE 20.6 *Ricinus communis*—Castor bean. Plant is much more toxic with parenteral exposure. If beans are swallowed whole, no problems are expected.

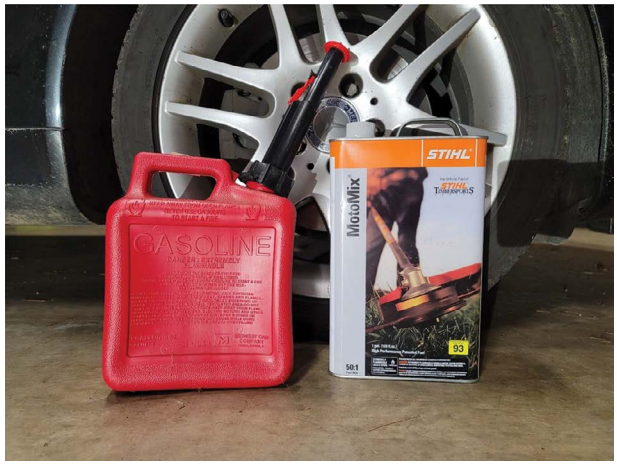

FIGURE 20.7 Light petroleum distillates are volatile and can cause CNS depression, dermal lesions, and aspiration pneumonia. (*Courtesy of Tim Williams*.)

FIGURE 20.8 Pseudoephedrine acts like an amphetamine stimulant in pets. (*Courtesy of Tim Williams*.)

FIGURE 20.9 *Taxus* spp.—Yew. (*Courtesy of Laura Stern*.)

FIGURE 20.10 Alcoholic beverages are a common source of ethanol. (*Courtesy of Tim Williams*.)

FIGURE 20.11 Windshield washer fluid contains methanol. The label reads "can cause blindness and death." This does not happen in nonprimates. (*Courtesy of Tim Williams*.)

FIGURE 20.12 Isopropyl alcohol can be absorbed dermally as well as orally.

Alcohols are all metabolized in the liver (95%) by alcohol dehydrogenase (ADH) to acetaldehyde and then by aldehyde dehydrogenase to an acid. With methanol, primates can develop blindness and seizures. This does not happen in dogs and cats.

Clinical Presentation

Clinical signs develop within 30 minutes to 2 hours post ingestion. Alcohol is irritating to the stomach, and high blood levels will also stimulate emesis. Vomiting, CNS depression, and ataxia (drunkenness) are common. In severe cases, hypothermia, hypotension, hypoglycemia, tremors, seizures, respiratory depression, coma, and death can occur. The risk of aspiration is increased as high blood levels slow the muscles that control the epiglottis.

Diagnosis

History and clinical signs; ethanol levels may be determined from blood, serum, plasma, and urine, but they are seldom done in pets.

Management

The amount of ethanol needed to cause intoxication will vary depending on the type of alcohol ingested (Table 20.2). Emesis may be induced if asymptomatic (risk of aspiration). Activated charcoal is not indicated. Heart rate (HR), blood pressure (BP), and body temperature should be monitored. In animals demonstrating clinical signs, acid–base status and glucose should be monitored for the development of metabolic acidosis

TABLE 20.2 Ethanol concentrations in alcoholic beverages and other household products

	Proof	Percent ethanol v/v
Light beer	5–7	2.5–3.5
Beer	8–12	4–6
Ale	10–16	5–8
Wine, craft beer (barley wine, imperial stouts)	20–40	10–20
Mouthwash		14–27
Amaretto	34–56	17–28
Aftershave		19–90
Schnapps	40–100	20–50
Coffee liqueurs	42–53	21–26.5
Brandy	70–80	35–40
Bourbon, whiskey	80–90	40–45
Rum, cognac, vodka	80–82	40–41
Tequila	80–92	40–46
Gin	80–94	40–47
Cologne/perfume		50
Hand sanitizers		60–95

and hypoglycemia. Intravenous fluids should be given to prevent dehydration and to support the cardiovascular system. Maropitant, dextrose, and sodium bicarbonate should be used as needed. In severely affected comatose patients, the patient's oxygen status should be monitored, and the airway should be protected. Yohimbine, atipamezole, and naloxone have been tried to reverse coma with variable results. Hemodialysis can increase excretion of alcohols.

Prognosis

There are no published minimum lethal oral doses of alcohols in dogs or cats, with most animals recovering within 12–24 hours. Animals that are comatose or who develop aspiration pneumonia have a guarded to grave prognosis. Isopropyl is thought to be 3x more toxic than ethanol.

AMPHETAMINES

Definition/Overview

Amphetamines can be found in both prescription forms (attention deficit hyperactivity disorder [ADHD], weight loss medications) and illicit forms (methamphetamine, methylenedioxymethamphetamine [MDMA], crack).

Pathophysiology

Amphetamines are sympathomimetic alkaloids that stimulate alpha- and beta-adrenergic receptors, causing the release of endogenous catecholamines at synapses in the brain and the heart. This causes peripheral vasoconstriction and cardiac stimulation resulting in hypertension, tachycardia, ataxia, agitation, tremors, and seizures. Amphetamines also increase serotonin and dopamine release in the CNS.

Clinical Presentation

Agitation, tachycardia, hypertension, tremors, and seizures can occur. The time frame will vary with the form of amphetamine ingested. Peak plasma concentrations of amphetamine occur 1–3 hours after ingestion of immediate release or illicit products. Extended-release products (ADHD medications) may have a lag of up to 8 hours before clinical signs are seen.

Diagnosis

History and clinical signs; urine drug screens are not validated in animals but can be used to help with diagnosis.

Management

Asymptomatic animals can have emesis induced and activated charcoal administered. Fluid therapy is important to enhance elimination and for cardiovascular support. Phenothiazines (acepromazine, chlorpromazine) are the drugs of choice for controlling agitation. Diazepam can worsen dysphoria. Cyproheptadine may aid in managing some of the CNS effects secondary to increased serotonin (see Serotoninergic Medications). If tachycardia persists, propranolol or atenolol may be used. Signs may last up to 48–72 hours in severe cases.

Prognosis

Most animals do well if their cardiovascular signs are controlled.

AVERMECTINS

Definition/Overview

Avermectins are macrocyclic lactone parasiticides and include ivermectin, milbemycin, selamectin, doramectin, abamectin, and moxidectin (Figure 20.13).

Pathophysiology

Avermectins bind to glutamate-gated chloride channels in nematodes and arthropods causing hyperpolarization by enhancing the movement of chloride ions into the cell. This results in paralysis. In mammals, avermectins potentiate the release and binding of gamma-aminobutyric acid (GABA) in the CNS. In dogs with the ABCB1 (MDR1) mutation, more avermectin remains in the CNS, resulting in neurologic signs. Labeled preventative doses for moxidectin and ivermectin are safe even in ABCB1 mutation patients.

Clinical Presentation

The most common clinical signs include depression, weakness, recumbency, ataxia, and coma. Other

FIGURE 20.13 Avermectins are commonly used in heartworm medications.

reported signs include tremors, seizures, transient blindness, bradycardia, and hyperthermia. Most severe cases are secondary to veterinary miscalculation with injections or dogs ingesting horse dewormers.

Diagnosis

History and clinical signs; laboratory diagnosis is usually delayed.

Management

If the exposure has just occurred (oral) and the animal is asymptomatic, induce vomiting. Activated charcoal can be given. If the animal becomes comatose, use lipids. Treatment can take days to weeks, and supportive care is very important.

Prognosis

Clinical signs in ivermectin "sensitive" and "nonsensitive" breeds start at 150 mcg/kg and 2,000 mcg/kg, respectively. Prognosis depends on the dose and speed of onset of clinical signs, with animals developing clinical signs within the first 4 hours having a worse prognosis.

BROMETHALIN

Definition/Overview

Bromethalin is a neurotoxic rodenticide (Figure 20.14).

Pathophysiology

Bromethalin uncouples oxidative phosphorylation in CNS mitochondria. This reduction of adenosine triphosphate (ATP) leads to insufficient energy for maintaining sodium-potassium ion channel pumps. Loss of pump activity causes cerebral and spinal cord edema, retention of water in the myelin lamellae, and demyelination injury to long nerves. Continued swelling of the lamellae results in increased intracranial and cerebrospinal fluid (CSF) pressure that is typically unresponsive to therapy.

FIGURE 20.14 Bromethalin baits have become very common with the restrictions placed on second generation anticoagulants. (*Courtesy of Tim Williams.*)

Clinical Presentation

There are two syndromes, high dose (acute) and low dose (chronic). The acute syndrome is seen at doses higher than the lethal dose (LD). Signs can begin within 12–24 hours and include severe tremors, hyperthermia, seizures, coma, and death. With the chronic syndrome, signs may not appear for 72–96 hours and include hindlimb ataxia and paresis, decreased proprioception, CNS depression, and fine muscle tremors.

Diagnosis

History and clinical signs; histopathology is used for confirmation.

Management

For acute intoxication, decontamination is very important. Once significant clinical signs occur, they are difficult to control. Emesis and activated charcoal (multiple doses may be needed) should be performed in the asymptomatic patient. Treatment (mannitol, corticosteroids, diazepam) is directed at controlling the clinical signs and decreasing cerebral edema. Since most of the drug is located within myelin, efficacy is poor. Animals with sublethal doses will require symptomatic and supportive care, with improvement being noted over several weeks.

Prognosis

Once clinical signs occur, prognosis is guarded to grave. Cats are far more sensitive to bromethalin than dogs. Dogs under 16 weeks of age appear to be more at risk, with an LD as low as 0.9 mg/kg.

Cannabis sativa (MARIJUANA)

Definition/Overview

Marijuana (*Cannabis sativa*) is used both recreationally and medicinally in people. As the societal stigma with its use has decreased, more animals are presenting to veterinarians with intoxication. Historically, most pet exposures to marijuana were ingestions of plant material. Now edibles (cookies, brownies, etc., [Figure 20.15]) and concentrates (oils, waxes, shatters) are more common sources for intoxication.

Pathophysiology

The main toxic principle of marijuana is a resin called tetrahydrocannabinol (THC). THC levels have increased in cannabis over the years due to selective

FIGURE 20.15 Edibles are attractive to pets. A "normal" human dose is 10 mg THC. (*Courtesy of Tim Williams.*)

breeding. THC levels in plant material range from 1% to 8%, extracts 28%, and hash oil up to 50%. THC affects various types of neurotransmitters, including dopaminergic, cholinergic, noradrenergic, serotonergic, and GABA.

Clinical Presentation

Clinical signs are dependent on the type of exposure, with inhalational producing signs within 6–12 minutes. Absorption is unpredictable with oral ingestion, with clinical signs often being delayed. Clinical signs can last up to 72 hours with common clinical signs exhibited being lethargy, disorientation, bradycardia, hypothermia, mydriasis, urinary incontinence, as well as CNS signs (ataxia, hyperesthesia, and tremors). Exposure to concentrates may result in patients becoming hypotensive and comatose.

Diagnosis

History and clinical signs. Over-the-counter urine drug screening tests have not been validated for use in dogs.

Management

For acute intoxications in asymptomatic patients, emesis is induced with hydrogen peroxide, since marijuana is an antiemetic at the CRTZ. Activated charcoal is generally not needed. Many cases with plant material ingestion can be managed at home with confinement and monitoring. Symptomatic and supportive care for more severely affected patients consists of intravenous fluids, sedatives (acepromazine 0.05–0.1 mg/mg IV) and muscle relaxants (diazepam 0.25–0.5 mg/kg slowly IV). While receiving in hospital treatment, heart rate (HR), respiratory function, blood pressure, and body temperature should be monitored. Intravenous lipid therapy may be helpful for severely affected (hypotensive, comatose) animals.

Prognosis

Most animals recover well from acute intoxications. Patients that are more severely affected or that consume edibles or concentrates carry a worse prognosis.

CHOLINESTERASE INHIBITORS (ORGANOPHOSPHORUS AND CARBAMATES)

Definition/Overview

These compounds are commonly used as insecticides but are also found in chemical warfare agents (VX, sarin, soman, tabun). Common organophosphates (OPs) include chlorpyrifos, malathion, and tetrachlorvinphos. Common carbamates are aldicarb, carbaryl, methomyl, and propoxur. Cholinesterase inhibitors are being replaced by more insect-specific insecticides.

Pathophysiology

Acetylcholine (ACh) is a neurotransmitter released at synapses and neuromuscular junctions. It facilitates nerve transmission at preganglionic to postganglionic neurons of parasympathetic and sympathetic nervous systems and postganglionic parasympathetic and sympathetic fibers to effector organs and sweat glands. It also facilitates nerve transmission at the motor nerves to skeletal muscle. The enzyme acetylcholinesterase (AChE) found in the synapse rapidly hydrolyzes ACh to control the level and duration of synaptic transmission. Acetylcholinesterase inhibitors bind to and inhibit function of AChE. Without functional AChE, ACh accumulates and causes excessive postsynaptic stimulation. This leads to muscarinic and nicotinic clinical signs.

OPs phosphorylate the enzyme by binding to an esteratic site, while carbamates carbamylate the enzyme. This means that OPs are often referred to as irreversible inhibitors of AChE, and carbamates are reversible. As OPs "age" (chemical change that strengthens the bond to the AChE enzyme), the enzyme will not regain activity, and new enzymes must be synthesized.

Clinical Presentation

Clinical signs appear within a few minutes to several hours after exposure. Signs can be associated with either the muscarinic or nicotinic effects. The muscarinic signs include SLUDDE signs (salivation, lacrimation, urination, defecation, dyspnea, emesis) as well as miosis and bradycardia. Dyspnea is the result of increased bronchial secretions, bronchoconstriction, and decreased contraction of the respiratory muscles. Nicotinic signs are muscle tremors, twitching, weakness, and paresis progressing to paralysis. Central nervous system signs are hyperactivity, tremors, and seizures.

Diagnosis

Whole blood AChE activity (<25% normal activity confirms toxicosis).

Management

Emesis is not recommended due to the potential for rapid onset of clinical signs. Activated charcoal with a cathartic can be given in cases of recent ingestions if asymptomatic. Monitor respiratory effort and HR. Atropine (0.2 mg/kg, one-quarter IV, rest IM or SQ) is an anticholinergic and can be used if animal is bradycardic or has harsh lung sounds. Pralidoxime (2-PAM) is used to treat the nicotinic effects. It reactivates the AChE enzyme. It is not indicated for carbamates and will not work with OPs once aging has occurred. Diazepam or methocarbamol can be used for the nicotinic signs if needed. Because carbamates bind with acetylcholine on a reversible basis, the inhibition of acetylcholinesterase is temporary. Therefore, carbamates have a shorter duration of action that organophosphate insecticides.

Prognosis

There is a wide range of toxicity for these products, and prognosis depends on the dose and clinical signs. Animals suffering from seizures and/or respiratory distress have a guarded prognosis. Cats are especially sensitive to cholinesterase inhibitors.

LEAD

Definition/Overview

Lead is a heavy metal found in various forms (elemental, inorganic, and organic) and from varied sources. Dogs and cats may be exposed to automotive batteries, bone meal supplements, ceramic glazes, lead weights (fishing sinkers, curtain weights), lead-based paints (old houses, artist's paints), lead bullets/shot, lead solder, putty and caulk, linoleum, electronic equipment, roofing felt, and decorative objects. Animals that are shot can develop lead poisoning only if the retained bullet is in an acidic environment (synovial joint, area of inflammation [Figure 20.16]).

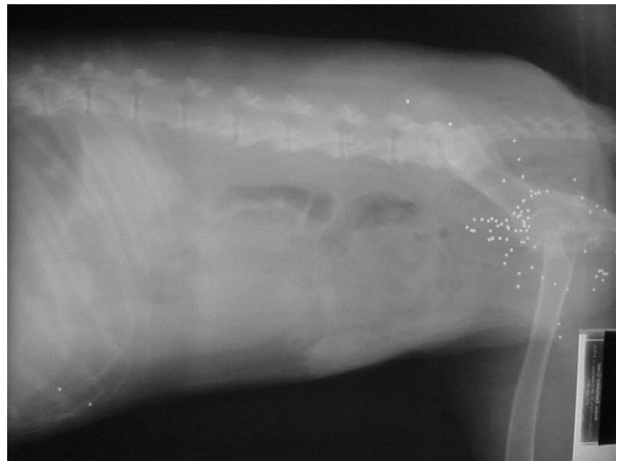

FIGURE 20.16 Lead shot remaining in muscle tissue of dog.

Pathophysiology

Lead can be absorbed from the gastrointestinal or respiratory tract. Lead interferes with multiple organ systems, cell types, enzymes, and tissues within the body.

Young animals absorb lead more readily than adults. Lead is especially toxic to the fetus and young as it inhibits brain development and disrupts the blood–brain barrier. Lead affects central and peripheral neurotransmission by inhibiting calcium. It also interferes with enzymes involved in heme synthesis, resulting in red blood cell abnormalities (basophilic stippling) and anemia. Alterations in synaptic transmission in visceral smooth muscle can alter intestinal motility and tone leading to lead colic. Lead is stored long term in bone.

Clinical Presentation

While lead can affect various body systems, dogs and cats show neurologic and gastrointestinal signs most commonly. Acute lead poisoning is characterized by colic, anorexia, behavior changes, ataxia, tremors, and seizures. Chronic lead poisoning can present with abdominal discomfort, vomiting, diarrhea, anorexia, lethargy, weight loss, anemia, behavior changes, intermittent seizures, and megaesophagus (cats; rare).

Diagnosis

While radiographs with radiopaque objects and findings such as anemia, NRBCs, and basophilic stippling can suggest lead intoxication, whole blood lead levels are the preferred diagnostic test (more than 90% of circulating lead is bound to erythrocytes). Blood lead levels above 0.3–0.35 ppm (30–35 ug/dL) indicate significant lead exposure. With appropriate clinical signs, these levels support the finding of lead toxicosis. Blood lead levels greater than 0.6 ppm (60 ug/dL) are diagnostic for lead toxicosis. With chronic lead poisoning radiopaque lines can be seen in the metaphyseal regions.

Management

Once stabilized, any lead remaining in the GI tract should be removed (emesis, lavage, endoscopy, surgery, enema). Activated charcoal does not bind to heavy metals. Chelation therapy can be started afterwards if indicated. There are several choices of chelation agents: Calcium disodium ethylene diamine tetraacetate (Ca-EDTA), British anti-Lewisite (BAL), d-penicillamine (cuprimine) and succimer (dimercaptosuccinic acid [DMSA]). Refer to Table 20.3 for advantages and disadvantages in chelator selection. Shot or bullets in synovial joints should be surgically removed.

TABLE 20.3 The pros and cons of various lead chelators

Chelator	Pros	Cons
Ca-EDTA	– Most efficient	– Nephrotoxic – Painful injections if undiluted – Chelates essential minerals
BAL	– Removes lead from brain	– Nephrotoxic – Painful injections
Penicillamine	– Oral	– Vomiting – Nephrotoxic – Chelates essential minerals
DMSA	– Oral (rectally if vomiting) – Does not chelate essential minerals – Can use with lead in GI tract	– Expensive

Prognosis

Good in most cases with an early diagnosis and appropriate therapy. The source of the lead must be removed from environment.

METHYLXANTHINES (CHOCOLATE, TEA, COFFEE, GUARANA)

Definition/Overview

Methylxanthines (caffeine, theobromine, theophylline) are stimulants. Chocolate (Figure 20.17), coffee (Figure 20.18), tea, colas, and some human stimulant drugs (NoDoz®, Vivarin®) are common sources of methylxanthines.

FIGURE 20.17 Chocolate will vary in darkness. The darker the chocolate, the more methylxanthines it contains by weight. (*Courtesy of Tim Williams*.)

FIGURE 20.18 Chocolate-covered espresso beans contain both theobromine and caffeine, while coffee only contains caffeine. (*Courtesy of Tim Williams*.)

Pathophysiology

Methylxanthines are thought to antagonize adenosine receptors and stimulate the sympathetic nervous system, resulting in gastrointestinal, cardiac, and neurologic signs. Methylxanthines stimulate the CNS, act on the kidney to stimulate diuresis, and increase the contractility of cardiac and skeletal muscle.

Clinical Presentation

Depending on the form in which the methylxanthine is ingested, onset can be quick (i.e., within 30 minutes) or delayed (i.e., up to 12 hours post ingestion e.g., chocolate). Mild signs, including agitation, polyuria, polydipsia, vomiting, and diarrhea, have been seen with methylxanthine levels over 20 mg/kg. Doses over 40 mg/kg have cardiac signs, with sinus tachycardia being most common. Doses over 60 mg/kg of methylxanthines can cause neurologic signs like tremors and seizures. Death is generally due to cardiac arrhythmias or respiratory failure. Refer to Table 20.4 for theobromine and caffeine content of various types of chocolates.

TABLE 20.4 Caffeine and theobromine content of chocolate

Compound	Caffeine (mg/g)	Theobromine (mg/g)
White chocolate	0.03	0.01
Milk chocolate	0.2	2.04
Semi-sweet (dark) chocolate	0.77	4.86
Unsweetened (baking) chocolate	1.65	13.86
Cocoa powder	2.46	25.99

Diagnosis

History and clinical signs.

Management

Management will vary depending on the dose ingested and clinical signs exhibited. If the patient is asymptomatic, emesis can be induced. Activated charcoal should only be given if over a lethal dose of methylxanthines were ingested. Intravenous fluid therapy should be used as methylxanthines are diuretics. Monitor HR and rhythm, body temperature, and BP as needed. Acepromazine is the drug of choice to treat agitation and mild hypertension. Methocarbamol can be used for tremors, propranolol for tachycardia, and diazepam for seizures. Depending on which type of methylxanthines were ingested (half-life [dog]: Caffeine = 4.5 hours; theobromine = 16.5 hours) signs may persist up to 72 hours.

Prognosis

Prognosis in most cases is good with appropriate care. The lethal dose of theobromine and caffeine is 100–300 mg/kg.

NICOTINE, *Nicotiana tabacum* (TOBACCO)

Definition/Overview

Nicotine is an alkaloid derived from both cultivated (*Nicotiana tabacum*) and wild tobaccos (*N. attenuata*, *N. trigonophylla*). It is found in cigarettes, cigars, other tobacco products (stuff, chewing), patches, gums, nasal sprays, vape liquids, and some insecticides. Refer to Table 20.5 for nicotine content.

Pathophysiology

Nicotine mimics acetylcholine (ACh) at sympathetic and parasympathetic ganglia, neuromuscular junctions of skeletal muscle, and at some synapses in the CNS. Low doses cause depolarization and stimulation of receptors, while higher doses cause stimulation followed by blockade at autonomic ganglia and myoneural junctions of skeletal muscle. Nicotine is poorly absorbed from the stomach but well absorbed from the small intestine. Death is usually due to respiratory failure.

TABLE 20.5 Nicotine amounts

Product	Amount of nicotine
Gum	2–4 mg/piece (Caution: Some contain xylitol)
Low-yield cigarettes	3–8 mg each
Snuff	4.6–32 mg/g (moist) or 12.4–15.6 mg/g (dry)
Nasal spray	10 mg/mL
Cigarettes	13–30 mg each
Patches	15–144 mg each
Cigars Cigar butt	15–40 mg each 5–7 mg each
Liquid nicotine (vape liquid)	0–250 mg/mL

Clinical Presentation

Vomiting is most common as nicotine effects the CRTZ. Other signs include initial excitation, tachypnea, salivation, emesis, and diarrhea, with larger doses causing lethargy, muscle weakness, hypotension, slow respirations, collapse, coma, cardiac arrest, and death.

Diagnosis

History and clinical signs; nicotine can be detected in urine, blood, liver, kidney, or GI contents but not in a timely manner.

Management

If asymptomatic, induce emesis and potentially give activated charcoal. Monitor HR and BP. Symptomatic care includes IV fluids, oxygen, and/or artificial ventilation. Atropine can be given if parasympathetic effects are present. Antacids are contraindicated because they enhance absorption of nicotine. The duration of signs is dose dependent and can vary from 1 to 2 hours following mild exposure up to 24 hours for severe exposures.

Prognosis

Prognosis is most cases is good; it becomes poor if depressive signs occur. The oral LD_{50} (dog) is 9.2 mg/kg.

OPIOIDS, OPIATES

Definition/Overview

Opioids and opiates are synthetic or natural compounds used for pain control in human and veterinary medicine (Figure 20.19). There are both prescription and illicit substances (buprenorphine, butorphanol, codeine, fentanyl, heroin, hydrocodone, hydromorphone, loperamide, methadone, morphine, naloxone, oxycodone, oxymorphone, and tramadol).

Pathophysiology

Opioids act in the CNS to elevate the pain threshold. Opioids are well absorbed from the GI tract, but bioavailability is variable. Some opioids have a large first pass effect (i.e., fentanyl) and must be administered by other routes (CRI, buccal, transdermal) to reach therapeutic blood levels.

Clinical Presentation

Depression and ataxia are most common, but bradycardia and hypotension may be seen with larger doses.

FIGURE 20.19 Many opioids are in combination with acetaminophen. The APAP is usually more dangerous than the opioid.

Respiratory depression is rare in dogs and cats. Cats may show excitatory behavior and urinary retention.

Diagnosis

History and clinical signs; opioids can be detected in urine or serum.

Management

Naloxone (0.04–0.1 mg/kg IV, inhalation [IN], IM) is antidotal. It may need to be repeated as the duration of action is only 60–90 minutes. Treatment times will vary with the half-life of the opioid.

Prognosis

If cardiovascular function can be maintained, then prognosis is good.

PYRETHRINS AND PYRETHROIDS

Definition/Overview

Pyrethrins and pyrethroids are insecticides. Common names include allethrin, bifenthrin, cyfluthrin, cyhalothrin, cypermethrin, deltamethrin, esfenvalerate, etofenprox, permethrin, phenothrin, tetramethrin, and tralomethrin. They are found in shampoos, dips, foggers, spot-ons, granules, and sprays. Concentration is a key factor in determining the risk of toxicosis.

Pathophysiology

Pyrethrins bind to sodium channels on nerves, causing them to remain open and repetitively fire. Most animals are exposed orally or dermally. Cats which interact with recently spot-on treated dogs may be at risk of toxicosis during the period where the product spreads on the haircoat.

Clinical Presentation

Exposures to the low concentration products rarely cause more than GI upset or drooling (the exception is bifenthrin in dogs which can cause tremors). Ear twitching and paw flicking is sometimes seen in cats. Dermal hypersensitivity reactions can be seen with the topical concentrated spot-on products (pruritus, erythema, fasciculations). Concentrated products can also cause vomiting, hypersalivation, muscle tremors, seizures, and possibly death. Onset of signs is within 24 hours.

Diagnosis

History and clinical signs.

Management

Treatment includes bathing with liquid dish washing detergent for dermal exposures and controlling the tremors. High-dose methocarbamol (55–220 mg/kg IV) works best for tremor control. For dermal hypersensitivity reactions, antihistamines or steroids are sometimes needed. Pyrethrins have no direct action of the liver or kidneys, but fluids are needed to protect the kidneys from myoglobinuria secondary to tremors. Diazepam can be used for seizure control. Lipid therapy may be used if there is no response to traditional therapies. Treatment may last 24–48 hours.

Prognosis

Cats are more sensitive to concentrated pyrethrins than dogs but have a good prognosis with appropriate treatment.

SALT TOXICOSIS (WATER DEPRIVATION)

Definition/Overview

Hypernatremia from salt poisoning can be due to either ingestion of excess sodium (direct sodium ion toxicosis), water deprivation (indirect sodium ion toxicosis), or fluid shifts (indirect sodium ion toxicosis secondary to free water loss). With direct sodium ion toxicosis, there is excess sodium intake (brine, homemade playdough, rock salt, bouillon cubes, seawater). With indirect sodium ion toxicosis, there is either decreased water intake or osmotic agents in the GI tract that cause a loss of free water from the vasculature.

Pathophysiology

Sodium acts as a mucosal irritant stimulating vomiting. As sodium is absorbed from the GI tract, the serum sodium increases. Sodium then passively diffuses into the CSF, increasing its sodium concentration. Elevations in brain sodium leads to neurologic signs (ataxia, tremors, seizures). Sodium uses ATP for active transport out of the CSF. Unfortunately, elevated sodium levels in

the CNS inhibit glycolysis, so there is no ATP production, and the removal of sodium from the brain does not occur. The brain protects itself from dehydration by producing idiogenic osmoles (amines). This takes about 24 hours to occur. The danger with these osmoles is that blood levels of sodium fall more rapidly than brain levels, so a concentration gradient is established. Water will follow the concentration gradient and enter the CSF, resulting in cerebral edema and severe neurologic signs. It is very dangerous to quickly rehydrate animals with chronic hypernatremia.

Clinical Presentation

Vomiting generally occurs within 2 hours of ingestion. Polyuria, polydipsia, tremors, seizures, hyperthermia, and death can occur.

Diagnosis

Serum sodium >160 mEq/L.

Management

Management changes depending on the timeframe of hypernatremia. If acute hypernatremia (<24 hours), the sodium can be dropped quickly with low-sodium IV fluids (D5W) and plain water enemas. With chronic hypernatremia (>24 hours), idiogenic osmoles have formed in the brain, and the sodium must be dropped slowly to prevent cerebral edema. The hypernatremia is corrected over 48–72 hours using fluids that most closely match the serum sodium.

Prognosis

The prognosis is good for acute hypernatremia but guarded for chronic. The minimal lethal dose for sodium chloride in dogs is 4 g/kg.

SEROTONERGIC MEDICATIONS

Definition/Overview

There are several classes of pharmaceuticals that affect serotonin levels in the CNS (5-hydroxytryptophan [5-HTP], monoamine oxidase inhibitors [MAOIs], serotonin and norepinephrine reuptake inhibitors [SNRIs], selective serotonin reuptake inhibitors [SSRIs], tricyclic antidepressants [TCAs], and novel antidepressants). Refer to Table 20.6 for more information.

TABLE 20.6 Serotoninergic medications

Classification	Common generics
Amphetamines	Amphetamine, dextroamphetamine, lisdexamfetamine, methylphenidate
MAOI	Phenelzine, selegiline, tranylcypromine
SSRI	Citalopram, escitalopram, fluoxetine, paroxetine, sertraline
SNRI	Desvenlafaxine, duloxetine, venlafaxine
TCA	Amitriptyline, clomipramine, doxepin, imipramine, nortriptyline
Novel antidepressants	Bupropion, trazodone, vilazodone

Pathophysiology

Different class of drugs have different mechanisms to increase serotonin in the CNS: Increased production (5-HTP), increase release (amphetamines, MAOIs, cocaine), inhibit metabolism (MAOIs), inhibit serotonin reuptake (SSRI, SNRI, TCA, amphetamines, cocaine, dextromethorphan) and serotonin agonists (buspirone, sumatriptan, LSD). High levels of serotonin in the CNS result in "serotonin syndrome" and are characterized by gastrointestinal, cardiovascular, neurologic, and respiratory signs.

Clinical Presentation

Lethargy and ataxia are common with low-dose exposures. As the doses rise, serotonin syndrome occurs and is characterized by vomiting, vocalization, mydriasis, disorientation, tremors, tachycardia, hypertension, blindness, and hyperthermia. Seizures, coma, and death are rare with most serotonergic medications (more common with 5-HTP).

Diagnosis

History and clinical signs.

Management

Emesis can be attempted in asymptomatic pets with recent exposures. Activated charcoal binds to serotonergic medications and can be given if asymptomatic. Monitor body temperature. Start IV fluids to support the cardiovascular system, aid in thermoregulation, and maintain renal blood flow. Phenothiazines (acepromazine, chlorpromazine) work well for controlling agitation. The use of cyproheptadine (1.1 mg/kg p.o. dogs; 2–4 mg p.o. cats), a nonselective serotonin antagonist, has shown to be a helpful adjunct in managing the stimulatory signs. Propranolol also has some serotonin blocking effect and may be of benefit if animals are tachycardic. Diazepam can be used for seizures.

Prognosis

Good for most serotoninergic medications. 5-HTP ingestion is more serious and has a guarded prognosis.

TREMORGENIC MYCOTOXINS

Definition/Overview

Tremorgenic mycotoxins are indole alkaloid compounds produced by molds. These toxins are produced from a variety of different fungi that grow on dairy products,

grains, nuts, and legumes. Compost piles and fruit/nut trees in the environment may provide a source of tremorgens.

Pathophysiology

Tremorgenic mycotoxins inhibit glycine leading to full-body tremors.

Clinical Presentation

Signs start as fine muscle tremors and can progress to more severe full-body tremors when stimulated. Vomiting is common. Hyperactivity, seizures, tachycardia, and death are rare.

Diagnosis

History and clinical signs; laboratory confirmation is available but not timely.

Management

Asymptomatic animals exposed to moldy foods should be decontaminated via emesis. Activated charcoal may be given. Tremors respond best to large doses of methocarbamol (55–220 mg/kg IV to effect). Supportive care includes intravenous fluids and thermoregulation. Signs may persist for several days.

Prognosis

Good in most cases, guarded if seizures occur.

Hepatic

The liver is the largest organ in the body and metabolizes almost every xenobiotic introduced into the body. There are various mechanisms of hepatic injury, and the liver can respond to toxic insults with hepatic lipidosis, hepatocellular necrosis (centrilobular, midzonal, periportal, massive), nodular regeneration, pigmentation, megalocytosis, biliary system damage, neoplasia, and liver atrophy. Refer to Table 20.1 for a list of selected heptatotoxicants.

ACETAMINOPHEN (PARACETAMOL)

Definition/Overview

Acetaminophen (paracetamol, nonaspirin pain reliever, APAP) is a synthetic nonopiate derivative of p-aminophenol.

Pathophysiology

APAP acts primarily in the CNS to increase the pain threshold. The metabolism of acetaminophen occurs primarily in the liver. There are three major pathways: Glucuronide conjugation, sulfate conjugation, and oxidation by cytochrome P450 enzymes. Glucuronide and sulfate conjugation form nontoxic metabolites. Cats, unfortunately, have only about one-tenth the acetaminophen biotransformation ability of dogs due to decreased microsomal uridine 5'-diphospho (UDP)-glucuronosyltransferase enzyme activity. Cats mostly use the sulfate conjugation pathway, but it can be saturated due to the limited availability of inorganic sulfates. Acetaminophen-induced hepatoxicity is due to the formation of the oxidative metabolite, N-acetyl-para-benzoquinone imine (NAPQI). This is produced by the cytochrome P450s as the other pathways become saturated. Centrilobular hepatic necrosis is most common due to the concentration of P450s in that area. If glutathione (GSH) is available, NAPQI will be bound and inactivated. GSH stores become depleted 16–24 hours after exposure to acetaminophen, increasing the risk of cellular damage. Another acetaminophen metabolite is para-aminophenol (PAP). It has been implicated in causing methemoglobinemia. GSH becomes depleted in erythrocytes, and hemoglobin is oxidized to methemoglobin, which cannot carry oxygen. Methemoglobin values increase within 2–4 hours, followed by Heinz body formation (Figure 20.20).

Clinical Presentation

Depression, weakness, tachypnea, tachycardia, and chocolate-colored gums are seen most commonly. Facial or paw edema can occur, along with death. Liver necrosis is less common in cats than in dogs. Clinical signs of methemoglobinemia may last 3–4 days. Hepatic injury may not resolve for several weeks.

Diagnosis

History and clinical signs; laboratory confirmation is not timely.

Management

Emesis can be induced, but peak blood levels are reached in 10–120 minutes. Activated charcoal can

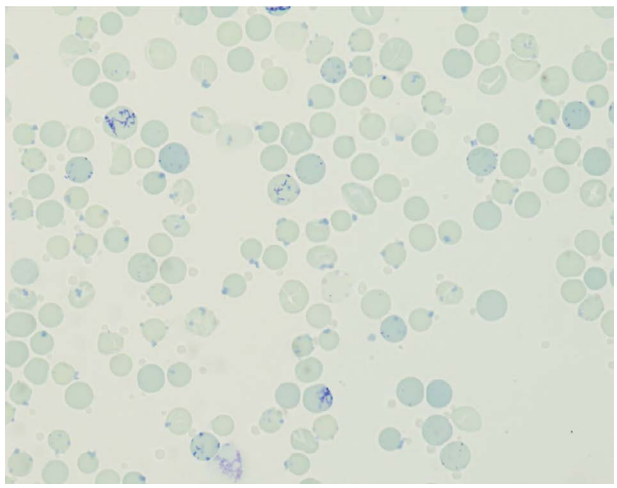

FIGURE 20.20 Heinz body anemia. Canine blood, 100x, new methylene blue stain. (*Courtesy of Amy Schnelle, University of Illinois Urbana-Champaign.*)

be given if the pet is asymptomatic. Monitor liver values for 48 hours and give liver protectants (SAMe) as needed. Symptomatic patients need initial stabilization, including oxygen if dyspneic. N-acetylcysteine (Mucomyst®, NAC) is antidotal as it is a precursor in the synthesis of glutathione, provides sulfhydryl groups for sulfate conjugation, and it can bind directly with NAPQI. NAC decreases the half-life of methemoglobinemia in cats from 10 to 5 hours. An initial loading dose of 140 mg/kg (dilute to 5% in dextrose or sterile water) is given, followed by 70 mg/kg p.o. q.i.d. for 7 treatments. Continue treatment until normal. Ascorbic acid provides a slow-acting, nonenzymatic reduction of methemoglobin back to hemoglobin.

Prognosis

Prognosis is good if the animal is treated promptly. Animals with severe signs of methemoglobinemia or with hepatic damage have a guarded-to-poor prognosis.

HEPATOTOXIC MUSHROOMS

Definition/Overview

Amanita, *Galerina*, and *Lepiota* spp. mushrooms have been associated with liver necrosis.

Pathophysiology

Hepatotoxic mushrooms contain amatoxins. Amatoxins are bicyclic octapeptides that inhibit ribosomal protein synthesis and cause loss of cytoskeletal function, resulting in hepatocyte necrosis. Amatoxins are first taken up by cells in the GI tract, causing vomiting. Then, following systemic absorption, the amatoxins are taken up into hepatocytes via OATP1B3, where they cause liver damage.

Clinical Presentation

Vomiting (6–24 hours) is usually the first sign followed by lethargy and diarrhea. The hepatic phase (icterus, hypoglycemia, coagulopathy, coma) begins 36–48 hours after ingestion. Many humans require liver transplantation.

Diagnosis

History and clinical signs; cage side tests and laboratory confirmation from urine are available.

Management

Emesis and activated charcoal are recommended in witnessed exposures for the first 1–2 hours. Later implementation can worsen the situation. Monitor serum glucose, liver and renal values, acid/base, electrolytes, packed cell volume/total protein (PCV/TP), and coagulation parameters. Significant amounts of amatoxin are eliminated in the urine during the first 48 hours, so a diuretic rate of intravenous fluids is helpful. The goal is to sequester amatoxins in the gallbladder to decrease the risk of liver necrosis. The animal should be n.p.o. to limit gallbladder contraction. This should be continued until the liver values begin to improve. Octreotide (10–20 ug bolus IV then 10–20 ug/h CRI) will inhibit gallbladder contraction and inhibit the OATP1B3 transporter molecule (decrease hepatocyte amatoxin exposure). Silibinin (milk thistle) reduces the uptake of amanitin into hepatocytes, but it is not available in the United States in the injectable form (oral has poor bioavailability). Percutaneous bile drainage (ultrasound-guided needle aspiration) will remove the amatoxins from the body. Historically, treatment with acetylcysteine, penicillin G, and cimetidine has had poor results. Because amatoxins are cleared from the serum in the first 24–48 hours either by the kidneys or via uptake into hepatocytes, extracorporeal elimination techniques are not likely to be useful.

Prognosis

Prognosis is guarded to grave.

XYLITOL

Definition/Overview

Xylitol is a sugar alcohol used as a natural sweetener. It is found in sugar-free products from gums, candies, pudding, high-protein peanut butter, toothpaste, quick dissolve and chewable medications, as well as in powdered form for baking.

Pathophysiology

In humans, xylitol does not cause a significant increase in blood glucose or insulin secretion. However, in dogs, xylitol causes rapid, dose-dependent insulin release followed by hypoglycemia. With larger doses, liver necrosis can occur. It is thought that xylitol uses the pentose phosphate pathway (PPP) instead of the tricarboxylic acid (TCA; Krebs cycle) for metabolism. This means there is a shortage of ATP. Hypoglycemia can start at 100 mg/kg and liver effects around 400 mg/kg.

Clinical Presentation

Initial signs fit with hypoglycemia, vomiting, weakness, ataxia, depression, hypokalemia, seizures, and coma.

Diagnosis

History and clinical signs.

Management

Emesis can be induced if asymptomatic. Activated charcoal is not efficacious. Depending on the form of xylitol ingested, dogs can show signs of hypoglycemia in as few as 30 minutes (powder, candy, medications), or it may be delayed for several hours (gum). Dextrose (bolus +/- CRI) can be administered to treat hypoglycemia. It may

also be used to support the liver. Treatment should continue until blood glucose normalizes. Other liver protectants such as SAMe or n-acetylcysteine may be started, but it is unknown how efficacious they are. With liver necrosis, monitoring of coagulation values and plasma transfusions may be needed.

Prognosis

Good in most cases, guarded when liver necrosis occurs.

Renal

The kidney is susceptible to toxicants because of its high relative blood flow (~25% of cardiac output) compared with its low percentage of total body weight. The proximal tubule is the most sensitive portion the nephron to both hypoxia and toxicosis. There are many toxicants that can directly and indirectly affect the kidneys (refer to Table 20.1).

CHOLECALCIFEROL AND VITAMIN D_3 ANALOGS

Definition/Overview

Vitamin D and vitamin D analog toxicoses (calcipotriene, calcitriol) are becoming more common. In addition to prescription-strength vitamin D capsules (50,000 IU) and psoriasis creams (Dovonex®, Taclonex®), over-the-counter (OTC) vitamin D has become more popular, and there has also been an increase in cholecalciferol-containing rodenticides.

Pathophysiology

Cholecalciferol and vitamin D analogs cause elevations of serum calcium and phosphorus, leading to soft tissue mineralization and renal failure. Cholecalciferol is metabolized to 25-hydroxycholecalciferol (calcifediol) and then to 1,25-dihydroxycholecalciferol (calcitriol = active metabolite). Calcitriol increases intestinal absorption of calcium, stimulates bone resorption, and increases renal tubular reabsorption of calcium. Elevated serum calcium causes heart issues and bleeding secondary to mineralization of the vessels, kidneys, stomach wall, and lungs.

Clinical Presentation

As serum calcium begins to rise, vomiting, depression, polyuria, and polydipsia begin by 12–18 hours post ingestion. Elevations in phosphorus can be seen within 12 hours, with elevations in calcium, BUN, and creatinine being noted within 24 hours. As soft tissue mineralization progresses, the pet will become oliguric, then anuric. Problematic doses can be as low as 0.1 mg/kg.

Diagnosis

Elevated calcium with confirmatory clinical signs.

Management

Timing of emesis varies depending on the form ingested. If tablets or creams have been ingested, emesis should occur within 60 minutes; for bait, within the first 4 hours. Decontamination should continue with one dose of activated charcoal followed by cholestyramine (300 mg/kg q.8 h. for 4 days). Obtain baseline (<8 hours post exposure) calcium, phosphorus, blood urea nitrogen (BUN), and creatinine for future comparison. Monitor calcium daily for 4 days. If no elevations of calcium are seen by 4 days, no further treatment is needed. If calcium is rising, bisphosphonates (pamidronate, zoledronate) can be used to inhibit osteoclasts. Other treatments to reduce calcium include 0.9% sodium chloride (NaCl) fluids, furosemide, and prednisolone (adjust fluids accordingly). Sodium chloride and furosemide increase calcium excretion in the urine. Steroids reduce bone resorption, decrease intestinal absorption, and increase renal excretion of calcium. Phosphate binders should also be administered. The animal should be maintained on a low-calcium diet. Monitor blood values frequently for 5–6 weeks. Treatment may be prolonged because of the long half-life of calcifediol (16–30 days).

Prognosis

Prognosis decreases with prolonged elevations in calcium. Lesions from soft tissue mineralization (renal, cardiac, GI) are not reversible and may result in long-term sequelae or sudden death. Anuria is a poor prognostic factor.

ETHYLENE GLYCOL

Definition/Overview

Ethylene glycol (EG) is found most commonly in automotive radiator antifreeze (Figure 20.21) but can also be found in brake fluids, aircraft deicers, condensers, heat exchangers, snow globes, home solar units, and portable basketball goal post bases.

FIGURE 20.21 Ethylene glycol antifreeze can be purchased in both full strength (95%–100%) and prediluted (50%). (*Courtesy of Tim Williams.*)

Pathophysiology

As a parent compound, EG is about as toxic as other alcohols. The metabolites are, unfortunately, quite toxic. Ethylene glycol is initially oxidized to glycolaldehyde by alcohol dehydrogenase (ADH), it is then oxidized to glycolic acid, and then to glyoxylic acid. Glyoxylic acid is primarily converted to oxalic acid. Ethylene glycol and glycolaldehyde are mainly responsible for the initial CNS signs. The accumulation of glycolic acid and glyoxylic acid cause metabolic acidosis. Acidosis will alter consciousness and increase cerebral damage. Glycolic acid accumulates because the lactic dehydrogenase enzyme that metabolizes glycolic to glyoxylic acid becomes saturated. Renal tubular injury is from the direct nephrotoxic action of glycolaldehyde and glyoxylate on the renal tubules as well as mechanical injury and obstruction by calcium oxalate crystals.

Clinical Presentation

Due to the metabolism of EG, the clinical signs will change as time progresses. The initial signs of ataxia, lethargy, and polyuria/polydipsia (PU/PD) are from the alcohol effects in the CNS and are seen around 30 minutes post exposure. The pet may appear to recover or worsen. The cardiopulmonary stage generally occurs from 12 to 24 hours following exposure. Tachypnea, tachycardia, depression, and pulmonary edema may occur as this is due to the severe acidosis and electrolyte disturbances that are from the metabolites. The renal stage can be seen as early as 12 hours, especially in cats, but is generally seen within 24–72 hours following exposure. Clinical signs include azotemia, depression, anorexia, vomiting, abdominal pain, oral ulcers, oliguria/anuria, and seizures. This is due to renal tubular injury from EG metabolites and calcium oxalate crystals. Urinalysis shows low urine SG, glucosuria, and possibly calcium oxalate crystals (only 40% of animals develop these). BUN and creatinine become elevated but usually not before 12 hours post exposure; therefore, BUN and creatinine are of minimal benefit in diagnosing early exposures. Death can occur at any stage.

Diagnosis

Diagnosis is based on history, clinical signs, and confirmatory laboratory testing. There are some cage side tests available for in clinic use. Make sure to read the insert about potential false-positive results. EG levels may be able to be run at a human hospital. Greater than 50 mg/dL in dogs is significant. In cats, any level above zero should be treated. Other supportive tests include measuring anion gap (>25 mEq/L) or serum osmolal gap (>20 mOsm/kg). Observation, via Wood lamp, of fluorescence in urine, stomach contents, or on paws/muzzle may suggest exposure (fluorescein dye is added to automotive antifreeze to help in detecting radiator leaks).

Management

Treatment of EG toxicosis must be timely and aggressive. For recent (within 45 minutes) exposures and asymptomatic animals, induce vomiting or perform gastric lavage. Activated charcoal does not bind well to EG. Based on exposure history and/or diagnostic test results, the use of either fomepizole or ethanol infusion is indicated. IV ethanol and fomepizole (4-MP, 4-methylpyrazole) are used to delay the breakdown of EG to its more toxic metabolites. Best results with either of these treatments require initiation of treatment as soon as possible following ingestion. The dose for 20% ethanol in the dog: 5.5 mL/kg q4hr for 5 treatments; then every 6 hrs for 4 treatments. Cats: 5.0 mL/kg q6hrs for 5 treatments; then q8hrs for 4 treatments. Ethanol has the advantages of being inexpensive and readily available, but it has some serious drawbacks, including worsening of metabolic acidosis and CNS depression. These side effects are lessened if using a CRI instead of bolus dosing. Fomepizole is administered every 12 hours for 36 hours. The main drawback with fomepizole is the cost and the need to have it compounded. Symptomatic animals should be stabilized as needed. IV diuresis is important, high infusion rates of crystalloids are necessary to correct dehydration and hypoperfusion. Treat acidosis and renal failure as needed. Oliguric or anuric animals may require hemodialysis. Treatment should be continued until animals are clinically normal and have had at least 24 hours with normal renal function and acid–base parameters.

Prognosis

Prognosis is good to grave depending on the degree of exposure, length of time between exposure and treatment, and aggressiveness of treatment. The presence of oliguria/anuria indicates a grave prognosis.

LILIUM spp. AND *HEMEROCALLIS* spp. (LILIES)

Definition/Overview

Members of the *Lilium* (Figure 20.22) and *Hemerocallis* genera (Easter lilies, tiger lilies, day lilies, etc.) have been incriminated in causing acute kidney injury in cats.

FIGURE 20.22 White Oriental lily – *Lilium.* (*Courtesy of Laura Stern.*)

Pathophysiology

The toxin is unknown, but even minor exposures (bite on a leaf, ingestion of pollen) may result in toxicosis. On histopathology, there is proximal convoluted tubule degeneration and necrosis with denudation of basement membrane and filling of tubular lumen with cellular debris.

Clinical Presentation

Vomiting begins within a few hours after exposure. Elevations in BUN, creatinine, phosphorus, and potassium are detectable as early as 12 hours post ingestion. Within 24–72 hours of ingestion, oliguric to anuric renal failure develops accompanied by depression, anorexia, and dehydration. Abundant casts, proteinuria, glucosuria, and isosthenuria are found on urinalysis within 24 hours of ingestion, reflecting lily-induced damage to renal tubular cells. In severe cases, death or euthanasia due to acute renal failure generally occurs within 3–6 days of ingestion.

Diagnosis

History and clinical signs.

Management

Intravenous fluid therapy is the most important part of treatment. A diuretic rate should be administered for 48 hours, and urine output monitored. Baseline renal values should be obtained upon presentation and then repeated at 24 and 48 hours. In severe cases, hemodialysis may aid in managing renal failure until tubular regeneration occurs (10–14 days or longer).

Prognosis

When fluids are initiated within 18 hours of ingestion, prognosis is good. Conversely, delaying treatment beyond 18 hours frequently results in death or euthanasia.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs)

Definition/Overview

Nonsteroidal anti-inflammatory drugs (NSAIDs) are marketed for both human and veterinary use. Common NSAIDs include ibuprofen (Figure 20.23), naproxen, celecoxib, flurbiprofen, piroxicam, diclofenac, ketoprofen, carprofen (Figure 20.24), etodolac, meloxicam, and deracoxib.

Pathophysiology

NSAIDs decrease pain and inflammation by blocking the conversion of arachidonic acid to prostaglandins through cyclooxygenase inhibition. This decreases pain but also stops the beneficial effects of prostaglandins, leading to increased production of gastric acid and pepsin, decreased secretion of the protective mucous layer in the stomach and small intestine, and decreased blood flow to the gastric mucosa and kidneys. These changes put the animal at risk of GI ulcers and acute kidney injury (AKI). Hepatotoxicity can be seen with any NSAID and is thought to be an idiosyncratic process.

FIGURE 20.23 Ibuprofen is one of the most common toxicants in dogs. (*Courtesy of Tim Williams.*)

FIGURE 20.24 Chewable carprofen is very palatable, and pets will eat multiple tablets if available.

Clinical Presentation

Vomiting is usually the first clinical sign. The onset of GI upset is generally within the first 2–6 hours after ingestion, with GI hemorrhage and ulceration occurring 12 hours to 4 days post exposure. Renal failure often occurs within the first 12–48 hours after exposure. Some NSAIDs (ibuprofen) can cause neurologic signs (ataxia, seizures, coma) at high doses. This occurs within a few hours after exposure, and the mechanism is unknown.

Diagnosis

History and clinical signs; laboratory confirmation is usually not timely.

Management

If the exposure was <1 hour and the animal is asymptomatic, emesis can be induced. Activated charcoal can be given if the dose is of renal concern or higher. Intravenous fluids and gastroprotectants are the mainstays of therapy. Assisted ventilation and supplemental oxygen may be required if the animal is comatose. Seizures should be treated with diazepam. Both naloxone and lipids have been used to reverse the coma seen in ibuprofen toxicosis with mixed results. Severe cases may benefit from therapeutic plasma exchange. Most hepatotoxicity cases are reversible with discontinuation of the medication and supportive care.

Prognosis

Prognosis in most cases is good with therapy. Cats are thought to be more sensitive to NSAID toxicosis than dogs due to their limited glucuronyl-conjugating capacity. Dogs ingesting doses of >50 mg/kg can develop GI ulcers, and at >125 mg/kg, AKI will develop. At doses >400 mg/kg, CNS signs can develop. Cats who ingest ibuprofen are at risk of developing GI ulceration at >5 mg/kg and AKI at >20 mg/kg. Naproxen has a half-life of 74 hours in the dog, as it undergoes extensive enterohepatic recirculation. Ulcerative gastritis is possible in dogs at 5 mg/kg of naproxen, and doses of >10 mg/kg can cause AKI. Doses of 20 mg/kg and 40 mg/kg will induce GI ulceration and AKI, respectively. Cats will develop GI ulceration at 4 mg/kg and AKI at 8 mg/kg. COX selectivity is not protective in overdose situations. Dogs will develop GI ulceration at 15 mg/kg and AKI at 30 mg/kg.

VITIS spp. (GRAPES AND RAISINS)

Definition/Overview

Members of the *Vitis* spp. have been documented to cause vomiting and AKI in some dogs.

Pathophysiology

Unknown toxin causes proximal renal tubular necrosis in some dogs.

Clinical Presentation

Vomiting usually begins within 6 hours of ingesting the grapes/raisins, followed by elevations of BUN and creatinine in 12–18 hours.

Diagnosis

History and clinical signs.

Management

If the ingestion was in the past 8 hours and the animal is asymptomatic, emesis can be attempted. Monitor renal values for 48 hours. Intravenous fluids at a diuretic rate are the most important part of therapy. If renal values are normal at 48 hours, the patient can be discharged. Symptomatic care for vomiting, diarrhea, or other signs may be required.

Prognosis

Prognosis variable and unpredictable with some dogs being asymptomatic with ingestion, while others may develop mild GI signs and recover. Dogs developing severe oliguria or anuria are generally poorly responsive in attempts to increase urine production (mixed results with peritoneal and hemodialysis).

Cardiorespiratory

There are several risk factors for toxic effects on the cardiovascular and respiratory systems. The heart needs a steady supply of nutrients (ATP, oxygen, etc.), and it receives all of the systemic circulation. The cardiac muscle also does not have the ability to regenerate. The lungs receive almost all inhaled toxins. Refer to Table 20.1 for a list of potential cardiovascular and respiratory toxicants.

ALBUTEROL

Definition/Overview

Albuterol is a synthetic sympathomimetic amine used as a bronchodilator in the treatment of asthma. It comes as tablets, liquid, and as an inhaler.

Pathophysiology

Albuterol is normally a beta-2 receptor agonist. In overdose situations, albuterol stimulates beta-1 receptors, causing increased inotropic and chronotropic effects on the heart.

Clinical Presentation

Dogs are usually exposed by chewing on inhalers. This leads to a quick onset and prolonged duration signs. The most common signs are tachycardia, vomiting, depression, tachypnea, hyperactivity, muscle tremors, hypokalemia, and muscle weakness. Death has rarely been reported. Clinical signs generally resolve within 12 hours but may persist for up to 48 hours.

Diagnosis

History and clinical signs.

Management

Decontamination is not advised for inhaler, solution, or syrup exposure due to rapid absorption and onset of actions. Emesis and activated charcoal can be given

with tablet ingestion. Monitor heart rate and rhythm, body temperature, and serum potassium. Propranolol (0.02–0.06 mg/kg IV, titrate up as needed) or other nonselective beta-blockers should be administered if heart rates greater than 160–180 bpm are observed. Propranolol slows the heart rate, has direct myocardial depressant effects, and helps normalize serum potassium levels. Potassium should be supplemented as needed. Agitation can be treated with diazepam or low-dose acepromazine.

Prognosis

Prognosis in most cases is good. Animals with known or underlying cardiac disease may be at risk for decompensation and sudden death.

CARBON MONOXIDE (CO)

Definition/Overview

Carbon monoxide is a colorless, odorless, and tasteless gas produced by incomplete combustion of hydrocarbon fuels. Pets are most commonly exposed to malfunctioning gas water heaters, space heaters, or furnaces in tight or poorly ventilated spaces.

Pathophysiology

CO is rapidly absorbed through the lungs. The affinity of hemoglobin for CO is 250 times greater than for oxygen (O_2). This forms carboxyhemoglobin, which has a decreased ability to release oxygen, resulting in systemic tissue hypoxia.

Clinical Presentation

Animals will present with cherry-red mucous membranes and skin; however, they are demonstrating signs of hypoxia (lethargy, weakness, dyspnea, coma, seizures, and death).

Diagnosis

History and clinical signs; confirmation can be made by measuring carboxyhemoglobin levels in whole blood (stable for several days, keep refrigerated).

Management

Therapy consists of oxygen; a hyperbaric chamber can decrease treatment time.

Prognosis

Good to grave depending on degree of hypoxia.

PHENYLPROPANOLAMINE

Definition/Overview

Phenylpropanolamine (PPA) is a sympathomimetic agent used in veterinary medicine for controlling urinary incontinence in dogs.

Pathophysiology

PPA indirectly stimulates both alpha and beta receptors by causing the release of norepinephrine. It also acts on peripheral alpha receptors, with a weak effect on beta receptors. This results in vasoconstriction and severe hypertension.

Clinical Presentation

Initially animals are agitated and tachycardic. As the blood pressure begins to rise, the animals will become lethargic, hypertensive, and bradycardic (reflex bradycardia). The pet may develop erythema and piloerection. Signs start within 30–90 minutes and may continue up to 48 hours, depending on dose.

Diagnosis

History and clinical signs.

Management

Emesis may be induced if the ingestion was within 10–15 minutes. Activated charcoal can be given if the patient is asymptomatic. Heart rate and blood pressure should be closely monitored. Mild agitation and mild hypertension may respond to acepromazine. Nitroprusside or other pressor agents can be used to manage more severe hypertension. Animals should be put on IV fluids to protect renal function and help with thermoregulation.

Prognosis

Severe signs appear at doses above 20 mg/kg. If the blood pressure can be controlled, prognosis is good.

Hematopoietic

A variety of toxicants can affect the formation or function of red blood cells. The site of action may be in the circulation, the clotting cascade, or in the bone marrow.

ALLIUM spp. (ONIONS, GARLIC)

Definition/Overview

Allium spp. are commonly used in cooking (garlic, onions, shallots, leeks, chives [Figure 20.25]). The volatile oils that give these products their distinctive smell are also pharmaceutically active.

Pathophysiology

The *Allium* genus contains propyl disulfide compounds that cause oxidative damage to the red blood cells (RBCs). This leads to anemia.

Clinical Presentation

Vomiting can occur right after ingestion, but the hematological changes do not occur until 3–7 days post

FIGURE 20.25 Members of the *Allium* genus include (L to R) yellow onions, garlic, red onions, and shallots. (*Courtesy of Tim Williams*.)

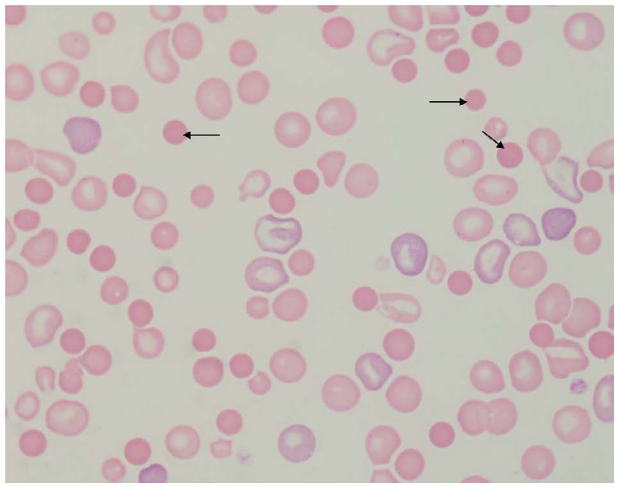

FIGURE 20.26 Spherocytes, indicated by black arrows. Canine blood, 100x, Wright-Giemsa stain. (*Courtesy of Amy Schnelle, University of Illinois Urbana-Champaign*.)

ingestion. Heinz bodies, eccentrocytes, spherocytes (see Figure 20.26), hemolysis, and anemia occur secondary to oxidative damage. Patients may present weak, tachypneic, and tachycardic.

Diagnosis

History and clinical signs.

Management

Emesis and charcoal can be given if the amount is over a dose of concern. Decontaminate dogs that have ingested >10 g/kg of garlic or 15 g/kg of onion. Decontaminate cats that have ingested >1 g/kg of garlic or 5 g/kg of onion. Mild gastrointestinal signs can be managed with antiemetics. Blood work should be monitored, and if anemia develops, a blood transfusion may be needed.

Prognosis

Good. Cat hemoglobin is more sensitive to oxidative damage due to having more sulfhydryl groups on their RBCs.

ANTICOAGULANT RODENTICIDES

Definition/Overview

Anticoagulant rodenticides are toxic to the consumer and potentially cause relay toxicosis (poisonous to pet that ate the poisoned rodents).

Pathophysiology

Anticoagulant rodenticides inhibit the activity of vitamin K1 epoxide reductase. This stops the activation of clotting factors II, VII, IX, and X, and a coagulopathy develops.

Clinical Presentation

Initial clinical signs are vague and then the subsequent signs will depend on where the bleeding is occurring. Because the body has several days' worth of active vitamin K stored in the liver (the site of the reactivation activity), there is a delayed onset of effect on blood clotting after ingestion of an anticoagulant. Hemothorax is the most common presentation (dyspnea, pale gums, weakness), but bleeding can occur anywhere. Petechiae and ecchymoses are seen later in the course of illness after the platelet numbers have been depleted in smaller bleeds.

Diagnosis

History, clinical signs, prothrombin time (patient) testing; specific rodenticides can be identified by veterinary laboratories. (Note that if point-of-care diagnostic tests are unavailable, the clinician can easily determine the Whole Blood Clotting Time. If >20 minutes, treatment can proceed while awaiting outside laboratory test results. It is understood that this test is not as accurate as the prothrombin time, but it can save lives while awaiting delayed lab results.)

Management

Emesis can be induced if ingestion has occurred within the last 4 hours. One dose of activated charcoal may be given. Depending on the dose ingested, PT testing could be performed (48–72 hours after ingestion), or the pet could be started on vitamin K_1 therapy (2.5–5 mg/kg per day divided subcutaneously for the first day and orally subsequently). If the animal is actively bleeding, start vitamin K_1 and give clotting factors via a whole blood transfusion, fresh frozen plasma, or fresh plasma. Minimize physical activity throughout therapy.

Prognosis

Prognosis depends upon where the bleeding occurs (bleeding into the brain or spinal cord carries a grave prognosis).

FIGURE 20.27 Serum with gross hemolysis. (*Courtesy of Amy Schnelle, University of Illinois Urbana-Champaign.*)

ZINC

Definition/Overview

Zinc can be found in U.S. pennies (minted after 1983), screws, bolts, nuts, game pieces, and any galvanized metals.

Pathophysiology

The stomach acid ionizes the zinc, which is then absorbed into the circulation. Zinc causes oxidative damage to the RBC leading to hemolysis (see Figure 20.27), hemoglobinuria, and secondary renal injury.

Clinical Presentation

Vomiting, lethargy, anorexia, hemoglobinuria, weakness, and pale gums are common. Hemolysis and anemia are seen on the complete blood count (CBC). Radiography may reveal the presence of metal objects within the stomach.

Diagnosis

Serum zinc levels (need special blue topped tube), abdominal radiographs.

Management

The zinc must be removed from the GI tract (emesis, endoscopy, surgery). Activated charcoal does not bind to heavy metals. Treatment for symptomatic animals should include blood transfusion as needed, intravenous fluids, and other supportive care. The use of chelators is not necessary.

Prognosis

Good to guarded depending on how long the zinc has been in the stomach.

Gastrointestinal

A wide range of toxins can affect the GI tract from mild vomiting and diarrhea to severe loss of fluids and blood (hypovolemic shock). Refer to Table 20.1 for selected gastrointestinal toxicants.

ASPIRIN

Definition/Overview

Aspirin (acetylsalicylic acid, ASA) is a salicylate ester of acetic acid and a weak acid It is used to decrease pain and treat fevers.

Pathophysiology

Aspirin reduces pain and inflammation by inhibiting cyclooxygenase, which reduces prostaglandin and thromboxane synthesis. At very high doses, aspirin and other salicylates uncouple oxidative phosphorylation leading to decreased ATP production. Salicylates also affect platelet aggregation and can cause increased bleeding times.

Clinical Presentation

Vomiting is the most common sign and can be seen at any dose. In dogs, GI ulcers can be seen at doses >150 mg/kg, and >400 mg/kg can cause liver injury, fever, and seizures. Respiratory alkalosis can occur acutely followed by metabolic acidosis.

Diagnosis

History and clinical signs.

Management

Emesis can be performed in the asymptomatic animal. Activated charcoal can be given if over a hepatotoxic dose. Maintain hydration and start GI protectants. Liver values, glucose, acid–base status, and electrolytes should be monitored. Assisted ventilation and supplemental oxygen may be required if the animal is comatose. Seizures should be treated with diazepam. Fluids and whole blood may be needed to control hypotension and hemorrhage.

Prognosis

Prognosis is good if the animal is treated promptly. Cats are more sensitive as they are deficient in glucuronyl transferase and have prolonged excretion due to decreased metabolism.

CORROSIVE, CAUSTICS, AND DETERGENTS

Definition/Overview

Acids are corrosive with a low pH. They are found in toilet bowl cleaners, drain openers, metal cleaners, antirust compounds, automobile battery fluid, and pool sanitizers (Figures 20.28 and 20.29). Alkalis (sodium

FIGURE 20.28 Acid-based bathroom cleaner. Keep pets away until rinsed and dried. (*Courtesy of Tim Williams*.)

FIGURE 20.29 Reading labels is important, even products with similar names can be different. The center product is an acid (oxalic acid), while the left and right are a combination of alkaline (sodium carbonate, sodium hydrosulfite) and acid (citric acid). (*Courtesy of Tim Williams*.)

FIGURE 20.30 Alkaline automatic dishwasher pacs. (*Courtesy of Tim Williams*.)

FIGURE 20.31 Anionic and nonionic detergents. Can see mild GI signs if ingested. (*Courtesy of Tim Williams*.)

or potassium hydroxide, ammonium hydroxide, sodium or potassium hydroxide, potassium permanganate) are caustics with a high pH (>11). They are found in drain openers, oven cleaners, industrial cleaners, bathroom and household sanitizers, hair relaxers, alkaline batteries, electric dishwasher detergents, low-phosphate detergents, and cement (Figure 20.30). Detergents are classified according to their charge in solution: Nonionic, anionic, cationic. Anionic and nonionic detergents are found in shampoos, hand dishwashing detergents, and laundry detergents (Figure 20.31). Cationic detergents are found in fabric softeners, germicides, disinfectants, and sanitizers (Figure 20.32).

Pathophysiology

Acids produce coagulative necrosis, and the severity of tissue damage is directly related to the concentration. Coagulative necrosis is painful. Alkalis produce

FIGURE 20.32 Cationic detergent. Concentration determines whether it is an irritant (ready-to-use product) or corrosive (concentrate). (*Courtesy of Tim Williams*.)

liquefactive necrosis. Liquefactive necrosis kills the nerve endings, so animals will continue to chew, and more extensive damage can occur. Anionic and nonionic detergents are just mucosal irritants, while cationic detergents can dissolve superficial layers of epithelial tissue.

Clinical Presentation

Nonionic, anionic, and dilute solutions of acids, alkalis, and cationic detergents can cause mild oral or dermal irritation. Vomiting is expected to be self-limiting. Signs due to concentrated acids, alkalis, or cationic detergents are often indistinguishable from each other. Hypersalivation, gagging, pawing at the mouth, vomiting +/- blood, and oral ulcers. Hyperthermia (>104°F) can be seen with alkalis and cationic detergents. There can potentially be esophageal and gastric ulcers. Esophageal and gastric damage is more likely with alkalis. Dermal exposure can cause pain, erythema, and full-thickness burns. It may take up to 12 hours for the full extent of the damage to be seen with alkalis and cationic detergents.

Diagnosis

History and clinical signs.

Management

Do not induce emesis or give activated charcoal. Dilution with milk or water as soon as possible after exposure is recommended. Opioids should be used for pain control. Sucralfate slurries and GI protectants should be started. If the burns are severe, antibiotics, nutritional support (blenderized food or gastrostomy tube), and fluids may be needed.

Prognosis

Good for exposures to nonionic, anionic detergents or dilute acids, alkalis, and cationic detergents. Prognosis is good to guarded with concentrated acids, alkalis and cationic detergents. Most recover without any long-term problems, but the prognosis worsens for animals with esophageal burns (stricture formation).

INSOLUBLE CALCIUM OXALATE-CONTAINING PLANTS

Definition/Overview

Many of the most common houseplants are in the Araceae family and contain insoluble calcium oxalate crystals. Refer to Table 20.7 for a list of plants.

Pathophysiology

Insoluble calcium oxalate crystals are needle shaped. These raphides are packing into idioblasts within the plant. When the leaf is damaged, the broken idioblast allows sap/saliva to enter, and the swelling ejects the raphides. These needles penetrate oral mucosa and cause pain. In severe cases, swelling of oral tissues can occur.

TABLE 20.7 Insoluble calcium oxalate plants

Genus	Common name
Aglaonema spp.	Chinese evergreen
Alocasia spp. or *Colocasia* spp.	Elephant's ear
Anthurium spp.	Flamingo plant
Arisaema triphyllum	Jack-in-the-pulpit
Arum maculatum	Arum, cuckoo pint
Caladium spp.	Caladium, elephant's ear
Dieffenbachia spp. (Figure 20.33)	Dieffenbachia, dumb cane
Epipremnum spp.	Pothos, Devil's ivy
Monstera spp.	Cutleaf philodendron, Swiss cheese plant
Philodendron spp. (Figure 20.34)	Philodendron
Schefflera spp.	Umbrella tree
Spathiphyllum spp.	Peace lily
Syngonium podophyllum	Nephthytis
Zantedeschia aethiopica	Calla lily, Arum lily

Clinical Presentation

There is a quick onset of hypersalivation, gagging, and potentially vomiting. In rare cases, there can be swelling of the oral cavity and pharynx (obstruction is extremely rare).

FIGURE 20.33 *Dieffenbachia* spp.—Dieffenbachia, Dumbcane.

FIGURE 20.34 *Philodendron* spp.—Philodendron.

Diagnosis

History and clinical signs.

Management

Oral milk or water should be given. Calcium-containing products are thought to precipitate soluble oxalates in the oral cavity and reduce pain.

Prognosis

Good. Clinical signs usually resolve within a few hours with no lasting effects.

CHAPTER 21

Infectious Diseases
CHAPTER 21.1 Dogs

Stuart Walton

Introduction 873
Bacterial Infections 873
Viral Infections 886
Recommended Further Readings 913

The discussion on infectious diseases that follows is not intended to be comprehensive. Instead, the diseases presented in this chapter represent the most common infections encountered in dogs seen in clinical practice. Updates on practical, accessible, diagnostic testing protocols, treatment recommendations, and prevention/vaccination are included.

INTRODUCTION

Successful management of infectious disease requires a combination of early, reliable, definitive diagnostic tests, and aggressive interventional therapy. Advanced diagnostic technology has not only increased our awareness of the spectrum of infectious agents capable of causing clinical illness in companion animals, it has also made it quite clear that coinfection (i.e., simultaneous infection with two or more pathogens in the same patient) is prevalent in veterinary medicine and can be a major influence in the outcome. To better provide early, aggressive, successful medical therapy, it is important for clinicians to assimilate historical and clinical information, as well as accurately and critically evaluate performed diagnostic tests so that an accurate diagnosis can be made.

The following chapter on infectious diseases is not intended to be comprehensive. Instead, the diseases presented in this chapter represent the most common infections encountered in dogs and cats seen in clinical practice. Updates on practical, accessible, diagnostic testing protocols, treatment recommendations, and prevention/vaccination are included.

BACTERIAL INFECTIONS

CANINE INFECTIOUS RESPIRATORY DISEASE

Definition/Overview

Canine infectious respiratory disease (CIRD) complex, also known as "kennel cough," is an endemic, highly contagious upper respiratory tract infection that occurs acutely in dogs. Disease is multifactorial, manifesting as a cough. It is caused by a number of pathogens occurring individually or as coinfections. Occasionally, lower respiratory disease (bronchopneumonia) will result and may become life-threatening, particularly in young dogs. CIRD can occur at any age with illness occurring when large numbers of dogs are in close contact (i.e., animal shelters, boarding facilities, day-care facilities, or dog parks).

Etiopathogenesis

The bacterial and viral pathogenic agents implicated in CIRD are summarized in Tables 21.1.1. and 21.1.2. Incubation period can be up to 10 days depending on the pathogen. Pathophysiology varies with all CIRD pathogens that cause upper respiratory tract pathology. Traditional CIRD involves both viral and bacterial agents (i.e., canine parainfluenza virus (CPIV), canine adenovirus (CAV), canine distemper virus (CDV), canine herpesvirus (CHV), and *Bordetella bronchiseptica*). New, emerging, and novel pathogens associated with CIRD include canine influenza virus (CIV), canine

DOI: 10.1201/9781003254591-41

TABLE 21.1.1 Common bacterial respiratory pathogens implicated in canine infectious respiratory disease

Pathogen	Incubation period	Preclinical shedding	Duration of shedding	Persistent infection
Bordetella bronchiseptica	3–10 days	Yes	Several weeks	Recovered up to 14 weeks after clinical resolution
Streptococcus equi subspecies *Zooepidemicus*	1–3 weeks	Yes	1–2 weeks	Possible
Mycoplasma spp.	1–4 weeks	Yes	Several weeks	Up to 3 weeks in lung tissue
Chlamydophila	Unknown	Yes	Unknown	Possible

TABLE 21.1.2 Common viral respiratory pathogens implicated in canine infectious respiratory disease

Pathogen	Incubation period	Preclinical shedding	Duration of shedding	Persistent infection
Canine parainfluenza virus (CPIV)	< 1 week	Yes	1 week	No
Canine adenovirus (CAV-2)	< 1 week	Yes	1 week	No
Canine distemper virus (CDV)	1–3 weeks	Yes	< 1 month	No
Canine herpesvirus (CHV)	< 1 week	Yes	2 weeks	Yes
Canine influenza virus (CIV)	2–4 days	Yes	7–21+ days	No
Canine respiratory coronavirus (CRCov)	< 1 week	Yes	2 weeks	No

respiratory coronavirus (CRCoV), canine pneumovirus, canine bocavirus, canine hepacivirus, canine picornavirus, *Mycoplasma cynos*, and *Streptococcus equi* subsp. *zooepidemicus* (*S. zooepidemicus*).

Bordetella is a Gram-negative coccobacilli bacterium capable of causing disease in a variety of species, including cats, pigs, rabbits, and people. Transmission is airborne through both direct and indirect contact (i.e., contaminated bedding, food bowls, water bowls). Upon entering the body, the organism expresses virulence factors linked to a gene complex (Bvg), which aid in adherence of the organism and damage to ciliated respiratory epithelial cells. This causes ciliostasis and excessive mucus secretion due to failure of mucociliary clearance, predisposing affected patients to secondary opportunistic infections.

Streptococcus equi subspecies *zooepidemicus*, a β-hemolytic Lancefield group C *Streptococcus* is responsible for severe, acute to peracute upper respiratory tract infections and acute, severe hemorrhagic bronchopneumonia in dogs. Pathogenesis of disease is not fully understood but is thought to involve exotoxins which act as superantigens significantly augmenting the patient's immune response comparable with human streptococcal toxic shock syndrome. Coinfection with other pathogens is possible, which may worsen severity of infection after exposure to *S. zooepidemicus*.

Mycoplasma spp. are normal commensals that colonize mucous membranes of the upper respiratory tract. Their exact role in CIRD is still debatable. *Mycoplasma cynos* has been associated with pneumonia in dogs, although it is still unclear whether it is a primary or secondary opportunistic pathogen, as it has also been cultured from the lungs of healthy dogs. Younger dogs are more likely to be infected.

Canine adenovirus type 2 (CAV-2) and canine parainfluenza virus (CPIV) are the best recognized viruses for causing CIRD. They cause inflammation of the laryngeal, tracheal, and bronchial epithelium. Both diseases cause mild-to-moderate, self-limiting disease as solo pathogens; however, when there is coinfection with other pathogens, more serious illness can ensue.

Canine influenza virus (CIV) is an H3N8 virus that is known to have been derived from the equine influenza virus. Virus shedding is generally limited to less than 14 days post infection. Experimentally infected dogs demonstrate fever and mild inflammation involving tracheal epithelium. Viral pneumonitis is uncommon. Clinical infection is generally considered to be mild unless the dog is coinfected. Bacterial pathogens (discussed previously) in combination with CIV can result severe respiratory disease and death.

Canine distemper virus (CDV) is not commonly implicated as a primary agent of CIRD because respiratory disease is just one of the many severe systemic manifestations that occur in unvaccinated dogs. Canine respiratory coronavirus (CRCoV), and canine pneumovirus (CPnV) infections appear to occur less commonly and may actually be most important as cofactors in CIRD.

Clinical Presentation

Clinical signs are variable. Typically, cases are mild and self-limiting consisting of a paroxysmal "goose honk" cough, sneezing, oculonasal discharge, and increased

tracheal sensitivity. Some patients can develop more severe clinical signs depending on age, immune status, and the presence of coinfections. Clinical signs in these patients may include fever, lethargy, anorexia, and dyspnea. The occurrence of coinfection explains, at least in part, why predicting clinical outcomes of CIRD in individual dogs can be difficult, and it also explains why well-vaccinated dogs still develop kennel cough.

Viral pathogens tend to be associated with acute-onset productive cough that lasts 1–2 weeks. Some patients will only develop mild or no clinical signs (seroconversion only). Coughing may persist for several weeks, even though the virus is usually cleared within 2 weeks following the development of clinical signs.

Patients with bacterial infection are systemically unwell. The characteristic "goose honk" cough is usually accompanied with fever, anorexia, mucopurulent nasal and ocular discharge, orthopnea, and dyspnea. Life-threatening pneumonia has been reported in young animals.

Differential Diagnosis

Understanding, and more importantly, distinguishing causes of acute coughing in patients is key for selection of diagnostics, initiating empiric medical therapy, and the institution of proper preventative/control measures to prevent further infection to other animals. Nine organisms play a role in CIRD (Tables 21.1.1 and 21.1.2).

Diagnosis

Diagnosis is often made based on a thorough history and physical examination. History should include recent boarding, dog park visits, or day-care stays. Dogs are usually systemically well and will typically exhibit mild clinical signs such as paroxysmal breathing, harsh "goose honk" cough, serous ocular or nasal discharge, and/or sneezing. Ancillary diagnostics (complete blood count [CBC], serum biochemistry, urinalysis, and thoracic radiographs) are usually unremarkable. Further diagnostics are indicated in dogs with a persistent cough (> 7–10 days) who have severe rapidly progressing clinical signs. In these unwell dogs, a neutrophilia with left shift and changes on thoracic radiographs may be present (i.e., bronchointerstitial to alveolar pulmonary pattern). Upper respiratory tract bacterial cultures (conjunctival, nasal, oropharyngeal, tracheal) should be interpreted with caution, as normal microbial flora and many CIRD pathogens may be isolated, especially in otherwise healthy animals. *Bordetella bronchiseptica* or *M. cynos* isolation in animals with consistent clinical signs supports infection; however, coinfection with other CIRD pathogens should also be considered. Commercial canine respiratory disease panel polymerase chain reaction (PCR) assays (conjunctival, nasal, and pharyngeal swabs) are available from most diagnostic laboratories, which has led to increased detection of CIRD pathogens and provided information regarding the presence of coinfections. Samples should be collected in patients with clinical signs of < 4 days.

Management

Treatment/Prognosis

Under the current guidelines, no specific therapy is indicated in patients that are systemically well with a good appetite as most cases are self-limiting and will resolve in spite of treatment. Minimizing cough precipitating situations (i.e., avoidance of excitement, avoidance of neck leashes, etc.) is advised. Cough suppressants can be used to reduce cough frequency and severity; however, caution is advised in prescribing these if the cough is productive due to reduced bacterial clearance and the possibility of a secondary bacterial pneumonia developing. In otherwise healthy patients, short-term treatment (≤ 5 days) with anti-inflammatory corticosteroids (e.g., prednisolone at 0.5 mg/kg p.o. once or twice daily) reduces not only inflammation but also reduces the intensity of cough. Antimicrobial therapy is indicated in patients that are systemically unwell or who have a persistent cough for > 1 week. Empiric antimicrobial therapy should be based on the most likely agent to be present. Considerations for antibiotic selection should also include the ability of antimicrobials to achieve good airway concentration and penetrate airway secretions as well as safety margins for their use. Doxycycline (2.5–5.0 mg/kg p.o. q.12 h. for 5–7 days), azithromycin, and fluoroquinolones achieve good airway concentrations, while beta-lactam drugs (e.g., amoxicillin/clavulanate) achieve lung tissue concentrations but do not penetrate airway secretions well. Fluoroquinolones should be reserved for more severe infections. Fluoroquinolones and tetracyclines may cause cartilaginous defects in young animals and dental staining in puppies.

Severely affected animals may require hospitalization, parenteral fluids, oxygen therapy, nebulization/coupage, and nutritional support.

Prognosis for simple uncomplicated disease is good to excellent. Clinical signs may persist beyond the time of viral shedding. Infected puppies appear to be at greater risk for developing complications associated with CIRD (e.g., bronchopneumonia). Outcomes are directly related to the severity of disease and any coinfection present.

Prevention

Vaccines are available for the most common CIRD pathogens (Table 21.1.3). In general, these vaccines do not produce immunity. Rather, they are effective in reducing severity of cough in challenged dogs. Several types of vaccine (Tables 21.1.4 and 21.1.5) are available

TABLE 21.1.3 Vaccines (available in the United States) for prevention against known CIRD pathogens

– *Bordetella bronchiseptica*
– Canine parainfluenza virus
– Canine adenovirus-2
– Canine distemper virus
– Canine influenza virus

TABLE 21.1.4 Initial vaccination recommendations for dogs based on the 2017 American Animal Hospital Association (AAHA) vaccination guidelines

Core vaccines	Administration	First booster
MLV or recombinant Canine distemper virus + MLV parvovirus + MLV adenovirus-2 ± MLV parainfluenza virus*	3 doses recommended between 6 and 16 weeks of age (e.g., 8, 12, and 16 weeks of age) Dogs ≥ 16 weeks should receive 2 doses 2–4 weeks apart**	Administer a single dose (of a combination product) at 1 year following the last dose in the initial series
Rabies (killed) 1-year and 3-year labeled vaccines available	Administer single dose not earlier than 12 weeks of age (state/local/provincial laws apply)	Administer a single dose of vaccine no later than 1 year following administration of the first dose regardless of age (state/local/provincial laws apply)
Noncore vaccines	Administration	First booster
Bordetella bronchiseptica + canine parainfluenza virus (IN only) (Some IN products may also contain CAV-2 antigen)	Single IN dose generally administered between 8 and 16 weeks of age Intranasal vaccine may be administered as early as 3–4 weeks of age	Where sustained risk of exposure, administer a single dose 1 year following the last dose administered No known value administering IN vaccine every 6 months
Bordetella bronchiseptica only (monovalent) Three options available – Parenteral (killed bacterium) – IN (avirulent live) – Intraoral (avirulent live)	Two parenteral SQ doses initially administered 2–4 weeks apart beginning ≥ 8 weeks of age Single IN dose beginning ≥ 3 weeks of age Single oral dose into the buccal pouch ≥ 8 weeks of age	Where sustained risk of exposure, administer a single dose 1 year following the last dose administered
Leptospira (killed) 4-serovar SQ – Serovar *L. canicola* – Serovar *L. icterohaemorrhagiae* – Serovar *L. grippotyphosa* – Serovar *L. pomona* (2-way leptospirosis vaccines not recommended by either AAHA or the American College of Veterinary Internal Medicine)	Two initial doses, 2–4 weeks apart, administered at ≥ 8 weeks of age	Where sustained risk of exposure, administer a single dose at 1 year following completion of last dose
Borrelia burgdorferi (canine Lyme disease) SQ Four vaccine types currently available – Killed (whole cell bacterin [OspA] or whole cell bacterin [OspA + C]) – Recombinant (OspA or chimeric-recombinant OspA + OspC)	Two initial doses, 2–4 weeks apart, administered at ≥ 8 weeks of age	Where sustained risk of exposure, administer a single dose at 1 year following completion of last dose Option – Dogs traveling into Lyme-disease endemic areas from nonendemic areas may be at increased risk for exposure and infection – Vaccination may be indicated for these dogs – Administer 2 vaccine doses 2–4 weeks apart – Last dose should be administered 2–4 weeks prior to travel
Canine influenza virus-H3N8 SQ (killed)	Two initial doses, 2–4 weeks apart, administered at ≥ 6 weeks of age Any at risk dog for exposure to influenza virus vaccination against both H3N2 and H3N8 strains recommended	Where sustained risk of exposure, administer is sustained, administer a single dose at 1 year following completion of last dose
Canine influenza virus-H3N2 SQ (killed)	Two initial doses, 2–4 weeks apart, administered at ≥ 6 weeks of age Any at risk dog for exposure to influenza virus vaccination against both H3N2 and H3N8 strains recommended	Where sustained risk of exposure, administer is sustained, administer a single dose at 1 year following completion of last dose

* Parainfluenza administered as combination as DA2PPi.

** A minimum interval of 2 weeks between any 2 doses of vaccine is recommended.

Canine coronavirus vaccination is not recommended.

Crotalus atrox (western diamondback rattlesnake) vaccine should only be used in dogs with a defined risk for exposure. Follow the manufacturer's recommendations for dosing.

IN, intranasal; MLV, modified live virus.

TABLE 21.1.5 Booster recommendations for adult dogs

- After completing the initial series of core vaccines (distemper + parvovirus + adenovirus–2), it is recommended to administer a single dose (combination vaccine) at intervals of every 3 years (or longer)
  - Note: Substantial data exists demonstrating protective immunity for dogs at least 5 years following MLV vaccine administration in the absence of maternally derived antibody
- In the United States, all states currently recognize and accept the use of "3 year" rabies vaccines in dogs
  - Note: Some local municipalities may mandate stricter booster requirements (i.e., annually)
- *Noncore vaccines:* Administer annually where risk of exposure is sustained

for administration to dogs by the intranasal, oral, and parenteral (subcutaneous) route. The constituents and the routes of administration of commercially available vaccines vary. The route of vaccine administration indicated by the manufacturer must be strictly adhered to.

Quarantining new shelter arrivals for 1 week and isolating all dogs showing clinical signs of respiratory infection may help reduce the risk of exposure to CIRD pathogens. Likewise, ensuring animals are appropriately vaccinated upon intake will help reduce risk of exposure. Strict hygiene protocols with hand sanitation, cleaning contaminated clothing, hands, equipment, and surfaces should be mandatory as this will limit disease spread.

LYME BORRELIOSIS (BORRELIOSIS; CANINE LYME DISEASE)

See Tick-Borne Disease.

CANINE BOTULISM

Definition/Overview

Botulism is a rare neuroparalytic disorder of dogs and humans caused by intoxication of botulinum neurotoxin produced by *Clostridium botulinum* (most common), *Clostridium baratii*, and *Clostridium butyricum*.

Etiopathogenesis

Clostridium botulinum is a Gram-positive, spore-forming, anaerobic bacterium that indirectly causes clinical signs from the production of neurotoxins. Seven botulinal neurotoxins have been identified (A–G), which result in flaccid lower motor neuron paralysis. This bacterium, normally found in organic-rich environments, produces vegetative cells and spores that are highly conserved in the environment. The most common source of toxin is raw and spoiled food or carrion. In dogs, botulinum neurotoxin type C is most commonly associated with clinical illness in dogs. Following ingestion of rotten food, lysis of vegetative cells and spores occurs, resulting in botulinum toxin being released as a preformed toxin. The toxin, which is stable at low pH, passages through the stomach into the small intestine where it dissociates and releases botulinum neurotoxin. Botulinum neurotoxin is then rapidly absorbed across the small intestine by endocytosis. It then enters the lymphatic system followed by the bloodstream. From there, the toxin leaves the circulation and enters tissue fluids, binding rapidly and irreversibly to presynaptic membrane receptors at cholinergic nerve terminals. This interrupts acetylcholine release, resulting in lower motor neuron and autonomic nervous system dysfunction (sympathetic and parasympathetic).

Clinical Presentation

Clinical signs can take up to 6 days after ingestion of contaminated food to develop. Severity of disease is associated with amount of toxin ingested, individual susceptibility, and speed of onset of clinical sign development. Initially, affected dogs develop progressive ascending symmetric weakness, followed by progressive ascending flaccid paralysis beginning with the pelvic limbs (Figure 21.1.1). On neurological examination, patients are often tetraparetic or tetraplegic with severely decreased to absent spinal reflexes. Patients have a normal mental status while maintaining a tail wag and pain perception. Cranial nerve abnormalities include mydriasis with a reduced pupillary light response, decreased jaw tone, ptyalism, diminished palpebral reflexes, constipation, urine retention, and weak vocalization. Severely affected dogs may have trouble breathing, associated with decreased muscular tone. Affected patients appear to have decreased swallowing reflexes which may predispose them to aspiration pneumonia. Death may result in a small number of patients due to respiratory paralysis or secondary respiratory/urinary tract infections.

FIGURE 21.1.1 The toxin of *Clostridium botulinum* can cause a severe bulbar and lower motor neuron paralysis, causing impaired respiration and requiring life-preserving ventilatory support. (*Courtesy of M. Schaer.*)

Differential Diagnosis

Rabies is an important differential among dogs with overt signs of botulism toxicity. In addition, dysautonomia, myasthenia gravis, polyradiculoneuritis, and intoxications like organophosphate and carbamate intoxications should be considered.

Diagnosis

Botulism is usually suspected from a history of access to spoiled, rotten, or raw food and progressive symmetric hindlimb lower muscle neuron paresis accompanied by cranial nerve abnormalities and disruption of the parasympathetic system. Because the toxin is dietary in origin, animals in the same household may be affected. However, isolated cases are also possible. Routine laboratory tests (CBC, serum biochemistry, urinalysis [UA]) are usually unremarkable. Thoracic radiographs should be performed in any case suspected of having botulism, as megaesophagus and subsequent aspiration pneumonia are usually present. Definitive diagnosis is made based on finding botulinum toxin in serum (10 mL), feces, vomitus/stomach contents, or in samples of spoiled ingested food (50 g). It should be noted that identification of the *C. botulinum* organism from feces is not necessarily diagnostic. In clinical practice, clinicians should contact laboratories prior to sample collection and submission to verify the volume required and sample preparation for each specimen type.

Samples should be:

1. Collected early during disease when clinical signs are maximal to be diagnostic as circulating toxin levels are rapidly degraded, often low, or may be absent in source material.
2. Refrigerated (not frozen) and examined as soon as possible.
3. Labeled as biological hazards because people are much more susceptible to botulism toxin than dogs or cats.

Electromyogram (EMG), if available, may show spontaneous electrical activity (fibrillations, positive sharp waves) in any affected muscles after 2 weeks of paralysis but may also be normal.

Management

Treatment/Prognosis

Botulinum toxin causes degeneration of the affected synapse rather than death of the affected neuron. Recovery from toxicity occurs with new endplate formation. Therefore, the mainstay of treatment of botulism is supportive care once clinical signs are present, as antitoxin is not effective once botulinum toxin is already bound to membrane receptors. Antitoxin type C can be administered to asymptomatic dogs suspected of recent (within 1 hour) ingestion of contaminated food and ongoing intestinal absorption of botulinal toxin. Always have epinephrine ready to administer at a dose of 0.01 mg/kg IM if anaphylaxis occurs. The cornerstones of supportive care are nutritional support and physical therapy. Patients are often hospitalized initially until stable (1–3 weeks).

Patients should:

1. Be maintained on well-padded, soft, clean bedding and repositioned every 4–6 hours to avoid the development of pressure sores/ulcers.
2. Be maintained in sternal recumbency to facilitate easier eating and interaction with their environment.
3. Have their urinary bladder frequently emptied (every 6–8 hours) to prevent urinary retention and secondary urinary tract infection. This is performed either by manual expression or via intermittent or permanent placement of a urinary catheter.
4. Have both eyes lubricated with artificial tears frequently (every 4 hours) to protect corneas from desiccation and ulcer development.
5. Have a balanced nutritional plan formulated and be monitored while eating and drinking. Enteral or parenteral nutrition should be considered in animals with either a poor gag reflex or megaesophagus as they are at risk of aspiration pneumonia.
6. Have physical therapy in the form of passive range of motion and massage every 6 hours to avoid muscle contracture and atrophy as well as to help maintain joint movement.

Antibiotics should not be routinely prescribed in affected patients unless a secondary bacterial infection is diagnosed (e.g., aspiration pneumonia, urinary tract infection).

Prevention

Thorough cooking of food (i.e., 80°C [176°F] for 30 minutes or to 100°C [212°F] for 10 minutes) and preventing access of dogs to raw meat, contaminated food, and carrion is best to prevent disease.

Public Health Implications

Botulism is not transmitted from dogs to humans.

CANINE BRUCELLOSIS

Definition/Overview

Clinical disease of canine brucellosis is attributed to infection with *Brucella canis*, a Gram-negative intracellular aerobic coccobacillus. Disease manifests as infertility, epididymitis, and late-term abortion. Other *Brucella* species, including *B. melitensis*, *B. abortus*, and *B. suis*, can infect dogs. Infection follows after the ingestion of contaminated placentas or aborted fetuses of livestock. Dogs do not play a significant role in the transmission of infection. *Brucella canis* predominantly affects domestic dogs, with the organism primarily being shed reproductive fluids (e.g., vaginal discharge, semen).

Etiopathogenesis

Clinical disease is caused by *Brucella canis* as well as other *Brucella* species (e.g., *B. melitensis*, *B. abortus*, and *B. suis*). Disease transmission occurs through oronasal, genital, or conjunctival mucosal inoculation during normal reproductive, social, and grooming activities in dogs. After attachment to and penetration of the mucosal barrier, bacteria are transported as free bacteria or within phagocytic cells to regional lymph nodes (e.g., retropharyngeal, inguinal, superficial iliac), the liver, spleen, and possibly bone marrow. After infection and replication (1 week to 1 month), bacteria move into the blood stream causing an intermittent bacteremia. Bacteria target "steroid-dependent" reproductive tissues (e.g., prostate, testicles, epididymides, gravid uterus, and placenta). Once bacteria accumulate within this tissue among others (i.e., mammary tissue, spleen, lymph nodes, intervertebral disc, eyes, kidneys, and meninges), affected animals become infertile and experience cyclical fevers. Shedding of the organism occurs in females (vulvar secretions after abortion [≤ 6 weeks], during estrus) and males (semen for up to 2 years after infection). Minor transmission routes include in utero, broken skin surfaces, blood transfusions, feces, milk, and fomites (e.g., contaminated syringes, food bowls, clothing, vaginoscopes).

Clinical Presentation

The most common clinical sign associated with *B. canis* infection is infertility. However, a wide range of nonreproductive signs can occur, with dogs being systemically well at presentation.

Female dogs infected venereally experience either early embryonic death (i.e., up to 3 weeks after transmission), which is consistent with infertility, or experience late-term spontaneous abortion (i.e., 45–55 days' gestation). Females will develop vaginal discharge (mucoid, serosanguinous, or gray green) that may persist for up to 6 weeks post abortion. Puppies surviving to term will either be weak and die within several weeks of birth, be clinically normal initially but then develop clinical signs associated with infection, or test positive for the disease later in life.

Male dogs may have more obvious clinical signs manifest initially as epididymitis, scrotal swelling, pain, and edema. As disease becomes more chronic, the testicles may become atrophied with epididymal swelling resolving. *Brucella canis* can also localize within the prostate, leading to prostatitis clinically manifesting as difficulty urinating/defecating and an enlarged, painful prostate on rectal examination. Ultimately males develop infertility due to spermatogenic arrest (antisperm agglutinating antibodies and delayed-type hypersensitivity reactions against spermatozoa).

Nonreproductive clinical manifestations of *B. canis* infection include chronic uveitis, endophthalmitis, and discospondylitis (Figure 21.1.2 and Table 21.1.6).

Differential Diagnosis

In male dogs, clinical disease may be silent. Among females, vaginitis and/or open pyometra should be considered. Occasionally, dogs will present with acute neurologic signs consistent with intervertebral disc disease or discospondylitis.

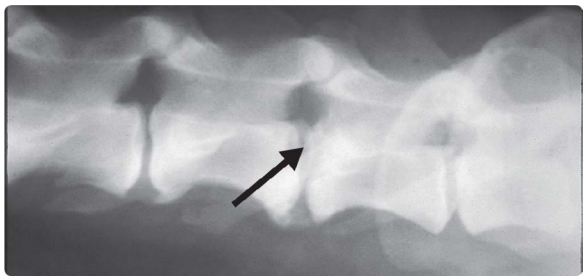

FIGURE 21.1.2 Radiograph depicting discospondylitis in a dog, which can be caused by *Brucella canis*.

TABLE 21.1.6 Nonreproductive clinical signs associated with *B. canis* infection

Clinical signs
– Ocular   – Blepharospasm, aqueous flare, constricted pupils, synechiae, hypopyon, hyphema
– Discospondylitis   – Stiffness, back pain, lameness, exercise intolerance, paresis, paralysis due to spinal compression
– Lymphadenitis (common)
– Pyogranulomatous dermatitis (rare)
– Endocarditis (rare)
– Appendicular osteomyelitis (rare)
– Meningoencephalitis (unknown frequency)
– Decreased appetite
– Weight loss
– Lethargy
– Fever (rare)

Diagnosis

A thorough history, including the reproductivity activity, meticulous physical examination paying specific attention to male/female genitalia and peripheral lymph nodes should be performed. The presence of back pain and uveitis should warrant additional diagnostics in sexually mature dogs. Routine diagnostics (e.g., CBC, serum biochemistry, and urinalysis) are often unremarkable. Blood culture is considered the "gold standard" for diagnosis of early infection as > 50% of dogs will be bacteremic up to a year following infection. Culture of other fluids (e.g., urine, semen, post-abortion vaginal discharge) or tissue (e.g., aborted placenta and aborted fetal tissue) may be positive during the first 3 months of infection; however, this testing is not widely available.

Definitive diagnosis is usually based on serologic testing. Testing relies upon an agglutination reaction between canine *B. canis* antibodies and bacterial cytoplasmic protein antigens. Seroconversion producing a positive test can take up to 12 weeks after exposure for

TABLE 21.1.7 Available serologic tests for *B. canis* infection

Test	Advantages	Disadvantages
Agar gel immunodiffusion (AGID)	– Confirmation tests for suspected *B. canis* cases detected initially by RSAT or ME-RSAT – Serum Ab test – Identifies chronically infected	– Not used as screening test – Lag time to develop Ab (up to 4 weeks) – Variable turnaround time (up to 48 hours) – Variable rates of false-negative results
Rapid slide agglutination test (RSAT)	– Serum Ab test – Short turnaround time (RSAT 2 minutes) – Highly sensitive	– Lag time to develop Ab (up to 4 weeks) – May take up to 8–12+ weeks for positive test results – Variable rates of false-positive results – Decreased sensitivity for chronically infected due to intermittent bacteremia
Modified rapid slide agglutination test (ME-RSAT)	– Serum Ab test – 2-mercaptoethanol incorporated into RSAT test to inactivate IgM preventing misidentification of positive sera	
Tube agglutination test (TAT)	– Serum Ab test – 1:200 titer is positive for infection – Identifies chronically infected	– Erratic availability of testing – Cross reaction with other infectious agents – No commercial tests for TAT

anti–*B canis* antibodies. The most common serologic tests include agar gel immunodiffusion (AGID), rapid slide agglutination test (RSAT), tube agglutination test (TAT), microagglutination test (MAT), complement fixation test (CFT), and several enzyme-linked immunosorbent assay (ELISA) protocols with different antigens (Table 21.1.7). Indirect immunofluorescent antibody (IFA) testing and ELISA assays are not in widespread use and may not be available to clinicians.

Limitations of serologic testing include nonspecific reactions (occurs with hemolyzed sera, samples with high lipid content, or because of cross-reaction with other pathogens [e.g., *Pseudomonas* spp., *Streptococcus* spp., *Staphylococcus* spp., etc.]). Mercaptoethanol rapid slide agglutination (ME-RSAT) point-of-care (POC) test is performed initially as a screening test. This is followed by the agar gel immunodiffusion test, which is used to confirm infection in dogs that are positive with POC testing. PCR testing of whole blood (not serum) is more sensitive than blood culture or serologic testing. Additionally, PCR testing of vaginal swab samples may be used to confirm positive test results.

Management

Treatment/Prognosis

Treatment is generally discouraged in infected animals due to organism persistence within cells. Euthanasia is generally recommended for these animals. In breeding facilities, voluntary quarantining is mandated to ensure no animals are being introduced or sold/relocated. There should be no breeding, and isolation of positive dogs is advised. Recommended guidelines include:

1. Do not allow infected and uninfected dogs to share common areas as bacteria can have prolonged survival in the environment (days to weeks).
2. Use separate feeding and watering dishes.
3. Care for the negative dogs first, then suspected positive dogs, followed by positive dogs.

Serum positive patients with no clinical signs should be isolated and allowed to self-eliminate the organism if possible. These patients may take up to 2–3 years to spontaneously recover.

Treatment, when attempted, should involve spaying/neutering the patient followed by antibiotic therapy. Combination antibiotic therapy is recommended (Table 21.1.8), with multiple protocols being recommended. Some success has been reported using enrofloxacin (5 mg/kg p.o. q.24 h.) for 4 weeks alone. Once the antibiotic treatment cycle is completed, AGID testing is repeated with testing performed every 3 months until results are negative on at least two consecutive occasions. For animals that return positive results, repeat treatment is necessary. Relapses are common once antimicrobials

TABLE 21.1.8 Antimicrobial therapy for *B. canis* infection

Therapy	Length of therapy

‡‡ 5–10 mg/kg p.o. q.24 h.

are discontinued, necessitating repetitive courses of antibiotics. Post therapy, patients are retested. Persistently positive patients are retreated and tested again until the patient has a negative test. Once negative, patients are retested every 4–6 months with treatment repeated as necessary. It is important to note that the therapy is not curative, and the dog may be a risk to other dogs and humans, especially young children, older persons, and immunocompromised individuals.

Brucella ocular infections are difficult to treat, and enucleation is generally recommended as the eye can act as a persistent nidus of infection.

Prevention

Risk of infection is greatest among dogs utilized in breeding programs or maintained in breeding kennels. Prevention strategies in breeding facilities include:

1. Quarantining and testing all new additions to kennels. Due to the lag time with many of the diagnostic tests, dogs should test negative on serial screening tests (ME-RSAT or TAT) performed 8 weeks apart prior to coming out of quarantine.
2. Artificial insemination to decrease male dog's exposure to disease. Unfortunately, this does not protect females from disease.
3. Periodic testing of all of the dogs twice a year in kennels. Kennel screening can help decrease exposure in the event a positive dog is introduced to the kennel.
4. Routine disinfection using 2.5% sodium hypochlorite, quaternary ammonium compounds, or 70% ethanol with a minimum of 10-minute contact time to clean facilities and equipment.

Public Health Implications

Canine brucellosis is regarded as a zoonotic infection. Both natural and laboratory-acquired infections have been reported. Caution should be taken when handling aborted tissues and discharges from dogs suspected of having brucellosis.

LEPTOSPIROSIS

See also Chapter 13.

Definition/Overview

Leptospirosis is caused by a Gram-negative, motile spirochete bacterium with worldwide distribution known to cause disease in dogs, humans, and many other animal species. Disease in canines is primarily caused by *L. interrogans* and *L. kirschneri*. Species are further classified into serovars based on surface O antigen serology. Closely related serovars are further divided into serogroups, with at least 10 being potentially important for dogs. Serogroups implicated in causing infection include *L. canicola*, *L. icterohaemorrhagiae*, *L. grippotyphosa*, *L. pomona*, and *L. bratislava*.

Etiopathogenesis

Ten serogroups are known to infect and cause disease in dogs. Serogroups implicated in causing infection include *L. canicola*, *L. icterohaemorrhagiae*, *L. grippotyphosa*, *L. pomona*, and *L. bratislava*. Persistence in the environment is through a reservoir host, most commonly rodents, with the organism being shed in the urine. Pathogenic serovars can remain viable in water or soil for weeks to months.

Clinically affected dogs are more likely to be living in close proximity to water and have indirect exposure to wildlife. Infection is seasonal, with outbreaks being linked to heavy rainfall or flooding. Transmission is via either direct contact of mucous membranes or broken skin with the urine from infected animals or by indirect contact with contaminated soil or surface water. Infection can also occur through bite wounds, ingestion of infected tissues/fluids, and by venereal and placental transfer. Initially, leptospires bind inhibitors of complement activation evading the host immune response and a bacteremic phase, lasting for 10 days, establishes via hematogenous spread. Bacteria then invade the kidney and liver, among other organs, with bacteria then being shed in the urine. Once there is an effective host immune response, the organism is cleared from the bloodstream. Following clearance, Leptospira persist in "immune-privileged sites" such as the eye and renal tubules.

Clinical Presentation

Clinical manifestation of disease is highly variable and dependent on patient age, geographical location, host immune response, and strain of pathogen. Common presenting clinical signs are related to various combinations of vasculitis, acute kidney injury (AKI), and liver impairment (**Figure 21.1.3**). Other clinical signs can include fever, pulmonary hemorrhage, uveitis, myositis, and reproductive failure. Acute infection is characterized by fever (39.4°C–40.0°C [103°F–104°F]), a reluctance to move due to pain, and myositis. Clinical signs associated with AKI include polyuria, polydipsia, dehydration, vomiting, diarrhea, inappetence, lethargy, or abdominal pain.

Differential Diagnosis

Acute-onset signs associated with leptospirosis may manifest as any one of several serious systemic illnesses, including acute kidney injury/chronic kidney disease, acute hepatitis, neoplasia, adverse drug reaction, polyarthritis, myositis (e.g., canine toxoplasmosis), pneumonia, and spinal cord injury.

Diagnosis

The diagnosis of leptospirosis is typically based on presenting clinical signs and clinician intuition. Clinicians should suspect leptospirosis in dogs with signs of renal or hepatic failure, uveitis, pulmonary hemorrhage, or abortion. Findings on CBC may include neutrophilia

FIGURE 21.1.3 Bilirubinuria in an icteric dog with leptospirosis-induced hepatitis. The urine of dogs infected with leptospirosis can remain infectious for several weeks or months following clinical recovery.

with/without a left shift and a nonregenerative anemia. Up to 60% of patients will present with thrombocytopenia. This is accompanied by varying degrees of an azotemia (up to 80% of cases) or hepatic injury (30%–50% of patients) as evidenced by increased serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and hyperbilirubinemia. Increases in ALP and bilirubin are more common than increases in serum ALT. The former changes are often found with concurrent electrolyte abnormalities (e.g., hyponatremia, hypokalemia, hypochloremia, and/or hyperphosphatemia). Patients are commonly isosthenuric, with glucosuria, proteinuria, and hematuria being common. Often there is an active urine sediment (i.e., low numbers of white blood cells, red blood cells, and granular casts). Urine should always be submitted for quantitative culture and sensitivity to rule out other causes of acute kidney injury such as pyelonephritis.

Definitive diagnostic tests for leptospirosis are divided into 2 broad categories (Table 21.1.9):

1. Direct bacterial visualization detection tests (e.g., culture, dark field microscopy, or PCR). These diagnostics are best used early in the course of disease in patients naïve to antimicrobial therapy. These tests may detect disease earlier compared to the microscopic agglutination test (MAT) (i.e., peracute/acute phase). For PCR, both urine and blood should be collected and tested separately to increase the test sensitivity. Commencement of antibiotics prior to performance of a PCR may result in false negative test results.
2. Antibody detection tests (e.g., point-of-care [POC] and MAT). Currently, there are two rapid, simple to perform, commercial POC antibody tests: The Zoetis WITNESS test and the IDEXX SNAP test. The WITNESS POC test is recommended for the initial screening of acutely ill dogs suspected to have leptospirosis as it can detect *Leptospira*-specific antibodies earlier compared to both the MAT and SNAP. A positive test is highly supportive for a diagnosis of leptospirosis. A negative test should be viewed with caution and retesting performed in 7–10 days.

TABLE 21.1.9 Diagnostic tests for leptospirosis

Test	Results	Sample submission
Point of care – WITNESS – SNAP Lepto test	– Initial screening test – Ab detection 7–10 days post infection	– Serum
Microscopic agglutination test (MAT)	– Collect acute and convalescent specimens 7–14 days apart – A fourfold rise in Ab titer is consistent with active infection – False-negative MAT during first week of infection	– Serum
Polymerase chain reaction (PCR)	– Detects leptospiral DNA before development of Ab – Perform within 7–10 days of illness (i.e., bacteriuric and bacteremic phase of disease, respectively)	– Whole blood or urine – Can submit on kidney or lung tissue

The "gold standard" serologic test for leptospirosis is the MAT. The test reports titers to common serogroups. Seroconversion can take over a week to occur (i.e., negative MAT test with early disease). A titer to any serovar of > 1:800 with compatible clinical signs is consistent with infection. Submission of two samples, representing acute and convalescent titers, collected 7–14 days apart is advised. A 4-fold increase in titer supports infection. Medical therapy may blunt antibody production and prevent this expected rise. Vaccination results in positive MAT (1:6400) with titers of > 1:1600 persisting for up to a year after vaccination.

Management

Treatment/Prognosis

Individualized therapeutic plans consisting of antimicrobials and supportive care is based upon a thorough clinical and clinicopathologic evaluation as well as the severity of organ system dysfunction. Therapies should

be based on both American College of Veterinary Internal Medicine (ACVIM) and European College of Veterinary Internal Medicine (ECVIM) guidelines. Dogs with clinical signs associated with leptospirosis require hospitalization and intensive supportive therapy. Aggressive fluid replacement with a balanced and buffered crystalloid (e.g., lactated Ringer solution [LRS] or Norm-R) is indicated initially to replace fluid losses and maintain renal perfusion. Hydration status should be monitored every 6 hours (i.e., changes in body weight, respiratory rate, blood pressure). An indwelling urinary catheter is recommended to monitor urine output and reduce environmental contamination and exposure of staff to infectious urine. Urinary catheters are left in place until patients are polyuric. In euhydrated, oliguric (urine output < 2 mL/kg/h) or anuric patients initial use of osmotic diuretics (e.g., 20% mannitol) at 0.5 g/kg IV over 30–60 minutes followed by furosemide 2 mg/kg IV q.6–8 h. or 2 mg/kg followed by a constant rate infusion of 0.25–1 mg/kg/h IV may be required. Hemodialysis is recommended in patients that do not respond to therapy. Urinary catheter care should be performed every 6 hours to reduce the risk of nosocomial infection, and once removed (within 12 hours), urine should be collected via cystocentesis and cultured. In systemically unwell patients, supportive care correcting electrolyte and acid–base derangements, administering antiemetics, antihypertensives, pain control medications, and nutritional support are important. Parenteral antibiotic therapy is initiated in systemically unwell patients (ampicillin at 20 mg/kg IV q.6 h. or ampicillin/sulbactam (Unasyn; Pfizer; New York (NY) at 30 mg/kg IV). Dose intervals should be increased in severely azotemic animals. Patients should be transitioned to oral doxycycline (5 mg/kg p.o. q.12 h. or 10 mg/kg q.24 h. for 2 weeks) once stable, as penicillins do not clear leptospires from the renal tubules or eliminate the patient's carrier state.

Prognosis is highly variable and dependent upon clinical signs at presentation and aggressiveness of medical therapy. The reported survival rate to hospital discharge is approximately 80%. Dogs with acute onset of clinical signs associated with icterus and disseminated intravascular coagulation (DIC), or dogs requiring but not receiving hemodialysis, have a poor prognosis. Dogs with subacute leptospirosis, with evidence of mild renal disease have a fair prognosis for recovery if treatment is instituted early and maintained for a minimum of 2 weeks. Recovered patients may have lasting chronic renal changes requiring long-term management and monitoring for chronic kidney disease.

Prevention

Vaccination is recommended for any dog in an endemic area and is advised for dogs with access to outdoors (yard, dog park, etc.). Vaccines are annual with a bacterin against the four most common *Leptospira* serovars currently diagnosed in dogs: *L. icterohaemorrhagiae*, *L. canicola*, *L. grippotyphosa*, and *L. pomona* being available in North America (see Table 21.1.4). Available vaccines are serovar specific and do not provide any cross-protection against other serovars. Initial immunization involves 2–3 injections at 2- to 3-week intervals beginning at 12 weeks of age.

Public Health Implications

Leptospirosis is zoonotic. Contaminated dog urine is infectious and poses a risk for both humans and other susceptible animals. Those working directly with animals are at increased risk of exposure as are immunocompromised people and children. Any hospitalized dog that is either suspected of having or confirmed to have leptospirosis should be handled appropriately (i.e., limit movement of patient while hospitalized, place warning signs on patient's cage, wear personal protective equipment (gloves, disposable gown, eyewear/facemask) when handling the patient, clean cages with disinfectant solutions that will inactivate leptospires (e.g., bleach, iodine-based products, accelerated hydrogen peroxide, quaternary ammonium, etc.). In patients receiving appropriate antimicrobial therapy, risk of infection decreases significantly after 72 hours of treatment. It is recommended that any other dogs living in the same household should receive oral doxycycline therapy for 2 weeks as exposure histories are probably similar.

TETANUS

Definition/Overview

Tetanus is a rare, noncommunicable, neurologic disease characterized by spastic paralysis of dogs and humans. It is caused by tetanus neurotoxin (TeNT), a potent neurotoxin produced by *Clostridium tetani*, an environmental soilborne, Gram-positive, sporulating, anaerobic bacterium. Infection and clinical disease often result from wound contamination with *C. tetani* spores.

Etiopathogenesis

Clostridium tetani is a ubiquitous organism found in the soil from all parts of the world. There is a higher incidence of infection in warm humid regions (i.e., West and Central Africa, Southeast Asia, India, the Pacific Islands, and the southern United States). Tetanus occurs after *C. tetani* spores contaminate a wound and secrete TeNT (i.e., tetanospasmin and tetanolysin). These toxins diffuse locally from the site of infection and bind with demyelinated nerve endings. Bound TeNT is internalized, routed to endocytic vesicles, and then undergoes retrograde axonal transport to neuronal cell bodies in the central nervous system (CNS). Within the CNS, TeNT binds irreversibly to inhibitory neurons preventing the regulated release of glycine and gamma-aminobutyric acid (GABA), allowing excessive firing of motor neurons producing rigidity and tetanic spasms of voluntary muscles. Recovery is dependent on the development of new axon terminals.

FIGURE 21.1.4 Generalized tetanus in this 5-month-old Airedale is characterized by profound limb and neck rigidity and erect ears.

Clinical Presentation

Clinical signs vary depending on severity of disease and are usually seen 5–10 days after exposure. Clinical disease appears as either a systemic (generalized) or localized disease process. These signs may last for several weeks. Generalized disease is characterized initially by ocular and facial abnormalities (contracted facial musculature, trismus, retracted lips, wrinkled forehead, rictus grin, miosis, enophthalmos, prolapse of the third eyelid). The ears are typically held close together and erect. Hypertonus of masticatory muscles is responsible for trismus, also known as "lockjaw." As the disease progresses, spastic paralysis accompanied by opisthotonos and tetanic spasming of the muscles of the trunk and upper and lower limbs develops (Figure 21.1.4). Hyperthermia can result from excessive muscular activity. The patellar reflex may be accentuated but may be difficult to assess because of muscle stiffness.

In localized tetanus, the muscles of the infected region become painful and stiff. Gradually, the opposite extremity becomes involved. With time, localized tetanus can become generalized. Affected patients can develop spasms when stimulated by touch, light, or noise.

Patients may also be affected by episodes of tachycardia (supraventricular or less commonly ventricular), systemic hypertension, alternating with bradycardia and hypotension. Death results from respiratory failure as a result of laryngeal, diaphragmatic, and respiratory muscle paralysis.

Differential Diagnosis

Muscle rigor and conformational changes associated with localized and generalized tetanus are characteristic of the disease. Differential diagnoses that should be considered include rabies, encephalitis, meningitis, toxins (e.g., strychnine), and trauma, particularly trauma involving the CNS.

Diagnosis

Diagnosis is based upon recognition of characteristic spastic paralysis accompanied by a history of a recent wound. Physical evidence of a wound or skin penetration may not be apparent on physical examination. Complete blood count often reveals a neutrophilic leukocytosis with a left shift. Creatinine kinase and aspartate aminotransferase may be elevated due to sustained recumbency and tetanic muscle spasming.

Identification of TeNT in biological samples is not indicated, as animals that develop signs of tetanus usually have low levels of TeNT. Likewise, there is limited utility of serological testing for antibodies to TeNT and isolation of *C. tetani* from contaminated wounds, as both procedures are laborious and have a low diagnostic yield.

Management

Treatment/Prognosis

Dogs with clinical signs require intensive supportive care. Severely affected animals with respiratory compromise due to excessive tetanic muscle spasms may need to be anaesthetized, intubated, and placed on positive-pressure ventilation. Those with mild clinical signs often respond well with minimal hospitalization time. In cases of generalized tetanus, intensive treatment may be as long as 3–4 weeks.

Therapy consists of:

1. *Antitoxin:* Immunization with either equine antitetanus serum (IV or IM) or human immunoglobulin-VF (IM). Tetanus antitoxin neutralizes unbound toxin or toxin that has yet to be formed. It does not bind to the toxin within the axon. Slow intravenous administration (5–10 minutes) is recommended in patients with acute disease (i.e., early stages), with therapeutic concentrations being reached faster compared with IM or SC administration. A test dose (0.1 mL) of antitoxin is recommended either SC or intradermally 15–30 minutes prior to IV administration, as IV administration is commonly associated with anaphylaxis. Development of a wheal at the site of injection may indicate antitoxin hypersensitivity; however, false-positive tests are known to occur. Affected patients should be pretreated with a glucocorticoid or an antihistamine prior to administration of the IV dose. Circumferential intralesional therapy and injections of small dose of antitoxin proximal to the wound may be performed (Table 21.1.10).
2. *Surgery:* Wound exploration and debridement may be indicated to remove foreign material and devitalized tissue for wounds as this may be a continued source of toxin. Prior to surgery, antitoxin should be administered, as further toxin may be released into the circulation with tissue manipulation.
3. *Antimicrobial therapy:* The goal of antimicrobial therapy is to eliminate *C. tetani* organisms and prevent further toxin production. Chosen antibiotics have good tissue penetration and have good efficacy against anaerobic organisms. Intravenous routes are preferred in critical dogs/cats with tetanus. Once eating, patients are transitioned to oral antibiotics (Table 21.1.10).

TABLE 21.1.10 Recommended therapeutics for tetanus

Drug	Dose	Route
Antitoxin		
– Equine antitoxin	100–1,000 U/kg	IV, IM, SC
– Human tetanus immunoglobulin	500–1,000 U per site 500–2,000 U near wound	Intralesional IM
Antimicrobials		
– Penicillin G*	20–100,000 units/kg q.6–12h.	IV, IM or SC
– Metronidazole (preferred)**	10–15 mg/kg q.8–12h.	IV p.o.
– Amoxicillin-clavulanate	13 mg/kg q.12h. 30 mg/kg q.8h.	IV IV
– Ampicillin-sulbactam	3–10 q.8–12h. 11–33 mg/kg q.8–12h.	IV p.o.
– Clindamycin		
Sedative and muscle relaxants		
– Phenothiazine		
– Chlorpromazine	0.5–2 mg/kg***	IV, IM, SC
– Acepromazine	0.01–0.07 mg/kg***	IV
– Barbiturates		
– Phenobarbital	2 mg/kg†	IV
– Benzodiazepines		
– Diazepam††	0.2–0.5 mg/kg	IV
– Midazolam†††	0.1–0.2 mg/kg	IV, IM
– Skeletal muscle relaxant		
– Methocarbamol	44 mg/kg‡	IV
– Anesthetic agents		
– Propofol‡‡	1–2 mg/kg	IV
Autonomic agents		
– Atropine	0.02–0.04 mg/kg	IV, IM, SC
– Glycopyrrolate	0.005–0.01 mg/kg	IV, IM, SC
Others		
– Magnesium	100 mg/kg	IV

* Potassium (aqueous), sodium salt, procaine salt.
Procaine salt given IM administered close to wound site.
Penicillin G 1440–1680 U = 1 mg.

** Bactericidal and able to penetrate anaerobic tissue.

*** Maximum dose IV of 3 mg in any dog.

† Every 20–30 minutes to effect and a maximum 24-hour dose of 24 mg/kg. If given at constant-rate infusion, use 1 mg/kg per hour.

†† Initial diazepam bolus dose may be as high as 0.95 mg/kg IV, followed by constant rate infusion of 0.2–0.4 mg/kg per hour.

††† If given at constant rate infusion, use 0.6–1.8 mg/kg per hour.

‡ Administer rapidly half of the estimated dose. Pause until animal starts to relax, then administer to affect. Do not exceed total cumulative dose of 330 mg/kg.

‡‡ If given at constant-rate infusion, use 0.5–2 mg/kg per hour for severe muscle rigidity and CNS excitability.

IM, intramuscular; IV, intravenous; p.o., by mouth; SC, subcutaneous.

4. *Sedative and muscle relaxants:* Muscle rigidity and spasming is controlled using mono or combination therapy drugs. These drugs indirectly control the hyperthermia resulting from uncontrolled muscle contractions. A combination of phenothiazines with barbiturates are effective in controlling convulsions, muscle stiffness, and opisthotonos. Benzodiazepines can be used in lieu of barbiturates. Methocarbamol, a skeletal muscle relaxant, may be used initially in severely affected animals to control muscle rigidity. After the patient is stabilized, this is replaced by either a phenothiazine/barbiturate or a phenothiazine/benzodiazepine combination. Adjunctive use of magnesium sulfate to help reduce tetanic muscle spasms has been utilized in veterinary patients. Muscle relaxation is facilitated by reducing calcium entry into presynaptic terminals at the neuromuscular junction and by decreasing the sensitivity of the motor endplates to acetylcholine.
5. *Autonomic agents:* Occasionally autonomic agents are required to control the cardiac rhythm as bradyarrhythmia (i.e., HR < 60 beats per minute) may occur. This type of arrhythmia is often self-limiting.
6. *Supportive care:* Patients should:
   i. Be hospitalized in a quiet, dark, well-padded environment with minimal stimulus.
   ii. Be repositioned every 4–6 hours to avoid the development of pressure sores/ulcers.
   iii. Have their urinary bladder frequently emptied (every 6–8 hours) via manual expression or catheterization to prevent urinary retention and secondary urinary tract infection.
   iv. Have a balanced nutritional plan formulated and be monitored while eating and drinking. Enteral (nasogastric/nasoesophageal tube, percutaneous endoscopic gastrostomy [PEG]/esophagostomy tubes) or parenteral nutrition should be considered as animals have problems prehending and swallowing food. Animals being tube fed are at risk of developing aspiration pneumonia.
   v. Antiemetics, prokinetics, and gastrointestinal protectants are also commonly utilized in patients with tetanus.

Complications associated with tetanus include the development of aspiration pneumonia secondary to either feeding a patient that is unable to prehend/swallow or due to the development of a hiatal hernia or megaesophagus. Other reported complications include respiratory failure, laryngeal paralysis, systemic hypertension, hyperthermia, rhabdomyolysis-induced acute kidney injury, and disseminated intravascular coagulopathy.

Prognosis

Prognosis is directly related to the degree of systemic involvement, with survival rates of 50%–92% being reported. Patients with localized tetanus (i.e., peripheral limb) have a better prognosis compared to patients with generalized tetanus.

Prevention

Tetanus toxoid is only administered to patients with acute-onset signs.

Public Health Implications

Tetanus is not a zoonotic disease.

VIRAL INFECTIONS

ADENOVIRUS-1 INFECTIONS (INFECTIOUS CANINE HEPATITIS)

Definition/Overview

Infectious canine hepatitis (ICH) is a systemic disease of dogs caused by canine adenovirus type 1 (CAV-1). Canine adenovirus type 1 also causes disease in wolves, coyotes, skunks, and bears, as well as encephalitis in foxes. The virus is a nonenveloped, icosahedral, double-stranded DNA virus that is genetically and antigenically related to canine adenovirus type 2 (CAV-2). Found globally, it commonly causes disease in dogs less than a year of age. It can survive in the environment for months at room temperature. Recently, CAV-1 has reemerged, sporadically causing a severe, often fatal disease.

Etiopathogenesis

Active infection results in the virus being shed in many bodily fluids (i.e., saliva, feces, and urine). Viral shedding in urine is long-lasting (up to 6–9 months post infection). Although the virus may persist in the kidney for several months post infection, urine contamination is not an important source of infection for susceptible dogs. Viral transmission is through close contact or indirectly through exposure to contaminated fomites (i.e., hands, utensils, and clothing). After oronasal exposure, CAV-1 rapidly replicates within the tonsils before disseminating to regional lymph nodes and the bloodstream via lymphatics. Viremia develops 4–6 days post exposure. The virus principally targets the liver and vascular endothelial cells within a variety of tissue (e.g., lungs, liver, kidneys, spleen, and eye). The virus replicates within the nucleus of these cells, forming virions, causing cell death that results in hemorrhage, inflammation, and necrosis. Clinical signs develop after an initial incubation period (i.e., 4–9 days), with an antibody response appearing after 7 days, which limits further tissue damage. There is good correlation between antibody titer and protection from infection. Pyelonephritis, anterior uveitis, and corneal edema may be observed in dogs recovering from acute illness. This is most likely due to viral persistence within the renal glomeruli, uveal structures of the eye (the iris and ciliary body), and the cornea, which triggers immune complex formation leading to inflammation.

Clinical Presentation

Infection is common in dogs < 1 year of age, with the most severe infections occurring in dogs from birth to 3 weeks of age. Three overlapping disease syndromes are recognized.

1. Peracute disease characterized by a brief illness (< 24–48 hours) followed by circulatory collapse, coma, and death.
2. Acute disease (most common) is associated with high mortality rates (approximately 10%–30%). Dogs with acute disease either recover or die within a 2-week period. Variable clinical signs include a transient or biphasic fever (> 40°C), tachycardia, enlarged tonsils, tachypnea, coughing associated with bronchopneumonia, inappetence, lethargy, weakness, vomiting, hematemesis, and diarrhea with or without blood. Bleeding diathesis due to vascular endothelial damage may be seen (e.g., petechial/ecchymotic hemorrhages and epistaxis). Neurological signs (e.g., seizures, ataxia, circling, apparent blindness, head pressing, and nystagmus) are rare in dogs. Corneal edema ("hepatitis blue eye") occurs in the first week of illness.
3. Chronic disease results from partial immunity. Death occurs weeks to months after initial infection.

Differential Diagnosis

Differentials for this disease should include poisoning, canine distemper virus, canine herpesvirus, canine parvovirus, fading puppy syndrome, leptospirosis, lymphoma, sepsis, and acute hepatitis.

Diagnosis

Although considered rare, infection should be suspected in any dog less than a year of age that is either unvaccinated or has a questionable vaccination history, who has concurrent fever, respiratory or gastrointestinal signs, or has evidence of hepatic disease. Likewise, any dog that develops corneal edema should have infectious canine hepatitis as a possible differential. Antemortem laboratory abnormalities are variable and may include a leukopenia (initially lymphopenia followed by neutropenia), anemia, and thrombocytopenia. During the acute viremic stage, there are variable changes to both direct/indirect liver function tests (bilirubin, albumin, glucose, ammonia) and liver enzymes (ALT, AST, and serum ALP). Coagulation defects consistent with DIC are possible.

Antemortem diagnosis is made based on virus isolation. In dogs surviving acute disease, CAV-1 may be able to be isolated from the urine, as the virus localizes and persists within the kidney for at least 6 months following initial infection. Alternatively, inclusion bodies may be discovered following cytologic examination of hepatic aspirates or impressions of hepatic biopsies.

Definitive diagnosis is achieved on postmortem examination. Dogs dying from acute disease will typically have findings of edema and hemorrhage of superficial lymph nodes and subcutaneous tissue, particularly in the area of the neck. Petechial and ecchymotic hemorrhage is commonly found throughout the abdomen. The gallbladder is characteristically thickened and edematous. Ocular lesions are characterized by anterior uveitis and corneal edema.

Management

Treatment/Prognosis

There is no specific antiviral therapy, with treatment being symptomatic and supportive until hepatocellular

repair can occur. Clinical management encompasses aggressive fluid therapy with isotonic fluids (e.g., lactated Ringer's solution), electrolyte and glucose supplementation where indicated, antiemetics, antacids, whole blood or plasma transfusions, and enteral nutrition. Monitoring the patient's hydration status is crucial, as patients are susceptible to fluid overload due to increased vascular permeability and hypoalbuminemia. Patients with severe hepatic necrosis may develop acute liver failure and subsequent hepatic encephalopathy. These patients should be managed with cleansing acidifying lactulose enemas, oral lactulose (in the absence of vomiting), and empiric antimicrobials (i.e., metronidazole, neomycin, ampicillin). Dogs with corneal edema without corneal ulceration can be treated with topical ophthalmic preparations of glucocorticoids and atropine to prevent glaucoma.

Prognosis is dependent on the immune status of the affected dog, severity of disease, and possibly the virus strain. Dogs recovering from the acute form of disease may develop chronic hepatitis and fibrosis or glomerulonephritis.

Prevention

Infection caused by CAV-1 has been controlled in domestic dog populations because of vaccination. Parenteral modified live CAV-2 vaccines (see Tables 21.1.4 and 21.1.5) are now used in vaccination programs due to the strong antigenic relationship between CAV-1 and CAV-2 and because modified live CAV-1 vaccines have historically caused adverse reactions. Maternal antibodies may interfere with immunization until puppies are 12 weeks of age. Vaccines are administered every 3–4 weeks from 6 weeks of age, with the last vaccine given no earlier than 16 weeks of age. Readers should be aware that a CAV-2 vaccine is currently offered in combination with *B. bronchiseptica* and canine parainfluenza for intranasal (mucosal) administration (see Table 21.1.4).

Public Health Implications

Canine adenoviruses do not pose a risk to human health.

CANINE INFLUENZA

See also Canine Infectious Respiratory Disease.

Definition/Overview

Canine influenza is a term used to describe disease induced by any influenza virus infection in dogs. These enveloped single-stranded RNA viruses belong to the family Orthomyxoviridae and have a complex natural history. Influenza A viruses, which are naturally found in the gastrointestinal tract of bird populations, can occasionally "spill over" into nonavian populations. Subtypes of influenza A viruses, which are specified by their antigenic surface glycoproteins, hemagglutinin (HA) and neuraminidase (N), are responsible for infection in dogs. H3N8 and H3N2 CIV are responsible for disease in dogs. H3N8, which originated from cross-species transmission of an equine influenza A virus, was first discovered in early 2004 in a racing greyhound kennel in Florida. H3N2 CIV, which originated in avian species, initially emerged from China and Korea in 2004–2005. Transfer of the CIV subtypes to dogs from birds and horses is thought to have been facilitated by the presence of hemagglutinin binding receptors on the bronchial/bronchioalveolar epithelial and tracheal/bronchial epithelial cells, respectively. Both diseases are associated with mild upper respiratory tract disease.

Etiopathogenesis

Transmission of the virus is via direct (i.e., oronasal contact or inhalation of aerosolized droplets) or indirect contact via fomites (e.g., clothing, footwear, food, and water bowls, etc.). Dogs housed in communal facilities (e.g., kennels, shelters, etc.) are at a higher risk of exposure to circulating CIV.

The virus enters and replicates in the mucosal epithelium cells lining the airways from the nose to the terminal airways. Viral replication leads to epithelial cell necrosis and destruction of the respiratory epithelial barrier, predisposing patients to secondary bacterial infection (e.g., *Bordetella bronchiseptica, E. coli, Klebsiella* spp., etc.). When affected, alveoli walls in the lower respiratory tract become thickened with inflammatory cells, which may lead to bronchopneumonia (< 20% of cases). The virus may also cause lymphocytic or neutrophilic rhinitis. Clinical signs usually develop within 2–5 days with viral shedding limited to 7–10 days post infection.

Clinical Presentation

There is no breed predilection. Immunocompromised dogs, puppies, and elderly dogs are at higher risk for infection. Approximately 80% of infected dogs will demonstrate clinical signs with two clinical syndromes being described. The first is a mild upper respiratory tract infection, which is usually self-limiting and manifests as a nonproductive dry cough, nasal discharge, fever, ocular discharge, lethargy, and anorexia. Up to 5% of dogs will develop more severe lower respiratory tract disease (i.e., pneumonia). Clinical signs associated with this form of disease include a productive cough, fever (104°F–106°F), increased respiratory rate and effort, purulent nasal discharge, lethargy, and anorexia. Hemorrhagic pneumonia and subsequent death has been reported in greyhounds with H3N8 infections.

Differential Diagnosis

Many dogs with H3N8 infection are subclinical. Those that do develop clinical disease are most likely to present with signs consistent with canine infectious respiratory disease (CIRD) complex. Viral pathogens associated with this disease complex include parainfluenza, adenovirus-2, respiratory coronavirus and herpesvirus-1 as well as others. Bacterial infections implicated in CIRD

include *Bordetella bronchiseptica*, *Mycoplasma* spp., and *Streptococcus zooepidemicus*. Additionally, in more severely affected animals, canine distemper virus, fungal or bacterial pneumonia are all considerations.

Diagnosis

No point-of-care rapid assay is available for the diagnosis of canine influenza. PCR is the preferred clinical diagnostic test. Samples for PCR should be collected early within the course of infection (i.e., within 4–5 days of clinical signs developing). Beyond that period, viral shedding declines and may have even ended. Pooled swab samples from multiple sites, including nose, conjunctiva, and pharynx, with a plastic handled swab is recommended.

In patients with clinical signs greater than 5 days, serology can be performed using acute and convalescent titers. Clinical diagnosis of recent infection in these patients is predicated on documenting a ≥ 4-fold rise in antibody titer over a 2- to 4-week period. A single, positive titer only denotes prior exposure or vaccination.

Management

Treatment/Prognosis

Treatment consists of symptomatic and supportive care based on the presenting clinical signs and laboratory tests. Most CIV infections are self-limiting resolving over several weeks. Dogs with a cough +/- nasal discharge should be isolated from other dogs for at least 7–10 days and have restricted exercise. Patients developing clinical signs (inappetence, fever with mucopurulent discharge) or radiographic evidence of pneumonia require more aggressive therapy. This will include intravenous fluids to maintain hydration, antimicrobial therapy for systemically unwell patients, supplemental oxygen, and nebulization/coupage. Ideally, antibiotic choices should be guided by tracheal wash or bronchoalveolar lavage diagnostics. In patients not undergoing this diagnostic testing, empiric broad-spectrum antibiotic therapy is recommended. Commonly used antibiotics include amoxicillin-clavulanate, azithromycin, doxycycline, and enrofloxacin. Cough suppressants should not be used in patients with a productive cough or evidence of pneumonia.

Prevention

Inactivated (killed) CIV vaccines against H3N2 and H3N8 CIV are currently available (see Table 21.1.4). These vaccines are noncore with at-risk dogs (frequently boarded dogs, dogs competing in sporting events, dogs frequenting dog parks or dog shows, or shelter animals) being recommended for vaccination. Vaccination does not prevent infection nor shedding of virus following exposure. However, vaccination will mitigate the severity of disease and decreases the period of virus shedding among exposed/infected dogs. Also recommended is isolation of infected dogs from other household animals for 28 days, restricting access into and out of kennels for up to 1–2 weeks following an outbreak, and regular cleaning and disinfection of both equipment and facilities with a 1:30 dilution of bleach or quaternary ammonium compounds.

Public Health Implications

Although human influenza viruses have been recovered from dogs and cats, CIV is not considered to represent a threat to human health.

CANINE ENTERIC CORONAVIRUS

Definition/Overview

Canine enteric coronavirus (CECoV) is a large, spherical, enveloped, single-stranded, positive-sense RNA virus that is named for the ultrastructural "crown-like" (corona) appearance of the spike proteins on the virion surface. It is a common infection in dogs and has a worldwide distribution. Although dogs of all ages can be affected, CECoV is considered to be a common cause of mild, self-limiting diarrhea in young puppies. More severe disease has been reported in combination with other pathogens, including canine parvovirus-2 and canine adenovirus-1. Although CECoV is highly contagious and capable of spreading rapidly among susceptible dogs, the overall incidence of disease is considered to be low.

Etiopathogenesis

Canine coronavirus is transmitted via the fecal–oral route. Disease is more prevalent in dogs housed in more densely populated (e.g., kennels or shelters) contaminated environments. Following ingestion, the virus infects and replicates within the cytoplasm of mature enterocytes (i.e., apical and lateral enterocytes of the intestinal villi). Incubation is 1–4 days. These cells then die and slough into the intestinal lumen. Loss of mature villi causes villus atrophy, leading to loss of normal digestive and absorptive functions of the small intestine. Small bowel diarrhea and dehydration are observed clinically. Concurrent coinfection with other viral pathogens (e.g., canine parvovirus) can lead to complications such as intussusceptions or more severe forms of disease (e.g., hemorrhagic enteritis).

Clinical Presentation

Canine coronavirus is a highly contagious disease. Disease most commonly effects dogs under 12 weeks of age. Clinical signs are usually mild and self-limiting with small intestinal diarrhea predominating (Figure 21.1.5). Feces are described as malodorous, orange in color, and may contain blood. In severe cases, dehydration, electrolyte imbalances, and vomiting may ensue. These clinical signs are difficult to distinguish from other causes of infectious enteritis (e.g., canine parvovirus).

FIGURE 21.1.5 Diarrhea is a common sign of canine coronavirus infection. (*Courtesy of Pfizer Ltd.*)

Differential Diagnosis

Infection can mimic several causes of mild enteritis of puppies (e.g., intestinal parasites, dietary indiscretion, and food intolerance). Other reasonable infectious disease differentials include viral disease (e.g., canine rotavirus, canine distemper virus, and canine parvovirus), bacterial enteritis (e.g., clostridial enteritis, *E. coli*, salmonellosis), and protozoal enteritis (e.g., coccidiosis, giardiasis, cryptosporidiosis). Affected puppies should also be evaluated for the presence of intussusception.

Diagnosis

Several commercial veterinary diagnostic laboratories offer real-time PCR assays for the detection of CECoV and other enteric infectious pathogens based on isolation of the virus in fresh feces. Assays may detect as few as 1,000 copies of viral DNA per milligram of stool.

Management

Treatment/Prognosis

Supportive therapy is the mainstay of treatment with CECoV infection inconsistently causing clinical disease. Disease is typically mild and self-limiting, with most cases not requiring therapeutic intervention. In severe cases, electrolyte and fluid replacement is indicated to counter the effects of fluid loss, acidosis, and rarely shock.

Prevention

Both killed and modified live CECoV vaccines are currently available. With disease commonly being mild and self-limiting and the fact that these vaccines provide only incomplete protection against CECoV infection, vaccination is not currently recommended. Furthermore, the value of vaccinating adult animals is limited by the fact that natural resistance to the disease occurs with age.

Public Health Implications

CCV is not zoonotic.

CANINE ORAL PAPILLOMA INFECTION (PAPILLOMATOSIS)

See also Chapter 18.

Definition/Overview

Canine oral papillomavirus 1 (CPV-1) is a small, nonenveloped, double-stranded DNA virus belonging to the Papillomaviridae family. It is host specific, spread by direct contact or contact with the virus in the environment, targeting keratinizing and mucous membrane tissue. The virus predominantly affects young dogs (≤ 2 years) causing cauliflower-like warts of the lips and mucocutaneous junctions. There is no sex or breed predilection. Malignant transformation of papillomavirus-induced tumors is extremely rare.

Etiopathogenesis

The virus infects basal cells of the skin through microabrasions. During this asymptomatic phase (4 weeks), the virus replicates within these cells. Clinical presentation is determined by the degree of cell proliferation induced by CPV-1, with most dogs (> 50%) having no clinical symptoms. Lesions develop when CPV-1 replication is amplified, resulting in hyperplasia development in the stratum spinosum and the generation of cauliflower-like wart growths of the lips and oral cavity with acanthosis and hyperkeratosis. Many dogs remain clinically well. Age and immune status of affected dogs may determine the outcome of infection, with spontaneous wart regression being reported young healthy dogs (i.e., 2–12 months), while older and/or immunosuppressed dogs have a higher risk of developing not only persistent clinical disease but also neoplastic transformation of lesions.

Clinical Presentation

Disease commonly occurs in young dogs (≤ 2 years), with the oral mucosa, lips, and mucocutaneous junctions being the most common tissue affected (**Figure 21.1.6**).

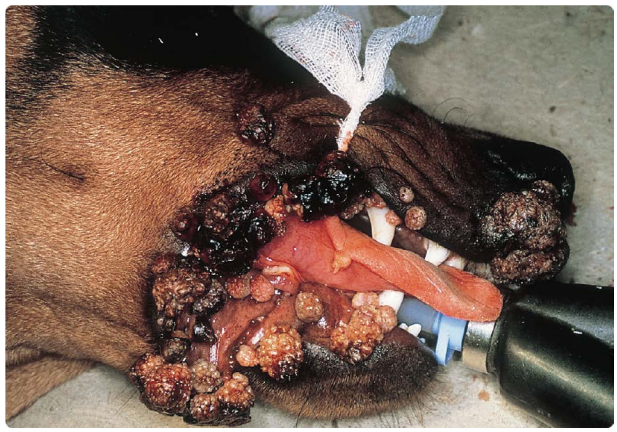

FIGURE 21.1.6 Advanced viral oral papillomatosis in a young Dobermann.

Other affected tissue includes the eyelids, palate, tongue, pharynx, epiglottis, and esophagus. Papillomas most frequently occur in small clusters with occasional severe manifestation being noted (Figure 21.1.6). Associated signs include secondary oral ulcerations/infection, halitosis, hypersalivation, minor bleeding of affected tissue, and discomfort. Dogs with severe disease may find it difficult or painful to eat or have problems breathing.

Differential Diagnosis

Benign and malignant oral neoplasms (e.g., epulides, fibroma, hemangioma, hemangiopericytoma, and histiocytoma).

Diagnosis

Diagnosis is based on characteristic physical examination findings and the clinical history, which may negate further laboratory testing. In questionable cases, full-thickness excisional biopsies with adjacent normal tissue should be obtained to perform histologic examination. PCR assays to detect CPV-1 DNA can be performed on Cytobrush or biopsy samples.

Management

Treatment/Prognosis

Most papillomas will spontaneously regress over time (2–12 months) following their initial appearance. In papillomas that do not regress or cause problems due to their size or location, surgical excision, cryosurgery, or electrosurgery is indicated. This has been associated with increased recurrence. Anecdotally, it has been reported that simply crushing 5–15 of the tumors may provoke spontaneous regression and, thereby, shorten the course of disease. Prognosis of this disease is excellent.

Prevention

Most papillomas are self-resolving. Preventing close contact between an affected dog and a dog that has never had papillomas is advisable. Currently a commercial vaccine does not exist.

CANINE DISTEMPER VIRUS (DISTEMPER, "HARD-PAD DISEASE")

Definition/Overview

Canine distemper virus (CDV) is a single-stranded RNA virus belonging to the genus *Morbillivirus*, family Paramyxoviridae. It is highly contagious, causing severe multisystemic disease characterized by fever, respiratory disease, enteric signs, and neurologic disorders. Viral transmission is via direct animal contact with infected animals shedding viral secretions up to 2 weeks after acute systemic illness. The virus is quickly inactivated in the environment, being especially susceptible to disinfectants, UV light, drying, and temperatures > 50°C–60°C (122°F–140°F). At freezing temperatures, the virus is reported to survive for several weeks.

Etiopathogenesis

Canine distemper virus has a broad host range, primarily infecting carnivores as well as the giant panda and certain primates. Dogs are the primary host and the likely reservoir for infection. Infection can sometimes occur concurrently with canine infectious respiratory disease complex infections. In unvaccinated animals, CDV poses a significant health threat. In unvaccinated dogs, infection can occur at any age, with unvaccinated puppies between 3 and 6 months of age being most commonly affected once they have lost their maternally derived antibody.

Disease transmission from infected animals is via aerosol or microdroplet contact with the epithelium of the nose or oral cavity of naive animals. Transplacental infection can occur from infected dams. Once attached, the virus invades and multiplies within tissue macrophages spreading to local lymphatics, tonsils, and bronchial lymph nodes, which results in severe immunosuppression. The virus then disseminates throughout the body via the lymphatics, infecting the spleen, liver, and gastrointestinal tract (4–6 days post infection [PI]), followed by hematogenous spread to epithelial tissue and CNS tissue (8–9 days PI). Viral shedding into the environment initiates with epithelial colonization. Clinical signs and viral clearance are related to the virus strain and animal's immune response. Animals with an adequate immune system are able to eliminate the virus within 2 weeks of infection. Animals with a poor immune status have global dissemination of the virus to epithelial tissue of the skin, gastrointestinal, respiratory, and genitourinary tract among others, which ultimately results in death. Those animals mounting a poor immune response may develop secondary bacterial infections resulting in more severe clinical illness. Viral spread and persistence in the uveal tissue, neurons, and integument such as the footpads occurs in animals mounting an intermediate response.

Clinical Presentation

Clinical signs are variable and depend on strain virulence and animal's immune status. Greater than 50% of CDV infections may be subclinical because of an adequate immune response, resulting in clearance of the virus within 2 weeks. In animals demonstrating clinical signs, respiratory signs predominate. Initially in mild cases, there is a transient fever, lethargy, anorexia, and leukopenia corresponding to immunosuppression at 3–6 days PI. This is usually accompanied by coughing, dyspnea, and discharge from the eyes and nose.

In dogs mounting a poor immune response, clinical signs are more severe with gastrointestinal signs of vomiting, diarrhea, and tenesmus accompanying the aforementioned clinical signs. Dehydration may develop due to persistent anorexia, vomiting, and diarrhea.

Central nervous system (CNS) signs may coincide with or can occur 1–3 weeks following recovery from systemic disease. Neurological signs, whether acute or chronic, are progressive and typically affect both recovery from infection and prognosis. Signs vary according to the area of CNS involved. Seizures, cerebellar, and vestibular signs accompanied by ataxia and myoclonus (i.e., involuntary rhythmic muscle twitching) are common. Focal facial seizures (i.e., "chewing gums") often occur in dogs developing polioencephalomalacia of the temporal lobes (Figure 21.1.7).

Other clinical findings may include enamel hypoplasia prior (Figure 21.1.8) to the eruption of permanent teeth and ocular signs of keratoconjunctivitis sicca, anterior uveitis, optic neuritis (associated with sudden-onset blindness), as well as retinal degeneration and necrosis involving both the tapetal and nontapetal fundus. On funduscopic examination, chronic inactive retinal lesions are seen as hyperreflective areas in the tapetum, often called "gold medallion lesions" (Figure 21.1.9). Young, growing, large-breed dogs between 3 and 6 months of age can develop metaphyseal osteosclerosis and hypertrophic osteodystrophy of the long bones.

FIGURE 21.1.7 A 3-year-old unvaccinated Pointer presented with acute-onset seizures followed by progressive neurologic signs and eventual coma.

FIGURE 21.1.8 Enamel hypoplasia in a 1-year-old dog that recovered from CDV infection at 3–4 months of age.

FIGURE 21.1.9 Hyperreflective tapetum in a dog that recovered from CDV infection.

Differential Diagnosis

Canine distemper, although rare, is associated with a complex array of clinical signs, depending on the individual animal. Alternative diseases to consider include rabies, pneumonia (a common secondary event), *B. bronchiseptica* infection, idiopathic epilepsy, hypoglycemia, CNS trauma, and renal failure.

Diagnosis

Canine distemper virus infection should be considered in any febrile puppy with multisystemic symptoms. Antemortem diagnosis is challenging when presented with a patient having only respiratory, gastrointestinal, or neurological signs due to insensitive laboratory diagnostic assays. Often a combination of laboratory tests is required, testing multiple specimens (blood, urine, conjunctival smears, and CSF) from different anatomic locations is required to establish a diagnosis. Conversely, distemper virus should be suspected in a young unvaccinated dog presenting with severe gastrointestinal, respiratory, and neurological signs, especially when myoclonus is present.

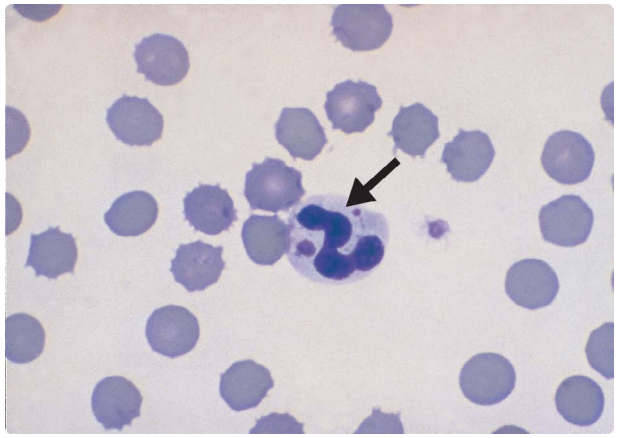

FIGURE 21.1.10 Distemper inclusion body (arrow) in a peripheral blood neutrophil collected from a dog with acute CDV infection.

Hematologic changes may include lymphopenia, thrombocytopenia, and regenerative anemia. Occasionally, CDV cytoplasmic and intranuclear inclusion bodies (Figure 21.1.10) may be found in peripheral blood smears, especially in early infection, or conjunctival swabs/scrapings of white blood cell (WBC) lines (mainly lymphocytes) and epithelial cells, respectively. Inclusion bodies are best elucidated in blood films stained with a quick Romanowski-type stain [e.g., Diff-Quik]. Examination of buffy coat smears and bone marrow aspirates may increase the chances of detecting inclusions.

Cerebrospinal fluid analysis may be normal in cases of acute, noninflammatory encephalomyelitis. Chronic infection may reveal an increased intracranial pressure causing a rapid flow rate of CSF, increased protein concentration (> 0.25 g/L [25 mg/dL]), and a mononuclear pleocytosis (> 10 cells/μL, primarily lymphocytes). Increased distemper-specific IgG in the CSF is definitive for infection, as it is locally produced, with vaccine-induced CDV antibody not usually being present in CSF.

Other diagnostic tests for CDV infection include immunocytology, immunohistochemistry, serum antibody testing, and virus isolation. These require special sample preparation and equipment and are not available in all diagnostic laboratories. PCR is not only sensitive and specific for diagnosing CDV but is also useful for differentiating a virulent from viral vaccine strain. Samples for collection and analysis include whole blood, serum, CSF, conjunctival swabs, buffy coat smears, respiratory lavage specimens, impression smears of tissue specimens, and urine sediment.

Immunofluorescent testing can be performed on conjunctival, tonsillar, respiratory, and genital epithelium. It should be noted that immunofluorescence is typically positive for only the first 3 weeks post infection in the conjunctival and urinary epithelium due to increasing antibody titers and virus neutralization. In dogs mounting an intermediate response, CDV may persist for ≥ 60 days in the skin, uveal tissue, CNS tissue, and footpads.

Management

Treatment/Prognosis

There is no specific anti-CDV therapy with treatment consisting of supportive care. Dogs with mild respiratory or gastrointestinal distemper may recover spontaneously without treatment. Supportive care consists of parenteral fluids, antiemetics, electrolyte supplementation, maintaining adequate nutrition, artificial tears, and managing secondary bacterial infections. Ideally, treatment for secondary bacterial pneumonia should be guided by tracheal wash or bronchoalveolar lavage diagnostics. Alternatively, empiric broad-spectrum antibiotic therapy using amoxicillin-clavulanate, azithromycin, and doxycycline as monotherapies or initiating combination parenteral therapy in patients with severe pneumonia using ampicillin and enrofloxacin is recommended. In those patients that do develop severe, progressive CNS signs, euthanasia should be recommended. For patients that develop seizures, myoclonus, and optic neuritis, anticonvulsant therapy and muscle relaxants should be considered along with anti-inflammatory therapy (i.e., corticosteroids) to reduce edema.

Prevention

Vaccination with either an attenuated live or recombinant vaccine is recommended (see Table 21.1.4). These vaccines are safe and are highly efficacious. While most manufacturers recommend three doses of vaccine between 6 and 16 weeks of age, the duration of immunity (DOI) following the initial booster vaccination (1 year following the last of the initial series inoculations) has been documented to persist for at least 5 years. Current guidelines recommend triennial administration of booster vaccine in adult dogs. Furthermore, dogs recovering from natural infection are expected to have lifelong immunity. Rarely, dogs vaccinated with the Rockborn strain of CDV have been reported to develop postvaccinal encephalitis. Postvaccinal encephalitis has been reported in neonatal puppies subsequent to the vaccination of pregnant dogs at or near parturition. Vaccination of pregnant dogs is not recommended.

In high-risk environments such as animal shelters, administration of a single dose of recombinant CDV vaccine to puppies given hours before shelter entry can provide protective immunity from severe disease despite the presence of maternal antibody.

Public Health Implications

CDV infection is not considered to be zoonotic.

CANINE PARVOVIRUS INFECTION

See also Chapter 9.

Definition/Overview

Canine parvovirus type 2 (CPV-2) is a common cause of acute canine enteritis with high morbidity and mortality

rates in untreated dogs worldwide. First recognized in the mid-to-late 1970s, this small, nonenveloped, single-stranded DNA virus has three variants (CPV-2a, CPV-2b, and CPV-2c), all with similar pathogenicity leading to indistinguishable clinical disease. Disease is common in dogs younger than 6 months of age and adults with insufficient immunity. It principally infects rapidly dividing cells of the gastrointestinal tract, bone marrow, lymphoid tissue, and cardiac myocytes. The virus, which is ubiquitous, can survive up to for more than a year in the environment. Exposure of naïve dogs to the virus occurs through contact with infected feces, vomitus, or fomites (e.g., clothing, floors, and utensils). Seasonal prevalence and breed predisposition are geographically variable. Vaccination along with good hygiene practice has been demonstrated to be crucial in prevention of infection.

Etiopathogenesis

All three variants (CPV-2 a, b, c) are able to cause clinical disease. There are a number of factors may precipitate or exacerbate parvoviral infection. These include a lack of protective immunity, comorbid conditions (e.g., intestinal parasites), and stressful environments (e.g., overcrowding, unsanitary living conditions). Breeds at risk for severe CPV infection include Rottweilers, Dobermann Pinschers, American Pit Bulls, Terriers, Labrador Retrievers, and German Shepherd Dogs. The reasons for this are unclear. Males are more prone to infection, with most dogs succumbing to infection during the summer. Transmission to susceptible dogs occurs directly (fecal–oral route) or indirectly (oronasal exposure) through either contact with infected feces, vomitus, or fomites (e.g., clothing, floors, and utensils). The incubation period is 7–14 days. Post exposure, the virus localizes and replicates within the lymph nodes (i.e., oropharyngeal and mesenteric) and thymus before disseminating and localizing into rapidly dividing cells of the gastrointestinal tract (i.e., tongue, oral cavity, esophagus, small intestine), bone marrow, cardiac myocytes, and lymphoid tissue. Viral shedding starts several days prior to the development of clinical signs and progressively declines over 3–4 weeks postexposure. Clinical signs are related to virus-induced destruction of rapidly dividing cells (i.e., intestinal crypt epithelial cells, thymus, lymph nodes, and bone marrow precursor cells) resulting in vomiting, diarrhea, dehydration, bacterial translocation from the gastrointestinal tract, profound leukopenia (mainly neutropenia and/or lymphopenia), metabolic acidosis (or alkalosis), systemic inflammatory response syndrome (SIRS), multiorgan dysfunction, and finally death.

Clinical Presentation

Clinical signs associated with CPV infection are highly variable, ranging from inapparent infection to acute fatal disease. Historically, affected dogs developed clinical signs associated with enteritis and myocarditis. Today, clinical signs associated with myocarditis are rare (Figure 21.1.11). Common clinical signs associated with acute enteritis include lethargy, inappetence, vomiting, and small bowel mucoid to hemorrhagic diarrhea with disease mostly seen in puppies (i.e., < 6 months of age). Affected animals may become dehydrated and hypovolemic due to excessive gastrointestinal fluid losses. Viral destruction of rapidly dividing cells may result in malabsorption of nutrients, loss of electrolytes, and gastrointestinal bacterial translocation with subsequent development of systemic bacteremia. Signs associated with this include pallor, prolonged capillary refill time, fever or hypothermia, abdominal discomfort, and neuroglycopenia. Small intestinal intussusception can occur, manifesting as a painful, firm, tubular soft tissue mass effect found on abdominal palpation.

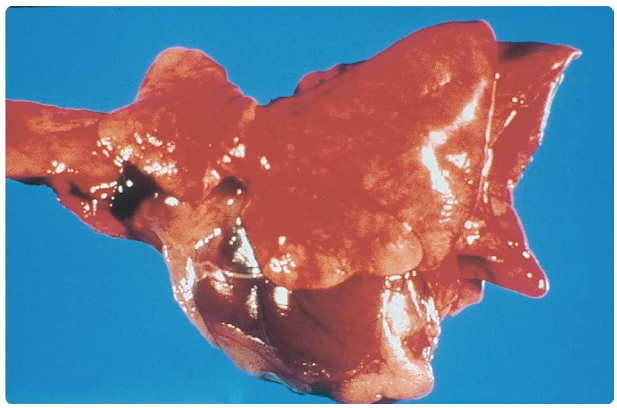

FIGURE 21.1.11 Viral myocarditis in conjunction with CPV in dogs is associated with ventricular arrhythmias, congestive heart failure, pulmonary edema, and death.

Differential Diagnosis

Differentials include bacterial, viral, parasitic, and protozoal enteritis, gastrointestinal foreign body, intussusception, pancreatitis, hypoadrenocorticism (Addison's disease), and poisoning or toxicity.

Diagnosis

Diagnosis is based upon a combination of clinical signs, physical exam findings, hematology, and point-of-care testing. All young dogs presenting with acute-onset diarrhea should be evaluated using an ELISA fecal antigen test. In acute disease, profound leukopenia and lymphopenia will develop within 7–10 days following exposure. The most common screening and detection test is a point of care immunochromatographic ELISA test. These tests are highly specific (few false-positive results); however, the period during which parvovirus can be detected in feces appears limited. Recent vaccination (< 10 days) with modified live virus can result in false-positive results. As such, any recently vaccinated puppy with clinical signs of vomiting and diarrhea should be viewed as a true infection or have further testing performed (i.e., PCR). Polymerase chain reaction tests are definitive, differentiating the recently

vaccinated from the truly infected by detecting virus particles in the feces. False-negative fecal ELISA tests can occur due to testing prior to viral shedding, low fecal viral loads, and higher serum antibody titers.

Management

Treatment/Prognosis

Outpatient treatment may be instituted for patients with mild clinical signs or when owners have financial constraints. This protocol recommends initial stabilization with parenteral fluids (15–45 mL/kg IV), electrolyte replacement, and glucose supplementation (2.5% dextrose at 1–2 mL/kg). Patients are then discharged and have subcutaneous crystalloid fluid therapy (40 mL/kg) divided q.8 h., cefovecin, once at 8 mg/kg SC once, buprenorphine 0.02 mg/kg SC q.6 h., and maropitant at 1 mg/kg SC q.24 h. Syringe feeding of Hill's a/d every 6 hours (1 mL/kg p.o.) is also performed. See Table 21.1.11 for drug therapy.

The mainstay of treatment is supportive, consisting of parenteral fluids to restore intravascular volume and maintain hydration and enteral nutrition (i.e., nasogastric tube feeding) to help prevent enterocyte atrophy and provide nutrients required for healing. Other treatments such as antiemetics (e.g., maropitant and ondansetron) decrease nausea and the frequency of vomiting events. Because patients are at risk for developing a bacteremia, broad-spectrum antimicrobials are recommended in all patients. Patients with abdominal discomfort secondary to vomiting, ileus, and possible intussusception are treated with a multifaceted, individualized approach based on the patient's level of pain. The initial choice of analgesic agent is an opioid (full or partial μ agonist). Then, depending on the severity of pain, an NMDA (N-methyl-D-aspartate) antagonist (e.g., ketamine) and/or a local anesthetic agent (e.g., lidocaine) may be added adjunctively as intravenous constant-rate infusions.

To restore the fecal microbiota, fecal transplantation from a healthy host has been found to resolve diarrhea earlier, decrease the length of hospitalization, and improve survival (10 g of feces diluted in 10 mL of sterile 0.9% saline).

Survival rate ranges from 60%–90% with prognosis being dependent upon the severity of clinical signs at presentation. Patients that are severely dehydrated, hypovolemic, lymphopenic, and hypoalbuminemic have a poorer prognosis. Likewise, concurrent comorbidities are associated with a poorer prognosis.

TABLE 21.1.11 Drug therapy for parvovirus infection

Drug	Dosage
Antibiotic	
– Ampicillin	20–40 mg/kg IV q.8 h.
– Ampicillin-sulbactam	30–50 mg/kg IV q.6–8 h.
– Cefovecin	8 mg/kg SC once
– Cefoxitin	20–30 mg/kg IV q.8 h.
– Enrofloxacin	10 mg/kg IV q.24 h.
– Metronidazole	10 mg/kg IV q.8 h.
Antiemetics	
– Ondansetron	0.5 mg/kg IV q.8 h.
– Maropitant	1 mg/kg IV, SC q.24 h.
Analgesia	
– Butorphanol	0.1–0.2 mg/kg/h
– Buprenorphine	0.01–0.02 mg/kg IV q.8 h.
– Methadone	0.1–0.2 mg/kg IV q.6 h.
– Morphine	0.1–0.2 mg/kg IV, IM, SC q.8 h.
– Hydromorphone	0.1 mg/kg IV, IM q.8 h.
– Fentanyl	1–5 μg/kg/h IV CRI
– Ketamine	5–20 μg/kg/min IV CRI
– Lidocaine	25–50 μg/kg/min IV CRI
Antiparasitic drugs	
– Pyrantel pamoate*	5–10 mg/kg p.o. q.24 h. (repeat in 7–10 days)
– Fenbendazole**	50 mg/kg p.o. q.24 h. for 3–5 days
– Sulfadimethoxine†	50–60 mg/kg p.o. q.24 h. for 5–20 days
– Metronidazole††	10–30 mg/kg p.o. q.12 h. for 5–7 days

* Efficacy against *Toxocara canis* and *Ancylostoma* spp.

** Efficacy against *Giardia duodenalis, Ancylostoma* spp., *Trichuris vulpis*, and *T. canis.*

Repeat fenbendazole dose for *T. vulpis* in 3 weeks then again in 3 months.

† Efficacy against *Isospora* spp.

†† Efficacy against *G. duodenalis*.

Prevention

Effective immunization programs provide effective protection of individual pet patients and decrease the susceptible population of animals (i.e., provide "herd immunity"). Today, all CVP vaccines are attenuated (modified live) virus (see Table 21.1.4). These vaccines provide prolonged (7 years or longer) immunity. Three doses of vaccine are recommended between 6 and 16 weeks of age. A booster dose is administered 1 year later, then every 3 years thereafter. In dogs that are 16 weeks or older, two doses 2–4 weeks apart are generally recommended. Isolation of new puppies is essential to prevent exposure to CPV. Puppies should not be exposed to other dogs until the puppy has received its full series of vaccinations.

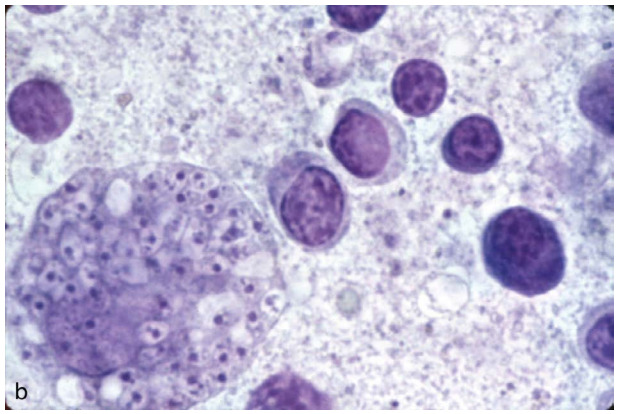
There are several potential reasons for vaccinated dogs to remain susceptible to infection. Maternally derived antibody interference with vaccination in young dogs and genetically predisposed non- and low responders (to vaccination) are among the most important. Subsequent to vaccination, transient lymphopenia (4–6 days) and shedding of vaccine virus are possible. Dogs tested with the ELISA fecal antigen test may actually have a transiently positive test result during the time of vaccine virus shedding. Immunity derived from natural infection and recovery is a minimum of 20 months and may last for life.

Public Health Implications

CPV is not zoonotic and poses no threat to human health.

CANINE RABIES

Definition/Overview



Rabies is regarded as a fatal viral zoonotic acute disease infecting both humans and animals. Disease is caused by an enveloped, bullet-shaped, single-stranded RNA virus of the *Lyssavirus* genus, family Rhabdoviridae. Infection leads to development of a fatal encephalitis in mammals, characterized by CNS signs resulting in an initial paralysis followed by death soon after. The virus is unstable in the environment, being readily inactivated by conventional disinfectants, ultraviolet light, and heat.

Etiopathogenesis

Rabies can infect all mammalian groups. Currently, wild animals, including raccoons, foxes, coyotes, and skunks, account for greater than 92% of rabies caused by animals. The incidence of wildlife rabies correlates with the incidence of rabies in dogs and cats. The virus enters the body through infected saliva via a bite from an infected animal. Transmission via other routes (e.g., scratch, mucosal exposure) is possible but rare. Once deposited in the subcutaneous tissues or muscles, rabies virus glycoprotein binds to postsynaptic nicotinic acetylcholine receptor of peripheral nerves travelling retrograde within axons towards the CNS. Once in the spinal cord, the virus disseminates throughout and radiates from the CNS, spreading along neuroanatomical pathways and to multiple organs (i.e., heart, gastrointestinal tract, skin, and salivary glands) via the parasympathetic nervous system. Within the salivary gland, there are high concentrations of rabies virus, which allows transmission to additional animals when bitten. The virus is excreted in saliva for a brief period of time, typically 1–5 days before onset of clinical signs and continues until death. Typically, the incubation period lasts 20–90 days.

There are two clinical forms: An encephalitic or "furious" form (80% of cases) and a paralytic or "dumb" form (Figure 21.1.12a). The underlying pathogenetic mechanisms of these are poorly defined; however, it is thought that the paralytic form reflects a greater burden of disease in the spinal cord, nerve roots, and peripheral nerves, whereas encephalitic form reflects greater involvement in the brain.

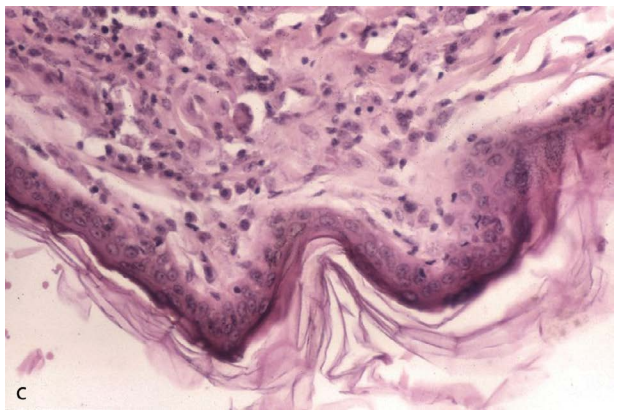


FIGURE 21.1.12 (a) Progressive lower motor neuron paralysis with cranial nerve deficits similar to those shown here can be early signs of "dumb" rabies in the dog. **(b)** Cytology showing Leishmania amastigotes within macrophage. **(c)** Histopathology of dog skin showing promastigotes in the epidermal region. (a, *Courtesy of M. Schaer.*)

Clinical Presentation

Due to the variation in clinical signs and disease progression, affected animals do not necessarily fit into one classification. The course of disease typically lasts 3–8 days. Recognized clinical stages of disease include the prodromal, furious, and paralytic stages. During the prodromal period, clinical signs are nonspecific and can include minor behavioral changes. These signs, if recognized, usually last 2–3 days in dogs. As dogs enter the excitatory phase ("furious" phase: 1–7 days), they may suddenly become vicious and behave erratically. These dogs will become restless and irritable, developing heightened sensitivities to visual and auditory stimuli. Some dogs may bypass this phase and progress directly from the prodromal to the paralytic stage. The paralytic stage is the final stage and is characterized by weakness and eventually paralysis. The area where the bite wound occurred is initially affected, followed by a progressive ascending paralysis affecting the neck and head. This phase lasts 2–4 days, ending in death from respiratory failure. The course of rabies typically lasts 3–8 days in dogs.

Differential Diagnosis

Rabies should be strongly suspected in any dog with acute onset of neurological signs associated with behavior change, especially in dogs that do not have a vaccination history. Other differentials include canine distemper, intracranial neoplasms, other causes of encephalitis and seizures, pseudorabies, toxins that cause CNS signs, sepsis, tetanus, and botulism.

Diagnosis

Definitive antemortem diagnosis is not possible with rabies being suspected in patients presenting with acute onset of behavioral changes and flaccid paralysis. Postmortem definitive diagnosis is made by demonstrating rabies virus antigen by direct fluorescent antibody (DFA) test in nervous tissue (brain and spinal cord). The entire head or spinal cord should be submitted as soon as possible after humane euthanasia to ensure an accurate diagnosis. Tissue should be chilled or refrigerated and not frozen. Other diagnostic assays available include PCR testing of nervous system tissue (e.g., brain, spinal cord, and CSF), histologic identification of Negri bodies (intracytoplasmic eosinophilic inclusions), and mouse/cell culture inoculation.

TABLE 21.1.12 Algorithm for dogs sustaining a bite from an unknown or unvaccinated animal

Scenario	Action
Vaccinated dog exposed to a confirmed or suspected rabid animal	Assessment, wound cleansing, and booster vaccination Quarantine and observance by owner for 45 days
Vaccinated dog overdue for a booster vaccine exposed to a confirmed or suspected rabid animal	If overdue for a rabies booster vaccine with past rabies vaccine documentation, quarantine and observance by owner for 45 days If overdue for a rabies booster vaccine without appropriate documentation, consult local public health authorities to determine quarantine period and utility of serologic testing to provide proof of an anamnestic response
Unvaccinated dog that has never been vaccinated exposed to a confirmed or suspected rabid animal	Euthanasia recommended

Note: If during quarantine, signs suggestive of rabies develop (e.g., paralysis or seizures), the animal should be euthanized and submitted for rabies testing.

Management

Treatment/Prognosis

No premortem tests or effective treatments are available for rabies. Dogs sustaining a bite from an unknown or unvaccinated animal should be immediately vaccinated and quarantined or euthanized as recommended (Table 21.1.12).

Eliminating feral animals or wildlife populations that harbor rabies is not economically feasible, nor is it socially or ecologically acceptable. As such, immunization is paramount to protect dogs.

Prevention

Inactivated (killed) vaccines are available for use in dogs (see Table 21.1.4). Rabies vaccination is a core vaccine in dogs and is the only companion animal vaccine required by law in most states. After vaccination, a rabies vaccination certificate verifying the vaccinate, the health of the vaccinate, the product used, the booster interval, and the administering veterinarian is issued to identify vaccinated dogs.

The first dose is given at a minimum of 3 months of age because of the potential interference by maternally derived antibodies. Regardless of the age at first vaccination, a single booster vaccine is repeated 1 year after the initial vaccine. Subsequent boosters are performed either annually or triennially depending on the labeled duration of immunity of the vaccine used. Where required, veterinarians are expected to follow state, provincial, or local law. Serologic testing can be done to establish an individual dog's response to vaccination but cannot be utilized to forgo revaccination where legally required. Some states may allow a medical exemption from a rabies booster vaccination. Testing may be required prior to shipment of dogs to rabies-free countries or regions of the world.

Public Health Implications

Any human that is exposed to rabies-infected saliva is at risk of developing rabies. Any wounds that are sustained should be washed with soap and water, and then professional healthcare should be sought. Healthcare professionals will decide if you need postexposure prophylaxis (PEP). These decisions are based upon the type of exposure, the animal you were exposed to, whether the animal is available for testing, and knowledge of rabies prevalence in the geographic area.

Postexposure prophylaxis consists of immune globulin and four doses of rabies vaccine over a 14-day period. The first rabies vaccine is administered immediately after exposure. For further information, refer to the CDC rabies website.

VECTOR-BORNE DISEASE

Definition/Overview

Canine leishmaniasis, caused by *Leishmania infantum*, is a zoonotic vector-borne disease caused by *Leishmania infantum*. Female phlebotomine sand flies act as vectors spreading disease primarily between animals and

secondarily to humans. It is endemic in more than 70 countries and is a common disease in the Mediterranean region and Central and South America. Clinical presentation is highly variable, with most dogs not developing clinical disease and remaining asymptomatic. Of the dogs that become clinical, disease ranges from self-healing cutaneous wounds (i.e., cutaneous leishmaniasis) to fatal disseminated visceral disease (i.e., visceral leishmaniasis). Cure is rare, and relapses are frequent, especially in endemic areas.

Etiopathogenesis

Leishmaniasis caused by protozoal *Leishmania* spp. is a disease affecting the mononuclear phagocyte system of mammals, with the dog being not only a major reservoir for infection but also playing a key role in transmission. Disease in dogs and cats is caused by *Leishmania infantum*, also known as *Leishmania chagasi*. Disease transmission occurs during female sandfly feeding. Leishmania parasites have a digenetic life cycle. The first is a promastigote flagellate form which resides within the midgut of sandflies. Here, these protozoa reproduce then migrate to the foregut and mouthparts of sandflies. Upon feeding, these promastigotes are inoculated into the dermis and are then phagocytized by macrophages. Within the macrophage, they then evolve into the amastigote form, replicating continuously within the phagolysosome until the macrophage ruptures. Liberated amastigotes then are free to disseminate via the lymphatics and blood and infect other macrophages rich tissue (i.e., spleen, liver, bone marrow, lymph node, etc.). Amastigotes are ingested by female sandflies during feeding and then revert back into the promastigote flagellate form over a week. Other modes of disease transmission include vertical transmission from bitches to puppies, venereal transmission, and transmission through blood transfusions.

Clinical Presentation

Clinical signs may develop months to years after initial inoculation. Clinical manifestation of disease is highly variable with parasite strain, genetics, and the host immune status all affecting the clinical course of disease. Cutaneous lesions are common and often noted prior to signs associated with systemic infection. Dogs generally present with peripheral lymphadenopathy and either localized or disseminated nonpruritic exfoliative dermatitis with or without alopecia, pustular dermatitis, nasal hyperkeratosis, nasal depigmentation, and onychogryphosis (abnormally long or brittle claws). Systemic signs of disease include anorexia, lethargy, weight loss, pallor, splenomegaly, and hepatomegaly. Other clinical manifestations of disease characterized by anemia, thrombocytopenia with subsequent bleeding/melena, lameness, joint swelling, uveitis, vasculitis, and glomerulonephritis culminating in nephrotic syndrome are thought to be the result of the development of autoantibodies and circulating immune complexes. Keratoconjunctivitis may result from the direct infection of the lacrimal gland by *Leishmania*.

Differential Diagnosis

Initial cutaneous disease differentials include demodicosis, bacterial dermatitis, dermatophytosis, discoid lupus erythematosus, follicular dysplasia, cutaneous lymphoma, nasal parakeratosis, pemphigus erythematosus, pemphigus foliaceus, sebaceous adenitis, seborrhea, sterile granuloma/pyogranuloma syndrome, systemic lupus erythematosus, and zinc-responsive dermatosis. Differentials for visceral leishmaniasis include babesiosis, canine distemper virus, ehrlichiosis, hepatozoonosis, and systemic lupus erythematosus.

Diagnosis

Successful diagnosis is dependent upon both the presenting clinical signs and epidemiological origin of disease. Common laboratory abnormalities found on complete blood count, serum chemistry, and urinalysis include a normocytic, normochromic, nonregenerative anemia; hyperglobulinemia; and renal azotemia with proteinuria. Confirmational diagnostic tests include both direct testing to confirm the presence of the parasite and indirect testing to detect the host's response to the parasite. Diagnostic assays include cytologic or histopathologic examination of affected tissues, organism culture, PCR assays of infected tissue, and serology. In endemic areas, results from these tests may need to be interpreted critically in association with presenting clinical signs.

Fine-needle aspiration and skin scrapes should be performed on peripheral lymph nodes, papules, nodules, and ulcerative cutaneous lesions, respectively, to look for amastigotes within lesions (**Figure 21.1.12b**). Likewise, bone marrow, splenic, and hepatic aspirates may be performed to confirm a diagnosis of leishmaniasis. A simple skin biopsy of what appears to be normal-appearing skin can histopathologically demonstrate the promastigote stage of *Leishmania* (**Figure 21.1.12c**).

Biopsy and histopathology can be used to demonstrate the presence of *Leishmania* when cytology is negative. Besides conventional H&E staining, presence of amastigotes can be confirmed using immunohistochemistry, in situ hybridization, or PCR on formalin-fixed and paraffin-embedded specimens.

PCR may be performed on any sampled tissue or biologic fluid. PCR is a sensitive technique for the diagnosis of leishmaniasis when organisms are not routinely identified on cytology or histopathology. Conjunctival, oral, and nasal swabs are very sensitive for the detection of *Leishmania* spp. DNA, providing positive results earlier when compared to the sampling or other tissue or biologic fluid.

The most common serological tests to detect anti-leishmanial antibodies are immunofluorescent antibody test (IFAT), enzyme-linked immunosorbent assay (SNAP canine *Leishmania* antibody test kit, IDEXX Laboratories), and immunochromatographic POC testing. Sensitivity and specificity varies depending on the test chosen, with IFA and the SNAP antibody tests both being highly sensitive and specific for leishmaniasis.

Diagnosis using serology alone may prove difficult as the time for seroconversion can be long (i.e., approximately 5 months) and because the *Leishmania* vaccine elicits a long-standing low-to-medium antileishmanial antibody titer.

Management

Treatment/Prognosis

Cures are rarely achieved, and disease can recur after successful therapy. Treatment is ultimately aimed at eliminating disease and a cure; however, even if treatment does not provide a cure, it may increase life expectancy and improve quality of life in addition to reducing parasite load (Table 21.1.13). For reasons of public health and to prevent re-infection, ectoparasiticides that contain permethrin are recommended.

Drugs that either inhibit protozoal enzymes, interfere with protein synthesis, or damage protozoal DNA have been used with varying degrees of success. Clinical improvement, if observed, generally occurs within 1–2 months of initiating therapy. Clinical remission of disease is variable and has been reported in 65%–100% of patients using combination therapies, with recurrence rates of up to 10% being reported.

Prevention

Prevention should focus on preventing contact with sandflies either through physical barriers (fine-mesh nets in windows and kennels) or chemical barriers (repellents); the use of domperidone (Leisguard, available in Europe), a dopamine D2 receptor antagonist that activates phagocytic cells and enhances killing of the parasite; and through vaccination. Several commercial vaccines are currently available in other countries; however, they have low protective efficacy.

Public Health Implications

Leishmaniasis is a zoonotic disease. Dogs and cats serve as reservoirs for human disease. Each year it is estimated that there are 700,000–1.2 million new cases of cutaneous leishmaniasis and < 100,000 new cases of visceral leishmaniasis. People of all ages are at risk for infection, with the immunocompromised, people that are poverty stricken, and the malnourished being at a higher risk for infection. The World Health Organization currently recommends that people who are diagnosed receive effective, prompt treatment to reduce both the prevalence and the transmission of disease and that vector control, disease surveillance, and control of reservoir hosts should be utilized to reduce and interrupt disease transmission.

TICK-BORNE DISEASE

Tick-borne diseases are caused by etiologic agents that are transmitted from ticks to dogs. Such agents include *Ehrlichia, Anaplasma, Babesia, Rickettsia,* hemotropic

TABLE 21.1.13 Treatment recommendations for canine leishmaniosis

Drug	Dose protocol	Duration	Potential adverse effects
Allopurinol*	10 mg/kg p.o. b.i.d.	At least 6–12 months or until clinical and serological resolution of disease	Xanthine urolithiasis**
Amphotericin B deoxycholate	0.5 mg/kg IV twice per week	2 months	Nephrotoxicity
Lipid-complexed amphotericin B	3 mg/kg IV	Monday, Wednesday, Friday (optimal treatment length unknown)	Nephrotoxicity
Meglumine antimoniate†	75–100 mg/kg SQ s.i.d. or 40–75 mg/kg SQ s.i.d.	4 weeks	Nephrotoxicity Possibly myocardiotoxic in dogs
Sodium stibogluconate	50 mg/kg IV, SQ s.i.d.	3–4 weeks	Nephrotoxicity
Miltefosine	2 mg/kg p.o. s.i.d.	28 days	Gastrointestinal upset
Allopurinol + Meglumine antimoniate†,‡	10 mg/kg p.o. b.i.d. 100 mg/kg SQ s.i.d.	12 months 4 weeks	Urolithiasis and nephrotoxicity
Allopurinol + Miltefosine††	10 mg/kg p.o. b.i.d. 2 mg/kg p.o. s.i.d.	12 months 28 days	Urolithiasis and gastrointestinal upset
Marbofloxacin‡‡	2 mg/kg p.o. s.i.d.	28 days	–

* Most effective for the dermatologic form.

** Rare.

† Currently unavailable in the United States without federal and state permits.

†† Combination does not result in parasitologic cure.

‡ Treatment of choice. Treat until resolution of clinical signs and quantitative serology becomes negative.

‡‡ Reduced signs of clinical disease and parasite load.

TABLE 21.1.14 Common tick-borne diseases

Disease	Agent	Vector	Infected cell type	Geographic distribution
Ehrlichia canis	Rickettsial	*Rhipicephalus sanguineus*	Monocyte Macrophage	– Nationwide – Southern United States
Ehrlichia ewingii *Ehrlichia chaffeensis*	Rickettsial	*Amblyomma americanum*	Granulocytes	– Central – Southeast – North Atlantic coast
Anaplasma phagocytophilum	Rickettsial	*Ixodes scapularis* *Ixodes pacificus*	Granulocytes	– Northeast – Midwest – West Coast
Anaplasma platys	Rickettsial	*Rhipicephalus sanguineus*	Platelets	– Nationwide – South Central – Southwestern United States
Borrelia burgdorferi	Spirochete	*Ixodes scapularis* *Ixodes pacificus*		– Northeast – Midwest – West Coast – Southern Canada – Recent expansion in Mid-Atlantic
Large-form *Babesia*	Protozoan	*Rhipicephalus sanguineus* *Dermacentor reticulatus*	Red blood cells	– Nationwide
Small-form *Babesia*	Protozoan	*Haemaphysalis* spp. *Ixodes*	Red blood cells	– Nationwide
Rocky Mountain spotted fever	Rickettsial	*Dermacentor variabilis* *Dermacentor andersoni* *Amblyomma americanum* *Rhipicephalus sanguineus*	Endothelial cells	– South Atlantic region – Pacific region – West South-Central region

Mycoplasma, *Hepatozoon americanum*, and *Borrelia* species. Discussed in this section are the more common diseases transmitted to dogs (Table 21.1.14).

Etiopathogenesis

Most ticks that cause disease in dogs are a three-host hard tick (i.e., each stage feeds on a different host after molting) belonging to the Ixodidae family (Figure 21.1.13). After hatching, larval ticks and then nymphs feed on hosts for several days, dropping off and molting with each successful meal. After becoming an adult and feeding, adults are able to reproduce. Once they attach to the skin through biting mouth parts, ticks cement themselves into the skin. Blood feeding occurs usually within 24–36 hours after attachment. While feeding, ticks secrete anticoagulant and anti-inflammatory agents from their salivary glands to ensure their survival and avoidance of the host's immune response.

FIGURE 21.1.13 The nymphal and adult life stages of the brown dog tick *Rhipicephalus sanguineus*. (*Courtesy of D.J. Meyer.*)

For ticks to become vectors of disease, ticks must first become infected. This usually occurs when they ingest a blood meal from an infected reservoir host. At the time of feeding, the host's infection must be blood-borne. Once ingested, these microbes are phagocytosed by gut cells whereby they multiply and disseminate to other organs. Infection persists within ticks due to transstadial (i.e., molting) or transovarial (i.e., infected ova) transmission. Persistence varies depending on the microorganism involved.

When a naïve host is parasitized by a tick, microbes within the tick multiply and disseminate within the tick. Transmission of infection occurs via saliva, coxal fluid, regurgitation, contamination, or a combination of routes. Feeding disease transmission time is highly variable between ticks and microorganisms, ranging from 3–48 hours.

Clinical Presentation

Infection is usually seasonal, with disease prevalence dependent on environmental temperature, humidity, the activity of ticks, tick geographic distribution, and the presence of adequate hosts. Over the recent years, disease has spread due to environmental change (e.g., global warming) and urbanization. All dogs are susceptible to tick-borne disease with infection commonly producing both hematologic changes and single/multiorgan dysfunction (Table 21.1.15). Common clinical signs include fever, lethargy, anorexia, lymphadenopathy, chronic cyclic anemia, thrombocytopenia, polyarthropathy, uveitis, and vasculitis. Animals with an incomplete protective immune response may develop chronic subclinical disease, which can recrudesce with stress or concurrent disease. Infection with multiple microorganisms is possible through heavy exposure to ticks. These coinfections may explain variations in clinical presentation, pathogenicity, and variable response to medical therapy.

Diagnosis

Unfortunately, there is no diagnostic test that is 100% sensitive or specific. Diagnosis should be made based on geographical location, lifestyle, history, presenting clinical signs, hematologic abnormalities, and serology. Complete blood count, serum chemistry, and urinalysis have variable nonspecific changes. Sampling of peripheral blood is most often used to detect exposure to or infection with tick-borne disease agents. Commonly used tests include cytological examination (i.e., blood smear or buffy coat evaluation), serological testing, and PCR (Table 21.1.16).

Routine cytological evaluation of blood smears should be included for any patients suspected of having tick-borne disease. Although not considered a sensitive

TABLE 21.1.15 Clinical overview of tick-borne disease

Disease	Agent	Transmission	Incubation period	Clinical signs
Borreliosis	Spirochete	≥ 50-hour attachment	2–5 months	Fever, shifting-leg lameness, joint swelling, joint pain, malaise, and decreased appetite
Ehrlichiosis	Rickettsial	24- to 48-hour attachment	1–3 weeks	Fever, thrombocytopenia, hemorrhage, lymphadenopathy, splenomegaly, pancytopenia, peripheral edema, and uveitis
Anaplasmosis	Rickettsial	36- to 48-hour attachment	1–3 weeks	Lethargy, fever, lameness, vomiting, diarrhea, lymphadenopathy, splenomegaly, and bleeding tendencies
Rickettsia rickettsii	Rickettsial	≤ 48-hour attachment	2 days to 2 weeks	Fever, ocular signs (i.e., mucopurulent discharge scleral/conjunctival injection, scleral/conjunctival/retinal hemorrhage, conjunctivitis, uveitis, retinitis), generalized lymphadenopathy, splenomegaly, nasal discharge, tachypnea, peripheral edema, bleeding tendencies, and neurological signs (paresis, ataxia, hyperesthesia, vestibular signs, stupor, seizures, coma)
Babesiosis	Protozoal	2- to 3-day attachment	10 days to 3 weeks	Fever, hemolytic anemia, splenomegaly, lymphadenopathy, and thrombocytopenia

TABLE 21.1.16 Comparisons of testing for tick-borne disease

Diagnostic method	Benefits	Limitations
Blood smear evaluation	– Rapid in-clinic assay – Visualization of organisms confirms presence of *Anaplasma* species, *Ehrlichia* species, and protozoal organisms	– Low sensitivity – Unable to differentiate between *Anaplasma* and *Ehrlichia* species
Serologic testing	– Point-of-care (POC) tests detect antibodies to several different organisms in one assay – Follow-up panel from diagnostic laboratories to provide quantitative results – Paired (acute and convalescent) samples identify rising or falling titers (i.e., recent infection)	– Usefulness in acute infection – Antibodies test (confirms exposure but not active infection) – Cross-reactivity common especially IFA (includes nonpathogenic organisms)
Whole blood PCR	– Widely available – Sensitive for acute infections before antibiotics – Sensitive for identifying *Babesia* and *Hepatozoon* – More specific than serologic testing	– Lag time for results to come back – Less reliable when very low circulating organisms/chronic infection/antibiotic treatment – False-positive results due to presence of closely related agents

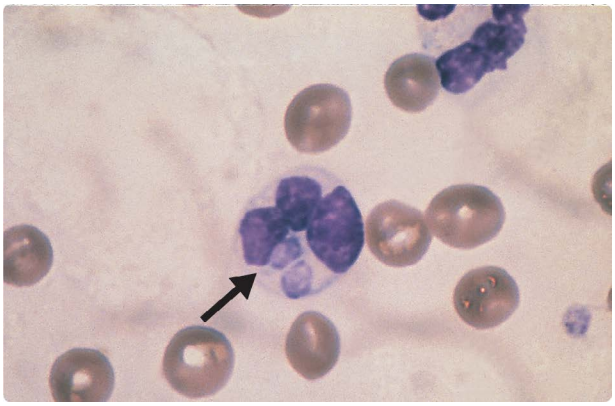

FIGURE 21.1.14 This blood smear, taken from a dog with ehrlichiosis, shows an *Ehrlichia* spp. morula (arrow) within the cytoplasm of a neutrophil. (*Courtesy of D.J. Meyer.*)

test, the ability to detect organisms is dependent on the phase of infection and skill of clinical pathologist, with organisms being abundant in the acute phase of infection. Cytology may demonstrate circulating organisms within red blood cells (e.g., *Babesia*), neutrophils (e.g., *Ehrlichia* and *Anaplasma*), monocytes (e.g., *Ehrlichia*), and platelets (e.g., *Anaplasma*) (Figures 21.1.14 and 21.1.15).

Polymerase chain reaction detects the presence of either DNA or RNA of infectious organisms. This testing is now widely available, easy to perform, and is both highly sensitive and specific. It is important to remember, however, that the organism must be present in the peripheral circulation to be detected. It is generally performed during the acute phase of infection, as organisms are usually present in their highest numbers. Although sensitive, a negative result does not rule out active infection.

Historically, antibody testing was used to diagnose tick-borne disease. Today, even though PCR is used more frequently in the definitive diagnosis of tick-borne disease, antibody testing is still used as both a screening test to detect the presence of organisms or to determine exposure of patients to tickborne organisms. Serological testing is via indirect immunofluorescence antibody (IFA) tests and commercially available

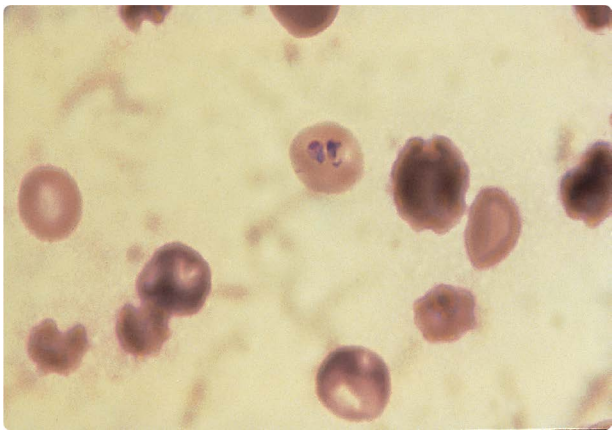

FIGURE 21.1.15 Canine *Babesia* organisms shown as intraerythrocytic protozoal organisms.

immunochromatography based point-of-care (POC) tests. These are used as part of routine annual vector-borne disease screening and as a diagnostic tool when dogs present with clinical signs. Initial POC screening rapidly detects antibodies against 5 tick-borne pathogens (*Ehrlichia canis*, *Ehrlichia ewingii*, *Anaplasma platys*, *Anaplasma phagocytophilum*, *and B. burgdorferi*) in a single sample of canine serum, plasma, or whole blood. Tests are sensitive only after seroconversion has occurred, meaning that it is of more value in diagnosing chronic infection, when PCR may be negative. Antibody detection against a tick-borne pathogen also indicates that dogs have mounted an immune response against the organism and does not necessarily translate to active infection. Active infection determined by IFA is denoted by a fourfold increase in antibody titer within 2–4 weeks with accompanying clinical signs. In clinic, POC ELISAs have similar performance to other commercial assays. Sensitivity may be increased by combining PCR and serology or demonstrating seroconversion using increasing convalescent titers. When considering positive results on a single sample, it is important to consider both the causative organism along with the pathophysiology of disease, geographic location, and presenting clinical signs. Cross reactivity is also possible between organisms of the same genus and genera. Following exposure, antibody titers decline slowly and may persist for long periods of time (i.e., months to years). To confirm whether disease/illness is being caused by one of these pathogens, in addition to the serologic evidence, a complete medical history, physical examination, and appropriate hematologic, biochemical, and PCR-based diagnostic tests may be needed.

Ehrlichiosis/Anaplasmosis

Cytology for microscopic identification of morulae in circulating neutrophils, monocytes, or platelets may be used to diagnose active infection. The sensitivity of this test is highly variable and dependent upon the stage of disease (i.e., associated with acute parasitemia). Positive point-of-care testing, with a history of tick exposure and concurrent clinical signs is usually supportive of a diagnosis; however, point-of-care assays are not able to distinguish *E. ewingii* from *E. canis* or *A. phagocytophilum* from *A. platys*. A negative point-of-care test in a symptomatic dog warrants further diagnostic testing (i.e., PCR or acute and convalescent titers) to confirm infection. For chronic ehrlichiosis, diagnosis may be difficult due to waxing and waning clinical signs and laboratory abnormalities. If clinicians are suspicious of chronic disease, it is important to realize that diagnosis is reliant upon a combination of diagnostic tests (POC test, IFA, PCR), accompanied by concurrent laboratory abnormalities (CBC, serum chemistry, and urinalysis) and clinical signs associated with disease. Treatment is often prolonged (i.e., 6–8 weeks). Successful treatment should not target seronegativity as antibody titers can remain positive or gradually decline (over 6–9 months) post treatment.

Babesiosis

Definitive diagnosis is usually made via cytology, serology, or PCR alone or in combination with each other. Whole blood examination or buffy coat smears are used to identify organisms within red blood cells. To maximize chances of parasite recovery, evaluation of either ear or toenail blood is recommended. Variable seroreactivity occurs with babesiosis. A fourfold IFA titer change (acute and convalescent) over time (2–4 weeks) indicates infection. Some dogs will not develop detectable antibody titers despite chronic infection. Polymerase chain reaction will confirm active infection and is able to identify which species of *Babesia* is causing disease. Serial sampling (≥ 2 samples obtained 2–4 weeks apart) will increase the sensitivity of PCR to approximately 100%. Successful treatment is reliant upon either two consecutive negative PCRs at 60 and 90 days post treatment.

Lyme Disease/Borreliosis

In endemic areas, ≥ 75% seropositivity can occur. This does not translate into clinical disease, with only 5%–10% of seropositive patients developing clinical signs. There is no pathognomonic test, with diagnosis being based upon a combination of tick exposure, history, clinical signs, exclusion of other disease, and response to treatment. The C6 serology POC testing determines not only exposure but also discriminates natural exposure from vaccination. Positive serology accompanied with clinical signs associated with disease translates to active infection. IFA and ELISA serology detect antibodies to Lyme vaccine and, therefore, should be interpreted with caution in vaccinated patients (i.e., false positive). Western Blot serology can differentiate natural exposure from vaccine antibodies but is difficult to perform and requires technical expertise. Polymerase chain reaction testing is used on tissue samples (e.g., skin or joint) but is an insensitive test when whole blood samples are used. Annual screening of previously treated dogs is recommended by qualitative ELISA. Follow-up complete blood count, serum chemistry, and urinalysis are also recommended for the rest of the patient's life to monitor for the development of proteinuria, identify cytopenias, and ascertain the patient's renal status.

Rocky Mountain Spotted Fever

Accurate diagnosis is important as canine infection can occur before or coincide with household/community outbreaks (i.e., dogs are sentinels for rickettsial disease in people). In patients with acute onset of clinical signs, paired acute and convalescent titers (2–4 weeks) should be performed, with a fourfold titer change indicating infection. Likewise, a single high titer of ≥ 1:1024 is consistent with an active infection. Detection of organisms via positive immunofluorescence of skin biopsies or PCR confirms active infection. PCR may be falsely negative due to low circulating organisms.

Treatment and Prognosis

Systemically well patients can be treated as outpatients once a diagnosis is made (Table 21.1.17). Educating owners about tick control and prevention is essential in management. Avoiding tick-infested areas whenever possible, mowing open grass areas regularly, removing overgrown plant debris, and pruning shrubs and trees are basic measures that can reduce both wildlife and tick numbers. Early removal of attached ticks by owners may reduce transmission. Year-round application of topical ectoparasiticides is critical for preventing infection and disease. In recent years, a number of studies have demonstrated decreased transmission of vector-borne infections in association with their use (Table 21.1.18).

Ehrlichiosis/Anaplasmosis

Rapid clinical improvement is notable within 24–48 hours of successful medical therapy. Short courses

TABLE 21.1.17 Drug therapies for tick-borne diseases

Causative organism	Drug	Dose	Length of treatment
Ehrlichia canis *Ehrlichia ewingii* *Ehrlichia chaffeensis*	Doxycycline Minocycline Rifampicin	5 mg/kg p.o. q.12 h. 5–10 mg/kg p.o. q.12–24 h. 10–15 mg/kg p.o. q.12 h.	30 days 30 days 7–21 days
Anaplasma phagocytophilum *Anaplasma platys*	Doxycycline	5 mg/kg p.o. q.12 h. or 10 mg/kg p.o. q.24 h.	14–28 days*
Lyme borreliosis	Doxycycline Ampicillin/amoxicillin	5–10 mg/kg p.o. q.12–24 h. 20 mg/kg p.o. q.8 h.	30 days
Rocky Mounted spotted fever	Doxycycline Chloramphenicol Enrofloxacin	5 mg/kg p.o. q.12 h. 30 mg/kg p.o. q.8 h. 3–5 mg/kg p.o. q.12 h.	7–14 days
Large-form *Babesia* Small-form *Babesia*	Imidocarb dipropionate Diminazene aceturate Atovaquone Azithromycin	7.5 mg/kg IM once 7 mg/kg IM 3.5 mg/kg IM once 13.3 mg/kg p.o. q.8 h. 10 mg/kg p.o. q.24 h.	Repeat in 14 days 10 days

* Optimal duration of therapy unknown.

TABLE 21.1.18 Ectoparasiticides for tick control

Product	Active ingredient	Route	Length of action
Activyl Tick Plus	Indoxacarb	Topical	1 month
Advantage Multi	Imidacloprid Moxidectin	Topical	1 month
K9 Advantix II	Permethrin Imidacloprid	Topical	1 month
Bravecto	Fluralaner	Oral Topical	3 months
Certifect	Fipronil (S)-methoprene Amitraz	Topical	1 month
Credelio	Lotilaner	Oral	1 month
Frontline Plus Frontline Tritak	Fipronil (S)-methoprene	Topical	1 month
NexGard	Afoxolaner	Oral	1 month
NexGard Spectra	Afoxolaner Milbemycin oxime	Oral	1 month
Preventic tick collar	Amitraz	Collar	3 months
Revolution	Selamectin	Topical	1 month
Seresto	Imidacloprid Flumethrin	Collar	8 months
Simparica	Sarolaner	Oral	1 month
Simparica Trio	Sarolaner Moxidectin Pyrantel	Oral	1 month
Trifexis	Spinosad Milbemycin oxime	Oral	1 month
Vectra 3D	Permethrin Dinotefuran Pyriproxyfen	Topical	1 month

of glucocorticoid therapy (prednisone/prednisolone at 1–2 mg/kg per day p.o. for 2–7 day) may be used in dogs with lameness, joint pain, uveitis, hemolytic anemia, thrombocytopenia, or vasculitis. Complete blood counts and serum chemistries are used to monitor therapy with neutrophil, monocytes, and platelet counts, typically increasing and normalizing within 24–48 hours and 14 days, respectively. Polymerase chain reaction assays can be used to monitor response to therapy, with assays being performed 2 weeks after therapy has ended.

Chronic *E. canis* infections are difficult to monitor and treat. Patients with chronic infection should be treated for 6–8 weeks with doxycycline. Success of treatment is measured by monitoring platelet counts and PCR. Serum antibody monitoring is not reliable for the assessment of successful therapy as antibody titers gradually decline over time (i.e., 6–9 months) to become negative. Organisms can also remain sequestered in the spleen after medical therapy.

Coinfection with other tick-borne organisms is possible, especially with *A. platys* and *A. phagocytophilum* infection. Because of this, some clinicians recommend treating these infections with 30 days of doxycycline.

Overall prognosis for acutely infected dogs is good. Spontaneous resolution of disease has been reported in some dogs with ehrlichiosis. If marked improvement is not seen within 24–48 hours after initiation of antimicrobial therapy, restaging for other diseases or infectious agents is recommended.

In dogs with chronic ehrlichial disease, prognosis is poorer. Negative prognostic indicators include pancytopenia, prolonged activated partial thromboplastin time, and hypokalemia.

Babesiosis

For babesiosis the mainstays of treatment are:

1. Elimination of the organism
2. Blood transfusion(s) to treat severe anemia
3. Supportive care to treat complications and metabolic derangements

A number of drugs and drug protocols have been used in the treatment of canine babesiosis (see Table 21.1.17). It is important to recognize that infectious *Babesia* spp. have dissimilar drug susceptibilities when treating patients. Treatment often reduces parasitemia and results in resolution of clinical signs. It is important to remember that organisms may not be eliminated and that dogs diagnosed with *Babesia* spp. should be considered permanent carriers of the infection.

Babesia canis, *B. rossi*, and *B. vogeli* are most successfully treated with imidocarb dipropionate (7.5 mg/kg IM once or 2 doses of 7 mg/kg IM, 2 weeks apart). This is the only FDA-approved drug for use in infected dogs in the United States. It is effective against acute infection; however, many patients continue to be carriers with subclinical disease. Side effects can include injection site pain, hypersalivation, lacrimation, gastrointestinal signs, and trembling. Diminazene aceturate may also be used against *B. canis*, *B. rossi*, and *B. vogeli*, but it is not FDA approved for treatment of canine babesiosis in the United States. In countries like South Africa where it can be used, treatment efficacy is variable, with the drug tending to be more effective against large-form *Babesia* spp.

Babesia gibsoni and small *Babesia* spp. are considered more difficult to treat than *B. canis vogeli* and large *Babesia*. Combining atovaquone (13.3 mg/kg, p.o. q.8 h. for 10 days) with azithromycin (10 mg/kg, p.o. q.24 h. for 10 days) can either reduce parasitemia or eliminate infection altogether in the majority of dogs.

Other antiprotozoal drugs that have been used with variable success include phenamidine, pentamidine, parvaquone, and artemisinin derivatives. Doxycycline, minocycline, clindamycin, enrofloxacin, and metronidazole have demonstrated variable antiprotozoal activity. Adjunctive use of glucocorticoids to counteract immune-mediated infection complications is controversial as it may worsen parasitemia. A 2- to 3-week tapering course of glucocorticoids may be used if necessary.

Lyme Disease/Borreliosis

a. Treatment of Lyme arthritis
For classical disease (i.e., fever, joint swelling, lameness, fever, and mild lymphadenopathy), doxycycline and minocycline are the preferred antimicrobials. Response is rapid, usually occurring within the first 24–48 hours. Optimum treatment length and drug dosage are unknown. However, due to the possibility of concurrent coinfection, 4 weeks of antimicrobial therapy is recommended. Amoxicillin, administered for 1 month, or cefovecin (Convenia), administered twice 2 weeks apart, are equally effective. Even with 4 weeks of antimicrobial therapy, some dogs do not clear *B. burgdorferi* organisms. Concurrent analgesia (e.g., gabapentin) should be evaluated on a case-by-case basis. Nonsteroidal anti-inflammatories should be avoided as glucocorticoids are indicated in cases of immune-mediated polyarthropathies in nonresponsive dogs. In dogs that either do not respond to therapy or that relapse, additional diagnostics (e.g., vector-borne disease diagnostic testing, orthopedic radiographs, and arthrocentesis) should be performed to exclude other potential causes such as infectious diseases, immune-mediated disease, soft tissue trauma (e.g., ligamental or meniscal tears), septic arthritis, or degenerative joint disease. All seropositive dogs with Lyme arthritis should be tested for proteinuria.

b. Treatment for Lyme-associated protein-losing nephropathy (PLN)
Proteinuria is seen in < 2% of *B. burgdorferi* seropositive dogs. When diagnosed, PLN associated with Lyme nephritis requires more aggressive therapy. Antemortem diagnosis is one of exclusion in *B. burgdorferi* seropositive dogs as there are no validated staining techniques to prove that the immune-complex glomerulonephritis (ICGN) is Lyme specific. A thorough diagnostic evaluation is warranted for both staging and to rule out other diseases causing the PLN. Besides antimicrobial therapy (see Table 21.1.17), treatment recommendations are based on standard treatment protocols for ICGN and PLN as recommended by the IRIS Canine Glomerulonephritis Study Group. This includes IV fluid therapy, a renin–angiotensin aldosterone system inhibitor (angiotensin-converting enzyme inhibitor or aldosterone receptor [RAAS] blocker), antithrombotics, protein- and phosphorus-restricted diets, omega-3 fatty acids, and antihypertensives as needed. In nonresponders with rapidly progressive disease, severe azotemia (serum creatinine concentration > 5 mg/dL) and severe hypoalbuminemia (serum albumin concentration < 2.0 g/dL), or if a renal biopsy documents immune-complex glomerulonephritis, immunosuppressive drugs (mycophenolate at 5 mg/kg p.o. q.12 h. increasing to 10 mg/kg if no gastrointestinal upset with tapering doses of prednisolone at 1 mg/kg p.o. q.12 h.) are recommended. Other immunosuppressants used to treat ICGN include azathioprine, cyclosporine, chlorambucil, and cyclophosphamide.

Efficacy of treatment is assessed by sequential monitoring of proteinuria, blood pressure, serum albumin concentration, and kidney function tests. At least 12 weeks of immunosuppressive treatment is recommended. Quantitative C6 testing can be used to monitor response to therapy. Pre- and post-treatment (6 month) C6 levels should be evaluated. Dogs experiencing ≥ 50% antibody reduction are considered to have responded to treatment.

c. Treatment of healthy nonproteinuric seropositive dogs
B. burgdorferi antibody testing is recommended annually for any dog living in endemic areas. In any dog that is seropositive, recommended screening tests include a complete blood count, serum chemistry, urinalysis, and urine protein-to-creatinine ratio. Currently, there is debate and controversy about the treatment of nonclinical, nonproteinuric, seropositive dogs. Current recommendations are that patients are not treated and that these patients are subsequently screened for proteinuria 2–3 times a year. In fact, even if dogs have been treated with antimicrobials, it is recommended that they are screened for proteinuria as clearance of microorganisms may not occur. If proteinuria is detected, screening of these patients should include urine culture, urine protein-to-creatinine ratio, blood pressure, complete blood count, serum chemistry, and diagnostic imaging (thoracic and abdominal).

Vaccination

There are several commercial vaccines available against Lyme disease (see Table 21.1.4) These vaccines stimulate the formation of antibodies against outer surface proteins normally expressed by *Borrelia* spp. when they reside within the tick. The overall outcome is halting of disease transmission through arresting of bacterial growth and the prevention of the organism invading the salivary gland of the tick. In endemic areas, vaccination is recommended for healthy seronegative dogs and healthy (nonclinical, nonproteinuric) seropositive dogs. Vaccination is not recommended for sick or proteinuric dogs. Prior to vaccination, all dogs should be tested for *B. burgdorferi*. Vaccination should not replace adequate, year-round tick control.

Rocky Mountain Spotted Fever

Antimicrobial therapy is initiated immediately based on clinical suspicion of disease. Both enrofloxacin and chloramphenicol are considered as equally effective as doxycycline, the treatment of choice. Doxycycline will eliminate *A. phagocytophilum*, *Ehrlichia* spp., and *B. burgdorferi*, which may be present as coinfections. Due to the acute nature and severity of disease, many patients are hospitalized. In order to avoid iatrogenic cerebral edema, caution should be exercised when administering parenteral fluids due to loss of vascular integrity. Prognosis is good to excellent in patients that are treated early and aggressively, with marked improvement usually noted within 24–48 hours of initiating therapy. In severely affected patients, CNS signs may persist even with successful therapy.

Public Health Implications

Canine ehrlichiosis is not a zoonotic disease; however, appropriate protective precautions (e.g., gloves) should

be taken when removing ticks or handling biological samples collected from dogs.

Human anaplasmosis, described as "influenza-like illness after a tick bite," closely resembles the disease in dogs. Disease is usually self-limiting in immunocompetent patients, typically resolving in 2 months. Severe illness tends to occur in the elderly or immunosuppressed. Dogs may act as sentinels for human exposure through mechanical carriage of ticks to humans. Appropriate protective precautions (e.g., gloves) should be taken when removing ticks or handling biological samples collected from dogs.

Babesia is not a zoonotic disease to immunocompetent people, with the majority of infections being mild or asymptomatic. Splenectomized people or people > 55 years of age are at risk of infection either through tick bites or, less commonly, through blood transfusions.

Lyme disease is the most common vector-borne disease of humans in the Northern Hemisphere; however, dogs do not pose a zoonotic risk to humans. Instead, they may act as environmental sentinels, indicating an increased risk of exposure in endemic areas.

Rocky Mountain spotted fever is a disease that can affect humans, with dogs acting as environmental sentinels for disease in endemic areas. Once a confirmed diagnosis has been made, veterinarians should inform owners that they are at risk of acquiring infection.

FUNGAL DISEASE

CANINE SINONASAL ASPERGILLOSIS

Definition/Overview

Sinonasal aspergillosis (SNA) is the second most common cause of nasal discharge in dogs and accounts for up to 34% of all chronic sinonasal nasal diseases. It is caused by *Aspergillus fumigatus*, a ubiquitous, saprophytic fungus. Organisms colonize and destroy tissue within the nasal cavity and frontal sinuses. Destruction is not directly related to fungal colonization but rather the host inflammatory responses and dermonecrolytic endotoxin produced by organisms. Mesocephalic and dolichocephalic dogs are commonly affected, with disease rarely disseminating.

Etiopathogenesis

Sinonasal aspergillosis is caused by several *Aspergillus* spp. *Aspergillus fumigatus* is most commonly associated with infection. Other fungal species capable of causing mycotic rhinosinusitis include *A. niger*, *A. nidulans*, and *A. flavus* as well as *Penicillium* spp. These organisms grow abundantly on organic debris (e.g., rotting vegetation, wood chips, compost, etc.). Pathogenesis of SNA is poorly understood. Impaired cell-mediated immunity and immunodeficiency are hypothesized as potential predisposing causes. This has not been definitively proven, with most dogs being systemically healthy. A history of facial trauma, nasal foreign bodies, and dental disease has been previously reported in some patients. Genesis of infection results from airborne conidia being inhaled, adhering to, and penetrating respiratory epithelial cells. The organism is able to evade host defense mechanisms through production of gliotoxin, which may reduce mucociliary function and impair phagocytosis.

Clinical Presentation

Dogs affected by SNA are young to middle-aged (3 months to 11 years) and have a chronic history of mucopurulent to purulent nasal discharge (unilateral/bilateral) that is refractory to empiric antibiotic therapy. Other signs reported include sneezing, epistaxis, facial pain, and depigmentation/ulceration of nasal planum, which is pathognomonic for disease (Figure 21.1.16). Other clinical signs that may develop depending on the severity of disease include severe facial deformity, epiphora, and seizures.

Differential Diagnosis

Differentials for chronic nasal disease include an extension of dental disease (i.e., oronasal fistula), neoplasia, rhinitis (lymphoplasmacytic and allergic), nasal foreign body, and cryptococcosis (rare in dogs). Bacterial rhinitis is a common secondary manifestation of intranasal disease and, regardless of the cause, should not be considered a primary diagnosis.

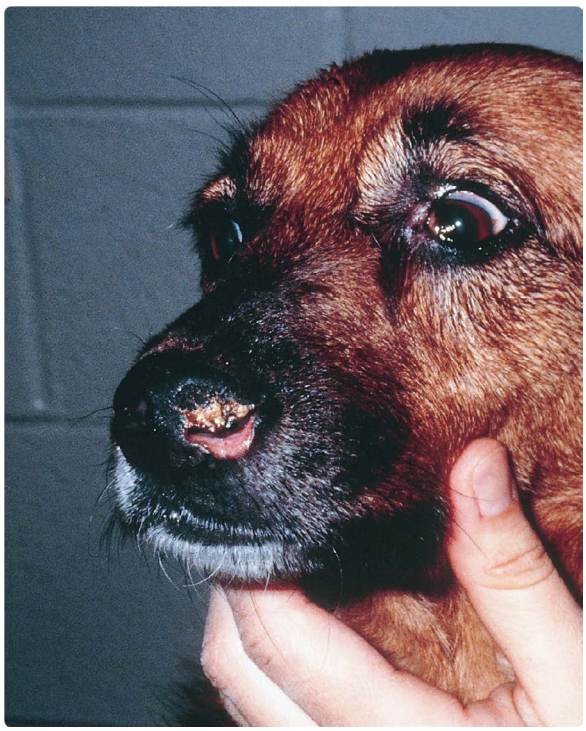

FIGURE 21.1.16 Erosion of the planum nasale in a 4-year-old mixed-breed dog with nasal aspergillosis of at least 6 months' duration.

Diagnosis

Confirmation of disease is based upon a combination of clinical signs, diagnostic imaging (computed tomography [CT] of the skull or skull radiographs), visualization of lesions with rhinoscopy/sinuscopy, histopathology, cytology, and fungal culture (Figures 21.1.17–21.1.19). Skull CT is not only a strong predictor of disease (approximately 90% accuracy), but it also allows assessment of cribriform plate integrity. Cytology and fungal culture alone are not good indicators of disease, as *Aspergillus* spp. and *Penicillium* spp. may occur as contaminants in the nasal cavity. Serological tests (*Aspergillus* antibody diffusion test, immunoglobulin G enzyme-linked immunosorbent assay) may be used in conjunction with the previous diagnostics but should not be used as the sole means for clinical diagnosis or patient management decisions. Other serological tests like the *Aspergillus* galactomannan antigen enzyme immunoassay (EIA) should not be used for screening potential cases of SNA. In the author's experience, serologic evidence of nasal mycosis is less reliable than direct visualization, culture, and cytology. Rhinoscopy/sinuscopy demonstrating turbinate destruction, mucoid nasal discharge, and fungal plaques is performed with either rigid endoscope or flexible pediatric bronchoscope. Biopsies obtained should have fungal culture performed as well as be evaluated cytologically and histologically.

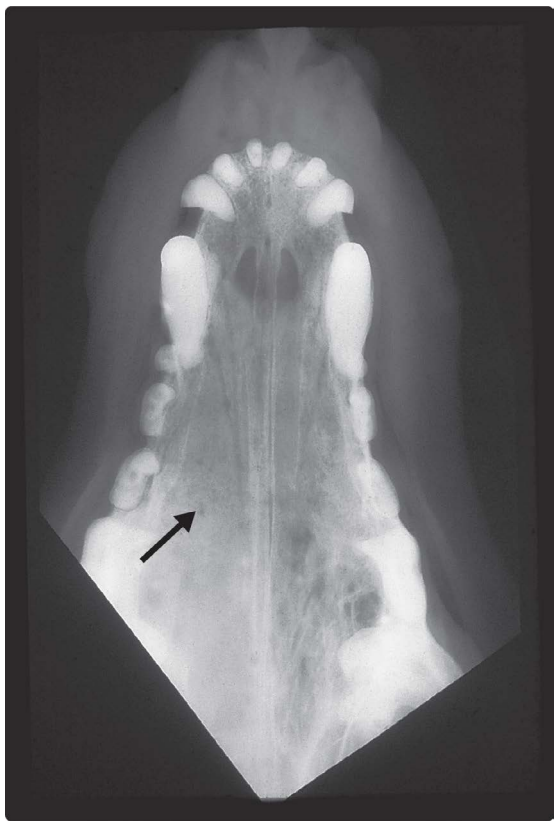

FIGURE 21.1.17 Occlusal radiographic projection of the nasal cavity of a dog with a 7-month history of nasal discharge not responsive to antibiotics. Note the loss of turbinate detail (arrow).

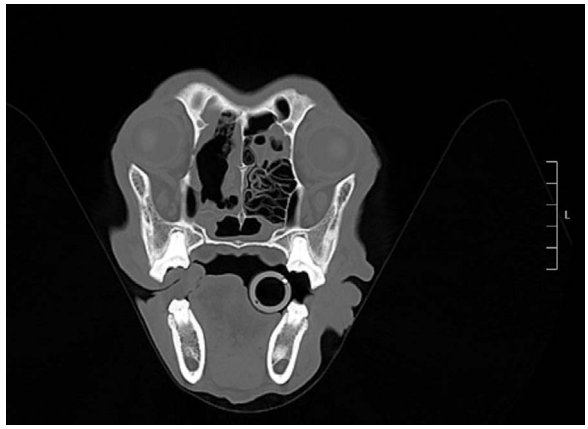

FIGURE 21.1.18 Transverse image of the nasal cavity at the level of the carnassial tooth of a 7-year-old MC mixed-breed dog with severe and near complete lysis of the ethmoid turbinates within the right nasal cavity. Minimal, multifocal osteolysis is also noted along the ventrolateral aspect (orbit) of the right frontal bone.

Management

Treatment/Prognosis

In recent years, treatment recommendations have changed for this disease. There are now multiple treatment options described. There is currently no consensus on the most effective therapy, with chosen therapies being based on personal or regional preferences. Historically, oral treatments with antifungal drugs (itraconazole 5 mg/kg p.o. q.12 h. for 10 weeks minimum or fluconazole 2.5–5.0 mg/kg p.o. q.12 h. for 10 weeks minimum) have generally poor-to-moderate efficacy. More recently, improved clinical remission rates have been observed using a combination treatment with posaconazole (5–10 mg/kg p.o. q.12–24 h.) and terbinafine (30–40 mg/kg p.o. q.24 h.) in dogs with refractory SNA disease.

Topical antifungal administration is the most widely used method and involves direct application of antifungals onto infected tissue. Various techniques have been described, ranging from surgically implanted

FIGURE 21.1.19 Rhinoscopic view of nasal aspergillosis showing fungal rhinitis. Of note are the characteristic gray–white plaques.

administration catheters in the frontal sinuses, endoscopic placement of temporary frontal sinus catheters, trephination of the frontal sinuses with instillation of depot therapy, to noninvasive techniques of rhinoscopy/frontal sinus sinuscopy with subsequent depot therapy. Today, 1% clotrimazole liquid flush followed by depot cream and 1%–2% enilconazole liquid preparations are most commonly used in both invasive and noninvasive techniques. Reported success rates are variable with 46.6%–85.7% having positive outcomes after the first treatment and 89.5%–100% of cases being cured after multiple treatments. Treatment protocols are aimed at filling the left and right nasal cavities with commercially available antifungal agent (i.e., 1% clotrimazole liquid/cream or 1%–2% enilconazole liquid) after debridement of the fungal plaques. Frontal sinus trephination may be utilized with this procedure. Sinonasal aspergillosis-associated lysis of the cribriform plate, lysis of the floor of a frontal sinus, or both is not necessarily a contraindication to topical therapy as long as potential adverse effects from the therapy are discussed with owners.

Resolution of clinical signs following treatment is considered a success. It is not uncommon for patients to have a persistent mild nasal discharge (serous to mucopurulent) due to either secondary bacterial infections or a chronic rhinitis/sinusitis from significant intranasal architectural changes. The author will usually repeat rhinoscopy/sinuscopy at 4–6 weeks post debridement and infusion to determine the success of therapy or whether a repeat treatment may be warranted. Antibody titers are not indicated to evaluate the response to treatment as they may remain positive for up to 5 years following successful treatment.

Prevention

Avoidance is impractical and unrealistic as *Aspergillus* spp. and *Penicillium* spp. are ubiquitous in the environment. There is no commercial vaccine to prevent aspergillosis or penicilliosis.

Public Health Implications

Infection is usually acquired from the environment and is not considered to be zoonotic.

Systemic Fungal Infections

Fungal pathogens are separated into primary (true) fungal pathogens and opportunistic pathogens. True fungal pathogens are able to cause disease in any animal regardless of their immune status. These fungi require a vertebrate host to complete their life cycle (i.e., provide nutrients, grow, and reproduce). Opportunistic fungi are ubiquitous in the environment, causing infection after accidental penetration of intact skin barriers or when animals are immunocompromised, have immunologic defects, or concurrent illness. Infections may be cutaneous, subcutaneous, or systemic.

True fungal pathogens are dimorphic and are converted from a nonpathogenic mold in the environment to a pathogenic yeast or spherule in the body. Typically, infections occur after inhalation of airborne conidia,

FIGURE 21.1.20 *Blastomyces dermatitidis* nasal granuloma on the nares of a young Rottweiler dog. (*Courtesy of M. Schaer.*)

although in some cases cutaneous inoculation of the fungus occurs (Figure 21.1.20). In veterinary medicine *Blastomyces dermatitidis* (blastomycosis), *Coccidioides immitis* (coccidioidomycosis), *Histoplasma capsulatum* (histoplasmosis), and *Sporothrix schenckii* are frequently encountered (Tables 21.1.19 and 21.1.20). Each of these organisms has been historically isolated from soil within specific geographic regions throughout the world. In recent years, these fungi have spread and are becoming more frequently recognized due to environmental change (i.e., global warming), rising populations in endemic areas, more travel, and with the increased use of immunosuppressants.

Opportunistic fungal pathogens are ubiquitous in the environment and have a preferred habitat independent of a living host. Virulence is inherently low, with organisms not sufficiently pathogenic to cause infection in healthy individuals. This changes when there is inhalation of spores or penetration of intact skin/mucosal barriers in immunocompromised patients or patients receiving immunosuppressive therapy. Infection can be localized, causing superficial cutaneous nonhealing wounds or can cause life-threatening systemic illness. *Aspergillus* spp. *and Cryptococcus* spp. are the most common of these fungal infections. Other opportunistic fungi of veterinary importance include phaeohyphomycosis, hyalohyphomycosis, and eumycotic mycetomas (Tables 21.1.19 and 21.1.20).

Etiopathogenesis

In susceptible animals, transition from the environment to the pathogenic form results in a change in cell shape, cell wall composition, antigenic molecules, and expression of virulence. This results in alteration and downregulation of an animal's immune response. Organisms are then able to reproduce and either locally disturb tissue structure and function, or disseminate to multiple organs through either lymphatic or hematogenous spread. Overt clinical signs are dependent on the organ system(s) infected. It is still unclear why some animals, subsequent to exposure, develop severe disseminated disease while others remain healthy. Although antibody does develop in response to infection, it is not protective. Recovery from mycotic disease is attributed to cell-mediated immunity.

TABLE 21.1.19 Systemic fungal organisms of veterinary importance

Dimorphic fungi	Infection	Transmission
Blastomyces dermatitidis	Blastomycosis	Inhalation Wound contamination
Histoplasma capsulatum	Histoplasmosis	Inhalation Ingestion
Coccidioides immitis	Coccidioidomycosis	Inhalation
Sporothrix schenckii	Sporotrichosis	Cutaneous/subcutaneous inoculation Inhalation
Opportunistic fungi	**Infection**	**Transmission**
Cryptococcus neoformans *Cryptococcus gatii*	Cryptococcosis	Inhalation
Aspergillus terreus *Aspergillus deflectus* *Aspergillus flavus* *Aspergillus niger*	Aspergillosis	Inhalation
Phaeohyphomycosis (pigmented)	Phaeohyphomycosis	Cutaneous inoculation
Hyalohyphomycosis (nonpigmented)	Hyalohyphomycosis	Cutaneous inoculation
Eumycotic mycetoma (black/white tissue grains within tissue)	Eumycotic mycetoma	Cutaneous inoculation Contaminated wounds

TABLE 21.1.20 Morphological characteristics and signalment of dogs affected by systemic fungi

Organism	Signalment		
	Breed	**Age**	**Sex**
Blastomycosis (5–20 µm)	Large breed (>15 kg) > small breed Sporting dogs & hounds (e.g., Coonhounds, Pointers, Weimaraners, etc.) Nonsporting breeds at increased risk (e.g., Dobermann)	2–4 years	Males > females (slight)
Histoplasmosis (2–4 µm)	Increased exposure in sporting/working dogs (e.g., Pointers, Weimaraners, and Brittany Spaniels)	2–4 years and 4–7 years more likely to develop disease	No sex predisposition
Coccidioidomycosis (10–200 µm)	No breed, age, or sex predilection		
Sporotrichosis (4–6 µm)	No breed predisposition	6 months to 12 years	No sex predisposition
Cryptococcosis (4–10 µm surrounded by up to 30 µm capsule)	German Shepherd Dog, Dobermann Pinschers, Great Danes, Cocker Spaniels	4 years	No sex predisposition
Systemic aspergillosis (2–3 µm)	German Shepherd Dog, Rhodesian Ridgeback	2–8 years of age (median 4.5 years)	Females > males
Phaeohyphomycosis Pigmented Hyphae (2–5 µm) Irregularly swollen up to 25 µm	No breed, age, or sex predilection		
Hyalohyphomycosis Nonpigmented Septate with acute angular branching	Most commonly affects young, large-breed dogs		
Eumycotic mycetoma	No breed, age, or sex predilection		

Clinical Presentation

Animals may present with nondescript clinical signs, including fever, anorexia, weight loss, and lethargy. Clinical signs are dependent upon the causative fungal organism and the organ system(s) affected. True fungal pathogens are more common in young dogs (1–5 years). Predominant clinical findings for each fungus are summarized in Table 21.1.21. Since the respiratory tract is the portal of entry for true fungal pathogens, coughing, dyspnea, and tachypnea predominate (Figure 21.1.21a, b).

Differential Diagnosis

Systemic mycoses can occur in dogs of any signalment, especially when they live in or have a travel history to endemic areas or have a history of immunosuppressive drug treatment. Infection should be suspected in dogs with fever; nodular, cavitary, or lobar pulmonary lesions (Figure 21.1.21a, b); osteolytic bone lesions; ocular inflammation such as uveitis or chorioretinitis; discospondylitis; enlarged lymph nodes or cutaneous nodules. Dogs refractory to empiric medical therapy should have a thorough diagnostic evaluation that includes appropriate tests for fungal disease.

Diagnosis

Table 21.1.22 represents an overview of the preferred diagnostic tests for systemic fungal infections. Cytology and histopathology are useful diagnostic tools. Cytopathology is an excellent tool for identifying disease if both the organism and concurrent granulomatous

TABLE 21.1.21 Summary of the predominant clinical findings for systemic fungal diseases

Infectious disease	Common clinical signs

Blastomycosis*	– Variable clinical signs (fever, lymphadenopathy)
	– Respiratory (common)
	  – Cough, dyspnea, exercise intolerance
	– Ocular disease (common)
	  – Anterior uveitis, endophthalmitis, optic neuritis
	– Skin disease (common)
	  – Cutaneous/subcutaneous nodules often with draining tracts

Histoplasmosis	– Fever, cough, dyspnea, diarrhea (large bowel > small, mixed), hematochezia (common) – Occasionally present with polyarthritis, peripheral lymphadenopathy, chorioretinitis, CNS disease, skin lesions
Coccidioidomycosis*	– Cough, weakness, lethargy, anorexia, weight loss, fever (103°F–106°F) (common) – Lameness with painful, swollen boney lesions – Localized lymphadenopathy, ocular lesions, and skin lesions, especially overlying bone lesions – Diarrhea
Sporotrichosis	– Variable clinical signs (anorexia, weight loss, fever, sneezing, and dyspnea) – Non painful, cutaneous, ulcerative, lesions with draining tracts (most common) – Bridge of nose, nasal planum, eyelids, and pinnae – Regional lymphadenomegaly

Cryptococcosis	– Variable clinical signs (anorexia, weight loss, and lethargy)
	– Respiratory disease (common)
	  – Sneezing, mucopurulent nasal discharge
	– CNS disease (common)
	  – Dull mentation, blindness, hypermetria, cranial nerve deficits (V, VII, and VIII)
	– Ocular disease (common)
	  – Granulomatous chorioretinitis, retinal detachment most common
	– Skin disease
	  – Nodular ulcerative draining lesions
	  – (Head, feet, nail beds, and mucous membranes)

Systemic aspergillosis	– Variable clinical signs (anorexia, weight loss, fever, lethargy, and peripheral lymphadenomegaly) – Vertebral pain, paraparesis, paraplegia, lameness with swelling, cutaneous draining tracts, AKI (most common)

Phaeohyphomycosis	– Cutaneous, ulcerative, lesions with draining tracts or visible mass (most common)
	  – Digits, pinnae, nasal planum
	– Regional lymphadenomegaly
	– Meningoencephalitis reported
	  – (Obtundation, seizures, tremors, ataxia)

Hyalohyphomycosis	– Manifests as either localized cutaneous/osseous infection or disseminated disease involving multiple organs (i.e., kidney, bone marrow, lymph nodes, liver, spleen, bone, intervertebral discs, and CNS)
Eumycotic mycetoma	– Localized granulomas forming “fungal grains” within the skin, subcutaneous tissue, or muscle with draining tracts

* Respiratory and nonspecific clinical signs common.

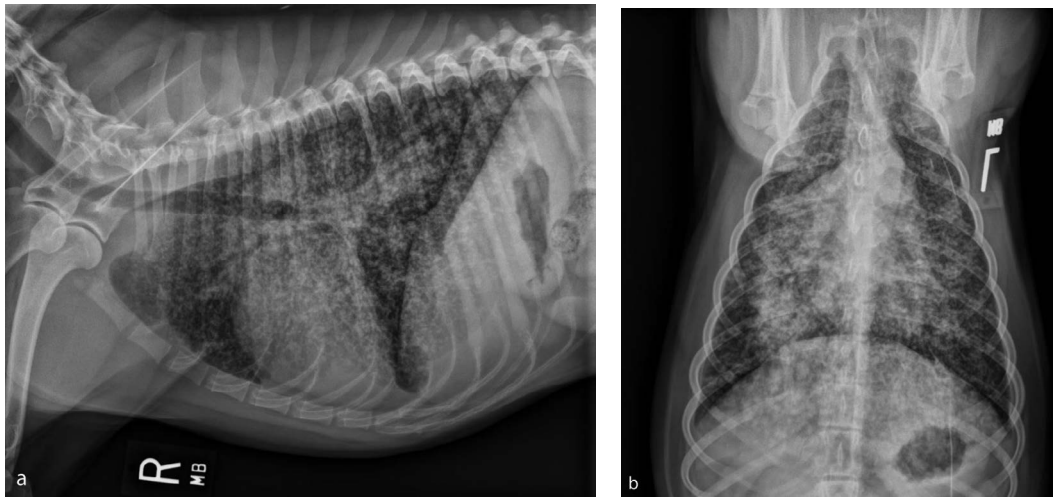

FIGURE 21.1.21 a, b Thoracic radiographs (lateral and DV) of 3-year-old female spayed Dalmatian with a week-long history of inappetence, lethargy, gagging, and coughing episodes. There is a severe, diffuse, miliary pulmonary pattern with a structured component characterized by multifocal, ill-defined, round, soft tissue opaque nodules measuring up to 2 cm in diameter.

inflammation are present (Figures 21.1.22–21.1.24). Samples for cytology include bone marrow, lymph node, and body fluid (BAL, CSF, urine, etc.) aspirates. Fungal morphologic features, including size, shape, budding pattern, presence or absence of septations, and branching pattern, provide valuable information when attempting to correctly identify the microorganism in question. Similarly, histopathology is used to describe both the fungal morphology, the presence or absence of tissue invasion, and the host reaction to the infection.

Fungal culture is not routinely performed in the case of true pathogenic fungi due to risk of exposure to laboratory workers and because fungal organisms are slow growing (i.e., long turnaround times between sampling and results). Culturing of opportunistic fungal infections from obtained clinical specimens (i.e., tissue, sputum, urine, wound, or blood) ensures isolation of the causative fungal agent and determination of the sensitivity of the isolated fungi to antifungal agents. Given that both cytology and histopathology may be invasive tests and give false-negative results, alternative tests have now been developed. Antibody tests are used for the diagnosis of coccidioidomycosis (Table 21.1.22). These tests are not useful in the diagnosis of histoplasmosis and blastomycosis due to their low sensitivity and specificity. More recently, antigen testing for systemic histoplasmosis, blastomycosis, and aspergillosis has become available through MiraVista Diagnostics, Indianapolis, IN. These tests are not only useful in the diagnosis of fungal infections but also useful for monitoring of disease response

TABLE 21.1.22 Preferred diagnostic assays for systemic fungal disease

[a] *Blastomyces* cell wall galactomannan quantitative antigen EIA (MiraVista Diagnostics, Indianapolis, IN). Sensitivity: Urine (93.5%) > serum (87%). Cross-reactivity with histoplasmosis and other fungal pathogens may occur.

[b] *H. capsulatum* antigen (MiraVista Diagnostics, Indianapolis, IN). Sensitivity: Urine > serum. Cross-reactivity with blastomycosis and other fungal pathogens may occur.

[c] Clinical sensitivity for diagnosis is low (< 40%). Antibody testing is preferred for initial testing.

[d] Latex agglutination assay for detection of cryptococcal polysaccharide capsular antigen. Highly sensitive and specific (> 95%) test for cryptococcosis in dogs and cats.

[e] *Aspergillus* galactomannan antigen ELISA assay highly sensitive for diagnosis of disseminated aspergillosis (serum or urine).

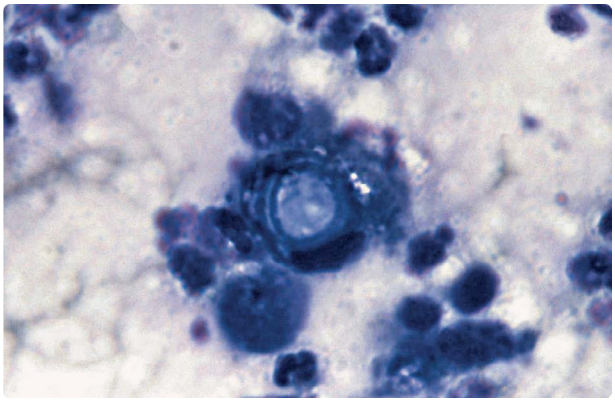

FIGURE 21.1.22 Microscopic appearance of a *Blastomyces* spore taken on a "touch prep" sample from the dog's nasal lesion. (*Courtesy of M. Schaer.*)

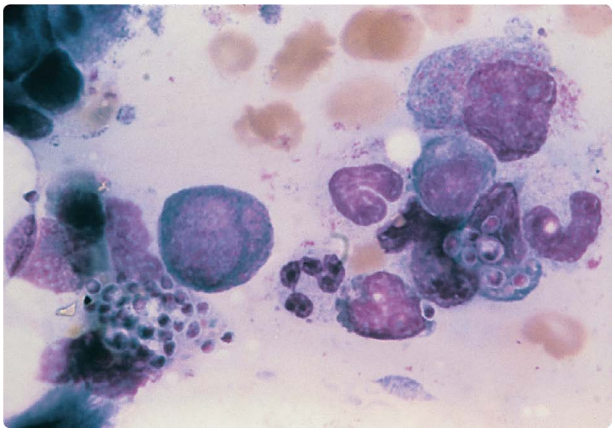

FIGURE 21.1.23 Clusters of *H. capsulatum* in the macrophages in the bone marrow of dog with diffuse histoplasmosis.

to antifungal therapy. Both urine and serum may be used as specimens, with urine being more sensitive. Cross-reactivity between different fungal antigens can occur, especially between *Blastomyces* and *Histoplasma* antigens, and among mold pathogen antigens. Other alternative diagnostics currently receiving increased attention include molecular diagnostics (e.g., real-time PCR assays), especially when dealing with opportunistic fungal infections or when classical methods for fungal detection (i.e., cytopathology, histopathology, and culture) have failed to identify fungal organisms.

Management

Treatment/Prognosis

Prognosis is variable and is dependent upon the immune status of the dog and whether disease is localized or disseminated. Cure is most likely in dogs with localized disease or in dogs where infection is secondary to medical immunosuppression. It should be noted that cost associated with treatment and disease severity may ultimately determine the prognosis. Systemic corticosteroids are indicated to reduce inflammation associated with severe disease. Nonsteroidal anti-inflammatory drugs (NSAIDs) are utilized when there is significant lameness and bone pain associated with infection. Triazole antifungals are considered "first-line therapy" for true fungal pathogens. These drugs inhibit ergosterol synthesis, resulting in cell wall damage, increased cell permeability, and eventual cell lysis. Triazoles commonly used include itraconazole, fluconazole, and voriconazole. Newer azoles (e.g., posaconazole) are generally cost prohibitive. Use of compounded azoles should be avoided due to variable drug concentrations within formulations. Single-agent itraconazole is considered first-line therapy in most situations, especially when bone lesions are present. In cases where there is CNS or urinary involvement, fluconazole is considered to be first-line therapy.

In dogs with rapidly progressive disease or when conventional antifungal therapy has failed, treatment with amphotericin B (AMB) should be considered. It is administered intravenously or subcutaneously. Adverse effects are associated with dose-dependent nephrotoxicity, attributable to the drug's vasoconstrictive and tubulotoxic effects. Newer lipid formulations are less nephrotoxic, allowing for higher cumulative drug doses and improved effectiveness.

Therapy for opportunistic fungal infection is challenging and often consists of aggressive surgical resection and prolonged medical treatment with antifungals (≥ 6 months). Immunosuppressants should be either discontinued altogether or tapered to the lowest effective dose possible to allow the immune system to fight infection. Failure to taper/discontinue immunosuppressant therapy may result in either progression of disease or patient death. Aggressive surgical excision with wide margins (≥ 2 cm) or amputation of a distal extremity is the treatment of choice for phaeohyphomycosis, localized hyalohyphomycosis, and mycetomas. New modalities, such as CO_2 lasers, have been utilized at the author's workplace for cutaneous fungal infections of the digits and nasal planum in both dogs and cats. The laser allows for precise ablation of the abnormal tissue without causing harm to the healthy tissues around the lesion, making it ideal for the digits, around the eyes, and nasal planum. Wounds created from these procedures are left open to heal through secondary intention. The treatment protocols for dogs infected with systemic mycoses are summarized in Table 21.1.23.

TABLE 21.1.23 Recommended treatment protocols for systemic mycotic infections

Mycotic infection	Treatment protocol
Blastomycosis[a]	**Mild-to-moderate cases** – Itraconazole[b] at 5 mg/kg p.o. q.12–24 h.[c] **Severe cases** – Amphotericin B (deoxycholate or lipid-complexed)[d] combined with Itraconazole at 5 mg/kg p.o. q.12–24 h.[e]
Histoplasmosis	**Mild-to-moderate cases** – Itraconazole[f] at 5 mg/kg p.o. q.12–24 h. **Severe cases** (i.e., pulmonary, acute disseminated, or CNS disease) – Amphotericin B combined with itraconazole – Fluconazole at 5 mg/kg p.o. q.12 h. can be substituted with itraconazole if CNS disease[e]
Coccidioidomycosis	**Mild-to-moderate cases** – Fluconazole at 5 mg/kg p.o. q.12 h. in patients with CNS disease – Itraconazole at 5 mg/kg p.o. q.24 h. in patients with bone involvement[g] **Severe or refractory cases** – Amphotericin B (deoxycholate or lipid-complexed) alone or in combination with an azole therapy (itraconazole/voriconazole/posaconazole)
Sporotrichosis	– Itraconazole at 5 mg/kg p.o. q.12–24 h. – Fluconazole at 5–10 mg/kg p.o. q.12–24 h. – Ketoconazole at 10–15 mg/kg p.o. q.12 h.[h] **Refractory cases** – Alternative antifungal therapy supersaturated potassium iodide (SSKI), potassium iodide at 2.5–20 mg/kg p.o. q.24 h.[i]

Cryptococcosis	– Itraconazole at 5 mg/kg p.o. q.12–24 h.
	Disseminated or CNS disease
	– Amphotericin B (deoxycholate or lipid-complexed) and fluconazole at 5–10 mg/kg p.o. q.12–24 h.
	– Alternatives to fluconazole
	  – Voriconazole 4–5 mg/kg p.o. q.12 h.
	  – Posaconazole 5–10 mg/kg p.o. q.12–24 h.

Aspergillosis	– Itraconazole at 5 mg/kg p.o. q.12–24 h. as monotherapy (2 months to 3 years survival) – Posaconazole at 5–10 mg/kg p.o. q.12–24 h. as monotherapy (6 weeks to 17 months survival) – Itraconazole at 5 mg/kg p.o. q.12–24 h. or voriconazole at 4–5 mg/kg p.o. q.12 h. or posaconazole at 5–10 mg/kg p.o. q.12–24 h. in combination with terbinafine at 30–40 mg/kg p.o. q.24 h. – Amphotericin B (deoxycholate or lipid-complexed) in combination with azole therapy (itraconazole/posaconazole/voriconazole)
Phaeohyphomycosis[j]	– Aggressive surgical resection in combination with itraconazole at 5 mg/kg p.o. q.12–24 h. or posaconazole at 5–10 mg/kg p.o. q.12–24 h. or voriconazole at 4–5 mg/kg p.o. q.12 h.
Hyalohyphomycosis[j]	**Immunosuppressed** – Taper/discontinue immunosuppression and combine with oral azole therapy (itraconazole, voriconazole, or posaconazole) **Localized disease** – Aggressive surgical resection in combination with itraconazole at 5 mg/kg p.o. q.12–24 h. or posaconazole at 5–10 mg/kg p.o. q.12–24 h. **Systemic disease** – Amphotericin B (deoxycholate or lipid-complexed) in combination with itraconazole at 5 mg/kg p.o. q.12–24 h.
Eumycotic mycetoma[j]	Surgery in combination with itraconazole at 5 mg/kg p.o. q.12–24 h.

[a] Duration of therapy based upon clinical signs, serial serological, and radiographic image monitoring (e.g., every 4–8 weeks).

[b] First-line therapy.

[c] Equivalent efficacy to 5 mg/kg p.o. q.12 h.

[d] Prior to each treatment, blood and urine should be collected for a CBC, renal panel, and urinalysis. Use three times a week (4 weeks) or until azotemia develops.
Deoxycholate may be administered IV or *SC.

IV protocol: Prior to and after treatment (1 hour), 0.9% NaCl administered IV at 1.5–2 times maintenance rate. Infusion lines should be flushed with D5W before treatment. 0.5 mg/kg of amphotericin B is transferred to a 500 mL bag of D5W and administered IV over 4–6 hours.

SC protocol: 0.8 mg/kg of amphotericin B is transferred to a 500 mL bag of 0.45% sodium chloride in 2.5% dextrose.

* Sterile injection site abscesses may form with this protocol.

Lipid-complexed administered IV.

Amphotericin B (3 mg/kg) is diluted to 1 mg/mL in D5W and administered IV over 1–2 hours.

[e] Supportive care with supplemental oxygen, nebulization, coupage, and tapering dose of systemic anti-inflammatory glucocorticoids (0.5–1 mg/kg prednisone equivalent).

[f] Itraconazole over fluconazole treatment.

[g] Itraconazole preferred in patients failing to respond to fluconazole treatment.

[h] More likely to result in relapses.

[i] Toxic side effects common (anorexia, vomiting, diarrhea, and lethargy).

[j] Discontinue or taper immunosuppressive therapy to the lowest effective dose.

Prevention

Preventing exposure to fungal organisms is difficult, especially in endemic areas, given that most fungal organisms are ubiquitous.

Public Health Implications

Both humans and animals can be infected with all of the organisms discussed in this section. There is no known transmission from dogs or cats to humans or other animals.

BACTERIAL INFECTIONS

FELINE RESPIRATORY TRACT

FELINE CHLAMYDIOSIS

See also Chapter 19.

Definition/Overview

Feline chlamydiosis is caused by the obligate intracellular Gram-negative organism *Chlamydia felis*. The organism, which is relatively unstable outside the host, is associated with upper respiratory and ocular (conjunctival) infections. Limited studies suggest that chlamydiosis infection comprises approximately 5% of upper respiratory infections in cats in the United States. In the United Kingdom, it is estimated that up to 30% of respiratory disease in cats is associated with *C. felis* infection.

Etiology

Genomic classification of Chlamydiaceae had divided this family into two genera: *Chlamydophila* and *Chlamydia*. However, full genome sequencing has resulted in a recommendation to revert to a single genus, *Chlamydia*.

Pathophysiology

There is still limited information on the pathogenesis of this infection in cats; however, chronic infections, particularly among households of cats, have been documented. *C. felis* has been isolated from experimentally infected cats for periods of up to 18 months, suggesting the development of a carrier state subsequent to recovery.

Clinical Presentation

C. felis infection in cats is most commonly associated with unilateral or bilateral conjunctivitis (acute or chronic) and chemosis (**Figure 21.2.1**). Ocular ulceration is not common and can increase suspicion of other infectious agent involvement (e.g., feline herpesvirus-1 [FHV-1]). Occasional sneezing (much less than that associated with viral upper respiratory disease) is also reported. Systemic illness is uncommon. Currently, there is no known direct association between *C. felis* infection and feline reproductive disease.

Differential Diagnosis

Infections with FHV, feline calicivirus (FCV), *Bordetella bronchiseptica*, and/or *Mycoplasma felis*; conjunctival injury.

FIGURE 21.2.1 Bilateral conjunctivitis in a 2-year-old cat with chlamydiosis.

DOI: 10.1201/9781003254591-42

Diagnosis

Polymerase chain reaction (PCR) detection of *C. felis* from conjunctival swabs is the preferred method of diagnosis. Since the organism is intracellular, it is important to submit swabs that contain sufficient cellular material. Cotton swabs should be used; plain sterile tubes without transport medium are required for transport. Cats suspected of having chlamydiosis could also be tested for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) infection.

Management

Treatment/Prognosis

Tetracyclines are regarded as the most effective antibiotics for use against *C. felis* infection in cats. Because this organism is known to disseminate, systemic treatment is more effective than local topical treatment. Oral doxycycline (5 mg/kg p.o. q.12 h. or 10 mg/kg p.o. q.24 h. for at least 4 weeks, or at least 2 weeks after clinical resolution, whichever is longer) can also be given. Oral doxycycline should be followed with 5 mL of water when administering this antimicrobial to cats due to esophagitis risk. Azithromycin treatment has not been shown to completely eliminate *C. felis* infection and is not currently recommended. In young kittens, clavulanate-potentiated amoxicillin may be preferred to avoid side effects.

Prevention

The most effective means of preventing chlamydiosis in cats is to limit exposure of susceptible kittens and cats to any cat with signs of respiratory or conjunctival disease. However, within catteries, animal shelters, and boarding catteries, preventing contact with infected carrier cats may be difficult or impossible to achieve. Both killed adjuvanted and live nonadjuvanted *C. felis* vaccines are approved for use in cats (Table 21.2.1). These vaccines appear to give reasonable protection against clinical signs of disease, but not against infection. The current recommendation for administration of *C. felis* vaccine is limited to those cats with known or suspected risk of exposure and in households with a history of disease.

Public Health Implications

C. felis is generally regarded as a pathogen unique to the cat. Isolated reports of human self-limiting conjunctivitis with *C. felis* have raised concern regarding occasional zoonotic infection, but *C. felis* is not regarded as an important zoonotic disease. *Chlamydia psittaci* primarily infects birds and is an important zoonotic agent of atypical pneumonia in humans via birds.

STREPTOCOCCAL INFECTIONS

Streptococcal species are occasionally considered as a cause of respiratory disease in cats. *Streptococcus canis* is most prevalent in cats and exists as a commensal but can be associated with upper respiratory tract disease, neonatal septicemia, abscesses, pneumonia, osteomyelitis, and polyarthritis. *Streptococcus equi* subsp. *zooepidemicus* has been recognized as an emerging feline respiratory pathogen associated with bronchopneumonia and pneumonia, as well as meningoencephalitis, often with a fatal course. Close confinement of cats, such as in shelters, appears to be a major risk factor. Horses are common carriers of this bacterium, and so contact with horses is a potential source of infection. PCR and culture are used for diagnosis, and treatment with broad-spectrum antibiotics (trimethoprim–sulfamethoxazole has been used) should be initiated as soon as possible and, if appropriate, adapted to the results of culture and sensitivity tests.

FELINE BORDETELLOSIS

Definition/Overview

Evidence that *B. bronchiseptica* is a significant primary respiratory pathogen of cats is lacking in the clinical literature but has been shown experimentally. The most compelling evidence supporting *B. bronchiseptica* as a respiratory pathogen in naturally infected cats is limited predominantly to clusters of kittens with concurrent viral upper respiratory infection, especially calicivirus. In these cases, *B. bronchiseptica* infection was associated with severe, frequently fatal, bronchopneumonia in kittens. Bordetellosis could also be considered in the differential diagnosis list for cats presented with acute or chronic coughing.

Etiology

Bordetella bronchiseptica is an aerobic, Gram-negative coccobacillus associated with respiratory infections in a variety of species. The organism is frequently found as part of the normal oral and upper respiratory tract flora in cats. Therefore, its role as a primary pathogen is debated but is an accepted secondary pathogen.

Pathophysiology

Bordetella bronchiseptica colonizes the ciliated respiratory epithelial cells in the trachea and nasal cavity and as such is shed in oral and nasal secretions of infected cats (experimentally 19 days post infection). Upon infection, both endotoxins and exotoxins are released, and these together with other injuries cause stasis of respiratory cilia, significantly compromising clearance mechanisms (mucociliary apparatus), often leading to chronic infections. As it affects both dogs and cats, cross-infection can occur.

Clinical Presentation

The predominant clinical signs include cough, fever, sneezing, purulent ocular/nasal discharge, and regional

TABLE 21.2.1 General vaccination recommendations of pet cats/kittens (based on the 2020 AAHA/AAFP Feline Vaccination Guidelines and the 2020 European ABCD Vaccination Matrix)

Core vaccines	Primary course start	First booster and thereafter

– Feline panleukopenia (FPV), herpesvirus (FHV), and calicivirus (FCV)
– Both MLV and killed vaccines exist with and without adjuvant
  – MLV often favored for more rapid onset of action and usual lack of adjuvant
  – Intranasal MLV vaccines exist for FHV and FCV in some countries, which give very rapid protection in high-risk situations
	– *Primary kitten (≤16 weeks of age) series:* Administer 1 dose as early as 6 weeks of age, then every 3–4 weeks until 16–20 weeks of age
	  – MDA interferes with vaccine efficacy
	– *Primary adult (>16 weeks of age):* Administer 2 doses 3–4 weeks apart
		– At 6–12 months of age, consider younger age for first booster if concern that MDAs may have been present at the time of last primary kitten vaccination
		– Thereafter, revaccinate every 3 years for FPV
		– For FHV and FCV, can revaccinate every 3 years if low risk (indoor only, visits to vet occasionally) or annually if higher risk (regular contact with other cats with outdoor access)

– Rabies – Can be noncore in countries free from rabies/pets that do not travel – Both recombinant and killed rabies vaccines exist	– Follow state/local/provincial or government (e.g., for pet travel) laws and manufacturer's recommendation	– Follow state/local/provincial or government (e.g., for pet travel) laws and manufacturer's recommendation (vaccines are licensed with 1 or 3-yearly intervals)

– Feline leukemia virus (FeLV)
– Both recombinant and killed vaccines exist, without and with adjuvant
– Core in kittens and young adults due to age-related susceptibility
  – Thereafter, can be considered as noncore dependent on risk
– In some countries, some FeLV vaccines are licensed with 3-yearly intervals
	– *Primary kitten (≤16 weeks of age) series:* Administer 2 doses, from 8 weeks of age and 3–4 weeks later
	– *Primary adult if required (>16 weeks of age):* Administer 2 doses, 3–4 weeks apart
		– 12 months after last vaccine
		– Thereafter, revaccinate according to risk
		  – Annually if regular exposure to FeLV infected cats or cats of unknown FeLV status
		  – Every 2–3 years* if low risk of exposure to FeLV-infected cats
		  – No requirement if no risk of exposure to FeLV
		* ABCD recommends yearly boosters until the cat is 3 years of age due to age-related susceptibility—then frequency adjusted based on risk

Noncore vaccines	**Primary course start**	**First booster and thereafter**
– FeLV	– 2 initial doses 3–4 weeks apart, can begin at 8 weeks of age	– 1 year later, booster every 1–3 years depending on circumstances (see references)
– *Chlamydia felis* – Both nonadjuvanted MLV and adjuvanted killed vaccines available	– 2 initial doses 3–4 weeks apart, if indicated, from 8–9 weeks of age	– 1 year later and then booster annually where there is documented risk of exposure or history of disease – Indications for use of this product are limited
– Feline *Bordetella bronchiseptica* – Attenuated live intranasal nonadjuvanted vaccine, not routinely used	– A single dose, administered intranasally, as early as 4 weeks of age, if indicated	– 1 year later and then booster annually where there is documented risk of exposure – Indications for use are limited to multicat households where there is history of disease

Guidelines to be consulted directly for further information as well as recommendations for shelter and/or breeding cats. Core vaccines are recommended for all cats. Noncore vaccines are recommended based on an individualized risk–benefit assessment.

Notes:

- Route for administration is SC unless specified as intranasal administration.
- The feline infectious peritonitis and feline immunodeficiency virus vaccines are not recommended.
- Inactivated (killed) adjuvanted vaccines can be considered when vaccination of a pregnant queens, but manufacturer's recommendations must be followed.
- When considering any vaccination or injection, the development of a feline injection site sarcoma (FISS) is a consideration. There is no definitive proof of the pathogenesis of FISS despite extensive research, but the most widely accepted hypothesis suggests that chronic inflammation at the site of an injection of an irritating substance acts as a trigger for subsequent malignant transformation. Therefore, an assessment of the infection risk is recommended for all vaccines in cats.

AAFP, American Association of Feline Practitioners; ABCD, Advisory Board for Cat Diseases; MDAs, maternal-derived antibodies; MLV, modified live virus.

lymphadenomegaly (Figures 21.2.2 and 21.2.3). Clinical signs are reported to resolve within 10 days, assuming coinfections and/or complications of pneumonia do not develop. Kittens (< 10 weeks) appear to be most prone to developing serious bronchopneumonia associated with feline bordetellosis. Clinical signs include dyspnea, cyanosis, and death. Coughing is more likely to be reported in kittens with bordetellosis than in adults.

Differential Diagnosis

Clinical illness associated with bordetellosis is characteristically associated with other respiratory pathogens such as FCV or FHV. Other differential diagnoses include cleft palate associated with aspiration pneumonia and bacterial pneumonia (e.g., *M. felis*).

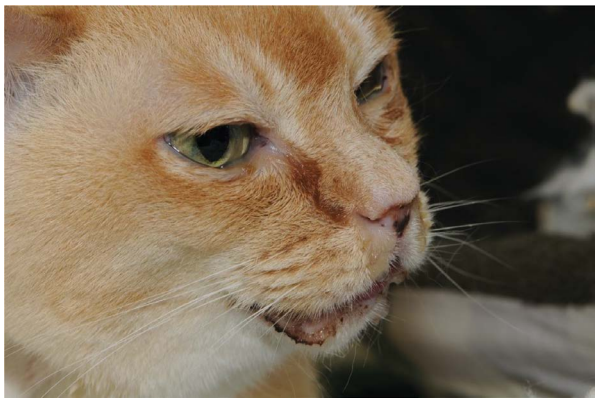

FIGURE 21.2.2 The upper respiratory signs associated with *Bordetella* infection are difficult to distinguish from other causes of feline infectious respiratory disease such as feline calicivirus or feline herpesvirus. (*Courtesy of S. Taylor.*)

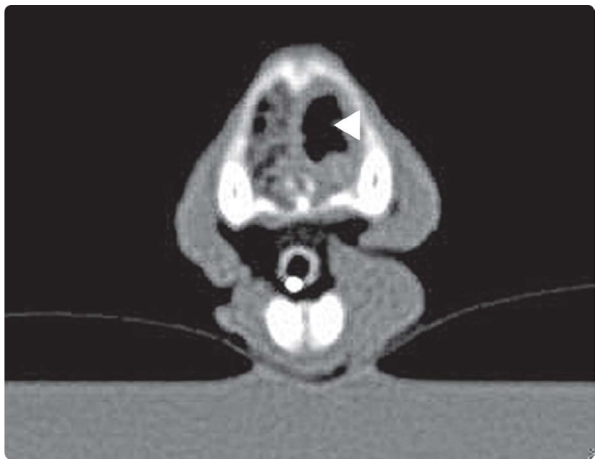

FIGURE 21.2.3 CT of the nasal and sinus areas of a Siamese cat with chronic rhinosinusitis and positive bacterial culture results for *Bordetella* spp. Note the absence of turbinates, perhaps due to the destructive nature of a primary feline herpesvirus infection, which is particularly visible on the right side (arrowhead). (*Courtesy of M. Schaer.*)

Diagnosis

The identification of *B. bronchiseptica* in the lower respiratory tract of clinically affected cats is considered diagnostic. Samples can be collected by bronchoalveolar lavage (BAL) or transtracheal wash and submitted for PCR and culture. Routine cytology of BAL samples often yields polymorphonuclear leukocytes, macrophages, and bacteria.

Bordetella bronchiseptica can be detected from respiratory secretions in the oropharynx, nasal cavity, or conjunctival sulcus of kittens and cats with upper respiratory disease and healthy cats; therefore, positive bacterial culture or PCR test results do not equate to causation of clinical signs in these cases.

Management

Bordetella bronchiseptica is susceptible to commonly used disinfectants. In a multicat household or shelter, stress management, including reduction of overcrowding to reduce disease transmission and thorough cleaning and disinfection to reduce fomite transmission of upper respiratory pathogens, should be instituted.

Treatment/Prognosis

Several antimicrobial agents are appropriate for use in kittens and cats with clinical signs associated with *B. bronchiseptica*. Considering the potential outcome for kittens concurrently infected with viral upper respiratory infection (e.g., FCV or FHV), antimicrobial therapy is justified in affected kittens to prevent development of bronchopneumonia. Doxycycline (5 mg/kg p.o. q.12 h. or 10 mg/kg p.o. q.24 h. with 5 mL water to follow; permanently stained dentition is a possible adverse effect in young kittens) is the initial treatment of choice. Other options include amoxicillin–clavulanate and pradofloxacin[1], both of which have published efficacy in the treatment of feline bordetellosis. In both dogs and cats, *B. bronchiseptica* can persist for as long as 12 weeks following the initial infection. Extended treatment durations of 4 weeks or longer are not unusual. In addition, many cats require additional supportive therapy, including intravenous fluid and nutritional support; some require more intensive care.

Prevention

A modified live *B. bronchiseptica* vaccine has been licensed for topical (intranasal) administration in cats and kittens. Considering the overall low incidence of clinical disease and the difficulty in documenting infections attributable to *B. bronchiseptica* in kittens, it is currently recommended that this vaccine be limited to use in multicat households where there are documented clinical infections with *B. bronchiseptica*, either as a single pathogen or as a comorbid infection with FHV and/or FCV. Currently, there appears to be little indication for the routine vaccination of adult cats against feline *B. bronchiseptica* (see Table 21.2.1).

Public Health Implications

Although there are limited reports of *B. bronchiseptica* infections occurring in people, some of which included exposure to dogs, there is no evidence to support direct transmission from cats to humans. However, transmission between cats and dogs has been documented using molecular techniques. One should follow dosage recommendation by manufacturer in your country as this varies due to licensing.

MYCOPLASMA FELIS INFECTION

Definition/Overview

Mycoplasma felis has been isolated from the upper respiratory tracts of cats with clinical signs of upper respiratory tract disease and also from healthy cats, so it is considered an upper respiratory tract commensal.

Whether acting as a primary pathogen or secondary opportunistic invader, *Mycoplasma* spp. are important infectious agents in feline upper and lower respiratory tract disease.

Etiology

Mycoplasma spp. are intracellular bacteria bound by a single limiting cell membrane (i.e., they lack a cell wall). *Mycoplasma* spp. have been recovered from the normal flora of the upper respiratory tract, conjunctiva, and genital tract of cats.

Pathophysiology

Mycoplasma infections are generally spread by direct contact or fomite transmission. They often act as opportunistic pathogens where cats are stressed or overcrowded or when there are comorbid infections.

Clinical Presentation

The most common clinical signs are upper respiratory and ocular: Sneezing, nasal discharge, conjunctivitis, and/or ocular discharge. Pyrexia and inappetence can occur. Lower respiratory tract infections have also been reported, accompanied by coughing, dyspnea/tachypnea, bronchopneumonia, and/or suppurative bronchitis. Screening for this pathogen in cats presenting for chronic respiratory disease, especially those poorly responsive to antimicrobials is recommended. Rare reports of association with polyarthritis exist.

Differential Diagnosis

The most common pathogens causing upper respiratory tract disease in cats are FHV-1, FCV, *M. felis*, *B. bronchiseptica*, and *C. felis*. Other causes of feline pneumonia include bacterial, fungal, and parasitic pathogens; aspiration pneumonia; and neoplasia.

Diagnosis

The identification of *M. felis* in the lower respiratory tract of clinically affected cats is considered diagnostic, for example via BAL. Commercially available PCR testing is thought to be the most sensitive diagnostic tool available. Consideration of contamination from the upper respiratory tract as a cause false-positives is important. Quantitative PCR results can aid in assessing clinical relevance.

Because of their fastidious nature and limited ability for survival outside the host, bacterial culture of *Mycoplasma* spp. is challenging so not routinely performed.

Management

Treatment/Prognosis

Doxycycline (10 mg/kg p.o. q.24 h.; 5 mL water should be administered after every dose; permanently stained dentition is a possible adverse effect in young kittens) is the treatment of choice. Prolonged courses (up to 6 weeks) might be necessary to reduce pathogen load to undetectable levels using quantitative PCR testing, but clinical resolution of infection typically occurs in 1–2 weeks. *M. felis* also has published in-vitro and in-vivo susceptibility to fluoroquinolones such as marbofloxacin (2.7–5.5 mg/kg p.o. q.24 h. for 6 weeks), macrolides (azithromycin), and lincosamides (clindamycin 10–15 mg/kg p.o. q.12 h.).

There are no antimicrobial regimens that are proven to clear infection, and *M. felis* persists in the host for extended periods, resisting clearance using intracellular localization, immunomodulatory effects, and surface antigen variations. For this reason, clinical resolution might be more important than achieving negative PCR results post treatment.

Prevention

Stress management is paramount to environmental control, and special attention should be given to reducing overcrowding to reduce disease transmission. Thorough cleaning and disinfection is required to reduce fomite transmission of upper respiratory pathogens. *M. felis* is susceptible to routine disinfectants as it lacks a cell wall. Population management is the main prevention tool in multicat environments. There are currently no vaccines available for the prevention of *M. felis* infection.

Public Health Implications

There have been isolated case reports of human infections with *M. felis*, but the vast majority of human *Mycoplasma* infections have been due to *Mycoplasma* spp. not found in cats or dogs.

OTHER

HEMOPLASMAS (HEMOTROPIC MYCOPLASMAS)

See also Chapter 16.

Definition/Overview

Mycoplasma haemofelis (formerly *Haemobartonella felis*) belongs to a genus of small (0.3–1 μm) wall-less bacteria that live on red blood cells (RBCs) closely related to mycoplasmas; they are sometimes called the "hemoplasmas." Acute infections are characterized by rapid-onset hemolytic anemia, hence the name "infectious anemia." While chronic *M. haemofelis* infection is characterized by episodes of fluctuating parasitemia, clinical anemia does not usually occur in the absence of comorbidities. Persistent Coombs-positive autoagglutination by antibodies bound to RBCs can be found in cats with acute anemia due to *M. haemofelis* infection.

Other species of hemoplasmas known to infect cats are "*Candidatus Mycoplasma haemominutum*" and "*Candidatus Mycoplasma turicensis*." However, infections with these species appear to be subclinical in cats unless concurrent disease is present. "*Ca. M.*

haemominutum" is usually the most common species found in studies followed by *M. haemofelis* and "*Ca. M. turicensis*." Infections with more than one hemoplasma species are relatively common.

Etiology

The natural mode of hemoplasma transmission in cats is not known. Older, male nonpedigree cats, outdoor access, and a history of fighting have been associated with infection. Direct cat-to-cat infection by casual contact, such as mutual grooming, is thought to be unlikely, while transfusion of blood from apparently healthy carrier cats is an effective means of transmitting *M. haemofelis*. Vectors such as fleas and ticks may be involved in transmission, although this has not yet been conclusively shown. Vertical transmission has been shown for other hemoplasmas but has not been definitively shown for feline hemoplasmas.

Pathophysiology

Acute *M. haemofelis* infection can be fatal if left untreated due to severe hemolytic anemia (usually extravascular), although in some cases only mild anemia results. Cats that ultimately recover from acute infections can remain chronically infected for years, although long-term carrier status may be more common with "*Ca. M. haemominutum*" infections. Depending on the intrinsic immunologic and phagocytic responses, chronic carrier cats may manifest small numbers of organisms on the surface of RBCs or may manifest no evidence of infection until stressed (e.g., chronic corticosteroid therapy, FeLV/FIV-positive status). Other factors such as the health status of the cat and possibly even the transmission route of infection may play a role in the outcome of hemoplasma infection with any species.

Clinical Presentation

While acute infections are often associated with significant anemia, many cats with chronic infections are asymptomatic or show only mild anemia and manifest few, if any, clinical signs. When clinical signs are present, they are most likely related to anemia (i.e., weakness, lethargy, pallor, and splenomegaly). Intermittent pyrexia may be present. Cats are only occasionally noted to be icteric.

Differential Diagnosis

Primary immune-mediated hemolytic anemia (IMHA), secondary IMHA (e.g., secondary to drugs, neoplasia, infections), cytauxzoonosis, retroviral infection, babesiosis, Heinz body-associated hemolysis, hypophosphatemia, and inherited red blood cell disorders such as pyruvate kinase deficiency are important differential diagnoses.

Diagnosis

Pathogenic hemoplasma infections typically cause a regenerative anemia that is macrocytic and hypochromic, although reticulocytosis is not always evident. Positive Coombs test results have been reported in acute hemoplasmosis. Hyperbilirubinemia is seen occasionally due to hemolysis, and hypoxic damage to the liver may result in increased activities of alanine aminotransferase (ALT). Hyperproteinemia is sometimes seen in cats. Retrovirus testing may be positive in cats (particularly FIV).

Definitive diagnosis of hemoplasma infection relies upon PCR diagnosis, which can identify with species is present as well as bacterial loads present in the blood if a quantitative PCR assay is used. Hemoplasmas may also be visible on blood smear cytology (Figure 21.2.4), but this method is known to have very poor sensitivity, as well as an inability to reliably differentiate between species. Stain precipitate and Howell–Jolly bodies are commonly mistaken for hemoplasma organisms on blood smear examinations performed in-house.

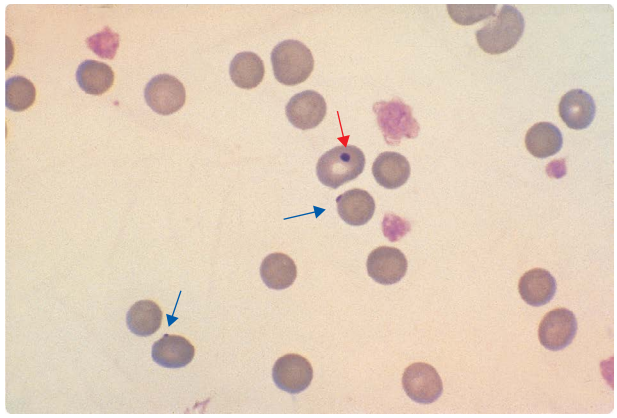

FIGURE 21.2.4 Peripheral blood smear from a cat demonstrating faint staining *Mycoplasma haemofelis* on the red blood cell surface (blue arrows) with a nearby Howell-Jolly body (red arrow), which is a nuclear remnant. Romanowsky-type stains can be used (e.g., Wright, Giemsa, Diff-Quik®) to stain blood smears.

Management

Treatment/Prognosis

Transfusion of whole blood or packed red blood cells if available may be required in severely anemic cats with marked clinical signs associated with acute-onset anemia.

Doxycycline (5 mg/kg p.o. q.12 h. or 10 mg/kg p.o. q.24 h. for 2–4 weeks, followed at each administration by 5 mL water) is recommended for treatment in cats showing clinical signs associated with *M. haemofelis* infection. If this is the first episode of hemoplasmosis in a cat which shows a rapid clinical response to treatment, 2 weeks of doxycycline may be adequate with no further monitoring. However, if the patient is a more complex case (e.g., repeated episode, concurrent disease, and/or clinical signs do not improve within 3 days), blood organism numbers can be monitored by quantitative PCR to ensure they are decreasing with treatment. Repeat hematology profiles are also helpful to assess response to treatment.

Fluoroquinolones such as marbofloxacin (2–5.5 mg/kg[1] p.o. q.24 h.) and pradofloxacin (3–4.5 mg/kg[1] p.o. q.24 h.) can be used as second-line agents if there has been inadequate clinical response to doxycycline.

Although clinical signs of infection can improve with appropriate antibiotic treatment, clearance of infection does not always result. This needs to be considered as chronic infection can result in relapses of clinical disease, although this is not believed to be common. However, a recent treatment protocol to clear chronic *M. haemofelis* infection has been published, comprising 4 weeks of doxycycline followed by 2 weeks of marbofloxacin for any cats that remain positive by quantitative PCR (as determined by repeated testing on multiple occasions) after doxycycline treatment. Treatment breaks of up to 4 weeks between the courses of doxycycline and marbofloxacin did not influence outcome. This may be of value to use in cats with *M. haemofelis* infection that have had particularly severe disease and/or reactivation of infection.

Immunosuppressive glucocorticoid treatment to suppress any IMHA associated with hemoplasmosis is not recommended because antibiotic treatment and supportive care alone are usually adequate, even in animals with positive Coombs testing. Glucocorticoids may cause hemoplasma infection reactivation.

The prognosis for uncomplicated *M. haemofelis* infection in cats is good, assuming that treatment can be administered and is tolerated by the cat.

Prevention

Since vectors may be involved in the transmission of feline hemoplasmosis, ectoparasiticide prevention is advised. Blood donors should be screened for hemoplasma infection by PCR before use. There is no vaccine available for hemoplasmosis.

Public Health Implications

Infections have been described in humans with novel hemoplasma species, as well as very occasional case reports documenting infection with species that have possibly originated in cats. This raises the possibility of zoonotic infections, and so good hygiene measures should be adopted when handling infected cats.

FELINE MYCOBACTERIA

Definition/Overview

Mycobacterial infections are a global health problem in animals and humans with geographical variation worldwide. They are intracellular acid-fast aerobic bacilliform bacteria (AFB), usually slow growing, that can be resistant in the environment. Those of feline importance are in the tuberculosis (TB) complex group (these form tubercles on pathology) or the nontuberculous mycobacteria (NTM) group, which includes feline leprosy (FL) organisms. Mycobacterial taxonomy is complex. Geographical variation exists in prevalence.

Etiology

The TB complex group are obligate pathogens and include *Mycobacterium tuberculosis* (mainly infects humans, not seen in cats), *Mycobacterium bovis* (infects cattle, cats, and rarely humans), and *Mycobacterium microti* (infects small rodents and cats). *Mycobacterium bovis* and *M. microti* can be transmitted via bites with small rodents, ingestion of infected milk or meat (e.g., raw meat diets), and occasionally via direct cat-to-cat contact or indirect contact. The NTM group comprise many slow-growing (e.g., *Mycobacterium avium-intracellulare* complex [MAC]) or rapid-growing (e.g., *Mycobacterium fortuitum*) species, and the FL group includes *Mycobacterium lepraemurium*. The NTM have pathogenic potential but are generally saprophytic or opportunistic, e.g., soil contamination of wounds or following rodent bite. MAC transmission may be possible via ingestion of infected meat or contact with bird feces.

Pathophysiology

Mycobacterial infections center on macrophages and are characterized by granulomatous and pyogranulomatous inflammation. TB complex species can result in tubercle formation and systemic disease with disseminated internal lesions (with *M. bovis* more than *M. microti*) as well as skin lesions. NTM infections typically involve the skin and subcutaneous tissues, rarely causing systemic disease except for MAC infections. Rapid-growing species often result in panniculitis due to their preference for adipose tissue. FL infections in cats are restricted to the skin, with localized and rarely disseminated cutaneous nodules resulting.

Clinical Presentation

TB and FL often occur in adult male cats with outdoor access (likely due to hunting and fighting) without evidence of immunosuppression. Obese outdoor cats are at increased risk of non-FL NTM infections. Siamese, Abyssinians, and Somalis are at increased risk of disseminated MAC infection. A recent outbreak of *M. bovis* in the UK occurred via ingestion in indoor-only pedigree cats that were fed a commercial raw wild venison diet.

Cats with TB usually present with cutaneous signs: Nodules (± ulceration) or nonhealing draining wounds, primarily on the head, extremities, or tail base. Regional or generalized lymphadenopathy is common. Systemic pulmonary involvement can occur, although outward signs of respiratory disease (coughing, tachypnea, dyspnea) may not occur. Weight loss and anorexia may occur. Bone involvement can result in lameness and/or pain. Occasionally ocular uveitis occurs.

NTM infections usually present as cutaneous/subcutaneous nodules ± ulceration (resembling localized TB) and/or granulomatous panniculitis (multiple punctate draining tracts; "pepper pot" appearance), which can progress to involve significant areas of painful, ulcerated and nonhealing tissue (often inguinal fat pads,

flanks, and/or tail base). Systemic signs sometimes occur, e.g., with MAC infection, such as neurological or pulmonary signs.

Cats with FL NTM have nodular cutaneous signs; alopecic or ulcerated nonpainful nodules that are mobile on palpation, typically on the head or limbs. Regional lymphadenopathy may occur, but systemic involvement is very rare.

Differential Diagnosis

Conditions which affect the skin should be considered as differential diagnoses such as bacterial infections (abscesses, actinomycosis, nocardiosis, rhodococcosis, etc.), fungal infections (blastomycosis, cryptococcosis, mycetoma, histoplasmosis, etc.), neoplasia, foreign body granuloma. Systemic signs involving the lungs and gastrointestinal tract should have relevant differential diagnoses considered such as inflammatory disease (e.g., feline asthma, inflammatory bowel disease), infectious disease (e.g., toxoplasmosis, feline infectious peritonitis, salmonellosis), and neoplastic disease (e.g., lymphoma, adenocarcinoma, metastatic disease).

Diagnosis

Hematology and biochemistry changes are nonspecific, although hypercalcemia due to granulomatous disease may occur. Thoracic imaging is variable and nonspecific, ranging from no abnormalities to bronchial, alveolar, or interstitial nodular mixed patterns and/or mediastinal and perihilar lymphadenopathy. Appendicular radiographs may show bone osteolysis or proliferative lesions. Abdominal ultrasonography can be useful in finding mesenteric lymphadenopathy or other abnormalities (e.g., in kidneys, liver). It can also be used a guide to obtain fine-needle aspirates (FNAs) of observed abnormalities.

FNAs or smears from skin lesions (nodules, ulcers, draining tracts) or lymph nodes show granulomatous changes and should be stained for AFB using, e.g., Ziehl-Neelsen (ZN) staining, although a negative cytology result does not rule out mycobacterial infection. If cytology suggests granulomatous inflammation with or without ZN-positive staining, a biopsy for histology should be obtained, as well as fresh nonfixed samples for culture and PCR. Histopathology in affected cases can vary depending on the mycobacterial species involved (pyogranulomatous or granulomatous inflammation, necrosis, panniculitis, etc.) and allows acid-fast staining with ZN, although organism numbers may be too few to allow visualization. If mycobacterial infection is suspected, it is mandatory to keep fresh biopsy samples frozen without formalin for subsequent culture and PCR. Gloves and aseptic practice are required to handle cytology or biopsy samples from suspected cases due to zoonotic risk.

A positive culture from a fresh tissue sample or FNA is most useful to confirm the diagnosis and identify the species to help guide treatment, prognosis, and assessment of zoonotic risk. However, culture needs to be done in a specialized laboratory, and many species take a long time to grow (2–3 months) or even fail to grow (such as FL species and some forms of NTM infection). Due to these limitations, PCR has evolved as a useful adjunctive test on fresh samples (tissue but also on FNAs and stained smears) that can identify the species quickly, and a positive result can be followed by sequencing in specialized laboratories investigating outbreaks. The availability of PCR testing is limited. Both culture and PCR testing are costly.

Feline interferon gamma (IFN-ɣ) release assay blood testing, currently available in the UK, shows promise for the antemortem diagnosis of TB. The test measures the T-cell response (IFN-ɣ production) in peripheral blood mononuclear cells to three different antigens. The pattern of any positive results identifies whether the cat is infected with a pathogenic or less pathogenic TB complex species and/or whether it has been exposed to environmental NTM species. It is useful to determine whether *M. bovis* and *M. microti* infection is most likely to determine the zoonotic risk to guide treatment in suspected cases.

Management

Treatment/Prognosis

In the case of a diagnosis of disseminated *M. bovis*, it is important to discuss whether cats should be treated at all due to zoonotic implications and concern around antimicrobial resistance developing in human TB as a result of antimicrobial use in cats. In some countries, euthanasia of confirmed cases of *M. bovis* is mandatory. In others, if treatment is being considered, the costs and compliance issues of the long treatment need to be carefully discussed with owners, as well as the recommendation for keeping the cat indoors during treatment. Additionally, owners are advised to contact their own doctor for screening. TB complex treatment comprises 2 months of oral triple therapy with rifampicin (10 mg/kg q.24 h.), a fluoroquinolone (although marbofloxacin [2 mg/kg q.24 h.] may be effective, pradofloxacin [3–5 mg/kg q.24 h.; different dose for tablets versus liquid] is now preferred), and a macrolide (azithromycin (5–15 mg/kg q.24 h.] or clarithromycin (7–15 mg/kg q.12 h.]) is recommended, followed by a further 4- to 7-month treatment with two of these drugs (usually fluoroquinolone and macrolide). If triple therapy is not possible, then two of the drugs should be given for 6–9 months. Hematology and biochemistry should be monitored for possible side effects, especially hepatotoxicity with rifampicin. Rifampicin can discolor body fluids orange and cause anorexia, erythema, pruritus, and anaphylaxis. Clarithromycin can cause pinnal/generalized erythema. More recently, a 3-month course of triple therapy alone, or triple therapy given for 2–3 months beyond resolution of clinical signs or static thoracic imaging abnormalities (typically comprising 4–6 months of treatment), has been described as unpublished observations for the treatment of TB in cats. To aid compliance, medications can be given combined

within a single gelatin capsule, as liquid formulations, or via an esophagostomy tube. Surgery is sometimes used to treat solitary cutaneous lesions but is difficult for diffuse cutaneous disease due to wound dehiscence and local recurrence.

Treatment of MAC complex, slow and rapidly growing NTM depends on the infecting species. Culture and susceptibility results are useful to guide treatment choice, if available. Oral clarithromycin and rifampicin or clofazimine (4–8 mg/kg q.24 h. or q.48 h.) are given for *M. avium* cases, alongside, if possible, doxycycline (5 mg/kg q.12 h. or 10 mg/kg q.24 h.) or pradofloxacin. Other NTM species show variable responses to antibiotics, but generally two or three antibiotics are used. Clarithromycin and pradofloxacin together are good for certain species (e.g., *M. chelonae-abscessus*), while a fluoroquinolone and doxycycline are better for others (e.g., *M. smegmatis*). Treatment should continue 1–2 months beyond clinical resolution; up to 12 months of treatment needed for extensive/systemic infections. Surgical resection may comprise part of the treatment for severe panniculitis case, with reconstructive surgery sometimes needed.

Treatment of FL NTM comprises surgical removal of solitary lesions, which may be curative. If further treatment is required, dual or triple antibiotic treatment should include clarithromycin, rifampicin, pradofloxacin, and/or clofazimine, typically for 2–3 months.

It is hard to assess prognosis accurately, as not all reported cases have been treated appropriately. TB infections have remission rates of 70%–90%, although outbreaks in younger cats have a poor prognosis. Imaging abnormalities only resolve in a few cases. The prognosis for MAC, slow and rapidly growing NTM is variable; good to guarded, depending on the species involved (*M. avium* infections and those with extensive panniculitis, especially due to *M. fortuitum*, are particularly poor). For FL NTM, the prognosis varies from good to poor.

Prevention

There is currently no vaccine available for mycobacteriosis in cats. Restriction of access to potential sources of infection (e.g., prey species) may be difficult in outdoor cats. Although an uncommon source of infection, avoiding the feeding of raw meat diets and unpasteurized milk from sources where TB is endemic is important. Prevention of transmission within veterinary clinics involves the use of hand washes and disinfectants that are mycobactericidal, e.g., 60%–90% alcohols (e.g., Sterillium), halogenated tertiary amines (e.g., Anigene, Anistel), and 3% iodine preparations. Investigations on suspected cases should be performed at the end of the day in well-ventilated rooms, with breathing systems and endotracheal tubes disposed of after use. Strict asepsis is very important, as nosocomial spread of mycobacterial infections has been reported.

Public Health Implications

Despite *M. bovis* being zoonotic and infecting humans, cat-to-human transmission is of very low risk and very rarely reported. *M. microti* is less of a zoonotic concern, with cat-to-human transmission never reported. Of the NTM, only *M. avium* can be zoonotic (in immunosuppressed people). Cat-to-human transmission of NTM has not been reported.

Despite the very low transmission risk with *M. bovis*, the zoonotic potential of this agent is important to be aware of and discuss with owners and personnel in clinics dealing with TB cases. People are at heightened risk of TB infection if they are under 5 years old, are pregnant, are HIV positive, or have other immunocompromising condition. It is generally thought that protracted exposure is required for cat-to-human infection. A single high-dose inoculation could result in transmission of infection, so care is always required. When collecting samples from cats, the zoonotic risk should be considered; inhalation of organisms from cats with respiratory signs/coughing and/or contact with organisms present in draining wounds. A fitted filtering face mask should be worn when in close proximity of coughing cases (e.g., during intubation, collecting BALs) to prevent inhalation. Gloves and protective clothing should be used when handling cases with draining skin lesions to avoid spread to other cats, as well as covering of any open sores/wounds in personnel to prevent zoonotic transmission. If open surgery is required on a suspected TB patient, an appropriately filtered airflow helmet is required. Following euthanasia of a TB patient, cremation rather than burial should be recommended to reduce the risk of environmental contamination.

FELINE LEPTOSPIROSIS

Definition/Overview

Although a significant disease of dogs and humans, the pathogenic role of *Leptospira* in cats in unknown and currently not often clinically recognized.

Etiology

Leptospirosis is mainly a disease of dogs caused by spirochetes of the genus *Leptospira*. Antigenically related serovars are grouped into serogroups. These bacteria are maintained in the environment by mammalian reservoir hosts who shed *Leptospira* in their urine (mainly rodents). Hosts become infected by direct contact with infected urine or indirectly via contaminated soil or surface water. Cats can become infected by these routes but also through ingestion of rodents. They develop antibodies (4%–33.3% depending on geographical location) and shed *Leptospira* in their urine with a prevalence of up to 68%. Therefore, their role as a healthy reservoir host is poorly understood. Outdoor cats are considered to be higher risk. The presence of another cat in the household significantly increases the likelihood of seropositivity.

Pathophysiology

Leptospirosis spreads hematogenously, enabled by the ability to evade the host immune system. Leptospiremia

then occurs, usually lasting around 7 days, creating an often multisystemic disease. After 10 days, *Leptospira* have entered the renal tubules and start to be eliminated in the urine. How long they are shed in the urine of cats is currently unknown, but it has been shown to occur up to 8 months post infection with little to no association with clinical disease. Interstitial nephritis has been documented on renal histopathology of affected cats. Whether this goes on to cause chronic renal damage and insufficiency is unclear.

Clinical Presentation

Clinical signs of acute disease in cats is rare. Further understanding of *Leptospira* as potential pathogen in feline renal disease (both acute and chronic) is needed. In the few case reports available, a possibly longer incubation period compared to dogs has been suggested. Therefore, perhaps there is more of a role as a trigger for chronic kidney disease we are yet to fully understand. Other reported clinical signs in confirmed infected cats have included polyuria, polydipsia, hematuria, uveitis, lameness, lethargy, anorexia, gastrointestinal signs (vomiting and diarrhea), presence of effusions, inflammatory lesions of skin and digits, and nonspecific pain. Hepatic lesions appear to be much less common in cats compared to dogs.

Differential Diagnosis

Chronic kidney disease, urinary tract infection, urolithiasis, pyelonephritis, calicivirus, FIP, leishmania, and other inflammatory/infectious diseases, including babesiosis.

Diagnosis

The need to screen for this disease in cats is debatable given our limited understanding of the importance of the disease in this species. Most affected cats are moderately to severely azotemic on presentation and hyperphosphatemia has been reported. Diagnosis is usually based on demonstration of antibodies (microscopic agglutination titer [MAT] or enzyme-linked immunosorbent assay [ELISA]) and/or *Leptospira* deoxyribonucleic acid (DNA) by blood or urine reverse transcription PCR (RT-PCR; care as previous antibiotic therapy often causes false negatives for this test). For further information, see the canine section.

Management

Treatment/Prognosis

As the pathogenic role is poorly understood in cats, no treatment is currently recommended unless other causes of presenting clinical signs are excluded. The approach to treatment is the same as described in dogs, with additional care over administration of oral doxycycline and risk of esophagitis. Prognosis depends on the severity of organ damage.

Prevention

Vaccination is not currently advised for cats. Reduction or prevention of exposure to stagnant water, predation opportunities, and keeping the cat indoors can help.

Public Health Implications

Leptospirosis is a recognized zoonotic disease as such the role of cats as chronic reservoir hosts/carriers needs further investigation.

FELINE ACTINOMYCOSIS AND NOCARDIOSIS

Definition/Overview

Actinomycosis and nocardiosis are rare chronic infections, reported in both dogs and cats. Disease is caused by a variety of anaerobic (actinomycosis) and aerobic (nocardiosis) actinomycetes.

Etiology

Actinomyces spp. and *Nocardia* spp. are branching, filamentous, Gram-positive bacteria. Both organisms are ubiquitous found in soil. *Actinomyces* spp. also inhabit the oral cavity of cats as normal flora. Infections are opportunistic and usually occur subsequent to mechanical disruption of mucosal barriers, such as inoculation of skin with contaminated plant material or, less often, bite wounds. Actinomycosis is more prevalent, especially in cats, than nocardiosis.

Pathophysiology

Entry and spread of infection depend on the host's immunocompetence. In both infections, hematologic and biochemical findings are nonspecific and typical of any pyogenic inflammatory process. There is usually a leukocytosis with a left shift.

Clinical Presentation

Feline Actinomycosis

Feline actinomycosis is most often associated with subcutaneous cat bite abscess formation or pyothorax. Lymphadenopathy, fever, and weight loss may occur. A viscous, opaque, foul-smelling exudate is characteristic.

Feline Nocardiosis

Feline nocardiosis infections are characterized by suppurative or pyogranulomatous inflammation that can be localized (cutaneous–subcutaneous or pulmonary) or disseminated (systemic with lesions in two or more separate sites such as joints, central nervous system [CNS]). The cutaneous form is the most common and often presents with abscess formation and fistulous tracts with serosanguineous discharge or nonhealing

wounds. The pulmonary form is associated with coughing, dyspnea, fever, and pyothorax.

Differential Diagnosis

Penetrating (subcutaneous) injury, neoplasia, and mycobacterial infections (especially those associated with panniculitis) are among the most important differential diagnoses for actinomycosis. Pneumonia (bacterial, parasitic, viral, or protozoal [toxoplasmosis]) is an important differential diagnosis for nocardiosis. As *Actinomyces* spp. and *Nocardia* spp. are opportunistic pathogens, all infected cats should be tested for FeLV and FIV.

Diagnosis

Feline Actinomycosis

Recovery of multiple bacterial pathogens from the exudate is common. Cytology of samples, e.g., an exudate may reveal so-called yellow sulfur granules (aggregates of bacteria), which can occasionally be visualized without microscopy (Figures 21.2.5 and 21.2.6). Cytologic assessment of exudates is complicated by the presence of mixed bacterial populations, but typically, pyogranulomatous inflammation is present. *Actinomyces* in the exudate may be difficult to visualize, but they should appear as Gram-positive filamentous organisms. Attempts to culture *Actinomyces* spp. from exudates are complicated by bacterial overgrowth and the need for anaerobic conditions.

Feline Nocardiosis

Cytology of exudates can reveal the Gram-positive filamentous organisms, although the presence of mixed bacterial populations is rare. Microscopically, filaments are finer than fungal filaments (less than 1 µm) and can be identified using Bourke's modification of Gram stain. Filaments do not stain with Romanowsky stains. Culture confirms the diagnosis.

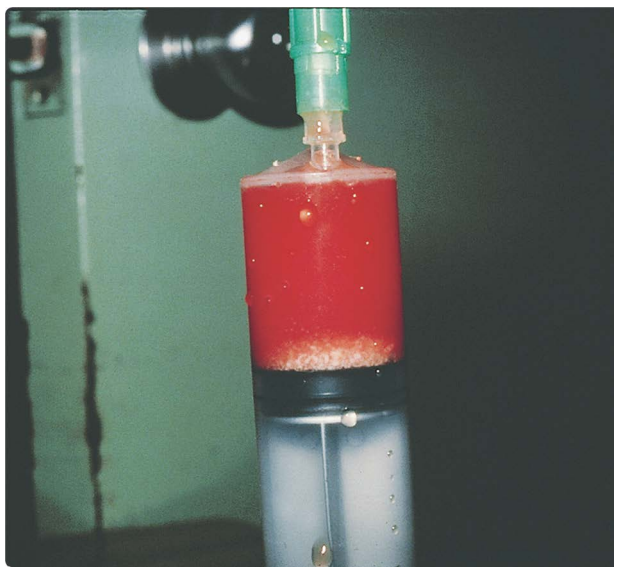

FIGURE 21.2.5 Suppurative exudate containing "sulfur" granules, taken from a feline patient with suppurative pleuritis caused by *Actinomyces* infection, is shown in the syringe.

FIGURE 21.2.6 The cat is having thoracic exudate aspirated through chest drains.

Management

Treatment/Prognosis

Both diseases are best treated with surgical drainage and debridement of affected areas (e.g., abscesses, effusion drainage), except in cases with disseminated infection. Treatment with antimicrobials is essential for weeks because of limited drug penetration of the dense granulomatous tissue.

Feline Actinomycosis

Penicillin G (100,000 U/kg IV or SC q.6–8 h.) or penicillin V (phenoxymethylpenicillin, 40 mg/kg p.o. q.8 h.) is the recommended treatment for feline actinomycosis. Clindamycin, minocycline, erythromycin, and amoxicillin are good alternative antibiotics. Antimicrobial penetration of the granulomas is difficult and, therefore, dictates extended therapy. Once effective drainage has been established, treatment should continue for a minimum of 2 weeks or as long as necessary for clinical and microbiological cure. Once treatment has been initiated, the volume of discharge is frequently reduced. The clinician should attempt to identify the extent of draining tracts and the possibility of a foreign body within the wound site or tract. Treatment is significantly complicated by infections associated with migrating foreign bodies. Animals that fail to respond to initial drainage and antimicrobial therapy should undergo exploratory surgery in an attempt to identify the underlying cause. Assuming that effective drainage can be established, the inciting foreign material removed, and antibiotic therapy administered appropriately, the prognosis for cure is excellent.

Feline Nocardiosis

Feline nocardiosis has a considerably poorer prognosis than actinomycosis. Sulfonamides are the recommended drugs in the management of nocardiosis (e.g.,

trimethoprim-sulfadiazine: 15–30 mg/kg p.o. q.12 h.) and should be administered in gelatin capsules or reformulated for cats to avoid salivation on administration. Doxycycline (5 mg/kg p.o. q.12 h. or 10 mg/kg p.o. q.24 h., with water to follow), in combination with amoxicillin (20 mg/kg p.o. q.12 h.) has also been used. Paradoxically, amoxicillin–clavulanate and fluoroquinolones are not effective. Although response to therapy may be noted within 7–10 days following the onset of treatment, extended treatment periods of 2 months or longer are usually required. Cats that do not have easily resectable nocardial lesions have a poor prognosis.

Prevention

There is currently no vaccine on the market for the prevention of either actinomycosis or nocardiosis in cats.

Public Health Implications

Although human cases of actinomycosis and nocardiosis are reported, human infections are not directly transmitted from infected dogs or cats. Individuals handling material from draining wounds should use normal routine precautions to avoid inadvertent contact with infectious material.

For discussion of tetanus, refer to Chapter 13.

VECTOR-TRANSMITTED PATHOGENS

FELINE BARTONELLOSIS

Definition/Overview

Feline bartonellosis is a flea-borne disease generally attributed to infection with *Bartonella henselae*. Although infected cats rarely show obvious clinical signs of illness, the relationship between feline *B. henselae* infection and human cat scratch disease (CSD) has prompted intensive research. Over 20 species of *Bartonella* are now recognized worldwide, although their role as pathogens in feline and human disease is still poorly understood.

Etiology

Bartonellae are small, Gram-negative intracellular bacteria. Cats are primary reservoirs of three species: *B. henselae*, *B. clarridgeiae*, and *B. koehlerae*. *B. henselae* is present within RBCs ingested by the flea on feeding but is mainly transmitted by inoculation of the skin by infected flea feces (infective for approximately 9 days) present on the cat's claws through scratching. Successful transmission by *Ixodes ricinus* has also been described. In Europe, the antibody prevalence is reported to be 8%–53%.

Pathophysiology

A prolonged (> 1 year), fluctuating bacteremia occurs in infected cats, which are usually young (< 2 years old). When the infection is first acquired, animals may have a transient lymphadenopathy and low-grade fever. Despite the duration of bacteremia, there seem to be no long-lasting effects.

Clinical Presentation

Many infected cats are asymptomatic. In the small number of cases documented, bartonellosis was described as a self-limiting, febrile illness lasting for 2–3 days, with clinical signs of lethargy and mild postural reaction deficits in all limbs. In all cases, the clinical signs resolved without the administration of antimicrobial therapy. Chronically bacteremic cats are typically healthy, as cats act as reservoirs of infection for the host-adapted *B. henselae*. A number of studies have attempted to link clinical signs or laboratory abnormalities with *Bartonella* seropositivity, including hyperglobulinemia, urinary tract disease, hematuria, CNS disease, and osteoarthritis, but the strength of evidence in these reports has been variable. Additionally, response to treatment for *Bartonella* has been documented in case reports of feline uveitis, endocarditis, and myocarditis.

Differential Diagnosis

Since experimental infections have demonstrated transient pyrexia, mild anemia, localized or generalized lymphadenopathy, and/or mild CNS signs, bartonellosis could reasonably be included in the differential diagnosis list for cats with any of those presenting signs. FeLV and FIV testing is indicated.

Diagnosis

Seropositivity (IFA or ELISA) is common among healthy cats and generally only denotes prior exposure to any of several genetic varieties of *Bartonellae*. Positive serologic results do not appear to be related to bacteremia. Therefore, serology is more useful to exclude *Bartonella* from the differential diagnosis list. Currently, blood or tissue culture remains the preferred means of confirming the diagnosis, but these tests might need to be performed repeatedly to avoid false-negative results from fluctuating bacteremia and again do not prove disease causation due to high prevalence in healthy cats. PCR testing can be performed on blood, aqueous humor, oropharyngeal swabs, and CSF or tissue aspirates, and submission of multiple specimen types from a single case increases test sensitivity.

Management

Treatment/Prognosis

Although marbofloxacin (5 mg/kg p.o. q.12–24 h. for 6 weeks) or doxycycline (5 mg/kg p.o. q.12 h. or 10 mg/kg p.o. q.24 h. for 2–4 weeks) is the recommended treatment, failure to clear infection is still common. Azithromycin (10 mg/kg p.o. q.24 h. for 7 days,

followed by 10 mg/kg p.o. q.48 h. for 6–12 weeks) and amoxicillin–clavulanate (62.5 mg p.o. q.12 h. for 2 months) have also been reported to resolve infection. However, because clinical disease is seldom associated with infection, the value of treating infected cats may be limited to households in which cats reside with immunocompromised humans.

Prevention

There is currently no vaccine available for bartonellosis in cats. However, effective flea and tick management is deemed to be a prudent means of minimizing the risk of infection. Blood donors should be screened for *Bartonella* antibodies. Avoid rough play and ensure cats' claws remained trimmed.

Public Health Implications

A variety of clinical disorders in humans (e.g., bacillary angiomatosis, peliosis, relapsing fever, neuroretinitis, uveitis, endocarditis, and neurologic disorders), as well as CSD, have been associated with *Bartonella* spp. infection. Infections are most profound in people with human immunodeficiency virus (HIV) and other causes of immunosuppression. Although infections do develop in immunocompetent individuals, these infections tend to be subclinical or localized to regional lymph nodes.

There is a strong relationship between *B. henselae* infection and human CSD. Despite the fact that CSD in humans has for years been associated with cat scratches, there is considerable speculation as to the actual means of transmission between cats and humans. Currently, it appears that feline saliva is not an effective means of transmitting *B. henselae* to humans. However, there is increased awareness of the important role played by fleas in human infections, so the risk of exposure to arthropod vectors, not only to cats, should be considered in suspected human infections.

PLAGUE

Definition/Overview

Plague is an uncommon infection of cats caused by the facultative anaerobic, Gram-negative bacterium *Yersinia pestis* transmitted by *Xenopsylla cheopis* fleas. The organism has been sustained for centuries by chronic bacteremia in wild rodents and prairie dogs. In the United States, reported cases of plague have a seasonal distribution, corresponding to when rodents and fleas are most active, and humans are most likely to be outdoors (February–August).

Although infections in domestic animals are uncommon, the fact that both domestic and feral cats are susceptible to *Y. pestis* infection, and that cats are a documented source of human infection, means that plague must be regarded as a significant zoonotic infection of cats. Although dogs can become infected, their susceptibility is considerably less than cats.

Etiology

Transmission of the bacterium to susceptible hosts occurs predominantly through flea bites or the ingestion of infected rodents or lagomorphs; humans, dogs, and cats are usually accidental hosts and are not responsible for the transmission of infection. However, infection can also be transmitted directly through contact with broken skin or by inhalation of infectious microdroplets from cats or humans infected with the pneumonic form of plague.

Pathophysiology

The incubation period depends on the route of entry of the organism: 2–6 days with flea bites; 1–3 days after inhalation or ingestion. Typically, there is evidence of neutrophilic leukocytosis with a left shift and lymphopenia, hyperglycemia, azotemia, hypokalemia, hypoalbuminemia, hyperglobulinemia, hypochloremia, hyperbilirubinemia, and increased alkaline phosphatase (ALP) and alanine aminotransferase (ALT) activity.

Clinical Presentation

Three clinical forms of *Y. pestis* infection have been recognized in cats: Bubonic (most common), septicemic, and pneumonic. Following ingestion of infected rodents, cats that become infected typically develop fever, necrotic stomatitis, and lymphadenomegaly (due to suppurative lymphadenitis), particularly around the head and neck. Lymph nodes may rupture and drain through to the skin surface. Subsequently, septicemia may develop in a small number of cats (septicemic plague). Fever, shock, disseminated intravascular coagulation (DIC), and pneumonitis are short-lived signs that precede death. Hematogenous spread of the organism to the lungs in cats culminates in pneumonic plague, which is particularly likely to be fatal.

Within endemic areas (particularly the Southwestern United States and western coastal states), cats presented with persistent fever, lymph node enlargement, tonsillar enlargement, necrotic stomatitis, facial ulceration, or abdominal distension should be evaluated for plague.

Differential Diagnosis

Any cat living in, or from, a plague-endemic area should be considered suspect if presented for stomatitis, chronic respiratory disease, and/or lymphadenomegaly. Feline frontal sinusitis/rhinitis, sepsis, neoplasia, toxemia, pyometra, and lymphoma are important differential diagnoses for feline plague.

Diagnosis

Diagnosis of feline plague is based on identification of the organism collected from cultured tissue, fluid, or blood. Smears can be made from aspirates collected from draining lesions and enlarged lymph nodes; Gram-negative bacteria with a bipolar safety pin shape can be visualized. Cultures from tonsils are reported to

be particularly important in confirming a diagnosis; however, recent antimicrobial treatment might cause false-negative results. Colonies might take 48 hours to appear; they are a significant biohazard and should be sent to recommended laboratories obtained on the advice of local public health authorities. Acute and convalescent antibody titers can also be used to document infection. Since the incubation period is relatively short (1–6 days), seronegative results can occur initially in infected cats. A fourfold rise in antibody titer over 3–4 weeks is necessary to distinguish active disease from prior exposure. Because of the zoonotic potential of feline plague, attempts to culture the organism in a veterinary practice are discouraged. IFA testing can be performed on heat fixed slides of tissue aspirates or on impression smears collected at necropsy and submitted to recommended testing facilities. Specimens should not be shipped to routine veterinary diagnostic laboratories; local public health authorities should be contacted regarding approved testing laboratories and specific shipping instructions.

Management

Treatment/Prognosis

Because of the time delay involved in confirming a diagnosis, treatment is typically initiated pending results. Medical management of suspected cases includes treatment for fleas, flushing abscesses or draining lymph nodes, and administering antimicrobial therapy for a minimum of 10 days. It is particularly important that all cats suspected of having plague be handled by persons wearing full personal protective equipment, including examination gloves, gowns, and a surgical mask and goggles or a full face mask. Extreme care should be taken when working with cats that manifest signs of pneumonia. All suspect cases should be isolated for at least the first 4 days of antimicrobial therapy, and the number of people in contact with the case should be reduced to the bare minimum.

Although several antimicrobials have been effective against *Y. pestis* in cats, drug resistant strains are being isolated with increasing frequency. Administration of doxycycline (10 mg/kg IV or p.o. q.24 h. 10 days; administer IV diluted in 100 mL of lactated Ringer's solution over 2 hours) is recommended. Parenteral treatment is recommended for at least the first 72 hours to avoid contact with the oral cavity of infected cats. Alternatively, aminoglycosides (gentamicin [5–8 mg/kg IV, IM, or SC q.24 h. for 10 days], chloramphenicol [25–50 mg/kg p.o. q.12 h. for 10 days; 12–30 mg/kg IV, IM, or SC q.12 h. for 10 days], and trimethoprim–sulfamethoxazole [30 mg/kg p.o. q.12 h. for 10 days]) also have efficacy against *Y. pestis*. Cats that have been exposed to plague may be treated prophylactically with doxycycline (10 mg/kg IV or p.o. q.24 h. for at least 7 days). The prognosis for cats with clinical signs associated with plague depends on treatment status. Up to 75% of infected cats may die if untreated, but > 90% of cats treated with appropriate antimicrobial therapy survive.

Prevention

Effective flea control is the best means of preventing infection. In addition, dogs and cats should be restricted from hunting and access to carcasses of dead rodents or rabbits.

Public Health Implications

Humans most commonly become infected by infected flea bites, but inhalation and direct contact are other possible routes of infection. The risk of human exposure to plague appears to be greatest in the Western United States, particularly California, Arizona, and New Mexico. Because human plague infection, particularly pneumonic plague, has a significant mortality rate, veterinarians working in endemic areas should be particularly alert to potential infections in cats. Because domestic animal cases are now relatively rare, underrecognition could be problematic. Furthermore, there appears to be an increased risk of exposure when maintaining and treating nondomestic cats living in endemic areas. Attempts should be made to limit exposure to these potential carriers.

FELINE BABESIOSIS

See also Chapter 21.1.

Definition/Overview

Cats appear less predisposed to babesiosis when compared to dogs, so little is known about common clinical signs and/or disease course. Multiple *Babesia* species have been identified in cats, but *Babesia felis sensu stricto* is the most clinically important. Younger cats (< 3 years old), Siamese, and Oriental cats appear predisposed, with the disease being more prevalent in the summer months, most likely due to increased activity of the assumed tick vector.

Etiology

Babesia is a protozoa piroplasm endemic worldwide, mostly South Africa. The small *Babesia felis sensu stricto* is the important pathogenic species in cats. The definitive tick vector has not yet been identified. Transmission studies are also lacking.

Pathophysiology

Babesia species replicate in red blood cells (RBCs) to form merozoites. Ticks are infected by ingesting merozoites during feeding. Merozoites replicate within the tick salivary gland to form sporozoites. Maturation of the sporozoites occurs at the time of tick attachment, thus requiring an attachment time of 2–3 days before transmission can occur. When infected ticks feed, the sporozoites are then regurgitated into the host bloodstream. The subsequent intraerythrocytic infection leads to a hemolytic anemia. Blood transfusions are another possible method of transmission.

Clinical Presentation

Most clinical signs are attributable to the hemolytic anemia (e.g., pale mucous membranes, lethargy). Pyrexia and jaundice are uncommon. However, clinical signs may be mild due to the chronicity of infection and the cat's ability to adapt to the level of anemia (experimentally does not peak until 3 weeks post infection). More severe clinical signs occur in the presence of coinfections, such as with FeLV/FIV and splenectomized cats. Life-threatening complications include acute kidney injury, hepatopathies, pulmonary compromise, and neurological disorders.

Differential Diagnosis

Primary immune-mediated hemolytic anemia (IMHA); secondary IMHA (to drugs, neoplasia, infections, cytauxzoonosis, retroviruses, babesiosis, Heinz bodies, hypophosphatemia); pyruvate kinase deficiency, and other inherited hematological disorders.

Diagnosis

Whole blood PCR is the diagnostic test of choice. Due to low level of parasitemia, direct visualization of merozoites on blood smear is rare. Bloodwork often reveals a regenerative macrocytic hypochromic anemia, hyperbilirubinemia, moderate-to-marked increases in ALT activity, and increased total protein/hyperglobulinemia due to a polyclonal gammopathy. Coombs and autoagglutination tests can be positive. Serology is not recommended for diagnosis.

Coinfection with other erythrocytic pathogens, including *Mycoplasma* spp., and *Cytauxzoon felis*, has been reported in up to 30% of cases. As vectors for *Bartonella* spp. and *Babesia* spp. overlap, coinfection may also exist in cats, but it has yet to be documented.

Management

Treatment/Prognosis

Primaquine phosphate (0.5–1 mg/kg p.o., IV or IM once or daily for 3 consecutive days). Recrudescence can occur a few weeks later, which if associated with continued clinical signs, repeat treatment is recommended. Doses exceeding 1 mg/kg can be lethal in cats. Chronic, persistent infections and cyclical disease recurrence can occur. Treatment for asymptomatic chronic carriers with persistent parasitemia is not recommended at this time. However, monitoring via routine complete blood count (CBC) evaluation and blood smear analysis is indicated. Mortality rates of 15%–20% are reported in acute severe disease.

Prevention

Effective tick control and reduced exposure to ticks.

Public Health Implications

Feline babesiosis is not a known zoonotic disease.

FELINE ANAPLASMOSIS

Definition/Overview

Anaplasmosis is a tick-borne disease caused by *Anaplasma phagocytophilum*. Estimated prevalence varies widely depending on the geographical location. Although clinical signs are nonspecific, moderate-to-marked thrombocytopenia is the common hematological finding.

Etiology

Anaplasma phagocytophilum is an intracellular Gram-negative bacteria transmitted by the *Ixodes* tick species within 24–48 hours of tick attachment. Rodents and wild ruminants are the most common reservoirs. Blood transfusions are another potential source of infection. Transplacental infection in cats has not been described. In Europe, estimated serological prevalence is 0%–33.3% and in the United States 4.3%–37.6%. Direct pathogen detection via PCR or within a blood smear in Europe is 0%–23.1% and 0%–6.9% in the United States and in a recent study of UK ticks 0.9%. Outdoor cats have an increased risk of disease due to tick exposure. Increased self-grooming of cats compared to dogs may also contribute to species differences.

Pathophysiology

Infection is spread via an infected tick bite. The bacteria invades neutrophils, forming morulae, where it is then spread hematogenously and via lymphatics. The immune function of the neutrophil is compromised, leading to further dissemination of the organism.

Clinical Presentation

Clinical signs of acute disease develop after a 1- to 2-week incubation period, often after only a few days postvector contact. Usually, signs are nonspecific, including lethargy, pyrexia, anorexia, and conjunctivitis. Painful abdomen and limbs have also been reported in up to 30% of cats within one case series. Gingivitis, calculus, weight loss, and neurological signs are also reported but in < 10% of cases. Asymptomatic and chronic infections are rare.

Differential Diagnosis

Feline upper respiratory tract disease (e.g., chlamydia, FHV, FCV), FeLV/FIV, immune-mediated thrombocytopenia (primary or secondary), and other tick-borne disease (including Ehrlichiosis).

Diagnosis

Mild-to-moderate thrombocytopenia is the most common finding, followed by anemia, and should raise suspicion of this disease. Visual detection of morulae within neutrophils raises suspicion but must be confirmed with PCR. PCR can be performed on whole blood, buffy

coat, bone marrow, or splenic samples. False-negative PCR results can occur in chronic infections due to low levels of parasitemia. Rapid serological testing, such as the SNAP 4DX Plus Assay (IDEXX) ELISA are available and can be used in cats. False-negative serology tests could occur early in the course of infection (seroconversion taking approximately 2 weeks' post infection to occur), but false positives can occur due to cross-reaction with other pathogens, such as *Ehrlichia* spp.

Management

Treatment/Prognosis

Doxycycline (10 mg/kg p.o. s.i.d. for 28 days) is the treatment of choice. This should always be administered with food or water to prevent esophagitis. Clinical signs usually rapidly improve following antimicrobial treatment. The exact duration of treatment to ensure clinical resolution in cats is unknown.

Prevention

Effective tick control, regular checking for and removal of ticks and reduced exposure to ticks.

Public Health Implications

Possible cause of granulocytic anaplasmosis in humans.

FELINE CYTAUXZOONOSIS

Definition/Overview

Cytauxzoonosis is mainly a disease found in the United States, but occasionally cats from Europe are affected, although likely caused by different species. Literature suggests that different species vary in their pathogenicity, thus causing both symptomatic and asymptomatic disease. *Cytauxzoon felis* is a tick-borne pathogen causing hemolytic anemia and subsequent jaundice in cats from endemic areas and is further discussed later.

Etiology

Bobcats and pumas are the main reservoir host of this disease and are subclinically affected. The main tick vector in the United States is *Amblyomma americanum*, but *Dermacentor variabilis* has also been shown to be a competent vector. Blood transfusion is another possible method of transmission.

Pathophysiology

In the acute phase of disease, schizont-infected macrophages obstruct blood vessels, disrupting blood flow to various tissues leading to circulatory impairment and multiorgan failure. In addition, merozoites released from macrophages infect red blood cells. This intraerythrocytic infection leads to a hemolytic anemia. The pathogenesis and route of transmission of other *Cytauxzoon* spp. requires further investigation.

Clinical Presentation

Incubation period is 5–20 days. Cats usually present with pyrexia, anorexia, vomiting, depression, icterus, signs of anemia, dyspnea, hepatosplenomegaly, and occasionally coagulation disorders.

Differential Diagnosis

Primary immune-mediated hemolytic anemia (IMHA); secondary IMHA (to drugs, neoplasia, infections, retroviruses, babesiosis, Heinz bodies, hypophosphatemia, and hemoplasmosis); pyruvate kinase deficiency; and other inherited hematological disorders.

Diagnosis

Detection of the organism either cytologically on blood smears, tissue histopathology or PCR from blood, spleen/liver aspirates, bone marrow, or lymph node aspirates. Serology is not commercially available. Routine blood work often reveals a regenerative anemia, neutrophilia, thrombocytopenia may or may not be present, and hyperbilirubinemia. A recent study showed that despite severe histologic evidence of disease there are no pathognomonic thoracic radiographic findings in cats with acute cytauxzoonosis. However, pulmonary infiltrates can occur.

Management

Treatment/Prognosis

Combination therapy with atovaquone (15 mg/kg p.o. q.8 h.) and azithromycin (10 mg/kg p.o. q.24 h.) is the treatment of choice. Diminazene or imidocarb do not perform as well. Other supportive treatment, such as blood transfusions, as necessary. It was previously considered a fatal disease, but many cats will survive and become subclinical carriers with chronic asymptomatic parasitemia.

Prevention

Housing indoors or regular tick prevention is advised. The consensus statements of the European Advisory Board on Cat Disease (ABCD) and the American College of Veterinary Internal Medicine (ACVIM) recommend that in endemic areas only PCR-negative cats should be used as donors.

Public Health Implications

Cytauxzoon felis is not a known zoonotic pathogen.

FELINE LEISHMANIA

Definition/Overview

The prevalence of *Leishmania infantum* in cats is significantly lower than in dogs. Although a rare disease in this species, it still has significance clinically and possibly in disease transmission, with cats being potential reservoirs of infection for sandflies.

Etiology

The disease is transmitted by an infected sandfly feeding on the host. Blood transfusion is another possible method of transmission.

Pathophysiology

The vector infects the host with promastigotes, which transform into amastigotes able to replicate within macrophages and trigger a granulomatous inflammatory reaction. The outcome of infection is based on host immune response, as in dogs. The production of high-level antibody levels also contributes to presenting signs through deposition of immune complexes, for example in the kidneys. The disease is never cured but can remain in a latent/subclinical state for prolonged periods.

Clinical Presentation

Feline leishmaniosis (FeL) is a chronic disease with an incubation period of months to years that is more commonly associated with subclinical infection. However, cats can present similarly to dogs. Nodular, ulcerative, or scaly skin lesions and lymphadenopathy are the most common presenting signs with weight loss, uveitis, and lethargy. Most cases of feline leishmaniosis are immunocompromised due to concurrent FeLV/FIV infection, medication, or other significant comorbidities.

Differential Diagnosis

Conditions which affect the skin should be considered as differential diagnoses such as bacterial infections (abscesses, actinomycosis, nocardiosis, rhodococcosis, mycobacteria, etc.), fungal infections (blastomycosis, cryptococcosis, mycetoma, histoplasmosis, etc.), poxvirus, neoplasia, and foreign body granuloma. Other differentials include leptospirosis, toxoplasmosis, glomerulonephritis, neoplasia, and other chronic immune-mediated/infectious disease.

Diagnosis

Initially, a quantitative antibody test should be performed if clinical signs of FeLV are present. A high antibody titer in this situation is considered diagnostic. If low positive or negative results are obtained, then tests to detect the parasite are warranted. These parasitological tests include cytology/histopathology of skin lesions, PCR (lesions, lymph node, conjunctival swab, or blood), or culture.

Routine blood and urine screening most commonly identifies hyperglobulinemia, mild-to-moderate nonregenerative anemia and proteinuria.

Management

Treatment/Prognosis

Empirical treatment protocols are the same as in dogs; however, controlled clinical studies are lacking. Side effects are also similar, in addition to pruritus in one study. It should also be considered that propylene glycol is among the excipients of the oral miltefosine (Editors' Note: Might not be readily available in the United States) licensed for the treatment of dogs with leishmaniosis, which has been linked to Heinz body formation and decreased feline RBC life span. Prognosis is considered good unless there are significant comorbidities but does not appear to be affected by concurrent FIV infection in one study.

Prevention

General sandfly bite prevention, bearing in mind pyrethroids are toxic to cats. The only pyrethroid formulation licensed for cats is the flumethrin collar, which in field studies did reduce the incidence of FeLV.

Public Health Implication

Leishmaniosis is a zoonotic disease the role of the cat as a potential reservoir of disease requires further study.

VIRAL INFECTIONS

FELINE VIRAL UPPER RESPIRATORY INFECTION

Definition/Overview

Feline viral upper respiratory infection is generally attributable to either or both of two viruses: Herpesvirus (FHV-1) and calicivirus (FCV). It is important to acknowledge that bacterial upper respiratory tract infections with *B. bronchiseptica*, *C. felis*, *M. felis*, *Staphylococcus* spp., and/or *Streptococcus* spp. may concurrently infect cats with FHV-1 or FCV, thereby complicating the course of clinical disease.

While FHV-1 causes fairly uniform clinical disease, several strains of FCV have been identified and are known to vary in their clinical effects, anatomic localization, virulence, and antigenicity. Despite widespread vaccination against FHV-1 and FCV, these viruses still occur very frequently in the domestic cat population, particularly in multiple cat households and animal shelters.

Etiology

Transmission from infected to susceptible cats occurs most commonly by direct contact via ocular/nasal and respiratory secretions and through fomites; airborne transmission is not thought to be important, although sneezed droplets can spray over 1–2 meters. FCV has also been detected in the urine and feces of infected cats and in flea feces. Cats living in high-density populations are known to be particularly susceptible to infection because crowding facilitates viral transmission, and stress reduces immune function as well as precipitating reactivation and shedding. Young kittens may, therefore, acquire infection at an early age, depending on maternally derived antibodies and

subsequent immunity. Those that recover from the acute infection are likely to develop a chronic carrier state with either FHV-1 or FCV. This chronic carrier state usually persists for months to years (likely for life in the case of FHV-1 carriers) and contributes significantly to the persistence of the virus within cat populations, particularly in multicat environments. FHV-1 shedding by carriers is intermittent but can be precipitated by stress or immunosuppressive therapy; FCV shedding is usually constant but can fluctuate in individuals.

Pathophysiology

After initial acute infection, FHV-1 is carried as a latent virus, usually in the trigeminal ganglia. Reactivation and thus intermittent periods of shedding in oronasal and conjunctival secretions may occur for 1–3 weeks following a "stressful" episode (e.g., boarding, general anesthesia, corticosteroid therapy, parturition). During this time, cats may manifest mild clinical signs, but they are capable of shedding virulent virus. High positivity rates (25%–50%) are found in acute upper respiratory tract disease cats when sampled.

It has been reported that 50% of FCV-recovered cats develop a carrier state and shed virus for at least 75 days after infection. Although chronic FCV carriers may shed virus for weeks to possibly years following the initial infection and be clinically well, they shed virus continuously from conjunctival, nasal, and oral secretions and, as such, pose a significant risk to susceptible kittens and adults.

Clinical Presentation

The hallmark clinical sign of acute viral upper respiratory disease (URD) is sneezing and hypersalivation frequently accompanied by a serous to mucopurulent nasal and ocular discharge, dehydration, anorexia, and varying degrees of conjunctival hyperemia and chemosis (Figures 21.2.7 and 21.2.8). Acute URD being defined as < 10 days in duration.

FIGURE 21.2.8 Cat with unilateral conjunctivitis and photophobia due to feline herpesvirus.

Oral ulceration can be common among FCV-infected cats but is relatively uncommon in FHV-1 infections. Ocular signs of conjunctivitis, keratitis, dendritic ulceration (Figure 21.2.9), corneal sequestra, and profound chemosis are more likely to occur in cats with FHV-1 than with FCV. Self-resolving polyarthropathy and pyrexia (limping kitten syndrome) can occur in juvenile cats infected with FCV (Figure 21.2.10), often following acute oral/respiratory signs, but has not been reported in association with FHV-1.

However, attempting to distinguish one viral infection from another on the basis of clinical signs is particularly difficult, and coinfections (predominantly causing pneumonia in kittens) also occur. Clinical signs and history are usually sufficient to make a clinical diagnosis of viral upper respiratory infection. Given the treatment options available, it is not always important to distinguish one viral infection from another, although environmental disinfection requires compounds capable of inactivating enveloped viruses in FCV outbreaks.

FHV-1 carrier cats may manifest with chronic rhinitis because of permanent viral turbinate lysis. Clinical signs characteristically resolve during periods

of antimicrobial administration, only to reappear following discontinuation of the drug. Chronic immune-mediated signs associated with viral infection, such as stromal keratitis (FHV-1) and gingivostomatitis (FCV) can occur.

Virulent-systemic feline calicivirus (VS-FCV) strains have different pathogenesis and clinical presentation. They are detailed in further section.

Differential Diagnosis

Ocular signs of acute viral upper respiratory infection in kittens, such as severe conjunctivitis and chemosis, may be consistent with *C. felis* infection, although the viral infection is characteristically associated with more severe respiratory signs. *Bordetella bronchiseptica* may cause opportunistic infections culminating in pneumonia and sudden death among kittens with acute viral respiratory disease. *M. felis* infection can cause acute upper respiratory and/or ocular signs and is a cause of bacterial pneumonia in cats.

Diagnosis

Commercial veterinary laboratories offer PCR testing for feline upper respiratory tract pathogens, including FHV-1 and FCV. A sterile cotton-tipped swab with a plastic (not wooden) stem is used to collect specimens from the conjunctival sac and tongue/oropharynx (preferred if only one site possible). The swab should be transported in a plain sterile tube that does not contain transport medium. Because of the high number of vaccinates and the frequency of chronic carrier cats, serology has not been a valuable aid. Due to its high sensitivity, a quantitative PCR can further guide on the importance of a positive sample and must always be interpreted in view of the presenting clinical signs. Topical anesthetics and fluorescein could affect the PCR sensitivity. A negative result does not rule out infection. Other pathogens can also be screened for using the same sample. Serology is of limited value for diagnosis.

Management

Treatment/Prognosis

The focus of treatment for cats with viral upper respiratory infection, whether it be FHV-1 or FCV, centers around the ability to provide good nursing care, enteral nutrition, fluid and electrolyte replacement, and antimicrobial therapy to combat secondary bacterial infection. Doxycycline (10 mg/kg p.o. q.24 h. for 7–10 days) is a good empiric choice, as it is also effective against *C. felis*, *B. bronchiseptica*, and *M. felis*. Dehydration results from reduced food and fluid intake and losses via secretions, which can be copious. In severe cases, dyspnea can occur. Placement of a nasoesophageal or esophagostomy feeding tube facilitates the administration of fluids and calories to affected cats (Figure 21.2.11). Regular saline nebulization (q.4–6 h. for approximately 15 minutes) can help loosen secretions, reduce congestion, and improve comfort. Intermittent saline nasal flushing, eye drops, and mucolytic agents (e.g., bromhexine) can also be helpful. There is no evidence for the use of maropitant specifically for these pathogens, but it is sometimes used in cats with upper respiratory tract disease. Following rehydration, NSAIDs could be considered if necessary to reduce pain and pyrexia.

There is no antiviral therapy registered for use in FHV-1- or FCV-infected cats. The popular anti-herpesvirus drug used in human herpesvirus infection, acyclovir, has been studied in cats and shown not to be effective against FHV-1. It can cause leukopenia and anemia, which are reversible when therapy is discontinued. There have been promising reports of favorable responses to treatment with famciclovir in cats naturally infected with FHV-1, but these have mostly been anecdotal or the result of uncontrolled studies. Dose and dose frequency are critical with this drug, and the cost of therapy at the currently recommended dose rate of 90 mg/kg q.12 h. is prohibitive in most cases. However,

FIGURE 21.2.11 A nasoesophageal tube being used to provide fluids and calories to an anorexic cat with acute viral upper respiratory tract infection. (*Courtesy of the Feline Centre, Langford Vets, University of Bristol*.)

in cats with ulcerative keratitis associated with FHV-1, ophthalmic trifluridine (1% solution) can be administered topically at 4- to 6-hour intervals until 1 week beyond resolution of clinical signs. A commercially available hyperimmune serum containing antibodies to FHV-1, FCV, and FPV is available in some countries. In the limited studies available, cats showed more rapid clinical improvement initially when compared to placebo. However, this benefit was lost at day 7, so the treatment benefit is questionable. Studies do not suggest the use of feline interferon-omega or oral L-lysine show any additional benefit beyond routine symptomatic treatment in acute respiratory disease.

The prognosis for recovery from acute viral upper respiratory infection is excellent if supportive care is provided and the cat housed to avoid known risk factors for clinical disease, such as stress due to overcrowding. In the absence of treatment, most infections are self-limiting in 10–14 days. However, secondary bacterial infections can become severe. Complicating pneumonia is especially devastating in kittens, particularly if *B. bronchiseptica* is involved, and may culminate in high mortality rates among litters of affected kittens. The long-term prognosis is dependent on the establishment of a chronic carrier state and, potentially, anatomic damage to the eye and turbinates (FHV-1) or the development of chronic oral conditions, which are thought to be FCV related. Associated clinical signs of infection in cats recovered from acute infection are usually intermittent (sneezing, ocular and nasal discharge) but can be continuous (ocular and/or nasal discharge, sneezing, gingivostomatitis). Following recovery from acute infection, development of a carrier state is common for both viruses. It is thought that many FCV-infected cats will develop a carrier state for months to years following infection, and almost all FHV-1 infected cats develop a carrier state following recovery that will persist for the life of the cat.

Prevention

Environmental and hygiene factors are important. FHV-1 is an enveloped DNA virus that is extremely labile outside the host, being inactivated within a few minutes at 56°C and by most commercial disinfectants, so except in situations with densely housed cats (e.g., catteries), environmental contamination is not a common source of infection. FCV, on the other hand, is an unenveloped ribonucleic acid (RNA) virus that can survive outside the host for up to a month on dry surfaces at room temperature and is not susceptible to some commonly used disinfectants, such as quaternary ammonium compounds. Effective substances include sodium hypochlorite (5% bleach diluted at 1:32), potassium peroxymonosulfate, chlorine dioxide, and other virucidal approved commercial products. Washing of laundry including bedding at > 60°C is also advised. Limiting cat group sizes, quarantine of new cats, separating sick cats, limiting new cat introductions, and regular flea prevention also all help in prevention by reducing stress and exposure.

Parenteral (killed and modified live) and topical (intranasal/intraocular) vaccines are commercially available in some countries. Vaccination helps protect cats from the severe effects of clinical disease but not against infection/becoming carriers. Intranasal vaccination should only be administered with a vaccine approved for use by this route, and mild sneezing is common for 3–5 days after vaccination. However, severe clinical upper respiratory signs can occur if injectable vaccines are administered intranasally. Current recommendation is that boosters are administered every 3 years from 1 year after the primary series (Table 21.2.1). Measurement of antibody testing against FHV-1 or FCV can be used before vaccination to determine if a booster is required, as effective immunity against both of these agents requires both an antibody response and cell-mediated immunity, and correlation between antibody levels and protection is poor.

Public Health Implications

Despite concerns that human infection can result from contact with an infected cat, the infections must be considered independent. Neither FHV-1 nor FCV is considered to be a human pathogen and, as such, poses no risk to human health.

VIRULENT SYSTEMIC CALICIVIRUS INFECTION

Definition/Overview

A small number of infectious disease outbreaks within cluster households of cats has been associated with a VS-FCV. Initially reported as "hemorrhagic FCV," the limited number of infections caused by this highly infectious emerging pathogen has resulted in mortality rates of up to 70% in previously healthy adult cats. Prior vaccination with a combination FHV-1/FCV vaccine for the prevention of upper respiratory infections may not provide cross-protection against the VS-FCV because in every outbreak of VS-FCV, a genetically distinct strain of FCV has been involved.

Etiology

The ability of FCV to infect cats whether or not they are vaccinated, and for infected cats to develop a chronic carrier state associated with persistent shedding from the nasopharynx, explains the high prevalence of calicivirus in the general cat population. Although each VS-FCV has been associated with a separate mutation of one of the feline caliciviral strains, similar clinical presentations have been reported. Outbreaks have been reported among both vaccinated and unvaccinated cats. Index cases from all reported outbreaks have come from crowded, high-stress environments, such as shelters, rescues, and sometimes veterinary clinics. This highly contagious virus is transmitted by infected cats and their fomites; just a few hairs have acted as fomites and transmitted infection in some outbreaks.

Pathophysiology

Changes in the capsid gene of FCV, or in virus–host interactions, are thought to be responsible for VS-FCV infection. Affected cats develop severe acute systemic illness caused by multiorgan damage, likely due to widespread vasculitis and vascular compromise, systemic inflammatory response syndrome (SIRS), and DIC. Unlike the usual field strains of FCV, adult cats are particularly affected by VS-FCV, perhaps because the immune response to the virus is responsible for some of the clinical manifestations of disease.

Clinical Presentation

Initially, the infection may present as moderate-to-severe upper respiratory infection. However, the disease rapidly progresses, and clinical signs include fever, facial, limb edema, ulceration, and crusting of the face, muzzle, feet, and pinnae. Viral invasion of both epithelium and endothelium occurs, and visceral involvement (lungs, pancreas, liver) with jaundice can occur. DIC can ensue (with overt hemorrhage in some cases), and mortality rates are high (up to 70%), especially among adult cats. Laboratory findings are nonspecific. Necropsy findings include necrosis of major organs such as the liver, spleen, pancreas, lung, and GI tract. Laboratory testing cannot distinguish VS-FCV from regular field strains of FCV, and carriage rates for FCV are high (approximately 25%–30%) among the general feline population.

Similar clinical signs occur in a less fatal manifestation of FCV known as "paw and mouth disease." Whether this is caused by less pathogenic but similar strains of the virus is unknown.

There are currently no specific diagnostic assays for VS-FCV.

Differential Diagnosis

The differential diagnosis includes sepsis, vasculitis, systemic toxicity, envenomation, cutaneous neoplasia, or severe viral upper respiratory infection. Systemic signs may include laboratory and clinical evidence of acute pancreatitis or acute liver failure (e.g., jaundice). Feline panleukopenia virus is a differential diagnosis for sudden death and can also be a comorbid infection, especially in shelter outbreaks.

Diagnosis

In order to identify cases of VS-FCV, it is advisable to both demonstrate FCV infection and confirm antigen in what are otherwise considered unusual sites such as the liver.

Management

Treatment/Prognosis

Because of the high morbidity and mortality associated with outbreaks, deaths usually occur over a relatively short initial period, followed by prolonged clinical recovery for severely ill but surviving cats. If an outbreak can be contained within a population, spread of the virus is typically limited. However, VS-FCV is extremely easily transmitted to other cats by fomites (hands, hair, clothing, food dishes); therefore, strict control procedures, including isolation, quarantine, thorough disinfection with appropriate agents, and the use of disposable personal protective equipment by all personnel in contact with infected or exposed cats must be implemented in order to effectively contain an outbreak. Sadly, there is no clearly defined quarantine period after which cats are guaranteed to be safe. Supportive care is indicated, although the rapid course of infection may not yield effective patient care and long-term survival. If possible, infected cats should be cared for on an outpatient basis by a minimum number of staff. Ideally, catteries, rescues, shelters, and veterinary hospitals should be closed for at least 4 weeks to prevent disease transmission until the outbreak is under control.

Prevention

Population management by reduction of overcrowding in multicat housing and adoption of healthy cats into low-density homes reduces the risk of a VS-FCV outbreak. Vaccines have been introduced into the UK and the United States for the prevention of VS-FCV infection. However, every reported outbreak of VS-FCV has been due to a genetically distinct viral strain. Additionally, protection is not provided until at least 2 weeks after the second vaccination with VS-FCV vaccines because they are inactivated.

Public Health Implications

VS-FCV poses no known threat to human health.

FELINE LOWER RESPIRATORY TRACT VIRAL INFECTION

FELINE POXVIRUS

Definition/Overview

Feline poxvirus is an orthopoxvirus and an emerging feline respiratory pathogen, endemic within Northern Europe.

Etiology

Hunting cats are considered most at risk due to exposure to wild rodent reservoir hosts, with disease incidence peaking in the autumn. There are two forms of clinical feline cowpox that occur as a result of disease, cutaneous and pulmonary. Transmission between cats has been reported, and dry scabs can hold their infectivity in the environment for several months.

Pathophysiology

The primary lesion/site of inoculation is cutaneous, with replication within macrophages and monocytes in local lymph nodes. Following a period of viremia, secondary lesions develop in the lungs and sometimes spleen.

Clinical Presentation

In feline cutaneous poxvirus, lesions are most commonly found on the head, ears, and paws, as infection is most often associated with rodent bite/contact. Multifocal discrete nodular (Figure 21.2.12) or ulcerative/crusting skin lesions and/or dermatitis occur, developing approximately 10 days post infection. Ulcerative oral lesions can develop in up to 20% of infected cases, which contributes to oral pain and anorexia. As ulcerative skin lesions heal, usually spontaneously after 4–5 weeks, round areas of alopecia remain (Figure 21.2.13). Nonspecific systemic signs of viremia follow, including lethargy, pyrexia, and inappetence. In cats affected with the pulmonary poxvirus form, clinical signs will occur due to the effects of a necrotizing pneumonia with or without pleural effusion and/or lung lobe consolidation. The presence of skin lesions and lung lobe consolidation on imaging increases suspicion. Cats in this phase of disease will often present with a cough, and progressive dyspnea will occur.

Skin lesions in pox cases can continue to develop for 6–8 weeks after infection and may take up to 12 weeks to fully resolve.

Multifocal discrete nodular (Figure 21.2.12) or healing ulcerative skin lesions with circular areas of alopecia remaining (Figure 21.2.13).

FIGURE 21.2.12 Multifocal discrete nodular skin lesions with circular areas of alopecia in a cat with feline cutaneous poxvirus.

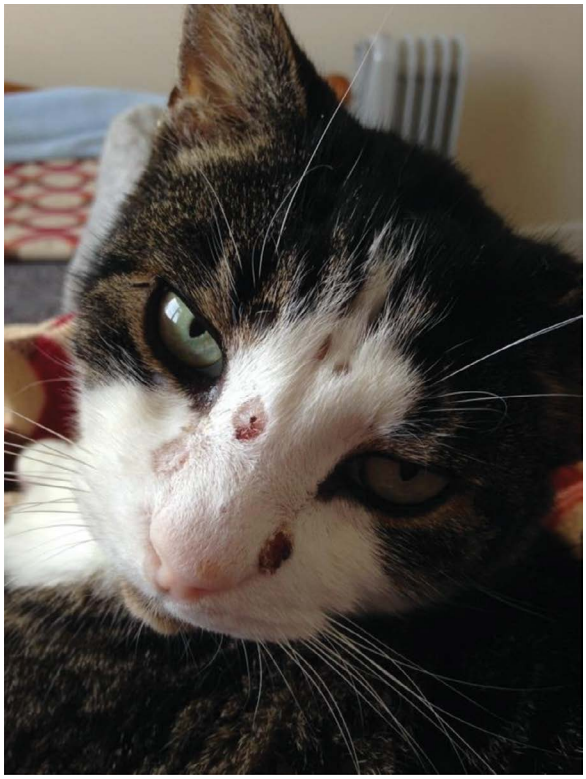

FIGURE 21.2.13 Multifocal discrete healing ulcerative skin lesions on the face of a cat with feline cutaneous poxvirus. Note the circular areas of alopecia surrounding the healing ulcers.

Differential Diagnosis

Dermatologic cryptococcosis; other mycoses, mycobacteriosis, nocardiosis, neoplasia (e.g., squamous cell carcinoma), herpetic dermatitis, and eosinophilic granuloma complex.

Diagnosis

For feline cutaneous poxvirus, diagnosis revolves around sampling of the abnormal skin lesions. Samples of skin lesions (dry scab/skin biopsy) are submitted for virus detection using PCR (most common; rapid result), culture (> 7 days until result), electron microscopy, or visualization of inclusion bodies on histopathology. Paired serology is possible, with titers rising 2 weeks following infection, but is not commonly available.

In diagnosis of feline pulmonary poxvirus, similar diagnostic tests are available for fluid or tissue samples obtained. Those most likely available would be pleural or bronchoalveolar lavage (BAL) fluid. Other options include lung fine-needle aspirate or oropharyngeal swabs. Cytology of respiratory fluid samples are usually predominantly neutrophilic.

Thoracic imaging can assist in the diagnosis and treatment through detection of pneumonia, pleural effusion, and lung lobe consolidation, which increases index of suspicion.

Management

Treatment/Prognosis

Barrier nursing of the affected patient is required. As a virus, no specific treatment is available; therefore, supportive therapy is paramount. Cats suffering with pleural effusion and subsequent respiratory compromise require oxygen therapy and therapeutic thoracocentesis. If tolerated, saline nebulization can help expel excessive respiratory secretions associated with the necrotizing pneumonia. In addition, nutritional support, such as a nasoesophageal feeding tube, and antinausea medication may be required. Skin nodules often progress to ulcers to ulcerated scabs, so it is important to prevent secondary skin infections through topical management/skin cleaning if needed. There is no current supportive evidence for antiviral or interferon treatment. In the few case studies available, some cats had coinfections with other pathogens, which caused more severe clinical signs (e.g., FeLV/FIV, herpesvirus), so testing for these should also be considered.

There are a few factors considered to affect prognosis. These include the poxvirus strain, the route and site of infection (pulmonary is worse), dose of inoculated virus, and the presence of systemic immunosuppression (e.g., FeLV/FIV or concurrent immunosuppressive glucocorticoid treatment).

Prevention

There is no vaccination currently available. Reducing exposure to reservoir hosts and keeping cats indoors are potential options. Prolonged survival in the environment can occur, as such appropriate disinfection of affected areas is needed following a confirmed case.

Effective products against feline poxvirus include 0.8% sodium hydroxide, 1% sodium hypochlorite (bleach), quaternary ammonium compounds, 3% iodine and phenolic compounds, 0.2% chloramine T.

Public Health Implications

Feline poxvirus is a known zoonosis, usually causing mild and self-limiting pustular skin lesions of the hands and face (contact areas) in humans. However, severe and fatal cases can occur. Gloves must be worn at all times during handling of suspected cases.

FELINE RETROVIRUS INFECTION

FELINE LEUKEMIA VIRUS

Definition/Overview

FeLV is a single-stranded RNA virus (oncornavirus) belonging to the retrovirus group. FeLV is a pathogenic, oncogenic (tumor-producing) virus that replicates within numerous tissues in cats, including bone marrow, salivary glands, and epithelial cells.

Etiology

The virus is spread both vertically (in utero or through milk) and horizontally (from cat to cat) usually through "friendly" contact, such as mutual grooming, but also through bites. FeLV does not survive for long outside the host under dry conditions and is readily inactivated by disinfectants, soap, heating, and drying. Although transmission via fomites is very unlikely, small amounts of virus can survive for at least 48 hours if kept moist at room temperature. Transmission via blood transfusions can also occur. Subtypes A, B, C, and T exist; the FeLV-A subtype is ubiquitous and present in all infections. The virus has worldwide distribution.

Pathophysiology

The biology of FeLV infection in cats is highly complex. Susceptibility to FeLV infection is greatest in kittens under 4 months of age. Following FeLV infection, usually via the oronasal mucosa after constant exposure to chronically shedding cats or via a bite wound, FeLV viral replication occurs in local lymphoid tissues. During replication, FeLV RNA integrates into the host feline cells, producing proviral DNA via FeLV reverse transcriptase; this proviral DNA can be detected by PCR testing. The FeLV can then spread via circulating monocytes and lymphocytes to other lymphoid tissues. This equates to the "primary viremia," which is associated with the presence of free p27 FeLV antigen in the blood, detectable by screening tests. If the FeLV is not contained by the immune response and is able to reach the bone marrow, viral replication occurs in the bone marrow so that neutrophil and platelet precursors become FeLV infected. This bone marrow stage is associated with the presence of cell-associated p27 FeLV antigen in the blood, which can be detected by the immunofluorescence antibody (IFA) test. Thereafter, if the FeLV is still not contained, other granulocytes become infected, and the "secondary viremia" occurs, which allows spread of FeLV throughout the body, including in epithelial cells. FeLV virus is shed in high amounts in saliva and nasal secretions with lower amounts in urine and feces (and milk if lactating). This full course of infection is only completed in progressively infected cats. In cats in which the immune response is able to contain the FeLV before this course is completed, regressive or abortive infection results, depending on the time at which the cat's immune response is effective.

The outcome of FeLV infection is influenced by factors such as age of the cat (younger cats more susceptible to progressive infection), the strain/pathogenicity of FeLV, the infectious pressure, and the immune response of the host. These factors influence the balance between the host and the virus. Although suppression of the virus by the host immune response, when it occurs, usually happens within a few weeks of FeLV exposure, it can take many weeks or months for the immune response to gain the upper hand over the virus.

There are three main possible outcomes of FeLV infection in cats:

1. *Progressive infection:* Extensive virus replication occurs in the lymphoid tissues and then in the bone marrow and epithelial tissues, with shedding of infectious virus. Progressively infected cats become p27 antigen positive within 2–3 weeks (and always by 6 weeks) of FeLV exposure and remain so lifelong, with persistent high levels of FeLV (viral) RNA and proviral DNA in the blood. Indeed, FeLV proviral DNA and plasma viral RNA are usually detectable by PCR in the blood within 1–2 weeks of FeLV exposure, often before blood FeLV p27 antigen is detectable. These cats are usually confirmed as being progressively FeLV infected by repeat positive p27 antigen testing after several weeks.

Progressive infected cats often develop FeLV-associated disease, e.g., lymphoma, nonregenerative anemia, leukemia, opportunistic infections, and/or immunodeficiencies, after which the prognosis is poor, although some can survive for long periods with proper care.

2. *Regressive infection:* Fortunately, most FeLV infected cats undergo regressive infection and are unlikely to develop FeLV-related disease. Here, sufficient FeLV-specific immunity (viral neutralizing antibodies and cytotoxic T-lymphocytes) occurs so that FeLV replication is contained before or at the time of bone marrow infection. Despite the FeLV-specific immunity that occurs in regressive infections, FeLV is still integrated into the genome of infected cells permanently, and this may or may not be accompanied by transient viral shedding (i.e., a transient viremia). Cats that do not undergo viral shedding remain negative on p27 antigen blood tests throughout. Cats that do undergo transient viral shedding are transiently p27 antigenemic within 2–3 weeks of FeLV exposure, with shedding usually completed by 4 weeks (but can be up to 16 weeks) post infection. The length of this transient shedding determines the optimal time period between repeat p27 antigen testing following a positive result to differentiate between progressive (continually p27 antigen positive) and regressive (becomes p27 antigen negative) infections. Waiting 16 weeks for retesting is quite lengthy, so a compromise of 6 weeks before retesting is advised. The eventual negative p27 antigen test that occurs in regressive infection readily distinguishes it from progressive infection. Additionally, blood loads of FeLV proviral DNA and viral RNA also eventually distinguish between progressive and regressive FeLV infection because, although both progressive and regressive infections are associated with similar high blood proviral DNA and viral RNA loads during initial infection, levels of proviral and viral RNA subsequently fall in regressively infected cats compared to progressively infected cats.

It had been thought that regressively infected cats were at little risk of developing FeLV-associated diseases, with provirus presence contributing to protection from FeLV-associated disease, but reactivation of infection and ensuing viral replication in cats has been reported, albeit uncommonly, and can be associated with lymphoma. The risk of reactivation of viremia is said to decrease over time. Others have suggested that the regressive state itself, without reactivation of viremia, may be associated with clinical disease such as lymphoma and bone marrow suppression.

3. *Abortive infection:* These cats mount an effective immune response on exposure to low doses of FeLV early in infection. They never test provirus PCR positive or p27 antigen positive at any stage but are identified by the presence of anti-FeLV antibodies (more specifically antibodies to FeLV p15E protein, an envelope transmembrane protein), a test for which has recently become available. It used to be thought that abortive outcome of FeLV infection was rather uncommon compared to regressive and progressive infection, but more recent data suggest that it is a very common outcome of FeLV infection, unless there is intense infectious pressure, comorbidities, or stress, in which case regressive or progressive infections are more common.

Additionally, focal or atypical infections have been rarely described where anatomically localized viral replication (e.g., in the bladder, eyes, mammary glands) exists that can result in intermittent p27 antigenemia, with accompanying positive p27 ELISA test results. Weak positive, discordant, or fluctuating positive/negative p27 ELISA results can occur.

Clinical Presentation

FeLV infection risk factors identified include mixed-breed, outdoor access, male gender, entire status, living in multicat environments with five or more cats, originating from geographic areas with a high FeLV prevalence, and/or lack of FeLV vaccination and being sick. Clinical signs of FeLV infection are highly variable and potentially involve any organ system. FeLV-infected cats are at risk of developing solid tumors (e.g., lymphoma) or leukemia, bone marrow suppression involving leukocytes and erythrocytes, and increased susceptibility to bacterial, viral, and/or fungal infections. Immune complex disease affecting renal function and causing polyarthritis has also been documented, as have reproductive (including embryonic deaths and stillbirths) and CNS disorders.

Differential Diagnosis

Cats presenting with any chronic, debilitating illness, fever, or weight loss should be tested for FeLV, regardless of age. Chronic upper respiratory infection, stomatitis, gingivitis, and periodontitis are common respiratory/oral signs that justify testing. Since FeLV has oncogenic potential, cats with neoplasia, especially lymphoid tumors, should be tested. Hematologic abnormalities such as nonregenerative anemia, lymphoblastic leukemia, leukopenia, thrombocytopenia, or thrombocytosis (> 1 million platelets/mm^3) can be associated with FeLV.

Diagnosis

Because of the nonspecific nature of clinical signs associated with FeLV infection, it is essential that FeLV testing is performed on sick cats presented for evaluation that may have been exposed to FeLV. Additionally, FeLV testing is recommended after cats are acquired, before FeLV vaccination and following potential exposure to an infected cat. Testing is done on blood samples.

Most point-of-care tests detect free FeLV p27 antigen in the blood of infected cats, often as an ELISA or rapid immunomigration tests, and these are used as screening tests. Many have good sensitivity and specificity, with positive results occurring 2–3 weeks after FeLV infection. However, disease prevalence affects the positive and negative predictive value of any diagnostic test, so false-positive results with these tests are more likely in areas of low FeLV prevalence and in cats with a low risk of infection (e.g., if testing is done in healthy cats pre-vaccination).

IFA testing detects cell-associated FeLV p27 antigen in the blood, within leukocytes on smears, and is a highly specific test, although it only becomes positive about 3 weeks after p27 antigen tests become positive; this is because IFA is only positive if bone marrow infection (which occurs usually about 4–7 [but up to 16] weeks after infection). False negatives are possible with leukopenias. IFA-positive cats are usually progressively infected as most, but not all, with bone marrow infection go on to develop progressive infection rather than revert to regressive infection.

FeLV PCR assays detect either viral RNA (in free virus particles and cell-associated during viral replication) or DNA (provirus, integrated into the cellular genome of the cat) in blood following DNA and RNA extraction. Standard PCR detects FeLV proviral DNA, whereas reverse-transcriptase (RT-)PCR detects FeLV viral RNA. Cats become blood RNA positive within 1 week of FeLV exposure and blood provirus DNA positive within 2 weeks of FeLV exposure. FeLV proviral PCR assays are widely available and generate positive results with both progressive and regressive infections. However, in regressive infections, FeLV proviral loads are lower, and p27 antigenemia and IFA tests are negative, in contrast to progressive infections in which FeLV proviral loads are high, and p27 antigenemia or IFA tests are positive. FeLV viral RNA RT-PCR assays are not widely available but have been used on pooled saliva swabs to determine FeLV prevalence in large-scale studies without blood sampling. An isothermal PCR point-of-care test that amplifies FeLV provirus ± RNA has been described showing some promise, but extraction of DNA and RNA is required, complicating its point-of-care test use.

If initial screening testing with point-of-care screening tests is inconclusive for any reason, testing should be repeated, preferably by a veterinary diagnostic laboratory using IFA or PCR. If a positive result is confirmed, consideration of whether repeat testing (6 weeks later) is indicated to differentiate between regressive and progressive infection. The cat's health status, clinical signs, signalment, and history at the time of testing will all factor into how likely the cat is to have progressive FeLV infection and its associated poor prognosis.

Management

Treatment/Prognosis

Healthy FeLV-infected cats should be housed indoors (or with confined outdoor access), neutered, not fed raw meat, and be kept away from other cats to limit the risk of disease transmission, ideally in single cat households. If this is not possible, cats in contact with an FeLV-infected cat that do not show any evidence of FeLV infection (regressive nor progressive infection) should be vaccinated, although protection cannot be guaranteed. Veterinary checks should be performed on infected cats at least every 6 months. Weight loss, lymphadenopathy, clinical signs of upper respiratory infection (e.g., ocular or nasal discharge), and oral health are particularly important to note, as well as ophthalmic examinations. Routine hematology, serum biochemistry, urinalysis, urine culture, and fecal examination may be indicated and can be done annually.

The prognosis for infected cats is highly variable depending on the stage of infection, host immunity, FeLV strain and specific disease manifested during the course of infection, and the availability of supportive treatment for secondary infections. Although a small percentage of FeLV-positive cats may remain healthy for several years, the prognosis for progressive FeLV is poor. Most progressive infected cats living within cluster households are expected to die within 3 years from the time of diagnosis. One study confirmed that cats infected with FeLV, or dual FeLV and FIV, survived significantly shorter times than uninfected or cats infected with FIV alone. Reduced red blood cell counts at the time of diagnosis of either FeLV or FIV infection is associated with reduced survival time compared to infected cats with normal counts at diagnosis. Progressive infected single household cats given supportive medical care could potentially have longer survival times.

Specific treatment modalities for FeLV-infected cats are directed at the clinical manifestation of illness. Immunomodulatory and antiretroviral treatments have been attempted (Table 21.2.2). Results of treatment are highly variable and have not yet been subjected to controlled studies. As in FIV-infected cats, azidothymidine (AZT) and recombinant interferon have been used to treat FeLV-infected cats. The dosage regimens recommended for these products are outlined in Table 21.2.2. Lymphoma is the most common solid tumor associated with FeLV infection. Several chemotherapeutic combinations have been recommended, and administration of corticosteroids is minimally effective as a single-agent treatment modality for FeLV-induced cancer. CHOP (cyclophosphamide, hydroxydaunorubicin [doxorubicin], Oncovin [vincristine], and prednisone) and CHOP-based protocols are widely used in cats diagnosed with lymphoma and can be successful. A recent study showed an excellent response rate with a novel multidrug

TABLE 21.2.2 Treatment protocols in the management of FeLV

Immunomodulation therapy

- Recombinant human interferon-alpha (rHu-IFN) (Roferon-A, Hoffmann LaRoche) or recombinant feline interferon-ω (rIFN-ω) (Virbagen Omega; Virbac) (the availability of these drugs varies, but the feline product is preferentially used as human products can induce neutralizing antibodies)
  - Various dosing regimens are described for rHu-IFN
    - *High dose:* 1,000–10,000 U/kg IM q.24 h. for 3–7 weeks; treatment beyond this period is associated with anti-interferon antibody
    - *Low dose:* 30 U p.o. q.24 h. for life
  - Various dosing regimens are described for rIFN-ω
    - *High dose:* 1 million U/kg SQ s.i.d. for 5 consecutive days for 3 courses starting on days 0, 14, and 60 (the licensed protocol for Virbagen Omega); has been associated with improved clinical scores and survival, especially in cats that were sick at the start of treatment
    - *Low dose:* 100,000 U/cat p.o. s.i.d. for 90 days

Antiviral therapy

- Azidothymidine (formerly called AZT) (5 mg/kg p.o. or SQ q.12 h.; some use 10 mg/kg p.o. or SQ q.12 h., and this higher dose should be used carefully as side effects can develop—bone marrow toxicity [anemia, neutropenia]—so monitor hematology)
  - Better for FIV infection than FeLV infection, though mild benefits have been reported
  - For SQ injection, the lyophilized product should be diluted in isotonic saline solution to prevent local irritation
  - For p.o. application, syrup or gelatin capsules can be used
- Raltegravir, an oral integrase inhibitor, has been used in experimental FeLV infection but with limited long-term results
  - Treatment was associated with significantly reduced plasma FeLV RNA loads, but then levels rebounded 4 weeks following termination of treatment; this agent does not prevent FeLV viremia

Cytopenia therapy

- Recombinant human erythropoietin (100 IU/kg SC q.48 h. for 2 weeks or until the desired hematocrit is reached)
  - Anti-erythropoietin antibody may develop against exogenous and endogenous erythropoietin, but this appears to be less likely with the longer acting recombinant human erythropoietin (rHuEPO) darbepoetin

lomustine-based chemotherapy protocol (LOPH [lomustine, vincristine, prednisolone and hydroxydaunorubicin]) for cats with high-grade multicentric or mediastinal lymphoma in an area in Brazil endemic for FeLV. In most cases, only cats that achieve complete remission after induction chemotherapy go on to have long-term disease-free status. FeLV status does not affect initial response to chemotherapy, but positive retroviral status negatively affects long-term survival, mostly because of the occurrence of other FeLV-related disorders.

Cats with myelosuppressive disease have a particularly poor prognosis and are best managed with transfusions as needed to resolve the anemia, although this is costly and is needed repeatedly. Recombinant human erythropoietin can be used for clinical signs associated with anemia (hematocrit < 0.2 L/L [20%]) (see Table 21.2.2). FeLV-infected cats with immune-mediated diseases (e.g., immune-mediated hemolytic anemia, immune-mediated polyarthritis) can benefit from the cautious use of oral prednisolone (2 mg/kg per day). FeLV-infected cats with severe gingivostomatitis are most likely to benefit long-term from full mouth extraction, including tooth roots rather than medical management, although appropriate short-term medical options (e.g., recombinant IFN, AZT, or lactoferrin topically [40 mg/kg q.24 h.]) to the oral mucosa can be tried.

RetroMAD1 is a commercially available recombinant chimeric protein. Oral administration of 0.4 mg/kg p.o. q.24 h. to symptomatic cats with progressive FeLV infection in a multicenter trial in Brazil found some improvement in clinical signs (gingivitis, anemia, upper respiratory tract disease) and survival rate compared to untreated cats, although further controlled studies are necessary to corroborate these results before this drug can be recommended.

Prevention

Currently, several vaccine types are available that offer relatively good protection against FeLV. Adjuvanted killed whole virus, recombinant subunit, and a genetically engineered subunit recombinant canary pox vector vaccine exist. FeLV vaccines are usually considered noncore, although the 2020 American Animal Hospital Association and the American Association of Feline Practitioners (AAHA/AAFP) feline vaccination guideline recommends FeLV vaccines as core vaccines for kittens and young adults due to their age-related susceptibility (see Table 21.2.1). Routine testing, as well as vaccination of cats determined to be at risk, are key factors in FeLV prevention. Adult indoor cats are least susceptible to infection. As with any vaccination decision, risk assessment for infection should be made on an individual basis, based on lifestyle factors and local prevalence. None of the currently available FeLV vaccines will cause false-positive tests for FeLV antigen on either screening or IFA tests. FeLV testing should ideally be performed before vaccination to establish FeLV infection status, although the prevalence of FeLV in healthy cats will be low, affecting the positive predictive value of a positive screening test result in this situation. Routine vaccination with core vaccines (e.g., calicivirus) are indicated in FeLV-infected cats that need protection based on their lifestyle. Although killed inactivated, rather than MLV, vaccines are recommended by some for retrovirus infected cats, there is no evidence confirming killed vaccines to be safer.

Public health implications

FeLV in cats is not regarded as a human health hazard.

FELINE IMMUNODEFICIENCY VIRUS

Definition/Overview

First described in 1987, FIV is an RNA retrovirus (lentivirus) infection unique to cats.

Etiology

Transmission among cats occurs primarily through bite wounds and fighting. Blood transfusions can also transmit infection. Vertical transmission of FIV has been reported but is not common. The virus survives only minutes outside the host and is susceptible to all disinfectants.

Pathophysiology

FIV is a lentivirus and, therefore, shares many properties with other retroviruses such as HIV. Many different FIV subtypes with marked nucleotide sequence differences exist with worldwide geographical variation. FIV replicates in lymphoid organs and spreads to other tissues of the body via mononuclear cells during which time the cat may show mild illness (e.g., anorexia, malaise, lymphadenopathy, pyrexia). Viremia peaks a few (8–12) weeks post-infection, after which the level of infection decreases to low levels as the cat mounts an immune response to FIV. Antibodies are produced about 2–6 weeks post infection (although can up to 12 weeks) but are ineffective at clearing infection. Following the initial viremia, the cat enters an asymptomatic period of variable duration (often several years and can be lifelong) during which time progressive dysfunction of the immune system occurs with a reduction in the CD4+-to-CD8+ (T-helper-to-cytotoxic lymphocyte) ratio. This can eventually lead to the development of feline acquired immunodeficiency syndrome (AIDS) characterized by risk of tumors, secondary infections, stomatitis, immune-mediated diseases, and neurologic disorders.

Clinical Presentation

The major risk factors for infection are male gender, entire status, and outdoor access. Cats with illness due to FIV manifest a wide variety of nonspecific clinical signs. Dermatitis, stomatitis, ocular disease, renal insufficiency, lower urinary tract infections, neurologic abnormalities, and opportunistic infections have been reported (Figures 21.2.14 and 21.2.15). FIV infection is significantly associated with the development of lymphoma. However, many cats with FIV infection manifest no clinical signs and can eventually die of unrelated causes. Laboratory findings in cats with FIV infection are often nonspecific and contribute little to establishing a diagnosis of FIV infection. Mild, nonregenerative anemia, neutropenia, lymphopenia, and hypergammaglobulinemia (with a hyperproteinemia) are commonly found on routine hematology and serum biochemistry.

Differential Diagnosis

Any adult cat presented for chronic or debilitating illness, fever, or weight loss should routinely be tested for FIV, as well as FeLV. Cats with anemia, neutropenia, stomatitis, glossitis, lymphoma, or chronic upper respiratory infection should be evaluated for FIV infection. FIP is an important differential diagnosis among FIV-infected cats with significant hypergammaglobulinemia.

FIGURE 21.2.14 Chronic inflammatory skin disease is sometimes diagnosed in cats infected with FIV.

Diagnosis

Detection of FIV-specific antibodies in blood or serum is the most widely accepted means of establishing a diagnosis. Point-of-care ELISA and rapid immunomigration tests are reliable as screening tests for the detection of anti-FIV antibodies, although kits vary in the type of specific FIV antibodies (typically one or two) they test for. However, any positive screening FIV antibody result must be confirmed, especially if the FIV exposure risk is low in the tested cat, due to lower positive predictive value of a positive test with decreasing prevalence of FIV in a population. Interpretation of a positive antibody test in kittens under 6 months of age

FIGURE 21.2.15 Chronic stomatitis in a cat.

is complicated by the fact that maternal antibody from an infected queen may be transferred via the colostrum to kittens. Indeed, most kittens born to an FIV-infected queen will not be infected. Additionally, cats vaccinated against FIV, using the commercially available inactivated (killed) vaccine available in some countries (currently only Australia, New Zealand, and Japan), can be antibody positive on some screening tests in the absence of FIV infection due to vaccine-induced antibodies that can last for at least 7 years after vaccination. In these cases, PCR is indicated to determine true FIV infection.

In some countries Western blotting (WB) and immunofluorescence tests are available to detect a wider range and number of specific FIV antibodies, increasing sensitivity and specificity compared to screening tests that typically detect only one or two specific FIV antibodies. Recent work confirmed the increased sensitivity of WB over screening ELISA tests, suggesting that if cats with a high suspicion of FIV infection are negative on a screening test, they should be further investigated with a more sensitive test such as WB, i.e., unexpected negative results for FIV on screening tests should be followed up as well as unexpected positive results.

FIV PCR tests generally detect FIV provirus, whereas RT-PCR detects FIV RNA; those commercially available usually detect provirus. A positive result is regarded as confirmation of positive FIV status. However, negative FIV PCR results do not necessarily mean that the cat is not infected, as PCR might not detect all subtype strains as there is much variation in sequence among FIV subtypes, making it impossible for single PCR assays to identify all subtypes. Additionally, FIV proviral and viral loads may be low in cat, especially during the asymptomatic period. PCR testing does not detect vaccine virus. As for FeLV, an isothermal PCR point-of-care test that can amplify FIV provirus and RNA has been described, but limitations exist around its use.

Management

Treatment/Prognosis

Healthy FIV-infected cats should be housed indoors (or with confined outdoor access), neutered, not fed raw meat, and be kept away from other cats to limit the risk of disease transmission, ideally in single cat households. Veterinary checks should be performed as for FeLV-infected cats.

It can be many years before an FIV-infected cat develops feline AIDS, and until this time, the cat's quality of life can be excellent, so diagnosis of FIV in a healthy cat is not a reason for euthanasia. Indeed, studies have increasingly shown that FIV-infected cats can survive as long as uninfected cats and that the management and housing conditions of cats might impact on disease progression and survival in FIV-infected cats. This may be due to stress and exposure to (opportunistic) pathogens. Reduced red blood cell counts at the time of diagnosis is associated with reduced survival time.

There is currently no FIV-specific antiviral therapy available. The use of azidothymidine (AZT) as for FeLV (see Table 21.2.2 for dosages) can cause clinical improvement, particularly in FIV-infected cats with stomatitis or neurological disease, and increased CD4+-to-CD8+ ratios in a small number of published studies, but significant side effects, particularly anemia, can occur. AZT-resistant mutant FIV viruses can arise during long-term (years) treatment. Recombinant interferon treatment (see Table 21.2.2) has been associated with improved clinical scores, especially in cats showing clinical signs of gingivitis/gingivostomatitis. Recombinant human erythropoietin (see Table 21.2.2) has improved red and white blood cell counts in experimentally-infected FIV cats.

FIV-infected cats can be susceptible to chronic inflammatory and secondary infections. Supportive treatment is indicated and may, in those cats that respond to treatment, extend the life of the clinically infected cat for several months or years. As for FeLV, routine vaccination with core vaccines should be given in FIV-infected cats that need protection based on their lifestyle.

Prevention

The most effective means of preventing FIV infection is to limit exposure to, and agonistic encounters with, FIV-infected cats that could result in biting. Published studies have demonstrated that casual contact between harmoniously cohabiting FIV-positive and FIV-negative cats over years may not result in viral transmission, despite mutual grooming, minor episodes of aggression, and sharing food and water dishes, litter pans, and bedding. However, careful management is required when cats are first introduced to one another, as the potential for agonistic interactions that could result in FIV transmission is increased. Because of this, it is important to determine FIV status before cats are introduced to one another and then to observe interactions until the likelihood of aggression resulting in penetrating bite wounds is remote. If there is a reasonable suspicion that such agonistic interactions will occur when the cats are unobserved, FIV-positive and FIV-negative cats should be segregated from one another, and the most reliable method of preventing transmission is to keep FIV-infected cats away from non-infected cats.

One FIV vaccine is licensed for use in cats (see Table 21.2.1); it was available in the United States and Canada until 2015 and is now only available in Australia, New Zealand, and Japan. However, it has only shown protective rate of 56% under field conditions, and its use interferes with FIV screening test interpretation, and so it is not commonly used.

ENTERIC VIRAL INFECTION

FELINE CORONAVIRUSES

Definition/Overview

Feline infectious peritonitis (FIP) is a serious disease in cats caused by virulent mutations of an enteric feline coronavirus (FCoV) in the genus *Alphacoronavirus*.

The recently emerged severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is very distinct and different to FCoV, belonging to a different genus *Betacoronavirus* and is described separately later.

As mutations arise in FCoV, the viruses can lose their tropism for enterocytes and can gain both tropism for monocytes and macrophages as well as an ability to replicate at high levels within with cells that have an affinity for the endothelium of venules in the serosa, omentum, pleura, meninges, and uveal tract. Varied mutations in the 3, 7b and spike genes of FCoV have been implicated the switch to a pathogenic virus associated with FIP. Clinical FIP is characterized by widespread immune-mediated vasculitis and/or pyogranulomas, manifesting as high-protein effusions in body cavities and/or tissue granulomas. While the disease course from the onset of clinical signs until death can be variable, ranging from weeks to months, it is usually shorter in younger cats and those with effusions. The mortality rate is extremely high.

Etiology

Feline coronaviruses are large-enveloped RNA viruses commonly isolated from the feces of cats, particularly those in multicat households. Infection is typically acquired by kittens or young cats from exposure to shedding cats via the fecal–oral route. Mutation from a less virulent FCoV to a virulent form associated with FIP is thought to occur at some point after FCoV infection between viral replication in enterocytes and with efficient replication in macrophages. Direct transmission of FIP between cats is thought to be extremely rare, since cases are generally believed to arise as a result of in vivo mutation in an FCoV-infected cat.

Pathophysiology

Initially, the virus replicates in oropharyngeal tissues and in the enterocytes at the tips of the intestinal villi. The manifestation of infection depends on several predisposing factors, including the immune response and genetic factors in the host and the strain and dose of virus. A vigorous cell-mediated immune response is required for protection from FIP, while antibodies produced in response to infection enhance the uptake and replication of FCoV in macrophages and contribute to the immune-mediated vasculitis, which results in effusions. If the antibody-mediated immune response predominates, effusions tend to result, whereas if a cell-mediated immune response also occurs, the development of effusions may be suppressed. It is important to remember that there is overlap between the effusive and noneffusive forms of FIP, and these manifestations should be considered as a spectrum; brief episodes of effusive disease can occur before a noneffusive form predominates, and conversely, in the terminal stages of a noneffusive form, effusions may form.

Clinical Presentation

FIP most commonly occurs in cats of 2 years of age and younger. A recent history of stress (e.g., adoption, being in a shelter, neutering, upper respiratory tract disease, vaccination) is commonly apparent. Nonspecific clinical signs care common and include lethargy, anorexia, and weight loss (or failure to gain weight/stunted growth in kittens). A fever, which can be fluctuating and that is moderate and typically < 40°C (but sometimes can be higher) and that is refractory to many drugs and nonresponsive to antibiotics, is commonly present. Icterus can occur, more commonly in cats with effusions, but the degree of hyperbilirubinemia is often not high enough to result in clinical jaundice. When effusions form, they comprise viscous, high protein-content fluid in the abdominal and/or, less often, the pleural cavity and pericardial sac, resulting in clinical signs of abdominal swelling (**Figure 21.2.16** and **21.2.17**) and/or tachypnea/dyspnea. Effusions can also result in scrotal swelling in entire male cats (**Figure 21.2.18**). Pyogranulomatous lesions occur predominantly in the abdominal cavity, particularly in the liver, mesenteric lymph nodes, intestines, spleen, and kidney, where irregular outlines and/or enlargement may be appreciated on abdominal palpation. Pyogranulomatous lesions can also occur in the thoracic cavity, eyes, or CNS. Ocular signs of FIP can include anterior and/or posterior uveitis; hyphema, hypopyon, keratic precipitates ("mutton fat" deposits on the ventral corneal endothelium; **Figure 21.2.19**), retinal detachment, perivascular cuffing, hemorrhage, and retinitis. A variety of neurologic signs can develop, depending on the particular site(s) within the CNS in which lesions occur, and include ataxia, hyperesthesia, nystagmus, seizures, behavioral and mental state changes, and cranial nerve deficits.

Cats with suspected FIP in a veterinary clinic should be handled and housed like any other cat with routine infection control measures, as any cat is a potential source of FCoV infection; it is not necessary to isolate the cat.

Differential Diagnosis

Differential diagnoses for cats with abdominal effusions include hepatic- or cardiac- (rare) associated

FIGURE 21.2.16 Eight-month-old neutered male Siamese cat with effusions due to FIP. Note the abdominal distension due to the peritoneal effusion.

FIGURE 21.2.17 Eight-month-old neutered male Siamese cat with effusions due to FIP. Note the abdominal distension due to the peritoneal effusion.

ascites, cholangiohepatitis complex, septic peritonitis, neoplasia, and pregnancy. Among cats with significant accumulation of pleural fluid, neoplasia, cardiac failure, exudative pleuritis (pyothorax), and chylothorax are reasonable differential diagnoses that should be considered. Neoplasia and toxoplasmosis can both cause bicavity effusions in the abdomen and thorax. Differential diagnoses for cats with FIP in the absence of an effusion are extensive depending on the organ system(s) involved (e.g., neurologic/ocular signs [seizures, posterior paralysis, toxoplasmosis, neoplasia, idiopathic encephalomyelitis/meningitis, retinitis with or without retinal detachment, uveitis ± keratic precipitates and hyphema], and mesenteric lymphadenopathy [mycobacterial infection, neoplasia]).

FIGURE 21.2.18 Eight-month-old neutered male Siamese cat with effusions due to FIP. Note the scrotal effusion.

Diagnosis

Immunostaining for FCoV Antigen in Association with Pathology

The only reference method for definitively diagnosing FIP antemortem is histopathology with immunohistochemistry on biopsy specimens showing pyogranuloma formation and/or vasculitis associated with the presence of FCoV antigen (Figures 21.2.20 and 21.2.21a, b). While this method is highly specific, its accuracy is dependent on specimen (showing pathology) selection and the expertise of the pathologist reading the slides. Additionally, it may be difficult to justify collection of large biopsy specimens in sick cats, and so other less invasive diagnostic methods, particularly effusion analysis, are often used to help the veterinarian decide on the likelihood of FIP. The presence of FCoV antigen in macrophages can also be demonstrated by immunocytochemistry or immunofluorescence on effusion (Figure 21.2.22a, b) and fine-needle aspirate (FNA) (as well as cerebrospinal fluid [CSF] and ocular aqueous humor in neurologic and ocular cases) samples that show cytological features consistent with FIP, i.e., the presence of neutrophils and macrophages. This is widely used in Europe and Australia where positive results performed by reputable diagnostic laboratories are consistent with a diagnosis of FIP, although a negative result does not rule out FIP due to the paucity of cells and/or FCoV antigen in some samples.

Approach to Cases with and without Effusions

When an effusion is present, a likelihood of FIP can be determined quickly antemortem by examination of an effusion sample recovered from any body cavity and showing it to be consistent with FIP. Ultrasonography or radiography can be used to identify or confirm the presence of effusions and to assist in sample collection. The effusions in FIP are highly viscous with a high protein content (> 35 g/L [3.5 g/dL]) (Figure 21.2.23). Cytologic evaluation of the fluid usually reveals a relatively low cell count (< 5,000 nucleated cells/μL), although counts can be higher on occasion (up to 20,000 nucleated cells/μL). Cells comprise low-to-moderate numbers of neutrophils and macrophages and some lymphocytes

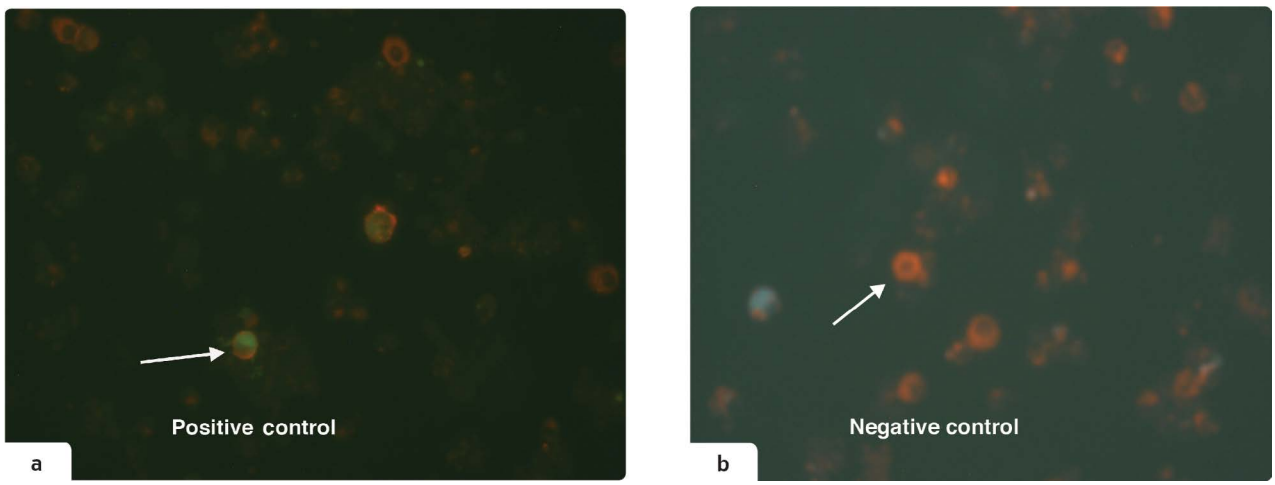

FIGURE 21.2.22 (a) Direct immunofluorescence staining of feline abdominal effusion—positive control specimen (arrow). (b) Direct immunofluorescence staining of feline abdominal effusion—negative control specimen (arrow).

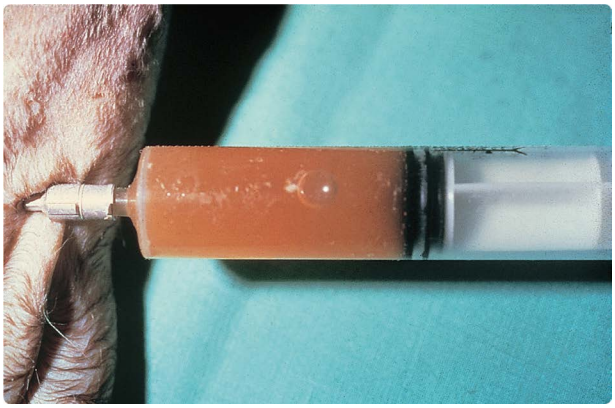

FIGURE 21.2.23 Abdominocentesis in a cat with FIP and an abdominal effusion reveals the characteristic viscous, high specific gravity exudate. Note that in some cases the globulin concentration of the fluid is sufficiently high that the sample might clot when exposed to air.

(Figure 21.2.24). The albumin-to-globulin ratio of the effusion is usually < 0.4, whereas a value of > 0.8 helps to rule out FIP.

The Rivalta test can be done as a point-of-care test (Figure 21.2.25). It involves placing a drop of effusion fluid into a tube containing weak acetic acid and watching for a characteristic clot to appear. This test gives positive results with FIP effusions but also with exudates collected from cases of lymphoma or septic effusions. It is limited by the subjective interpretation needed, although a negative Rivalta test can be useful to rule out a diagnosis of FIP.

When an effusion is not present in a suspected case of FIP, the diagnostic approach is more problematic due to difficulties accessing affected tissue sample biopsies, contraindications (such as the need for general anesthesia) to taking biopsies from a sick cat, and/or costs involved in tissue sample collection. Currently, there is no noninvasive, confirmatory test available for cats with FIP that do not have effusions, although in some cases valuable information can be gained through analysis

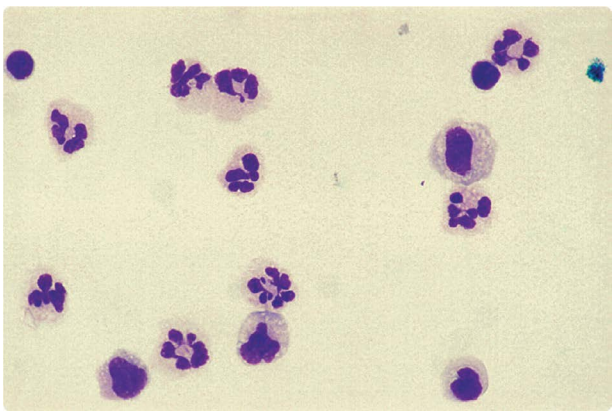

FIGURE 21.2.24 Cytopathology of abdominal fluid from a cat with FIP and an effusion, characterized as a relatively low cellular count fluid containing a mixture of neutrophils and macrophages (pyogranulomatous effusion).

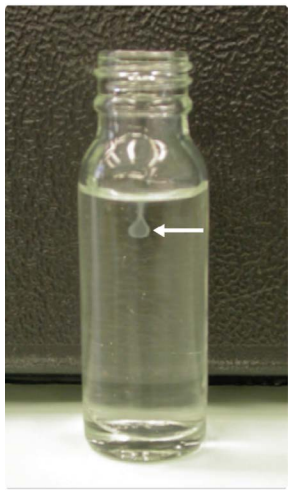

FIGURE 21.2.25 Positive Rivalta's test from a cat with effusive FIP showing clotted droplet of effusion (arrow) in weak acetic acid (made by combining 8 mL of distilled water at room temperature and one drop of 98% acetic acid).

of fine-needle aspirate (FNA) samples collected from affected organs, if accessible, as described in further section.

Hematology and Biochemistry

Routine hematology changes are nonspecific but can show lymphopenia, neutrophilia, a left shift, and/or a mild-to-moderate normocytic, normochromic anemia. An immune-mediated hemolytic anemia occasionally occurs. On serum biochemistry, elevated serum bilirubin may occur, with values are not always correlated with elevated liver enzymes. Hyperproteinemia may occur; a hyperglobulinemia is typical with a slight decrease in the albumin fraction is typical. When FIP disease prevalence is low, a A:G ratio > 0.6 can rule out FIP, but a low A:G ratio does not confirm a diagnosis of FIP. The hyperglobulinemia is due to a polyclonal hypergammaglobulinemia, and although serum protein electrophoresis provides a graphic portrayal of the serum proteins, this test does not provide definitive diagnostic information as other chronic infections (e.g., FeLV and FIV) may produce similar findings.

Acute phase proteins (APPs) are produced in the liver in many inflammatory and noninflammatory diseases, and so increases are not specific to FIP. Alpha-1-acid glycoprotein (AGP) is a major APP in cats, and assays are available for its measurement in some countries. Moderately elevated serum AGP concentration of > 1.5 mg/mL is frequently reported in cats with FIP and may be helpful in raising the suspicion of a diagnosis of FIP.

FCoV Antibody Serology

There is no reliable serologic test for the diagnosis of FIP; available serological assays detect antibodies against any FCoV, not just those associated with FIP. As FCoV infection is common in multicat households,

many healthy cats are seropositive, sometimes with very high titer, making it impossible to differentiate cats with and without FIP based on titer alone.

Reverse-Transcriptase Polymerase Chain Reaction for FCoV RNA Detection

The detection of FCoV antigen in samples by immunostaining, described earlier, shows the presence of the virus in pathological lesions and is a reliable test for FIP when positive. Polymerase chain reaction (PCR) assays detect FCoV RNA in samples by reverse-transcriptase (RT-)-PCR. RT-PCR can be performed on many sample types such as effusions, FNAs, and CSF where the presence of high levels of FCoV RNA in association with other features consistent with FIP (e.g., cytology) is highly supportive of a diagnosis of FIP. However, positive RT-PCR tests alone cannot confirm a diagnosis of FIP, as it is known that FCoV RNA can be present systemically in cats in the absence of FIP. Additionally, the levels of FCoV RNA present in samples from cats with FIP can be variable and may not be detectable in some cases. Recently, positive RT-PCR results on FNAs, particularly from mesenteric lymph nodes from cats without effusions, have proved highly supportive of a diagnosis of FIP. Other potential samples for FNA include the liver, spleen, and kidneys. Blood samples are not recommended for FCoV RNA testing due to the low levels present in cats with FIP. FCoV RT-PCR can also be performed on fecal samples, but this is primarily used to identify cats that are shedding FCoV for the management of infection in a multicat household, and it is not used to diagnose FIP, as it is known that many healthy cats without FIP shed FCoV.

FCoV Spike Gene Mutation Analysis Following FCoV RNA Detection by RT-PCR

Following detection of FCoV RNA in a sample by RT-PCR, varied molecular techniques can be used to derive spike (S) gene sequence data for the FCoV present. However, such techniques are not always successful in FCoV RT-PCR-positive samples, as low FCoV levels preclude sequence analysis, and FCoV sequence variability can prevent targeted sequencing techniques from generating sequence data. The reason for the focus on S gene sequences was because it was believed that specific sequence changes in this region were correlated with the development of FIP, thus potentially being a useful diagnostic test for FIP. Subsequent work suggested that S gene mutations were associated with the acquisition of monocyte/macrophage tropism to allow FCoV to spread systemically outside of the gut and contribute to the development of FIP rather than being diagnostic of FIP, per se, and thus their diagnostic usefulness was limited.

MRI and CSF Sampling

Advanced imaging using magnetic resonance imaging (MRI) may be helpful in neurologic cases of FIP, as can sampling of CSF for analysis via cytology, protein measurement, PCR, and/or immunocytochemistry.

Management of FIP

Treatment/Prognosis

Historically, no effective causal treatment was available for FIP, so cats with confirmed FIP had a grave prognosis, dying or being euthanized after only a few days to weeks. A variety of anti-inflammatory and immunosuppressive treatments have been recommended as palliative care (e.g., prednisolone, 2–4 mg/kg p.o. q.24 h., with reducing doses as needed, to control signs) although no controlled studies exist to document their benefit. Feline interferon-omega (IFN-ω) is used by some clinicians in the treatment of FIP; however, a randomized, placebo-controlled, double-blind treatment study in cats with confirmed FIP did not show any benefit of IFN-ω treatment.

In recent years, newer antivirals, especially protease inhibitors (which inhibit formation of FCoV viral proteins) and nucleoside analogs (which inhibit FCoV RNA formation), show huge promise for the effective treatment of FIP. Recent published studies have documented the efficacy of newer antiviral compounds, such as the protease inhibitor GC376, and especially the nucleoside analog GS-441524 (given subcutaneously or orally), in the treatment of naturally occurring FIP, with courses of GS-441524 given for at least 12 weeks appearing to be especially efficacious in young cats with effusions. Higher doses and longer courses of treatment are usually required for cases with ocular and/or neurological signs of FIP. However, neither GC376 nor GS-441524 are currently licensed for use in animals, making acquisition or administration of these agents by vets illegal in many countries. Thus, some owners are sourcing these agents online and administrating them to their cats themselves in the absence of veterinary care, which does pose animal welfare concerns. Some vets monitor cases receiving treatment from their owners to help ensure appropriate supportive care is available. Monitoring can include clinical signs, e.g., appetite, activity, weight, and temperature measurements, as well as hematology and biochemistry, e.g., globulin, albumin-to-globulin ratio, bilirubin, lymphocyte count, and/or hematocrit. Remdesivir (GS-5734) is a prodrug of GS-441524 and is licensed for use in humans but not animals. Evidence from field case descriptions suggests that injectable remdesivir (given intravenously and/or subcutaneously) is also effective for the treatment of FIP in cats. Thus, much promise exists for the use of these antiviral agents for FIP treatment, especially once licensed products become available.

Prevention

A modified live FIP vaccine is commercially available in some countries, but it is not recommended for use, as there is insufficient evidence that it induces clinically relevant protection.

Management of FCoV

Since FCoV is transmitted predominantly via the fecal–oral route, hygiene is the mainstay of FIP control in multicat environments. FCoV infection is maintained in households by continual cycles of infection and re-infection in the cats, the source of infection being feces in the litter tray. Reducing the FCoV infection pressure and risk of transmission is important and can be helped by keeping cats in small stable groups of three or less, observing strict hygiene (especially litter trays), and providing outdoor access if possible. Although FCoV is only rarely shed in saliva, food and water bowls should be cleaned daily using detergent or in a dishwasher at a cycle of at least 60°C because of the risk of fomite contamination. Fecal shedding of FCoV occurs over several months or sometimes lifelong, especially in multicat households. Identification of cats that are persistently shedding a high FCoV load and their separation from low shedders and fecal RT-PCR-negative cats has been suggested for reducing transmission rates. However, the optimal fecal sampling protocol for RT-PCR testing has not been determined, although at least three fecal samples collected at intervals between 1 week and 1 month has been suggested. Additionally, FCoV-infected cats should not be exposed to stressful situations.

Some studies described the successful use of an oral nucleoside analog to eliminate FCoV shedding (identified by fecal RT-qPCR) in cats in households with endemic FCoV infection where owners were wanting to eliminate FCoV shedding due to previous FIP cases in their households. A potential problem with this approach is that because FCoV is so common in multicat households, and can be carried on fomites, it is very difficult to maintain an FCoV-negative status long term. Additionally, the risk of the development of resistance to antiviral agents is present, and so many advise that the use of antivirals should be preserved only for the treatment of cats with FIP.

Public Health Implications

FIP and FCoV pose no known public health risk.

SARs-CoV-2

SARS-CoV-2 is very distinct and different to FCoV and is the cause of COVID-19 in humans. Felids have been shown to be susceptible to SARS-CoV-2 infection, and a few natural cases of feline SARS-CoV-2 infections have been described in cats living in households with COVID-19-positive people; however, these numbers are extremely low compared to the millions of human infections documented. Cats have not been shown to transmit infection to people. To reduce the risk of infection, close contact with pet cats should be avoided by people with COVID-19 alongside standard hygiene measures, but cats should not be re-homed or relinquished. Infections in cats are generally without clinical signs, but occasionally respiratory signs and/or enteric signs are described. The testing of cats for SARS-CoV-2 infection is not generally recommended unless required by regulatory authorities.

FELINE PANLEUKOPENIA (FELINE PARVOVIRUS)

Definition/Overview

Feline panleukopenia (FPL) is caused by a small, non-enveloped, single-stranded DNA parvovirus recognized in cats worldwide. Once a common fatal viral infection, feline panleukopenia virus (FPV) infection is a rare disease among vaccinated pet cats. However, FPV infection regularly occurs in cats housed in animal shelters and can also affect breeding catteries, and recent outbreaks in unvaccinated cats have been described in Australia. FPV can also replicate in dogs, although it is not shed in their feces. Canine parvovirus (CPV) type 2 arose from FPV via mutations, and although it initially could not replicate in cats, all current variants of CPV type 2 (i.e., a–c) can now infect and cause disease in cats.

Etiology

FPV infection is transmitted by contact with the feces, saliva, and/or secretions of infected cats, or by fomite (e.g., bedding, litter trays, food and water bowls, clothing) or in utero transmission, and fecal–oral transmission is most important. Virus is shed in feces for up to 6 weeks (but is typically much shorter) following recovery from clinical disease. The virus is very stable in the environment, capable of persisting outside the host or on fomites for at least 1 year, so even cats with an indoor only lifestyle cannot always avoid encountering FPV. Some unvaccinated adult cats can acquire natural immunity subsequent to subclinical infection via low-level viral exposure to infected cats or fomites. Kittens are more likely to become infected (Figure 21.2.26), but once clinical infection occurs, both kittens and adults have similar mortality rates.

Pathophysiology

The virus requires rapidly multiplying cells for replication, so it has a tropism for those tissues with a high

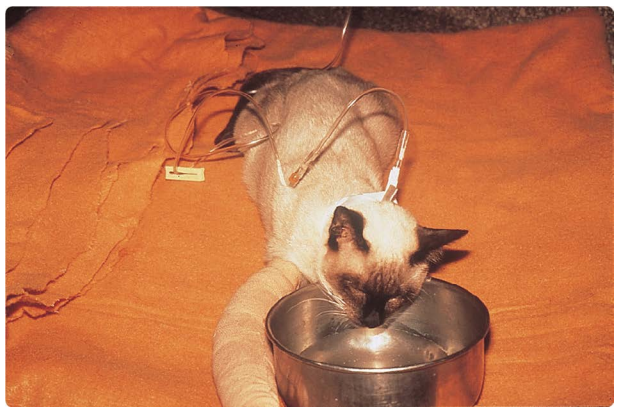

FIGURE 21.2.26 This young Siamese kitten had marked vomiting, diarrhea, and fever caused by feline panleukopenia virus. It was an unvaccinated cat that was hospitalized for a fracture repair. (*Courtesy of M. Schaer.*)

mitotic rate (e.g., bone marrow, lymphoid organs, and the intestinal crypts). Cellular depletion and immunosuppression occur when lymphoid tissue is infected, and myeloid cell populations are depleted by bone marrow infection; thus, panleukopenia results. Intestinal crypt infection (particularly in the jejunum and ileum) impairs regeneration of the epithelium, resulting in shortening or intestinal villi and malabsorption, increased permeability, and hemorrhagic diarrhea with translocation of intestinal bacteria. Fetal and neonatal infection targets the CNS, including the cerebrum, cerebellum, retinae, and optic nerves. Fetal death, fetal absorption, abortion, or mummified fetuses can occur in infected pregnant queens. Blindness and cerebellar hypoplasia, manifesting as nonprogressive hypermetria and ataxia are common among kittens infected as neonates.

Clinical Presentation

Following FPV exposure, clinical disease is more likely to develop in unvaccinated kittens under 5 months of age, as they are less likely to have protective antibody titers. It should be remembered that vaccinated kittens can be infected if maternal-derived antibodies (MDAs) were present at the time of their vaccination, as these can interfere with the response to vaccination. Kittens suckling queens with high antibody titers are likely to receive large amounts of anti-FPV antibodies, prolonging interference with the immune response to vaccination, sometimes until 16–20 weeks of age.

When clinical disease develops, the onset is acute and may culminate in death within 12 hours, sometimes without apparent clinical signs of disease. Infected cats generally present with clinical signs, including lethargy, anorexia, vomiting, diarrhea, fever, and/or dehydration. Death can result from shock, DIC, secondary bacterial infections, and/or profound dehydration. One retrospective study reported that clinical recovery most often occurred approximately 5 days after the onset of clinical signs (range 1–9 days), while in fatal cases, death occurred approximately 1 day after the onset of clinical signs (range 0–9 days). Cerebellar hypoplasia is a clinical finding among kittens born to queens infected during pregnancy. Affected kittens ambulate with a characteristic broad-based stance and manifest hypermetric movements, but mentation is normal. Intention tremors of the head may occur when food is offered to affected kittens. One or more of a litter of kittens may be affected. The condition is not progressive, so affected cats can make good pets if their clinical signs allow good quality of life.

One study reported that low leukocyte counts (< 1,000 leukocytes/μL), hypoproteinemia (less than 30 g/L [3 g/dL]), and hypokalemia (< 4 mmol/L) were poor prognostic indicators in FPV-infected cats, while another found that total thyroxine measurement at hospital administration was of prognostic value.

Differential Diagnosis

Intestinal parasitism, including coccidiosis, infectious enteritis, intussusception, and poisoning, are consistent with acute, enteric FPV infection, particularly in young cats. *Salmonella* infections can cause hemorrhagic diarrhea and panleukopenia. Sepsis and enteric foreign body may also be considered. Neurologic signs associated with cerebellar hypoplasia may be consistent with acute head trauma.

Diagnosis

Infected cats usually have a history of possible exposure to FPV and risk factors for infection, such as lack of a vaccination history and/or age less than 16 weeks.

The hallmark laboratory finding in kittens with FPV infection is a leukocyte count between 50 and 3,000 cells/μL; this can be determined in practice with microscopic examination of a simple blood smear showing profound neutropenia and lymphopenia. Thrombocytopenia is occasionally reported. Biochemical profiles are of little value in establishing a diagnosis of FPV infection but can document azotemia due to dehydration and hypoalbuminemia and/or hypokalemia due to intestinal losses and anorexia.

Point-of-care fecal antigen tests, e.g., ELISAs, exist for both FPV and CPV, with both being able to detect FPV antigen. A positive test result confirms infection in clinically affected cases. However, a negative test result does not rule out infection, since viral shedding is intermittent and may only be detectable in feces for 24–48 hours after infection. Polymerase chain reaction (PCR) assays can be used to detect FPV strains in fecal samples as well as whole blood, bone marrow, and tissue samples. However, healthy cats can test PCR positive in feces. Both fecal antigen and PCR tests can be positive for at least 4 weeks after vaccination with modified live virus (MLV) vaccines, although this is uncommon.

Virus isolation is an effective means of diagnosing infection but is not routinely available in clinical practice.

A full necropsy should be performed on any cat suspected to have succumbed to FPV infection, as histopathology of the intestinal tract can show characteristic intestinal crypt necrosis and dilate crypts filled with necrotic material. Neonatally infected cats may have cerebellar hypoplasia or retinal degeneration.

Management

Treatment/Prognosis

There is no specific antiviral therapy available for the treatment of FPV-infected cats. While feline recombinant interferon-ω has been used successfully to treat CPV, one feline study using the agent as a preventive measure before an FPV outbreak was unable to demonstrate improved outcomes in treated kittens. Intensive supportive therapy and nursing care offer the only reasonable means of treating clinically affected cats. A single dose of serum or plasma from an immune or recovered cat can be administered through a filter either subcutaneously or intraperitoneally, to cross-matched, exposed, unvaccinated kittens (2 mL in kittens < 12 weeks; 4 mL in kittens ≥ 12 weeks), although this is of most value when administered before the onset of clinical signs, i.e.,

for prevention following exposure rather than treatment. Only one dose can be administered, to prevent subsequent anaphylaxis, and vaccination against FPV should be delayed in treated kittens by 3–4 weeks to prevent antibody interference with the immune response. Once recommenced, the course of vaccination should continue 2–4 weeks longer than usual (up to 18–24 weeks old).

Parenterally administered balanced electrolyte solutions, such as lactated Ringer's solution, are of utmost importance in replacement of electrolytes and fluids in affected cats. Fluid therapy can be given intravenously or intraosseously (in small kittens). Parenterally administered metoclopramide (0.2–0.4 mg/kg SC q.6–8 h. or 1–2 mg/kg IV over 24 hours as a constant rate infusion) can be used in persistent vomiting. Maropitant (1 mg/kg SC q.24 h.) is an alternative antiemetic. Appetite stimulants, such as mirtazapine (2 mg per cat p.o. q.48 h.), can be used during the recovery phase. A highly digestible, bland diet can be offered once vomiting is under control.

Antimicrobial therapy may be indicated, since secondary bacterial infections and sepsis are common complications resulting from viral injury to the intestinal mucosa. Parenteral ampicillin (10–20 mg/kg IV or SC q.8 h.) is a good empiric choice.

Prognosis for peracute panleukopenia is poor because many cats die within 12 hours. Median survival time after hospitalization was 3 days in a study of shelter cats, with death more likely in cats that were lethargic, were hypothermic, and had poor body condition. Kittens with cerebellar hypoplasia can make suitable pets depending on the severity of their neurologic abnormalities.

Prevention

Excellent vaccines are available for immunization of kittens against FPV (see Table 21.2.1), and FPV vaccines are considered core vaccines. Current FPV vaccines appear to afford protection against CPV variants.

MDAs interfere with vaccination and typically wane by 12 weeks of age to allow an active immunological response to vaccination to occur. Thus, many vaccination datasheets for pets and breeding cats recommend an initial vaccination at 8–9 weeks of age followed by a second vaccination 3–4 weeks later for the primary course. However, MDAs can sometimes persist as far as 20 weeks of age, and so guidelines often recommend that the last FPV primary vaccine be administered at 16–20 weeks of age as by this age, in most kittens, MDA will have waned, although this is not always the case. In shelter or rescue cats that are unlikely to have MDAs and are vulnerable, they can receive their primary vaccination from 6 weeks of age. A booster vaccination is then recommended for all cats at 6–12 months of age to further enhance the likelihood of vaccine-induced immunity being induced in cats that did not adequately respond to the primary vaccination course due to MDA. Thereafter boosters are only required every 3 years for FPV, as solid immunity is known to last for many years after vaccination.

Cats that do recover from natural infection probably derive lifelong immunity.

Both MLV and killed adjuvanted parenteral vaccines are available (see Table 21.2.1). Although MLV vaccines are used predominantly in clinical practice due to their more rapid onset of protection and better resistance to MDAs, even a single dose of a killed FPV vaccine can rapidly induce good antibody responses in naïve cats quickly. MLV vaccines should not be administered to kittens < 4 weeks of age or pregnant queens, as vaccine virus may replicate in the cerebellum of unborn kittens and kittens < 6 weeks old and may cause neurologic signs after birth. It has been recommended that immunocompromised cats should not receive MLV vaccines, but one study in cats with retrovirus infection demonstrated no adverse effects and similar responses to healthy cats following a MLV FPV vaccine. Boosters every 3 years are recommended after the primary course; however, antibody testing can be performed before vaccination, as FPV-specific antibodies are strongly correlated with protection. Some commercially available point-of-care tests are available for FPV antibody testing. Cats which possess FPV antibodies do not need to be revaccinated at that time point, and it is known that many cats already have antibodies even if not vaccinated previously.

FPV is long lived in the environment and resistant to many disinfectants such as quaternary ammonium. Bleach (1:32 solution used within 24 hours of dilution and protected from light) or accelerated hydrogen peroxide- or potassium peroxymonosulfate-based disinfectants should be used with a contact time of at least 10 minutes, after thorough cleaning to remove all organic material.

Public Health Implications

FPV poses no risk to human health.

FELINE TOROVIRUS

Definition/Overview

Toroviruses are similar to coronaviruses and have been detected in several species. There is some evidence to suggest a link in cats to protrusion of the third eyelid and diarrhea.

Etiology

Toroviruses are members of *Torovirinae* of the family *Coronaviridae* and are large, enveloped, single-stranded RNA viruses. Toroviruses have been implicated in human diarrheal disease, but consensus on their importance is lacking.

Pathophysiology

Suspected fecal–oral infection transmission, but information is lacking.

Clinical Presentation

Suspected involvement occurs in mainly young cats with protruding third eyelids (nictating membranes) and concurrent mild enteritis. This usually self-resolves within a few days with or without supportive treatment. Vision may be temporarily impaired due to physical obstruction of the pupil by the third eyelid. Mild hyperthermia may be present at the time of presentation.

Differential Diagnosis

Screening for an underlying enteropathy and/or upper respiratory tract pathogens may be warranted.

Diagnosis

No tests are currently commercially available, so diagnosis is based on clinical suspicion. Experimentally RT-PCR on fecal samples can be performed.

Management

Treatment/Prognosis

Supportive treatment may or may not be required. Prognosis is considered to be good.

Prevention

Likely endemic in the feline population, practice basic hygiene practices.

Public Health Implications

No available information.

OTHER VIRAL INFECTIONS

FELINE RABIES

See also Chapter 14.

Definition/Overview

Feline rabies virus infection has worldwide importance, particularly in the United States, although similar to that described in the dog, the incidence of feline rabies has been greater since the mid-1980s. This is considered to be associated with cats' nocturnal behavior and encounters with wildlife vectors and probable lower rabies vaccination rates. It is also known that younger cats, as well as dogs, are more susceptible to rabies virus infection than adult animals. The high concentration of rabies virus in the saliva of infected cats poses a particular threat to humans because of their popularity as companion animal pets and their ability to penetrate skin with their teeth. It has been estimated that < 20% of domestic cats in the United States are ever vaccinated against rabies. This fact, combined with the increasing incidence of wildlife rabies in the Mid-Atlantic and Northeastern United States, justifies efforts to promote feline rabies vaccination.

Etiology

Rabies is caused by an RNA virus of the *Rhabdoviridae* family. In areas with good pet vaccination programs, wildlife tend to be the major reservoirs and vectors, whereas in areas with poor programs, domesticated animals are the major reservoirs and vectors.

Pathophysiology

After inoculation into the subcutaneous tissues and muscle, usually by a bite or a scratch from an infected animal, the virus replicates in muscle cells at the bite site for weeks to months before attaching to peripheral nerve endings and undergoing retrograde migration up nerve axons to the CNS. Rabies virus replicates in the spinal ganglia, from where it disseminates throughout the CNS and continues replicating. The virus is then transported out of the CNS to other body tissues, including the salivary glands, through peripheral, motor, and sensory nerves. An animal is infectious when the salivary glands are affected. Infectious virus may be shed in saliva for up to 13 days before clinical signs of illness are manifest. Although deemed an uncommon mode of transmission, contact transfer has been experimentally demonstrated.

Clinical Presentation

The average incubation period for rabies is 2 months but varies from just over 1 week to up to 6 months and is shorter the higher the viral dose and/or if the site of inoculation is close to the CNS and/or the viral dose high. Clinical rabies infection in cats, like dogs, is divided into two general categories: Furious and paralytic. A prodromal phase can also occur before the furious stage, but it is often subclinical. Prodromal clinical signs, if they occur, include vague neurologic and behavioral changes, irritation at the site of viral inoculation (even if the wound has healed), fever, and increased agitation lasting for 1–2 days. As the disease progresses, about 90% of affected cats manifest the furious type of disease, which lasts up to 7 days and is due to an encephalitis. Affected cats show exaggerated emotional responses, becoming particularly aggressive toward humans as well as other animals and inanimate objects. Affected cats may aimlessly run or pace continuously until they collapse and act disorientated. In contrast to dogs, cats with rabies frequently manifest increased vocalization and a change in the pitch of voice. Other signs of cranial nerve and forebrain involvement can be seen including absent/reduced palpebral, corneal and pupillary reflexes, strabismus, dropped jaw, hypersalivation, seizures, twitching, and tremors. Most affected cats die within a few days. In cats that survive this first phase, clinical signs progress to paralytic disease. Affected cats manifest ataxia, flaccid ascending paraparesis, which often involves the site of inoculation,

incoordination, paralysis, coma, and death from respiratory arrest.

Differential Diagnosis

Kittens and cats infected with and shedding rabies may not manifest clinical signs, at least during the early stages of infection. (Any cat with unexplainable neurologic and/or behavioral changes should be considered suspect for rabies, especially if unvaccinated in an endemic country.) Neoplasia, spinal or head trauma, and poisoning or toxicity are important differential diagnoses for feline rabies. In the United States, the use of killed and recombinant rabies vaccines in cats has eliminated vaccine-induced signs of rabies.

Diagnosis

No specific changes are characteristic of rabies infection on hematology, serum biochemistry, or CSF analysis. Serum tests to detect anti-rabies virus antibodies in infected animals are often negative. Direct IFA staining or immunohistochemistry of nervous tissue collected at necropsy is the most common and gold-standard method of confirming rabies infection in both dogs and cats (Figure 21.2.27). Reverse transcriptase (RT)-PCR is a sensitive and specific test that can provide fast (within hours) results when neural tissues and/or saliva are submitted for testing. However, attempts to make antemortem diagnoses of rabies in animals are not recommended, and a negative RT-PCR test performed on saliva cannot be used to rule out rabies.

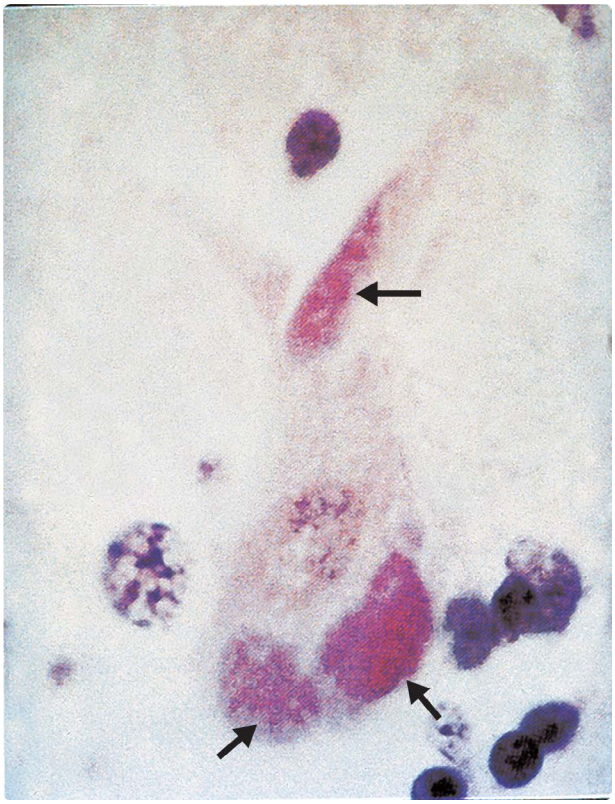

FIGURE 21.2.27 Rabies causes characteristic microscopic Negri bodies (arrows) in the brains of affected animals. (*From Kassira JP (1997). (ed.)* Images in Clinical Medicine. *Selections from the* New England Journal of Medicine*, with permission.*)

Management

Treatment/Prognosis

The zoonotic threat posed by rabies virus infection in cats justifies strict isolation and quarantine of cats suspected of or known to be infected. Treatment should not be attempted due to zoonotic potential. The prognosis for recovery from the clinical infection is grave, and euthanasia is recommended.

Prevention

Killed (adjuvanted) virus vaccines (1 year and 3 years) and a feline recombinant (adjuvant-free) rabies vaccine are available for use in cats. Current standards for vaccination of cats against rabies are outlined in Table 21.2.1. Where feline rabies vaccine is mandated by law, the first dose of vaccine can be given as early as 3 months of age. A second dose, administered 1 year following the date of the initial rabies vaccine, is required. Today, there is considerable variation among states and countries as to the frequency of booster vaccinations in adult cats. It is recommended that rabies vaccinations should be administered as low as possible on the right hindlimb, so that if a sarcoma develops subsequent to vaccination, there is a history of the type of vaccine used at the site. Vaccination intervals range from 1 to 3 years depending on the specific product used. While rare, there have been cases of rabies in vaccinated animals when vaccinations have been allowed to lapse.

Public Health Implications

As with dogs, any human exposed to the saliva of a cat suspected of having rabies should be considered exposed, and immediate isolation and treatment should be instituted. Treatment of a bite wound in a person caused by any domestic or feral cat must be treated aggressively by washing thoroughly as soon after the injury as possible. Irrigation of the wound with large quantities of a 20% aqueous soap solution or quaternary ammonium solution (e.g., benzalkonium chloride) is recommended. Humans who receive unprovoked bite wounds from feral or free-roaming cats have the highest risk of exposure. In endemic countries, approach stray cats with caution and appropriate protective equipment, even if they appear healthy. In addition to local wound treatment, these individuals are justifiably treated according to standard postexposure prophylaxis. Rabies virus is fragile and quickly inactivated outside the host and susceptible to routine disinfectants. Once saliva and/or tissue has dried, it is no longer deemed infectious.

FUNGAL INFECTIONS

FELINE CRYPTOCOCCOSIS

Definition/Overview

Cryptococcosis is an important noncontagious fungal disease of cats worldwide, and infection is usually via inhalation of environmental basidiospores. Infection is usually in the nasal cavity, although CNS signs can occur if infection breaks through the cribriform plate; pulmonary infections are rare. Dermatologic infections with ulcerative cutaneous lesions can also occur, as can disseminated infections, which are associated with clinical signs, including lethargy, cachexia, meningoencephalomyelitis, uveitis, chorioretinitis, osteomyelitis and polyarthritis, systemic lymphadenitis, or multiorgan involvement, including renal infection.

Etiology

Cryptococcus spp. are encapsulated, and most feline infections are due to *C. neoformans* and *C. gatii* species complexes. *C. neoformans* is usually associated with avian feces, particularly pigeon, but has also been isolated from decaying vegetation. Asymptomatic colonization of the respiratory tract is the most usual outcome of environmental exposure.

Pathophysiology

Cryptococcus is not a contagious disease. Infection comes from a contaminated environment. The cryptococcal capsule contains protective factors that can inhibit phagocytosis, so infection can be disseminated via infected macrophages and neutrophils. There is debate in the published literature regarding the possible role of immunosuppression in clinical infection. The incubation period varies from months to years, and fungal factors, such as infective burden, genotype, and virulence factors, as well as the host immune response, determine the outcome of exposure. Once established in the nasal cavity or lung, hematogenous and host cell–cell spread can occur to the lymph nodes, eye, skin, and CNS.

Clinical Presentation

Cats with nasal cryptococcosis usually present with a chronic unilateral nasal discharge (serous, mucopurulent, or hemorrhagic), often accompanied by unilateral or bilateral swelling that can be followed by ulcerative nasofacial lesions (see Figures 21.2.28–21.2.30). Submandibular lymph nodes are usually enlarged. Nasopharyngeal granulomas can sometimes protrude from the nostrils, causing stertor, dyspnea, and open-mouth breathing. Otitis media and vestibular signs can also develop as a consequence. Blindness can result from ocular infection, and if the cribriform plate is breached, intracranial neurologic signs (e.g., seizures), including blindness from optic neuritis and/or chorioretinitis, can ensue (Figure 21.2.31; see also Figure 19.25).

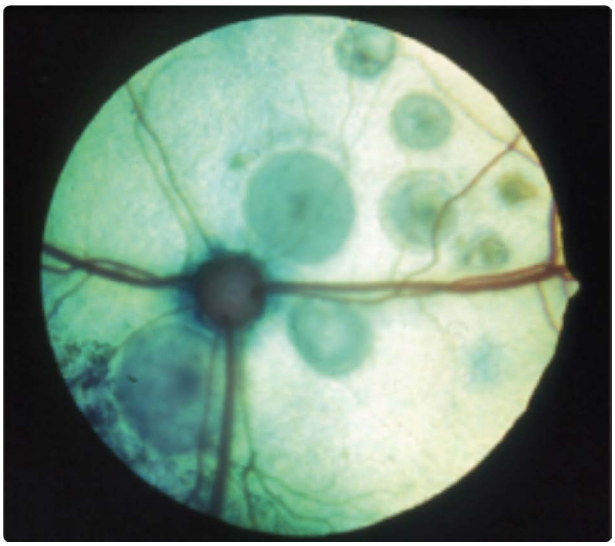

FIGURE 21.2.31 A funduscopic view showing cryptococcal chorioretinitis in a cat. (*Courtesy of D. Brooks*.)

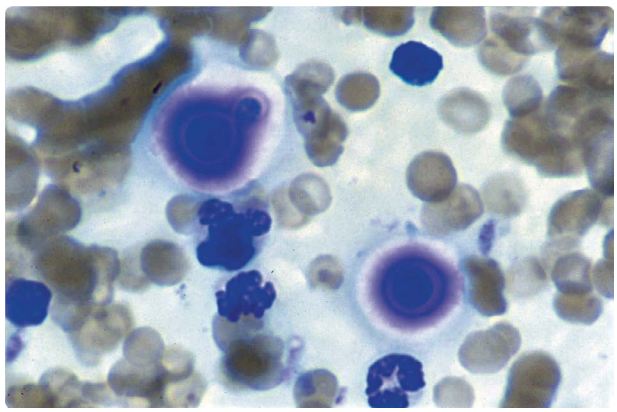

FIGURE 21.2.32 A cytology specimen stained with new methylene blue showing *Cryptococcus neoformans* spores. Note the thick capsule and the daughter spore. (*Courtesy of M. Schaer*.)

Dermatologic infection presents as single or multiple ulcerated or nonulcerated cutaneous masses (atypical presentation). Hematogenous spread can lead to multiorgan involvement, including lymphadenitis and polyarthritis. Systemic fungal dissemination and chronic infection can contribute to cachexia and depression.

Differential Diagnosis

Cryptococcal rhinitis can cause similar signs to infections with FHV-1, FCV, *C. felis*, *B. bronchiseptica*, *M. felis*, or *Aspergillus* spp.; neoplasia (e.g., nasal lymphoma), foreign bodies (e.g., plant awns), and oronasal fistulae should also be considered. Ocular and CNS signs could also be caused by neoplasia (e.g., lymphoma, meningioma), toxoplasmosis, FIP, or bacterial meningitis. The differential diagnosis for the cutaneous form in cats includes other deep mycoses, mycobacteriosis, nocardiosis, neoplasia (e.g., squamous cell carcinoma) herpetic dermatitis, and eosinophilic granuloma complex.

Diagnosis

Direct organism visualization via cytologic examination of tissue aspirates (such as directly from nasal masses), infected body fluids, or impression smears of cutaneous lesions or biopsies, stained with Romanowsky-type stains (Wright, Giemsa, Diff-Quik®) is often performed first. This usually reveals pink to violet round or budding extracellular *Cryptococcus* organisms with thick, unstained capsules (see Figure 21.2.32). Histopathology can also be performed on biopsy specimens. Cryptococcal culture can be performed after incubation for 10 days. Diagnostic imaging, including radiography and advanced imaging (CT and MRI) when appropriate, should be performed for further evaluation of clinical signs.

The latex cryptococcal antigen agglutination test (LCAT) to detect capsular antigen in serum, CSF, or urine is the diagnostic test of choice and, if possible, should be performed early in the diagnostic workup. It is both sensitive and specific, meaning that false-positive and negative results are uncommon.

Management

Published prospective controlled studies do not exist for the treatment of cryptococcal infections. Sinonasal disease is often treated with a combination of debulking therapy followed by prolonged courses of azole therapy (itraconazole 50–100 mg per cat p.o. q,24 h., fluconazole 50 mg per cat p.o. q.24 h., or ketoconazole 10 mg/kg p.o. q.12 h.), sometimes in combination with amphotericin B. Regular (1- to 2-month) liver enzyme testing should be performed for possible azole-related hepatotoxicity, and treatment should continue until the LCAT titer is zero. A four- to fivefold reduction in LCAT titer indicates an adequate response. LCAT titers should be repeated every 3–6 months thereafter so that recrudescent infections can be diagnosed early. Amphotericin B is the most efficacious anticryptococcal drug and can be administered as amphotericin deoxycholate (0.25–0.5 mg/kg per cat of 5 mg/mL stock solution diluted in 350 mL of 0.45% NaCl with 2.5% dextrose SC 2 or 3 times weekly to a cumulative dose of 10–15 mg/kg; nephrotoxicity can occur) or as liposomal amphotericin B (1–1.5 mg/kg IV q.48 h. to a cumulative dose of 12–15 mg/kg; administer as a 1–2 mg/mL solution in 5% dextrose by IV infusion over 1–2 hours; this is less nephrotoxic than amphotericin B deoxycholate, but azotemia can occur). Monotherapy with 5-flucytosine should not be used because of the potential for drug resistance to develop, but it is synergistic with amphotericin B (25–50 mg/kg p.o. q.6 h.). The combination of flucytosine and amphotericin B is recommended for feline CNS infections or cats that fail azole therapy. Fluconazole can be substituted for 5-flucytosine in CNS infections if 5-flucytosine is unaffordable, as it can penetrate the blood–brain barrier.

Localized cutaneous disease can often be treated successfully with fluconazole (10 mg/kg p.o. q.12 h.)

until lesions are completely resolved and cryptococcal LCAT titer reduces to zero. As with sinonasal or CNS infections, a four- to fivefold reduction in LCAT titer indicates an adequate response, and LCAT titers should be repeated every 3–6 months thereafter so that recrudescent infections can be diagnosed early. Surgical excision of any nodules can also be considered.

Prevention

Avoidance of exposure to environmental sources can usually be achieved by indoor only housing; however, cases have occurred in indoor only cats in endemic areas.

Public Health Implications

Infection is acquired from direct exposure to contaminated environmental sources such as avian feces and rotting vegetation. Since there is no aerosolization of cryptococcal organisms from infected tissues, infection is not transmitted between animals or from infected animals to people.

FELINE ASPERGILLOSIS

See also Chapter 6.

Definition/Overview

Although aspergillosis does occur in the cat, the incidence of infection is far less than that in the dog. There are two anatomic forms of upper respiratory tract aspergillosis in cats, and both commence in the nasal cavity: Sinonasal aspergillosis (causing local signs of chronic nasal infection) and more commonly (65% cases) invasive sino-orbital aspergillosis (with signs of orbital and local soft tissue swelling). This is in contrast with the dog, in which 99% of cases are noninvasive and sinonasal. Disseminated aspergillosis is typically associated with immunosuppression, and while it has been reported in the cat, it is rare. Invasive focal (non-upper respiratory tract) infections have also been the subject of rare feline case reports.

Etiology

Aspergillosis is caused by several species of fungus of the genus *Aspergillus*, which occurs in rotting vegetation, moldy hay, and sewage. Animals become infected through inhalation of airborne spores. *A. fumigatus* and *A. niger* are most commonly associated with sinonasal aspergillosis (SNA), while *A. felis* and *A. udagawae* are the most common isolate responsible for sino-orbital aspergillosis (SOA).

Pathophysiology

Colonization is usually prevented by a local immune response to inhaled spores involving mucociliary clearance, macrophages, and dendritic cells that recognize specific fungal epitopes. In cats where this immune response is suboptimal, the spores adhere to and invade the respiratory epithelium, destroying surrounding cells and avoiding phagocytosis. Infection usually occurs in young to middle-aged cats, those with previous viral upper respiratory tract infections, and brachycephalic breeds, such as Himalayans. Association with damage to the normal mucosal barrier as a consequence of nasal trauma, foreign bodies, and neoplasia has also been reported. SNA progresses to SOA via development of direct naso-orbital communication due to bone lysis.

Clinical Presentation

Cats with upper respiratory tract aspergillosis can present with sneezing, stertor, unilateral or bilateral serous to mucopurulent nasal discharge, mild ipsilateral mandibular lymphadenopathy, and clinical signs relating to periorbital involvement, such as exophthalmos and third eyelid protrusion. Epistaxis, pyrexia, and/or a discharging sinus or soft tissue mass involving the nasal bone or frontal sinus are less commonly seen.

Differential Diagnosis

Differential diagnoses include viral upper respiratory disease (FHV-1 and/or FCV), nasal cryptococcosis or other fungal infection (e.g., sporotrichosis, phaeohyphomycosis), nasal neoplasia (e.g., lymphoma, squamous cell carcinoma), nasal foreign body, penetrating bite wound, tooth root abscess, oronasal fistula, trauma to the nasal cavity or frontal sinus, or congenital abnormalities such as choanal atresia or palatine defects.

Diagnosis

Diagnostic tools include serology, radiography, advanced imaging (CT and/or MRI), rhinosinuscopy, cytology, histology, fungal culture, and molecular identification. Identification of fungal hyphae on cytology or histologic examination of biopsy specimens or sinonasal fungal plaques can confirm aspergillosis. Ventrodorsal radiography with the animal's mouth open usually reveals major lysis of the turbinates and increased radiolucency. CT has become the imaging technique of choice for sinonasal aspergillosis because it shows clearly the destruction of the turbinates, increased soft tissue attenuation in the nasal cavity, and fluid or soft tissue accumulation in the frontal and sphenoid sinuses; signs are usually bilateral. MRI is preferred for assessment of intracranial soft tissue. In sino-orbital aspergillosis, a ventromedial orbital mass with dorsolateral displacement of the globe and lytic lesions in the paranasal bones are also visualized. The cribriform plate should be inspected for integrity before topical antifungal treatment is considered. Nasopharyngoscopy, rhinoscopy, and/or sinuscopy usually reveals white to greenish gray colonies, which are typical of nasal aspergillosis. Hematology is unremarkable, and a stress or inflammatory leukogram with eosinophilia can be found; mild-to-severe hyperglobulinemia on serum biochemistry is relatively common. For species identification, PCR is required.

Antibody detection assays can be useful as supportive tests but are not confirmatory for diagnosis.

Management/Prognosis

Before treatment commences, the fungal isolate and its susceptibility should be identified, and the integrity of the cribriform plate should be determined on CT examination. Endoscopy and saline irrigation should be used to débride fungal plaques from the nasal cavity and frontal sinuses. Sinus trephination may be required. Pretreatment assessment of renal and liver function should be undertaken because of the hepatotoxic and nephrotoxic nature of the systemic therapies used.

For noninvasive sinonasal infections (and intact cribriform plate), topical 1-hour intranasal infusions with 1% clotrimazole or enilconazole solution can be administered under general anesthesia. Antifungal creams, as used in dogs, are not usually recommended as they are more likely to cause postprocedure airway obstruction. The head should be tilted to ensure drainage of the infusion at the end of the procedure. Systemic antifungal agents can be considered depending on case severity. Repeat treatments are commonly required to resolve infection (ideally cessation of clinical signs and imaging abnormalities (endoscopy +/– repeat CT).

For invasive sino-orbital infections (paranasal soft tissue infiltration and orbital involvement and/or interruption of the cribriform plate), systemic antifungal therapy using itraconazole (10 mg/kg p.o. q.24 h. with food; hepatotoxicity can occur), or posaconazole (2.5–3.75 mg/kg q.12 h. with food; hepatotoxicity can occur), perhaps combined with terbinafine or amphotericin B (deoxycholate (0.25–0.5 mg/kg per cat of 5 mg/mL stock solution diluted in 350 mL of 0.45% NaCl with 2.5% dextrose SC 2 or 3 times weekly to a cumulative dose of 10–15 mg/kg or liposomal (1–1.5 mg/kg IV q.48 h. to a cumulative dose of 12–15 mg/kg; administer as a 1–2 mg/mL solution in 5% dextrose by IV infusion over 1–2 hours; this is less nephrotoxic than amphotericin B deoxycholate, but azotemia can occur). *Aspergillus* spp. are intrinsically resistant to fluconazole therapy. At least 6 months of therapy is often required, and reinfections or relapses can occur. Treatment should be continued for at least 1 month beyond cessation of clinical signs. No benefit of surgical excision of granulomas over medical treatment alone in SOA has been demonstrated.

The prognosis for feline SNA is generally favorable with intensive treatment, while SOA has a poor prognosis, although there are only a handful of published case reports.

FELINE DERMATOPHYTOSIS

See also Chapter 18.

Definition/Overview

This is the most common fungal infection in the cat and presents primarily as a superficial skin disease. It presents with scaling to regular areas of circular alopecia with occasional erythematous margin around a healed center ("ringworm"). The majority of cases are caused by *Microsporum canis* and transmitted by direct contact.

SYSTEMIC MYCOSES

Definition/Overview

The systemic (or deep) mycoses are those infections in dogs and cats caused by *Blastomyces dermatitidis* (blastomycosis), *Coccidioides immitis* (coccidioidomycosis), *Cryptococcus neoformans* (cryptococcosis), and *Histoplasma capsulatum* (histoplasmosis). Each of the organisms listed can be isolated from soil within specific geographic regions throughout the world. Despite the mapping of endemic areas within the United States, the frequency with which pets travel throughout the country suggests that both dogs and, less commonly, cats can be presented with clinical disease outside of defined endemic areas. Since humans and animals share the environment in which soil contamination exists, it is not unusual to see the prevalence of animal infections correspond to the prevalence of human infections.

Etiology

The respiratory tract is the primary route of exposure among susceptible cats. Given the ubiquitous nature of the organisms in soil, it is obvious that many more animals will be exposed than will become clinically ill.

Pathophysiology

In susceptible animals, primary infection generally begins in the lung once the organism reaches the terminal airways. From there, dissemination to multiple organs is possible. In the clinical setting, it is the particular organ or organ systems infected that are responsible for the clinical signs. It is still unclear why some animals, subsequent to exposure, develop severe disseminated disease, while others remain healthy. It has been suggested that disseminated disease is a consequence of exposure in immunocompromised animals. Although antibody does develop in response to infection, it is not protective. Recovery from mycotic disease is attributed to cell-mediated immunity.

Clinical Presentation

In the few reported cases of systemic mycosis in cats, there appears to be no age, breed, or sex predilection to infection. In most cases, clinical signs include weight loss, decreased appetite, and lethargy. Since the respiratory tract is the portal of entry, clinical signs of pneumonia, including cough and dyspnea, are reported. Systemic signs include diarrhea, lameness, abdominal effusion, skin lesions, renal or hepatic failure, and ocular disease, but the signs vary depending on the particular organism involved.

TABLE 21.2.3 Summary of the major clinical signs and recommended biopsy sites for systemic mycotic infections in cats

	Feline	
Mycotic infection	**Presenting signs**	**Recommended biopsy site**
Histoplasmosis	– Dyspnea, tachypnea, possible abnormal lung sounds – Enlarged lymph nodes – Splenomegaly, hepatomegaly	– Bone marrow aspiration/biopsy – Fine-needle aspiration of lung and/or lymph node
Cryptococcosis	– Cryptococcosis is the most common systemic mycotic infection in cats – *Upper respiratory signs predominate:* Sneezing with mucoid nasal discharge not responsive to antimicrobials – A polypoid mass may be visible at the external nares/nasal bridge – Mandibular lymphadenomegaly – Subcutaneous papules or nodules	– Cytologic examination of FNAs from masses, exudate from the nose and skin stained with new methylene blue or Gram stain is preferred over Wright and India ink
Blastomycosis	– Uncommon in cats – When present, signs are similar to dogs – Dyspnea, weight loss, draining skin lesions, and visual impairment are most commonly reported	– Fine-needle aspiration of enlarged lymph nodes and other affected body sites – Cytopathology of skin lesions or exudate (conventional stains may be used)
Coccidioidomycosis	– Similar to the dog – Skin lesions without evidence of a bone lesion are most common – Respiratory signs are rare	– Skin biopsy involving tissue affected with micro abscesses – Multiple biopsies may be required – Attempting to culture *C. immitis* in practice is not recommended

Differential Diagnosis

The list of differential diagnoses for clinical signs associated with any of the systemic mycoses is extensive, depending on the primary organ system(s) involved. However, cachexia associated with neoplasia is one of the most important differentials to consider. Pneumonia, sepsis, enteritis, hepatic insufficiency, and polyarthritis are among the other differentials that apply.

Diagnosis

Bone marrow and other tissues are important sources for obtaining samples for a cytologic diagnosis (Figure 21.2.32). In dogs and cats with overt clinical signs and external manifestations of disease, it is practical, in the clinical setting, to identify the specific organism involved. The predominant clinical findings and the preferred tissue for identification of organisms are summarized in Table 21.2.3.

Thoracic radiographs are indicated in any dog or cat suspected of having a systemic mycotic infection. A diffuse, miliary to nodular interstitial pulmonary infiltrate is a common clinical finding, particularly in animals with signs of respiratory disease (Figure 21.2.33). The most common sites of biopsy for cytologic evaluation and diagnosis for each of the major systemic mycoses are summarized in Table 21.2.3.

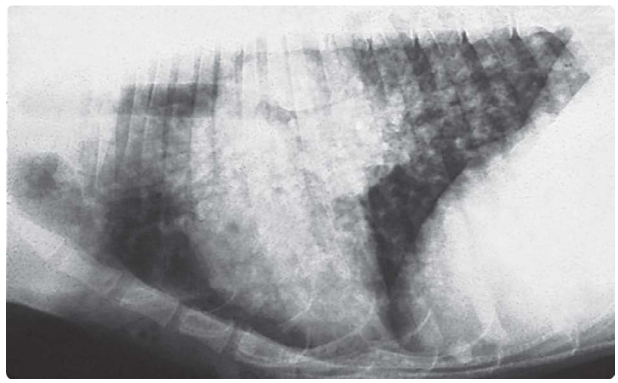

FIGURE 21.2.33 Lateral radiograph of a 2-year-old dog with a diffuse interstitial lung pattern characteristic of mycotic pneumonia.

Management

Treatment/Prognosis

The treatment protocols for cats infected with each of the four systemic mycoses described in this section are summarized in Table 21.2.4. However, the cost associated with treatment and the severity of clinical signs associated with the infection may ultimately determine the prognosis.

Prevention

There is currently no vaccine available for any of the systemic fungal infections. Given the ubiquitous nature of the organisms in soil, preventing exposure is extremely difficult in endemic areas. Chemical decontamination of the soil with formaldehyde solution is possible, but this is impractical for treating large areas.

Public Health Implications

Despite the fact that both humans and animals can be infected with each of the organisms discussed in this section, there is no known transmission from dogs or cats to humans or other animals. None of the systemic

TABLE 21.2.4 Recommended and alternative treatment protocols for systemic mycotic infections in cats

Mycotic infection	Feline
Histoplasmosis	Itraconazole (10 mg/kg p.o. q.12 h. for 4–6 months) (oral solution is recommended) **Alternatives** – Fluconazole (2.5–5.0 mg/kg p.o. q.12–24 h. for 4–6 months) or – Amphotericin B (deoxycholate) (0.25–0.5 mg/kg IV only administered on alternate days until a cumulative dose of 4–8 mg/kg is achieved)
Cryptococcosis	Itraconazole (10–20 mg/kg p.o. q.24 h. for at least 6 and up to 18 months) **Alternatives** – Fluconazole (2.5–5.0 mg/kg p.o. q.12–24 h. for 6–10 months) or – Flucytosine (75 mg/kg p.o. q.12 h. for 1–9 months) plus amphotericin B (deoxycholate) (0.1–0.5 mg/kg IV only administered on alternate days until a cumulative dose of 4–8 mg/kg is achieved) – (Recommended for patients with CNS involvement) Note: Amphotericin B is the only drug that is fungicidal
Blastomycosis	Itraconazole (5 mg/kg p.o. q.12 h. for 2 months or at least until 1 month following resolution of signs) **Alternative** – Amphotericin B (deoxycholate) (0.1–0.5 mg/kg IV only administered on alternate days until a cumulative dose of 4–8 mg/kg is achieved)
Coccidioidomycosis	Ketoconazole (50 mg [total] p.o. q.12 h.; expect to treat for up to 12 months) **Alternative** – Itraconazole (25–50 mg [total] p.o. q.12–24 h. for 8–12 months)

mycoses discussed in this section are considered zoonotic diseases.

PARASITIC INFECTIONS

PULMONARY PARASITES – FELINE LUNGWORM

Chapter 6 also covers this area and other infectious agents.

Definition/Overview

Lungworms are emerging parasites of the lower respiratory tract of cats. Several nematode species of importance are being increasingly recognized as a cause of respiratory signs, particularly in younger cats. Prevalence rates very and are linked to the cat's lifestyle and ecological factors. Wild cats are important hosts of some species.

Etiology

Aelurostrongylus abstrusus is the most important and most prevalent feline lungworm worldwide. Others of importance are *Troglostrongylus brevior* (especially in Mediterranean/Balkan countries and the Middle East) and *Capillaria aerophila* (syn. *Eucoleus aerophilus*, worldwide distribution), and mixed lungworm infestations are increasingly reported. *A. abstrusus* and *T. brevior* have indirect life cycles involving mollusks (slugs or snails) as intermediate hosts. Mollusks are penetrated by larvae hatched from eggs laid in the cat's respiratory tract, which are coughed up and swallowed and then excreted in their feces. The infective larvae are then shed in mucus from the mollusk. *T. brevior* may also be vertically transmitted, causing severe disease in kittens. *Capillaria aerophila* has a direct cycle, and eggs laid in the cat's respiratory tract are coughed up and swallowed and then excreted in their feces; earthworms can act as paratenic hosts. Cats become lungworm infected by ingesting intermediate or paratenic hosts containing larvae, which then migrate from the intestinal tract to the lungs where they mature into adults.

Cats of any age can be infected, but it is more prevalent in younger cats of less than 4 years and in cats with outdoor access.

Pathophysiology

Eggs, larvae, and adults accumulate in the alveoli, bronchioles, and arteries, inducing granulomatous or mixed inflammation. Bacterial complications such as mucopurulent bronchopneumonia or pyothorax can occur. In severe disease, pulmonary hypertension and right-sided heart disease can result.

Clinical Presentation

The severity of clinical signs depends on the lungworm species and numbers as well as the cat's immune response to infection. Respiratory signs can be absent, mild, or severe. They include nasal discharge, sneezing, coughing, tachypnea, dyspnea, diffuse bronchopneumonia, pyothorax, or pneumothorax. Kittens/younger cats and cats with mixed infestations generally develop more severe disease. *A. abstrusus* and *T. brevior* are more pathogenic. Asymptomatic carriage of *C. aerophila* is common. Lungworm is reported as a cause of anesthesia-associated death in cats.

Differential Diagnosis

These include common conditions of the lower respiratory tract such as feline bronchial disease and feline asthma. Other differentials include pneumonia, fungal disease, toxoplasmosis, feline infectious peritonitis, and neoplasia.

Diagnosis

The Baermann method, based on larval migration, detects the live larvae of *A. abstrusus* and *T. brevior*, while flotation is used to detect *C. aerophila* eggs, but both these methods are insensitive and require trained personnel to identify species. Ideally, fecal samples should be collected over 3 days. PCR assays now exist for diagnosis in feces, and pharyngeal swab PCR shows promise for *A. abstrusus* and *T. brevior* diagnosis. Thoracic imaging provides information on severity of disease, but changes are nonspecific, including interstitial, alveolar, and/or bronchial abnormalities. Although lungworm may be visible in bronchoalveolar lavage samples, anesthesia required for this procedure is a risk in cats with lungworm infection.

Management

Treatment/Prognosis

Even in cats showing severe clinical signs, widespread radiographic changes, and/or pulmonary hypertension, suitable treatment is usually very effective, although supportive care may be required with oxygen and thoracocentesis (pyothorax).

Several anthelminthic products are effective in eradicating infection, although studies published vary in lungworm species evaluated and labeled uses vary. Agents effective for *A. abstrusus* include oral fenbendazole, spot-on moxidectin 1%, and spot-on emodepside 2.1%. The latter has been shown to be effective via two repeated doses of emodepside spot-on applied with a 2-week interval. Spot-on eprinomectin 0.4% is also effective for *A. abstrusus*. Fewer studies have been done on the response of *T. brevior* and *C. aerophila* to treatment, but spot-on products containing emodepside, eprinomectin, or moxidectin appear to be effective. The Baermann test should be repeated after treatment to confirm cessation of larvae shedding.

Prevention

No vaccine is available for the prevention of lungworm in cats. Avoiding outdoor access reduces hunting behavior and the risk for predation of intermediate or paratenic hosts, although this may not be possible in many cats that need outdoor access for behavioral needs.

Spot-on moxidectin 1% and eprinomectin 0.4% can prevent *A. abstrusus* and *T. brevior* infections.

Public Health Implications

Capillaria aerophila has zoonotic potential as it infects many mammalian species, including humans, in which it occasionally causes respiratory disease.

GASTROINTESTINAL PARASITES

The scope of this subject is too extensive to cover in the current chapter and they are discussed in Chapter 9. The two most common gastrointestinal parasites of clinical concern will be discussed briefly here: Feline tritrichomonas and giardiasis.

FELINE TRITRICHOMONAS

Tritrichomonas is protozoan parasite causing predominantly pungent large intestinal diarrhea (mucous, hematochezia) usually in young cats from multicat households. Presence of perianal swelling and fecal incontinence raises suspicion. Not all infections are associated with clinical signs. Transmission is via the fecal–oral route.

Diagnosis in the presence of clinical signs is based on detection of motile trophozoites in wet mount preparations or by PCR from feces (sample collection by insertion of a fecal loop into the rectum may be more reliable than colonic washes).

Treatment is either supportive as infections are often self-limiting, but this can take months, or consideration of ronidazole (30 mg/kg per day p.o. for 14 days), an unlicensed product that carries the risk of neurotoxicity. Relapses occur in up to 25% of cases. Addition of a probiotic to treatment has shown some promise. Ideally, affected cats are isolated, and strict hygiene with regular litter tray cleaning, using routine disinfectants, is advised. It is not considered to be a zoonosis.

GIARDIASIS

Giardia is a protozoan parasite causing typically small intestinal diarrhea (although large intestinal characteristics such as occasional mucus and fresh blood can be seen) and weight loss in young cats (< 1 year old) from multicat households. Many infections are subclinical, so cause and effect can be hard to prove.

Initial treatment consists of fenbendazole (50 mg/kg p.o. s.i.d. 5–7 days) and environmental management. Giardia cysts are highly infectious and resistant in the environment, so only a small number are needed to cause infection or re-infection. Regular high temperature washing of food and water bowls, removal of feces, and quaternary ammonium compounds with a 1-minute contact time to clean contaminated surfaces is important. Alternatively, metronidazole (25 mg/kg p.o. s.i.d. for 5 days; higher doses are associated with neurotoxicity). In cases of repeated episodes in a multicat environment, treatment of all in-contact cats should be considered.

There is no current evidence of transmission from cats to humans, but due to potential risk, normal hygiene measures are advised.

POLYSYSTEMIC INFECTIONS

FELINE TOXOPLASMOSIS

Definition/Overview

Feline toxoplasmosis is caused by infection with the obligate intracellular coccidian parasite *Toxoplasma gondii*. Several genotypes exist worldwide. Around 35% of cats are seropositive for *T. gondii* antibodies, with higher percentages reported in Australia (52%) and Africa (51%) and lower percentages in Asia (27%). The organism is capable of infecting virtually all species of warm-blooded animals, including humans, although cats are the only definitive hosts for the parasite.

Etiology

Infection of cats or kittens from infected queens occurs via ingestion of cysts, transplacentally, or transmammary. While infection via ingestion of sporulated oocysts in cat feces is possible, this is thought to be rare because of fastidious elimination habits in cats. Cats with outdoor access are especially at risk of exposure subsequent to hunting and ingesting *T. gondii* cysts in the tissues of intermediate hosts or mechanical vectors such as cockroaches and rodents; indoor-only cats can also have access to intermediate hosts as well as via raw meat feeding.

Pathophysiology

As the cat is the definitive host of *T. gondii*, it is the only species where the parasite undergoes the enteroepithelial cycle, where infection in intestinal cells undergoes asexual and sexual phases to produce oocysts, which are passed in the feces. After primary infection, cats shed unsporulated oocysts in the feces for up to 3 weeks (usually 1–2 weeks) before the immune response stops oocyst shedding. Oocysts sporulate and become infective in 1–5 days, and the resulting oocysts remain viable for up to 18 months in suitable environmental temperature and humidity conditions before being ingested by warm-blooded intermediate hosts. Repeat oocyst shedding after the primary infection cycle in cats is rare, even in immunosuppressed cats. Clinical abnormalities associated with the enteroepithelial cycle are uncommon, but self-limiting small bowel diarrhea has been reported in some cats.

In the cat and all other mammals, the extraepithelial cycle occurs. After contact with cat feces containing sporulated oocysts, or ingestion of bradyzoite cysts in infected tissues, sporozoites penetrate the intestinal wall and develop into an actively replicating phase (tachyzoites), which spread via the blood and lymphatic circulation to localize infected tissues. As the host immune system responds, parasitic replication slows, and bradyzoites are then formed in tissue cysts and remain in the host for life. The extraepithelial cycle does not result in oocyst production.

Clinical illness subsequent to the ingestion of tissue cysts or oocysts or reactivation of latent infection is uncommon in cats. The reason that some cats develop significant clinical disease while many others do not is likely due to parasite virulence factors and the immune response of the host. Immunosuppression due to high-dose corticosteroid and cyclosporine therapy and FIV infection has been associated with recrudescent *T. gondii* infection. Additionally, naïve *T. gondii* infection in cats receiving immunosuppressive therapy, such as cyclosporine, can sometimes be fatal due to disseminated toxoplasmosis.

Clinical Presentation

Clinical signs of extraepithelial toxoplasmosis, if present, can include neurological signs (ataxia, seizures, encephalitis [Figure 21.2.34]), muscle pain (sometimes myocarditis), pulmonary disease (dyspnea, cough), ocular inflammation (uveitis, chorioretinitis, glaucoma, and retinal detachment have been reported (see Figure 19.24), hepatitis (occasionally with icterus), pancreatitis, dermatitis (nodules, panniculitis), and fever. In kittens, pulmonary and hepatic disease tends to be most life threatening. Transplacental infection can cause abortion and stillbirths.

Differential Diagnosis

For cats with neurological signs, consider FIP, FeLV, FIV, and neoplasia as differential diagnoses, while for those with respiratory signs, consider bacterial pneumonia/pyothorax, mycobacterial disease, lungworm, and heart disease. Inflammatory ocular disease can occur with FIP, FeLV, FIV, and mycobacterial disease. Among kittens, sudden death may be reported, so feline panleukopenia virus infection should be considered. FeLV and FIV testing is indicated.

Diagnosis

Hematologic and biochemical changes reported in cats with *T. gondii* disease are nonspecific but can include mild

FIGURE 21.2.34 This 4-year-old Domestic Shorthair cat has diffuse *Toxoplasma* encephalitis. The cat was euthanized, and the diagnosis confirmed on necropsy. (*Courtesy of M. Schaer.*)

anemia, leukocytosis, eosinophilia, and polyclonal hyperglobulinemia. Depending on the degree of hepatitis present, liver enzymes and serum bilirubin may be increased. Creatine kinase is elevated with myositis. Radiographic evidence of pneumonia or thoracic or abdominal effusions may be present, and ultrasonography may show changes with pancreatitis or hepatitis. Sampling may demonstrate evidence of tachyzoites on bronchoalveolar lavages or fine-needle aspiration of the lung (if accessible and safe to perform) or other affected sites (e.g., dermal nodules, bile, CSF) or effusions and provides a definitive diagnosis. PCR assays for *T. gondii* can also be performed on these samples, and positive results provide supporting evidence for a diagnosis of toxoplasmosis.

Since infected cats harbor *T. gondii* tissue cysts for life, measurement of serum anti-*T. gondii* antibodies is not always helpful for diagnosis. Anti-*T. gondii* IgM antibodies are associated with recent or recrudescent extraepithelial infection (from 2 until 16 weeks after infection), and anti-*T. gondii* IgG antibodies generally indicate infection of at least 10 days' duration, but neither of these antibody measurements correlate with active disease. In the absence of demonstration of tachyzoites on sampling, and in the presence of clinical signs consistent with toxoplasmosis, a tentative antemortem diagnosis can be based on a combination of: (1) An IgM titer higher than 1:64; (2) a fourfold or greater increase in IgG titer; and (3) positive response to treatment for toxoplasmosis.

Routine fecal examination of cats suspected of having toxoplasmosis is not helpful in diagnosis, as most cats are no longer shedding oocysts by the time clinical signs of extraepithelial infection occur. Following primary infection, cats usually shed *T. gondii* oocysts for only 1–2 weeks, and repeat oocyst shedding is rare. Additionally, microscopically *T. gondii* oocysts are indistinguishable from *Hammondia hammondi* oocysts, necessitating PCR to differentiate.

Management

Treatment/Prognosis

Cats with extraepithelial toxoplasmosis can be treated with clindamycin (10–15 mg/kg p.o. q.12 h. for 4 weeks) or trimethoprim/sulfa combination antimicrobial drugs (15 mg/kg p.o. q.12 h. for 4 weeks). Clinical improvement is expected within 7 days following onset of therapy. If clinical response does not occur with one drug within 7 days, therapy with the other drug can be tried. Cats with clinical uveitis associated with toxoplasmosis may be treated with topical (e.g., 1% prednisolone acetate) or systemic corticosteroids in combination with a topical mydriatic to prevent secondary lens luxation and glaucoma. Cats with hepatic, CNS, or pulmonary disease, and those with concurrent FeLV or FIV, carry a poorer prognosis with treatment. Complete resolution of signs might not occur in neurologic infections after clinical resolution.

Prevention

Treatment does not eliminate extraepithelial *T. gondii* infection, and reactivated infection is always possible. No vaccine is commercially available. Preventing kittens and cats from hunting (including ingesting transport hosts such as cockroaches) and feeding only commercially prepared cat food, without raw meat supplements, is a highly effective means of preventing infection. Freezing meat kills cysts too. Assessing the toxoplasma status of cats before starting cyclosporine therapy can be helpful, as if the cat is seronegative, then the earlier mentioned preventative measures can be taken to reduce the possibility of *T. gondii* infection when immunosuppressive treatment is started. Some have suggested giving clindamycin to cats for 3–4 weeks before starting cyclosporine, but the efficacy of this has not been confirmed.

Public Health Implications

Since the cat is a definitive host for *T. gondii* and is capable of excreting oocysts in feces during the enteroepithelial phase of infection, the cat represents a potential threat to human health, although oocyst excretion typically only occurs during 1–2 weeks over the cat's lifetime and is usually asymptomatic. Excreted oocysts are not infectious until they have undergone sporulation (approximately 48 hours at room temperature), so quick clearing of litter trays should help prevent human contact with sporulated oocysts during feces removal from trays. Because of fastidious grooming habits, cats are unlikely to harbor infective oocysts on their hair coat. Thus, the cat is a rare source of direct infection to people. Oocysts are resistant to disinfectants, and boiling water is superior to liquid disinfectants. Steam cleaning can be used to decontaminate hard, impervious surfaces.

Cat owners who are regarded as being at risk of infection, such as immunocompromised individuals or seronegative pregnant women, with *T. gondii* can take basic precautions to avoid exposure. If possible, at-risk individuals should not have access to litter pans; however, cleaning litter boxes at least every 24 hours will minimize the chance of exposure to sporulated oocysts, as outlined previously, and gloves should be worn. Since sporulated oocysts can survive in the environment for up to 18 months or more, avoiding locations where cats are likely to defecate and/or wearing gloves while working in soil can minimize the risk of exposure to humans, although cats do tend to bury their feces. Most human infections are acquired by eating undercooked meat containing tissue cysts, and the prevalence of protective antibody titers against *T. gondii* is high in people who eat meat. Washing fruit and vegetables that could be contaminated by soil is also important. Human infection can result in mild self-limiting malaise, fever, and lymphadenopathy and is commonly misdiagnosed. Primary infection during pregnancy can result in clinical toxoplasmosis in the fetus, with stillbirths, CNS, and ocular disease.

NOTE

1. For all of the drugs mentioned in this section, it is advised that the dosage recommendations by manufacturers in your country be followed, as they will vary due to each country's licensing requirements.

INTRODUCTION

The immune system interfaces with virtually all other body systems and consequently almost all diseases have an immunologic aspect. For example, the immune system will respond appropriately to the presence of infectious or neoplastic disease, or the existence of a chronic disease state may lead to secondary immunosuppression. More importantly, there is a wide range of diseases that have an immunopathological basis, and these are the focus of this chapter. In order to fully understand these primary immunologic disorders, a solid working knowledge of the immune system is required. This chapter will briefly overview current knowledge of the immune response and immunopathology, and then discuss the four major categories of immune-mediated disease: (1) Allergic disease; (2) autoimmune disease; (3) primary immunodeficiency disease; and (4) immune system neoplasia. Many of the key diseases within these groups are discussed in the individual systems-based chapters of this book. These will be cross-referenced from this chapter, and only selected immunologic disorders not covered elsewhere will be presented here.

THE IMMUNE RESPONSE

The immune system may be fundamentally considered in terms of innate and adaptive immunity. Innate immunity encompasses the more primitive, nonspecific defense mechanisms of the body, while adaptive immunity is antigen-specific, considerably more potent, and encompasses the phenomenon of immunologic memory. It is now known that activity within the innate immune system directs the nature of the subsequent adaptive response. The key cell that links these two systems is the dendritic antigen presenting cell (APC).

Innate Immunity

The innate immune system is most dominant at the mucocutaneous barriers of the body, which are the front line of exposure to pathogens. The microanatomic aspects of these barriers themselves are considered part of the innate immune system and are represented by structures such as:

- The thick, keratinized epidermis of the skin, which is coated by antimicrobial secretions of the sebaceous and sweat glands (**Figure 22.1**).
- The mucociliary escalator of the lower respiratory tract.
- The peristaltic motion of the intestinal tract, coupled with the rapid turnover of enterocytes and secretion of a wide range of enzymatic and antimicrobial substances.

Similarly, the natural microflora of many of these surfaces provides powerful competitive exclusion to pathogens and may also be considered an innate protective feature.

These barrier functions are supported by the soluble and cellular constituents of the innate immune system. The former include secreted immunologic molecules such as components of the alternative complement pathway, antimicrobial peptides such as the "defensins," selected proinflammatory cytokines (such as interleukin [IL]-1, IL-6, and tumor necrosis factor [TNF]-α), and polyreactive IgA and IgM. The cellular components of the innate immune system include nonspecific phagocytic cells (neutrophils and macrophages), the natural killer (NK) cells, which undertake cytotoxic destruction of target cells (e.g., virally infected cells or tumor

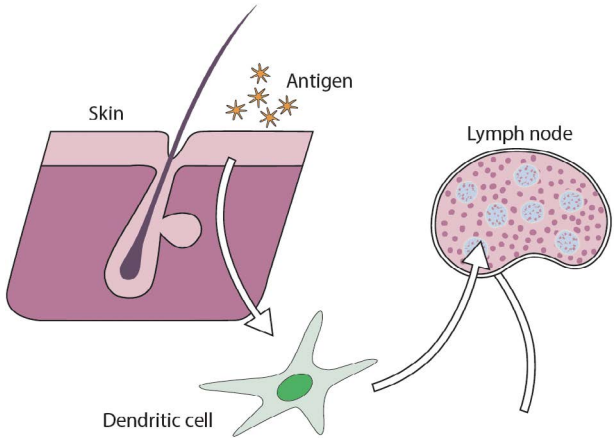

FIGURE 22.2 The dendritic cell is the key link between the innate and adaptive immune systems. In this example, percutaneously absorbed antigen is taken up by an epidermal Langerhans cell and translocated to regional lymphoid tissue via the dermal lymphatic drainage.

cells) in a less specific fashion than T lymphocytes, and the specialized subset of T lymphocytes that express an antigen-specific T-cell receptor (TCR) comprised of a γ and δ chain (γδ TCR).

These components of innate immunity work together to provide immediate protection following exposure to a potential pathogen. Although a relatively less effective means of immune defense, the innate immune system is crucial for the provision of this protective cover until the adaptive response is activated, mobilized, and recruited to the site of pathogen exposure.

The Dendritic Cell—Link between Innate and Adaptive Immunity

The dendritic APC provides the link between innate and adaptive immunity. Dendritic cells are widely distributed throughout the tissues of the body, and are particularly prominent at the mucocutaneous barriers. Some of the best characterized dendritic cells are those of the skin, and these include the epidermal Langerhans cell and the dermal dendritic cells. The primary role of the dendritic cell is the capture of foreign antigen as it penetrates these barriers, the "processing" of this antigen to a form which can stimulate adaptive immunity, and the translocation of antigen from the peripheral point of exposure to the regional draining lymphoid tissue for induction of the adaptive immune response (Figure 22.2).

The initial encounter between foreign antigen and dendritic cell involves a series of dendritic cell receptor molecules termed "pattern recognition receptors" (PRRs) or "Toll-like receptors" (TLRs). These PRRs are expressed either on the surface membrane of the dendritic cell or within the cytoplasm. They interact with ligands that are derived from foreign antigen (e.g., pathogenic microorganisms) or damaged body cells. These ligands are termed "pathogen-associated molecular patterns" (PAMPs) or "microbe-associated molecular patterns" and include structural antigens expressed on the surface of microbes (e.g., lipopolysaccharide) or their internal constituents (e.g., portions of microbial DNA). Ligands derived from altered tissue cells are referred to as "damage- associated molecular patterns." The interaction between PRR and PAMP permits the foreign antigen to be internalized into the cytoplasm of the dendritic cell where it may enter one of two distinct intracellular antigen processing pathways. The first of these pathways involves the enzymatic degradation of the antigen within a cytoplasmic membrane-enclosed compartment. Within this compartment, the complex antigenic structure is degraded into small peptide constituents (of the order of 25 amino acids in length), which become associated with molecules that line the inner surface of the compartment. These are the class II molecules of the major histocompatibility complex (MHC), which are pivotal to the generation of the immune response. Following this "processing" event, the combination of MHC class II and peptide becomes re-expressed on the surface of the dendritic cell, such that the dendritic cell is now "presenting" the antigen–MHC complex (thus the terminology "antigen-presenting cell").

The second intracellular antigen-processing pathway involves degradation of antigen within a distinct cytoplasmic compartment known as the proteasome. Within the proteasome, slightly smaller peptide fragments (10 amino acids in length) are generated, which are then translocated into the cytoplasmic Golgi apparatus where they become associated with class I molecules of the MHC. These complexes of class I MHC and antigenic peptide are also then expressed on the surface of the dendritic cell.

Which of these intracellular processing pathways is activated is determined by the nature of the foreign antigen and, therefore, which of the dendritic cell PRRs become engaged. Broadly speaking, the majority of antigens that are derived from outside of the body (exogenous antigens) and require phagocytosis or pinocytosis enter the MHC class II expression pathway. In contrast, antigens that are derived from within tissue cells (endogenous antigens [e.g., viral antigens synthesized in the cytoplasm from viral genetic material within the cell] or tumor antigens expressed by a tissue cell) are processed by the class I pathway. These pathways are not mutually exclusive, so it is possible for an antigen to be processed by both routes ("cross-presentation").

The antigen-processing procedure involves not only expression of MHC–peptide on the surface of the dendritic cell, but the upregulation of other (co-stimulatory) molecules on the dendritic cell surface and the secretion of soluble intercellular messengers (cytokines) by the activated APC (Figure 22.3). Again, the nature of these co-stimulatory molecules and the type of cytokines are directed by the nature of the inciting antigen and the intracellular signaling pathways triggered when that antigen binds to particular dendritic cell PRRs. All of these outcomes of antigen processing (e.g., presentation by MHC I or II, the nature of co-stimulatory molecules and cytokines) will in turn determine the type of adaptive immune response that is made to the antigen. Thus, the dendritic cell truly is the link between innate and adaptive immunity and the key factor determining the quality of the adaptive immune response.

All of the events described above occur within the dendritic APC, but the second major role of this cell is in translocation of antigen from the site of exposure (e.g., at a mucocutaneous surface) to the regional draining lymphoid tissue. This procedure involves the antigen-laden dendritic cell entering the tissue lymphatics where it travels to the lymph node and enters the T-cell area (paracortex) of the node.

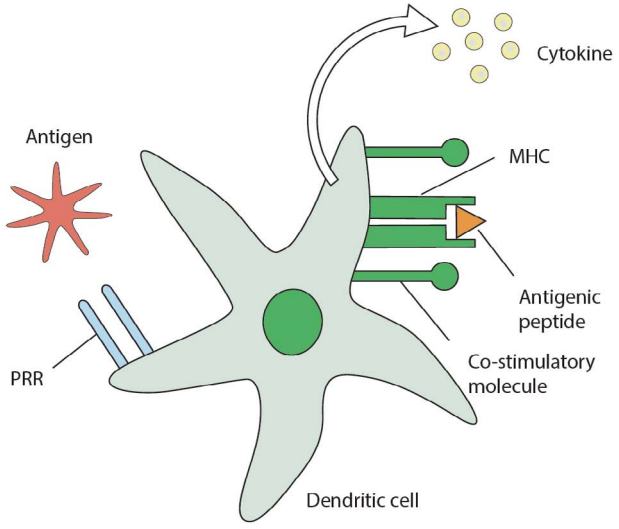

FIGURE 22.3 The APC (dendritic cell) engages foreign antigen via surface PRRs. The antigen is internalized, processed, and re-presented on the surface of the cell associated with a class II MHC molecule. The dendritic cell also upregulates the expression of co-stimulatory molecules and secretes co-stimulatory cytokines.

The Adaptive Immune Response

Once the antigen-laden dendritic cell arrives in the lymph node paracortex it remains relatively stationary, while numerous T lymphocytes approach it to "test out" whether their TCRs are designed to be able to bind to the combination of antigenic peptide and MHC expressed by the APC. These T cells express a receptor comprised of an α and β chain, the antigen-binding capacity of which has been predetermined by gene rearrangements within the cell. The T- and B-cell populations of the body between them bear an enormous range of receptor specificities (the receptor "repertoire"), which are designed to be able to interact with any foreign antigen that may ever be encountered by that individual. In order to maximize the potential for any one T or B cell to encounter the antigen that they are 'pre-programmed' to recognize, the lymphoid cells of the body continually recirculate through a complex pathway involving the tissues, lymphatics, and vascular circulation ("immune surveillance"). The recirculating T cells within the lymph node paracortex may or may not be relevant to a particular antigen expressed by any one dendritic cell at any time. *In-vivo* video microscopy of labeled T cells and dendritic cells has shown that an APC within the paracortex might be expected to be approached by up to 500 different T cells each hour.

Possibly the most amazing feature of the immune response is that such interactions between APCs and T cells do occur and result in generation of the adaptive immune response. For antigens that have never before been encountered by the individual, the "naïve" T cell that associates with the APC is not yet committed to generating an adaptive immune response of any particular type. Again, it is the dendritic cell that now determines the nature of this adaptive response by the way in which it signals the naïve T cell.

Dendritic cells expressing antigenic peptide primarily associated with MHC class II are most likely to stimulate that subset of T cells bearing the CD4 ('cluster of differentiation' molecule number 4) molecule (T helper [Th] cells), whereas class I-peptide expression is more likely to activate the CD8-expressing T-cell subset (T cytotoxic [Tc] cells). There are a number of key functional subpopulations of $CD4^+$ T cells and which of these is preferentially activated by activation of the naïve $CD4^+$ T cell precursor by the dendritic cell determines the functional nature of the ensuing adaptive immune response.

Signaling of the naïve $CD4^+$ T cell, involving release of APC-derived cytokines such as IL-12, IL-18, and IL-27 and activation through the T-cell intracellular signaling pathway STAT 4, results in differentiation of the naïve cell into a mature Th1 cell. The Th1 cell is defined functionally by production of the cytokines IL-2 and interferon (IFN)-γ and by the initiation of an adaptive immune response dominated by cell-mediated immunity

(CMI). CMI involves the activation of cytotoxic CD8+ T cells and NK cells for destruction of virally infected or neoplastic target cells, or the activation of macrophages to permit destruction of an intracellular pathogen such as *Leishmania*, *Salmonella*, or *Mycobacterium*. The Th1-driven immune response features only limited antibody production of those IgG subclasses that might be involved in opsonization or antibody-dependent cell-mediated cytotoxicity. Consequently, the antigens that induce this form of immune response are largely exogenous pathogens of the type listed above (Figure 22.4).

By contrast, signaling of the naïve CD4+ T cell, involving release of APC-derived cytokines such as IL-4 and activation through the T-cell intracellular signaling pathway STAT 6, results in differentiation of the naïve cell into a mature Th2 cell. The Th2 cell is defined functionally by production of the cytokines IL-4, IL-5, IL-6, IL-9, and IL-13 and by the initiation of an adaptive immune response dominated by humoral (antibody-mediated) immunity. Such antibody responses (involving production of alternative IgG subclasses to those above, IgA and IgE) might be required in adaptive immune responses driven by the presence of pathogens such as yeasts, *Escherichia coli*, or helminth parasites (Figure 22.4).

Activation of the naïve CD4+ T cell via the STAT 3 pathway and APC-derived IL-6, IL-23, or transforming growth factor (TGF)-β results in differentiation into a Th17 cell. Th17 cells are defined by their production of IL-17 and have a key role in the defense against bacterial and fungal infections.

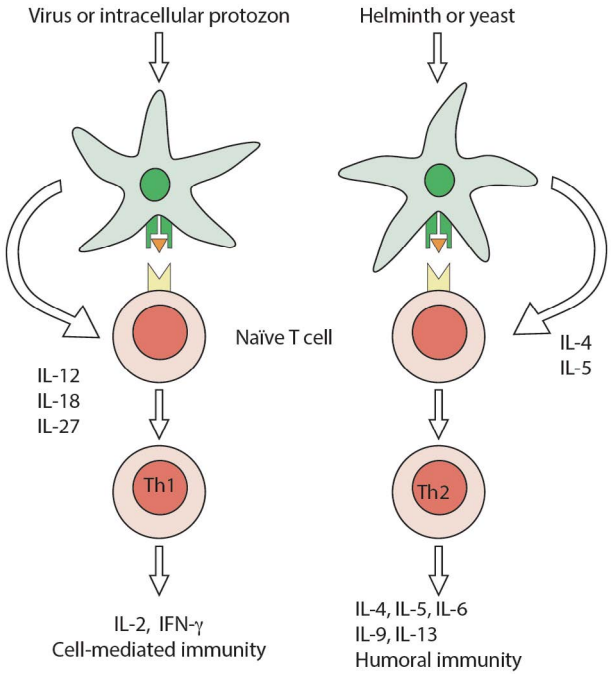

FIGURE 22.4 Processed antigen is presented by the dendritic cell to naïve CD4+ T lymphocytes. The nature of the inciting antigen determines the type of stimulatory signal provided by the dendritic cell and thus the pathway of differentiation of the T cell. Differentiation towards Th1 promotes a cell-mediated effector immune response, whereas the Th2 subpopulation induces a humoral effector response.

Although less well understood, the dendritic cell–T cell encounter is also likely to control the differentiation of the subsets of CD4+ T cells that are involved in suppression (or "downregulation"') of the immune response. The major suppressive populations include the CD4+CD25+ "natural suppressor cells," which are constitutively present in the body, the CD4+ IL-10 producing "induced suppressor cells" (T regulatory cells [Tregs]), which are induced following antigen exposure, and the Th3 cells that are important in the regulation of mucosal immune responses and defined by the production of TGF-β.

The activation of T cells by interaction with APCs involves not only determination of the qualitative nature of the adaptive immune response, but the expansion of antigen-relevant clones of T cells via the process of clonal proliferation. This generates large numbers of antigen-specific T cells that mediate the effector immune response. At least some of these T cells are required for activation of antigen-specific B lymphocytes, which will undertake the humoral immune response.

B-cell activation proceeds in a different fashion to that described for T cells. B cells within the lymphoid tissue reside in primary follicles. Antigen-specific B cells similarly require a combination of activation signals. The first of these comes from the antigen itself, which is recognized by the B-cell receptor (BCR) or surface membrane immunoglobulin. The naïve B cell expresses the combination of IgD and IgM receptor molecules of identical, genetically determined, antigen specificity. The BCR recognizes a large, conformational determinant of antigen (rather than an MHC-associated peptide fragment). This antigenic determinant may be present in soluble form in the B cell environment or may be physically delivered on the surface of an APC. Again, only those B cells bearing antigen-relevant BCRs will be able to recognize antigen, and continual B-cell recirculation is important to maximize the chance of this occurrence. For the majority of (T-dependent) antigens, B-cell activation requires T-cell help. It is now known that following Th cell activation (as described above), some of these cells migrate from the paracortex into the margins of primary follicles, where they encounter B cells carrying receptors for the same stimulating antigen (Figure 22.5).

Following BCR–antigen recognition, the B cell internalizes these surface molecules into a cytoplasmic compartment where there is antigen processing and association with MHC class II molecules as described for the dendritic cell. The B cell also presents these MHC–antigen complexes on its surface membrane. T-cell help for B-cell activation takes the form of:

- TCR binding MHC–peptide on the B-cell surface.
- The interaction of other co-stimulatory molecules on the surface of each cell.
- The release of co-stimulatory cytokines from the T cell (e.g., IL-4, IL-5), which bind cytokine receptors on the B-cell surface (Figure 22.6).

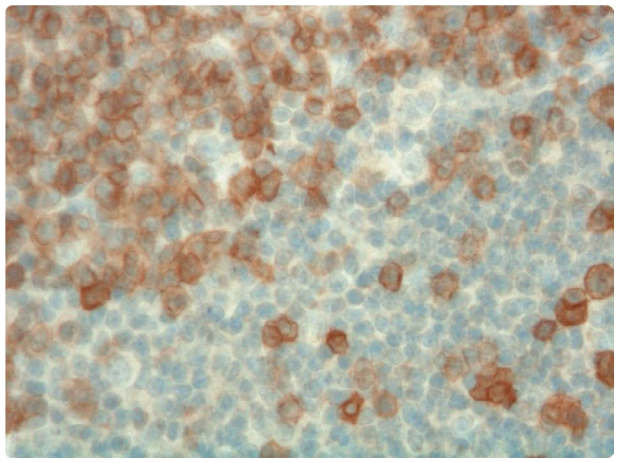

FIGURE 22.5 Canine lymph node labeled to show expression of the T-cell marker CD3. The image includes the junction between paracortex and a primary lymphoid follicle. Scattered T cells are found within the follicular (B cell) area. These helper cells will provide co-stimulation for antigen-activated B cells and generation of a secondary lymphoid follicle.

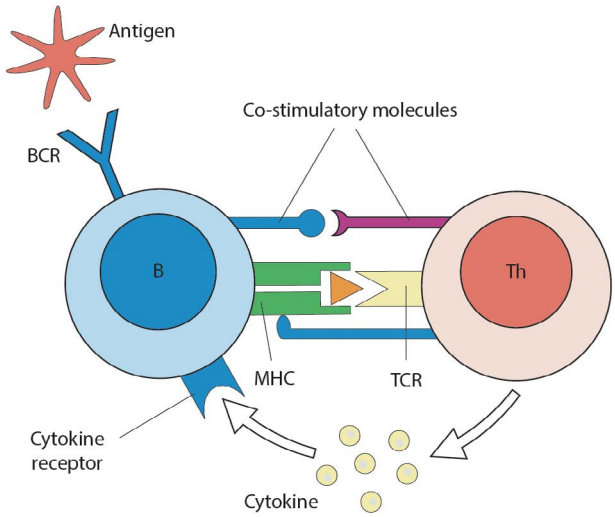

FIGURE 22.6 Provision of T-cell help for activation of a B cell. The B lymphocyte recognizes intact antigen through surface immunoglobulin (the B-cell receptor). The B cell internalizes the antigen, processes it, and re-presents a peptide fragment of antigen associated with an MHC class II molecule. The T helper cell physically interacts with the B cell through the TCR and engagement of co-stimulatory molecules expressed on the surface of each cell. In addition, the T cell releases co-stimulatory cytokine that binds cytokine receptor on the target B cell.

B-cell activation also results in clonal proliferation, which in the case of a B cell is shown by the formation of a secondary follicle with a blastic germinal center and surrounding mantle zone of small lymphocytes. Additionally, the stimulated B cells undergo the "immunoglobulin class switch," which involves genetic recombination to permit expression of a single immunoglobulin class (generally IgG, IgA, or IgE). The type of immunoglobulin is determined by the type of Th cell (Th1 versus Th2) and in turn by the nature of the stimulating antigen (see above). For example, an intestinal helminth parasite is most likely to stimulate Th2 activation and IgE class switching within the mesenteric lymph node. The end stage of B-cell activation is transformation of that B cell into a plasma cell, which can actively secrete immunoglobulin of the predetermined class and antigen specificity.

Having expanded antigen-specific T- and B-cell populations within the regional lymphoid tissue, the next (effector) phase of the immune response necessitates these cells leaving the node within efferent lymph, which eventually drains into the vascular circulation. The antigen-specific lymphocytes circulate in the blood until they encounter modified endothelial cells bearing molecules ("vascular addressins") that bind to ligands on the circulating cells ("homing receptors") and enable the circulating lymphocytes to be arrested in their flow and to diapedese between endothelia into the tissue containing the inciting antigen. Having attained this position, these lymphocytes of the adaptive immune system are now able to reinforce the innate immunity that has, to date, dealt with the initiating pathogen. The nature of this effector immune response is determined by the nature of the pathogen and those aspects of the immunologic armory that are best able to eliminate it. For example, the cutaneous immune response to *Leishmania* would best be served by the action of Th1 lymphocytes producing IFN-γ, which may stimulate parasitized macrophages and allow them to destroy the pathogen that was replicating within their cytoplasm. Concurrently, the activation of IgG-secreting plasma cells would provide antigen-specific antibody that might bind and neutralize free amastigotes that were released from ruptured parasitized cells. In this instance, a Th2 response with dominant humoral immunity would not be protective, which is exactly the situation that arises in susceptible dogs that succumb to the infection.

The final stage of the adaptive immune response involves suppression of the response when it is no longer required (i.e., when antigen is eliminated). Such suppression is an active event, and primarily involves the range of Tregs described above. Through either physical contact or inhibitory cytokine production, or both, suppressor cells are able to inhibit the function or physically remove (by induction of apoptosis) the effector populations. The antigen-stimulated cells are never entirely removed, as for each immune response that is made, a residual population of long-lived memory T and B lymphocytes persists, generally for the lifetime of the individual.

IMMUNOPATHOGENIC MECHANISMS

Despite the wide array of antigens that might potentially be encountered by an individual (e.g., infectious agents, allergens, tissue alloantigens, autoantigens, tumor antigens), the immune system generally responds to stimulation by using one or more of a series of well-defined immunopathogenic mechanisms. These were defined many years ago by Gell and Coombs as types I to IV hypersensitivity, and this classification still provides a

useful framework for consideration of immune effector function. These are best considered as "immunopathogenic mechanisms" rather than "hypersensitivity mechanisms" because while they do form the basis for allergic (hypersensitivity) disease, the same mechanisms are involved in other immune-mediated diseases (e.g., autoimmune disease) and in beneficial immune responses to foreign antigens (for which reason they probably evolved initially).

Type I (Immediate) Hypersensitivity

Type I hypersensitivity follows exposure to antigens that selectively trigger Th2 lymphocytes and the production of IgE antibodies. These antibodies bind specific receptor molecules on the surface of basophils and tissue mast cells, and when the sensitized individual is re-exposed to antigen there is binding and cross-linking of these cell-bound IgE molecules. This results in rapid (within 15–20 minutes, thus "immediate" hypersensitivity) mast cell or basophil degranulation, with the release of a wide range of proinflammatory mediators that lead to the well-recognized clinical effects of such reactions, which may be localized or generalized (anaphylactic) (Figures 22.7 and 22.8). These effects include:

- Vasodilation with tissue edema and egress of plasma protein and leukocytes.
- Bronchoconstriction via contraction of smooth muscle.
- Cutaneous pruritus caused by interaction with neurologic pathways.

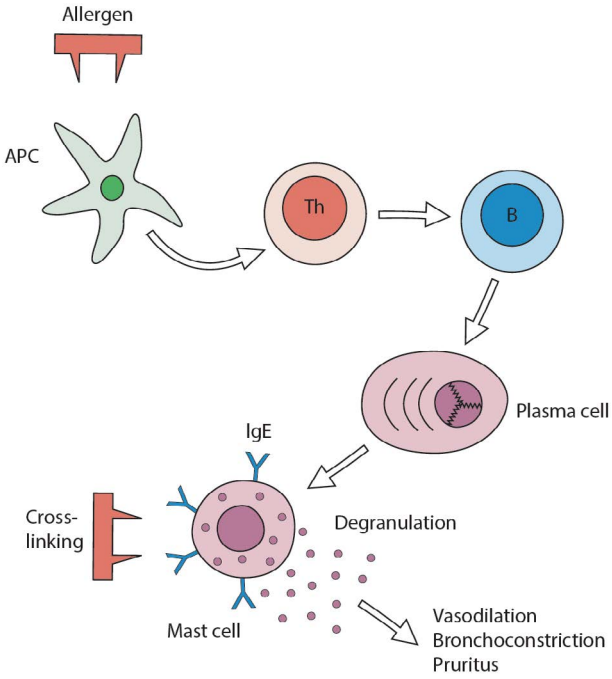

FIGURE 22.7 The type I hypersensitivity reaction. Presentation of allergen by dendritic cells results in stimulation of Th2 immunity, with the generation of allergen-specific IgE antibodies that coat mucocutaneous mast cells. On re-exposure to allergen, there is mast cell degranulation, which mediates the classical clinical features of this reaction.

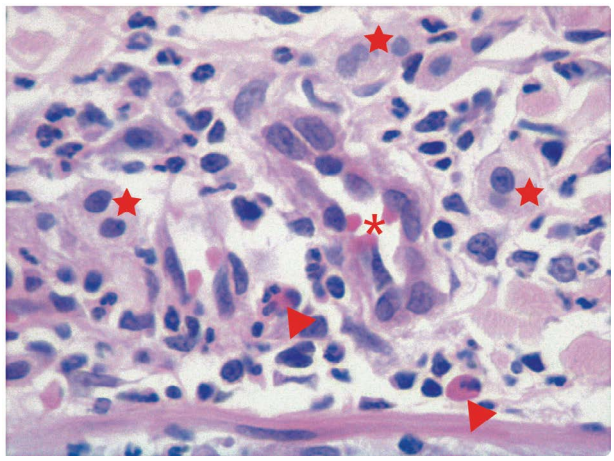

FIGURE 22.8 Skin biopsy from a 5-year-old Domestic Shorthair cat with pruritus and miliary dermatitis. The histopathologic features are characteristic of a type I hypersensitivity reaction. There is a mixed inflammatory infiltration surrounding the superficial dermal vessel (asterisk), which includes small clusters of mast cells (stars) and eosinophils (arrowheads).

The type I reaction probably evolved to provide protective immunity in the case of intestinal helminth parasitism, but it is now most widely recognized as the mechanism underlying the range of allergic diseases of the skin, conjunctivae, respiratory tract, and gastrointestinal tract of the dog and cat.

Type II (Antibody-Mediated) Hypersensitivity

In this reaction, the individual is sensitized to produce antibody that attaches to the surface of a target cell and subsequently activates the classical pathway of the complement system. The deposition of complement molecules onto the target cell surface leads to destruction of that target via either formation of the membrane attack complex of complement with osmotic lysis of the cell or phagocytosis of the immunoglobulin and complement opsonized target (Figure 22.9a, b). The classical target cell for this type of reaction is the erythrocyte, and type II hypersensitivity is the immunopathogenic mechanism that underlies diseases such as immune-mediated hemolytic anemia (IMHA) or blood transfusion reactions. Also included in this category are disorders involving the interaction of antibody with receptor molecules, classically causing either receptor blockade (e.g., antibody to the neuromuscular acetylcholine receptor [AChR] in myasthenia gravis) or receptor activation (e.g., stimulation of the thyroid stimulating hormone receptor by antibody in human Grave's disease).

Type III (Immune Complex) Hypersensitivity

This immunopathogenic mechanism has two distinct subtypes defined by the relative proportions of antigen and antibody involved in the reaction. In antibody

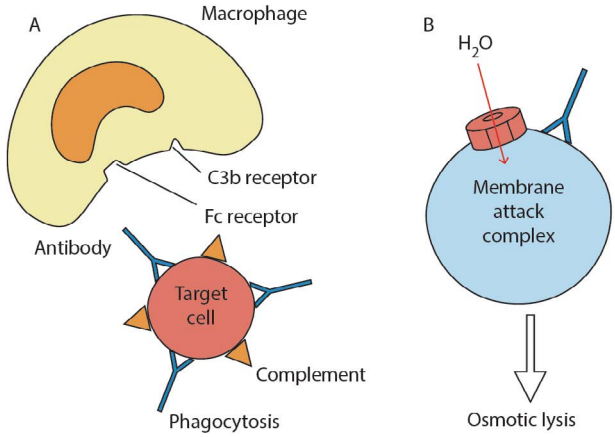

FIGURE 22.9 The type II hypersensitivity reaction. Immunologic sensitization leads to production of antibody that coats a target cell and activates complement deposition via the classical pathway. **(a)** The target cell is thus opsonized for phagocytosis by a macrophage bearing Fc and C3b receptors. **(b)** Alternatively, the membrane attack complex of complement inserts through the cell membrane, creating an ionic imbalance and resulting in a net influx of water into the target cell cytoplasm with subsequent lysis of the target.

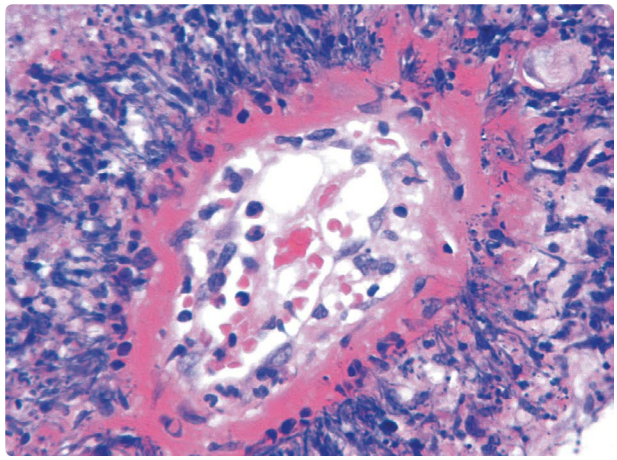

FIGURE 22.10 Cutaneous vasculitis in a dog. This is one of multiple affected dermal blood vessels in biopsy samples taken from ulcerative lesions on the flanks and scrotum of an 11-year-old dog. There is deposition of fibrin in the remains of the wall of this vessel, together with numerous apoptotic neutrophils within the wall and within the surrounding dermal collagen. The cause of this presumptive type III hypersensitivity reaction was not ascertained.

excess type III hypersensitivity, the individual is sensitized to mount a marked antibody response to antigen. On re-exposure to that antigen, the high concentrations of antibody that may be found at the site of antigen entry immediately bind to the antigen at the site of exposure.

The antigen–antibody interaction results in local formation of insoluble immune complexes, with subsequent activation of complement and production of inflammatory mediators and local recruitment of inflammatory cells. The classical example of such a reaction is the human 'Arthus reaction' involving exposure to inhaled antigens (of an occupational nature), with the development of pulmonary disease post exposure in a sensitized individual. Such reactions are rarely documented in the dog and cat.

In antigen excess type III hypersensitivity there are higher concentrations of antigen than antibody, resulting in the formation of small, soluble immune complexes that circulate in the bloodstream. Depending on the nature of the antigen and antibody involved and vascular factors (e.g., endothelial damage, turbulent flow), these complexes may become lodged in the walls of small capillaries in predilection sites such as the renal glomerulus, synovium, uveal tract, and cutaneous basement membrane zone. The ensuing local inflammation (vasculitis) may lead to thrombosis and ischemic necrosis of the tissue supplied by the vessel (Figure 22.10). This form of type III reaction is not uncommon in dogs and cats and, although the inciting antigens are rarely identified, they are often presumed to be of infectious origin and such type III reactions to be post-infectious immune sequelae. A classical example of such a reaction is immune complex glomerulonephritis secondary to *Leishmania* or *Borrelia* infection in the dog (Figure 22.11). Such reactions are also likely to have a role in diseases such as cutaneous lupus erythematosus (CLE), immune-mediated polyarthritis, and immune-mediated uveitis.

Type IV (Delayed) Hypersensitivity

This hypersensitivity reaction involves cellular rather than humoral immunopathologic mechanisms. The response to local tissue re-exposure to antigen in a sensitized individual is the activation of memory T cells, with the recruitment of mononuclear cells (chiefly macrophages, $CD4^+$, and $CD8^+$ T cells) into the site of antigenic exposure via activation of endothelia that permits this site-specific migration. Local tissue damage is mediated

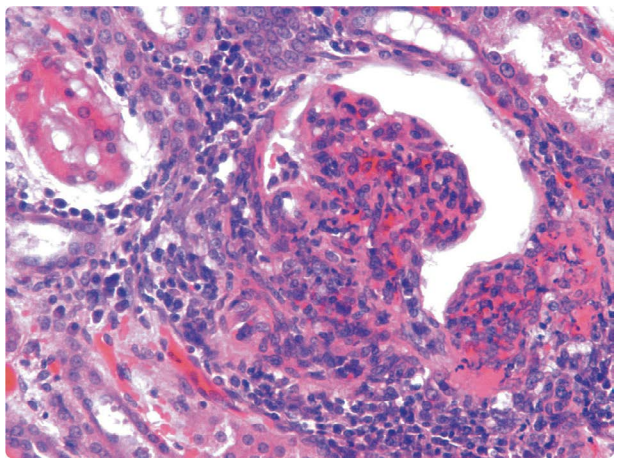

FIGURE 22.11 Section of kidney from a dog with leishmaniasis. There is mononuclear cell infiltration of the interstitium, with distortion and inflammation of the glomerular tuft. Arterial vessels in this section had clear evidence of leukocytoclastic vasculitis. The pathogenesis of these lesions likely involves the deposition of immune complexes containing IgG antibody and *Leishmania* antigen.

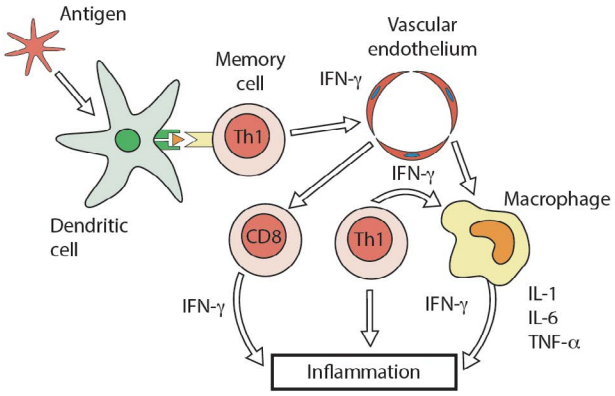

FIGURE 22.12 In type IV hypersensitivity, re-exposure to the sensitizing antigen leads to local activation of memory Th1 cells. These secrete IFN-γ, which activates vascular endothelium and permits recruitment of further T cells (Th1 and $CD8^+$) and macrophages. These in turn secrete further cytokines, which mediate the local inflammatory reaction.

by the infiltrating cells and the cytokines that they produce (Figure 22.12). The activation of T-cell memory and recruitment of mononuclear cells takes some time to occur (classically 72 hours), leading to the description of this reaction as "delayed type hypersensitivity." This type of immunopathologic mechanism is the classical manifestation of a protective Th1 response to a range of tissue pathogens, but when used inappropriately, it forms the basis of the contact hypersensitivity reaction or autoimmune reactions involving cellular infiltration (e.g., immune-mediated polyarthritis, lymphocytic thyroiditis, granulomatous meningoencephalitis).

IMMUNE-MEDIATED DISEASES

Immune-mediated diseases arise when the range of immunologic mechanisms described above are activated inappropriately to produce tissue pathology and clinical signs. This is clearly the case in the range of allergic diseases where there is an inappropriate and excessive immune response (involving combinations of type I and IV reactions) to allergens (e.g., aeroallergens, arthropod-derived allergens) to which a clinically normal individual might be exposed but fail to respond. The allergic diseases are of immense clinical significance in both human and veterinary medicine, and consequently are widely researched and relatively well characterized in terms of their immunopathogenesis.

ALLERGIC DISEASES

There are clear genetic predispositions to the development of allergy in human families and breeds and pedigrees of dog, yet the genetic basis of allergy is not well characterized. Several genome-wide association studies searching for single nucleotide polymorphisms in genes that might be associated with canine atopic dermatitis have produced conflicting data. Whatever the genetic basis, it is clear that some individuals (human and canine) have a predisposition to make high IgE responses to ubiquitous environmental allergens. Such individuals also have reduced effectiveness of immunoregulation, and the allergic state correlates with lack of induced regulatory T cell function (e.g., IL-10-producing Tregs). In addition to genetic and immunologic factors, there are clear environmental influences over the development of allergic disease. This may be as simple as environmental exposure, and reduction of exposure levels to causative allergens is one part of the clinical management of such disorders. In human medicine, much research has focused on the "hygiene hypothesis," which links the high incidence of juvenile allergy and autoimmune disease to lack of exposure to infectious microbes and intestinal parasites in early childhood. Such exposure to infectious agents, particularly those present at the intestinal mucosa, is critical for generating Tregs.

AUTOIMMUNE DISEASES

The second major group of immune-mediated disorders are the autoimmune diseases. These too involve an inappropriate and excessive induction of type II, type III, or type IV hypersensitivity to self-antigens (autoantigens) in the presence of reduced effectiveness of natural Tregs, which would normally prevent such reactions. Clinically normal humans and animals (including dogs) harbor, as part of their lymphocyte repertoire, T and B cells bearing receptors able to recognize self-antigens. These autoreactive cells are normally kept in check by a range of immunoregulatory mechanisms, including:

- Deletion of autoreactive T cells as part of intrathymic development or within the body tissues after thymic emigration.
- Exposure to autoantigen but failure to activate (anergy).
- Failure to expose to autoantigen by lack of antigen presentation or physical sequestration of antigen (immunologic ignorance).
- The activity of natural Tregs.
- Failing to provide autoreactive B cells with T-cell help.

When these control mechanisms fail (leading to loss of immunologic tolerance to autoantigens), an autoimmune reaction with tissue pathology and clinical signs may arise.

As for allergic disease, there is a clear genetic predisposition to autoimmunity in dogs, but such predispositions (for allergic or autoimmune disease) are not well-recognized in feline medicine. The strongest genetic linkages are with specific allotypic variants of the genes encoding MHC molecules. Associations with class II MHC gene haplotypes are now described for a range of canine autoimmune diseases, including rheumatoid arthritis, IMHA, lymphocytic thyroiditis, hypoadrenocorticism, necrotizing meningoencephalitis, diabetes mellitus, and breed-associated chronic hepatitis.

While it was once considered that autoimmunity involved a spontaneously arising immunologic defect in a genetically predisposed individual, there is now recognition that autoimmune diseases have many defined predisposing and trigger factors. Predisposing factors include age (autoimmunity is generally a phenomenon of middle to old age), gender, and lifestyle (e.g., stress, exercise, diet). A recent study has shown that neutered dogs are more likely to die from immune-mediated diseases. Trigger factors are largely environmental and include exposure to drugs, vaccines, and infectious agents. In fact, most autoimmune disease is now considered to be a post-infectious phenomenon and in humans, the active infection may precede onset of the autoimmune disease by months or years. Finally, other chronic disease states (particularly neoplasia or chronic inflammatory disease) may sufficiently disturb immune homeostasis to result in secondary autoimmunity.

This growing concept of recognized trigger factors for autoimmune disease has reshaped the way in which we think about these disorders in companion animal medicine. One example of this changing trend has been the impact of molecular diagnostic methodology for the range of arthropod-transmitted infectious agents that are generally unculturable and may remain cryptic within an infected animal ("stealth pathogens"). The use of molecular diagnostics increasingly allows us to attribute "idiopathic" disease to an infectious agent, and modify management protocols accordingly.

PRIMARY IMMUNODEFICIENCY DISORDERS

The third category of immune-mediated diseases includes the primary immunodeficiency disorders. Instead of being an inappropriate excess of immunity (as in allergy or autoimmunity) this is the reverse scenario, which means that there is an inability to mount a protective immune response due to a congenital, inherited genetic mutation in a gene encoding a key immunologic molecule. Such defects may occur at different levels of immunologic development and consequently lead to clinical disease of varying severity. For example, some defects mean that the animal fails to develop adequate T and B lymphocytes (e.g., X-linked severe combined immunodeficiency; X-SCID), with severely impaired immunity and death during early life. By contrast, a more subtle immunodeficiency (e.g., selective IgA deficiency) may not lead to clinical disease or produce only mild changes. A wide range of primary immunodeficiency disorders is documented in humans and for many the precise genetic mutation is known. A similarly wide range of disorders is suggested to have an immunodeficiency basis in numerous breeds of dog, but only a few of these have been defined at the molecular level. Thus, many of this group of canine diseases should only be considered putative immunodeficiencies at this time. Of note is the fascinating dichotomy between cat and dog in this regard; primary immunodeficiency is extremely rare in the cat, with only a handful of reported cases.

IMMUNE SYSTEM NEOPLASIA

The final group of immunologic disorders comprises those of immune system neoplasia. Although not classically an "immune-mediated" pathology, these tumors are clear manifestations of an abnormal immune system and can impair the remaining immune function of an animal, thus leading to immunocompromise. These disorders include lymphoma, lymphoid leukemia, plasmacytoma, and multiple myeloma, and arguably might also include neoplasia affecting adjunct immune cells such as dendritic cells (the range of histiocytic neoplasia) and mast cells. There are many gaps in our knowledge of the factors that underlie the development of this range of tumors. In cats, retroviral infection has a role, although these diseases still occur in geographical areas with a low prevalence of feline leukemia virus infection or where vaccination and testing programs have reduced the prevalence of infection. There are some well-documented genetic associations for canine lymphoma (e.g., Boxer) and histiocytic neoplasia (e.g., Bernese Mountain Dog, Flat-coated Retriever) and limited epidemiological studies have suggested a role for various environmental carcinogens (e.g., cigarette smoke and feline lymphoma, pesticides and radiation for canine lymphoma).

Although these disorders may be considered as individual entities, there is some linkage between them, as they are all manifestations of disturbed immune system homeostasis. It is possible for more than one type of immunologic abnormality to exist in any one patient at any one time, and a number of such associations are recognized, including:

- Thymoma and myasthenia gravis
- IgA deficiency and autoimmunity
- Inflammatory bowel disease and immune-mediated thrombocytopenia (IMTP) or IMHA
- Lymphoma or leukemia and IMHA

Similarly, different types of autoimmune disease may be recognized concurrently (e.g., combinations of IMHA, IMTP, and immune-mediated neutropenia; IMNP) or may present as multisystemic autoimmune disease (e.g., systemic lupus erythematosus, SLE).

LABORATORY DIAGNOSIS OF IMMUNE-MEDIATED DISEASE

Allergic Disease

Key to the diagnosis and management of allergic disease is identification of the causative allergen. This may be addressed through obtaining a detailed exposure history or by determining whether there is clinical improvement following dietary trial, parasiticidal treatment, or following removal of the animal from the normal environment. For aeroallergens and arthropod-derived allergens (e.g., flea saliva), the generally accepted "gold standard" diagnostic procedure remains the

intradermal test, and some experimental studies have described efficacy of patch testing for demonstration of late-phase responses. Intradermal or percutaneous challenge has not proven reproducible for the diagnosis of food allergy. The use of serologic testing has increased, and many specialists now use these tests in parallel with traditional methodology.

Serologic tests are designed to demonstrate the presence of circulating allergen-specific IgE and/or IgG antibodies. Such tests are almost all based on the ELISA, but vary in the technology used for immunoglobulin detection. Most involve coating test allergens onto the plastic wells of the plate and subsequent incubation with patient serum and then an enzyme-linked detecting reagent (Figure 22.13). The most novel detection technology involves the application of a recombinant version of the IgE Fc receptor molecule. Serologic testing can be informative, but it does not necessarily correlate with intradermal test results, which measure cutaneous mast cell-bound IgE (rather than free antibody in the circulation).

At the research level (but not clinically available), tests such as *in-vitro* mast cell degranulation, blood lymphocyte allergen stimulation (with measurement of cytokine gene transcription), and western blotting for fine definition of the serologic response, have been employed.

Autoimmune Disease

The aim of immunodiagnostic testing in autoimmunity is to confirm an autoimmune pathogenesis by demonstrating circulating or cell- or tissue-bound antibody (and/or complement) relevant to the clinical presentation of the animal. Although a number of autoimmune diseases involve cell-mediated immunopathogenesis, it is not possible at present routinely to investigate these aspects of clinical disease. The key to logical application of these tests is to become familiar with the purpose and limitations of each. For example, there is little rationale in selecting a Coombs test to support the diagnosis of a dog with putative immune-mediated polyarthritis unless that animal is concurrently anemic.

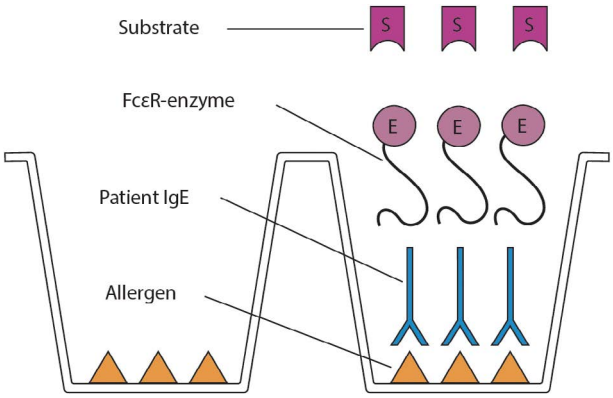

FIGURE 22.13 Serologic testing for allergen-specific IgE antibody. The wells of a microtitration plate are coated with allergen and subsequently incubated with patient serum. Serum allergen-specific IgE binds to the target and this interaction is visualized by the detection reagent (recombinant Fce receptor conjugated to alkaline phosphatase) and enzyme substrate.

Coombs Test

The most widely available immunodiagnostic test for autoimmunity is the Coombs test. This is indicated to support the diagnosis of IMHA in an animal with appropriate clinical and hematologic features. The aim of the test is to demonstrate the presence of IgG/IgM/complement C3b on the surface of patient erythrocytes as presumptive evidence that these immunoreactants are involved in the hemolytic reaction (Figure 22.14). There are numerous reasons for false-positive and false-negative Coombs tests, but the most common reason for the latter is that a complete test has not been performed. Many commercial laboratories offer a simple Coombs test using only a polyvalent Coombs reagent, with minimal titration at a single incubation temperature. A full Coombs test (which is more likely to provide a positive result) should use a combination of polyvalent and specific antisera (for IgG, IgM, and complement C3) that are fully titrated in a microtiter system at both 4°C and 37°C. An alternative approach to diagnosis using flow cytometry to detect red cell-bound antibodies is not widely available.

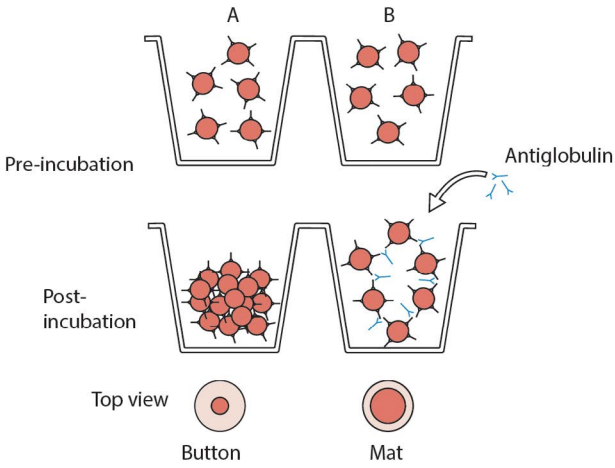

FIGURE 22.14 Coombs test. Wells A and B of a microtiter plate contain a suspension of washed erythrocytes from an animal with IMHA. The patient red cells are coated with antibody *in vivo*. An antiglobulin reagent (e.g., one of polyvalent canine Coombs reagent, anti-dog IgG, anti-dog IgM, or anti-dog complement C3) is added to well B only. After a period of incubation, the wells are examined for gross evidence of agglutination. In well B, the antiglobulin has cross-linked Ig molecules on the patient erythrocytes to form a lattice-like structure that appears as a diffuse mat of red cells that covers the base of the well (agglutination). In well A, no antiglobulin has been added, so the erythrocytes settle to the base of the well by gravity, forming a tight "button" of packed red cells. In a complete Coombs test, the different antiglobulin reagents would be fully titrated and the test performed in duplicate at both 4°C and 37°C.

Antiplatelet and Antineutrophil Antibody Detection

The detection of antiplatelet antibody in IMTP or antineutrophil antibody in IMNP is rarely available outside of specialist laboratories. A range of approaches to the detection of platelet-bound Ig has been attempted including immunofluorescence, ELISA-based, and radioimmunoassay-based tests. The most sensitive modality has proven to be flow cytometric detection using fluorochrome-labeled antibodies, but this is not widely available. Older test methodologies, such as the platelet factor 3 test and megakaryocyte immunofluorescence, can no longer be recommended. One limitation of direct testing for platelet-bound Ig is the fact that thrombocytopenic animals are often so markedly thrombocytopenic that it is difficult to harvest sufficient cells for analysis. IMNP has only recently been well-documented as a disease and although flow cytometric testing is feasible, availability is limited.

Serum Antinuclear Antibody Detection

The detection of serum antinuclear antibody (ANA) is widely available. The most commonly employed test involves the layering of diluted patient serum onto substrates of nucleated cells grown in monolayers on a sectored microscope slide. ANA bound to the nucleus is subsequently detected by use of an anti-IgG reagent coupled to a fluorochrome or enzyme (Figures 22.15 and 22.16). The test is read by microscopic examination for the pattern of nuclear labeling and determination of the titer. Classically, the ANA test is used to support the diagnosis of SLE, but it may also be present in animals with other autoimmune diseases. The key to interpretation is the titer, as many clinically normal animals and animals with chronic inflammatory, infectious, or neoplastic disease may have low-titered ANA as a reflection of cell turnover.

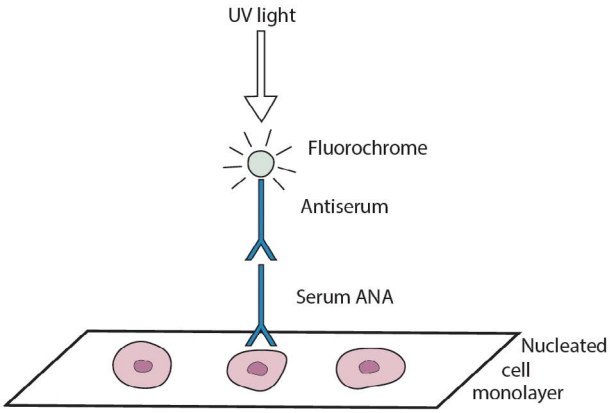

FIGURE 22.15 The antinuclear antibody (ANA) assay. Serial dilutions of patient serum are incubated with a source of nucleated cells to permit any ANA to bind to target antigens. Binding is visualized by subsequent incubation with an antiserum coupled to either a fluorochrome (for examination under UV light) or an enzyme (for reaction with substrate for light microscopic examination).

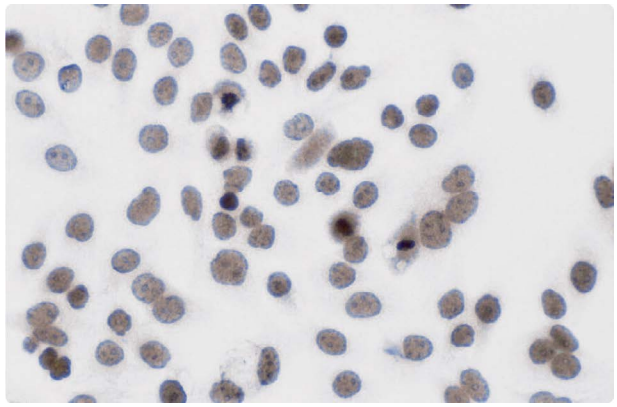

FIGURE 22.16 Positive ANA reaction as shown by immunoperoxidase labeling of nuclei within the target cell line.

Rheumatoid Factor Tests

Serum or synovial fluid rheumatoid factor (RF) may be tested in order to support a diagnosis of immune-mediated polyarthritis. Ideally, both RF and ANA would be requested in such patients as either autoantibody may be present, despite the fact that RF is classically reported to be associated with erosive rheumatoid arthritis. RF is an IgM (or rarely IgA) autoantibody with specificity for an IgG molecule that in turn is bound to an undefined antigen (Figure 22.17). RF may have a role in the pathogenesis of polyarthritis, and is thought to be formed in the synovium and leak into the circulating blood. RF may be detected by ELISA, in which target IgG is coated to the wells of a microtitration tray, or via the Rose Waller test in which the target IgG is affixed to the surface of erythrocytes and the RF causes cross-linking of target IgG and therefore agglutination of these cells.

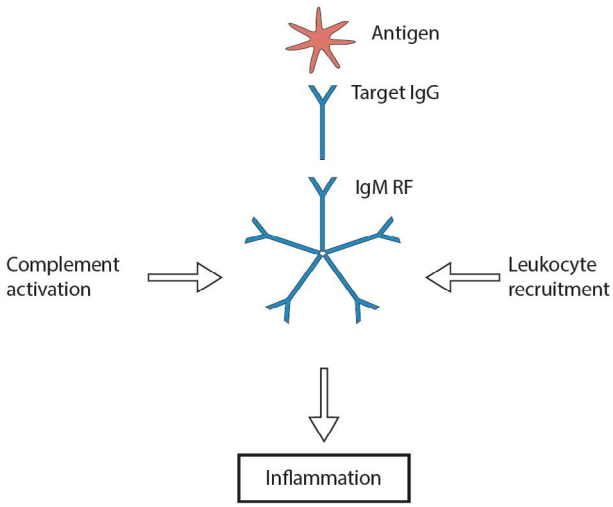

FIGURE 22.17 Rheumatoid factor (RF). An undefined synovial antigen is complexed with an IgG antibody, which in turn forms the target for the IgM RF. Binding of RF leads to activation of the classical pathway of complement and subsequent recruitment of leukocytes. RF may thus have a role in the pathogenesis of polyarthritis in addition to being a useful serologic marker of disease.

Other Autoantibody Tests

Other commonly used autoantibody tests include those for thyroglobulin autoantibodies in dogs with hypothyroidism attributed to lymphocytic thyroiditis, and for AChR autoantibodies in dogs with putative myasthenia gravis. Thyroglobulin autoantibody testing is widely available, but only one laboratory internationally offers the AChR autoantibody test.

Immunohistochemistry

For some autoimmune diseases (e.g., autoimmune skin disease, immune complex glomerulonephritis), immunohistochemistry or immunofluorescence testing has been employed in order to demonstrate the presence of immunoglobulin and/or complement within lesional tissue (Figure 22.18). Such testing is not particularly sensitive, but it can be helpful in supporting a diagnosis where histopathology is equivocal.

Immunodeficiency Disease

The diagnosis of immunodeficiency disease is one of the great frustrations of clinical veterinary medicine. At the research level, it has proven possible to assess the competence of all aspects of the immune system (i.e., immunoglobulin, complement, phagocytic cell and lymphocyte function, cytokine production), but such testing is not available commercially. Consequently, the diagnosis of primary immunodeficiency largely relies on simple measures of immune system assessment (e.g., hematology, serum protein electrophoresis, lymphoid tissue histopathology) together with characterization of any secondary infection. The only readily available immunodiagnostic test is determination of serum immunoglobulin concentration by single radial immunodiffusion (SRID)

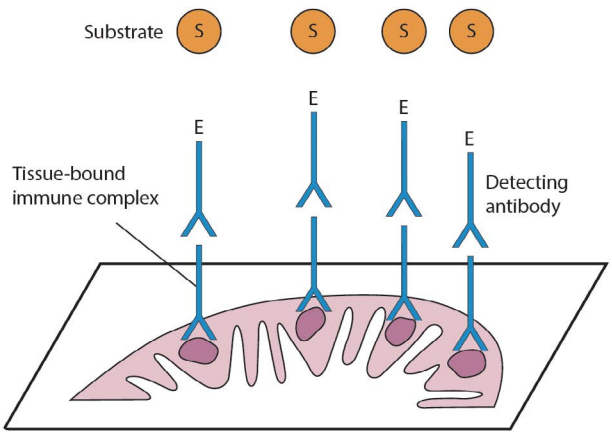

FIGURE 22.18 Immunohistochemistry. The microscope slide displays a section of kidney with suspected immune complexes localized to the glomerular capillaries. The immunoglobulin component of these complexes is detected by overlaying the section with an enzyme-linked antiserum (e.g., anti-dog IgG). On application of the appropriate substrate, there is a color change at the site of antibody binding, confirming the presence of immune complex.

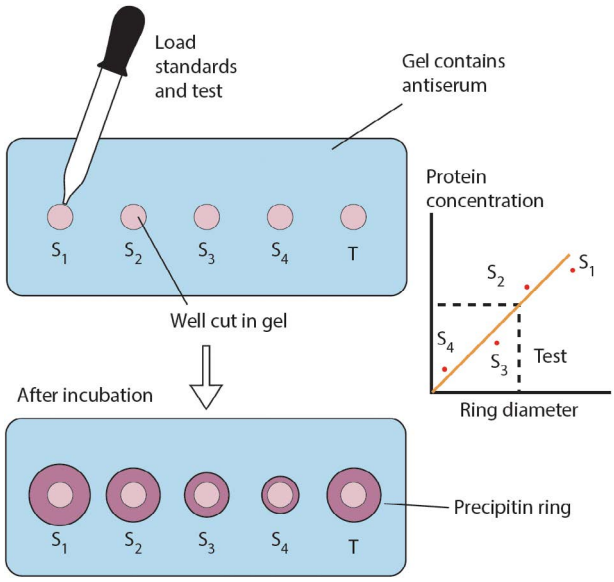

FIGURE 22.19 Single radial immunodiffusion. This test is used to determine the concentration of immunoglobulin in patient serum. An agarose gel is poured within which is mixed an antiserum (e.g., anti-dog IgG). Wells are cut into the gel and loaded with a precise volume of standards of known concentration and the patient sample. During an overnight incubation, IgG diffuses from the wells into the gel matrix where it encounters antiserum that precipitates the IgG. The higher the concentration of IgG, the larger the diameter of the precipitin ring obtained. A standard curve derived from the four samples of known value is used to determine the concentration in the test sample.

(Figure 22.19). For the dog, the serum concentrations of IgG, IgM, and IgA can be determined, but there are few reference ranges for animals of different age and breed. Specialist laboratories that have flow cytometry may offer blood lymphocyte phenotyping, generally to determine the relative proportions of $CD4^+$ and $CD8^+$ T cells and $CD21^+$ B cells among the circulating lymphoid population. These percentages should be related back to absolute lymphocyte number (as for a differential leukocyte count). At present there is relatively sparse information about how such changes correlate with disease, but marked decreases might be predicted in some immunodeficiency states. Finally, for a limited number of canine immunodeficiencies, molecular diagnostic tests have been developed after elucidation of the genetic mutation underlying the disease. These include tests for X-SCID, canine leukocyte adhesion deficiency (CLAD), the trapped neutrophil syndrome in Border Collies, and cyclic hematopoiesis in the gray Collie dog.

Immune System Neoplasia

The front line for diagnosis of immune system neoplasia is clinical and imaging examination, hematology and bone marrow analysis, cytology, and biopsy. In recent years there has been wide uptake of tissue immunohistochemistry for confirmation of the phenotype of round cell neoplasia. Following routine light microscopic diagnosis, most pathology laboratories are able to apply

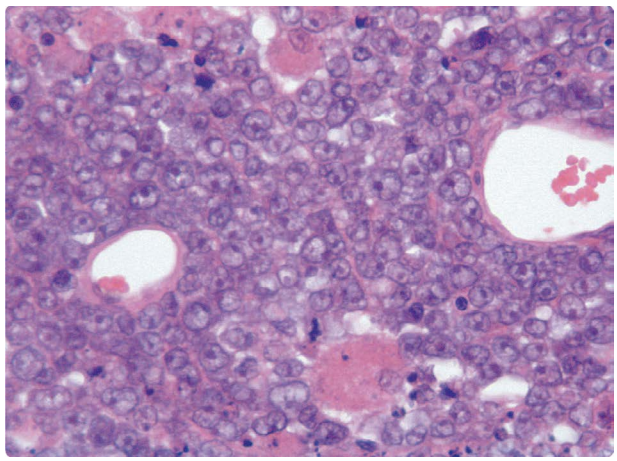

FIGURE 22.20 Lymphoma immunophenotyping. Section of skin from a dog with dermal lymphoma. The H&E-stained section reveals a closely packed population of blastic cells with a vesicular, cleaved nucleus, with central prominent nucleolus and minimal cytoplasm.

antisera in order to determine whether the neoplasm is of T cell, B cell, or histiocytic origin (Figures 22.20 and 22.21). In similar fashion, some laboratories offer immunocytochemical or flow cytometric testing of cellular suspensions derived from a fine-needle aspirate, which provides a similar (but more rapid) outcome. Flow cytometric testing has also become available for the determination of the nature of leukemia, and a range of lymphoid and myeloid markers are generally employed to phenotype such neoplastic populations. The most recent advance in this area of diagnosis has been the development of "clonality testing." This molecular test can determine whether a population of lymphoid cells is clonal (and therefore neoplastic) by examining restriction in rearrangements in TCR and BCR genes. Such testing is of particular benefit in distinguishing between a reactive and a neoplastic lymphoid infiltration (for example in the intestinal mucosa) or for monitoring the presence of residual neoplastic cells in blood or tissue throughout chemotherapy. These new diagnostic

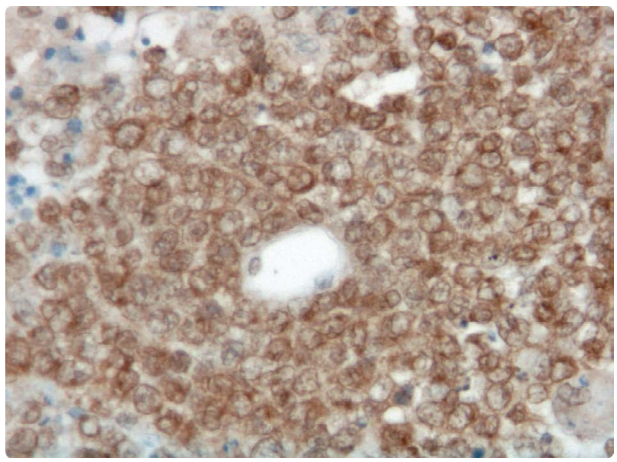

FIGURE 22.21 Immunolabeling with anti-CD79a reveals this to be a B-cell lymphoma.

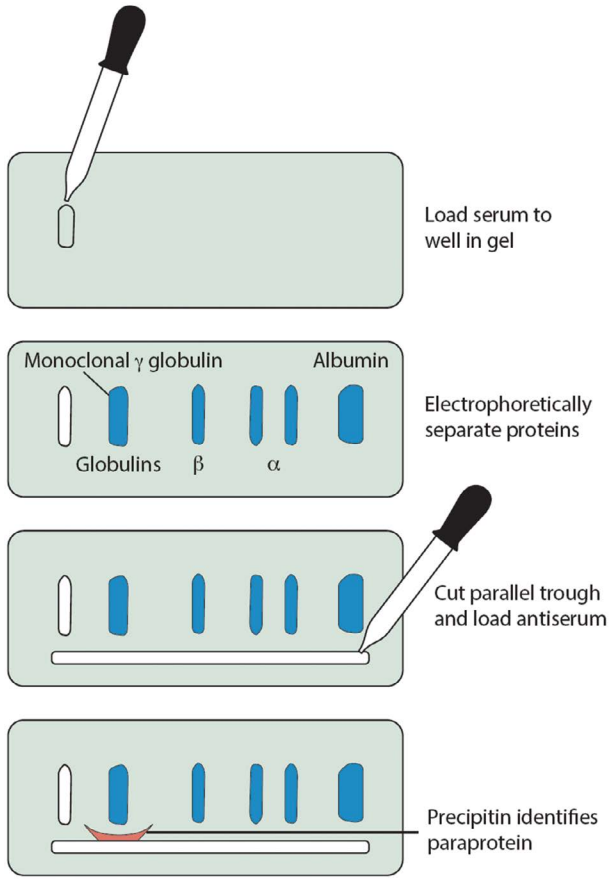

FIGURE 22.22 Immunoelectrophoresis. Serum from a patient with suspected paraproteinemia is separated electrophoretically in a gel matrix. Following this, a trough is cut into the gel parallel to the separated proteins and loaded with antiserum (e.g., anti-dog IgG-γ heavy chain). During a period of incubation, the antiserum diffuses from the trough to react specifically with the paraprotein and form an arc of precipitation. The position of this arc relative to that produced with normal serum immunoglobulin indicates that the paraprotein carries altered charge and is thus structurally altered.

approaches to tumor classification have helped to refine prognosis for canine lymphoma. Two recent studies have shown the longest median survival time (or event-free survival time) for low-grade T-cell lymphoma, the shortest survival time for high-grade T-cell lymphoma, and intermediate survival for dogs with B-cell lymphoma.

Multiple myeloma is characterized in part by serum paraproteinemia, resulting in a monoclonal gammopathy identified by serum protein electrophoresis. The immunodiagnostic workup in this disease entails more detailed analysis of this paraprotein. The traditional means of achieving this is via immunoelectrophoresis (Figure 22.22) in which the identity of the paraprotein (class of Ig) is determined together with demonstration of altered electrophoretic mobility confirming the abnormal physicochemical properties of the molecule. Similar information can be derived from immunofixation or western blotting studies, although in reality, typing of paraprotein is not routinely performed in cases satisfying the diagnostic criteria for this disease.

MAJOR IMMUNE-MEDIATED DISEASES

This section will review the major immune-mediated disorders of companion animals. Where these are described elsewhere in this book by body system, a cross-reference to the appropriate chapter will be given. Significant features of diseases that are not discussed elsewhere will be described in this chapter; however, this list is not exhaustive, and less common entities are not included.

ALLERGIC DISEASES

ATOPIC DERMATITIS

See Chapter 18.

FLEA ALLERGY DERMATITIS

See Chapter 18.

FOOD ALLERGY

See Chapter 18.

FELINE EOSINOPHILIC GRANULOMA COMPLEX

See Chapter 18.

ALLERGIC RHINITIS

See Chapter 6.

FELINE ASTHMA

See Chapter 6.

CANINE EOSINOPHILIC BRONCHOPNEUMOPATHY

See Chapter 6.

ALLERGIC CONJUNCTIVITIS

See also Chapter 19.

Definition/Overview

Allergic conjunctivitis may occur as a distinct entity or in conjunction with cutaneous allergy. The likely mechanism is type I hypersensitivity.

Clinical Presentation

The clinical features include conjunctival erythema and edema, pruritus, and ocular discharge. There may be secondary bacterial infection, and blepharitis and keratitis may also occur. Conjunctival lymphoid follicular hyperplasia may be visible grossly or on biopsy.

Diagnosis

Diagnosis may involve cytologic examination (eosinophils and mast cells may be expected) and the investigation of concurrent cutaneous hypersensitivity.

CONTACT HYPERSENSITIVITY

RHEUMATOID ARTHRITIS

See Chapter 15.

IMMUNE-MEDIATED POLYARTHRITIS

See Chapter 15.

PEMPHIGUS FOLIACEUS

See also Chapter 18.

Definition/Overview

Pemphigus foliaceus is the most common of the pemphigus disorders that are characterized by the formation

of autoantibody specific for the desmosomal intercellular adhesion molecules that join together the epidermal keratinocytes. Less common pemphigus variants include pemphigus vulgaris, pemphigus erythematosus, and pan-epidermal pustular pemphigus (pemphigus vegetans).

Pathophysiology

Autoantibody binding leads to physical disruption of these junctions and local activation of the complement and plasminogen–plasmin pathways. Vesicles form within the epidermis, and these contain the separated keratinocytes (acanthocytes). There is chemotactic attraction of neutrophils and/or eosinophils into these spaces to form sterile pustules.

Clinical Presentation

Classically, in pemphigus foliaceus the pustules are subcorneal in location, which is likely related to the distribution of the target autoantigen (Figure 22.23). Direct immunohistochemistry may be used to demonstrate the intercellular deposition of immunoglobulin and/or complement (Figure 22.24). Clinically, intact vesicles or pustules are rarely observed, and the predominant lesion is of crusting affecting the face, feet, and trunk.

Diagnosis

Diagnosis is by skin biopsy.

Management

Treatment involves immunosuppressive doses of oral glucocorticoid.

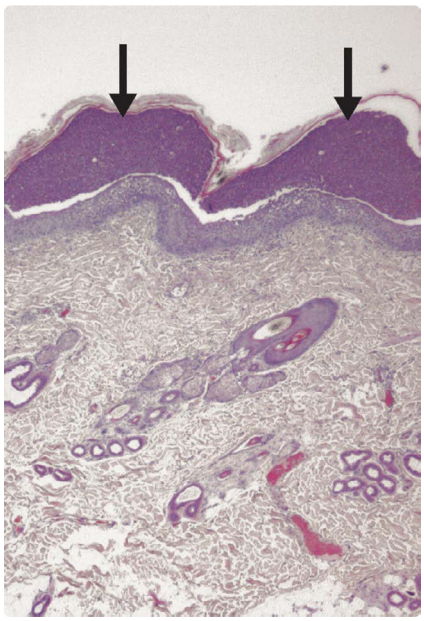

FIGURE 22.23 Skin biopsy from a 10-year-old Collie-cross dog with a generalized pustular and crusting dermatosis. There is a large, intact subcorneal pustule filled by nondegenerate neutrophils and acanthocytes (arrows). These features are consistent with pemphigus foliaceus.

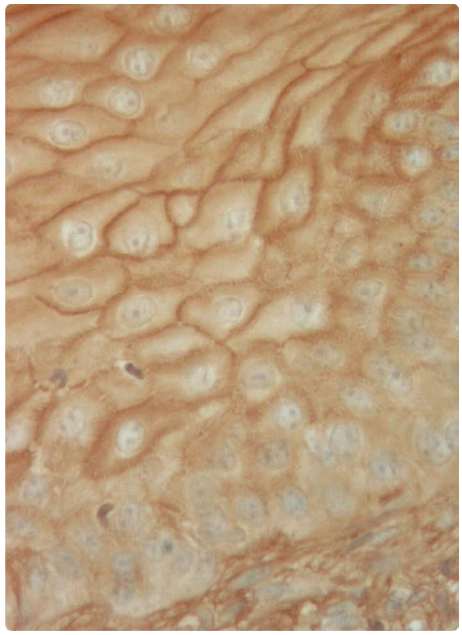

FIGURE 22.24 Skin biopsy from a 9-year-old German Shepherd Dog with pemphigus foliaceus confirmed histologically. This biopsy is labeled to detect IgG, which is present associated with the desmosomes of the mid to superficial level keratinocytes. Note there is no intercellular deposition associated with the basal cells.

BULLOUS PEMPHIGOID

Definition/Overview

Bullous pemphigoid is an autoimmune disease in which autoantibody targets structures within the hemidesmosome that anchors the basal keratinocytes into the basement membrane zone between epidermis and dermis. Bullous pemphigoid variants include epidermolysis bullosa acquisita, linear IgA bullous disease, and mucous membrane pemphigoid.

Pathophysiology

Disruption of this adhesion results in separation of the epidermis from the dermis, with formation of a cleft lined by the basal keratinocytes (uppermost) and basement membrane (lowermost). This space may become filled with fluid and/or inflammatory cells.

Clinical Presentation

Clinically, the bullous lesions are often disrupted, and the presentation is of ulceration that particularly affects the oral mucocutaneous junctions, axilla, groin, and footpads.

Diagnosis

Diagnosis is by biopsy and immunohistochemistry may be used to demonstrate the deposition of immunoglobulin/complement within the basement membrane zone.

Management

Treatment is by immunosuppression, and adjunct immunosuppression may be required in addition to oral glucocorticoid.

CUTANEOUS LUPUS ERYTHEMATOSUS

See also Chapter 18.

Definition/Overview

CLE is the name given to a group of immune-mediated skin diseases with a common pathogenesis. The prototype disorder of this group is discoid lupus erythematosus, which is now termed "nasal planum CLE." Other diseases within the CLE group include oral cavity or mucocutaneous CLE, generalized CLE, vesicular CLE of Collies and Shelties, exfoliative CLE of German Shorthaired Pointers, and lupoid onychodystrophy.

Pathophysiology

CLE has a complex pathogenesis, which in part involves infiltration of the basement membrane and epidermis by lymphocytes ("interface dermatitis") that target and destroy individual keratinocytes by induction of apoptosis (Figure 22.25). Additionally, there is deposition of immunoglobulin/complement at the basement membrane zone, although this may be an "epiphenomenon" rather than having a direct role in pathogenesis. Exposure to ultraviolet (UV) light is thought to play a role in the triggering of this disease.

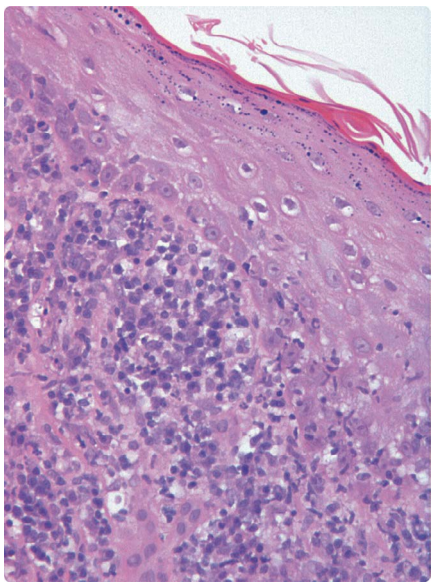

FIGURE 22.25 Skin biopsy from a 16-year-old German Shepherd Dog with depigmentation and loss of "cobblestone" pattern to the nasal planum. There is a lymphoplasmacytic interface dermatitis with prominence of the basement membrane and mild hydropic degeneration of the basal keratinocyte layer. The other key feature of "nasal planum cutaneous lupus erythematosus" not present in this field is individual keratinocyte apoptosis at higher levels.

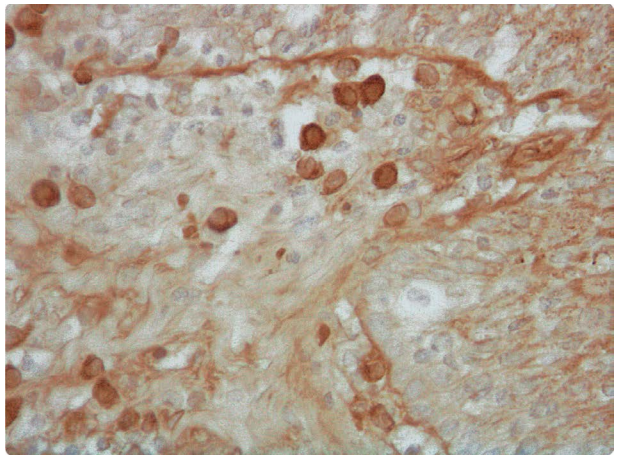

FIGURE 22.26 Skin biopsy from an 8-year-old male Norfolk Terrier with histopathologic evidence of interface dermatitis. The slide is immunolabeled to demonstrate the presence of IgG. There is a linear deposit of this immunoglobulin at the basement membrane zone between epidermis and dermis, and the cytoplasm of IgG^+ plasma cells within the dermal infiltrate is also labeled.

Diagnosis

Diagnosis is by skin biopsy, and immunohistochemistry may be used to demonstrate the local deposition of immunoreactant (Figure 22.26).

Management

A range of therapeutic options is proposed, most commonly involving the use of combination tetracycline (doxycycline) and niacinamide, topical glucocorticoid, or oral glucocorticoid at anti-inflammatory (rarely immunosuppressive) doses.

DERMATOMYOSITIS

Definition/Overview

This immune-mediated disorder primarily occurs in Collies and Shelties and is inherited as autosomally dominant with variable expression.

Pathophysiology

The pathogenesis is poorly defined, but is thought to involve immune complex deposition, as elevation in circulating immune complexes is documented before the onset of clinical signs. UV light and estrus are suggested trigger factors.

Clinical Presentation

This disease affects young dogs (under 6 months of age). They develop alopecic, erythematous, scaling, crusting, or ulcerative lesions that target the face, oral mucocutaneous junctions, pinnae, limbs, footpads, and tail tip. Concurrent muscular involvement particularly affects

facial and limb muscle groups, and these have inflammation and atrophy on biopsy and display electromyographic abnormalities. Megaesophagus may also occur. The outcome is variable; some dogs may show spontaneous resolution of disease, in others it may be cyclical, and in others progressive.

Management

Treatment options include immunosuppressive oral glucocorticoids, vitamin E, and pentoxifylline.

ERYTHEMA MULTIFORME/TOXIC EPIDERMAL NECROLYSIS

Definition/Overview

These disorders are found at each end of a spectrum of entities defined on the basis of their severity: Erythema multiforme (EM) minor, EM major, Stevens–Johnson syndrome (SJS), SJS–toxic epidermal necrolysis (TEN) overlap syndrome, and TEN.

Pathophysiology

These diseases may be triggered by drug administration or infection and involve an interface inflammatory infiltration of lymphocytes that induce cytotoxic apoptosis in small groups of keratinocytes (EM), through to full-thickness epidermal necrosis and ulceration (TEN) (**Figure 22.27**).

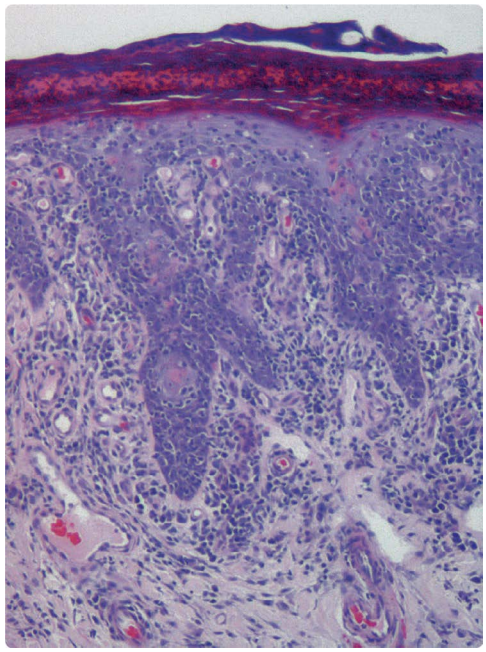

FIGURE 22.27 Skin biopsy from a 10-year-old West Highland White Terrier with severe, generalized crusting dermatosis. There is interface dermatitis with clusters of apoptotic keratinocytes within the epidermis associated with the infiltrating lymphocytes ("satellitosis"). These features are consistent with erythema multiforme.

Clinical Presentation

Lesions may be localized or generalized and affect cutaneous and/or mucocutaneous surfaces. The lesions of EM are relatively mild erythematous macules, papules, or confluent plaques, which may regress spontaneously following removal of the trigger. By contrast, TEN is a severe disease due to loss of fluid, electrolytes, and colloid from the ulcerated lesions, with high potential for secondary bacterial infection.

Management

Standard immunosuppressive glucocorticoid regimes are often ineffectual in these diseases, but IV administration of human immunoglobulin has proven beneficial.

PANNUS

Definition/Overview

Pannus (chronic superficial keratitis/keratoconjunctivitis) is a putative immune-mediated disorder of the cornea that particularly affects German Shepherd Dogs and may be triggered by UV light exposure.

Pathophysiology

There is lymphocytic infiltration, vascularization, and fibrosis of the superficial corneal stroma, which extends from the limbus.

Management

Application of topical cyclosporine has proven efficacious in management of this disease.

SYSTEMIC LUPUS ERYTHEMATOSUS

Definition/Overview

SLE is a rare disease of the dog and even less common in the cat. SLE is the prototype multisystemic autoimmune disease and is defined by strict diagnostic criteria. The simplest of these criteria are:

- The animal must show multisystemic disease involving at least two distinct body systems.
- The disease affecting these body systems must be compatible with an immune-mediated process and laboratory evidence of an immunologic pathogenesis for these changes must be obtained.
- The animal must have a high-titered serum ANA.

Although these criteria are simple, they are generally very difficult to satisfy; therefore, in many cases a diagnosis of an "SLE-overlap" syndrome (with partial fulfilment of the criteria) is made.

Pathophysiology

The most common clinicopathologic manifestations of canine SLE include IMHA, IMTP, immune complex glomerulonephritis, polyarthritis, and immune-mediated skin disease. In endemic areas, it is important to rule out arthropod-transmitted infectious disease (particularly leishmaniasis), which can mimic the clinical presentation of SLE. SLE has also been induced by drugs and may arise secondary to underlying lymphoid or myeloid neoplasia. SLE may be inherited, and early research demonstrated that it was possible to establish breeding lines in which there were dogs with serologic and clinical abnormalities of autoimmunity (but with no clear mode of inheritance).

Diagnosis

Multiple diagnostic and immunodiagnostic procedures may be required to support the diagnosis of SLE.

Management

Treatment is generally by immunosuppressive oral glucocorticoid therapy.

PRIMARY IMMUNODEFICIENCY DISEASE

IgA DEFICIENCY

Definition/Overview

Selective IgA deficiency is the most commonly reported canine immunodeficiency disorder and is most often suggested in animals that have chronic, recurrent infectious disease, most often of the mucocutaneous surfaces.

Etiology/Pathophysiology

The spectrum of infectious diseases associated with IgA deficiency includes pyoderma, demodicosis, rhinitis, bronchopneumonia, inflammatory bowel disease, and antibiotic-responsive diarrhea. IgA deficiency has

been definitively documented in the Shar Pei and in one colony of Beagle dogs. IgA deficiency has been proposed to be part of the pathogenesis in Irish Wolfhounds with chronic, recurrent rhinitis–bronchopneumonia syndrome, but although these dogs have subnormal serum IgA, the concentration of this immunoglobulin in bronchoalveolar lavage fluid is normal to elevated. IgA deficiency has been suggested to predispose to allergic disease, and there is evidence that (as for humans) there is an association with autoimmunity. Some of the IgA deficient Beagle dogs described above had serum RF, and IgA deficiency was widespread in a colony of English Cocker Spaniels in which there was also frequent occurrence of a variety of autoimmune diseases.

IgA deficiency has been proposed to underlie the multiple immunologic, infectious, and inflammatory diseases to which the German Shepherd Dog is predisposed. Although German Shepherd Dogs generally have normal serum IgA, there is increasing evidence for an inability to secrete sufficient mucosal IgA in dogs of this breed, and the IgA deficient phenotype may be particularly associated with inflammatory bowel disease and antibiotic-responsive diarrhea. Dogs have four genetic variants of IgA, and it is of note that all German Shepherd Dogs have a restricted genotype that is homozygous for a single variant.

Diagnosis

Diagnosis of IgA deficiency is not straightforward. In clinical practice the only test that is widely available is SRID for determination of serum IgA concentration. This test is insufficiently sensitive to measure the lower IgA concentrations that are found in secretions. IgA deficiency (in both man and dog) is not a simple genetic mutation in the gene encoding the α heavy chain. Instead, it is a relative immunodeficiency that in dogs is defined as serum IgA concentration persistently lower than 0.22 mg/ml. The serum concentration should be measured on at least two occasions (at least 1 week apart), as there are both day-to-day and diurnal variations in canine serum IgA concentration.

PUTATIVE IgG DEFICIENCY

Definition/Overview

Selective IgG deficiency has recently been reported to occur in young Cavalier King Charles Spaniels with pneumonia caused by *Pneumocystis carinii*. Infection with this opportunist organism is a hallmark of immunodeficiency disease, and is also the clinical presentation of a putative immunodeficiency disorder affecting Miniature Dachshunds. These latter dogs may also have subnormal concentrations of serum IgM and IgA and reduced responsiveness of blood lymphocytes to nonspecific stimulation with mitogens. In both breeds this is a relatively subtle immunodeficiency, as affected dogs appear to recover with appropriate antimicrobial therapy, although pulmonary disease may be recurrent. IgG deficiency is also the major immunologic feature of the disorder affecting Weimaraner dogs that is described below.

Diagnosis

IgG deficiency is determined by a consistently low serum concentration (below 10 mg/ml in adult dogs) of this immunoglobulin as determined by SRID.

COMPLEMENT C3 DEFICIENCY

Definition/Overview

Deficiency of the third component of complement (C3) has been reported only once, in an experimental colony of Brittanys. Affected dogs were more susceptible to infection and some developed glomerular disease.

WEIMARANER IMMUNODEFICIENCY

Definition/Overview

This complex disorder is now recognized in the Weimaraner breed internationally.

Clinical Presentation

Affected dogs are young adults (6–12 months of age) that present with chronic recurrent infections of multiple body sites, particularly mucosal and cutaneous surfaces. Another feature is the presence of hypertrophic osteodystrophy (HOD), which is more consistently a feature in affected dogs in the United States (where the disease is known as HOD of Weimaraners [Figures 22.28–22.30]). The most consistent immunologic abnormality in affected dogs is subnormal serum IgG, and in patients that are serially monitored this immunoglobulin appears never to attain its normal range.

FIGURE 22.28 This 3-month-old Weimaraner puppy had severe debilitating hypertrophic osteodystrophy that was complicated by bacterial sepsis. The dog was hospitalized in intensive care in order to receive parenteral fluid support and antibiotics.

FIGURE 22.29 Severe metaphyseal swelling.

FIGURE 22.30 The puppy also became septic and developed hemorrhagic skin bullae from which bacteria were isolated. It also had meningitis and several abscesses that were found on postmortem examination. (*Courtesy of M. Schaer.*)

Some dogs also have IgM and/or IgA deficiency and in the United States, neutrophil function defects have also been documented. The most unusual feature of this disorder is that the clinical signs appear to be triggered by vaccination and the disease often has clinical onset around the time of the 12-month booster vaccine.

Management

The prognosis for this disease is variable; some dogs spontaneously recover, others have chronic recurrent disease, and some die during the initial disease outbreak. Antiinflammatory doses of glucocorticoids appear to provide the best therapeutic outcome.

SEVERE COMBINED IMMUNODEFICIENCY

See Chapter 16.

CANINE LEUKOCYTE ADHESION DEFICIENCY

Definition/Overview

CLAD affects Irish Setters (Red and, rarely, Red and White dogs) internationally.

Pathophysiology

Affected dogs develop chronic recurrent infections of multiple body sites from a young age. This is one of the few examples of a canine immunodeficiency disorder for which the precise genetic mutation and associated pathogenesis have been determined. The gene defect means that affected dogs are unable to express the adhesion molecules CD11b and CD18 on the surface of granulocytes. Consequently, these cells are unable to interact with ligands on vascular endothelium to mediate exocytosis from blood into tissue. These dogs therefore develop severe infection of tissues (without pus formation) associated with a striking blood neutrophilia.

Diagnosis

A molecular diagnostic test is available to determine the carrier status of Irish Setters (the disease is autosomal recessive in inheritance) and with the cooperation of the breed association, this trait has been virtually eliminated. This can be regarded as one of the great success stories of veterinary immunology.

Management

As immunodeficiency disorders are untreatable (except experimentally), testing and genetic counseling offer the most practical approach to management.

CYCLIC HEMATOPOIESIS

See also Chapter 16.

Definition/Overview

Recent experimental studies (using this canine disease as a model for the human equivalent) have identified the precise genetic mutation of this disorder, which lies in the gene encoding the adaptor protein complex 3 β subunit, the effect of which is to disrupt the intracellular movement of neutrophil elastase.

Management

Gene replacement therapy has been developed in an experimental setting.

THYMIC HYPOPLASIA AND HYPOTRICHOSIS OF BIRMAN CATS

Definition/Overview

This is one of the few documented primary immunodeficiency disorders of cats, and was reported in a single litter of kittens. The association between hairlessness and thymic development is also well-recognized in particular inbred experimental strains of "nude" rats and mice, and is also likely to affect the Mexican Hairless Dog.

IMMUNE SYSTEM NEOPLASIA

LYMPHOMA

See Chapters 16, 18, and 19.

LYMPHOID LEUKEMIA

See Chapter 16.

PLASMACYTOMA

Definition/Overview

This benign plasma cell tumor is documented in both dogs and cats and generally presents as a single nodular mass arising on the face (lip), ears, and feet. The plasma cells may display considerable pleomorphism histologically (Figure 22.31), but these tumors do not recur after excision and only rarely progress to multiple myeloma.

MULTIPLE MYELOMA

Definition/Overview

Multiple myeloma is a malignant plasma cell tumor that targets the bone marrow in dogs and soft tissue (particularly liver and spleen) in cats, although a range of sites may be affected in both species (Figure 22.32).

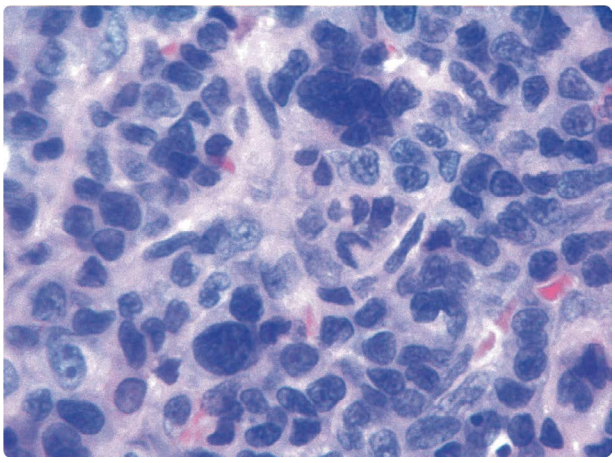

FIGURE 22.31 Section from a discrete nodular mass excised from the pinna of an 8-year-old male Dachshund. The tumor comprises a closely packed sheet of plasmacytoid cells, with scattered examples of multinucleate cells and cells with giant nuclei (both represented here). Although cytologically this appears to be an aggressive neoplasm, these are generally benign lesions that do not recur following excision.

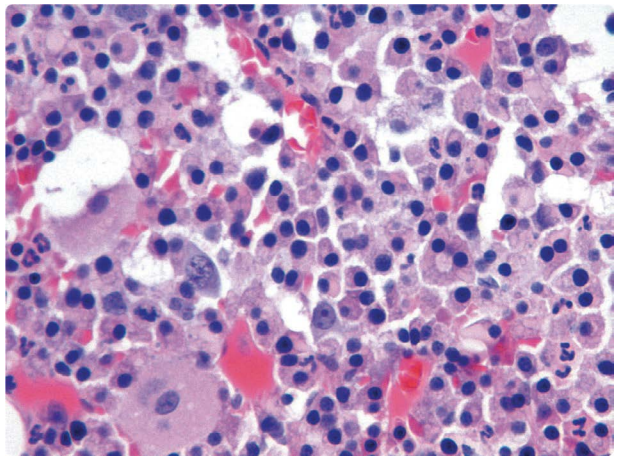

FIGURE 22.32 Bone marrow core biopsy from a 12-year-old neutered female Golden Retriever with monoclonal gammopathy identified on serum protein electrophoresis. The medullary cavity is filled by well-differentiated neoplastic plasma cells, which have virtually excluded the hemopoietic lineages in this field. The large cell at the base of the image is a megakaryocyte.

Pathophysiology

The proliferating plasma cells are associated with two distinct paraneoplastic effects. The first relates to the production of parathyroid hormone-like peptide, which leads to osteoclastic resorption of bone and the development of focal "punched-out" osteolytic lesions. The second is the characteristic secretion of a structurally abnormal immunoglobulin (paraprotein), which appears as a monoclonal gammopathy on protein electrophoresis.

These paraproteins are more commonly IgG than IgA or IgM, and rarely may take the form of free heavy or light chains that are not assembled into an immunoglobulin structure. Free light chains are of sufficiently low molecular weight to pass through the glomerular filter and be present in urine as "Bence–Jones protein." IgA and IgM paraproteins may be associated with serum hyperviscosity and a range of secondary effects related to this.

Diagnosis

Diagnosis of multiple myeloma relies on identification of characteristic clinical and radiographic features and the presence of monoclonal gammopathy. Further immunodiagnostic investigation of this gammopathy is discussed above. Important differentials for monoclonal gammopathy include particular infectious diseases such as ehrlichiosis and leishmaniasis in the dog and feline infectious peritonitis virus infection in the cat. A range of tests may be applied to the identification of Bence Jones proteinuria.

Management

Chemotherapeutic protocols are described for management of this disease.

HISTIOCYTIC NEOPLASIA

See also Chapter 18.

Definition/Overview

A spectrum of histiocytic neoplasia is documented in the dog, and it has a particular predilection for Bernese Mountain Dogs and Flat-coated Retrievers.

Pathophysiology

Immunohistochemical studies have defined this group of tumors as being of dendritic cell origin. The disorders range from the benign and spontaneously regressive histiocytoma of young dogs through to the reactive disorders (cutaneous and systemic histiocytosis) and the malignancies (localized and disseminated histiocytic sarcoma) (**Figure 22.33**).

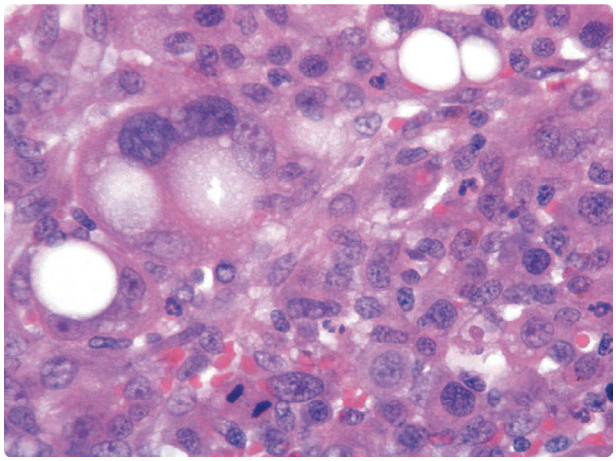

FIGURE 22.33 Section from a pulmonary mass taken at necropsy from a 6-year-old neutered female Bernese Mountain Dog. The mass comprises a sheet of highly pleomorphic histiocytic cells with abundant eosinophilic to mildly vacuolated cytoplasm and a round, pale nucleus with chromatin clumps. There are both multinucleate cells and cells with giant nuclei present. A mitotic figure is present at the lower edge of the image. The sternal lymph nodes of this dog were also infiltrated.

Diagnosis

Diagnosis is by biopsy, and immunohistochemical confirmation is now widely applied.

MAST CELL TUMOR

INTRODUCTION

Intravenous (IV) fluid therapy is routinely prescribed to dogs and cats secondary to a wide range of clinical scenarios. These include but are not limited to hypovolemia secondary to hemorrhage or gastrointestinal/renal fluid loss and distributive shock due to sepsis or other noninfectious causes of systemic inflammation, such as pancreatitis or severe burns. Fluid therapy is also indicated for endocrine disorders such as diabetic ketoacidosis and Addisonian crisis and for diuresis for acute toxin ingestion and perioperative hemodynamic optimization. Despite the recognized benefits of fluid therapy in these situations, evidence-based medicine is rarely applied, and often the fluid choice and volume of fluids administered are inappropriate. In most cases, such inadequate fluid regimens may not lead to overt harmful effects because of the inability of the kidneys and cardiovascular system to compensate for the excessive volume or supraphysiological loads of electrolytes delivered to the renal tubules. On the other hand, inadequate fluid therapy prescriptions may lead to delayed fluid resuscitation during shock states, while excessive accumulation of total body water (TBW) can lead to volume overload and tissue edema, furthering cardiovascular, respiratory, and renal dysfunction in the critically ill patient. There is a great variation of bedside determination of the optimal type, volume, and rate of fluid administration, likely due to the lack of objective diagnostic parameters that accurately identify volume deficits in dogs and cats. This chapter aims to introduce the latest trends in clinical application of fluid therapy, including stages of fluid therapy, types of fluids, development of a fluid plan, and monitoring fluid balance.

STAGES OF FLUID THERAPY

Based on the fact that most dogs and cats requiring fluid therapy have a dynamic fluid balance during the acute phase of critical illness, IV fluid therapy prescriptions are not static. They should evolve based on the cardiovascular evaluation and fluid balance of the patient. Over the past decade, a conceptual framework that defines the four stages of fluid therapy has been defined to better guide clinicians during the decision-making process of fluid prescription in patients with dynamic fluid changes. The four stages have been defined as: (1) Rescue, (2) optimization, (3) stabilization, and (4) de-escalation (**Figure 23.1**).

The rescue stage characterizes patients presenting with life-threatening conditions such as shock secondary to hypovolemia or vasodilation, leading to tissue hypoperfusion and ischemia. This stage of fluid therapy is commonly applied to patients during the first 30 minutes to the first 2 hours after presentation to the hospital, when the patient is at risk of death if aggressive fluid resuscitation does not partially or entirely restore organ perfusion. Signs of shock and hypovolemia may vary between species and physiological stages. Many texts advocate providing "shock dose" fluids to patients with signs of hypovolemic shock. The volumes quoted are usually 90 mL/kg (dog) and 60 mL/kg (cat); this actually represents the entire blood volume of the animal. Clinically, it is rarely necessary to administer this large a volume of crystalloid fluids. During the rescue stage, smaller aliquot boluses of IV replacement (isotonic) fluids, 10–20 mL/kg in the dog and 5–10 mL/kg in the cat, are indicated to restore normal perfusion parameters (normal heart rate, normotension, improved mental status). Over-resuscitation can be as harmful as

DOI: 10.1201/9781003254591-45

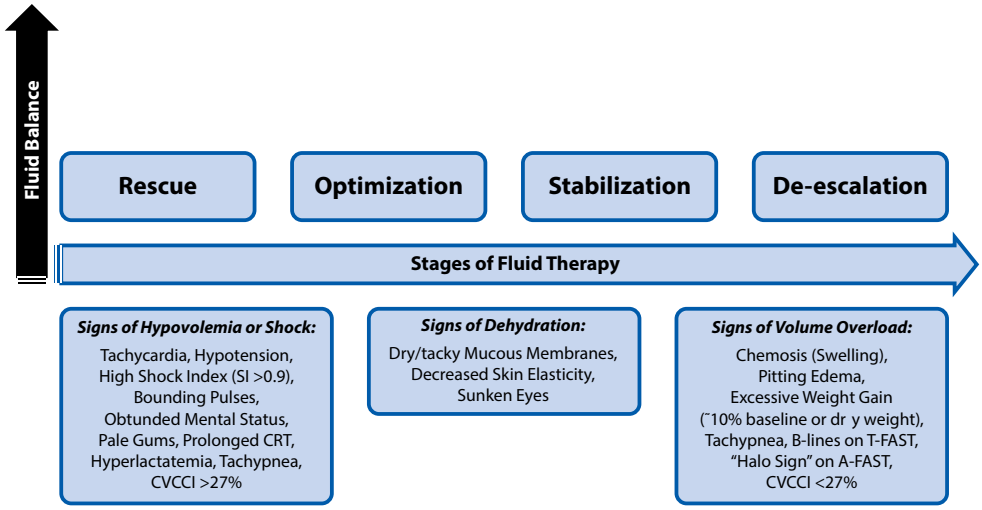

FIGURE 23.1 Stages of fluid therapy and clinical signs associated with the dynamic fluid balance of dogs and cats during hospitalization. CVCCI, Caudal Vena Cava Collapsibility Index.

under-resuscitating the patient, and goal-directed therapy can be instituted to prevent organ dysfunction from persistent ischemia due to decreased effective circulating volume.

In very specific situations, a second major strategy is low-volume resuscitation, or "hypotensive resuscitation" (to a mean arterial pressure of ~60 mmHg or a Doppler blood pressure of ~90 mmHg) in patients that are bleeding excessively until the hemorrhage is controlled. The use of hypertonic fluids such as 7.2% hypertonic saline is also indicated in such cases of severe acute hemorrhage to avoid a large volume of crystalloids being delivered that may lead to hypocoagulable states due to hypothermia and dilution of coagulation factors. During this phase, the clinician must also identify underlying causes of hypovolemia and shock, such as sepsis or septic shock, in order to effectively address the cause of the patient's critical state. While IV bolus therapy of crystalloids can be lifesaving during the rescue stage, excessive fluid therapy without early pressor support in septic patients may lead to fluid overload, organ edema, and fluid extravasation due to endothelial dysfunction.

The optimization stage of fluid therapy applies during the following 6–8 hours after the rescue phase, once the patient is no longer at imminent risk of death. During this phase, the patient requires ongoing fluid therapy to restore tissue perfusion and mitigate fluid losses due to vomiting, diarrhea, or polyuria. This phase also applies to patients presenting to the hospital with clinical signs of dehydration (Figure 23.1), in addition to having hypovolemia or shock. Fluid therapy regimens for these patients may require additional or initial boluses of fluids to improve their hemodynamic status, and fluid therapy should be aimed at restoring volume deficits, provide maintenance volume, and replace ongoing losses. There is vast heterogenicity among patients presenting with signs or without signs of dehydration despite ongoing loses, which makes fluid therapy regimens subjective and based on the clinician's best assessment of the patient. The most relevant part of the optimization phase is to have end-goals such as providing a certain volume over a certain number of hours to replace deficits and losses while avoiding liberal fluid therapy. Careful bedside monitoring of the patient with serial physical exams will help assess response to fluid therapy during this phase and prevent falling behind or exceeding fluid requirements due to the dynamic status of the patient. Normalization of hemodynamic variables such as lactate clearance, shock index (SI), and collapsibility of the caudal vena cava are also helpful for evaluation of hemodynamic optimization but are not superior to the direct observation and evaluation by the clinician.

Once the hemodynamic parameters of the patient are normalized or stable, the stabilization stage of fluid therapy is aimed at providing organ support while preventing iatrogenic complications. Such complications might include fluid overload, renal vasoconstriction, and decreased glomerular filtration rate (GFR) secondary to supraphysiological loads of chloride delivered to the renal tubular lumen, hypertension, and fluid extravasation. In this stage, clinicians should consider using maintenance or hypotonic fluids, which will decrease supraphysiological doses of electrolytes delivered with replacements (isotonic fluids). The stabilization stage may last days to weeks depending on the patient's underlying condition. This is where it becomes imperative to consider the incorporation of early enteral nutrition into the fluid plan to provide the patient with adequate nutrients during the recovery phases of critical illness. Once normal blood pressure and adequate tissue perfusion are achieved, early enteral nutrition helps deliver fluids and nutrients to the patient in a more physiological manner, while improving gastrointestinal (GI) function and supporting the immune system.

Finally, the de-escalation stage is aimed at recognizing patients who no longer require fluid support and may need fluid removal during their time in hospital. It is common practice to believe that all hospitalized

patients should be on IV fluids. Still, patients that voluntarily drink water and eat or have feeding tubes placed and are only having insensible losses may no longer require IV fluid support. Another essential concept is fluid removal in patients where fluid overload is recognized. Fluid removal may be achieved via diuretic therapy or simply by stopping fluid and allowing patients to urinate the excess circulating volume if oliguria or anuria are not developed as a consequence of fluid overload. More advanced forms of fluid removal, such as ultrafiltration with hemodialysis platforms, can be used, especially in patients with diagnosed with acute kidney injury and renal dysfunction. The goal is to achieve a neutral fluid balance, or in some cases, such as patients with pulmonary parenchymal disease (e.g. pneumonia, pulmonary contusions, or noncardiogenic pulmonary edema), a negative fluid balance may prove beneficial in their outcome. Clinicians using conservative fluid therapy and goal therapy are constantly de-escalating their patients based on their hemodynamic responses and assessment.

TYPES OF FLUIDS

Isotonic crystalloids, also called replacement fluids, are electrolyte-containing fluids with a composition similar to the extracellular fluid composition the patient. These fluids are the most common type of fluid used in veterinary medicine and are of particular importance during the rescue and optimization stages of fluid therapy. See Table 23.1 for commonly used isotonic crystalloid fluids in veterinary medicine. These fluids are considered isotonic because they have an osmolality closely resembling that of plasma (290–310 mOsm/L). Most crystalloids contain buffers such as lactate, acetate, and/or gluconate, which are useful for correcting metabolic acidosis commonly encountered in sick and critically ill patients. The only exception is 0.9% NaCl, which does not contain a buffer and is, therefore, considered an acidifying fluid. Infused crystalloids rapidly distribute into the extracellular fluid, and only a small portion (25%–30%) of the delivered volume remains in the intravascular space after the first 30 minutes post infusion. Isotonic crystalloids are theoretically used only for replacement volumes during the rescue and optimization stages in dehydrated or hypovolemic animals. Still, it is common practice to use these isotonic crystalloids as the maintenance fluid, since the kidneys can adapt and increase the excretion fraction of high doses of electrolytes delivered with these fluids. It is also more "convenient" to use a single fluid type and a single pump rather than having multiple fluid bags and several infusion pumps running simultaneously.

Large doses of chloride-rich containing fluids have recently been shown to increase the risk of acute kidney injury in people. The concentration of chloride in different types of isotonic crystalloids is shown in Table 23.1. As seen in the table, chloride concentration in a 0.9% saline solution is almost 1.5 times greater than other balanced crystalloids (154 mEq/L versus 108 mEq/L in LRS or 98 mEq/L in Plasma-Lyte 148 and Normosol-R). High chloride loads delivered to the macula densa induce renal afferent artery vasoconstriction and lead to reduced renal tissue perfusion and reduction in GFR, increasing the risk of acute kidney injury and volume overload due to fluid retention. One of the common reasons to use 0.9% NaCl is that this isotonic crystalloid is devoid of potassium, thus making it attractive for managing hyperkalemic patients. Multiple studies in cats with urethral obstructions have shown that cats receiving balanced crystalloids (LRS, Plasma-Lyte-148) had a more rapid resolution of metabolic acidosis, and potassium levels 6 hours post resuscitation trended lower when compared to cats that received 0.9% NaCl. Nowadays, the use of 0.9% NaCl is decreasing in veterinary medicine, but in certain conditions such as patients with hypochloremic metabolic alkalosis secondary to upper gastrointestinal obstructions, hypercalcemia, and mild hyponatremias, the use of saline solution may prove beneficial.

Hypotonic crystalloids, also called maintenance fluids, are fluids with lower osmolality compared to that of plasma and with lower electrolytes concentrations compared to isotonic crystalloids. These fluids have minimal concentrations of solutes to maintain body homeostasis. See Table 23.2 for commonly used hypotonic crystalloid fluids in veterinary medicine. They are

TABLE 23.1 Commonly used isotonic crystalloids in veterinary medicine with their correspondent electrolyte and buffer composition

Fluid type	Osmolality (mOsm/L)	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	Mg^{2+} (mEq/L)	Ca^{2+} (mEq/L)	Buffer (mEq/L)
0.9% NaCl	308	154	0	154	0	0	0
Lactated Ringer's solution	273	130	4	109	0	3	Lactate 28
Plasma-Lyte 148	295	140	5	98	3	0	Acetate 27 Gluconate 23
Normosol-R	295	140	5	98	3	0	Acetate-27 Gluconate 23

For Na^+, K^+, and Cl^-: 1 mEq/L = 1 mmol/L. For Ca^{2+} and Mg^{2+}: 1 mEq/L = 0.5 mmol/L.

Fluid type	Osmolality (mOsm/L)	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	Mg^{2+} (mEq/L)	Ca^{2+} (mEq/L)	Buffer (mEq/L)
0.45% NaCl	155	77	0	77	0	0	0
½ LRS + 2.5% Dextrose	265	65	2	55	0	1	Lactate 14
Plasma-Lyte-56	110	40	13	40	3	0	Acetate 16
Normosol-M	110	40	13	40	3	0	Acetate 16
D5W Water + 5% Dextrose	252	0	0	0	0	0	0

For the electrolytes Na^+, K^+, and Cl^-: 1 mEq/L = 1 mmol/L. For Ca^{2+} and Mg^{2+}: 1 mEq/L = 0.5 mmol/L.

made to replace the normal losses of water and electrolytes lost through respiration, urination, defecation, and other insensible losses. These insensible losses are low in sodium and high in potassium. It is essential to realize that maintenance fluids and hypotonic fluids can be dangerous to bolus or administer at high rates, as the water concentration gradient between the intravascular and intracellular compartments may lead to a rapid shift of water into the red blood cell and cause cell lysis. Dextrose is often added to maintenance fluids to supply calories to the patient and increase the osmolality of the fluid, preventing rapid shifts of water in case of an accidental rapid administration of the fluid.

The lower sodium and chloride profiles of hypotonic fluids make them ideal for providing maintenance rates of fluids to patients with cardiac and renal disease.

In patients with hypernatremia ($[Na^+]_{serum}$>160 mEq/L], the use of water + 5% dextrose (D5W) can be used to replace the free water deficit using the following calculation:

$$\text{Free Water Deficit (L)} = \left(\left\{\left[Na^+\right]_{current} / \left[Na^+\right]_{normal}\right\} - 1\right) \times \text{Body Weight (kg)} \times 0.6$$

This fluid should never be administered if electrolyte monitoring cannot be performed at minimum of every 6–8 hours to prevent rapid drops in sodium, leading to osmotic demyelination resulting in seizures, coma, and even death. The free water deficit volume can be replaced using D5W over a safe period (48 hours or longer) with caution not to decrease the plasma sodium more than 0.5–1.0 mEq/L per hour or more than 12 mEq/L over a 24-hour period. In addition to D5W, hypernatremic animals should receive an isotonic solution (same sodium concentration as the patient) to provide maintenance fluids and ongoing loss replacement. This objective can be achieved by adding a calculated volume of hypertonic saline to replacement fluids. For example, 7.2% NaCl contains 1,232 mEq/L of sodium and 1,232 mEq/L of chloride; therefore, each milliliter of this solution contains 1.232 mEq of sodium. If the patient has a sodium of 180 mEq/L, and you choose LRS as your replacement fluid ($[Na^+]$ 130 mEq/L), you will need to add 50 mEq/L of sodium, which will translate to 40.6 mL of 7.2% NaCl.

Hypertonic crystalloids are crystalloids that cause a rapid and transient osmotic shift of water from the intravascular space to the extracellular compartment, leading to a transient volume expansion. The most common hypertonic crystalloids are various saline solutions containing 3%, 5%, and 7.2% of sodium chloride in solution. Hypertonic saline use is common nowadays in emergency settings for the acute management of specific conditions such as severe hypovolemia from acute hemorrhage and increased intracranial pressure from traumatic brain injury (**Figure 23.2a, b**). Hypertonic saline decreases blood viscosity, which results in a positive rheological effect and enhances microcirculatory perfusion. Hypertonic saline also increases preload and causes a mild vasodilation that helps to increase cardiac output and coronary artery perfusion in critically ill animals. Furthermore, it has immunomodulatory effects and may increase heart contractility. The doses of hypertonic saline used in small animals range from 2 to 5 mL/kg, over 5–10 minutes. This dose can be repeated, but particular attention should be given to serum electrolyte concentrations. Hypertonic saline should not be given to animals with signs of dehydration and chronic clinical signs of water loss (vomiting, diarrhea, polyuria), especially if the patient's serum sodium concentration is unknown.

Synthetic colloids are suspensions containing large molecules (molecular weight >10,000 daltons) dissolved typically in 0.9% NaCl. Hydroxyethyl starches, dextrans, and gelatins are examples of synthetic colloids. Hydroxyethyl starches are the most commonly used synthetic colloid solutions in veterinary medicine. These large molecules do not readily filter across the vascular endothelium and remain in the intravascular space for longer periods compared to crystalloid solutions. Once these particles are filtered through the glomerulus, they are reabsorbed by the proximal tubular epithelium and cause renal tubular vacuolization, damaging this part of the nephron. The volumes of synthetic colloids administered to critically ill dogs has been correlated with the damage of the proximal tubular epithelium in proportional magnitudes. Despite the promising benefits of the use of colloids, the revision of the Starling

FIGURE 23.2 **(a)** Six-year-old mixed-breed dog receiving an IV bolus of hypertonic fluids before administration of blood products due to exsanguinating hemorrhage secondary to ballistic trauma to the abdomen. **(b)** Three-year-old Maltese dog receiving hypertonic saline as part of treatment of traumatic brain injury secondary to vehicular trauma.

forces and the effect of the endothelial glycocalyx in vascular permeability have shown that the beneficial use of colloids, synthetic or not, only applies at higher capillary pressures. Several studies have shown that colloids are not superior to crystalloids during resuscitation stages in critical illness. The 2016 surviving sepsis campaign has a strong recommendation against the use of synthetic colloid solutions for intravascular volume replacement. The use of synthetic colloid fluids has been slowly decreasing among specialty veterinary hospitals, and in the author's experience, synthetic colloids are no longer recommended for intravascular expansion and management of critically ill animals.

BLOOD PRODUCTS AND TRANSFUSIONS

Blood products and transfusion are sometimes required for the management of patients with acute and chronic conditions. The aim is to re-establish appropriate levels of circulating hemoglobin and improve oxygen delivery (DO_2) in patients with severe anemia and replace coagulation factors in patients with coagulopathies. The indications and triggers for blood transfusions are beyond the scope of this chapter. In general, patients with slow-onset anemia with decreased DO_2, will have hematocrit values <20% and have changes associated with poor tissue perfusion (tachycardia, pale mucous membranes, mental dullness or stupor, tachypnea). Patients with acute exsanguinating hemorrhage, on the other hand, may have hematocrit levels >20% while still showing signs of poor tissue perfusion, as seen in cases of hemoabdomen. The transfusion of packed red blood cells (pRBCs) is recommended in patients with anemia to prevent antigenic stimulation and decrease the risk of transfusion reactions associated with whole blood and unnecessary blood components. Ideally, all patients should be blood typed before a transfusion, and donors should also be blood typed to decrease the risk of transfusion reactions with whole blood or packed red blood cells products. In the emergency setting and in patients with critical conditions, the use of cross-matching is not absolutely required if appropriate blood typing has been performed, especially in dogs with their first blood transfusion, as they do not have pre-existing alloantibodies. Cross-matching in cats is considered more necessary due to the presence Mik cell antigens, or in dogs and cats that have received transfusion after the first 3–5 days. The use of IV fluid pumps to deliver whole blood or pRBC transfusions has been associated with red blood cell damage and lower viability of the transfused product; therefore, the use of syringe pumps in small patients (cats and dogs <10 kg) with blood filter sets is recommended. In cases involving severe exsanguinating hemorrhage or life-threatening anemias, gravity flow or pressure infusion bags can be used as an alternative form of blood product delivery (Figure 23.3a, b). The volumes of whole blood or pRBC transfusion recommended for anemia management are presented in Table 23.3. The rate of transfusion delivery will be dependent on the hemodynamic status of the patients. In patients with chronic anemias or those without evidence of impending cardiopulmonary arrest, transfusions can be delivered over 4 hours with close monitoring for the development of transfusion reactions. In patients with life-threatening anemias where

FIGURE 23.3 **(a)** A 6-year-old mixed-breed dog (same dog from **Figure 23.2a**) receiving a bolus of pRBC (15 mL/kg DEA 1.1 negative) due to exsanguinating hemorrhage secondary to ballistic trauma to the abdomen. **(b)** A 5-year-old cat receiving a unit of pRBC (30 mL type A) via syringe pump through a 170-micron filter before its fourth dialysis session due to acute kidney injury (AKI) secondary to lily toxicity.

there is no time to monitor for transfusion reactions, the rate of blood product delivery will be determined by the patient's degree of urgency. Rapid infusions can be facilitated with pressure infusion bags.

Plasma products (fresh frozen plasma, stored plasma, cryoprecipitate-poor plasma), also considered natural colloids, can be used as part of the resuscitation strategies in patients with severe bleeding in order to replace proteins and coagulation products lost in acute blood-loss conditions. The most common indication for plasma product transfusion is for the replacement of coagulation factors in cases of anticoagulant rodenticide toxicity, hepatic failure, or hereditary conditions such as hemophilia (Table 23.3). The use of plasma products for specific conditions such as pancreatitis and parvoviral enteritis is now contraindicated due to higher mortality rates observed in patients with pancreatitis treated with plasma transfusions. With these conditions, the hypercoagulable state associated with the systemic inflammatory response syndrome

TABLE 23.3 List of blood products, volumes and rates, and indications for transfusion therapies in veterinary medicine

Blood product	Dose/volume recommended	Indications
Fresh whole blood ***or*** ***Stored whole blood***	– 20 mL/kg to increase the HCT by 10% – Infusion rate of 5 mL/kg/h for stable patients	– Patients with anemia and signs of decreased DO_2 where pRBC is not available – Neonatal and pediatric patients where the required transfusion volume is low enough to not warrant waste of an entire unit of pRBC – Patients with anemia secondary to hemorrhage from coagulopathies, as fresh whole blood contains coagulation factors in addition to red and white blood cells and platelets
Packed red blood cells (pRBC)	– 15 mL/kg to increase the HCT by 10% – Infusion rate of 3–4 mL/kg/h for stable patients	– Patients with anemia and signs of decreased DO_2
Fresh frozen plasma	– 10–15 mL/kg – Infusion rate of 3–4 mL/kg/h for stable patients	– Replacement of coagulation factors – It also contains albumin, globulins, and antithrombin
Cryoprecipitate	– 1–2 mL/kg or 50 mL/10 kg	– Treatment of hemophilia A, von Willebrand disease and hypofibrinogenemia
Cryoprecipitate-poor plasma	– 1–2 mL/kg or 50 mL/10 kg	– Treatment of coagulation factors II, VII, IX, and XI deficiencies

(SIRS) may develop secondary to vascular endothelial dysfunction. Finally, the use of plasma transfusions to correct hypoalbuminemia in conditions such as protein-losing enteropathies and nephropathies are controversial, as patients receiving 18 mL/kg of fresh frozen plasma did not show an increase in serum albumin concentrations. The volume of fresh frozen plasma required to increase serum albumin concentrations by 1 g/dL may be up 40–45 mL/kg, equal to half the blood volume in dogs (90 mL/kg). Plasma products are, therefore, reserved for management of acute hemorrhage and coagulopathies because of these limitations. The indications and volumes of plasma products are presented in **Table 24.3**.

DEVELOPING A FLUID PLAN

IV fluid therapy is used to correct dehydration or volume deficits, provide maintenance of daily water balance and electrolyte needs, and replace ongoing losses such as vomiting, diarrhea, or polyuria. The type of fluid depends on the type of fluid loss suspected to be causing the volume deficit, and combination therapy is sometimes required to provide appropriate water and solute balance. Patients with signs of dehydration should have the estimated percentage of dehydration replaced over a short period (6–10 hours). Once the deficit has been calculated and the rate at which that deficit will be replaced, then a fluid therapy regimen can be created following the next steps:

- *Replacement*
  The replacement volume should be calculated by using the formula:

  $$\text{Body Weight (kg)} \times \text{Estimated Percent Dehydration (\%)} = \textbf{Deficit (L)}$$

  Then the fluid rate should be calculated using the time over which the deficit volume (in mL) will be replaced:

  $$\textbf{Deficit}\,(\text{mL})/\textbf{Time in Hours} = \textbf{Rate}\,(\text{in mL/hr})$$

  If a shock bolus has been given, this volume can be subtracted from the total deficit, and the remaining volume given over the time in hours considered appropriate for replacement. It is very difficult to accurately determine the volume deficit of sick and critically ill patients; therefore, subtracting the volume of the IV bolus is not always required, since during the rescue phases of fluid therapy patients have active ongoing losses, and re-distribution of circulating volume may affect deficit assessment. Dehydration estimates should take body habitus into consideration: Frail patients might normally have decreased skin turgor, while obese patients can have normal skin elasticity while being dehydrated.

  Subcutaneous (SQ) fluids are commonly administered in general and emergency practice. Suppose the animal is being treated with subcutaneous fluids on an outpatient basis. In that case, the aim of SQ fluid therapy should be aimed to at least replace the volume deficit of the patient (**Figure 23.4**) or provide maintenance for the next 24 hours in patients without clinical evidence of dehydration (40–60 mL/kg).

FIGURE 23.4 Prolonged skin elasticity in an 8-year-old, spayed female cat approximately 6%–8% dehydrated. The cat's weight is 4.5 kg; therefore, based on 8% dehydration, the deficit would be 0.36 L (4.5 kg × 8%; or 4.5 kg × 0.08) or 360 mL. If subcutaneous fluids were chosen as treatment for dehydration, this patient should receive between 270 and 360 mL of subcutaneous fluids to attempt rehydration.

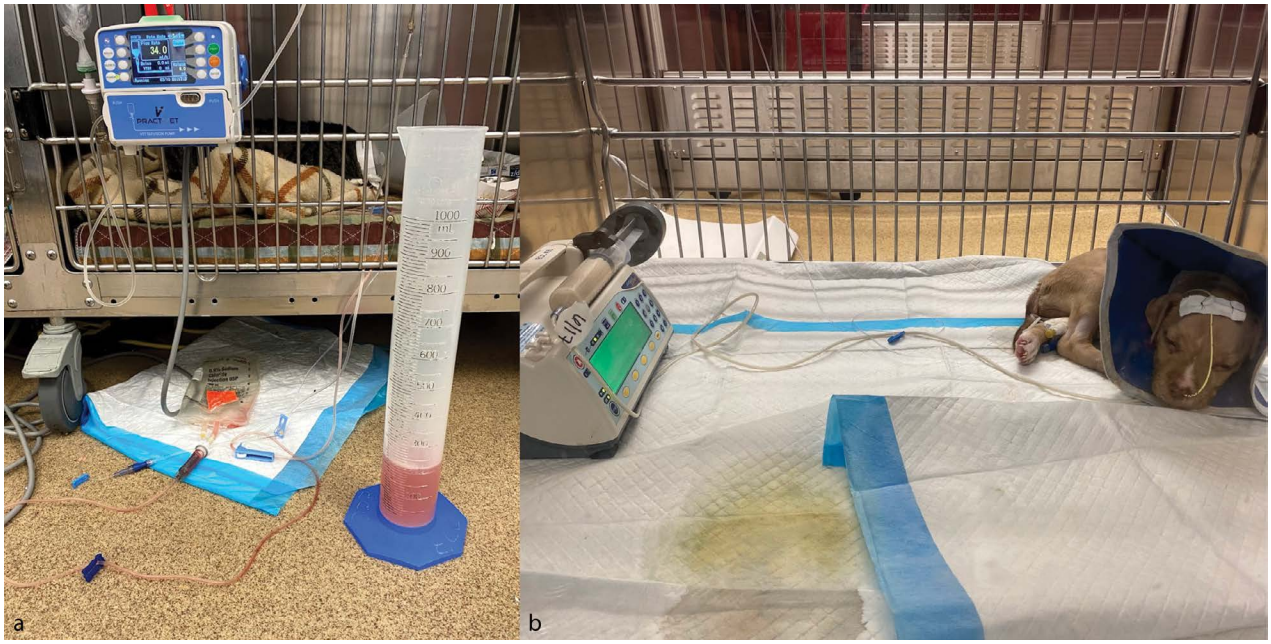

FIGURE 23.5 **(a)** Urine collection and measurement from a urinary collection system in a 2-year-old male cat with urethral obstruction secondary to feline idiopathic cystitis. **(b)** Disposable pads containing urine from a 2-month-old Pitbull puppy being treated for parvo viral enteritis and early enteral nutritional support via a nasogastric tube.

- *Ongoing losses*

  Ongoing losses can be calculated by either measuring urine output in animals with polyuric conditions and measuring or estimating the volume of diarrhea/vomitus that the animal is losing per hour in animals with gastrointestinal signs or both. Urine output can be measured via urinary catheterization, which is commonly performed in cases of urethral obstruction (Figure 23.5a, b) or during the first days of acute kidney injury. Still, urinary catheterization is not always indicated as it increases the risk of ascending infections and patient discomfort. In patients where urinary catheterization is not indicated, the measurement of urine output or GI losses can be performed via direct weighing of disposable pads. In most instances, the volume of GI losses is an educated estimate that should be accounted for in fluid regimen plans.
- *Maintenance*

  Several formulas for maintenance rates of fluids are available, and no consensus has been reached regarding which formula is best. Maintenance fluid needs are variable for each animal, with pediatric and geriatric animals requiring different volumes. Some of the formulas used include:

  1. 30 (BW in kg) + 70 = total volume (mL per 24 hours)
  2. $70 \times [BW_{kg}]^{0.75}$ = total volume (mL per 24 hours)

  This formula is considered more accurate for very small animals <2 kg (not including neonates or pediatrics) or very large animals >40 kg.

  3. 40–60 mL/kg per day (mL per 24 hours)

  This formula is mostly dictated by clinical experience where most clinicians will use 40–50 mL/kg per day for cats and geriatric animals.

It is imperative to recognize that if the replacement volume will be delivered over a short period (<24 hours), then the fluid volumes will initially include rates for:

Replacement + Ongoing losses + Maintenance

Once the replacement volume has been delivered and the patient is euvolemic and no longer shows signs of fluid deficits, the fluid rate and volume are amounts that decreased to:

Ongoing losses + Maintenance

MONITORING FLUID THERAPY AND FLUID BALANCE

In the last decade, special attention has been paid to monitoring fluid balance in hospitalized and critically ill patients, as fluid overload has been directly correlated with increased risk of mortality and development of comorbidities in people and veterinary patients. Fluid overload is defined as an increase of 10% or more from basal or ideal body weight. Liberal fluid therapy is commonly practiced in human and veterinary hospitals, with fluids rates at two to four times the maintenance rates without adequate therapeutic goals and monitoring endpoints. Not only will inappropriate fluid prescriptions increase the risk of volume overload, but lack of monitoring of fluid balance will increase the risk of fluid accumulation and edema formation. High fluid rates lead to increased central venous pressure, increased myocardial atrial stretch, and release of atrial natriuretic peptides. The consequences are endothelial

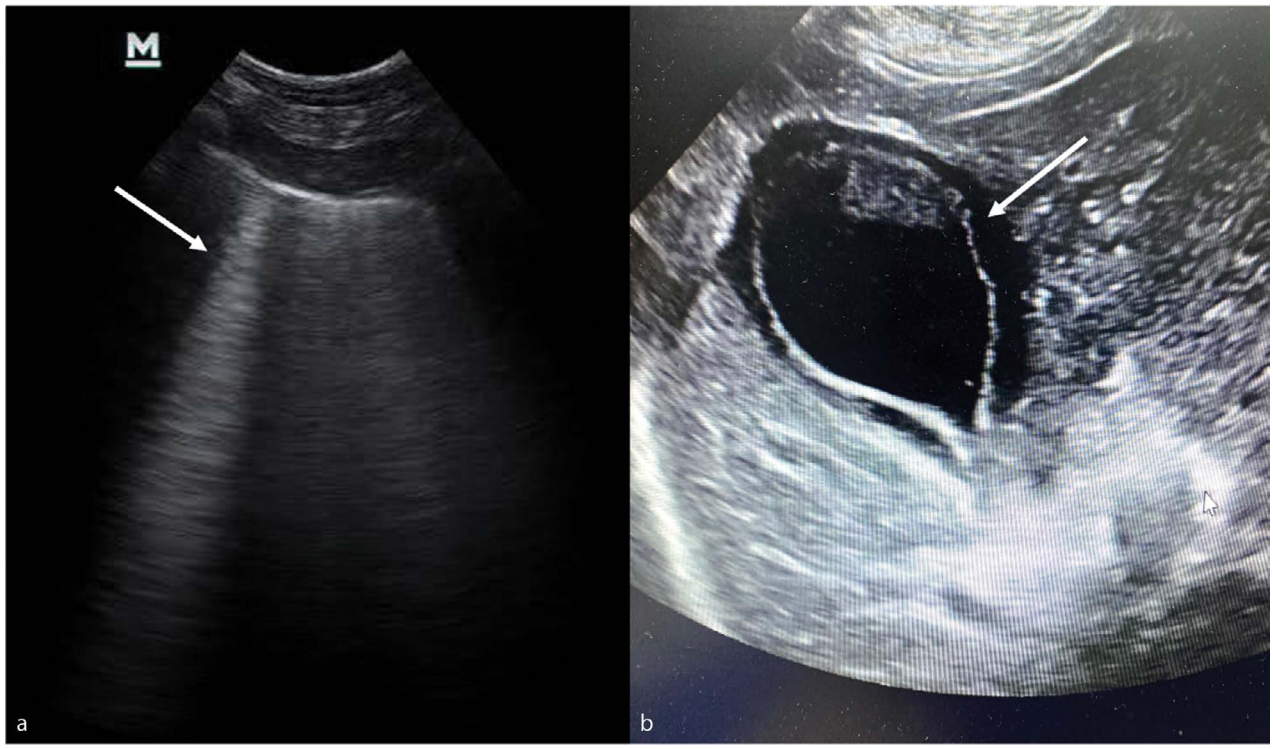

FIGURE 23.6 **(a)** Point-of-care lung ultrasound in a dog with oliguric acute kidney injury and a 7% increase in ideal body weight showing hyperechoic vertical lines (B-lines or comet-tails represented by white arrow) extending from the pleural space to the end of ultrasound field. **(b)** Abdominal point-of-care ultrasound in a dog with fluid overload, showing evidence of gallbladder wall edema represented by a hypoechoic rim or halo sign.

dysfunction, increased vascular permeability, and decreased lymphatic flow, leading to water accumulation in various organs (kidneys, heart, liver, and GI tract). Visceral edema tends to develop earlier in patients with volume overload due to rapid increases in central venous pressure, even before pitting edema is clinically evident. The percentage of fluid overload (%FO) can be calculated by the following formula:

$$\%SF = \left[\left(V_{tot}IN - V_{tot}OUT\right)/\text{basal body weight}\right] \times 100$$

$V_{tot}IN$ represents the volume of fluids that the patient has received, and $V_{tot}OUT$ represents the volume of urine and gastrointestinal losses. The development of visceral edema carries significant consequences in organ function, more specifically in the kidneys where water and electrolyte balance are tightly regulated. Renal edema secondary to volume overload results in decreased glomerular filtration rates, increased sodium and water retention, azotemia, oliguria-anuria, and worsening of volume overload. Other signs of volume overload include cardiac edema, which results in decreased systolic function, contractility, and reduction in cardiac output. Gastrointestinal edema worsens signs of vomiting, regurgitation, and diarrhea in hospitalized veterinary patients. For these and many other reasons, close monitoring of fluid balance leads to better outcomes in critically ill patients.

One of the easiest and least invasive ways of monitoring fluid balance in hospitalized patients is by frequent and consistent body weight assessment. Daily body weight measurements allow the clinician to reassess the risk of volume overload in hospitalized patients and evaluate the efficacy of fluid therapy when trying to restore fluid deficits. It is recommended to weigh the patient consistently after voiding or emptying the urinary bladder in order to prevent significant fluctuation in body weight secondary to urine retention. More advanced methods of fluid balance monitoring such as central venous pressure, pulmonary capillary pressure, and arterial pulse pressure variation are not routinely performed in veterinary patients. With the widespread use of ultrasound in veterinary hospitals, other monitoring techniques are becoming available to monitor patients for signs of volume overload. Point of care ultrasound can be used cageside to evaluate the presence of fluid accumulation in visceral organs, such as development of B-lines in the lungs or halo sign in the gallbladder (Figure 23.6a, b).

CONCLUSIONS

- Intravenous (IV) fluids should be prescribed as any other medication, with appropriate doses and dosage adjustments based on response to therapy.
- Fluid therapy is a dynamic intervention with four different stages: Rescue, optimization, stabilization, and de-escalation.

- The choice of fluids should be tailored to the patient's current physiological status. Avoiding chloride-rich solutions and synthetic colloids has become the cornerstone of fluid therapy in critically ill animals.
- Like any therapy, IV fluids can have harmful and deleterious effects. Especial attention should be paid to fluid balance and avoiding fluid overload in hospitalized patients.

INTRODUCTION

Pain management is an important component of animal welfare and an inspiring area of modern veterinary medicine. Advances on the knowledge of acute and chronic pain assessment and treatment in dogs and cats have occurred in the last decade supporting the practice of evidence-based pain medicine in these species.

Pain negatively affects the quality of life of dogs and cats and induces behavioral changes that affect the owner–pet bond. It causes unnecessary fear, anxiety, and stress, leading to negative mental states and causes sympathetic nervous system activation, altered food intake and metabolism. For these reasons, the management of animal pain has become a significant component of clinical practice.

OVERVIEW OF PAIN PHYSIOLOGY

According to the International Association for the Study of Pain (IASP), pain is defined as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage." This definition, updated in 2020, considers the following:

- Pain is a personal experience influenced by biological, psychological, and social factors.
- The multiplicity of mind–body interactions is acknowledged.
- Pain is different from nociception (nociception refers to the neural processing of noxious stimuli, whereas pain requires conscious perception, is associated with emotions and influenced by numerous internal and external factors).
- Animals are learning throughout their life's experiences, including that of pain.
- Inability to communicate does not negate the possibility that an animal is experiencing pain.

The Pain Pathway

The somatosensory system comprises the structures implicated in the processing of nociceptive information (Figure 24.1), which occurs via four main steps: Transduction, transmission, modulation, and perception. These are further described as follows.

Transduction starts with the activation of nociceptors present in the skin, muscles, joints, and viscera. Nociceptors are highly specialized structures that respond to different types of noxious or potentially tissue-damaging stimuli such as mechanical, thermal (hot and cold), and chemical stimuli. If the stimulus is of enough intensity that it reaches the threshold for an action potential, a nerve impulse is generated.

Transmission occurs when the nociceptive impulse travels from different types of primary afferent fibers (Figure 24.2) to the dorsal horn of the spinal cord. Primary afferents have a unique morphology which allows the nociceptive signal to travel in both directions within the neuron (i.e., the nociceptor can send and

Aβ	Large myelinated and rapidly conducting fibers involved in low threshold innocuous mechanical stimulation (e.g., touch).
Aδ	Thinly myelinated and slowly conducting fibers primarily involved in nociceptive signaling (i.e., fast pain).
C	Unmyelinated and very slowly conducting fibers primarily involved in nociceptive signaling (i.e., slow pain).

FIGURE 24.2 Primary afferent fibers can be divided into three types based on their structure, diameters, and conduction velocity.

receive messages from either end). Their unique capacity to release neurotransmitters peripherally underlies the process of neurogenic inflammation. A subgroup of C fibers, "silent" nociceptors, are mechanically insensitive but can become sensitized during inflammation.

Modulation occurs at different levels of the peripheral and central nervous systems (CNS) where the nociceptive message can be amplified or inhibited depending on the nature of the neurotransmitters released and the pathway being activated. Examples of excitatory neurotransmitters include glutamate and substance P. Examples of inhibitory neurotransmitters include gamma-aminobutyric acid (GABA), noradrenaline, serotonin, and opioids, which bind to their receptors to decrease neuronal excitability.

Perception of pain occurs when the nociceptive signal is integrated in the cerebral cortex, and the stimulus is consciously perceived. Perception of noxious stimuli involves the incorporation of emotional attributes in the thalamus and cortical structures to these sensory signals. Pain perception is affected not only by the neurobiology of each individual but also by numerous variables,

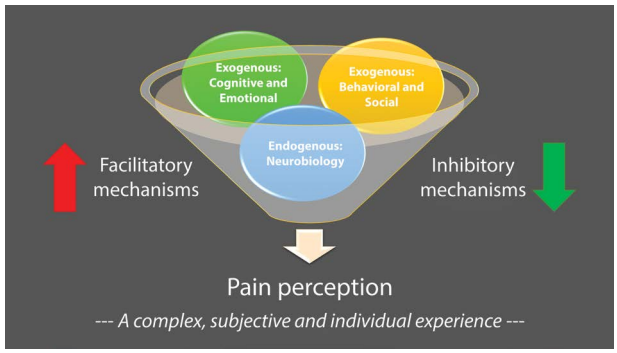

FIGURE 24.3 Factors influencing pain perception.

including past experiences, environmental and social contexts (Figure 24.3).

IMPORTANT CONCEPTS IN PAIN MEDICINE

Peripheral and Central Sensitization

Peripheral sensitization is characterized by sensitization of peripheral nociceptors (Figure 24.4). When tissue injury occurs, the release of inflammatory mediators such as prostaglandins and nerve growth factor (NGF) render peripheral nociceptors sensitized and hyperexcitable. Thus, the threshold for nociceptor activation is reduced, and the magnitude of response is increased. Activation of "silent" nociceptors and of neighboring nociceptors from undamaged healthy tissues also occurs. The persistent activation of peripheral fibers and constant input to the spinal cord contribute to the development of central sensitization.

Central sensitization is the increased responsiveness of nociceptive neurons in the CNS characterized by three main processes: Increased membrane excitability, facilitated synaptic strength, and decreased inhibitory influences (i.e., disinhibition). Neuroplasticity and neuroimmune interactions can further enhance neuronal excitability and decrease inhibitory currents. These are generally short-lived and reversible; nevertheless, they can become pathologic in the face of sustained inflammation or nerve injury.

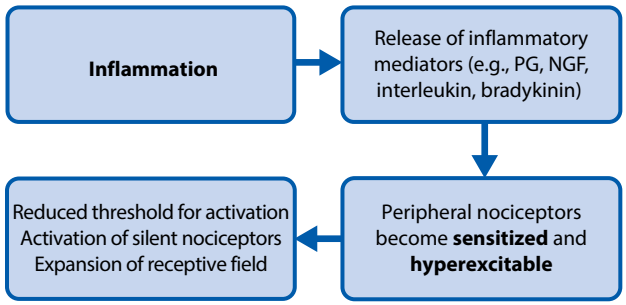

FIGURE 24.4 Schematic representation of the mechanisms involved with peripheral sensitization. NGF, nerve growth factor; PG, prostaglandins.

Hyperalgesia and Allodynia

The clinical manifestations from peripheral and central sensitization are known as hyperalgesia and allodynia. Hyperalgesia refers to increased sensitivity to pain due to a stimulus that normally provokes pain (the quality of the sensation is not altered; what changes is the severity of that sensation). Allodynia refers to pain due to a stimulus that does not normally provoke pain (the quality of the sensation is altered).

CLINICAL PAIN

Considering the complexity of the pain pathway and its enormous potential for interindividual variability, one can appreciate how the pain profile can be diverse among patients being affected by the same condition. It also explains the varied response of patients to therapeutic interventions.

Pain can be classified according to its type, duration, anatomical localization, etc. What really matters is understanding that pain is a dynamic process and that patients might have different contributions to the overall pain experience (Figure 24.5). For example, an older dog with osteosarcoma, hip dysplasia, severe periodontal disease, and cystitis has all these conditions contributing to the overall pain experience. In terms of location, there is bone pain, joint pain, orofacial pain, and visceral pain. In terms of type, there is inflammatory, neuropathic, and cancer pain. In terms of duration, most conditions are chronic, whereas the cystitis is likely acute. Regardless, the pain experience is the result from all these conditions and all the internal and external factors previously discussed (pain facilitation and pain inhibition, and cognitive, behavioral, social, and environmental components). Recognizing all these players is helpful for assessing pain and planning treatment with an evidence-based confidence.

Nociceptive pain refers to physiological pain that serves for protection (e.g., contact with a hot object, painful pinch, or chemical burn).

Inflammatory pain involves the release of inflammatory mediators which sensitize nociceptors, resulting in pain, redness, swelling, heat, and loss of function. It can be involved with adaptive (e.g., postoperative pain or acute trauma) and maladaptive (e.g., osteoarthritis [OA], cancer, gingivitis) processes. Persistent inflammation and release of substance P and NGF in the periphery can lead to neurogenic inflammation. In neurogenic inflammation, cells from the dorsal horn of the spinal cord release chemicals which fire backwards down on the nociceptors, further releasing neurotransmitters such as NGF, which then sensitizes peripheral nociceptors, reinforcing this vicious cycle (Figure 24.6).

Adaptive (acute)	Maladaptive (chronic)
Associated with potential or actual tissue damage Purpose: Avoid or minimize damage during healing Self-limiting Ex: Postoperative pain, trauma	Not associated with healing Persists beyond the expected course of the acute disease No clear end-point Can exist without a cause Ex: OA, cancer, gingivitis, etc.

FIGURE 24.5 Differences between adaptive and maladaptive pain. (*Adapted from Ref*. 31.)

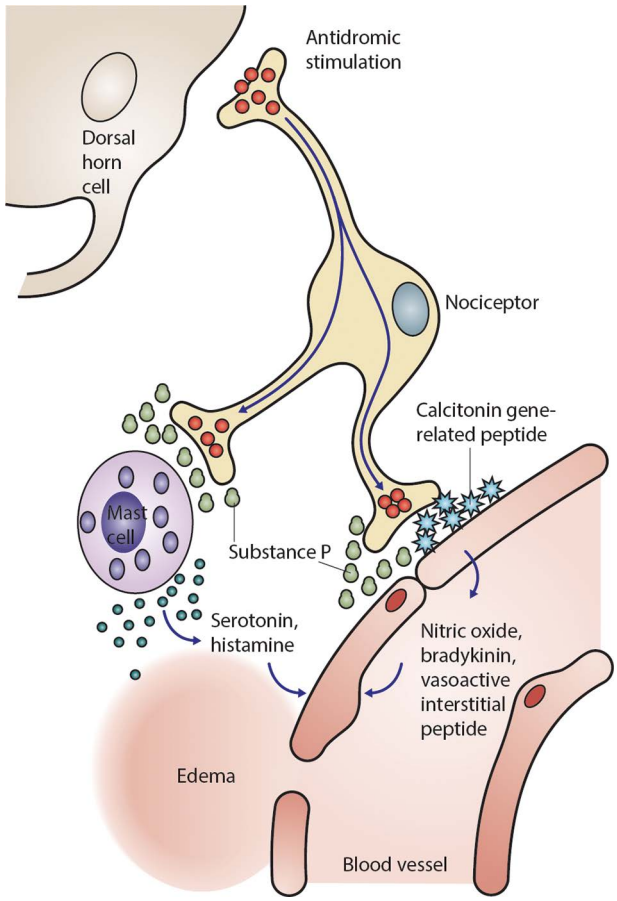

FIGURE 24.6 Neurogenic inflammation involves an antidromic firing of neurons (action potentials fire backwards down the nociceptors). Packets of chemicals located at the peripheral terminals are released. Thereafter, pain signals from peripheral nerves are heightened, and the cycle of chronic pain is continued.

Neuropathic pain is defined as pain caused by a lesion or disease of the somatosensory nervous system. It is characterized by two key concepts: Inappropriate activity in nociceptive fibers and central changes in sensory processing. Examples include intervertebral disc disease (IVDD), syringomyelia, Chiari-like malformation, diabetes-induced neuropathy, OA, cancer, chronic gingivostomatitis, feline orofacial pain syndrome, persistent postsurgical pain following amputations (including tail docking in dogs and onychectomy in cats).

Cancer pain is regarded by some as a separate pain entity because of complex interactions between cancers, the somatosensory system, and the immune system (Figure 24.7). Briefly, within the tumor

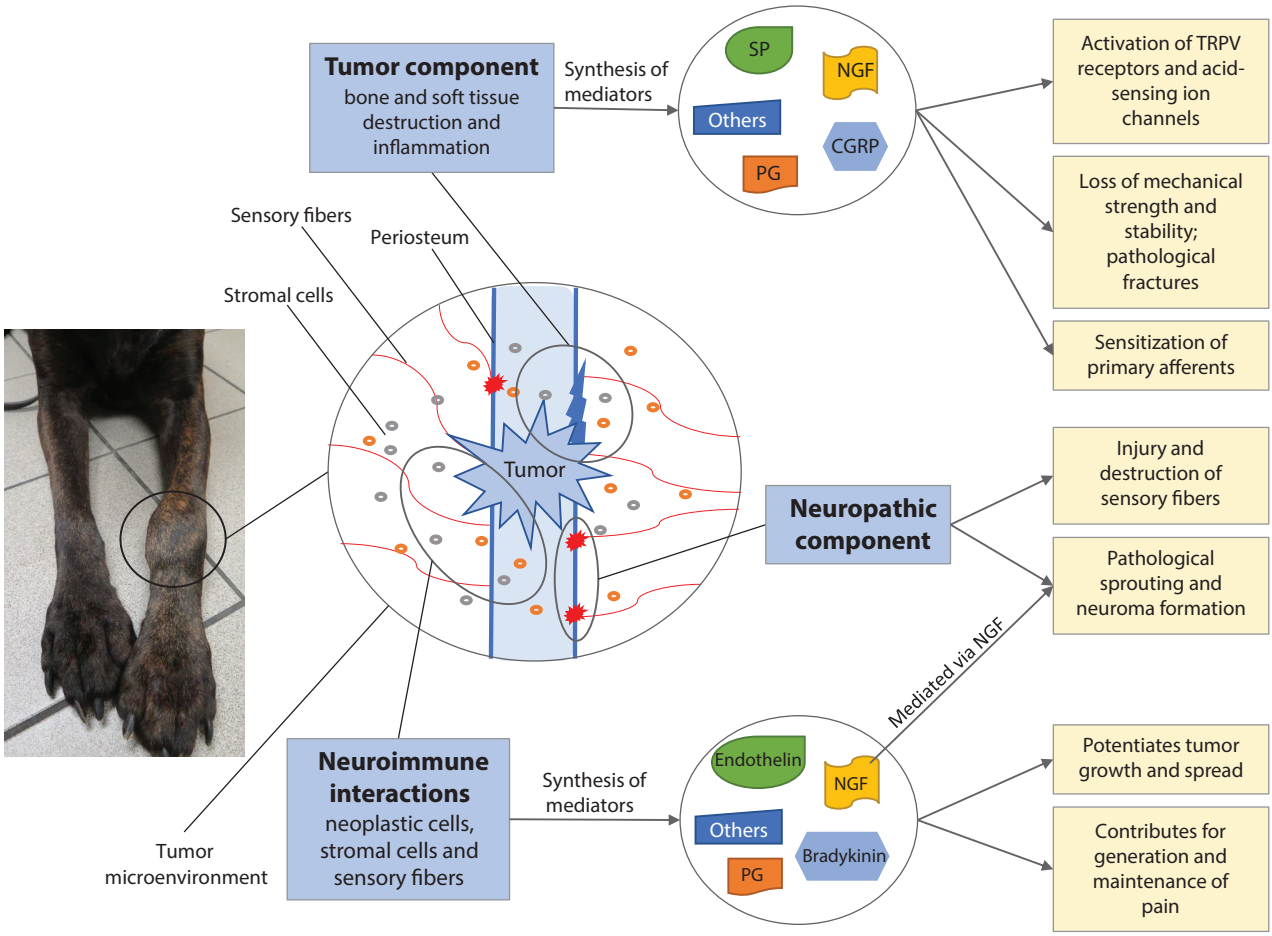

FIGURE 24.7 Cancer pain in dogs with osteosarcoma is the result of a complex interaction between the tumor, the somatosensory system, and the immune system. CGRP, calcitonin gene-related peptide; NGF, nerve growth factor; PG, prostaglandin; SP, substance P. (*Modified from Monteiro (2019).* Assessment of Chronic Pain in Companion Animals: Development and Concurrent Validation of Neurophysiological Methods *(PhD thesis; Université de Montréal).*)

microenvironment, interaction between neoplastic cells, stromal cells and sensory fibers synthetize and secrete a number of mediators resulting in sensitization of primary afferent neurons, regulation of angiogenesis, and potentiation of tumor growth and spread.

PAIN ASSESSMENT

Pain is a personal, complex, and multidimensional experience composed of sensory and emotional components. Therefore, the intrinsic challenge of veterinarians is to assess such an experience in animals. One of the main reasons for the inappropriate treatment of pain is inadequate pain assessment. Pain is now considered as the 4th vital sign, and its assessment should be incorporated into the clinical evaluation of all animal patients (Figure 24.8).

Pain assessment relies on the observation of pain-related behaviors and is aided by the use of validated pain scales. Physiological changes such as increases in heart rate and respiratory rates, pupil size and neuroendocrine assays (e.g. cortisol) are poorly specific for pain.

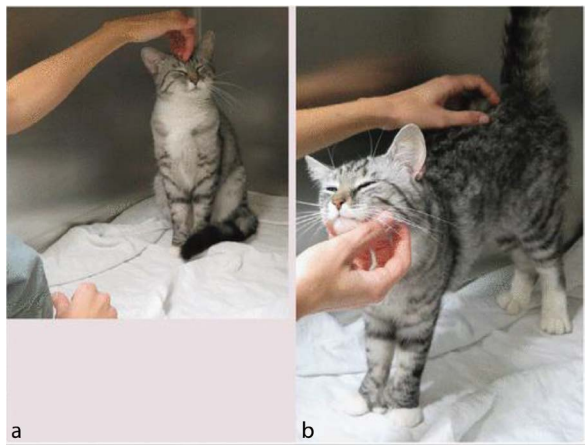

FIGURE 24.8 Pain assessment should be performed in all patients. This young female cat is evaluated for pain prior to surgery. First, she is assessed at a distance. Then, the cage door is opened, and her willingness to interact and response to palpation are performed. Having baseline pain assessment is helpful when evaluating animals postoperatively. (*Reprinted from* J Feline Med Surg *2019;21(1):25–34. Steagall and Monteiro, Acute pain in cats: Recent advances in clinical assessment. SAGE Publishing.*)

Acute Pain Assessment

For animals undergoing surgery, the veterinarian or technician should assess the animal's behavior before surgery for a baseline pain evaluation. The frequency of pain assessment following surgery will depend on the type of surgery, the condition of the animal prior to surgery, and the analgesic protocol. In studies involving dogs and cats undergoing ovariohysterectomy and receiving a multimodal analgesic protocol, including nonsteroidal anti-inflammatory drugs (NSAIDs) ± local anesthetics ± opioids, pain scores are higher than baseline from 30 minutes up until 4–6 hours after surgery. Animals that are sleeping, eating, or grooming should not be disturbed for pain assessment.

In dogs and cats with acute pain, commonly observed pain-related behaviors include:

- Decreased activity
- Decreased attention to the surroundings
- Changes in body posture (e.g., cats with abdominal pain show hunched posture; dogs with abdominal pain show praying position; Figures 24.9 and 24.10)

FIGURE 24.9 Dog with postoperative abdominal pain showing the "praying position" following ovariohysterectomy.

FIGURE 24.10 Cat with abdominal pain due to acute pancreatitis showing a hunched-up body position. The Feline Grimace Scale score for this cat was 7/10, indicating the need for administration of rescue analgesia. The scores for each action unit were as follows: 2 for ear position, 0 for orbital tightening, 2 for muzzle tension, 2 for whisker position, and 1 for head position.

- Attention to the wound; reaction to gentle palpation of the wound
- Vocalization
- Withdrawing; hiding; unwilling to interact
- Changes in facial expression
- Decreased appetite; decreased or increased grooming (cats)
- Growling; groaning; fear-motivated aggression

Chronic Pain Assessment

The assessment of chronic pain relies heavily on owner-reported changes in behavior (including home-made videos). In dogs, useful information can be generally collected from the physical exam (e.g., response to palpation, lameness, etc.). Cats tend to be more fearful in hospital settings, and less information is usually gained from physical exam.

Chronic pain manifests as a continuous flow of high, moderate, and low levels of pain. Thus, behaviors are influenced by dynamic changes in environmental and physiological demands, varying from day to day.

In dogs and cats with chronic pain, commonly observed pain-related behaviors include:

- Decreased activity and exercise intolerance
- Decreased ability to perform routine activities (e.g., cats become reluctant to jump up and down and/or use steps for doing this; cats no longer groom as they used to; dogs have difficulty in getting into the car or climbing the stairs; dogs no longer come to greet owners at the door)
- Decreased socialization towards owners and other pets
- Inappropriate/difficult elimination (e.g., cats might find it difficult to enter the litter box; dogs might have difficulty in squatting)
- Changes in demeanor (e.g., development of aggression/escape reaction when picked up or when a certain area of the body is touched)
- Sudden vocalization/agitation (e.g., cats with feline hyperesthesia syndrome might suddenly reach for their back with intense grooming behavior hair-plucking; dogs with persistent postsurgical pain after tail docking might develop spontaneous and severe pain at the stump and suddenly start chasing it vigorously)
- Difficulty rising to standing after long periods of rest

PAIN SCALES

Pain scales ensure a systematic approach to pain assessment (Figure 24.11). In most cases, acute pain scales are completed by the veterinarian or technician, whereas chronic pain scales are completed by owners. A brief description of the most validated pain scales is given here.

Acute pain scales for dogs

- *Glasgow Composite Measure Pain Scale-Short Form* (CMPS-SF): The maximum score is 24; the cutoff score for administration of rescue analgesia is ≥ 6/24 (or ≥ equal to 5/20 when mobility cannot be assessed). Available at https://www.newmetrica.com/acute-pain-measurement/.

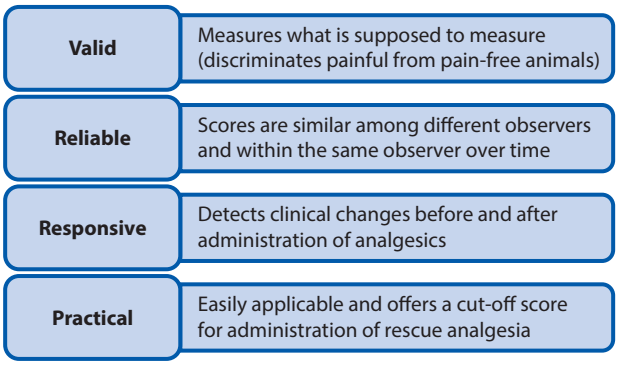

FIGURE 24.11 Using a validated pain scales means that rigorous scientific methods were undertaken to ensure that the scale is valid, reliable, responsive, and practical.

- *Melbourne Pain Scale* (MPS): The maximum score is 27; no cutoff score is available. Available in the original article (32).
- The Colorado State University Canine Acute Pain Scale has not undergone formal scientific validation. Other validated tools should be preferred until further information is available.

Acute pain scales for cats

- *Feline Grimace Scale* (FGS): Based on changes in facial expression (ear position, orbital tightening; muzzle tension; whisker position; head position) (**Figure 24.10**). The maximum score is 10; the cutoff score for administration of rescue analgesia is ≥ 4/10. The FGS has been validated for use by veterinarians, veterinary technicians, veterinary students, and cat owners. Available at www.felinegrimacescale.com.
- *UNESP–Botucatu Cat Pain Scale* (UCAPS): The maximum score is 12; the cutoff score for administration of rescue analgesia is ≥ 4/12. Available at www.animalpain.org.
- *Glasgow Composite Measure Pain Scale–Feline* (CMPS-Feline): The maximum score is 20; the cutoff score for administration of rescue analgesia is ≥ 5/20. Available at www.newmetrica.com/acute-pain-measurement/.
- The Colorado State University Feline Acute Pain Scale has undergone reliability testing. Validity is yet to be demonstrated. Other validated tools should be preferred until further information is available.

Chronic pain scales for dogs

- *Canine Brief Pain Inventory* (CBPI): Developed for use in dogs with OA and bone cancer. Evaluates pain severity and pain interference with function. Available at https://www.vet.upenn.edu/research/clinical-trials-vcic/our-services/pennchart/cbpi-tool.
- *ACVS Canine Orthopedic Index* (COI): Developed for use in dogs with OA. Evaluates stiffness, gait, function, and quality of life. Available at https://www.vet.upenn.edu/research/clinical-trials-vcic/our-services/pennchart/canine-orthopedic-index.
- *Liverpool Osteoarthritis in Dogs* (LOAD): Developed for use in dogs with OA. Evaluates general mobility and mobility at exercise. Available at https://www.galliprantvet.com/us/en/coast-tools.
- *Canine Osteoarthritis Staging Tool* (COAST): Developed as a staging tool in which the dog and the joint are assessed in steps for determining the dog's COAST stage. Available at https://www.galliprantvet.com/us/en/coast-tools.

Chronic pain scales for cats

- *Feline Musculoskeletal Pain Screening Checklist* (Feline MiPSC): Developed to increase awareness of OA in cats and as a tool for screening of cats with OA-associated pain. Available at https://journals.sagepub.com/doi/full/10.1177/1098612X20907424.
- *Feline Musculoskeletal Pain Index* (FMPI): Developed for use in cats with OA. Evaluates mobility, ability to perform daily activities, and interaction with other pets and people. Available at https://cvm.ncsu.edu/research/labs/clinical-sciences/comparative-pain-research/clinical-metrology-instruments/.
- *Client-Specific Outcome Measure* (CSOM): Developed for use in cats with OA. Three activities particular to the cat and its home are chosen and evaluated over time. Available at https://cvm.ncsu.edu/research/labs/clinical-sciences/comparative-pain-research/clinical-metrology-instruments/.

PRINCIPLES OF PAIN MANAGEMENT

Failure to recognize and adequately treat pain can result in negative physiological effects and the development of peripheral and central sensitization (**Figure 24.12**).

Oligoanalgesia refers to the inadequate treatment of acute perioperative pain. This results in postoperative impedance of routine activities, increased stress and anxiety. In humans, oligoanalgesia in patients undergoing major surgery (limb amputation, thoracotomy, mastectomy, and orthopedic procedures) can lead to the development of persistent postsurgical pain. Understanding the principles of acute and chronic pain management assist the veterinarian in developing an effective analgesic regimen and prevent oligoanalgesia.

Prior to formulating an analgesic plan, key concepts should be considered which will dictate the type, route, and frequency of administration of the analgesic drug(s)

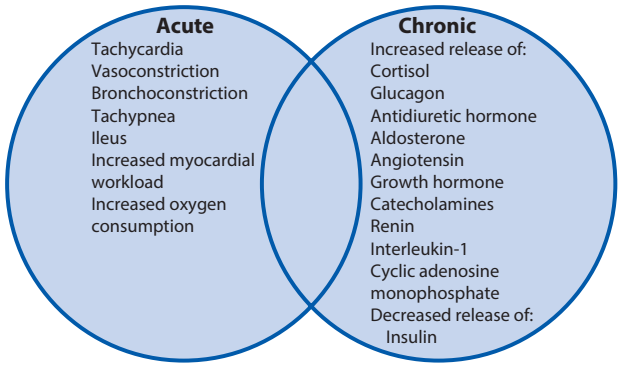

FIGURE 24.12 Acute and chronic effects of inadequately treated pain.

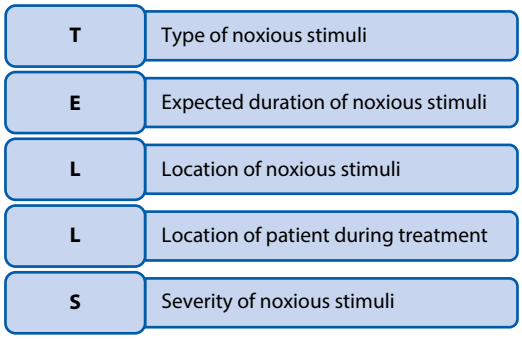

FIGURE 24.13 TELLS is an acronym used to describe the characteristics of a patient's pain and help formulate an analgesic plan (dose, frequency, type, and route of the analgesic drug).

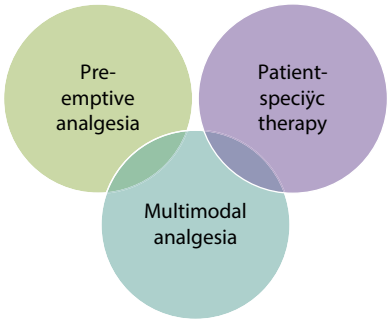

FIGURE 24.14 Fundamental principles of managing pain in dogs and cats.

(Figure 24.13). The analgesic plan should be focused around three fundamental principles (Figure 24.14). These practices involve the administration of various analgesic drugs and techniques to target multiple receptors involved in the pain pathway (i.e., mechanism-based therapy).

Pre-Emptive Analgesia

Pre-emptive analgesia involves the administration of an analgesic drug prior to surgical noxious insult (i.e., skin incision) to reduce or prevent nociceptive impulse transmission. This technique is generally more effective in reducing postoperative pain when compared to a similar dose of the same analgesic administered after the painful insult (i.e., pain pathway is already sensitized). Incorporating pre-emptive analgesic techniques in clinical practice can prevent peripheral and central sensitization, decreased intraoperative responses to noxious stimuli (i.e., increases in blood pressure, heart rate, respiratory rate, and purposeful movement), and prevent persistent postsurgical pain. It may also reduce the requirement for postoperative administration of opioids and its associated adverse effects. Clinical examples of pre-emptive analgesic techniques are described in Box 24.1.

Multimodal Analgesia

Multimodal (balanced) analgesia is the gold standard for pain control and refers to the use of two or more analgesic interventions, including pharmacological and nonpharmacological techniques with varying mechanisms of action (Figure 24.15).

Box 24.1 Techniques to employ pre-emptive analgesia in veterinary patients

- Administration of a pure μ-opioid receptor agonist as premedication prior to surgery
- Administration of coinduction agents with potential analgesic properties such as ketamine or lidocaine
- Performing local regional techniques (i.e., epidural, infiltrative line block, nerve block) with local anesthetics
- Oral administration of NSAIDs, tramadol, pregabalin, and/or gabapentin prior to surgery
- Transdermal administration of a buprenorphine or fentanyl patch 24–48 hours prior to surgery

The combination of different agents (e.g., α_2 adrenoreceptor agonists and opioids) can provide additive or synergistic analgesic effects resulting in improved perioperative comfort. It also allows for reduced doses of each individual analgesic agent, reducing the incidence and severity of adverse effects. Commonly used drugs in multimodal analgesic protocols include opioid receptor agonists, N-methyl-D-aspartate (NMDA) receptor antagonists, local anesthetics, α_2 adrenoreceptor agonists, NSAIDs, gabapentin, pregabalin, tramadol, and nonpharmaceutical adjuncts (e.g., electroacupuncture and physical rehabilitation). The combination of pre-emptive and multimodal analgesia provides the best benefit. Dosage recommendations for the most commonly used analgesics in dogs and cats are available on Table 24.1.

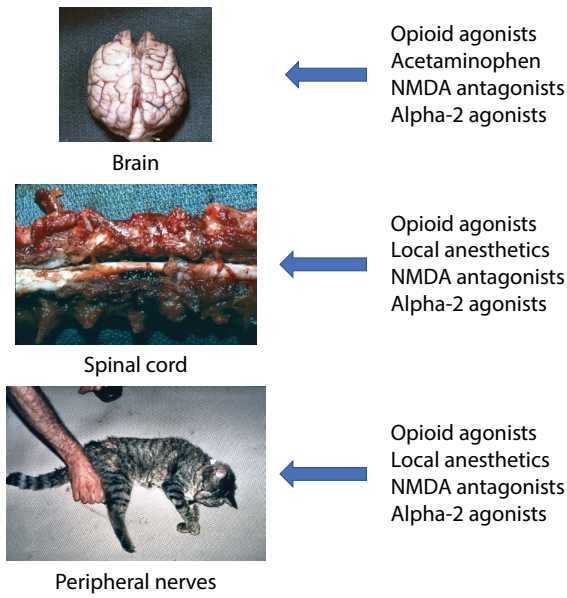

FIGURE 24.15 Multimodal (balanced) analgesia is the gold standard for pain control and refers to the use of two or more analgesic interventions, including pharmacological and nonpharmacological techniques with varying mechanisms of action. (*Courtesy of M. Schaer.*)

TABLE 24.1 Commonly used analgesic and adjuvant drugs in canine and feline pain management

	Dose	Species	Route of administration	Duration of effect	Comments
Opioids					
Morphine	0.3–1.0 mg/kg	Canine	IM, IV	3–4 hours	Caution with rapid IV administration: histamine release
	0.2–0.4 mg/kg	Feline	IM, IV	3–4 hours	
	0.2 mg/kg loading dose, then 0.1–0.5 mg/kg/hour	Canine	IV then CRI, administer bolus slowly		
	0.2 mg/kg loading dose, then 0.05–0.1 mg/kg/hour	Feline	IV then CRI, administer bolus slowly		
	0.1 mg/kg preservative free	Canine Feline	Epidural	12–24 hours	
	0.01 mg/kg preservative free	Canine Feline	Intrathecal	12–24 hours	
	0.1 mg/kg diluted to 0.5 mL/kg in sterile 0.9% saline	Canine	Intra-articular		
Meperidine	3–5 mg/kg	Canine Feline	IM, SC	1–2 hours	
Methadone	0.2–0.75 mg/kg	Canine Feline	IM, IV	2–4 hours	NMDA antagonist activity
Oxymorphone	0.05–0.2 mg/kg	Canine	IM, IV, SC	3–4 hours	Minimal histamine release
	0.03–0.1 mg/kg	Feline	IM, IV	3–4 hours	
Hydromorphone	0.05–0.2 mg/kg	Canine	IM, IV	2–4 hours	Emesis observed when administered IM Hyperthermia observed in cats
	0.025–0.1	Feline	IM, IV	2–4 hours	
Fentanyl	2–5 μg/kg initial dose, then 3–10 μg/kg/hour	Canine	IV then CRI		
	2–5 μg/kg initial dose, then 2–10 μg/kg/hour	Feline	IV then CRI		
Fentanyl patch	25 μg/hour	Canine (3–10 kg body weight)	Transdermal	1–3 days	12–24 hours to reach peak concentrations
	50 μg/hour	Canine (10–20 kg body weight)	Transdermal	1–3 days	
	75 μg/hour	Canine (20–30 kg body weight)	Transdermal	1–3 days	
	100 μg/hour	Canine (>30 kg body weight)	Transdermal	1–3 days	
	25–50 μg/hour	Feline		≤6 days	6 hours to reach peak concentrations
Remifentanil	6–20 μg/kg/h	Canine Feline	CRI		May induce hyperalgesia Ultra-short duration of action
Buprenorphine	0.01–0.04 mg/kg	Canine Feline	IM, IV, SC, OTM	4–8 hours	The IV and IM provide superior analgesia The SC route does not appear to provide adequate analgesia Inconsistent results after OTM administration

(*Continued*)

TABLE 24.1 Commonly used analgesic and adjuvant drugs in canine and feline pain management (*Continued*)

	Dose	Species	Route of administration	Duration of effect	Comments
Buprenorphine (high concentration 1.8 mg/mL)	0.24 mg/kg	Feline	SC	24 hours	Administer for up to three days
Tramadol	3–5 mg/kg	Feline	p.o.	8–12 hours	Seems to be effective in cats but not in dogs with OA
Alpha-2 agonists					
Dexmedetomidine 0.5 or 0.1 mg/ml	1–5 µg/kg	Canine	IM, IV	0.5–1.5 hours	Sedation, bradycardia, vomiting (cats) Consider lower doses when administered IV Only higher doses provide analgesia when used alone For medetomidine use twice the dosing recommendations made for dexmedetomidine
	1–10 µg/kg	Feline	IM, IV	0.5–1.5 hours	
	1 µg/kg, then 0.5–2 µg/kg/hour	Canine Feline	IV slowly over 10 minutes then CRI		
	1–5 µg/kg	Canine Feline	Epidural		
	2–5 µg/kg	Canine Feline	Intra-articular		
NMDA antagonists					
Ketamine	0.5–1 mg/kg, then 0.2–1 mg/kg/hour	Canine Feline	IV then CRI		
Amantadine	3–5 mg/kg	Canine Feline	p.o.	12–24 hours	Chronic painful conditions with a neuropathic pain component
Methadone	0.1–0.5 mg/kg	Canine Feline	IM, IV	2–4 hours	Opioid derivative
Tricyclic antidepressant					
Amitriptyline	1–4 mg/kg	Canine Feline	p.o.	12–24 hours	Chronic painful conditions Avoid combining to serotoninergic drugs
Ca^{2++} channel modulator					
Gabapentin	5–10 mg/kg	Canine Feline	p.o.	8–12 hours	Higher doses are anecdotally used Dose is limited by the amount of sedation observed
Local anesthetics					
Lidocaine (1–2%)	≤6.0 mg/kg	Canine	Perineural	1–2 hours	Onset 10–15 minutes Maximum dose: 12 mg/kg (canine), 6 mg/kg (feline)
	≤3.0 mg/kg	Feline	Perineural	1–2 hours	
	2–4 mg/kg, then 25–80 mcg/kg/minute	Canine	IV then CRI		Caution as a CRI in cats due to the cardiovascular depressant effects
	05–1 mg/kg, then 10–40 mcg/kg/minute	Feline	Slow IV then CRI		
Bupivacaine (0.25–0.5%)	≤2.0 mg/kg	Canine	Perineural	2–6 hours	Onset 20–30 minutes Maximum dose: 2 mg/kg (canine or feline)
	≤1.0 mg/kg	Feline	Perineural	2–6 hours	
Liposome encapsulated bupivacaine (13.3 mg/mL Nocita®)	0.4 mL/kg	Canine Feline	Infiltration	72 hours	Can dilute 1:1 with sterile 0.9% saline or Lactated Ringer's Solution

(*Continued*)

TABLE 24.1 Commonly used analgesic and adjuvant drugs in canine and feline pain management (*Continued*)

	Dose	Species	Route of administration	Duration of effect	Comments
Mepivacaine (1–2%)	≤6.0 mg/kg	Canine	Perineural	2–2.5 hours	
	≤3.0 mg/kg	Feline	Perineural	2–2.5 hours	
Non-steroidal anti-inflammatory drugs (NSAIDs)					
Carprofen (injectable and tablet)	4.4 mg/kg	Canine	SC or p.o.	24 hours	
Deracoxib (tablet)	1–4 mg/kg	Canine	p.o.	24 hours	
Firocoxib (tablet)	5 mg/kg	Canine	p.o.	24 hours	
Meloxicam (injectable, tablet or oral suspension)	0.2 mg/kg once followed by 0.1 mg/kg	Canine	IV, SC, p.o.	24 hours	
Meloxicam (injectable or oral suspension)	0.2–0.3 mg/kg once followed by 0.05–0.1 mg/kg	Feline	SC, p.o.	24 hours	Palatable oral suspension Lower doses (0.02–0.05 mg/kg) are used long-term in cats with chronic pain
Robenacoxib (injectable and tablet)	2 mg/kg	Canine	SC, p.o.	24 hours	
Robenacoxib (injectable and tablet)	1–2.4 mg/kg	Feline	SC, p.o.	24 hours	Lowest effective dose in long-term treatment
Cannabinoids					
CBD oil	2 mg/kg	Canine	p.o.	12 hours	
Adjunctive drugs frequently administered with analgesics					
Acepromazine	0.005–0.05 mg/kg	Canine	IM, IV, SC	8–12 hours	No intrinsic analgesic properties, but used to potentiate or prolong analgesic drugs
	0.01–0.1 mg/kg	Feline	IM, SC	8–12 hours	
Midazolam	0.1–0.2 mg/kg	Canine Feline	IV	2–4 hours	No intrinsic analgesic properties, but used to potentiate or prolong analgesic drugs
	0.25–1.0 mg/kg	Canine Feline	p.o.	12–24 hours	

Patient-Related Factors

Patient-specific therapy has gained popularity in veterinary medicine. Individual variation in drug responses can lead to unforeseen toxicity or failure to respond to therapy. For example, genetic polymorphisms of metabolizing enzymes in dogs have significant clinical implications in opioid drug metabolism, duration of effect, and oral bioavailability. As we further understand the intricacies of veterinary pharmacogenetics, there is potential to better predict dosage regimens, improve perioperative analgesia, and reduce the incidence of adverse effects. Patient-specific therapy also includes the concept that "not one size fits all," and standardized protocols should be avoided. In a broader sense, analgesics effective in cats may not provide the same degree of pain relief in dogs. As observed with the administration of oral tramadol, evidence supports its efficacy as a sole analgesic agent in cats but not in dogs. The patient's medical history, physical exam, and diagnostic results should be used to dictate and appropriate analgesic regimen. Emphasis should be placed on reviewing the patient's hepatic, renal, cardiopulmonary and neurologic status, behavior, current and predicted degree of pain, age, species, and breed. For example, an ovariohysterectomy in a geriatric canine patient with

several comorbidities may not receive the same analgesic protocol as an adolescent healthy cat undergoing the same procedure.

The duration of pain (acute versus chronic) impacts prescribing methods. Administration methods for sustained pain relief include transdermal patches (e.g., fentanyl or buprenorphine patch); sustained-release, liposomal encapsulated (Nocita™); high-concentration (Simbadol™) or oral formulations; constant rate infusions; or lumbosacral and peripheral nerve catheters. Additionally, the choice of analgesic is largely influenced by pain severity. In mild-to-moderate pain, an opioid such as buprenorphine may be effective for pain relief; however, with severe pain, a potent opioid receptor agonist such as fentanyl may be required. The site or origin of the noxious stimuli is also important, particularly when performing locoregional techniques. The administration of local anesthetics is extremely effective in treating acute and chronic pain if (1) the anesthetist can determine the noxious stimuli's site of origin and (2) is familiar with anatomy associated with locoregional anesthesia.

Hospital-Related Factors

Management of pain is also impacted by hospital-related factors (Figure 24.16). The frequency and route of analgesic administration depends on the hours of service of the hospital. If a patient needs to be discharged prematurely due to lack of overnight staff or left unattended throughout the night, practitioners need to rely on longer-lasting oral, sustained-release, or transdermal analgesic drugs, whereas in hospitals with continuous 24-hour service, constant rate infusions (CRI) or parenteral therapy might be preferred. It is also crucial that the hospital staff is available and educated for appropriate pain assessment and management. Globally, 39%–77% of veterinarians acknowledge their ability to identify pain is inadequate. This deficiency in knowledge creates a "domino effect" on to those expected to learn from them (e.g., veterinary technicians and staff members).

Hospital-related stress has important implications in pain management (Figure 24.17). It can result from noncyclic and artificial lighting, excessive noise, nonfamiliar (e.g., disinfectants, medications, humans) and animal-emitted (e.g., anal gland secretions, pheromones) scents, extremes in temperature, unfamiliar or uncomfortable housing, proximity to unfamiliar animals, interrupted sleep, fear, and pain. Alterations in the levels of dopamine, oxytocin, and endogenous opiates as observed during stress can distort the normal responses to pain masking the ability of a veterinarian to assess pain. Chronic stress also can contribute to the development of hyperalgesia and reduced efficacy of opioid analgesics. Furthermore, stress has the ability to weaken and disrupt the gastrointestinal (GI) system resulting in visceral pain. Painful patients experiencing stress often require higher analgesic doses than those that are stress-free, with the former increasing the incidence for drug-related adverse effects and complications. Strategies to reduce stress, fear, and anxiety can lead to reduction in analgesic requirements.

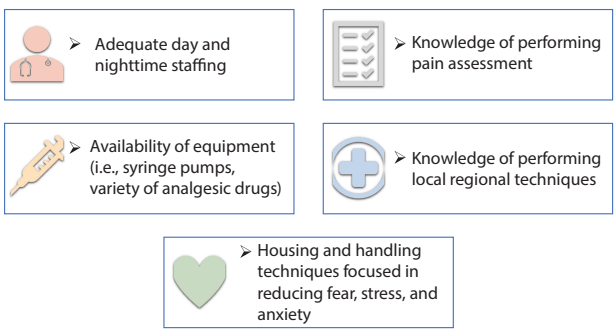

FIGURE 24.16 Hospital-related factors impacting pain management.

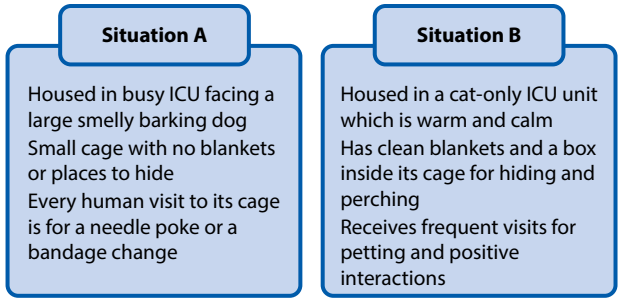

FIGURE 24.17 Stress and patient care can influence pain perception. Imagine the same cat after a fracture repair with the same analgesic protocol in situation A or B. Certainly, in situation B, the cat is more comfortable, feels safer, and is less fearful, anxious, and stressed. Pain perception is thus decreased, and the cat is more likely to be in a positive mental state contributing to its welfare during hospitalization.

LOCAL ANESTHETICS

Local anesthetics are one of the most versatile classes of drugs when treating pain and are used to treat somatic, visceral, and neuropathic pain during acute and chronic states. This versatility can be attributed to the variety of routes, formulations, and concentrations in which they can be administered. Administration by the IV (lidocaine only), epidural, intrathecal, transdermal, infiltrative, perineural, and topical routes can produce analgesia in dogs and cats. Several formulations and concentrations are available for veterinary use depending on the duration and severity of pain.

Local anesthetics prevent the nociceptive impulse from reaching the spinal cord (depolarization and propagation) via nonselective blocking of voltage-gated sodium channels located within nerve fibers. Local regional techniques in dogs and cats are discussed in detail elsewhere (see Recommended Further Readings). Lidocaine, bupivacaine, mepivacaine, or ropivacaine are most commonly used.

Adverse effects are dependent on systemic absorption and plasma concentrations. Generally, central nervous system signs are observed first (e.g., agitation, muscle twitching, seizures, and/or convulsions). Cardiovascular adverse effects may include hypotension, myocardial

depression, and arrythmias. At high plasma concentrations, unconsciousness, apnea, cardiovascular collapse, and death may occur.

Local Anesthetics at-a-Glance

Lidocaine (1% or 2% concentrations)

- The most versatile local anesthetic as it can be administered topically, intravenously, epidurally, subcutaneously, and perineurally.
- Onset 5–10 minutes, and duration is typically 1–3 hours.
- Also possesses anti-inflammatory and antiarrhythmic properties.
- Can be administered as a CRI to help prevent central sensitization and treat perioperative pain associated with orthopedic and abdominal procedures, particularly when combined with opioids and NMDA receptor antagonists.
- May cause significant reductions in cardiac output when administered as a CRI in cats. Consider using lower dosages (35–50 mcg/kg/min) in multimodal analgesic protocols and monitor blood pressure closely.
- Transdermal 5% lidocaine patches are commercially approved for humans. Pharmacokinetic studies in dogs and cats suggest highly variable absorption rates with limited adverse effects. Evidence to support their analgesic efficacy when placed over the surgical incision has yet to be confirmed. Veterinarians should not rely on 5% lidocaine patches as a sole postoperative analgesic in dogs and cats.

Mepivacaine (1% or 2% concentrations)

- Similar onset to lidocaine but with a longer duration of action of 2–4 hours.
- Less commonly used in small animal practice.
- Not recommended for intravenous administration.

Bupivacaine (0.125%–0.75% concentrations; 0.5% is the most commonly used)

- Slower onset of action of 20–30 minutes but with a longer duration of action of 6–8 hours.
- Not recommended for intravenous administration.
- More cardiotoxic than lidocaine.
- Frequently used for nerve blocks and neuraxial anesthesia.
- Available in a variety of concentrations which can allow for differential blockade (i.e., sensory anesthesia without motor blockade when using bupivacaine concentrations <0.25%).

Ropivacaine (0.25%–0.75% concentrations)

- Similar onset and duration of action when compared to bupivacaine.
- Lower potential for inducing cardiovascular and central nervous system toxicity.
- At concentrations similar to bupivacaine (0.5%), it has a reduced chance of inducing motor blockade, making it optimal when neuraxial anesthesia is recommended.
- Not recommended for intravenous administration.

FIGURE 24.18 An infiltrative local anesthetic block using Nocita™ along an incision. (*Courtesy of Irina Yankin.*)

Bupivacaine liposome injectable suspension (Nocita™ 13.3 mg/mL)

- Doses of 5.3 mg/kg in dogs and 10.6 mg/kg in cats.
- Currently approved for local infiltration into the surgical site following cranial cruciate ligament surgery in dogs and for peripheral nerve block for regional analgesia following onychectomy in cats (Note: Onychectomy is not advocated by the authors or Nocita).
- Provides up to 72 hours of analgesia.
- Onset of action generally occurs within 15–20 minutes following administration.
- Administered as an infiltrative locoregional block in a variety of surgeries at the site of surgical incision in dogs and cats during tissue closure (Figure 24.18).
- Should not be combined with other local anesthetics or hypotonic solutions as this can disrupt the liposomal particles causing systemic toxicity.
- Can administer up to 0.4 mL/kg of Nocita™. If more volume is required to cover the surgical area, combine with an equal volume of sterile 0.9% saline or lactated Ringers solution.

Eutectic mixture of local anesthetics (EMLA®) cream

- 2.5% lidocaine and 2.5% prilocaine (Figure 24.19a).
- Topical anesthetic used to desensitize mucous membranes or intact clean bare skin.
- Facilitates procedures such as intravenous catheter placement, small surgical incisions (e.g., skin cutdown to the jugular vein performed during noninvasive cardiac procedures), and thoracentesis (Figure 24.19b).

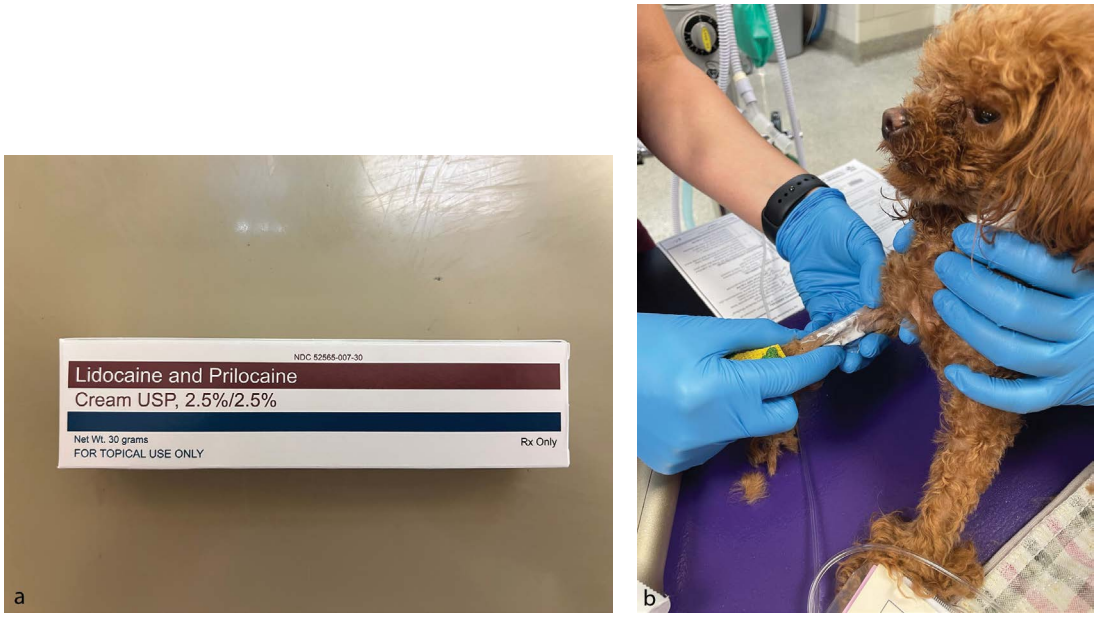

FIGURE 24.19 The eutectic mixture of local anesthetics (EMLA®) cream **(a)** is applied over the shaved skin and covered for 15–20 minutes before asepsis. Local anesthesia of the skin facilitates venous catheterization in anxious/fearful dogs and cats **(b)**.

OPIOIDS

Opioid analgesics are effective in the management of visceral, oncologic, somatic, and neuropathic pain in dogs and cats. They are reliable and efficacious analgesics, considered relatively safe, and have the benefit of reversibility. Adverse effects following opioid administration are generally mild and most often easily managed (Figure 24.20 and Table 24.2).

Opioid analgesics have been readily available for general veterinary use until recently. Recent shortages were a sequala of production quota reductions associated with the global opioid crisis, particularly with pure μ-opioid receptor agonists, set forth by the Drug Enforcement Agency. The national opioid crisis has hindered veterinarians' ability in prescribing opioids; however, it has strengthened our understanding and confidence in utilizing multimodal analgesic techniques.

Urinary retention (neuraxial morphine)	**Vomiting** (morphine and hydromorphone)	**Gastrointestinal Ileus**
Pruritis (neuraxial morphine)	**Hypoventilation**	**Hyperthermia** (hydromorphone most common)
Histamine reaction (intravenous morphine or meperidine)	**Bradycardia**	**Euphoria or dysphoria**

FIGURE 24.20 Adverse effects associated with opioid analgesics.

Opioids bind to opioid receptors in the central and peripheral nervous system, resulting in decreased release of excitatory neurotransmitters (presynaptic terminals) and hyperpolarization of neuronal membranes (postsynaptic terminals), reducing the propagation of nociceptive stimuli. There are three main types of opioid receptors responsible for analgesia: μ, κ, and δ. Pure μ-opioid receptor agonists yield a dose-dependent intensification in effect until maximum stimulation of the receptors is achieved. Partial μ-opioid receptor agonists yield a dose-dependent response that plateaus at an effect less than that observed with pure μ-opioid receptor agonists (Figure 24.21). Generally, opioids can be classified as pure μ-opioid receptor agonists, partial μ-opioid receptor agonists, or μ-mixed opioid receptor agonists/antagonists.

Opioid versatility is in part attributed to their routes of administration: Intravenous (IV), subcutaneous (SC), intramuscular (IM), sublingual, oral, intrathecal, epidural, perineural, transdermal, and intraarticular. Intravenous administration provides the most rapid onset and least variation in analgesic efficacy. Subcutaneous route is considered less painful than IM at injection; however, in cats, greater individual variations and reduced analgesic efficacy was observed with SC administration of hydromorphone or standard concentration buprenorphine (0.3 mg/mL). Vomiting is more commonly observed following hydromorphone and morphine administration via IM and SC than the IV route.

The sublingual route requires minimal restraint and administration is pain-free. It bypasses first-pass metabolism allowing for higher systemic bioavailability when compared to oral administration. Buprenorphine (0.01–0.02 mg/kg) or methadone (0.6 mg/kg) can be

TABLE 24.2 Adverse effects following opioid administration and their suggested treatment

Opioid	Adverse effect	Treatment
Hydromorphone Morphine	Vomiting	– Maropitant 1 m/kg SC or IV 30–60 minutes prior to opioid in dogs and cats – Maropitant 2–4 mg/kg p.o. 2 hours prior or 8 mg 2.5 hours prior to opioid in dogs or cats, respectively – Metoclopramide 0.2 mg/kg IM or 0.5 mg/kg SC 30–45 minutes prior to opioid in dogs – Acepromazine 0.05 mg/kg IM 15 minutes prior to opioid
Morphine	Urinary retention following epidural or spinal administration	– Gentle bladder expression – Urinary catheter placement – Bethanechol 2.5–5 mg p.o. q.8–12 h in dogs or cats – Naloxone generally is not effective for opioid induced urinary retention
	Histamine (IV administration)	– Diphenhydramine 2 mg/kg IV or p.o. q.8 h as needed – Supportive therapy as needed
	Pruritis following epidural or spinal administration	– Ondansetron 0.1–0.2 mg/kg IV q.12 h as needed
All opioids (specifically pure μ-opioid receptor agonists)	Hypoventilation	– Administer positive pressure ventilation – Naloxone reversal 0.01–0.04 mg/kg IV slowly to effect in dogs and cats – Maintain an end-tidal CO_2 of 35–45 mmHg
	Bradycardia	– Atropine 0.02–0.04 mg/kg IV in dogs and cats – Glycopyrrolate 0.01–0.02 mg/kg IV in dogs and cats
	Hyperthermia (cats)	– Naloxone reversal 0.01–0.04 mg/kg IV slowly to effect – Supportive therapy as needed
	Ileus (chronic administration)	– Reduce opioid dose and frequency – Consider multimodal analgesic therapy

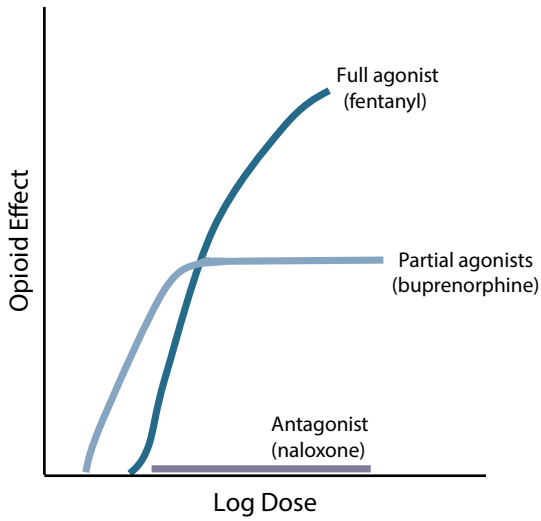

FIGURE 24.21 Dose-response curves for full and partial μ-opioid receptor agonists and a full μ-opioid receptor antagonist.

administered by the sublingual route in cats. Systemic absorption following sublingual administration is dependent on oral mucosal pH, which might be altered with infection or inflammation in cats with stomatitis and impact opioid systemic absorption. In dogs, sublingual buprenorphine provides analgesia; however, high doses are required (0.12 mg/kg), which could be cost prohibitive and result in excessive volumes, increasing the likelihood for accidental swallowing and loss through hypersalivation. Despite the sublingual route's ease of administration and practicality, it has been reported to provide less perioperative analgesia when compared to the IV and IM route in cats.

Epidural or intrathecal administration of opioids is effective in treating somatic and visceral pain without interfering with sensory or motor function or the sympathetic nervous system. Neuraxial morphine's prolonged duration of effect is attributed to long residence time in the cerebrospinal fluid and delayed systemic absorption within the vertebral canal. Urinary retention has been reported following the epidural administration of morphine in dogs but not following buprenorphine.

Opioid receptors have been identified within intra-articular and periarticular inflamed tissue following experimentally induced arthritis in dogs. Minimal adverse effects are reported via this route when administered aseptically.

Transdermal opioid patches are used for pain management in dogs and cats for up to 72–96 hours. Fentanyl patches can be incorporated into multimodal analgesic perioperative protocols, particularly when CRIs or overnight hospitalization are not available. They can also be added to chronic pain management protocols when oral analgesic and anti-inflammatory agents are not adequate. The onset of transdermal fentanyl is delayed and often requires a minimum of 12 or 24 hours of application prior to providing analgesia in cats and dogs, respectively. Significant variability in drug plasma concentrations were reported when using fentanyl patches in these species. Evidence of efficacy of transdermal buprenorphine patches in small animals are lacking.

Oral administration of opioids produces poor bioavailability (20%–60%), large individual variability, and limited analgesic efficacy in dogs. There is limited evidence to support the oral administration of opioids such as codeine, oxycodone, or hydrocodone in dogs or cats.

Opioids at-a-Glance

Pure μ-Opioid Receptor Agonists

Morphine

- Duration of analgesia 2–4 and 4–6 hours in dogs and cats, respectively, via traditional routes (e.g., IV, IM, SC).
- Onset and duration of analgesia is within 40 minutes and up to 24 hours, respectively, when administered via the epidural (0.1 mg/kg) or spinal route (0.01 mg/kg).
- May provide a greater degree of sedation than other pure μ-opioid receptor agonists due to its agonistic effects on the κ-receptor.
- Can be administered as a CRI with low incidence of hypersensitivity reactions in dogs and cats.
- Intraarticular administration (0.1 mg/kg diluted to 0.5 mL/kg in sterile 0.9% saline) can be used as part of a multimodal analgesic technique following orthopedic procedures.

Hydromorphone

- Duration of analgesia 2–6 and 4–6 hours in dogs and cats, respectively, via traditional routes.
- Age affects hydromorphone-induced antinociception; shorter duration (< 1 hour) and reduced magnitude of antinociception was recorded in cats 6 months of age when compared to 12 months.
- Contributes to opioid-induced hyperthermia in cats. Incidence is increased with intraoperative hypothermia and ketamine and inhalant anesthetics administration.

Methadone

- Duration of analgesia 3–4 and 4 hours in dogs and cats, respectively, via traditional routes.
- May serve as a weak NMDA receptor antagonist; useful in central sensitization, chronic pain, and opioid-induced hyperalgesia.
- Low incidence of vomiting and nausea.

Oxymorphone

- Duration of analgesia 2–4 and 4–6 hours in dogs and cats, respectively, via traditional routes.
- Low incidence of vomiting and nausea.
- Expense and availability have limited its use in the United States.

Meperidine (pethidine)

- Duration of analgesia 1–2 hours in dogs and cats when administered IM.
- Produces significant histamine release when administered IV.
- Anticholinergic effects resulting in increases in heart rate.

Fentanyl

- Short duration of analgesia, 1–2 hours, in dogs and cats when administered as an IV bolus.
- Recommended as a CRI.
- Caution with the accumulation of plasma fentanyl concentrations following prolonged infusions (> 3 hours).
- Induces more pronounced cardiopulmonary adverse effects when compared to other μ-opioid receptor agonists.

Remifentanil

- Short duration of analgesia (< 10 minutes) due to its metabolism via plasma cholinesterases; recommended as a CRI.
- May cause opioid-induced hyperalgesia; however, a one-time dose of a NMDA receptor antagonist immediately prior to its administration may prevent this occurrence.
- May induce profound bradycardia.

Partial μ-Opioid Receptor Agonists

Buprenorphine

- Standard formulation/concentration (0.3 mg/mL) provides up to 6–12 hours of analgesia in dogs and cats via traditional routes.
- High concentration buprenorphine (Simbadol™ 1.8 mg/mL) provides up to 24 hours of analgesia when administered SC in cats.
- Slow onset of analgesic action (30–60 minutes); provides less analgesia when compared to pure μ-opioid receptor agonists (ceiling effect).
- Sublingual and SC (excluding Simbadol™) routes produce unreliable analgesia in cats.
- Strong affinity for the μ-opioid receptor and may be difficult to displace from the μ-receptor.
- Reduced adverse effects when compared to pure μ-opioid receptor agonists.
- Has been used in conjunction with bupivacaine for perineural injections at 0.003–0.004 mg/kg. May prolong the duration of analgesia (> 24 hours) of local anesthetics following infraorbital nerve blocks in dogs.
- Epidural buprenorphine (0.005 mg/kg) provides similar duration of analgesia as morphine with less adverse effects (e.g., urinary retention).

Mixed Opioid Receptor μ-Antagonist/κ-Agonists

Butorphanol

- Evidence supports butorphanol as a very weak μ-agonist rather than a μ-opioid receptor antagonist.
- Weak analgesic and not recommended for the management of acute or chronic pain.
- Duration of analgesia 1–2 hours in dogs and cats.
- Useful as a reversal agent (0.02–0.1 mg/kg) for pure μ-opioid receptor agonists.

ALPHA-2 ADRENOCEPTOR AGONISTS

Alpha-2 adrenoceptor agonists are incorporated into multimodal analgesic protocols in acutely painful patients and in the attenuation or reversal of allodynia in patients with neuropathic or opioid-resistant pain. Dexmedetomidine and medetomidine are the most common α_2 agonists used in small animal practice. Dexmedetomidine is the dextrorotary enantiomer of the racemic mixture medetomidine and has replaced medetomidine in the United States. Dexmedetomidine (0.5 mg/mL) is approximately twice as potent as medetomidine (analgesic and sedative effects). This concentration allows clinicians to use the same injection volume as medetomidine. A 0.1 mg/mL concentration of dexmedetomidine is available for smaller patients.

High doses (e.g., 40 mcg/kg dexmedetomidine IM or sublingual) are required to provide analgesia when administered as the sole analgesic, which may lead to cardiopulmonary depression and morbidity and mortality in critically ill patients. In clinical practice, the authors administer dexmedetomidine CRI (0.5–2 mcg/kg/h) in a multimodal approach. Sedation is observed at lower plasma concentrations than those required for analgesia. Therefore, sedation in dogs and cats following the administration of dexmedetomidine or medetomidine does not correlate with analgesia.

Alpha-2 adrenoceptor agonists provide enhanced or synergistic analgesic and sedative effects when combined with opioids due to the simultaneous activation of opioid receptor subtypes and α_2 adrenoreceptors. With traditional parenteral routes, dexmedetomidine's and medetomidine's duration of analgesia is approximately 60 minutes. When opioids are unavailable, α_2 adrenoreceptor agonists can be administered with ketamine, NSAIDs, and locoregional techniques to provide adequate perioperative multimodal analgesia.

Alpha-2 adrenoceptor agonists bind to α_2 receptors located in the cerebral cortex, brain stem, and spinal cord, resulting in dose-dependent sedation, muscle relaxation, and spinal and supraspinal analgesia. The mechanism of analgesia involves (1) presynaptic and postsynaptic inhibition in the spinal cord dorsal horn, resulting in reduced membrane depolarization and enhanced hyperpolarization; (2) direct inhibition of noradrenaline release; (3) depolarization of descending noradrenergic pathways; (4) peripheral analgesic effect via inhibition of pain transmission within Aδ and C fibers; and (5) local analgesic effect via stimulation of α_2 receptors.

Dexmedetomidine can be administered via the IV, IM, SC, sublingual, perineural, and epidural routes. It is well absorbed through the oral mucosa (doses required to provide antinociception are similar to the IM route). There is limited literature regarding the neuraxial administration of dexmedetomidine and medetomidine in small animals. Epidural dexmedetomidine (4 mcg/kg) combined with bupivacaine (1 mg/kg) provided similar postoperative analgesia when compared to epidural morphine (0.1 mg/kg) and bupivacaine (1 mg/kg) in dogs undergoing orthopedic procedures; time to return to normal hindlimb motor function was delayed. Medetomidine (10 mcg/kg) may produce dose-dependent antinociception when administered epidurally in dogs for up to 90 minutes. Epidural administration of α_2 adrenoreceptor agonists may still result in dose-dependent mild-to-moderate cardiovascular changes; caution should be taken in critically ill patients. Veterinarians should also avoid contamination of multiuse nonpreservative-free vials when performing neuraxial administration. Dexmedetomidine (0.1 mcg/kg or 1 mcg/mL of local anesthetic) and medetomidine (0.01 mg/kg) have been administered with local anesthetics to prolong the latter's duration of sensory blockade (reduced systemic absorption of local anesthetics through local vasoconstriction). The authors administer dexmedetomidine with bupivacaine in thoracic limb, pelvic limb and dental nerve blocks, and intraperitoneally.

Adverse effects are dose-dependent but can be significant in compromised patients (Box 24.2). Atipamezole can be administered IV slowly (half the original volume of dexmedetomidine) or IM (equal to the original volume of dexmedetomidine) to reverse the behavioral effects associated with dexmedetomidine (0.5 mg/mL). Administration of atipamezole has not been shown to reverse the unwanted cardiovascular effects associated with dexmedetomidine in cats. Administration of atipamezole should be one-fifth the original volume of the low-concentration (0.1 mg/mL) dexmedetomidine.

Box 24.2 Adverse effects associated with α_2 adrenoreceptor agonists in dogs and cats (adverse effects are dose-dependent and exacerbated when administered with opioid analgesics)

- Sedation
- Vagal-induced bradyarrhythmias (first- and second-degree atrioventricular heart block)
- Biphasic blood pressure response (hypertension followed by hypotension)
- Hyperglycemia via suppression of insulin release
- Reduced packed cell volume
- Diuresis due to decreased antidiuretic hormone
- Mild reduction in respiratory rate (dogs greater than cats)
- Vomiting via stimulation of the chemoreceptor trigger zone in dogs and cats (up to 20% and 90% incidence, respectively)

Alpha-2 Adrenoceptor Agonists at-a-Glance

Dexmedetomidine/medetomidine

- Dose-dependent sedation and analgesia.
- Enhances the analgesic efficacy of opioids.
- May be beneficial in patients with neuropathic pain.
- Analgesia is observed at higher plasma concentrations than those producing sedation.
- Not recommended as a sole analgesic agent.

- Reversal of dexmedetomidine with atipamezole may not alleviate the negative effects on heart rate and blood pressure in cats.
- Caution with the administration of anticholinergics during the initial cardiovascular phase (bradycardia, peripheral vasoconstriction) of α_2 adrenoreceptor agonists because of significant hypertension.
- Caution in patients with significant systemic cardiovascular disease.
- Can be administered via a variety of routes (e.g., IV, IM, SC, sublingual, perineural).

N-METHYL-D-ASPARTATE (NMDA) RECEPTOR ANTAGONISTS

NMDA receptor antagonists are becoming increasingly popular for the management of pain in dogs and cats. In humans, it is incorporated into multimodal analgesic protocols when treating acute, chronic, and neuropathic pain. The NMDA receptor plays a critical role in the development of central sensitization or "wind-up" pain. The efficacy of NMDA antagonists is enhanced when administered preemptively in dogs undergoing surgery. In cats, NMDA receptor antagonists have been effective when used as an adjunct analgesic agent to treat neuropathic pain, hyperalgesia, and allodynia. Ketamine, the most common NMDA receptor antagonist used in veterinary medicine, exerts its action at several sites within the central nervous system. Its primary mode of action is via noncompetitive antagonism of NMDA receptors preventing the binding of glutamate. Other mechanisms involve opioid receptors (μ, κ, δ), nicotinic and muscarinergic receptors, monoaminergic receptors, and sodium, potassium, and calcium channels. Amantadine, an oral antiviral agent and NMDA-receptor antagonist, is used as an adjuvant for management of chronic pain in dogs and cats. However, few clinical studies evaluating its efficacy are available.

Ketamine can be administered via the IV, IM, SC, or neuraxial route; however, it is most commonly administered as a CRI due to its short analgesic duration of action. A ketamine bolus of 0.5–1 mg/kg immediately followed by a CRI of 30 or 50 mcg/kg/min results in a transient (20 minutes following discontinuation of CRI) increase in mechanical antinociception in dogs. At these doses, plasma ketamine concentrations are maintained between 100 and 200 ng/mL, which is required when administered as an analgesic agent. Adverse psychomimetic effects may occur at these doses, but the duration is short lived (< 20 minutes) following ketamine's discontinuation. Ketamine's ability in providing adequate visceral analgesia has been questioned. In dogs, a ketamine CRI of 40 mcg/kg/min following a 1 mg/kg IV bolus did not result in adequate postoperative analgesia in dogs undergoing ovariohysterectomy. However, a preemptive ketamine CRI (50 mcg/kg/min) combined with a lidocaine CRI (100 mcg/kg/min) enhanced the attenuation of central sensitization and improved perioperative analgesia in a canine ovariohysterectomy model.

Low-dose ketamine infusions have been suggested as part of multimodal analgesic CRI regimens. These low doses may enhance the degree of analgesia with reduced adverse effects (e.g., dysphoria). For example, dogs undergoing forelimb amputations administered a fentanyl and low-dose ketamine CRI intraoperatively (10 mcg/kg/min) and for 18 hours postoperatively (2 mcg/kg/min) had lower pain scores and were more active when compared to those receiving only fentanyl. When administered as a sole agent to conscious dogs, a low-dose ketamine CRI (10 mcg/kg/min following a 0.5 mg/kg IV bolus) did not produce adequate plasma concentrations to provide antinociception (<100 ng/mL). Similar results were found in cats administered a 5 or 23 mcg/kg/min CRI of ketamine. At these doses, caution when used as a sole analgesic agent.

Ketamine has also been used successfully as an adjunct agent in protocols when opioids are not readily available. In these circumstances, NSAIDS and local regional blocks are also recommended. Ketamine infusions are also effective in treating central sensitization or wind-up pain. For example, a ketamine CRI of 10 mcg/kg/min used in conjunction with several other analgesic and anti-inflammatory agents was effective in managing a feline patient which developed severe neuropathic pain due to trauma.

Ketamine

- Used for the treatment of neuropathic pain and central sensitization.
- More effective as a pre-emptive analgesic.
- Generally recommended as a CRI.
- Evidence is lacking regarding its effectiveness in managing visceral pain.
- Low-dose ketamine infusions are good alternative when used in multimodal regimens when opioids are not readily available.
- Adverse psychomotor effects may have confounding effects on some pain scales leading to erroneous administration of rescue analgesia.

Amantadine

- Limited adverse effects when administered orally at 3–5 mg/kg q.12–24 h.
- May be useful in dogs with osteoarthritic pain refractory to NSAID therapy.
- Improved owner-identified mobility and owner-perceived quality of life in cats with OA at 5 mg/kg q.24 h.
- High-dose amantadine (~14 mg/kg) and meloxicam have been used to treat chronic neuropathic pain in a dog.
- Suitable drug for at-home chronic pain management with limited abuse potential.
- Limited clinical studies evaluating its efficacy in dogs and cats and, therefore, should not be used as a sole analgesic.

Methadone

- Considered a weak NMDA-receptor antagonist.
- Has been used to treat neuropathic pain and opioid-induced hyperalgesia in humans.
- See previous section on opioids.

Magnesium

- Inhibits calcium ions entering cells by blocking NMDA receptors.
- Has been administered in humans for the treatment of central sensitization and neuropathic and postoperative pain.
- Limited evidence to support its analgesic efficacy in small animals.
- Dosages (5–15 mg/kg IV bolus administered over 15 minutes followed by a CRI of 15mg/kg/h) are extrapolated from human studies.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs) AND OTHER ANTI-INFLAMMATORIES

Anti-inflammatory drugs act on different pathways of the arachidonic acid cascade (Figure 24.22). NSAIDs are the most widely used analgesics in veterinary medicine. Extensive research supports the safety and efficacy of contemporary NSAIDs for the management of acute and chronic pain in dogs and cats. They are excellent analgesics but have narrow safety margins. By inhibiting COX enzymes (COX-1 and COX-2), NSAIDs inhibit the production of prostaglandins, resulting in anti-inflammatory, analgesic, and antipyretic effects, as well as adverse-effects. Adverse effects are generally self-limiting and related to gastrointestinal signs. Provided that patient selection and monitoring are performed, most patients can be safely administered NSAIDs. Serious adverse effects usually result from inappropriate administration (e.g., higher than recommended doses, administration in close temporal association with corticosteroids or other NSAIDs, patients with unstable disease), although idiosyncratic events of acute liver toxicosis have been reported.

In acute pain management, NSAIDs should always be considered as part of a multimodal protocols ideally combined with opioids and local anesthetics. In healthy, normovolemic patients undergoing surgery, preemptive administration of NSAIDs is recommended for optimal efficacy. Provision of fluid therapy and monitoring of blood pressure are important. If significant bleeding, hypotension, or hypovolemia are risks, NSAIDs can be administered at the end of the procedure.

In chronic pain management, particularly OA, NSAIDs are the first line of analgesics used in combination with nonpharmacological analgesic strategies. As pain and dysfunction progresses, adjuvant analgesics

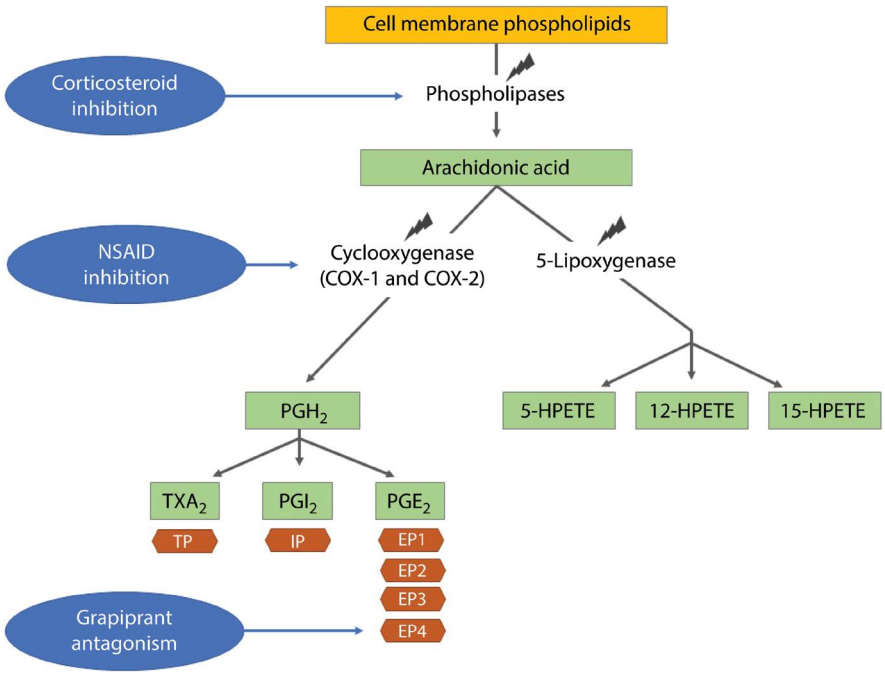

FIGURE 24.22 A simplified version of the arachidonic acid cascade with focus on cyclooxygenase (COX)-dependent prostaglandin production and points of various types of drug activity. Corticosteroids act by inhibiting the action of phospholipase enzymes early in the cascade. Nonsteroidal anti-inflammatory drugs (NSAIDs) act by inhibiting COX-1 and COX-2 enzymes with consequent inhibition of prostaglandin biosynthesis. Grapiprant is an antagonist of EP4 receptor. EP1–EP4, prostaglandin E2 receptor; HPETE, hydroperoxyeicosatetraenate; IP, prostacyclin receptor; PGE2, prostaglandin E2; PGH2, prostaglandin H2; PGI2, prostacyclin; TP, thromboxane receptor; TXA2, thromboxane. (*Reprinted from* Vet Clin North Amer Sm Anim Pract, *49, Monteiro and Steagall, Anti-inflammatory drugs, 993–1011, Copyright (2019). Reprinted with permission from Elsevier*.)

are added to the protocol. Client education and continuous monitoring are paramount.

Relative contraindications include history of gastrointestinal disease, NSAID intolerance, uncontrolled renal or hepatic disease, anemia, coagulopathy, hypovolemia or dehydration, hypotension, and administration should be concomitant or in close association with corticosteroids or other NSAIDs. The risks and benefits of NSAID therapy should be considered for all patients.

Intolerance can happen with one NSAID but not others. When switching between NSAIDs, a washout period of 3–5 days is anecdotally used in patients without clinical signs. Other analgesics should be provided during this period.

NSAIDs can be safely administered long term to cats with concomitant chronic pain and stable chronic kidney disease. In this case, the following should be respected/considered:

- Stable chronic disease (IRIS stages 1 and 2)
- Long-term maintenance of hydration
- Minimal effective dosage should be used
- General guidelines for the management of chronic kidney disease (CKD) should be followed
- Owners should be educated about possible risks and actions to take
- Continued monitoring is imperative
- Environmental optimization, weight control and other nonpharmacological analgesic therapies must be used in combination with NSAIDs

Grapiprant acts further down on the arachidonic acid cascade (**Figure 24.22**). This drug is licensed for the management of pain and inflammation associated with canine OA (2 mg/kg orally every 24 hours) in several countries. Acetaminophen has weak anti-inflammatory properties but produces analgesic and antipyretic effects (inhibition of prostaglandin E2 in the CNS). It is absolutely contraindicated in cats (risk of acetaminophen toxicosis). Its use in dogs is mostly anecdotal. Corticosteroids can have potent anti-inflammatory and immunosuppressive properties, yet they should not be viewed as a classic analgesic. There is little evidence to support their use as analgesics and they can produce serious adverse effects.

GABAPENTIN

Gabapentin is an anticonvulsant drug with analgesic properties. It produces analgesia by reducing neuronal excitability and blocking calcium channels. In dogs and cats, the drug has high oral bioavailability; elimination half-life is approximately 3–4 hours, suggesting the need for frequent oral dosing.

There is a conflicting body of evidence in people regarding the role of preoperative administration of gabapentin or pregabalin in reducing pain and opioid consumption in the postoperative period. In dogs and cats, studies generally favor the use of gabapentin perioperatively when combined with opioids and other analgesics. For example, in a study in cats undergoing ovariohysterectomy, gabapentin (50 mg per os (p.o.) administered 12 and 1 hour before surgery) with buprenorphine provided similar analgesia as meloxicam with buprenorphine. The perioperative use of gabapentin might be particularly relevant in situations of limited drug availability or in patients in which NSAIDs are contraindicated.

Gabapentin is widely used the management of neuropathic pain in dogs and cats, including persistent postsurgical pain (e.g., amputation, chronic pain syndrome after feline onychectomy), feline orofacial pain syndrome, diabetes-induced neuropathy, IVDD, OA-related pain, cancer-related pain, Chiari-like malformation, and syringomyelia.

Gabapentin is considered a safe drug with no known contraindications. It is eliminated by the kidneys and for this reason might be used with caution in patients with renal disease. Sedation and ataxia can occur. Start the treatment at lower doses and increase gradually until analgesic response is observed. An analgesic trial of 4–6 weeks may be required. Note that nonveterinary pharmacies might carry formulations of gabapentin containing xylitol, which can be toxic at large doses in dogs.

TRICYCLIC ANTIDEPRESSANTS

Tricyclic antidepressants, such as amitriptyline, are the first line of analgesics for neuropathic pain in people along with gabapentin. In veterinary medicine, it has been used in the management of oncologic and neuropathic pain in dogs, pain associated with interstitial cystitis in cats, and chronic osteoarthritis. Amitriptyline inhibits the reuptake of norepinephrine and serotonin and possesses α_1 antagonistic, antihistaminic, and anticholinergic effects. Onset of peak effects generally occurs after 2–4 weeks of oral administration and, therefore, is not recommended in the management of acute perioperative pain. Generally dosing for pain is 1–4 mg/kg p.o. administered once to twice daily. Dosing up to 12.5 mg/kg p.o. once daily have been used in cats to treat interstitial cystitis with minimal adverse effects. Adverse effects include sedation, weight gain, and reduced grooming. Limited studies are available in dogs and cats. Avoid administration in combination with other serotoninergic drugs, including tramadol, due to the risk of serotonin toxicity.

CANNABINOIDS

Cannabinoids bind to cannabinoid receptors to modulate the release of neurotransmitters and neuronal excitability, activate inhibitory pathways, and reduce neuroinflammatory signaling. They exist in three forms: Endocannabinoids, produced by the body; phytocannabinoids, produced from plants; and synthetic cannabinoids, produced in laboratories. Delta-9-tetrahydrocannabinol

(THC) is generally associated to the psychoactive properties whereas cannabinol (CBD) to the analgesic properties. Three recent clinical trials involving dogs with OA show analgesic efficacy of CBD oil (1–2 mg/kg b.i.d.) when used alone or in combination with other analgesics (NSAIDs, gabapentin, amitriptyline). In these studies, CDB oil treatments were administered via oral or transmucosal route for 4–12 weeks, and no clinically relevant adverse effects were reported.

The pharmacokinetics of a single dose of CBD oil (2 mg/kg p.o.) showed marked differences in absorption and elimination between dogs and cats. Administration of this same dose for 12 weeks in healthy dogs and cats did not show any detrimental effects based on complete blood count and biochemistry values. However, administration was stressful in cats, resulting in excessive licking and headshaking. Based on the data available to date, administration of these dosages in dogs seems to be generally safe and effective. The use of cannabinoids in cats is not yet recommended due to limited pharmacokinetic data, stressful administration, and unknown efficacy and/or dosage regimen.

FIGURE 24.23 A cat comfortably recovers from anesthesia and surgery under warm blankets in a quiet location. "Tender loving care" concepts are applied in addition to analgesics to keep the cat comfortable with no pain, stress, fear, or anxiety. MONOCLONAL ANTIBODIES

Nerve growth factor (NFG) is a cytokine that regulates key mechanisms involved in inflammatory and neuropathic pain contributing to peripheral and central sensitization. Canine- and feline-specific anti-NGF monoclonal antibodies were investigated in dogs and cats with OA, respectively. Following a single subcutaneous injection, anti-NGF antibodies were shown to be safe and effective, providing 4–6 weeks of analgesia (increased levels of activity and improved owner-reported clinical signs) with no observable adverse-effects in dogs and cats. The clear advantages related to administration, duration of effect, and safety profile make them promising analgesics, and these drugs are becoming available in some countries including the United States.

NONPHARMACOLOGICAL PAIN MANAGEMENT STRATEGIES

Nonpharmacological therapies are highly important in the management of pain. They include the general concept of "care" or "TLC" (tender loving care) (**Figure 24.23**) as well as ice therapy, acupuncture, weight control, nutrition, nutraceuticals, physical therapy, massage, transcutaneous electrical nerve stimulation, photobiomodulation therapy, targeted pulse electromagnetic field therapy, etc. However, some of these therapies might not be accepted by all patients, and others have little to no evidence to support their use. The decision to incorporate nondrug therapies is affected by patient- and owner-associated factors as well as by their potential for analgesic effects, scientific evidence available, cost and time commitment, and acceptability to the patient, all of which must be thoroughly discussed with owners, particularly in chronic pain management. As previously discussed, emotions can modulate pain. Thus, any nondrug therapy that is well accepted by the patient and promotes positive mental states should be encouraged.

In acute pain management, nondrug therapies would include ice therapy, control of nausea, providing thermal comfort, noise reduction, stress and fear reduction, frequent and supported opportunities for urination and defecation in mobility impaired patients, promoting positive interactions with caretakers, massage, petting, brushing, providing clean and comfortable housing, and using feline-friendly handling techniques in cats (**Figure 24.8**).

In chronic pain management, particularly OA, strategies for the control of weight and increase in physical activity are paramount. In dogs, a careful dietary program in combination with slowly progressive increase in physical activity using leash walks is performed. Environmental adaptations such as the provision of carpets or ramps are considered. In cats, weight control is also performed in combination with environmental optimization, including the provision of condos, shelves, scratch posts, disposition of key environmental resources around the house, steps to facilitate jumping up and down, etc. (**Figure 24.24a, b**). For dogs and cats, the use of feed puzzles is highly encouraged to prolong feeding times, increase satiety, and promote physical and mental stimulation around feeding. Play sessions could also be prescribed to increase physical activity. Finally, euthanasia must remain as the ultimate treatment option to end pain and suffering in cases of poor prognosis, scheduling or financial constraints, or lack of response to therapy.

CASE EXAMPLE

Case 24.1: Pain Management for a Dog with a Pathologic Long Bone Fracture

Signalment

11-year-old intact male Labrador Retriever mixed-breed dog (**Figures 24.25** and **24.26**)

Presenting Complaint

Presented for an acute onset of non-weight-bearing lameness and severe redness and swelling of the left hindlimb.

Pertinent Medical History

No history of concurrent medical conditions.

FIGURE 24.25 A 4-year-old male dog in the immediate postoperative period.

Diagnosis

Pelvic limb radiographs show left femur fracture with marked soft tissue swelling and osteolytic lesion over the left femur.

Diagnosis and Surgical Procedure

Pathologic fracture due to osteosarcoma of the left hindlimb. Emergent surgery for a left hindlimb amputation.

Pain Assessment

Short Form of the Glasgow Composite Pain Scale Score: 11/15 (section B and C omitted). Severe, acute, somatic, with potential for neuropathic and wind-up development.

FIGURE 24.26 The same dog 48 hours postoperative.

Analgesic Regimen Suggestions

- Perioperative plan
  - CRI suggestions (choose one or a combination of)
    - Fentanyl (loading dose (LD) 3–5 mcg/kg IV followed by 5–10 mcg/kg/h)
    - Lidocaine (LD 1–2 mg/kg IV followed by 2–4 mg/kg/h)
    - Ketamine (LD 1–2 mg/kg IV followed by 0.3–1 mg/kg/h)
    - Dexmedetomidine (LD 0.5–1 mcg/kg IV administered slowly over 10 minutes followed by 0.5–1 mcg/kg/h)

  - Local regional anesthesia (one or the combination of)
    - Lumbosacral epidural with 0.5% bupivacaine at 0.5–1 mg/kg combined with morphine at 0.1 mg/kg diluted (if needed) to a total volume of 0.2 mL/kg
    - Nocita 0.4 mL/kg infiltrative administration at the site of incision during surgical closure
- Postoperative suggestions
  - Immediate 24–72 hours
    - Lumbosacral epidural may provide up to 24 hours of analgesia
    - Nocita May provide up to 72 hours of analgesia
    - Continue CRIs if needed but at lower dosages (choose one or a combination of)
- Fentanyl 3–5 mcg/kg/h
- Lidocaine 1.5–2 mg/kg/h
- Ketamine 0.3–0.5 mg/kg/h
- Dexmedetomidine 0.5–1 mcg/kg/h
  - Pending health status consider injectable NSAIDs (i.e., carprofen or meloxicam)
  - Following 48–72 hours
  - Wean off CRIs over a 24-hour period
  - Transition to oral analgesics for 7–10 days pending patient's comfort level (a combination of)
- NSAIDs (carprofen or meloxicam as directed)
- Tramadol 2–6 mg/kg twice daily
- Gabapentin 5–10 mg/kg once to twice daily
- Amantadine 3–5 mg/kg once to twice daily

CHAPTER 25

Nutrition of the Critically Ill Dog and Cat

Justin Shmalberg

Introduction 1019
Current Evidence 1019
Clinical Evaluation 1020
Timing of Nutritional Support 1023
Nutritional and Caloric Requirements 1024
Diet Evaluation and Comparison 1025
Nutrient Considerations 1026
Routes of Administration 1027
Conclusion 1036
Recommended Further Readings 1036

INTRODUCTION

Nutrition is increasingly recognized as an essential component of veterinary evaluation and treatment. The provision of adequate calories and nutrients in critically ill patients has received significant attention in recent years. Nevertheless, controversy and varying quality of evidence persist. Noninterventional retrospective studies demonstrate that critically ill patients are less likely to be fed to meet estimated caloric requirements and are also more likely to have extended hospital stays. However, the retrospective nature of these studies limits the ability to draw a clear link between caloric deficit and patient outcome. Such studies do document a failure by clinicians to provide specific nutritional orders, suggesting that nutrition is often overlooked regardless of clinician opinion on the merits of nutritional support. One controlled study of early enteral nutrition in puppies hospitalized for parvovirus infection did document an earlier clinical improvement in those patients fed through a nasoesophageal tube. Therefore, specific critical patients are likely to benefit from voluntary and assisted enteral nutrition.

CURRENT EVIDENCE

Critical care veterinary nutrition has been poorly studied in hypothesis-driven research. Consequently, nutritional evidence from human nutritional research often guides interventions in clinical practice. Acute illness in both humans and other animals is characterized by a reduction in appetite and increased catabolism of endogenous reserves of protein. These effects are mediated by a complex milieu of cytokines, including tumor necrosis factor-alpha, interleukin (IL)-6, IL-1B, hormones such as cortisol, epinephrine, glucagon-like peptide 1, changes in resting metabolic rate, and the immune response. The decline in lean body mass secondary to protein catabolism has been associated with prolonged hospital stay and rehabilitation in human patients. Provision of protein and/or essential amino acids has decreased the magnitude of muscle loss in some studies. Such data have not been collected for veterinary patients but are thought to be similar. Fasting may have protective effects, however, on some aspects of recovery. Starvation is associated with increases in protein recycling through the ubiquitin–proteasome pathway, which processes damaged or potentially toxic proteins. Other studies in human subjects determined that delivery of the full calculated nutritional requirement was associated with increased morbidity compared with those patients receiving more conservative nutritional interventions. Therefore, the timing and the type of nutritional intervention in critical patients is still the subject of much debate.

Human nutritional studies in acute or hospitalized patients are often characterized by small sample sizes and differing patient populations, making meta-analyses challenging. The paucity of data in the veterinary literature makes definitive conclusions even more elusive. Experience with hospitalized human subjects suggests that nutritional best practices may vary with different diseases; recommendations for patients with acute kidney injury (AKI) or chronic kidney disease (CKD) are quite different, for example. As such, veterinary patients likely also experience different condition- and individual-specific requirements for nutrients and for calories. The level of sophistication of evidence-based interventions in veterinary medicine is therefore poor. Interestingly, dogs display increased adaptability to starvation compared with humans and are evolutionarily

DOI: 10.1201/9781003254591-47

programed for significant postprandial fasting. Cats, conversely, have constitutive upregulation of gluconeogenesis and a lower gastric volume, suggesting adaptability to frequent feedings. Future studies are needed to better refine clinical knowledge, and the guidelines contained herein should be critically evaluated in such a context.

CLINICAL EVALUATION

Nutritional intervention relies on a complete and thorough clinical examination. Specific attention must be paid to body condition score (BCS), muscle condition, visible markers of nutritional status such as dermis and coat, and appropriate identification of comorbidities. A detailed diet history is equally critical. The initial diet history may be complicated by triage and stabilization of the patient as well as owners' focus on other critical aspects of their animal's care. However, historical diet information should be obtained at the earliest opportunity. This permits detection of chronic malnutrition due to hyporexia, chronic gastrointestinal (GI) abnormalities, or previous dietary deficiencies. The provision of nutrition should ideally be tailored to the individual based on the clinician's subsequent synthesis of owner input and examination findings.

History

A diet history is a commonly overlooked aspect of nutritional assessment. Historical information can provide information about a patient's caloric requirements, feeding habits, recent caloric intake, and food preferences. The latter is especially important in cats, who may be neophobic, especially during acute hospitalization. An awareness of recent calorie consumption can determine the timing of nutritional intervention. For example, a hospitalized cat with several weeks of marked hyporexia should receive nutritional support sooner to prevent hepatic lipidosis, compared with a cat with acute anorexia. Some individual dogs may receive food in the home environment at an amount close to the resting fed energy requirement used for hospitalized patients. Dogs of some breeds, such as Labrador Retrievers, Newfoundlands, and Corgis, commonly consume less than calculated with predictive equations. Such factors are critical when individualizing care.

A thorough diet history may not be possible at a patient's initial presentation. However, technicians or the supervising clinician should try to obtain this information following triage. The diet history should include:

- The type of food commonly fed, including brand, type, and flavor
- The type and quantity of treats and supplemental foods
- Specifics regarding dietary supplements
- Feeding habits (free-choice, meal fed)
- Food allergies, aversions, or preferences

Clients may need to investigate packaging at home before providing pertinent details given the diversity of foods on the market and the distracted focus of many owners during their pet's illness. Such detailed information is necessary to determine the caloric content and nutrient profile of various foods. Dietary supplements are increasingly encountered, and the potential for toxicity and interactions between herbs and drugs has been reported. Knowledge of feeding habits can provide useful information regarding the likelihood of a patient eating on a particular schedule. Some dogs, with small breeds appearing overrepresented, are accustomed to being fed free-choice and may not be accustomed to the scheduled feeding initiated during hospitalization. Food allergies and intolerance are frequently reported by owners; regardless of the merits of these claims, care should be taken to avoid significant dietary changes in order to prevent acute GI signs. A diet history form can be designed to incorporate these questions and be tailored to a particular practice; such forms can also be employed during therapeutic weight loss.

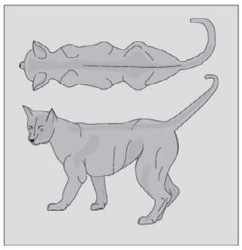
Body Weight and Condition

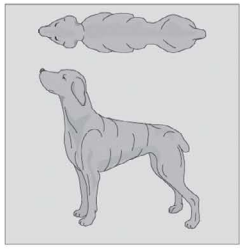
Body weight is frequently measured in clinical patients, primarily for assessing fluid status. Acute changes are most likely fluid related, but repeated measures in chronically treated patients can suggest inadequate nutritional intake. Ideal body weight is also the basis for predictive caloric requirement equations. Patients with effusions, edema, and extensive neoplasia are more reliably assessed by BCS and muscle condition score (MCS) than by body weight.

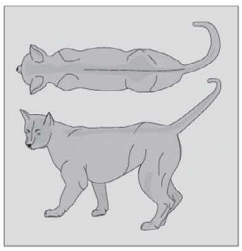
Body condition scoring provides an assessment of energy reserves, primarily adipose tissue. A 9-point system of scoring has been objectively validated, with 4–5/9 representing ideal body weight (**Figure 25.1**). This is characterized by a clearly visible waist, an "abdominal tuck" when viewed from the side, and minimal fat covering over the ribs. Many sighthounds display a normal body condition of 3/9. Some breed standards and purebred dog owners may regard 6/9 as ideal for the breed, but unlike sighthounds, there is no physiologic advantage to this preference.

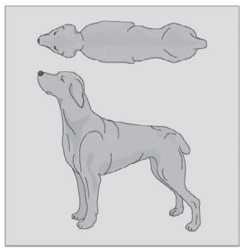
Ideal body weight is calculated for overweight dogs (BCS 6–9/9) using simple conversions. Assessments of patient adiposity demonstrate that each BCS over 5 represents 10%–15% over a patient's ideal body weight in dogs. For example, a 40 kg dog with a BCS of 8/9 is 30%–45% over ideal weight. Using the upper end of this range, the dog's measured body weight is 145% of ideal body weight, and, therefore, ideal body weight is equal to (40 kg)/(145%) or about 28 kg.

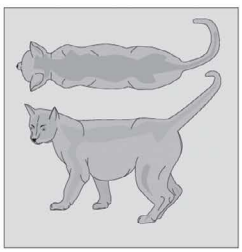
The ideal weight of most cats can be estimated by visual assessment. Most cats should be between 3 and 5 kg, so mathematical formulas are unnecessary. Overweight cats are predisposed to a number of conditions encountered in critical care medicine, including hepatic lipidosis, lower urinary tract obstruction, and diabetes mellitus.

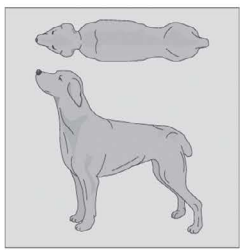






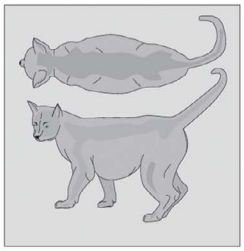


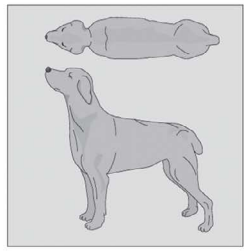


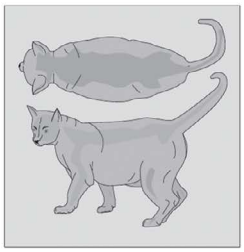


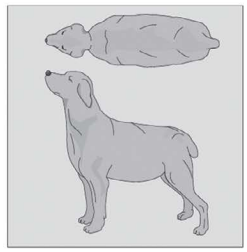
5 Point	Cat	Description	Dog	9 Point
1/5		Dogs: Ribs, lumbar vertebrae, pelvic bones, and all bony prominences evident from a distance. No discernible body fat. Obvious loss of muscle mass. Cats: Ribs visible on short-haired cats; no palpable fat; severe abdominal tuck; lumbar vertebrae and wings of ilia obvious and easily palpable.		1/9
1.5/5		Dogs: Ribs, lumbar vertebrae and pelvic bones easily visible. No palpable fat. Some evidence of other bony prominence. Minimal loss of muscle mass. Cats: Shared characteristics of BCS 1 and 3.		2/9
2/5		Dogs: Ribs easily palpated and may be visible with no palpable fat. Tops of lumbar vertebrae visible. Pelvic bones becoming prominent. Obvious waist. Cats: Ribs easily palpable with minimal fat covering; lumbar vertebrae obvious; obvious waist behind ribs; minimal abdominal fat.		3/9
2.5/5		Dogs: Ribs easily palpable, with minimal fat covering. Waist easily noted, viewed from above. Abdominal tuck evident. Cats: Shared characteristics of BCS 3 and 5.		4/9
3/5		Dogs: Ribs palpable without excess fat covering. Waist observed behind ribs when viewed from above. Abdomen tucked up when viewed. Cats: Well proportioned; waist observed behind ribs; ribs palpable with slight fat covering; abdominal fat pad minimal.		5/9

FIGURE 25.1 Objective 9-point body condition scoring (BCS) system. (*Continued*)









5 Point		Description		9 Point
3.5/5		Dogs: Ribs palpable with slight excess fat covering. Waist is discernible viewed from above but is not prominent. Abdominal tuck apparent. Cats: Shared characteristics of BCS 5 and 7.		6/9
4/5		Dogs: Ribs palpable with difficulty; heavy fat cover. Noticeable fat deposits over lumbar area and base of tail. Waist absent or barely visible. Abdominal tuck may be present. Cats: Ribs not easily palpable with moderate fat covering; waist poorly discernible; obvious rounding of abdomen; moderate abdominal fat pad.		7/9
4.5/5		Dogs: Ribs not palpable under very heavy fat cover, or palpable only with significant pressure. Heavy fat deposits over lumbar area and base of tail. Waist absent. No abdominal tuck. Obvious abdominal distension may be present. Cats: Shared characteristics of BCS 7 and 9.		8/9
5/5		Dogs: Massive fat deposits over thorax, spine, and base of tail. Waist and abdominal tuck absent. Fat deposits on neck and limbs. Obvious abdominal distention. Cats: Ribs not palpable under heavy fat cover; heavy fat deposits over lumber area, face, and limbs; distension of abdomen with no waist; extensive abdominal fat pad.		9/9

FIGURE 25.1 Objective 9-point body condition scoring (BCS) system. (*Continued*)

Muscle Condition

Protein catabolism and loss of lean body mass is poorly assessed with body condition scoring. A separate score has been developed to assess muscle, which is the primary source of amino acids in catabolic animals. Multiple methods of scoring are available, and some may be referred to as a cachexia score. The author uses a 3-point scale where 3/3 indicates normal muscle mass, 2/3 mild muscle wasting, 1/3 moderate, and 0/3 marked (Figure 25.2). The high rates of weight loss (>2% per week) seen in prolonged anorexia are characterized by loss of lean body mass as well as adipose stores. Therefore, a decline in both muscle condition and body condition is a sign of malnutrition.

Laboratory Markers

Laboratory values from significantly malnourished animals are often within normal limits. Biochemical profiles and complete blood counts are unreliable indicators of nutritional status. Severe hypoalbuminemia, for example, is rarely encountered with prolonged starvation as production is prioritized by the animal. Patients presenting with this condition are more likely to have decreased production or increased loss from another cause. Specialized diagnostic testing, such as amino acid profiles and vitamin levels, is available at some academic research laboratories. The extended turnaround times and limited published information on many of these tests in critical care settings limit their

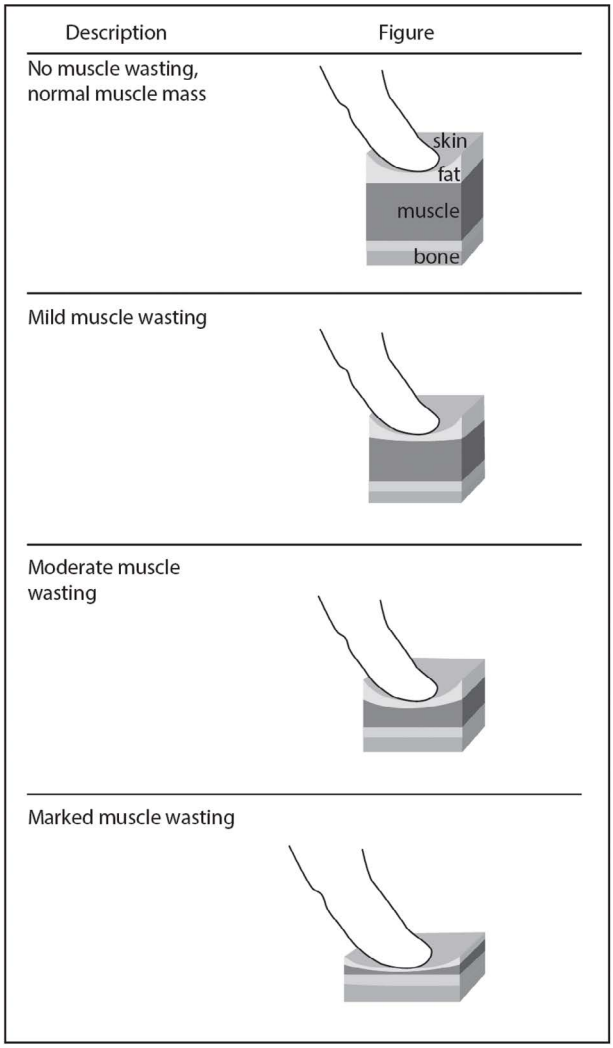


FIGURE 25.2 Objective 3-point muscle scoring system.

use to those cases where clinical suspicion of nutrient deficiency is high, such as in dilated cardiomyopathy in dogs fed lower protein diets or in suspected thiamine deficiency in cats.

TIMING OF NUTRITIONAL SUPPORT

The decision-making rubric for when to intervene with nutritional support is the most contested aspect of critical care nutrition. Current clinical guidelines in humans promote early enteral feeding and in the event of severe or lengthy caloric deficits parenteral nutrition (Figure 25.3). The trials that suggested a survival benefit for early enteral nutrition were small and contained interventions in the control group, such as parenteral nutrition, which could have worsened survival. A comparable controlled study in veterinary medicine enrolled puppies with parvovirus infection. All dogs in that study survived, so the statistically significant outcome measure was a 1-day reduction in clinical signs in dogs fed a liquid diet via a nasoesophageal tube. Enteral nutrition in dogs with septic peritonitis appeared to confer a survival benefit without any increased complication rate. Dogs are documented to survive longer with complete starvation compared with people, suggesting an adaptive ability to tolerate extended fasting. Dogs also display higher rates of fatty oxidation at rest and may therefore be uniquely suited to accommodating for increased lipolysis and beta-oxidation. Nutritional support is often provided earlier in the course of disease in cats due to concerns about hepatic lipidosis. However, only 1 of 12 cats experimentally receiving 25% of their energy requirements developed hyperbilirubinemia after 1 month, and provision of a high-protein diet at this reduced intake decreased hepatic lipid concentration. Early interventional nutrition at low caloric intakes may be protective against complications during illness,

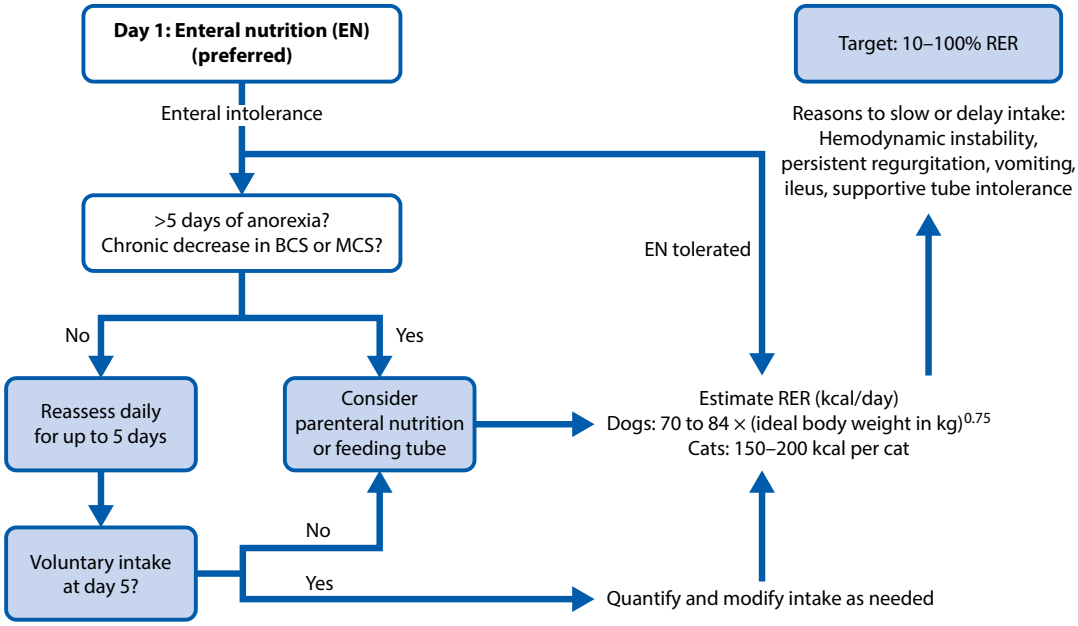

FIGURE 25.4 Proposed veterinary nutrition decision tree for critically ill patients. BCS, body condition score; MCS, muscle condition score; RER, resting energy requirements.

but further work is required and species-specific studies may not be translational to other animals. A simplified algorithm for veterinary patients is suggested in the absence of definitive information (Figure 25.4).

NUTRITIONAL AND CALORIC REQUIREMENTS

Dietary nutrient percentages or concentrations define a food's composition, but knowledge of the amount of food fed is critical to determining the dose of nutrients to be administered. Therefore, calculation of caloric needs and an accurate assessment of intake are critical in nutritional support. The hospitalized animal is generally less active than when at home, with the exception of some cats who may be less active during daily routines. The resting energy expenditure (REE) is commonly used as an assessment of fasting, resting land mammals in thermoneutral environments, which characterizes most hospitalized patients. The so-called Kleiber equation (70 × [ideal body weight in kg]$^{0.75}$) is used to calculate this figure. The logarithmic component explains why small animals consume more calories per unit of mass than large animals. For dogs between 5 and 25 kg, a simplified linear equation ([30 × ideal body weight in kg] + 70) kcal per day is employed. Ideal body weight is calculated from current body weight in obese patients to prevent overfeeding, as adipose tissue is less metabolically active than lean body mass.

Patients receiving nutritional support are not fasting, and therefore resting fed metabolic rate is more appropriate than REE. The digestion and conversion of nutritional substrates requires energy, generally about 10%–20% more than in fasting animals. The dramatic differences in energy expenditure between animals largely negate the benefits of using this higher amount, which requires a more complex formula or a second multiplication step. Clinicians historically also applied illness factors for specific conditions thought to be associated with increased metabolic rate (e.g., burns, sepsis, neoplasia). However, studies suggest that these factors are unnecessary and overestimate true caloric needs.

Cats, unlike dogs, present with relatively homogeneous ideal body weights of between 3 and 5 kg. Most resting cats, which includes both those hospitalized and indoor pets, should consume 200–250 calories per day. Equations are unnecessary in cats, and the author typically uses an estimate of 150 kcal per day for a small cat and 200 kcal per day for a larger cat. Most owners dramatically overfeed domestic cats, which could be detrimental if continued during treatment.

The percentage of energy requirements met with nutritional support is likely to affect morbidity and possibly mortality. Human energy requirements can be guided by indirect calorimetry, whereby a medical device measures oxygen consumption to determine the actual instantaneous metabolic rate of that individual. Such measurements are technically difficult and expensive. Human studies relying on predictive equations, similar to those used in veterinary medicine, produced hyperalimentation in some patients, which may increase overall morbidity. Conversely, in studies examining permissive underfeeding where the intentional provision of caloric intake is less than the calculated or measured requirements, the results generally show favorable or better outcomes compared with those receiving full caloric intake.

Parenteral nutrition in humans, when compared with fasting for up to a week, has in some studies produced poorer outcomes. The complications of IV nutrition include hyperglycemia, secondary infections, activation of the reticuloendothelial system, hyperlipidemia, and

thrombophlebitis. Hyperglycemia is the most commonly reported complication in the dog, but this is likely related to provision of high concentrations of dextrose. Dogs and cats appear to tolerate low-dextrose, high-amino acid, and high-fat diets better than human patients. It is therefore unclear if comparisons of enteral and parenteral nutrition in humans accurately reflect the clinical picture in small animals. Further research in veterinary medicine is necessary to compare fasting, permissive underfeeding, and feeding to meet calculated requirements.

DIET EVALUATION AND COMPARISON

Commercial pet foods are difficult to evaluate and compare using product packaging. Most veterinarians are interested in nutrient comparisons and generally turn to the guaranteed analysis on the product label to identify critical nutritional information. The label itself, which is generally modeled after Association of American Feed Control Officials suggested guidelines in the United States, may be misleading. First, the amounts listed are the minimum or maximum "guaranteed" to be present, and the percentages are "as fed," which includes the dietary moisture. Canned diets, containing approximately 80% water, have lower listed nutrient percentages than dry foods containing 10% moisture or less. Second, conversion to dry matter percentages overcomes the moisture variable, but there are other nutrients that add weight to the food but not calories, including fiber and ash. Nutritionists and veterinarians, therefore, should only compare foods on a caloric basis, commonly expressed as the grams of a particular nutrient per 1,000 calories (kcal) or 1 Mcal.

The caloric basis for commercial pet foods can be calculated using the guaranteed analysis and caloric density located on the bag. Specific simplified formulas are available (Figure 25.5). Some diets with low fat

STEP BY STEP: ESTIMATING NUTRIENT CONCENTRATION ON A CALORIC BASIS

Step 1	• Add 1.5% to protein percentage from pet food label • Add 1% to fat percentage from pet food label
Step 2	Divide kcal/kg by 10,000
Step 3	Divide estimated protein % and fat % by number obtained in Step 2

COMPARISON OF PET FOODS BY CALORIC BASIS

Canine Diets	**NRC RA*** (g/1000 kcal)	**Low** (g/1000 kcal)	**Moderate** (g/1000 kcal)	**High** (g/1000 kcal)
Protein	25	< 60	60–90	> 90
Fat	13.8	< 30	30–50	> 50

percentages on the label are not, in fact, fat restricted and, therefore, inappropriate for the long-term management of chronic active pancreatitis. Many weight loss diets appear restricted in nutrients on the label due to the inclusion of large amounts of fiber, but when fed at an appropriate number of calories, are often higher in nutrients. The caloric basis in many product guides is now readily available to veterinarians. Current nutrient profiles for diets encountered in many critical care centers are provided (see Table 25.1).

NUTRIENT CONSIDERATIONS

Water

Water is an important essential nutrient, the requirement for which is directly related to caloric requirements. Dogs generally require 1 mL of water per kcal consumed, and cats only about 0.6 mL of water per kcal consumed. Careful attention should be paid to voluntary water intake, and hydration should be frequently assessed to determine if intervention is needed.

Protein

Many acute illnesses increase the rate of skeletal muscle proteolysis and contribute to a decrease in lean body mass. Dietary protein can ameliorate some of this protein loss and is generally well-tolerated, with the common exceptions of severe renal disease or hepatic encephalopathy. In addition, if a patient's food intake is reduced, then a higher protein concentration in the diet is required to meet daily minimums. A hyporexic patient with AKI often should not consume a protein-restricted renal diet, for example, because it may be insufficient in the amount consumed to replace amino acid losses.

Specific amino acids have been discussed as an adjunct to nutritional therapy in the critically ill patient. Glutamine, a nonessential amino acid, is a nitrogen donor produced by skeletal muscle to provide substrate for amino acid production in critical tissues such as the GI mucosa and liver. Decreased glutamine levels have been documented in hospitalized human patients, but data on supplemental doses of glutamine have been mixed. Clinical studies in dogs are lacking, but a research study of fasted dogs suggested some positive effects on GI glutathione status. Most foods contain glutamine, especially animal protein sources, so the provision of dietary protein is likely more important than glutamine supplementation. Arginine, an essential amino acid in the dog and cat, is a precursor to nitric oxide and an intermediate in the urea cycle. Clinical utility in immunomodulation has been suggested, and one therapeutic diet administered to lymphoma patients includes elevated levels. However, patient selection for supplementation in human subjects is unclear, and no information is available for dogs and cats. Nevertheless, it is prudent to meet minimal requirements, as with all amino acids. The recommended allowance for protein is 25 g and 50 g per Mcal, respectively, for dogs and cats. Hospitalized animals may consume less than average pets, and, therefore, a provisional minimal concentration of 50 g of protein in dogs and 75 g of protein per Mcal in cats is recommended.

Fats

Fats and protein are essential macronutrients; there is no requirement for dietary carbohydrate. Glucogenic amino acids can form glucose, but fatty acids cannot and must be processed through beta-oxidation. Many fasting animals have higher rates of beta-oxidation than when fed, and small animals, especially the dog, may be distinctly adapted to high-fat diets during starvation. Fats are also more than twice as energy dense as protein and carbohydrate. The recommendations for dietary fats for maintenance are 13.8 and 22.5 g/Mcal in dogs and cats, respectively. As with protein, dietary concentrations should be increased for reduced intake; values of 30 g and 40 g, respectively, are advised. The type of fat may also modulate response to disease. Polyunsaturated fatty acids of the omega-3 and omega-6 fatty acid series are converted to inflammatory mediators in the prostaglandin and leukotriene classes as well as thromboxanes. In general, omega-3 fatty acids, such as eicosapentaenoic acid (EPA) and docosahexaenoic (DPA) found in marine sources such as fish, produce less potent inflammatory mediators, whereas omega-6 fatty

acids such as linoleic acid produce more potent mediators. A therapeutic dose of 1–3 mg of EPA+DHA per calorie has been suggested as an adjunct measure in the treatment of renal disease in order to possibly increase glomerular filtration rate, osteoarthritis due to a reduction in intra-articular cytokines, and in neoplasia likely due to chemosensitization. Parenteral lipid solutions have often contained minimal omega-3 fatty acids, although new products high in lipids derived from fish oil are now manufactured. The influence of these various lipid types when administered parenterally in clinical veterinary patients is not yet known.

Vitamins

Fat-soluble and water-soluble vitamins are commonly added to commercial pet foods. Water-soluble vitamins are of greatest concern in acute disease given the limited storage pools and the effect of diuresis on vitamin loss. B vitamins are the most common conditional deficiencies and broadly function as cofactors to cellular metabolism. Vitamin B12 deficiency requires long-term reduction in dietary intake. The lack of intrinsic factor production by the pancreas in cats (as opposed to the pancreas and stomach in dog) with chronic pancreatitis or with impaired absorption due to severe ileal disease in either species could warrant prophylactic supplementation of B12. Injectable B complex can be used to provide other B vitamins. Thiamine deficiency in cats causes anorexia, postural changes including ventroflexion, short seizures, and death if untreated. Clinical supplementation is warranted if these symptoms are encountered, especially in cats historically fed canned or unprocessed fish-based diets. In most clinical situations, supplementation of vitamins A, D, E, and K is not advised.

Minerals

Many minerals are stored in sufficient quantity by tissues so that acute supplementation is not needed except with obvious deficiencies. Adult dogs and cats, for example, have accessible calcium stores in bones. Conditions that cause acute electrolyte shifts, however, may prompt supplementation. Re-feeding syndrome has been reported in cats and humans; it has been theorized to occur in dogs but is poorly documented. The mechanism of re-feeding syndrome in severely emaciated patients is thought to be due to a rapid infusion of carbohydrate into the duodenum, which stimulates a large release of insulin, triggering intracellular electrolyte shifts and resulting in severe hypokalemia, hypophosphatemia, and hypomagnesemia. Fatal sequelae are possible. Therefore, diets given to emaciated animals should be replete in minerals and ideally high in protein and fat while low in carbohydrate; kitten and puppy foods generally provide suitable diets. Supplementation of other minerals, such as zinc for effects on immune function and selenium as a component of the intracellular antioxidant glutathione, has been recommended but poorly supported.

ROUTES OF ADMINISTRATION

Voluntary Intake

Voluntary food intake by hospitalized or acutely ill patients is ideal given the low cost and the ability of the animal to control the rate of feeding. Interventional nutrition is generally associated with a greater potential for iatrogenic harm than voluntary intake, except in those patients that have refractory vomiting or regurgitation despite normal appetite. Ideally, the animal's previous diet should be offered during hospitalization, especially for cats. Only if necessary should a single new and sacrificial diet be offered. Therapeutic diets intended for long-term feeding should not be offered during hospitalization or acute illness to avoid the development of food aversion. Similarly, offered foods should not be left in a cage with an animal unless that animal has a history of free-choice feeding and clinical suspicion is high that they will voluntarily consume food. The constant smell of a particular diet within the cage during a period of illness has been hypothesized to also trigger aversion. Ideally, voluntary intake should be precisely quantified to determine the percent of caloric requirement being met. Weighing of the food may be necessary for smaller animals.

Assisted Enteral Feeding

The decision to provide assistive support is guided by the patient's diet history, clinical assessment, and interventional logarithms (see Figure 25.4). Selection of the appropriate assistive strategy is critical for ensuring the best patient outcome.

Nasoenteral Feeding Tubes

Nasoenteral feeding tubes are generally employed for short-term inpatient feeding. These tubes can be placed without anesthesia or special equipment (Figure 25.6a–g). The measurement of the tube before placement varies based on the intended location of the distal aspect of the tube. Nasoesophageal tubes should be measured from the tip of the nose to ribs 7–9. Nasogastric tubes are measured from the tip of the nose to the last rib. Nasojejunal tubes are reported but require a weighted tube and fluoroscopy for accurate placement. Nasoenteral tubes are usually of 3- to 8-French size and are placed ventromedially in the nasal cavity following intranasal administration of a local anesthetic gel or topical ophthalmic solution. Entry into the ventral meatus permits passage of the tube through the nasal cavity into the esophagus. Animals should ideally be monitored for swallowing as the tube is passed. The distance from the nose to the medial canthus can be marked on the tube to guide when a swallow should be observed. The tube is passed to the measured length determined previously. Tubes are generally affixed to one of the nares with suture (a 22-gauge needle can be inserted first with suture passed through the sharp end of the needle and then the needle removed leaving the suture in tissue). Adhesive "super" or tissue glue may also be used, but

FIGURE 25.6 Nasoesophageal tube placement. **(a)** The nasoenteral tube is positioned for measurement. Rib 13 is used as a landmark for nasogastric tubes and ribs 7–9 for nasoesophageal tubes. **(b)** The desired length is marked with permanent ink. The distance from the naris to the medial canthus can also be marked to provide visual feedback as to when to monitor for a swallow response. **(c)** The tube is placed ventromedially to facilitate entry into the esophagus. Topical local anesthetic is recommended. **(d, e)** The tube is passed to the previous mark, and the tube affixed with a Chinese finger trap suture pattern, a skin staple, or glued to the fur near the lateral aspect of the naris. **(f)** One or two additional affixing sutures are placed to position the tube between the eyes so that the feeding end of the tube is caudal to the head. **(g)** An Elizabethan collar is placed to prevent the patient from dislodging the tube. Radiographs should confirm appropriate placement following placement. The aspiration of negative pressure and a lack of a cough with sterile saline administration can provide additional confirmation but may be inaccurate as the sole method of assessing placement.

removal of the tube can be more difficult and is presumably more painful for the patient. The tube is affixed in one or two additional sites in order to place it away from the eyes and for additional security. Placement is confirmed with a two-view thoracic radiograph. Negative pressure should be present if the tube is placed in the esophagus, and administration of sterile saline should not elicit a cough. Nasogastric tubes have been theorized to cause irritation of the lower esophageal sphincter and increased regurgitation or vomiting, but there have been no documented differences in complication rates. Nasogastric tubes facilitate assessment of residual gastric volumes, but large residual volumes are not associated with increased GI signs, and, therefore, routine monitoring and removal cannot be recommended. Complications of nasoenteral tubes include rhinitis, transient epistaxis, patient intolerance, and tracheal placement or feeding. Only liquid diets can be administered, either as a continuous infusion or in bolus feedings. Bolus feedings using nasojejunal tubes have been successful in clinical studies.

Esophagostomy Tube

Esophagostomy tubes are a convenient means of short- or long-term nutritional support that are well tolerated and free of significant side effects, with the exception of possible abscess formation around the tube site (**Figure 25.7a–m**). The tube is most easily placed in the left midcervical region with the patient anesthetized and in right lateral recumbency. A red rubber catheter or a commercially available feeding tube with a size greater than or equal to 5-French is measured from rib 7 to 9 to the anticipated exit point, and that measure is marked on the tube. For large dogs requiring significant volumes of food, stallion urinary catheters can be used to provide a greater diameter tube. Curved hemostats or Carmalt forceps are placed in the mouth following aseptic preparation of the lateral neck. The instrument tip is placed in the proximal esophagus, and lateral pressure is applied to "tent" the skin over the esophagus using the curved aspect of the forceps. An incision through all the tissue overlying the instrument tip is made until the instrument tip is exteriorized. The instrument handle is then opened and the tip of the catheter clamped firmly over the distal end of the tube. The tube is withdrawn aborally and the tip redirected orally into the esophagus as the tube is slowly withdrawn at the level of the skin until it "turns" and advances down the esophagus until the previous mark is reached. Two-view thoracic radiographs should be obtained in order to confirm placement. The tube can be used following anesthetic recovery, and both canned and liquid diets can be administered.

Gastrostomy Tube

Gastrostomy tubes are generally reserved for planned long-term nutritional support when esophageal bypass is clinically necessary due to megaesophagus, esophageal stricture, cervical disease, or for large volume feedings. "Low-profile" gastrostomy tubes may also be better tolerated than chronic esophagostomy tubes in some patients that require months to years of assisted feedings. Gastrostomy devices have a larger lumenal diameter (18–24 French) than esophagostomy tubes, allowing for a larger volume of fluid or food to be more easily administered. Tubes can be placed percutaneously with or without endoscopic support or surgically. The left side of the patient is aseptically prepared 1–2 cm caudal to the last rib and about one-third of the distance from epaxial muscles to ventral midline. Endoscopic insufflation of air permits endoscopic visualization of the stomach and allows for closer contact between the stomach and the abdominal wall. The endoscope permits tactile and visual (due to the light source) assessment of the position of the stomach to facilitate needle penetration (18 gauge, 1.5 inch) into the gastric lumen. A sterile flexible stylet or suture is then passed through the needle, grasped with endoscopic forceps in the stomach, and removed through the patient's oral cavity. A gastrostomy tube is then attached to the suture and the suture pulled orally until the tube exits the abdominal wall. A balloon or other device at the end of the tube prevents it from pulling through the abdominal wall, but the position of the tube should be marked to allow easy assessment of migrating tubes. A retainer flange is used to provide apposition of the stomach and the abdominal wall. Alternatively, the blind technique usually involves a special curved device, which is sized for the patient and passed orally into the stomach to provide visual assessment for needle penetration. Appropriate placement of blindly inserted tubes can be confirmed with liquid contrast and radiographs. Surgical techniques, described in greater detail in surgical texts, have the advantage of direct visualization of the tissues along with the ability to place intra-abdominal appositional sutures to prevent leakage of gastric contents due to separation of the peritoneal wall and gastric surface.

Gastrostomy tubes are generally well tolerated by small animals. However, Elizabethan collars must be employed in the first 2 weeks following placement, and animals should always be carefully monitored for licking or attempts at tube removal. Prevention of bacterial contamination in the tissues around the skin is critically important, as abscessation or chronic dermatitis can force premature removal of the tube. Both esophagostomy and gastrostomy tubes should be replaced as quickly as possible if inadvertently removed, as natural closure will rapidly occur.

Jejunostomy Tube

Jejunostomy tubes are reserved for patients that require gastric or duodenal bypass feeding. Such circumstances include severe pancreatitis, persistent vomiting or regurgitation, gastric or duodenal neoplasia, gastric hypomotility, or gastric outflow obstruction. Surgical placement with or without laparoscopy is generally required. Tubes cannot be removed for 7–14 days following insertion as creation of a stoma is required to prevent septic peritonitis, the most catastrophic of jejunostomy tube complications. Jejunostomy tubes may also be placed through

FIGURE 25.7 Esophagostomy tube placement. **(a)** The left lateral neck is aseptically prepared. **(b)** The esophagostomy tube is measured from the expected point of insertion to rib 7–9 and that distance marked on the tube with permanent ink. **(c)** A curved instrument is passed orally into the esophagus, and lateral pressure is applied until the instrument tip is palpated. **(d)** A stab incision is made over the tip of the instrument. **(e)** The curved instrument tip is moved laterally to exit the incision. **(f)** The distal end of the tube is grasped with the instrument. **(g)** The tube is pulled aborally with gentle traction. **(h)** The end of the tube is passed orally back into the esophagus while slowly pulling laterally on the syringe end of the tube in order to facilitate movement of the tube into the distal esophagus. **(i)** The tube is inserted to the level of the previous mark. **(j)** Chinese finger trap sutures are used to secure the tube to the dermis. **(k)** Antibiotic ointment and/or gauze is applied over the esophagostomy site. The catheter end of the tube is capped. **(l)** A nonocclusive bandage is applied to protect the area and secure the tube. **(m)** A thoracic radiograph confirms appropriate placement. (The arrow indicates the tip of the esophagostomy tube in front of the lower esophageal sphincter.)

a gastrostomy tube, but endoscopic or intraoperative guidance of the tube into the intestinal lumen is usually required. In both cases, tube diameter limits feeding to liquid enteral diets, and such diets are most commonly administered as a continuous infusion. However, three bolus feedings per day were not associated with increased adverse effects in one study. Dogs and cats also clinically appear to tolerate liquid diets of varying composition.

Tube Management

Tube feedings can be complicated by obstructions within the tube caused by saponification of fat, improperly mixed diets, pH changes, incompatible medications, and similar substances. Tubes are commonly flushed with warm water before and after each use, with an amount consistent with the volume of the tube. Carbonated beverages and pancreatic enzyme solutions may also prove helpful if obstructions do not respond to water alone.

Water is first administered following placement of an assistive feeding tube. Nasoenteral and esophagostomy tubes may be used shortly following recovery from any sedation or anesthesia. Other tubes that critically rely on stoma formation, such as gastrostomy or jejunostomy tubes, should be tested with water 12 hours after placement, and food can be administered about 24 hours after insertion. Esophagostomy and jejunostomy tubes should be wrapped when not being used and cleaned daily with disinfectant solution.

Dietary options for feeding tubes are dictated by the size of the feeding tube and the required caloric density. Clinical veterinary and human liquid diets with caloric densities of about 1–1.5 kcal/mL are used for small diameter tubes such as nasoenteral and jejunostomy tubes (Table 25.1). Human enteral diets should not be used in cats, given the more stringent nutritional requirements of this species, including an obligatory need for taurine and arachidonic acid, and higher protein intakes compared with dogs and humans. Canned diets can be employed in most other assistive feeding devices. Any canned diet is theoretically an option, but high-fiber diets have a very low-caloric density when mixed with sufficient water. High-calorie, low-fiber, moderate-to-high protein and fat diets facilitate the highest caloric densities (~1 kcal/mL; Table 25.2). Many "recovery" diets are commercially manufactured to permit ease of administration through a feeding tube.

Animals with feeding tubes may require frequent feedings. No significant differences in continuous infusions as opposed to bolus feedings have been identified. Aspiration and measurement of gastric residual volumes is not beneficial in most cases. Gastric volume is the limiting factor in determining the number of feedings. Clinical experience suggests that cats tolerate about 60 mL per feeding when administered over 10–15 minutes and, therefore, require about four feedings per day. Dogs display much greater gastric expansion with sufficient time. A figure of 50 mL/kg is commonly employed as an estimate of tolerated volume, but dogs are known to consume about 10% of body weight in a single meal. Many dogs can be fed on routine twice daily schedules with feeding tubes. Owners should be instructed that less frequent feedings may be possible but will require additional time at each feeding.

Parenteral Nutrition

IV administration of nutrients is reserved for those cases with documented or anticipated periods of prolonged hyporexia or anorexia. However, patients with low BCSs or MCSs may benefit from earlier intervention with parenteral nutrition. This method of nutritional support may be appropriate for animals with prolonged ileus, those receiving ventilator support, and those who display diffuse refractory GI symptoms. Parenteral nutrition requires specialized techniques and solutions that may not be available at all practices. The cost to feed patients with this method can be substantially higher than with enteral feeding.

IV nutrition can be administered through a central line (central parenteral nutrition) or through a dedicated peripheral catheter (peripheral parenteral nutrition). The terms total and partial parenteral nutrition are no longer used, as most veterinary parenteral nutrient mixtures do not meet the total nutrient requirements for patients. Frequent complications of parenteral nutrition include hyperglycemia and thrombophlebitis. Lowering the dextrose content of the solution can reduce the risk of the former, and the latter is reduced by placement of a central line. Peripheral parenteral nutrition solutions should have an osmolality no >650 mOsm/L. Infection, possibly leading to sepsis, is theoretically possible as some components of parenteral nutrition, such as IV lipid, could serve as a bacterial media. However, the high osmolality of parenteral nutrition solutions and careful technique usually prevent contamination of the fluid itself. Most parenteral nutrition-related infections occur due to migration of bacteria around the catheter site, so aseptic catheter technique is critically important. Only a dedicated catheter or a dedicated port on a multilumen catheter should be used. Injections should not be given through the same port as parenteral nutrition.

TABLE 25.2 Commercial diets marketed for tube feeding critical patients in the United States

Diet	Protein (g/1,000 kcal)	Fat (g/1,000 kcal)	Carbohydrate (g/1,000 kcal)	Caloric density (kcal/kg)
Royal Canin Recovery	97	63	11	1,039
Science Diet A/D	91	68	29	1,352
Purina CN	79	74	25	1,175

Consult product guides for current specifications.

TABLE 25.3 Common components of parenteral nutrition

Component	kcal/mL	mOsm/L
50% dextrose	1.7	2,525
5% dextrose	0.17	253
20% lipid	2.0	260
8.5% amino acids without electrolytes	~0.57	~700
8.5% amino acids with electrolytes	~0.57	~920

Peripheral solutions should be limited to <650 mOsm/L. The addition of electrolytes may increase osmolality. Hypertonic saline provides 1.2 mEq of sodium and chloride per milliliter and contains 2.4 mOsm/mL.

TABLE 25.5 A general parenteral nutrition solution for central administration

Component	Volume (mL)
8.5% amino acids without electrolytes	1,000
20% lipid	250
5% dextrose	500
Hypertonic (7.2%) saline	60
Heparin (1,000 units/mL)	1.8

The calorie distribution of nutrients is 20% protein (50 g/Mcal), 50% carbohydrate (125 g/Mcal), and 30% as lipid (33 g/Mcal). The caloric density is 0.93 kcal/mL, and the calculated osmolality is 1,200 mOsm/L. Electrolyte composition is 58 mEq/L sodium, 41 mEq/L chloride, and 2 mEq/L phosphorus. Additional electrolytes, minerals, and vitamins should be added as the patient's status dictates.

Parenteral mixtures generally contain carbohydrate, fat, and protein in the forms of dextrose, lipid emulsion, and amino acids (Table 25.3). Carbohydrate is not required in the formulation, and both cats and dogs have been managed with mixtures of only lipid emulsion and amino acids. The concentration of dextrose appears related to the incidence of hyperglycemia. IV lipid emulsions have been reported to impair reticuloendothelial system function in other species, which could have implications for their use in septic patients. Such solutions could also worsen hyperlipidemia and have been hypothesized to worsen pancreatitis. However, the effect of IV lipid on canine and feline pancreatitis is rarely reported, and both species have been managed for this condition with high-fat solutions. Peripheral parenteral nutrition solutions commonly contain increased lipid compared with centrally administered solutions, as lipid possesses a lower osmolality compared with other constituents (Tables 25.4 and 25.5). The higher basal rate of fatty acid oxidation has prompted some authors to advocate the use of lipid concentrations higher than those used in human nutrition.

Multiple amino acid solutions are available, each with a different blend of essential and nonessential amino acids. Products are produced with or without electrolytes. Electrolyte-containing products generally require supplemental potassium and phosphorus, especially in animals that have experienced prolonged anorexia or tissue catabolism. Insulin release causes both an intracellular shift of potassium and an increased cellular phosphate utilization related to the increased production of energy stores, such as adenosine triphosphate or creatine phosphate. Phosphorus is typically added to achieve a concentration of 5–10 mmol/L. Electrolyte-free amino acid solutions can be modified to include sodium and chloride at rates consistent with maintenance or replacement fluids as required through the addition of hypertonic (7.2%) saline.

Provision of water-soluble vitamins supports normal energy metabolism by providing essential cofactors in metabolic reactions. Some IV B complex solutions are low in vitamin B12, so this should be administered subcutaneous (SC) if deficiency is predicted. Fat-soluble vitamins may be added and are included in some multivitamin combinations designed for parenteral nutrition, but substantial reserves are likely present in many patients. Trace elements for parenteral administration are available but controversial.

The amount of protein in the form of amino acids to administer is controversial. Protein requirements may be expressed as a percentage of calories in some resources or as an amount in grams to be fed per day. Protein may also be given on top of the calculated caloric requirement (200 kcal for most cats, 70 × [ideal body weight in kg]$^{0.75}$ kcal for dogs) by some clinicians. The theory is that protein, when given above the calorie needs of an animal, will be more likely used for anabolic reactions rather than for ketogenesis or gluconeogenesis. The provision of dietary protein only partially reverses catabolism in many disease states characterized by high rates of nitrogen turnover and suspected protein loss. Provision of 20% of calories as protein (50 g/1,000 kcal) is adequate for most patients, although encephalopathy may warrant values as low as 40 g/1,000 kcal, and patients with other conditions with high protein requirements can be given solutions up to 28% of calories (70 g/1,000 kcal). Patients fed less than their expected caloric requirements need a solution with greater amino acid or fat concentrations to maintain a consistent "dose." Administration of low-concentration amino acid solutions (3%) is unlikely to prevent muscle

TABLE 25.4 A general parenteral nutrition solution for peripheral administration

Component	Volume (mL)
8.5% amino acids without electrolytes	500
20% lipid	250
5% dextrose	250
50% dextrose	25
Hypertonic (7.2%) saline	40
Heparin (1,000 units/mL)	1

The calorie distribution of nutrients is 23% protein (56 g/Mcal), 12% carbohydrate (30 g/Mcal), and 66% as lipid (73 g/Mcal). The caloric density is 0.71 kcal/mL, and the calculated osmolality is 600 mOsm/L. Electrolyte composition is 61 mEq/L sodium, 46 mEq/L chloride, and 4 mEq/L phosphorus. Additional electrolytes, minerals, and vitamins should be added as the patient's status dictates.

catabolism, especially in the absence of other macronutrients, as most of the amino acids would be converted to energy. Therefore, protein without adequate caloric intake is unlikely beneficial.

Parenteral nutrition requires special monitoring and careful administration. Parenteral nutrition solutions should be refrigerated and kept for no longer than 7–10 days after mixing. Vitamins, if administered, should be added just before hanging a bag to prevent degradation during storage. Careful aseptic techniques should be employed when connecting parenteral nutrition, and a new fluid line should be used with each new bag. Sterile gloves are used when spiking each bag and when connecting a new line to the patient's catheter. Injection ports can be disinfected and covered with sterile gauze, as can all connections between the bag and the patient. Some vitamins degrade with ultraviolet light, and when exposure is likely, the bag and the line should be covered with special amber sleeves, bandage material, or aluminum foil. The patient should be disconnected from parenteral nutrition only once daily. The bags can be wrapped and taken outside with the patient if necessary. Parenteral solutions may benefit from the inclusion of 1 unit of heparin per milliliter of mixture to prevent local thrombosis formation and prevent the need for periodic flushing with heparinized saline. Recommended monitoring includes electrolytes twice daily along with a hematocrit/total protein and a visual check of the serum for hyperlipidemia. Most patients can receive parenteral nutrition at one-half of the calculated energy requirements during hospitalization over the first 6–12 hours, with an increase to the full calculated rate thereafter, assuming that the patient tolerates the volume and is unlikely to suffer severe electrolyte shifts secondary to re-feeding.

Nutritional Reassessment

Nutritional reassessment is difficult in critically ill patients, as many commonly measured laboratory parameters are unreliable indicators of malnutrition. Electrolytes should be closely monitored during any nutritional intervention as feeding can create and correct potential abnormalities. Body weight is affected by fluid status, and both body condition and muscle condition scoring systems are unlikely to change during a hospitalization period of 1 week or less. Frequent monitoring of compliance to nutrition orders is preferred, as patient procedures, anesthetic events, failure to follow treatment sheets, and other factors may influence daily caloric intake. Tolerance to feeding plans should also be assessed because persistent vomiting, regurgitation, or diarrhea may warrant alterations to the nutrition orders.

Disease-Specific Considerations

A number of conditions encountered in critically ill patients may benefit from specific nutritional strategies. Each patient should be evaluated as an individual, but general recommendations exist for a variety of conditions.

Pancreatitis

Dietary triggers for acute and chronic active pancreatitis are well described, with ingestion of foods high in fat being the most common. Hyperstimulation of cholecystokinin has been hypothesized as a possible mechanism in combination with other patient factors, such as elevated cortisol, obesity, or hyperlipidemia. Evidence-based data on the nutritional treatment of acute pancreatitis are lacking. Many practitioners argue that withholding enteral nutrition in favor of fasting or parenteral nutrition decreases pancreatic stimulation and therefore reduces premature activation of pancreatic enzymes. However, pancreatic responses to nutrition may be abnormal in pancreatitis, so that enzyme activation is actually decreased in response to lumenal nutrition. Jejunostomy tube feeding in dogs and in humans has been tolerated in both species. Humans display lower morbidity when fed through such a tube compared with parenteral nutrition, but it is unclear if this is due to worsened outcome with total parenteral nutrition rather than a beneficial effect of enteral nutrition alone. Luminal nutrition is associated with reductions in the systemic inflammatory response and in preservation of the mucosal barrier, thereby reducing bacterial translocation. The ideal timing of enteral nutrition is unclear. Studies in canine parvovirus infection showed that early enteral nutrition improved outcome and that feeding was well tolerated irrespective of whether patients were vomiting or regurgitating.

Additional studies are required before definitive recommendations are made on the timing and type of feeding in canine pancreatitis. Dogs with chronic pancreatitis, however, do benefit from low-fat diets (<30 g/Mcal) following discharge. Most therapeutic diets labeled for pancreatitis meet this criterion. Clinicians should consider the expected caloric intake of a patient before making a dietary recommendation. Patients consuming large amounts of food to maintain an ideal body weight would require a lower concentration of fat than dogs consuming a very small amount. Access to high-fat treats and prepared diets intended for consumption by the owner should be restricted.

Serum triglycerides are an important aspect of patient monitoring as free fatty acids, very-low-density lipoprotein, and low-density lipoprotein increase in this condition. A decrease in lipoprotein lipase, causing a subsequent increase in triglyceride and chylomicrons, has been observed in humans but not yet in dogs. Low-fat diets reduce the hypertriglyceridemia in many cases, and provision of omega-3 fatty acids (EPA, DHA) could have an additive benefit along with niacin.

Feline pancreatitis displays many features distinct from those observed in dogs. Concurrent hepatobiliary or inflammatory bowel disease is commonly identified in cats affected with this condition. Premature activation of trypsinogen has been postulated as the mechanism, but the etiology is unclear. Cats presenting with pancreatitis display less vomiting than dogs, and enteral feeding is therefore less complicated. Supportive enteral feeding tubes (nasoenteral, esophagostomy) are often recommended for feline pancreatitis, as hepatic lipidosis

(discussed later) is a common clinical sequela in anorectic cats. Jejunostomy tubes are only rarely required. Fasting should be avoided. There is no evidence that dietary fat restriction is necessary in cats, which is in stark contrast to the evidence and clinical experience in dogs. Cats should receive parenteral vitamin B12 injections because intrinsic factor, the requisite cofactor for B12 absorption, is produced only in the pancreas in cats as opposed to both the stomach and pancreas of dogs.

Chronic Gastrointestinal Disease

Acute gastroenteritis and colitis often respond to fasting, and no specific nutritional interventions are required. There is emerging evidence that probiotics may shorten the duration of acute GI signs and that antibiotic administration may cause deleterious long-term shifts in the microbiome without a significant improvement in clinical signs. Patients may present with chronic GI complaints requiring stabilization. Such patients may suffer from malabsorption, protein-losing enteropathy, maldigestion, and reduced total and lean body mass. Many animals will have concurrent anorexia, and therefore consideration of assistive feeding devices is recommended. Feeding tubes appropriate for at-home use should be prioritized, as a protracted period of stabilization may be required while the underlying disease is managed. Food allergy or intolerance is a common differential for chronic GI disease, and diagnosis or exclusion of these conditions requires a strict food trial. Such trials are best started following patient discharge and only if an animal is voluntarily eating, as food aversion can develop due to perceived associations between diet and disease. Animals with a feeding tube can begin the diet immediately. Some authors advocate the routine use of hydrolyzed diets in the theory that food allergy may develop in patients with a compromised GI barrier. Novel protein diets are the other class of diets used to assess food allergy, but their use requires collection of a thorough diet history to exclude the possibility that an animal has previously received a particular protein source. Previously rare dietary protein sources such as rabbit, kangaroo, alligator, and venison are now available over the counter. Diet trials should last 12 weeks, and no other proteins, treats, or flavored medications should be given.

Chronic colitis may respond to hydrolyzed or novel protein diets. Dietary fiber and probiotics are additional considerations. Dietary fiber is generally classified as soluble or insoluble. Soluble fiber sources, such as gums and beet pulp, provide substrates for bacterial fermentation. Insoluble fibers, such as cellulose and peanut hulls, increase fecal bulk. Fiber modification influences intestinal transit, stool consistency, bacterial flora, and fecal moisture. Psyllium supplementation of foods has gained considerable attention. Psyllium, a partially fermentable fiber, contains mucilage that absorbs water and helps to normalize GI transit. It is frequently employed in the dietary management of feline megacolon. Probiotics, living microorganisms administered for health effects, may influence immune responses and nutrient absorption in the colon. Several veterinary specific probiotics have been shown to reduce the duration of diarrhea. However, product quality has been poor for some probiotic products marketed for animal use. The benefits of probiotics in patients receiving concurrent antibiotics are unclear but may help avoid undesired shifts in the microbiome.

Hepatic Lipidosis

Excessive accumulations of triglycerides in the hepatocytes of some anorectic, generally overweight cats produce hepatic dysfunction and cholestasis. The occurrence of this condition in cats but not in dogs is likely related to the metabolic peculiarities of the cat, a true carnivore. Cats display significant mobilization of triglycerides during fasting, which are transported to the liver for use as energy. In lipidotic cats, however, the rate of mobilization exceeds the rate of clearance. Carnitine complexes with fatty acids to facilitate transport across the mitochondrial membrane, and deficiency of this compound has been proposed as a cause in some cats. Oxidative stress may also be increased, and some B vitamins may be decreased as a function of prolonged anorexia or the condition itself. A variety of nutraceuticals have been recommended, such as carnitine (250 mg daily), SAMe (100–200 mg daily), B complex vitamins (added to fluids), and vitamin B12 (0.5–1 mL [500–1,000 µg] SC daily). Administration of caloric needs is likely more important than supplementation. Supportive feeding measures should be pursued as soon as possible in the disease course. Fat restriction is unnecessary. Despite the intrahepatic lipid accumulation, fat ingestion, when combined with other nutrients, decreases the release of peripheral lipid stores due to the action of insulin. High-protein diets (>90 g/Mcal) are commonly recommended as they may support tissue regeneration. Severely affected cats may display hepatic encephalopathy, and in these rare cases, the protein concentration of the diet should be reduced.

Hepatic Encephalopathy

Hepatic encephalopathy warrants immediate nutritional modification following initial stabilization. In addition to lactulose, which converts ammonia to ammonium, thus preventing absorption, neomycin, which decreases ammonia-producing urease-positive bacteria, and the correction of alkalosis, which prevents worsening of encephalopathy, dietary protein restriction is indicated in most patients. Estimates suggest that one-third of blood ammonia is from bacterial production and the remainder from dietary protein intake because encephalopathic patients lack adequate urea cycle activity to convert ammonia to blood urea nitrogen. Therefore, most dogs with average caloric intake ($90 \times BW^{0.75}$ kcal per day) should receive enough protein to prevent muscle catabolism and provide maintenance requirements, approximately 40–50 g/Mcal. Cats, with higher protein requirements, should receive around 70 g/Mcal. Protein-restricted diets may also be restricted in purine content, as the crude protein of the diet is derived from measurement of nitrogen, which includes amino acids, purines, and pyrimidines. Impaired

conversion of purines to allantoin results in increased uric acid excretion, predisposing to urate uroliths. Most therapeutic hepatic diets are appropriate for encephalopathic patients; however, patients consuming few calories may be fed a normal diet. Renal diets are not commonly recommended for extended feeding of the encephalopathic patient, as such diets tend to be alkalinizing, which worsens clinical signs. In addition to the standard therapies listed previously, soluble fiber has been suggested in the management of encephalopathy, mainly due to lactulose-like effects on lowering intestinal pH.

Renal Disease

Most patients with AKI or CKD do not require immediate dietary modification (see also Chapter 13). Azotemia may predispose to anorexia and nausea, and attempts to administer a new diet can result in profound food aversion. The role of nutrition in AKI is unclear, but it is generally accepted that such patients have high rates of protein catabolism and may therefore benefit from normal maintenance diets. If animals consume little food during hospitalization, high-protein diets may even be appropriate to prevent loss of lean body mass. CKD patients can typically be fed their historical diet during hospitalization. The effects of diet in CKD are well studied in both dogs and cats and directly impact survival when fed for extended periods. Advanced stages of renal disease may require assistive feeding tubes, primarily esophagostomy or gastrostomy, in order to facilitate owner administration of calories and sufficient water.

The features of most diets designed for CKD include reduced phosphorus and protein, elevated omega-3 fatty acids, reduced sodium, and increased caloric density. One diet fed to dogs with stage 3 and 4 CKD permitted a median survival time of about 600 days compared with 200 days in the control group. Similar findings of a feline diet marketed for renal disease were reported: 633 days versus 264 days. Another study of a different feline diet found a median survival time of 750 days. Commercially available kidney diets and calcitriol administration in dogs are, in fact, the only interventions for which grade 1 evidence exists. Different diets labeled for use in renal disease contain different ingredients and nutrient concentrations; therefore, product guides should be carefully reviewed if a patient requires more or less of a certain nutrient or if one particular product is refused. The amount of protein to administer to patients with renal failure is controversial and should probably be increased to the amount needed to maintain muscle condition. Protein does not appear as toxic to renal tubules in dogs and cats as in rodents, but protein frequently contains a large percentage of dietary phosphorus, which is reduced to prevent renal secondary hyperparathyroidism. No clinical studies exist that compare protein modification independent of phosphorus concentration. Animals who consume little food may benefit from higher protein diets. Those patients in stage 4 renal disease (www.iris-kidney.com) may require feeding tubes if voluntary intake is insufficient to maintain body weight. Therefore, interventions should be tailored to the patient's caloric intake and International Renal Interest Society (IRIS) stage (Figure 25.8).

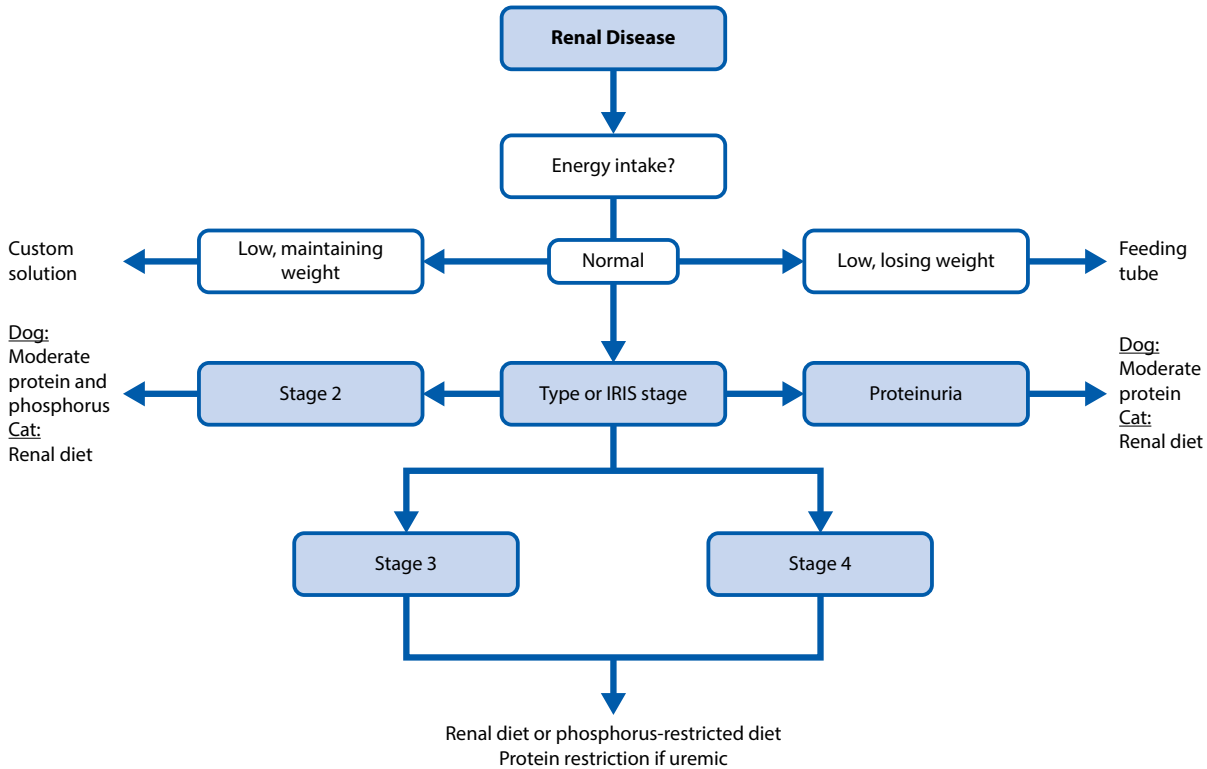

FIGURE 25.8 An algorithm for nutritional management of patients with renal disease.

CONCLUSION

Critical care patients benefit from frequent nutritional assessments during hospitalization. Controversies exist regarding when, how, and what to feed critically ill patients. However, most conditions benefit from a methodical approach to nutritional support. Those animals with significant anorexia, hyporexia, or reduction in MCS or BCS may require earlier interventions compared with animals who present with acute illness and adequate tissue reserves. Certain conditions such as sepsis may benefit from permissive underfeeding. In many conditions, the provision of some calories is preferred compared with no calories or caloric excess. Specific attention should be given to patients presenting with GI disease, pancreatitis, hepatic encephalopathy, hepatic lipidosis, and renal disease, as these conditions have well-defined nutritional considerations. Additional randomized controlled trials are needed to better characterize the influence of nutrition on patient outcome.

DEFINITION AND OVERVIEW

Human Obesity

In humans, obesity is defined as a disease in which adipose tissue has been accumulated to the point that health can be adversely affected. There are various methods of quantifying adiposity in people, the most common of which is the body mass index (BMI; weight [in kg] divided by height [in m^2]). Although not perfect, for the majority of the human population, this measure approximates to body fat mass. Epidemiologic studies have suggested that the optimal BMI for adult Caucasians is 20–25 and have further demonstrated that disease and mortality risk progressively increase when BMI exceeds this. Increased BMI has been categorized into "overweight" (BMI 25–30), "obese" (BMI 30–40), and morbidly obese (BMI >40), with each representing a progressive increase in disease and mortality risk. Some recent work has questioned whether people with an overweight BMI are genuinely at an increased risk of mortality and developing concurrent disease. This phenomenon might be explained by confounding, since some people with an ideal BMI have a concurrent disease that has caused them to lose weight. There has been a dramatic increase in the prevalence of this disease in the human population. According to the Centers for Disease Control in the United States, more than a third (35%) of adults are obese. However, this is not a problem that is limited to the westernized world and, indeed, the Overseas Development Institute has recently highlighted a growing concern in developing countries, with almost a billion adults now being classed as obese. Thus, obesity truly is an epidemic of global proportions.

Canine and Feline Obesity

As with humans, excess adiposity in companion animals can be categorized either as overweight or as obese, depending on the degree with which current weight exceeds ideal weight. Rather than using a measure equivalent to the BMI, most veterinarians will classify on the basis of the body condition score (BCS) (see **Figure 25.1**).

The WSAVA Global Nutrition Committee has recently recommended using the 9-integer unit BCS, with BCS 4/9–5/9 being ideal, 6/9–7/9 being overweight, and 8/9–9/9 being obese. Given that beyond 5/9 each integer unit represents ~10%–15% of excess weight, overweight animals are typically up to 20% above their ideal weight, while obese dogs are >20% above ideal. As in humans, various studies have suggested that adverse health effects can arise when dogs and cats are not maintained in optimal body condition. A number of recent international studies have determined the prevalence of excess body weight in dogs and cats: For dogs, 29%–39% are defined as overweight and 5%–20% as obese, while, for cats, 19%–29% are defined as overweight and 8%–10% as obese. Differences represent variations in the populations studied and methodology. Furthermore, as with human obesity, prevalence is increasing, with recent reports suggesting a 37% and 90% increase in prevalence over the last 5 years for dogs and cats, respectively.

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology

For body weight to remain stable, energy intake in food must match expenditure from basal metabolic rate, activity, and thermoregulation. When energy intake

DOI: 10.1201/9781003254591-48

exceeds expenditure, usually as a result of a number of risk factors, the net energy gained is stored in body fat. Adipose tissue can expand both by hypertrophy and/or hyperplasia: In some individuals, the response to energy imbalance is adipocyte hypertrophy while for others hyperplasia predominates, with a lesser degree of hypertrophy. Differences in the degree of hyperplasia to hypertrophy have recently been shown to be associated with the metabolic derangements that manifest as a result of obesity. Intriguingly, recent research has demonstrated that some cats can maintain a stable weight despite *ad libitum* feeding, likely by self-regulating intake. However, others are unable to do this and, if excess intake remains unchecked, weight gain develops gradually.

Thus, slow and insidious energy imbalance is a major factor, perhaps explaining why obesity is most prevalent in middle aged dogs and cats.

Pathophysiology

The clinical significance of obesity relates not to the accumulation of adipose tissue, *per se*, but to the effect this has on the function of other organs. There are two proposed mechanisms for such effects: "Mechanical" and "endocrine." Mechanical effects can occur from excessive weight of adipose tissue, and this can cause excessive loading of structures of the musculoskeletal system. Alternatively, effects may arise from the excess volume of the tissue and the effect this has on compressible structures, for instance of the respiratory (affecting breathing function) or urinary (causing incontinence) system. In addition, the excess volume and weight can affect the ability to groom, while the insulating effect of adipose tissue can create problems with reduced heat dissipation.

However, in addition to these mechanical problems, there may be effects due to derangement of the endocrine functions of white adipose tissue. A range of cytokines, chemokines, and other inflammation-related proteins, collectively termed "adipokines," are now known to be synthesized, suggesting that adipose tissue can influence the function of a variety of organ systems (**Figure 26.1a, b**). When there is expansion of adipose tissue, it can become hypoxic, causing derangement in adipokine synthesis and release. This can lead to a body wide state of chronic mild inflammation and, ultimately, to a range of end effects. In humans, increases in the production of certain inflammatory adipokines (e.g., leptin, tumor necrosis factor a, interleukin 6, plasminogen activator inhibitor 1, and haptoglobin) have been causally linked to the development of metabolic syndrome and other disorders linked to the obese state. As mentioned earlier, adipose tissue can expand both by hypertrophy (through increased cell size) and hyperplasia (through synthesis of new cells from preadipocytes). Individuals that predominantly react by adipocyte hypertrophy have greater hepatic fat deposition and more marked metabolic disturbances than those who do not. It is thought that these differences may arise through mitochondrial dysfunction, since the same studies demonstrated that mitochondrial gene expression pathways

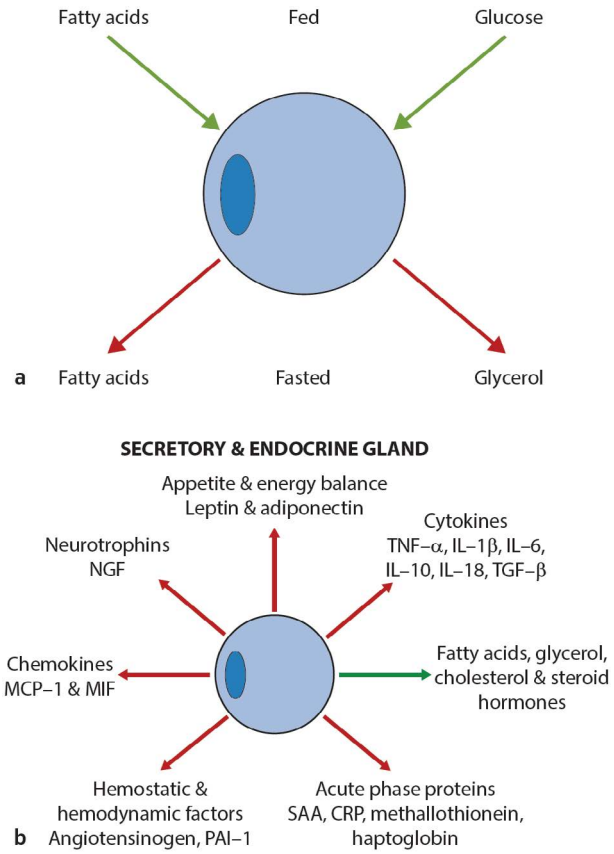

FIGURE 26.1 Evolving views of the biological functions of adipose tissue. **(a)** Adipocytes were previously considered to be inert storage depots releasing fuel as fatty acids and glycerol at times of fasting or starvation. **(b)** Recently, however, it has become increasingly clear that adipocytes are endocrine cells, which secrete important hormones, cytokines, vasoactive substances, and other peptides. This figure outlines the range of such proteins secreted from adipose tissue. CRP, C-reactive protein; IL, interleukin; MCP-1, monocyte chemoattractant protein-1; MIF, macrophage migration inhibitory factor; PAI-1, plasminogen activator inhibitor-1; SAA, serum amyloid A; TGF-b, transforming growth factor-b; TNF-a, tumor necrosis factor-a. (*From German AJ, Ryan VH, German AC, et al. (2010). Obesity, its associated disorders and the role of inflammatory adipokines in companion animals.* Vet J *185:4–9, reprinted with permission.*)

are downregulated, while inflammatory pathways are upregulated in the adipose tissue of affected individuals.

Inflammatory adipokine gene expression has been documented in both canine and feline white adipose tissue, and studies are now highlighting their effects in these species. As with humans, metabolic derangements are most evident. Increased plasma leptin concentrations have been shown to be independently associated with insulin sensitivity in lean and overweight cats. Other studies indicate decreased circulating adiponectin in obese dogs and cats, and this is also linked to insulin resistance. Furthermore, low serum adiponectin has been associated with failure of a subsequent weight loss program and excessive lean tissue loss during weight management. Increases in serum paraoxonase 1

have also recently been demonstrated and, once again, this is associated with insulin resistance. Further work is ongoing to better characterize these effects.

Risk Factors for the Development of Obesity

A number of risk factors are known to predispose to the development of obesity in dogs and cats, as outlined later.

Co-Existing Health Problems

Some diseases, such as hyperadrenocorticism, can cause polyphagia, and if the animal is allowed to consume more food, weight gain can occur. Other diseases can reduce energy expenditure, for instance by decreasing physical activity or slowing the basal metabolic rate. Orthopedic diseases that lead to lameness are a classic example of a disease that decreases activity, while hypothyroidism is, perhaps, the best example of a disease predisposing to weight gain by decreasing metabolic rate. Although thought to be a common endocrinopathy, relatively speaking, hypothyroidism is actually an uncommon cause of obesity in dogs. In this respect, the prevalence of hypothyroidism is reported to be <1%, and less than half are overweight (see Chapter 11), while the current prevalence of dogs that are above their ideal weight is much greater (typically 34%–59%); thus, only a minority of the overweight dogs attending veterinary practices are likely to have concurrent hypothyroidism. Furthermore, given that hypothyroidism is extremely rare in cats, it is a negligible cause of obesity in this species.

Beyond this, some therapeutic interventions can predispose to weight gain. One example is the use of drugs that stimulate appetite (e.g., glucocorticoids or anticonvulsants) but not energy requirement; here, weight gain can occur if the owner provides more food. A second example is surgical sterilization (spaying/neutering), which alters behavior by decreasing physical activity while increasing food-seeking behavior.

Rapid Early-Life Weight Gain

In humans, overly rapid gain of weight during the early years of life predicts the likelihood of being obese during adulthood. A similar phenomenon has recently been identified in cats. Although the reason for this phenomenon is not yet known, genetic factors are suggested to play a role. Armed with such knowledge, a simple comparison of the ratio of bodyweight between 2 months (i.e., 2nd vaccination) and 12 months of age (first annual booster) could be used to identify at-risk cats, enabling preventive strategies to be implemented (see ahead given in the text).

Age

As mentioned previously, the prevalence of both canine and feline obesity gradually increases throughout life, with the condition being most prevalent in middle aged animals. However, some individuals can become overweight even during growth. The prevalence of overweight and obesity decreases in senior animals, possibly due to the onset of various chronic diseases associated with the aging process.

Sex and Neutering

Some canine studies have suggested that female dogs are predisposed, while a recent feline study suggested males to be overrepresented. More importantly, neutering is an important risk factor for obesity in both species, with studies suggesting that this is the result of behavioral alterations rather than a direct effect on metabolism. In this respect, the hormonal changes produced by obesity lead to an increased food intake, decreased physical activity, or both. Given that neutering is typically an elective procedure, unwanted post-neutering weight gain is arguably preventable if body weight is monitored closely, and food intake adjusted accordingly (see ahead given in the text).

Breed

On rare occasions, single gene disorders can cause obesity in humans, but polygenic effects are more common with a number of predisposing genes recently identified. At the current time, no single-gene disorders have been described in either dogs or cats. Since there are a number of known breed predispositions in both dogs (e.g., Cocker Spaniels, Beagles, Labrador Retrievers, Golden Retrievers, Shetland Sheepdogs, Rottweilers, and mixed-breed dogs) and cats (e.g., Domestic Shorthair), genetic influences remain likely, although these are more likely to be due to polygenic effects. Gene mapping studies are underway to characterize the genetic influences in these companion animals.

Environment and Activity

Dogs and cats that live indoors are reportedly at greater risk of developing obesity than those who go outside. Similar findings have also been seen for indoor cats, including those that are apartment dwelling. Furthermore, cats that live with one or two other cats or with a dog may also be at increased risk.

Dietary Factors

Some published studies have suggested associations between companion animal obesity and diet type, but others have not. In one study, no difference in obesity prevalence was observed between dogs fed commercial food versus those fed a homemade diet. However, the cost of food might play a role, with inexpensive (grocery store) diets more likely to have been fed to obese dogs compared with more expensive foods; in contrast, obese cats are more likely to have been fed a premium food. Although, there have been many anecdotal suggestions that feeding a high carbohydrate diet to cats predisposes to obesity and diabetes mellitus, there is no evidence to support this assertion. In fact, increased dietary fat

rather than carbohydrate predisposes to weight gain in cats. Furthermore, obese cats more commonly have free choice of food intake. For dogs, obesity is correlated with the number of meals and snacks, the feeding of table scraps, and the animal being present when owners prepared or ate their own meal.

Owner Factors and Behavior

The owners of overweight dogs have a lower income than dogs of ideal weight, but this is not the case for cats. Owners of obese dogs also tend to overhumanize them, and this is also the case for cats, where owners often utilize their cat as a substitute for human companionship. Owners of overweight cats also spend less time playing with their pet and reward with food rather than extra play. Owners of both overweight cats and dogs are more likely to be overweight themselves, less interested in preventive health, and to observe their pet more closely during feeding.

Some studies have suggested that there may be behavioral influences on the development of feline obesity, including anxiety, depression, failure to establish normal feeding behavior, and failure to develop control of satiety. The human–animal relationship is also of importance and appears to be more intense in owners of obese cats. Cat owners usually feed their cats two meals per day, even though the wild ancestors of domestic cats are "trickle feeders" and eat many small meals each day. Misinterpretation of feline behavior on the part of the owner is a critical factor in feline obesity, with owners misreading behavior signals with regard to eating. In this respect, domestic cats prefer to eat alone and have no requirement for social interaction during this time. Thus, when a cat initiates contact, this would not normally be for food-related reasons. However, owners often mistakenly believe their cat to be hungry and asking for food; if they give food at this point, the cat will quickly learn that initiating contact results in a food reward. Another misconception is that it is only young cats that need play activity, but this is needed throughout life. Therefore, most cat owners do not bother to play with their cat once it has reached adulthood.

PATHOLOGICAL CONSEQUENCES OF OBESITY

Obesity-Associated Disorders in Humans, Dogs, and Cats

Obesity is known to have a number of significant effects in the dog and cat besides its adverse effects on the human body (Table 26.1), the most notable of which is

TABLE 26.1 Diseases associated with overweight and obesity in humans, dogs, and cats

Disease category	Species		
	Human	**Dog**	**Cat**
Endocrine and lipid	Type II diabetes, metabolic syndrome, dyslipidemias	Hypothyroidism, hyperadrenocorticism, diabetes mellitus, insulin resistance, metabolic syndrome (experimental)	Diabetes mellitus, hepatic lipidosis
Cardiorespiratory	Coronary heart disease, atherosclerosis, hypertension, obstructive sleep apnea, asthma	Tracheal collapse, expiratory airway dysfunction (experimental), hypertension (of doubtful clinical significance), portal vein thrombosis, myocardial hypoxia	
Orthopedic and impaired mobility	Osteoarthritis, musculoskeletal pain, gout	Osteoarthritis, cruciate ligament disease, humeral condylar fractures, intervertebral disc disease, hip dysplasia	Increased lameness
Oncological	Various cancers, including breast (postmenopausal), renal, endometrial, prostatic, esophageal, colonic/rectal, hepatocellular carcinoma	*Variable neoplasia risk:* Transitional cell carcinoma, mammary carcinoma (some but not all studies)	Increased neoplasia risk
Urogenital	Diabetic nephropathy	Urinary tract disease, urethral sphincter mechanism incompetence, calcium oxalate urolithiasis, transitional cell carcinoma, glomerular disease (experimental), dystocia	Increased risk of urinary tract disease
Alimentary	Pancreatitis, hepatic steatosis, cirrhosis	Pancreatitis	Increased oral cavity disease and gastrointestinal disease
Other	Depression, postoperative complications, various dermatologic diseases	Immune function	Increased risk of dermatoses

From German AJ, Ryan VH, German AC, et al. (2010). Obesity, its associated disorders and the role of inflammatory adipokines in companion animals. *Vet J* 185(1):4–9, reprinted with permission.

metabolic syndrome, whereby metabolic and vascular derangements develop that predispose the individual to type II diabetes mellitus and cardiovascular disease. As fat mass increases (especially within the abdomen), so does the severity of insulin resistance and, ultimately type II diabetes mellitus. Given this close association, it is not surprising that the prevalence of type II diabetes mellitus has increased at an equivalent rate to that of obesity. Obesity, through metabolic syndrome, also leads to cardiovascular disease, with an associated increased prevalence of coronary heart disease, atherosclerosis, hypertension, and dyslipidemias in people who are overweight. Most notably, metabolic syndrome is a predictor of a future vascular event and, therefore, its presence should prompt interventions aimed at reducing the risk of such problems.

Other obesity-associated comorbidities include respiratory disorders (especially sleep apnea and asthma), kidney disease (especially diabetic nephropathy), and osteoarthritis. Obesity is now the most important cause of liver disease, given the increased likelihood of affected patients developing steatosis, cirrhosis, and hepatocellular carcinoma. Obesity also increases the risk of certain types of cancer, most notably affecting the breast, prostate, ovary, colon/rectum, kidney, and esophagus.

Obesity-Associated Disorders in Companion Animals

Life Span

In a long-term prospective study, restricting caloric intake (by approximately 25%) in dogs was shown to maintain optimal body condition (BCS 4.5/9 vs. 6.8/9), and extend life span (based on time to euthanasia) by almost 2 years. In the same study, the restricted dogs were less likely to develop hip dysplasia (during growth) and osteoarthritis later in life (especially of the hip and shoulder joint). Finally, these dogs had improved glucose tolerance and lower circulating triglyceride concentrations compared with the *ad libitum* fed and overweight dogs.

Quality-of-Life Effects

In a recent study, health-related quality of life was assessed in obese dogs before and after weight loss. Quality of life was worse than for dogs at optimal weight but improved as a result of successful weight loss. These effects were most notable for "vitality" factors, which improved dramatically, and there was also less evidence of factors indicating chronic pain and emotional derangements. Moreover, the more body fat the dog lost, the greater the improvement in vitality. Dogs that failed to complete their weight loss program had worse quality of life at the outset than those successfully losing weight, most notably worse vitality and greater emotional disturbance.

Orthopedic Disorders

Of all disease associations, the link between obesity and orthopedic disease is most important in dogs. An increased prevalence of a variety of orthopedic disorders has been noted, including cranial cruciate ligament rupture, intervertebral disc disease, humeral condylar fractures, hip dysplasia, and osteoarthritis. Based on force plate analysis, weight reduction in obese dogs with osteoarthritis can lead to a substantial improvement in mobility.

As with dogs, obesity may be a risk factor for feline orthopedic disease. One study suggested that obese cats were five times more likely to be lame than normal condition cats, although not all studies confirm this finding. Further work is required to determine whether obesity truly has a causal effect on feline orthopedic disorders and, if so, what diseases specifically.

Endocrine and Metabolic Diseases

In dogs, associations between obesity and diabetes mellitus, hypothyroidism, and hyperadrenocorticism have been demonstrated; for cats, the only association is with diabetes mellitus. Cats most often suffer from a form of diabetes mellitus resembling human "type II" diabetes, with insulin resistance being a major factor. Successful weight loss improves insulin sensitivity, significantly reducing the requirement for exogenous insulin therapy.

In diabetic dogs, there is progressive beta cell loss and absolute insulin deficiency, meaning that an affected dog will always need lifelong insulin therapy. The pathogenesis of beta cell loss is poorly understood and might not be the same as human type I diabetes. Putative causes include pancreatitis and autoimmune-mediated beta cell destruction. Furthermore, a large-scale epidemiological study in dogs demonstrated an association between obesity and diabetes mellitus. Since obese dogs are also prone to pancreatitis, it might be that concurrence of this condition provides the causal link with diabetes mellitus. However, insulin resistance may also play a role because it is known to occur in experimental models of canine obesity. Indeed, a recent study of naturally occurring obesity in dogs has demonstrated that the percentage of body fat correlates with the degree of insulin resistance, and insulin sensitivity is improved significantly on successful weight loss.

Obesity can have marginal effects on thyroid homeostasis, but the changes are not biologically significant and are unlikely to affect the interpretation of thyroid function tests. In this respect, obese dogs have slightly greater total thyroxine (T4) and triiodothyronine (T3) concentrations than ideal weight dogs, but generally remain within the reference interval, and free T4, thyroid stimulating hormone (TSH), and TSH tests are not significantly different.

Hyperlipidemia and Dyslipidemia

Feline obesity has long been known to predispose to hepatic lipidosis, and epidemiological studies have confirmed this link. Experimental studies in obese dogs have demonstrated mild (but likely clinically insignificant) hypercholesterolemia, hypertriglyceridemia, and increased circulating phospholipid concentrations.

In contrast, experimental studies of canine obesity have demonstrated increased plasma nonesterified fatty acid and triglyceride concentrations (increased very low-density lipoprotein and high-density lipoprotein; decreased high-density lipoprotein cholesterol), which associate with insulin resistance.

Respiratory Function

A number of studies have now demonstrated that excessive body fat can adversely affect respiratory function in dogs, and the same is likely to be true in cats. Such effects are similar to those seen in humans and may help to explain the link between obesity and certain respiratory diseases in dogs, most notably tracheal collapse, laryngeal paralysis, and brachycephalic airway obstruction syndrome. The exact nature of the effects on respiratory function differs depending on the study. In one experimental study, airway resistance was markedly increased during hyperpnea but not when breathing normally. A second study demonstrated that obese dogs had a decreased tidal volume and increased respiratory rate, as well as increased airway reactivity. In a further study, obesity had a significant effect on oxygenation but not on oxygenation indices, being most closely negatively associated with thoracic fat percentage. Finally, in a further study, obesity was shown to negatively affect cardiopulmonary function, as determined by the 6-minute walk test. The human term "Pickwickian syndrome" is sometimes used to describe respiratory impairment in morbidly obese pet animals. This is taken from Charles Dickens' character, Mr. Pickwick, who showed the signs that the syndrome is named after.

Cardiac Function

In dogs, obesity is known to affect cardiac function, as demonstrated by alterations in cardiac rhythm and increases in left ventricular volume; there is no evidence of a similar association in cats. However, overweight cats with heart failure have reduced survival times compared with cats in normal body condition. Mild hypertension does occur in canine obesity, but the effect has not yet been shown to be as clinically significant as in humans.

Finally, obesity in dogs may be associated with portal vein thrombosis and myocardial hypoxia.

Neoplasia

Although epidemiological studies have demonstrated an association between obesity and the presence of neoplasia in both dogs and cats, such a link has not been confirmed in all studies. Other studies have examined associations with specific cancer types and, although not conclusive, links have been suggested with transitional cell carcinoma and mammary carcinoma.

Renal System Function and Disease

In experimental dogs, the onset of obesity is associated with glomerular pathology and changes in function, including increased plasma renin and insulin concentrations, mean arterial pressure, and renal blood flow. In a more recent study, a number of renal biomarkers were assessed in obese dogs with evidence of subclinical decreases in renal function, which improved after weight loss. However, it is unclear as to the significance of these changes and, most importantly, whether or not they may predispose to renal disease, as in humans. Associations have also been demonstrated between obesity and urethral sphincter mechanism incompetence, while obese animals have an increased risk of dystocia.

Other Disorders

Epidemiological studies have demonstrated associations between feline obesity and oral cavity disease, dermatologic disorders, and diarrhea. However, the reasons for such an association are not known.

CLINICAL PRESENTATION

Obesity is typically a disorder that develops insidiously and is most commonly seen in early middle age, with peak prevalence occurring in 6- to 10-year-old dogs and 5- to 11-year-old cats. In both species, prevalence declines in old age and is also less in growing dogs. The disease can be seen in dogs and cats of either sex, and typically (but not always) they are neutered. Any breed may be affected, although there are certain predispositions including Cocker Spaniels, Beagles, Labrador Retrievers, Golden Retrievers, Shetland Sheepdogs, Rottweilers, and mixed-breed dogs.

Clinical signs vary depending on how overweight the dog or cat is and the extent of obesity-associated diseases. Common signs directly attributable to the obesity include lethargy, exercise intolerance, increased respiratory rate and effort, abnormal respiratory tract sounds (e.g., stertor and stridor, often commonly while recumbent or sleeping), and altered gait (typically due to the mechanical effects of excessive truncal and limb fat deposition). Appetite can be variable; while some dogs are polyphagic and scavenging, some owners may report that their dog has a picky appetite and does not eat all of the food in its bowl. The latter is thought to be due to owners providing food vastly in excess of requirements and, often, giving significant numbers of food-based rewards. This means that the dog or cat can still overeat despite not eating everything they are given. Examples of clinical signs include lameness (orthopedic disease), abdominal pain (pancreatitis), vomiting (pancreatitis, hepatic lipidosis), icterus (hepatic lipidosis), polydipsia and polyuria (diabetes mellitus), coughing (respiratory disease), and incontinence (urethral sphincter mechanism incompetence).

On physical examination, altered body shape is always readily apparent, most easily determined using body condition scoring (see ahead given in the text). There may be signs of an associated disease, for instance abdominal pain with pancreatitis or pain on joint manipulation. Poor skin and coat condition is

often present, and cats that are markedly obese often have fecal soiling of the perineum due to inability to groom. In dogs with concurrent hypothyroidism or hyperadrenocorticism, alopecia and other typical skin changes may also be evident. Auscultation and abdominal palpation can be problematic given excess truncal fat deposition, both subcutaneously and within both body cavities. Likewise, while a pulse is usually palpable, it can be more difficult to determine pulse quality due to excess subcutaneous fat in the inguinal region. Thoracic auscultation can be muffled because of intra- and extrathoracic fat deposits.

DIFFERENTIAL DIAGNOSIS

In addition to body fat mass accumulation, other possible reasons for weight gain include changes in hydration status (usually iatrogenic) and intracavitary fluid accumulation (e.g., ascites). In such cases, the weight change is rapid, and other signs are expected. Thus, they can be readily distinguished from weight gain due to obesity. In male cats, gradual weight gain can also arise secondary to acromegaly, although weight gain results from increases in muscle mass, organomegaly, and increased bone mass, in addition to adipose tissue. Therefore, this can usually be distinguished on physical examination; however, this might be counteracted by co-existing diabetes mellitus.

Therefore, if weight gain is gradual, obesity is the most likely cause and the aim of the clinician is to distinguish "simple obesity" (due to energy imbalance) from cases that have arisen secondary to another disease, most notably hyperadrenocorticism or hypothyroidism (dogs). Other than this, possible differential diagnoses relate to the presence of other signs that may have developed secondary to associated diseases. Such lists can sometimes be extensive, given that the signs associated with obesity can be both diverse and nonspecific, and the diagnosis of simple obesity can only be made once other possibilities have been adequately excluded. Therefore, the differential diagnosis list needs to be tailored to the individual case. For example, in cases presenting with respiratory tract signs, consideration should be given to other possibilities that present insidiously in middle age such as upper respiratory tract diseases (e.g., laryngeal paralysis, brachycephalic airway disease), airway diseases (e.g., chronic airway disease), pulmonary disease (e.g., pulmonary neoplasia), and other intrathoracic diseases. In a similar manner, tailored differential diagnosis lists should be created when there are signs of lameness, vomiting, abdominal pain, and incontinence.

DIAGNOSIS

The overall aim is to confirm that the weight gain is the result of increased adipose tissue mass, determine which risk factors are present, and determine whether there is evidence of an underlying cause (e.g., endocrinopathy, iatrogenic weight gain) and whether other concurrent diseases might be present. In addition, the clinician should aim to determine current health status (which will influence how the case is investigated and managed) and quantify the degree of obesity. With regard to health status, it is critical to identify all concurrent diseases, whether or not they are likely to be directly related to the obesity. This will then enable the clinician to determine the most appropriate plan for weight management, determine both the ideal weight and an appropriate target weight, and also to decide on the safest and most effective approach for weight loss. The exact tests that are required in the individual case can then be decided.

History and Physical Examination

The first stage of diagnosis is to obtain a history, including diet history, and perform a physical examination. In addition to a standard medical history (including any prior or current therapy), the history should include details of diet, exercise, environment, the family unit (pets and people), lifestyle, and neuter status. Physical examination should focus on quantifying the obesity and determining the presence of associated diseases that are either causing or contributing to weight gain or presenting as incidental findings.

Body Weight Measurement

The dog or cat should be weighed on electronic scales that, ideally, have been calibrated for precision and accuracy, as well as being serviced regularly (e.g., annually). If test weights are not available, an item of known weight can be used instead (e.g., bag of dry dog food). It is advisable for the practice always to use the same set of electronic weigh scales for weight measurements, since this will minimize errors from readings obtained with different sets of scales. Adopting a practice policy of weighing all animals at every visit throughout life is recommended, combined with regular BCS assessment (see ahead given in the text); given that most cases of obesity develop later in life, there may be a historical record of an early adult weight (i.e., 1 year for cats, 2 years for dogs), where the animal was in ideal condition. This can be used to estimate the ideal weight of the patient (see ahead given in the text).

Clinical Assessment of Body Shape and Composition

Body Condition Scoring

The most widely accepted clinical method of assessing body composition is body condition scoring. BCS schemes assess adipose tissue mass through visual assessment and palpation. Although a number of methods are available, including a modification called the body fat index, the WSAVA Global Nutrition Committee has recently recommended the use of the 9-integer unit system, with an additional assessment for muscle mass

Box 26.1 Calculations for estimating ideal weight in obese cats and dogs

In published studies, each unit on a 9-point BCS scheme approximates to 10% of excess body weight. Therefore, a simple equation can be used to estimate the ideal weight of a dog or cat from current body weight and BCS:

Current weight = 50 kg

↓

Current condition score = 9/9 (~40% overweight)

↓

Ideal weight = 50 kg – (50 × 40/100) = 30 kg

Note: While this is a reasonable guide, due to individual variability, this equation can over- or underestimate ideal weight. If necessary, as weight loss progresses, adjustments to the estimated ideal weight may be needed.

(as + or –) (see Figures 26.2 and 26.3). This ensures consistency among clinicians.

Systems for determining BCS are the simplest indirect measures of body composition currently available. Such systems are repeatable when used by trained individuals and correlate well with body fat mass measured by dual-energy X-ray absorptiometry (DEXA), although owners tend to underestimate the shape of their dogs. BCSs can also be used determine how overweight a patient is, with each point (for a 9-unit system) correlating with ~10%–15% of excess total body weight. This will enable the degree of obesity to be determined and will enable the ideal weight to be estimated (Box 26.1). BCSs should also be used periodically during the weight program to check on progress and adjust target weight if required. However, this should not be done too frequently, as changes in body composition are relatively insensitive with, on average, a 10% change in body weight being required to change scores.

Zoometry

Various zoometric approaches have been described, usually performed with a tape measure. Measurements that correlate with overall "stature" (e.g., head, thorax, and limb length) are combined with measures that correlate with adiposity (e.g., body weight and body [thorax, abdomen, or neck] circumference). Equations are then used to predict body fat mass from these measurements. An early example was the Feline Body Mass Index™ while, more recently, a new zoometric system (Hill's Healthy Weight Protocol) was reported, which used a combination of four (dog) or six (cat) measurements. Both of these systems correlate well with body fat mass measured by DEXA. However, while these may be more objective than traditional BCS assessment, it is arguable as to whether or not they offer any real advantage. In this respect, they are more complicated to perform and require greater patient compliance. In addition, they may be more prone to errors of inaccuracy among investigators (who may measure differently) or to small patients (where minor errors in measurements could have a profound effect). Finally, the accuracy of such measurements decreases as patients become leaner.

Bioimpedance is another noninvasive method potentially applicable to first-opinion practice. However, handheld machines designed for dogs can be unreliable and are inferior to body condition scoring. Finally, photographs can provide a subjective means of demonstrating longer term changes in body weight to clients, thus highlighting success (Figure 26.2a–f). Techniques for indirect body condition assessment from photographs have also been described.

Further Investigations

Routine hematologic examination, clinical biochemistry, and urinalysis can provide general information on health but are not essential in all cases. Such procedures are more commonly performed in older animals or in animals where there are concerns about concurrent disease (based on the historical and physical examination findings). Depending on the case and the judgment of the attending clinician (i.e., if there is a suspicion of an associated disease), additional investigations may be required in some circumstances, with the exact tests required being at the discretion of the clinician. For instance, some cases may require measurement of blood pressure, assessment of thyroid and adrenal gland function in dogs, pancreatic enzyme measurement, fructosamine measurement for diabetes mellitus, survey radiography for possible orthopedic and respiratory disease, abdominal ultrasonography (most commonly to assess pancreas, liver, adrenal glands, kidneys, and lower urinary tract), fine-needle aspiration cytology, and/or liver biopsy (for suspected hepatic lipidosis). Bacterial culture of urine, bladder ultrasonography, and radiographic contrast studies might also be needed for cases presenting with lower urinary tract diseases.

Other Investigations

Advanced Body Composition Measurement

Body composition can be assessed in various ways. DEXA is precise and reliable and has been used extensively in research studies and in referral clinical practice (Figure 26.3a–c). It can help to determine ideal body weight and also be used to monitor progress with weight loss (i.e., determining loss of lean tissue). However, it is a specialist procedure, so is not needed in first-opinion practice where simpler methods suffice. Instead, such procedures should be considered for problem cases where weight loss has been problematic despite instigating a weight management regimen (see ahead given in the text).

Other advanced techniques, which have been validated for use in dogs and cats, include CT and MRI. Such techniques are arguably better at determining regional body fat mass distribution than DEXA.

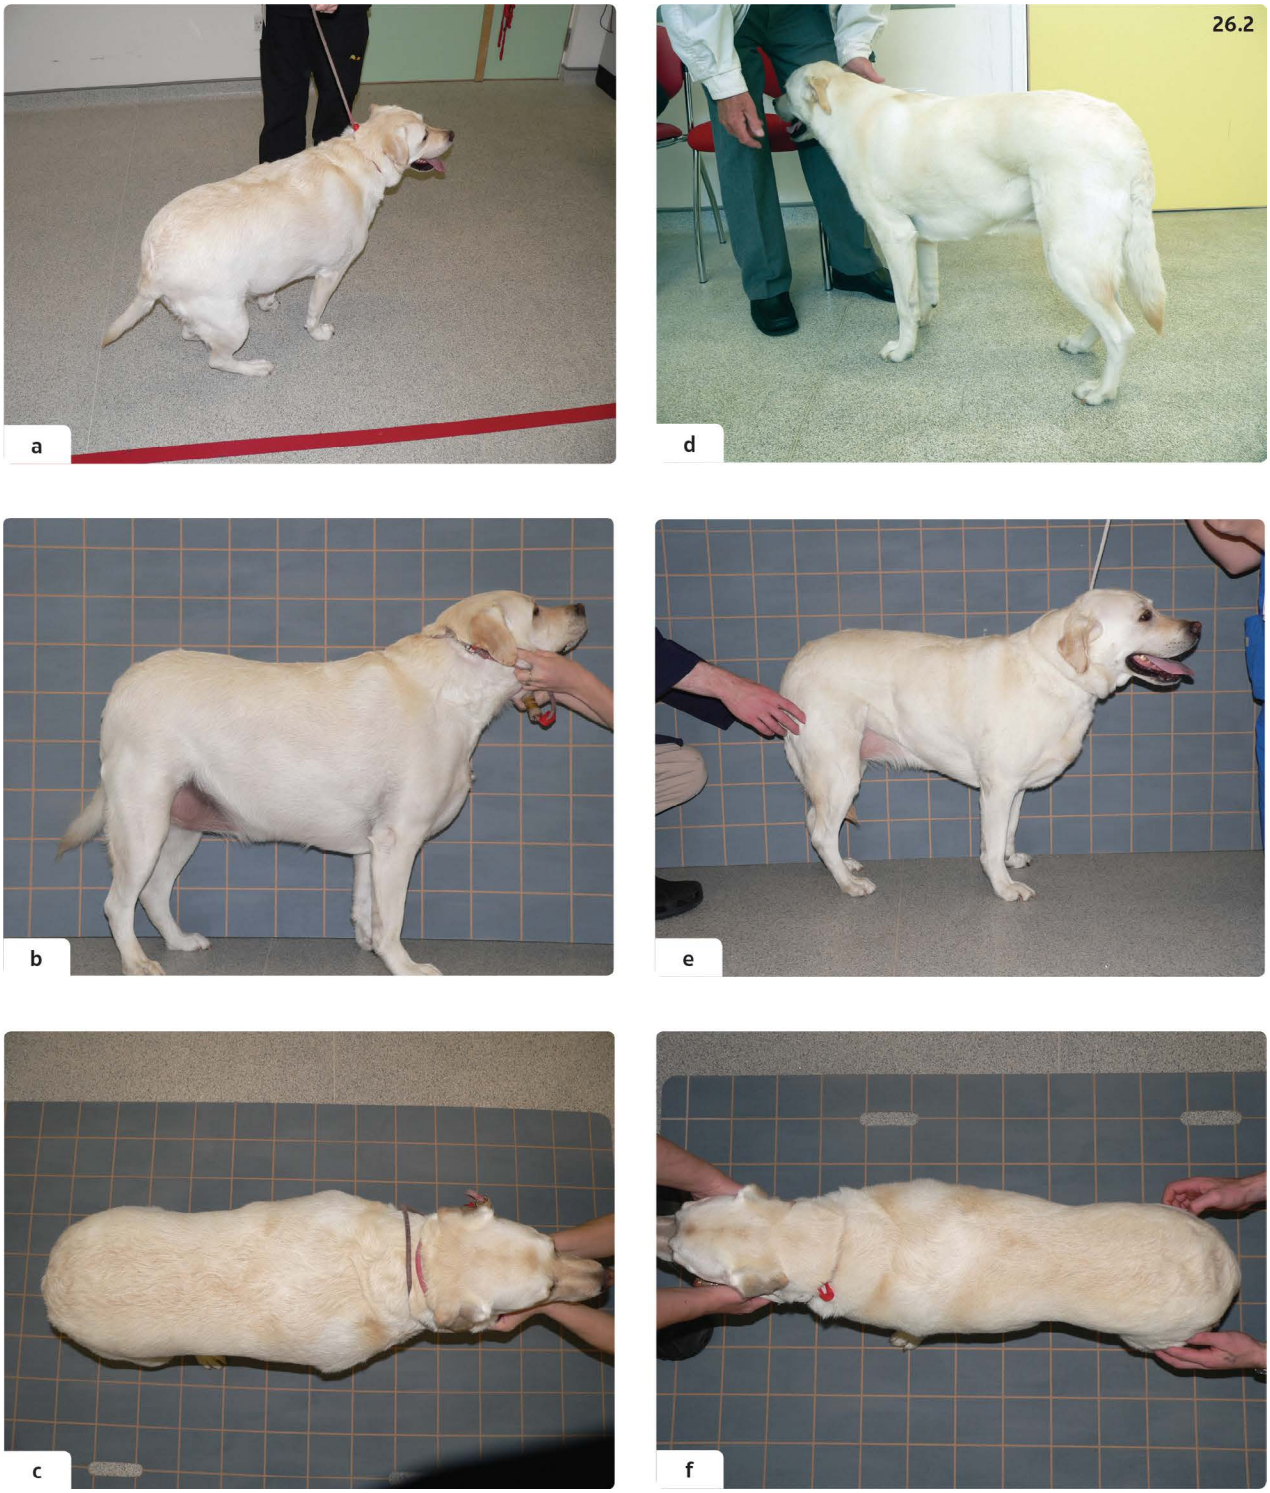

FIGURE 26.2 **(a–c)** Photographs of an obese 5-year-old neutered female Labrador Retriever weighing 49.0 kg (108.0 lb) and with a body condition score of 9/9. **(d–f)** Photographs of the same dog, 268 days later, after successful weight loss on a high-protein, high-fiber diet. Body weight had decreased to 33.6 kg (74.1 lb.), and condition score was 5/9. Total weight lost was 31% of starting body weight, at a rate of 0.8% per week.

However, they are more expensive and again are limited to referral institutions and have limited availability; once again, therefore, they are more appropriate for referral rather than primary care cases. Finally, assessment of total body water (typically using isotope studies) has been used extensively in a research setting for determining body composition in dogs and cats. However, such methods have not yet found a clinical application.

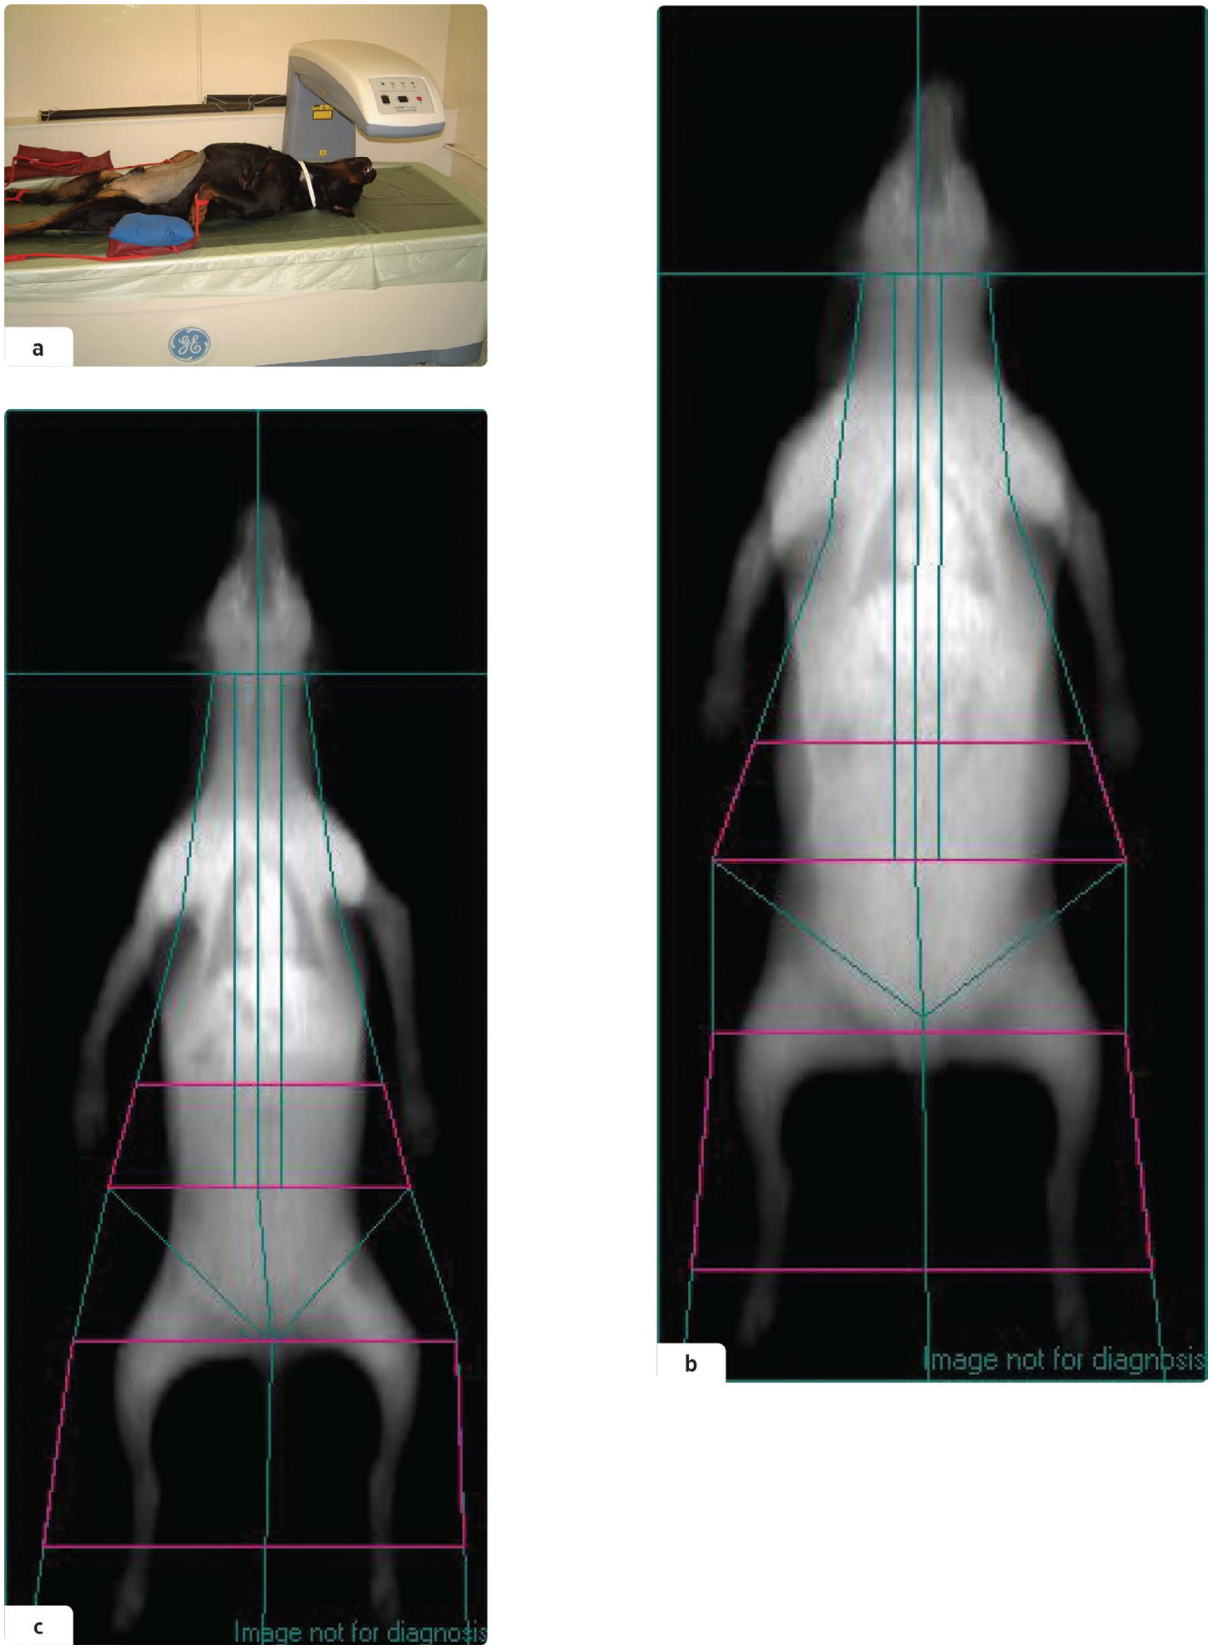

FIGURE 26.3 Dual-energy X-ray absorptiometry (DEXA) as a noninvasive means of determining body composition. **(a)** A fan-beam DEXA machine. **(b)** Image from a pre-weight-loss DEXA scan performed on the dog featured in **Figure 26.2**; body fat mass was estimated to be 51%. **(c)** Post-weight-loss DEXA scan from the dog featured in **Figure 26.2** demonstrating that body fat mass had declined to 36%. Based on the DEXA figures, the estimated composition of the body tissue lost was 83% fat and 17% lean.

Assessment of Metabolizable Energy Requirements and Energy Expenditure

For success in weight management, it is usually necessary to estimate the metabolizable energy requirement to maintain body weight (a.k.a. maintenance energy requirement [MER]). The most common method of determining MER is to use predictive equations, but such equations represent little more than an educated guess and, even in healthy individuals, may miss actual requirement by 50%. Research methods for determining MER include feeding experiments, while methods for determining energy expenditure (EE) (a proxy measure for MER) include indirect calorimetry and tracer studies such as double-labeled water. Arguably, indirect calorimetry is most applicable to the clinic; it has been widely used in human patients including for the determination of EE in the morbidly obese. Indirect calorimetry can provide reliable measurements of EE in healthy dogs, trauma cases, and cancer patients. However, this technique has not yet found a clinical application for obesity management. Portable indirect calorimeters have recently been developed for human patients and, once validated for dogs and cats, might provide a useful tool to help in weight management.

MANAGEMENT

In humans, the most successful approach to achieve weight loss is through bariatric surgery, but this is not likely to be either practical or ethically justifiable in companion animals. Dietary therapy is the most widely accepted method of weight management, although drug therapy (using microsomal membrane transfer protein [MTP] inhibitors) is also approved for the weight loss phase in dogs but not cats. The weight loss phase can be variable in length but is typically 6–18 months and occasionally prolonged (i.e., over 2 years).

Weight management in cats and dogs involves two stages: The weight loss phase whereby there is steady fat mass loss, and weight maintenance, which involves stabilizing body weight and preventing rebound. The fundamental aims of weight management are to improve quality of life and reduce associated disease risk. In so doing, you aim to change the relationship between pet and owner to one that promotes a healthy lifestyle. Thus, the amount of weight loss that you recommend and the target weight can vary. Unless the habits of the owner change for the long term, the management will fail, and weight regain will occur.

Target Weight, Ideal Weight, and Tailoring the Individual Plan

In setting a weight loss plan, it is essential to know the ideal weight, since this will be used to set the initial caloric intake (see ahead given in the text). The ideal weight is defined as the weight at which fat mass is optimal for that animal. In reality, there will be a range of weights that are deemed to be ideal, rather than a single weight (typically body fat <20% for domestic cats and <35% for dogs). If a historic weight measurement is available (e.g., an early adult weight), where the animal was in optimal condition, that weight corresponds to the animal's ideal. If such a weight is not available, an alternative approach is to determine ideal weight from the current weight and BCS. In this regard, each unit on the scale between 5/9 and 9/9 approximately corresponds to 10%–15% of excess weight. Therefore, with a simple calculation, the ideal weight can be calculated (see **Box 26.1**).

Although often used interchangeably, the terms target weight and ideal weight are not the same. The target weight is defined as the weight that the clinician determines to be an appropriate endpoint for weight loss. For some animals, the target weight and ideal weight may be equivalent, while for others target weight is greater. The main benefits of aiming for ideal weight (as your target) is that the greatest beneficial effects on disease prevention and life span extension might be expected. Such an approach would be most beneficial for young animals with a long-expected life span and free from concurrent disease. However, such benefits diminish in older cats and dogs, where remaining life span is shorter and concurrent diseases may already exist. Instead, weight management should focus on improving quality of life, and it may not be necessary to achieve ideal weight to achieve this. In fact, a study in dogs has revealed that reductions in severity of disease typically occur with modest (i.e., >5%) reductions in weight. Therefore, aiming for partial weight loss would be more realistic, quicker, and, arguably, more appropriate in older animals, especially those with concurrent disease. In humans, an "obesity paradox" has been identified. In this respect, being overweight increases the risk of developing certain diseases, but once that disease develops, increased BMI can improve survival. Examples of a similar obesity paradox have also been seen in animals with chronic kidney disease and cardiac disease, with a recent study demonstrating longer survival times in overweight cats. In such cases, only a modest weight reduction (of 5%–10%) would be recommended but aiming to maintain the patient within its overweight range. Such a weight loss protocol will not lead to significant loss of lean tissue but can improve quality of life.

Expected Rate of Weight Loss

The recommended rate of weight loss is controversial, since initial recommendations of 1%–2% per week were based on obese dogs managed in a colony setting, and not client-owned dogs. While such rates can be achieved early in the weight loss process (i.e., first 1–2 months), it becomes increasingly difficult to maintain this over the long term. Instead, an average rate of weight loss of 0.5%–1.0% per week is more realistic and appears to be safe. Overly rapid rates of weight loss (>2% per week) are not recommended since there is a potential to cause problems (e.g., excessive lean tissue loss or hepatic lipidosis [cats only]). However, in reality such rates are rare.

Slower rates of weight loss (<0.5% per week) might be acceptable, although the whole process will likely take longer and might be a source of owner frustration.

Dietary Management

Diet Formulation

Purpose-formulated weight loss diets are recommended because energy content is reduced. This helps to promote weight loss because rate is principally determined by energy intake. Weight loss diets are also supplemented with protein (amino acids) and micronutrients, relative to their energy content, and this ensures that deficiency states do not arise despite energy restriction. A recent study has demonstrated that, despite often marked energy restriction, nutrient deficiencies are not observed. While supplementing protein, relative to energy content, does not speed up the rate of weight loss, it ensures that lean tissue loss is minimized, and also has beneficial effects on satiety (see ahead given in the text). L-carnitine facilitates transport of fatty acids in mitochondria, assisting their oxidation, and supplementation in a weight loss diet also assists with maintaining lean tissue mass during weight loss, while supplementation of micronutrients, relative to energy content, ensures that deficiency states do not arise.

Altering the macronutrient content of a weight management diet can also improve satiety, and the most common approach is to supplement fiber content. However, in dogs, supplementing both protein and fiber provides an additive benefit, and such diets improve the outcome of weight loss by speeding up the overall rate, increasing the likelihood of reaching target weight, and preserving lean tissue. The situation is more complex for cats, since protein content is a key determinant of voluntary food intake and incorporating more can increase rather than decrease voluntary food intake. Furthermore, incorporating too much fiber can make the diet unpalatable. Therefore, for cats, the greatest effect on satiety occurs when fiber and protein are both moderately, rather than markedly, supplemented.

Energy Intake during Weight Loss

There are various approaches to calculating the energy intake required for controlled weight loss. Some clinicians recommend first calculating resting energy requirements for the current body weight (i.e., for dogs: 70 kcals × body weight 0.75/day), and then feeding 80% of this amount. While this has the benefits of simplicity, it does not take into account the degree of excess body weight and the initial response may be more variable. Adjustments may be required in the early weeks to determine the correct energy intake for the individual case.

The author prefers an approach whereby energy intake is, instead, based on ideal body weight and not the current weight. Arguably, this approach enables the clinician to produce a more precise starting point for the energy intake required for weight loss because the magnitude of excess weight is better factored in. Ideal weight can be estimated in various ways (see mentioned in the text earlier). Exact recommendations on energy intake are then varied depending on the species, gender, neuter status, and presence of co-existing (especially orthopedic) disease. In dogs, a recent study suggested that a typical starting allocation for weight loss should be approximately 60 kcal/kg metabolic body weight (MBW) at target weight 0.75, with neutered dogs requiring less energy than entire dogs and female dogs less than male dogs. However, while this initial allocation might be sufficient during the first few weeks of the weight loss program, energy intake often needs subsequently to be modified, as and when weight loss slows. Typically, small adjustments (of up to 5%) are made on each occasion. Indeed, in the canine study described earlier, mean energy intake over the entire weight loss period was 57 kcal/kg MBW at target weight.

Calculating energy intake for weight loss is simpler in cats, where a linear equation is suitable. In one study, an average starting allocation of 40 kcal/kg target weight was successful in most cats, with mean energy intake over the whole of weight loss being 32 kcal/kg. With this degree of restriction, the mean rate of weight loss is 0.8% body weight per week.

Whatever the method of determining food intake, precision in portioning is absolutely critical in order to ensure success. Use of measuring cups should be avoided since portion sizes are imprecise and variable (usually being overestimated). Instead, electronic kitchen scales to weigh out food portions are strongly recommended. If at all possible, owners should not give any additional food (e.g., table scraps or treats) and care should be taken to prevent the patient from scavenging. If desired, food can be given in two, or more, meals per day, preferably providing more food at times when the owner is with the pet (since this is when begging is most likely to occur). However, use of an interactive feeding device is preferred (e.g., puzzle feeding toy or modified feeding bowl). These devices have the effect of slowing food intake, thereby improving satiety.

Occasional treats may be sanctioned (preferably some of the weight management food or a dog treat of known caloric content [e.g., dental treat]), but it is essential to take them into account so that they are included in the overall allocation and provide <5% of total daily requirements.

Pharmaceutical Therapy and Weight Loss

Two drugs have been licensed for use in dogs (but NOT cats): Mitratapide and dirlotapide. Although they have now been available for a number of years, and there is reasonable evidence of efficacy, they have not been used widely in a clinical setting. Both of these drugs are MTP inhibitors and have a local effect on the intestinal epithelial cell, blocking the assembly and release of lipoprotein particles into the bloodstream. Dietary caloric intake is decreased both by decreasing lipid absorption and by decreasing appetite (the latter thought to be due to release of a satiety signal that acts centrally on the appetite center). The efficacy of these drugs declines if they are administered in conjunction with a low-fat

(<10%) diet. In Europe, both mitratapide and dirlotapide are licensed, but only dirlotapide is licensed in North America.

Mitratapide is only licensed for short-term use (i.e., 8 weeks) and was designed to kick-start a conventional weight loss program. In contrast, dirlotapide is licensed for continuous use for up to 12 months, which is sufficient for many, but not all, weight loss programs. Weight loss occurs at a steady rate (0.75% per week on average), but periodic increases in dose are required to maintain weight loss.

The most common side effects are vomiting and diarrhea, and these are observed in up to 20% of patients. If owners are forewarned that it may occur, then it is usually better tolerated. Anorexia can also occur. While these drugs can be successful in promoting weight loss, appetite returns rapidly when they are discontinued, and so other strategies (feeding and behavioral) must also be implemented to be successful. Without this, a rapid and predictable rebound occurs.

Lifestyle Management

Increasing physical activity is also recommended for most affected animals since it can assist in lean tissue preservation and, possibly, help to prevent the rapid regain in weight that can occur after a period of successful weight loss. It is also rewarding for owners since it represents an alternative to giving food-based rewards. Suitable exercise strategies in dogs include lead walking, swimming, hydrotherapy, and treadmills. Cats can be encouraged to increase their activity through regular play sessions with cat toys (e.g., fishing rod toys), motorized units, and puzzle feeders (see mentioned in the text earlier). Ideally, daily exercise should be taken and, for dogs, 30 minutes or more is preferred. For cats, short periods of play activity are used, typically 1–2 minutes at a time two or more times per day. The exercise program should be tailored to the individual and take account of any concurrent medical concerns.

Monitoring Weight Loss

Regular weight checks should be scheduled during weight loss. At the start of the program, it is best to book reweigh sessions at 2-week intervals, since this is the time when the owner is becoming accustomed to dramatic changes in lifestyle, and adjustments to the plan may be required if weight loss is progressing too quickly or too slowly. Thereafter, in patients where weight loss is progressing steadily, the interval between checks can be increased, but should not, ideally, exceed 4 weeks. More frequent checks may be needed in cases where weight loss is slow or stalls regularly. It is usually best if a dedicated member of staff takes charge of weight management. That way, they can get to know the client, and build up a trusting relationship, improving the likelihood of success. Given that some clients require intensive support throughout the program, it is advisable for staff to be trained in owner counseling.

Once the target weight is reached, food intake is increased gradually (typically in increments of up to 5%), until body weight stabilizes. Thereafter, weight checks should continue but the frequency can be gradually decreased. It is essential to continue to monitor body weight after ideal weight has been achieved to ensure that weight that was lost is not regained. Weight regain is a recognized phenomenon in humans who diet, although the reasons are still unclear. The most likely explanation is that when obese humans are returned to a lean state, their resting metabolic rate slows. Studies in dogs have also demonstrated a tendency for weight regain, although it affects fewer patients and rarely do dogs regain all the weight lost. Other studies have demonstrated that, as in humans, the MER is less after weight loss. In a recent study examining follow-up after successful weight loss, almost half of the dogs regained weight. Critically, when the diet was switched from the purpose-formulated weight management diet to a different diet (typically a standard maintenance diet), dogs were 20 times more likely to regain weight. Thus, owners should be strongly recommended to continue to feed the weight management diet, albeit to maintain weight rather than achieve further weight loss. In a similar study in cats, weight regain was again identified, and the problem was of a similar magnitude to dogs. However, the most notable factor associated with weight regain was age, with younger cats (<9 years of age) more likely to rebound.

PROGNOSIS

When an animal is predisposed to obesity, both through individual and environmental factors, many of these predispositions will remain after weight loss. Further, the post-weight loss MER is significantly less than it was prior to weight loss. For these reasons, obesity can only be managed and never cured, and the prognosis for long-term success is guarded. In the author's experience, most (80%–90%) cats and dogs lose at least 10% of weight on a program, with approximately two-thirds reaching their target weight. Recent work by the author has identified that initial body fat mass is negatively associated with the likelihood of reaching the target weight. Furthermore, dogs fed a dry weight management diet were more likely to succeed than those fed either wet food or a combination of wet and dry food. The remaining dogs and cats fail to lose significant weight and are commonly lost to follow-up. Owners of these animals often decide not to return to the clinic and become noncontactable. Thus, the exact reasons for discontinuing the program are difficult to determine.

PREVENTION

Given the variable outcome of weight management diets, prevention of obesity is likely to have a more significant beneficial effect on the health and welfare of all dogs and cats, rather than by treating once the problem

has developed. Advice on correct nutrition and exercise should be included in all puppy and kitten consultations and continued throughout the life of the animal. Body weight and BCS should be assessed at every consultation and also during the annual health check. Regularly monitoring body weight and BCS throughout life can enable subtle changes (e.g., ±5%) to be identified and rectified before the problem worsens. Veterinarians should also be alert to the weight gain that can occur as a consequence of neutering. It is advisable to schedule 2–3 checks for weight and BCS in the first 6–12 months after neutering to identify those patients that gain excessive amounts of weight at this time.

Finally, knowledge of pet ownership styles could ultimately be used to help in obesity prevention. If certain ownership styles were known to predispose to weight gain and obesity, then targeted owner education could be applied to owners with such styles. A recent study has identified that different populations of cat exist that respond differently to long-term *ad libitum* feeding. Some cats are unable to regulate their food intake, leading to gradual lifelong weight gain, while others maintain stable weight and optimal body condition lifelong, presumably by regulating intake. Therefore, this work suggests that different groups of cats have different feeding styles; some are regulators, while others tend to overeat. When it comes to preventing weight gain, attention should be paid to matching pet ownership style to feeding style. For example, an owner with an indulgent feeding style would be a bad match for a cat that overeats but is likely to be fine if they were to own a cat that self-regulates intake.

Lacrimal system manifestations of systemic disease
  keratoconjunctivitis sicca, 824–825
  Sjögren's-like syndrome, 825
Large intestine, diseases of, 341–359
  acute colitis, 341
  acute idiopathic colitis
    clinical presentation, 342
    diagnosis, 342
    etiology, 342
    management, 343
    pathophysiology, 342
    prognosis, 343
  anatomy and physiology, 341
  chronic colitis, 343
  chronic idiopathic colitis, 344
  chronic idiopathic large bowel diarrhea, 348
    clinical presentation, 348
    definition/overview, 348
    diagnosis, 348
    etiology/pathophysiology, 348
    management, 348
    prognosis, 348
  colorectal obstruction
    clinical presentation, 347
    diagnosis, 347
    differential diagnosis, 347
    etiology/pathophysiology, 347
    management, 347
    prognosis, 347
  constipation
    clinical presentation, 348
    definition/overview, 348
    diagnosis, 349
    differential diagnosis, 349
    etiology, 348
    management, 349–350
    prognosis, 350–351
  diet-responsive chronic colitis, 344
  functional large bowel disorders, 348
  fungal and oomycetal colitis, 343
  granulomatous colitis
    clinical presentation, 346
    definition/overview, 345
    diagnosis, 346
    etiology, 346
    management, 346–347
    prognosis, 347
  inflammatory bowel disease, 344
    diagnosis, 344–345
    differential diagnosis, 344
    etiology/pathophysiology, 344
    management, 345
    prognosis, 345
  parasitic colitis (whipworms), 343
    clinical presentation, 342
    definition/overview, 341–342
    diagnosis, 342
    differential diagnosis, 342
    etiology, 342
    management, 342
    pathophysiology, 342
  prognosis
    clinical presentation, 351–352
    diagnosis, 352
    differential diagnosis, 352
    etiology, 351
    management, 352
    pathophysiology, 351
    prognosis, 352
  rectal prolapse
    clinical presentation, 351
    definition/overview, 351
    diagnosis, 351
    etiology, 351
    management, 351
    prognosis, 351
  trichomoniasis, 343
    clinical presentation, 343
    diagnosis, 344
    differential diagnosis, 343
    etiology, 343
    management, 344
    pathophysiology, 343
    prognosis, 344
  whipworms, 343
Laryngeal diseases
  laryngeal edema
    clinical presentation, 204
    definition/overview/etiology, 204
    diagnosis, 204
    differential diagnosis, 204
    management/prognosis, 204
  laryngeal paralysis, cats, 203
  laryngeal paralysis, dogs
    clinical presentation, 202
    definition/overview, 202
    diagnosis, 202–203
    etiology, 202
    management/prognosis, 203
  laryngeal tumors
    clinical presentation, 204
    definition/overview, 203–204
    diagnosis, 204
    differential diagnosis, 204
    management/prognosis, 204
Laryngeal dysfunction, 18
Laryngeal edema
  clinical presentation, 204
  definition/overview/etiology, 204
  diagnosis, 204
  differential diagnosis, 204
  management/prognosis, 204
Laryngeal paralysis, 413
Laryngeal paralysis, cats, 203
Laryngeal paralysis, dogs
  clinical presentation, 202
  definition/overview, 202
  diagnosis, 202–203
  etiology, 202
  management/prognosis, 203
Laryngeal paralysis polyneuropathy complex, 582
Laryngeal tumors
  clinical presentation, 204
  definition/overview, 203–204
  diagnosis, 204
  differential diagnosis, 204
  management/prognosis, 204
L-deprenyl, 514
Lead, 856–857
Lead poisoning, 680–681
Left atrium, 246
Left ventricle, 245–246
Leiomyosarcoma, 157
Leishmania chagasi, 897
Leishmaniasis, 698
Leptomeningeal cysts, 564
Leptospirosis, 458
  clinical presentation, 881
  definition/overview, 881
  diagnosis, 881–882
  differential diagnosis, 881
  etiopathogenesis, 881
  management, 882–883
LES-achalasia-like syndrome, 299
Lesion localization, 580
Lethargy, 21
Leukemoid response, 685
Leukocyte disorders
  basophilia, 688
  chronic inflammatory monocytosis, 690
  corticosteroid-induced monocytosis, 690
  corticosteroid-induced neutrophilia and monocytosis, 684
  cyclic hematopoiesis, 693
  decreased production neutropenia, 692
  eosinophilia, 685–686
  hypereosinophilic syndrome, 687–688
  hypoadrenocorticism (Addison's disease), 686–687, 689
  inflammatory eosinophilia, 686
  inflammatory neutropenia, 691
  inflammatory neutrophilia, 684
  leukocytosis, 684
  leukopenia, 691
  lymphocytosis, 688–689
  mastocytemia, 690
  monocytosis, 689
  neutropenia, 691
  neutrophilia, 684
  paraneoplastic eosinophilia, 687
  peripheral destruction neutropenia, 692
  physiologic and corticosteroid-induced neutrophilia and monocytosis, 684
  reactive mastocytemia, 690–691
  redistribution neutropenia, 691–692
  severe combined immunodeficiency, 693–694
Leukocytosis, 684
Leukopenia, 691
Lidocaine, 1008
Lilium spp. and *Hemerocallis* spp. (lilies), 864–865
Lily ingestion, 459–460
Linear foreign material, 157
Lipomas, 101
Liquid diarrhea, 21
Liver, 137
  alterations in hepatic opacity, 138–139
  increased liver size, 137–138
  reduced liver size, 138
Liver parenchyma, 138
Liverpool Osteoarthritis in Dogs (LOAD), 1002
Lizard poisoning, 369
Lockjaw, 884
Lower airway and lung disorders
  bacterial bronchopneumonia
    clinical presentation, 210
    definition/overview, 210
    diagnosis, 210–211
    etiology, 210
    management, 211
    pathophysiology, 210
    prognosis, 211

canine infectious respiratory disease complex in young dogs ("kennel cough")
clinical presentation, 209
definition/overview, 209
diagnosis, 209
etiology, 209
management, 210
pathophysiology, 209
chronic bronchitis in dogs
clinical presentation, 215
definition/overview, 215
diagnosis, 215
differential diagnosis, 215
etiology, 215
management, 215
pathophysiology, 215
prognosis, 215
eosinophilic bronchopneumopathy in dogs
clinical presentation, 213–214
diagnosis, 214
differential diagnosis, 214
etiology/pathophysiology, 213
management, 214
prognosis, 215
parasitic bronchopneumopathy in dogs
clinical presentation, 213
definition/overview/etiology, 213
diagnosis, 213
management, 213
prognosis, 213
patients with lower airway and lung disease, 207–209
primary ciliary dyskinesia
clinical presentation, 212
definition/overview, 211–212
diagnosis, 212–213
etiology, 212
management, 213
prognosis, 213
Lower airway(s) obstruction, 30–31
Lower esophageal sphincter (LES), 299
Lower respiratory tract (LRT) obstruction, 30
Lower urinary tract
urethra, 149–150
urinary bladder, 147–149
Lung lobe torsion
clinical presentation, 228
definition/overview, 228
diagnosis, 228–229
differential diagnosis, 228
etiology, 228
management, 229–230
pathophysiology, 228
prognosis, 230
Lungs, thoracic abnormalities interpretation
alveolar pulmonary pattern, 126–127
bronchial pulmonary pattern, 129
interstitial pulmonary pattern, 127–129
vascular pulmonary pattern, 129–130
Lungworm testing, 31
Lupoid onychitis, 778–779
Lyme borreliosis, 877
Lymphedema, 58
Lymph nodes, 115–116
Lymphocytic thyroiditis, 408, 978
Lymphocytosis, 688–689
Lymphoid neoplasia, 701
acute lymphoblastic leukemia, 705–706
acute myeloid leukemia, 710–711
chronic lymphocytic leukemia, 704–705
extramedullary plasmacytoma, 707–708
histiocytic sarcoma, 711
lymphoma, 701–704
multiple myeloma, 706–707
myelodysplastic syndrome, 708
myeloid (nonlymphoid) neoplasms, 708
myeloproliferative neoplasms, 709–710
Lymphoma, 143, 157, 701–704
Lymphosarcoma, 821–822
Lysis, 103
Lysosomal storage diseases, 696–697, 840

M

Macrolides, 19
Macrothrombocytopenia, 700
Magnesium, 1013
Magnetic resonance imaging, 645
Maintenance fluids, 989–990
Malassezia spp. dermatitis, 762–763
Male reproductive tract, 146–147
Malignant histiocytosis, 711
Malignant pituitary tumors, 425
Malocclusion
clinical presentation, 169
definition/overview, 168–169
diagnosis, 169
differential diagnosis, 169
etiology, 169
management, 169
prognosis, 169
Maropitant, 19
Marrow atrophy, hypoplasia, or aplasia, 677
Mass effect, 136
Masticatory muscle myositis, 825–826, 979
Mastocytemia, 690
Maxillofacial/jaw fractures
clinical presentation, 174
definition/overview, 174
diagnosis, 174–175
differential diagnosis, 174
etiology/pathophysiology, 174
management, 175
progonsis, 175
Medetomidine, 29
Mediastinal gas – pneumomediastinum, 109–110
Mediastinal masses, 110
Mediastinal shift, 110
Medical communication styles, 4
Medical discharge, 9
Megacolon, 158
Megaesophagus
clinical presentation, 299
definition/overview, 298
diagnosis, 299–300
differential diagnosis, 299
etiology, 298–299
management, 300
pathophysiology, 299
prognosis, 300–301
Melbourne Pain Scale (MPS), 1002
Melena, 21
Meningeal cysts, 564
Meningoencephalitis, 820–821
Meperidine (pethidine), 1011
Mepivacaine, 1008
Metabolic diseases, 514
Metabolic disorders
craniomandibular osteopathy, 622–624
hyperadrenocorticism, 625–626
hypertrophic osteodystrophy, 624–625
panosteitis, 622
Metastatic neoplasms, 106
Methadone, 1011, 1013
Methemoglobinemia, 683–684
Methimazole, 413
Methylxanthines, 857–858
Microangiopathic hemolytic anemia, 669
Mild-to-moderate hypercalcemia, 421
Mineralization, 146
Missing teeth
clinical presentation, 171
definition/overview, 170
diagnosis, 171
differential diagnosis, 171
etiology, 170
management, 171
pathophysiology, 170–171
prognosis, 171
Mitral valve dysplasia
clinical presentation, 257
definition/overview, 257
diagnosis, 257
differential diagnosis, 257
management, 257
pathophysiology, 257
prognosis, 257
Monocytosis, 689
Morphine, 1011
Mucociliary elevator, 17
Mucocutaneous pyoderma, 757–758
Mucoid feces, 22
Mucolipidosis II, 841
Mucopolysaccharidoses, 841
Mucosal inflammation, 22
Mucous membranes, 238
Multiple myeloma, 706–707
Muscular dystrophy, 595
clinical presentation, 594
definition/overview, 593–594
diagnosis, 594
etiology, 594
management, 594
pathophysiology, 594
Musculoskeletal disorders and injuries, 603
anomalies
advanced surgical reconstruction, 622
ectrodactyly, 619
growth deformities, 620–622
osteochondrodysplasia, 620
arthroscopy, 646
computed tomography, 645–646
cranial cruciate ligament rupture, 613–615
chronic degenerative tendinopathies, 617–619
developmental luxations, 615–617
degenerative disorders
degenerative joint disease, 605–607
elbow dysplasia, 608–611
hip dysplasia, 607–608
osteochondrosis, 611–612
retained endochondral cartilage core, 612–613

examination, 603–605
history, 603
iatrogenic disorders, 637
synostosis, 637
idiopathic disorders
bone cysts, 638–639
Legg–Calvé–Perthes disease, 637–638
multiple cartilaginous exostoses, 640–641
secondary hypertrophic osteopathy, 639–640
infection/inflammation
inflammatory arthritides, 633–636
suppurative osteomyelitis, 632–633
magnetic resonance imaging, 645
metabolic disorders
craniomandibular osteopathy, 622–624
hyperadrenocorticism, 625–626
hypertrophic osteodystrophy, 624–625
panosteitis, 622
neoplasia, 626
primary bone tumors, 626–628
squamous cell carcinoma, 630–631
synovial cell sarcoma, 629–630
vascular tumors of bone, 628–629
nutritional disorders
hypervitaminosis A, 631–632
rickets/osteomalacia, 631
toxicity and trauma
collateral ligament rupture/injury, 644–645
lead poisoning, 641–642
traumatic luxations, 642–644
Myasthenia gravis, 979
clinical presentation, 590–591
definition/overview, 590
diagnosis, 591
etiology, 590
management, 591
pathophysiology, 590
Mycoplasma felis infection
clinical presentation, 918
definition/overview, 917–918
diagnosis, 918
differential diagnosis, 918
etiology, 918
management, 918
pathophysiology, 918
Mycotic rhinosinusitis, cats
clinical presentation, 193
definition/overview, 193
diagnosis, 193
differential diagnosis, 193
etiology, 193
management, 193
prognosis, 193
Mycotic rhinosinusitis, dogs
clinical presentation, 190–191
definition/overview, 190
diagnosis, 191–192
differential diagnosis, 191
etiology, 190
management, 192
pathophysiology, 190
prognosis, 192
Myelodysplastic syndrome, 708
Myeloid (nonlymphoid) neoplasms, 708
Myeloma, 701
Myeloproliferative neoplasms, 709–710
Myocarditis
clinical presentation, 270
definition/overview, 269
diagnosis, 271
differential diagnosis, 270–271
etiology, 269–270
management, 271
pathophysiology, 270
prognosis, 271
Myoclonic seizures, 80
Myoglobin, 61–62
Myopathies
centronuclear myopathy
clinical presentation, 595
definition/overview, 595
diagnosis, 595
etiology, 595
management, 595
pathophysiology, 595
Cushing's myopathy
clinical presentation, 593
definition/overview, 592
diagnosis, 593
etiology, 593
management, 593
pathophysiology, 593
endocrine myopathies, 592
exercise-induced collapse in Labrador Retrievers
clinical signs, 598
definition/overview, 597
etiology, 597
management, 598
pathophysiology, 597–598
exertional rhabdomyolysis, malignant hyperthermia, and rhabdomyolysis
clinical presentation, 599
definition/overview, 599
diagnosis, 599–600
etiology, 599
management, 600
pathophysiology, 599
fibrotic myopathy
clinical presentation, 598–599
definition/overview, 598
diagnosis, 599
etiology, 598
management, 599
pathophysiology, 598
hypokalemic myopathy
clinical presentation, 596
definition/overview, 596
diagnosis, 596
etiology, 596
management, 596–597
pathophysiology, 596
hypothyroid myopathy
clinical presentation, 593
definition/overview, 593
diagnosis, 593
etiology, 593
management, 593
pathophysiology, 593
idiopathic polymyositis
clinical presentation, 601
definition/overview, 600
diagnosis, 601
etiology, 601
management, 601
pathophysiology, 601
inflammatory myopathies, 600
clinical presentation, 600
definition/overview, 600
diagnosis, 600
etiology, 600
management, 600
pathophysiology, 600
inherited myopathy in Great Danes
clinical presentation, 595
definition/overview, 595
diagnosis, 596
etiology, 595
management, 596
muscular dystrophy
clinical presentation, 594
definition/overview, 593–594
diagnosis, 594
etiology, 594
management, 594
pathophysiology, 594
myotonia congenita
clinical presentation, 597
definition/overview, 597
diagnosis, 597
etiology, 597
management, 597
pathophysiology, 597
noninflammatory myopathies, 592–594
steroid myopathy
clinical presentation, 592
definition/overview, 592
diagnosis, 592
etiology, 592
management, 592
pathophysiology, 592
Myotonia, 595
Myotonia congenita
clinical presentation, 597
definition/overview, 597
diagnosis, 597
etiology, 597
management, 597
pathophysiology, 597
Myxedema coma, 409

N

Nasal, sinus, and/or nasopharyngeal disorders, 188–190
Nasal cavity, 38
Nasopharyngeal polyp
clinical presentation, 196
diagnosis, management, and prognosis, 196
etiology/pathophysiology, 196
Nasopharyngeal stenosis and choanal atresia
clinical presentation, 196
definition/overview, 196
diagnosis/management/prognosis, 196
Neck lesions, 177
Necrotizing meningo (leuko) encephalitis
clinical presentation, 527
definition/overview, 527
diagnosis, 527–528
differential diagnosis, 527
etiology, 527
management, 528
pathophysiology, 527

Nematodiasis, 810
Neoplasia, 42, 101, 626
  primary bone tumors, 626–628
  squamous cell carcinoma, 630–631
  synovial cell sarcoma, 629–630
  vascular tumors of bone, 628–629
Neoplasia of orbit, 826–887
Neoplastic diseases, 569
  clinical presentation, 517
  definition/overview, 516–517
  diagnosis, 517
  differential diagnosis, 517
  pathophysiology, 517
Neoplastic processes, 34
Nephrocalcinosis, 144
Nephrogenic diabetes insipidus (NDI), 401
Nephroliths, 144
Nephrology/urology, 452–453
  acute kidney injury
    advanced renal therapies, 460
    cholecalciferol-based rodenticides, 459
    clinical presentation, 453
    complete blood count, 455
    definition/overview, 453
    diagnosis, 453–454
    differential diagnosis, 453
    drug dosage, 458
    emesis, 457–458
    ethylene glycol, 453, 458–459
    ethylene glycol test, 455–456
    etiology, 453
    grapes and raisins, 459
    hyperkalemia, 457
    infectious disease serology, 455
    leptospirosis, 458
    lily ingestion, 459–460
    management, 456–457
    metabolic acidosis, 457
    NSAID toxicity, 459
    pathophysiology, 453
    prognosis, 460
    radiographs and ultrasound, 455
    serum chemistry, 455
    specific toxin ingestion, 458–460
    urine culture, 454–455
  amyloid and glomerulonephropathy (GN) therapies
    blood pressure, 472
    diet therapy, 471
    fluid therapy, 471
    prognosis, 471
    thromboembolism, 471
  chronic kidney disease
    advanced renal therapies, 467
    anorexia, 466–467
    clinical presentation, 461
    control of acidosis, 463
    definition/overview, 460
    diagnosis, 461–462
    diet, 466
    differential diagnosis, 461
    fluid therapy, 462
    hyperphosphatemia, 463–465
    management, 462–467
    pathophysiology, 460–461
    potassium, 463
    prognosis, 467
    proteinuria, 465
    staging, 462
    treatment of anemia, 465–466
  cystic disease
    clinical presentation, 499
    definition/overview, 498
    diagnosis, 499
    differential diagnosis, 499
    etiology, 499
    management, 499–500
    pathophysiology, 499
    prognosis, 500
  feline lower urinary tract disease, 484
    clinical presentation, 486
    definition/overview, 484
    diagnosis, 486
    differential diagnosis, 486
    etiology, 484
    idiopathic cystitis, 484
    management, 486–490
    pathophysiology, 484
    prognosis, 490
    urethral plugs, 484
    urinary tract infections, 484–486
  hypertension
    clinical presentation, 473
    definition/overview, 472
    diagnosis, 473–476
    etiology, 472
    management, 476–478
    pathophysiology, 472–473
    prognosis, 478
  incontinence
    clinical presentation, 481
    definition/overview, 478
    diagnosis, 481–482
    differential diagnosis, 481
    etiology, 478
    management, 482–484
    pathophysiology, 478–480
  protein-losing nephropathy
    amyloidosis, 468
    amyloidosis *versus* glomerulonephritis, 470–471
    amyloid-specific treatment, 471
    clinical presentation, 469–470
    definition/overview, 467
    diagnosis, 470
    glomerulonephritis, 468–469
    GN specific treatment, 471
    immunosuppression, 471
    management, 470–471
    pathophysiology, 467–469
  renal tumors
    clinical presentation, 500
    definition/overview, 500
    diagnosis, 500
    differential diagnosis, 500
    etiology, 500
    management, 500
    pathophysiology, 500
  urinary tract infection
    clinical presentation, 501
    definition/overview, 500
    diagnosis, 501–502
    differential diagnosis, 501
    etiology, 501
    management, 502
    pathophysiology, 501
    prognosis, 502
  urolithiasis
    canine calcium oxalate, 496
    canine cystine, 497
    canine struvite uroliths, 495–496

differential diagnosis, 896
etiopathogenesis, 895
management, 896
tick-borne disease, 898–899
babesiosis, 902–903
clinical presentation, 900
diagnosis, 900–902
ehrlichiosis/anaplasmosis, 901–903
etiopathogenesis, 899
Lyme disease/borreliosis, 902, 904
Rocky Mountain spotted fever, 902, 904–905
treatment and prognosis, 902–904
vaccination, 904
vector-borne disease
clinical presentation, 897
definition/overview, 896–897
diagnosis, 897–898
differential diagnosis, 897
etiopathogenesis, 897
management, 898
Viral intestinal infections, 318
Visceral pleura, 104
Viscoelastic coagulation monitor (VCM), 39
Viscoelastic testing, 39
Vitis spp. (grapes and raisins), 866
Vomiting, 90
clinical approach
acute vomiting, 91–93
chronic vomiting, 93
treatment, 93
common causes, 91
differential diagnoses, 91
expulsion, 90
pathophysiology, 90–91
prodromal phase, 90
response, 90
retching, 90
Von Willebrand's disease, 38

W

Weakness, differential diagnosis of, 89
Weight loss/cachexia, 238
Weimaraner immunodeficiency, 980
Wenckebach phenomenon, 282–283
Whipworms, 343
Wood's lamp, 750

X

Xylitol, 862–863

Y

Yellow sulfur granules, 924

Z

Zinc, 869
Zinc-responsive dermatosis, 832
Zoometry, 1044
Zoonotic disease, 454
Zygomycetes, 751
